where the p_σ orbital is directed at the proton and n may vary from 1 to 2. The effective nuclear charge for the neutral oxygen atom by Slater's rules is 2.275. For the case $n = 2$, corresponding to the species $O^=$, ρ_B reduces to a spherical charge distribution with eight electrons. The transfer of charge to the oxygen atom for any value of n is simply $2(n - 1)$. The value of n must be greater than unity to balance the forces exerted on the proton by the A species for the values of R encountered in hydrogen bonding. This is physically reasonable. For a given value of R, r_a and r_b are varied until the force on the proton is zero. The results of the calculations for a range of R values are shown in Fig. 2. All

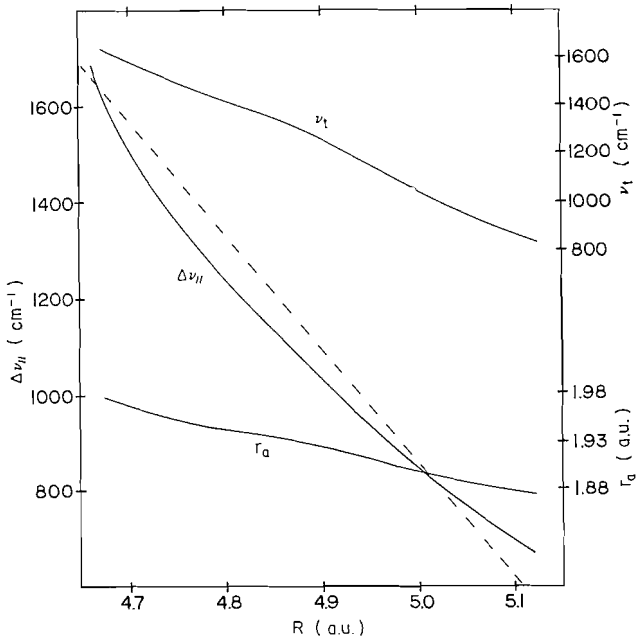

FIG. 2. The calculated values of $\Delta\nu_{\parallel}$, ν_t, and r_a for a hydrogen bonded O—H····O system. The dotted curve is the "experimental" curve of ref. 6. For ice, $\nu_t \sim 850$ cm^{-1} ($R = 5.22$ a.u.) and for carboxylic acids, $\nu_t \sim 950$ cm^{-1} ($R = 5.16$ a.u.).

three graphs were obtained by using just one point on the $\Delta\nu_{\parallel}$ vs. R plot to fix the value of n at 1.27. The predictions of $\Delta\nu_{\parallel}$ are in good agreement with experiment. The calculated curve always lies within ± 100 cm^{-1} of the straight line relation, which is the actual spread of the experimental results. The curve of r_a versus R lies within the observed limits of the "average" experimental curve (7). The present model does not distinguish between the two perpendicular force constants. The sum of these two constants is simply $4\pi\rho(H) - k_{\parallel}$. In hydrogen-bonded systems where A—H is polyatomic the two values of $\nu_{\perp}$ are not necessarily the same. Originally A—H has an in-plane bending mode ν_b and an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

out-of-plane bending mode ν_t. On hydrogen bonding ν_b increases only slightly ($\sim$50 cm^{-1}) but ν_t may undergo remarkable increases and approach ν_b in value. The value of ν_b in hydrogen-bonded systems where water is the acid species is in the range of 1650 cm^{-1} or a k_b of 0.1030 a.u. (7). We can predict a value of ν_t by subtracting this value for k_b from $4\pi\rho(\mathrm{H}) - k_\parallel$, the remainder being k_t. Thus we are testing the prediction that the sum of the force constants for ν_b and ν_t should add up to $4\pi\rho(\mathrm{H}) - k_\parallel$. There is a scarcity of data for ν_t but two experimental observations at values of R just outside the range of Fig. 2 are given in the figure caption. They are for the cubic ice structure and hydrogen-bonded carboxylic acids (7). The values of ν_t (or the total $4\pi\rho(\mathrm{H}) - k_\parallel$) are thus quite reasonable at large values of R. The predicted values of ν_t for shorter R values are seen to approach ν_b. Thus as the hydrogen bond is shortened the model predicts that ν_b and ν_t approach one another in value. In fact as R is further decreased, $k_\parallel$ should become quite small corresponding to a relatively flat-bottomed potential well (as previously suggested by Reid (5)) and the $\nu_\perp$ modes could conceivably surpass $\nu_\parallel$ in value. The same model could be applied to the case where the proton has been transferred and r_a is then greater than r_b, i.e., the system has shifted to the second minimum of a double-well potential.

While the model does not purport to yield the exact values of the electron density at the proton (it is purposely underestimated), it does lead to the conclusion that this density should decrease on hydrogen bond formation. This prediction is in accord with the observation that the proton resonance signal of the hydrogen in the hydrogen bond is shifted to lower magnetic fields relative to its position in the unassociated molecule (8). While, as Pople (9) has pointed out, this decrease in magnetic shielding constant does not necessarily imply a decrease in the electron density at the proton, the present model could account for the observations.

IV. APPLICATION TO TRANSITION STATES OF PROTON TRANSFER REACTIONS

We assume that the potential energy surface in the immediate vicinity of the transition state has zero curvature, i.e., that $k_\parallel$ must equal zero (10, 11). Since F_H and $k_\parallel$ must both be zero at the transition state, equations [1] and [6] will allow one to predict values of both r_a and R. In general, for given density distributions ρ_A and ρ_B there will be only one value of r_a and one value of R which will cause equations [1] and [6] to equal zero simultaneously. For a transition state molecule, equation [4] reduces to

$$[7] \qquad 2k_\perp = 4\pi\rho(\mathrm{H}).$$

This equation, which relates the total electron density at the proton to the restoring force constants for its perpendicular motions, is of great importance in the discussion of isotope effects.

The variation of the force on the proton with r for a given density distribution on either the acid or the base species is shown in Fig. 3. The force initially increases from zero with increasing r because more negative charge is contained in the region between the proton and the nucleus of A or B. Eventually, however, the increase in r becomes overriding and the force decreases. The value of r at which the force is a maximum decreases, and the force itself increases as the total amount of charge is increased, as polarization of the charge density is increased, or as the effective nuclear charge for the orbitals is increased. A discussion of the forces exerted by the electron density distributions obtained from s, p_σ, p_π, and d orbitals may be found in ref. 12. Briefly, these forces decrease in the order $p_\sigma > s > p_\pi$. Thus in Fig. 2 the lower force curve represents a density distribution which may contain a smaller amount of absolute charge or is less polarized than the density

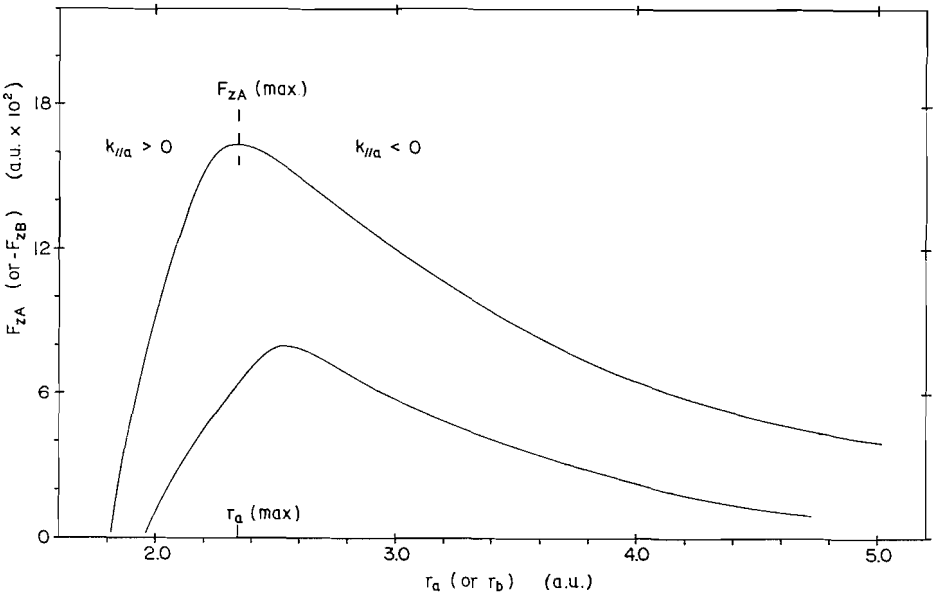

FIG. 3. The variation of F_{zA} or F_{zB} with r_a or r_b. r_a (max.) is the value of r_a at which F_{zA} is a maximum.

given by the upper curve. When we refer to the relative strengths of the acid and base we do so with reference to the respective force curves generated by ρ_A and ρ_B. The species which exerts the greater force on the proton for any value of r will be the stronger of the two, both considered as bases, or the weaker of the two, both considered as acids. We thus have a definite relation between acid or base strength and the electron density distribution.

The terms in equations [3] or [6] for $k_\parallel$ may be regrouped to yield

$$k_\parallel = k_{\parallel a} + k_{\parallel b}$$

where

$$k_{\parallel a} = \frac{2Z_A}{r_a^3} + (4/3)\pi\rho_A(H) - \int\left(\frac{3\cos^2\theta - 1}{r^3}\right)\rho_A d\tau$$

and a corresponding equation for $k_{\parallel b}$. If $k_\parallel$ is to equal zero, either $k_{\parallel a} = -k_{\parallel b}$ or $k_{\parallel a} = k_{\parallel b} = 0$. Since $k_{\parallel a}$ is the gradient of the force F_{zA}, $k_{\parallel a}$ will equal zero only when F_{zA} is a maximum. The same is true for $k_{\parallel b}$. For values of $F_{zA} < F_{zA}$ (max.), $k_{\parallel a}$ is positive, and for values of $F_{zA} > F_{zA}$ (max.), $k_{\parallel a}$ is negative, as illustrated in Fig. 3. Therefore, when ρ_A and ρ_B are identical the transition state will be symmetrical and will occur at a value of $r_a = r_b = r$(max.). Consider next the case where $\rho_A > \rho_B$, i.e., considering both A and B as bases, A is the stronger of the two. Since either $k_{\parallel a}$ or $k_{\parallel b}$ must now be negative in order that their sum equal zero, either $r_a > r_a$(max.) or $r_b > r_b$(max.). In this case both F_z and $k_\parallel$ can be made equal to zero only when $r_a > r_a$(max.) and $r_b < r_b$(max.). Only by having $r_a > r_a$(max.) can $|k_{\parallel a}|$ be reduced to equal $k_{\parallel b}$ with the forces equal and opposite at the same time. In the region $r_a < r_a$(max.) the slope of the F_{zA} curve is too great for values of $F_{zA} = -F_{zB}$. Thus if the density of the acid is held fixed, the original A—H bond must be progressively more broken in the transition state as the strength of the attacking base is decreased. By the same arguments, when $\rho_B > \rho_A$, i.e., the attacking base is a stronger base than is the A^- species, the transition state will occur when

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$r_b > r_b(\text{max.})$ and $r_a < r_a(\text{max.})$. Chemists speak of bonds being more or less than "half broken" in the transition state. We can give a quantitative interpretation to this statement which conveys the same intuitive feeling in terms of $r(\text{max.})$. The distance $r(\text{max.})$ determines the point at which the contribution of either the acid or base to the total force constant changes sign. For $r < r(\text{max.})$ a further increase in r results in an increased force tending to pull the proton back. For $r > r(\text{max.})$ a further increase in r leads to a further decrease in the force tending to bind the proton. Thus when the attacking base is the stronger of the two, the transition state occurs when the original A—H bond is less than "half broken" and the proton is still bound by a positive restoring force constant to the A^- species. When the attacking base is the weaker of the two, then the original A—H bond is more than "half broken" and the new bond is more than "half formed"; i.e., the proton is now bound by a positive restoring force constant to the base rather than to the acid. The other possibility, that of considering a constant density on the base and varying the strength of the A—H species is obtained by simply considering the reverse of the above reactions, i.e.,

$$BH + A^- \rightarrow B^- + A\text{—}H$$

as the transition state species will be identical.

Numerical examples for various acids and bases are given in Tables I and II. The data

TABLE I*

in Table I are for the simplest type of model, a spherical charge density on both the acid and base species. The model for the acid is that used in the hydrogen bond calculations and the same density is employed for the base with a varying amount of negative charge. When $\delta = 1$, $\rho_A \equiv \rho_B$ and the transition state is the symmetrical one with $r = r(\text{max.})$. The original bond is half broken and the new bond is half formed. As the base strength is decreased r_a increases, r_b is decreased, and R increases. Thus the weaker the base in a series such as this, the "looser" the transition state becomes. This is also reflected in the decrease in $4\pi\rho(H)$ and decreasing values of $\nu_\perp$.

In Table II the acid model is retained but the base density is polarized. The first entry is for a model of the oxygen in the hydroxide ion where we have attempted to take into

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

account the fact that the electron density has some preferential p_σ character in the direction of the O—H···O bond. This makes this base stronger than the base with the spherical density even though the total charge is the same on each. The remaining entries are for the base model employed previously in the hydrogen bond calculations with varying amounts of charge. This base is also polarized, i.e., not spherically symmetrical. The model for the hydroxide ion gives a stronger base than the original base A^- species. This is a result of the enhanced force of the base due to the polarization of its charge density. A further decrease in δ results in a weaker attacking base, to values of $r_a > r_a(\text{max.})$ and to values of $r_b < r_b(\text{max.})$. The values of R at first decrease and then increase. The strongest base is able to balance the force and field gradient at large values of R. As the base is weakened R must decrease to achieve a balance and when $\rho_B \sim \rho_A$, R will be a minimum. Further decrease in the base strength necessitates a greater increase in r_a (past $r_a(\text{max.})$) to achieve a balance for both force and field gradient. The variation in the total density at the proton reflects the variation in R, being larger when R is small, and decreasing when R increases. Thus $\nu_\perp$ at first increases, and subsequently decreases. The strength of binding of the proton is proportional to the total electron density at the proton and the separate densities $4\pi\rho_A(H)$ and $4\pi\rho_B(H)$ are included in the tables to illustrate the relative strengths of binding of the acid and base species.

In all of the above examples we have assumed that the density distribution in the acid species remained fixed, regardless of the strength of the base (or vice versa for the reverse reaction). This would correspond roughly to the removal of a proton from an O—H bond which is not conjugated with the rest of the molecule. Because of this fact the proton in all of the transition states so far discussed is relatively tightly bonded (either to the acid or to the base species) as evidenced by the values of $\nu_\perp$ and $4\pi\rho(H)$. There are many chemical reactions in which more than "one bond" is changing at a time and the various changes are coupled together by a facile exchange of electron density from one reacting center to another. There are also many conjugated systems whose reactions show a strong dependence on the possibility of charge density being transferred to or from the reacting center. Thus it is of interest to consider models for transition states in which the density on A (or B) may be increased or decreased quite markedly from what it was initially. As pointed out above, if ρ_A is considered constant, the original A—H bond must be progressively lengthened to attain the transition state as the strength of the base is decreased. The accompanying increase in the energy of activation can be considered as due to the increasing amount of work necessary to stretch r_a to the required value. From this result one can argue that the energy of activation will be minimized if ρ_A (or ρ_B) can be adjusted, by means of electron withdrawal or release, so that ρ_A approaches ρ_B in value. This will result in transition states in which $r_a \sim r_b$. In Table III data are given for symmetrical transition states calculated for the spherical O^- model with varying values for δ.

We now find a wide variation in the binding of the proton in the transition state as

TABLE III

Data for symmetrical transition states with varying total charge

δ	r	R	$4\pi\rho(H)$	$\nu_\perp$
1.0	2.32	4.64	0.2411	1790
0.5	2.58	5.16	0.0925	1100
0.4	2.67	5.34	0.0668	940
0.3	2.78	5.56	0.0449	770

reflected in the decreasing values of $4\pi\rho(H)$ and $\nu_\perp$. Only in a symmetrical or close to symmetrical transition state can the forces and field gradients be balanced for a loosely bound proton at values of R which are not unreasonably large. Thus if ρ_A is fixed and much greater than ρ_B, the transition state occurs only when r_A has increased to such a large value that R is unreasonable (many times larger than twice the van der Waals' radii). In other words the energy of activation for the removal of a proton from a weak acid by a weak base is so large the reaction does not occur.

V. CONSEQUENCES IN THE INTERPRETATION OF H—D ISOTOPE EFFECTS

Most discussions of hydrogen–deuterium kinetic isotope effects are carried out in terms of a linear model for the transition state in which the bending frequencies are ignored. Examples are the papers of Westheimer (13) and Bigeleisen (14). Bell (15) has given a model for a proton transfer transition state in which a bare proton is placed between two negative charges. This would correspond to the present equation [3] with both ρ_A and ρ_B contracted to the A and B nuclei respectively giving $(Z_A - Q_A) = (Z_B - Q_B) = -1$ and $4\pi\rho(H) = 0$. Then from equation [4] one finds that $2k_\perp = -k_\parallel$. Considering the potential surface at the transition state to have a small negative curvature ($k_\parallel$ is negative) Bell's model necessarily leads to small values for $k_\perp$ and $\nu_\perp$. Bell then demonstrates that the contribution to the isotope effect from $\nu_\perp$ when small in value effectively cancels the contribution from the tunnelling effect. A bare proton is a very idealized model and is bound to underestimate the value of $\nu_\perp$ as ρ_A and ρ_B must always be of finite extent in space and thus $4\pi\rho(H) \neq 0$. Even the present model underestimates $4\pi\rho(H)$ as mentioned in Section II, but hopefully this underestimation is compensated by the neglect of the term which describes the change in density as the proton vibrates. That Bell's model must seriously underestimate $\nu_\perp$ is most easily seen when it is realized that it would predict negative force constants and thus imaginary frequencies for the bending motions in hydrogen-bonded systems for which $k_\parallel$ is positive. In actual fact, as noted in Section III, experimentally it is found that $\nu_b \sim 1600$ cm^{-1} and $\nu_t \sim 800$ cm^{-1}.

The "symmetric" stretching mode (i.e., the other linear motion of the three atom system A—H—B, which in the symmetrical case involves only motions of A and B), plays a dominant role in the above-mentioned discussions (13, 14, 15). The importance of this motion in determining the pre-exponential factor in isotope effect calculations is very well treated in all three expositions. This factor involves only the ratios of the hydrogen and deuterium frequencies, and thus is not dependent upon their absolute magnitudes. The present model cannot predict the second linear frequency (call it ν_s) as A and B are held rigid. It would be possible to add an empirical potential term to our potential expression dependent only upon R and thus obtain a more complete description of the three-atom system. This destroys the simplicity of the model and adds another adjustable parameter which detracts from the predictions that can be made with the present model. Furthermore, we wish to restrict our attention to the exponential term* and all experimental evidence points to the fact that ν_s is invariably small in value and thus relatively not as important as $\nu_\perp$ in determining the total difference in zero-point energies. In all cases where ν_s has been observed for hydrogen-bonded species involving oxygen it has appeared in the region of 250 cm^{-1} or less (7), while $\nu_\perp$ (i.e., ν_t and ν_b) is of the order of 800 cm^{-1} and often higher. Even in the $(HFH)^-$ ion, the shortest hydrogen bond known,

**Westheimer (13) has argued that the pre-exponential factor is always close to unity regardless of the symmetry of the transition state and thus the isotope effect is determined largely by zero-point energy differences as determined here.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the value of ν_s is only 600 cm^{-1} as compared to a $\nu_\perp = 1200$ cm^{-1}. In addition, the contribution from $\nu_\perp$ must be doubled since it is degenerate.

Referring first to Tables I and II, it is evident that for all the unsymmetrical transition states $\nu_\perp$ and hence the isotopic shifts in $\nu_\perp$ are quite large in the transition state. The isotope effects for these reactions should thus be quite small or inverse, i.e., less than the "normal" effect of ~10. Westheimer's (13) approach also leads one to expect small isotope effects for unsymmetrical transition states but for a different reason. His argument is that ν_s in the unsymmetrical case will have a significant zero-point energy difference and it is this difference which makes the large contribution in the transition state. This is difficult to reconcile with all known values of ν_s, which would lead one to expect only small zero-point energy differences for this motion. The present model thus ascribes the small isotope effects associated with unsymmetrical transition states as due to the large values of $\nu_\perp$. As pointed out earlier when $r_A \gtrless r_B$ the proton is necessarily relatively tightly bound and hence $\nu_\perp$ must be appreciable in value.

Consider next the results of Table III and symmetrical transition states. Since $\nu_\perp$ can now vary from very large values (~2000 cm^{-1}) to very small values (~700 cm^{-1}), a whole range of isotope effects from very small or inverse to large are possible, *all for a symmetrical transition state.* This is at direct variance with the previous theories which predict only large isotope effects for symmetrical transition states as ν_s in these cases does not involve any motion of the hydrogen atom. Hence it does not contribute to the zero-point energy difference. The present model predicts that for a reaction in which charge density can be readily delocalized, it is possible for the proton to be "tightly or loosely" bonded (large or small values of ρ(H) and $\nu_\perp$) in a symmetrical transition state. There is no a priori reason for not believing this to be possible.

It is an accepted consequence of the previous theories that in a system in which the acid or base strength can be varied over a wide range, one would expect the accompanying isotope effects to pass through a maximum, corresponding to the symmetrical transition state. This has never been observed. As argued earlier, when the electron density is subject to a facile increase or decrease in the transition state, the geometry could always be close to the symmetrical case. A series of such symmetrical transition states will yield isotope effects which simply decrease as the base is made stronger and the proton is increasingly more tightly bound in the transition state. Results of this nature have been observed, an example being the decomposition of substituted β-keto acids (16). In this case as substituents were changed so as to increase the basicity of the keto oxygen, the isotope effect underwent a regular decrease. In this and other systems where this regular decrease in the isotope effect has been observed, a mechanism is available for the adjustment of the electron density on the A and B species such that a symmetrical transition state could result.

A different variation in isotope effect with base strength can be observed in a system with a more or less rigid electron density in the original A—H bond. Consider the results in Table II. The frequency $\nu_\perp$ at first increases and R decreases with increasing base strength. Thus there should be an initial decrease in the isotope effect. After the symmetrical case, which has close to the *minimum* isotope effect, decreasing the strength of the base leads to a further increase in the isotope effect as $\nu_\perp$ again decreases in value. Here then is a prediction in direct contradiction to the previous ones (13, 14). A variation in base strength in a system with an A—H bond which cannot readily delocalize a developing negative charge should yield a set of isotope effects which pass through a minimum, rather than a maximum.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The predictions of the present model are obtained by considering $\nu_\perp$ and ignoring ν_s, which in a sense is the other possible extreme to the previous models. We have, however, presented both experimental and theoretical results which would seem to indicate that $\nu_\perp$ can be an order or orders of magnitude larger than ν_s. The truth without a doubt involves consideration of both. It is hoped, however, that this model has at least indicated that $\nu_\perp$ can be of crucial importance to an understanding of isotope effects for proton transfer reactions. Other workers (11, 17) have discussed the importance of $\nu_\perp$ for hydrogen atom abstraction reactions. The present model is restricted to proton transfer reactions for only in this case are Platt's basic assumptions valid.

Analytical expressions for the force integrals have been previously reported (18). The method of Pitzer *et al.* (19) was used to derive expressions for the field gradient integrals. All the integrals were calculated on an IBM 650.

ACKNOWLEDGMENT

The author is grateful to Professor A. N. Bourns for helpful discussions concerning the application of the present results to the interpretation of kinetic isotope effects.

EFFECT OF PRESSURE ON THE ACID-CATALYZED ENOLIZATION OF ACETONE AND ACETOPHENONE IN VARIOUS ETHANOL–WATER SOLVENTS. ORIGIN OF THE ENTHALPY–ENTROPY COMPENSATION EFFECT[1]

B. T. BALIGA[2] AND E. WHALLEY
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received March 17, 1964

ABSTRACT

The effect of pressure, temperature, and solvent composition on the rate of the acid-catalyzed enolization of acetone and acetophenone, and the solvent deuterium isotope effect for the enolization of acetophenone, have been measured by following the iodination. The solvent deuterium isotope effect (k^{D_2O}/k^{H_2O}) for the enolization of acetophenone in 16.2% w/w ethanol–water is $2.50\pm\sim0.05$, which undoubtedly proves that there is a pre-equilibrium proton transfer. The effect of solvent in the range water to 33.4% w/w ethanol in water on the rate of enolization of both acetone and acetophenone is small at atmospheric pressure, but is about four times larger at 3 kbar. This cannot be explained on simple electrostatic grounds, and indicates that any simple electrostatic explanation of the solvent effect at atmospheric pressure is invalid. The volumes of activation for the enolizations are strongly dependent on the solvent, that for acetone varying from $-2.1\pm\sim0.5$ to $-6.9\pm\sim0.7$ cm^3 mole^{-1} between solvents water and 33.4% w/w ethanol in water.

An examination has been made of the enthalpy–entropy compensation effect. It is shown that in general if the rate or equilibrium constant of a reaction does not change with changing conditions (such as solvent, substituents, etc.) then either the quantities of activation at constant pressure, $\Delta H_p^{\ddagger}$ and $\Delta S_p^{\ddagger}$, or the corresponding quantities at constant volume, $\Delta U_v^{\ddagger}$ and $\Delta S_v^{\ddagger}$, must vary in a compensating manner, and the existence of an energy–entropy compensation effect is inevitable. For the enolization of acetone and acetophenone in ethanol–water mixtures, $\Delta U_v^{\ddagger}$ and $\Delta S_v^{\ddagger}$ vary only slightly with solvent, whereas $\Delta H_p^{\ddagger}$ and $\Delta S_p^{\ddagger}$ vary in a compensating manner. The main causes of the compensation effect in the constant-pressure parameters are, in a sense, the change with changing solvent of the thermal expansion of the solvent and of the volume of activation of the reaction. On the other hand, both the constant-pressure and the constant-volume parameters vary with substituent from acetone to acetophenone, and the constant-volume parameters vary the more.

1. INTRODUCTION

The acid-catalyzed enolization of ketones is a well-studied reaction (1). It can be conveniently followed by the halogenation (2–5) and the deuterium exchange (6) of the ketones, and by their racemization (7) if they have an asymmetric α-carbon atom. The rates of all these processes are usually identical, and when followed by halogenation they are of zero order in halogen, the zero-order rate constant being itself of first order in both ketone and catalyst. The mechanism of enolization when catalyzed by strong acids is accepted on good grounds to be (see ref. 1 for discussions)

$$R{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}CH_3 + H_3O^+ \underset{}{\overset{\text{fast}}{\rightleftharpoons}} R{-}\overset{\displaystyle \overset{+}{O}H}{\overset{|}{C}}{=}CH_2 + H_2O$$

$$R{-}\overset{\displaystyle \overset{+}{O}H}{\overset{|}{C}}{=}CH_2 + H_2O \xrightarrow{\text{slow}} R{-}\overset{\displaystyle OH}{\overset{|}{C}}{=}CH_2 + H_3O^+.$$

Halogenation then occurs by rapid addition to the enol. The incorporation of a molecule of water in the transition state is not kinetically proved. There is, however, little doubt

[1]*N.R.C. No. 7959.*
[2]*N.R.C. Postdoctoral Fellow 1962–64.*

that it occurs, on the grounds that analogy with the observed base catalysis (1) suggests that water is itself acting as a base. In addition, the entropy of activation, which is usually about -15 cal deg^{-1} mole^{-1} (8), strongly suggests (9–11) that a water molecule is incorporated into the transition state.

Few measurements have been made of the volumes of activation of proton abstraction reactions, and for purposes of comparison with other reactions the volume of activation of the acid-catalyzed enolization of acetone and acetophenone would be interesting. In addition, there are several other points of interest. In the first place, few systematic measurements have been made of the effect of solvent on volumes of activation, and the iodination of ketones is a suitable example of a particular class of reaction that would be worth studying. In the second place, the rate of the reaction is little affected by solvent. It is shown in Section 2 of this paper that for such a reaction, the enthalpy and entropy of activation at constant pressure, or the energy and entropy of activation at constant volume, or both, must vary with solvent so as to compensate one another in the free-energy (energy–enthalpy compensation effect). It is of interest to determine whether only one set of parameters has an appreciable compensation effect or whether both have.

We have therefore measured the effect of temperature and pressure on the rates of the acid-catalyzed iodination of acetone and acetophenone in several ethanol–water mixtures. There was no firm evidence that the iodination of acetophenone goes by a pre-equilibrium proton transfer. The solvent deuterium isotope effect on the rate has therefore been measured to verify it.

2. THE ENTHALPY–ENTROPY COMPENSATION EFFECT

It is frequently found that the enthalpy and entropy changes, ΔH and ΔS, of a reaction, either of its rate or its equilibrium, change with changing conditions in the same direction, so that the changes can be said to compensate one another partially in the free energy ΔG $(= \Delta H - T\Delta S)$. The changing conditions can be a change of solvent for a given reaction, a change of substituents in a series of compounds undergoing a similar reaction, and so on. This compensation has frequently been called the enthalpy–entropy compensation effect. The existence of this effect is frequently considered surprising. The purpose of the following discussion is to show that it is in fact inevitable for many reactions and other processes except in special circumstances.

We first emphasize that processes can be considered to occur at constant pressure or at constant volume (or of course with neither pressure nor volume constant, but these conditions are less interesting). The most useful free energy for constant-pressure processes is the Gibbs free energy, and we have, using the subscript p to indicate the constant-pressure condition

$$\Delta G_p = \Delta H_p - T\Delta S_p. \qquad [1]$$

The most useful free energy for constant-volume processes is the Helmholtz free energy A, and we have

$$\Delta A_v = \Delta U_v - T\Delta S_v \qquad [2]$$

where U is the intrinsic energy, and the subscript v indicates constant-volume conditions. If the rate or equilibrium constant of a reaction is a function of temperature and pressure and not of the extent of reaction then

$$\Delta G_p = \Delta A_v. \qquad [3]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

This condition holds in dilute solution. Both the constant-pressure and the constant-volume parameters are equally fundamental thermodynamic parameters, and there is much to be said for the point of view that the constant-volume parameters are simpler than the constant-pressure parameters.

The relation between the quantities of activation at constant pressure and at constant volume can be derived by applying the operational equation

$$\left(\frac{\partial}{\partial T}\right)_v = \left(\frac{\partial}{\partial T}\right)_p + \frac{\alpha}{\kappa}\left(\frac{\partial}{\partial p}\right)_T, \qquad [4]$$

where α is the isopiestic thermal expansivity of the system and κ its isothermal compressibility. This equation can be applied to any quantity that is a function of the temperature and pressure only. It can be applied to ΔG_p $(= \Delta A_v)$ to give

$$\left(\frac{\partial \Delta A_v}{\partial T}\right)_v = \left(\frac{\partial \Delta G_p}{\partial T}\right)_p + \frac{\alpha}{\kappa}\left(\frac{\partial \Delta G_p}{\partial p}\right)_T, \qquad [5]$$

from which

$$T\Delta S_v = T\Delta S_p - T\alpha\Delta V/\kappa, \qquad [6]$$

and hence,

$$\Delta U_v = \Delta H_p - T\alpha\Delta V/\kappa. \qquad [7]$$

We consider first a reaction for which ΔG_p and ΔA_v do not change with the changing conditions. There is no energy–entropy compensation effect in the constant-volume parameters ΔU_v and ΔS_v if both are also independent of the changing conditions. There is then, however, an enthalpy–entropy compensation effect in ΔH_p and ΔS_p, unless the quantity $T\alpha\Delta V/\kappa$ does not vary with changing conditions. Conversely, if there is no enthalpy–entropy compensation effect in the constant-pressure parameters, there is one in the constant-volume parameters unless $T\alpha\Delta V/\kappa$ does not vary with changing conditions. If the changing conditions are changing solvent, α, ΔV, and κ will, in general, all vary and consequently $\alpha\Delta V/\kappa$ will, in general, vary. If the changing conditions are changing substituents in a homologous series, ΔV will, in general, vary. It follows therefore that if ΔG_p and ΔA_v do not vary or vary only slightly, then either the constant-pressure or the constant-volume parameters will usually tend to vary in a compensating manner because of the variation in $T\alpha\Delta V/\kappa$. There may of course be other factors that tend to make the activation parameters vary, and they may dominate the variation in $T\alpha\Delta V/\kappa$.

If ΔG_p or ΔA_v vary strongly there need not necessarily be an enthalpy–entropy or energy–entropy compensation effect unless the variation in $T\alpha\Delta V/\kappa$ is very strong and of the right sign.

In the rest of this section we shall discuss the inevitability of compensation for the particular case of varying temperature and varying pressure. If the changing conditions are merely changing temperature for the same reaction in the same solvent, the changes of the activation parameters necessarily compensate one another. For example

$$\left(\frac{\partial \Delta H_p}{\partial T}\right)_p = T\left(\frac{\partial \Delta S_p}{\partial T}\right)_p = \Delta C_p \qquad [8]$$

and

$$\left(\frac{\partial \Delta U_v}{\partial T}\right)_v = T\left(\frac{\partial \Delta S_v}{\partial T}\right)_v = \Delta C_v. \qquad [9]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Since ΔC_p and ΔC_v are related by the equation (21)

$$[10] \qquad \Delta C_p - \Delta C_v = \frac{T\alpha\Delta V}{\kappa}\left\{\left(\frac{\partial}{\partial T}\ln\frac{\alpha\Delta V^2}{\kappa^2}\right)_p + \frac{\alpha}{\kappa}\left(\frac{\partial}{\partial p}\ln\frac{\Delta V}{\kappa}\right)_T\right\},$$

then either ΔC_p or ΔC_v must differ from zero unless the quantity on the right-hand side of eq. 10 is zero. Consequently, either $\partial\Delta H_p/\partial T$ and $T\partial\Delta S_p/\partial T$, or $\partial\Delta U_v/\partial T$ and $T\partial\Delta S_v/\partial T$, or both, have the same sign, and so there is an energy–entropy compensation effect in at least one of the sets of activation parameters, except in the event that both ΔC_p and ΔC_v are zero.

The volume change of the reaction can be divided into an enthalpy and an entropy part as follows,

$$[11] \qquad \begin{aligned}\Delta V &= \partial\Delta G_p/\partial p,\\ &= (\partial\Delta H_p/\partial p) - T\,(\partial\Delta S_p/\partial p).\end{aligned}$$

Since for the processes we are considering

$$\Delta G_p = \Delta A_v,$$

we can also write

$$[12] \qquad \begin{aligned}\Delta V &= \partial\Delta A_v/\partial p,\\ &= (\partial\Delta U_v/\partial p) - T\,(\partial\Delta S_v/\partial p).\end{aligned}$$

The relation between $\partial\Delta U_v/\partial p$ and $\partial\Delta H_p/\partial T$ is from eq. 7

$$[13] \qquad \frac{\partial\Delta U_v}{\partial p} = \frac{\partial\Delta H_p}{\partial p} - T\frac{\partial}{\partial p}\left(\frac{\alpha\Delta V}{\kappa}\right),$$

and the relation between $\partial\Delta S_v/\partial p$ and $\partial\Delta S_p/\partial p$ is

$$[14] \qquad \frac{\partial\Delta S_v}{\partial p} = \frac{\partial\Delta S_p}{\partial p} - \frac{\partial}{\partial p}\left(\frac{\alpha\Delta V}{\kappa}\right).$$

It follows from these considerations that a zero value of ΔV will necessitate a compensation effect either in $\partial\Delta H_p/\partial p$ and $T\partial\Delta S_p/\partial p$, or in $\partial\Delta U_v/\partial p$ and $T\partial\Delta S_v/\partial p$, or of course in both, unless the quantity $\partial\,(\alpha\Delta V/\kappa)/\partial p$ is zero. There may, of course, be other factors that tend to induce compensation.

The existence of compensation in the variation of the Arrhenius energy and the pre-exponential factor with pressure was first observed experimentally many years ago (12).

3. EXPERIMENTAL

Materials

Mallinckrodt A.R. acetone and Fisher Certified Reagent acetophenone were used directly. Absolute ethanol was used in preparing ethanol–water solvents. D_2O (99.6%) was obtained from Atomic Energy of Canada, Ltd. Ethanol-d_1 was prepared in this laboratory according to the method of Burr (13); it was shown by infrared spectroscopy to be at least 95% deuterated in the hydroxyl group. All other chemicals were of reagent grade.

Kinetics at Atmospheric Pressure

Stock standard aqueous solutions of acetone (0.5 *M*), iodine (0.01 *M*), and perchloric acid (1 *M*) were prepared. A stock solution of acetophenone (0.5 *M*) was made in absolute ethanol. The reaction solution was made in a 100 ml volumetric flask by pipetting to 50 ml of water, standard solutions of perchloric acid (5 ml), ketone (10 ml), and iodine (10 ml). For experiments in water the solution was made up to 100 ml with water. For experiments in ethanol–water solvents, either 20 or 40 ml of ethanol was added before making up the volume to 100 ml with water to give respectively 16.2 and 33.4% w/w ethanol in water. After thorough mixing, the flask was immersed in a water thermostat whose temperature was controlled to ±0.005 °C and was measured by a platinum resistance thermometer. The temperature was maintained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

at 25, 35, and 45 °C for acetone and at 30, 40, and 50 °C for acetophenone. At successive intervals, 10 ml of the reaction solution was removed and titrated with aqueous sodium thiosulphate (0.002 *N*) using starch as indicator. To ensure temperature equilibrium, at least 20 min was allowed before the first sample was removed. About six points were taken and the reaction was followed nearly to completion. Blank experiments without ketone established that iodine did not react with the medium. The absence of iodine at the end of the reaction showed that the reaction went to completion.

For experiments with acetophenone in solvent 16.2% w/w ethanol-d_1 in D_2O, the reaction solution was made in a 25-ml volumetric flask. The acetophenone and perchloric acid (~0.2 g 70.0% w/w $HClO_4$) were weighed directly into the flask, which contained 5 ml of ethanol-d_1, and the flask was nearly filled with D_2O. Three milliliters of a stock iodine solution (~0.008 *M*) in D_2O was added and the solution was made up to 25 ml with D_2O. The proportion of deuterium in this solvent was at least 99%. Five milliliters of the reacting solution was periodically titrated with thiosulphate (0.001 *N*). Four points were taken and the reaction was followed nearly to completion.

In the foregoing experiments, the initial concentration of acetone and the concentration of perchloric acid were about 0.05 *M* at 25 °C and 0.025 *M* at the higher temperatures. The initial concentration of acetophenone and the concentration of perchloric acid were about 0.05 *M* at 30 and 40 °C and 0.03 *M* at 50 °C. The initial concentration of iodine was ~0.001 *M* throughout.

Kinetics at High Pressures

The high-pressure technique was similar to that used previously (14) except for the following modification. Since iodine reacted appreciably with the sampling valve (E of Fig. 1 of ref. 14) a batch method was used to follow the reaction. The reaction vessel was a 2-oz polyethylene bottle provided with a tight-fitting leak-proof cap. The part of the pressure apparatus beyond the junction block F (see Fig. 1 of ref. 14) was eliminated.

The reaction solution was made as in the experiments at atmospheric pressure, a stopwatch being started (stopwatch reading *a*, which is zero) when the iodine solution was added. The polyethylene bottle was filled almost completely with the reaction solution immediately after the solution was mixed, and was placed inside the pressure vessel. The pressure vessel was filled with oil, assembled, immersed in the thermostat, and quickly brought up to pressure. When the desired pressure as read on the Bourdon gauge was reached, the time was noted on the stopwatch (stopwatch reading *b*). After one-half hour (stopwatch reading *c*), the pressure was released and the bottle was removed. The outside oil was wiped off and 10 ml of the solution were pipetted out and titrated (stopwatch reading *d*) with thiosulphate (0.002 *N*). This titer reading was taken as that for zero time. Other samples were put into the bottle and left for different times, i.e., the time interval between *b* and *c* was either 1, 1.5, or 2 h. Four points were taken for each run. The time intervals between *a* and *b* and between *c* and *d* were kept exactly the same for all four samples. In a typical experiment at a pressure of 3 kbar, the time interval between *a* and *b* was 8 min and that between *c* and *d* was 7 min. A blank experiment at 3 kbar without addition of the ketone showed that iodine did not react with the medium. The absence of iodine after a sufficient time at 3 kbar showed that the reaction went to completion. The initial concentration of ketone and the concentration of acid were about 0.05 *M* except for the runs at 3 kbar in 33.4% w/w ethanol in water, for which concentrations of about 0.025 *M* were used.

In all the kinetic experiments the initial concentrations of ketone and acid were kept nearly equal in order to suppress the effect of autocatalysis on the rate of iodination. Further, the molar ratios of ketone to iodine were high enough to exclude the possibility of any di-iodination.

4. RESULTS

All kinetic runs were accurately zero order in iodine, and the zero-order rate constants at atmospheric pressure were obtained by least-squares analysis using a digital computer. The reason for this was that the effect of solvent on the enthalpy and entropy of activation was required, and rate constants of maximum accuracy were required to determine this. The rate constants at higher pressures were obtained by the usual graphical method. The second-order rate constants k_a were obtained by dividing the zero-order constants by the product of the concentrations of ketone and perchloric acid. For kinetic runs in water, the rate constants were corrected for compression of the solution (15) which was assumed without significant error to be that of water. Similar corrections for compression could not be applied to rate constants in ethanol–water solvents since compression of these solutions has not been extensively measured. The rate constants in these solvents were therefore only corrected for the thermal expansion of the solvent at atmospheric pressure. The rate constants at atmospheric pressure are given in Table I, and those at higher pressures in Table II. Our mean value for $10^6 k_a$/l mole^{-1} s^{-1} for acetone (see

*k is k_a for solvent water, and $k_a\rho(p)/\rho$ (1 bar), where $\rho(p)$ and ρ(1 bar) are the densities of the solvent at pressure p and 1 bar respectively, for solvents ethanol–water.

Table I) at atmospheric pressure in water is 27.6, which is in good agreement with the literature values; a collection of these can be found elsewhere (16).

The main quantities to be derived from the rate constants that are of interest in this work are the effect of solvent on the enthalpies and entropies of activation at constant pressure, and on the volumes of activation. If k_1 and k_2 represent rate constants at the same temperature in two different solvents, and $\Delta H_p^{\ddagger}$ and $\Delta S_p^{\ddagger}$ represent the enthalpy and entropy of activation in the same solvents, then

[15] $$\ln k_2/k_1 = \Delta\Delta H_p^{\ddagger}/RT - \Delta\Delta S_p^{\ddagger}/R$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where

[16] $$\Delta\Delta H_p^{\neq} = \Delta H_{p_1}^{\neq} - \Delta H_{p_2}^{\neq},$$

and

[17] $$\Delta\Delta S_p^{\neq} = \Delta S_{p_1}^{\neq} - \Delta S_{p_2}^{\neq}.$$

Plots of log k_2/k_1 against $1/T$ yield $\Delta\Delta H_p^{\neq}$ and $\Delta\Delta S_p^{\neq}$. These are shown in Fig. 1, and the

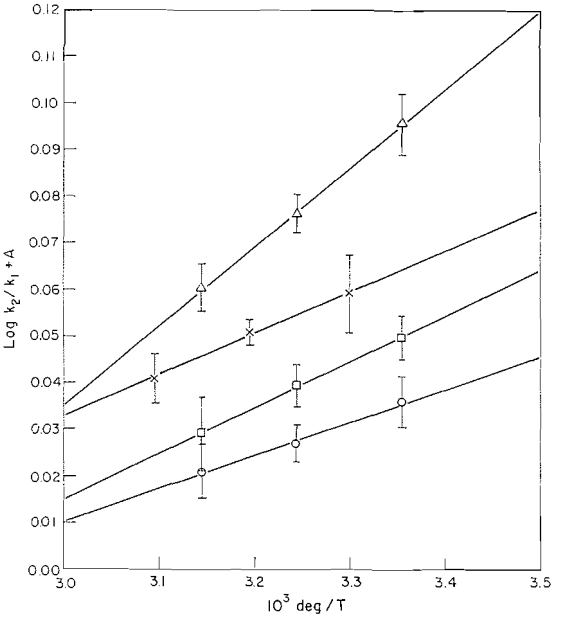

FIG. 1. $\text{Log}_{10}\, k_2/k_1$ against $1/T$ for the acid-catalyzed enolization (iodination) of acetone and acetophenone. Points △, □, and ○ refer to acetone, and × refers to acetophenone. △ ($A = 0$); 33.4% w/w ethanol in water : water. □ ($A = 0.01$), × ($A = 0.02$); 33.4% w/w ethanol in water : 16.2% w/w ethanol in water. ○ ($A = -0.02$); 16.2% w/w ethanol in water : water.

quantities $\Delta\Delta H_p^{\neq}$ and $\Delta\Delta S_p^{\neq}$ are listed in Table IV together with approximate estimates of their standard errors. The values were verified by plotting (plots not shown) $T \log k_2/k_1$ against T. The Arrhenius parameters themselves for the enolization of acetone in water in the range 25–45° obtained by the usual graphical method, are

$$E_A = 20.5 \pm \sim 0.2 \text{ kcal mole}^{-1},$$

$$\log_{10} A/\text{l mole}^{-1}\,\text{s}^{-1} = 10.5 \pm \sim 0.1.$$

These are in excellent agreement with the literature values 20.6 kcal mole^{-1} and 10.6 respectively (17). The Arrhenius parameters for the enolization of acetophenone in 16.2% w/w ethanol in water in the range 30–50 °C are

$$E_A = 21.5 \pm \sim 0.2 \text{ kcal mole}^{-1},$$

$$\log_{10} A/\text{l mole}^{-1}\,\text{s}^{-1} = 10.9 \pm \sim 0.1.$$

Plots of the logarithms of the rate constants against pressure are shown in Figs. 2 and 3. The volumes of activation were obtained by extrapolating plots of log $k(p_2)/k(p_1)$

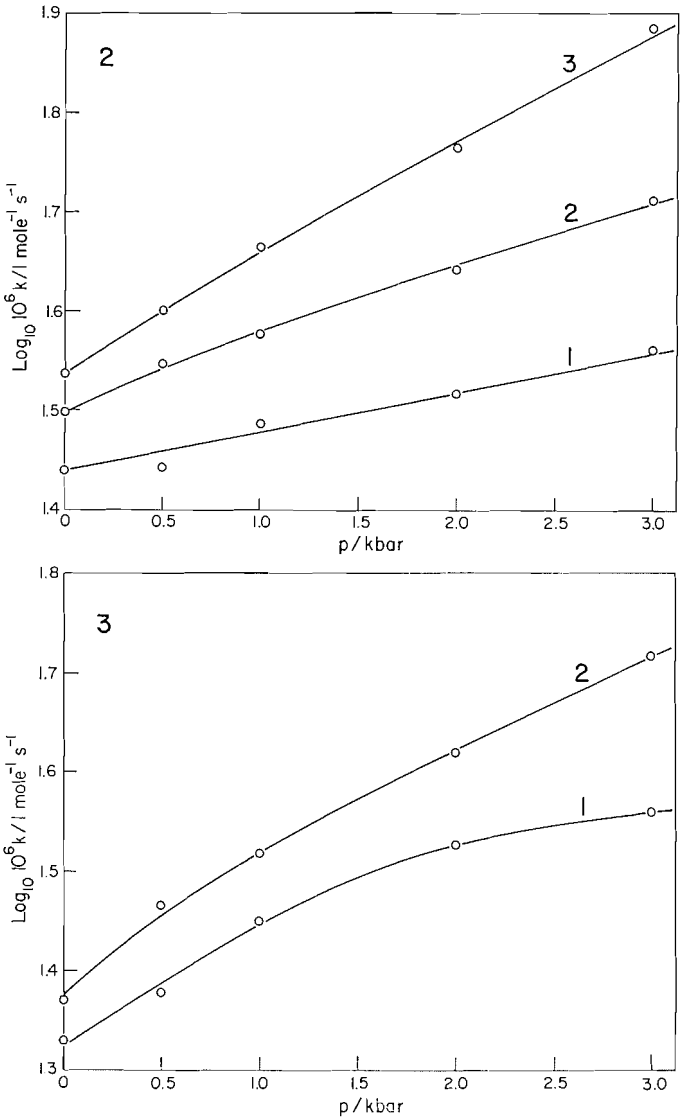

FIG. 2. Effect of pressure on the rate of enolization of acetone at 25.00 °C. Curve 1: in water. Curve 2: in 16.2% w/w ethanol in water. Curve 3: in 33.4% w/w ethanol in water.

FIG. 3. Effect of pressure on the rate of enolization of acetophenone at 30.00 °C. Curve 1: in 16.2% w/w ethanol in water. Curve 2: in 33.4% w/w ethanol in water.

against $\frac{1}{2}(p_2 + p_1)$ to zero pressure, where p_1 and p_2 are adjacent pressures at which the rate constants were measured. The differences in the volumes of activation in two solvents were verified by plotting log k_1/k_2, where k_1 and k_2 are the rate constants in two solvents at the same temperature and pressure, against p. For ethanol–water solvents the compression of the reaction mixture was allowed for by subtracting κRT from the value of $-RT\partial \ln k/\partial p$ at zero pressure (for a similar correction see ref. 18) where κ is the compressibility of the solvent at zero pressure. Using the compressibilities of ethanol–water mixtures as interpolated from Moesveld's data (19), i.e., 39.5×10^{-6} and 44.5×10^{-6}

bar^{-1} respectively, the value of κRT in 16.2% w/w ethanol in water is 1.0 cm^3 mole^{-1}, and in 33.4% w/w ethanol in water is 1.1 cm^3 mole^{-1}. The volumes of activation are given in Table III.

TABLE III

Volumes of activation for the acid-catalyzed enolization of acetone and of acetophenone

Ketone	Solvent	Temp. (°C)	$\Delta V^{\neq}$/cm^3 mole^{-1}
Acetone	Water	25.00	$-2.1\pm\sim0.5$
	16.2% w/w ethanol in water		$-4.2\pm\sim0.7$
	33.4% w/w ethanol in water		$-6.9\pm\sim0.7$
Acetophenone	16.2% w/w ethanol in water	30.00	$-6.0\pm\sim0.7$
	33.4% w/w ethanol in water		$-8.6\pm\sim1.0$

The effect of solvent on the rate constant at various pressures is shown in Fig. 4. The

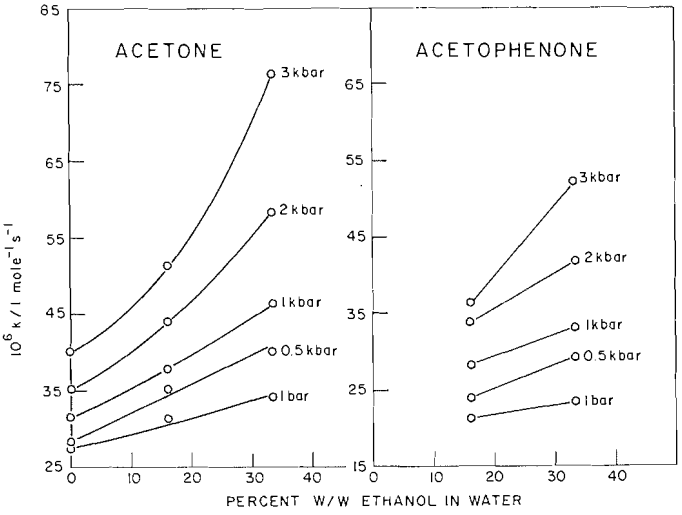

FIG. 4. Effect of solvent on the rate of enolization of acetone at 25.00 °C and of acetophenone at 30.00 °C at different pressures. The definition of k is given in the footnote of Table II.

rate constants for acetone in water at various pressures shown in this plot are uncorrected for compression of the solution, so that a true comparison with the rate constants in ethanol–water solvents, which are also uncorrected for compression, can be made. Because acetophenone is almost insoluble in water, it was not possible to study its iodination kinetics in water under comparable conditions to those used for acetone. The curves for acetophenone in Fig. 4 were therefore drawn as straight, although by comparison with the curves for acetone, they are probably not accurately straight.

5. DISCUSSION

1. Solvent Deuterium Isotope Effect for the Enolization of Acetophenone

The solvent deuterium isotope effect for the enolization of acetophenone k^{D_2O}/k^{H_2O} in 16.2% w/w ethanol in water is $2.50\pm\sim0.05$. This undoubtedly proves that there is a pre-equilibrium proton transfer to the ketone preceding the rate-determining step. The value is similar to the value 2.1 reported (6) for acetone.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

2. Effect of Solvent on the Rate of Enolization

The effect of solvent on the rate of enolization is quite small at atmospheric pressure. Between 0 and 16.2% w/w ethanol in water the rate for acetone increases by about 10%, and between 16.2 and 33.4% w/w ethanol in water the rate for both acetone and acetophenone increases also by about 10%. Solvent effects of a similar magnitude were previously observed for the iodination of acetone in ethanol–water (20) and for the bromination of acetone and acetophenone in acetic acid – water (8) at atmospheric pressure. The slight increase in the rate is in the direction expected if it were due mainly to the electrostatic interaction between the reactants and the solvent, and the electrostatic charge were dispersed over a larger volume in the transition state than in the initial state without a significant increase in the dipole and higher moments (21). However, the change of rate is so small that any small electrostatic effects of this kind could easily be swamped by changes of more specific interactions between the reactants and the solvent. The results cannot therefore be taken as indicating the direction of the change of the polarity when the transition state is formed.

Furthermore, the effect of solvent on the rate (see Fig. 4) is about four times larger at 3 kbar than at 1 bar. The effect of solvent on the compression is much too small to account for this effect. It appears from Figs. 2 and 3 that if the rate constant as a function of pressure could be extrapolated smoothly into the region of negative pressures, then the solvent effect would change sign at about −1 kbar, and at pressures below this, increasing the concentration of organic solvent in the mixture would cause the reaction rate to decrease. The pressure at which the effect of solvent on the rate changes sign has actually been observed for the acid-catalyzed hydrolysis of methyl acetate (Withey, Poulton, Whalley, unpublished work), and more detailed comments will be made when this work is published. It is, nevertheless, clear that caution should be used when one is attempting to interpret small effects of solvent on the rate constant.

The large effect of pressure on the solvent effect for both the enolization of ketones and the hydrolysis of methyl acetate cannot be explained on simple electrostatic grounds, and indicates that any explanation of the solvent effect at 1 bar on simple electrostatic grounds is invalid. Rather, the small solvent effect at 1 bar is almost certainly due to two or more larger effects that in large part cancel one another. The relatively large effect of pressure on the solvent effect is probably due to a smaller relative effect of pressure on one or more of these component solvent effects.

The effect of pressure on the solvent effect and the effect of solvent on the volume of activation are, of course, different ways of describing the same thing. Because

$$\frac{\partial}{\partial x}\left(\frac{\partial \ln k}{\partial p}\right)_T = \frac{\partial}{\partial p}\left(\frac{\partial \ln k}{\partial x}\right)_T$$

where x is the concentration of one component of the solvent mixture, then

$$\frac{\partial}{\partial p}\left(\frac{\partial \ln k}{\partial x}\right) = -\frac{1}{RT}\frac{\partial \Delta V^{\neq}}{\partial x}.$$

The discussion of the effect of solvent on the volume of activation in Section 5.4 is therefore relevant also to this section.

3. Volumes of Activation in Water

The volume of activation for the enolization of acetone in water is $-2.1 \pm \sim 0.5$ cm^3 mole^{-1}. The volume of activation for the enolization of acetophenone is not known in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

water, but it is 1.8 cm^3 $mole^{-1}$ more negative than that of acetone in both 16.2 and 33.4% w/w ethanol in water. It is likely therefore that the volume of activation for acetophenone in water is about -3.9 cm^3 $mole^{-1}$.

Because the ketones are only slightly protonated under the experimental conditions, the volumes of activation are the difference in partial volume between the transition state and the initial ketone and hydronium ion. The volumes of activation for acid-catalyzed reactions of the kind

$$R + H_3O^+ \overset{\text{fast}}{\rightleftharpoons} RH^+ + H_2O,$$

$$RH^+ + H_2O \overset{\text{slow}}{\longrightarrow} \text{products},$$

where a new H_2O—C bond is formed in the slow step are usually about -8 to -12 cm^3 $mole^{-1}$ (21), and similar values are usually found for reactions of the kind (21)

$$R_1O^- + R_2X \rightarrow R_1OR_2 + X^-.$$

It is therefore at first sight a little surprising to find -2.1 cm^3 $mole^{-1}$ for the enolization of acetone. There are probably two reasons for the high volume of activation.

For approximate purposes a volume of activation can be divided into two parts (21), $\Delta V_r^{\neq}$ which is the change of volume due directly to the changing interaction of the reacting molecules with one another, and $\Delta V_s^{\neq}$, which is the change of volume due directly to the changing interaction of the reacting molecules with the solvent. For bimolecular reactions such as we are discussing $\Delta V_r^{\neq}$ is approximately the contraction (or expansion) of the interatomic distance when a partial valence bond is formed (or broken) multiplied by the cross-sectional area perpendicular to the bond. Both the contraction and the cross-sectional area are probably smaller when a water molecule substitutes at a hydrogen atom than when it substitutes at a carbon atom. Consequently, $\Delta V_r^{\neq}$ for the acid-catalyzed enolization of ketone is probably less negative than that for bimolecular (A-2) acid-catalyzed hydrolyses.

If for approximate purposes we represent part of the interaction between an ion and its solvent by that between a charged spherically symmetrical ion and a continuous dielectric, then $\Delta V_s^{\neq}$ can be represented in part as the difference between reactants and transition state of the quantity (22),

$$[18] \qquad \tfrac{1}{2}N\frac{z^2e^2}{a}\left\{\frac{\partial\epsilon^{-1}}{\partial p} + \left(1 - \frac{1}{\epsilon}\right)\frac{\partial \ln a}{\partial p}\right\}$$

where N is Avogadro's number, z is the number of electronic charges e on the ion, a is the radius of the cavity containing the ion, and ϵ is the dielectric constant. The transition state for the enolization of acetone can be represented by

$$CH_3—\overset{\overset{OH^{\delta+}}{\|}}{C}=CH_2\cdots H\cdots OH_2^{(1-\delta)+},$$

and that for a typical A-2 reaction such as the acid-catalyzed hydrolysis of diethyl ether can be represented as

$$CH_3—CH_2\cdots\overset{\overset{(1-\delta)+}{OH_2}}{\overset{|}{O}}H^{\delta+}—CH_2—CH_3.$$

The positive charge is clearly more widely dispersed in the ketone transition state than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

in the ether transition state, and consequently the effective radius of the charge can be considered to be greater. In both transition states the effective radius is, of course, greater than in the initial hydronium ion. $\Delta V_s^{\ddagger}$ for both reactions will therefore be positve and will be more positive for the ketone reaction than for the ether reaction. The increase of volume is composed of an increase of the volume of both the reactants and the solvent due to the decrease of the interaction between them (22).

We see therefore that both $\Delta V_r^{\ddagger}$ and $\Delta V_s^{\ddagger}$ are probably algebraically larger for the ketone enolization than for the ether hydrolysis, and so the volume of activation is probably algebraically larger, in agreement with observation. It is clear that where there is a possibility of a large dispersion of charge, caution may be required in using volumes of activation to help determine mechanisms (21).

The fact that the volumes of activation for acetone and acetophenone are not greatly different and that of acetophenone is more negative than that of acetone suggests that there is little dispersion of charge into the benzene ring of acetophenone. The relatively small effect of para substituents on the rate of enolization of substituted acetophenones (8) agrees well with this view.

4. Effect of Solvent on Volume of Activation

The effect of solvent on the volume of activation (Table III) for both acetone and acetophenone is rather large, the volume of activation for acetone in 33.4% w/w ethanol–water being over three times the value for water. The volumes of activation for the acid-catalyzed hydrolysis of methyl acetate (Withey, Poulton, and Whalley, unpublished work) changes by about the same amount in solvent acetone–water as does that for acetone in ethanol–water of similar concentration, although the relative change for methyl acetate is smaller due to its volume of activation in water being four times bigger than that for acetone (23).

The effect of solvent on a volume of activation is almost by definition an effect on $\Delta V_s^{\ddagger}$ if the mechanism does not change. We have seen in Section 5.3 that $\Delta V_s^{\ddagger}$ is probably positive, and so to explain the observed decrease in $\Delta V^{\ddagger}$ with increasing proportion of organic solvent in terms of the ion-dielectric theory represented by equation 18 requires that $\partial\epsilon^{-1}/\partial p$ should increase in the range of solvent water to 33.4% w/w ethanol–water. This is not a priori unlikely, in spite of the fact that $\partial\epsilon^{-1}/\partial p$ for ethanol is much smaller than that for water (24) because the initial effect of adding ethanol to water is to cause the compressibility to decrease (19). A little more information can be obtained from theory. The dielectric constant of a mixture of polar substances can be represented approximately by the expression (25)

$$[19] \qquad \frac{(\epsilon - 1)(2\epsilon + 1)}{9\epsilon} V = \sum_i \frac{(\epsilon_i - 1)(2\epsilon_i + 1)}{9\epsilon_i} x_i V_i$$

where ϵ and ϵ_i are the dielectric constants of the mixture and of pure component i, V and V_i are the molar volumes of the solution and of component i, and x_i is the mole fraction of component i. For ethanol–water mixtures at room temperature the dielectric constants are much greater than unity, and equation [19] can be simplified approximately to

$$[20] \qquad \epsilon V = \sum_i \epsilon_i V_i x_i,$$

which can also be written

$$[21] \qquad \epsilon = \sum_i \epsilon_i \varphi_i$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where φ_i is the volume fraction of component i,

[22] $$\varphi_i = V_i x_i / V.$$

By differentiating equation [21] with respect to pressure and introducing the isothermal compressibility κ_i and the pressure coefficient ζ_i of the dielectric constant

$$\zeta_i = \partial \ln \epsilon_i / \partial p,$$

we find

[23] $$\frac{\partial \epsilon^{-1}}{\partial p} = -\epsilon^{-2} \sum \epsilon_i \varphi_i (\zeta_i - \kappa_i + \kappa).$$

The values of $\partial \epsilon^{-1}/\partial p$ for various ethanol–water mixtures calculated according to equation [23] are as follows.

Solvent	$10^6(\partial \epsilon^{-1}/\partial p)$/bar^{-1}
Water	−0.74
16.2% w/w ethanol in water	−0.74
33.4% w/w ethanol in water	−0.91
Ethanol	−3.58

It seems likely therefore that $\partial \epsilon^{-1}/\partial p$ changes little between water and 33.4% w/w ethanol in water, and perhaps slightly decreases. The effect of solvent on $\Delta V_s^{\neq}$ cannot therefore be explained on the basis of ion-dielectric theory if equation [23] is moderately accurate. It is possibile that part of the decrease in $\Delta V_s^{\neq}$ with increasing proportion of organic solvent is due to there being greater unmixing of water and ethanol around the H_3O^+ ion than around the transition state; since water and ethanol have a larger volume when unmixed than when mixed, greater unmixing around the H_3O^+ ion than around the transition state would tend to make $\Delta V_s^{\neq}$ smaller in water–ethanol mixtures than in water. This could, in principle, be treated in terms of the dielectric theory, but it is not worthwhile. There are also other interactions between the reactant and the solvent about which little is known quantitatively, and they are probably playing their part.

5. Quantities of Activation at Constant Pressure and at Constant Volume: Variation with Solvent

The free-energy of activation ($\Delta G_p^{\neq}$ or $\Delta A_v^{\neq}$) for the enolization of acetone and acetophenone in ethanol–water mixtures changes little with solvent. The volumes of activation for the reactions are not zero, and change considerably with changing solvent. It follows, according to the arguments given in section 2, that there should be compensation either in $\Delta H_p^{\neq}$ and $T\Delta S_p^{\neq}$ or in $\Delta U_v^{\neq}$ and $T\Delta S_v^{\neq}$. The differences, $\Delta\Delta H_p^{\neq}$ and $T\Delta\Delta S_p^{\neq}$, in $\Delta H_p^{\neq}$ and $T\Delta S_p^{\neq}$ between solvents are listed in Table IV together with the changes in $T\alpha\Delta V^{\neq}/\kappa$ and in $\Delta U_v^{\neq}$ and $T\Delta S_v^{\neq}$. It is clear that the intrinsic energy and entropy of activation at constant volume change much less with changing solvent than do the enthalpy and entropy of activation at constant pressure. There is therefore a significant energy–entropy compensation in the constant-pressure parameters of activation but not in the constant-volume parameters. There have been several suggestions in the past that quantities of activation at constant volume should be more easily understood than quantities of activation at constant pressure (see ref. 21 for references). There has, however, been no previous reliable test of this suggestion. A test was made 25 years ago using the homogeneous dimerization of cyclopentadiene (26) but doubts have recently been cast (27) on the reliability of the experimental results used (28).

TABLE IV

Changes with solvent of the activation parameters for the acid-catalyzed enolization of acetone and acetophenone. The temperature range was 25–45 °C for acetone and 30–50 °C for acetophenone. Temperature-dependent parameters were evaluated at 25 °C for acetone and at 30 °C for acetophenone

Ketone	Solvent	$\Delta\Delta G_p^{\ddagger}$ (= $\Delta\Delta A_v^{\ddagger}$)* cal mole^{-1} ±∼5	$\Delta\Delta H_p^{\ddagger}$ cal mole^{-1} ±∼120	$T\Delta\Delta S_p^{\ddagger}$ cal mole^{-1} ±∼120	$T\Delta(\alpha\Delta V^{\ddagger}/\kappa)$† cal mole^{-1} ±∼100	$\Delta\Delta U_v^{\ddagger}$ cal mole^{-1} ±∼150	$T\Delta\Delta S_v^{\ddagger}$ cal mole^{-1} ±∼150
Acetone	16.2% w/w ethanol in water	76	325	250	216	109	34
	33.4% w/w ethanol in water	130	775	645	572	203	73
Acetophenone	33.4% w/w ethanol in water	54	405	350	373	32	−23

*Solvent 1 (eqs. 15–17) for acetone is water and for acetophenone is 16.2% w/w ethanol in water. Solvent 2 is listed in column 2 of this table. The quantities $\Delta\Delta G_p^{\ddagger}$ were evaluated from the equation $\Delta\Delta G_p^{\ddagger} = RT \ln k_2/k_1$ where T refers to the temperature at which $\Delta V^{\ddagger}$ has been measured. The quantities $\Delta\Delta H_p^{\ddagger}$ and $T\Delta\Delta S_p^{\ddagger}$ were obtained from plots shown in Fig. 1.

†The thermal expansion ($10^6\,\alpha$/deg^{-1}) for water is 248 (25 °C), for 16.2% w/w ethanol in water is 396 at 25 °C, and 441 at 30 °C, and for 33.4% w/w ethanol in water is 594 at 25 °C, and 613 at 30 °C. These were obtained by plotting log (density) against temperature and evaluating the slopes at the temperatures desired. The densities were taken from the literature (31). The compressibilities ($10^6\,\kappa$/bar^{-1}) of these solvents from Moesveld's data (19) are 43.9, 39.5, and 44.5 respectively at 25 °C, and the same values were assumed for 30 °C. T is the temperature at which $\Delta V^{\ddagger}$ has been measured.

TABLE V

Changes with substituent of the activation parameters for the acid-catalyzed enolization of acetone and acetophenone at 30 °C
($\Delta\Delta$ = $\Delta_{\text{acetophenone}} - \Delta_{\text{acetone}}$)

Solvent	$\Delta\Delta G_p^{\ddagger}$ (= $\Delta\Delta A_v^{\ddagger}$) cal mole^{-1} ±∼5	$\Delta\Delta H_p^{\ddagger}$ cal mole^{-1} ±∼120	$T\Delta\Delta S_p^{\ddagger}$ cal mole^{-1} ±∼120	$T\alpha\Delta V/\kappa$ cal mole^{-1} ±∼100	$\Delta\Delta U_v^{\ddagger}$ cal mole^{-1} ±∼150	$T\Delta\Delta S_v^{\ddagger}$ cal mole^{-1} ±∼150
16.2% w/w ethanol in water	563	1365	803	−146	1511	949
33.4% w/w ethanol in water	557	1510	953	−170	1680	1123

Many attempts have been made in the past to explain the observed enthalpy–entropy compensation effect in a variety of systems (29, 30 and references quoted there). For the system investigated here, the fact that there is little energy–entropy compensation in the constant-volume parameters seems to require no special explanation. The explanation of the enthalpy–entropy compensation in the constant-pressure parameters requires an explanation of the variation of $\alpha\Delta V^{\neq}/\kappa$ with solvent, because of the relationship in equations [6] and [7]. For the enolization of acetone in water and in 33.4% w/w ethanol in water, α changes from 248×10^{-6} to 594×10^{-6} deg^{-1} (Table IV, footnote), $\Delta V^{\neq}$ changes from -2.1 to -6.9 cm^3 mole^{-1} (Table III), and κ changes from 43.9×10^{-6} to 44.5×10^{-6} bar^{-1}. The changes of these quantities between water and 16.2% w/w ethanol in water for the enolization of acetone, and between 16.2% w/w and 33.4% w/w ethanol in water for the enolization of acetophenone (see Tables III and IV) are similar to these changes. The change in $\alpha\Delta V^{\neq}/\kappa$ is therefore due about equally to changes in the thermal expansivity and in the volume of activation and hardly at all to changes in the compressibility. The causes of the change of the volume of activation with solvent are discussed in Section 5.4. The change of the thermal expansitivity with solvent is undoubtedly due largely to the small thermal expansivity of water due to its peculiar structure. The thermal expansivitity of pure water is of course zero near 4 °C, and then the quantities of activation at constant pressure and at constant volume are equal.

6. Quantities of Activation at Constant Pressure and at Constant Volume: Variation with Substituent

Since the intrinsic energy and entropy of activation at constant volume change little with changing solvent (Section 5.5) although the enthalpy and entropy of activation at constant pressure change appreciably, it is worth investigating the change of the two sets of activation parameters with changing substituent. The differences in the activation parameters at constant pressure were obtained from plots analogous to those in Fig. 1. For this purpose, rate constants for acetone at 30 °C were interpolated from Arrhenius plots. The results for both 16.2% w/w and 33.4% w/w ethanol in water are summarized in Table V. There is compensation in both the constant-pressure and the constant-volume parameters, and the compensation in the constant-volume parameters is the greater. There is little doubt that attempts to explain the compensation quantitatively should be based on the constant-volume parameters.

6. CONCLUSIONS

The most important conclusions derived from the experiments reported in this paper are as follows:

1. The effect of solvent on the rate of a reaction may be greatly influenced by pressure, and care is required in interpreting solvent effects, particularly small solvent effects, at atmospheric pressure. It is wise to study the effect of both temperature and pressure on the solvent effect.

2. Reactions whose rates change only slightly with changing conditions (such as substituents, solvent, etc.) inevitably will have an energy–entropy compensation effect in either the enthalpy and entropy of activation at constant pressure or in the energy and entropy of activation at constant volume, or, of course, in both sets of parameters. There is no significant compensation in the variation with solvent of the constant-volume parameters for the enolization of acetone and of acetophenone in ethanol–water mixtures; the compensation in the constant-pressure parameters can be ascribed about

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

equally to changes in the thermal expansion and in the volume of activation with changing solvent. There is more compensation in the variation with substituent of the constant-volume parameters for the enolization of acetone and acetophenone than in the constant-pressure parameters. Attempts to explain the compensation in quantitative terms should doubtless be based on the constant-volume parameters if these differ significantly from the constant-pressure parameters.

ACKNOWLEDGMENTS

We are grateful to Mr. R. Ironside for the infrared analysis and to Mr. A. Lavergne for help with the high-pressure apparatus.

KINETICS AND MECHANISMS OF THE THERMAL DECOMPOSITION OF ACETALDEHYDE

I. THE UNINHIBITED REACTION

M. Eusuf and K. J. Laidler
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received March 5, 1964

ABSTRACT

The kinetics of the uninhibited decomposition of acetaldehyde have been reexamined. The initial rates of the decomposition of pure acetaldehyde show strict three-halves-order dependence at temperatures from 480 to 525 °C, and the activation energy is 47.6 kcal per mole. Foreign gases, which decrease the rate of reaction, cause a significant increase in order. The rate of ethane formation is second order in acetaldehyde, and Trenwith has found the hydrogen formation to be second order in acetaldehyde. The results are shown to be consistent only with a mechanism involving second-order initiation and the third-order reaction $2CH_3 + M \rightarrow C_2H_6 + M$ as the terminating step. The rate of the initiation process is increased only to a small extent by the addition of inert foreign gases; it is suggested that the initial process may be $CH_3CHO + CH_3CHO \rightarrow CH_3CHOH + CH_3CO$, with a subsequent breakdown of CH_3CHOH into $CH_3CHO + H$. The mechanism is shown to account for the overall kinetic behavior and for the formation of the minor products.

INTRODUCTION

Steacie (1) commented that "the acetaldehyde decomposition is remarkable for the lack of agreement of both mechanism and experimental fact, and for the complications involved." The Rice-Herzfeld mechanism (2), involving first-order initiation and second-order termination ($CH_3 + CH_3$), is a straightforward example of a mechanism leading to three-halves-order kinetics and has commonly been regarded as giving a correct interpretation of the acetaldehyde decomposition. On the other hand, Bril, Goldfinger, Letort, Mattys, and Niclause (3, 4) have proposed an alternative explanation, based largely on the results of experiments in which foreign gases were added to the reaction system; their conclusion was that the termination step, the combination of methyl radicals, is in its third-order region and that the initiation reaction is hardly affected by inert gases. The work of Laidler and Wojciechowski (5) on the ethane decomposition also led to the conclusion that, under the usual conditions of pyrolysis experiments, the methyl-radical combination reaction is third order. A difficulty still remains, however, since a third-order termination reaction requires a second-order initiation reaction in order for the overall order to be three-halves; this, however, appears to be inconsistent with the conclusion that the initiation reaction is hardly influenced by the addition of several foreign gases. The fact that initiation is second order has received support from a recent investigation by Trenwith (6), who found that the rate of hydrogen production (which should be a good measure of the rate of initiation) is second order in acetaldehyde.

Further doubt about the mechanism has arisen as a result of Quinn's work (7) on the kinetics of methane production in the ethane decomposition. This appeared at first sight to require that the dissociation of ethane into $2CH_3$ is first order and the methyl radical combination, therefore, second order, which is inconsistent with conclusions from the acetaldehyde work. Quinn's results are not, however, compelling, since there is a possibility, as suggested by Danby, Spall, Stubbs, and Hinshelwood (8), that the predominant source of methane is the reaction

$$C_2H_6 \rightarrow CH_4 + CH_2.$$

This might occur as a first-order process and be much more important than the second-order dissociation of ethane into methyl radicals. This suggestion was put forward to explain the fact that the methane production is only very slightly inhibited by nitric oxide.

In view of these various difficulties it was decided to reinvestigate the reaction, both uninhibited and inhibited by nitric oxide (see Part II). Since a very large amount of reliable experimental work has been done on this problem, it was not thought necessary, in the present investigation of the uninhibited reaction, to carry out a great deal of additional experimental work. The work has, in fact, been confined to checking the overall order, to studying the kinetics of formation of the minor product ethane, and to obtaining some specific quantitative information about the effect of added foreign gases; in particular, the effect of foreign gases (CO_2, CH_4, N_2, CO, and C_2H_6) on the order of the reaction has been carefully studied. On the basis of these results a mechanism is proposed for the overall reaction.

EXPERIMENTAL

It has been well established by previous work (8–13) that the only major products of the acetaldehyde decomposition are CH_4 and CO and that a pressure increase of 1 mm corresponds to the decomposition of 1 mm of acetaldehyde within the experimental error of 2%. The pressure technique has therefore been used entirely in the present investigation. A quartz Bourdon gauge was used, and its arm was attached to the armature of a Statham pressure transducer which was under some strain. The output from the transducer was recorded on a Philips pen-and-ink recorder, and initial rates were obtained by measuring the initial slopes of the records. The apparatus was calibrated from time to time and was found to be very stable; the displacement on the recorder varied exactly linearly with the pressure difference. The maximum sensitivity of the particular arrangement used was 0.5 inch displacement per mm Hg. All of the runs were, however, done at 1/10 or 1/20 of the maximum sensitivity, in order to give higher stability. Higher sensitivities could readily be obtained by modifications of the Bourdon gauge and in other ways, but only at the expense of a decrease in stability.

The procedure in carrying out a run was to maintain the outside pressure at a value that was slightly less than the initial pressure of the decomposing gas; as the reaction proceeded the differential pressure increased and could be followed on the recorder.

The reaction vessel was a pyrex cylinder 21 cm long and 4 cm in diameter, with a dead space of about 1% of the total volume. It was confined in a furnace consisting of a copper block, the temperature of which was controlled to within 0.2 °C by means of a thermocouple-activated controller. The temperature was measured using a thermocouple and a Minimite potentiometer.

Analysis of the minor product ethane was carried out using gas-phase chromatography. After a certain residence time in the furnace the reaction was stopped by allowing the gas to expand. Acetaldehyde was removed from the expanded gas by a dry ice – acetone mixture, and ethane was condensed in a small evacuated bulb surrounded by liquid nitrogen. With helium as carrier gas the ethane was passed through the chromatographic-analysis unit containing a 2 meter column packed with silica gel and maintained at 30 °C; the gas-chromatographic results were calibrated against known samples taken from the reaction vessel.

The acetaldehyde used was an Eastman product. It was purified by several bulb-to-bulb distillations at temperatures from 0 to −70 °C, special care being taken to free the compound completely from oxygen. The foreign gases used were Matheson Research Grade chemicals and were purified by several distillations.

RESULTS

The results were initially not very reproducible, but after several runs had been carried out in the same vessel a high degree of reproducibility was achieved.

The decomposition was studied from 480 to 525 °C and over the pressure range of 30 to 579 mm Hg. Figure 1 shows a double-logarithmic plot of rate against pressure and shows that the reaction is accurately of three-halves-order over the whole range of temperature and pressure; this agrees with the work of Boyer, Niclause, and Letort (14); Freeman, Danby, and Hinshelwood (15); and Imai, Yoshida, and Toyama (16). Figure 2 shows an Arrhenius plot, and from it the following rate expression is derived:

$$k = 1.16 \times 10^{13}\, e^{-47600/RT}\ cc^{1/2}\ mole^{-1/2}\ s^{-1}.$$

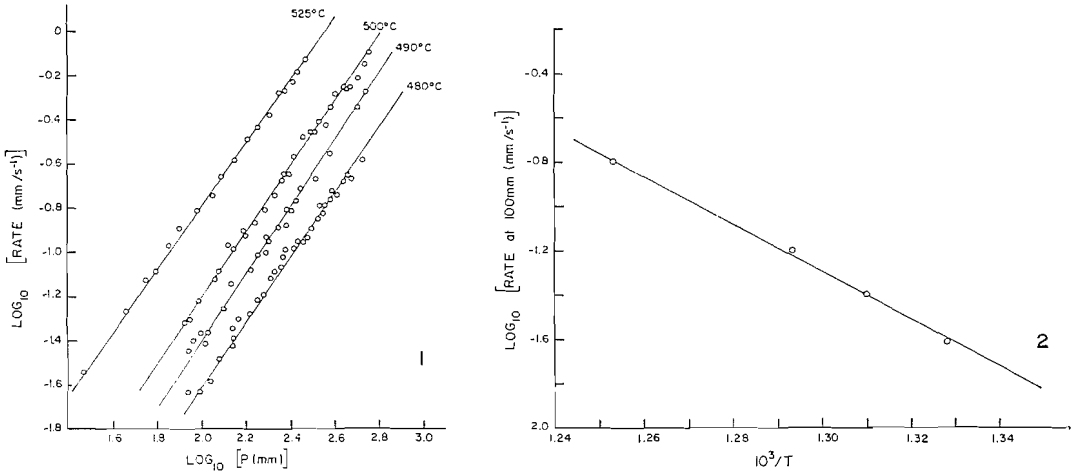

FIG. 1. Plots of log rate against log pressure for the uninhibited reaction.
FIG. 2. Arrhenius plot for the uninhibited reaction.

The activation energy agrees satisfactorily with the value of 48.0 kcal per mole obtained by Boyer, Niclause, and Letort (14) and of 47.7 kcal per mole at high pressure obtained by Fletcher and Hinshelwood (9).

Added foreign gases were found to bring about a decrease in the rate of the reaction, over the entire pressure range investigated, and to increase the order significantly. Figure 3 shows the effect of adding 100 mm of various foreign gases at 525 °C. The order of the

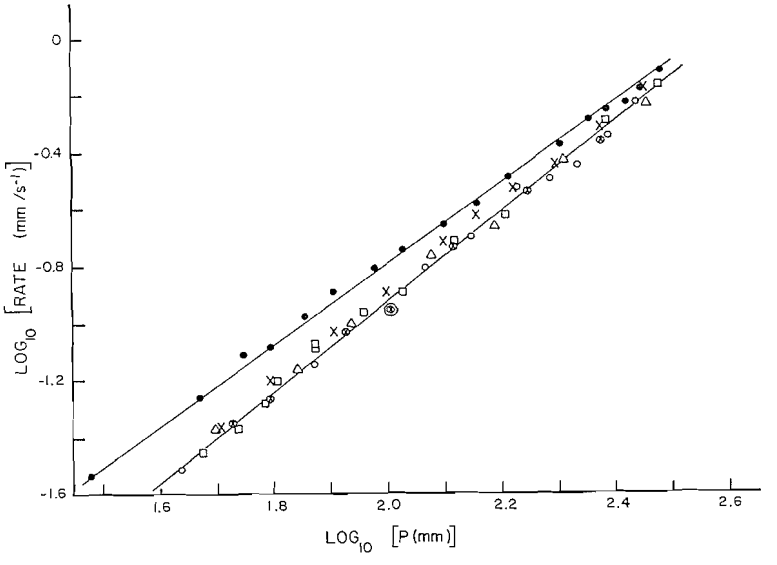

FIG. 3. Plots of log rate against log pressure showing the effects of 100 mm of added foreign gases at 525 °C. The black circles denote rates with no added foreign gases. Rates with added CO_2 are shown as ○, those with CH_4 as □, those with N_2 as △, those with CO as ⊗, and those with C_2H_6 as ×.

reaction has been increased from 1.5 to about 1.6. The figure further shows that essentially the same effect is brought about by adding the same pressure of carbon dioxide, methane, nitrogen, carbon monoxide, and ethane.

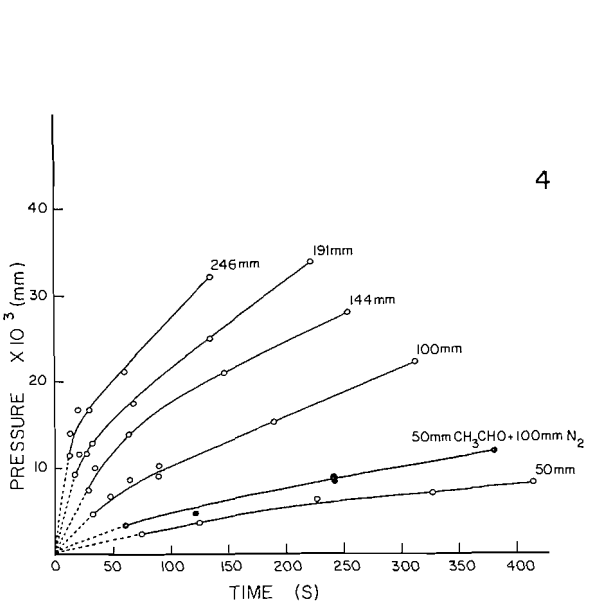

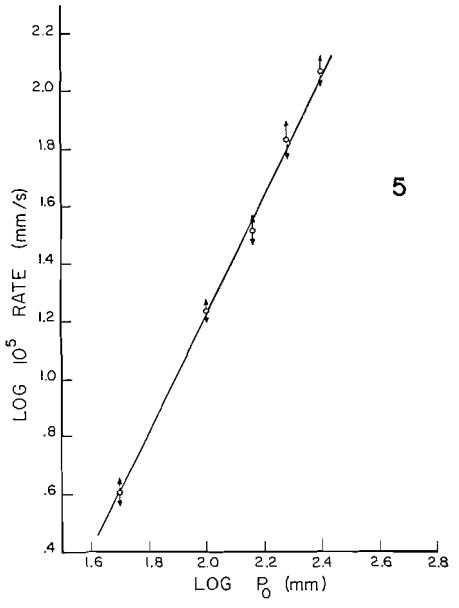

FIG. 4. Plots of the amount of ethane formed as a function of time with different initial pressures of acetaldehyde at 525 °C.

FIG. 5. Plots of log initial rate of formation of ethane against log initial pressure of acetaldehyde at 525 °C.

Figure 4 shows a plot of the amount of ethane formed as a function of time; the estimates of initial slopes have a probable error of 10%. In Fig. 5 the logarithms of the initial slopes, with the probable errors shown, are plotted against the logarithms of the initial acetaldehyde pressure; the slope is close to 2. Figure 4 also shows that the rate of ethane formation is increased by the addition of nitrogen.

DISCUSSION

The Reaction Mechanism

The principal difficulty that exists with regard to the mechanism of the acetaldehyde pyrolysis may be formulated as follows. If one uses the terminology introduced by Laidler, Sagert, and Wojciechowski (17) the possible mechanisms leading to 3/2-order kinetics are ${}^1\beta\beta_{3/2}$, ${}^2\beta\mu_{3/2}$, and ${}^2\beta\beta M_{3/2}$. The first of these, ${}^1\beta\beta_{3/2}$, is the original Rice-Herzfeld scheme; it can be rejected as predicting no inert-gas effect, and because it seems clear that the β radicals, being methyl radicals, must combine by third-order processes (5, 18). The second possibility must be rejected as predicting acceleration by inert gases. The third possibility in its simplest form leads to little or no inert-gas effect; it will now be shown, however, that a modification of the ${}^2\beta\beta M_{3/2}$ mechanism can be made to explain the results in a quantitative fashion.

What is needed is a mechanism that involves third-order termination—and in this way explains the inhibition by inert gases—and an initiation reaction that, as found in particular by Bril, Goldfinger, Letort, Mattys, and Niclause (3, 4), is only slightly affected by inert gas. The initiation reaction must, however, be in its second-order region, and acceleration by inert gas is normally to be expected. Since a variety of inert gases (CO_2, CO, CH_4, N_2, and C_2H_6) give the same effect, it would seem unreasonable to postulate that the gases involved are abnormally ineffective in transferring energy on collision to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

an acetaldehyde molecule. If, however, one postulates that an acetaldehyde molecule plays a very specific role in bringing about the decomposition of another acetaldehyde molecule, the difficulty disappears. The suggestion that is here made is that the initial step in the acetaldehyde decomposition occurs predominantly by the reverse of the "complex" mechanism for radical-combination reactions that has been proposed by Rabinowitch (19) and emphasized by Porter (20) on the basis of experimental results; this mechanism has recently been considered theoretically by Eusuf and Laidler (21). Specifically, it is suggested that the acetaldehyde initiation occurs as the hydrogen-atom transfer reaction

[1′] $$2CH_3CHO \rightarrow CH_3CO + CH_3CHOH$$

followed by

[2] $$CH_3CHOH \rightarrow CH_3CHO + H.$$

The overall process is the split of CH_3CHO into $CH_3CO + H$; the CH_3CHOH radical may also abstract a hydrogen atom from an acetaldehyde molecule or combine with the most abundant radical CH_3. The consequences of these reactions will be considered in a later section. The initiation reaction is second order but is unaffected by inert gases, since one of the acetaldehyde molecules plays a specific role in bringing about dissociation of the other.

The contribution of the proposed initiation reaction by hydrogen transfer may be compared with that of the corresponding splitting reaction

[1] $$2CH_3CHO \rightarrow CH_3 + CHO + CH_3CHO$$

in the following way. According to Benson (22) reaction [1] is more endothermic by about 27 kcal per mole than reaction [1′], and the entropy changes of reactions [1] and [1′] are 28.5 cal $mole^{-1}$ deg^{-1} and 4.5 cal $mole^{-1}$ deg^{-1} respectively (for the standard state of 1 mole per litre). The ratio of equilibrium constants of the two reactions is then calculated to be, at 800 °K,

$$K_1'/K_1 = k_1' \, k_{-1}/k_1 \, k_{-1}' = 1.4 \times 10^5 \text{ ml mole}^{-1}.$$

The value of k_{-1}' may be predicted to a reasonable approximation by simple collision theory and is estimated at 1×10^{14} cc $mole^{-1}$ s^{-1} at 800 °K. The rate of combination of CH_3 and CHO radicals to form CH_3CHO is smaller than that of two CH_3 radicals by a factor of at least 10 (22). The third-order rate constant for the combination of methyl radicals has been estimated at 3.5×10^{18} cc^2 $mole^{-2}$ s^{-1} at 800 °K (23). The maximum value of k_{-1} at 800 °K is, therefore, 3.5×10^{17} cc^2 $mole^{-2}$ s^{-1}. From this it follows that

$$k_1'/k_1 = 40.$$

Even if one allows an uncertainty of 4 kcal per mole in the value of ΔH, and of one power of 10 in the value of k_{-1}', the contribution of reaction [1′] is at least one third of that of reaction [1] at 800 °K and more at lower temperatures. The fact that foreign gases have only a small effect on the initiation reaction indicates that reaction [1′] is probably much more important than reaction [1]. However, both types of initiation will be included in the present scheme of reactions for the sake of completeness.

The reaction mechanism to which these considerations lead is

[1] $$2CH_3CHO \rightarrow CH_3 + CHO + CH_3CHO$$

[1*a*] $$CH_3CHO + X \rightarrow CH_3 + CHO + X$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[1′] $2CH_3CHO \rightarrow CH_3CHOH + CH_3CO$

[2] $CH_3CHOH \rightarrow CH_3CHO + H$

[2a] $CHO + X \rightarrow CO + H + X$

[3] $H + CH_3CHO \rightarrow H_2 + CH_3CO$

[4] $CH_3CO + X \rightarrow CH_3 + CO + X$

[5] $CH_3 + CH_3CHO \rightarrow CH_4 + CH_3CO$

[6] $2CH_3 + CH_3CHO \rightarrow C_2H_6 + CH_3CHO$

[6a] $2CH_3 + X \rightarrow C_2H_6 + X$

Application of the steady-state treatment to this scheme leads to the following expressions for the radical concentrations:

[i] $$[CH_3] = \left\{\frac{k_1[CH_3CHO]^2 + k_1'[CH_3CHO]^2 + k_{1a}[CH_3CHO][X]}{k_6[CH_3CHO] + k_{6a}[X]}\right\}^{1/2}$$

[ii] $$[CH_3CO] \simeq \frac{k_5}{k_4}\frac{[CH_3CHO]}{[X]}\left\{\frac{k_1[CH_3CHO]^2 + k_1'[CH_3CHO]^2 + k_{1a}[CH_3CHO][X]}{k_6[CH_3CHO] + k_{6a}[X]}\right\}^{1/2}$$

[iii] $$[CH_3CHOH] = (k_1'/k_2)[CH_3CHO]^2$$

[iv] $$[H] = (k_1/k_3)[CH_3CHO] + (k_1'/k_3)[CH_3CHO] + (k_{1a}/k_3)[X]$$

[v] $$[CHO] = (k_1/k_{2a})[CH_3CHO]^2/[X] + (k_{1a}/k_{2a})[CH_3CHO].$$

The rate of disappearance of acetaldehyde is given by

[vi] $$v = k_5\left\{\frac{(k_1 + k_1')[CH_3CHO] + k_{1a}[X]}{k_6[CH_3CHO] + k_{6a}[X]}\right\}^{1/2}[CH_3CHO]^{3/2}.$$

The rate of disappearance of pure acetaldehyde is therefore

[vii] $$v = k_5\{(k_1 + k_1')/k_6\}^{1/2}[CH_3CHO]^{3/2}.$$

This rate equation is in agreement with the experimental order of three halves for the decomposition of pure acetaldehyde.

Influence of Foreign Gases

Foreign gases such as CO_2, CH_4, CO, N_2, and C_2H_6 inhibit the decomposition of acetaldehyde and increase the order of reaction. The general rate equation [vi] accounts for the observed increase in order as the inert-gas concentration is increased, provided that k_{1a} is small and k_{6a} large.

On the basis of the observed inert-gas effect it is now possible to arrive at a conclusion as to the importance of reaction [1a] as the initiation reaction, in comparison with reactions [1] and [1′], and the importance of reaction [6a] as the termination reaction, in comparison with reaction [6]. With the use of equations [vi] and [vii], the ratio of rates in the presence (v_X) and absence (v_0) of inert gas X can be written as

[viii] $$\frac{v_X}{v_0} = \left\{\frac{[CH_3CHO] + \frac{k_{1a}}{k_1 + k_1'}[X]}{[CH_3CHO] + \frac{k_{6a}}{k_6}[X]}\right\}^{1/2} = \left\{\frac{[CH_3CHO] + r_1[X]}{[CH_3CHO] + r_t[X]}\right\}^{1/2}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

An equation similar to [viii] has been employed by Bril *et al.* (3, 4). The values of r_1 and r_t thus obtained from Fig. 3 are as follows:

$$r_1 = 0.19$$

$$r_t = 1.02.$$

However, these results are highly sensitive to the slopes of the lines in Fig. 3; the r_1 value might, for example, be as high as 0.3. The above results show that reaction [1*a*] plays a smaller part than [1] and [1′] in the initiation reaction and that the efficiencies of CO_2, CH_4, N_2, CO, and C_2H_6 and CH_3CHO in bringing about recombination of methyl radicals are approximately the same. The values of r_1 and r_t are slightly higher than those obtained by Bril *et al.* (3, 4). Traces of oxygen may have a significant effect on the values of r_1 and r_t.

Formation of Ethane

The results given in Figs. 4 and 5 show that the rate of formation of ethane is proportional to the square of the acetaldehyde concentration. Reaction [6] is the only reaction that might be expected to produce ethane. According to the proposed mechanism the rate of formation of ethane from pure acetaldehyde is

[ix] $$v_{C_2H_6} = k_6[CH_3]^2\,[CH_3CHO]$$

[x] $$= (k_1 + k_1')\,[CH_3CHO]^2$$

in agreement with the experimental result. It is obvious that the square in this rate expression will only arise if the initiation reaction is second order. The experimental result that the rate of ethane formation is second order in acetaldehyde is therefore strong evidence that the initiation process is second order and strong evidence for the mechanism proposed.

Formation of Hydrogen

Equally strong evidence is provided by Trenwith's result (6) that the hydrogen production is second order in acetaldehyde. According to the mechanism

[xi] $$v_{H_2} = k_3\,[H]\,[CH_3CHO]$$

[xii] $$= (k_1 + k_1')\,[CH_3CHO]^2,$$

second-order behavior is again only predicted if the initiation reaction is second order.

Trenwith (6) has also found that the hydrogen production shows an induction period of a minute or so, the actual value varying with the temperature and surface area of the reaction vessel but being independent of the acetaldehyde pressure. Trenwith explains this in terms of the initiation reaction

$$CH_3CHO \rightarrow CH_3 + CHO \qquad \text{(second order)}$$

followed by

$$CHO \rightarrow H + CO \qquad \text{(on the surface)}$$

and

$$H + CH_3CHO \rightarrow H_2 + CH_3CO.$$

To explain an induction period of the order of a minute it is necessary to postulate that the half-life of the intermediate CHO is of the order of a minute. The difficulty, however, in assuming that the dissociation of CHO occurs primarily on the surface with such a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

half-life is that the homogeneous decomposition of CHO almost certainly occurs much more rapidly; studies of the photolysis of aldehydes indicate for this reaction an activation energy of about 14 kcal per mole, which would correspond to a half-life of a very small fraction of a second.

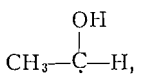
A more plausible interpretation of Trenwith's results on the induction period would seem to be provided in terms of the initiation reaction

$$CH_3CHO + CH_3CHO \rightarrow CH_3CO + CH_3CHOH$$

followed by

$$CH_3CHOH \rightarrow CH_3CHO + H,$$

the latter reaction occurring primarily on the surface. The intermediate CH_3CHOH, which probably has the structure



may well have a stability of over 40 kcal so that its dissociation in the gas phase may be slow; there is therefore no difficulty in assuming that it mainly decomposes on the surface. Trenwith's results on the variation of induction period with temperature indicate a frequency factor of $10^{5.3}$ s^{-1} and an activation energy of 26.3 kcal; the very low frequency factor is understandable if it is a surface reaction.

Trenwith (6) reported that the frequency factor for the production of hydrogen, and therefore for the initiation reaction, is $\sim 10^{20}$ cc $mole^{-1}$ s^{-1}. The overall frequency factor was found in the present investigation to be 1.16×10^{13} $cc^{1/2}$ $mole^{-1/2}$ s^{-1}, and this is equal to $A_5(A_1/A_6)^{1/2}$, where the A's are the frequency factors for the elementary processes. A value of $\sim 10^{12}$ cc $mole^{-1}$ s^{-1} has been given for A_5 by Brinton and Volman (24), and A_6 has been estimated (23) as 3.5×10^{18} cc^2 $mole^{-2}$ s^{-1}. These values lead to an estimate of $\sim 5 \times 10^{20}$ for A_1, in reasonable agreement with Trenwith's value.

Formation of Acetone

In a private communication Trenwith (25) has informed us of his results on the formation of acetone, the rate of which is greater than the rate of formation of ethane. At first sight it might be thought that acetone would be formed by the reaction

$$CH_3 + CH_3CO \rightarrow CH_3COCH_3$$

and that this termination reaction is more important than the methyl radical recombination. There are, however, two serious objections to this:

(1) This reaction is a termination reaction of the $\beta\mu$ type, and to obtain three-halves order kinetics the initiation reaction must be second order. This type of mechanism cannot, however, explain the fact that foreign gases reduce the rate of reaction.

(2) If $CH_3 + CH_3CO$ is an important termination reaction in the thermal decomposition of acetaldehyde, it should be so a fortiori in the photochemical decomposition where the temperatures are lower and the radical concentrations, especially of CH_3CO, may be higher. Calvert and Gruver (26) (cf. also Steacie, ref. 1), however, find that acetone formation is unimportant in the photochemical decomposition of acetaldehyde.

This difference between the thermal and photochemical results suggests that the acetone formation is controlled by some process that is temperature dependent. The most plausible reaction would seem to be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[7] $$CH_3 + CH_3CHO \rightarrow CH_3-\underset{\displaystyle CH_3}{\overset{\displaystyle \dot{O}}{\overset{|}{\underset{|}{C}}}}-H \rightarrow CH_3COCH_3 + H.$$

Several other reactions of this type, involving initial addition of a radical to a double bond, have been proposed (27–29). The hydrogen atoms produced will come to equilibrium with acetaldehyde molecules

[8] $$H + CH_3CHO \rightleftarrows CH_3CHOH,$$

and, owing to the slowness of the dissociation of the radical CH_3CHOH, there will be an induction period for the production of hydrogen molecules.

The point of view that has been arrived at is, therefore, that hydrogen production is due to the two reactions [2] and [7], with the equilibrium [8] leading to an induction period. The maximum rate of hydrogen production by reaction [7] will be roughly equal to the rate of production of acetone. Since hydrogen is also produced as a result of reaction [2], the maximum rate of its production will be somewhat greater than that of acetone, which is what Trenwith (25) found.

Formation of Other Minor Products

Other minor products which have been found in the acetaldehyde pyrolysis are propylene and water (11) and ethylene (15, 25). These products are readily explained as arising through the intermediate CH_3CHOH, as follows:

$$CH_3CHOH + CH_3CHO \rightarrow CH_3CH_2OH + CH_3CO$$
$$CH_3CH_2OH \rightarrow C_2H_4 + H_2O$$
$$CH_3CH_2OH \rightarrow CH_3CHO + H_2$$
$$CH_3CHOH + CH_3 \rightarrow (CH_3)_2CHOH$$
$$(CH_3)_2CHOH \rightarrow CH_3CH{=}CH_2 + H_2O$$
$$(CH_3)_2CHOH \rightarrow CH_3COCH_3 + H_2$$

ACKNOWLEDGMENTS

The authors are indebted to Drs. Margaret H. Back and B. W. Wojciechowski for valuable help and suggestions, and to Dr. P. J. Thomas for a helpful discussion. They also thank Dr. A. B. Trenwith for discussions and for sending them information about his recent unpublished work. One of us (M. E.) is grateful to the Canadian Commonwealth Scholarship and Fellowship Committee for the award of a scholarship. The work was supported in part by the National Research Council and in part by the Petroleum Research Fund.

KINETICS AND MECHANISMS OF THE THERMAL DECOMPOSITION OF ACETALDEHYDE

II. THE REACTION IN THE PRESENCE OF NITRIC OXIDE

M. EUSUF AND K. J. LAIDLER
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received March 5, 1964

ABSTRACT

The decomposition of acetaldehyde has been reinvestigated in the presence of various amounts of nitric oxide, over a range of temperatures (495 to 525 °C) and acetaldehyde pressures (36 to 340 mm Hg). At higher acetaldehyde pressures there is no inhibition, the rate steadily increasing with increasing nitric oxide concentration; at low acetaldehyde concentrations increasing amounts of nitric oxide first give inhibition and then give catalysis. The degree of inhibition increases with decrease in temperature. As the nitric oxide concentration is increased, the order rises above 3/2 and then falls to 3/2 again. At higher nitric oxide concentrations the rate varies with $[CH_3CHO]^{3/2}[NO]^{1/2}$. All of the facts are explained by a mechanism according to which initiation occurs by

$$CH_3CHO + NO \rightarrow CH_3CO + HNO$$

together with the processes occurring in the absence of nitric oxide (cf. Part I). Termination is considered to involve the reaction occurring in the case of no inhibition ($CH_3 + CH_3 + X \rightarrow C_2H_6 + X$) together with

$$CH_3 + CH_3NO \rightarrow C_2H_6 + NO$$

and

$$2\ CH_3NO \rightarrow C_2H_6 + 2\ NO.$$

Application of the mechanism to the results is discussed in detail.

INTRODUCTION

The influence of nitric oxide on the kinetics of the thermal decomposition of acetaldehyde has been the subject of a considerable number of investigations (1–5). The reaction has usually been discussed on the assumption that it occurs by a combination of molecular and free-radical mechanisms, the sole function of the nitric oxide being to remove radicals. Wojciechowski and Laidler (6, 7) have recently proposed that when organic decompositions are inhibited by nitric oxide an important role is played by a reaction in which the nitric oxide molecule abstracts a hydrogen atom from the substrate molecule; in addition, they have proposed that chain termination may occur by reaction between radicals and species such as HNO and CH_3NO. These proposals have been successful in leading to a quantitative interpretation of a number of organic decompositions (8–12). The acetaldehyde behavior is a good deal more complicated than the cases previously investigated, and its study therefore provides a valuable test of the validity of the proposed mechanisms. The present paper describes the results of an experimental reinvestigation of the reaction and presents a free-radical mechanism, based on the ideas previously put forward in this laboratory, that appears to be consistent with the results.

EXPERIMENTAL

The apparatus and procedures were the same as described in Part I (13). the nitric oxide used was Matheson Research Grade and was purified by the method of Hughes (14); the distillate collected was completely colorless. Acetaldehyde and nitric oxide were mixed in a spherical flask in appropriate proportions, and complete mixing was ensured by producing a temperature gradient and allowing the gases to stand together for at least 30 minutes.

RESULTS

Figures 1, 2, and 3 show the effects of nitric oxide on the rate under various conditions. Figure 1 shows that at a relatively low acetaldehyde pressure (52 mm) there is inhibition followed by catalysis; the degree of inhibition decreases with increasing temperatures, there being very little inhibition at 525 °C. The degree of inhibition with acetaldehyde is always very much less than that with the hydrocarbons. Figure 2 shows how the inhibition

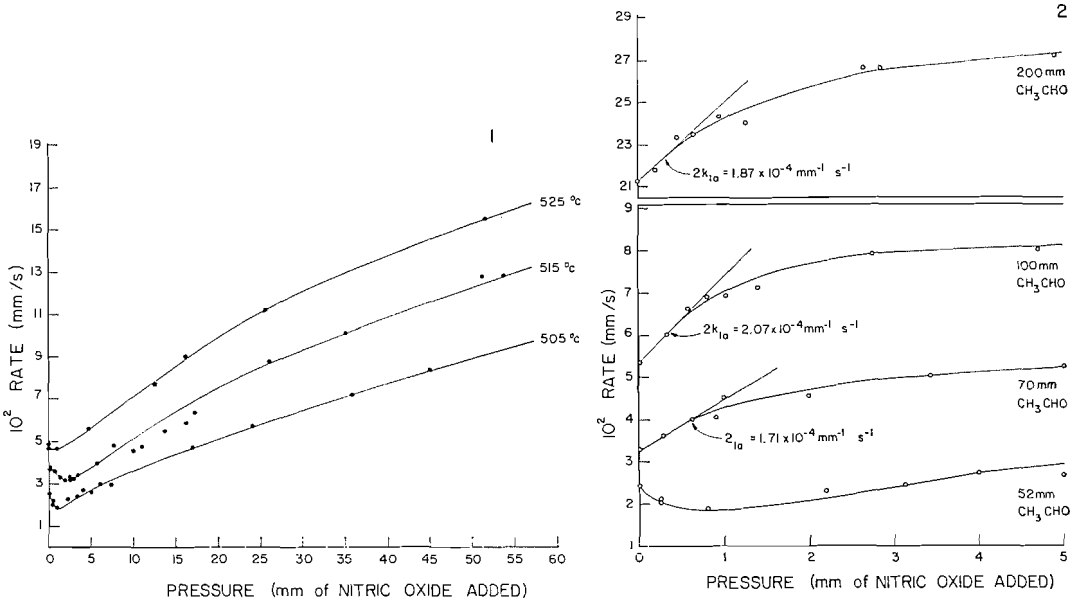

FIG. 1. Effect of temperature on the inhibition by nitric oxide. (Pressure of acetaldehyde = 52 mm).
FIG. 2. Plots of rates against the pressures of nitric oxide added at various acetaldehyde pressures at 505 °C.

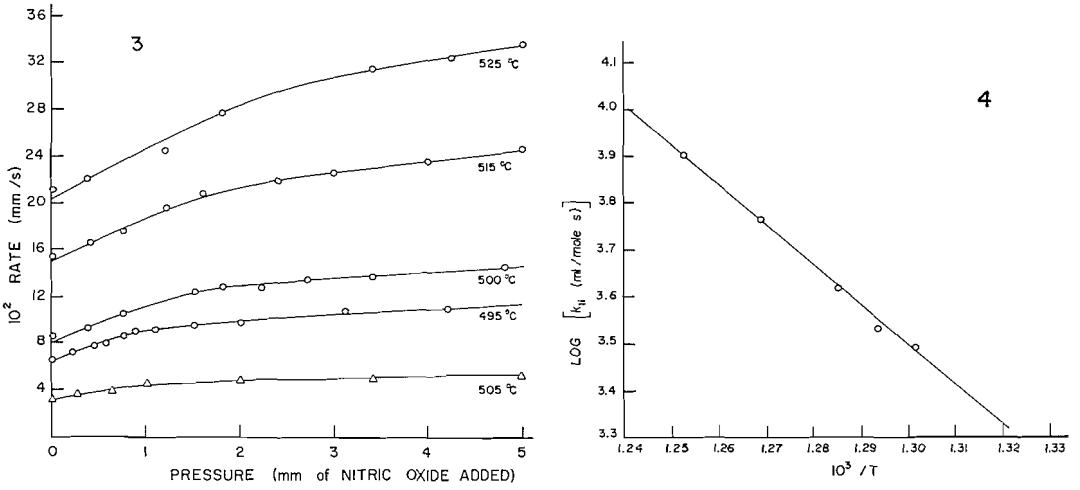

FIG. 3. Plots of rates against the pressures of nitric oxide at different temperatures. ○, 152 mm acetaldehyde; △, 70 mm acetaldehyde.
FIG. 4. Arrhenius plot, the rate constants being those obtained by dividing the initial slopes (Fig. 3) by twice the acetaldehyde concentrations.

curves vary with the acetaldehyde concentration, there being no inhibition at the higher pressures. It will be seen later that at higher acetaldehyde pressures and lower nitric oxide pressures the rate is equal to

$$[i] \qquad v = 2k_{1a}[CH_3CHO][NO] + k'[CH_3CHO]^n$$

where $3/2 < n < 2$ and k_{1a} is the rate constant for the reaction $CH_3CHO + NO \rightarrow CH_3CO + HNO$. From the initial slopes of the curves in Fig. 2, values of k_{1a} have been calculated and are approximately constant.

Figure 3 shows plots of rate against nitric oxide concentration at two acetaldehyde pressures (70 and 152 mm) and at various temperatures. From the k_{1a} values calculated from the initial slopes the Arrhenius plot shown in Fig. 4 has been obtained; the activation energy is 38.9 kcal per mole, and the rate constant can be represented by

$$k_{1a} = 3.46 \times 10^{14}\, e^{-38900/RT} \text{ cc mole}^{-1}\text{ s}^{-1}.$$

The results indicate that the order of the reaction with respect to acetaldehyde is 3/2 when the ratio $[NO]/[CH_3CHO]$ is high, but is greater than 3/2 when the ratio is low. This effect is shown in Fig. 5: the order is 3/2 over the entire range of acetaldehyde pressures when the pressure of nitric oxide is 50 mm, but the order is approximately 1.8 at higher acetaldehyde pressures when the nitric oxide pressure is 5 mm. Figure 6 confirms the 3/2 order at the higher nitric oxide pressure and at four temperatures. The results of Freeman, Danby, and Hinshelwood (4) are added for comparison and are seen to be in excellent agreement.

At higher acetaldehyde pressures the rate varies not only with $[CH_3CHO]^{3/2}$ but with $[NO]^{1/2}$; this result, which was reported by Freeman, Danby, and Hinshelwood (4), is

FIG. 8. Arrhenius plot in the region of 3/2 order with respect to acetaldehyde and 1/2 order with respect to nitric oxide.

illustrated by Fig. 7. Figure 8 shows an Arrhenius plot for this region, in which the rate varies with $[CH_3CHO]^{3/2}$ $[NO]^{1/2}$, and leads to the rate constant

$$k = 2.2 \times 10^{15}\, e^{-43500/RT} \text{ cc mole}^{-1}\, s^{-1}.$$

The main results for orders of reaction are summarized in Fig. 9.

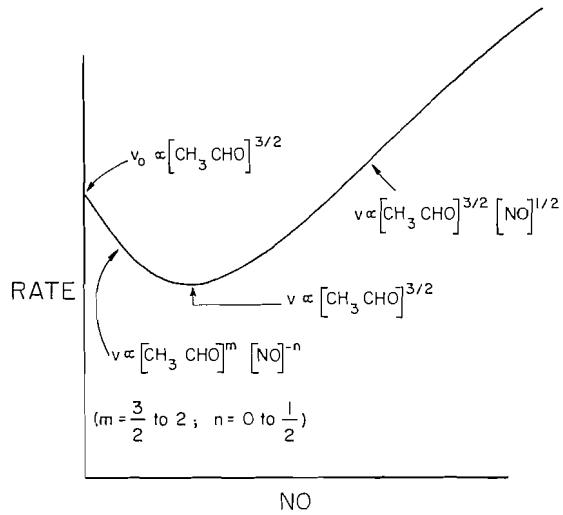

FIG. 9. Schematic diagram showing the reaction orders at various concentrations of nitric oxide.

DISCUSSION

The Reaction Mechanism

In treating the decompositions of hydrocarbons and of ether it has proved expedient to consider, as a separate problem, the situation at maximal inhibition; under these conditions the nitric-oxide-induced initiation reaction can be shown to be much more

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

important than the other initiation processes. In the acetaldehyde decomposition, however, there is no flat region when velocity is plotted against nitric oxide concentration. The situation is therefore more complicated, in that one must take into account the initiation processes that occur in the absence of nitric oxide (cf. Part I) together with the reaction

$$NO + CH_3CHO \rightarrow CH_3CO + HNO.$$

In the same way one must include the termination process for the uninhibited reaction (cf. Part I), together with the termination reactions that become important after nitric oxide is added:

$$CH_3 + CH_3NO \rightarrow C_2H_6 + NO$$
$$CH_3NO + CH_3NO \rightarrow C_2H_6 + 2NO.$$

The last reaction has been omitted in previous schemes, but must be included here on account of the higher CH_3NO concentrations resulting from the somewhat lower temperatures employed.

The complete scheme may be written as

[1] $2CH_3CHO \rightarrow CH_3 + CHO + CH_3CHO$

[1′] $2CH_3CHO \rightarrow CH_3CHOH + CH_3CO$

[1i] $CH_3CHO + NO \rightarrow HNO + CH_3CO$

[2a] $X + CHO \rightarrow CO + H + X$

[2] $CH_3CHOH \rightarrow CH_3CHO + H$

[2i] $X + HNO \rightarrow H + NO + X$

[3] $H + CH_3CHO \rightarrow H_2 + CH_3CO$

[4] $CH_3CO + X \rightarrow CH_3 + CO + X$

[5] $CH_3 + CH_3CHO \rightarrow CH_4 + CH_3CO$

[5i] $CH_3NO + CH_3CHO \rightarrow CH_4 + CH_3CO + NO$

$$CH_3 + NO + X \underset{[-9]}{\overset{[9]}{\rightleftharpoons}} CH_3NO + X \underset{[-10]}{\overset{[10]}{\rightleftharpoons}} CH_2{=}NOH + X \xrightarrow{[11]} HCN + H_2O \text{ etc.}$$

[6a] $2CH_3 + X \rightarrow C_2H_6 + X$

[6i] $CH_3 + CH_3NO \rightarrow C_2H_6 + NO$

[6i′] $CH_3NO + CH_3NO \rightarrow C_2H_6 + 2NO.$

The numbering is consistent with the mechanism of Part I. X represents a third body, which may be acetaldehyde itself.

Application of the steady-state treatment, with the usual approximations, leads to the following expressions for the concentrations of CH_3CO, CH_3, and CH_3NO and for the rate of decomposition.

[ii] $$[CH_3CO] = \left(\frac{(k_1 + 2k_1')[CH_3CHO] + 2k_{1i}[NO] + k_5[CH_3] + k_{5i}[CH_3NO]}{k_4}\right)\frac{[CH_3CHO]}{[X]}$$

[iii] $$[CH_3] = \left(\frac{(k_1 + k_1')[CH_3CHO] + k_{1i}[NO]}{k_{6a}[X] + k_{6i}K_9[NO] + k_{6i}'K_9^2[NO]^2}\right)^{1/2}[CH_3CHO]^{1/2}$$

[iv] $$[CH_3NO] = K_9[CH_3][NO] \qquad (K_9 = k_9/k_{-9})$$

[v] $$v = 2(k_1 + k_1')[CH_3CHO]^2 + 2k_{1i}[CH_3CHO][NO] + k_5[CH_3][CH_3CHO] + k_{5i}[CH_3NO][CH_3CHO]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$[\text{vi}] \qquad = 2k_{1\text{i}}[CH_3CHO][NO] + k_5\left(\frac{k_1 + k_1'}{k_6}\right)^{1/2} \frac{\left(1 + \frac{k_{5\text{i}}}{k_5}K_9[NO]\right)\left([CH_3CHO] + \frac{k_{1\text{i}}}{(k_1 + k_1')}[NO]\right)^{1/2}}{\left([CH_3CHO] + \frac{k_{6\text{i}}}{k_6}K_9[NO] + \frac{k_{6\text{i}}'}{k_6}K_9^2[NO]^2\right)^{1/2}}[CH_3CHO]^{3/2}$$

A number of important special cases of this rate equation are as follows.

(1) If [NO] is zero the equation reduces to

$$v = k_5\left(\frac{k_1 + k_1'}{k_6}\right)^{1/2}[CH_3CHO]^{3/2}.$$

This is merely a check that in the absence of nitric oxide the equation reduces to equation [vii] of Part I.

(2) It can be shown by conventional methods that the second term in equation [vi] passes through a minimum only if

$$[CH_3CHO] < \frac{\frac{k_{6\text{i}}}{k_6}K_9 - \frac{k_{1\text{i}}}{(k_1 + k_1')}}{2\frac{k_{5\text{i}}}{k_5}}.$$

This explains why there is inhibition only at low concentrations of acetaldehyde; at higher concentrations the rate increases steadily with increasing nitric oxide concentration.

(3) If [NO] is sufficiently small that

$$\frac{k_{5\text{i}}}{k_5}K_9[NO] \ll 1, \qquad \frac{k_{6\text{i}}'}{k_6}K_9^2[NO]^2 \ll \frac{k_{6\text{i}}}{k_6}K_9[NO],$$

and

$$\frac{k_{1\text{i}}}{(k_1 + k_1')}[NO] \ll [CH_3CHO],$$

the rate equation reduces to

$$[\text{vii}] \qquad v = 2k_{1\text{i}}[CH_3CHO][NO] + k_5\left(\frac{k_1 + k_1'}{k_6}\right)^{1/2}\frac{[CH_3CHO]^2}{\left([CH_3CHO] + \frac{k_{6\text{i}}}{k_6}K_9[NO]\right)^{1/2}}$$

of which the first term is usually smaller than the second. Three sub-cases are of particular interest.

(*a*) If $[CH_3CHO]$ is also sufficiently small, there will be inhibition by nitric oxide, and the order with respect to acetaldehyde will be between 3/2 and 2. This is exactly the behavior observed. In the limit of very low acetaldehyde concentrations the order will be 2, and the rate will vary with $1/[NO]^{1/2}$.

(*b*) If $[CH_3CHO]$ is not small, the term $(k_{6\text{i}}/k_6)K_9[NO]$ in equation [vii] will be negligible, and there will be no appreciable inhibition. Instead there will be acceleration at all concentrations of nitric oxide, owing to the increase in the term $2k_{1\text{i}}[CH_3CHO][NO]$. It was on this basis that the value of $k_{1\text{i}}$, and that of the corresponding activation energy E, is calculated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(*c*) If [CH_3CHO] is small but [NO] is not particularly small, the dominant terms in equation [vi] are

$$\frac{k_{5i}}{k_5}K_9[NO], \qquad \frac{k_{1i}}{k_1 + k_1'}[NO], \qquad \text{and} \qquad \frac{k_{6i}'}{k_6}K_9^2[NO]^2.$$

Under these circumstances the rate equation reduces to

[viii] $$v = 2k_{1i}[CH_3CHO][NO] + k_{5i}\left(\frac{k_{1i}}{k_{6i}'}\right)^{1/2}[CH_3CHO]^{3/2}[NO]^{1/2}.$$

If [NO] is not too high, the second term is dominant, and the orders with respect to acetaldehyde and nitric oxide will therefore be 3/2 and 1/2 respectively, in agreement with experiment.

The Elementary Reactions

Some of the postulated elementary reactions may now be considered in more detail; those occurring in the uninhibited reaction were dealt with in Part I, and only the reactions involving nitric oxide are discussed here. The experimental results show that under certain conditions the reaction is 1/2 order in nitric oxide, and this fact is a very strong indication that nitric oxide is involved in the initiation of a chain reaction. On this basis one can exclude, as an important reaction, the process

$$CH_3CHO + NO \rightarrow CH_4 + CO + NO$$

postulated by Freeman, Danby, and Hinshelwood (4). Freeman *et al.* also suggested the reaction

$$CH_3CHO + NO \rightarrow NO + 2R + \text{product}$$

but this would have a higher activation energy than the experimental value of 38.9 kcal. Reaction [1i], on the other hand, is endothermic by 36.4 kcal (on the basis of $D(HNO)$ = 48.6 kcal and $D(CH_3CO—H)$ = 85 kcal per mole); the activation energy is entirely consistent with this and provides good support for the proposed reaction. Initiation might alternatively occur as

$$CH_3CHO + NO \rightarrow CH_3NO + CHO$$

but there is nothing to support this suggestion.

Reaction [5i], the abstraction of a hydrogen atom by CH_3NO, is an important reaction in the present scheme, since it explains why the degree of inhibition of the acetaldehyde decomposition is much smaller than with hydrocarbon decompositions, in which the analogous reaction has a higher activation energy and therefore occurs more slowly. A reaction analogous to [5i] has been postulated by Szabó and Márta (15, 16) as playing a role in the propionaldehyde decomposition. Ree, Yang, and Eyring (17) have also considered reactions of the same type and have described the action of nitric oxide as a "saloon effect"; the nitric oxide molecule is playing the role of a "chaperon" but acts as a negative catalyst by making the radical less reactive. Ree *et al.* have suggested a method for estimating the activation energies for reactions such as [5i]. For this reaction their method leads to a value of 26 kcal per mole, to be compared with 39.5 in the case of abstraction from a hydrocarbon molecule.

The disappearance of CH_3NO by reactions [10] and [11] has been suggested by Mitchell and Hinshelwood (18). Reaction [11] has been demonstrated by Taylor and Bender (19), and the occurrence of reaction [10] is suggested by the work of Gowenlock and Trotman (20), Batt and Gowenlock (21), and Lüttke (22). Some evidence for reaction [−10] is obtained from the work of Taylor and Bender (19), who found that ethane is formed in the decomposition of formaldoxime $CH_2{=}NOH$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Reaction [6i] was suggested by Freeman, Danby, and Hinshelwood (4) in the acetaldehyde decomposition induced by nitric oxide, and McKenney, Wojciechowski, and Laidler (11) postulate it in the dimethyl ether decomposition. Hoare (23) has also found evidence for reaction between nitrosomethane and methyl radicals in the photolysis of acetone at 200 °C. At this lower temperature he found that an average of between 2 and 3 methyl radicals were used up per nitric oxide molecule. Reaction [6i′] was first postulated by Taylor and Vesselowsky (24) in the decomposition of nitromethane, and Szabó and Márta (15, 16) have postulated the analogous reaction involving C_2H_5NO in the propionaldehyde decomposition. An attempt to detect the chain-ending products in the absence and presence of nitric oxide has been made by Freeman, Danby, and Hinshelwood (4), who found that the ratio C_2H_6/CH_4 is increased by the addition of nitric oxide. That nitric oxide reduces markedly the concentration of CH_3 radicals is now beyond question. The increase of ethane production in the presence of nitric oxide must, therefore, be attributed to the occurrence of reactions [6i] and [6i′]. In other words, nitric oxide acts as a 'chaperon' in the combination of methyl radicals. This is an example of the radical–molecule complex mechanism which has recently been considered theoretically by Eusuf and Laidler (25). Porter, Szabó, and Townsend (26) have shown that reactions analogous to [6i] and [6i′] occur in the combination of iodine atoms.

An estimate of the activation energy for reaction [6i′] can be made on the basis of the experimental activation energy of 43.5 kcal for the reaction in which the rate varies with $[CH_3CHO]^{3/2}[NO]^{1/2}$. This activation energy is seen from equation [viii] to be $E_{5i} + \frac{1}{2}(E_{1i} - E_{6i}')$. E_{1i} has been seen to be 38.9 kcal, and E_{5i} was estimated above to be 26 kcal. These figures lead to a value of 3.9 kcal per mole for E_{6i}', which seems reasonable.

ACKNOWLEDGMENTS

One of us (M. E.) is grateful to the Canadian Commonwealth Scholarship and Fellowship Committee for the award of a scholarship. The work was supported in part by the National Research Council of Canada and in part by the Petroleum Research Fund.

RADIOLYSIS OF CYCLOHEXANONE

I. PURE LIQUID

AJIT SINGH AND GORDON R. FREEMAN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received January 31, 1964

ABSTRACT

The G values of the major products of the gamma-radiolysis of liquid cyclohexanone are: hydrogen (0.76), carbon monoxide (0.45), 1-pentene (0.22), 5-hexenal (0.85), cyclohexenone (0.4), cyclohexanol (0.5), "dimer" (1.15), and polymer (1.8 cyclohexanone units). A large number of minor products were also measured.

The amount of ring cleavage that occurs in cyclohexanone is much greater than that which occurs in the radiolysis of cyclohexane. The increase has been attributed to the influence of the carbonyl group on the course of the reaction. Ring cleavage occurs preferentially at the C—C bonds to the carbonyl group.

Much of the radiolytic reaction appears to occur from energy states higher than those of importance in the photolytic studies.

INTRODUCTION

One aim of this investigation was to determine whether the presence of a carbonyl group in a molecule would cause bond cleavage to occur preferentially adjacent to it in a radiation chemical primary reaction. The net amount of ring cleavage that occurs during the radiolysis of liquid cyclohexane is small (1, 2). In cyclohexanone, the activating effect of the carbonyl group should appear as ring cleavage. Moreover, it does not seem likely that ring cleavage would occur in secondary chemical reactions.

The radiolysis of various ketones has been the subject of limited investigations (3–12). Acetone has been studied in some detail (3–9) but, except for a cursory study of cyclopentanone (10), cyclic ketones have been neglected. Some ketones have also been used as solutes in the study of the radiolyses of hydrocarbons, alcohols, and water (13–16).

EXPERIMENTAL

Materials

Cyclohexanone (Eastman Kodak White Label and Allied Chemical) was distilled through an 18 in. fractionating column filled with glass helices. The middle 50% of the distillate was collected and redistilled several times. Multiple distillations reduced the amount of impurities that was initially present, but led simultaneously to the formation of a small amount of an unidentified impurity (U.I.). The purified ketone used in most of the experiments contained less than 0.02% total impurities with each of U.I., cyclohexanol, and cyclohexenone being less than 0.01%. The purity was measured by gas chromatography using Ucon, Carbowax, silicone grease, and Apiezon L columns.

Singly distilled ketone (impurities $<0.04\%$) was used for the 10 ml samples that were irradiated for the measurement of the polymer yield. The distilled ketone was kept in a desiccator until used.

The 2,2′-diketodicyclohexyl (DKDC) was prepared by the reaction of di-*tert*-butyl peroxide with cyclohexanone (17). Gas chromatographic analysis of the reaction mixture indicated the formation of several other dimeric products besides DKDC. Infrared spectral analyses of these dimers showed that they were closely related to DKDC. The reaction mixture was distilled twice under vacuum and the fraction used (b.p. 123°/1–2 mm) contained $\sim$83% DKDC.

The following is a list of the gas chromatographic materials used, with the suppliers given in brackets. Kromat FB, Kromat CE, high activity charcoal, and medium activity silica gel (Burrell Corp.); Carborundum 60SGM (Carborundum Co.); Carbowax 1540 and Ucon LB-1800X (Carbide and Carbon Chemicals Co.); silicone grease (Dow Corning); silicone rubber (Wilkins Instrument and Research Inc.); di-*n*-decyl phthalate (Eastman Kodak); Apiezon L grease (Metropolitan-Vickers Electrical Co.).

Preparation of Samples

Most cells were filled by distillation under vacuum of thoroughly degassed cyclohexanone; others were

filled with a pipette and then degassed under vacuum. Gaseous product yields were the same for both methods.

The density of cyclohexanone at various temperatures was calculated from data in the International Critical Tables.

Irradiation of Samples

The samples were irradiated with ^{60}Co γ-rays. Dose rates were determined with the Fricke dosimeter, using $G(Fe^{3+}) = 15.5$, $\epsilon(Fe^{3+}) = 2225$ at 25 °C and 304 mμ, and the electron densities of the Fricke dosimeter and cyclohexanone. The sample temperature during irradiation was 24 ± 3 °C.

Analyses

Gaseous products were separated by successive distillations through two traps at −196° and then at −70°. Each fraction was collected and measured in a combination Toepler pump – McLeod gauge and then analyzed by gas chromatography. The remaining liquid was analyzed for C_6 products only. Samples that were used only for the analysis of liquid products were opened just before use and were corked and kept in a desiccator between injections of aliquots onto the gas chromatograph. The samples that were irradiated for the estimation of polymeric products, other than dimers, were broken open and most of the contents removed by vacuum distillation at room temperature. When the cyclohexanone seemed to have been removed, the cell was weighed. The soluble contents of the cell were removed by rinsing it with three aliquots of about 1 ml each of Spectrograde chloroform. The chloroform solution so obtained was analyzed by gas chromatography for its monomer and dimer content. The cell was dried and weighed again. The weight of polymer was deduced from the loss of weight of the cell, after correction for the presence of monomer and dimer.

The chloroform soluble polymer was sent to Germany for molecular weight determinations and for C, H, and O analyses.*

Some of the cells were analyzed for insoluble polymer by combustion.*

The identification of most of the products was based on their gas chromatographic retention times, together with information from their infrared and mass spectral analyses. A modified procedure (18) for the reaction of formaldehyde with Eegrive's reagent (19) was used to test for the presence of that aldehyde. A modified (18) arsenious oxide method (20) was used for the estimation of peroxides.

Authentic samples of the identified products were used for calibrations, as far as possible. Calibration factors from 5-hexen-2-one were used for 5-hexenal. Factors from 2-cyclohexenone and DKDC were used for cyclohexenone and dimers, respectively.

Identification of Products

The details of identification of only the less commonly available compounds will be reported here.

5-Hexenal

An authentic sample of 5-hexenal could not be obtained commercially, so this compound was identified as one of the radiolysis products as follows: The retention times of the radiolysis product on various gas chromatographic columns were compared with those of related compounds under the same conditions (18). Infrared analysis of the product, collected after separation on Ucon, di-*n*-decyl phthalate, and Carbowax columns, indicated the presence of $CH_2{=}CH$ (bands at 3070–3080 cm^{-1} and 905 cm^{-1}), C=C (band at 1638 cm^{-1}), aldehydic C—H (2710 cm^{-1} and 2810 cm^{-1}), and C=O (1714 cm^{-1}). If the product was an α,β-unsaturated aldehyde the C=O vibrations should have been in the region 1680–1705 cm^{-1}, and if it had contained a ketonic group in a four or five membered ring the C=O vibrations should have been in the region 1740–1775 cm^{-1}. Thus, the infrared spectrum of the product is consistent with its identification as 5-hexenal.

The product was collected from the Ucon column for mass spectral analysis. A blank from the column was collected for 240 s, whereas the 5-hexenal product peak was collected for 112 s. The blank was assumed to be uniform during the two collections. The mass spectrum of the 5-hexenal, suitably corrected for the blank, is given in Table I. The values for the corresponding ions in the cyclohexanone mass spectrum are listed for comparison. The values of the abundances of the various ions are given relative to the most abundant ion in a given spectrum as 100. Ions that have abundance values less than 3 in 5-hexenal have been omitted. The present mass spectrum of 5-hexenal agrees well with the one obtained by Srinivasan (21). Values of ions from water (m/e = 17 and 18), air (m/e = 28, 32, and 44), and carbon tetrachloride (m/e = 35, 37, 47, 49, 82–86, and 117–123) have been omitted. Carbon tetrachloride contamination of the 5-hexenal was a result of the collection procedure.

Unidentified Impurity (U.I.)

The unidentified impurity gave a doublet peak on the Ucon column. Its infrared spectrum indicated the presence of C=C (1638 cm^{-1}) and a C=O in a C_5 ring (1740 cm^{-1}). Such a product has not been reported in the pyrolysis of cyclohexanone (22).

Cyclohexenone

Cyclohexenone was separated from cyclohexanone on the Ucon and Carbowax columns. Its infrared

53	12.9	2.8	98	11.1	38.6
54	*100.0*	7.5			

spectrum showed the presence of C=C—C=O (1686 cm^{-1}) and CH=CH (3015, 1305, and 665 cm^{-1}) (23), thus indicating the presence of 2-cyclohexenone. However, the presence of 3-cyclohexenone cannot be ruled out on the basis of this work.

C_{12} Products

Analysis of radiolyzed cyclohexanone on the silicone grease column gave five peaks (two of which were doublets) in the region of DKDC. The retention time of the largest peak agreed with that of DKDC and the four smaller peaks were considered to be due to similar compounds.

Quantitative Results

Fragmentation Products

The yield of hydrogen seems to decrease slightly whereas that of carbon monoxide appears to increase slightly with increasing dose (Fig. 1). The initial yields, i.e., the G values extrapolated to zero dose, are $G_i(H_2) = 0.76 \pm 0.03$ and $G_i(CO) = 0.45 \pm 0.03$.

The yields of other fragmentation products were also measured and their yields were independent of dose, within experimental error. The results are summarized in Tables II and III.

TABLE II

Initial yields of major products

Product	G_i[a]
Hydrogen	0.76 ± 0.03
Carbon monoxide	0.45 ± 0.03
1-Pentene	0.22 ± 0.04
5-Hexenal	0.85 ± 0.15
Cyclohexenone	0.4 ± 0.2
Cyclohexanol	0.5 ± 0.3
Total dimer[b]	1.2 ± 0.4
Polymer	1.8 ± 0.3[c]

[a]The possible error, in each case, is estimated visually from appropriate plots.

[b]The value, $G_i \approx 1.2$, was obtained from the average of the G values for total dimer obtained from two columns (silicone grease and Apiezon L).

[c]This value is obtained by linear extrapolation to zero dose from the values obtained in the region 1.8–9.2 (10^{20} eV/ml), and the linear extrapolation might not be valid (see Fig. 4).

C_6 Products

The yields of 5-hexenal and cyclohexenone decrease with increasing dose (Fig. 2). The initial yield of 5-hexenal is 0.85 ± 0.15. The accuracy of the cyclohexenone measurements was not as good as the precision shown in Fig. 2A. Cyclohexenone was measured on the tail of the cyclohexanone peak, and the calibration

Cyclopentane	0.04±0.01
2-Pentene	~0.004
Peroxides	≤0.3[d]
Polymer ($CHCl_3$ insoluble)	~0.1[e]

[a]Unless otherwise stated.
[b]The possible error is estimated visually from the appropriate figures.
[c]Extrapolated value for zero dose, G_i.
[d]On the basis of analysis of two samples, one each at 2×10^{20} eV/ml and 5×10^{20} eV/ml.
[e]Average of four samples in the range 1.8–9.2 (10^{20} eV/ml).

factors, determined at various times, were only constant to within about 50%. Therefore, G_i(cyclohexenone) = 0.4±0.2.

Difficulty was also experienced in separating cyclohexanol from a large excess of cyclohexanone. Thus, the results obtained for cyclohexanol are not too satisfactory (Fig. 3). It appears that G_i(cyclohexanol) = 0.5±0.3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

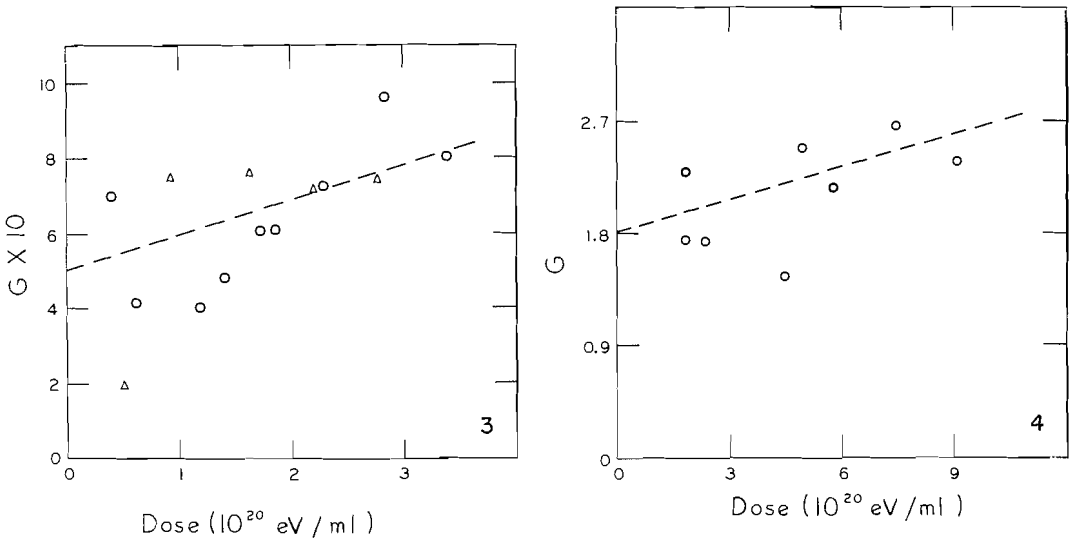

FIG. 3. Cyclohexanol: O average of values from the Ucon and the Carbowax columns; △ values from the Ucon column.
FIG. 4. Yield of polymer.

C_{12} Products

The C_{12} products were analyzed on Apiezon L and on silicone grease columns. At least five different C_{12} compounds were formed but only DKDC was available for standard calibrations. For this reason, it is estimated that the value of G_i(total dimer) = 1.2 might be in error by as much as 0.4 units (Table II). The yield had decreased to G(total dimer) = 0.8 at a dose of 3.4×10^{20} eV/ml. About 50% of the total dimer was DKDC.

Polymer

The yield of the chloroform soluble polymer, in units of cyclohexanone molecules consumed to form polymer, is shown as a function of dose in Fig. 4. The polymer yield probably increases with increasing dose and G_i(polymer) appears to be about 1.8.

For one sample (dose = 5×10^{20} eV/ml), the volatile contents of the cell were removed in the usual way and the cell was sealed while still under vacuum. The cell was then sent to Germany for microanalysis of its remaining contents.* The average composition of the samples referred to in Fig. 4 was polymer:dimer:monomer::70:19:11, and it was assumed that the sample sent for analysis had the same composition. The results of the microanalysis of the polymer, corrected for dimer and monomer content, are shown in Table IV. The values for cyclohexanone are given for comparison. The C, H, and O values are quite similar to

TABLE IV

The yield of polymer that was insoluble in chloroform was determined for four irradiated samples and two blanks. The blanks were cells that had been filled and put through the usual polymer analysis procedure, but had not been irradiated. The average value of G(insoluble polymer) was about 0.1 cyclohexanone units for the irradiated samples.

DISCUSSION

The initial yields of the major products of the radiolysis of cyclohexanone are listed in Table II. Yields of the minor products are given in Table III. In general, the variations of the yields with dose may be attributed to secondary reactions.

Ring Opening

Extent of Ring Opening

An estimate of the amount of ring opening that occurs during the radiolysis of cyclohexanone is given by

$$[1] \qquad G(\text{ring opening}) \approx G_1(\text{CO} + \text{5-hexenal}) = 1.3.$$

The actual amount of ring opening might be greater than this, depending upon the identity of the dimeric and polymeric products and the mechanism of formation of 5-hexenal (e.g., if 5-hexenal were formed by intramolecular disproportionation of pentamethylene acyl diradicals, $\dot{C}H_2(CH_2)_4\dot{C}O$, then since some of the diradicals would likely regenerate cyclohexanone by intramolecular combination, the observed yield of 5-hexenal would give too low an estimate of the amount of primary ring opening).

An estimate of the amount of initial C—H bond breakage is given by

$$[2] \qquad G(\text{initial C—H breakage}) \approx G_1(H_2 + \text{c-}C_6H_{11}OH) = 1.3.$$

The actual amount of initial C—H bond breakage might be much greater, depending on the identity of the dimeric and polymeric products and on the mechanism of formation of the various products.

The value of the ratio of the amount of ring opening to the amount of initial C—H breakage is given by the ratio of expressions [1] and [2]. Therefore,

$$[3] \qquad (\text{ring opening/initial C—H breakage}) \approx 1.0.$$

In the radiolysis of cyclohexane (1),

$$[4] \quad G(\text{ring opening}) \approx G_1(\text{1-hexene} + \text{methylcyclopentane} + \text{cyclohexylhexene-1}) = 0.77.$$

The actual amount of ring opening may be somewhat greater, depending on the mechanism of formation of 1-hexene, methylcyclopentane, and cyclohexylhexene-1.

An estimate of the amount of initial C—H bond breakage is given by $G_1(H_2)$, which is equal to 5.6 (2). Therefore,

$$(\text{ring opening/initial C—H breakage}) \approx 0.14.$$

[3]Ratio, 1/2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Similar ratios can also be calculated, on the basis of available results, for methylcyclohexane (24) and for *n*-hexane (25, 26); the data for the four compounds are summarized in Table V. Despite large uncertainties in these values, there are significant differences. In column 3 it is seen that the closed rings of cyclohexane and methylcyclohexane are more stable than the open chain of *n*-hexane, probably due in part to the inability of the free radical ends formed on ring cleavage to escape one another by diffusion, with consequent high probability of reformation of the ring. The cyclohexanone ring, however, is *less* stable than the open chain of *n*-hexane, illustrating the powerful effect of the carbonyl group on the primary radiation chemical reaction.

Site of Ring Opening

The formation of carbon monoxide and 5-hexenal implies cleavage of C—C bonds adjacent to the carbonyl group. Products corresponding to ring opening in other positions were not observed. This behavior, common to both the radiolysis and photolysis of ketones (27), could be attributed to a localization of energy in the carbonyl group, or might simply represent rupture of the weakest bond in the molecule (28). It is impossible at present to distinguish between these two causes in either system. However, the localization of radiolytic activation in specific parts of molecules, before chemical reaction occurs, has been suggested before (29) and it seems probable that it is occurring in the cyclohexanone system.

Comparison of Radiolysis and Photolysis of Cyclohexanone

It is of interest to compare the distribution of reaction products in the radiolytic and photolytic systems to see if any information can be obtained about the relative levels of excitation of the species that undergo reaction.

Carbon monoxide is a major product of both liquid and vapor phase photolyses of cyclohexanone (30–34). The present work shows that it is also a major product of the radiolysis of liquid cyclohexanone. Ethylene, propylene, 1-pentene, and cyclopentane are formed in the radiolysis of the ketone. They were found to be important products of the vapor phase photolysis but seem not to have been looked for in the liquid phase photolysis (34).

Srinivasan found that 5-hexenal is a product of the vapor and liquid phase photolyses of cyclohexanone (34). He also showed that the rate of 5-hexenal formation was 3.7 times greater than that of carbon monoxide in the vapor phase and was about 11 times greater in the liquid phase. The radiolytic yield of 5-hexenal from liquid cyclohexanone is only about twice the radiolytic yield of carbon monoxide.

Polymer formation in the vapor phase photolysis has been reported (32, 33) and Blacet and Miller suggested that the polymer formation increases at lower wavelengths (33). Polymer is a major product of the radiolysis of the ketone.

Hydrogen, cyclohexanol, cyclohexenone, and "dimer" are major products of the radiolysis, but their formation has not been reported in the photolytic studies. It is not certain whether they were looked for. It may be pointed out that the C—H bond dissociation energies in the ketone are likely to be ~90–95 kcal/mole (D(iso-C_3H_7—H) = 94 kcal/mole (28*a*)), so the energy of the light quantum is not sufficient to break a C—H bond where light of wavelength greater than ~300–310 mμ has been used. In the photolysis of cyclopentanone at 313 mμ, hydrogen was reported not to be a product (10). Photolytic formation of cyclohexanol from cyclohexanone has been suggested (35) but it is not certain whether it has been observed as a product.

A large number of minor products are formed in the radiolysis of the ketone, e.g.,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

acetylene, propane, cyclopropane, etc., which have not been reported in the photolytic studies.

It may be concluded that the energy states involved in the radiolytic formation of hydrogen are higher than the energy states involved in most of the photolysis studies. The other products of radiolysis that have not been reported in the photolysis studies may also result from higher energy states. The difference in the relative yields of 5-hexenal and carbon monoxide in the photolysis and radiolysis of liquid cyclohexanone is also indicative of higher states in the radiolysis. However, it is difficult to say whether these states differ mainly in their electronic levels or in their vibrational levels.

ACKNOWLEDGMENTS

The authors are grateful to Dr. R. Srinivasan for sending mass spectral data of 5-hexenal. They also thank Dr. S. Usiskin and the Government of Alberta Cancer Clinic for use of the ^{60}Co therapy unit.

Financial support for this work was received from the National Research Council. Part of the results in this paper were reported at the Annual Conference of the Chemical Institute of Canada, Toronto, June, 1963. The yields of some of the products have been revised slightly from those in the earlier report.

RADIOLYSIS OF CYCLOHEXANONE

II. EFFECT OF SOLUTES ON PRODUCTS INVOLVING C—H BOND RUPTURE

AJIT SINGH AND GORDON R. FREEMAN
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received January 31, 1964

ABSTRACT

Some of the products whose formation, during the radiolysis of cyclohexanone, involves the rupture of C—H bonds are hydrogen, cyclohexanol, 2,2′-diketodicyclohexyl, and probably other "dimers" of cyclohexanone.

Benzene appears to inhibit the formation of hydrogen mainly by an activation transfer process. The influence of 2,3-dimethyl-1,3-butadiene (DMB) on the hydrogen yield is more complex and probably involves more than one inhibition reaction.

Less than one mole percent of DMB or of oxygen inhibits the formation of cyclohexanol and of dimers to below their limits of detection on the analytical system ($G < 0.2$). This is probably due to the scavenging of free radicals (G(scavengeable radicals) = 4). Benzene is much less efficient than DMB or oxygen in inhibiting the formation of cyclohexanol and of dimers of cyclohexanone.

INTRODUCTION

The radiolysis of liquid cyclohexanone in binary solutions has been studied in an attempt to elucidate the mechanisms of the formation of some of the products (1). Mechanisms that involve C—H but not C—C bond rupture are considered here.

Benzene has been widely used as an inhibitor in radiolytic studies, (e.g., refs. 2–4). Patrick and Burton studied the radiolysis of propionaldehyde in the presence of benzene (4) and concluded that benzene does not protect propionaldehyde but sensitizes its decomposition. This was attributed to energy transfer from benzene to a low-lying excited state of propionaldehyde.

The photoionization potentials of benzene, propionaldehyde, and cyclohexanone are 9.25, 9.98, and 9.14 eV, respectively (5) and they show absorption maxima in the near ultraviolet at about 260, 285±15, and 290 mμ, respectively (6). It was therefore considered interesting to see whether benzene would protect or sensitize the radiolytic decomposition of cyclohexanone.

It appeared that 2,3-dimethyl-1,3-butadiene (DMB) might be a good radical scavenger (7) and this led to an investigation of its effect on the radiolysis of cyclohexanone.

Oxygen was primarily used to briefly compare its scavenging action with that of DMB.

EXPERIMENTAL

Most of the experimental techniques were described earlier (1). Certain modifications of the techniques were required for this work and these will be described here.

Materials

Phillips Research Grade benzene was distilled and stored under vacuum. Gas chromatographic analysis, using Ucon, Carbowax, silicone grease, and Apiezon L columns, did not reveal detectable amounts of impurities in the benzene. DMB was obtained from Chemical Procurement Labs., K & K Laboratories, and Matheson, Coleman, and Bell. It was distilled under vacuum from a flask at −25 °C into a reservoir at −196 °C. This procedure eliminated high boiling impurities and less than 0.5% of other impurities remained. The distilled DMB was carefully degassed and stored under vacuum.

Preparation and Irradiation of Samples

The amounts of benzene and DMB were measured as liquid in a calibrated tube or as vapor in a calibrated bulb. DMB was distilled from the cooled reservoir (−25 °C) to the measuring tube. For the samples with

added oxygen, a measured amount of cyclohexanone was distilled into the cell and was kept frozen with Dry Ice. Dry oxygen was let into the cell, its pressure recorded, and the cell sealed off. The various solutions were irradiated to a dose of 5.92 ± 0.12 (10^{-4} eV/e$^-$,) which is about 1.9×10^{20} eV/ml. Thus the cyclohexanone in all mixtures received the same dose. The yields of several products were measured as a function of the electron fraction, ϵ_s, of the solute.

Calibrations of Cyclohexanol

The resolution of the cyclohexanol peak from the cyclohexanone peak, on both the Ucon and the Carbowax columns, was not very good and it varied with the amount of the ketone injected. It was therefore necessary to determine a calibration curve for cyclohexanol for each different solution of cyclohexanone and inhibitor used.

RESULTS

If the radiolysis products of a component X in a binary solution are unaffected by the presence of the other component Y, and vice versa, then the expected G value, G_{ex}, for a product P from the solution should be given approximately by the expression:

$$[1] \qquad G_{ex}(P) = G_x^0(P)\ \epsilon_x + G_y^0(P)\ \epsilon_y$$

where G_x^0 (P) and G_y^0 (P) refer to the yields of P from pure X and pure Y, respectively, and ϵ_x and ϵ_y refer to the electron fractions of X and Y in the solution radiolyzed. The values of G_{ex} in the figures are represented by linear dashed lines. Most of the end points are averages of more than one determination.

Hydrogen

The decrease of the hydrogen yield in the low solute concentration region ($\epsilon_s \leq 0.1$) is more pronounced in the DMB solutions (Fig. 1A) than in the benzene solutions (Fig. 1B). However, the decrease is greater than that expected on the basis of equation 1 in both cases. $G(H_2) = 0.038$ for pure benzene and $G(H_2) = 0.19$ for DMB. Hydrogen was not measured for the oxygen solutions.

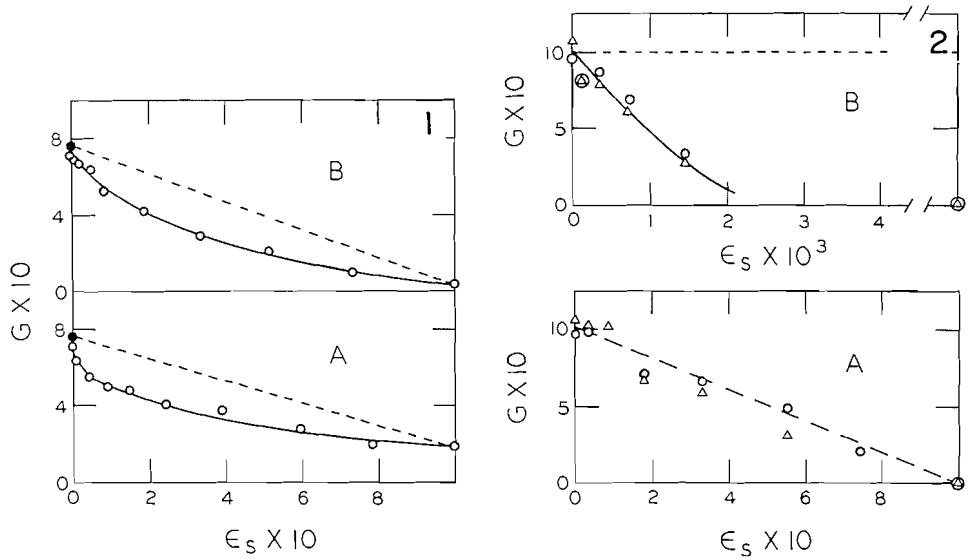

FIG. 1. Hydrogen: ϵ_s = electron fraction of solute; dose = 5.92 ± 0.12 (10^{-4} eV/e$^-$); dashed lines refer to G_{ex}. (A) 2,3-Dimethyl-1,3-butadiene solutions: ○ H_2; ● G_i (H_2). (B) Benzene solutions: ○ H_2; ● G_i (H_2).

Cyclohexanol

The cyclohexanol yield seemed to decrease about linearly with increasing electron fraction of benzene (Fig. 2). However, in sharp contrast to this, in the DMB solutions the cyclohexanol yield decreased so rapidly that it was not visible as a product in samples containing greater than about 2×10^{-3} electron fraction of the diene. The cyclohexanol yield could not be determined in the oxygen solutions, because of uncertainty in the blank value.

Cyclohexenone

The radiolytic yield of cyclohexenone from pure cyclohexanone is small at this high dose ($G \approx 0.2$ at 1.9×10^{20} eV/ml (1)). It was not seen as a product in any of the solutions ($G < 0.2$).

Cyclohexanone "Dimers"

The G value of total cyclohexanone dimers decreases gradually with increasing benzene concentration, almost all the values being lower than G_{ex} (Fig. 3A). The yields of 2,2′-

diketodicyclohexyl (DKDC) and of dimer D-1, as obtained by analysis on the silicone grease column, are shown in Fig. 4A and B. They follow a pattern similar to that of the total dimer.

In the DMB solutions, the yields of cyclohexanone dimers decrease very rapidly with increasing electron fraction of the diene (Figs. 3 and 4). The yield had decreased to below the detection limit of about 0.2 G units at $\epsilon_s = 2 \times 10^{-3}$. The three samples with electron fractions of DMB equal to 1×10^{-3}, 2×10^{-3}, and 3×10^{-3} were large samples (20 ml) prepared mainly for polymer analysis and received a lower dose rate (2.3×10^{18} eV/ml h) than did the other samples (5.2×10^{18} eV/ml h) referred to in Figs. 3 and 4. Cyclohexanone dimer formation was inhibited to below the detection limit ($G < 0.2$) in both oxygen solutions.

Additional Products

DMB Solutions

Analysis of radiolyzed pure DMB on Apiezon L and silicone grease columns showed one big peak and three very small peaks after the DMB peak. The big peak, by comparison of its retention time with that of *n*-dodecane, was tentatively identified as the "dimer" of DMB.

The yield of the dimer of DMB increases very rapidly with increasing diene concentration at low concentrations, then remains constant for $\epsilon_s > 0.1$ (Fig. 5B). The G value is greater than G_{ex} throughout.

In the solutions with $\epsilon_s > 0.02$, several new products were formed (4 new peaks on the Apiezon L column and 6 new peaks on the silicone grease column). The new product

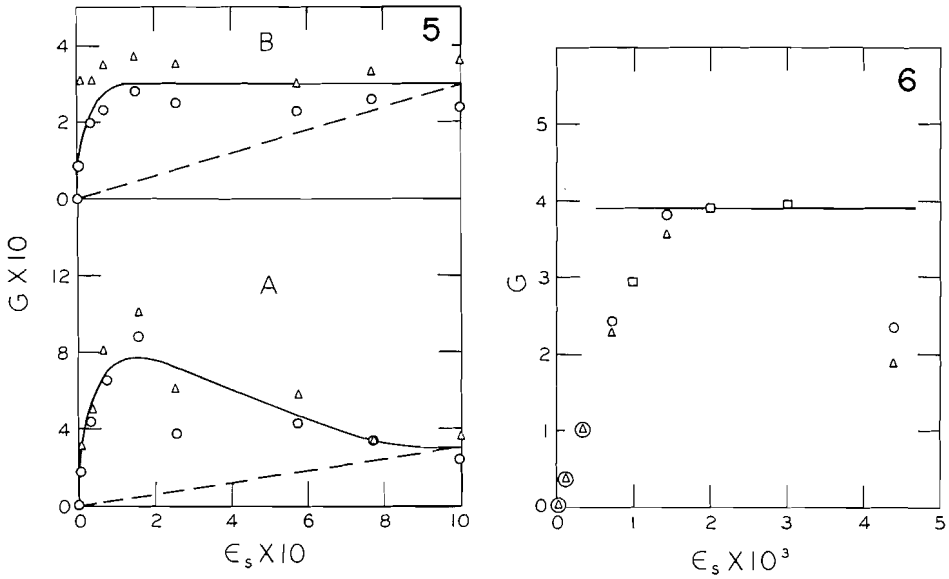

FIG. 5. Dimers that include 2,3-dimethyl-1,3-butadiene units: ϵ_s = electron fraction of the solute; dose = 5.92±0.12 (10^{-4} eV/e$^-$); dashed lines refer to G_{ex}. ○ Apiezon L column; △ silicone grease column. (A) Total C_{12} minus the dimers of cyclohexanone; (B) dimer of DMB.

FIG. 6. G(consumption) of DMB: ϵ_s = electron fraction of DMB; $G = G$(consumption) of DMB; dose = 5.92±0.12 (10^{-4} eV/e$^-$). Dose rate ≈ 5.2×10^{18} eV/ml h); △ silicone grease column; ○ Apiezon L column. Dose rate ≈ 2.3×10^{18} eV/ml h; □ Apiezon L column. NOTE: The values from the sample with $\epsilon_s = 4.4 \times 10^{-3}$ are less trustworthy since they are based on the measurement of a small difference between two large quantities (DMB remaining = 84%).

peaks appeared between the dimer peak of DMB and the dimer peaks of pure cyclohexanone, on both columns. It is likely that these peaks correspond to "mixed" dimers formed from the diene and the ketone. The combined yield of the mixed dimers plus the dimer of DMB is shown in Fig. 5A. The calibration curves of DKDC were used for calculation of the yields in Fig. 5. Thus the absolute G values in this figure might be wrong by as much as a factor of two, but the shapes of the curves are probably correct.

It is interesting to note that the new C_{12} products were absent in the region of $\epsilon_s = 3 \times 10^{-3}$, where the formation of cyclohexanol and the cyclohexanone dimers was completely inhibited. At these low concentrations of DMB, its rate of destruction was measureable (Table I and Fig. 6). The value of G(consumption) of DMB in the maximally

inhibited system was about 4. Since no gas chromatographic peaks corresponding to new products were observed in this concentration region, the amounts of polymer formed and DMB consumed were measured for a series of 20 ml samples (Table II, see also Table I and Fig. 6). It appears from Table II that the polymer contains an approximately 1:1

mole ratio of DMB:cyclohexanone. The average molecular weight of the polymer from two samples with $\epsilon_s = 2.0 \times 10^{-3}$ (dose = 5.9×10^{-4} eV/e$^-$) was 400±30.*

Oxygen Solutions

Peroxides were formed in good yield (Table III), but their identity was not determined.

When the irradiated solution was analyzed on the Apiezon L column, a large product peak was obtained after the cyclohexanone peak. By comparison of the product retention time with those of quinone and hydroquinone, it was tentatively identified as a hydroxycyclohexanone or a cyclohexanedione or a mixture of both. The G values for the product

were estimated to be ~0.8 and ~1.2 from samples with oxygen pressures of 71 and 412 mm, respectively, assuming a calibration factor equal to that of cyclohexanone. There were also three minor products, one of which had the same retention time as caproic acid ($G \approx 0.1$, when calibration factor is assumed equal to that of cyclohexanone).

DISCUSSION

Hydrogen

Benzene and DMB decrease the radiolytic yield of hydrogen from cyclohexanone (Fig. 1). The decrease in hydrogen yield might be due to protection of the ketone by an activation transfer mechanism, which reduces the amount of initial decomposition of the ketone itself, or it might be due to a scavenging mechanism that involves precursors of hydrogen (e.g. H atoms), or it might be a combination of the two. In the following discussion the 'activation transfer-type' and the 'scavenging-type' mechanisms are considered separately.

Several different mechanisms might yield the same type of rate equation. It was therefore decided to classify the mechanisms according to the type of rate equation they obeyed. In an activation transfer-type mechanism, the reaction between the solute and an activated species is in competition with a first order decomposition reaction of the activated species which results in the product under consideration. In a scavenger-type mechanism, the reaction between the solute and an activated species is in competition with a second order reaction of the activated species which results in the product under consideration.

It is assumed in the following treatments that the yield of hydrogen from the direct radiolysis of the solute is proportional to the electron fraction of the solute in the sample.

Mechanism 1 (Activation Transfer-Type)

(1) $C_6H_{10}O \xrightarrow{I_1} C_6H_{10}O^*$
(2) $C_6H_{10}O^* \rightarrow H_2 + P_1$
(3) $C_6H_{10}O^* + S \rightarrow C_6H_{10}O + S^*$
(4) $S^* \rightarrow H_2 + P_2$
(5) $\rightarrow S$

where S refers to the solute. Reactions 2 and 4 could each involve more than one molecule and both could involve more steps than one. Products P_1 and P_2 may each refer to more than one entity.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The rate of formation of $C_6H_{10}O^*$ is represented by I_1, which is assumed to be proportional to the electron fraction of cyclohexanone, ϵ_c, in the samples.

$$G(C_6H_{10}O^*) = AI_1 \quad [2]$$

where A is a proportionality constant that includes the irradiation dose rate.

The following expression is obtained by the usual steady state treatment of mechanism 1.

$$(1 + u\,[S])\,\rho_1 = 1 + v\,[S] \quad [3]$$

where

$$u = k_3k_4/k_2\,(k_4 + k_5), \quad [4]$$

$$v = k_3/k_2, \quad [5]$$

and

$$\rho_1 = \frac{I_1}{d[H_2]/dt} = \frac{G_{ex}(H_2)_c}{G_{obs}(H_2) - G_s^0(H_2)\epsilon_s}. \quad [6]$$

An equation of the same form as equation 3 can also be obtained from a mechanism that involves charge transfer (8).

The value of ρ_1 can be obtained from experimental data. The production of hydrogen by direct radiolysis of the solute has been excluded from the mechanism, so the "expected" yield of hydrogen is given by

$$G_{ex}\,(H_2)_c = G_c^0\,(H_2)\;\epsilon_c = 0.71\;\epsilon_c \quad [7]$$

at the dose used.* Similarly, $d[H_2]/dt$ excludes the hydrogen produced by direct radiolysis of the solute.

If the value of u were known, the left hand side of equation 3 could be plotted against [S] and a straight line with an intercept of unity would be obtained, if mechanism 1 were applicable. In the present case, various arbitrary values of u (0 to 5) were assumed and several plots of equation 3 were made to see if a straight line with an intercept of unity could be obtained.

(i) Benzene Solutions

For the results from the benzene solutions, the best straight line plot was obtained with $u = 0$ (Fig. 7). A plot with $u = 0.5$ is also shown in Fig. 7 for comparison. The slope of the line with $u = 0$ gives $v = 0.2$ l/mole. The value $u = 0$ means that benzene does not produce an appreciable amount of hydrogen subsequent to protection of cyclohexanone by activation transfer. Many previous workers (e.g. ref. 2) have made the assumption that benzene does not produce hydrogen subsequent to energy absorption from another component in the system, and this is equivalent to the $u = 0$ obtained here.

It is reasonable to expect that either of the reactions 6 and 7

$$A^* + B \rightarrow A + B^* \quad (6)$$

$$A + B^* \rightarrow A^* + B \quad (7)$$

**When the yield of hydrogen from pure cyclohexanone at zero dose, $G_i(H_2) = 0.76$, was used instead of the yield at the dose used in these experiments, the kinetic plots did not give intercepts of unity, even when a straight line was obtained. The use of $G_c^0(H_2) = 0.71$ in equation 7 involves the assumption that the secondary products of radiolysis have a similar effect on the yield of hydrogen in the pure ketone and in the solutions.*

The curves for $u = 0$ and $u = 1.0$ have been normalized to that for $u = 0.3$, using the point ● (i.e. the values of R_1 have been altered to R_1', where $R_1' = f(R_1 - 1) + 1$; for the triangles and squares $f = 1.3$ and 0.65, respectively). This facilitates the comparison of the linearity of the plots. Triangles and squares are not shown for [S] < 1.1, because they differ negligibly from the circles in this region.

might occur, depending on the relative heights of the energy levels involved (2, 9). The energies of the lowest excited states and the ionization potentials of cyclohexanone and benzene are shown in Table IV.

TABLE IV

Energies of lowest excited states and ionization potentials*

Compound	Triplet	Singlet	Ionization potentials
Cyclohexanone	2.8†	4.27 (6)	9.14 (5)
Benzene	3.58 (11)	4.76 (6, 11)	9.25 (5)
DMB	~2.6 (15)	5.4 (6)	~8.7 (13)

*The energies are expressed in eV and the numbers in parentheses are the references.
†Estimated by comparison with the states of cyclopentanone (6, 11).

Charge transfer from the ground state cyclohexanone ion to a benzene molecule is improbable because the process is endothermic.

States in the vicinity of 4.1 eV (300 mμ) do not contribute significantly to the production of hydrogen (see ref. 1), probably because nearly all of the absorbed energy would have to become localized as vibrational energy in one or two C—H bonds. Such a great degree of vibrational energy localization in the molecule is improbable. Thus, if excited states

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of the cyclohexanone molecule are involved in the radiolytic production of hydrogen, they must be higher than the lowest singlet and they might well be higher than the lowest states of benzene. Energy transfer from such excited states to benzene, with consequent reduction of the hydrogen yield, would then be possible.

This type of argument is also applicable to the previously studied radiolysis of propionaldehyde (4). Patrick and Burton considered that the inhibition of hydrogen formation was due to the scavenging of hydrogen atoms by benzene (4). Hydrogen has been shown to be a minor product of the photolysis of propionaldehyde even at 238 mμ, or 5.20 eV ($\Phi(CO) \simeq 1$, $\Phi(H_2) \simeq 0.1$, ref. 12). The lowest excited singlet state of propionaldehyde is at about 4.35 eV and its triplet would be still lower in energy (6, 10). Thus, in the radiolysis of propionaldehyde, hydrogen formation must have been due to species with much more energy than that possessed by the lowest excited singlet and triplet states. Inhibition of hydrogen formation by energy transfer to benzene might therefore be possible.

(ii) DMB Solutions

Since the lowest excited states of the ketone are probably not involved in hydrogen production, activation transfer, whether as charge or as excitation energy, must be considered as one possible means of inhibition of hydrogen formation (see Table IV).

A satisfactory straight line could not be obtained with the results from the DMB solutions (Fig. 8) and it appears that this simple mechanism does not apply. It is evident from Fig. 1 that the effect of DMB in the low concentration region ($\epsilon_s < 0.05$) is much greater than the effect of benzene in the same region. At higher concentrations, both solutes appear to have similar effects.

Two processes involving the diene are evident at $\epsilon_s > 1 \times 10^{-2}$, with a maximum at $\epsilon_s \simeq 0.1$. These involve a sharp increase in the yield of the dimer of DMB (Fig. 5B) and a sharp increase of yield of the mixed dimers of cyclohexanone and DMB (Fig. 5A minus Fig. 5B). Both of these effects might result from reactions which contribute to the inhibition of hydrogen formation. An activation transfer-type process is probably involved in the formation of one or both of the types of dimers (containing two and one DMB units, respectively) because the shapes of both of the curves together (Fig. 5) cannot be explained by a simple radical scavenging mechanism. In any case, the scavenging of large ketone radicals is not responsible for the formation of these products because they were not formed at very low diene concentrations ($\epsilon_s \simeq 3 \times 10^{-3}$) where the inhibition of cyclohexanol and the dimers of cyclohexanone was virtually complete. Reactions such as

$$DMB^* + DMB \rightarrow (DMB)_2$$

and

$$C_6H_{10}O^* + DMB \rightarrow C_{12}H_{20}O$$

might be involved (15).

Mechanism 2 (Scavenging-Type)

(8)	$C_6H_{10}O \xrightarrow{I_2} C_6H_{10}O^*$
(9)	$C_6H_{10}O^* \rightarrow H + \cdot C_6H_9O$
(10)	$H + C_6H_{10}O \rightarrow H_2 + \cdot C_6H_9O$
(11)	$\rightarrow (C_6H_{11}O)\cdot$
(12)	$H + S \rightarrow H_2 + R\cdot$
(13)	$\rightarrow HS\cdot$

where R· represents the radical obtained by abstracting a hydrogen atom from S and I_2 has a meaning similar to that of I_1 in mechanism 1.

Steady state treatment of mechanism II yields

$$(1 + y[S]/[C_6H_{10}O])\,\rho_2 = 1 + z\,[S]/[C_6H_{10}O] \quad [8]$$

where

$$y = k_{12}/k_{10} \quad [9]$$

$$\rho_2 = (k_{10}/(k_{10} + k_{11}))/(I_2/(d[H_2]/dt) \quad [10]$$

and

$$z = (k_{12} + k_{13})/(k_{10} + k_{11}). \quad [11]$$

It may be pointed out here that equations of the same form as equation 8 can be obtained from other mechanisms than mechanism 2. Two such mechanisms involve "scavenging" of positive charges and of electrons (8).

Experimentally, ρ_2 is the same as ρ_1,

$$\rho_2 = \frac{0.71\,\epsilon_c}{G_{obs}(H_2) - G_s^0(H_2)\epsilon_s} \quad [12]$$

Various arbitrary values were assumed for y (0 to 5) and the left hand side of equation [8] was plotted against ($[S]/[C_6H_{10}O]$) in an attempt to obtain a straight line with an intercept of unity.

(i) Benzene Solutions

The kinetics plots were not as sensitive to variation in y as might be desired. The best straight line was obtained with $y = 1$ and yielded $z = 3$ (Fig. 9). Plots with $y = 0$ and $y = 2$ are shown for comparison.

For mechanism 2, the values $y = 1$ and $z = 3$ mean that (*a*) the overall rate constant for the reaction of hydrogen atoms with benzene was about three times greater than the corresponding rate constant for the reaction of hydrogen atoms with cyclohexanone; (*b*) the rate constants for hydrogen abstraction by an H atom from benzene, k_{12}, and from cyclohexanone, k_{10}, had the same value.

Since the bond dissociation energies of the C—H bonds in cyclohexanone are likely <95 kcal/mole,* whereas the C—H dissociation energy in benzene is 102 kcal/mole (16), k_{12} would not be expected to be equal to k_{10}. Thus, mechanism 2 seems to be inapplicable in the present case.

The observed values of y and z also make the charge scavenging mechanisms seem improbable (8).

(ii) DMB Solutions

A satisfactory plot could not be obtained (Fig. 10).

To summarize, the role of benzene in reducing the yield of hydrogen appears to involve interference with precursors of hydrogen other than hydrogen atoms. An activation transfer-type mechanism appears to provide a better explanation of the results than does a scavenging-type mechanism. The role of DMB in reducing the hydrogen yield appears to be more complex and probably involves more than one process. Neither the presence nor the absence of hydrogen atoms in the system has been established.

**The C—H bonds on the carbons β and γ to the carbonyl group probably have dissociation energies similar to D(iso-C_3H_7—H) = 94 kcal/mole. The C—H bonds on the carbons α to the carbonyl group are probably weaker than this, due to the formation of a radical that possesses resonance stabilization energy.*

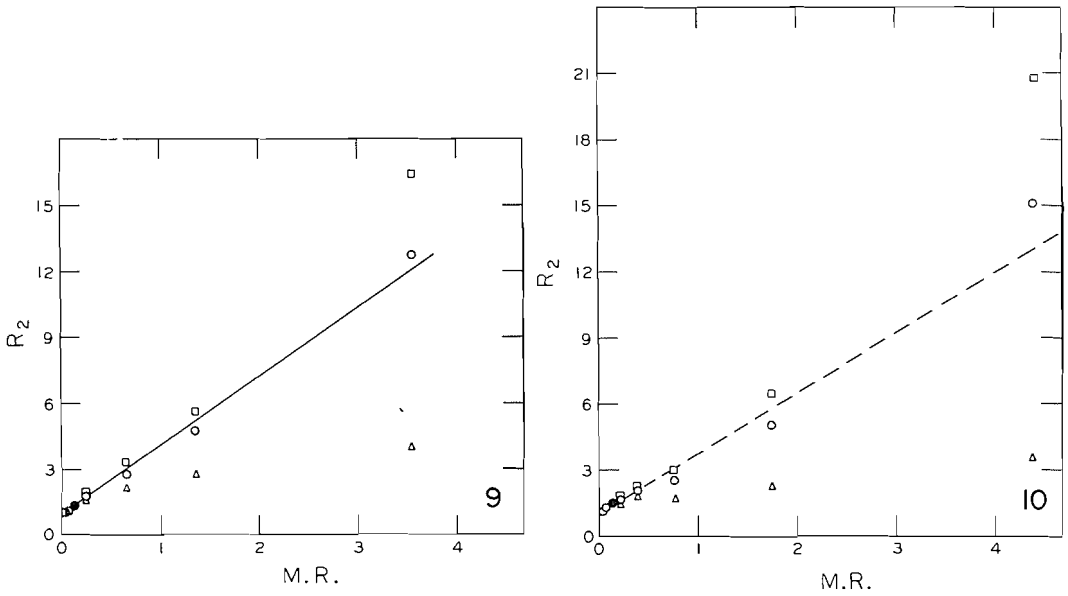

FIG. 9. Kinetic plot for scavenging-type mechanism: $R_2 = (1 + y\,[S]/[C_6H_{10}O])\,\rho_2$; [S] = benzene concentration (M); M.R. = $[S]/[C_6H_{10}O]$; △ $y = 0$; ○ $y = 1$; □ $y = 2$. The points for $y = 0$ and $y = 2$ have been normalized to the curve for $y = 1$, using the point ● (i.e. the values of R_2 have been altered to R_2', where $R_2' = f(R_2 - 1) + 1$; for the triangles and squares $f = 1.13$ and 0.90, respectively). This facilitates the comparison of the linearity of the plots. Triangles and squares are not shown for M.R. < 0.13 because they differ negligibly from the circles in this region.

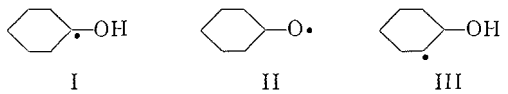
FIG. 10. Kinetic plot for scavenging-type mechanism: $R_2 = (1 + y\,[S]/[C_6H_{10}O])\,\rho_2$; [S] = DMB concentration (M); M.R. = $[S]/[C_6H_{10}O]$. △ $y = 0$; ○ $y = 1$; □ $y = 2$. The points for $y = 0$ and $y = 2$ have been normalized to the curve for $y = 1$, using the point ● (i.e. the values of R_2 have been altered to $R_2' = f(R_2 - 1) + 1$; for the triangles and squares $f = 1.13$ and 0.90, respectively). This facilitates the comparison of the linearity of the plots. Triangles and squares are not shown for M.R. < 0.13 because they differ negligibly from the circles in this region.

Cyclohexanol

Very small amounts of DMB inhibit the formation of cyclohexanol, whereas benzene has little or no effect. This is consistent with a free radical mechanism for the formation of the alcohol because DMB is a very good radical scavenger and benzene is a very poor one (7, 17).

The cyclohexanol is probably formed by abstraction and disproportionation reactions of the $(C_6H_{11}O)\cdot$ radical. This radical can be formed in several different ways (8) and its most probable structure is I. Structures II and III are also possible, but they are probably

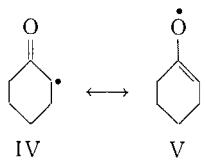


I II III

formed to much smaller extents than is I (8).

C_{12} Products

The C_{12} products are probably formed by the combination of radicals. Half of the dimer yield is accounted for by DKDC (on the silicone grease column; G(total dimer) = 1.53, G(DKDC) = 0.79) which suggests that radical IV is produced in good yield in the system.



IV V

(14) $2\,\mathrm{IV} \rightarrow \mathrm{DKDC}.$

The reaction

(15) $2\,\mathrm{V} \rightarrow$ 
does not occur to a great extent because the yield of peroxides is low ($G \leqslant 0.3$).

Other $\cdot C_6H_9O$ radicals and $(C_6H_{11}O)\cdot$ radicals probably also contribute to C_{12} formation.

Very small amounts of DMB or of oxygen inhibit the formation of cyclohexanone dimers. This can be attributed to the radical scavenging properties of the two additives (7, 18).

The effect of benzene on the radiolytic formation of cyclohexanone dimers (Fig. 3A) is in sharp contrast to the effect of DMB (Fig. 3B). Benzene is a poor radical scavenger and its inhibiting effect might be due to an activation transfer process, although an inefficient radical scavenging action cannot be ruled out.

Further Comments on the Role of Very Low Concentrations of DMB in the Radiolysis of Cyclohexanone

In the low concentration region ($\epsilon_s < 3 \times 10^{-3}$), DMB inhibits the formation of cyclohexanol and the dimers (Figs. 2 and 3). It was suggested in the preceding discussion that the diene was acting as a radical scavenger in these instances. The attack of a free radical on the diene would give an allylic radical (VI).

$$\mathrm{R} + \mathrm{CH_2{=}C(CH_3){-}{-}C(CH_3){=}CH_2} \rightarrow \mathrm{R{-}CH_2{-}C(CH_3)\cdots C(CH_3)\cdots CH_2}$$

VI

The main fate of radical VI is to combine with another free radical to form a product larger than C_{12}. DMB is not consumed in a chain reaction (Fig. 6), so radical VI does not initiate a chain. Nor does radical VI abstract hydrogen or disproportionate to an appreciable extent to form mono-oxo-C_{12} compounds because such products were not observed in solutions with $\epsilon_s \approx 2 \times 10^{-3}$ where the yields of cyclohexanone dimers and cyclohexanol had been reduced to zero.

At DMB concentrations $>1.5 \times 10^{-3}$, radical VI would be the dominant radical in the system, so the main radical reaction product would be the dimer of VI. The formation of polymer with a 1:1 ratio of DMB units to cyclohexanone units in it is consistent with this conclusion. The measured molecular weight (400 ± 30) and iodine number (138 ± 22) of the polymer are in quite good agreement with the molecular weight (360) and iodine number (141) of the dimer of VI.

The Value of G(Scavengeable Radicals)

According to the preceding discussion, the value of G(scavengeable radicals) should equal the value of G(consumption) of DMB in the maximally inhibited reaction. Thus, G(radicals) = 4 (Fig. 6).

The average value of G(peroxides) from the two oxygen containing samples is about 3 (Table III). Since a peroxide may represent either one or two molecules of ketone, a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

value of G(radicals) $\geqslant 3$ may be estimated from this measurement. The yield of dioxocyclohexanes was estimated to be $G \simeq 1$. Thus the value of G(radicals) from the oxygen containing samples would be $\gtrsim 4$.

Thus it appears that G(scavengeable radicals) $\simeq 4$.

An upper limit of the value of G(scavengeable radicals) in pure cyclohexanone can be calculated from the decrease in yields of the various products by low concentrations of DMB and is about 6 ± 3. The uncertainty in this value is due to uncertainties about the mechanisms of formation of the products, to lack of precision in the measurements of the initial product yields, and to the detection limits of the products in the analyses of the solutions.

The overlap of the measured and calculated values of G(scavengeable radicals) is not impressive but is consistent with the proposed free radical mechanisms.

GAS–LIQUID CHROMATOGRAPHY OF TERPENES

PART XI. THE VOLATILE OIL OF THE LEAVES OF JUNIPERUS SCOPULORUM SARG.[1,2]

E. VON RUDLOFF AND F. M. COUCHMAN[3]

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received March 16, 1964

ABSTRACT

The neutral leaf oil of Rocky Mountain juniper was analyzed by gas–liquid chromatography. *d*-Sabinene was found to be the major constituent (45.7%) and smaller amounts of *d*-limonene (11.4%), *d*-α-pinene (4.2%), γ-terpinene (1.15%), *p*-cymene (1.4%), *l*-linalool (1.2%), *d*-terpinen-4-ol (2.9%), citronellol (0.2%), *l*-β-elemene (0.2–0.3%), three isomeric cadinenes (2.7%), *l*-elemol (6.0%), and safrole (1.85%) were isolated. α-Thujene, camphene, car-3-ene, myrcene, α-terpinene, terpinolene, thujone, isothujone, methyl citronellate, sabinyl acetate, sabinol, geraniol, α- and δ-cadin*ol*, and *trans*-isoeugenol were tentatively identified. An unidentified acetate (II) (4.7%) was isolated from the oxygenated sesquiterpene fraction and another appears to be present in trace amounts.

The composition of the oils from the leaves of four local ornamental plants was found to differ significantly from that of the wild juniper.

Rocky Mountain juniper (*Juniperus scopulorum* Sarg.) is a small bushy tree found mainly in the mountainous areas of Alberta and British Columbia. Except for ornamental purposes this juniper has not any commercial use. The literature is devoid of any reference as to the chemical composition of the foliage or wood. In part IX of this series the analysis of the volatile oil of the leaves of the savin juniper (*J. sabina* L.) was described (1). This communication deals with a similar analysis of the leaf oil of the Rocky Mountain juniper.

In previous work (2) it was noted that prefractionation by fractional distillation may result in considerable isomerization of some terpenes. Prefractionation by low resolution preparative gas–liquid chromatography (g.l.c.) was employed without apparent rearrangement or decomposition (1, 2), but the yield of low boiling monoterpenes was far from satisfactory. In addition, direct preparative g.l.c. of the total oil does not permit collection of many of the minor constituents. Kugler and Kovats (3) report similar findings and have developed group displacement chromatography on modified silica gel to overcome these difficulties. In the present study silicic acid was similarly pretreated with polyethylene glycol to deactivate catalytic sites. On this adsorbent the oil was prefractionated into hydrocarbons and oxygenated components by elution chromatography without apparent rearrangement, dehydration, or polymerization of the more labile components. These fractions were then further subdivided into mono- and sesqui-terpene fractions by preparative g.l.c. on short columns. These four groups were fractionated further into single components by preparative g.l.c. All major and most minor constituents could thus be isolated and characterized, and several of the trace components were tentatively identified by their relative retention times (r.r.t.). The percentage composition (Table I) was determined by measurement of the area under the peaks obtained in linear temperature-programmed runs (Fig. 1). The components identified by r.r.t. only are shown in parentheses. Kugler and Kovats (3) report an analytical error of 3%. However, Janak (4) has shown that the error may be considerably higher on peaks of small area. In our previous studies the errors recorded appeared to be within the range reported by Janak, except that in isothermal runs the

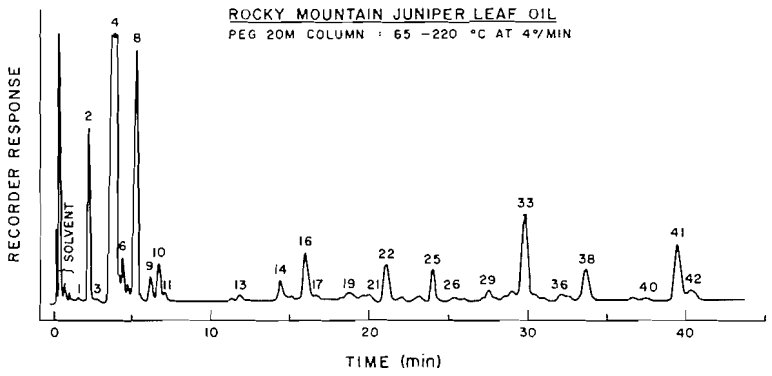

FIG. 1. Gas chromatogram of the volatile oil of Rocky Mountain juniper leaves (6 ft × 3/16 in. o.d. polyethylene glycol 20M column, temperature programmed from 65 to 220 °C at 4° per minute).

values for compounds of high r.r.t. were invariably low. This difficulty was largely overcome by employing temperature programming (1). In the present study an instrument which permitted linear programming was available for the analytical runs and the errors encountered in duplicate runs, or on different columns, were lower than those reported by Janak, but it is unlikely that trace components were recorded with an error of less than 10 to 20%.

Comparison of the composition of the leaf oils from Rocky Mountain and savin junipers shows that both contain *d*-sabinene as a major component and the same monoterpene hydrocarbons, although the limonene content (11.4%) of the former was markedly higher. Common to both oils are also thujone, isothujone, methyl citronellate, terpinen-4-ol, citronellol, geraniol, the cadinene isomers, elemol, and perhaps cadinols. These similarities suggest a close phylogenetic relationship between the two juniper species, but the presence of large amounts of sabinyl acetate and some sabinol in the oil of savin may be a significant difference. Also noteworthy are the relatively high amounts of *l*-elemol, safrole, and the unidentified acetate II (peak 41) in the oil from Rocky Mountain juniper leaves. The latter also contained some *l*-linalool (1.2%) which was not isolated from the oil of savin (the trace component 16 did, however, have the same r.r.t. value).

Since the foliage of the Rocky Mountain juniper was obtained from a prairie location (Indian Head, Saskatchewan), it was possible that the composition of the oil was not typical for this species. Therefore, a small amount of the foliage of Rocky Mountain juniper from the Invermere district, B.C., was steam-distilled and the oil analyzed by linear temperature-programmed g.l.c. No significant qualitative differences were recorded (see Table I, last column) and it is thus probable that the composition of the oil is not markedly influenced by environmental factors. The somewhat lower relative amounts of monoterpenes, especially sabinene and limonene, and correspondingly larger amounts of linalool, terpinen-4-ol and elemene, safrole, component 29 or 30, and elemol are the only noteworthy quantitative differences.

A few garden-variety (ornamental) Rocky Mountain junipers were available locally and small amounts of leaf oils were obtained from four plants. The percentage composition was determined by temperature-programmed g.l.c. and the major components are listed in Table II. Peaks were directly compared with those from the charts of the oils discussed

*3–4 years old (commercial seedlings).

above, and some very marked quantitative differences were noticed. Thus, the oil from all four local plants had a lower content of the major monoterpene hydrocarbons, most noticeable being the low content of sabinene in plant D and the virtual absence of limonene in the other three. The content of oxygenated monoterpenes also differed somewhat; e.g. the content of linalool in the oil from plant E was 14.1% as compared with 1–3% in that of the wild trees. No significant differences were found in the sesquiterpene hydrocarbon range, but safrole was found only in trace amounts in plants C, E, and F. The markedly higher content of the components in the oxygenated sesquiterpene range is also noteworthy.

Most noticeable is the fact that the oil from plant F contained over 20% elemol and all four oils had a surprisingly high content of component 41 (acetate II). It is possible that the latter has chemotaxonomic significance, and attempts to isolate sufficient amounts for complete characterization are now being made. The large amounts of component 31 in the oils from plants C, D, and E, and of component 30 in that from plant D, are also noteworthy. Since all leaves were harvested during winter, seasonal variations cannot account for the differences recorded. One possibility is that the differences are due to age, the local plants all being relatively young (3–4 years old). Alternatively, the garden varieties may differ genetically from the wild plants. It follows that for the determination of the taxonomically representative composition of conifer leaf oils, the leaves of mature, wild species should be used.

EXPERIMENTAL

The g.l.c. techniques used have been described previously (1, 2). In addition, a F&M model 500 (F&M Scientific Corp.) chromatograph was used for analytical runs using linear temperature programming. Optical rotations were measured at 25 ± 2 °C of either undiluted material or chloroform solutions (1 to 5%). Infrared spectra were recorded with a Perkin–Elmer model 21 double beam spectrophotometer as films between sodium chloride plates. Individual components were identified by comparison of their infrared spectra and relative retention times (r.r.t.).

Materials

The foliage of Rocky Mountain juniper was obtained from the Indian Head Forest Nursery, Saskatchewan (Plant A). Woody branches and berries were removed and the residual leaves (3.90 kg) were steam-distilled for 3–4 h. The distillate was taken up in ether, washed with bicarbonate solution and water, dried over anhydrous sodium sulphate, and the ether then evaporated at 70–80 °C. The residual oil (58.9 g, 1.51%) had n_D 1.4790; $[\alpha]_D$ +40.3°. Acidification of the bicarbonate solution gave only trace amounts of ether-soluble acids. The foliage (5–10 g) from mature Rocky Mountain juniper from the Invermere district, B.C. (Plant B), and from local garden variety plants (3–4 years old, plants C–F) was steam-distilled and the volatile oil (50–100 mg) was isolated as above. Reference compounds were those obtained previously (1, 2). The liquid phases used in g.l.c. columns were commercial products.

Analytical Chromatograms

Temperature-programmed (linear) chromatograms were obtained with 2–3 μl aliquots of oil using 6 ft × 3/16 in. o.d. polyethylene glycol (PEG 20M) or Apiezon N (A–N) columns (Fig. 1). The percentage composition was determined by measurement of the area under each peak (triangulation method) and the average values from two runs on the PEG 20M column are shown in Table I. The values for those components which were unresolved on this column (e.g. α-thujene and α-pinene) were obtained from runs on other columns.

The r.r.t. values and purity of isolated components were determined on PEG 20M, A–N, polyethylene glycol adipate polyester (APEG), rapeseed oil (RO), and ethylene glycol bis-(propionitrile) (EGPN) columns under the conditions (isothermal) described previously (1, 2). The r.r.t. values of monoterpenes were measured relative to limonene, oxygenated monoterpenes and sesquiterpenes relative to camphor, and oxygenated sesquiterpenes relative to cedrol (see Table I).

Prefractionation

Silicic acid was impregnated with polyethylene glycol (carbowax 20M) as described by Kugler and Kovats (3). Aliquots (1.0 g) of oil of savin (1), oil tansy (2), Rocky Mountain juniper leaf oil, and a synthetic mixture of α-pinene, limonene, *p*-cymene, linalool, citronellol, nerol, fenchyl alcohol, and carvone were dissolved in a little hexane and transferred to the top of a column containing the deactivated silicic acid (20–25 g). Elution with hexane (300 ml) gave a mixture of hydrocarbons which showed no oxygenated terpenes on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

g.l.c. analysis. The column was then eluted with methanol (300 ml) and the material eluted showed on g.l.c. analysis less than 2% hydrocarbons and all the oxygenated terpenes previously recorded in the mixtures. Equally good results were obtained when only 10 g modified silicic acid were used, but with 5 g the separation was much poorer.

To test whether any dehydration could be detected, similar runs were carried out with linalool (0.45 g) and *l*-elemol (0.08) alone. In each case, no hydrocarbon peak was recorded and the parent alcohol was recovered unchanged. However, the recovery of elemol was only 85% and it is thus possible that some polymerization does take place.

Rocky Mountain juniper leaf oil (10.63 g) was chromatographed as above on deactivated silicic acid (100 g) to give a hydrocarbon fraction (6.42 g) and the oxygenated terpenes (4.22 g). Aliquots (500 μl) of the hydrocarbon mixture were injected onto a 3 ft × 3/8 in. o.d. SE-30 silicone polymer (25% on Chromosorb W, 40–60 mesh) column, which was programmed (non-linear) from 80 to 150 °C in 20 min. The monoterpenes were eluted within 11 min and collected as a single fraction in an ice-cooled collection flask (5 ml). The sesquiterpenes were collected similarly as a second, unresolved fraction. In the same manner aliquots (100 μl) of the oxygenated terpenes were fractionated into mono- and sesqui-terpenes by use of a 3 ft × 3/8 in. o.d. A–N (20% on Gaschrom P, 60–80 mesh) column, programmed from 100 to 220 °C in 30 min.

Monoterpene Hydrocarbons

Preparative g.l.c. of the monoterpene hydrocarbon fraction (repeated injections of 200 μl aliquots) on a 20 ft × 3/8 in. PEG 20M column programmed from 80 to 160 °C in 50 min resulted in the isolation of components 2, 4, 8, 9, and 10. Component 2 was found to be a mixture of α-pinene and tentatively identified α-thujene (r.r.t. = 0.35 and 0.29 on the A–N and EGPN columns). Component 4, the major constituent of the oil, corresponded in all respects to sabinene; n_D 1.4666; $[\alpha]_D$ +108.0° (*c*, 2.0). The g.l.c. analysis did not reveal the presence of any β-pinene, but up to 2 or 3% of this terpene would not be detectable in sabinene (1). The r.r.t. values and spectral properties showed component 8 to be *d*-limonene; n_D 1.4686; $[\alpha]_D$ +104.6° (*c*, 1.8); component 9: γ-terpinene; n_D 1.4732; and component 10: *p*-cymene. Component 1 could not be isolated and components 3, 5, 6, 7, and 11 were obtained only impure and in small amounts. The r.r.t. values showed the latter to correspond to camphene, car-3-ene, myrcene, α-terpinene, and terpinolene respectively. The infrared spectra of the impure fractions were compatible with these assignments.

Oxygenated Monoterpenes

Aliquots (100 μl) of the mixture of oxygenated monoterpenes were chromatographed on a 6 ft × 3/8 in. PEG 20M column (100 to 210 °C in 35 min). Components 14, 16*a*, and 25*a* were isolated almost pure and were found to correspond to *l*-linalool (n_D 1.4610; $[\alpha]_D$ −12.5°), *d*-terpinen-4-ol (n_D 1.4733; $[\alpha]_D$ +19.7°) and safrole (n_D 1.5214) respectively. Analytical g.l.c. on the A–N column showed that safrole (component 25*a*) could be contaminated by a small amount of geraniol. Component 22*b* was obtained impure (n_D 1.4738; $[\alpha]_D$ +30°). It had the typical smell of citronellol and r.r.t. as well as the infrared spectrum were compatible with this assignment. Components 12, 13, 15, 18, and 19*b* could only be identified tentatively by r.r.t. on the analytical PEG 20M, APEG, A–N, and RO columns (see Table I).

Sesquiterpene Hydrocarbons

Preparative g.l.c. on the 20 ft × 3/8 in. o.d. PEG 20M column (30 μl aliquots, 150 to 205 °C in 50 min) gave components 16*b*, 19*a*, 20, and 22*a* in a fairly pure state. Component 16*b* corresponded to β-elemene, n_D 1.4992, $[\alpha]_D$ −6.0°. Since column chromatography of β-elemol had not given any hydrocarbons (see above), β-elemene is considered to be a genuine component of the oil. Component 19*a* was an unidentified hydrocarbon, n_D 1.5035, $[\alpha]_D$ −8.0°, having r.r.t. values similar to β-caryophyllene, but its infrared spectrum differed somewhat from that of authentic β-caryophyllene (unresolved absorption band at 1377 cm^{-1}; additional bands of medium intensity at 1125, 1050, and 910 cm^{-1}). Component 20 corresponded to the cadinene isomer of low r.r.t. value isolated previously from the oil of savin (1), and found in spruce leaf oils (5, 6); n_D 1.5048; $[\alpha]_D$ −58.4°. Component 22*a* corresponded to cadinene, n_D 1.5057, $[\alpha]_D$ +113.0°, and analytical g.l.c. showed it to be a mixture of γ- and δ-cadinene.

Oxygenated Sesquiterpenes

Aliquots (20 μl) of the last fraction were chromatographed on the 6 ft PEG 20M column (160 to 220 °C in 30 min) and components 33, 36, 38, and 41 could be isolated in a fairly pure state. Component 33 corresponded to *l*-elemol; n_D 1.4993; $[\alpha]_D$ −6.9°. Component 36, n_D 1.5096, $[\alpha]_D$ −13.6°, had the r.r.t. of α-cadinol and γ-eudesmol, but since these two alcohols cannot be distinguished (from one another) by their infrared spectra (7), the identification is uncertain. Component 41 had n_D 1.5000 and $[\alpha]_D$ +147.2° and its infrared spectrum suggested it to be an alcohol containing an acetate group (strong bands at 1730–1720 and 1245 cm^{-1}). When a methanolic solution of this component and sodium methoxide was left overnight the compound appeared to be unchanged. A mixed fraction corresponding to components 33 and 34 was also isolated. As expected, the infrared spectrum showed elemol to be present, but in addition bands at 1735 and 1260–1245 cm^{-1} were recorded. This suggests that component 34 may be another acetate. Component 38 had the retention characteristics and infrared spectrum of δ-cadinol, but seeding with an authentic specimen (m.p. 139–140 °C) failed to induce crystallization.

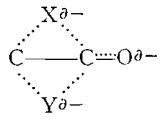
MECHANISM OF THE BIMOLECULAR NUCLEOPHILIC DISPLACEMENT REACTION ON α-HALOCARBONYL COMPOUNDS

A. Joseph Sisti and Seymour Lowell[1]
Chemistry Department, Adelphi University, Garden City, New York
Received January 9, 1964

ABSTRACT

Two mechanisms have previously been postulated for the high reactivity of α-halocarbonyl compounds in the nucleophilic displacement reaction. Kinetic data for α-halocarbonyl compounds and various nucleophiles (cyanate, acetate, azide, and thiocyanate) in anhydrous methanol are presented. The new data, in conjunction with previously reported results, are in better agreement with the concept of neighboring group overlap than with that of Pearson's electrostatic facilitation between the nucleophile and the α-carbonyl group.

The enhanced reactivity exhibited by α-haloketones in the bimolecular nucleophilic displacement reaction is well known. To a lesser extent, related compounds, α-halonitriles, amides, and esters, manifest similar reactivity. Various interpretations have been offered for the unusual reactivity of these compounds. On the basis of previous evidence (1, 2) many of these interpretations are no longer seriously considered. Two mechanisms are, however, consistent with the data available. Pearson and co-workers (1) postulate that the enhancement results from the proximity of the positively charged carbonyl-carbon atom which electrostatically facilitates the approach of the nucleophile along its normal path to the adjacent carbon atom. They also mention that the enhancement should be larger for the more polarizable nucleophile, since it can be more easily facilitated electrostatically to the reaction site. The mechanism suggested by Dewar (3) and Winstein (see footnote 16 in ref. 4) is based upon neighboring group orbital overlap with the adjoining electron-deficient carbon atom. Thus, the transition state with α-haloketones



I

is envisaged as including partial bonding of the reagent with the *p*-orbital of the carbonyl-carbon (I). Bartlett and Trachtenberg (2) pointed out that for the latter mechanism to obtain certain stereochemical requirements must be fulfilled. Thus, kinetic measurements (iodide in acetone) were conducted on two model phenacyl systems (II and III). Compound II, which is structurally incapable of attaining the prescribed geometry in the transition

III

[1]*Taken largely from the Ph.D. thesis of S. Lowell, Adelphi University, June 1963.*

state, reacted 9000 times slower than compound III at 0°. These results tend to substantiate the mechanism of Dewar and Winstein. However, the lack of typical phenacyl reactivity in compound II is also consistent with the electrostatic mechanism of Pearson (1), since the electrostatically most favored path, by way of the positive end of the carbonyl dipole, is structurally prohibited (2). The previously reported relative rate ratios, presented in Table I, also do not allow a clear differentiation between the two mechanisms. However,

it has been pointed out by Bartlett (2) that pyridine which possesses no charge to be acted upon electrostatically, but which does possess an electron pair for neighboring group orbital overlap, is subject to the activating influence of the carbonyl-carbon.

A recently postulated (5) implication of the neighboring group orbital overlap mechanism is the importance of the relative sizes of the electronic orbitals. The rate-enhancing effect seems to be more pronounced when the entering and leaving groups are not first row elements (1) and hence the larger orbitals should be capable of more effective neighboring group overlap.

According to Pearson, α-halocarbonyl and related compounds exhibit rate-enhancement, relative to *n*-propyl halide, because of charge (electrostatics) on the nucleophile. The Winstein–Dewar mechanism manifests enhancement because of neighboring group overlap, and that the magnitude of the enhancement should vary with the orbital size of the entering and leaving reagents. A kinetic study is presented in which three charged nucleophiles with relatively small bonding orbitals and one charged nucleophile with a relatively large bonding orbital were reacted with a series of α-halocarbonyl compounds in an attempt to differentiate between the two mechanisms.

EXPERIMENTAL*

Reagents

All organic chlorides used were commercial products. They were redistilled or recrystallized repeatedly (3–5 times) before use. The chlorides employed were: *n*-propyl chloride (washed with concentrated sulphuric acid before distillation), phenacyl chloride, benzyl chloride, ethyl chloroacetate, and α-chloroacetone. Methanol and ethanol were distilled from magnesium methoxide and ethoxide, respectively. Silver nitrate solutions were prepared from Baker and Adamson analytical reagent grade after drying. Sodium azide (Eastman) was purified by repeated crystallizations from water, then washed with acetone, and dried to constant weight. Sodium ethoxide solution, prepared by treating anhydrous ethanol with sodium, was standardized by titration in water with potassium acid phthalate to the phenolphthalein end point. Solutions of sodium acetate (Baker, reagent grade), potassium cyanate (Baker, reagent grade), potassium thiocyanate (Baker, reagent grade), potassium iodate (Matheson), and sodium thiosulphate (Eastman) were prepared after drying to constant weight.

**All melting points and boiling points were uncorrected. All organic compounds were used within 24 h after purification.*

General Procedure

In all kinetic studies the solutions were prepared so that the initial concentrations of reactants were in a volume of 25 ml at room temperature. The required volumes of freshly prepared reactants were added from calibrated burettes directly into 100 ml volumetric flasks. The reaction was quenched by the addition of the contents of each flask to a separatory funnel containing an organic solvent (50 ml) and water (100 ml). The layers were separated and analysis was made for the water soluble product or water soluble reactant. Each rate constant given involved a minimum of six flasks and a maximum of ten, each removed at varying time intervals.

Sodium Acetate

The rate constants for sodium acetate and the four organic chlorides in anhydrous methanol were determined as above. Ether was used for quenching the reaction. The method of Fajans (6) was employed for the determination of chloride produced.* At each temperature (45.1° and 55°) equal initial concentrations of each reactant were used: acetate and *n*-propyl chloride 0.400 *M*, acetate and phenacyl chloride 0.222 *M* and 0.142 *M*, acetate and ethyl chloroacetate 0.250 *M*, and acetate and α-chloroacetone 0.250 *M*. An additional kinetic study at 45.1° was conducted in which each flask contained unequal and different concentrations of reactants: organic chlorides 0.100 *M*–0.500 *M*, acetate 0.100 *M*–0.400 *M*. Good results were obtained (from usual second order rate equations), indicating overall second order kinetics and first order in each reactant.

Sodium Azide

All kinetic data were obtained at 30° and 40° in methanol except for phenacyl chloride which was studied at 45.1° and 55.0°. The analytical method described by Swain (7) was used. Kinetic studies were made at the two above temperatures in which unequal and different concentrations of each reactant were employed: organic chlorides 0.020 *M*–0.140 *M*; azide 0.030 *M*–0.160 *M*. The results revealed good overall second order kinetics, first order in each reactant.

Potassium Thiocyanate

All kinetic data were obtained at 30° in anhydrous methanol. The method of Crowell (8) was employed for kinetic measurements. Unequal and different concentrations of each reactant in each flask were used: organic chlorides 0.040 *M*–0.140 *M*; thiocyanate 0.060 *M*–0.160 *M*. Satisfactory results were obtained indicating overall second order kinetics and first order in each component.

Potassium Cyanate

The reaction was quenched with 50 ml of ether and 100 ml of water. The layers were separated and the water solution was acidified to pH 2–3 and boiled 15 min to hydrolyze the cyanate to carbon dioxide and ammonia. The solution was then made basic and boiled for 15 min to expel ammonia. The pH was adjusted to 6.5–7.0 and then the method of Fajans (6) was employed to determine chloride ion concentration. Measured amounts of cyanate in water, and measured amounts of cyanate in presence of measured amounts of chloride in water solution were subjected to the above procedure. The first revealed no cyanate present and the second gave values of chloride ion to within 3% error. All kinetic determinations were conducted at 30° in absolute methanol. Kinetic runs employed *n*-propyl chloride 0.200 *M*–0.800 *M*; cyanate 0.400 *M*–0.096 *M*; all others, cyanate 0.050 *M*–0.100 *M*; and α-chloroacetone, phenacyl chloride, and ethyl chloroacetate 0.050 *M*–0.100 *M*. Overall second order kinetics, first order in each component, were obtained.

Kinetic results were taken over one to four half-lives and are presented in Table II.

Product Analysis

Adequate product studies have been previously conducted and indicate the reaction with α-haloketones and the nucleophiles employed to be nucleophilic substitution reactions. Phenacyl chloride: with potassium acetate yields phenacyl acetate, m.40° (9); with potassium thiocyanate yields phenacyl thiocyanate, m.74° (10); with sodium azide yields phenacyl azide, m.17° (11). Adequate studies were also performed with α-chloroacetone which with sodium azide yields α-azidoacetone (12) and with potassium thiocyanate yields α-thiocyanoacetone (13). All the above reactions were conducted in ethanolic or methanolic solutions. No product studies were undertaken with potassium cyanate.

RESULTS AND DISCUSSIONS

Table II presents the specific reaction rate constants for all reactions. The kinetic order for each reaction studied was overall second order and additional studies indicated each reaction was first order in each component (see experimental). Table II shows the

**The value of the rate constant for benzyl chloride and sodium ethoxide in absolute ethanol at 25° (each reactant 0.300 M) was 3.71 × 10^{-5} l $mole^{-1}$ s^{-1}. The value was obtained by the method of Fajans for chloride determination. The value agrees with that reported, E. D. Hughes, C. W. Bevan, and C. K. Ingold, Nature, 171, 301 (1953), to within 1%.*

Phenacyl chloride	228	276	179	770

relative rates for all the organic substrates employed with each of the four nucleophiles.

The results in Tables I and III may be interpreted as evidence against the Pearson mechanism. The amount of rate-enhancement (relative to n-propyl halide) with the nucleophiles, cyanate, azide, acetate, and pyridine, charged and uncharged, is less than the enhancement of the larger charged and uncharged nucleophiles. It is of interest to note, in particular, the relative rate ratios of azide and cyanate ions. Azide and cyanate, in addition to their charge, possess relatively high polarizabilities (14) and yet their response to the electrostatic activating influence of the α-carbonyl group is comparatively small and essentially the same as the less polarizable nucleophiles, acetate ion and uncharged pyridine. It appears that all the results presented (Table I, III, and the work of Bartlett) are more consistent with the Winstein–Dewar interpretation than the Pearson concept; namely, the enhancement with all nucleophiles is due to additional bonding (covalent) in the transition state with the electron deficient carbonyl-carbon (I). It should be pointed out that one cannot say that the total energy of the additional bonding in the transition state is void of any contribution due to electrostatic interaction. The differences in the relative rate ratios are also tentatively related to the variance in the orbital size of the nucleophiles, i.e., the larger bonding orbital results in more effective neighboring group overlap and a larger relative rate ratio.

In conclusion, the lack of reactivity of certain compounds related to the α-halocarbonyl compounds, namely α-halonitro and α-halosulphonyl compounds, is worthy of comment. Nitrochloromethane and chloromethyl phenyl sulphone have been found unreactive with iodide in acetone (1, 15). Pearson (1) states that the access to the backside of the α-carbon atom, in the region of the positive end of the dipole, in sulphones and nitro compounds is blocked by the negatively charged oxygen atoms. Evidence for the steric rather than the electrical retarding effect of the nitro and sulphonyl groups was supplied by Bordwell (15)

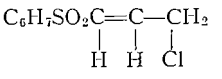
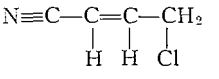
who found that 1-*p*-toluenesulphonyl-3-chloro-1-propene, IV, and 1-cyano-3-chloro-1-propene, V, reacted, with iodide in acetone at 0°, 1100 and 1400 times faster than *n*-butyl

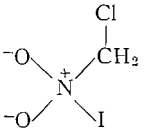


IV



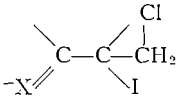
V

chloride. However, the lack of reactivity of nitrochloromethane is also consistent with the Dewar–Winstein concept. Inclusion of the contributing structure, VI, in the transition state may be destabilizing since two negative charges are brought closer together. Similar



VI

considerations may be offered for the α-halosulphones. Compounds of type IV and V may also have their reactivity accounted for by the Dewar–Winstein concept by inclusion of the stabilizing contributing structure, VII, in the transition state. Since the group,



VII

C═C—X, (X = —NO_2, RSO_2—, —CN), possesses similar electrical properties as the carbonyl group, the postulate appears reasonable.

THE SYNTHESIS OF SOME DERIVATIVES OF 3,4-METHYLENEDIOXYBENZENE

PRITAM SINGH AND LOUIS BERLINGUET
Department of Biochemistry, Faculty of Medicine, Laval University, Quebec, Quebec
Received July 17, 1963

ABSTRACT

A few derivatives of 3,4-methylenedioxy-α-nitromethylbenzyl alcohol (I) have been prepared. Chlorination with hydrochloric acid and potassium chlorate gave 6-chloro-3,4-methylenedioxy-α-nitromethylbenzyl alcohol (II) which on refluxing with acetic anhydride and sodium acetate gave 6-chloro-3,4-methylenedioxy-ω-nitrostyrene (III). Attempted reduction of (I) with ammonium formate resulted in dehydration to give 3,4-methylenedioxy-ω-nitrostyrene (IV). Reduction of (I) with hydrazine hydrate gave an isobenzaldoxime (VI).

β-(3,4-Methylenedioxyphenyl) serine (VII) was prepared by the condensation of piperonal with glycine. α,β-Dibromo-β-(3,4-methylenedioxyphenyl) propionic acid could not be aminated by a dilute aqueous solution of ethylamine. Decarboxylation and elimination of HBr took place to give ω-bromo-3,4-methylenedioxystyrene (VIII).

INTRODUCTION

The methylenedioxy group is present in many alkaloids with important physiological properties like piperine, narcotine, hydrastine, berberine, etc. Piperonal and its derivatives have been extensively studied biologically. Thus piperonal acts as a vasodilator (1) and thiosemicarbazones of piperonal have been found to inhibit the growth of BCG tuberculus bacteria in vitro (2). It was thought interesting to synthesize some derivatives of 3,4-methylenedioxybenzene with a lateral chain containing amino alcohol groupings for biological evaluation.

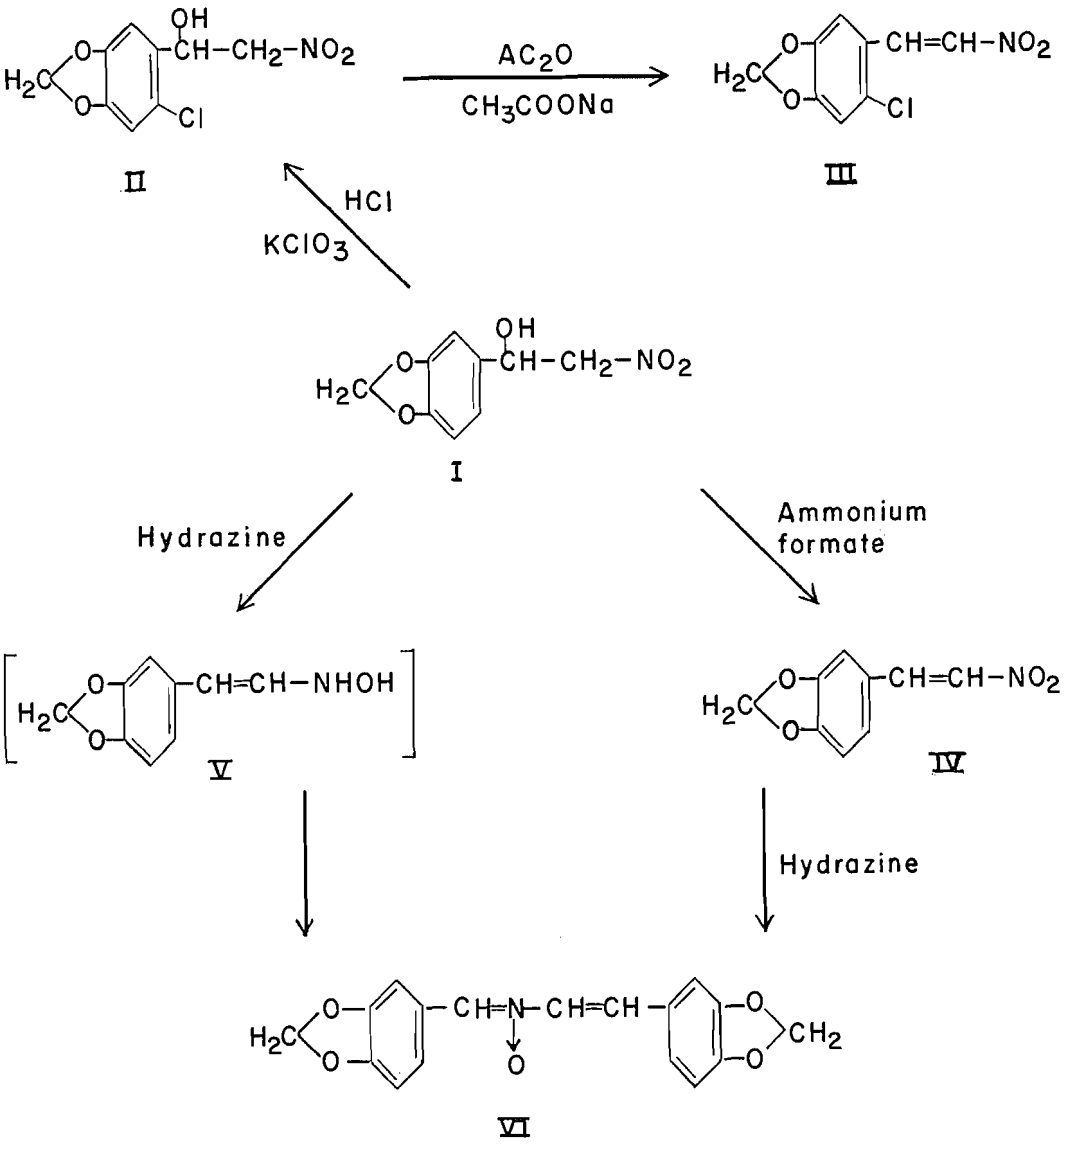
RESULTS

It is a well-known fact that halogen substitution, especially chlorination, often enhances the biological activity in a given series of compounds. 3,4-Methylenedioxy-α-nitromethylbenzyl alcohol (I), prepared from piperonal and nitromethane according to the method of Heacock *et al.* (3), was chlorinated with concentrated hydrochloric acid and potassium chlorate. Monochlorination in the 6-position took place and the structure of 6-chloro-3,4-methylenedioxy-α-nitromethylbenzyl alcohol (II) was confirmed by alkaline oxidation of II with potassium permanganate to give 6-chloropiperonylic acid. On refluxing with acetic anhydride and freshly fused sodium acetate, (II) underwent dehydration and 6-chloro-3,4-methylenedioxy-ω-nitrostyrene (III) was obtained.

Heacock, Hutzinger, and Nerenberg recently prepared 3,4-methylenedioxy-α-aminoethylbenzyl alcohol in satisfactory yield by the catalytic hydrogenation of (I) (4). Several different methods of reduction were tried to reduce the nitro group while avoiding the α–β dehydration. When ammonium formate was used as a reducing agent to reduce (I), such a dehydration happened to give 3,4-methylenedioxy-ω-nitrostyrene (IV).

Since this dehydration has been shown to be easily brought about by mineral acids, it was thought formic acid was responsible for it. However, a mixture of 85% formic acid and ethanol (1:4 v/v) did not react with (I). We then tried alkaline reduction with hydrazine hydrate which has been used with some success in the reduction of a nitro group into an amino group (5). But (I), on treatment with hydrazine hydrate, gave with excellent yield a compound to which we have assigned the structure of an isobenzaldoxime (VI).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



In the above reaction, the formation of the intermediate ω-hydroxylamino-3,4-methylenedioxystyrene (V) by dehydration and reduction was suggested, because the same isobenzaldoxime (VI) could also be prepared by reduction of 3,4-methylenedioxy-ω-nitrostyrene (IV) with hydrazine hydrate. Heacock *et al.* (4) prepared N-(β-hydroxy-β-(3,4-methylenedioxyphenyl)-ethyl)-3′,4′-methylenedioxyisobenzaldoxime from (I) by catalytic hydrogenation with only two moles of hydrogen. The unstable nature of the intermediate hydroxylamino derivative in alkaline medium and the formation of the corresponding isobenzaldoxime has also been shown by Allais (6). It would thus appear that the ultimate product of this alkaline reduction in our case is N-β-(3,4-methylenedioxyphenylvinyl)-3′,4′-methylenedioxyisobenzaldoxime (VI).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In view of preparing another compound containing the 3,4-methylenedioxphenyl grouping, piperonal was condensed with glycine in presence of alcoholic sodium hydroxide solution (7). A mixture of compounds was obtained from which β-(3,4-methylenedioxyphenyl) serine (VII) could be isolated in 15–20% yield. Drying at 100° for 24 hours at 2 mm pressure was necessary to obtain a pure, dry sample having a melting point of 171–175 ° dec. Kanao and Schinozuka (8) have given a melting point of 200–201° for (VII), while Mahajani and Ray (9) gave a melting point of 125–127°, also for (VII). Probably they were dealing with different isomers. Our compound when chromatographed on paper gave only one spot. It also gave a positive test for α-amino-β-hydroxy amino acids (10).

Efforts to substitute an amino group for a bromine atom in α,β-dibromo-β-(3,4-methylenedioxyphenyl) propionic acid by means of 1% ethylamine gave ω-bromo-3,4-methylenedioxystyrene (VIII). This compound could also be prepared by replacing 1% ethylamine with 0.5 *M* sodium hydroxide in the above reaction. Trumbull and his coworkers (11) have discussed the mechanism of a similar decarboxylative elimination to give ω-bromostyrene. By replacement of 1% ethylamine or sodium hydroxide with dicyclohexylamine or potassium phthalamide, the same type of elimination seemed to take place, since only dicyclohexylamine hydrobromide and phthalimide could be isolated from the reaction mixtures.

EXPERIMENTAL

Infrared spectra were recorded with a Beckman IR-4 spectrophotometer using KBr pellets containing 0.5% by weight of sample. The reported spectra are all calibrated. Ultraviolet spectra were recorded with a Beckman DB spectrophotometer. Analyses were made by Micro-Tech Laboratories, Skokie, Illinois. Melting points are not corrected.

3,4-Methylenedioxy-α-nitromethylbenzyl Alcohol (I)

This was prepared by the method of Heacock *et al.* (3): λ_{max}^{EtOH}, 285 mμ; E_{max}, 8440. Inflection at 235 mμ. V_{max} in cm^{-1}: 3250–3125 (m) (O—H stretching frequency, intermolecular hydrogen bonds); 1565 (s) (C—NO_2 asymm.); 1555 (s), 1510 (s), 1450 (s), 1385 (s), (C—NO_2 asymm.); 1340 (m), 1245 (m).

6-Chloro-3,4-Methylenedioxy-α-nitromethylbenzyl Alcohol (II)

Concentrated HCl (2.5 ml) was added to a solution of 3,4-methylenedioxy-α-nitromethylbenzyl alcohol (1 g in 10 ml ethanol) at room temperature (25°). To prevent a rise in temperature and a possible dehydration, the mixture was cooled. A solution of sodium chlorate (1 g) in water (2.5 ml) was then added and the mixture left undisturbed overnight. Next morning 0.75 g of (II) were obtained (yield varies from 50–70%). Two crystallizations from CCl_4 gave the analytical sample: m.p. 120°; λ_{max}^{EtOH}: 265, 244 mμ; E_{max}: 8575 and 8600 respectively. V_{max} in cm^{-1}: 3250–3125 (m) (O—H); 1565 (s) (C—NO_2 asymm.); 1555 (s), 1490 (m), 1420 (m), 1385 (m) (C—NO_2 asymm.); 1285 (m), 1250 (s), 715 (w) (C—Cl). Anal. Calc. for $C_9H_8ClNO_5$ (245.5): C, 44.08; H, 3.26; N, 5.71. Found: C, 43.81; H, 3.03; N, 5.65.

Alkaline Oxidation of 6-Chloro-3,4-Methylenedioxy-α-nitromethylbenzyl Alcohol (II) to Give 6-Chloropiperonylic Acid

A suspension of 6-chloro-3,4-methylenedioxy-α-nitromethylbenzyl alcohol (0.5 g) in water (10 ml) and aqueous sodium hydroxide (2 *N*, 1.5 ml) was oxidized with 50 ml of a 3% aqueous solution of potassium permanganate at reflux temperature for 5 h. After filtration, the reaction mixture was acidified with dilute sulphuric acid and the white solid that precipitated was crystallized from aqueous ethanol. Colorless needles of 6-chloropiperonylic acid, m.p. 198°, were obtained (m.p. lit. 200°) (12). Anal. Calc. for $C_8H_5ClO_4$ (200.5): C, 47.88; H, 2.49; Cl, 17.45. Found: C, 47.63; H, 2.30; Cl, 17.70. This compound showed no depression in melting point when mixed with an authentic sample of 6-chloropiperonylic acid prepared by the method of Orr *et al.* (12). Infrared spectra of the two samples were also identical.

6-Chloro-3,4-Methylenedioxy-ω-nitrostyrene (III)

A mixture of 6-chloro-3,4-methylenedioxy-α-nitromethylbenzyl alcohol (II) (1 g; 0.004 mole) and freshly fused sodium acetate (1 g), was refluxed with 10 ml of acetic anhydride for ½ h. The reaction mixture was cooled and poured over ice. The yellow solid obtained was filtered and washed free of acidity with water. Recrystallization of the crude product from alcohol gave 6-chloro-3,4-methylenedioxy-ω-nitrostyrene (0.8 g; 72%) in yellow needles (m.p. 156°). λ_{max}^{EtOH}: 368, 316, 264 mμ; E_{max}: 18 368, 11 500, 16 359 respectively. Inflection at 252 mμ. V_{max} in cm^{-1}: 1620 (m), 1510 (m), 1490 (sh), 1425 (w), 1375 (w), 1330 (m),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

1290 (m), 700 (w) (C—Cl). Anal. Calc. for $C_9H_6ClNO_4$ (227.5): C, 47.47; H, 2.64; N, 6.15. Found: C, 47.22; H, 2.53; N, 5.88.

The same compound (III) can also be prepared by treating 1 g of (II) with a mixture of acetic anhydride (10 ml), and pyridine (three drops) overnight at room temperature with a yield of 81%.

3,4-Methylenedioxy-ω-nitrostyrene (IV)

Compound (I) (1 g; 0.005 mole) and ammonium formate (1 g; 0.016 mole) were dissolved in 20 ml of ethanol (95%) and the mixture refluxed for 30 min. The solution was then evaporated to dryness *in vacuo*, washed with water, and dried. Recrystallization of the residue from benzene gave 3,4-methylene-ω-nitrostyrene (0.5 g; 55%) in yellow needles (m.p. 162°), m.p. lit. 159° (13). λ_{max}^{EtOH}: 364, 260 mμ; E_{max}: 16 600, 13 124 respectively. Inflection at 310 and 245 mμ. V_{max} in cm^{-1}: 1640 (m), 1500 (s), 1460 (s), 1370 (m), 1340 (m), 1270 (s), 1250 (s). Anal. Calc. for $C_9H_7NO_4$ (193): C, 55.96; H, 3.62; N, 7.25. Found: C, 56.63; H, 3.65; N, 7.18.

The treatment of 3,4-methylenedioxy-α-nitromethylbenzyl alcohol (I) (1 g; 0.005 mole) with 2.5 ml of formic acid (85%), 10 ml ethanol, at reflux temperature for 1½ h gave no 3,4-methylenedioxy-ω-nitrostyrene (IV). The yield of unreacted material (I) was 0.8 g (80%). But the 3,4-methylenedioxy-ω-nitrostyrene (IV) could be prepared by adding 1 g (0.005 mole) of (I) to a mixture of 4 ml of acetic anhydride and a few drops of pyridine and stirring them at room temperature overnight. The yield of (IV) was 60%. The two samples of 3,4-methylenedioxy-ω-nitrostyrene (IV) obtained by treatment of (I) either with ammonium formate or with acetic anhydride plus pyridine gave identical melting points, ultraviolet spectra, and showed no depression in mixed melting point determination.

N-β(3,4-Methylenedioxyphenylvinyl)-3′,4′-methylenedioxyisobenzaldoxime (VI)

To 5 g (0.025 mole) of 3,4-methylenedioxy-α-nitromethylbenzyl alcohol (I) were added 50 ml of ethanol and 7 ml of 85% hydrazine hydrate. The mixture was refluxed for 45 min and then evaporated to dryness in vacuum. Three crystallizations of the residue from benzene gave the analytical sample. Yield 2.8 g (89%), m.p. 205°. λ_{max}^{EtOH}: 344, 235; E_{max}: 29 545 and 22 703 respectively. Inflection at 292 mμ. V_{max} in cm^{-1}: 1635 (m) conjugated (C=N); 1610 (m) (C=C stretching vibration); 1510 (s), 1495 (sh), 1460 (s), 1360 (w), 1310 (w), 1265 (s), 1195 (w). Anal. Calc. for $C_{17}H_{13}NO_5$: C, 65.59; H, 4.18; N, 4.50; mol. wt. 311. Found: C, 65.11; H, 4.11; N, 4.39; mol. wt. (Rast) 303.

This compound (VI) could also be prepared from 3,4-methylenedioxy-ω-nitrostyrene (IV) in an identical manner. The two samples of (VI) obtained from these two different starting materials, (I) and (IV), gave superimposable infrared and ultraviolet spectra and showed no depression in melting point on mixed melting point determination.

β-(3,4-Methylenedioxyphenyl) Serine (VII)

Piperonal (16.2 g; 0.108 mole) and glycine (4 g; 0.053 mole) were mixed in 20 ml of ethanol. To this mixture was added a solution of 3.2 g (0.08 mole) of sodium hydroxide in 40 ml of water. The mixture was stirred at room temperature (29°) for 48 h, and then neutralized with dilute HCl. After filtration, the white solid that separated was recrystallized from dioxane. A crystalline compound (m.p. 181°) was obtained and was not further identified. (Found: C, 67.83; H, 4.69; N, 3.48%.) When the mother liquor from the above filtration was concentrated by vacuum evaporation and cooled, 2.4 g of a solid separated. This on repeated recrystallizations from hot water gave the pure β-(3,4-methylenedioxyphenyl) serine (VII) (m.p. 171–175° dec., yield varies from 15–20%). Drying *in vacuo* at 2 mm during 24 h at 100° was found to be necessary to completely dry the compound. No attempt was made to isolate the isomers. Sörensen titration of 0.1 g of (VII) gave a neutralization equivalent of 238 (theory, 225). On paper chromatography using Whatman paper No. 1 and the solvent systems pyridine–water (80:20) or phenol–water (81:19), only one spot in each case after spraying with ninhydrin was obtained. R_f values were respectively 0.51 and 0.76. The same spots also gave a positive test for α-amino-β-hydroxy compound when treated with periodic acid and Nessler's reagent (10). $\lambda_{max}^{H_2O}$: 285, 235 mμ. E_{max}: 4100, 4500 respectively. V_{max} in cm^{-1}: 3525 (m), 3200 (s), 3075 (s), 2900 (s), 2025 (w), 1660 (s) (NH_3^+ deformation frequency); 1610 (s) (ionic carboxyl); 1510 (s) (NH_3^+ deformation frequency); 1445 (s), 1400 (s), 1350 (s), 1320 (m). Anal. Calc. for $C_{10}H_{11}NO_5$ (225): C, 53.33; H, 4.90; N, 6.22. Found: C, 53.11; H, 5.21; N, 5.98.

ω-Bromo-3,4-Methylenedioxystyrene (VIII)

α,β-Dibromo-β-(3,4-methylenedioxyphenyl) propionic acid (5 g; 0.014 mole) prepared according to the method of Feuerstein (14) was added slowly in small portions into 280 ml of 1% aqueous solution of ethylamine, cooled to 0 °C. The reaction mixture was stirred at 0 °C for 2 h and then filtered to obtain 1.8 g (56% yield) of ω-bromo-3,4-methylenedioxystyrene, melting at 57–58° (m.p. lit. 59°) (14). This compound could be purified further by crystallization from *n*-hexane. λ_{max}^{EtOH}: 308, 276 mμ; E_{max}: 14 755, 18 160 respectively. V_{max} in cm^{-1}: 1610 (s), 1600 (s), 1510 (s), 1490 (s), 1480 (s), 1440 (s). Anal. Calc. for $C_9H_7BrO_2$ (227): Br, 35.24. Found: 35.11.

The compound (VIII) could also be prepared by substituting 250 ml of 0.5 *M* sodium hydroxide solution for aqueous 1% ethylamine in the above reaction. The reaction was carried out at 55° for 1 h. On acidification with dilute HCl, an oil was obtained which, when crystallized from *n*-hexane, gave crystals melting at 58°.

The yield of ω-bromo-3,4-methylenedioxystyrene was 40%. A mixed melting point with the compound prepared by reaction with 1% aqueous ethylamine showed no depression, and infrared spectra of the two samples were superimposable.

EFFECTS OF CHLORINE AND BROMINE ON THE RADIOLYSIS OF GASEOUS HCl

R. A. LEE,* R. S. DAVIDOW, AND D. A. ARMSTRONG
Department of Chemistry, University of Alberta, Calgary, Alberta
Received March 31, 1964

ABSTRACT

Using an ionization chamber method, it has been shown that the energy required to create an ion pair in gaseous HCl, W_{HCl}, is 24.4 ± 0.6 eV. The hydrogen yield, $G(H_2)_{HCl\ gas\ at\ 23\ °C} = 8.0 \pm 0.3$, was independent of HCl pressure in the range 19 to 119 cm of Hg. The effects of added bromine demonstrate that at least two species are involved in hydrogen formation, and there are strong indications that one of these is an electron. A second species, designated as H^{II} and formed with a yield $G_{H^{II}} = 2.5$, is not readily scavenged by bromine. The use of chlorine as a scavenger also provides evidence for the presence of more than one hydrogen-forming species. The data of an earlier study of the α-particle radiolysis have been corrected for back reactions of the chlorine which accumulated in the system. The corrected results are in reasonable agreement with those of this study.

INTRODUCTION

The α-particle radiolysis of gaseous HCl was studied in 1932 by Vandame (1). He observed a decrease in the decomposition yield at higher doses and attributed it to back reactions involving hydrogen and chlorine. In view of his observations it was clear that any further study of this system would have to take into account the possible effects of these products on the kinetics of the decomposition. In this study we have investigated the hydrogen yield produced in the ^{60}Co γ-radiolysis of gaseous HCl in the presence of chlorine at concentrations in the range 0–6 mole percent. For reasons which will become apparent later, the effects of bromine over the same concentration range have also been examined. As pointed out in an earlier publication (2), the data also provide evidence for more than one hydrogen-forming species in irradiated gaseous HCl.

EXPERIMENTAL

Apparatus and Chemicals

The vacuum lines employed for the preparation of hydrogen halide samples and the measurement of the hydrogen yields were as previously described (3). The irradiation cells were filled to the desired pressure with hydrogen halide, which had been purified by preirradiation and distillation. Matheson research grade Argon was used without further purification.

The pyrex irradiation cells were usually about 300 ml in volume. Those in which ionization currents were to be measured were of the design shown in Fig. 1. The 2.5-mm thick cylindrical wall, C, was coated internally with colloidal graphite to form the collecting electrode. The central high voltage electrode, A, which consisted of a 7-mm O.D. pyrex tube, and the guard ring, B, were coated in a similar manner. After the coatings had been applied through the tube, D, its end was sealed to form a thimble trap for condensing the hydrogen halide in a liquid nitrogen bath. Tungsten wires passing through the glass walls provided contact between the graphite coatings and the shielded electrical leads A^1, B^1, and C^1. Gases were admitted to the irradiation cell via a stopcock attached to a 30-cm extension of tube E. This stopcock was shielded during irradiations. For some experiments, in which the effects of certain variables were being examined, uncoated cylindrical or spherical cells were employed. All cells were baked out at about 300 °C under vacuum prior to use.

In all but a few experiments, which will be mentioned specifically later, the irradiation source was a 200 curie ^{60}Co unit purchased from Atomic Energy of Canada Ltd. The source was lowered into a concrete cave to a point about 15 cm from the center of the irradiation cells. These were held vertically in an aluminum canister.

Two high voltage supplies of standard design were used in measuring the ionization currents. One covered

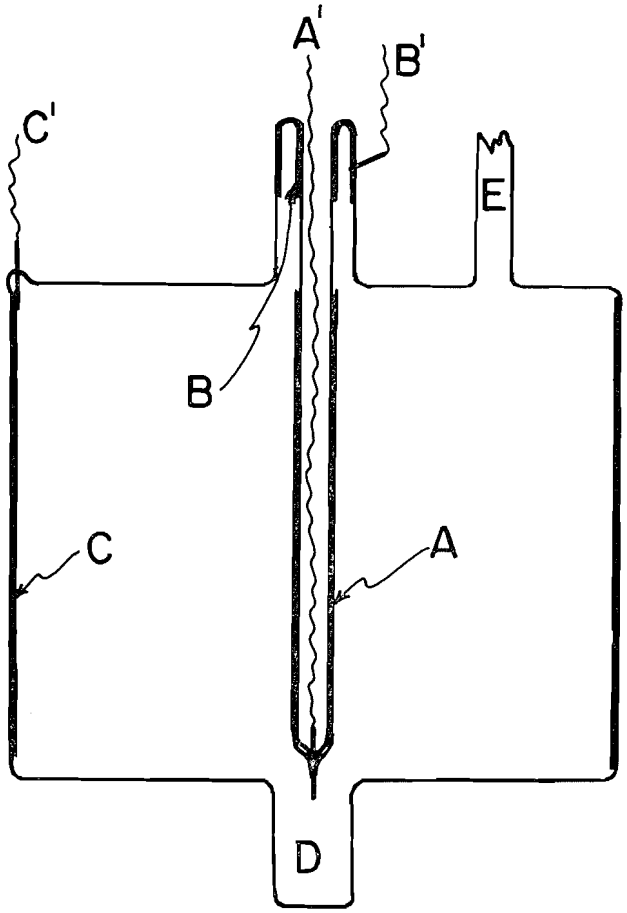

FIG. 1. Irradiation cell for determination W_{HCl} and $G(H_2)_{HCl\ (gas)}$. Double lines represent graphite coatings. Volume of cell = 230 ml; diameter = 7.0 cm.

the range 0–500 V and the second 0–2000 V. One or other of these was connected to the inner electrode, A, and provision was made for reversing the polarity. The ionization currents from the collecting electrode to ground varied between 10^{-8} and 10^{-6} A, and were measured with a Keithley model 621 electrometer. The guard ring, B, was connected directly to ground. All electrical connections to the irradiation cells were passed through a small aperture in the wall of the irradiation cave.

Dosimetry

The simplest and most direct method of dosimetry for gaseous systems is by the measurement of saturation ionization currents. These can be converted to absorbed energy once the value of W, the energy required to create an ion-pair in the gas, is known. Experimental values of W for the hydrogen halides are not available, but reliable measurements of W (see ref. 4) have been obtained for most of the inert gases. Since any given hydrogen halide has the same total number of electrons as the inert gas adjacent to the particular halogen in the periodic table, their electron stopping powers will not differ appreciably and their Compton scattering cross sections will be the same. Thus the energies absorbed by a hydrogen halide and the isoelectronic inert gas at equal pressures in cells subjected to the same flux of ^{60}Co γ-radiation will be very similar. Corrections for the small difference in the stopping powers of the two molecules may be made by means of the Bethe equation.

A somewhat similar approach was employed earlier by Zubler, Hamill, and Williams (5) in their study of the X-radiolysis of HBr and HBr – inert gas mixtures. The use of ^{60}Co γ-rays in the present study represents a distinct advantage, since energy is absorbed almost entirely from secondary electrons arising in γ-ray interactions with the cell walls.

RESULTS AND DISCUSSION

Measurement of W_{HCl} and $G(H_2)_{HCl\ gas}$

As shown in Fig. 2 satisfactory ionization current plateaus were obtained with air, HCl, and argon. Figure 3 shows that the relation between the saturation ionization currents and the pressures of the irradiated gases were linear for all three gases over the

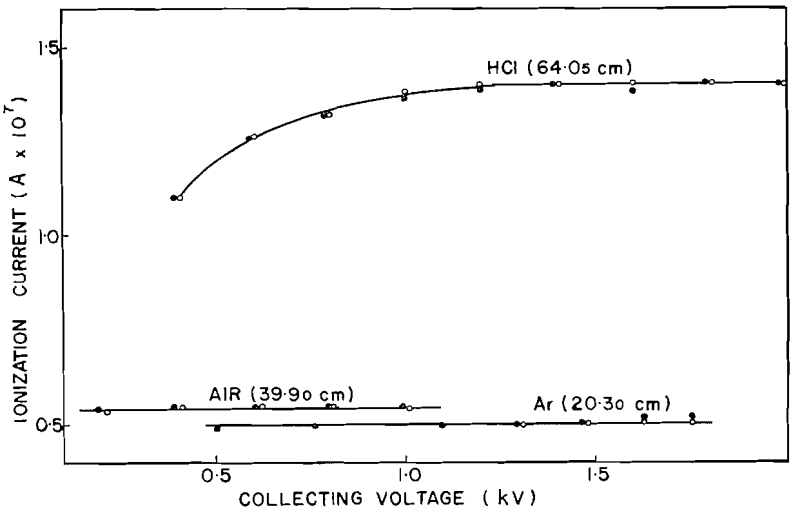

FIG. 2. Typical ionization current – voltage relationships: Open symbols—center electrode negative. Filled symbols—center electrode positive. Where points coincide exactly they have been placed adjacent to each other in the horizontal plane.

range of pressures employed. The slopes of the best lines through the plots in Fig. 3 were $J_{Ar} = 2.0_0$, $J_{HCl} = 2.2_4$, and $J_{air} = 1.3_5 \times 10^{-9}$ A per cm pressure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The energy absorbed per cm pressure per second in pure HCl must be equal to the left hand side of the expression:

$$[i] \qquad (W_{HCl} \times J_{HCl})/e = (W_{Ar} \times J_{Ar}\rho_{Ar}^{HCl})/e$$

where e is the electronic charge. If the energy absorption is assumed to be proportional to the stopping powers of the gases and ρ_{Ar}^{HCl} is taken as the ratio of the stopping powers for HCl and Argon, then the remainder of expression [i] follows. As a check on this J_{Ar}/J_{air} was evaluated using an expression analogous to [i] to relate the energy absorption in air and argon. The stopping power ratio ρ_{air}^{Ar} was calculated by means of the equation of Bethe (ref. 6, p. 98, equation 40) with mean excitation potentials of 174* and 85 eV for argon (7) and air (8) respectively. The value of ρ_{air}^{Ar} varied from 1.16, at 1 MeV to 1.11 at 0.05 MeV. The value chosen, 1.13, corresponded to a weighed mean electron energy of about 0.15 MeV (cf. the weighed mean energy in ref. 9) and, together with $W_{air} = 33.7$ and $W_{Ar} = 26.2$ eV (4), gave a ratio for $J_{Ar}/J_{air} = 1.46$. This is in good agreement with the experimental ratio of 1.48. A similar calculation with ρ_{air}^{Ar} based on the ratio of Compton scattering cross sections would predict $J_{Ar}/J_{air} = 1.61$.

The stopping power ratio ρ_{Ar}^{HCl} was evaluated in the same way as ρ_{air}^{Ar} with the mean excitation potentials of hydrogen and chlorine taken as 13.5 and 169 eV (7) respectively. Over the energy range 1.0 to 0.05 MeV the variation is comparatively small (1.02_1 to 1.03_2). It is rather unlikely that the ratio $\rho_{Ar}^{HCl} = 1.0_{28}$, employed in the subsequent calculation of W_{HCl}, can be in error by more than $\pm 1\%$. Substitution of this figure, the above value of W_{Ar}, and the experimental ratio J_{HCl}/J_{Ar} into expression [i] gave $W_{HCl} = 24.4 \pm 0.6$ eV. Hence G (positive ions) must be 100/24.4 (= 4.1), and G_c should be essentially the same.

From the right hand side of expression [i] it can be shown that the dose rate for HCl in cells of the type shown in Fig. 1 was $2.0_3 \times 10^{13}$ eV per minute per cm pressure. Using this factor, the experimental hydrogen yields in moles per minute per cm pressure may be converted to $G(H_2)$ values. The results of four individual determinations have been presented in Table I. The mean value of $G(H_2)_{HCl\ gas\ at\ 23\ °C}$ is 8.0 ± 0.3, and $(M/N)_{-HCl}$

**Calculated from the relationship $I = 9.7 \times Z$. The factor 9.7 is smaller than the experimental value of 10.6 found by Brolley and Ribe (see ref. 8). However, 9.7 is more in keeping with the theoretical analysis made by Brandt (7).*

is 3.9 ± 0.1. It should be emphasized that in separate experiments $G(H_2)$ was found to be independent of absorbed dose over the range $6 \times 10^{17} - 1.7 \times 10^{18}$ eV. Hence, in this range any dose dependence must lie within our experimental error. The reason for the significant differences between our mean value of $(M/N)_{-HCl}$ and Vandame's apparent values will be discussed later.

The effect of HCl pressure on the hydrogen yields was investigated in uncoated pyrex cells of similar volume to those shown in Fig. 1. In Fig. 4 the rate of hydrogen formation

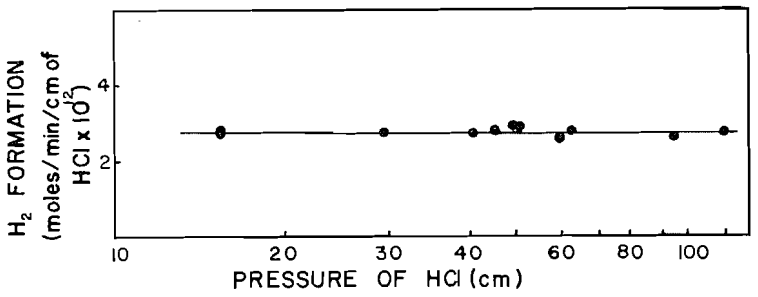

FIG. 4. Effect of pressure on the hydrogen yield from gaseous HCl at 23 °C. Note: dose rate ∝ pressure.

per cm pressure of HCl has been plotted as a function of HCl pressure. Since the dose rate was directly proportional to HCl pressure, the constancy in the rate of formation of hydrogen indicates that $G(H_2)$ is independent of pressure over the range 19 to 119 cm. In view of this, HCl was used as its own dosimeter in all subsequent experiments.

The Effects of Scavengers

The effect of chlorine on the hydrogen yields from gaseous HCl is shown in curve A of Fig. 5. The closed triangles and circles depict results obtained in spherical bulbs of volume 228 and 3690 ml respectively. In both cases HCl pressures were in the range 50–60 cm, varying slightly from one experiment to the next. It can be seen that in this HCl pressure range the effect of chlorine is, within experimental error, independent of bulb size, and hence of surface to volume ratio.

Assuming, as for the liquid phase radiolysis (10), that HCl and chlorine compete for a reactive species, H^1, in accordance with the equations:

[1] $$H^1 + HCl \rightarrow H_2 + \text{products}$$

[2] $$H^1 + Cl_2 \rightarrow \text{products other than } H_2$$

one may carry out the usual kinetic analysis, plotting $1/\Delta G(H_2)$ as a function of $(HCl)/(Cl_2)$. This leads to $G_{H^1} = 6.7$ and $k_{H^1 + HCl}/k_{H^1 + Cl_2} = 3.9 \times 10^{-3}$. In view of the fact that G_{H^1} is less than $G(H_2)$ it is necessary to postulate the existence of a second species, H^{11}. The apparent yield of this is $G_{H^{11}} = 1.3$.

On the basis of the above parameters it may be shown that at any particular chlorine concentration $G(H_2)$ is given by the empirical expression:

[ii] $$G(H_2) = 1.3 + 6.7\left(1 + \frac{(Cl_2)}{3.9 \times 10^{-3}(HCl)}\right)^{-1}.$$

Curve A in Fig. 5 was calculated by means of [ii], and the agreement with the experimental points is quite satisfactory. It is obvious from this curve that the accumulation

of chlorine during the course of an irradiolysis of pure HCl would cause a depletion in the apparent radiolytic yield as Vandame postulated. In the present study the concentration of hydrogen or chlorine (the yields of the two must obviously be equivalent) seldom rose above 0.01 mole percent in any given experiment, and this depletion could not have been significant. However, in Vandame's work percentages of chlorine as large as 0.6 occurred. Corrections to his results may now be applied on the basis of the data of curve A. At any given chlorine concentration the rate of hydrogen formation will be:

[iii] $$\frac{d(H_2)}{dt} = R \times G(H_2)\left\{\alpha \times \left(1 + \frac{k_{H^1+Cl_2}(Cl_2)}{k_{H^1+HCl}(HCl)}\right)^{-1} + (1-\alpha)\right\}$$

where $G(H_2)$ is the "true" initial total hydrogen yield, α represents the proportion of hydrogen formed by H^1 ($\alpha = 6.7_0/8.0_1 = 0.83_2$), and R is the dose rate in eV per unit volume per unit time. Assuming that the values of $k_{H^1+HCl}/k_{H^1+Cl_2}$ and α for the α-particle radiolysis are the same as those above, we may substitute them in expression [iii] and integrate between zero and the time t, at which the yield of hydrogen or chlorine

was measured. This leads to expression (iv), where D $(= Rt)$ is the total accumulated dose per unit volume at time t:

$$[\text{iv}] \qquad G(H_2) = \frac{1}{D}\left[\frac{(Cl_2)}{0.167} - 0.268\ (HCl)\log_{10}\left\{1 + 42.8\frac{(Cl_2)}{(HCl)}\right\}\right].$$

Values of $G(H_2)$ calculated by means of this expression from the data of Table II in Vandame's paper have been included in Table I above. In these calculations it was necessary to replace the figure used by Vandame for the number of ion pairs formed per α-particle by the energy per α-particle (5.48 MeV). No other alterations to his data were made, and the volume of all of his irradiation cells was taken, as he stated, to be 150 ml. An expression analogous to [iv] may be developed for correcting his ion pair yields. Both the corrected and the apparent yields are given in Table I. From this it can be seen that the corrected ion pair yields show a much smaller dose dependence than did the uncorrected ones. Also the corrected ion pair yields and the $G(H_2)$ values are equal to or slightly larger than those obtained in this study. Thus it seems that the discrepancy noted earlier was largely due to a lack of correction for the back reaction involving chlorine.

Experiments analogous to those above (3) have shown that in liquid HCl at -79 °C G_{H^I} is much smaller and $G_{H^{II}}$ much larger ($G_{H^I\ (HCl\ liquid\ at\ -79\ °C)} = 2.4$; $G_{H^{II}\ (HCl\ liquid\ at\ -79\ °C)} = 4.3$). Also $k_{H^I + HCl}/k_{H^I + Cl_2}$ was smaller in liquid HCl ($= 1.7 \times 10^{-3}$). The combination of these three features made it possible to observe the scavenging of H^{II} at high chlorine concentrations, and $k_{H^{II} + HCl}/k_{H^{II} + Cl_2}$ in liquid HCl was shown to be 0.10. This value was sufficiently small to warrant a correction to the apparent values of G_{H^I} and $G_{H^{II}}$ for the scavenging of H^{II} (the values given above are the corrected ones). Obviously Cl_2 may also scavenge H^{II} in gaseous HCl. However, with $G_{H^I} > G_{H^{II}}$ and $k_{H^I + HCl}/k_{H^I + Cl_2}$ larger than in the liquid phase (and hence closer to $k_{H^{II} + HCl}/k_{H^{II} + Cl_2}$) it is not possible to evaluate $k_{H^{II} + HCl}/k_{H^{II} + Cl_2}$ with any reasonable degree of accuracy. Corrections to the apparent values of G_{H^I} and $G_{H^{II}}$* cannot, therefore, be made and they must be treated as upper and lower limits respectively. This does not affect the validity of expression [iv], which is an empirical relationship (cf. the agreement of curve A in Fig. 5 with the experimental points).

To obtain further information about the relative proportions of H^I and H^{II} in gaseous HCl, the effect of bromine under a variety of different conditions was also investigated. As shown in Fig. 5, curve B, the results were similar to those reported earlier by Armstrong and Lee (2), which are in fact included. With small additions of bromine there was a very sharp drop in $G(H_2)$ to a limiting "plateau yield," which decreased only slightly as the bromine concentration was increased beyond 1 mole percent. The position of this plateau was within experimental error independent of HCl pressure, radiation cell volume, and dose rate.† It was also unaffected by coating the irradiation cells with colloidal graphite. It is of considerable interest to be able to decide whether or not this plateau is due to contributions from heterogeneous processes. As a first approximation the rate at which reactive intermediates diffuse to the walls should be inversely proportional to the pressure of HCl (P_{HCl}) and the square of the radius of the irradiation cell (r^2). On the other hand the rate at which they undergo homogeneous combination should be proportional to dose rate (I). The values of IPr^2 have been given for the various points in Fig.

If $k_{H^{II} + HCl}/k_{H^{II} + Cl_2}$ has the same value in gaseous HCl as in liquid HCl, then about 30% of H^{II} would be scavenged at 5 mole percent Cl_2. The errors in G_{H^I} and $G_{H^{II}}$ may therefore be quite large.

†*We are indebted to Dr. J. Stone of the Research Chemistry Branch of Atomic Energy of Canada for the two irradiations at the highest dose rate.*

5. It can be seen that the position of the plateau was unaffected by considerable variations in the value of this function. In view of these observations it is extremely unlikely that heterogeneous processes are involved under the conditions of this study. Hence we attribute the hydrogen produced in the bromine concentration range corresponding to the plateau to homogeneous reactions of the species designated above as H^{II}. From the relatively small decreases in hydrogen yield occurring at bromine concentrations in excess of 1 mole percent it may be concluded that (as in liquid HCl (10)) bromine does not compete efficiently for the species H^{II}. The yields of H^{I} and H^{II} measured with bromine are therefore probably closer to the true primary yields than those obtained above with chlorine.

Turning to the region of lower concentrations and assuming (as for chlorine) that bromine competes with HCl for a reactive species, H^{I}, the same kinetic analysis gives $G_{H^{I}} = 5.5$, $G_{H^{II}} = 2.5$, and $k_{H^{I}+HCl}/k_{H^{I}+Br_2} = 2.3 \times 10^{-4}$. Similar effects of bromine in liquid HCl at -79 °C (10) have been attributed to a competition for thermal hydrogen atoms, k_{H+HCl}/k_{H+Br_2} being equal to 8×10^{-4}. In view of the higher temperature and since $E_{H+HCl} > E_{H+Br_2}$* (10), the gas phase ratio should be larger if the same species is involved. In fact it is smaller. Thus it seems that H^{I} in gaseous HCl may not be the same as the species observed in liquid HCl. To confirm this we have made use of the fact that the rate constant ratio k_{H+HBr}/k_{H+Br_2} at 25 °C is known from conventional studies to be $0.1_2 \pm 0.0_2$ (11). The effects of bromine on the hydrogen yields from a gaseous sample of HCl containing 5 mole percent HBr are shown in Fig. 5, curve C. Assuming that HCl and HBr both compete with bromine for H^{I}, one may derive the expression:

$$[v] \qquad \frac{1}{\Delta G(H_2)} = \frac{1}{G_{H^{I}}}\left\{1 + \frac{k_{H^{I}+HCl}(HCl) + k_{H^{I}+HBr}(HBr)}{k_{H^{I}+Br_2}(Br_2)}\right\}$$

and $k_{H^{I}+HBr}/k_{H^{I}+Br_2}$ may be found from the slope of the usual plot on substituting $(k_{H^{I}+HCl})/k_{H^{I}+Br_2})$ from above, the concentrations of HCl and HBr, and $1/G_{H^{I}}$ from the intercept. In this way $k_{H^{I}+HBr}/k_{H^{I}+Br_2}$ was shown to be 5×10^{-3}. It is thus clear that thermal hydrogen atoms cannot be the only species with which bromine reacts in gaseous HCl. The above rate constant ratios should therefore be regarded as "complex" rate constant ratios.

At this point the ionic and free radical reactions, which are responsible for the effects observed, will be considered briefly. As in liquid HCl (see ref. 3 for a more detailed discussion of the following processes) one would expect the formation of HCl^+ ions, viz.:

$$[3] \qquad HCl \rightarrow HCl^+ + e$$

to be the main ionization process. Within a few collisions these ions should undergo reaction [4]:

$$[4] \qquad HCl^+ + HCl \rightarrow H_2Cl^+ + Cl.$$

During the course of their thermalization electrons in the appropriate energy ranges may cause electronic excitation (required energy $\simeq 7$ eV):

$$[5] \qquad e + HCl \rightarrow HCl^* + e$$

$$[5a] \qquad HCl^* \rightarrow H^* + Cl,$$

*E = *activation energy.*

or undergo resonance capture (0.7 − 1.8 eV):

[6] $$e + HCl \rightarrow H + Cl^-.$$

Hence, the major ionic species taking part in neutralization reactions would be:

$$e,\ Cl^-,\ \text{and}\ H_2Cl^+,$$

and ion combinations such as the following would be expected to occur:

[7] $$H_2Cl^+ + e \rightarrow H + HCl$$

[8*a*] $$H_2Cl^+ + Cl^- \rightarrow 2HCl$$

[8*b*] $$\rightarrow H_2 + 2Cl$$

[8*c*] $$\rightarrow H + Cl + HCl.$$

In pure HCl the hydrogen atoms formed in [6], [7], and [8*c*] would give rise to molecular hydrogen through reaction [9]:

[9] $$H + HCl \rightarrow H_2 + Cl.$$

Scavenging of these hydrogen atoms by bromine and chlorine could account in part for the depletion of the hydrogen yield over the concentration range 0–2 mole percent of scavenger. However, as shown above, bromine must react with some sepcies in addition to hydrogen atoms. In view of the rapidity of reaction [4], charge exchange between HCl^+ and Br_2 is unlikely. Also reactions between this halogen and H_2Cl^+ are improbable on energetic grounds. It seems, therefore, that bromine must be scavenging electrons. Strong support for this comes from the fact that its cross section for electron capture in reaction [10] increases from zero for electrons of energy in excess of 1.3 eV to a maximum value

[10] $$e + Br_2 \rightarrow Br^- + Br$$

for electrons of zero energy (12). Its behavior is thus analogous to that of iodine, and the actual magnitude of its capture cross section should also be similar ($\sigma_{e + I_2} \simeq 10^{-16}$ cm^2 (13)). In contrast to bromine and iodine, the electron energy range for resonance capture by chlorine is much higher (1.6 − 3.2 eV (12)). It is not, therefore, likely to be a good electron scavenger (cf. (14)), and its much lower efficiency for suppressing the hydrogen yield from gaseous HCl can be explained on this basis.

At an HCl pressure of 60 cm in our ionization chamber, the saturation ionization current was approximately 10^{-7} A. This corresponds to a rate of formation of ions of 2.8×10^9 ions.ml^{-1}.s^{-1}. Taking 10^{-6} ml.ions^{-1}.s^{-1} as a reasonable order of magnitude for the coefficient of ion recombination (see ref. 15), the steady state ion concentration was estimated to be about 5×10^7 ions.ml^{-1}. From this figure and the above cross section it can be shown that the ratio of electron–ion combination to electron capture by bromine at 1 mole % concentration would be of the order of 10^{-4}. It is thus quite clear that bromine may compete with positive ions for electrons under the conditions of our study. It may also be in competition with reaction [6] and with a modified form of it, [6*a*], viz.:

[6*a*] $$e_{(HCl)} \rightarrow H + Cl^-_{(HCl)}$$

which occurs within an electron–HCl molecule cluster. Mass spectrometric studies (16) in other systems containing polar molecules and measurements of ionic mobilities in HCl

and HCl–air mixtures (17) indicate that such clustering will be important under the conditions of temperature and HCl pressure existing in this study. Reactions such as [6*a*] cannot, therefore, be overlooked, and as previously (3, 10) pointed out the capture of thermal electrons is more probable when more than one HCl molecule is involved. Bromine would probably compete for clustered electrons in accordance with the equation:

[10*a*] $$e_{(HCl)} + Br_2 \rightarrow Br + Br^-_{(HCl)}.$$

An additional effect of the clustering of both negative and positive ions would be to reduce the exothermicity of the ion recombination reactions. Thus the excess kinetic energies of the atoms formed in reactions [7], [8*b*], and [8*c*], all of which would be highly exothermic with unclustered ions, should be much less under the conditions of the present study.

The hydrogen produced in the presence of bromine at concentrations in excess of 1 mole percent obviously cannot result from electron–ion combinations. If the species H^{II} is identified as a hot hydrogen atom formed in the reaction sequence [5]–[5*a*], the discrepancies between the values of G_{H^I} and $G_{H^{II}}$ determined with chlorine and bromine would have to be attributed (cf. above) to the fact that chlorine is not sufficiently discriminating in its reactivity toward H^I and H^{II} to indicate their true yields. Also there are reasons for believing that the proportion of hot hydrogen atoms, which undergo thermalization before reacting, may be greater in the gas phase than in the liquid phase (18). Thus, if 3.9 dissociative excitations occurred per 100 eV in gaseous HCl and 1.4 of the resulting hot atoms were thermalized before reacting, one could account for $G_{H^{II}} = 2.5$ and also for the fact that $G_{H^I} - G_e = 1.4$.* In liquid HCl where virtually all hot hydrogen atoms may react before being thermalized, $G_{H^{II}}$ has a value of 4.3.

The only reasonable alternative to the above would be that H^{II} is a composite species consisting of negative halide ions (Cl^- or Br^-, the latter coming from reaction [10] or [10*a*]) and H_2Cl^+ ions. The number of these combining as in [8*b*] to form hydrogen molecules directly might depend on whether Cl^- or Br^- were involved. In this way an alternative explanation can be provided for H^{II} and for the discrepancies between the values of $G_{H^{II}}$ and G_{H^I} determined with chlorine and bromine.

However, since liquid HCl undergoes autoprotolysis (cf. (3)), one would expect [8*a*] to predominate in the liquid phase. Thus it is not easy to explain the larger value of $G_{H^{II}}$ in the liquid phase on the basis of reaction [8*b*].

SUMMARY AND CONCLUSIONS

1. The value of $G(H_2)$ for the γ- (or fast electron) radiolysis of gaseous HCl at 23 °C and over the pressure range 19–119 cm of Hg is 8.0 ± 0.3. The value for α-particle radiolysis is the same or slightly larger.

2. The energy, W_{HCl}, required to create an ion pair in HCl is 24.4 ± 0.6 eV, and hence $G_{HCl^+} \simeq G_e \simeq 4.1$. To explain the fact that $G(H_2)$ is almost twice this, it is necessary to postulate sequences of ionic reactions which give rise to two hydrogen atoms (or molecules) per ion pair (for example: [3]–[4]–[6 or 6*a*]–[8*b* or 8*c*]; or concurrent reaction sequences involving initially both ionization and dissociative excitation (for example: [3]–[4]–[6 or 6*a*]–[8*a*] and [5]–[5*a*]).

3. The effects of bromine on the hydrogen yield show that more than one mode of

**It should be pointed out that, since W = 24.4 eV and the ionization potential of* HCl *is only 12.9 eV (19), there is energy available for at least as many as five excitations per 100 eV. The only alternative explanation for the difference between G_{H^I} and G_e would be the formation of 1.4 thermal hydrogen atoms in a reaction such as [8c].*

hydrogen formation is operative. One of these seems to involve hydrogen atoms formed from electron precursors, and, in contrast to its behavior in liquid HCl, bromine scavenges these electrons with high efficiency. The fact that it does not scavenge them efficiently in liquid HCl must be attributed to their much shorter lifetime in the liquid phase (10).

4. As indicated by the effects of bromine the total yield of thermal hydrogen atoms and hydrogen atoms formed from electron precursors is $G_{H^1} = 5.5$. This is much larger than the yield of the corresponding species in liquid HCl at −79 °C. In contrast the yield of the species H^{11} in gaseous HCl ($G_{H^{11}} = 2.5$) is much smaller than in liquid HCl.

5. The effects of chlorine also provide evidence for more than one mode of hydrogen formation. However, chlorine appears to react much less rapidly with electrons than bromine, and its effect may be almost entirely due to the scavenging of hydrogen atoms.

A SPECTROPHOTOMETRIC REEXAMINATION OF THE SPECTRA AND STABILITIES OF THE IRON (III) – TIRON COMPLEXES

W. A. E. McBryde
Department of Chemistry, University of Waterloo, Waterloo, Ontario
Received January 7, 1964

ABSTRACT

Variations in the spectra of the aqueous solutions of the iron (III) – sodium catechol disulphonate (Tiron) complexes may be interpreted in relation to pH of the solutions to show which complexes are present at any chosen pH. With this knowledge it is possible in this system to evaluate equilibrium constants for the formation of each complex in turn. Combining these with separately determined acidity constants for Tiron, the stability constants of the complexes may be calculated. These have been determined for background solutions of potassium nitrate or sodium perchlorate each at three different concentrations, and for three different ratios of reagent to metal. Averages of a number of determinations made under these conditions are given in Table III of the paper. The constant K_1 in perchlorate media shows an unmistakable dependence suggestive of the existence of a protonated species at low pH as well as the simple complex ML. However, there is some ambiguity in the interpretation of the results so that the exact nature of the protonated complex cannot be decided.

INTRODUCTION

In a previous communication (1) the spectrophotometric method introduced by Vareille (2) for determining the successive formation constants of a series of metallic complexes was discussed in some detail. In particular it was shown that the method can only be applied provided the formation constants sought are widely enough separated to give, under appropriate conditions, solutions containing all of the metal exclusively as *one* or *two* species (including the uncomplexed metal). Furthermore, the most suitable complexes for study by this method are those which, as the ligand concentration is changed, will each in turn at some point comprise the *only* metallic species in solution.

The present paper reports a reexamination of the reaction between iron (III) and sodium catechol disulphonate (Tiron) by the Vareille method. This particular reaction was chosen for further study for several reasons. For instance, it was considered desirable to measure "conditional" equilibrium constants at several ionic strengths, since our own observations (3) as well as those of others (4) suggest that even at constant pH and ratio of ligand to metal, different hues of color, indicating different proportions of the colored complex species, are formed according to the ionic strength of the solution. Furthermore, it was hoped to bring additional evidence to bear on the claimed existence of a protonated metallic complex, MHL (5). Finally, it was of interest to try to define conditions under which the metal in solution could be completely converted to the single species ML, for the following reason. It has been noted previously that the red *tris*-complex, ML_3, is produced in alkaline solution irrespective of whether the solution is prepared from an iron (II) or an iron (III) salt; evidently the much greater stability of the iron (III) complex compared to that of iron (II) results in a marked lowering of the reduction potential so that the iron (II) complex is rapidly oxidized by the air (6) or, at high enough pH, by the solvent (3). Similar oxidation was not observed in media suitable for formation of the 1:1 complex. If conditions could be found in which the latter could be produced in stoichiometric amounts, an analytical procedure might be possible in which iron (III) could be determined in the presence of iron (II) in acidic solution, while in the same solution made alkaline total iron could be determined.

For personal use only.

PRINCIPLE OF THE METHOD

In applying Vareille's method for this work certain extensions of the original procedure were introduced. From the optical density of any solution containing metal and ligand, an extinction coefficient based on the total molarity of the metal may be calculated. Calling this ϵ_M, it is evident that

$$\epsilon_M = \epsilon_0 \alpha_0 + \epsilon_1 \alpha_1 + \epsilon_2 \alpha_2 + \epsilon_3 \alpha_3 \quad [1]$$

for a system of three complexes. The symbol α gives the fraction of the metal in the designated species, and the subscripts 0----3 refer respectively to M, ML, ML_2, and ML_3.

From spectra of solutions having a fixed molarity of iron (III) and Tiron and adjusted to various values of pH, values of ϵ_M were obtained, and plotted against pH. The information to be gained from such a plot may be seen by inspection of Fig. 1; two of the wavelengths for which data are portrayed (534 mμ, 670 mμ) are those at which isobestic points occur. The basis of Vareille's method is that one may infer from the horizontal regions in this plot, plus a knowledge of the identity of the complexes found at various regions of pH (1), the following information:

above pH 6.3, $\alpha_3 = 1$; between pH 4.4 and 6.3, $\alpha_2 + \alpha_3 = 1$; at pH 4.3, $\alpha_2 = 1$; between pH 2.8 and 4.2, $\alpha_1 + \alpha_2 = 1$; at pH 2.7, $\alpha_1 = 1$; below pH 2.6, $\alpha_0 + \alpha_1 = 1$.

It is thus possible to obtain at pH 2.7, 4.3, and 6.3 respectively the values of ϵ_1, ϵ_2, and ϵ_3 at any chosen wavelength. It is to be understood that the values and ranges of pH quoted refer only to the experimental conditions under which the data of Fig. 1 were obtained.

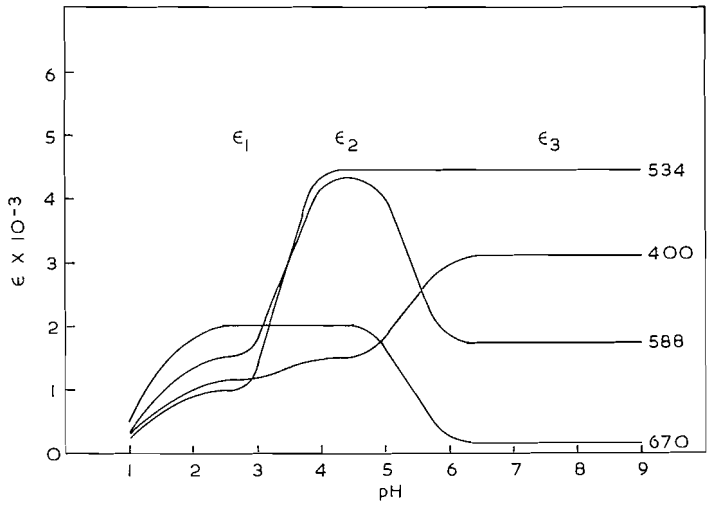

FIG. 1. Variation of molar extinction coefficient for iron (III) – Tiron solutions as a function of pH and at indicated wavelengths. $[M]_T \sim 2 \times 10^{-4}$ M; $[L]_T \sim 2 \times 10^{-3}$ M; 0.5 M KNO_3 background.

Given these characteristics, the composition of mixtures of pairs of metallic species can be deduced from values of ϵ_M. The value of $\epsilon_0 \sim 0$ in the range of wavelengths investigated. Equilibrium constants, $\mathcal{K}_n$, were then calculated for the reactions

$$ML_{n-1} + H_2L = ML_n + 2H \qquad (n = 1, 2, 3)$$

by the expression

$$[2] \qquad \mathcal{K}_n = a_n \, H^2/[H_2L]$$

in which

$$[3] \qquad a_n = (\epsilon_{n-1} - \epsilon_M)/(\epsilon_M - \epsilon_n) = [ML_n]/[ML_{n-1}]$$

$$[4] \qquad H = \text{antilog } (-pH)$$

$$[5] \qquad [H_2L] = ([H_2L]_T - \bar{n}[M]_T)\,(1 + K_{a_1}/H)^{-1}$$

$$[6] \qquad \bar{n} = (n - 1) + a_n/(a_n + 1) = (n - 1) + \alpha_n$$

In these $\bar{n}$ gives the degree of complex formation as defined by Bjerrum. In this system of complexes it has been shown above that at certain values of pH, $\alpha_n = 1$ (for $n = 1$, 2, or 3). Below each such pH is a region where $\alpha_n + \alpha_{n-1} = 1$. In these regions

$$\begin{aligned} \bar{n} &= (n - 1)\alpha_{n-1} + n\alpha_n \\ &= (n - 1)(\alpha_{n-1} + \alpha_n) + \alpha_n \\ &= (n - 1) + \alpha_n. \end{aligned}$$

By substituting from equation [3] in $\alpha_n/(\alpha_n + 1)$ one obtains $[ML_n]/([ML_n] + [ML_{n-1}])$ which is α_n. This is the source of equation [6].

Tiron is represented by H_2L; this stands for the catechol part of the molecule, the sulphonate groups being ionized and assumed inactive in complex formation. By measuring the pH and optical density of any solution in which $(\alpha_n + \alpha_{n-1}) = 1$ an appropriate value of $\mathcal{K}_n$ could be calculated. For calculation of $\mathcal{K}_1$,it is understood that the quantity a_1 gives the ratio [ML]/[M]; however, the quantity [M] includes free ferric ion as well as any products of its hydrolysis. To calculate from a_1 by equation [2] we have divided the expression on the right-hand side by the fraction of the unbound iron (III) actually in the ionic state. Appropriate values of this fraction were taken from calculations [7] based on Hedstrom's hydrolysis constants (8); Fig. 2 shows values of this fraction as a function of pH for concentrations of iron (III) below 10^{-3} molar.

A separate value for the equilibrium constant was obtained from each measurement of

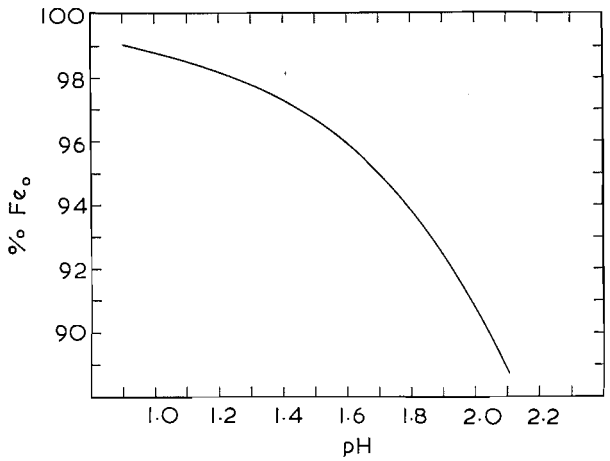

FIG. 2. Percentage of unhydrolyzed iron (III) in solutions $> 10^{-3}$ *M*.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

optical density subject to the restriction that a_n fell between 0.1 and 10. Furthermore, there was no restriction upon the wavelength at which such measurements were made, so that several estimates of $\mathscr{K}_n$ could be obtained from one solution. In the method suggested by Vareille, measurements were made only at wavelengths at which isobestic points occurred, and a single estimate of $\mathscr{K}_n$ made by locating from a graph such as Fig. 1 the pH at which $a_n = 1$ ($n = 2$ or 3).

The acid dissociation constants of Tiron were determined by following the pH during titration of weighed portions with standard alkali. Empirical relationships between pH as detected by a glass electrode and stoichiometric concentrations of free hydrogen or hydroxide ion were first obtained by adding known amounts of acid or alkali to neutral aqueous solutions. It was then assumed that any pH value could be converted to a value of [OH] or [H] in a solution of ionic strength the same as that taken for calibration. The degree of hydrogen bound to Tiron, $\bar{n}_H$ (the average number of hydrogen ions per molecule of Tiron) was given by one or other of the following equations.
In acidic solution

$$\bar{n}_H = ([H]_T - [H])/[H_2L]_T. \quad [7]$$

(This refers to hydrogen bound to the sulphonate groups.)

In neutral or alkaline solution

$$\bar{n}_H = 2 - ([B]_T - [OH])/[H_2L]_T. \quad [8]$$

(This refers to the degree of protonation of L.)

In neutral solution [OH] is negligibly small compared to the other terms. For

$$H_2L = HL + H, \quad pK_{a_1} = pH - \log\{[B]_T/([H_2L]_T - [B]_T)\}. \quad [9]$$

For

$$HL = L + H, \quad pK_{a_2} = pH + \log [\bar{n}_H/(1 - \bar{n}_H)]. \quad [10]$$

The formation constants of the various complexes are given by the relationship

$$K_n = \frac{\mathscr{K}_n}{K_{a_1} K_{a_2}}. \quad [11]$$

It should be noted that the formation constants derived in this way are defined by concentrations of the participating species. They were determined in solutions to which had been added an indifferent electrolyte in sufficient quantity to maintain a known and constant ionic strength. Sets of formation constants were measured at each of these ionic strengths and with two different background electrolytes. These are therefore "conditional" constants applicable, strictly speaking, only in the medium for which they were determined. The acidity constants defined by equations [9] and [10], and the reaction constants defined by equation [2] all contain the quantity H, which is operationally defined, and is neither a concentration nor an activity. These constants, sometimes called Brönsted constants, serve here as means of determining the formation constants.

The foregoing procedure is an extension of that proposed by Vareille in two respects. In his work plots such as Fig. 1 were given and applied only at the wavelengths at which isobestic points were found. Clearly once the spectra of the individual complexes have been identified, there need be no restriction on the wavelength chosen for observation, and indeed one may select wavelengths at which the values of ϵ_n and ϵ_{n-1} in equation [3] differ

most widely. Secondly, Vareille confined his evaluation of $\mathscr{K}_2$ and $\mathscr{K}_3$ to the case where a_2 or $a_3 = 1$. What has been done here is to use each corresponding pair of measurements of ϵ_M and pH to find an independent value of $\mathscr{K}$.

RESULTS AND DISCUSSION

From the variation of optical density with pH it was possible, as outlined above, to elicit the absorption spectra of the three individual complexes. These are displayed for solutions in 0.5 *M* potassium nitrate in Fig. 3. Somewhat surprisingly the absorption

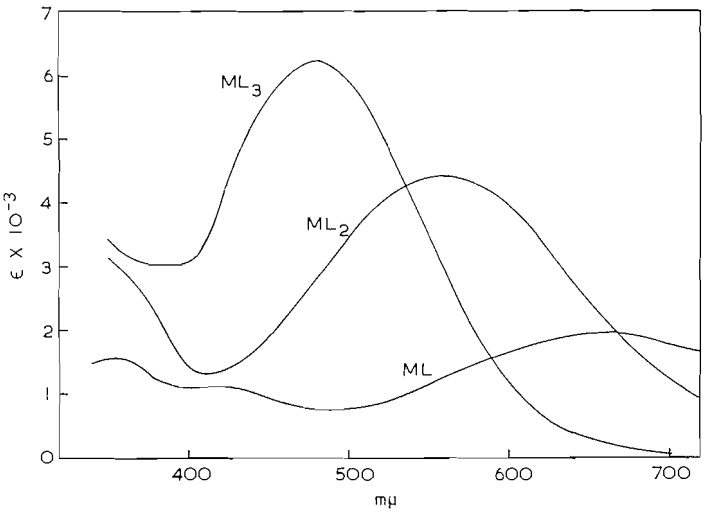

FIG. 3. Absorption spectra of the three iron (III) – Tiron complexes: 0.5 *M* KNO_3 background.

spectra, and hence the wavelength of isobestic points, proved to be slightly different in the different background solutions used. The values of λ_{max} and ϵ_{max} differed between nitrate and perchlorate, and between background solutions of different molarity. The range of values observed was as follows:

FeL:	λ_{max}	670–676 mμ,	ϵ_{max}	1840–1960
FeL_2:		560–562		4550–4600
FeL_3:		478–482		6150–6240

The cause of this variation is not known, but, from the fact that the shift in λ_{max} is appreciable for the complex ML_3, one may presumably rule out the formation of mixed complexes. A more probable explanation, which more applies the higher the degree of complex formation, is that interactions of the complexes occur with cations of the background solution. Such interactions have been postulated by Dyrssen (9), and have been thought to account for shifts in the spectra of the 1:1 ferric–Tiron complex in magnesium perchlorate solutions as compared with sodium perchlorate (3).

At the outset of this work it had been planned to use potassium nitrate as the indifferent electrolyte with which to regulate the ionic strength of the medium. In the more acidic solutions required to measure $\mathscr{K}_1$, however, it became apparent that some change in the Tiron—possibly oxidation by acidified nitrate—was taking place as evidenced by absorption at 400 mμ, and ultimately by a yellow color in the solution. Since the extent of this

For personal use only.

reaction could not readily be determined, and since it introduced an uncertainty in evaluating $[H_2L]$ (equation [5]), a shift was made to a perchlorate medium in which no evidence of this deterioration of the Tiron was observed.

TABLE I

Acidity constants for Tiron (nitrate or perchlorate background)

Background	pK_{a_1}	pK_{a_2}
0.1 *M*	7.65 – 7.69	12.47 – 12.55
0.5 *M*	7.36 – 7.43	12.09 – 12.11
1.0 *M*	7.17	11.74 – 11.81

In Table I are shown values of the acidity constants for Tiron as measured in the two media. The difference between the results with the two background salts was not considered significant. These may also be compared with the values obtained by Schwarzenbach in 0.1 *M* potassium chloride ($pK_{a_1} = 7.66$; $pK_{a_2} = 12.6$). The variation of pK_a is roughly linear with the square root of ionic strength. Extrapolation to zero ionic strength permits the following crude estimates of the thermodynamic dissociation constants: $pK_{a_1} = 7.9$; $pK_{a_2} = 12.9$.

TABLE II

Selected values of molar extinction coefficients for complexes

Nitrate background				Perchlorate background			
λ	ϵ_1	ϵ_2	ϵ_3	λ	ϵ_1	ϵ_2	ϵ_3
400	1130	1480	3090	430		1420	4380
534	980	4440	4440	480			5870
588	1530	4300	1710	500	740	3730	5570
670	1990	1990	150	550	1120	4400	
				600	1620	3730	

Table II lists the values of the molar extinction coefficients selected for evaluation of a in equation [3]. Two of the wavelengths chosen for measurements with nitrate solutions were those at which isobestic points occurred; for the perchlorate solutions wavelengths were taken at which a marked difference in ϵ for adjacent complexes was found.

Table III summarizes all the results for stability constants found at each of three ionic strengths and for three ratios of reagent to metal. The number shown for K_n is an average of six to ten measurements (varying in pH) at each of three wavelengths, except for a few cases with nitrate solutions where only two wavelengths were used. Along with each result is given the average deviation within the set, and these give some indication of the precision of which the method is capable. The variations in K measured at different wavelengths was much greater than the variations among a set made at one wavelength. This fact revealed that the weakest feature in the method is the selection of appropriate ϵ_n values for the individual complexes. Values of K_2 and K_3 showed no dependence on pH; the same could not be said of K_1, and this is the cause of the rather high average deviations for this quantity when measured in perchlorate solutions. The variation of $\mathcal{K}_1$ with pH was made the object of further study, and this was largely confined to perchlorate solutions because of the uncertainty referred to previously in the fate of Tiron in the nitrate solutions at low pH.

	0.1 *M*		25.0±10.2	

It was found that $\mathscr{K}_1$ was larger the higher the acidity of the solutions. The spread in values lay approximately within the range pH 1 to 2. Many additional solutions were prepared having pH within this range and various ratios of reagent to metal; the optical densities of each solution were measured at three wavelengths. Some of the results are displayed in Fig. 4; the points shown are the averages for each solution of results at three wavelengths. There can be no doubt that the quantity $aH^2/[H_2L]$ shows some dependence on H; similar trends were found at each level of ionic strength of sodium perchlorate. Schwarzenbach (5) has also observed a variation in the apparent K_1 for this system at low pH, and accounted for this by postulating the formation of a protonated species MHL.

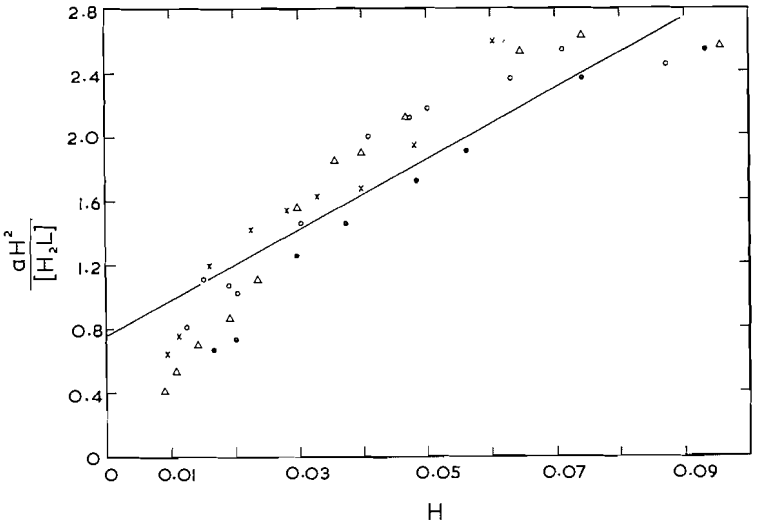

FIG. 4. Variation of apparent $\mathscr{K}_1$ ($= aH^2/[H_2L]$) with H: 0.5 *M* $NaClO_4$ background; $[M]_T \sim 2 \times 10^{-4}$; and ligand to metal ratios: × = 5:1; ○ = 10:1; △ = 10:2; ● = 20:1.

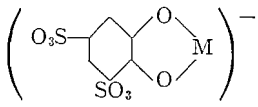
The experimental techniques used do not permit any decision to be made concerning the site of this protonation. In Schwarzenbach's discussion of this reaction protonation is assumed to take place on a sulphonate group of the Tiron; this assumption is open to question. Tiron solutions can be titrated with strong acid, and no evidence found from pH measurements of any hydrogen ion being taken up by the molecule down to pH 1. The formula of the complex ML is, presumably,



bearing a net charge one unit less negative than the anion of Tiron itself. If we assume that the sulphonate groups in Tiron show no affinity for protons down to pH 1, it seems unlikely that they would show increased tendency to accept protons in the complex. Yet Schwarzenbach's results and ours indicate that interaction of the ML complex with protons occurs above pH 1.

Another possible site for proton exchange in this complex is the hydration shell of the metallic ion which will only partially have been displaced as a result of coordination of one Tiron molecule. There is, however, no variation of $\mathscr{K}_1$ with H in the case of ferric sulphosalicylate or ferric salicylate in the same region of pH and in the same medium (10). These complexes are otherwise fairly similar to the Tiron complexes, and one would expect hydrolysis of the latter to be parallelled by hydrolysis of the former.

It was found that no change in absorption spectrum, in the sense of shifts of absorption maxima or the appearance or disappearance of absorption peaks, occurred in the visible or adjacent ultraviolet region throughout the range of pH in which the protonation appeared to be taking place. If we assume that a protonated species does exist, there seem from the observed spectra to be only two possible conclusions: either it has the same molar extinction coefficient as the unprotonated species, or it has an extinction coefficient undistinguishable from the uncomplexed metal. Making the former assumption, and calling K_H the acidity constant of the protonated species, it can be shown that

$$a\mathrm{H}^2/[\mathrm{H_2L}] = \mathscr{K}_1 + (\mathscr{K}_1\mathrm{H}/K_\mathrm{H}).$$

With reference to Fig. 4, a correlation line through the experimental points should have $\mathscr{K}_1$ as intercept and $\mathscr{K}_1/K_H$ as slope. Correlation lines were found by a least squares calculation with the following results:

Molarity $NaClO_4$	No. of solutions	$\mathscr{K}_1$	K_H	pK_H	Average deviation
0.1	35	0.46	0.018	1.8	0.165
0.5	135	0.75	0.034	1.5	0.36
1.0	51	0.39	0.015	1.8	0.15

The average deviation refers to values of $a\mathrm{H}^2/[\mathrm{H_2L}]$ above and below the line. The value of pK_H for 0.1 M $NaClO_4$ may be compared with Schwarzenbach's value of 1.80 in 0.1 M KCl. It is regrettable that, in spite of a very large number of determinations in 0.5 M $NaClO_4$, the average deviation was as high as shown; this fact creates some doubts about the higher value of $\mathscr{K}_1$ (and hence of K_H) in this medium. The position of the regression line in Fig. 4 is considerably influenced by the values of $a\mathrm{H}^2/[\mathrm{H_2L}]$ at higher H; if the values above H = 0.07 are not included, a regression line much closer to the other two is obtained.

In the event that the protonated species is non-absorbing in the spectral region examined, the quantity a ($= \epsilon_M/(\epsilon_1 - \epsilon_M)$) gives the ratio [ML]/([M] + [MHL]) instead of ([ML] + [MHL])/[M]. This leads to a different relationship involving K_H, namely,

$$[H_2L]/aH^2 = 1/\mathscr{K}_1 + ([H_2L]/K_HH).$$

Provided that there is a sufficient excess of Tiron present $[H_2L] \sim [H_2L]_T$, and is constant for a series of solutions. In this case a plot of the quantity on the left-hand side of the equation against 1/H should also be linear with intercept $1/\mathscr{K}_1$, and have a slope from which K_H can be obtained. Figure 5 shows the data for 0.1 M $NaClO_4$ as background electrolyte,

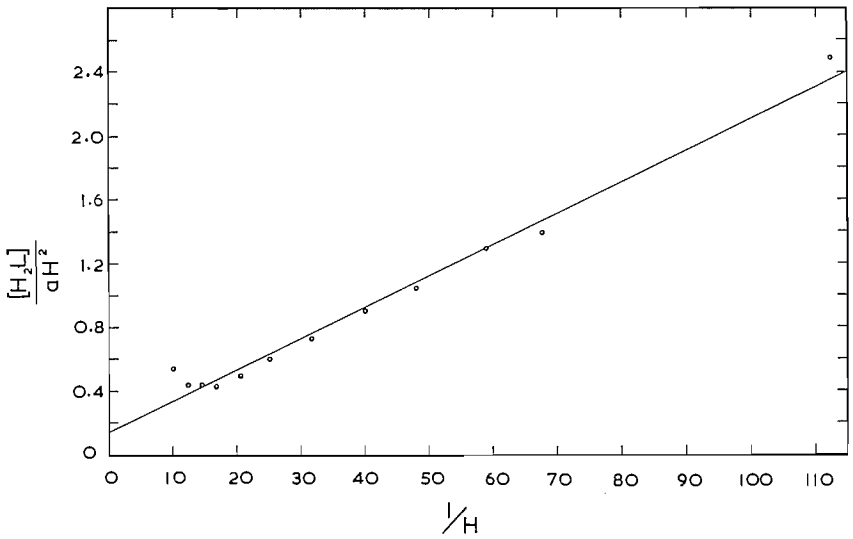


FIG. 5. Variation of apparent $1/\mathscr{K}_1$ ($= [H_2L]/aH^2$) with 1/H: 0.1 M $NaClO_4$ background; $[M]_T \sim 2 \times 10^{-4}$; $[L]_T \sim 2 \times 10^{-3}$.

and it is seen that such a representation also may apply to them. A summary of results for regression lines calculated by least squares, and the resulting values for K_H are given below.

Medium $NaClO_4$	$[L]_T/[M]_T$	No. cases	$\mathscr{K}_1$	K_H	pK_H	Average deviation
0.1 M	10:1	12	6.8	0.09	1.0	0.062
0.5 M	5:1	11	6.2	0.065	1.2	0.05
	10:1	12	4.0	0.15	0.8	0.05
	20:1	9	7.7	0.16	0.8	0.05
1.0 M	10:1	15	5.7	0.10	1.0	0.031

These results do not at all rule out the possibility that the protonated complex is non-absorbing at the wavelengths examined. Moreover, if one takes the data of Willi and Schwarzenbach (5, p. 534) and plots the reciprocal of their $K[H]^2$ (equivalent to our $aH^2/[H_2L]$) against the reciprocal of [H] (equivalent to our H) one gets a reasonably linear relationship, from which we infer that a non-absorbing protonated complex is not ruled out by their measurements. Owing to the fact that their data are taken off a Job curve it is not practical for us to try to evaluate $[H_2L]$, or hence K_H, from this plot.

The results given above leave little doubt concerning the existence of a protonated complex species below pH 2, in agreement with Willi and Schwarzenbach. It is not possible to deduce from the results where the proton may be attached in this species, nor whether the complex is absorbing or non-absorbing in the region 400–700 mμ. If it does absorb light, its extinction coefficient must be identical with the non-protonated species. If it does not, one may speculate whether the formation of the protonated species involves opening of the chelate ring as a result of addition of a proton at one of the phenolic groups. There is a lack of evidence for the equivalent reaction in nitrate solutions owing to observable deterioration of the Tiron in acidified nitrate solutions. These considerations make it difficult to select a value for $\mathcal{K}_1$ and hence of K_1 for the *mono-* complex in perchlorate solutions. In the absence of further evidence the results for the first stability constant given in Table III are averages of the values obtained without regard to their hydrogen-ion dependence. A few preliminary measurements were made with pyrocatechol as the ligand following the same procedures as with Tiron. The spectra of the resulting solutions showed rather rapid changes with time, and it appeared that the method described in this paper would require some modification before it could successfully be applied to catechol complexes.

Finally, a word should be added about the reaction of ferrous and ferric solutions with Tiron. Below pH 3 a freshly prepared ferrous iron solution gave very little or no color with Tiron. But when solutions containing both ferrous and ferric iron were treated under the same conditions the color developed was roughly equivalent to the total iron present. The induced oxidation of the ferrous iron in the presence of the ferric–Tiron solutions thus rules out the possible discrimination between the two oxidation states for analytical purposes.

EXPERIMENTAL

The Tiron was purchased as the colorimetric reagent sold by British Drug Houses, Ltd. or the G. F. Smith Chemical Co. Each lot was assayed for purity by titration of a weighed portion with standard alkali to the end-point for neutralization of the first phenolic hydrogen as determined with a pH meter. All lots used proved to be 99% or greater in purity if the assumption were made that Tiron was the only acidic substance in the sample. The molarity of solutions of this reagent was calculated with proper regard to the indicated purity.

All other chemicals used were of reagent grade and not further purified. Stock solutions of ferric nitrate in dilute nitric acid or of ferric perchlorate in dilute perchloric acid were standardized gravimetrically by precipitation of the hydrous oxide. A concentrated sodium perchlorate solution, which by dilution could provide selected background ionic strengths, was standardized by passing measured volumes through a column of ion-exchange resin in the hydrogen form, with subsequent titration of the acid set free in the effluent (11).

All pH measurements were made with glass electrodes previously standardized and checked with two or more buffer solutions prepared according to N.B.S. specifications from reagent grade chemicals. Solutions of iron plus Tiron were adjusted in acidity by the addition of small amounts of acid or alkali by means of hypodermic needles; no buffers were used in any of these solutions.

Preliminary spectral measurements on solutions of complexes were made with a Bausch and Lomb Model 505 spectrophotometer. All optical densities required for calculation of ϵ_M were measured in a Beckman Model DU spectrophotometer in 1-cm matched cells. The cell compartment in the latter was fitted out with thermospacers through which water maintained at 25 °C was circulated. The temperature of the solutions was not otherwise controlled, but the prevailing temperature in the laboratory remained quite steady in the range 22 to 25 °C.

ACKNOWLEDGMENTS

This investigation was supported by a grant from the National Research Council of Canada, for which the author records his appreciation. His thanks also go to Miss Jeanne Wittig and Miss Janet Rohr for technical assistance.

RÉACTION DU SULFURE DE BORE AVEC QUELQUES GROUPES CARBONYLES

S. JERUMANIS ET J. M. LALANCETTE
Faculté des Sciences, Université de Sherbrooke, Sherbrooke, Québec

Reçu le 15 janvier 1964

ABSTRACT

The reactions of boron sulphide with some types of carbonyls have been studied. The reaction of boron sulphide with aromatic aldehydes and aliphatic aldehydes which have been deprived of active hydrogen in the α position gives a good yield of the corresponding trithioaldehydes. This reaction is examined for four aldehydes, namely, benzaldehyde, 3-methylbenzaldehyde, 3-nitrobenzaldehyde, and 2,2′-dimethylpropionaldehyde. Through this study the authors have brought out a method which enables either the α-trithiobenzaldehyde, m.p. 166–167 °C, or the β-trithiobenzaldehyde, m.p. 225–226 °C, to be obtained selectively. The reaction of 3-methylbenzaldehyde with boron sulphide yields only one β stereoisomer, but nitrobenzaldehyde remains completely inert. The aldehydes having one active hydrogen in the α position undergo a dehydrogenation at the same time as the oxygen is being replaced by one atom of sulphur. 2,2′-Dimethylthiopropanal exists in a trimeric state at normal temperatures and becomes monomeric at higher temperatures, whereas the trithiobenzaldehydes do not depolymerize. Methyl benzoate reacts with boron sulphide to give tetraphenyldioxadiene. The structure of this extremely inert substance has been established mainly by physical means: infrared, ultraviolet, and n.m.r. spectra. The reaction of benzophenone and acetophenone with boron sulphide has been investigated. The former has been found inert to the action of the sulphide, and the latter reacts quite readily to give 2,4-diphenylthiophene. The structure of this thiophene is established by desulphuration over nickel. The role of boron sulphide as dehydrogenating and deoxygenating agent is discussed, and a laboratory preparation of boron sulphide is described.

INTRODUCTION

La chimie du sulfure de bore n'a pas connu d'apports notables depuis les travaux de Moissan (1, 2) relatifs à la préparation et à la structure de ce composé.

Au cours d'une investigation systématique de l'interaction du sulfure de bore avec divers types de molécules organiques, nous avons voulu étudier le comportement du groupe carbonyle en présence de ce sulfure. Des tests préliminaires ont indiqué qu'un groupe carbonyle rattaché à une chaîne purement aliphatique donne avec le sulfure de bore une réaction relativement complexe, accompagnée à la fois de déshydrogénation indiquée par un dégagement de H_2S et de substitution du soufre à l'oxygène du groupe C=O démontrée par la disparition de la bande carbonyle chez le spectre infrarouge du produit de la réaction. Nous avons voulu aborder le problème par l'étude de carbonyles portés par des molécules à caractère aromatique, afin de prévenir si possible la déshydrogénation et d'observer uniquement la réaction carbonyle – sulfure de bore.

Réactions de quelques groupes carbonyles cétoniques

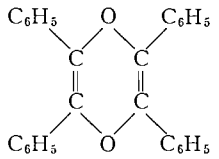
La première cétone étudiée, la benzophénone, s'est montrée tout à fait inerte vis-à-vis de ce sulfure. L'acétophénone, par contre, réagit énergiquement avec ce sulfure. La réaction est spontanée, s'accompagne d'un dégagement de H_2S et est complétée par un reflux. Au terme du reflux, la totalité du sulfure a réagi et s'est transformée en anhydride borique. De la fraction organique, il a été possible d'isoler un solide blanc, p.f. 121–122 °C, le diphényl-2,4 thiophène. Traitée par le nickel de Raney saturé d'hydrogène (3), cette molécule subit une désulfurisation accompagnée de dégagement de H_2S. Au terme de la réaction, on retrouve un hydrocarbure qu'on a identifié comme étant le diphényl-1,3 butane. La substance de dégradation présente les mêmes spectres dans l'infrarouge (4) et l'ultraviolet qu'un échantillon de diphényl-1,3 butane synthétique préparé à partir de

l'acétophénone et du phényl-2 éthanol-1. Les mesures par résonances magnétiques nucléaires confirment également l'identité du produit de dégradation au produit de synthèse.

Comme cette méthode de désulfurisation a souvent été employée sans que l'on note de réarrangements (5, 6), on peut donc conclure que le diphényl-1,3 butane est représentatif du squelette moléculaire de la substance p.f. 121–122 °C. Les eaux mères de la cristallisation du diphényl-1,3 thiophène à l'évaporation, laissaient un résidu résineux de couleur pourpre, répondant à la description donnée par Champaigne (7) pour la thioacétophénone. Cette substance polymérique dont le spectre infrarouge est dépourvu de bandes carbonyles donne un test positif pour le soufre.

Réaction du benzoate de méthyle

Nous avons constaté que certains esters réagissent avec le sulfure de bore, la réaction procédant selon le mode déjà indiqué, à savoir par une déshydrogénation et désoxygénation simultanées. Cette réactivité ayant été établie par des tests préliminaires, nous avons voulu préciser le comportement du benzoate de méthyle vis-à-vis de ce sulfure. Nous avons noté qu'à la température de reflux de l'ester, soit vers 200 °C, la réaction s'amorce subitement avec un dégagement assez abondant de H_2S. Après un contact prolongé, la masse réactionnelle est filtrée, et on note que le sulfure de bore s'est transformé en anhydride borique. La fraction liquide libère un solide blanc, qu'on a démontré être le tétraphényl-dioxadiène, I. La structure de cette substance, d'une grande stabilité, a pu être établie par



I

des mesures physiques, la dégradation chimique s'avérant inefficace.

Le spectre de résonance magnétique nucléaire révèle l'absence complète de protons aliphatiques dans la molécule, résultat en accord avec le spectre ultraviolet indiquant un système fortement conjugué (ϵ de 23 800 à 237 mμ) et les analyses élémentaires qui montrent une teneur assez faible en hydrogène (5.16%). Le spectre infrarouge présente les bandes propres à des C—H aromatiques dans les régions de 3060 cm^{-1} et 1500 cm^{-1}, et les bandes dans la région de 1050 cm^{-1} suggèrent un groupe éther sur la molécule. L'oxygène positivement indiqué par l'analyse élémentaire de I ne peut être qu'un oxygène de type éther, la possibilité d'un alcool ou d'un carbonyle étant définitivement éliminée par l'absence de bandes caractéristiques dans le spectre infrarouge, et la possibilité de peroxyde ou d'époxyde devant être rejetée par suite de l'inertie de I vis-à-vis l'hydrure de lithium et d'aluminium.

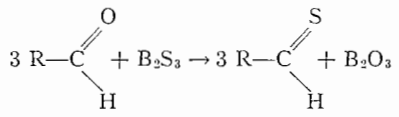
Le spectre de résonance magnétique nucléaire indique la présence de protons aromatiques (δ vers 7.0 p.p.m.). Cependant, au lieu du singlet normalement attendu pour les protons aromatiques portés par le noyau benzénique, on retrouve un triplet (δ = 6.9 p.p.m.) représentant 40% du total des protons et un singlet (δ = 7.1 p.p.m.) représentant 60% des protons. Le triplet à 6.9 p.p.m. ne peut indiquer des protons oléfiniques par suite de son intensité (40%). En effet, un tel pourcentage de ce type d'hydrogène apparaît inconciliable avec les analyses élémentaires et la grande inertie de la substance vis-à-vis les agents d'oxydation. Le dédoublement des bandes, qui ne peuvent être dues qu'à des protons

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

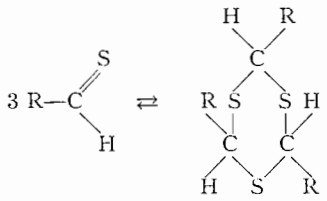
aromatiques, pourrait possiblement s'expliquer par un couplage entre les hydrogènes portés par les différents groupes benzéniques.

Réaction de quelques aldéhydes dépourvus d'hydrogène en α

Ayant constaté que les aldéhydes portant en position α un hydrogène actif subissent une déshydrogénation en même temps que la substitution de l'oxygène par un atome de soufre, nous avons choisi des aldéhydes dépourvus d'hydrogène actif tel que les aldéhydes benzoïques, méthyl-4 benzoïque, nitro-3 benzoïque et diméthyl-2,2 propionique. Tous ces aldéhydes simples tant aliphatique qu'aromatiques donnent une réaction exothermique avec le sulfure de bore conduisant à l'anhydride borique et au trithioaldéhyde correspondant. Cependant, le nitro-3 benzaldéhyde ne donne pas de réaction avec le sulfure de bore, sous les conditions expérimentales usuelles.



Les thioaldéhydes formés ont une grande tendance à se polymériser. En général, les trois molécules d'un monothioaldéhyde se condensent pour donner le trithioaldéhyde cyclique, composé alternativement de trois atomes de carbone et de trois atomes de soufre.



La trimérisation est fortement accélérée par la présence d'un catalyseur tel que l'acide chlorhydrique ou l'iode élémentaire (8). Dans le cas de l'aldéhyde diméthyl-2,2 thiopropionique, la forme trimérique peut être mise en équilibre avec le monomère par le chauffage. En effet, cet aldéhyde existe sous une forme de trimère à la température normale et devient monomérique à la température élévée. Cette transformation a été vérifiée par la détermination cryoscopique du poids moléculaire de ce thioaldéhyde dans le benzène et dans le camphre. Le poids moléculaire trouvé à 175 °C est bien près de celui du monomère (calculé pour le monomère: 102.2; trouvé: 112), mais il se rapproche beaucoup du trimère si on travaille dans le benzène à basse température (calculé pour trimère: 306.6; trouvé: 285). La forme trimérique des thioaldéhydes aromatiques n'admet pas l'équilibre avec la forme monomérique, la température de décomposition étant plus basse que la température de mise en équilibre.

Etant donné que chaque carbone de trithiobenzaldéhyde porte un atome d'hydrogène et un phényle, cette molécule existe sous deux formes stéréoisomériques α ou β, selon la position relative des trois phényles (9). La forme dite α (*cis*) de l'aldéhyde trithiobenzoïque est moins stable et par chauffage dans le chloroforme, dans le sulfure de carbone, ou dans le benzène se transforme, en présence d'un catalyseur (I_2), en isomère β (*trans*) plus stable. La transformation à l'état de solution est lente et incomplète, mais à l'état fondu la transformation est accompagnée d'une forte décomposition (10).

Forme α (*cis*) Forme β (*trans*)

Cependant, on a trouvé que les trithiobenzaldéhydes substitués ne présente qu'un seul stéréomère β (10).

Préparation des isomères α et β de l'aldéhyde trithiobenzoïque

Parmi les auteurs qui ont étudié la question des trithioaldéhydes, certains se sont intéressés à la transformation de l'isomère α en isomère β (8, 9, 10) ou à la réversibilité de ce phénomène et d'autres ont essayé la préparation sélective des deux stéréoisomères (10). Jusqu'ici, la recristallisation répétée du mélange qui se forme à partir du H_2S et de l'aldéhyde dans l'alcool éthylique saturé par l'acide chlorhydrique était le seul moyen pour obtenir l'isomère α de l'aldéhyde trithiobenzoïque. Mais par cette méthode, le rendement en isomère α est faible. En étudiant ce problème de la synthèse stéréoisomérique, nous avons constaté que la formation d'un ou de l'autre isomère de l'aldéhyde trithiobenzoïque peut être déterminée par la nature de l'énergie d'activation apportée au milieu réactionnel.

L'aldéhyde β-trithiobenzoïque

Ce thioaldéhyde se forme presque à l'état pur si la réaction du sulfure de bore avec l'aldéhyde benzoïque est activée par la chaleur. A cause de l'insolubilité du sulfure de bore dans le benzène, qui sert comme solvent, la réaction se passe en milieu hétérogène et par conséquent nécessite un long contact de deux réactifs pour être complète. L'ébullition dans le benzène du produit brut en présence des quelques cristaux d'iode ou de l'acide chlorhydrique assure l'absence complète d'isomère α dans le produit final.

L'aldéhyde α-trithiobenzoïque

La formation d'isomère α nécessite une source d'énergie plus riche. Dans ce but nous avons employé la lumière ultraviolette. Cette façon de procéder paraît une excellente méthode pour la préparation de l'aldéhyde α-trithiobenzoïque. Après la première recristallisation dans le benzène, la substance est déjà pure, comme l'indique son point de fusion.

Préparation du sulfure de bore

Parmi les différentes méthodes qui s'offrent pour la préparation du sulfure de bore: réaction d'échange de l'anhydride borique avec le sulfure d'aluminium (11), réaction du H_2S sur le bore élémentaire (12), et l'action du soufre sur le bore (1), cette dernière méthode a été trouvée la plus pratique, à l'échelle du laboratoire. Cette synthèse ne va pas sans certaines difficultés, car l'union directe des éléments ne débute que vers 650 °C et la réaction tend à s'emballer, par suite de son caractère exothermique. De plus, à ces températures, le sulfure de bore s'avère extrêmement corrosif, attaquant le verre du type "pyrex" ou "Vycor". Ces difficultés expérimentales (réaction explosive, corrosion) sont contrôlées en travaillant en présence d'un excès de soufre, que l'on peut ensuite enlever du produit réactionnel par des lavages au sulfure de carbone. Il nous a été ainsi possible de préparer le sulfure avec des rendements de l'ordre de 65–75%, le composé indiquant 85 à 90% de B_2S_3. Comme l'impureté principale dans le sulfure est constituée de bore élémentaire

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(10–12%) très inerte vis-à-vis les réactifs organiques, nous avons utilisé ce matériel tel quel sans qu'il ait été nécessaire de recourir à une purification plus poussée par sublimation.

Conclusions

L'action du sulfure de bore sur un groupe carbonyle est donc double. Elle implique une désoxygénation et parallèlement une déshydrogénation. Thermodynamiquement, la désoxygénation peut s'expliquer par la grande différence dans la chaleur de formation du sulfure de bore, −57.0 kcal/mole (13), et de l'anhydride borique, −302.0 kcal/mole (13). Cette différence rend compte de la stabilisation apportée au système par l'interchange d'un soufre pour un oxygène sur l'atome de bore.

L'utilisation du sulfure de bore comme agent de sulfuration des molécules organiques constitue une alternative intéressante à la méthode de Pall (14, 15) faisant appel au tri ou penta-sulfure de phosphore comme source de soufre.

Avec les carbonyles aldéhydiques dépourvus d'hydrogènes en α, la réaction s'arrête à un interchange de l'oxygène pour un soufre sur le fragment organique. Le mécanisme suivant lequel cet échange s'opère pourrait possiblement procéder par voie radicalaire, du fait de l'influence de l'irradiation ultraviolette sur l'orientation de la réaction. La forme α, rapportée par Baumann (9) comme correspondant à une structure *cis*, est produite par irradiation ultraviolette alors que la forme β (*trans*) résulte de l'action de B_2S_3 sur le benzaldéhyde en absence de cette source énergétique, et ce fait semble confirmer les conformations assignées par cet auteur à ces deux molécules. Car la forme *cis* (α) correspond à des interactions beaucoup plus importantes que la forme *trans* (β) (modèle Peterson). L'inertie du *p*-nitrobenzaldéhyde peut se comprendre en fonction d'une désactivation du carbonyle par le groupe nitré en position para ou peut résulter d'une action inhibitrice de ce dernier groupement dans l'alternative d'un mécanisme radicalaire. L'état actuel de la question ne permet pas d'opter pour l'une ou l'autre de ces possibilités.

Dans le cas des carbonyles ayant plusieurs hydrogènes portés en α, la substitution de l'oxygène au soufre sur le bore s'accompagne de modifications profondes des réactifs organiques et conduit à des composés fortement déshydrogénés. Bien qu'il soit difficile d'en préciser le mécanisme, un tel type de réaction présente un intérêt certain car il permet d'accéder à des structures nouvelles et difficiles à obtenir par d'autres voies, tel le tétraphényldioxadiène.

PARTIE EXPERIMENTALE*

1. Réaction du sulfure de bore avec des carbonyles cétoniques

1.1 Réaction du sulfure de bore en présence d'acétophénone

A une suspension de 32 g (0.27 mole) de sulfure de bore dans 100 ml de benzène anhydre, on ajoute 110 g (0.92 mole) d'acétophenone "Reagent". La réaction est spontanée à la température de la pièce et très exothermique, en absence de diluant. Suit un reflux de 48 heures, en milieu benzénique, accompagnée de dégagement de H_2S. Au terme de ce contact, le mélange réactionnel est filtré à chaud. Le résidu solide à la filtration qui ne renferme pas de sulfure de bore est constitué d'anhydride borique. Il demeure infondu à 360 °C, et le traitement par un peu d'eau bouillante (3 heures) le transforme en acide borique, p.f. 179–181 °C. Le filtrat, après concentration sous vide, est cristallisé dans l'éther. On retrouve ainsi, après traitement au charbon actif, 12.0 g (25% de la théorie en fonction de l'acétophénone utilisée) de plaquettes minces blanches, p.f. 121–122 °C. Calculé pour $C_{16}H_{12}S$: C, 81.34; H, 5.12; S, 13.54. Trouvé: C, 81.61; H, 5.02; S, 13.40. Spectre infrarouge (10% dans CCl_4, 0.1 mm): épaulement à 3100 cm^{-1}, bandes à 3068 cm^{-1} (moyenne), 3040 cm^{-1} (moyenne), 1599 cm^{-1} (moyenne-forte), 1486 cm^{-1} (moyenne-forte), 1449 cm^{-1} (moyenne), 1363 cm^{-1} (faible), 902 cm^{-1} (faible), 881 cm^{-1} (moyenne), 838 cm^{-1} (moyenne). Spectre ultraviolet (solution

**Les points de fusion ont été déterminés en tubes capillaires et ne sont pas corrigés. Les spectres infrarouges ont été mesurés à l'aide d'un spectromètre "Perkin-Elmer", modèle 125. Les spectres ultraviolets ont été déterminés à l'aide d'un spectromètre "Perkin-Elmer", modèle 4000. Les mesures de résonance magnétiquen ucléaire ont été effectuées à l'aide d'un appareil "Varian", modèle A-60. Les analyses élémentaires sont de C. Daessle, Montréal.*

4.36×10^{-5} *M* dans l'éthanol absolu à 25 °C): ϵ de 21 440 à 256 mμ; ϵ de 10 000 à 302 mμ. Spectre de résonance magnétique nucléaire: aucune absorption dans la région des protons aliphatiques; bandes multiples entre 7.17 et 7.70 p.p.m., ce qui indique des protons oléfiniques et aromatiques.

1.2 Désulfurisation du diphényl-2,4 thiophène

Une solution de 7.0 g (0.029 mole) du composé p.f. 121–122 °C dans 150 ml d'alcool absolu est traitée par 30 g de nickel de Raney saturé d'hydrogène. La solution est refluée pendant 21 heures. Le reflux s'accompagne d'un dégagement de H_2S. Le catalyseur est filtré, et le filtrat, après concentration sous vide, est doublé de volume par addition d'eau et extrait par l'éther. La solution éthérée est séchée sur chlorure de calcium et concentrée sous Widmer. Le résidu, après distillation pèse 5.0 g, soit 82% de la quantité théorique. Après redistillation sur sodium un échantillon analytique présente les constantes suivantes: éb. 145 °C/18 mm Hg; n_D^{21} 1.5535. Décrit pour le diphenyl-1,3 butane: éb. 150 °C/22 mm; n_D^{20} 1.5535. Spectre infrarouge (solution 10% dans CCl_4 cellule 0.1 mm): bandes à 3105 cm^{-1} (faible), 3083 cm^{-1} (moyenne), 3063 cm^{-1} (forte), 3028 cm^{-1} (forte), 2959 cm^{-1} (forte), 2923 cm^{-1} (forte), 2861 cm^{-1} (moyenne), 2858 cm^{-1} (moyenne). Spectre de r.m.n.: protons aliphatiques à 1.3 p.p.m. (CH_3), à 2.0 p.p.m. (CH_2), à 2.5 p.p.m. (CH), et à 7.1 p.p.m. (protons aromatiques).

1.2.1 Préparation du diphényl-1,3 butane

On prépare le chloro-1 phényl-2 éthane par l'action de 50 g (0.42 mole) de chlorure de thionyle sur 50 g (0.41 mole) de phenyl-2 éthanol-1, à reflux. Par distillation on retrouve 33 g (0.24 mole) du dérivé halogéné cherché; éb. 80 °C/10 mm; décrit, 86 °C/12 mm. Ce dérivé halogéné dans l'éther 33 g (0.24 mole) est ajouté à une suspension de 5.6 g (0.23 mole) de magnésium dans l'éther. Après la mise en solution du métal, une solution éthérée contenant 30 g (0.25 mole) d'acétophénone est ajoutée au magnésium. Les opérations habituelles conduisent au diphényl-1,3 butanol-3, 50 g (0.22 mole) qui est immédiatement déshydraté par l'acide phosphorique 85%, à 170 °C.

Le produit de la déshydratation, après chromatographie sur alumine (alumine Woehm, activité 1, élution par éther de pétrole, éb. 30–40 °C) est hydrogéné en présence de nickel de Raney, à la pression atmosphérique. Le produit saturé, (41 g, 0.19 mole) est chromatographié sur alumine Woehm (activité 1, élution par l'éther de pétrole, éb. 30–40 °C) et redistillé deux fois sur sodium; éb. 149 °C/20 mm, n_D^{21} 1.5535. Spectre infrarouge (solution 10% dans CCl_4, cellule 0.1 mm): bandes à 3105 cm^{-1} (faible), 3083 cm^{-1} (moyenne), 3063 cm^{-1} (forte), 3028 cm^{-1} (forte), 2959 cm^{-1} (forte), 2923 cm^{-1} (forte), 2861 cm^{-1} (moyenne), 2858 cm^{-1} (moyenne). Spectre de résonance magnétique nucléaire: protons aliphatiques à 1.3 p.p.m. (CH_3), à 2.0 p.p.m. (CH_2), à 2.5 p.p.m. (CH), et à 7.1 p.p.m. (protons aromatiques).

1.3 Réaction du sulfure de bore avec la benzophénone

Une solution de 14 g (0.77 mole) de benzophénone dans 125 ml de benzène anhydre est refluée pendant 43 heures en présence de 8.5 g (0.073 mole) de sulfure de bore. La solution se colore en bleu au cours du reflux. La masse réactionelle est filtrée. La fraction solide semble être en quasi totalité du sulfure de bore non réagi (réaction violente de ce résidu avec l'eau). La fraction liquide est distillée sous vide à la température de la pièce pour éliminer le benzène, et le résidu est fractionné sous vide. On retrouve une seule fraction, éb. 160–165 °C/13 mm, p.f. 43–45 °C, représentant 94% du poids de substance mis en expérience. Décrit pour la benzophénone: éb. 172 °C/19 mm, p.f. 45–48 °C. Les spectres infrarouges d'un échantillon authentique de benzophénone et de cette fraction sont identiques.

2. Réaction du sulfure de bore avec un carbonyle ester

2.1 Réaction du sulfure de bore en présence de benzoate de méthyle

On chauffe à reflux (200 °C), pendant 28 heures, en atmosphère inerte, une suspension de sulfure de bore finement pulvérisé (21.0 g, 0.18 mole) dans 75 g (0.55 mole) de benzoate de méthyle redistillé. Après un contact de quelques minutes à la température de reflux, la réaction s'amorce brusquement et s'accompagne d'un abondant dégagement de H_2S. Cette évolution gazeuse se maintient, en diminuant, tout au long de la réaction. Après ce contact, la masse réactionelle est filtrée à chaud, et la fraction solide est lavée par 20 ml de benzoate de méthyle bouillant. Cette fraction solide ne renferme plus de sulfure de bore mais s'avère être de l'anhydride borique. Le filtrat est concentrée sous vide, et le résidu, repris par de l'éthanol, est cristallisé dans ce solvant après traitement au charbon actif. On retrouve ainsi 11.3 g (0.029 mole, 30% de la théorie, en fonction du benzoate de méthyle utilisé) de fines aiguilles blanches, p.f. 184–185 °C. Spectre infrarouge (solution à 10% dans le tétrachlorure de carbone, cellules 0.1 mm, KBr): bandes à 3078 cm^{-1} (faible), 3059 cm^{-1} (moyenne), 3022 cm^{-1} (faible), 1598 cm^{-1} (moyenne), 1574 cm^{-1} (très faible), 1493 cm^{-1} (moyenne), 1476 cm^{-1} (moyenne), 1441 cm^{-1} (moyenne), 1069 cm^{-1} (faible), 1025 cm^{-1} (faible), 912 cm^{-1} (très faible), 905 cm^{-1} (très faible). Spectre ultraviolet (éthanol absolu): ϵ de 23 800 à 237 mμ. Spectre de résonance magnétique nucléaire (solution à 10% dans le tétrachlorure de carbone, référence tétraméthylsilane): absence de protons aliphatiques; triplet à $\delta = 6.9$ p.p.m. (40% du total des protons) et singlet à $\delta = 7.1$ p.p.m. (60% du total des protons). Calculé pour $C_{28}H_{20}O_2$: C, 86.57; H, 5.19; O, 8.24. Trouvé: C, 87.08; H, 5.16; O, 8.31. Poids moléculaire (méthode de Rast): calculé 388.4; trouvé 427.

2.2 Dégradation de la substance p.f. 184–185 °C

Cette substance semble extrêmement résistante aux agents de réduction. Ainsi, le diborane, sous les conditions expérimentales usuelles (16) est sans effet sur le composé que l'on récupère quantitativement au

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

terme de la réaction (p.f. du produit brut traité par le diborane, 182–183 °C). De même, l'hydrure de lithium et d'aluminium n'affecte pas le produit que l'on retrouve intact après un reflux de 8 heures, dans l'éther éthylique en présence de $LiAlH_4$. L'oxydation également ne va pas sans difficulté. L'acide nitrique 20% bouillant (reflux de 24 heures) n'attaque pas la molécule, de même que le peroxyde d'hydrogène 30% (reflux de 2 heures). Le permanganate de potassium en milieu alcalin et le bichromate de sodium en milieu acide sont également sans effet. L'inertie de la substance vis-à-vis ces réactifs d'oxydation peut s'expliquer, en partie, par sa grande insolubilité en milieu aqueux. L'oxydation par CrO_3 en milieu acétique a donné, avec difficulté, de faibles rendements (3–5%) en acide benzoïque.

L'action de l'acide iodhydrique ou de l'iodure d'acétyle (17) visant à effectuer l'ouverture d'un éther sur la substance I n'a pas conduit à des espèces purifiables par les techniques usuelles.

3. Préparation des trithioaldéhydes

3.1 β-Trithiobenzaldéhyde

Dans un ballon de 1/2 litre on introduit 23.7 g (0.2 mole) de sulfure de bore et 100 ml de benzène anhydre séché sur la colonne d'oxyde d'aluminium. Le sulfure de bore est maintenu en suspension par une agitation magnétique, et une solution de 29 g (0.27 mole) d'aldéhyde benzoïque dans 100 ml du benzène anhydre est ajoutée goutte à goutte. Pour éviter l'oxidation de l'aldéhyde benzoïque par l'oxygène de l'air et la décomposition du sulfure de bore par l'humidité, le milieu réactionnel est maintenu sous l'atmosphère de l'azote sec. Au cours de l'addition d'aldéhyde, le ballon se réchauffe sensiblement et le benzène se colore légèrement rouge-brun. Quand toute la quantité de réactif est introduite, le mélange est agité et chauffé à reflux du benzène pendant 20 heures.

Le mélange réactionnel est alors filtré à chaud sur l'amiante et refroidi. Les cristaux formés dans le filtrat sont séparés par la filtration et bouillis dans le benzène, en présence de quelques miligrammes d'iode, pendant deux heures pour s'assurer que l'isomère α de l'aldéhyde trithiobenzoïque est transformé complètement en isomère β. Après refroidissement les cristaux sont filtrés et recristallisés dans le benzène. Une nouvelle filtration à froid donne l'aldéhyde β-trithiobenzoïque pur. Cette substance se présente sous forme d'aiguilles blanches très stables et sans odeur. P.f. 225–226 °C. Rdt. 85–90%. Calculé pour $(C_6H_5CHS)_3$: C, 68.81; H, 4.95%; S, 26.24. Trouvé: C, 69.03; H, 5.01; S, 26.10.

3.2 α-Trithiobenzaldéhyde

12 g (0.10 mole) de sulfure de bore est mis en suspension, par une agitation magnétique, dans 100 ml du benzène anhydre. La quantité stoechiométrique de l'aldéhyde benzoïque, préalablement dissout dans 50 ml du benzène anhydre, est ajouté goutte à goutte. Le ballon contenant le mélange réactionel est éclairé par une lampe U.V. (3660 Å) et la solution benzénique portée à ébullition. Après 20 heures environ la réaction est terminée. Le mélange est filtré à chaud sur l'amiante, et le produit formé par refroidissement du filtrat est séparé par une nouvelle filtration. Recristallisé dans le benzène, l'aldéhyde α-trithiobenzoïque précipite sous forme d'aiguilles blanches. P.f. 166–167 °C. Rdt. 90%. Calculé pour $(C_6H_5CHS)_3$: C, 68.81; H, 4.95; S, 26.24. Trouvé: C, 68.92; H, 4.97; S, 26.18.

3.3 Méthyl-3 trithiobenzaldéhyde

En utilisant la même technique que pour la synthèse de l'aldéhyde β-trithiobenzoïque (excepté la transformation catalytique), 12 g (0.10 mole) l'aldéhyde méthyl-3 benzoïque est transformé en trithioaldéhyde correspondant. P.f. 208–210 °C. Rdt. 80–85%. Calculé pour $(CH_3C_6H_4CHS)_3$: S, 23.51. Trouvé: S, 23.72.

3.4 Nitro-4 trithiobenzaldéhyde

15.1 g (0.1 mole) de nitro-4 benzaldéhyde est mis en contact pendant 24 heures avec le sulfure de bore dans les mêmes conditions que l'aldéhyde méthyl-3 benzoïque. Puis le mélange est filtré à chaud et le filtrat refroidi. La précipitation n'apparaît pas. On chasse le benzène sous pression réduite, à température peu élevée. Après évaporation à sec, l'huile jaune restante cristallise; p.f. 50 °C. Le produit est ensuite dissout dans le benzène, décoloré au noir animal, et récupéré par évaporation du solvant; p.f. 52–53 °C. D'après le point de fusion, le produit obtenu est donc l'aldéhyde nitro-4 benzoïque (p.f. 53 °C) inchangé, dont ont retrouve 95% de la quantité mise en expérience.

3.5 L'aldéhyde diméthyl-2,2 trithiopropionique

A une suspension de 7.2 g (0.06 mole) de sulfure de bore dans 30 ml de benzène anhydre, on ajoute sous bonne agitation une solution de 10.0 g (0.16 mole) de l'aldéhyde diméthyl-2,2 propionique dans 20 ml du même solvant. On opère en atmosphère d'azote sec. La réaction s'accompagne d'un léger échauffement de la solution benzénique et dégage une très faible quantité d'acide sulfhydrique. Ce gaz est déterminé sous forme de sulfure de plomb en barbottant le courant d'azote à la sortie de l'appareil dans une solution à 10% d'acétate de plomb.

Après addition de l'aldéhyde suit un léger reflux pendant 18 heures. Le sulfure de plomb ainsi formé pèse 1.42 g. (0.006 mole) après filtration et séchage à poids constant à 100 °C. Le mélange réactionnel est alors filtré et le filtrat concentré par évaporation sous vide. On retrouve ainsi 9.6 g d'une huile rouge foncé qui cristallise lentement. Le solide était extrait par de l'éther de pétrole éb. 30–40 °C et cette solution éthérée passée sur une colonne à chromatographie (50 g d'alumine Woehm neutre, activité 1). L'éther de pétrole élue 8.9 g d'un solide rougeâtre que l'on recristallise dans le même solvant. On trouve ainsi 6.1 g (0.06 mole)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

de fines aiguilles blanches, p.f. 110-112 °C, qui s'avèrent être l'aldéhyde diméthyl-2,2 trithiopropionique. Poids moléculaire par méthode de Rast à 175 °C, 112; par cryoscopie dans le benzène à 10 °C, 285. Calculé pour $C_5H_{10}S$: PM = 102.20; C, 58.76; H, 9.86; S, 31.38. Trouvé: C, 58.56; H, 9.77; S, 31.20.

4. Préparation du sulfure de bore

Une portion d'environ 40 g d'un mélange bien homogène de bore élémentaire 98% (1 mole) finement pulvérisé et de soufre pulvérisé (1.5 mole) est introduite dans une éprouvette en verre épais, 25 mm × 200 mm. L'éprouvette, maintenue inclinée à 45° est purgée par un lent courant d'azote et bouchée par un tampon de laine de verre. Le mélange est alors fondu et chauffé également jusqu'à inflammation de la masse réactionnelle. Le chauffage est ajusté de façon à maintenir la masse au rouge, pendant quelques minutes. Après refroidissement, l'éprouvette est brisée pour libérer le culot de sulfure de bore brut, qui est pulvérisé à l'aide d'un pulvérisateur "Waring Blendor" à l'abri de l'humidité. Suivent trois lavages par le sulfure de carbone anhydre, afin d'enlever le soufre contaminant le sulfure. On obtient ainsi une fine poudre noire extrêmement hygroscopique, qui représente 65–75% de la théorie, le principal facteur d'abaissement du rendement étant la sublimation du sulfure, au cours de sa formation à haute température. Le titre en sulfure de bore du produit de la réaction est déterminé par hydrolyse au moyen de l'eau et détermination du H_2S sous forme de sulfure de plomb, à partir d'une solution à 10% d'acétate de plomb. Au cours d'une expérience typique, un échantillon de 1.00 g de sulfure donne 5.20 g de sulfure de plomb, soit un titre de 85%. L'impureté principale du sulfure est constituée de bore élémentaire (10–12%) isolé en hydrolysant un échantillon de 1.00 g de sulfure par large excès d'eau bouillante. Le résidu à la filtration de cette solution pèse de 0.100 à 0.120 g suivant les échantillons et est identique au bore élémentaire utilisé pour la préparation du sulfure.

REMERCIEMENTS

Les auteurs remercient le "Defence Research Board of Canada" (J. M. L., octroi No. 9530-30) et le Conseil National de Recherches du Canada (S. J.) de leur assistance financière, ainsi que le professeur J. C. Richer, de l'Université de Montréal, qui a bien voulu effectuer les mesures de résonance magnétique nucléaire.

AZOXYCOMPOUNDS

I. THE PHOTOLYSIS OF AZOXYMETHANE[1]

B. G. GOWENLOCK[2]
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received March 31, 1964

ABSTRACT

A study of the photolysis of azoxymethane has been made. The reaction products include nitrogen, nitrous oxide, methane, and ethane. The ratio N_2:N_2O is independent of temperature and two primary photolytic processes are postulated to account for this fact. On the assumption that methane arises from the reaction $CH_3 + CH_3N_2OCH_3 \rightarrow CH_4 + CH_2N_2OCH_3$, the activation energy of this reaction is 6 ± 2 kcal/mole. Other reactions that take place during the photolysis are discussed.

INTRODUCTION

Azoxymethane and other azoxyalkanes were prepared by Langley, Lythgoe, and Rayner in 1952 (1). A survey of the literature indicates that little attention has been directed to these compounds, the bulk of the published work relating to aromatic azoxyalkanes. By analogy with azoalkanes, it is expected that the primary photolytic (2) and pyrolytic (3) processes will produce two radicals and nitrous oxide. Thus for azoxymethane we expect the reaction [1] to occur.

[1] $$CH_3{-}\underset{\underset{O}{\downarrow}}{N}{=}N{-}CH_3 \xrightarrow{h\nu} CH_3 + N_2O + CH_3.$$

EXPERIMENTAL

Materials

Azoxymethane was prepared by Dr. L. C. Leitch and Mr. N. Kraut by the literature method (1). It was a colorless, mobile liquid with a vapor pressure of about 20 mm at 20 °C. A sample was vaporized and its ultraviolet spectrum determined with a Cary recording spectrophotometer. This spectrum was similar to that given for an ethanol solution (1) and the wavelength of maximum absorption was 212–213 mμ (217 mμ in ethanol (1)). Reference samples of other materials for mass spectrometry and gas chromatography were provided by Dr. F. P. Lossing.

Apparatus

A conventional photolysis apparatus was used. The light source was a Hanovia S-500 medium pressure mercury arc operated on a regulated supply. It was used without filter or lens in order to allow sufficient products to be accumulated in a run of one hour's duration. The beam of light from the lamp passed through two copper tubes, which connected the lamp to the reaction vessel (5 cm diameter and 15 cm length). A piece of thick cardboard could be inserted between the two tubes in order to shut off the arc from the reaction vessel. The reaction vessel could be heated electrically and was mounted in a hot box. The reaction system was isolated from the reactant reservoir gas analysis apparatus and main vacuum line by greaseless mercury cut-offs. Pressures of reactants were measured by means of a spiral gauge, mounted within the hot box, and used as a null instrument in conjunction with a mercury U-tube manometer.

Procedure and Analysis

Thoroughly degassed azoxymethane was admitted to the reaction vessel and the pressure measured. The light beam was allowed to enter the reaction vessel and the run allowed to proceed for 1 h. The products of the run were trapped out at liquid nitrogen temperatures and the remaining noncondensable gases transferred to a combined Toepler/gas burette. After the quantity of the gas was measured, the sample was transferred to a mass spectrometer sampling tube. On occasion a portion was also transferred to a

[1]*Issued as N.R.C. No. 7984.*
[2]*Visiting Scientist, N.R.C., 1963. Permanent address: Department of Chemistry, University of Birmingham, Birmingham, England.*

crusher tube for gas chromatographic analysis using a zeolite column. Further fractions were taken into the Toepler/gas burette, measured, and analyzed. The temperatures and analytical techniques employed were: −160° (mass spectrometry), −131°, −78°, and room temperature (gas–liquid chromatography). All gas–liquid chromatographic analyses were carried out on a Perkin–Elmer fractometer, using a 1 m column of Carbowax 1500 on powdered teflon, helium carrier gas, 50 °C, flow rate 150 cc/min.

RESULTS AND DISCUSSION

The most volatile reaction products were nitrogen, nitrous oxide, methane, and ethane. It was shown by both mass spectrometry and gas chromatography that hydrogen, oxygen, and nitric oxide were absent from the reaction products. The azoxymethane concentration was not varied significantly; the temperature was varied from 27° to 121°, and the ratio N_2:N_2O remained constant at 0.20 ± 0.02 (8 runs). This constancy suggests that the nitrogen is produced by a primary process and the simplest reaction that can be written to account for this is:

[2] $$CH_3{-}\underset{\underset{O}{\downarrow}}{N}{=}N{-}CH_3 \xrightarrow{h\nu} CH_3 + N_2 + OCH_3.$$

Reaction [2] is presumed to take place simultaneously with reaction [1]. Further support for the occurrence of nitrogen elimination from azoxymethane is given by pyrolyzing azoxymethane on a heated quartz surface ($\simeq$ 600 °C) in the inlet of a mass spectrometer, where the primary decomposition process [3] takes place,

[3] $$CH_3{-}\underset{\underset{O}{\downarrow}}{N}{=}N{-}CH_3 \rightarrow CH_3OCH_3 + N_2,$$

and any production of methyl radicals is consequent upon decomposition of the dimethyl ether. (The author is indebted to Dr. F. P. Lossing for this observation.) In addition, pyrolysis of a sample of azoxymethane at about 340 °C for 3.5 h produced nitrogen and nitrous oxide in the ratio 0.92, again indicating the importance of nitrogen production. These observations were contrary to our initial expectation and further investigation is underway. We are unaware of any evidence in the literature for thermal or photolytic production of nitrogen from azoxy compounds, and note that the reaction [2] is more favorable thermochemically than reaction [1] by about 50 kcal/mole (4).

Methane and ethane are prominent reaction products and it is likely that these will be produced from reactions [4] and [5] respectively.

[4] $$CH_3 + CH_3{-}\underset{\underset{O}{\downarrow}}{N}{=}N{-}CH_3 \rightarrow CH_4 + CH_2{-}\underset{\underset{O}{\downarrow}}{N}{=}N{-}CH_3 \text{ (or } CH_3{-}\underset{\underset{O}{\downarrow}}{N}{=}N{-}CH_2\text{)}.$$

[5] $$CH_3 + CH_3 \rightarrow C_2H_6.$$

Consequently, preliminary values have been obtained for the kinetic parameters of reaction [4], $E_4 = 6\pm2$ kcal/mole, $P_4 \simeq 10^{-2}$. It is to be emphasized that these are only preliminary values; it is hoped to obtain a greater number of points over a wider range of experimental conditions. These values compare favorably with those obtained (2) for the comparable reaction [6], $E_6 = 7.6\pm0.2$ kcal/mole, $P_6 \simeq 10^{-3}$.

[6] $$CH_3 + CH_3N{=}NCH_3 \rightarrow CH_4 + CH_2N{=}NCH_3.$$

The ratio $(\frac{1}{2}CH_4 + C_2H_6)/N_2O$ was less than unity and decreased smoothly from about 0.74 at 27° to 0.39 at 121°. Admittedly, this approach to the product balance ignores the contribution of reaction [2], but it makes possible a comparison with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

azomethane results (2) where the corresponding ratio fell from 0.85 at room temperature to 0.28 at 128°. It was therefore expected that methyl radicals would add to azoxymethane in similar fashion to the azomethane reactions, i.e., [7] and [8] and (or) [9] and [10].

[7] $$CH_3 + CH_3{-}\underset{\underset{O}{\downarrow}}{N}{=}N{-}CH_3 \rightarrow CH_3{-}\underset{\underset{CH_3O}{|}}{N}{-}N{-}CH_3.$$

[8] $$CH_3 + CH_3{-}\underset{\underset{CH_3O}{|}}{N}{-}N{-}CH_3 \rightarrow CH_3{-}\underset{\underset{CH_3O}{|}}{N}{-}N{-}(CH_3)_2.$$

[9] $$CH_3 + CH_3{-}\underset{\underset{O}{\downarrow}}{N}{=}N{-}CH_3 \rightarrow CH_3{-}\underset{\underset{O}{|}}{N}{-}N{-}(CH_3)_2.$$

[10] $$CH_3 + CH_3{-}\underset{\underset{O}{|}}{N}{-}N{-}(CH_3)_2 \rightarrow CH_3{-}\underset{\underset{CH_3O}{|}}{N}{-}N{-}(CH_3)_2.$$

Mass spectrometric investigations of the fractions resolved from g.l.c. analysis of the less volatile reaction products gave no peaks above 80 implying the absence of trimethyl methoxyhydrazine. It is possible that trimethylhydroxylamine (cracking pattern due to Bromberger and Phillips (5)) is formed, and also an azocompound $CH_3{-}N{=}N{-}OCH_3$. Discussion of routes to such products is postponed pending further more detailed investigation of the photolysis, and of reaction products from reaction of methyl radicals with azoxymethane. Methyl alcohol and trace quantities of dimethyl ether were identified from g.l.c. analysis.

A referee has suggested that nitrogen elimination could proceed by reaction [11],

[11] $$CH_3{-}\underset{\underset{O}{\downarrow}}{N}{=}N{-}CH_3 \xrightarrow{h\nu} O + CH_3{-}N{=}N{-}CH_3,$$

followed by photolysis of the azomethane to give nitrogen and hydrocarbon products. This possibility cannot be eliminated completely, but there is some evidence to suggest that it is unlikely. At least some tetramethylhydrazine would be expected as a reaction product, and the absence of peaks above 80 in the mass spectrum of the less volatile products is difficult to reconcile with the presence of azomethane implied by reaction [11]. Reaction [2] is more favorable than reaction [11] by about 70 kcal/mole. If reaction [11] does occur then the absence of oxygen and nitric oxide in the reaction products can be regarded as evidence for the absence of reactions [12] and [13] (because of unfavorable energy requirements, E_{12} and E_{13} being of the order 20 kcal/mole (6)),

[12] $$O + N_2O \rightarrow 2NO$$

[13] $$O + N_2O \rightarrow N_2 + O_2,$$

and the absence of oxygen atom recombination reactions. Photolysis of azoxymethane – nitric oxide mixtures and analysis for nitrogen dioxide reaction product may answer this problem, provided that there is no methyl radical catalyzed disproportionation of the nitric oxide under these reaction conditions. Further evidence against reaction [11] is to be found in the methyl alcohol reaction product of which the methoxy radical is the obvious precursor.

ACKNOWLEDGMENTS

The author is indebted to the National Research Council for the award of the post of visiting scientist during the tenure of which this work was carried out. He wishes to

FURTHER EVIDENCE FOR THE DIENONE-IMINE INTERMEDIATE IN THE FISCHER INDOLE SYNTHESIS

AN UNCATALYZED FISCHER REACTION UNDER MILD CONDITIONS[1]

F. P. ROBINSON[2] AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta

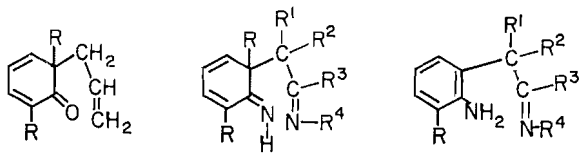
Received March 9, 1964

ABSTRACT

Evidence has been presented for the transient formation of a dienone-imine intermediate in the Fischer indole synthesis analogous to the dienone intermediate found in the Claisen rearrangement. The isolation of methylamine hydrochloride, 8-chloro-1,2,3,4-tetrahydrocarbazole, and 5-amino-6-chloro-9-methyl-1,2,3,4-tetrahydrocarbazole from the room temperature, uncatalyzed condensation between cyclohexanone and N′-methyl-2,6-dichlorophenylhydrazine under enamine synthesis conditions can be rationalized only on the assumption of the occurrence of a dienone-imine intermediate. An example of a facile, uncatalyzed Fischer cyclization at room temperature has been described.

INTRODUCTION

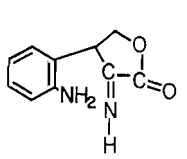
Carlin and Fisher (1) have pointed out the close analogy between the mechanism of the Claisen rearrangement (2, 3) and the Robinson mechanism (4) for the Fischer indole synthesis.* A discussion of the Fischer indole synthesis with particular reference to the mechanistic aspect has appeared recently (5). Although the dienone intermediate (I, R = CH_3) has been isolated as the Diels–Alder adduct (6) and has actually been prepared and shown to be a true intermediate in the Claisen rearrangement (7, 8), isolation of the analogous dienone-imine (II, R = CH_3) from the Fischer reaction has not yet been achieved.



I II III

There are, however, several instances in which a compound of structure III (R = H) has actually been obtained from the Fischer cyclization. Such a compound (III) could quite logically arise from a dienone-imine precursor (II, R = R^4 = H) in which aromatization occurred very rapidly and unavoidably by a tautomeric shift of the hydrogen atom. The isolation of the sparingly soluble hydrochloride of the compound α-amino-β-(*o*-aminophenyl)-γ-butyrolactone (IV) from the cyclization of α-keto-γ-butyrolactone phenylhydrazone (9, 10) and of 3-acetylamino-2-(*o*-aminophenyl)-butene-2 (V) from the treatment of 2-(N,N′-diacetyl-β-phenylhydrazino)-butene-2 (VIII) with hot aqueous potassium hydroxide (11) are specific cases which illustrate this point.

[1]*Taken from the thesis of F. P. Robinson submitted to the Faculty of Graduate Studies of the University of Alberta in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*
[2]*Present address: Department of Chemistry, University of Victoria, Victoria, B.C.*
**A. A. Arbuzov and Y. P. Kitaev, J. Gen. Chem. U.S.S.R. 27, 2388 (1957), have stated that both the Claisen rearrangement and the Fischer indole synthesis are specific cases of the general intramolecular rearrangement in a polarized 1,6-conjugated system.*

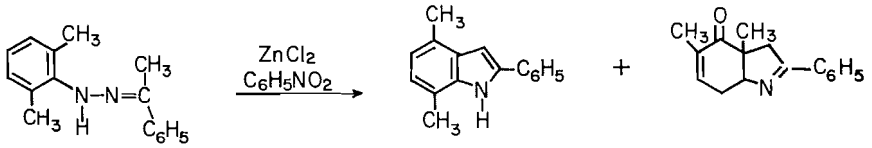


IV

V

There have been reported, also, a number of products obtained from the reaction of phenylhydrazones under Fischer cyclizing conditions which are readily explained only on the basis of a dienone-imine intermediate (II). Examples of these are the isolation of 5,7-dihaloindoles resulting from the halogen migration and interchange during the reaction of 2,6-dihalophenylhydrazones in the presence of zinc halides (1, 12, 13), and of both 2-phenyl-3*a*, 5-dimethyl-3*a*,4,7,7*a*-tetrahydro[3H]pseudoindolone-4 (VI) and the methyl migration product 4,7-dimethyl-3-phenylindole (VII) from the reaction of acetophenone 2,6-dimethylphenylhydrazone in the presence of zinc chloride (14) (equation *a*).

(a)



VII VI

An attempt was made by Carlin *et al.* (15) to trap the dienone-imine "intermediate" in the zinc chloride catalyzed reaction of ethyl pyruvate 2,6-dimethylphenylhydrazone as the Diels–Alder adduct with maleic anhydride as had been done by Conroy and Firestone for the Claisen rearrangement of allyl 2,6-dimethylphenyl ether (6). However, no product was obtained indicative of such an adduct, a result considered to be due to the much more rapid conversion of the dienone-imine intermediate into the indole (15). To our knowledge, no other attempt to secure the dienone-imine intermediate has been reported.

This paper describes the isolation from the Fischer indole synthesis of certain products, the formation of which can be rationalized only on the basis of a dienone-imine intermediate.

RESULTS AND DISCUSSION

The isolation from the acid-catalyzed reaction between methyl ethyl ketone phenylhydrazone and acetic anhydride (11) of 2-(N,N′-diacetyl-β-phenylhydrazino)-butene-2, (VIII), which is the diacetylated enamine considered to be the first stage of the Robinson mechanism for the Fischer indole synthesis (4), has suggested the preparation of enamines as starting materials for indole formation. Since such an enamine is one step along in the accepted scheme for Fischer indole synthesis, subsequent conversion of this enamine to an indole might be relatively easily accomplished. Suvorov (11) has shown that acid catalysis is not necessary, although probably helpful, for the second stage of the Fischer indole synthesis; that of conversion of the enamine (VIII) to (IX), the compound analogous to the product of ortho benzidine rearrangement. He found that (IX) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

(b) 
VIII IX

obtained by heating the intermediate diacetyl compound (VIII) in refluxing aqueous sodium hydroxide (equation *b*). Thus, if a suitable enamine were prepared, it might be readily converted to the indole merely by exposure to moderate heat. If, in addition, the 2 and 6 positions of the phenyl group are blocked by substituents which would prevent rapid aromatization (II → III, R = H), it might thus be possible to form, and either retain or trap, the dienone-imine under mild conditions (equation *c*). For the present

(c) 
X XI

work, the 2,6-dichlorophenylhydrazine rather than the 2,6-dimethylphenylhydrazine was chosen in view of the latter's well-known instability in air (14). To ensure enamine formation, this hydrazine was converted to the N′-methyl derivative (X).

Formylation of 2,6-dichlorophenylhydrazine (1) with formamide in acetic acid (16) rather than with 50% formic acid (17) gave a good yield of N′-formyl-2,6-dichlorophenylhydrazine which, even with excess methyl sulphate, gave only the monomethyl derivative, N′-formyl-N′-methyl-2,6-dichlorophenylhydrazine (XII). Elemental analysis and a nuclear magnetic resonance spectrum agreed with this structure. Additional proof that the methyl group was on the nitrogen atom remote from the phenyl substituent was obtained by reduction of the formylated hydrazine with Raney nickel and hydrazine (18) to 2,6-dichloroaniline (equation *d*).

(d) 
XII

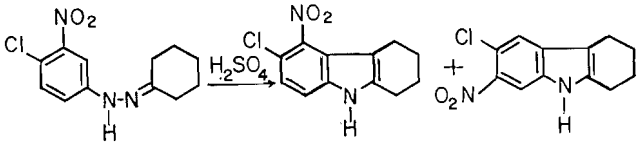
When N′-methyl-2,6-dichlorophenylhydrazine was condensed with cyclohexanone under conditions advocated for enamine preparation (19), using a Dean–Stark apparatus (20) to collect the water removed azeotropically by boiling benzene, a precipitate of methylamine hydrochloride appeared. From the residual dark oil obtained after removal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of the hydrochloride and the benzene, no pure compound could be isolated. However, the formation of methylamine hydrochloride indicated that a reaction had occurred, in all likelihood forming an indole, since the β-nitrogen atom in hydrazones is eliminated as ammonia during the Fischer cyclization to indoles (21, 32). When the enamine formation was repeated, but this time, to avoid decomposition of products, with the reaction temperature maintained at about 20° by removal of the benzene and water under vacuum with a rotary evaporator, methylamine hydrochloride was again obtained (~15% yield). The residual yellow oil, left after removal of the precipitate and the solvent, when passed through a column of neutral alumina with Skellysolve B as eluant, afforded a 14% yield of a compound which proved to be identical in all respects with an authentic sample of 8-chloro-1,2,3,4-tetrahydrocarbazole (12). Further elution with a 1:1 mixture of Skellysolve B and benzene gave a compound whose elemental analysis and n.m.r. spectrum agreed with the structure 5-amino-6-chloro-9-methyl-1,2,3,4-tetrahydrocarbazole (XVI).

An authentic sample of this compound was prepared from the mixture obtained by Plant and Rosser's (22) cyclization of cyclohexanone 4-chloro-3-nitrophenylhydrazone. Of the two possible products of this reaction, 6-chloro-5-nitro-1,2,3,4-tetrahydrocarbazole and 6-chloro-7-nitro-1,2,3,4-tetrahydrocarbazole (equation *e*), one was later identified (23) as the 6-chloro-5-nitro-1,2,3,4-tetrahydrocarbazole (XIII) by its reduction with tin

(e)

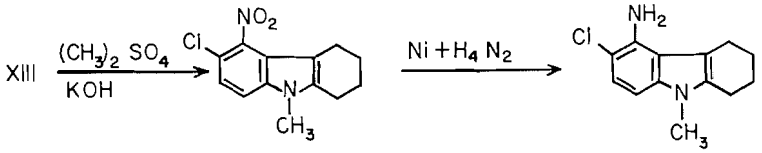


XIII XIV

and hydrochloric acid to the known 5-amino-1,2,3,4,4*a*,9*a*-hexahydrocarbazole. The other isomer, (XIV), must then be the 6-chloro-7-nitrotetrahydrocarbazole.

Compound (XIII) was first converted to the N-methyl derivative (XV) and then reduced with Raney nickel and hydrazine (24) to 5-amino-6-chloro-9-methyl-1,2,3,4-tetrahydrocarbazole (XVI) (equation *f*).

(f)



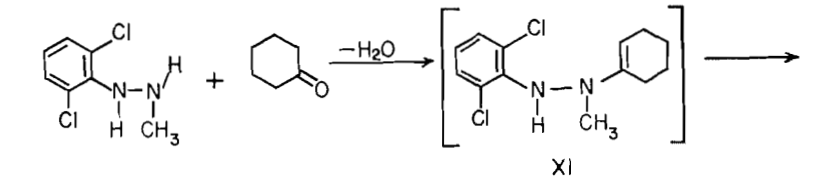
XV XVI

The overall reaction between cyclohexanone and N′-methyl-2,6-dichlorophenylhydrazine can be represented by equation *g*. No enamine corresponding to structure (XI) was obtained.

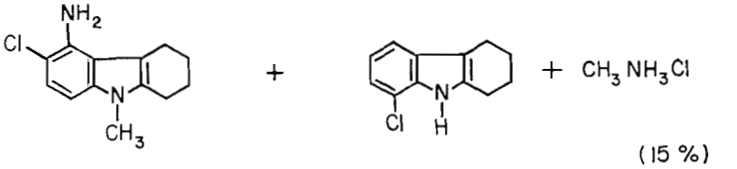
In our opinion the isolation of both (XVI) and (XVII) is further evidence in favor of the dienone-imine intermediate. Such an intermediate readily explains the formation of (XVI) as shown by the following scheme (equation *h*).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(g)

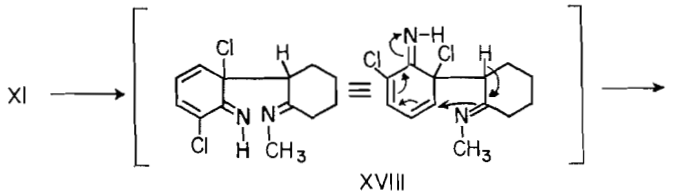


XI

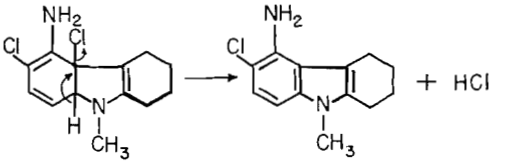


XVI (21 %) XVII (14 %) (15 %)

(h)



XVIII

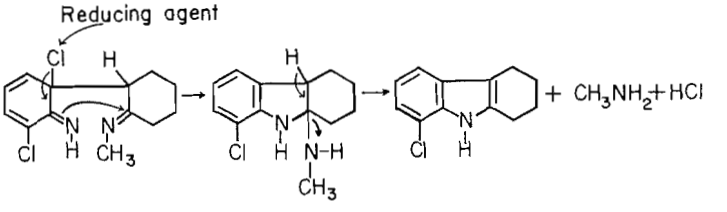


XVI

The mechanism of the formation of compound (XVI) is analogous to that proposed (14) for the formation of 2-phenyl-3*a*,5-dimethyl-3*a*,4,7,7*a*-tetrahydro[3H]pseudoindolone (VI) from the zinc chloride catalyzed cyclization of acetophenone 2,6-dimethylphenylhydrazone.

The formation of the product (XVII) can also be explained on the basis of the dienone-imine intermediate (XVIII) if one postulates that a readily oxidizable substance in the reaction mixture permits the reductive removal of the allylic halogen atom in the dienone-imine intermediate via the scheme shown in equation *i*. That the presence of oxidizable

(i)



substances does promote the reductive removal of halogen, most likely at the reactive dienone-imine stage, has been supported by the isolation of much 2-allyl-6-chlorophenol during the thermal rearrangement of allyl 2,6-dichlorophenyl ether, particularly in a solvent (e.g. decalin) which is readily oxidizable (25). The isolation of 7-chloroindoles from the stannous chloride catalyzed cyclization of 2,6-dichlorophenylhydrazones (12) can be considered as another example of this reductive removal of allylic halogen at the dienone-imine stage.

The failure as yet to obtain the desired enamine (XI) might be due to the presence of the N′-methyl group which could facilitate cleavage of the N—N bond with subsequent formation of the dienone-imine (XVIII) which then rapidly decomposes. It is known that α-N-methylphenylhydrazones are very readily converted to 1-methylindoles (26, 27).

To our knowledge, this is the first example of a room temperature, non-catalyzed Fischer indole synthesis. The mild conditions required and the much cleaner reaction obtained might now permit isolation of products which under the usual more stringent conditions end up as tars. The surprising ease of the conversion of the enamine (XI) to the dienone-imine and then to indole products supports Suvorov's suggestion that this step need not be acid-catalyzed (11). It might now be possible to obtain, under these modified conditions, an intermediate analogous to compound II (R = CH_3).

We are continuing work on these interesting aspects of the reaction.

EXPERIMENTAL

Preparation of Phenylhydrazines

N′-Formyl-2,6-dichlorophenylhydrazine

Formylation of 2,6-dichlorophenylhydrazine was carried out by the following modification of the method described by Baker *et al.* (16). The use of 50% formic acid (17) proved to be less satisfactory in our experiments.

To a solution of 33.6 g (0.19 mole) of 2,6-dichlorophenylhydrazine (1) in 150 ml of glacial acetic acid was added 7.6 ml (0.19 mole) of formamide in a dropwise fashion. The resulting solution was stirred at room temperature for 1 h during which time the solution thickened because of the formation of a colorless precipitate. The thick slurry was then diluted with 150 ml of water and the solid collected. Crystallization from ethanol gave 29.6 g (76%) of pure product melting at 160–161°. Calc. for $C_7H_6N_2Cl_2O$: C, 40.99; H, 2.95; N, 13.66; Cl, 34.58. Found: C, 41.09; H, 3.10; N, 13.84; Cl, 34.72.

N′-Methyl-N′-formyl-2,6-dichlorophenylhydrazine

Methylation was accomplished by the following modification of a published procedure (17).

To a solution of 41 g (0.20 mole) of N′-formyl-2,6-dichlorophenylhydrazine in 200 ml of dimethylsulphoxide both 21.4 ml (0.22 mole) of dimethylsulphate and a solution of 8.8 g (0.22 mole) of sodium hydroxide in 20 ml of water were added simultaneously and dropwise. The reaction mixture was stirred for 2 h and then diluted with 150 ml of water. The oil which separated solidified on cooling. This oily solid was collected and crystallized from Skellysolve B, yielding 27.6 g (63%) of N′-formyl-N′-methyl-2,6-dichlorophenylhydrazine, m.p. 73–75°. Calc. for $C_8H_8N_2Cl_2O$: C, 43.86, H, 3.68, N, 12.79; Cl, 32.37. Found: C, 43.57; H, 3.64; N, 12.17; Cl, 32.54. That the methyl group was attached to the N′-nitrogen atom was shown by Raney nickel – hydrazine reduction (18) of the compound and isolation of the known 2,6-dichloroaniline. The other product, N-methylformanide was not isolated. The n.m.r. spectrum of N′-formyl-N′-methyl-2,6-dichlorophenylhydrazine showed a sharp signal for the methyl group at 7.1 τ and also agreed with the structure assigned.

N-Methyl-2,6-dichlorophenylhydrazine Hydrochloride

The following procedure is a modification of that described by Neber *et al.* (17).

A solution of 43.8 g (0.20 mole) of N′-formyl-N′-methyl-2,6-dichlorophenylhydrazine, 80 ml of concentrated hydrochloric acid, and 60 ml of ethanol was refluxed for 6 h. The solution was cooled, and poured into ice water whereupon an oil separated. An ether extract of this oil was dried ($MgSO_4$) and after removal of the drying agent was treated with anhydrous hydrogen chloride gas until precipitation of the hydrochloride of N′-methyl-2,6-dichlorophenylhydrazine was complete. Crystallization from ethanol gave 30.5 g (67%) of pure N′-methyl-2,6-dichlorophenylhydrazine hydrochloride, melting at 181–182°. Calc. for $C_7H_8N_2Cl_3$: C, 36.95; H, 3.99; N, 12.31; Cl, 46.75. Found: C, 36.84; H, 3.89; N, 12.36; Cl, 46.61. The infrared spectrum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of this compound showed the following bands: 3220 cm^{-1} (NH), a broad peak centered at 2930 cm^{-1} (CH_3), 2690 cm^{-1} (NH_2^+) (28), and a peak at 1560 cm^{-1} (aromatic unsaturation). The n.m.r. spectrum in D_2O showed signals at 7.0 τ (singlet, N—CH_3), 5.3 τ (singlet for DOH), and an AB_2 pattern at 2.3 to 2.9 τ. The hydrazine could be preserved undecomposed if kept as the hydrochloride.

4-Chloro-3-nitrophenylhydrazine

The 4-chloro-3-nitroaniline (29) was converted to 4-chloro-3-nitrophenylhydrazine by the procedure of Plant and Rosser (22). However, after the solution had been left to stand overnight, the precipitated hydrazine hydrochloride was separated by filtration (rather than heated again as these authors advocated) and dissolved in 200 ml of boiling water. The resulting solution was then filtered free of insoluble material and the filtrate treated with saturated aqueous sodium acetate to precipitate the hydrazine. This product was *crystallized immediately from Skellysolve B.* If the crystallization was not done at once, decomposition resulted. Yield of 4-chloro-3-nitrophenylhydrazine was 45.3%, m.p. 108–109° (reported m.p. 109° (22)).

Preparation and Cyclization of Phenylhydrazones

Cyclohexanone o-Chlorophenylhydrazone

This compound was prepared in 91% yield according to published directions (12). This compound decomposed readily, hence had to be used soon after its preparation.

Cyclization was accomplished preferably by the boron trifluoride – etherate procedure described by Snyder and Smith (30), affording an 82% yield of 8-chloro-1,2,3,4-tetrahydrocarbazole, m.p. 55–56° (from benzene – Skellysolve B). Reported m.p. 56° (12). The product decomposed rapidly at room temperature.

Cyclohexanone 4-Chloro-3-nitrophenylhydrazone

This compound was prepared in 84% yield according to the procedure of Plant and Rosser (22) and cyclized with boron trifluoride – etherate (30). The solid obtained was repeatedly crystallized from ethanol yielding 6-chloro-7-nitro-1,2,3,4-tetrahydrocarbazole (44%) melting at 186–187°, reported m.p. 184° (22, 23). Removal of the ethanol from the filtrate gave a yellow solid which when crystallized from benzene gave 6-chloro-5-nitro-1,2,3,4-tetrahydrocarbazole (11%) having the reported melting point of 162–163° (22, 23).

6-Chloro-5-nitro-9-methyl-1,2,3,4-tetrahydrocarbazole

6-Chloro-5-nitro-1,2,3,4-tetrahydrocarbazole was converted to 6-chloro-5-nitro-9-methyl-1,2,3,4-tetrahydrocarbazole by use of methyl sulphate according to published procedure (31). Yield of pure material, 61%, m.p. 154–155° (from ethanol). Calc. for $C_{13}H_{13}N_2O_2Cl$: C, 58.98; H, 4.95; N, 10.59; Cl, 13.40. Found: C, 59.09; H, 5.19; N, 10.50; Cl, 13.21.

That the nitrogen atom at position 9 had been methylated was shown by the disappearance of the NH signal at 4.94 τ found in the n.m.r. spectrum of the starting material, and the appearance of the N—CH_3 signal at 6.65 τ in the spectrum of the product.

5-Amino-6-Chloro-9-methyl-1,2,3,4-tetrahydrocarbazole

The nitro group of 6-chloro-5-nitro-9-methyl-1,2,3,4-tetrahydrocarbazole was reduced with Raney nickel and hydrazine (24). The solid amine obtained after removal of the nickel and the solvent was crystallized from ethanol and yielded pure material (79%) melting at 90–91°. Calc. for $C_{13}H_{15}N_2Cl$: C, 66.51; H, 6.44; N, 11.94; Cl, 15.11. Found: C, 66.64; H, 6.57; N, 12.18; Cl, 14.98. The n.m.r. spectrum in $CDCl_3$ showed the following signals: an aromatic AB pattern at 3.0–3.8 τ, N—H at 5.9 τ, N—CH_3 at 6.75 τ, methylene at 7.24, 7.58, and 8.30 τ.

Treatment of the amine in a small amount of benzene with a slight excess of acetic anhydride heated on the steam bath for 10 min afforded colorless crystals (from ethanol) of the N-acetyl derivative, m.p. 245°. Calc. for $C_{15}H_{17}N_2ClO$: C, 65.09; H, 6.18; N, 10.11; Cl, 12.81. Found: C, 65.24; H, 5.96; N, 10.29; Cl, 13.09.

Condensation of Cyclohexanone with N'-Methyl-2,6-dichlorophenylhydrazine

A quantity (6.84 g, 0.03 mole) of N'-methyl-2,6-dichlorophenylhydrazine hydrochloride was dissolved in water. The resulting solution was basified with dilute sodium hydroxide and the oil which separated was extracted with two 25 ml portions of ether. The combined extracts were dried ($MgSO_4$) and freed from ether with a rotary evaporator. To the residue left in the evaporator was added 50 ml of benzene followed by 2.94 g (0.03 mole) of cyclohexanone and the resulting solution slowly reduced to half its original volume in the rotary evaporator (bath temperature ~20°). A colorless precipitate was removed by filtration and when crystallized from ethanol it melted at 222–225° (0.30 g, 14.8%). This precipitate was quite water soluble. Its aqueous solution gave an instantaneous precipitate with silver nitrate. The aqueous solution of this colorless precipitate, when made alkaline with sodium hydroxide, produced an ammoniacal odor. Mixed melting point, and n.m.r. spectrum showed it to be identical with methylamine hydrochloride.

The rest of the benzene solution, after removal of the methylamine hydrochloride, was freed from benzene and gave a yellow oil. By chromatography on neutral alumina with Skellysolve B as eluant, 0.86 g (14.0%) of a pale yellow solid melting at 55–56° was obtained. This compound was shown to be identical with 8-chloro-1,2,3,4-tetrahydrocarbazole by mixed melting point and by infrared and n.m.r. spectra comparison with an

For personal use only.

authentic sample (12). The compound was too unstable to be sent away for elemental analysis. Its infrared spectrum showed bonded N—H at 3100 cm^{-1}. The n.m.r. spectrum showed methylene signals at 7.29 τ and 8.20 τ and an N—H signal at 1.39 τ.

Further elution of the remaining material on the column with a 1:1 mixture of Skellysolve B and benzene yielded a tan, crystalline solid, m.p. 87–90°. Crystallization from alcohol gave 1.48 g (21%) of a colorless material, m.p. 90–91°. Calc. for $C_{13}H_{15}N_2Cl$: C, 66.51; H, 6.44; N, 11.94; Cl, 15.11. Found: C, 66.59; H, 6.49; N, 11.75; Cl, 15.37. The n.m.r. spectrum in $CDCl_3$ showed an aromatic AB pattern in the region 3.0 to 3.8 τ, an $-NH_2$ signal at 5.9 τ, an N—CH_3 signal at 6.75 τ, and methylene signals at 7.24, 7.58, and 8.30 τ. The above data agreed with the structure 5-amino-6-chloro-9-methyl-1,2,3,4-tetrahydrocarbazole. This compound showed properties identical with those of an authentic sample of 5-amino-6-chloro-9-methyl-1,2,3,4-tetrahydrocarbazole prepared by another route described above.

THE RATE OF REACTION OF ACTIVE NITROGEN WITH ETHANE, PROPANE, AND NEOPENTANE[1]

W. E. JONES[2] AND C. A. WINKLER
Upper Atmosphere Chemistry Research Group, McGill University, Montreal, Quebec
Received August 2, 1963

ABSTRACT

The reactions of active nitrogen with ethane, propane, and neopentane have been studied over the temperature range 0 to 450 °C. A cobalt probe technique was used to stop the reactions after various reaction times. Second order rate constants have been calculated on the assumption that nitrogen atoms are the only reactive species in active nitrogen. Broken Arrhenius lines were obtained for both the ethane and neopentane reactions but this behavior was not observed with the propane reaction. The dual activation energies have been attributed to a mechanism involving initiation by both excited molecules and either nitrogen or hydrogen atoms. Methods are outlined by which an estimate has been made of the concentration of excited species assumed to be involved in the ethane reaction.

INTRODUCTION

In previous investigations of the reactions of ethane (1, 2), propane (3), and neopentane (4) with active nitrogen, approximate rate constants, activation energies, and steric factors were evaluated from hydrogen cyanide yields at various temperatures, on the assumption that the reactions were second order. While there appeared to be only one activation energy associated with the propane reaction over the whole temperature range studied, the data for each of the other two reactions were found to correspond to two activation energies, one at lower, the other at higher temperatures. The values for the three reactions were:

Reaction	Temp. range (°C)	Activation energy	Steric factor	Reference
Ethane	−100 to 150	3	10^{-4}	2
	150 to 475	6	10^{-2}	
Neopentane	−40 to 115	2	10^{-5}	4
	150 to 350	7	10^{-3}	
Propane	63 to 250	6	10^{-2} to 10^{-3}	3

It was suggested that the results for ethane (2) and neopentane (3) could be explained by the concomitant attack of the parent hydrocarbon by both nitrogen atoms and hydrogen atoms formed by the nitrogen atom reaction, or by the presence of two reactive species in active nitrogen. The nature of such a second species is open to question, but recent evidence (5, 6, 7) suggests that the excited nitrogen molecule $N_2(A^3\Sigma_u^+)$ is capable of initiating reactions (8) with saturated hydrocarbons such as methane and ethane.

Recently, methods (9) have been developed by which active nitrogen reactions can be quenched at various points downstream from the reactant jet, with the advantage that reaction time may be controlled and more reliable estimates of the rate constants obtained. In the present study, a cobalt target (10) has been used to quench the active

nitrogen reactions with ethane, propane, and neopentane, to check the validity of the earlier results for these reactions.

EXPERIMENTAL

Ethylene, ethane, propane, and neopentane (Matheson Co. of Canada) were purified by two bulb-to-bulb distillations, only the middle two-thirds from each distillation being retained. 'Bone dry' nitrogen (Linde Air Products) was passed over heated copper to remove traces of oxygen, and through a liquid air trap to remove traces of water and carbon dioxide.

The apparatus was essentially similar to that used in a previous investigation in this laboratory (10), but incorporated several minor changes. The nitrogen stream, after passing through the flowmeter, could be admitted to the reaction system after activation by either a condensed discharge or by a microwave generator (Raytheon, 2450 Mc/s, 125 W). The flow rate of molecular nitrogen at a pressure of 2.2 mm Hg was 216×10^{-6} mole/s. A controlled small amount of water vapor was added to the nitrogen stream before it entered either discharge. It was assumed that this acted only as an efficient wall poison, and had no significant effect on the active nitrogen reactions (5).

Hydrocarbon entered the gas stream through a bulb with six small holes spaced at equal distances around its circumference. A constriction in the 25 mm i.d. reaction tube, just above the reactant jet, prevented back diffusion of the reaction mixture and resulted in a sharply defined initiation of the reaction at the hydrocarbon inlet, from where the zero time of reaction was measured. Provision was made to heat or cool the reaction tube, to permit measurements over the temperature range from about 0 to 450 °C.

Reaction rates were determined by measuring the amount of hydrogen cyanide produced when the reaction was terminated at different positions downstream from the reactant jet, that is, after different reaction times. The hydrogen cyanide was trapped at liquid air temperature, and its amount estimated by titration, as outlined previously (10).

It was convenient to estimate the relative nitrogen atom concentrations, in the 'active nitrogen' produced both by microwave and condensed discharges, from the maximum yields of hydrogen cyanide obtained from the ethylene – active nitrogen reaction (5). They were found to be quite constant over a wide temperature range for the conditions of the present study. The values so obtained should be regarded, perhaps, as minima, since the concentrations determined by the familiar nitric oxide titration method would have been higher by a factor of about 1.5 (cf. ref. 5).

To avoid inaccuracies that might result from contamination of the walls of the reaction vessel by particles of catalyst from the target, measurements were made only for movement of the quenching target from the bottom to the top of the reaction tube, i.e., for successively shorter reaction times. When the target reached the position of closest approach to the reactant jet, it was removed and the reaction vessel was cleaned and dried thoroughly. The nitrogen atom concentration was determined before proceeding with the next series of measurements, and periodically throughout the experiments, to ensure that any change in its value would be known.

RESULTS AND DISCUSSION

To compare the present results with those of earlier work, second order rate constants for the three reactions were calculated on the assumption that the reaction of each molecule of hydrocarbon produced hydrogen cyanide equivalent to the number of carbon atoms in the reactant molecule, and that nitrogen atoms were the only reactive species present in the active nitrogen. The integrated rate equation for ethane has the form

$$k = \frac{2.303}{t(a - 2b)} \log \frac{b(a - 2x)}{a(b - x)}$$

where x is the amount of ethane consumed, approximately one-half the hydrogen cyanide produced; a is the initial concentration of nitrogen atoms; b is the initial concentration of ethane; t is the duration of the reaction. Integrated rate equations similar to this, but with suitable corrections for the number of hydrogen cyanide molecules produced per molecule of hydrocarbon, have also been used to calculate the second order rate constants for the reactions of nitrogen atoms with neopentane and propane. The reproducibility of the measurements is indicated by the typical values for the second order rate constants given in Table I.

The reaction of ethane with active nitrogen produced by the condensed discharge was studied over the temperature range 5 to 430 °C, at approximately 50° intervals. The production of hydrogen cyanide was measured at each temperature, for several flow rates of ethane, at three different reaction times. Typical plots to illustrate the variation of hydrogen cyanide production with ethane flow rate are shown in Fig. 1. The plots show a behavior somewhat similar to the induction effect observed previously (2). Close inspection of these curves suggests that this induction effect involves a rapid initial production of hydrogen cyanide, followed by a tendency for the curve to level out, which is followed, in turn, by a second gradual increase in production of hydrogen cyanide to a plateau value. This behavior is well illustrated by the lowest curve of Fig. 1B. The reaction of ethane with active nitrogen produced by the microwave discharge was also

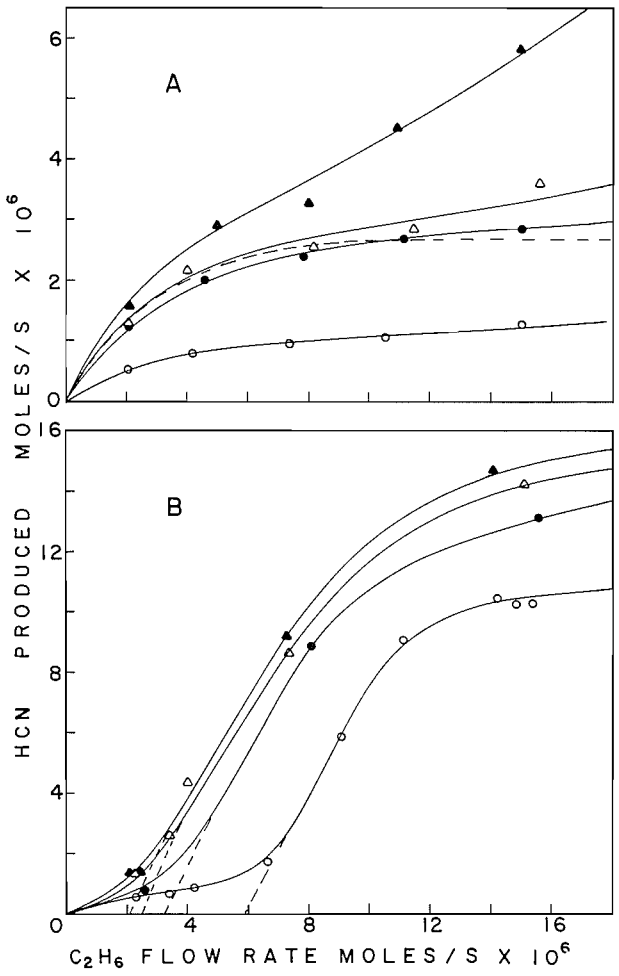

FIG. 1. Production of hydrogen cyanide at various reaction times from the reaction of ethane with active nitrogen produced by a condensed discharge: (A) temperature 80 °C, ○ 20.5 × 10^{-3} s, ● 51.2 × 10^{-3} s, △ 76.8 × 10^{-3} s, ▲ 102.4 × 10^{-3} s; (B) temperature 380 °C, ○ 10 × 10^{-3} s, ● 24.9 × 10^{-3} s, △ 37.4 × 10^{-3} s, ▲ 49.9 × 10^{-3} s.

studied over a wide temperature range (0 to 430 °C), but plots similar to those of Fig. 1 were not made, owing to the low yield.

The second order rate constants (averages of those found for several ethane flow rates at three or more different reaction times for each temperature) are given in Table II and shown graphically in the Arrhenius plot, Fig. 2A. The plot clearly confirms the earlier observation that different activation energies are associated with the reaction in the low and high temperature ranges. The results for the microwave and condensed discharges are in excellent agreement in the higher temperature range but do not agree as well for low temperatures. The differences, however, are of the same order as the experimental error.

The reaction of neopentane was studied only with active nitrogen produced by the microwave discharge. The average second order rate constants are given in Table II and shown graphically in Fig. 2B. Neopentane shows the same type of behavior as

ethane, i.e., different activation energies for low and high temperature ranges, and the results are in agreement quantitatively with those of earlier work (4).

The reaction with propane was also studied only with the microwave system. Average values for the second order rate constants are given in Table II, and an Arrhenius plot of these in Fig. 2B.

The kinetic constants, inferred from the second order rate constants for the reactions of active nitrogen with all three of the hydrocarbons studied are summarized in Table III.

TABLE III

Summary of kinetic constants calculated from Arrhenius plots of the second order rate constants assuming atomic nitrogen as reactive species

	Activation energy (kcal mole^{-1})	A (cc molecule^{-1} s^{-1})	Z (cc molecule^{-1} s^{-1})	P
Ethane				
Low temp. range	1.7	8.7×10^{-15}	4.2×10^{-10}	2.0×10^{-5}
High temp. range	7.0	3.8×10^{-12}	6.2×10^{-10}	6×10^{-3}
Neopentane				
Low temp. range	1.5	4.8×10^{-15}	4.5×10^{-10}	1.0×10^{-5}
High temp. range	6.6	2.3×10^{-12}	6.7×10^{-10}	3.4×10^{-3}
Propane	5.5	8.7×10^{-12}	4.6×10^{-10}	1.9×10^{-2}

It will be noted that the activation energies and steric factors are quite similar for the ethane and neopentane reactions for both the low and high temperature ranges, and that the values differ considerably from the corresponding values for the propane reaction. It should be emphasized, perhaps, that these values are all based on the rate constants calculated on the assumption that nitrogen atoms are the only reactive species in active nitrogen. The values obtained are of the same order of magnitude as those obtained in earlier investigations.

The induction effect with concentration of reactant (Figs. 1A and 1B) was not observed for the shorter reaction times (20.5 and 51.2 ms) at low temperatures, over the range of reactant flow rates used, but it did become evident for the longer reaction times. This suggests that, in these two reactions, some initiating step is followed by other reactions leading to the formation of hydrogen cyanide. From the grouping of the curves for the ethane reaction in Fig. 1A, it appeared that a plateau to represent the amount of the initiating reaction with this reactant may be drawn as indicated by the dashed curve. This plateau value corresponds to about 2.8 μmoles/s of hydrogen cyanide, from which it might be tentatively concluded that the flow rate of the initiating species was about 1.4 μmoles/s.

If the minimum nitrogen atom flow rate is taken to be about 18 μmoles/s, from the maximum hydrogen cyanide production from ethylene, it is unlikely that nitrogen atoms should be responsible for initiating a reaction that attains a plateau in hydrogen cyanide production at only 2.8 μmoles/s. Accordingly, it is suggested that this low plateau corresponds to the flow rate of an excited molecular species, perhaps $N_2(A^3\Sigma_u^+)$. Such a species, by collision with the hydrocarbon, might bring about its excitation or decomposition, and thereby initiate subsequent reactions that lead to the formation of hydrogen cyanide.

The above argument would suggest that the maximum amount of hydrogen cyanide produced at sufficiently low temperatures, e.g. 0 °C, might be governed entirely by the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

extent of the initiating reaction, i.e., by the flow rate of the initiating species. The maximum yield of hydrogen cyanide at this temperature was 2.8 μmoles/s (Table I), which might again be taken to correspond to a flow rate of 1.4 μmoles/s for the initiating species.

From Fig. 1B, the induction effect appears to be marked at higher temperatures. This behavior would be expected if the amount of reaction caused by an initiating species remained relatively unaltered, while subsequent reactions became pronounced as the temperature was increased. If the steeper portions of the curves, representing hydrogen cyanide production from the subsequent reactions, are extrapolated to the axis of ethane flow rate, the intercepts might be interpreted to be the flow rates of ethane necessary for the second reaction to become significant at the given reaction time. A plot of these intercepts against the reciprocal of the corresponding distance of the cobalt target from the reactant jet (i.e., 1/time of reaction) is shown in Fig. 3. If the line in Fig. 3 is extrapo-

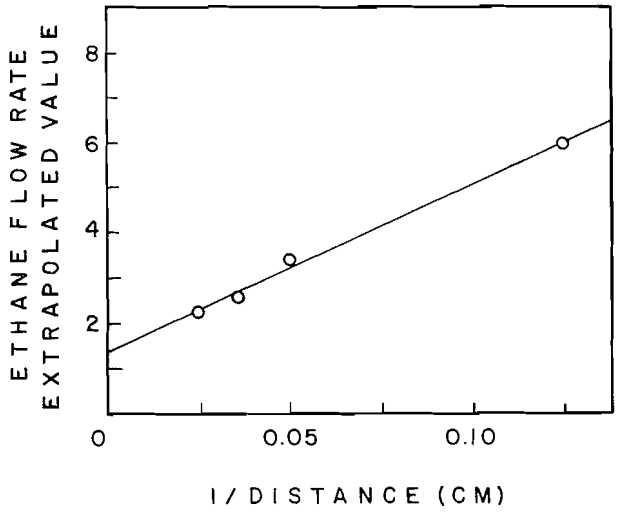

FIG. 3. Variation in the minimum amount of ethane necessary before the secondary atom reaction becomes noticeable.

lated to a value of zero for the reciprocal of distance, corresponding to infinite reaction time, a value of 1.4 μmoles/s is obtained for the minimum flow rate of ethane required for the subsequent reactions to become significant, i.e., the maximum amount of ethane that will react with the initiating species. This value is in good agreement with the previous estimates of concentration for the possible initiating species.

The accelerated production of hydrogen cyanide with increase of either reaction time or temperature might be due to increased extent of direct nitrogen atom reaction with the hydrocarbon under such conditions. However, it seems more likely, particularly in view of the long induction effect in the curve for the shortest reaction time at 380 °C, that the increased production of hydrogen cyanide results from fast nitrogen atom reactions with free radicals formed when the hydrocarbons are attacked by hydrogen atoms produced in the initiating step or in subsequent nitrogen atom reactions.

In summary, it would seem that the reaction scheme appropriate to lower temperatures and short reaction times might be represented by

$$N_2^* + RH \rightarrow N_2 + RH^*,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

followed by fast reactions of nitrogen atoms with RH*, or free radicals derived from its decomposition, to produce hydrogen cyanide and other products, including hydrogen atoms. At higher temperatures, production of hydrogen cyanide is probably increased to some extent by direct nitrogen atom attack on the hydrocarbon, but mainly by a reaction sequence of a type exemplified by

$$C_2H_6 + H \rightarrow C_2H_5 + H_2$$
$$C_2H_5 + N \rightarrow HCN + CH_3 + H$$
$$CH_3 + N \rightarrow HCN + 2H.$$

The activation energies for the reactions of nitrogen atoms, or hydrogen atoms, with hydrocarbons are of comparable magnitude, and considerably higher than the activation energy that might be expected for the formation of hydrogen cyanide by the mechanism involving an energy transfer and subsequent nitrogen atom reactions, as outlined above. The observed increase in hydrogen cyanide production with increase of temperature, and the change in slope of the Arrhenius lines for the ethane and neopentane reactions, would therefore be in accord with the mechanisms proposed for the different experimental conditions.

Since the reaction with propane gave no indication of two activation energy values, it seems likely that it involves only direct nitrogen atom attack to produce hydrogen cyanide. It would seem, at least, that the direct nitrogen atom reaction masks any participation of excited molecules or hydrogen atoms that might be present in this reaction.

Although attempts have been made to resolve mathematically the kinetic behavior reflected in Figs. 1A and 1B, no satisfactory treatment has yet been developed.

THE IONIZATION BEHAVIOR OF AMIDES IN CONCENTRATED SULPHURIC ACIDS

I. A NEW ACIDITY FUNCTION BASED ON A SET OF PRIMARY AMIDE INDICATORS

ABSTRACT

A set of eight suitably substituted primary amides of progressively weaker basicity have been prepared. Their ionization curves have been determined in sulphuric acids by spectrophotometric methods. These show good overlap and parallelism for successive indicators, enabling the pK values of the indicators to be determined by direct stepwise comparison. Using these pK values and measured ionization ratios, values of a new acidity function, H_A, have been obtained for aqueous solutions up to 82% sulphuric acid. The H_A function decreases much less rapidly than H_0 in this range, being nearly 3 log units less negative at the highest acidity studied. The reasons for this large difference are discussed. The H_A function is shown to be applicable to other amides which have not been employed as indicators.

INTRODUCTION

The acidity function H_0 was originally conceived by Hammett and Deyrup (1) to describe the ionization behavior of weak organic bases in concentrated acid solutions. It has been assumed to be generally applicable to uncharged bases ionizing by simple proton addition, as in

$$B + H^+ \rightleftharpoons BH^+$$

for which $K_{BH^+} = a_B \cdot a_{H^+}/a_{BH^+}$ is the thermodynamic equilibrium constant defined in terms of molar activities. The acidity function is defined by

$$H_0 = -\log (a_{H^+} \cdot f_B/f_{BH^+}) = pK_{BH^+} - \log [BH^+]/[B].$$

The only well recognized exceptions of this charge type have been carbinol and olefin type bases which form carbonium ions on protonation. These have been found to follow the H_R (2) and H_R' (3) functions respectively.

Recently it has been recognized that the applicability of the H_0 function is considerably more limited than was at one time supposed. This question has been discussed in an excellent and comprehensive review by Arnett (4). The limited generality of the H_0 scale has been clearly demonstrated by the results of two recent investigations. Jorgenson and Hartter (5) have redetermined the H_0 scale using a set of structurally related indicators composed solely of primary anilines, unlike the original Hammett indicators, which although mainly of this type, included an N,N-disubstituted aniline as well as several oxygen type bases. Their new H_0 scale shows considerable divergence from that based on the old set of indicators (1). This demonstrates that acidity functions of the H_0 type are strongly dependent on structural changes in the indicators, even for simple bases of the same charge type. Previously (6) it has been shown that many amides are not Hammett bases, although they ionize by simple proton addition (7). This was shown by the fact that slopes of their log $[BH^+]/[B]$ values against H_0 were far from unity, as required by the

defining equation, and that these deviations were too large to be explained by medium effects on the absorption spectra used to obtain ionization ratios.

Thus the results of all previous pK determinations on amides, employing the H_0 scale, do not yield thermodynamic equilibrium constants, but "pK" values in the sense described by Arnett (4). These correspond numerically to the H_0 values of the acids in which the base is half-ionized.

Therefore in general structure pK correlations for weak bases must be interpreted with caution. In addition, rate–acidity function correlations such as those of Bunnett (8), and their interpretation in terms of hydration changes (9), lose much significance in cases where it can be shown that the acidity scale used is not applicable to the type of substrate being considered.

We have therefore investigated the possibility that primary amides are following some other "general" acidity function and wish to report values of a new acidity function, H_A. This function is based on a set of structurally related primary amide indicators and appears to be generally applicable to the ionization behavior of this class of base. It is considerably different numerically to the H_0 scale even in moderately concentrated acids.

EXPERIMENTAL

Indicators

The following commercially available indicators were recrystallized to constant melting point: 3,4,5-trimethoxybenzamide from methanol–water; m.p. 178.5–179.5 °C (lit. m.p. 176–177 °C (10)); 2,4-dichloro-3,4-dinitrobenzamide from aqueous ethanol; m.p. 262–263 °C. We are unable to find a reported melting point for this compound but analysis gave C, 30.18; H, 1.01; N, 14.96; Cl, 25.59. Calculated for $C_7H_3N_3Cl_2O_5$: C, 30.0; H, 1.07; N, 15.0; Cl, 25.35. Samples of *p*-methoxybenzamide, m.p. 166–167 °C (lit. m.p. 163 °C (11)) and *m*-nitrobenzamide, m.p. 140–141 °C (lit. m.p. 141–143 °C (11)) were kindly supplied to us by Professor J. T. Edward of McGill University. These were also recrystallized to constant melting point before use. The remaining indicators were prepared as follows from the corresponding carboxylic acids, which are all commercially available. The acid chloride was prepared by a standard method (12) and reacted with cold aqueous ammonia to give 3,5-dinitro-4-methylbenzamide, which was recrystallized from aqueous ethanol; m.p. 189.2–190.5 °C (lit. m.p. 187 °C (13)). Calculated for $C_8H_7N_3O_5$: C, 42.7; H, 3.18; N, 18.7. Found: C, 42.6; H, 3.06; N, 18.6. The same method was used for 2,3,6-trichlorobenzamide. This amide has apparently not been prepared previously; m.p. 170–171 °C. Calculated for $C_7H_4Cl_3NO$: C, 37.4; H, 1.78; Cl, 47.5; N, 6.24. Found: C, 37.3; H, 1.45; Cl, 47.48; N, 6.09. A modified method (14, 15) was used to prepare 2,4,6-trinitrobenzamide. This was recrystallized from benzene – acetone – petroleum ether; m.p. 267.5–268.5 °C (lit. m.p. 264 °C (15)). Calculated for $C_7H_4N_4O_7$: C, 32.8; H, 1.56; N, 21.87. Found: C, 32.75; H, 1.50; N, 22.0. Our 2-pyrrolecarboxamide was prepared by the method of Fischer and Van Slyke (16); the product being recrystallized from water; m.p. 174.5–175.5 °C (lit. m.p. 176.5 °C (16)). Calculated for $C_5H_6N_2O$: C, 54.55; H, 5.45; N, 25.45. Found: C, 54.13; H, 5.85; N, 25.25.

Sulphuric Acids

Sulphuric acid solutions ranging from 0.001 N to 90% by weight were prepared by diluting Fischer C. P. Reagent Grade sulphuric acid (95% min.). Concentrations were determined by titrating weighed samples with standard sodium hydroxide.

Measurement of Ultraviolet Spectra

All spectra were measured on a Bausch and Lomb Spectronic 505 Recording Spectrophotometer using 1 cm quartz cells and a thermostatically controlled cell-block at 25±0.05 °C. Solutions of indicators were prepared as described previously (17). It has been shown (18) that hydrolysis of the amides is negligible during the time required to measure spectra. Periodic checks of solutions of various acid concentrations confirmed this in the present work.

Treatment of Data

Since all compounds gave clearly defined absorption peaks in acid solutions strong enough to convert them essentially to their ionized forms, the wavelengths near this peak, $\lambda_{BH^+}{}^{max}$, were used to determine ionization ratios. Absorption spectra of the free base forms obtained in water or dilute acids showed some absorption at this wavelength but the change in ϵ at $\lambda_{BH^+}{}^{max}$ on going from essentially free base to conjugate acid was in every case large. Plots of ϵ against H_0 were examined for different λ in the region of $\lambda_{BH^+}{}^{max}$. Sigmoid type curves were obtained and that wavelength which gave the smoothest curve was chosen to calculate ionization ratios. These were obtained from the relation

$$I = [BH^+]/[B] = (\epsilon - \epsilon_B)/(\epsilon_{BH^+} - \epsilon)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where ϵ_B is the absorption at $\lambda_{BH^+}^{max}$ in a solution in which the base is completely un-ionized, ϵ_{BH^+} is the corresponding value in a solution where it is essentially completely ionized and is the value in a solution of intermediate acidity. Values of ϵ_B and ϵ_{BH^+} were obtained for individual compounds as follows. The H_0 value at the inflection point of the above sigmoid curve was assumed to correspond approximately to the point of 50% ionization ([B] = [BH$^+$]). Acid solutions having H_0 values 2 log units above and below this value were taken to be acids in which the base was completely unionized and fully ionized respectively, and their ϵ values taken as first approximate ϵ_B and ϵ_{BH^+} values. These were then used to obtain approximate log I values. Plots of these log I values against percent H_2SO_4 showed good parallelism and overlap for successive indicators. These were then used in the standard stepwise procedure to calculate a set of approximate pK values for the indicators and from these a first approximate set of amide acidity function values was obtained. Since this function decreased less steeply than the H_0 function, our original assumptions about the acids corresponding to ϵ_B and ϵ_{BH^+} were in error. This was particularly the case on the strongly acid side of the 50% ionization point. Next, acids of lower and higher acidities than before were chosen to obtain ϵ_B and ϵ_{BH^+} values respectively. These were chosen to correspond (on the first approximate amide acidity scale) to values ± 1.5 log units about the 50% ionization point. Thus it was hoped to minimize medium effects according to the method of Stewart and Granger (19). These new ϵ_B and ϵ_{BH^+} values were then used to obtain a further set of log I values and the whole calculation of pK and amide acidity function values repeated. It was again necessary to make small corrections in the acid concentrations used to obtain ϵ_B and ϵ_{BH^+}. These were very small in the less concentrated acids used to obtain ϵ_B. The whole procedure was reiterated until no further significant changes in the acidity function or pK values were produced and the acids used to obtain ϵ_B and ϵ_{BH^+} were at least 1.5 log units either side of the pK value. By using the method of Stewart and Granger (19) to select the 0% and 100% ionization acids, errors of about 3% in ϵ_B and ϵ_{BH^+} can be introduced by the arbitrary choice of ± 1.5 log units, if there are no spectral shifts produced by the solvent. However, since the arms of the sigmoid curve are in fact sloping because of spectral shifts, it is felt that introducing a possible error of known magnitude is far less serious than choosing extremely strong acids to obtain ϵ_{BH^+} and thereby introducing errors of unknown magnitude.

Plots of the final log I values against the final acidity function values give straight lines of unit slope. All the individual values of the amide acidity function lie closely on a smooth curve when plotted against acid concentration.

RESULTS AND DISCUSSION

Selection of Indicators and Measurement of Ionization Ratios

Guided by the same general criteria as Jorgenson and Hartter (5), we have prepared a set of structurally related primary amides of progressively weaker base strength. These are principally benzamides substituted in various positions of the benzene ring with methoxy, methyl, halogen, and nitro groups, chosen so that their measurable ionization ranges overlap as much as possible for successive indicators. The overall range of measurable ionization behavior for this set extends from 5–82% aqueous sulphuric acid. Individual indicators were chosen on the following basis. The slopes of plots of log I versus the H_0 function were obtained for 22 primary amides, using previously reported data (6, 17) as well as data obtained in the present study. Except for two widely deviating points (*o*-toluamide and *p*-nitrobenzamide) the values of these slopes fall in the range 0.49–0.78. (Redetermination of the slope (0.62) for *m*-toluamide showed that the previously reported (6) value of 1.00 is incorrect.) These values are not randomly scattered within this range but show a general trend, depending on the acidity region in which the amide undergoes extensive ionization. The most strongly basic amides studied have log I versus H_0 slopes of approximately 0.7–0.8, decreasing to slopes of 0.5–0.6 for the most weakly basic. It was this general trend of deviation from H_0 type behavior which suggested the possibility that an amide acidity function could be constructed. Eight amides were then chosen which had the most representative slopes and which gave the best overlap and parallelism of indicator ratio curves spanning the above acidity range.

Ionization ratios (I = [BH$^+$]/[B]) for all indicators were determined by spectrophotometric methods. The amides used have strong absorption maxima in the 215–260 mμ region. On protonation the spectra undergo changes in both λ_{max} and intensity as shown in Table I. In some cases both the neutral molecule and the cation give well-defined peaks

which are separated by 25–30 mμ. In other cases this separation is less, notably for the nitro derivatives, and in two cases the absorption of the free base appears as a shoulder on the side of a more intense band occurring below 200 mμ. However, in more strongly acid solutions where protonation has occurred, all compounds give well-defined absorption maxima. In cases where the absorption maxima of the free base (λ_B) and of the conjugate acid (λ_{BH^+}) are well defined and separated, the method of Davis and Geissman (20) has been most frequently employed to obtain log I values. This involves using data obtained at both wavelengths. Since this was not in general the case in the present work, it was decided for uniformity to use data obtained at one wavelength only, namely λ_{BH^+}, to calculate I values. This method gives reliable ionization ratios if there is a large change in intensity at this wavelength in going from the neutral base to the conjugate acid. This was the case with every compound studied. The values obtained give smooth sigmoid curves when plotted against acid concentration. Varying the choice of λ_{BH^+} by 5 mμ resulted in only small changes (±1%) in the log I values obtained. As a check, the method of Davis and Geissman was used where possible. The ionization curves obtained by each method were identical within the experimental error. In one case only, that of 2,4,6-trinitrobenzamide, the position of the absorption maximum does not shift appreciably with increasing acidity. However, as the acidity is increased, the spectrum undergoes a large increase in intensity and a plot of intensity against acidity does give a titration-type curve. This is considered to be the least reliable of the indicators used. Fortunately it is the weakest indicator base in the set and has therefore not been used to determine any further pK values. Nonetheless its ionization behavior does parallel that of the preceding indicators, and the base strength determined for it on the basis of the I values is in good agreement with what would be predicted from substituent effects, as will be shown in the second part of this series of papers.

The ionization ratios for these amides in various acid concentrations are listed in Table II. The values for each indicator give smooth curves when plotted against percent acid as shown in Fig. 1, with the expected progressive steepening of slopes at higher acidities. These curves are almost linear, although linearity is not necessarily to be expected when log I is plotted against this concentration scale, as is customary (5). The parallelism between overlapping indicator curves is good and shows that Hammett's activity coefficient postulate (4) is valid for this set of structurally related indicators. This means that

$$\log (f_{A_iH^+} f_{A_j} / f_{A_i} \cdot f_{A_jH^+}) = 0$$

for two amide indicators A_i, A_j in any given solution where their log I values are both measurable. Thus the activity coefficient behavior of this set of amides is reasonably independent of changes in structure. The relationship

$$pK_{A_iH^+} - pK_{A_jH^+} = \log [A_iH^+]/[A_i] - \log [A_jH^+]/[A_j] - \log (f_{A_i} f_{A_jH^+} / f_{A_iH^+} f_{A_j})$$

which holds for any two indicators, can therefore be reduced to

$$[1] \qquad pK_{A_iH^+} - pK_{A_jH^+} = \log [A_iH^+]/[A_i] - \log [A_jH^+]/[A_j]$$

for use in solutions where the ionization ratios of each are measurable. Hence the pK_{AH^+} value of any of these amides can be determined by direct stepwise comparison providing the pK_{AH^+} value of the preceding indicator is known.

Consideration of Medium Effects on Indicator Curves

The values of ϵ^{max} and λ^{max} are both affected by changes in the medium, independently

of the changes produced by protonation. These medium effects are of uncertain magnitude and extremely difficult to correct for adequately. Since these could substantially affect the slopes of ionization curves on which acidity functions are based, several methods of attempting to correct for these effects have been considered. Apart from the previously mentioned method of Davis and Geissman (20), which leads to a partial cancellation of medium effects on ϵ values, there are two other methods available. One is the well-known isobestic point method, which has been used by Hammett (21), and involves shifting absorption curves laterally until they all intersect at a common point, as they theoretically should in the absence of medium effects. Ionization ratios are then calculated from ϵ values based on these shifted curves. A second method has been described previously (6)

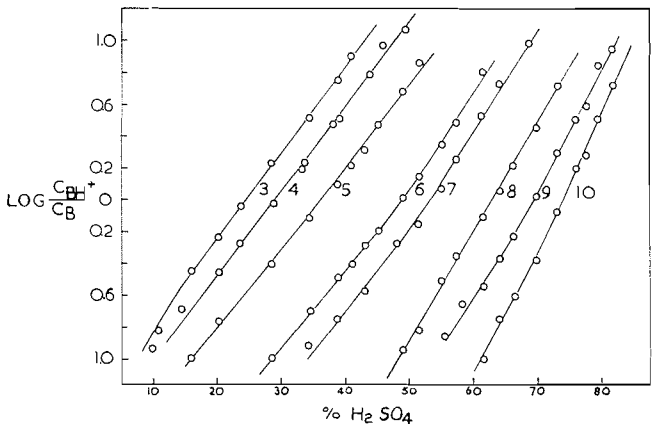

FIG. 1. Ionization curves for amide indicators in concentrated sulphuric acids (for indicator numbers see Table III).

and involves the assumption that medium effects are approximately linearly dependent on acidity. Corrected ϵ values are then obtained by an extrapolation procedure. Edward and Meacock (22) have reported substantial medium effects on the spectra of *p*-methoxybenzamide. We have analyzed our data for this compound by four different methods, using absorption spectra measured in 14 different solutions in the range 0–58% sulphuric acid. The log I values obtained have been treated by the method of least squares. The results are shown below.

Method	Slope vs. H_0	"pK"	Slope vs. H_A	pK_{BH^+}	Ref.
Davis and Geissman	0.67	−1.79	0.99	−1.50	(20)
Isobestic point	0.77	−1.77	1.08	−1.47	(21)
Linear extrapolation	0.75	−1.68	—	—	(6)
Present method	0.70	−1.71	1.00	−1.44	
Average	0.72	−1.74	1.02	−1.47	

Although there are some large differences in individual log I values, there is reasonable agreement between the slopes and intercepts of the ionization curves obtained by the different methods. Since the differences which result are not large none of these correction methods was applied to the data used to obtain ionization curves in the present study. All of these correction methods are at best inadequate for the following reasons. The Davis and Geissman method only gives good linear plots if λ_B^{max} and $\lambda_{BH^+}^{max}$ are well separated. This was not the case with several of the amides studied. The isobestic point method involves arbitrariness in deciding how to shift experimental absorption curves to produce an approximate isobestic point. Different isobestic points can be chosen, giving different indicator ratios. Further, the procedure is laborious and does not give good linear log I plots. Application of the linear extrapolation method requires knowledge of an acidity scale which itself is not subject to medium effects.

Since medium effects can not be eliminated satisfactorily it was decided to limit their seriousness by using the approach of Stewart and Granger (19) as described previously. It can easily be shown that if medium effects result in errors in individual ϵ values as large as 10%, fortuitous cancellation will result in errors of only about 2–3% in the slopes of indicator curves obtained using the method described in this paper. In addition most

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

of the spectral measurements were carried out in only moderately concentrated acids where medium effects are less serious than in the concentrated range (1).

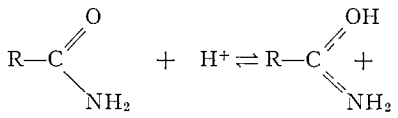
Selection of Primary Indicator

In order to carry out the standard stepwise method of determining pK values, it is necessary to choose a primary indicator base whose ionization behavior can be studied in dilute aqueous solution, where

$$\mathrm{pH} = \mathrm{p}K_{\mathrm{HIn}^+} - \log [\mathrm{HIn}^+]/[\mathrm{In}] \quad .$$

and the activity coefficients of all species involved can be taken to be approximately unity. In this way potentiometric determination of pH and the observable indicator ratio will yield a respectable thermodynamic equilibrium constant. All pK values determined from this by direct comparison will also be thermodynamic equilibrium constants, referred back to ideal dilute aqueous solution as standard state, as will be any acidity function based on these values.

In the present work we are studying ionization equilibria of primary amides. Therefore it is evident that the primary indicator should if possible be an amide. The difficulty is



that amides as a class are considerably weaker bases than amines and it has so far proved impossible to find a primary amide which is strong enough to be measurably ionized in dilute aqueous solution. The strongest bases in this class that we have been able to find are acetamide, propionamide, 2-pyrrolecarboxamide, *p*-anisamide, and 2-hydroxyphenylurea, in order of decreasing basicity. None of these is measurably ionized in the region accessible to accurate measurements with the glass electrode. While it is true that the introduction of electron-donating substituents would produce stronger bases, it is unlikely that any of the derivatives would be appreciably ionized in dilute aqueous solution either. It is known that the ionization of amides is not very sensitive to substituent effects, particularly resonance effects (23). For example, *p*-methoxy substitution only changes the half ionization point of benzamide from 36% to 29% sulphuric acid. It is unlikely that even 2,4,6-trimethoxybenzamide would be sufficiently strong to ionize in the pH range. This is illustrated by considering that in the acid dissociation of benzoic acids, which has a similar ρ value to the basic ionization of amides (24), 2,4,6-trimethoxybenzoic acid has a pK_a only 0.63 log units different from that of benzoic acid itself (25).

We have therefore selected as primary indicator *p*-nitroaniline, which was used to establish the H_0 scale. In this case we have assumed that the variation of $f_{\mathrm{AH}^+}/f_{\mathrm{A}}$ for amide type bases will be very similar to the variation of $f_{\mathrm{BH}^+}/f_{\mathrm{B}}$ for the aniline type, over a limited region of acidity extending from 0–2 M sulphuric acid. This assumption is not strictly valid (6), but since the acidity region considered is narrow, it is reasonable that $f_{\mathrm{BH}^+}f_{\mathrm{A}}/f_{\mathrm{AH}^+}f_{\mathrm{B}}$ will not differ significantly from unity in this range. As a secondary indicator we have selected 2-pyrrolecarboxamide, for the following reasons. It is stable enough in dilute acids and its absorption characteristics are such that consistent and reliable log I values can be obtained. Its measurable ionization range overlaps considerably those of *p*-nitro- and *o*-nitro-aniline, as well as those of two of the more strongly basic amides, so that it can be used to bridge the pK gap between dilute solution and those acids where the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

benzamides are appreciably ionized. The nuclear magnetic resonance (n.m.r.) spectrum of this compound in fluorosulphuric acid at low temperatures shows that it protonates on the carbonyl oxygen like the other amides studied (26).

The log I versus concentration curve for 2-pyrrolecarboxamide is reasonably parallel with those of the two nitroanilines as shown in Fig. 2. Thus the above assumption about

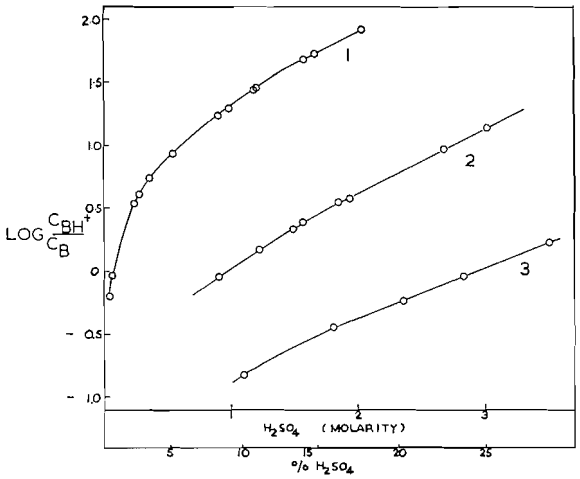


FIG. 2. Ionization curves for (1) *p*-nitroaniline, (2) *o*-nitroaniline, (3) 2-pyrrolecarboxamide in dilute sulphuric acid region.

activity coefficient behavior appears to be valid. Its curve is also closely parallel with those of *p*-methoxy and 3,4,5-trimethoxybenzamide as shown in Fig. 1. We have used the available data for *p*-nitro- and *o*-nitro-aniline (27) as well as our own data to establish the pK value for this secondary indicator using Equation [1]. The results are shown in Table I, the average pK value for 2-pyrrolecarboxamide calculated from a large number of measurements in several different acids. The agreement between the values is quite good, giving an average value of -1.23 ± 0.04 for the pK of this indicator. This value has been adopted as a standard for the determination of pK for the remaining amide indicators. It should be noted that any uncertainty introduced by the above treatment as to the absolute value of this pK will be carried through to any pK's or acidity function values determined from it.

Determination of pK Values of Indicators

The pK values of the other seven primary amides have been obtained by direct stepwise comparison using Equation [1] and the above pK of 2-pyrrolecarboxamide as a starting point. We have calculated successive pK values from ionization ratios for each overlapping pair of indicators, taking data directly from the experimental points where possible. In a few cases interpolations have been made from the best smooth curves through the experimental points. Only log I values in the range ±1.0 (corresponding to 10–90% protonation) were used, since the experimental uncertainty increases rapidly as the ionization ratio takes on very high or very low values. The individual values for a given indicator, obtained in each case from data in several different acids, show good agreement. These have been averaged and are given in Table I. The eight compounds listed constitute a structurally uniform set of amide indicators, suitable for obtaining acidity values for solutions up to 80% sulphuric acid.

The H_A Acidity Scale in Sulphuric Acid

We can now define a function, H_A, in an analogous manner to other acidity functions, such that

$$H_A = -\log (a_{H^+} f_A / f_{AH^+}) = pK_{AH^+} - \log [AH^+]/[A]$$

where pK_{AH^+} is the thermodynamic dissociation constant for an amide conjugate acid. Values of this function have been determined from the pK values and indicator ratios previously described. The individual H_A values for a given acid concentration were obtained using all indicators which were measurably protonated in that acid, again taking only log I values in the range ± 1.0. These H_A values are listed in Table III, along

‡H_A values for acids more dilute than this are assumed to be the same as the H_0 values of Bascombe and Bell (27).

with the particular indicators used for a given acid. Where more than one indicator was used, the H_A values were averaged. The agreement between the values obtained using different indicators is good. All values of H_A fall on a smooth curve when plotted against percent sulphuric acid. This curve is shown in Fig. 3 with the H_0 scale in the same acid range for comparison.

The difference between the two acidity functions is striking, even at moderate acid concentrations. For example, H_A is nearly 1 log unit less negative than H_0 even in 50% sulphuric acid, this difference becoming more than 3 log units at the highest acidities studied in the present work. This means that aqueous sulphuric acid can be up to 1000 times less effective in converting a primary amide to its conjugate acid than it is in the corresponding protonation of a primary amine of similar pK value. Thus the protonation behavior of the two types of base, although formally very similar, is considerably different

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

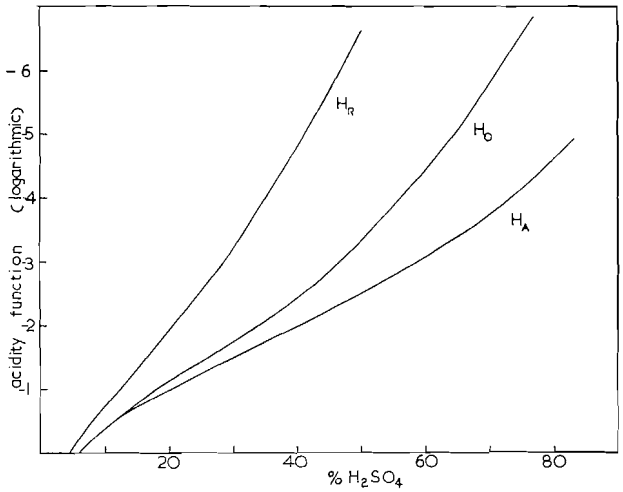

FIG. 3. Comparison of the H_A acidity function with H_0 and H_R. Values of H_0 taken from references 1, 5, and 27, and H_R from reference 2.

quantitatively. This again stresses the fact that acidity functions can be strongly dependent on indicator structure. The actual shape of the H_A curve is roughly similar to that for H_0 but is considerably less steep outside the dilute acid range and is approximately linear in the 10–60% acid region.

Comparison of the H_A and H_0 Functions

The reasons for the large observed differences in the ability of aqueous sulphuric acid to protonate primary amides as against primary amines are not immediately obvious. It is well recognized that the hydration requirements of the indicator species are important factors in determining the rate of rise of indicator acidity. This is especially true of the cations, rather than the neutral bases, as evidenced by the much more rapid rise of h_R with increasing acid concentration than that of h_0, carbonium ions being much less strongly hydrogen bonded to solvent molecules than anilinium ions. Just how this factor operates in the present case is not clear. If the two types of equilibria are written in terms of fully hydrated species, for the amides we have

$$AH^+(H_2O)_m + (a + p - m)H_2O \rightleftharpoons A(H_2O)_a + H^+(H_2O)_p$$

and for the anilines

$$BH^+(H_2O)_n + (b + p - n)H_2O \rightleftharpoons B(H_2O)_b + H^+(H_2O)_p.$$

We can now define the nonlogarithmic acidity functions in terms of fully hydrated species as

$$h_A = (a_{H^+(H_2O)_p} \cdot f_{A(H_2O)_a} / f_{AH^+(H_2O)_m} \cdot a_{H_2O}{}^{(a+p-m)})$$

$$h_0 = (a_{H^+(H_2O)_p} \cdot f_{B(H_2O)_b} / f_{BH^+(H_2O)_n} \cdot a_{H_2O}{}^{(b+p-n)})$$

The difference between the two functions can be expressed as the ratio

$$[2] \qquad h_A/h_0 = (f_{BH^+{}_h} \cdot f_{A_h} / f_{B_h} \cdot f_{AH^+{}_h})^{a_{H_2O}{}^{(m-a)-(n-b)}}$$

where the subscripts h refer to hydrated species. The less rapid increase of h_A with acidity

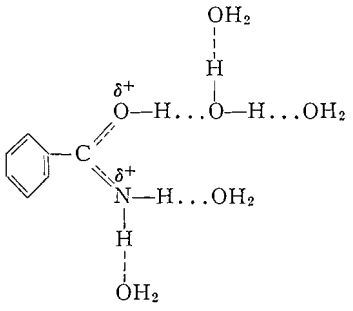
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

can be attributed to the hydration requirements of the amides in several ways. If the change in hydration on going from a neutral amide to a more strongly hydrated cation is greater than the corresponding hydration change on protonating an aniline, then $[(m - a) - (n - b)]$ will be positive. Hence, as the acid concentration is increased, and the water activity is decreased, h_A/h_0 will decrease, as is observed. If an amide conjugate acid is more strongly hydrated than the corresponding anilinium ion, f_{AH^+} will increase more rapidly with increasing acid than f_{BH^+}. Similarly, if a neutral amide is less strongly hydrated than the corresponding aniline, f_A will rise less rapidly than f_B. Each of these factors will contribute to a less rapid rise of h_A with acid concentration, when compared with h_0. Any or all of these factors may undergo significant variation with changes in the medium but their relative importance is difficult to predict. Assuming for the moment that the separation of terms in Equation [2] is valid, and that the net variation of the activity coefficient term is less important than that of the term in the water activity, we can write approximately

$$H_0 - H_A = [(m - a) - (n - b)] \log a_{H_2O} + \text{constant.}$$

Plotting $(H_0 - H_A)$ against $\log a_{H_2O}$ should then give a curve whose slope at any point can be related to the net hydration changes involved in the two types of equilibria. We have plotted $(H_0 - H_A)$ against available water activity data (28). The relationship is not linear, which is as expected, since even if the above assumptions are valid, the individual hydration numbers can take on different values in different regions of acidity, depending on the amount of "free" water available. The plot shows a steadily decreasing curvature as $\log a_{H_2O}$ is decreased. It is approximately linear over two wide regions, giving a slope of about 1.7 in the 30–60% acid range and about 0.75 in 70–85% range. This suggests that the net increase in hydration on protonation of an amide involves one or two more water molecules than the corresponding increase on protonation of an aniline. Taft (29) has suggested that a hydration number of 3 for an anilinium ion is reasonable in view of the fact that such an ion can hydrogen bond strongly to three water molecules through its acidic protons. However, considering only the numbers of such protons available for hydrogen bonding in the various indicator species, it is difficult to see how $[(m - a) - (n - b)]$ can differ very much from zero. One way around this difficulty is to postulate the following structure for the hydrated amide cation so that its hydration



number can be 5 in solutions where there is sufficient water available. In support of this it is known that [O—H...O] bonds are on the average considerably stronger than the [N—H...O] type (30). Further, aldehydes (31) and ketones (32) whose conjugate acids have only one acidic proton, follow the H_0 function reasonably well. This suggests strongly that a protonated carbonyl group is hydrated by more than one water molecule.

This simple explanation of the difference between H_A and H_0 obviously leaves much to be desired except in a qualitative sense, since we have neglected possible variations in the $\log(f_{BH^+_h} \cdot f_{A_h}/f_{B_h} \cdot f_{AH^+_h})$ term of Equation [2]. However, this term would also have to decrease as the water activity is decreased, to account for the observed differences in h_A and h_0, and would require similar kinds of hydration changes on protonation of amides and anilines, i.e. that $(m - a) > (n - b)$.

A knowledge of the activity coefficients of amides and their conjugate acids is clearly desirable in order to be able to assess the importance of the various terms in Equation [2]. We are at present investigating the activity coefficient behavior of some typical amides and their salts. We hope by comparing these results with Boyd's values for typical aniline indicators (33) to be able to assess more quantitatively the importance of the various factors involved.

The Applicability of the H_A Scale

It is evident that the H_A function, like any other acidity function, will be of limited generality. It is, however, important that it be applicable at least to primary amides as a class, in order that it may be used to obtain thermodynamic pK's for other amides and also be useful in studying reaction mechanisms. We have therefore tested the generality of H_A in the following way. Using available experimental data we have plotted log I values against H_A for 12 primary amides not used as indicators in the present work. Ten of these gave least mean squares slopes between 0.95 and 1.05 which can be considered as being effectively unity as required by the defining equation for H_A. The mean value and deviation for all 12 was 0.97 ± 0.06. Thus within the experimental uncertainty caused by medium shifts on the spectra towards the red, which would result in slopes of less than unity, these amides appear to be following H_A reasonably well. It would be interesting to test the generality of the H_0 function in a similar way using representative anilines. This has apparently not been done.

The behavior of the individual amides and the significance of derived pK values will be discussed in detail in Part II of this series.

Estimated Accuracy of the H_A Values

It is impossible to estimate precisely the numerical accuracy of any particular H_A value, since individual errors in determined pK values may be cumulative. Also, as mentioned previously, any uncertainty in the pK of the secondary standard base will be carried through to all subsequently determined pK's, and hence to any H_A values determined from them. The usual estimate of the experimental uncertainty in any pK value obtained by the standard spectrophotometric technique is ± 0.05 log unit. Therefore the H_A values should not be considered as known to any better than ± 0.1 units in the lower acidity range and probably ± 0.2 units in the more concentrated region above 60% acid. Nonetheless the following considerations give confidence in the reliability of the values within these limits. The parallelism of the indicator curves is good. These curves are closely spaced enough so that considerable overlap has been achieved. Hence not too much weight has been placed on any one indicator. The several H_A values obtained for any given solution are consistent and all experimental points fall closely on a smooth curve when plotted against concentration.

FRACTIONATION OF GERMANIUM ISOTOPES IN CHEMICAL REACTIONS

H. M. BROWN[1] AND H. R. KROUSE
Department of Physics, University of Alberta, Edmonton, Alberta
Received January 8, 1964

ABSTRACT

Isotopic vibrational frequencies and the corresponding partition-function ratios for several compounds containing Ge^{70} and Ge^{76} have been calculated at various temperatures. The theoretical equilibrium constants for germanium isotope-exchange reactions derived from these partition-function ratios indicate that noticeable germanium isotope fractionation might be effected with laboratory reactions. Calculated kinetic isotope effects in the breaking of diatomic bonds also predict observable alterations of the Ge^{70}/Ge^{76} ratio.

A kinetic isotope effect of 1.0% observed in the chemical reduction of GeO_2 to GeO is discussed.

INTRODUCTION

With the discovery of deuterium in 1932 by Urey, Brickwedde, and Murphy (1), it became apparent that the isotopes of an element differ noticeably in their physical and chemical behaviors. These differences are due to the dependence of many thermodynamic quantities upon the vibrational frequencies of the molecules, and the dependence in turn of these frequencies upon the masses of the constituent atoms. Lighter elements have received considerable study because of the large percentage mass differences between their isotopes. Heavy elements which possess a number of isotopes, however, may also have a significant percentage mass difference between their lightest and heaviest isotope, and therefore noticeable fractionation might be possible in natural and laboratory processes.

Element 32, germanium, is such an element, with five stable isotopes of mass numbers 70, 72, 73, 74, and 76 and approximate abundances of 20.5, 27.4, 7.8, 36.5, and 7.8% respectively. The percentage mass difference is about 8% between Ge^{70} and Ge^{76}. The isotopes of the element were first investigated mass spectrometrically by Aston in 1923 (2), and since then their abundances have been measured by a number of workers (Bainbridge (3), Dempster *et al.* (4), Hibbs *et al.* (5), Graham *et al.* (6), Reynolds (7), and Shima (8)).

Of these, Graham *et al.* (6) and Shima (8) investigated samples from various sources. Shima found no difference in the isotopic composition of germanium from eight meteorites and a terrestrial sample, outside of the error of his solid-source mass-spectrometric analyses. Graham *et al.* (6) had previously examined six samples from widely varying geographical and geological origins. Analyses were made with both $GeCl_4$ and GeF_4 in a gas-source mass spectrometer. Within the precision of their measurements, they found all but one of these samples to have the same isotope abundance. The sample which differed (0.7% in the Ge^{70}/Ge^{76} ratio) from the others had the lighter isotopes favored at the expense of the heavier ones, while the isotopes of intermediate mass were of about the same abundance as in the other samples. This is precisely the effect that one would expect in a natural isotope-fractionation process which is solely a function of mass.

The study reported here is a theoretical and experimental attempt to determine the extent to which the Ge^{70}/Ge^{76} ratio might be altered in laboratory and natural processes.

THEORY

Equilibrium Isotope Effects

Urey and Rittenburg (9) were the first to apply statistical mechanics to the calculation of equilibrium isotope-exchange constants. Later simplification by Urey (10) and by Bigeleisen and Mayer (11) has made it possible to calculate these constants (except in the case of hydrogen) solely from a knowledge of the isotopic vibrational frequencies of the participating molecules.

An isotopic-exchange reaction may be written

$$[1] \qquad aA_1 + bB_2 \rightleftharpoons aA_2 + bB_1$$

where the subscripts 1 and 2 refer to the light and heavy isotopes respectively, and A and B are molecules having the element under consideration as common constituent. The equilibrium constant for this exchange is given by

$$[2] \qquad K = \left[\frac{Q_{A_2}}{Q_{A_1}}\right]^a \Big/ \left[\frac{Q_{B_2}}{Q_{B_1}}\right]^b,$$

where the Q's are the total partition functions of the molecules. Urey (10) and Bigeleisen and Mayer (11) have shown that this constant can be expressed in terms of isotopic partition-function ratios Q_2'/Q_1' which depend only on the vibrational frequencies of the isotopic molecules. In this work the simplification of Bigeleisen and Mayer, where the ratio is given by

$$[3] \qquad \frac{Q_2'}{Q_1'} = \frac{\sigma_1}{\sigma_2}\left[1 + \sum_i \left(\frac{1}{2} - \frac{1}{u_{2i}} + \frac{1}{e^{u_{2i}} - 1}\right)\Delta u_i\right],$$

has been used. Here $u_i = hcw_i/kT$ and w_i is the i'th vibrational frequency in cm^{-1}. The summation is over i fundamental frequencies, a d-fold degeneracy being counted d times. The ratio of symmetry numbers σ_1/σ_2 is unity if the molecule under consideration contains only one atom of the element being exchanged or if the molecule contains more than one such atom, but these atoms occupy indistinguishable positions in the molecule and are all exchanged. $\Delta u_i = u_{1i} - u_{2i}$ is always positive. The function

$$G(u_i) = \frac{1}{2} - \frac{1}{u_{2i}} + \frac{1}{e^{u_{2i}} - 1}$$

has been tabulated by Bigeleisen and Mayer (11) for values of $0 \leq u \leq 25$.

Kinetic Isotope Effects

The general problem of reaction rates has been developed from a statistical viewpoint by Eyring (12) and by Evans and Polanyi (13). Bigeleisen (14) has used their "theory of absolute rates" to develop an expression for the ratio of reaction rates for competing isotopic reactions. It is

$$[4] \qquad \frac{k_1}{k_2} = \frac{K_1}{K_2}\cdot\frac{\sigma_1}{\sigma_2}\cdot\frac{\sigma_2^{\ddagger}}{\sigma_1^{\ddagger}}\cdot\frac{\nu_{1L}^{\ddagger}}{\nu_{2L}^{\ddagger}}\left\{1 + \sum_i^{3n-6} G(u_i)\Delta u_i - \sum_i^{3n-7} G(u_i^{\ddagger})\Delta u_i^{\ddagger}\right\}.$$

Here $G(u_i)$ is the free-energy function previously defined, ‡ refers to the activated complex of absolute reaction rate theory, σ_i are symmetry numbers, 1 and 2 refer to the light and heavy isotopes respectively, and $\nu_L^{\ddagger}$ is the imaginary frequency of vibration along the reaction coordinate. The ratio of transmission coefficients, K_1/K_2, has been shown by Hirschfelder and Wigner (15) to be nearly unity at and above room temperature.

The ratio $\nu_{1L}^{\pm}/\nu_{2L}^{\pm}$ is generally given the value $(\mu_2^*/\mu_1^*)^{\frac{1}{2}}$, where μ^* denotes the reduced mass along the reaction coordinate. Previously this was taken to be the reduced mass of the two atoms joined by the bond being ruptured, in agreement with work on classical models by Slater (16). Bigeleisen and Wolfsberg (17) suggest, however, that because the molecule is being torn into two fragments μ^* should be considered as the reduced mass of the two fragments.

Equation [4] is difficult to apply because of our limited knowledge of the activated complex and hence our inability to calculate the term

$$\sum_i^{3n-7} G(u_i^{\pm})\Delta u_i^{\pm}.$$

In general, however, the activated complex will be intermediate in form between the reactants and products, enabling two limits to be calculated for the ratio of rate constants. One limit arises when it is assumed that the activated complex is like the reactant, i.e.

$$\sum_i^{3n-6} G(u_i)\Delta u_i = \sum_i^{3n-7} G(u_i^{\pm})\Delta u_i^{\pm}.$$

In this case the ratio of rate constants is the ratio of the reduced masses and is temperature independent. If the activated complex is like the product, then

$$\sum_i^{3n-7} G(u_i^{\pm})\Delta u_i^{\pm} = \left(\sum_i^{3n-6} G(u_i)\Delta u_i\right)_{\text{product}}.$$

For a diatomic reactant molecule, since there is no vibrational frequency,

$$(G(u_i)\Delta u_i)_{\text{product}} = 0.$$

An experimentally measured ratio of rate constants is expected to fall within these two extremes.

THEORETICAL CALCULATIONS

Using the above theory, the partition function ratios for various compounds containing Ge^{70} and Ge^{76} were calculated. The vibrational frequencies for these isotopic molecules were calculated by means of known "force equations" from the experimentally observed frequencies, which were assumed to apply to the most abundant Ge^{74} molecules. These known "force equations" relate the fundamental vibrational frequencies to force constants and atomic weights on the assumption of a particular model for the molecule under consideration.

TABLE I

Diatomic molecular frequencies (cm^{-1})

Molecular species	Frequency		
	Obs. for species containing Ge^{74}(26)	Calc. for species containing Ge^{70}	Calc. for species containing Ge^{76}
GeS^{32}	572.2	577.1	569.9
$GeSe^{80}$	404.4	411.6	401.6
$GeCl^{35}$	404.9	408.5	403.2
$GeTe^{130}$	321.4	327.2	318.7
GeF	659.6	663.5	657.9
GeBr*	294.8	299.1	292.8
GeO^{16}	977.1	982.0	974.8

*Bromine has two isotopes 79 and 81 which are each approximately 50% abundant. Therefore the atomic weight was used in the calculation.

Tables I and II summarize the vibrational frequencies calculated for some diatomic and polyatomic species containing Ge^{70} and Ge^{76}. References to the spectroscopic data used, the set of force equations employed, and the method of calculation are given. In Table III the partition-function ratios and the equilibrium constants for some possible $Ge^{70} \leftrightarrow Ge^{76}$ exchange reactions are summarized. The equilibrium constant for an exchange reaction between any two compounds listed is contained in the body of the table

at the intersection of the appropriate row and column. An equilibrium constant greater than unity indicates that the heavier isotope will concentrate in the compound listed in the left column.

TABLE IV

Kinetic isotope effect: ratio of rate constants k_{70}/k_{76}

Temp. (°C)	GeS^{32}	$GeSe^{80}$	$GeCl^{35}$	$GeTe^{130}$	GeF^{19}	GeBr	GeO^{16}
Maximum value of k_{70}/k_{76}:							
0	1.021	1.031	1.018	1.033	1.016	1.026	1.020
25	1.020	1.029	1.017	1.032	1.015	1.025	1.018
100	1.015	1.028	1.016	1.030	1.013	1.024	1.015
250	1.015	1.025	1.015	1.028	1.011	1.023	1.011
Minimum value of k_{70}/k_{76}:							
	1.013	1.022	1.013	1.027	1.009	1.022	1.007

For diatomic species, Table IV shows the maximum and minimum values to be expected in the ratios of the rate constants in a kinetic isotope effect. These values indicate (for a particular molecular species and reaction temperature) how much faster the species with the lighter (Ge^{70}) isotope will react than that with the heavier (Ge^{76}) isotope in competitive reactions.

EXPERIMENTAL KINETIC ISOTOPE-EFFECT STUDY

Reduction of GeO_2

To see if the extent of isotope fractionation predicted theoretically could be verified experimentally, GeO_2 was partially reduced in an aqueous medium and a kinetic isotope effect was observed.

The reduction procedure was based upon the method of Dennis and Hulse (18) in which hypophosphorous acid was used as the reducing agent. Schenk (19) has represented this overall reaction by the following equation.

$$GeO_2 + H_3PO_2 = GeO + H_3PO_3$$

One gram of GeO_2 was dissolved in 500 ml of H_2O and the solution was made ~3 *N* with respect to HCl. This solution was heated to 100 °C, and 25 ml of 50% H_3PO_2 (also heated to 100 °C) were added with vigorous stirring. The reaction was stopped upon partial completion by neutralizing with NH_4OH. This neutralization precipitated hydrous GeO, which ranged in color from yellow to brown depending upon the extent of hydration. The times for various degrees of reduction were predetermined experimentally and found to be within the range of 1 to 2 minutes for 10% and 20% reductions at 100 °C. A 10% reduction at 80 °C with the above concentrations required 13 minutes. It would have been more convenient to have effected a partial reduction by adding the appropriate insufficiency of H_3PO_2, but all attempts to do this were unsuccessful. After precipitation, the hydrous GeO was separated from the solution by centrifuging and was then reoxidized to GeO_2 with H_2O_2. From this GeO_2 sample, GeF_4 gas was prepared by the method of Dennis and Laubengayer (20) and the Ge^{76}/Ge^{70} ratio was determined in a gas-source mass spectrometer. This ratio was compared to that of a standard GeF_4 sample prepared from "non-reduced" GeO_2.

Mass Spectrometry

Two different mass spectrometers were used during the course of the investigation. The first was a single collection 6 in. radius 60° magnetic analyzer with a strip-chart recorder to trace mass spectra "peaks". Normally the run procedure consisted of tracing 22 complete spectra of a sample and then similarly recording a "standard". Typically a run consisted of 3 or 4 such comparisons. To determine the relative abundances of the germanium isotopes, the relative peak heights were measured.

The second mass spectrometer was a 12 in. radius 90° magnetic-analyzer instrument employing simultaneous collection. A null method of recording was used where a measured portion of the voltage produced by one ion current is fed back inversely to cancel the voltage produced by the other ion current. A magnetic-valve system (21) enabled samples to be changed within about 5 minutes and allowed three continuous recordings of a sample and a standard to be made in 1 hour.

In both instruments, the most abundant ion spectrum GeF_3^+ was used. The sample-handling systems were of pyrex glass with metal Hoke valves, to eliminate contaminations from stopcock grease, and were designed to introduce both the standard and the sample into the mass spectrometer at the same pressure. Memory effects were present, but these were short time and did not cause much difficulty.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Contaminants included SiF_4 and HF, which were produced when $BaGeF_6$ was decomposed according to the Laubengayer method. It was felt that the HF was trapped when the crystals of $BaGeF_6$ were precipitated since heating the crystals below their decomposition temperature proved an effective means for HF removal. SiF_4 could be pumped away from the sample by using a solid–liquid ethyl alcohol bath. Another contamination was the presence of chloride species. This was believed to be due to the use of $BaCl_2$ in the preparation of $BaGeF_6$. This problem was most acute with small samples. Two difficulties arise: (*a*) the mass spectrometer cannot resolve the $Ge^{73}FCl^{35+}$ ion current from that of $Ge^{70}F_3^+$ and (*b*) germanium isotopes might exchange between the halide species and fractionate. Although corrections seem possible for contaminated samples, only the measurements from samples with negligible chloride content are reported here.

RESULTS AND DISCUSSION

Tables III and IV indicate that the Ge^{70}/Ge^{76} ratio might be altered by as much as 3% if mechanisms for such alterations existed.

The experimental results confirm the possibility of fractionating germanium isotopes. Measurements on five 10% reductions at 100 °C gave

$$R_{10} = \frac{(Ge^{70}/Ge^{76})_{\text{GeO product}}}{(Ge^{70}/Ge^{76})_{\text{unreduced GeO}_2}} = 1.010 \pm 0.002.$$

A 10% reduction at 80 °C gave a result slightly higher than the above average but within the standard deviation.

Four 20% reductions at 100 °C gave a much lower result,

$$R_{20} = \frac{(Ge^{70}/Ge^{76})_{\text{GeO product}}}{(Ge^{70}/Ge^{76})_{\text{unreduced GeO}_2}} = 1.004 \pm 0.001.$$

The mechanism and kinetics of this reduction have not been studied in detail. However, there is considerable agreement (22, 24) that GeO_2 is present as the un-ionized monomer in 3 *N* HCl (HCl does not start to complex with Ge^{IV} until >6 *N*). The reduced germanium is easily complexed by HCl and is likely present as $GeCl_3^-$ or $GeCl_4^=$ (24). It would appear that the oxygen in the product GeO is not that originally present in GeO_2. It seems desirable therefore to attribute the results to a kinetic isotope effect in the competitive reactions

$$^{70}GeO_2 \xrightarrow{k_{70}} {}^{70}Ge^{II}$$

$$^{76}GeO_2 \xrightarrow{k_{76}} {}^{76}Ge^{II}$$

where Ge^{II} simply refers to the various species with germanium present in the +2 valence state. Since in the reaction, oxygen atoms are being removed from the germanium, the simplest interpretation is that the observed isotope fractionation results during a germanium–oxygen bond breakage.

When R_{10} and R_{20} are corrected to zero reduction, they should of course give the same value. Using equations given by Bigeleisen and Wolfsberg (17), this was not found to be the case; R_{10} gave $k_{70}/k_{76} = 1.012 \pm 0.002$ while R_{20} gave $k_{70}/k_{76} = 1.006 \pm 0.001$. However, when the procedure is considered, this discrepancy is not surprising. Shenk (19) suggests that similarly prepared GeO usually contains a few percent of GeO_2. The presence of unreduced GeO_2 in the hydrous GeO precipitate would reduce the ratio *R*. Furthermore, since the solubilities of GeO_2 and GeO in neutral aqueous solution have been reported as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

0.45 g/100 ml (25) and 0.04 g/100 ml (23) respectively at 25 °C, it is probable that some of the reduced product remained dissolved in the reaction medium.

In two 10% reductions, the abundances of the other germanium isotopes were also compared. On the basis of the above interpretation it was found that

$$\frac{k_{70}}{k_{72}} = \frac{k_{72}}{k_{74}} = \frac{k_{74}}{k_{76}} = 1.003 \pm 0.001,$$

which is consistent with the results of R_{10}. GeO_2 completely reduced to GeO and reoxidized was found to be identical with unreacted GeO_2 with less than 0.05% standard deviation, suggesting that the inconsistency noted is a result of the limitations on chemical control of the reduction rather than in instrumentation.

Vibrational frequencies could not be found for GeO_2 monomer in solution, and attempts to measure them under the reaction conditions were unsuccessful. If a simplified model of the reaction is assumed, namely the breaking of a Ge–O diatomic bond, Table IV predicts a maximum and minimum value for k_{70}/k_{76} at 100 °C of 1.015 and 1.007.

This theoretical result further suggests that the fractionation observed represents the isotope effect in the breaking of a germanium–oxygen bond.

It would be desirable to study the mechanism of this reaction thoroughly, so that a more exact interpretation could be made of the isotope effect noted. The measurements are significant, however, in that they demonstrate the feasibility of fractionating germanium isotopes in chemical reactions.

ACKNOWLEDGMENTS

The authors are indebted to G. L. Cumming of the Physics Department, University of Alberta, Edmonton, for his part in the mass spectrometry in the initial stages of this study and to D. A. Everest of the National Chemical Laboratory, Teddington, Middlesex, for correspondence regarding the behavior of germanium in solution.

Financial assistance from the National Research Council, Ottawa, is also gratefully acknowledged.

THE TRANSMISSION OF THE POLAR EFFECTS OF SUBSTITUENTS IN AROMATIC AND ARYLALIPHATIC CARBOXYLIC ACIDS

REACTIONS OF THE ACIDS WITH DIAZODIPHENYLMETHANE IN ETHANOL

K. Bowden, N. B. Chapman, and J. Shorter
Chemistry Department, The University, Hull, England

Received February 4, 1964

ABSTRACT

Rate coefficients have been determined for the reactions in ethanol at 30° of diazodiphenylmethane with several groups of carboxylic acids. Each group included the parent acid and three nuclear substituted acids. The parent acids were: benzoic, phenylacetic, β-phenylpropionic, phenoxyacetic, and *trans*-cinnamic acid. The reactions of 3-fluoro- (or chloro-) or 4-methyl-biphenyl-4′-carboxylic, and of 9-X-10-anthroic acids (X = Me, Cl, or Br) were also studied similarly. The Hammett polar susceptibility constant, ρ, has been calculated for each set of reactions. The values of ρ are discussed in terms of transmission of electronic effects through the side-chain by a field effect, and for side-chains conjugated with the ring, by a π-electron effect, both of which are inversely proportional to the first power of the distance of the carbonyl group from the ring.

INTRODUCTION

In a recent series of papers, Chapman and Shorter and their co-workers have discussed the separation of polar and steric effects in the reactions of aromatic and arylaliphatic carboxylic acids and their esters (1–5). The reactions of carboxylic acids with diazodiphenylmethane have received particular attention (1, 3, 5). We have obtained the Hammett polar susceptibility constant, ρ (6), for the reactions with diazodiphenylmethane in ethanol of a number of aromatic and arylaliphatic acids of the type Ar—Y—CO_2H. One of us (K. B.) has already used these values of ρ, in conjunction with other published data, to discuss the transmission of polar effects by aryl and alkyl systems (7). We now present the experimental results underlying the values of ρ, and discuss further the influence of Y on the transmission of the polar effects of substituents in the aryl group on the reactivity towards diazodiphenylmethane of the carboxyl group in Ar—Y—CO_2H.

The kinetics of the reactions of carboxylic acids with diazodiphenylmethane have been studied in recent years, by using a spectrophotometric technique to follow the consumption of diazodiphenylmethane (see ref. 5 for references). In ethanolic solution diazodiphenylmethane reacts with carboxylic acids to form diphenylmethyl carboxylates:

$$R\cdot CO_2H + Ph_2C{:}N_2 \rightarrow R\cdot CO_2\cdot CHPh_2 + N_2.$$

There is also a concurrent reaction between solvent ethanol and diazodiphenylmethane, catalyzed by the acid to give ethyl diphenylmethyl ether:

$$EtOH + Ph_2C{:}N_2 \rightarrow Et\cdot O\cdot CHPh_2 + N_2.$$

Roberts, Watanabe, and McMahon (8) investigated the mechanism of each of these reactions, and concluded that these were essentially independent. However, Bowden, Buckley, Chapman, and Shorter (5), and Miller and O'Ferrall (9) have concluded that the ester and ether formation proceed by way of a common intermediate, the distinction between ester formation and ether formation arising only in the breakdown of the intermediate to the products. The mechanism involves a rate-determining proton transfer from the acid to the diazodiphenylmethane.

RESULTS AND DISCUSSION

Second order rate coefficients for the reactions of the carboxylic acids with diazodiphenylmethane in ethanol at 30° are assembled in Table I. We give also the values of R,

TABLE I

Reactions of carboxylic acids with diazodiphenylmethane in ethanol at 30°

Acid series	Substituent k_2^a,* (R)†			
Benzoic‡	H	*m*-Me	*m*-Cl	*m*-NO_2
	0.991 (59.1)	0.830 (61.1)	2.42 (60.0)	4.45_5 (60.0)

†Values of R (%; for significance see main text) are reproducible to ±0.2% (unit) or better.
‡Measurements by Mr. A. Buckley.

the ratio (%) of the amount of diazodiphenylmethane consumed in esterification to the total amount consumed (esterification plus etherification). In accordance with our view of the mechanism of the reaction (5), we do not correct the measured second order rate coefficient (k_2^a) to give the "true" rate coefficient (k) for the esterification (cf. refs. 1, 3, and 10); k_2^a is now understood to relate to the common rate-determining step. The values of R and of k_2^a for the various parent acids have been discussed elsewhere (5). Table I shows that the effect of substituents on R in each series is very small and no further comment is needed.

The choice of substituents in each series was partly governed by the accessibility of the acids and their solubility in ethanol. However, since the results were to be used to evaluate ρ-values, in accordance with the views of van Bekkum, Verkade, and Wepster (11), *meta* substituents were selected as far as possible, and *para* substituents capable of strong mesomeric interaction with the carboxyl group were avoided. In the correlation of log k_2^a with σ, the values of σ used for *meta* substituents were taken from ref. 11; for *para* substituents σ^n-values were used (11). The ρ-values for the reactions of the various series of acids listed in Table I are shown in Table II, together with ρ-values calculated from the results obtained by other authors for three related systems (12, 13, 14).

The correlation coefficients differ only slightly from unity except for reactions of the 9-X-10-anthroic acids. We therefore suggest that σ-values based on the behavior of benzene derivatives apply only in a limited way to the anthracene system, owing to the more extensive conjugation of the latter. (We have avoided substituents whose electronic effects might be influenced by steric interaction with the *peri*-hydrogen atoms.)

The values of ρ for the reactions of the various series of acids with diazodiphenylmethane in ethanol vary in parallel fashion with the ρ-values for the ionization of the acids (7) (a rho–rho relation; ref. 15). Such a relation is to be expected if, as we suggest, the mechanism of the diazodiphenylmethane reaction involves a rate-determining proton transfer (5, 9). Bowden tabulated ρ/ρ_0 values for several types of reaction of the various series of

acids (7), (ρ_0 is the susceptibility constant for the benzoic acid series, taken as a reference system). Besides the diazodiphenylmethane reaction, the processes considered were ionization in water and in 50% ethanol, and alkaline hydrolysis of ethyl esters in aqueous ethanol. Each series was discussed in terms of the mean value of ρ/ρ_0; the part played by the direct field effect, and by σ- and π-inductive effects in the transmission of the polar effects of substituents was tentatively assessed.

Bowden (7) calculated the direct field effect along the lines proposed by Kirkwood and Westheimer (16), with slight modification. According to Kirkwood and Westheimer the transmission of the effect of a dipolar substituent is determined by the factor $\cos\theta/r^2D'$, where r is the distance between the center of the dipole and the reaction center, D' the effective dielectric constant, and θ the angle between the line joining the reaction center to the center of the dipole and the axis of the dipole. Bowden calculated $\cos\theta/r^2$ for the various systems on the basis of a simple model. The center of the dipole was considered to be situated at the "*para*"-carbon atom of the aromatic ring in Ar—*Y*—CO_2H. The direction of the dipole vector was then taken as the line generated by joining the "*para*"-carbon atom to the carbon atom linked to the functional group. The reaction center was sited on the extension of the bond joining the carboxyl carbon to the ring, at a distance of 0.89 Å beyond the carbon of the carboxyl group. For each system $\cos\theta/r^2$ divided by the related quantity for the reference system (benzoic acid) was denoted by ϕ.

Values of ϕ are given in Table II. For β-phenylpropionic acid and phenoxyacetic acid, ϕ refers to the sterically preferred "*anti*"-conformer. If D' is nearly the same for all the systems, then $\rho/\rho_0 \sim \phi$ *provided that the main influence of the substituent is the direct field effect.* Whether the mean values of ρ/ρ_0 given by Bowden or the values of ρ/ρ_0 based on the diazodiphenylmethane reaction are used, ϕ is not equal to ρ/ρ_0, but there are qualitative similarities. For *trans*-cinnamic acid ϕ and ρ/ρ_0 agree well, but for β-phenylpropionic acid, which has almost the same value for ϕ, only very poorly. The high value of ρ/ρ_0 for *trans*-cinnamic acid as compared with β-phenylpropionic acid indicates the importance of a π-electron effect in the former acid; the agreement between ρ/ρ_0 and ϕ for *trans*-cinnamic

For personal use only.

acid must be largely fortuitous. This attempt to interpret ρ solely in terms of a direct field effect calculated as above is thus not very fruitful.

We therefore now present an interpretation of ρ/ρ_0, suggested by considering the way of calculating the direct field effect in benzene compounds recently developed by Dewar and Grisdale (17). These authors argue that the field effect on the 1-side-chain of a 3- or 4-dipolar substituent should be regarded as the effect at the 1-carbon atom of the charge induced at the 3- or 4-carbon atom by the attached substituent. Regarded in this way the field effect varies inversely with "distance", cf. the inverse dependence on ("distance")^2 in the Kirkwood–Westheimer approach (16). For the series of acids Ar—Y—CO_2H, we assume that the substituent effect which reaches the 1-carbon atom is transmitted from there to the reaction center (*a*) by a field effect which depends inversely on the distance between the 1-carbon atom and the carbon atom of the carboxyl group, and (*b*) if the carboxyl group, and Y, and Ar form a conjugated system, by a π-electron effect, also varying inversely with distance as above. The second effect will be present in the benzoic, *trans*-cinnamic, 3- or 4-X-biphenyl-4′-carboxylic, and phenylpropiolic acid series. We assume that the effective dielectric constant for (*a*) does not depend markedly on the nature of Y.

The π-electron effect for benzoic acid may be estimated from the results for 4-X-2,6-dimethylbenzoic acids, in which this effect is suppressed by the steric inhibition of conjugation caused by the *ortho*-methyl groups (5). The value of ρ/ρ_0 for 4-X-2,6-dimethylbenzoic acids is 0.68; we therefore take ρ/ρ_0 for 'unconjugated' benzoic acid as $\sim$0.70. (The results for the 9-X-10-anthroic acid series are also in accord with this; $\rho/\rho_0 = 0.74$. The 4- or 5-X-*o*-toluic acid system shows little suppression of conjugation; $\rho/\rho_0 = 0.94$; see ref. 1). Values of ρ/ρ_0 (calc.) for the phenylacetic, β-phenylpropionic, and phenoxyacetic acid series are given by the product of 0.70 and the distance between carbon atom 1 and the carboxyl-carbon in benzoic acid (1.48 Å), divided by the corresponding distance in the acid under consideration. (Distances were calculated from data in ref. 18). The "*anti*"-conformation was assumed for the β-phenylpropionic and phenoxyacetic acid series. The agreement between ρ/ρ_0 (calc.) and ρ/ρ_0 (obs.) is satisfactory, and far better than that between ϕ and ρ/ρ_0 (obs.).

For the conjugated acids we assume that the "distance ratio" should give ρ/ρ_0, i.e. the π-electron effect and field effect are treated together, and assumed to vary inversely with distance; the influence of any inherent differences in the degree of conjugation of the various systems is ignored. Again there is reasonable agreement between ρ/ρ_0 (calc.) and ρ/ρ_0 (obs.), although there are no doubt specific factors which our treatment neglects. For example the difference between the values of ρ/ρ_0 (calc.) for *trans*-cinnamic and phenylpropiolic acid is 0.03; the observed difference is 0.11. This suggests that the relatively inferior transmission of the triply bound system is not simply a matter of distance (7).

To sum up, it appears that a satisfactory, almost quantitative, account of the transmission of electronic effects through the side-chain in the systems we have studied can be given in terms of a direct field effect, and a π-electron effect, where appropriate, inversely dependent on distance.

EXPERIMENTAL

Materials

The acids were commercial samples or were prepared by standard methods. We thank Dr. G. W. Gray and Dr. R. C. Wilson for samples of substituted biphenylcarboxylic acids. The acids were recrystallized to constant m.p., and they had m.p. identical with, or very close to, those recorded in the literature. The equivalent weight of each acid was determined by titration, and found to be well within 1% of the calculated value. Where possible the purity of each acid was examined by vapor-phase chromatography of the methyl ester as described previously (5). No impurities were found.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Diazodiphenylmethane was prepared by the method of Schroeder and Katz (19). Solutions were stored in a refrigerator. Pure ethanol, b.p. 78.3°, n_D^{25} 1.3591 (lit. ref. 20, 78.3°, 1.35941), was prepared by Smith's method (21). Fischer titration (22) showed a water content < 0.02% by weight. The ethanol was stored and manipulated under dry nitrogen with very careful exclusion of atmospheric moisture.

Measurements

Values of k_2^a and R were determined as described previously (10).

One of us (K. B.) is indebted to the Department of Scientific and Industrial Research for a Research Studentship.

STUDIES ON THE THERMODYNAMICS AND CONDUCTANCES OF MOLTEN SALTS AND THEIR MIXTURES

PART IV. THE ELECTRICAL CONDUCTANCES OF MOLTEN LITHIUM CHLORATE AND OF ITS MIXTURES WITH PROPYL ALCOHOL, LITHIUM NITRATE, WATER, METHYL ALCOHOL, AND LITHIUM HYDROXIDE

A. N. Campbell and D. F. Williams
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received April 14, 1964

ABSTRACT

The electrical conductance and its temperature dependence of molten lithium chlorate have been determined. Similar results have been obtained for lithium chlorate melts containing small quantities of methyl alcohol, propyl alcohol, lithium nitrate, lithium hydroxide, and water.

The results obtained, taken in conjunction with the results of previous work, all indicate that the melt is complex. There is probably considerable association and this is especially evident slightly above the melting point: at temperatures in this region the temperature change of the properties of the lithium chlorate melt is greatest.

The activation energy of conductance is approximately the same as the activation energy of viscous flow, for pure lithium chlorate melt and for mixtures of lithium chlorate with lithium nitrate. From this it appears that the melt constituents are not principally the simple ions, but that some form of cohesion exists between the simple constituents of the melt.

The addition of water to the lithium chlorate melt causes the melt properties to alter considerably, especially the transport properties, viscosity and conductance. It is suggested that these changes may in part be due to a breakup of the structural entities of the pure melt, though the increase in electrical conductance cannot be completely explained in this way. A cryoscopic investigation seems to indicate that water is not present as such in the melt.

EXPERIMENTAL

Molten lithium chlorate does not attack pyrex glass and, therefore, a horizontal cell of conventional design was used. Since the specific conductances were high, it was necessary to make the central part of the cell of capillary glass, to increase the cell constant. The electrodes were widely separated to avoid the Parker effect. It was found by experiment that the apparent resistance varied by about 0.5%, as the frequency of the input signal was varied from 500 to 10 000 c s^{-1}. The resistance of the cell was measured at frequencies of 1000, 2000, 5000, and 10 000 c s^{-1}: the measured resistance was plotted against $1/\sqrt{\text{frequency}}$ and extrapolated to infinite frequency. A Jackson audio oscillator capable of delivering a low-power input at a frequency anywhere between 0 – 10 000 c s^{-1}, in conjunction with a Jones bridge and an amplifier coupled to an oscilloscope, were used. With this arrangement it was possible to detect a resistance change of 1 Ω in 10 000 Ω. The cell constants were determined with aqueous potassium chloride, at 25 °C, and corrected to the temperature of experiment by the method of Washburn (1).

A large double-jacketed thermostat was constructed. It contained Marcol G. X. oil, obtained from Imperial Oil Limited, and was heavily insulated with vermiculite. The oil polymerized and darkened rapidly but the loss of visibility was no great drawback here. A systematic probe of the oil bath showed that the temperature nowhere varied more than 0.05°. Our temperatures are correct to ±0.1°, and constant to ±0.05°.

The method of filling the cell with the extremely hygroscopic lithium chlorate should be obvious from the descriptions given in previous papers of this series (2). The cell was left in the thermostat for at least 2 h and the conductance then determined, using frequencies of 1000, 2000, 5000, and 10 000 c s^{-1}, followed by extrapolation to infinite frequency.

For experiments involving liquid additives, a calibrated syringe was filled with the necessary quantity, which was added to the melt through the cap of the cell. Solid lithium nitrate was added directly to the cell contents, but for lithium hydroxide a different technique was necessary. The mixture of lithium chlorate and lithium hydroxide was made up in the drybox, melted, and filtered through a coarse filter disc and then transferred to the conductance cell. This was necessary because unfiltered melts containing lithium hydroxide left a slight suspension in the melt.

For the study of freezing point depression a cryostat similar to that developed by Keenan (3) and by Janz (4) was used, but the very high viscosity of the medium caused considerable experimental difficulty.

RESULTS

The densities and specific and equivalent conductances, at 131.8 °C, of lithium chlorate and its mixtures containing small quantities of propyl alcohol, lithium nitrate, and water, are given in Table I. The equivalent conductances were calculated on two different

assumptions. The equivalent conductance of an aqueous solution is defined as the conductance of a volume of solution containing one gram equivalent of electrolyte, that is, the solvent is treated as an indifferent medium contributing nothing to the conductance. On the other hand, Bloom and Heymann (5) have determined the equivalent conductances of several salt mixtures, using as the equivalent weight the mean equivalent weight calculated by the mixture rule. Thus two different equivalent conductances result, one calculated on the assumption that lithium chlorate is the sole conducting body (λ_1) and one calculated by the method of Bloom and Heymann (λ_2). For mixtures containing water, λ_1 has been used, and λ_2 for the lithium chlorate – lithium nitrate mixtures. The analytical representation of the dependence of both specific and equivalent conductances on mole

λ_1 and λ_2, the Arrhenius equations for the dependence of conductance on temperature have been calculated. These equations are given in Table IV, together with the respective activation energies of conductance. The specific conductances of a lithium chlorate – lithium hydroxide mixture, and of a lithium chlorate – lithium hydroxide – water mixture were determined over the temperature range 130–170 °C. The results are given in Table V. The Arrhenius equations and the activation energies of conductance are given in Table VI.

0.860	0.069	0.071	104.0	5494	5667	5640

DISCUSSION

The specific conductance of pure lithium chlorate, 0.1150 Ω^{-1} cm^{-1} at 131.8 °C compares favorably with the figure obtained by Patterson (6), 0.1180, but is lower than that of Klotschko and Grigorjew (7). Their higher value for the specific conductance, 0.1252 Ω^{-1} cm^{-1}, and lower density value both indicate the presence of water in their sample.

For most fused salts, the specific conductance and other transport parameters lie within the following limits: K = 1–5 Ω^{-1} cm^{-1}; Λ = 30–150 cm^2 Ω^{-1} equiv^{-1}; ΔE_K = 1–5 kcal mole^{-1}. The values of K and Λ for lithium chlorate are slightly lower than those of

other salts of polyatomic anions which have low melting points, but they are considerably larger than those of salts which form covalent melts, such as mercuric chloride.

The ratio of activation energy of viscosity to activation energy of conductance normally has a value between 2–4 for ionic melts. The deviation of this ratio from unity is said to indicate that viscous flow in molten salts of this kind involves a greater configurational change than does the ionic migration in an electric field. The value of the ratio for lithium chlorate is 1.26, (see Part 2 of this series (2)), and, since this value is below the lower limit given above, this is thought to be indicative of association of some kind in the melt. For the nitrates, ΔE_η and ΔE_Λ are frequently found to be equal, and this is interpreted as showing that in the nitrates the species are not the simple ions: a similar deduction would, therefore, appear to be applicable to lithium chlorate.

A method of calculating the degree of dissociation of molten electrolytes has been put forward by Greenwood and Martin (8), which is indeed little more than the old classical rule of Arrhenius, and involves gross approximations and untenable assumptions such as the validity of the Walden rule. Nevertheless, the method does sometimes appear to give results in rough agreement with accepted values. Thus, for the salts KBr, $AgNO_3$, $CdCl_2$, AgI, and KNO_3, the values of α calculated by this method vary between 1.71 ($AgNO_3$) and 0.79 (KNO_3): the value for $LiClO_3$ is 0.80. For this calculation we have used the viscosity data of our earlier work (2). In so far as this calculation is reliable, it appears, therefore, that the lithium chlorate melt is completely ionized, although this conclusion is not in agreement with some of our other conclusions.

A recent theoretical equation (9)

$$\Lambda = \sum AT^{-1} \exp(-\Delta H/RT)$$

has been applied satisfactorily to the conductance process of the alkali halides, whose melts consist of simple symmetrical anions and cations. According to this theory, the experimental heat of activation for conductance, ΔH_Λ^+, is identified with the enthalpy of hole formation and that of the ionic jump, so that

$$\Delta H_{\text{jump}} + \Delta H_{\text{hole}} = \Delta H_\Lambda^+ + RT.$$

The enthalpy of hole formation can be calculated from Furth's equation (10)

$$\Delta H_{\text{hole}} = 4\pi r^2(\gamma - T(d\gamma/dT)).$$

Making the usual assumption that ΔH_{jump} is equal to about 0.1 ΔH_{hole} the values obtained for lithium chlorate and lithium nitrate at corresponding temperatures are:

Ion	Crystallographic ionic radius (Å)	Free energy of hole formation (kcal mole^{-1})	$\Delta H_{\text{jump}} + \Delta H_{\text{hole}}$ (kcal mole^{-1})	$\Delta H_\Lambda^+ + RT$
Li^+	0.60	0.55	0.98	6.5
ClO_3^-	2.00	6.17	9.4	
Li^+	0.60	0.72	0.99	5.8
NO_3	2.3	10.6	13.3	

The value for the calculated activation enthalpy of conductance for the lithium ion is seen to be much lower than the experimental enthalpy, in both cases, while the calculated activation enthalpies of the anions are both larger than the experimental values. Duke and Owens (11) have determined the transport number of the lithium ion in the lithium

nitrate melt as 0.84 ± 0.06, indicating that the conductance is primarily uni-ionic. Nevertheless, if the simple ions (principally Li^+) constituted the conducting species, the experimental activation energy should be close to that calculated for the Li^+ ion. Since this is not so, the radius of the ionic species involved in ionic migration in the lithium chlorate melt is not the same as the crystallographic radius of the lithium ion, but much larger, despite the fact that the cation is the principal conducting species. This, together with the fact that the activation energies of conductance and of viscous flow are approximately equal, indicates that the conducting species is associated in some manner, despite the result of the Greenwood and Martin calculation.

The self-consistency of our results is shown, when they are substituted in the equation proposed by Martin (12)

$$\Delta E_\Lambda = \Delta E_K + RT^2\alpha$$

where ΔE_K is the activation energy of specific conductance and ΔE_Λ the activation energy of equivalent conductance and α the coefficient of thermal expansion. Thus

$$\Delta E_K\ (6.02) + \alpha RT^2\ (0.16) = 6.18$$

compared with the experimental value of 6.12 kcal $mole^{-1}$.

The specific conductance of a lithium chlorate melt increases rapidly with the addition of small quantities of water, increases slightly with addition of small quantities of lithium nitrate, and decreases with the addition of propyl alcohol, methyl alcohol, and nitrobenzene. The slight increase of conductance caused by the addition of lithium nitrate is presumably due to the higher specific conductance of the latter, while the decrease in conductance due to the addition of organic compounds may be explained as a dilution effect. The smaller decrease in conductance due to methyl alcohol as compared with that caused by an equimolar addition of propyl alcohol may be due to the larger size of the propyl alcohol molecule and possibly also to a breakdown of the cluster effect in the presence of methyl alcohol, owing to the higher dielectric constant of the latter. The rapid increase in conductance on addition of water, however, must have a more profound cause: in part, no doubt, it is due to the decrease in viscosity. We suggest, as a possibility, that the small amount of water in the lithium salt melts may not be in the molecular form and that it may even be in the form of ions and that these play a direct part in the conductance of the melt.

If the results of Table I are calculated as equivalent conductances (λ_2), at 131.8 °C, these are seen to be practically independent of the concentration of lithium nitrate, when calculated by the method of Bloom. This apparent constancy must be considered as a coincidence, the decrease in the conductance of lithium chlorate being balanced by the increase due to lithium nitrate. Since the viscosities of these mixtures are greater than that of a (supercooled) lithium nitrate melt at the same temperature, it is not possible to calculate the deviation from ideality. On the other hand, the equivalent conductances of the lithium chlorate – water mixtures increase considerably as the water content increases.

The temperature effect on the conductance of the lithium chlorate – water, lithium chlorate – lithium nitrate, and lithium chlorate – propyl alcohol mixtures, is considerable, the specific conductance being doubled for a 40° rise in temperature. The activation energy of specific conductance decreases as the water content of the mixture increases, whereas the lithium nitrate mixtures exhibit an activation energy comparable to that of pure lithium chlorate, though a slight increase is noted at mole fraction 0.3. The addition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

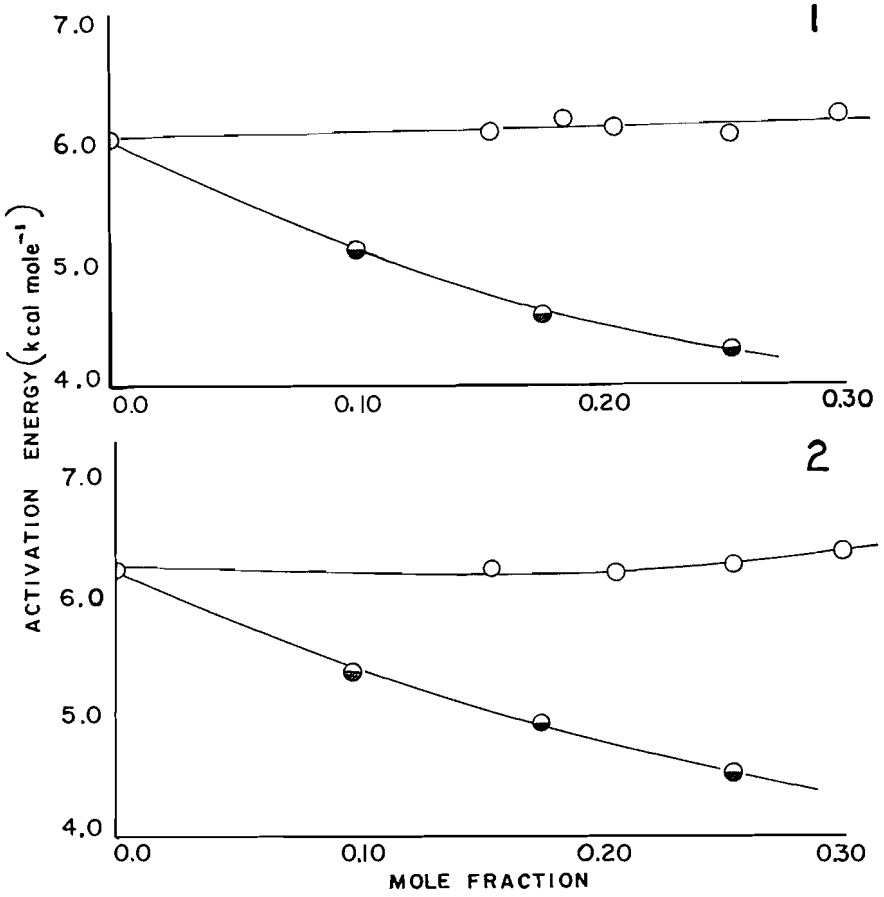
of methyl alcohol causes a decrease of activation energy, probably because of a decrease of viscosity. The activation energies of specific and of equivalent conductance, for lithium nitrate and for water mixtures with lithium chlorate, are plotted against mole fraction of additive in Figs. 1 and 2.



FIGS. 1 and 2. Activation energy of specific conductance vs. mole fraction: ◒ water mixtures, ○ lithium nitrate mixtures.

The question of the state of small amounts of water in molten salts is one of great importance but it is a question not easy to answer. We thought that the addition of lithium hydroxide to a lithium chlorate melt might, by adding free OH^- ions to the melt, increase the conductance. In fact, however, the conductance of a lithium chlorate – lithium hydroxide mixture (mole fraction = 0.076) is less than that of pure lithium chlorate, though the activation energy of conductance remains the same. This suggests that the average energy required for ionic migration in the lithium hydroxide mixture and in pure lithium chlorate is almost the same and, therefore, probably the OH^- ion plays only a small part in the conductance process, which is thus principally dependent on the Li^+ ion.

Since the addition of water increases the equivalent conductance considerably (λ_1), while the addition of lithium nitrate has little effect on λ_2, it is perhaps permissible to speculate whether under these circumstances water is not itself a conducting species. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

decrease in viscosity produced by the addition of water must, however, be taken into account in explaining the increased conductance and this has been done to some extent in Table VII, in which equimolar solutions of water and of lithium hydroxide are compared at temperatures at which their viscosities are the same. According to this table it would appear that the equivalent conductances are more or less the same, but this comparison, in turn, neglects the effect of temperature on ion velocity and this is not solely determined by viscosity. Thus, while λ_1 for the aqueous mixtures appears to be slightly less than that of pure lithium chlorate and the same as that of the lithium hydroxide mixture, the temperature of the aqueous mixture is 132° or 137° and those of pure lithium chlorate and of the lithium hydroxide mixtures are 13° higher. We suggest that, despite the Greenwood–Martin calculation, the addition of water may cause an increase of free ions (not necessarily from the lithium chlorate) available for conductance and even that water itself may take part in the conduction. The problem, therefore, becomes that of the determination of the state or molecular condition of small quantities of water in lithium chlorate melts.

TABLE VII

Equivalent conductances at temperatures of equal viscosity

	Viscosity = 0.235 P		Viscosity = 0.21 P	
Nature of melt	t (°C)	Equivalent conductance (λ_1)	t (°C)	Equivalent conductance (λ_1)
$LiClO_3$	145	6.4	150	6.9
$LiClO_3 + 0.07\ H_2O$	132	5.9	137	6.5
$LiClO_3 + 0.07$ LiOH	145	5.9	150	6.5

Though the Greenwood–Martin calculation implies that lithium chlorate is almost completely ionized in the molten state, the electrical conductivity is much lower than those of many salts formed either from salts having simple symmetrical anions and cations or salts having high melting points. Although there has been much controversy over methods for the experimental determination of transport numbers in a pure melt, there is general agreement that the result of Duke (11) for lithium nitrate ($t_{Li^+} = 0.9, t_{NO_3^-} = 0.1$) is of the correct order. Because of the similarity in size of the nitrate and chlorate ions, it is possible that lithium chlorate is also a uni-ionic conductor the current being carried practically entirely by the lithium ion. The experimental value of the activation energy of conductance, however, (6.1 kcal mole^{-1}) is not in agreement with that calculated for a lithium ion having its crystallographic radius, viz. 0.98 kcal mole^{-1}, and hence it is improbable that the simple Li^+ ion is the current-carrying unit: it is probably a much larger species. Indeed, since the ratio of the activation energy of viscous flow to that of electrical conductance is approximately unity, it would seem that the structural changes involved in viscous flow, which are dependent on the largest species present in the melt, are similar to those involved in conductance.

The viscosity of lithium chlorate is very high compared to those of other simple salts and this also indicates that the constituents of the melt are complex. Zinc chloride also has a high viscosity, because of the formation of large complex ions, but this type of association does not occur in the lithium chlorate melt, as is shown by the fact that the activation energy for viscous flow is independent of temperature, whereas for zinc chloride a considerable temperature dependence is found.

To summarize the work of this series of papers (2), it appears that the density, surface

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

tension, viscosity, and electrical conductance all indicate that the lithium chlorate melt has a considerably associated character. It is possible that the type of association which has been supposed to exist in a lithium nitrate melt is also present in molten lithium chlorate. From the properties we have investigated it is not possible to determine the actual constituents of the melt, nor the nature of the forces responsible for the presumed association, but we think it probable that the molten salt retains a considerable "liquid lattice" structure formed of large entities having a structure similar to that of the crystalline salt.

The large decrease in the viscosity of lithium chlorate, slightly above its melting point, produced by the addition of a small quantity of water, compared to the smaller decrease produced by the same addition at a higher temperature, indicates a strong interaction between water and the residual crystalline lattice, which is thought to exist in the melt just above its melting point. The addition of lithium hydroxide caused a slight decrease in the specific conductivity but no change in the activation energy of conductance, while addition of water caused a rapid increase in conductance and a decrease in activation energy. This suggests that the overall energy required for ionic conductance is unchanged by the addition of OH^- ion but that the addition of water causes a general increase in the ionic character of the melt. The decrease in the coefficient of expansion, as water is added, is also indicative of a decrease in association.

To understand further the nature of the water interaction, a cryoscopic investigation, with molten lithium chlorate as solvent, was undertaken: the additives were water and lithium nitrate respectively. The freezing point depression caused by lithium nitrate can only be due to the addition of one species foreign to the melt, viz. either molecular lithium nitrate or NO_3^- ion. At first glance, addition of water would be expected to have the same effect, per mole. However, our equilibrium studies of the lithium chlorate – water and lithium chlorate – lithium nitrate systems (13, 14) had indicated that the freezing point constants of the two systems were not the same. Using a cryostat similar to that developed by Keenan (3) and by Janz (4), we found the freezing point depression constant to be 6.9° per mole per 1000 g $LiClO_3$ considered as solvent, for lithium nitrate additions, and 12.4° for water. The latent heat of fusion of lithium chlorate calculated from the depression constant with lithium nitrate is 2.2 kcal per mole compared with the experimental value of Campbell and Nagarajan (2) of 2.47 kcal per mole. These results indicate that the addition of water forms more than one particle foreign to the lithium chlorate. To say that exactly twice as many particles originate from the water as from the lithium nitrate is too bold a statement since nothing is known about the activities of the two depressants in this unusual medium. If the above deduction is admitted on a qualitative basis, however, it follows that the water cannot retain its simple molecular character in the lithium chlorate melt. A nuclear magnetic resonance (n.m.r.) spectrum was taken of the proton resonance in a 0.15 *M* water mixture, at 131 °C, but only a single absorption peak was obtained. This may indicate that each proton of the water molecule was in the same environment within the melt but it is more likely that the rate of exchange of protons at this temperature is so great that the environment is averaged out in a n.m.r. spectrum.

A THEORETICAL STUDY OF RING CLOSURE

APPLICATION TO THE CYCLIC–LINEAR DISTRIBUTION IN POLYDIMETHYLSILOXANE[1]

J. B. CARMICHAEL[2] AND J. B. KINSINGER
Kedzie Chemical Laboratory, Michigan State University, East Lansing, Michigan

Received December 30, 1963

ABSTRACT

The purpose of this work was to provide insight into the formation of cyclics from fundamental considerations of chain geometry. The structural variables which must be specified are the length(s) of the valence bond in the skeletal structure, bond angle(s) in the skeletal structure, and the energetics and positions of the allowed conformations in the system. A mathematical model involving only these structural variables has been developed which is valid for chains with any number of bonds.

This model is applied to the polydimethylsiloxane system in which cyclic molecules containing from six to eighteen atoms in their skeletal structures make up approximately 12 to 20% by weight of the equilibrated system. A three-rotational-state model is assumed for the polydimethylsiloxane chain. The relationship between cyclic formation and other features of polymer behavior and structure will be interpreted in terms of the model. A good correlation is shown between the experimental equilibrium constant for octamethylcylcotetrasiloxane and the theoretical equilibrium constant from the model calculation.

INTRODUCTION

A major unsolved problem in inorganic polymerization is understanding why, on a molecular basis, cyclic molecules are formed in significant amounts.

In 1950, Stockmayer and Jacobson published a theoretical paper in which they predicted the equilibrium molecular size distributions of linear and cyclic molecules for polymers (1). A major assumption of this work was that the distribution of end-to-end distances (r) of a randomly coiled chain, ($W(r)\mathrm{d}r$), is Maxwellian. That is, $W(r)\mathrm{d}r = \beta^3/\pi^{3/2} \exp(r^2\beta^2) 4\pi r^2 \mathrm{d}r$, where $\beta^2 = 3/(2<r_0^2>)$ and $<r_0^2>$ represents the unperturbed mean-square end-to-end distance of the polymer. From this, a formalism was developed for the chain–cyclic distribution. However, no calculations based on this formalism were undertaken for polydimethylsiloxane.

Calculations were performed on the ring–chain equilibrium in polydecamethylene adipate and compared with experimental results. More ring structures were predicted than actually observed.

The purpose of this work is to provide insight into the formation of cyclics in the polydimethylsiloxane ring–chain equilibrium from detailed considerations of chain structure and geometry. A theoretical equilibrium constant for cyclic formation which can be compared with the experimental equilibrium constant is obtained.

DISCUSSION OF EXPERIMENTAL BACKGROUND

1. Occurrence of Cyclics in Polydimethylsiloxane

Hartung and Camiolo (2) have studied the equilibrium between linear and cyclic polymers in the polydimethylsiloxane system by reacting octamethylcyclotetrasiloxane with KOH catalyst in 25 to 75% by weight of xylene and quantitatively reported the equilibrium weight fraction of cyclic species from trimer to nonamer. A summary of these data extrapolated by us to the bulk polymer is seen in Table I.

[1]*Presented at the Inorganic Polymer Symposium, London, Ontario, September 4–6, 1963.*
[2]*Present address: Dow Corning Corporation, Midland, Michigan.*

TABLE I

Weight fraction of cyclic species in equilibrated polydimethylsiloxane $((CH_3)_2SiO)_n$ (2)

n	Weight fraction	Standard deviation
3	0.0017	0.0004
4	0.100	0.014
5	0.0610	0.0076
6	0.0185	0.0042
7	0.0038	0.0013
8	0.0025	0.0004
9	0.0017	0.0003

The decrease in abundance of dimethylsiloxane rings was discussed earlier by Flory (3) who stated, on the basis of less complete data than that of Hartung, that the trend is that expected if the decrease is due solely to the statistical decrease in probability of ring closure with increasing chain length, specific steric factors being of minor importance. He concluded that "the greater length of the Si–O bond and the large SiOSi angle may alleviate the repulsions between substituents (in this case $-CH_3$), which in rings consisting of $-CH_2-$ have been suggested as being responsible for both the strong preference for five- and six-membered rings and for the severe difficulty of forming rings of eight- to twelve-members."

2. Preferred Conformations and Molecular Structure of the Lower Cyclic Dimethylsiloxanes

The planarity of the six-membered ring, hexamethyclyclotrisiloxane, has been demonstrated by X-ray (4, 5) and electron (6) diffraction. Results of these investigations are summarized in Table II.

Tanaka has measured heats of formation of several of the lower members of the dimethyl and methyl-isopropoxycyclopolysiloxanes (7). From this data, he concludes that the six-membered ring has strain energy of up to 9 kcal/mole and that the higher rings are strain free. The conclusion that strain exists in the six-membered ring agrees with the smaller value of $\angle$ SiOSi found for this molecule (130° as compared with 140° in octamethylcyclotetrasiloxane and the linear polymer (8)).

One possible interpretation of the planarity of this ring, in terms of the structure of the polymer chain, is to postulate the existence of a *cis* conformation in the chain (9). This postulate will be explored later in this paper.

The structure of octamethylcyclotetrasiloxane has been studied by Steinfink *et al.* (10) and Yokoi (11). These results are summarized in Table II.

Yokoi has constructed six models that give theoretical intensity curves which approximate closely the experimental curve. Figures 1 and 2 are diagrams of these structures and the intensity curves respectively.

Structure B, which gives the best fit to the experimental curve, has a cradle form with four silicon atoms in a plane, one set of opposite oxygen atoms being above this plane and the other set of opposite oxygen atoms below this plane.

THEORETICAL DEVELOPMENT

1. Mechanism of Cyclic Formation

For an n-membered ring to form, the magnitude of the end-to-end chain vector ($|\boldsymbol{r}|$) must approach zero at that value of n. In the case of a preformed chain with an active end, $|\boldsymbol{r}|$ is the distance from the active end to any other link in the chain n links away. The value

TABLE II

Structure of hexamethylcyclotrisiloxane and octamethylcyclotetrasiloxane

Compound	Si–O (Å)	∠OSiO	∠SiOSi	Ref.	Comments
Hexamethylcyclotrisiloxane: 	1.64±0.03	109±4°	130±4°	5	Reported the $(Si–O)_3$ ring to be planar
$((CH_3)_2SiO)_3$	1.61	104°	136°	4	Reported ring to be planar
$((CH_3)_2SiO)_3$	1.66±0.04	115±5°	125±5°	6	Reported ring to be planar
Octamethylcyclotetrasiloxane: $((CH_3)_2SiO)_4$	1.65	109°	142.5°	10	X-ray diffraction. Ring is puckered
$((CH_3)_2SiO)_4$	1.63	109.5° (assumed)	140±5°	11	Electron diffraction. Best fit to theoretical intensity curves was cradle form of the ring, B (See Fig. 1)

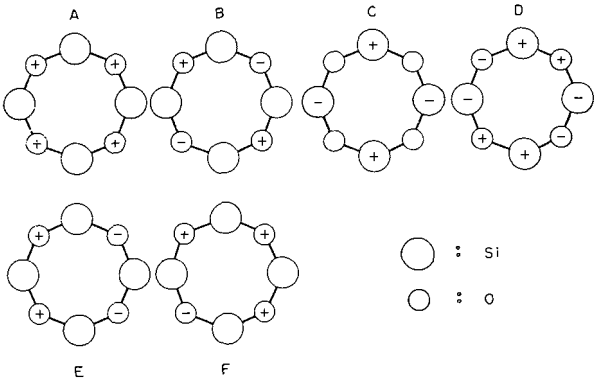

FIG. 1. Conceivable forms of octamethylcyclotetrasiloxane.

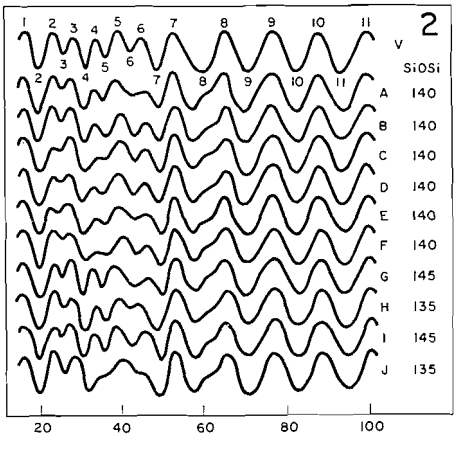
of $|r|$ is a function of the chain bond length (l), the bond angles in the chain (θ_1, θ_2), and the rotational states available to the chain (ϕ_i). Presently, we consider $|r|$ to be unperturbed by any solute species and dependent only on short-range intramolecular interactions. Also, we assume the condition for formation of a cyclic molecule is defined as $r < l$.

2. Assignment of Rotational States

From the X-ray diffraction study of the filled and vulcanized elastomer by Damaschun (8), calculation of the stable helical conformations of the structurally similar polyoxymethylene chain by Liquori *et al.* (12), and the measurement by Ciferri of the temperature coefficient of the polymer dimensions (13), the approximate plot of the potential energy vs. rotational angle in Fig. 3 was constructed for the polydimethylsiloxane chain where the



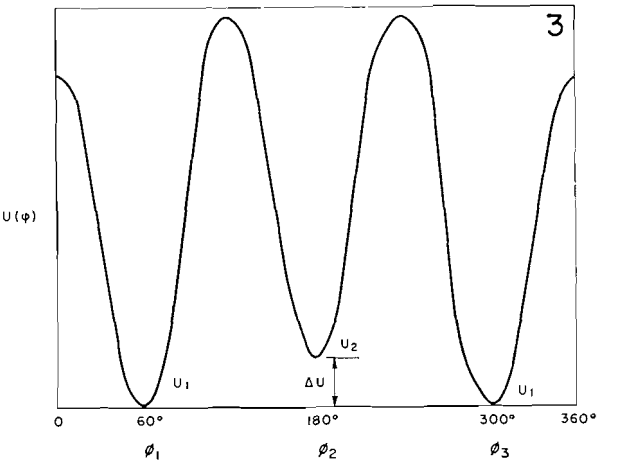


FIG. 2. Visual and theoretical intensity curves of octamethylcyclotetrasiloxane.
FIG. 3. Model for the polydimethylsiloxane chain.

chain conformations are considered to be statistically independent. Since each of the potential wells is symmetric about the minimum energy in the well, the continuous potential function can be well approximated by a point function. Thus, the chain is represented as an equilibrium mixture of discrete rotational conformations, G ($\phi = 60°$),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

T ($\phi = 180°$), G' ($\phi = 300°$). The *cis* conformation, C ($\phi = 0°$), is explored as a possibility in Results, Part 1. The conformations are assumed to be equally probable for computational simplification.

3. Development of Equations for $|\boldsymbol{r}|$ for the Polydimethylsiloxane Chain

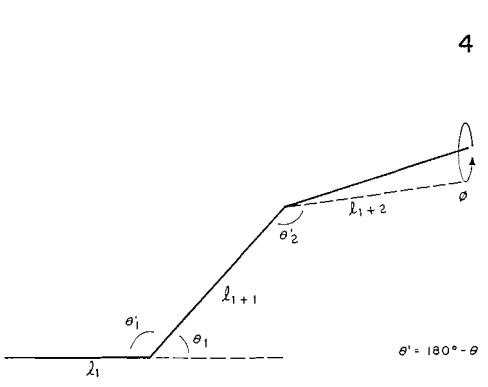
Consider now the polydimethylsiloxane chain, a representative segment of which is pictured in Fig. 4. Here $\theta_1' = \angle$ OSiO, $\theta_2' = \angle$ SiOSi.

The end-to-end distance vector $\boldsymbol{r}$ for a given total microscope conformation is

$$\boldsymbol{r} = \sum_{i=1}^{n} l_i,$$

where r is a function of the bond length, l, the supplements of the valence angles, θ_1 and θ_2, and the internal rotation angles, ϕ_i.

To each bond is attached an orthogonal coordinate system of its own. Then all of these coordinate systems can be transformed to a common system, here chosen to be the system attached to the bond l_1, by a series of successive elementary matrix transformations (14). The coordinate system attached to the first bond is chosen so that its z axis points in the direction of that bond, its y axis lies in the plane which passes through this bond and the bond preceding it, and its x axis points in the direction of the vector product $\boldsymbol{l}_1 \times \boldsymbol{l}_2$ of these two bond vectors (15).



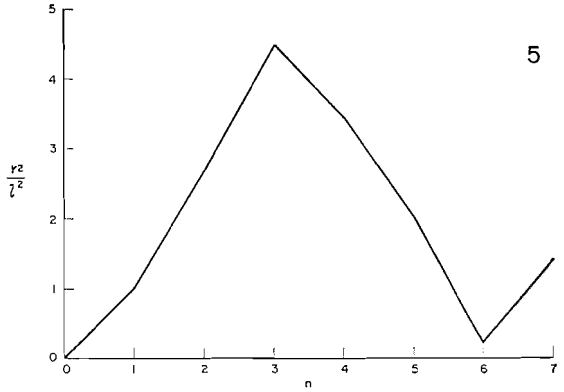


FIG. 4. Representation of siloxane chain segment.
FIG. 5. r^2/l^2 vs. n for all *cis* chain, $\angle$SiOSi = 140°, $\angle$OSiO = 109° 28′.

Consider now the transformation A which transforms the $(k + 1)$th coordinate system into the kth. It may be obtained by two successive elementary transformations. The first, θ, is a rotation of the $(k + 1)$th coordinate system by an angle θ around the x axis. This transformation leaves the x axis unchanged and rotates y and z in their own plane so that the z axis points in the direction of $\boldsymbol{l}_k$. This transformation is given by the matrix:

$$[\theta] = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\theta & \sin\theta \\ 0 & -\sin\theta & \cos\theta \end{bmatrix}.$$

Next the new coordinate system is rotated by an angle θ_k around the new z axis (i.e., around $\boldsymbol{l}_{k-1}$) until it will coincide with the kth coordinate system. Since this transformation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

leaves z unchanged and rotates y and x in their plane, it is given by the matrix:

$$[\phi] = \begin{bmatrix} \cos\phi_k & \sin\phi_k & 0 \\ -\sin\phi_k & \cos\phi_k & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

These two successive transformations are represented by the matrix product:

$$A = [\theta]\,[\phi] \begin{bmatrix} \cos\phi_k & \sin\phi_k & 0 \\ -\cos\theta\sin\phi_k & \cos\theta\cos\phi_k & \sin\theta \\ \sin\theta\sin\phi_k & -\sin\theta\cos\phi_k & \cos\theta \end{bmatrix}$$

and transform the $(k+1)$th coordinate system into the kth coordinate system. The vector $\boldsymbol{l}_{k+1}$ which in its own coordinate system was given by $\boldsymbol{l}_{k+1} = (0,0,l)$ is therefore expressed in the kth system by $\boldsymbol{l}_k = (0,0,l)A$, whereas l_k is represented in this system by $\boldsymbol{l}_k = (0,0,l)$. This procedure of elementary transformations may be repeated, transforming the coordinate systems of all bond vectors into that of the first one, $\boldsymbol{l}_1$.

For the polydimethylsiloxane chain, there must be two transformation matrices, corresponding to the two bond angles in the chain. These matrices are designated A_1 and A_2 so $\boldsymbol{l}_{1+2} = \boldsymbol{l}_i A_2 A_1$.

Thus, the $\boldsymbol{l}_{i+k}$ bond vector can be expressed back in terms of the $\boldsymbol{l}_i$ vector by the relation: $\boldsymbol{l}_{i+k} = \boldsymbol{l}_i(A_2A_1)^{k/2}$, an even integer.

To avoid the troublesome situation of fractional powers of the matrix product A_2A_1, two different expressions for $\boldsymbol{r}$ will be written; one for the case of an odd number of links in the polymer chain and the other for the case of an even number of links in the polymer chain.

In the system of coordinates previously described, the end-to-end distance is thus given: for n odd

$$[1] \qquad \boldsymbol{r} = (0,0,l)\,(I + A_1 + A_2A_1 + \ldots (A_2A_1)^{(n-5)/2} + A_1(A_2A_1)^{(n-5)/2} + (A_2A_1)^{(n-3)/2} + A_1(A_2A_1)^{(n-3)/2} + (A_2A_1)^{(n-1)/2}),$$

for n even

$$[2] \qquad \boldsymbol{r} = (0,0,l)\,(I + A_1 + A_2A_1 + \ldots A_1(A_2A_1)^{(n-6)/2} + (A_2A_1)^{(n-4)/2} + A_1(A_2A_1)^{(n-4)/2} + (A_2A_1)^{(n-2)/2} + A_1(A_2A_1)^{(n-2)/2}).$$

Note that in both cases, for n links in the chain, the last term in the expression for $\boldsymbol{r}$ must be the product of $n-1$ matrices.

RESULTS

1. *The Distribution of $|\boldsymbol{r}|$'s for a Three-Rotational-State Chain*

We consider now the entire set of $|\boldsymbol{r}|$'s for the case of a growing three-rotational-state chain. The total number of chain conformations increases as 3^{n-1}, where n = number of links in the chain. Many of the $|\boldsymbol{r}|$'s thus produced are degenerate. The cases of $n = 6$ and $n = 8$ will be examined in detail.

Consider the interval tabulation for the 243 $|\boldsymbol{r}|$'s at $n = 6$ in Table III. Note that no $|\boldsymbol{r}|$ falls within the range of 0 to l. If the three-state model were an exact description of the potential-energy profile in the chain and if the requirement for ring closure were $|\boldsymbol{r}| < l$, no

six-membered ring would form in the siloxane system. As pointed out, however, the six-membered ring does form and is planar. Two possible mechanisms for the formation of this ring are offered. Mechanism A: (1) A puckered six-membered ring is formed by a sequence of gauche rotational states, some or all of which are shifted from 60° and 300°

so that for this sequence $|\boldsymbol{r}| < l$. (2) The ring rearranges from the puckered form into the planar form. Since specific steric factors are thought not to influence ring configurations, due to the large SiOSi angle and the comparatively long SiO bond, a shift from a puckered to a planar ring form would probably require energy (since any puckered ring that could form would be expected to be rather stable). (3) In order to accommodate the geometrical requirements of the planar ring, the SiOSi bond angle shifts from 140° to 130°. This change in bond angle will require absorption of energy. Mechanism B: (1) A *cis* rotational state is available to the chain (probably with much lower probability of occupancy than the gauche and *trans* states). (2) The chain grows to a length of six links occupying all *cis* states. A graphical representation of this chain follows in Fig. 5. Plotted is r^2/l^2 vs. n where $r^2 = |\boldsymbol{r}|^2$. Calculation from the graph shows $|\boldsymbol{r}| = 0.49l$. Thus, the chain ends are slightly less than half a bond length apart at $n = 6$. For the ring to form, the bond angle SiOSi must compress from 140° to 130°.

The energy required to form the six-membered ring is probably least for mechanism B, so that if the *cis* state is available to the polymer chain, mechanism B may represent the most likely route to the formation of hexamethylcyclotrisiloxane.

Consider now the interval tabulation for the 2187 $|\boldsymbol{r}|$'s at $n = 8$ in Table III.

There are 12 $|\boldsymbol{r}|$'s in the range of 0 to $1l$. All of these are less than $0.5l$ and are probably within the range of cyclic-forming molecules. A list of all values of $|\boldsymbol{r}|/l < 1.3$ appears in Table IV. We recall that Yokoi postulated six reasonable structures for the eight-membered ring, octamethylcyclotetrasiloxane. Structure B, the structure which gives the best fit to the experimental radial distribution function, is formed by all the following sequences of configurations:

$G,G,G',G',G,G,G';$
$G',G',G,G,G',G',G;$
$G,G',G,G,G',G',G;$
$G',G,G',G',G,G,G';$
$T,G,G',G',G,G,G';$
$T,G',G,G,G',G',G.$

For structure B, $|\boldsymbol{r}| = 0.303l$.

Structure A has a crown form with the four silicon atoms in one plane and the four oxygen atoms lying in a plane above the silicons. This ring is formed by the sequences of configurations:

$G,G',G,G',G,G',G;$
$G',G,G',G,G',G,G';$
$G,G,G',G,G',G,G';$
$G',G',G,G',G,G',G;$
$T,G,G',G,G',G,G';$
$T,G',G,G',G,G',G.$

These 12 sets correspond to the 12 $|\boldsymbol{r}|$'s found to be less than $0.5l$ and are those most likely to form rings. These 12 $|\boldsymbol{r}|$'s represent 0.0548% of the total number of 2187 chains that are generated. The experimental evidence which must be reconciled is that 10% of an equilibrated polymer is octamethylcyclotetrasiloxane. The experimental data and theoretical calculation are compared through the equilibrium constant for the formation of octamethylcyclotetrasiloxane.

2. Equilibrium Constant for R_4 Formation

Following the treatment of Stockmayer and Jacobson (1), we consider a siloxane chain, C, of $(n + 4)$ –SiO– units in equilibrium with a chain of n units and a cyclic, R, of four units.

[3] $$C_{n+4} \rightleftharpoons C_n + R_4$$

[4] $$K = \frac{[C_n]\,[R_4]}{[C_{n+4}]}$$

Because the chains C_{n+4} and C_n lie very close to one another on the molecular weight distribution curve for the high polymer, $[C_{n+4}] \sim [C_n]$.

[5] $$\text{Therefore } K \sim [R_4]$$

A. Calculation of Experimental Equilibrium Constant

Density of $R_4 = 0.9558$ g/cm^3 at 20 °C
Density of polydimethylsiloxane = 0.9660 g/cm^3 at 25 °C (16)
Molal volume of $R_4 = 312$ cm^3/mole
Consider 1000 g of mixture: 100 g = R_4 and 900 g = C_n
Volume of $R_4 = 100$ g/0.9558 g cm^{-3} = 104.2 cm^3
Volume of $C_n = 900$ g/0.9660 g cm^{-3} = 931.0 cm^3

Total volume = 1035 cm^3, assuming volume additivity

[6] $K_{\text{exptl}} = 100$ g R_4/cm^3 = 100/74.13 moles of –SiO– units/cm^3
$K_{\text{exptl}} = 13.2 \times 10^{-4}$ moles of –SiO– units/cm^3

B. Calculation of Theoretical Equilibrium Constant

The general development here closely follows that of Stockmayer and Jacobson (1). Important departures are noted in the text.

Since reaction [3] involves no change in number of chemical bonds, we may assume it takes place with a negligible change of internal energy.* With this assumption, the prediction of K in [5] requires the calculation of the entropy change in the equilibrium reaction. For this purpose, reaction [3] is broken up into steps.

[7] $$C_{n+4} \rightleftharpoons C_n + C_4$$

[8] $$C_4 \rightleftharpoons R_4$$

For reaction [7], the entropy change is:

[9] $$S_7 = k \ln (V/2v_s)$$

where v_s is volume of the constrained skeletal atom under consideration, and V is the volume of the system as a whole which is available to this atom once the bond is broken. The symmetry number of a chain molecule is 2. In the Stockmayer–Jacobson development, v_s cancelled with the same term in the numerator of S_8, and calculation of v_s was unnecessary. In this development, v_s remains in the final expression for K and is calculated separately.

**For R_4 the assumption seems valid based on the freedom from bond angle strain in octamethylcyclotetrasiloxane. However, for R_3 where strained bond angles are present such an assumption would be invalid.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The entropy change in reaction [8] is:

$$S_8 = k \ln (P/4) \quad [10]$$

where P is the fraction of chains which will close. The symmetry number of an n-membered ring is $2n$. (The fact that the symmetry number of a siloxane chain is 2 means that either end has an equivalent opportunity to close back on itself to form a ring. For a ring containing n siloxane units, a symmetry number of $2n$ means that there are $2n$ equivalent bonds that can be broken when the ring reacts with a chain to form a larger chain.)

Combining the results of equations [9] and [10], the equilibrium constant is:

$$K = PV/8v_s. \quad [11]$$

In the Stockmayer–Jacobson development, P was obtained by assuming a Gaussian distribution of end-to-end distances and integrating over the volume element v_s. Here P is obtained from the set of chains generated from the three-rotational-state model and found to be 0.00548.

Calculation of v_s will complete the specification of variables from which K can be calculated. The approach is that of Mayer and Mayer (17). The one-dimensional length available to an atom (along the reaction coordinate giving its distance) from another atom to which it is bound is twice the average amplitude, $\frac{1}{2}\xi$, of vibration. The value of ξ as a function of temperature is given to a good approximation by the empirical equation:

$$\xi = (RT/D)^{1/2} \text{ Å} \quad [12]$$

where D is the energy necessary to break the chemical bond.

The two-dimensional surface available to an atom rotating about another is:

$$A = 4\pi r_0^2 \quad [13]$$

where r_0 is the distance between the two atoms.

The constrained atom of the molecule (the chain of $n + 4$ segments) moves in a shell of radius r_0 and thickness ξ about the atom regarded as free. Therefore, the volume, v_s, is:

$$v_s = 4\pi r_0^2 \xi. \quad [14]$$

For the Si–O bond,

$$r_0 = 1.65 \text{ Å}$$
$$D = 93 \text{ kcal/mole (18)}$$

at 135 °C,

$$\xi = 0.094 \text{ Å}.$$

Inserting these data into [14],

$$v_s = 3.2 \text{ Å}^3. \quad [15]$$

Substituting the values of v_s and P into [11] and assuming a system volume, V, of 1 cm^3, we find:

$$K = 3.6 \times 10^{-4}. \quad [16]$$

DISCUSSION

This result is tabulated with two values of K calculated from the Stockmayer–Jacobson theory and the experimental K in Table V. In no case is there good agreement between

TABLE V

Comparison of experimental and theoretical calculations of the equilibrium constant for R_4

Reference	$K \times 10^{-4}$ (moles/cm^3)
Hartung and Camiolo (2)	13.2
Stockmayer–Jacobson[a] (1)	1.2
Stockmayer–Jacobson[b] (1)	0.42
This work[a]	3.6

[a]Calculated assuming equally probable rotational states. For the Stockmayer–Jacobson calculation, $\langle r_{0f}^2 \rangle / nl^2 = 3.2$, where r_{0f}^2 refers to the mean square dimensions of a freely rotating siloxane chain with three rotational states at 60°, 180°, and 300° (9).

[b]Calculated using experimentally determined $\langle r_0^2 \rangle / nl^2 = 6.3$ (19).

theory and experiment. However, K calculated in this work represents an improvement over the earlier Stockmayer–Jacobson result. The only difference between the two derivations is in obtaining P and v_s. Stockmayer and Jacobson assumed a Gaussian distribution with an effective link length parameter, b, and we obtain P from a conformation model with equally probable rotational states. Also, we find it necessary to calculate v_s, whereas Stockmayer and Jacobson found K independent of v_s.

We must remember that Hartung's data, upon which the calculation of K_{exptl} was based, is data extrapolated for the undiluted polymer from solvent polymerizations. Certainly, Hartung meant this extrapolation as a guide to be used for predicting cyclic contents at solvent concentrations beyond the limits of those he used. We are, no doubt, subjecting the extrapolated concentration of R_4 to undue scrutiny in Table V. Moreover, recent work being carried out for undiluted polymerizations indicates that the concentration of R_4 is an increasing function of the average degree of polymerization of the linear portion and for very high molecular weights (10^6 g/mole) has the value of 7.4×10^{-4} moles of –SiO– units/cm^3 (20, 21). By comparison with this data, the value of K obtained in this work is about 50% low.

Certainly the model developed here is a primitive beginning to the ring closure problem. Evaluating preferred conformations and relating these to ring formation in siloxanes with other organic side groups could help provide fundamental groundings in this hitherto undeveloped area. No mention has been made here of specific solvent effects which are, at present, impossible to evaluate theoretically. No published data is available on the effect of media viscosity on cyclic concentration. It is hoped that this reexamination of the ring-closure problem will lead to further critical experimental studies.

APPENDIX

Probability of Ring Closure for a Preferred-Rotational-State Model

Let ΔE be the energy difference between gauche and *trans* rotational states.

Consider now the twelve paths which lead to formation of R_4. There are eight sequences which consist of all G or G' (seven in each sequence). Order is unimportant since a statistically independent model is assumed. There are four sequences beginning with T followed by G and G' states.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[i] $$P = 8P_s(P_G)_7 + 4P_sP_T(P_G)_6$$

[ii] $$P = 8(1)\left(\frac{1}{2 + e^{\Delta E/RT}}\right)^7 + 4(1)\left(\frac{e^{\Delta E/RT}}{2 + e^{\Delta E/RT}}\right)\left(\frac{1}{2 + e^{\Delta E/RT}}\right)^6$$

Simplifying [ii] yields:

[iii] $$P = 4\left(\frac{1}{2 + e^{\Delta E/RT}}\right)^6.$$

The equation [iii] is easily checked for the case of equally probable rotational states. Then $\Delta E = 0$, and

[iv] $$P = 4(\tfrac{1}{3})^6 = 0.00548.$$

If ΔE is assumed to equal -500 cal/mole (thus increasing the probability of gauche states),

[v] $$P = 4\left(\frac{1}{2 + e^{-500/RT}}\right)^6.$$

At 298 °K, $P = 0.0218$. From eqn. [11] in the text, $K = 14.3 \times 10^{-4}$. The assumption of an energy difference of 500 cal/mole is arbitrary but reasonable.

ACKNOWLEDGMENTS

The authors wish to thank the Wright-Patterson Air Force Base for the partial support of this work.

We wish to thank Professor W. H. Stockmayer for pointing out the utility of the equilibrium constant for cyclic formation in comparing experimental results with the theoretical calculations.

AN ELECTRON IMPACT STUDY OF METHYL PHENYL ETHERS

F. MEYER AND A. G. HARRISON[1]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received April 15, 1964

ABSTRACT

The mass spectra of anisole, anisole-methoxy-d_3, meta and para methylanisole, meta and para methyl-d_3-anisole, and meta and para methylanisole-methoxy-d_3 have been recorded. From the deuterium labelling and appearance potential studies, the main fragmentation paths on electron impact have been elucidated. The energetics of formation of the $CH_3OC_7H_6^+$ ion from the methylanisoles, benzyl methyl ether, 7-methoxycycloheptatriene, and the ethylanisoles have been studied.

INTRODUCTION

The mass spectra of the isomeric meta and para methoxybenzyl chlorides show large differences which are consistent with the interpretation that the $CH_3OC_7H_6^+$ ions formed by loss of Cl retain the benzyl configuration and therefore have different energy contents for the two isomers (1). Such differences usually are not encountered in the mass spectra of isomeric benzyl derivatives presumably because of rearrangement to the symmetrical tropylium structure (2). These observations have prompted us to undertake a detailed study of the mass spectra and energetics of ion formation for methoxybenzyl derivatives. The present paper reports a study of anisole, meta and para methylanisole, and meta and para ethylanisole. Since this work was begun, both Barnes and Occolowitz (3) and Pelah *et al.* (4) have reported surveys of the mass spectra of methoxy substituted aromatic systems. The information obtained by deuterium labelling in the present work provides a more detailed picture of the fragmentation paths and in many cases suggests fragmentation paths not considered by the previous workers.

EXPERIMENTAL

All mass spectra were obtained with an A.E.I. MS-2 Mass Spectrometer which has been described previously (1). Mass spectra were recorded at 50 V electron energy, 20 μA ionizing current, and a repeller voltage of 3 V (7 V/cm). Appearance potentials were measured as described previously (5) using xenon to calibrate the voltage scale.

Anisole, *m*-methylanisole, *p*-methylanisole, *p*-ethylanisole, and benzyl methyl ether were commercial samples. The *m*-ethylanisole was prepared by reaction of *m*-ethylphenol with sodium and methyl bromide. The methoxy-d_3 anisoles were prepared by reaction of the appropriate phenol with sodium and methyl-d_3 bromide (6). The *m*-methyl-d_3 and *p*-methyl-d_3 anisoles were prepared from the corresponding bromoanisoles by reaction of the Grignard reagent with dimethyl-d_6 sulphate. The methyl-d_3 bromide and dimethyl-d_6 sulphate were obtained from Merck, Sharp and Dohme, Montreal. Final purification of all anisoles was by gas chromatography on a diisodecylphthalate column.

The sample of 7-methoxycycloheptatriene was very kindly supplied by Mr. R. B. Medz and Professor H. J. Dauben, Jr., of the University of Washington.

RESULTS AND DISCUSSION

Anisole

The mass spectra of anisole and anisole-methoxy-d_3 are presented in Table I. Both spectra have been corrected for naturally occurring ^{13}C and, in addition, the spectrum of the deuterated molecule has been corrected, in the parent region only, for 0.9% anisole-d_2 as determined by low-energy analysis. The spectra show a rather large H/D isotope

Metastables

Anisole:

56.3: $108^+ \rightarrow 78^+$

45.4: $93^+ \rightarrow 65^+$

23.5: $65^+ \rightarrow 39^+$

Anisole-methoxy-d_3:

59.1: $111^+ \rightarrow 81^+$

57.7: $111^+ \rightarrow 80^+$

56.2: $111^+ \rightarrow 79^+$

45.4: $93^+ \rightarrow 65^+$

23.5: $65^+ \rightarrow 39^+$

effect amounting to 1.3 to 1.4 in those regions which involve C–H bond breaking or rearrangement. This is particularly evident in the parent-H region, the C_6 region, and the C_4 region, which is formed by decomposition of the C_6 ions. Such isotope effects make detailed calculations more difficult.

The ion of mass 93 in anisole remains practically completely at the same mass in the spectrum of the d_3 compound, although perhaps 6% of the total intensity appears at mass 94, suggesting a slight amount of exchange of the ring and methyl hydrogens in the parent ion. Similarly the mass spectrum of the deuterated compound shows little change in the C_5 region, providing confirmation for the fragmentation reaction [1] proposed by Barnes and Occolowitz (3).

[1] $$C_6H_5OCH_3^+ \rightarrow CH_3 + C_6H_5O^+ \rightarrow C_5H_5^+ + CO$$

The major differences in the two mass spectra occur in the C_6 region and in the C_4 region, which is formed by decomposition of the C_6 ions. The spectrum of anisole shows a peak of moderate intensity of mass 79 ($C_6H_7^+$) and, after isotope correction, a small peak at mass 80 which must correspond to the $C_6H_8^+$ ion. These ions have not been discussed by previous workers (3, 4). In the spectrum of the d_3 compound the ion of mass 80 has moved to mass 83, as expected, and an appreciable amount of the $C_6H_7^+$ intensity has moved to mass 82, indicating retention of all three methoxy hydrogens. The $C_6H_6^+$ ion has shifted predominantly to mass 79, indicating retention of one of the methyl hydrogens, while a rather large amount of the $C_6H_5^+$ intensity remains at mass 77, indicating that none of the methyl hydrogens have been retained.

If it is assumed that the H/D isotope effect applies equally to all ions in the C_6 region, a reasonable assignment of the ion contributions in the deuterated compound can be made. These assignments are shown in Table II. The data for the unlabelled anisole were obtained by multiplying the data of Table I by 1/1.3 to allow for the observed isotope effect. The following points are evident.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

TABLE II

Mass spectra of anisole and anisole-methoxy-d_3 in C_6 region

Mass	Anisole	Ion contribution	Anisole-d_3	Ion contribution
83			0.98	$C_6H_5D_3^+$
82			4.80	$C_6H_4D_3^+$
81			4.28	$C_6H_5D_2^+ = 2.68$, $C_6H_3D_3^+ = 1.60$
80	0.73	$C_6H_8^+$	3.29	$C_6H_4D_2^+$
79	7.46	$C_6H_7^+$	41.70	$C_6H_5D^+ = 38.40$, $C_6H_3D_2^+ = 3.30$
78	43.74	$C_6H_6^+$	3.36	$C_6H_4D^+$
77	12.49	$C_6H_5^+$	6.43	$C_6H_5^+$

The ratio $C_6H_4D_3/C_6H_5D_2$ is equal to 5/3 within experimental error and thus indicates complete scrambling of the ring and methyl hydrogens in formation of $C_6H_7^+$. This suggests reaction [2] as the mechanism of formation.

[2] $$C_6H_5OCH_3^+ \rightarrow CO + C_6H_8^+ \rightarrow H + C_6H_7^+$$

The appearance potential of $C_6H_7^+$ was found to be 12.1 ± 0.1 eV which leads to ΔH_f $(C_6H_7^+) = 237$ kcal/mole assuming reaction [2]. This value is in good agreement with the value of 235 kcal/mole reported from the appearance potential of this ion from cyclohexadiene (7) and with the value of 233 kcal/mole from appearance potentials in methyl-substituted cyclopentadienes (8).

The calculations in Table II indicate that 88% of the $C_6H_6^+$ ion is formed with retention of one of the methyl hydrogens, the remainder being formed with retention of two and of all three methyl hydrogens. The mechanism appears to be by direct rearrangement of the parent ion since metastables are found at masses 56.2, 57.7, and 59.1 corresponding to reactions [3], [4], and [5].

[3] $$C_6H_5OCD_3^+ \rightarrow C_6H_5D^+ + CD_2O$$

[4] $$C_6H_5OCD_3^+ \rightarrow C_6H_4D_2^+ + CDHO$$

[5] $$C_6H_5OCD_3^+ \rightarrow C_6H_3D_3^+ + CH_2O$$

Reactions [4] and [5] must involve exchange of the ring and methyl hydrogens in the parent ion. Low-energy scans indicated the energy dependence of the three reactions were identical.

The large intensity for $C_6H_5^+$ in the deuterated anisole shows that the major portion of the $C_6H_5^+$ ion cannot arise by decomposition of the $C_6H_6^+$ ion as proposed by previous workers (3, 4) nor by decomposition of the $C_6H_7^+$ ion, since in both cases extensive deuterium retention would be expected. The decomposition of $C_6H_7^+$ is probably responsible for formation of the $C_6H_4D^+$ and $C_6H_3D_2^+$ ions. No changes in the $C_6H_4D^+/C_6H_5^+$ ratio with electron energy could be detected indicating mechanisms of similar energetics. We suggest formation of $C_6H_5^+$ by reactions [6] and [7].

[6] $$C_6H_5OCH_3^+ \rightarrow CO + H + C_6H_7^+ \rightarrow H_2 + C_6H_5^+$$

[7] $$C_6H_5OCH_3^+ \rightarrow H + C_6H_5OCH_2^+ \rightarrow CH_2O + C_6H_5^+$$

The loss of hydrogen from the parent ion involves predominantly the methyl hydrogens as shown by the relative intensities at masses 109 and 108 in the deuterated anisole. This fact is consistent with reaction [7]. The appearance potential of $C_6H_5^+$ in anisole-d_3 was 15.0 ± 0.2 eV which leads to $\Delta H_f(C_6H_5^+) = 305$ kcal/mole assuming reaction [7], in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

agreement with the value of 305 kcal/mole reported by Momigny (9) from appearance potential studies in benzene and related compounds. Assumption of CD_3O as the neutral fragment leads to ΔH_f ($C_6H_5^+$) = 330 kcal/mole which appears unreasonably high.

Methylanisoles

The mass spectra of *m*-methylanisole, *p*-methylanisole, the methoxy-d_3 labelled molecules, and the methyl-d_3-anisoles are given in Table III. The important metastables

observed in the mass spectra are assembled in Table IV. The spectra have been corrected for ^{13}C and, for the labelled molecules, for deuterium isotopic impurity in the parent mass region. Again comparison of the spectra shows a considerable deuterium effect where C–H bond breaking or hydrogen rearrangement is involved.

The $CH_3OC_7H_6^+$ ion (mass 121) moves to mass 124 in the methoxy labelled compounds, indicating negligible loss of the methoxy hydrogens. For the methyl-d_3 compounds both the methyl and ring hydrogens are lost as shown by the peaks at masses 124 and 123. Neglecting any isotope effects the relative intensities show that loss of the methyl hydrogens accounts for 60% of the total in the para case and 46% in the meta case, whereas complete scrambling of the ring and methyl hydrogens should lead to 43% loss of the

methyl hydrogens. Since any isotope effect is likely to reduce the loss of the methyl deuteriums, it is quite evident that there is a pronounced preference for loss of the methyl hydrogens in the para case and a small preference in the meta case. The energetics of formation of the $CH_3OC_7H_6^+$ ions will be discussed in a later section.

The mass spectra of the labelled compounds are complex in the C_7 region, and it is not possible to define completely the reactions producing the $C_7H_9^+$, $C_7H_8^+$, and $C_7H_7^+$ ions. The methylanisoles show a significant intensity at mass 93 corresponding to $C_7H_9^+$, the ion being much more abundant in the meta isomer. In the methyl-d_3 compounds the ion shifts to mass 96, indicating retention of the ring methyl hydrogens, while in the methoxy-labelled compound the ion is found at masses 96, 95, and possibly 94, indicating interchange of the ring and methoxy hydrogens. The appearance potential from the meta isomer was 11.69 ± 0.1 eV yielding ΔH_f ($C_7H_9^+$) = 219 kcal/mole assuming H + CO as the neutral fragments, a fragmentation similar to that found for formation of $C_6H_7^+$ from anisole. This ionic heat of formation is in agreement with the value of 219 kcal/mole obtained by electron impact on methylcylopentadienes (8) but somewhat lower than the value of 231 kcal/mole obtained from appearance potentials in cycloheptadiene (10). The mechanism of formation would appear to be by reaction [8] although the details are not clear; there is no $C_7H_{10}^+$ intermediate similar to the intermediate in formation of $C_6H_8^+$ from anisole.

[8] $$CH_3C_6H_4OCH_3^+ \rightarrow H + CO + C_7H_9^+$$

Both the methylanisoles show a significant ion current at mass 92 ($C_7H_8^+$) formed by direct decomposition of the parent ion, as indicated by the metastable at mass 69.4 corresponding to reaction [9]. For the methyl-d_3 anisoles the ion current moves to mass 95 and the metastable to mass 72.0, indicating complete retention of the methyl hydrogens. In the methoxy-labelled compounds the metastable at 69.2 corresponds to reaction [10],

[9] $$CH_3OC_6H_4CH_3^+ \rightarrow CH_2O + C_7H_8^+$$

[10] $$CD_3OC_6H_4CH_3^+ \rightarrow CD_2O + C_7H_7D^+,$$

indicating transfer of one of the methoxy hydrogens to the ring. A portion of the ion current may have moved to mass 94, indicating some scrambling of the ring and methoxy hydrogens, similar to the formation of $C_6H_6^+$ in anisole.

The formation of $C_7H_7^+$ in the methylanisoles may occur by at least four reactions, indicated below.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[11] $CH_3OC_6H_4CH_3^+ \rightarrow H + CO + C_7H_9^+ \rightarrow H_2 + C_7H_7^+$

[12] $CH_3OC_6H_4CH_3^+ \rightarrow CH_2O + C_7H_8^+ \rightarrow H + C_7H_7^+$

[13] $CH_3OC_6H_4CH_3^+ \rightarrow H + CH_3OC_7H_6^+ \rightarrow CH_2O + C_7H_7^+$

[14] $CH_3OC_6H_4CH_3^+ \rightarrow CH_3O + C_7H_7^+$.

Reaction [11], involving decomposition of the $C_7H_9^+$ ion, is known from studies in methylcyclopentadienes (8) and other C_7H_{10} isomers (10, 11). Reaction [12] is a well-known decomposition of $C_7H_8^+$ ions (2), although the metastable observed previously (3) was not found in the present work. Reaction [13] is indicated by the metastable at mass 68.4 in the methylanisoles. For the methoxy-d_3 compounds reaction [13] should lead exclusively to $C_7H_6D^+$, while decomposition of the $C_7H_7D^+$ formed in reaction [12] should lead predominantly (88%) to $C_7H_6D^+$. The $C_7H_9^+$ intermediate of reaction [11] is found mainly as $C_7H_6D_3^+$ and $C_7H_7D_2^+$ and should lead to extensive deuterium retention in the $C_7H_7^+$ fragment. The large intensity at mass 91 ($C_7H_7^+$) in the methoxy-labelled compounds therefore cannot arise to a significant extent by these three reactions but must arise by a decomposition which involves complete loss of the methoxy group. The most logical reaction is [14] given above. Examination of the spectra suggests for both isomers a contribution to the $C_7H_7^+$ formation by reaction [14] amounting to a maximum of 9% of the parent ion intensity. The spectra are too complex to permit an assessment of the relative contributions of the other three reactions.

The $C_6H_7^+$ ion (mass 79) is formed by loss of CO from mass 107 as shown by the metastable at mass 58.3 corresponding to the last step of reaction [15].

[15] $CH_3OC_6H_4CH_3^+ \rightarrow CH_3 + CH_3C_6H_4O^+ \rightarrow CO + C_6H_7^+$

The mass spectra of the labelled compounds clearly show that the methoxy methyl is lost in this reaction sequence while the ring methyl is maintained. The remaining fragment ions in the C_6 region, predominantly $C_6H_6^+$ and $C_6H_5^+$, undoubtedly are formed by decomposition of the $C_6H_7^+$ ion. For the methyl-d_3-anisoles this ion becomes $C_6H_4D_3^+$ and provides an opportunity to examine the disposition of the hydrogens in these fragmentation processes. Table V compares the measured spectra with that calculated from the

ratio of 4:3. It is interesting to note that decomposition of $C_6H_7^+$ by reaction [16] does

[16] $$C_6H_7^+ \rightarrow C_4H_5^+ + C_2H_2$$

not involve complete loss of hydrogen identity. This is shown by the large intensity at mass 56 ($C_4H_2D_3^+$) in the methyl-d_3 compounds. Comparison of the 56/55 ratio shows that the loss of C_2H_2 to loss of C_2HD is approximately 1:1 rather than the 1:2 expected for complete scrambling.

The mass spectra of the labelled methylanisoles show considerable deuterium retention in the C_5, C_4, and C_3 regions, but detailed calculations do not appear to be justified. The mass spectra of the methylanisoles are compared in Fig. 1 with the spectra of the isomeric compounds, benzyl methyl ether and 7-methoxycylcoheptatriene. All four spectra are quite similar, as might be expected. The base peak for the methylanisoles is the parent ion due to the increased stability of the disubstituted aromatic system. For the other two isomers the base peak is mass 91, presumably the tropylium ion, $C_7H_7^+$. This ion can be formed in these cases by simple bond fission or a simple rearrangement, compared to the extensive rearrangement required for the methylanisoles. To a considerable extent the differences in the mass spectra can be explained by the differences in the stability of the molecule ion, as indicated by the data in Table VI, which presents the ionization potentials and some appearance potentials for the four isomers. The activation energies for decomposition of the methoxycycloheptatriene ion appear to be less than for the other isomers.

Perhaps the most surprising feature is the difference in the mass spectra of the two methylanisoles. The ionization potentials of the two isomers are practically identical and the appearance potentials of most of the major fragment ions are identical, yet the spectra show considerable differences in the parent-H and the C_7 region. These differences cannot be attributed to differences in activation energies for the fragmentation processes and may be due to steric factors.

Energetics of Formation of $CH_3OC_7H_6^+$

In previous work (1) it was concluded from appearance potential differences that the $CH_3OC_7H_6^+$ ions from the meta and para methoxybenzyl chlorides retained the benzyl

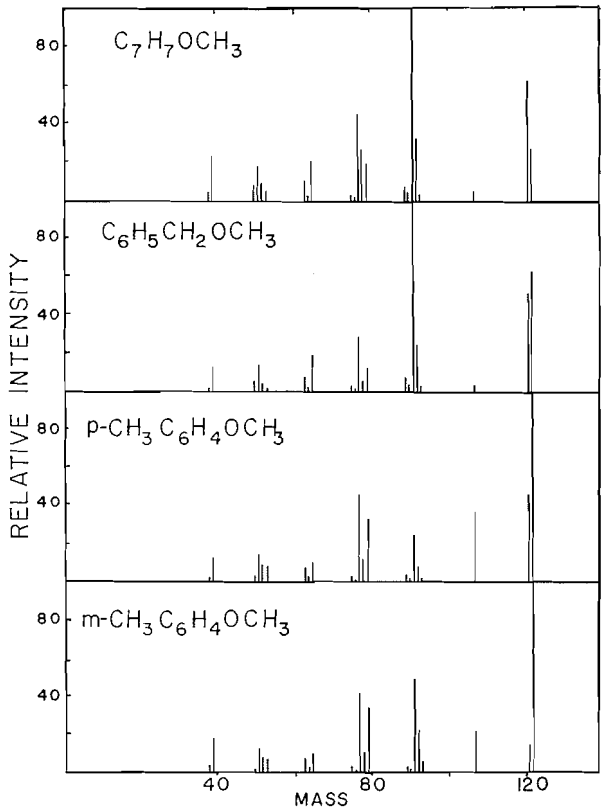

FIG. 1. Comparison of mass spectra of $C_7H_7OCH_3$ isomers.

configuration at the appearance potential threshold. One of the original objectives of the present work was to extend this investigation to other methoxybenzyl derivatives. To this end, a detailed study was made of the energetics of formation of the $CH_3OC_7H_6^+$ ion. Table VI records the data obtained for the methylanisoles, benzyl methyl ether, 7-methoxycycloheptatriene, and meta and para ethylanisole. In the latter compounds the methoxy group was labelled to distinguish the methyls lost in the dissociation process. The heats of formation of the methoxy compounds necessary for the calculations in Table VI were estimated by the bond-energy scheme due to Cox (12).

The appearance potentials of the $CH_3OC_7H_6^+$ ion from benzyl methyl ether and from methoxycycloheptatriene both lead to ΔH_f $(CH_3OC_7H_6^+) = 175 \pm 3$ kcal/mole. The mass spectra of these two compounds are practically identical, as discussed above, and it is probable that in both cases the $CH_3OC_7H_6^+$ ion has the tropylium structure. On the other hand, the data for the methylanisoles lead to ΔH_f $(CH_3OC_7H_6^+) = 201$ kcal/mole. The identity of the appearance potentials for both isomers indicates that the positional effect of the substituent has been lost. Furthermore, the extensive scrambling of the ring and methyl hydrogens (see above) in the dissociation process indicates a tropylium-like structure for the ion, by analogy with the behavior of toluene and related isomers (2). It should be noted that the appearance potentials for loss of the ring and methyl hydrogens are identical, as is shown by the data in Table VI. If this interpretation is correct for the methylanisoles, the appearance potential may only reflect the minimum energy required

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to form the lowest excited state of the molecule ion capable of decomposition to the $CH_3OC_7H_6^+$ ion.

For the meta and para ethylanisoles the appearance potentials of the $CD_3OC_7H_6^+$ ion differ by 0.9 eV in agreement with the difference of 0.99 eV predicted (1) for the energies of formation of the respective methoxybenzyl ions from the correlation (13) of these energies with the σ^+ constant for the substituent. This would suggest that in these cases the $CH_3OC_7H_6^+$ ion retains the benzyl structure. It should be noted, however, that the heat of formation calculated from the para isomer is not greatly different from the value obtained from benzyl methyl ether and methoxycycloheptatriene, while the value from the meta isomer is only slightly greater than that obtained from the methylanisoles. Since the data for the other isomers probably refer to methoxytropylium ions of different excitational energies, one cannot disregard the possibility that the results for the ethylanisoles also indicate the formation of tropylium ions of different excitational energies. If such is the case, it would indicate that the excited energy levels of the molecule ion differ considerably for the two isomeric ethylanisoles.

The mass spectra of the ethylanisoles show differences which are to be expected from the difference in energy content of the $CH_3OC_7H_6^+$ ion. Partial mass spectra of the unlabelled and methoxy-d_3 ethylanisoles are given in Table VII. In all cases loss of CH_3

TABLE VII

Partial mass spectra of ethylanisoles

	p-Ethylanisole		*m*-Ethylanisole

93	1.28	3.24	5.00	8.80
92	2.00	5.70	5.54	25.78
91	10.67	7.89	36.67	21.10
66		2.08		5.05
65	5.34	7.18	12.05	13.67

forms the base peak of the spectra, the spectra of the labelled molecules showing that this methyl is lost predominantly from the ethyl side chain. The major fragmentation path for the $CH_3OC_7H_6^+$ ion is by reaction [17] to give the tropylium ion.

[17] $$CH_3OC_7H_6^+ \rightarrow CH_2O + C_7H_7^+$$

This is supported by observation of the appropriate metastables in all cases. For the $CD_3OC_7H_6^+$ ion this fragmentation should lead exclusively to $C_7H_6D^+$ (mass 92). The mass 91 ion current in the labelled compounds must be ascribed to the $C_7H_7^+$ ion and must arise by a different path, presumably by decomposition of the $C_7H_9^+$ ion which is found in the spectra. We would suggest that the $C_7H_9^+$ is formed by reaction [18], which involves loss of the labelled methoxy methyl.

[18] $$C_2H_5C_6H_4OCH_3^+ \rightarrow CH_3 + C_2H_5C_6H_4O^+ \rightarrow CO + C_7H_9^+$$

The mass 92 in the labelled ethylanisoles is thus a measure of the $C_7H_7^+$ formed by reaction [17]. It is obvious that in the meta case the abundance of the $CH_3OC_7H_6^+$ ion in comparison with the parent ion or the $C_7H_7^+$ fragment is greatly reduced compared to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

para isomer. For the meta isomer not only is more energy required for formation of the $CH_3OC_7H_6^+$ ion but also the activation energy for further decomposition is reduced.

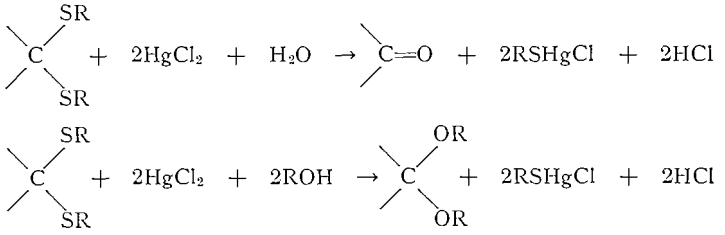
NOTES

ASYMMETRIC SYNTHESIS BY THE REACTION OF MERCURIC ACETATE WITH OPTICALLY ACTIVE THIOACETALS

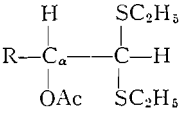
EDGAR PAGE PAINTER

Fischer (1) found that mercuric chloride removes —SR groups of thioacetals. The product in aqueous or alcohol solution with excess mercuric chloride is an aldehyde (or *gem*-diol) or an acetal formed by the overall reactions:



Unlike the above reactions where both thio groups are substituted, we find that acetoxy substitutes a single —SR group when thioacetals are dissolved in acetic acid – acetic anhydride mixtures with mercuric acetate (reaction 1).

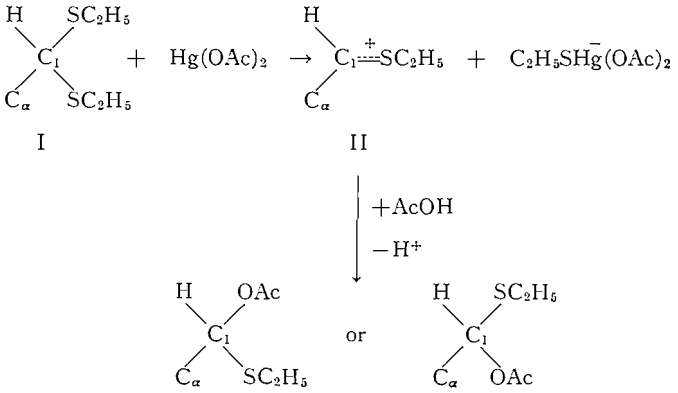
[1] 
Thioacetals which contain an asymmetric carbon (C_α in I) bonded to the acetal carbon have structural requirements for asymmetric induction so that unequal amounts of the thiohemiacetal acetates produced in reaction 1 would be expected. This is indeed the experimental result as each of four optically active substrates (which differ by R in I) give unequal amounts of diastereomers.



I

When one makes the reasonable assumption that substitution of thioacetals by the action of Lewis acids is in essence a process analogous to acid-catalyzed substitution of acetals (2, 3, 4), the reactive intermediate in the present case can be considered a carbonium (or sulphonium) ion.

By analogy to the cationic intermediate in the substitution of acetals (4), II may be considered planar. Bonding to C_1 (of II) is then similar to the many examples of asymmetric synthesis achieved by addition of nucleophiles to carbonyl compounds (5–9). In each case the new asymmetric center is the result of bonding to planar carbon adjacent



to an asymmetric carbon already in the molecule. Rules suggested by Cram and Abd Elhafez (7) to predict the major product by asymmetric induction in the carbonyl systems should then be applicable to our substrates.

Four substrates, the penta-O-acetyl diethyl dithioacetal of D-glucose (III), D-galactose (IV), D-mannose (V), and the tetra-O-acetyl diethyl dithioacetal of L-arabinose (VI), which have an asymmetric carbon bonded to the acetal carbon, are stable in solutions of acetic acid – acetic anhydride. Mercuric acetate reacts with each substrate. In each case a single ethylthio group is substituted by acetoxy to give 1-ethylthio-1-acetoxy products: III → VII; IV → VIII; V → IX; VI → X. Each of the crystalline products isolated (VII, VIII, and X) is one member of the pair of diastereomers expected. The product IX is a syrup which, presumably, is a mixture.

Measured rotations of the substrates, of the products in solution after the reaction with mercuric acetate, and of the isolated products are shown in Table I. Since the change

TABLE I

Measured rotation of 5% solutions of substrate and isolated products in equal volumes of acetic acid – acetic anhydride

Substrates		Rotation after reaction with $Hg(OAc)_2$	Products	
No.	Rotation		No.	Rotation
III	−0.33°	+0.39°	α-VII	+0.40°
IV	+0.34°	+1.45°	α-VIII	+1.72°
V	+1.21°	+0.61°	IX	+0.55°
VI	−1.40°	−0.17°	β-X	+0.18°

in mass in the substitution reaction is small (for the hexose derivative the molecular weight changes from 496 to 494), the rotations serve as a useful guide to product composition.

From the measured rotation and the yields of VII, it is seen that III is converted nearly quantitatively to α-VII. This example is then comparable to an addition to a carbonyl compound leading almost exclusively to a single isomer, as described by Benjamin, Schaeffer, and Collins (6). The high yields of α-VIII and β-X show that these are the major products in each case. The diastereomer from IV is designated α-VIII because we have isolated from the reaction mixture of IV crystalline products which are more levorotatory than the compound listed in Table I. The mother liquor from the crystallization of the diastereomer from VI gives a syrup more levorotatory than the reaction

For personal use only.

products; therefore, the product described (a member of the L-series) is designated β-X.

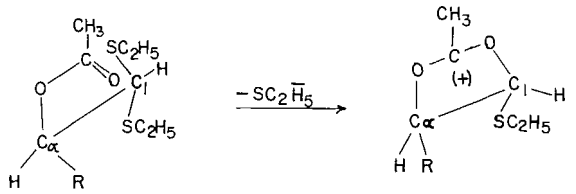
Since the isolated products, α-VII, α-VIII, and β-X, are stable in acetic acid – acetic anhydride solutions containing mercuric acetate, the α/β ratio of each pair of diastereomers is given by irreversible bonding of acetoxy to II; i.e., II does not form from 1-ethylthio-1-acetoxy products. Both α-VII and α-VIII have been prepared by esterifying the parent 2,3,4,5,6-penta-0-acetyl-1-S-ethyl monothiohemiacetals of D-glucose and D-galactose with acetic anhydride (10). In one case the substrate was isolated as a solid; in the other case the mixture of thiohemiacetals formed in the equilibrium

[2] 
XII XI XIII

was esterified. The diastereomer isolated in the larger amount from the glucose derivative was α-VII; a single diastereomer (α-VIII) was isolated from the galactose derivative. It is tempting to conclude that the same steric forces influence the product distribution (XII and XIII) in equation 2 that control the steric course of direct substitution described by equation 1. We cannot, however, be sure the esterified product composition is a measure of the above equilibrium because XII and XIII may not esterify at equal rates.

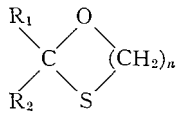
Heptaacetate (10, 11) was also identified as one of the products formed by esterification of the mixture in equation 2. This is a product of XI as we find that *aldehydo* pentaacetates of hexoses are converted to C_1-*gem*-diacetates in nearly quantitative yields by acetic anhydride with a catalyst. We are unable to find evidence for the formation of *gem*-diacetates in the reaction of dithioacetals with mercuric salts.

An acetoxy group in the favored conformation of I is in a position to give anchimeric assistance (12) when a C–S bond is broken by the action of mercuric salt.



The intermediate II*a* can react with acetic acid at C_1 to give substituted product VII, or at the acetoxy carbon to give (when the substrate is III) 3,4,5,6-tetra-0-acetyl-1,2-0-(1-acetoxy-ethylidine)*aldehydo*-D-glucose S-ethyl monothioacetal. The two products are analytically identical. There is no reason to question the structures of VII and VIII but the possibility of orthoacid structures among our products is not eliminated. Acetoxy is in a better position to give anchimeric assistance in our acyclic systems than it is in the favored conformation in some cyclic forms which give orthoester products.

Preferential C–O cleavage of hemithioacetals and ketals of the type has been demonstrated by Eliel and co-workers (13, 14) with aluminum chloride as the catalyst. Leggetter



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and Brown (15) recently applied the reaction to other substrates and found that aluminum chloride cleaved dioxolanes faster than oxathiolanes and dithiolanes not at all. Preferential bonding of Al^{3+} to oxygen to give C–O cleavage is expected; Hg^{2+} would be expected to preferentially bond to divalent sulphur but the C–S bond in our 1-ethylthio-1-acetoxy compounds was not cleaved. A question arises about why $C_2H_5S-\underset{|}{\overset{|}{C}}-SC_2H_5$ substitutes rapidly whereas $C_2H_5S-\underset{|}{\overset{|}{C}}-O\overset{O}{\overset{\|}{C}}CH_3$ does not in acetic acid solutions of mercuric acetate. The answer must lie in the cationic intermediate given by cleavage of a C–S bond. Whereas divalent sulphur is an electron donor to carbon giving the relatively stable intermediate,

$$\overset{+}{C}-SC_2H_5 \longleftrightarrow C=\overset{+}{S}C_2H_5$$

oxygen of the acetoxy group is such a poor electron donor that we are unable to detect substitution products of the unstable intermediate

$$\overset{+}{C}-O\overset{O}{\overset{\|}{C}}CH_3 \longleftrightarrow C=\overset{+}{O}\overset{O}{\overset{\|}{C}}CH_3.$$

EXPERIMENTAL

The O-acetyl derivatives of the diethyl dithioacetals were prepared by slow addition of the thioacetals (1 part) to acetic anhydride (8 parts) saturated with sodium acetate at 100–110°. After 2 h at this temperature the solution was allowed to cool to room temperature and the product was isolated and recrystallized by procedures described by Wolfrom (16).

Each of the four substrates was heated with from 1 to 3 moles of mercuric acetate in mixtures of acetic acid – acetic anhydride and the rotation (sodium D line) measured (in portions of the solutions cooled to room temperature) until there was no further change. In all cases the substitution reaction was essentially complete in a 1:1 mixture of acetic acid and acetic anhydride with excess mercuric acetate before the temperature reached 100°. Dissolved mercuric acetate does not significantly modify the rotation of isolated substitution products.

The following procedure was followed for the preparation of products. Five grams of substrate (III, IV, V or VI) plus 5 g of mercuric acetate were dissolved in 100 ml of acetic acid – acetic anhydride (equal volumes) and the flask heated in a water bath until the temperature in the reaction mixture reached 80°. When the reaction mixture had cooled to room temperature the volume of solvent was reduced under vacuum to about 20 ml. Twenty-five grams of sodium acetate and a quantity of crushed ice to give a final volume near 200 ml were added. The contents of the flask was frequently stirred until the acetic anhydride hydrolyzed (no separate phase evident) and kept at 0° or colder for an additional hour. The product from V was an oil; the other substrates gave a white crystalline mass. Each product was washed with several small portions of ice water and dried at room temperature.

*1,2,3,4,5,6-Hexa-O-acetyl-*D*-glucose S-ethyl Monothioacetal (α-VII)*

The crude product (above) from 5 g of III weighed 4.3 g and melted by 101°. Two crystallizations, by dissolving the product in hot 96% ethanol and cooling in the refrigerator, gave 3.3 g (66%) of pure α-VII, m.p. 104; α_D = +7.9 (acetic acid – acetic anhydride, C = 4, 29°), +12.6 (chloroform, C = 4, 26°), Calc. for $C_{20}H_{30}O_{12}S$: C, 48.57; H, 6.11; S, 6.48; acetoxy, 6 equiv./494 g. Found: C, 48.37; H, 6.10; S, 6.26; acetoxy, 6.02 equiv.

*1,2,3,4,5,6-Hexa-O-acetyl-*D*-galactose S-ethyl Monothioacetal (α-VIII)*

The crude product from 5 g of IV weighed 4.6 g and melted by 90°. This was dissolved in 20 ml of absolute methanol and the crystals, which formed overnight at −19°, were filtered and washed with methanol at −19°. A second recrystallization by the procedure just described gave 3.9 g (78%) of pure materials, m.p. 95–96°, α_D = +38.5 (chloroform, C = 4, 25°), +34.3 (acetic acid – acetic anhydride, C = 4, 25°). Calc. for $C_{20}H_{30}O_{12}S$: C, 48.57; H, 6.11; S, 6.48; acetoxy, 6 equiv./494 g. Found: C, 48.69; H, 6.03; S, 6.34; acetoxy, 6.08 equiv.

For personal use only.

*1,2,3,4,5,6-Hexa-O-acetyl-*D*-mannose S-ethyl Monothioacetal (IX)*

This product has not been crystallized. Different preparations gave α_D = 10.7 to 11.5 (acetic acid – acetic anhydride C = 4, 25°). The product contains S and gives a reducing sugar after treatment with sodium methoxide in methanol. Saponification gave 6.08 equiv. acetoxy/494 g.

*1,2,3,4,5-Penta-O-acetyl-*L*-arabinose S-ethyl Monothioacetal (β-X)*

The crude product was dissolved in $CHCl_3$ and filtered, and the solvent was removed at reduced pressure. The solid residue was dissolved in ethyl acetate and the volume reduced until crystallization began at room temperature. Two volumes of hexane were then added and after allowing the solution to stand overnight in the refrigerator the crystals were filtered and washed with hexane. The product was dissolved in hot absolute methanol and the volume reduced until crystals formed at room temperature. After the product was left overnight in the refrigerator it was washed with ice cold methanol. Yield 2.8 g (56%), m.p. 120°, α_D = +3.5 (acetic acid – acetic anhydride, C = 4, 25°), +6.3 (chloroform, C = 4, 24°). Calc. for $C_{17}H_{26}O_{10}S$; C, 48.34; H, 6.16; S, 7.58; acetoxy, 5 equiv./422 g. Found: C, 48.37; H, 6.02; S, 7.60; acetoxy, 4.99 equiv.

The author is grateful to Mr. Norman Kurihara for the acetoxy determinations and assistance in the preparation of acetylated dithioacetals.

THE ELECTRON PARAMAGNETIC RESONANCE SPECTRA OF THE 2-CYANO-2-PROPYL RADICAL AND RELATED SPECIES*

J. T. Pearson, P. Smith,† and T. C. Smith

The 2-cyano-2-propyl radical, $(CH_3)_2\dot{C}(CN)$, is a commonly used radical chain initiator and a model radical similar to some involved in vinyl polymerization (1, 2). Nevertheless it does not appear that the e.p.r. spectrum of this radical has been reported despite the considerable extra interest (3–9) originating from the observation (10) that it can react as though the unpaired electron is appreciably delocalized

$$(CH_3)_2\dot{C}—C\equiv N \leftrightarrow (CH_3)_2C=C=N\bullet.$$

The aim of the present investigation was to obtain a well-resolved e.p.r. spectrum for the 2-cyano-2-propyl radical in solution by use of the new and simple flow technique of Dixon and Norman (11).

THE ELECTRON PARAMAGNETIC RESONANCE SPECTRA OF THE 2-CYANO-2-PROPYL RADICAL AND RELATED SPECIES*

J. T. Pearson, P. Smith,† and T. C. Smith

The 2-cyano-2-propyl radical, $(CH_3)_2\dot{C}(CN)$, is a commonly used radical chain initiator and a model radical similar to some involved in vinyl polymerization (1, 2). Nevertheless it does not appear that the e.p.r. spectrum of this radical has been reported despite the considerable extra interest (3–9) originating from the observation (10) that it can react as though the unpaired electron is appreciably delocalized

$$(CH_3)_2\dot{C}—C\equiv N \leftrightarrow (CH_3)_2C=C=N\bullet.$$

The aim of the present investigation was to obtain a well-resolved e.p.r. spectrum for the 2-cyano-2-propyl radical in solution by use of the new and simple flow technique of Dixon and Norman (11).

*Supported by a grant from the United States Public Health Service, Division of General Medical Sciences.
†To whom correspondence should be addressed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

In this technique hydroxyl radicals are generated at room temperature within the cavity of an e.p.r. spectrometer by the reduction of hydrogen peroxide with titanous ions in acidified aqueous solution. When an organic substrate is present in the reactant streams it is attacked in secondary processes by the hydroxyl radicals and the products so formed can be detected by e.p.r. spectroscopy.

The substrate employed here was isobutyronitrile. This yielded the desired 2-cyano-2-propyl radical in sufficient concentration for a well-resolved e.p.r. spectrum to be successfully obtained. As expected this spectrum of the 2-cyano-2-propyl radical shows appreciable interaction of the unpaired electron with the nitrogen nucleus. Besides obtaining the e.p.r. spectrum of the 2-cyano-2-propyl radical another radical product from the reaction of hydroxyl radicals with isobutyronitrile was found and identified by its e.p.r. spectrum.

EXPERIMENTAL

A Varian (100 kc s^{-1}) V-4502-06 X-band e.p.r. spectrometer system was employed. It was equipped with the V-4548 aqueous solution sample cell accessory, the V-4532 dual-sample cavity attachment to the V-4531 multipurpose cavity, and the G-22A dual-channel graphic recorder. The flow system utilized the mixing arrangement of Dixon and Norman (11) and the aqueous solution cell accessory. The maximum total flowrate was 5 ml s^{-1}. The reactant streams were 0.1 *M* in sulphuric acid (Baker and Adamson, c. p.) and, respectively, 0.05 and 0.1 *M* in hydrogen peroxide (Becco, 98% w/w) and titanous chloride (Fisher, 20% w/w solution). The reaction temperature was 25 ± 1 °C. Isobutyronitrile (Eastman, yellow label) and acetonitrile (Fisher, certified reagent) were used without further purification, since no impurities were detected by vapor phase chromatography (v.p.c.) analysis. When the substrate was isobutyronitrile both reactant streams were made 0.3 *M* in nitrile. When acetonitrile was used in place of isobutyronitrile both reactant streams were 2 *M* in substrate. The hyperfine coupling constants were measured with peroxylamine disulphonate as the reference standard (12), with use of the dual-sample cavity, and on the assumption that the nitrogen hyperfine coupling constant is 13.0 ± 0.1 G (12).

RESULTS AND DISCUSSION

With isobutyronitrile as the substrate two superimposed spectra were observed as shown in Fig. 1. These are ascribed to the following radicals

I

II

These species are products of the abstraction by hydroxyl radicals of hydrogen atoms situated relative to the nitrile group on the 1- and 2-positions, respectively. Isotropic coupling constants for I and II are given in Table I.

TABLE I

Coupling constants for radicals formed by the reaction of hydroxyl radicals with isobutyronitrile

Radical	Spectral type	Coupling constants, G*		
		H_α	H_β	^{14}N
I	Septet (1:6:15:20:15:6:1) of triplets (1:1:1)	—	21.5 ±0.5	3.6 ±0.4
II	Triplet (1:2:1) of doublets (1:1)	23.2 ±0.4	25.1 ±0.5	—

*Each coupling constant given is the arithmetic mean of all measurements of that coupling constant taken from two consecutive field scans. The cited precision index is the maximum absolute deviation from the arithmetic mean. The designations α and β refer to the position relative to the carbon which bears the unpaired electron.

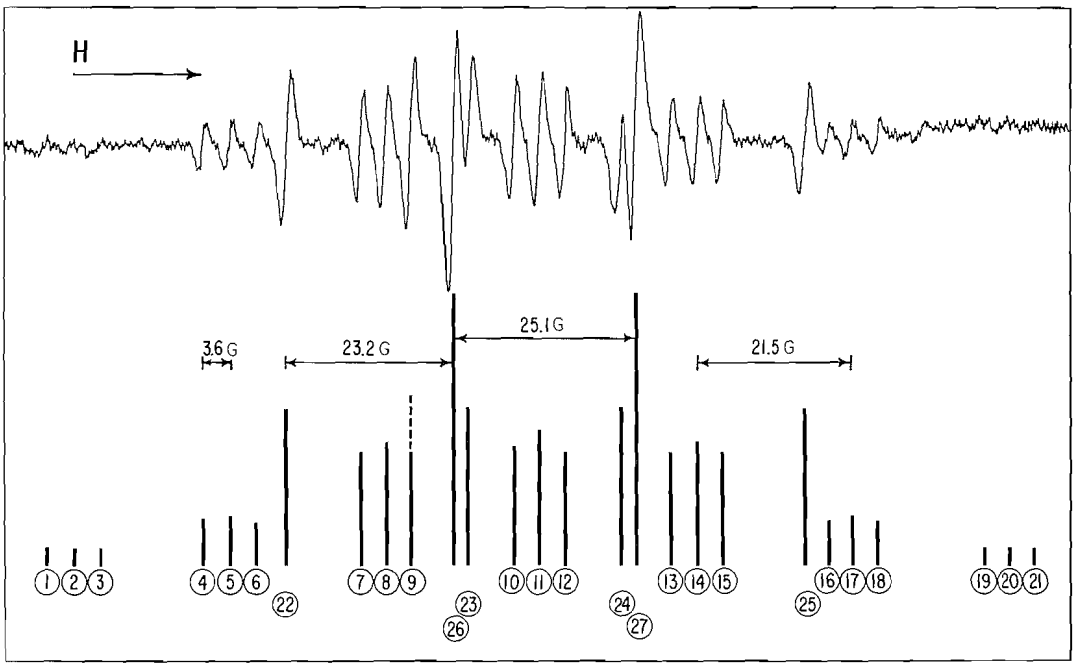

FIG. 1. The electron paramagnetic resonance spectrum for the reaction of hydroxyl radicals with isobutyronitrile; chart speed, 1 in. min^{-1}; time of scan, 25 min. Lines numbered 1 through 21 refer to radical I; lines 22 through 27, to radical II. Line 9 is abnormally intense because of the superimposed singlet signal from unreacted hydroxyl radicals.

The major splitting in the spectrum assigned to radical I is analogous to that reported (11) for the predominant radical formed by attack of hydroxyl radicals on isopropyl alcohol $(CH_3)_2\dot{C}(OH)$. The minor splitting because of coupling with the nitrogen is experimentally indistinguishable from the value of 3.53 ± 0.05 G recently claimed for the acrylonitrile monomer radical, $(HOCH_2)\dot{C}H(CN)$, by Fischer (13). The narrow six-line spectrum is ascribed to radical II. It consists of an overlapping triplet of doublets arising from successive coupling with the protons located with reference to the unpaired electron on the α- and β-position, respectively, i.e., the α- and β-proton couplings are non-equivalent, unlike those reported for the analogous radical $(\cdot CH_2)CH(OH)(CH_3)$ formed from isopropyl alcohol (11).

More nitriles are being studied under these conditions, e.g., acetonitrile. This substrate gives rise to two or more superimposed spectra. The most intense, a triplet (1:2:1) of triplets (1:1:1), has been assigned to the cyano-methyl radical $\cdot CH_2CN$. The rest of the spectrum consists of four (1:2:2:1) triplets (1:1:1) and may be a consequence of radical addition with, perhaps, accompanying polymerization. This feature has not been clearly settled but is receiving further attention along with the investigation of spectra from other nitriles.

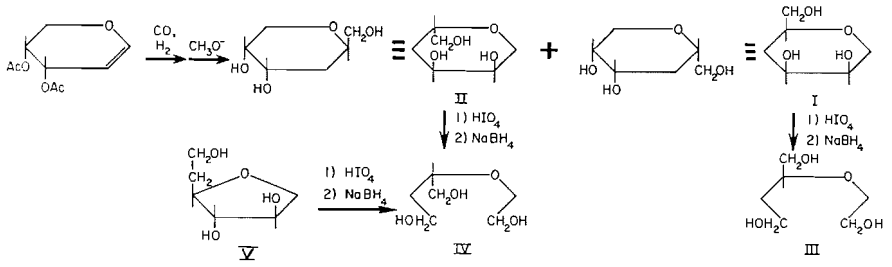
THE REACTION OF UNSATURATED CARBOHYDRATES WITH CARBON MONOXIDE AND HYDROGEN. III. STRUCTURE AND STEREOCHEMISTRY OF THE HEXITOLS FROM 3,4-DI-*O*-ACETYL-D-ARABINAL

ALEX ROSENTHAL AND HANS J. KOCH

In Part II of this series (1) it was shown that 3,4-di-*O*-acetyl-D-xylal reacted with carbon monoxide and hydrogen at a temperature of about 130° and at a pressure of about 4000 p.s.i. in the presence of dicobalt octacarbonyl to yield two anhydrodeoxyhexitols. This paper reports the results of an investigation of the application of a similar reaction to 3,4-di-*O*-acetyl-D-arabinal. The oxo product, first freed of catalyst, was deacetylated with methanolic sodium methoxide to afford a mixture of two hexitols contaminated with traces of sugars. Treatment of the mixture with sodium borohydride in water reduced the sugars to hexitols. Cellulose chromatography of the mixture gave the hexitols (I) and (II).



The structure and stereochemistry of the anhydrodeoxyhexitols (I) and (II) were determined in the same way as described in Part II of this series (1). Periodate oxidation of each hexitol (each consumed 1 molar equivalent of periodate) afforded sirupy dialdehydes. Sodium borohydride reduction of these dialdehydes yielded the triol ethers (III) and (IV), which had similar infrared spectra and equal but opposite optical rotations. Further confirmation that these triol ethers were enantiomers was provided by their characterization as crystalline *p*-nitrobenzoates with similar melting points. Direct comparison (m.p., mixed m.p., and infrared spectra) revealed that the *p*-nitrobenzoate of (IV) was identical with the *p*-nitrobenzoate of the triol ether obtained from 1,4-anhydro-5-deoxy-D-*arabino*-hexitol (V). Thus, the configuration of C-5 of the hexitol (II) is the same as that of C-4 of 1,4-anhydro-5-deoxy-D-*arabino*-hexitol (V), and compounds (I) and (II) are 1,5-anhydro-4-deoxy-D-*lyxo*-hexitol and 1,5-anhydro-4-deoxy-L-*ribo*-hexitol, respectively.

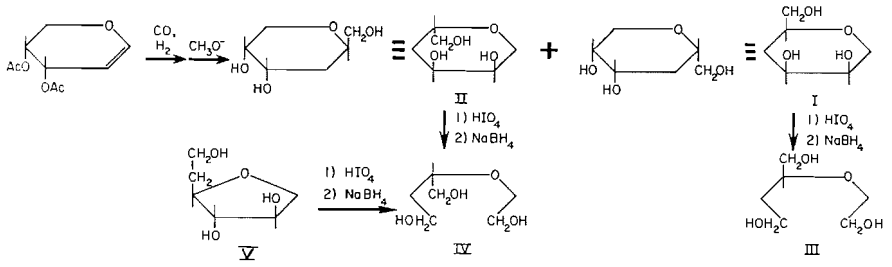
THE REACTION OF UNSATURATED CARBOHYDRATES WITH CARBON MONOXIDE AND HYDROGEN. III. STRUCTURE AND STEREOCHEMISTRY OF THE HEXITOLS FROM 3,4-DI-*O*-ACETYL-D-ARABINAL

ALEX ROSENTHAL AND HANS J. KOCH

In Part II of this series (1) it was shown that 3,4-di-*O*-acetyl-D-xylal reacted with carbon monoxide and hydrogen at a temperature of about 130° and at a pressure of about 4000 p.s.i. in the presence of dicobalt octacarbonyl to yield two anhydrodeoxyhexitols. This paper reports the results of an investigation of the application of a similar reaction to 3,4-di-*O*-acetyl-D-arabinal. The oxo product, first freed of catalyst, was deacetylated with methanolic sodium methoxide to afford a mixture of two hexitols contaminated with traces of sugars. Treatment of the mixture with sodium borohydride in water reduced the sugars to hexitols. Cellulose chromatography of the mixture gave the hexitols (I) and (II).



The structure and stereochemistry of the anhydrodeoxyhexitols (I) and (II) were determined in the same way as described in Part II of this series (1). Periodate oxidation of each hexitol (each consumed 1 molar equivalent of periodate) afforded sirupy dialdehydes. Sodium borohydride reduction of these dialdehydes yielded the triol ethers (III) and (IV), which had similar infrared spectra and equal but opposite optical rotations. Further confirmation that these triol ethers were enantiomers was provided by their characterization as crystalline *p*-nitrobenzoates with similar melting points. Direct comparison (m.p., mixed m.p., and infrared spectra) revealed that the *p*-nitrobenzoate of (IV) was identical with the *p*-nitrobenzoate of the triol ether obtained from 1,4-anhydro-5-deoxy-D-*arabino*-hexitol (V). Thus, the configuration of C-5 of the hexitol (II) is the same as that of C-4 of 1,4-anhydro-5-deoxy-D-*arabino*-hexitol (V), and compounds (I) and (II) are 1,5-anhydro-4-deoxy-D-*lyxo*-hexitol and 1,5-anhydro-4-deoxy-L-*ribo*-hexitol, respectively.

It is apparent that analysis of the nuclear magnetic resonance (n.m.r.) spectra (described in Experimental section) reveals the molecular structure of each of the anhydrodeoxyhexitols (I) and (II). Because each multiplet of peaks (equivalent to two hydrogens) occurs at about $\delta = 1.8$, it can be inferred from previous work (1) that each isomer possesses a methylene group on C-4. Thus, the two anhydrodeoxyhexitols must be linear and differ only in the configuration of C-5. The stereochemistry of C-5 of each of the anhydrodeoxyhexitols cannot be ascertained from the n.m.r. spectra because of overlapping peaks.

EXPERIMENTAL

General Considerations

These have been described previously (1).

*3,4-Di-O-acetyl-*D*-arabinal*

This was prepared following the procedure for the preparation of 3,4-di-*O*-acetyl-D-xylal (1).

*Reaction of 3,4-Di-O-acetyl-*D*-arabinal with Carbon Monoxide and Hydrogen to Yield 1,5-Anhydro-4-deoxy-*D*-lyxo-hexitol (I) and 1,5-Anhydro-4-deoxy-*L*-ribo-hexitol (II)*

The 3,4-Di-*O*-acetyl-D-arabinal (12 g) was allowed to react with 500 p.s.i. of carbon monoxide and 2500 p.s.i. of hydrogen in the presence of dicobalt octacarbonyl (2 g) for 1.5 h at 125°. The product (13 g), first freed of catalyst by filtration through Florisil, contained traces of reducing sugars. Reaction of the same substrate with carbon monoxide and hydrogen (1:8 by pressure) at 113° to 120° for 0.5 h yielded 33% reducing sugars and about 65% hexitols. The product was deacetylated with 0.1 *N* methanolic sodium methoxide. Sugars were reduced with sodium borohydride before separation of the hexitols by chromatography. Chromatography of 1.43 g of the deacetylated product on a powdered cellulose column (410 × 47 mm diam.) with water-saturated 1-butanol as developer yielded 0.80 g of fraction (I) and 0.55 g of fraction (II). Fractionation was also readily achieved using water-saturated 1-butanol containing 5% ethanol as developer.

Characterization of Fraction (I)

Fraction (I) (1,5-anhydro-4-deoxy-D-*lyxo*-hexitol) crystallized slowly when kept in a desiccator for several months over phosphorus pentoxide; m.p. 85–87°; $[\alpha]_D^{20}$ −50° (*c*, 1.7 water); $R_f = 0.26$. Attempts to crystallize (I) from methanol – isopropyl ether were unsuccessful. Anal. Calc. for $C_6H_{12}O_4$: C, 48.64; H, 8.17. Found: C, 48.38; H, 8.22. N.M.R. (deuterium oxide): multiplet of peaks, centered at $\delta = 1.68$ to 1.80, equal to 2 hydrogens. This spectrum was identical with that of a similar compound isolated by Gorin (2) from the hydrogenolysis of methyl-α-D-glucopyranoside.

Characterization of Fraction (II)

Fraction (II) (1,5-anhydro-4-deoxy-L-*ribo*-hexitol) solidified when kept in a desiccator over phosphorus pentoxide for several months. The substance was very hygroscopic. Attempts to crystallize (II) from various solvents were unsuccessful. $[\alpha]_D^{20}$ +29° (*c*, 2.5 water); $R_f = 0.36$. Anal. Calc. for $C_6H_{12}O_4$: C, 48.64; H, 8.17. Found: C, 48.49; H, 8.22. N.M.R. (deuterium oxide): multiplet of peaks, centered at $\delta = 1.60$ to 1.80, equal to 2 hydrogens.

*Preparation of 1,5-Anhydro-2,3,6-tri-O-benzoyl-4-deoxy-*D*-lyxo-hexitol*

Fraction (I) was benzoylated according to the procedure of Smith and Van Cleve (3) to yield sirupy 1,5-anhydro-2,3,6-tri-*O*-benzoyl-4-deoxy-D-*lyxo*-hexitol; $[\alpha]_D^{21}$ −63° (*c*, 3 ethanol). Anal. Calc. for $C_{27}H_{24}O_7$: C, 70.41; H, 5.25. Found: C, 70.60; H, 5.42.

*Preparation of 1,5-Anhydro-2,3,6-tri-O-benzoyl-4-deoxy-*L*-ribo-hexitol*

Fraction (II) was benzoylated in the usual way to yield 1,5-anhydro-2,3,6-tri-*O*-benzoyl-4-deoxy-L-*ribo*-hexitol, and the product was recrystallized from ethyl acetate – light petroleum ether, or methanol–water; m.p. 132–133°; $[\alpha]_D^{21}$ +79° (*c*, 1.58 chloroform). Anal. Calc. for $C_{27}H_{24}O_7$: C, 70.41; H, 5.25. Found: C, 70.75; H, 5.31.

Structure and Stereochemistry of Fractions (I) and (II)

Fraction (I) was oxidized, according to the procedure previously described (1), with 0.1 *M* periodic acid (1 molar equivalent consumed). The dialdehyde was immediately reduced with sodium borohydride to yield the triol ether (III); $[\alpha]_D^{21}$ −17° (*c*, 1 water). The triol ether was characterized as the *p*-nitrobenzoate; m.p. 102–102.5°; $[\alpha]_D^{22}$ −23° (*c*, 2 chloroform). Anal. Calc. for $C_{27}H_{23}N_3O_{13}$: C, 54.27; H, 3.88; N, 7.03. Found: C, 54.55; H, 3.96; N, 7.36.

Similarly fraction (II) was converted into the triol ether (IV); $[\alpha]_D^{24}$ +17° (*c*, 1 water). The infrared spectra of III and IV were similar. Reaction of the triol ether (IV) with *p*-nitrobenzoyl chloride in pyridine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

yielded the tris-*p*-nitrobenzoate; m.p. 102–102.5°; $[\alpha]_D^{22}$ +22.3 (*c*, 3.6 chloroform). Anal. Calc. for $C_{27}H_{23}N_3O_{13}$: C, 54.27; H, 3.88; N, 7.03. Found: C, 54.39; H, 3.98; N, 7.29.

The infrared spectra of the two *p*-nitrobenzoate derivatives were identical. The mixed m.p. of the tris-*p*-nitrobenzoate of compound (IV) and the tris-*p*-nitrobenzoate of 2-deoxy-3-*O*-(2-hydroxyethyl)-L-*glycero*-tetritol (1) (obtained by sodium borohydride reduction of the periodate oxidation product of authentic 1,4-anhydro-5-deoxy-D-*arabino*-hexitol (V)) was 101–103°. The infrared spectra of the two *p*-nitrobenzoates were identical.

PROPYLENE GAS HYDRATE STABILITY[1]

E. C. Clarke, R. W. Ford, and D. N. Glew

INTRODUCTION

Although the formation conditions for propane hydrate are well characterized (1, 2, 3), the comparable conditions for the formation of propylene hydrate from liquid water and propylene gas have been little studied and are known only approximately. From the three measurements available (3) it appears that the propylene hydrate is considerably less stable than the propane hydrate, in spite of the similar physical properties of the propylene and propane species. An experimental investigation of the propylene hydrate system has thus been made to better define the conditions for hydrate formation.

EXPERIMENTAL

The propylene was Matheson C.P. grade which was found by gas chromatography to contain 99.4 mole % propylene, 0.56 mole % propane, 127 p.p.m. ethane, and less than 10 p.p.m. of any other volatile impurity. The water was distilled and deionized by passage through a mixed ion exchange resin column, and subsequently outgassed in the hydrate cell prior to use.

The hydrate cell which was fabricated from stainless steel contained a stirrer operated by magnetic induction. The portion of the apparatus in which the hydrate was formed could be completely immersed in a large thermostat bath which could be regulated to ±0.001 °C. Pressure was measured using a 0–100 p.s.i., 10 in. diameter Heise gauge, which was calibrated by a dead-weight tester. The barometric pressure was recorded at each measurement. This procedure gave pressure accurate to ±0.1 p.s.i. or ±0.006 atm.

The temperature of the cell was measured relative to a block of stainless steel immersed in the same thermostat bath by means of a ten-junction copper–constantan thermocouple. The temperature of the block was measured by a platinum resistance thermometer which was calibrated at the triple point of water.

[1]*Contribution No. 122.*

yielded the tris-*p*-nitrobenzoate; m.p. 102–102.5°; $[\alpha]_D^{22}$ +22.3 (*c*, 3.6 chloroform). Anal. Calc. for $C_{27}H_{23}N_3O_{13}$: C, 54.27; H, 3.88; N, 7.03. Found: C, 54.39; H, 3.98; N, 7.29.

The infrared spectra of the two *p*-nitrobenzoate derivatives were identical. The mixed m.p. of the tris-*p*-nitrobenzoate of compound (IV) and the tris-*p*-nitrobenzoate of 2-deoxy-3-*O*-(2-hydroxyethyl)-L-*glycero*-tetritol (1) (obtained by sodium borohydride reduction of the periodate oxidation product of authentic 1,4-anhydro-5-deoxy-D-*arabino*-hexitol (V)) was 101–103°. PROPYLENE GAS HYDRATE STABILITY[1]

E. C. Clarke, R. W. Ford, and D. N. Glew

INTRODUCTION

Although the formation conditions for propane hydrate are well characterized (1, 2, 3), the comparable conditions for the formation of propylene hydrate from liquid water and propylene gas have been little studied and are known only approximately. From the three measurements available (3) it appears that the propylene hydrate is considerably less stable than the propane hydrate, in spite of the similar physical properties of the propylene and propane species. An experimental investigation of the propylene hydrate system has thus been made to better define the conditions for hydrate formation.

EXPERIMENTAL

The propylene was Matheson C.P. grade which was found by gas chromatography to contain 99.4 mole % propylene, 0.56 mole % propane, 127 p.p.m. ethane, and less than 10 p.p.m. of any other volatile impurity. The water was distilled and deionized by passage through a mixed ion exchange resin column, and subsequently outgassed in the hydrate cell prior to use.

The hydrate cell which was fabricated from stainless steel contained a stirrer operated by magnetic induction. The portion of the apparatus in which the hydrate was formed could be completely immersed in a large thermostat bath which could be regulated to ±0.001 °C. Pressure was measured using a 0–100 p.s.i., 10 in. diameter Heise gauge, which was calibrated by a dead-weight tester. The barometric pressure was recorded at each measurement. This procedure gave pressure accurate to ±0.1 p.s.i. or ±0.006 atm.

The temperature of the cell was measured relative to a block of stainless steel immersed in the same thermostat bath by means of a ten-junction copper–constantan thermocouple. The temperature of the block was measured by a platinum resistance thermometer which was calibrated at the triple point of water.

[1]*Contribution No. 122.*

Since this calibration has changed by less than the uncertainty in a single measurement during a period of six months, the accuracy of temperature measurement is ±0.0005 °C.

The vapor pressure of propylene was measured from −13 °C to +6 °C. Liquid propylene was condensed in the cell, the temperature of the thermostat adjusted, and the pressure measured when no further change occurred. The results are given in Table I. The data can be represented by the equation: $\log_{10} P = 4.30595 \pm 0.00006 - (968.4 \pm 0.8)1/T$; where T is in °K and P in atm. The standard deviation of the data from this equation is ±0.004 atm.

TABLE I

Vapor pressure of propylene

t(°C)	P(atm)	t(°C)	P(atm)
−12.856	3.850	0.102	5.782
−11.830	3.984	0.132	5.787
−10.854	4.112	0.582	5.858
−9.844	4.246	0.973	5.928
−8.846	4.386	1.571	6.034
−7.858	4.522	2.074	6.122
−6.872	4.667	2.590	6.220
−5.860	4.824	3.006	6.297
−4.896	4.971	3.494	6.385
−3.895	5.127	4.010	6.488
−2.906	5.286	4.514	6.585
−1.916	5.448	5.008	6.679
−0.936	5.610	5.401	6.757
−0.098	5.753	5.990	6.871
0.000	5.770		

For hydrate experiments, approximately 90 ml of distilled, deionized water was put in the cell and degassed by alternately evacuating and admitting propylene. This was repeated several times. The thermostat was adjusted to approximately 0 °C and sufficient propylene admitted to form a layer of liquid in the cell. While stirring the cell, some of the propylene was vented giving nuclei for hydrate formation. The system was then allowed to equilibrate by consuming the liquid propylene and forming more hydrate.

The values of the total pressure of the system $P(\mathrm{hl_lg})$ at a number of temperatures were determined, allowing at least 8 h for the system to attain equilibrium. The results are given in Table II. After subtracting the vapor pressure of water, and converting the pressure of propylene to fugacity by means of the extrapolated data of Farrington and Sage (4), the data were found to fit the equation: $\log_{10} f = 24.8309 \pm 0.0001 - (6610 \pm 20)1/T$. The standard deviation of the data about this line is ±0.004 atm. The value of ΔH for the decomposition $C_3H_6.nH_2O(h) \rightarrow C_3H_6(g) + nH_2O(l_1)$, is 30 230 ± 90 cal/mole. The accuracy

of this value is less than that indicated by the standard deviation given because of an estimated 10% uncertainty in the fugacities. It is estimated that this increases the uncertainty to ±300 cal/mole. This enthalpy-change value indicates that propylene forms a structure II gas hydrate of formula $C_3H_6.17H_2O$, isomorphous with the propane and bromochlorodifluoromethane hydrates (5).

The lower quadruple point was measured and found to be -0.134 ± 0.001 °C. The upper quadruple point, which was calculated as the point of intersection of the hydrate equilibrium line and the propylene vapor pressure line, was $+0.958 \pm 0.001$ °C.

THE FORMATION OF TRIBUTYLIODOAMMONIUM IODIDE IN THE URANYL PHOTOSENSITIZED REACTION WITH TETRABUTYLAMMONIUM IODIDE

J. K. S. Wan, E. A. Schuck,[1] J. K. Foote, and J. N. Pitts, Jr.[2]

Recently the photochemistry of the iodide ion in aqueous solution has been extensively studied (1–8). Absorption of light seems to produce an excited iodide ion which may then dissociate into an iodine atom and a solvated electron, or alternatively decay back to the ground state. Scavengers such as proton donors react with the solvated electron thus preventing the secondary cage recombination.

However, we have been unable to find previously published reports on the reactivity of aqueous iodide ions photosensitized by uranyl ion. Since the energy of binding the electron of the iodide ion in the first excited state is only about 35 kcal (9), it appears that photooxidation of the iodide ion might be brought about by photosensitization with uranyl ion in the longer wavelength region. We wish to report here the reaction of tetrabutylammonium iodide in aqueous solution sensitized by uranyl nitrate and to disclose a photochemical method for preparing tributyliodoammonium iodide.

When an aqueous solution of uranyl nitrate and tetrabutylammonium iodide (I) was irradiated at room temperature with the 3660 Å line from a mercury vapor lamp, a black precipitate was formed. In the absence of light, no precipitation was observed. The identity of the precipitate as tributyliodoammonium iodide, $(C_4H_9)_3IN^+I^-$ (II), was confirmed by elementary analysis, molecular weight determination, infrared and nuclear magnetic resonance (n.m.r.) analyses. The molecular weight was found experimentally to be 442: calculated for II is 439. The infrared spectrum taken in a KBr matrix was consistent with that expected for II. The n.m.r. spectrum exhibits three complex multiplets centered on τ values of A, 8.90; B, 8.40 and C, 6.75; with integrated areas being in the ratio 1.55:2:1. Peak A can be assigned to the methyl protons (9H), peak B to the methylene protons (12H), and peak C to the protons (6H) adjacent to the nitrogen atom. The ultraviolet spectrum taken in ethanol solution showed an absorption onset at 5000 Å with maxima at 3650 and 3200 Å.

THE FORMATION OF TRIBUTYLIODOAMMONIUM IODIDE IN THE URANYL PHOTOSENSITIZED REACTION WITH TETRABUTYLAMMONIUM IODIDE

J. K. S. Wan, E. A. Schuck,[1] J. K. Foote, and J. N. Pitts, Jr.[2]

Recently the photochemistry of the iodide ion in aqueous solution has been extensively studied (1–8). Absorption of light seems to produce an excited iodide ion which may then dissociate into an iodine atom and a solvated electron, or alternatively decay back to the ground state. Scavengers such as proton donors react with the solvated electron thus preventing the secondary cage recombination.

However, we have been unable to find previously published reports on the reactivity of aqueous iodide ions photosensitized by uranyl ion. Since the energy of binding the electron of the iodide ion in the first excited state is only about 35 kcal (9), it appears that photo-oxidation of the iodide ion might be brought about by photosensitization with uranyl ion in the longer wavelength region. We wish to report here the reaction of tetrabutyl-ammonium iodide in aqueous solution sensitized by uranyl nitrate and to disclose a photochemical method for preparing tributyliodoammonium iodide.

When an aqueous solution of uranyl nitrate and tetrabutylammonium iodide (I) was irradiated at room temperature with the 3660 Å line from a mercury vapor lamp, a black precipitate was formed. In the absence of light, no precipitation was observed. The identity of the precipitate as tributyliodoammonium iodide, $(C_4H_9)_3IN^+I^-$ (II), was confirmed by elementary analysis, molecular weight determination, infrared and nuclear magnetic resonance (n.m.r.) analyses. The molecular weight was found experimentally to be 442: calculated for II is 439. The infrared spectrum taken in a KBr matrix was consistent with that expected for II. The n.m.r. spectrum exhibits three complex multiplets centered on τ values of A, 8.90; B, 8.40 and C, 6.75; with integrated areas being in the ratio 1.55:2:1. Peak A can be assigned to the methyl protons (9H), peak B to the methylene protons (12H), and peak C to the protons (6H) adjacent to the nitrogen atom. The ultraviolet spectrum taken in ethanol solution showed an absorption onset at 5000 Å with maxima at 3650 and 3200 Å.

The product II exists at room temperature as a black powder with a melting point of 65–68 °C. The compound is stable at least up to 135 °C, and exhibits a reversible thermochromic phenomenon (from black to yellow) when warmed to 88 °C or higher. The infrared spectra of both color forms do not show any drastic changes.

A 1:1 molecular complex between tributyl amine and iodine was considered as possible reaction product. To this end the complex was prepared (10) and various spectra and other properties were determined. The complex exists at room temperature as a brown-yellowish oil and comparison of other spectra permitted elimination of this isomer. In addition, irradiation of a solution of uranyl nitrate, KI, and tributyl amine failed to produce II.

The rate of the photochemical reaction was followed by measuring the % transmission of the incident monochromatic light as a function of time. The concentrations of uranyl ion before and after irradiation were measured spectrophotometrically at 4200 Å and found to remain practically unchanged. To study the effect of pH on the rate of reaction, the solution was adjusted to the desired pH with nitric acid. The reaction rate was higher in acid medium and was dependent on the pH of the solution, rising rapidly in the region between pH 3 and 4. On the other hand, at a constant pH the reaction rate was found to increase with decreasing concentration of I.

The experimental data obtained to date are insufficient to establish the entire reaction mechanism, but seem to suggest that oxidation of the iodide ion is sensitized by the photoexcited uranyl ions, leading to an iodine atom and a solvated electron. The overall reaction may be

$$UO_2^{++} + R_4N^+ + 2I^- + H^+ \xrightarrow{h\nu} UO_2^{++} + R_3IN^+I^- + RH$$

where R is a butyl group. The effect of pH on the reaction rate can be explained by the hydrogen ions scavenging the solvated electron thus preventing iodine atom from cage recombination. In fact, it was observed that as the reaction proceeded, pH of the solution slowly increased. The observation in which the rate of reaction increases with decreasing concentration of tetrabutylammonium iodide suggests the presence of kinetically inactive ion pairs (11, 12).

The direct photolysis of an aqueous solution of I also was carried out by light shorter than 3000 Å. A black precipitate of II was recovered together with some free iodine. The formation of iodine could be due to the much higher light intensity which generated a high concentration of iodine atoms in a small volume, and (or) due to secondary photodecomposition of the product II. Further studies are in progress to investigate the photosensitized oxidation of iodide ions in a flow system, in an attempt to gain some insight into the mechanism of the reaction and the quantum efficiency of the sensitization.

EXPERIMENTAL

Polarographic grade of tetrabutylammonium iodide and analytical grade of uranyl nitrate were used in all experiments. Melting points were determined in capillary tubings and are uncorrected. The analyses were performed by C. F. Geiger, Ontario, California. The ultraviolet spectra were recorded on Cary spectrophotometer; infrared spectra were recorded on a Perkin–Elmer 221 spectrophotometer. Nuclear magnetic resonance spectra were taken at 60 Mc/s on a Varian A60 instrument using $CDCl_3$ as solvent and tetramethylsilane as an internal standard ($\tau = 10.0$). A Leeds and Northrups pH meter with glass electrodes was used for pH measurement, the instrument was standardized before and after each run with 0.05 *M* potassium acid phthalate (pH 4.01 at 25 °C). Molecular weight determinations were made using mg quantities of solute and 2 ml of acetone. Measurements were taken with a Mechrolab vapor pressure osometer model 301a, to determine vapor pressure lowering at 37 °C. The instrument was calibrated with benzil and with benzophenone solutions over a similar concentration range. Photosensitized reactions were carried

out with solutions in a pyrex cell and a 100 W PEK high pressure mercury lamp equipped with a 3660 Å interference filter as light source. The % transmission of the incident light was measured with a RCA 935 phototube–galvanometer system. For direct photolysis experiments, a quartz cell was used with a Hanovia medium pressure mercury arc as light source.

Photosensitized Reaction of Tetrabutylammonium Iodide

In a typical experiment, an aqueous solution (200 ml) of uranyl nitrate and I, each with an initial concentration of 0.02 *M*, was irradiated. The solution was stirred magnetically at a constant speed. After every few hours the black precipitate was filtered and the filtrate was subjected to further irradiation until no precipitation was observed. The combined precipitate was then dried at 130 °C; yield 0.8179 g (theoretical yield 0.8911 g). The product was insoluble in water, aqueous solutions of KI, acid and alkaline, ether, benzene, and carbon tetrachloride, but moderately soluble in alcohol and readily in acetone and chloroform. Found: C, 32.10; H, 5.98; N, 2.84; I, 59.44; calc. for II: C, 32.80; H, 6.15; N, 3.19; I, 57.86%.

In a similar experiment with 0.5800 g of ammonium iodide added, 1.5116 g of II was recovered.

Reaction of II with Silver Nitrate

A 0.1286 g sample (0.29 mmole) of II was dissolved in 400 ml ethanol in which an excess of saturated silver nitrate ethanolic solution was added. A yellow precipitate (0.6100 g, 0.26 mmole) of silver iodide was recovered at room temperature. This indicates that only one iodine atom was removed from the molecule II.

Photolysis of Tetrabutylammonium Iodide

An aqueous solution of I (200 ml) with an initial concentration of 0.02 *M* was irradiated in a quartz cell. When wavelengths shorter than 3200 Å were cut off by a pyrex filter, no reaction was observed. However, in the presence of light shorter than 3000 Å, a heavy brownish-black precipitate resulted. The precipitate was a mixture of II and iodine, after the latter was washed away with KI solution. The product II thus recovered weighed 0.6854 g.

THE RADIATION CHEMISTRY OF AQUEOUS SOLUTIONS OF CHLORAL HYDRATE AND OF BROMAL HYDRATE

R. G. MCINTOSH, R. L. EAGER, AND J. W. T. SPINKS

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received March 23, 1964

ABSTRACT

The radiation chemistry of aqueous solutions of chloral hydrate and of bromal hydrate has been further investigated. The electrical conductivity method of Andrews and Shore (1) was used to follow the appearance of acid. The yield of acid was found to be dependent on the dose rate, contrary to the conclusion reached by Andrews and Shore but in agreement with the results of other workers. A reexamination of Andrews and Shore's paper indicates that an incorrect interpretation was made of their data and reveals that, in fact, their data also indicate a dose rate dependence for the yield of acid. A free radical mechanism is proposed which is in good agreement with the observed dependence of the rate of formation of acid upon the dose rate and upon the solute concentration in both the presence and in the absence of oxygen.

Several reports have been published on the radiation chemistry of aqueous solutions of chloral hydrate (1–6) and of bromal hydrate (6–11). There is general agreement that one of the main products is the corresponding hydrohalic acid. In the earliest reported work, that of Andrews and Shore (1) on aqueous chloral hydrate solutions, the appearance of hydrochloric acid was followed by measurement of the electrical conductivity of the solution. A similar method was used by Hilsenrod (4). In the other work referred to, the production of acid was followed by titration with standard base. Andrews and Shore (1) interpreted their results in a manner which indicated that the G value (number of molecules of product per 100 eV of energy absorbed) of HCl was independent of dose rate. Hilsenrod (4) did not investigate the dose rate dependence. In contrast, all of the other workers (2, 3, 5, 6) reported a dose rate dependence, the G value being approximately inversely proportional to the square root of the dose rate. A similar dose rate dependence was found for aqueous solutions of bromal (6–9).

No satisfactory explanation for this large discrepancy in the dose rate dependence has been offered. While it seems unlikely, a possible explanation is that the different behavior reported arises because of the methods used to follow the appearance of the hydrohalic acid. The electrical conductivity method is not very specific, since the appearance of any electrolyte will result in an increase in electrical conductivity. The titration method is more specific, since it will respond only to acidic products. It should be noted that Andrews and Shore (1) did do some chloride analysis and pH measurements which indicated that the electrical conductivity measured by them was due mainly to hydrochloric acid. By titration with a base, they found that the amount of total acid present was somewhat larger than that which would be expected if only hydrochloric acid was responsible for the electrical conductivity. Similarly, Woods and Spinks (7), and Heusinger *et al.* (8)

found for ^{60}Co γ-irradiated bromal hydrate solutions that the total acid content of the solutions was somewhat larger than that of the hydrobromic acid present. The above observations would suggest that the reported discrepancy in the dose rate dependence is not due to the different methods used in following the appearance of the hydrohalic acid. In an attempt to resolve this difference, we decided to do a further study on the irradiation of aqueous solutions of chloral hydrate and of bromal hydrate by using the electrical conductivity method.

The electrical conductivity method would be expected to have several advantages over the titration method for following the appearance of the hydrohalic acid. The precision should be greater and the results should be obtained with less effort. Also, if the solution is irradiated in the conductivity cell, it is possible to follow the course of the reaction almost continuously. Because samples do not need to be withdrawn for analysis, the volume of the solution being irradiated is not altered and the dosimetry is simplified.

It was also felt that it would be worth while to bring together the results of the various workers referred to above so that their results together with those obtained in the present work could all be considered at one time.

EXPERIMENTAL

Apparatus and Reagents

The irradiations were made with a 90 curie ^{60}Co source housed in a concrete cave (12). Samples were located at various distances from the source in order to obtain different radiation intensities.

The Fricke ferrous sulphate dosimeter, as described by Weiss *et al.* (13), was used for dose determinations. The molar extinction coefficient of ferric ions was taken to be 2243 at a wavelength of 304 mμ. The G value of the dosimeter was taken to be 15.5 ferric ions per 100 eV of energy absorbed. When calculating the dose received by a sample, we corrected for the difference in the electron densities of the sample and of the dosimeter.

The conductivity cell was of the Arrhenius–Ostwald type. A thermometer was built into the cell, hence the temperature of the solution whose electrical conductivity was being determined was known. The cell constant was found to be 0.318 cm^{-1} by the use of a 0.0200 N potassium chloride solution. Preliminary experiments indicated that chloral hydrate would decompose, in the absence of radiation, when "platinized" platinum electrodes were used. This observation is in agreement with that made by Andrews and Shore (1). These authors found that no appreciable decomposition occurred when tungsten electrodes were used. In the present work, bright platinum electrodes were found to give results of acceptable accuracy and at the same time did not cause decomposition of either chloral hydrate or bromal hydrate. Electrical leads were run from the conductivity cell to a Wheatstone bridge located outside the cave.

Chloral hydrate of U.S.P. grade was used without further purification. Solutions of chloral hydrate were stored in the dark and were used within 4 days of preparation. Bromal hydrate was prepared by adding bromal to water and recrystallizing the product from a small volume of water. The solutions were stored in the dark and kept for only 3 days (9). The water used for preparing solutions for irradiation was purified by starting with distilled water and distilling it further, first from an alkaline permanganate solution, and then from an acidic dichromate solution. The water was finally passed through a mixed bed ion exchange resin column. The product had a specific conductance of 5×10^{-6} Ω^{-1} cm^{-1}.

The sample temperature was that of the cave, between 20 °C and 25 °C. The observed rates of change of specific conductance with time of irradiation were corrected to 25 °C by use of a temperature coefficient of 2.5% per °C for chloral hydrate solutions (2), and of 3.5% per °C for bromal hydrate solutions (7). Except for the determination of the cell constant, no correction was made for the effect of temperature on the equivalent conductance. This was justified by the fact that during a given run the temperature of the cave did not vary appreciably. Hence, the value obtained for the rate of reaction would not be affected, since it was determined by plotting specific conductances against time and measuring the slope of the resulting line.

The specific conductances of the unirradiated solutions were substracted from the specific conductances measured for the irradiated samples. These corrected specific conductances were used to indicate the extent of the reaction caused by the irradiation. Similarly, when the samples were titrated with standard base, a blank correction was made. For these titrations, the indicator was bromophenol blue.

RESULTS AND DISCUSSION

The relation between the specific conductances of the irradiated samples and the acid concentrations was found as follows. Samples of 1 M chloral hydrate or of 0.1 M bromal

413783

For personal use only.

hydrate solutions were irradiated for various lengths of time in glass-stoppered pyrex test tubes. The dose rate was 214 rad/min for the chloral hydrate solutions and 225 rad/min for the bromal hydrate solutions. After irradiation for known lengths of time, the samples were transferred to the conductivity cell and the specific conductances measured. The samples were then transferred back to the test tube in which they had been irradiated and titrated with standard alkali to determine the amount of acid present. Specific conductances were plotted against acid concentrations. The results for the chloral hydrate solutions are shown in Fig. 1, where the lower curve is for the irradiated samples. From the

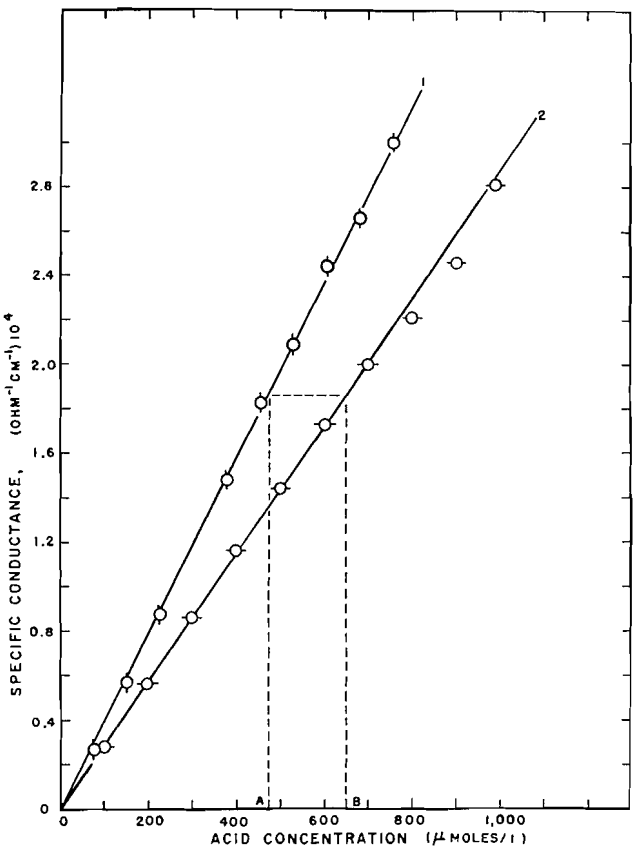

FIG. 1. Relation between specific conductance and acid concentration: ○ hydrochloric acid solutions; -○- irradiated 1 *M* chloral hydrate solutions.

slope of the straight line drawn through the experimental points, the conversion factor of 2.53 moles per l of acid per Ω^{-1} cm^{-1} was calculated. For bromal hydrate solutions the conversion factor was found to be 2.44 moles per l of acid per Ω^{-1} cm^{-1}.

The results from these experiments were also plotted in the form of specific conductance against total dose received. From the slopes of the resulting straight lines the *G* values may be calculated. These values are given later in Figs. 2 and 3. It is worth noting that these *G* values for irradiations done in the absence of platinum electrodes agree quite well with those obtained subsequently when the solutions were irradiated in the conductivity cell. Hence, it may be concluded that the presence of platinum electrodes did not affect the irradiation results.

The specific conductances of standard solutions of hydrochloric and of hydrobromic acid were also measured. The results of these measurements were plotted along with those for the irradiated solutions (see Fig. 1 for the hydrochloric acid results). If the only electrolyte produced in the irradiation was the haloform acid, and if this was also the only acid produced, then the specific conductances of the haloform acid solutions would be expected to fall on the same line as those of the irradiated samples, where both were plotted against acid concentration. This was found for the hydrobromic acid solutions and the irradiated bromal hydrate solutions. For the hydrochloric acid solutions and the irradiated chloral hydrate solutions, however, two distinct sets of results were found. In Fig. 1, the upper curve shows the results for the hydrochloric acid solutions. These results indicate that when chloral hydrate solutions are irradiated more alkali titratable acid is present than is indicated by the specific conductance if the latter were due solely to hydrochloric acid. For example, for an equivalent conductance of $1.86 \times 10^{-4}\ \Omega^{-1}\ cm^{-1}$ the hydrochloric acid concentration would be 471 μmoles per l (point A). However, in an irradiated chloral hydrate solution the total acid concentration is 650 μmoles per l (point B) for the same value of the equivalent conductance. Hence, the conclusion is reached that one or more weak acids are produced, as well as hydrochloric acid, when chloral hydrate solutions are irradiated. The results obtained for hydrobromic acid solutions and irradiated bromal hydrate solutions indicate that the only acid (and electrolyte) produced in the irradiation is hydrobromic acid.

The dependence of the reaction rate, expressed as μmoles of total acid (as a monoprotic acid) formed per l per min, and of the G value of total acid formed upon the dose rate was investigated. Both 1 M chloral hydrate solutions and 0.1 M bromal hydrate solutions were used. The results are given in Table I.

TABLE I

Dependence of the reaction rate and of the G value upon dose rate

1.0 M chloral hydrate solutions			0.1 M bromal hydrate solutions		
Dose rate (rad/min)	G_{acid}	Reaction rate (μmoles of acid l^{-1} min^{-1})	Dose rate (rad/min)	G_{acid}	Reaction rate (μmoles of acid l^{-1} min^{-1})

*Sample irradiated in test tube.

The dependence of the reaction rate and of the G value on the concentration for chloral hydrate solutions and for bromal hydrate solutions was also investigated. The dose rate for the chloral hydrate solutions was 250.0 rad/min and for the bromal hydrate solutions it was 114.5 rad/min. The results are given in Table II.

The G values are shown plotted against the dose rate in Fig. 2 for 1.0 M chloral hydrate solutions and in Fig. 3 for 0.1 M bromal hydrate solutions. Also plotted in Figs. 2 and 3

TABLE II

Dependence of the reaction rate and of the G value upon concentration

Chloral hydrate solutions 250 rad/min			Bromal hydrate solutions 115 rad/min		
Conc. (M)	G_{acid}	Reaction rate (μmoles of acid l^{-1} min^{-1})	Conc. (M)	G_{acid}	Reaction rate (μmoles of acid l^{-1} min^{-1})
1.0	192	52.4	1.0	367	49.5

0.1	82.4	21.5	0.01	128	15.2
0.01	57.4	14.9	0.001	46.2	5.5

are the results of other workers. Where necessary, these latter results have been recalculated to express yields as G values and dose rates as rad/min. It is apparent that all the results are in good agreement.

It is of particular interest to note that for 1.0 M chloral hydrate solutions, the single value reported by Andrews and Shore (1) for the yield agrees very well with the data obtained by other workers (see Fig. 2). While Andrews and Shore had reported that the yield was independent of the dose rate, it seemed to be almost too much of a coincidence that their data should agree so well with other data which showed a dose rate dependence. A rereading of reference 1 revealed that the conclusion that the yield was independent of dose rate had not been directly determined, but rather that it had been inferred by a use of the Beatty equation (14). The equation formulated by Beatty relates the efficiency of an X-ray tube to the atomic number, Z, of the target material and to the tube voltage, V, as follows:

$$[1] \qquad \text{efficiency} = \frac{\text{X-ray energy}}{\text{cathode ray energy}} = 1.4 \times 10^{-9} ZV$$

where "X-ray energy" is the energy per unit time of the X rays produced and "cathode ray energy" is the energy imparted by the tube to the cathode ray per unit time. Andrews and Shore made only one direct determination of the yield, the value being one molecule of HCl per 0.42 eV absorbed. This value was tentatively assumed to be independent of the dose rate. For various tube voltages, the experimentally found rates of production of HCl were used to calculate values for the X-ray energy produced per unit time. It is important to note that these calculated values for the rate of production of X-ray energy will be correct only if the yield is independent of dose rate. Andrews and Shore plotted these calculated rates of production of X-ray energy against the tube voltage and found a straight line relation (their Fig. 3). This was taken to be consistent with the Beatty equation, and hence, a verification of their assumption that the yield was independent of dose rate.

We believe that the above treatment was a misuse of the Beatty equation. What is believed to be a correct use of the equation follows. The right hand side of [1] can be rearranged to give:

$$[2] \qquad \text{X-ray energy} = 1.4 \times 10^{-9} \text{ (cathode ray energy) } ZV.$$

The rate at which cathode ray energy is supplied is proportional to V_e, where e is the electronic charge, hence [2] becomes:

$$[3] \qquad \text{X-ray energy} = BV^2$$

FIG. 3. Variation of G_{acid} with dose rate for 0.1 M bromal hydrate solutions: ○ present work; ◌́ present work, sample irradiated in a test tube; ◒ ^{60}Co γ-rays, Heusinger *et al.* (8); ◑ ^{60}Co γ-rays, Woods and Spinks (6).

where B is a constant for a given target material. The dose rate, I, will be proportional to the rate at which X-ray energy is produced, and hence, from equation [3] we have:

$$I \alpha V^2 \text{ or } V \alpha I^{0.5}. \qquad [4]$$

Equation [4] may be used with the data given by Andrews and Shore as follows. Regardless of the correctness of their assumption that the yield is independent of the dose rate, the data presented in their Fig. 3 shows they found that the rate of production of HCl was proportional to the first power of the applied voltage of the X-ray tube. According to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

equation [4], above, the rate, R, of production of HCl is then proportional to $I^{0.5}$. It would thus appear that the data of Andrews and Shore (1) are in agreement with those of other workers (i.e. that the yield, G, is proportional to $I^{-0.5}$).

Log–log plots were made of the data presented in Table I to see if they agreed with the equations:

$$G = KI^n \quad [5]$$

and

$$R = K'I^{n'}. \quad [6]$$

Here G has its usual significance, R is the reaction rate, expressed as μmoles of total acid (as a monoprotic acid) formed per l per min, and K, K', n, and n' are constants. Good linear relations were found. For the 1.0 M chloral hydrate solutions, the slopes of the straight lines drawn to give the best fit (by visual inspection) gave a value for n of -0.333 and a value for n' of 0.659. The values found for n and n' are consistent since it would be expected that

$$n' = 1 + n.$$

When values for the reaction rate from all sources (1, 2, 3, 5), together with those from the present work, for 1.0 M chloral hydrate solutions were similarly treated, a value of $n' = 0.660$ was obtained. This is a further indication of the good agreement between the results of the present work and those of other workers. Similarly, a value of 0.579 for n' was found for the 0.1 M bromal hydrate solutions. The difference between the values of n' for chloral hydrate and for bromal hydrate solutions may be partly due to the different concentrations used of the two compounds and, hence, not entirely because of a difference in the behavior of the two compounds.

Log–log plots were made of the data presented in Table II to see if they agreed with the equation:

$$R = K''[\text{solute}]^{n''}. \quad [7]$$

Good linear relations were found. For a dose rate of 250.0 rad/min, the value of n'' for chloral hydrate solutions was found to be 0.39. For bromal hydrate solutions, the value of n'' was found to be 0.34 at a dose rate of 114.5 rad/min.

The above results, in conjunction with those of other workers, lead to the following conclusions about the mechanism of the radiolysis of chloral and bromal hydrate solutions. They suggest that the reaction mechanisms are similar for both chloral hydrate and bromal hydrate solutions. The following points emphasize this similarity. The rate of production of acid is dependent to about the same extent upon both the dose rate and the solute concentration. For both compounds the presence of oxygen causes an increased rate of production of acid (2, 7, 8), the increase being about the same for both. The ratio of moles of hydrohalic acid produced per mole of oxygen originally present is essentially the same for both chloral hydrate and bromal hydrate solutions, the value being between 3 and 4 moles of hydrohalic acid per mole of oxygen (2, 6, 7, 8). It should be noted that the rate of production of acid remains constant at the higher rate while any oxygen is present in the solution and then falls abruptly with the exhaustion of the oxygen, i.e. apparently as long as any dissolved oxygen is present, the rate of production of acid is independent of the oxygen concentration. For both compounds the relatively large G values indicate a chain reaction mechanism.

For personal use only.

The only significant difference between the radiolyses of the two compounds appears to be in the ratio of total acid to hydrohalic acid. The yield of total acid agrees closely with that found for hydrobromic acid, whereas for chloral hydrate solutions the yield of total acid is higher than that of hydrochloric acid. In the present work, the ratio of total acid to hydrochloric acid was found to be 1.38:1 for chloral hydrate solutions. Andrews and Shore (1) found a value of 1.29:1 and Platford (15) found a value of 1.30:1 for this ratio. For bromal hydrate solutions, the 1:1 value found for the ratio of total acid to hydrobromic acid is not in complete agreement with the value of 1.20:1 found by Woods and Spinks (6) or of 1.16:1 found by Heusinger *et al.* (8). Regardless of the exact value of this ratio for bromal hydrate solutions, it appears that the ratio of the yield of total acid per mole of hydrohalic acid is significantly greater for chloral hydrate solutions than for bromal hydrate solutions. It is thought that this difference is not due to a fundamentally different mechanism for the radiolysis of these two compounds but rather that it can be explained as a variation of one basic mechanism.

The following mechanism is proposed for the radiolysis of aqueous solutions of chloral hydrate or of bromal hydrate. In the following, I is the dose rate, S represents a molecule of chloral hydrate or of bromal hydrate, a dot over a symbol represents a free radical, and "acid" represents the appropriate hydrohalic acid.

$$(a) \qquad H_2O \xrightarrow{I} \dot{R}$$

$$(b) \qquad \dot{R} + S \xrightarrow{k_b} \dot{S} + R$$

$$(c) \qquad \dot{S} + O_2 \xrightarrow{k_c} \dot{S}O_2$$

$$(d) \qquad \dot{S}O_2 \xrightarrow[H_2O]{k_d} 3\ \text{acid} + \dot{R}$$

$$(e) \qquad \dot{R} + \dot{S} \xrightarrow{k_e} \text{stable product (or products)}$$

When the steady state treatment is used to solve for the $\dot{S}O_2$ concentration, a complicated expression is obtained. The expression may be greatly simplified by assuming that $(k_d k_e/k_c)([\dot{S}O_2]/[O_2])$ may be neglected in comparison with $k_b[S]$. This assumption appears plausible since [S] will certainly be much greater than $[\dot{S}O_2]$. With this assumption, the following expression is obtained for the rate of production of acid:

$$[8] \qquad \frac{d}{dt}[\text{acid}] = 3\frac{k_b k_c}{k_e}[S]^{1/2} I^{1/2}$$

The dependence of the rate of production of acid upon the oxygen and chloral hydrate or bromal hydrate concentrations and upon the dose rate as predicted by equation [8] is in good agreement with the experimental results. The primary interaction of the radiation with water in dilute aqueous solutions as postulated in (*a*) is generally accepted. Reactions (*b*), (*c*), and (*d*) form a chain reaction which is consistent with the large G values observed. This sequence of reactions is also in agreement with the observed ratio of acid produced to oxygen consumed and results in a rate expression which is independent of oxygen concentration. Reaction (*d*) is considered to be a composite reaction, consisting of a series of successive steps. Reaction (*e*) is postulated for the chain termination step as it gives the correct dependence on both [S] and I of the rate of acid production.

The results presented in the present paper indicate that the rate of acid production is

proportional to the dose rate raised to the 0.66 or 0.58 power for chloral hydrate or bromal hydrate solutions respectively, rather than to the 0.5 power as indicated by equation [8]. This would suggest that the chain termination step is not exclusively reaction (*c*) but that the following reaction also occurs to a certain extent:

$$(f) \qquad \dot{R} \xrightarrow[M]{k_f} \text{end of chain.}$$

This would result in the value for the exponent of the dose rate lying between 0.5 and 1.0.

So far the nature of the radicals $\dot{R}$ and $\dot{S}$ has not been considered. The radical $\dot{R}$ produced in reaction (*a*) is very likely H or OH, or even both. In the latter case, k_b would be a composite rate constant. Some deductions about the radical $\dot{S}$ may be made from a consideration of the overall activation energy for the production of acid. According to equation [8], the overall activation energy will be a composite one, and hence, any discussion involving it should include a consideration of the three reactions (*b*), (*c*), and (*e*). It may be speculated, however, since the overall activation energy for the chloral hydrate radiolysis is less than, or at the most, equal to that for bromal hydrate (2, 5, 7), that the free radical $\dot{S}$ has resulted from an attack on the aldehyde end of the chloral hydrate or bromal hydrate molecule by $\dot{R}$. If the attack was on the halogen end of the molecule, it would be expected that the activation energy for the production of acid would be higher for chloral hydrate solutions because the bond strength of the C—Cl bond is greater than that for the C—Br bond.

For bromal hydrate solutions Heusinger *et al.* (8) found for oxygen depleted solutions that the ratio of the amount of total acid formed to the amount of hydrobromic acid formed was the same as when oxygen was present in the solution. This would suggest that in the absence of oxygen the mechanism is still much the same as in the presence of oxygen, except that reaction (*c*) does not occur and that reaction (*d*) would become

$$\dot{S} \xrightarrow[H_2O]{k_{d'}} 3 \text{ acid} + \dot{R}.$$

The steady state treatment yields

$$[9] \qquad \frac{d}{dt}[\text{acid}] = 3\frac{k_b k_{d'}}{k_e}[S]^{1/2} I^{1/2}.$$

for the rate of production of acid. A comparison of equation [8] and [9] shows that, on the basis of the proposed mechanisms, the slower reaction resulting from the absence of oxygen is due to $k_{d'}$ being smaller than k_c. It is not unreasonable to postulate that $k_{d'}$ would be smaller than k_c. For both chloral hydrate and bromal hydrate solutions, the rate in oxygen free solutions is about one-fifth of that in solutions where oxygen is present (3, 7); this indicates that $k_{d'} = 0.04\ k_c$.

ACKNOWLEDGMENTS

Grateful acknowledgment is made to the Atomic Energy Control Board for financial support. One of us (R. G. M.) wishes to thank the National Research Council for a bursary.

AMINO ACIDS AND PEPTIDES

II. SYNTHESIS OF ε-*N*-METHYL-L-LYSINE AND RELATED COMPOUNDS[1]

LEO BENOITON
Department of Biochemistry, Faculty of Medicine, University of Ottawa, Ottawa, Canada
Received March 20, 1964

ABSTRACT

ε-*N*-Methyl-L-lysine, ε-*N*-ethyl-L-lysine, and δ-*N*-methyl-L-ornithine have been synthesized by alkylation of the α-*N*-benzoyl-ω-*N*-*p*-toluenesulphonylamino acid. ε-*N*-Methyl-L-lysine was also prepared by the formaldehyde – formic acid methylation of α-*N*-carbobenzoxy-ε-*N*-benzyl-L-lysine, obtained by borohydride treatment of α-*N*-carbobenzoxy-L-lysine in the presence of benzaldehyde. ε-*N*,ε-*N*-Dimethyl-L-lysine, ε-*N*-benzyl-L-lysine, and ε-*N*-methyl-L-lysine ethyl ester were also prepared.

It has been shown that ε-*N*-methyl-lysine can replace lysine in the diet (2), is metabolized by rat kidney slices (2), and occurs in nature in flagellar proteins (3). We have recently reported the demethylation of ε-*N*-methyl-L-lysine by a rat kidney mitochondrial fraction (4) and have now carried out additional studies on the enzyme system involved (5). For these studies, optically active ε-*N*-methyl-lysine has been synthesized, together with several homologues. In this paper are described the synthesis of these compounds, namely, ε-*N*-methyl-, ε-*N*-ethyl-, ε-*N*-benzyl-, and ε-*N*,ε-*N*-dimethyl-L-lysine, and δ-*N*-methyl-L-ornithine, all of which are new compounds.

ε-*N*-Methyl-DL-lysine has previously been prepared (2, 6, 7) by methylation of ε-*N*-*p*-toluenesulphonylaminocaproic acid followed by α-amination by way of the bromo-derivative; and also by the action of methylamine on 5-δ-bromobutylhydantoin and subsequent saponification (8). However, neither of these procedures is adaptable to the synthesis of the optically active compounds which we desired for our studies.

There are two general classical methods for the preparation of *N*-monoalkylamino acids, namely, treatment of the arylsulphonylamino derivative with an alkyl iodide (9), or treatment of the appropriate halo derivative with an alkyl amine (10). Most of the optically active α-*N*-methylamino acids described have been prepared by the first of these (10), though it is now apparent that partial racemization has sometimes occurred (11). The second method leads to a racemate unless an optically active halide is used. If such is the case, a Walden inversion obtains (12). Since, in our case, we were concerned with the preparation of ω-*N*-alkylamino acids where no stereochemistry is involved, both of the above procedures could theoretically provide the desired compounds if the appropriate optically active α-amino acid were used as starting material.

Since α-*N*-methyl-L-lysine had already been prepared by alkylation of the α-*N*-arylsulphonyl-ε-*N*-benzoylamino acid (12), it was decided to investigate this approach for the synthesis of ε-*N*-methyl-L-lysine. ε-*N*-*p*-Toluenesulphonyl-L-lysine (I*a*) was benzoylated to the disubstituted derivative II*a*, which was treated with methyl iodide to give the ε-*N*-methyl derivative III*a*. Hydrolysis with fuming hydrobromic acid yielded the desired free *N*-methylamino acid IV*a*. Unfortunately, neither of the intermediates II*a* or III*a* could be crystallized. Extraction of III*a* into ether freed it of most of the unreacted II*a* but not completely, consequently the final product (IV*a*) was contaminated

with L-lysine up to 10%. This was established by enzymatic assay, using lysine decarboxylase (13). For purification, it was found expedient to destroy the contaminant by incubation of the mixture with lysine decarboxylase until the increase in pH due to the formation of cadavarine had stopped. ϵ-*N*-Substituted lysine derivatives are inert to lysine decarboxylase (13, 14). Analytically pure ϵ-*N*-methyl-L-lysine, containing less than 0.5% lysine, was thus obtained in a yield of 30% based on ϵ-*N*-*p*-toluenesulphonyl-L-lysine.

ϵ-*N*-Ethyl-L-lysine was obtained in the same manner, in a yield of 19%. When the same reactions were applied to ornithine, the intermediates II*c* and III*c* crystallized readily. As a result, δ-*N*-methyl-L-ornithine (IV*c*) was obtained pure without having to be subjected to enzymic digestion.

When most of our work on the properties of the enzyme which demethylates IV*a* had been completed (5), there appeared in the literature a new procedure for the synthesis of optically active *N*-monomethylamino acids (11). This procedure was applied to the appropriately protected lysine derivative thus providing a second synthesis for ϵ-*N*-methyl-L-lysine. α-*N*-Carbobenzoxy-L-lysine (V) was converted to the ϵ-*N*-benzyl derivative VI by borohydride reduction of the benzylidene derivative. This was reductively methylated to VII which, without isolation, was hydrogenated to give chromatographically pure ϵ-*N*-methyl-L-lysine (IV*a*), in a 42% yield based on V. The intermediate VI, on treatment with hydrogen bromide in acetic acid, gave ϵ-*N*-benzyl-L-lysine (IV*d*).

Of the two procedures described for the synthesis of ϵ-*N*-methyl-L-lysine, the second seems more attractive. However, it suffers from a shortcoming encountered in the preparation of the starting material, α-*N*-carbobenzoxy-L-lysine (15). We were not able to obtain yields of over 45% (reported yield, 71%) for this compound. In view of this, attempts were made to prepare ϵ-*N*-benzyl-L-lysine directly from lysine with the hope of converting

it into VI. ϵ-*N*-Benzylidene-L-lysine (15) was submitted to both sodium borohydride and catalytic reduction, but in neither case could the reaction be induced to go to completion. No satisfactory procedure could be devised for purifying the derivative formed, which admittedly could have been a mixture of both α- and ϵ-isomers, so this approach was abandoned.

At first, attempts were made at preparing ϵ-*N*-,ϵ-*N*-dimethyl-L-lysine by catalytic hydrogenation of α-*N*-benzoyl-L-lysine in the presence of formaldehyde (16) as has been reported for the racemate (7), but subsequent acid hydrolysis of the α-*N*-benzoyl-ϵ-*N*,ϵ-*N*-dimethyl-L-lysine failed to give material of acceptable purity. The compound was finally successfully prepared from the acetyl derivative, despite the fact that crystallization of α-*N*-acetyl-ϵ-*N*,ϵ-*N*-dimethyl-L-lysine was much more difficult than for the corresponding benzoyl derivative.

Esterification of ϵ-*N*-methyl-L-lysine was effected by the thionyl chloride method of Brenner (17). Chromatographic data for all the compounds synthesized are presented in Table I.

EXPERIMENTAL

Melting points were determined with a Kofler Hotbench. Optical rotations were determined at 23 °C with a Rudolph Model 62 polarimeter using a 2-dm tube. Compounds were dried at 60° before analysis.

ϵ-N-Methyl-L-lysine Hydrochloride (IVa)

By Methylation of ϵ-N-p-Toluenesulphonyl-L-lysine

To a cooled, stirred solution of ϵ-*N*-*p*-toluenesulphonyl-L-lysine (18) (9.0 g; 0.03 mole) in 1 *N* sodium hydroxide (30 ml) were added dropwise benzoyl chloride (3.8 ml; 0.033 mole) and 2 *N* sodium hydroxide (17.5 ml) over a ½h period. The mixture was stirred an additional hour at 25°, and was then acidified (HCl) to Congo red. The gum which separated out was extracted into ethyl acetate, the extract was washed twice with water, dried (Na_2SO_4), and evaporated to dryness. The residue was extracted with hot ether (3 × 75 ml) and the ether was discarded.

The residue was transferred to a pressure bottle with the aid of 2 *N* sodium hydroxide (60 ml). The mixture was warmed (40°), methyl iodide (1.25 ml; 0.02 mole) was added, and the mixture was heated (70°) while being stirred magnetically for 1 h. The solution was cooled (40°), and the addition of methyl iodide and heating were repeated twice more. The cooled solution was then acidified (HCl) to Congo red, extracted with ether (3 × 100 ml), and the extract was dried (Na_2SO_4) and evaporated down.

The residue was refluxed in 48% hydrobromic acid (75 ml) for 2 h. The mixture was cooled, water (75 ml) was added, and the precipitate was filtered off and discarded. The filtrate was repeatedly evaporated to dryness, the residue was dissolved in water, the solution was treated with charcoal, and Dowex 50 (H^+ form; 50 ml) was added. After stirring for 1 h, the resin was filtered off, washed thoroughly with water, and then stirred for 15 min in 5 *N* ammonium hydroxide (50 ml). The mixture was filtered, and the filtrate was evaporated to dryness. The residue was dissolved in water, with the pH of the solution being adjusted to 5.8 with hydrochloric acid. The product can be obtained at this stage by evaporating the solution and triturating the residue with ethanol. It contains, however, up to 10% of lysine as estimated with lysine decarboxylase (13).

To the solution (about 100 ml) was added lysine decarboxylase (0.1 g) and the mixture was incubated at 37°. The pH was readjusted back to 6 several times during the first hours of digestion. After 24 h more enzyme was added. Next day, the pH was adjusted to 5.8, charcoal was added, and the mixture was boiled for 5 min. The mixture, after being cooled in ice, was filtered through kieselguhr, the filtrate was evaporated down, and the residue was crystallized from water–ethanol. Yield: 1.76 g (30%), $[\alpha]_D$ +9.9° (2, water), +23.1 (1, 6 *N* HCl). The material contained less than 0.5% lysine as determined manometrically with lysine decarboxylase (13). Found: C, 42.5; H, 8.7; N, 14.0; *N*-CH_3, 7.4. $C_7H_{17}ClN_2O_2$ (196.7) requires C, 42.7; H, 8.7; N, 14.2; *N*-CH_3, 7.6%.

The *picrate*, m.p. 230°, from water, was prepared by adding a hot ethanolic solution of picric acid to a concentrated aqueous solution of the amino acid, freed of chloride by resin treatment as described above. Found: C, 40.35; H, 5.0; N, 18.1. $C_{13}H_{19}N_5O_9$ (389.3) requires C, 40.1; H, 4.9; N, 18.0%.

By Reductive Methylation of ε-N-Benzyl-L-lysine

To a mixture of unrecrystallized α-*N*-carbobenzoxy-L-lysine (V) (15) (5.62 g; 0.02 mole) in 2 *N* sodium hydroxide (10 ml) was added freshly distilled benzaldehyde (2 ml; 0.02 mole). After stirring for 20 min, sodium borohydride (0.23 g; 0.006 mole) was added in portions (0.05 g) over a ½ h period, while the temperature of the reaction mixture was being kept below 15°. After 15 min, the benzaldehyde and borohydride treatments were repeated. The mixture was stirred for an additional 2 h, then extracted twice with ether, and acidified (HCl) to pH 6.0. The thick oil which separated out gradually crystallized when the mixture was cooled. (If required, a seed crystal can be obtained by repeatedly evaporating the oil in the presence of ethanol.) Next day, the crystals were collected, washed with water, and recrystallized, by suspending them in boiling water and adding acetic acid until all had dissolved, to give 4.75 g (64%) of *α-N-carbobenzoxy-ε-N-benzyl-L-lysine (VI)*, m.p. 210°, $[\alpha]_D$+4.8° (2, acetic acid). Found: C, 68.3; H, 7.2; N, 7.7. $C_{21}H_{26}N_2O_4$ (370.4) requires C, 68.1; H, 7.1; N, 7.6%.

To VI (3.7 g; 0.01 mole) in formic acid (5 ml) at 100° was added dropwise 38% aqueous formaldehyde (0.90 ml) while the solution was being stirred magnetically. After an additional 15 min, 90% acetic acid was added and the mixture was hydrogenated over palladium on charcoal for 48 h. The catalyst was filtered off, 1 *N* hydrochloric acid (10 ml) was added, and the acetic acid was removed by evaporation. The residue was taken up in water, brought to pH 5.8 with lithium hydroxide, and the solution was evaporated down again. Trituration of the residue in ethanol, followed by recrystallization of the product from water–ethanol gave 1.30 g (66%) of pure *ε-N-methyl-L-lysine hydrochloride (IVa)*, $[\alpha]_D$+21.9° (2, 6 *N* HCl). Found: C, 42.7; H, 8.65; N, 14.3. $C_7H_{17}ClN_2O_2$ (196.7) requires C, 42.7; H, 8.7; N, 14.2%.

ε-N-Ethyl-L-lysine Hydrochloride (IVb)

This compound was prepared by the action of ethyl iodide on ε-*N*-*p*-toluenesulphonyl-L-lysine as described for the corresponding methyl amino acid (IV*a*) except that after the methylation had been completed and the solution acidified, the mixture was extracted with ethyl acetate. The extract was then worked up in the same manner, including the incubation with lysine decarboxylase. The final product was obtained as the monohydrochloride at pH 5.8 from water–ethanol. Yield: 1.2 g (19%), $[\alpha]_D$ +3.4°(6 *N* HCl). Found: C, 45.3; H, 9.1; N, 13.0. $C_8H_{19}ClN_2O_2$ (210.7) requires C, 45.6; H, 9.1; N, 13.3%.

ε-N-Benzyl-L-lysine Hydrochloride (IVd)

To VI (0.74 g) in dry acetic acid (10 ml) was added 38% hydrogen bromide in acetic acid (10 ml) (19). After 30 min, the acetic acid was removed by evaporation and the residue was triturated with ether. Crystallization from ethanol–ether gave material whose analysis indicated a C:H:N:Br ratio of 1:1:1:1½. Therefore the product was freed of bromide by absorption on Dowex 50, subsequently eluted with ammonium hydroxide, and crystallized as the monohydrochloride at pH 5.8 from water–ethanol. Yield: 0.20 g (37%), $[\alpha]_D$ +13.4° (1, water). Found: C, 57.1; H, 7.75; N, 10.3. $C_{13}H_{21}ClN_2O_2$ (272.8) requires C, 57.2; H, 7.8; N, 10.3%.

δ-N-Methyl-L-ornithine Hydrochloride (IVc)

To a cold solution of *δ-N-p*-toluenesulphonyl-L-ornithine (I*c*) (20) (8.59 g; 0.03 mole) in 1 *N* sodium hydroxide (30 ml) were added dropwise benzoyl chloride (3.84 ml; 0.033 mole) and 2 *N* sodium hydroxide (17.5 ml) over a ½ h period. The mixture was stirred an additional hour at 25°, and was then acidified (HCl) to Congo red. Ethyl acetate was added, resulting in the formation of a precipitate floating between the two layers. The material was filtered off, and recrystallized by dissolving in 1 *N* sodium hydroxide and adding an equivalent of hydrochloric acid to give 7.35 g (62.4%) of *α-N-benzoyl-δ-N-p-toluenesulphonyl-L-ornithine (IIc)*, m.p. 188°, soluble in ethanol and tetrahydrofuran, insoluble in chloroform and ether. A sample recrystallized from ethyl acetate had m.p. 189°, $[\alpha]_D$ −3.0° (2, dimethylformamide). Found: C, 58.2; H, 5.6; N, 7.0. $C_{19}H_{22}N_2O_5S$ (390.9) requires C, 58.4; H, 5.7; N, 7.2%.

This compound (II*c*) (7.03 g; 0.018 mole) in 2 *N* sodium hydroxide (80 ml) was methylated with methyl iodide (3 ml total) as described for the corresponding lysine derivative (II*a*). After methylation, the cooled mixture was acidified to Congo red, and the oil which separated out was solidified by trituration in cold water. The material was recrystallized from ethanol–water to give 5.0 g (69%) of *α-N-benzoyl-δ-N-methyl-δ-N-p-toluenesulphonyl-L-ornithine (IIIc)*, m.p. 163°, $[\alpha]_D$ −3.0° (2, dimethylformamide), soluble in chloroform,

For personal use only.

moderately in ether. Found: C, 59.7; H, 6.1; N, 6.7. $C_{20}H_{24}N_2O_5S$ (404.5) requires C, 59.4; H, 6.0; N, 6.9%.

This derivative (III*c*) (4.0 g) was refluxed in 48% hydrobromic acid (35 ml) for 2 h. Isolation of the amino acid by resin treatment as described for the corresponding lysine derivative and crystallization at pH 5.8 from water–ethanol afforded 1.1 g (55.8%) of *δ-N-methyl-L-ornithine hydrochloride (IV*c*)*, $[\alpha]_D$ +10.3° (2, water), +19.7° (2, 6 *N* HCl). Found: C, 39.7; H, 8.3; N, 15.0. $C_6H_{15}ClN_2O_2$ (182.7) requires C, 39.45; H, 8.3; N, 15.3%.

ε-N,ε-N-Dimethyl-L-lysine Hydrochloride

A mixture of *α-N*-acetyl-L-lysine (0.94 g; 0.005 mole) (21), 38% formaldehyde (3 ml), and palladium on charcoal catalyst (1 g) in a small volume of water was hydrogenated for 2 days. The filtered solution was repeatedly evaporated to dryness, and the residue was crystallized from ethanol–ether and finally ethanol, to give 0.63 g (50%) of *α-N-acetyl-ε-N,ε-N-dimethyl-L-lysine*, m.p. 196–198°, $[\alpha]_D$ +10.0° (2, water), slightly hygroscopic. A sample for analysis was dried at 80°. Found: C, 47.8; H, 9.6; N, 11.1. $C_{10}H_{20}N_2O_3.2H_2O$ (252.3) requires C, 47.6; H, 9.6; N, 11.1%.

In identical fashion, from *α-N*-benzoyl-L-lysine (5.0 g) (22), was obtained from ethanol–acetone, and finally acetone, 3.28 g (59%) of *α-N-benzoyl-ε-N,ε-N-dimethyl-L-lysine*, m.p. 209°, $[\alpha]_D$ +18.8° (1, water). Found: C, 64.9; H, 8.2; N, 9.9. $C_{15}H_{22}N_2O_3$ (278.3) requires C, 64.7; H, 8.0, N, 10.1%.

The acetyl derivative (1.62 g) was hydrolyzed by refluxing in 2 *N* hydrochloric acid (25 ml) for 1 h. Excess acid was removed by evaporation. The *ε-N,ε-N-dimethyl-L-lysine* was then converted to the monohydrochloride by the addition of Dowex 1 (OH^- form) to pH 6.0, and then obtained as a powder by precipitation from an ethanolic solution by the addition of ether. Yield: 0.81 g (60%), $[\alpha]_D$ +11.9° (1.8, water), slightly hygroscopic. A sample, reprecipitated, was dried at 80° for analysis. Found: C, 45.0; H, 9.0; N, 13.0. $C_8H_{19}ClN_2O_2$ (210.7) requires C, 45.6; H, 9.1; N, 13.3%.

ε-N-Methyl-L-lysine Ethyl Ester Dihydrochloride

ε-N-Methyl-L-lysine·HCl (0.59 g; 0.003 mole) was added to a solution of thionyl chloride (0.65 ml; 0.009 mole) in cold ethanol (5 ml) and the mixture was kept 24 h. Evaporation of the solvent, and reesterification gave a product still contaminated with starting material. The product was therefore dissolved in water, the solution was made alkaline with potassium carbonate, extracted with ether, and hydrogen chloride was bubbled through the solution. The ether was decanted off from the oil which separated out, and the product was crystallized from ethanol–ether. Yield: 0.51 g (66%), m.p. 145°, $[\alpha]_D$ +11.9° (2, water), hygroscopic. Found (dried at 80°): C, 41.7; H, 8.5; N, 10.8. $C_9H_{23}Cl_2N_2O_2$ (262.3) requires C, 41.2; H, 8.8; N, 10.7%.

CONSTITUTION OF A SYNTHETIC GLUCAN

III. PERIODATE OXIDATION

ABSTRACT

A synthetic glucan known to contain D-glucofuranose and D-glucopyranose units was subjected to a Smith periodate degradation. After mild acid hydrolysis any aldehydic compounds were oxidized with bromine and the neutral fragments separated from the acidic by ion exchange resins. The acidic portion, after lactonization and reduction, gave glycerol and a series of oligosaccharides. The neutral portion was resolved into glycerol, erythritol, and a series of seven fractions containing glycosides with degrees of polymerization up to eight. Each fraction which was homogeneous by paper chromatography contained at least two components. Some of these individual components were separated as their trimethylsilyl derivatives by vapor phase chromatography and the following glycosides were identified: 1-*O*-(α-D-glucopyranosyl)-glycerol, 1-*O*-(β-D-glucopyranosyl)-glycerol, 2-*O*-(D-xylofuranosyl)-D-erythritol, 2-*O*-(α-D-glucopyranosyl)-D-erythritol, 2-*O*-(β-D-glucopyranosyl)-D-erythritol, 1-*O*-(D-glucopyranosyl)-erythritol. These results demonstrate for the first time the separation of Smith degradation products by vapor phase chromatography. The presence in the polysaccharide of α and β linkages and the existence of D-glucofuranose residues are confirmed. The highly branched nature of the polymer is shown by the fact that four successive periodate oxidations and mild hydrolyses were necessary to oxidize all the hexose units.

Previous papers (1, 2) have demonstrated that the synthetic glucan prepared by Mora and his associates (3) has a highly branched structure in which all possible linkages except $1 \rightarrow 5$ have been found. In contrast to synthetic polysaccharides formed by acid treatment of monosaccharides at room temperature the polymers prepared by Mora contain a high proportion of sugar residues in the furanose form. The general features of the synthetic glucan have already been reported (1) and these results confirmed by a detailed study of the fragments obtained by hydrolysis of the fully methylated polysaccharide (2).

In recent years the Smith degradation (4) has been useful as a means of investigating the fine structure of polysaccharides and has been applied to hemicelluloses (5, 6, 7, 8), gums (9), and a synthetic xylan (10). The present paper reports the application of Smith's method to this synthetic glucan and in addition to providing further evidence on the structure discusses some of the problems which may be encountered in the separation of the cleavage fragments obtained by this technique.

The glucan was oxidized with periodate, reduced with borohydride, and hydrolyzed at room temperature for 8 h with 0.2 *N* hydrochloric acid. The solution was neutralized with lead carbonate and oxidized with bromine for 24 h in the presence of barium carbonate, after which the acidic and neutral compounds were separated by ion exchange resins.

The Neutral Fraction

The neutral fraction was shown to contain glycerol and erythritol, characterized as their *p*-nitrobenzoates, and at least seven non-reducing fractions (Table I) which were resolved

by paper chromatography. Several purifications were necessary and the losses were high, but the fractions eventually obtained were chromatographically homogeneous in several solvents. When these fractions were hydrolyzed and analyzed the presence of the four compounds glucose, xylose, glycerol, and erythritol strongly suggested that each fraction contained two components although they were not resolvable by paper chromatography or paper electrophoresis in borate buffer. Since the xylose must have arisen from the loss of C_6 from a glucofuranose unit it followed that if one of the compounds was a xylosyl erythritol it must be a xylofuranosyl erythritol. It should thus be possible to preferentially hydrolyze this furanoside. This was achieved by heating fraction 1 with 0.5 N H_2SO_4 at 50 °C for 4 h when chromatography showed the formation of xylose and erythritol in a 1:1 ratio and a component with an R_f identical with the original starting material. This latter was a glucopyranosyl glycerol, since on elution and hydrolysis it gave a 1:1 ratio of glucose and glycerol.

The hydrolysates of fractions 1, 2, and 3 were combined and the individual compounds separated by chromatography. Erythritol and glycerol were characterized as their *p*-nitrobenzoates while D-xylose and D-glucose were crystallized and converted to their phenylosazones.

For the higher fractions some estimate of their degree of polymerization (D.P.) was obtained by measuring the amount of formaldehyde (11) obtained by periodate oxidation (Table II). Formaldehyde will be obtained from glycosides terminated by glycerol substituted at position 1 and erythritol substituted at positions 1 or 2. Reduction and hydrolysis of the oxidized material gave some or all of ethylene glycol, glycerol, erythritol, glucose, and xylose as shown in Table II. By comparing the data for fractions 5 and 7 it will be noted that as the D.P. increases larger amounts of sugar survive the periodate oxidation indicating progressively complex structures for these fractions.

The hydrolysates of fractions 4–7 were combined and the individual compounds

characterized as before. In a similar manner the degradation products, ethylene glycol, glycerol, and erythritol were characterized as their *p*-nitrobenzoates.

Further work on these fractions was hindered by lack of suitable methods for separating each component, a problem accentuated by the small amounts available. The recent publication of a successful application of silylation to carbohydrates and the resolution of these derivatives by vapor phase chromatography (12) suggested that this method might be suitable in the present case, particularly since it had been used for tetrasaccharides as well as compounds of lower molecular weight.

Figure 1A shows the elution pattern for the silyl derivatives of fraction 1. Compounds 1*a* and 1*b* were desilylated and gave on hydrolysis glucose and glycerol in a 1:1 ratio. Periodate oxidation gave one molecular proportion of formaldehyde and reduction followed by hydrolysis gave glycerol and ethylene glycol in a 1:1 ratio. These results together with the observation that α-anomers have a lower retention time than the β-forms (12, 13) show that compound 1*a* is 1-*O*-(α-D-glucopyranosyl)-glycerol and that compound 1*b* is 1-*O*-(β-D-glucopyranosyl)-glycerol. The observed rotation of the latter, $[\alpha]_D$ 12°, is consistent with this assignment and a sufficient amount of this compound was obtained to form a crystalline *p*-nitrobenzoate. Compound 1*c* gave xylose and erythritol in a 1:1 ratio and periodate oxidation gave 1 mole of formaldehyde. Reduction and hydrolysis of the oxidized product gave glycerol as the only product. These results show compound 1*c* to be 2-*O*-(D-xylofuranosyl)-D-erythritol. The available evidence does not permit a decision as to whether only one anomer was present or the column was incapable of separating the two anomers.

Figure 1B shows the elution pattern for the silyl derivatives of fraction 2 and Tables III and IV record the properties and periodate data on the desilylated components. It thus follows that component 2*a* was 2-*O*-(α-D-glucopyranosyl)-D-erythritol, and that

TABLE III

Properties of components isolated from fraction 2

Component*	$[\alpha]_D$ in water	Composition	*p*-Nitrobenzoate, m.p. °C
2*a*	+50°	Glucose and erythritol in 1:1 ratio	190–194
2*b*	−10°		215–218
2*c*	+35°		205–208

TABLE IV

Periodate analysis of components isolated from fraction 2

Component*	Amount oxidized, mg	HCHO, mg	Mol. wt.	Hydrolysate of BH_4^- reduction product
2*a*	7	0.74	284	Glycerol
2*b*	10	1.05	286	Glycerol
2*c*	7	0.72	292	Ethylene glycol and glycerol 1:1

*See footnote Table III.

component 2*b* was the corresponding β-anomer. From the rotation component 2*c* was presumably 1-*O*-(α-D-glucopyranosyl)-erythritol. Although a small amount of xylosyl erythritol was known to be present in fraction 2, it was not detected.

Figure 1C shows an attempt to resolve the higher molecular weight material of fraction 3. Component 3*a*, appearing as two partially separated peaks, gave upon hydrolysis glucose, xylose, and glycerol in a 1:1:1 ratio. Periodate oxidation yielded an amount of formaldehyde corresponding to a molecular weight of 380 (calc. 390) and reduction followed by hydrolysis gave xylose, erythritol, glycerol, and ethylene glycol in a molar ratio of 1:1:2:2. These results indicate that at least two structurally different oligosaccharides were present. Some possible structures are (i) D-G_p(1 → 2 or 3)-D-Xyl_f(1 → 1)glycerol, (ii) D-Xyl_f(1 → 4)-D-G_p(1 → 1)glycerol, (iii) D-Xyl_f(1 → 6)-D-G_f(1 → 1)glycerol. Component 3*b* on hydrolysis gave glucose and erythritol in the ratio of 2:1 and the yield of formaldehyde obtained by periodate oxidation gave a molecular weight of 415 (calc. 446). Reduction and hydrolysis of the oxidized material gave glucose, erythritol, glycerol, and ethylene glycol in the ratio 1:2:8:1. The presence of some of the following structures could account for these results D-G_p(1 → 3 or 4 or 6)-D-G_p(1 → 1 or 2)-erythritol.

The Acidic Material

The acidic material from the bromine oxidation was eluted from the anion exchange resin with sodium hydroxide and passed through a cation exchange resin. The eluate was evaporated and heated *in vacuo* to effect lactonization. Reduction of this product with sodium borohydride gave glycerol together with several non-reducing oligosaccharides of which four were obtained in reasonable purity by several separations on paper. The analytical data of these fractions are shown in Table V. The presence of small amounts of

glucitol is presumably due to hydrolysis of some furanoside bonds in the mild acid treatment of the original polyol.

Successive Periodate Oxidations

A fresh sample of the glucan was oxidized with periodic acid and the polyaldehyde reduced with sodium borohydride. A portion of the polyalcohol was completely hydrolyzed and analyzed for sugars and polyols. The bulk of the polyalcohol was hydrolyzed with 0.1 *N* hydrochloric acid at room temperature for 4 h and then reoxidized with periodate. This treatment was repeated and it required a total of four oxidations to completely degrade all the sugar units in the polysaccharide, thus providing further convincing evidence of its highly branched character. This data is given in Table VI.

TABLE VI

CONCLUSIONS

A striking feature of this work is that it has been possible to isolate oligosaccharides up to an apparent D.P. of 8. By the same token it is unfortunate that the complexity of these fractions has precluded the determination of their structure in detail. The glucan which has been examined is a highly artificial polysaccharide containing as it does both glucofuranose and glucopyranose units joined by a wide variety of linkages.

The combination of the Smith degradation with vapor phase chromatography is shown to be most useful in structural investigations as suggested earlier (10) and the preparation of silyl derivatives to achieve adequate volatility has the additional merit that the original compound may be readily recovered by mild hydrolysis.

The identification of the anomers of 1-*O*-(D-glucopyranosyl)-glycerol provides experimental proof for the existence of α and β linkages and the identification of 2-*O*-(D-xylofuranosyl)-D-erythritol further confirms the existence of D-glucofuranose units in the polysaccharide.

Attention should be drawn to the observation that hexose-triitol and pentose-tetritol compounds may have the same mobility on paper chromatograms and that certain of these glycosides have high R_f values.

The isolation of glycerol from the acidic fraction demonstrates the presence of $1 \rightarrow 2$ linkages in the polymer as previously described (1). The highly branched nature of the glucan is confirmed by the fact that four periodate oxidations are required to degrade all the sugar units.

The complex nature of this glucan makes the further elucidation of its structure a matter of interest. No doubt useful information could be obtained by graded hydrolysis, enzymic hydrolysis, and acetolysis but lack of material prevents this.

EXPERIMENTAL

Chromatographic separations were carried out by the descending technique using Whatman 1 paper for qualitative and quantitative analyses. Whatman 3MM paper was used for preparative separations. Solvent systems were A, ethyl acetate:acetic acid:water (8:2:2) and B, ethyl acetate:pyridine:water (9:2:2). Spray reagents were *p*-anisidine trichloroacetate and ammoniacal silver nitrate.

Reducing sugars were estimated by the phenol – sulphuric acid method (14) and polyols by chromotropic acid after oxidation with periodate (11). Periodate uptake was measured by the arsenite method (15).

For vapor phase chromatography an aerograph A90-P2 instrument was used (i) with a 4.5-ft column (0.25-in diameter) containing 60/80 mesh firebrick coated with 20% GESF-96 and purchased from Wilkens

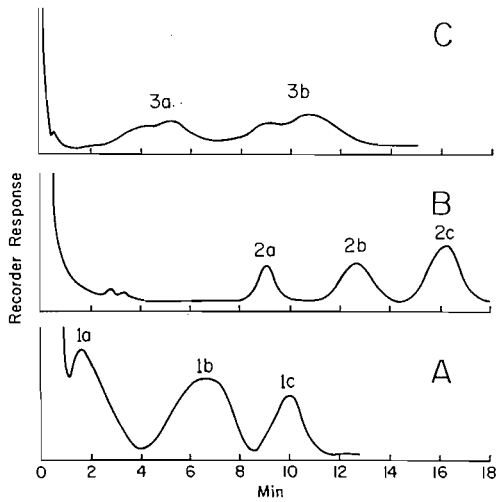

FIG. 1. Vapor phase chromatography of trimethysilylated fractions: (A) fraction 1, column temperature 165 °C, helium flow 120 ml/min; (B) fraction 2, column temperature 190 °C, helium flow 150 ml/min; (C) fraction 3, column temperature 265 °C, helium flow 180 ml/min.

Instrument and Research Inc. (column 1, Figs. 1A and 1B), (ii) with a 2-ft column packed with 10% S.E. 30 on Diatoport (column 2).

Evaporations were carried out *in vacuo* at 40 °C. Specific rotations are equilibrium values at 22 ± 2 °C. Melting points are uncorrected.

Smith Degradation

The oxidation (IO_4^-), reduction (BH_4^-), and mild hydrolysis (0.2 *N* HCl at 25 °C) has already been described (1) together with the bromine oxidation and the separation of the fragments into acidic and neutral portions.

Characterization of Components—Neutral Fraction

This fraction contained glycerol, erythritol, and seven non-reducing components (Table I). The former two have been characterized (1) and the experiments on the remainder are described here.

Fraction 1.—This fraction contained 56.6 mg, $[\alpha]_D$ 11° (*c*, 0.6 in H_2O). A portion was hydrolyzed for 8 h at 100 °C with H_2SO_4 (1 *N*) and after neutralization ($BaCO_3$), chromatographic examination (solvent A, 16 h) showed xylose, glucose, glycerol, and erythritol. The result of a typical analysis was: glucose 333 μg or 1.85 μmoles; xylose: 131 μg or 0.87 μmoles; glycerol: 177 μg or 1.92 μmoles; erythritol: 84 μg or 0.69 μmoles.

Fractions 2 and 3.—These fractions (Table I) were similarly analyzed and the hydrolysates of fractions 1, 2, and 3 were combined and separated on paper using solvent A. Glycerol and erythritol were converted to their tri- and tetra-*O*-*p*-nitrobenzoates, m.p. and mixed m.p. 189–192 °C and 252–254 °C respectively. D-Xylose was obtained crystalline, m.p. and mixed m.p. 142–144 °C, $[\alpha]_D$ 17° (*c*, 1.2 in H_2O); phenylosazone, m.p. 156–159 °C. D-Glucose crystallized spontaneously and had m.p. and mixed m.p. 144–145° C, $[\alpha]_D$ 51° (*c*, 1.1 in H_2O); phenylosazone, m.p. 203–206 °C.

Fraction 4.—This fraction contained 90 mg, $[\alpha]_D$ 25° (*c*, 0.9 in H_2O). (*a*) A portion (8.6 mg) was oxidized at 5 °C with periodic acid (12 ml, 0.1 *M*) and after 72 h 640 μg of formaldehyde had been produced (11). This indicated a D.P. of 3 on the assumption that each mole of glycoside gave one mole of formaldehyde.

Periodate and iodate were removed by the addition of barium carbonate, and sodium borohydride (15 mg) was added to the filtrate. The solution was left at room temperature for 24 h and then evaporated to dryness. Borate was removed (16) and the residue boiled with sulphuric acid (1 *N*) for 8 h. After neutralization and deionization, chromatography showed a glycerol to ethylene glycol ratio of 3:1. (*b*) A second portion (27 mg) was boiled with sulphuric acid (1 *N*) for 8 h and the hydrolysate shown to contain glucose, xylose, glycerol, and erythritol. These ratios and those for fractions 5, 6, and 7 are given in Tables I and II. The hydrolysates of fractions 4–7 were combined, resolved on paper, and identified as for fractions 1–3. Likewise the periodate degradation fragments of fractions 4–7 were combined and resolved on paper. Ethylene glycol was converted to the di-*p*-nitrobenzoate, m.p. 139–140 °C, and the glycerol, erythritol, D-glucose, and D-xylose characterized as before.

Vapor Phase Chromatography of Fractions 1, 2, and 3

Fraction 1.—A portion of this fraction was converted to the trimethylsilyl derivative (12) which was chromatographed without isolation using column 1 and the conditions shown in Fig. 1A. The components were condensed in 6-in lengths of glass tubing which were then immersed in 80% ethanol and refluxed for 24 h to effect desilylation. The structural determinations were carried out on the desilylated fractions. Component 1*a*, 1-*O*-(α-D-glucopyranosyl)-glycerol: a portion (7 mg) was hydrolyzed with 1 *N* H_2SO_4 and shown to contain glucose and glycerol in a 1:1 ratio. The remainder (12 mg) was oxidized with periodate and gave 1.45 mg of formaldehyde indicating a molecular weight of 250 (calc. 254). Periodate and iodate were removed by precipitation with barium carbonate and sodium borohydride (20 mg) added. After hydrolysis and deionization glycerol and ethylene glycol were identified chromatographically and shown to be present in a 1:1 molar ratio. Component 1*b*, 1-*O*-(β-D-glucopyranosyl)-glycerol: had $[\alpha]_D$ 12° (*c*, 2 in H_2O) and hydrolysis showed a 1:1 molar ratio of glucose and glycerol. Periodate oxidation and measurement of the formaldehyde (1.76 mg from 15 mg) gave a mol. wt. of 250 while reduction and hydrolysis gave ethylene glycol and glycerol in a 1:1 ratio. The remaining material (13 mg) formed a hexa-*p*-nitrobenzoate, m.p. 105–108 °C. Calc. for $C_{51}H_{36}O_{26}N_6$: N, 7.32%. Found: N, 7.30%. Component 1*c*, 2-*O*-(D-xylofuranosyl)-D-erythritol: (6 mg) gave on hydrolysis xylose and erythritol in a 1:1 ratio. A second portion (10 mg) gave 1.17 mg formaldehyde corresponding to a mol. wt. of 250 and hydrolysis of the reduced product showed only glycerol. An attempt to prepare a *p*-nitrobenzoate from the remaining material (8 mg) met with limited success. The yield was poor and the product melted at 165–174 °C.

Fraction 2.—This fraction was similarly resolved, using column 1, into three components (Fig. 1B) the properties of which are given in Table III and their analytical data in Table IV. Components 2*b* and 2*c* formed *p*-nitrobenzoates. Calc. for $C_{59}H_{41}O_{30}N_7$: N, 7.38%. For 2-*O*-(β-D-glucopyranosyl)-D-erythritol hepta-*O*-*p*-nitrobenzoate, found: N, 7.50%. For 1-*O*-(α-D-glucopyranosyl)-erythritol hepta-*O*-*p*-nitrobenzoate, found: N, 7.48%.

Fraction 3.—The resolution of this fraction was attempted using a 2-ft column (0.25-in diameter) packed with Diatoport* coated with 10% S.E. 30† with a helium flow rate of 180 ml/min at 260 °C. The results are shown in Fig. 1C. Component 3*a* was a mixture as seen by the incomplete separation of the peaks. Hydrolysis gave a glucose:xylose:glycerol ratio of 1:1:1. The formaldehyde produced on periodate oxidation indicated a mol. wt. of 380 while reduction and hydrolysis gave xylose:erythritol:glycerol:ethylene glycol as 1:1:2:2. Component 3*b* contained glucose and erythritol (2:1) and had an apparent mol. wt. of 380. Periodate oxidation, reduction, and hydrolysis gave glycerol:erythritol:glucose:ethylene glycol as 8:2:1:1.

Characterization of Components—Acid Fraction

The four non-reducing components with slower R_f values than glycerol (1) were hydrolyzed for 8 h with sulphuric acid (1 *N*) and the analytical data are presented in Table V.

Successive Periodate Oxidations of Glucan

The glucan (2.0 g) was oxidized with periodic acid, reduced with sodium borohydride, and the polyalcohol isolated. A small portion was completely hydrolyzed and the hydrolysate quantitatively analyzed. The bulk of the polyalcohol was hydrolyzed at room temperature with hydrochloric acid (0.1 *N*) for 4 h whereupon an excess of sodium periodate was added and the reaction sequence repeated. A total of four oxidations were performed and the results are summarized in Table VI.

PRIMARY PROCESS STUDIES BY MONOISOTOPIC PHOTOSENSITIZATION ON THE REACTIONS OF Hg $6(^3P_1)$ ATOMS WITH ALKYL CHLORIDES

J. K. S. WAN,[1] O. P. STRAUSZ, W. F. ALLEN, AND H. E. GUNNING
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received April 3, 1964

ABSTRACT

The specific nature of the primary process in the reaction of ^{202}Hg $6(^3P_1)$ atoms, photoexcited in natural mercury vapor by a cool ^{202}Hg electrodeless discharge source, with CH_3Cl has been examined in detail. Primary C–Cl bond scission occurs with unit efficiency. Quantum yields (φ) for the two primary modes of decomposition

$$^{202}Hg + Cl + CH_3 \overset{b}{\leftarrow} [CH_3Cl + {}^{202}Hg^*] \overset{a}{\rightarrow} {}^{202}HgCl + CH_3$$

were found to have values of 0.71 (b) and 0.29 (a). The effect of various reaction parameters on the ^{202}Hg enrichment in the calomel product has been investigated and the importance of isotopic mercury depletion in the reaction zone demonstrated by the use of intermittent illumination.

A brief study of the reaction of ethyl, *n*-propyl, *i*-propyl, *t*-butyl, and *n*-amyl chlorides has revealed a relation between the molecular structure of the alkyl chloride and the efficiency of the monoisotopic route (a) to calomel formation. Thus, while the reactions of all the normal alkyl chlorides have φ_a values between 0.29 and 0.32, φ_a (isopropyl chloride) is only 0.22 and φ_a (*t*-butyl chloride) is 0.17.

INTRODUCTION

Among the alkyl halides only methyl chloride has been studied in detail by mercury photosensitization. Thus Le Roy (1) has shown calomel to be a major product of the reaction. Masson and Steacie (2) studied the reaction at elevated temperatures in a static system at high mercury vapor concentrations and found that C–Cl bond rupture is the sole primary step and that it proceeds with unit quantum efficiency. They attributed calomel formation exclusively to chlorine atom abstraction by mercury atoms from secondary CH_2Cl radicals. This hypothesis, however, appears to be rather doubtful on energetic grounds. In addition Osborn and Gunning (3) have shown, by ^{202}Hg monoisotopic sensitization, that at least a fraction of the calomel product arises in the primary interaction between the Hg $6(^3P_1)$ atoms and CH_3Cl. The isotopic analyses in this latter study were accomplished by resonance absorbiometry (4).

In the present study, recent refinements in the technique of monoisotopic photosensitization have been employed to explore in detail the primary processes in the CH_3Cl reaction. In addition the effect of the alkyl side chain on the primary processes has been studied by examining the ethyl, *n*-propyl, *i*-propyl, *t*-butyl, and *n*-amyl chloride reactions. By such means it was hoped to resolve discrepancies in previous studies on the CH_3Cl reaction and, of greater importance, to gain some insight into the specific nature of the energy-transfer process in the interaction between RCl molecules and Hg $6(^3P_1)$ atoms.

EXPERIMENTAL

A standard single-pass high vacuum system was used. An umbrella-type mercury diffusion pump, installed between the gas inlet and reaction zone, served as mercury saturator. The exit condenser of the diffusion pump was temperature-regulated at 30 °C. The gas-inlet system was constructed so that a single gas, or a mixture of two gases in variable proportions, could be introduced. Flow rates were regulated by a pair of Hoke model 318 needle valves and by the interchangeable capillaries of the Schilling-type flow meters, which were calibrated separately for each gas used. The reaction cell, a quartz tube 1.5 cm i.d. and 60 cm

[1]*Present address: Department of Chemistry, University of California, Riverside, California.*

in length, wound into five helical coils 2.5 cm i.d., was attached to the system by a pair of ground-glass joints. Provision was made for the trapping of the effluent reactants for analysis.

The light source consisted of a quartz electrodeless discharge tube containing mercury, 98.3 atom % in ^{202}Hg. It was axially mounted within the coils of the spiral cell. The discharge was maintained by a 2450 Mc oscillator (Baird Atomic), operating at 80% power output. Ionization in the discharge was initiated by a Tesla coil. The temperature of the lamp wall was controlled by flowing a thin sheath of distilled water along it, thermostated at 18–20 °C.

For the intermittent-illumination studies a simple rotating tubular sector was devised. A quartz tube, 17.5 mm i.d., was coated with black vinyl tape leaving a vertical slit of desired width and was placed concentrically between the lamp and spiral reaction cell. The bottom of the tubing was securely mounted to a Sargent hollow-spindle rotor. The speed of rotation was controlled by a powerstat, and the angular velocity of the rotation measured with a stroboscope. Constant speed of rotation within 10% could thus be maintained. The direction of rotation of the sector was opposite to that of the gas flow.

For the experiments in which the isotopic composition of the effluent mercury was studied, the mercury samples were collected in a small U-trap, inserted in the line downstream from the reaction cell. The trap was filled with fresh copper turnings and maintained at 0 °C. All the experiments reported here were performed at 30 ± 5 °C.

For the isotopic analyses, recovery of mercury from the calomel product was effected by dissolution in hot ca. 0.01 *M* EDTA solution, followed by plating out on a freshly cleaned copper wire immersed in the solution. After removal from the solution the wire was thoroughly washed with distilled water, rinsed with methanol, and allowed to dry at room temperature. The mercury was distilled *in vacuo* from the copper to a breakseal for analysis.

All the isotopic analyses of the mercury samples were made with a Metropolitan-Vickers model MS-2, mercury-free mass spectrometer. The instrument was equipped with a special inlet system, provided with a low pressure constriction-free inlet tube leading directly from the sample to the ion source. Between analyses the inlet system was heated to 150–200 °C for about 30 minutes while pumping through a liquid nitrogen trap to insure against memory effects. At least twenty scans were allowed, and the heights of the last five peaks were taken to calculate the mean values for each isotope. No effort was made to analyze ^{196}Hg. From time to time standard mercury samples of various isotopic compositions from Oak Ridge National Laboratory were analyzed to check on the accuracy of the instrument.

The quantitative determination of calomel was carried out by EDTA titration (5) with Eriochrome Black-T indicator. Check determinations on known samples in the range 10^{-4}–10^{-5} mole indicated a ±2% error limit.

Gaseous reaction products were identified by g.c. retention times and mass spectrometric analyses of the separated chromatographic effluents. In the CH_3Cl reaction, non-condensables, after low-temperature fractionation, were separated on a charcoal column and the dichloroethane fraction was separated on a silica-gel column with He as carrier gas.

Methyl and ethyl chlorides, C.P., and propane, instrument grade, were from the Matheson Company. The remaining alkyl chlorides studied, 1-chloropropane, 2-chloropropane, 2-chloro-2-methyl-propane, and 1-chloropentane, were all Eastman products. The natural mercury was triply distilled. Standard isotopic-mercury samples were obtained from the Oak Ridge National Laboratory.

RESULTS

The products of the CH_3Cl reaction were calomel, methane, 1,2-dichloroethane, hydrogen chloride, traces of ethane, and possibly some ethyl chloride. The calomel products were more or less enriched in ^{202}Hg, depending on experimental conditions. Through a systematic study, the relations between product enrichment and the various reaction parameters were investigated in detail.

First the effect of flow rate on the fractional abundance of ^{202}Hg (f_{202}) was examined. In continuous illumination with flow rates increasing from 1 to 7 millimoles/min at a CH_3Cl pressure of 15 mm and $I \sim 1$ μeinstein/min, f_{202} increased from the natural abundance value of 0.298 to 0.373. The f_{202} data obtained under the conditions of intermittent illumination are presented in Table I. With increasing flow rate f_{202} increases in both cases but levels off at different flow rates: at ca. 0.37 for continuous and 0.50 for intermittent illumination. In Table I the total isotopic analyses are given to illustrate that all isotopes other than 202 are present in their natural distribution ratio, indicating that no overlap of the emission line envelope on absorption hyperfine contours adjacent to that of ^{202}Hg is occurring in the present system.

*Sector speed = 290±10 r.p.m., slit width = 2 mm, CH_3Cl pressure = 15±1 mm, exp. time = 40 min.
†Natural abundance.

The effect of mode of mercury recovery from the calomel product on the f_{202} values was also examined. It was found that dissolution in (*a*) KI–$Na_2S_2O_3$ solution (0.2 *N* in KI and 0.01 *N* in $Na_2S_2O_3$), (*b*) 0.01 *M* EDTA solution,[2] and (*c*) hot concentrated ammonia, all gave identical f_{202} values regardless of whether or not the calomel had been freed from adsorbed mercury by pumping before dissolution. It was thus concluded that exchange reactions between product and adsorbed mercury, after the photochemical reaction, are unimportant (6).

To establish optimum conditions for intermittent illumination a series of experiments was performed measuring f_{202} as a function of sector rotation speed and slit width. The

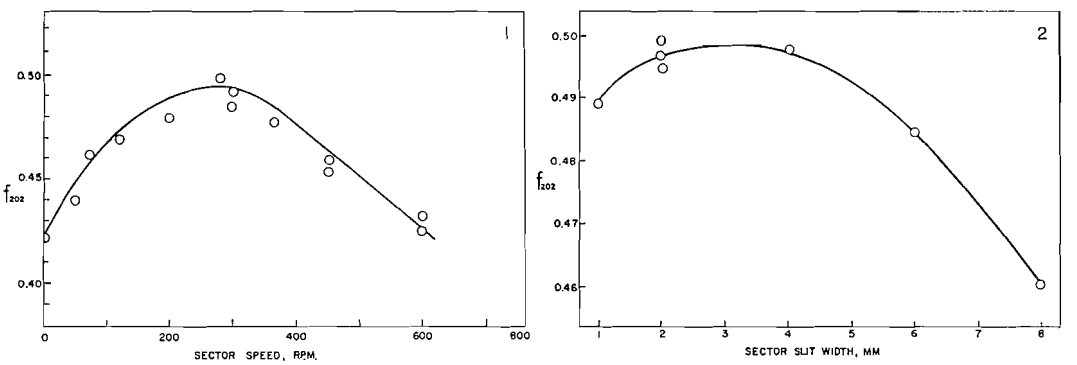

FIG. 1. Plot of f_{202} as a function of sector speed for the methyl chloride reaction at an exposure time of 40 min, sector slit width of 2 mm, and a pressure of 15 ± 1 mm.
FIG. 2. Plot of f_{202} as a function of sector slit width (sector speed = 280–300 r.p.m.) for the methyl chloride reaction at an exposure time of 40 min, flow rate of 6 millimoles/min, and a pressure of 15 ± 1 mm.

results are shown in Figs. 1 and 2. Maximum enrichments were obtained at a sector slit width of 2 mm and speed of rotation of 280–300 r.p.m.

A major problem in monoisotopic photosensitization studies is the effect of isotopic mercury depletion. Thus increasing flow rates lead to a more uniform distribution of

[2]*Solution of calomel in EDTA proceeds via the disproportionation of* Hg_2^{++} *to* Hg^{++} *and* Hg. *The absence of isotopic fractionation in this process was demonstrated experimentally.*

natural mercury throughout the entire cell, in contrast to the situation at low flow rates where a concentration gradient in ^{202}Hg exists along the linear length of the spiral cell. In the entrance coil ^{202}Hg will be present in natural abundance. However, during reaction, some ^{202}Hg is removed by $^{202}HgCl$ formation, and if the flow rate is insufficient to sweep this portion of substrate out of the illuminated zone immediately, accumulated depletion will lead to a continuous decrease of ^{202}Hg concentration as the gas stream traverses the remaining coils of the cell.

In order to determine the effect of depletion in the present study, a series of experiments was performed under optimum sector conditions and at various flow rates. The fractions of the calomel deposited along the cell axis were recovered in two separate portions, which are here labelled "entrance HgCl" and "exit HgCl", corresponding respectively to an individual recovery of mercury from calomel product from the first coil of the cell in which the gas flow entered, and the last two coils before the exit. In addition, the effluent mercury in the gas stream leaving the reaction cell was collected and analyzed for each run. The results are tabulated in Table II. It is of note that the "entrance HgCl" had the maximum

enrichment at all flow rates while the enrichment in the "exit HgCl", as well as the 202 content of the effluent mercury, increased with flow. At flow rates exceeding 3 millimoles per minute, both fractions of calomel are seen to have the same maximum enrichment, and the effluent mercury had a natural isotopic composition.

In a subsequent experiment, performed in the same reaction system as above, the vertical length of the sector slit was varied in each run so that only a fraction of the cell length was irradiated. The effluent mercury in each run was collected and analyzed. The

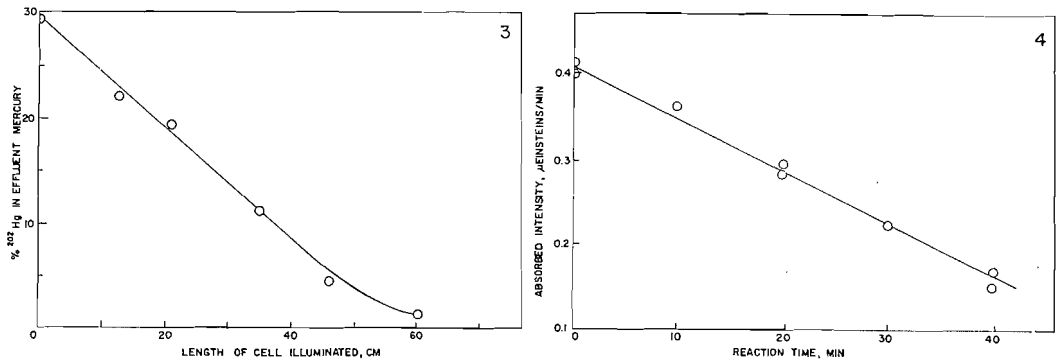

FIG. 3. Plot of percentage ^{202}Hg in the effluent mercury as a function of cell length illuminated in the methyl chloride reaction at an exposure time of 40 min, flow rate of 0.2 millimoles/min, sector slit width and speed of 2 mm and 280–300 r.p.m., and a pressure of 15 ± 1 mm.

FIG. 4. Plot of absorbed intensity as a function of reaction time for the methyl chloride reaction at a flow rate of 6 millimoles/min, sector slit width and speed of 2 mm and 600 r.p.m., and a pressure of 15 ± 1 mm.

plot of f_{202} versus irradiated cell length is given in Fig. 3. It is seen from the plot that for total cell-length illumination (60 cm), the ^{202}Hg concentration in the effluent mercury was only 1.6% and the mean concentration of ^{202}Hg present in the entire cell volume was only 16% instead of the natural abundance of 29.8%.

The quantum yield for calomel formation in continuous illumination was found to have a value of 0.86 mole/einstein at flow rates exceeding 4.8 millimole/min. φ_{HgCl} was also measured under intermittent illumination, and these values are reported in Table III. The determination of absorbed intensities by propane actinometry (7, 8) presented serious experimental difficulties, partly because of the complexity of the propane reaction itself and partly because of the decrease in the transparency of the cell wall in the course of an experiment, due to calomel deposition. For this transparency decrease a proper correction, based on the experimental curve shown in Fig. 4, was applied. This curve was obtained from light intensity measurements carried out in the reaction vessel, which was coated with calomel from the methyl chloride reaction performed previously for various times as shown on the abscissa of Fig. 4. It was assumed that the destruction of calomel, either by H-atoms or photolysis, is insignificant. The validity of this assumption was proven experimentally.

The rate and quantum yield data obtained for methane and 1,2-dichloroethane formation are given in Table IV.

From several check experiments it is estimated that maximum uncertainty in the

quantum yield measurements is ±10%, attributable largely to the uncertainty in the light intensity determinations.

The reactions of some of the higher alkyl chlorides were also examined. Product enrichment and quantum yield values as obtained under various experimental conditions for the ethyl, *n*-propyl, *i*-propyl, *t*-butyl, and *n*-amyl chloride reactions are shown graphically in Figs. 5–9 and the optimum values are summarized in Table V.

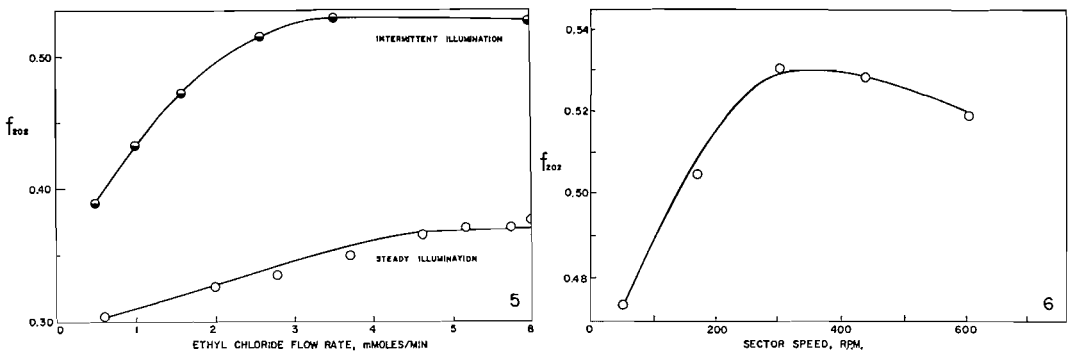

FIG. 5. Plot of f_{202} as a function of flow rate for 15 ± 1 mm ethyl chloride under steady illumination (exposure time = 45 min) and intermittent illumination (exposure time = 40 min), sector slit width and speed = 2 mm and 300 r.p.m.

FIG. 6. Plot of f_{202} as a function of sector speed for the ethyl chloride reaction at an exposure time of 40 min, flow rate of 6 millimoles/min, sector slit width of 2 mm, and a pressure of 15 ± 1 mm.

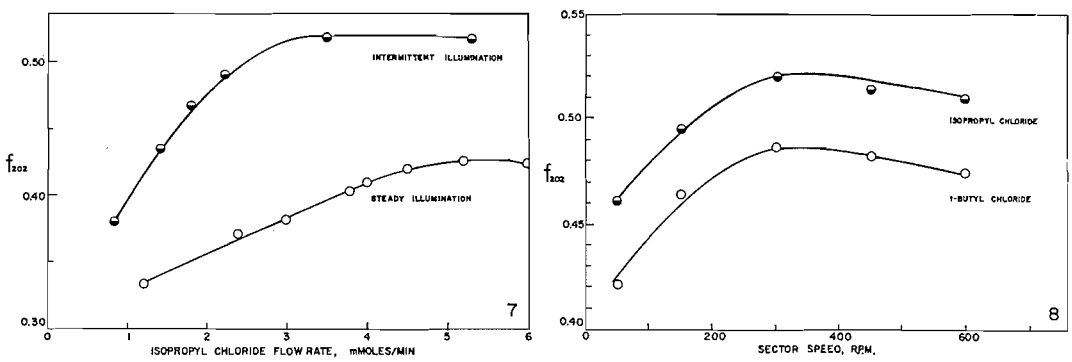

FIG. 7. Plot of f_{202} as a function of flow rate for 15 ± 1 mm isopropyl chloride under steady illumination (exposure time = 45 min) and intermittent illumination (exposure time = 40 min), sector slit width and speed = 2 mm and 300 r.p.m.

FIG. 8. Plot of f_{202} as a function of sector speed for 15 ± 1 mm isopropyl chloride and *t*-butyl chloride at an exposure time of 40 min, sector slit width of 2 mm, and flow rate of 5 millimoles/min.

In contrast to the HCl reaction (6, 9, 10), addition of 1,3-butadiene to the alkyl chloride systems was found to have no effect on the isotopic enrichment of the calomel products in agreement with previous studies (3). The inefficiency of butadiene in scavenging Cl atoms is probably associated with the formation of excited chlorobutenyl radicals, which at low pressures readily revert to butadiene and chlorine (11). Furthermore, it was observed that the calomel from all of the alkyl chloride reactions was free from desorbable mercury, indicating that no appreciable reduction of the solid calomel occurs during reaction. In this connection, since methyl radicals would be the most probable reducing

agent present during reaction, separate experiments were performed in which acetone was photolyzed in the presence of a deposit of calomel in the reaction cell; no detectable amounts of methyl chloride could be found after irradiation.

DISCUSSION

The nature of the reaction products suggests, in partial agreement with the conclusion of the previous studies (2, 3), the following mechanism for the methyl chloride reaction, where ^{n}Hg is natural mercury.

[1] $$^{n}Hg + h\nu_{202} \rightarrow {}^{202}Hg^*$$

[2*a*] $$^{202}Hg^* + CH_3Cl \rightarrow {}^{202}HgCl + CH_3$$

[2*b*] $$\rightarrow {}^{202}Hg + Cl + CH_3$$

[3*a*] $$Cl + {}^{n}Hg + M \rightarrow {}^{n}HgCl + M$$

[3*b*] $$2HgCl + M \rightarrow (HgCl)_2 + M$$

[4] $$CH_3 + CH_3Cl \rightarrow CH_4 + CH_2Cl$$

[5] $$2CH_2Cl \rightarrow C_2H_4Cl_2$$

[6] $$CH_3 + CH_2Cl \rightarrow C_2H_5Cl$$

[7] $$2CH_3 \rightarrow C_2H_6$$

[8] $$Cl + CH_3Cl \rightarrow HCl + CH_2Cl$$

The measured value for the total quantum yield of calomel, φ_{HgCl}, was 0.91, which is the minimal value for $\varphi_{[2]}$. Since step [8] has a low activation energy (Arrhenius parameters

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

are: log A = 10.4 in l mole s units, and E_a = 3.1 kcal/mole (12)) some of the Cl atoms formed in step [2*b*] are consumed in reaction [8]. Indeed, HCl was detected among the reaction products, but it was not measured quantitatively. Its yield, however, can be estimated from that of methane and dichloroethane. From the stoichiometry of the reaction it follows that

$$\varphi_{HCl} = 2\varphi_{C_2H_4Cl_2} - \varphi_{CH_4} = 0.90 - 0.81 = 0.09 \text{ mole/einstein},$$

and the combined quantum yield for primary steps [2*a*] and [2*b*] will be

$$\varphi_{[2]} = \varphi_{HgCl} + \varphi_{HCl} = 0.91 + 0.09 = 1.00 \text{ mole/einstein}.$$

Since reaction [7] is relatively unimportant, $\varphi_{C_2H_5Cl}$ may be crudely estimated:

$$\varphi_{C_2H_5Cl} = 1 - \varphi_{CH_4} = 1 - 2\varphi_{C_2H_4Cl_2} + \varphi_{HCl} = 0.19 \text{ mole/einstein}.$$

Although product accountability is reasonably good, the possibility of primary C–H bond scission to a minor extent cannot be completely ruled out from the present data. However, the absence of hydrogen among the reaction products would support omission of this primary step (13). The probability of C–H vs. C–Cl bond rupture can be estimated from the relative quenching efficiencies of the two groups within the molecule.[3] If we take $\sigma_Q^2(CH_3) \simeq 0.05$ and $\sigma_Q^2(Cl) \simeq 24$ Å^2, for the relative probability of C–H/C–Cl bond cleavage we obtain a value of ca. 0.002.

The efficiency of the abstraction reaction [4] may appear to be improbably high in view of Masson and Steacie's finding that E_a = 9.4 kcal/mole and $P = 2.8 \times 10^{-3}$ (12). However, the conditions under which the present determinations were performed (spacially intermittent illumination at low incident intensities) strongly favor abstraction over recombination.

Before attempting to evaluate the $\varphi_{[2a]}$ and $\varphi_{[2b]}$ values separately, we have to examine the reaction parameters influencing the magnitude of product enrichments. The importance of eliminating isotopic mercury depletion was convincingly demonstrated by the data of the previous section (Table II). The significant increase in f_{202} brought about by the application of the rotating sector is an interesting, although not surprising, result, indicating the seriousness of the isotopic mercury depletion effect and possibly also the presence of secondary processes destructive of ^{202}HgCl. The effect of intermittent illumination is largely, although not entirely, due to the attenuation of the incident light intensities. It is evident from the data of Table II that the enrichment at the entrance is only very slightly dependent on flow rates, while the exit and effluent mercury compositions are strongly dependent. This result is not much altered by sector speed. Thus the main effect of the sector is to slow down the rate of mercury consumption, thereby allowing sufficient time for the flow- and diffusion-controlled replenishment of natural mercury. If the Cl atoms in reaction [3] react with mercury depleted in ^{202}Hg instead of natural mercury, a diminution of f_{202} in the recovered calomel will result.

In the course of the present study it was demonstrated that the destruction of solid ^{1}HgCl (where ^{1}Hg is isotopically specific mercury) by isotopic exchange reactions during dissolution or by secondary free-radical attack under illumination is unimportant. Now, since the isotopic energy exchange: $^{1}Hg^* + {}^{n}Hg \rightarrow {}^{n}Hg^* + {}^{1}Hg$, has been shown to be insignificant at high substrate pressures (10, 15), the only conceivable reaction whereby isotopic calomel could be consumed is the gas-phase isotopic-exchange reaction

[9] $$^{202}HgCl + {}^{n}Hg \rightarrow {}^{n}HgCl + {}^{202}Hg.$$

[3]*The pertinent* σ_Q^2 *data are:* $CH_4 = 0.06$, $C_2H_6 = 0.1$, *neo*-$C_5H_{12} = 1.5$, $HCl = 24$, *and* $CH_3Cl = 24$ Å^2 *(14).*

The existence of an optimum speed for sector rotation (cf. Figs. 1, 6, and 8) may be due to this or some other similar type of reaction, although this assumption is rather speculative at present.

Now, the value of $\varphi_{[2a]}$ is given by the expression

$$[10] \qquad \varphi_{HgCl}(f_{202}(\max) - 0.298)/0.702 f_{202}^*,$$

where f_{202}^* is the fractional isotopic abundance in the discharge source. From the nature of monoisotopic photosensitization, it follows that for the evaluation of $\varphi_{[2a]}$ the maximum measured value of f_1 has to be considered. Substituting the experimental values in [10], we obtain $\varphi_{[2a]} = 0.29$ and thus $\varphi_{[2b]} = 0.71$ mole/einstein.

The kinetic features of all the higher chlorides studied, with respect to such parameters as flow and sector conditions, closely resemble those of the methyl chloride system. The quantum yields of calomel formation for all the *n*-isomers have values of 0.90–0.91. This is somewhat surprising, since, at least in the amyl chloride case, some C–H bond scission would be expected to occur in the primary step. The $\varphi_{[2a]}$ values, 0.29, 0.31, 0.32, and 0.32 mole/einstein respectively for CH_3Cl, C_2H_5Cl, *n*-C_3H_7Cl, and *n*-$C_5H_{11}Cl$, may indicate a minor trend upward with increasing chain length.

Isopropyl and *t*-butyl chlorides were studied to determine the effect on the primary process of increasing alkyl substitution on the α-carbon atom. Whereas values of the quantum yields of total calomel (φ_{HgCl}) and isotopically specific calomel (φ_1) were almost constant over the series of primary alkyl chlorides studied, both φ_{HgCl} and φ_1 decreased for the secondary and decreased again for the tertiary alkyl chlorides.

It is not clear whether this results from separate effects on the isotopically specific and non-specific processes which by chance balance to give little change in the total isotopic composition of the product, or whether a competing primary process (or processes) operates to decrease φ_{HgCl} but leave $\varphi_{[2a]}$ and $\varphi_{[3a]}$ in the same ratio.

Further discussion of the mechanisms of energy transfer and the nature of the transition complex formed in these systems between excited mercury atoms and substrates molecules will be advanced in some forthcoming communications from this laboratory.

THE PHENYL EFFECT IN DISTORTION POLARIZATION

HELMUT HUBER AND GEORGE F WRIGHT
Department of Chemistry, University of Toronto, Toronto, Ontario
Received October 18, 1963

ABSTRACT

Diphenylmercury has been used as a model to show that the electron and atom parts of the distortion polarization cannot reliably be evaluated by optical methods. The measured electron polarization extrapolated to infinite wavelength is larger than the combined electron and atom polarization measured at radio frequency. The difference has been defined as the "phenyl effect" and has been attributed to the mobility at radio frequencies of electrons in the resonance-hybridized orbitals of the aromatic nucleus. It has been suggested that the effect is general for aromatic compounds.

The total electric polarization of diphenylmercury has been measured or discussed by a number of workers (1–8). There is a discrepancy between this total polarization and the calculated electron polarization. It has been postulated (2) that this discrepancy is due to an abnormally high atom polarization. This postulation has been proven to be false on the basis of a direct measurement of the combined electron and atom polarization (6). Therefore the discrepancy is still in question.

It has been shown (6) that the total polarization of diphenylmercury in a number of solvents is strongly temperature dependent. Any dependence of atom polarization on temperature is so slight (9) that the discrepancy cannot be explained in this way. The atom polarization of the mercury atom does not seem to be involved in any abnormality because for at least one substance, dicyclohexylmercury (10), the measured distortion polarization is not abnormal.

The direct method for measurement of distortion polarization from the dielectric constant of randomly oriented compressed solids has been developed (11) to give good precision and many substances have been examined (10, 12). Among these substances some give the expected values on the basis of a calculated electronic polarization (13, 14). Other substances give values which are higher than the calculated P_E and these are of two types. The structures of one type have features such as conjugated linkages which ought to give high polarizations due to exaltation of P_E which would not be predicted from atom or bond polarizabilities. The other type contains highly polar groups which would be expected to contribute to high P_A. Thus distortion polarizations (P_E and P_A) which are equal to or greater than the calculated electron polarizations are not unexpected. On the other hand, there is another type of substance for which the measured distortion polarization is lower than the calculated P_E according to Eisenlohr (13) or Vogel (the additive P_E). This is the type in which aromatic groups, especially phenyl groups, are present.

Diphenylmercury is one of the substances for which the distortion polarizations measured at 5 mc are lower than the additive P_E. Since this is one of the substances for which the postulations (2) of high atom polarization have been proven to be in error by actual experimental determination, it has seemed worthwhile to try to evaluate experimentally the parts (P_E and P_A) of the distortion polarization separately. By this procedure some insight toward the underlying discrepancy might be found, together with an explanation for low distortion polarization and its relation to substances containing aromatic groups.

In order to evaluate the apparent abnormality in the distortion polarization of diphenylmercury, one must first have an opinion about its electronic polarization. There have been several opinions about this and some confusion in respect of the refractivity of mercury. A value of 11.2 cc for mercury was established by Wilde (15) from a series of primary alkyl bis-mercurials (C_1 to C_8), in contradiction of the value of 12.3 to 13.4 reported by others (16) with the assumption that the Eisenlohr value for methylene was constant throughout the series. Wilde's claim on the basis of his extrapolation method that methylene was not constant through the series seems to be valid but his further claim that the extrapolated value (11.0 ± 0.1) is the constant at $\lambda = 5893$ Å for mercury does not seem warranted. Thus Jones *et al.* (16) report much higher values for secondary and tertiary bis-mercurials. To be sure, the refractivity value derived from our experimental refraction at 5893 Å for 2-butyl-bis-mercury at 40 °C is lower (13.4 cc) than the 14.3 cc reported by Jones *et al.* but is much higher than Wilde's supposedly universal value. However, its magnitude is supported by the mercury value of 12.8 cc which we found from the refraction at 5893 Å at 40° for 2-butylmercuric chloride and of 13.5 cc at 50° for 2-butylmercuric bromide.

Actually Wilde's constant would seem to be discrepant from his own determination of the molar refraction of diphenylmercury (64.7 cc at 5893 Å and 15 °C) but his determination was made in the polarizing solvent, pyridine, so the apparent discrepancy (3.1 cc) may be explainable. However Wilde's experimental value of 64.7 cc is closer to that of Bergmann and Shutz (7) (65.2 cc, which has been used by Hampson and others) than is Wilde's calculated value of 61.6. Nor is the situation altered appreciably by calculation from Vogel's bond refractivities because the $MR_D = 62.6$ cc from double and single bond values or $MR_D = 62.1$ cc from aromatic ring bond summation are based on a bond refractivity for mercury of C—Hg = 6.5 cc which was derived from Wilde's value.

On the other hand the value of Bergmann and Schutz may be questioned because of the small differences between the refractive indices of the dilute solutions that they employed. For this reason we have measured the refractive indices experimentally by use of concentrated solutions containing up to 50 weight percent of diphenylmercury in dioxane at 40°. The relations between density and molecular refraction versus mole fraction are shown for wavelength 5893 Å in Fig. 1 and are linear. The molecular refraction of pure diphenylmercury may be calculated from the mixture relation,

$$R_{\text{mixture}} = \frac{n^2 - 1}{n^2 + 2} \cdot \frac{X_1 M_1 + (1 - X_1) M_2}{d}$$

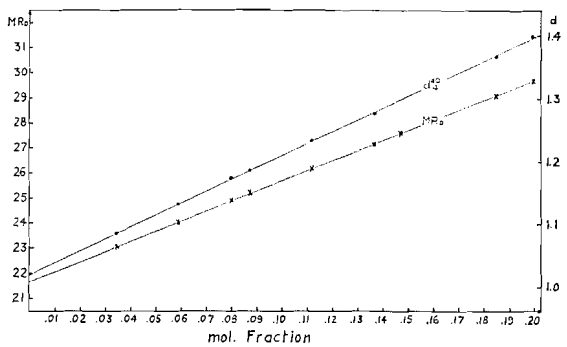

FIG. 1. Density and molecular refraction of diphenylmercury in dioxane.

where M_1 and M_2 are the molecular weights of diphenylmercury and dioxane respectively, X_1 is the mole fraction of the mercurial and d is the density for each solution of the series that was measured. This calculation leads to a molecular refraction at 5893 Å of 62.2 cc for diphenylmercury, surprisingly close to that of the additive values from atom or bond polarizabilities based on Wilde's constant but considerably lower than the extrapolated value obtained by Bergmann and Shutz with dilute solutions in benzene. We do not construe this apparent agreement as support for Wilde's constant when it is applied to groups which are not primary alkyl ones.

Of course the electronic polarization used in most electrical polarization studies is P_E at radio frequencies. Since this value cannot be determined directly, an approximation must be made by use of the Sellmeir extrapolation from linearly related optical dispersions to infinite wavelength. We have used the dioxane solutions at 40° for measurement at five wavelengths in the visible region. When the mixture relation is applied to these values, shown in Fig. 2, the following MR values are found: 64.1 cc at 4341 Å, 62.7 cc at 5460 Å, 62.3 cc at 5893 Å, and 61.8 cc at 6563 Å.

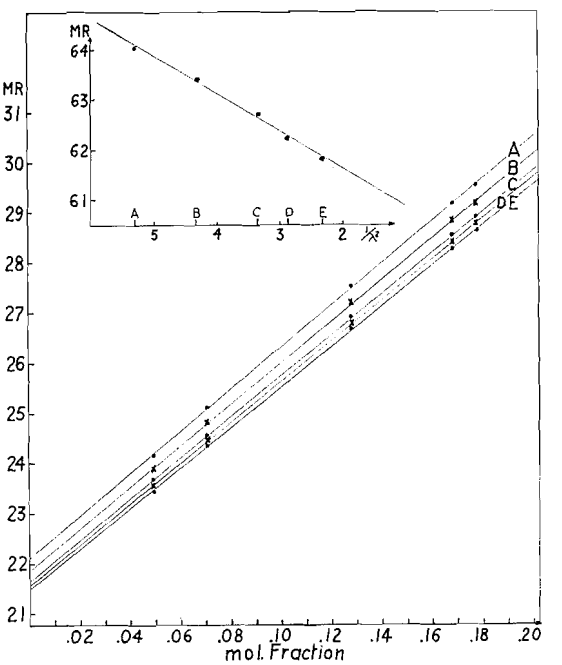

FIG. 2. Dispersion of diphenylmercury.

As may be seen from the insert of Fig. 2 these molecular refractions vary linearly with respect to the square of the wavelength and thus are applicable to the Sellmeir relation

$$R_\infty = \frac{\lambda_1^2 - \lambda_2^2}{(\lambda_1^2/R_1) - (\lambda_2^2/R_2)}$$

where R_1 and R_2 are any of the two molecular refractions at the appropriate wavelengths λ_1 and λ_2. The value of MR_∞ is found in this way to be 60.2 cc, which should be equal within experimental error to P_E at 10^6 c.p.s. The extrapolated value of 60.2 cc indicates that diphenylmercury is strongly dispersive of optical radiation to which it is exposed.

Among chemists who evaluate electric moments it is customary to arrive at the orientation polarization of substance by subtracting the molecular refraction for sodium D radiation (5892 Å) from the total polarization in the expectation that the difference between MR_D and MR_∞ will allow for the atom polarization of the substance.

Of course the assumption that this difference is approximate to the atom polarization is unwarranted and is justified only by the comparative difficulty in a separate evaluation of P_A. This evaluation may be done by the method of Whiffen (17) derived from the Kramers–Kronig relation. This may be expressed in terms of the contribution from each spectral absorption,

$$P_{A_j} = \frac{NC}{3\pi^2}\int \frac{\alpha(\nu)d\nu}{\nu^2 c},$$

where N is the Avogadro number, C is the velocity of the radiation, c is concentration, ν is the frequency of the jth absorption band, and α is the extinction coefficient integrated over the bandwidth $d\nu$. It may be seen that in the summation,

$$P_A = \sum P_{A_j},$$

the most important contributions will be those of low frequency, i.e. in the far infrared region. We have examined diphenylmercury in the region (300–50 cm^{-1}) as a dispersion in polyethylene wax (11) in the Perkin–Elmer 301 spectrometer.

The separate contributions to P_A are shown in Table I. The bands are found to be

TABLE I

Calculation of atom polarization for spectral absorption (900–50 cm^{-1}) by diphenylmercury

Sample No.	Freq. (cm^{-1})	Band envelope for	Baseline (% T)	Intensity (cm^2 $mole^{-1}$)	Band width (cm^{-1})	P_{A_j}
1[a]	100	Unsym.	80	38 474	29	12.99

2	735	Sym.[c]	93	1 895	38	0.09

[a]Examined in PE-301 as 15 w/w% in polyethylene wax.
[b]Examined in IR-4 with polyethylene wax in reference beam.
[c]The bands (IR-4) at 705 and 735 (from 10% solutions in benzene), unlike that at 460 cm^{-1} in benzene, are symmetrical.

unsymmetrical with "tailing" at the low-frequency side. This dissymmetry might be accounted as light scattering in the PE-301 at low frequencies: 100, 207, and 253 cm^{-1} but light scattering can not account for the unsymmetrical band at 460 cm^{-1} which has also been observed for benzene solutions by use of the IR-4 spectrophotometer. More likely the "tailing" is due to the so-called "hot bands" caused by transitions of order higher than $0 \rightarrow 1$ and is not due to instrumental error or to appreciable crystal lattice vibrations. Consequently integration over the entire band envelopes ought to be realistic and P_{A_j} values calculated in this way are shown in Table I as "unsym.". For the purpose of comparison P_{A_j} has also been calculated by exclusion of absorption outside of the symmetrical band expected from the contour on the high-frequency side of the bond. These values are listed in Table I as "sym.".

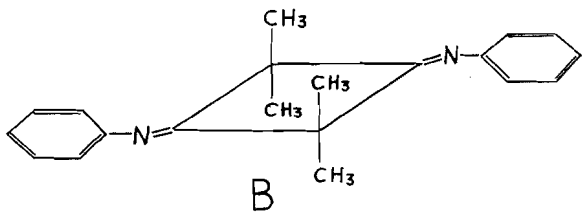
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

These results of Table I show that by either calculation the summation to P_A gives very large values. By inclusion of the entire bands (unsym.) the P_{A_j} is 23.2 cc. Limitation to symmetrical absorption still contributes 14.3 cc and neither value includes the minor contributions in the near infrared.

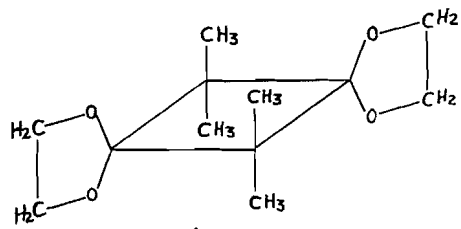
Because of the variation of total polarization for diphenylmercury with respect to temperature, a definite value does not exist. However, an approximate mean value of 69–70 cc may be specified. The difference between this P_T and our extrapolated P_E of 60.2 cc is less than the P_A values (23.2 cc or 14.4 cc) calculated from the spectral data. It would seem that the spectral data are quantitatively meaningless and cannot be used to support the postulation of abnormally high P_A for diphenylmercury. The situation remains unchanged in that not only is there no experimental basis for the postulation but there is experimental proof against it.

It remains to explain the discrepancy between our extrapolated P_E of 60.2 cc and our P_{E+A} of 57.1 cc with crystalline diphenylmercury at 10^6 c.p.s. This discrepancy is profound because P_E ought to be smaller, rather than 3.1 cc larger than P_{E+A}. Actually the discrepancy is not unexpected in view of our measurements of other substances containing phenyl groups (10, 12). Indeed a recent comparison of P_{E+A} for diphenylmercury and dicyclohexylmercury (10) shows that the difference is a property of the phenyl group.

The tendency for substances containing phenyl groups to show abnormal distortion polarization has been authenticated by a large number of examples in this laboratory. An additional and informative example is provided by comparison of P_D for N,N′-diphenyl-2,2,4,4-tetramethyl-1,3-cyclobutanediimine, B, with that of 6,6,12,12-tetramethyl-1,4,8,11-tetroxadispiro-[4,1-4,1]-dodecane, A. Both substances are solids, so their molecular refractions cannot conveniently be measured directly, but MR_D calculated by summation of atom polarizabilities (13) or bond polarizabilities (14) are 90.1 cc and 90.5 cc respectively (mean 90.3 cc) for B, whereas the distortion polarization calculated from measurement of



B



A

the dielectric constant of the compressed solid is 80.7 cc on the basis of a density of 1.098 determined by flotation. This large difference (−9.4 cc), which may be attributed to the presence of phenyl groups, is in marked contrast to the difference (+5.1 cc) between

MR_D (58.2 and 57.6 cc respectively, mean 57.9 cc) and P_D (63.0 cc based on flotation density of 1.20) for the dispirane, A. If the anil, B, has an atom polarization (unlikely) such as may be assigned to A it is hidden by the abnormally high diminution caused by the phenyl groups.

The appreciable number of phenyl substituted substances which have been shown (10) to have lower experimentally determined P_{E+A} values than would be expected from MR values leaves no doubt that a "phenyl effect" exists. One might expect that benzene itself would show the effect strongly but the only report of the dielectric constant of solid benzene (20) states that it leads to a higher rather than lower polarization than the MR_D. However the authors (21) have pointed out that their dielectric constants for solids "can be considered only as approximate" and, in experimental detail, that interspace between plates and dielectric is likely to be present in their apparatus. This interspace, which is not present in our apparatus, would lead to high results. Unfortunately our technique is not applicable to substances which melt below room temperature so a definitive P_{E+A} for benzene by our method is not now available.

If the "phenyl effect" was related to the electronic part of P_{E+A} then it ought to be observed from the refractive index of benzene at visible wavelengths. Actually a slight effect has been noted by Fajans and Bauer (22) and later by Syrkin *et al.* (23) as a small "negative exaltation". However the discrepancy of 0.17–0.3 cc between the Sellmeier extrapolation to MR_∞ of the refractive index of benzene and the MR_D calculated from bond or atom polarizabilities is smaller than we would expect in view of the approximate diminution (roughly 2 cc per phenyl group) which we have found from the dielectric constants of phenyl substituted compounds in the solid state. Of course the difference in spectral region must be considered. At radio frequencies, far from any absorption bands, the effect will not be complicated by anomalous dispersion, which may be expected to enhance the apparent polarization at frequencies slightly lower than those at which phenyl substituted compounds, and benzene itself, absorb in the ultraviolet region. On the basis of the "negative exaltation" of benzene at electronic frequencies the "phenyl effect" must involve the P_E part of the distortion polarization.

Actually the opposite effect, enhancement of reactance due to electron bonding, is the well-known phenomenon of positive exaltation in molecular refraction. This retardation of the speed of electromagnetic radiation at optical frequencies, (increased reactance) should also be observed at radio frequencies. A notable example is found (12) in P_{E+A} from the dielectric constant of crystalline β-carotene. This distortion polarization is 9–10 cc higher than would be calculated from bond or atom polarizabilities and may be attributed to the conjugated system in this substance.

In this sense the conjugation of double bonds, although it involves orbital hybridization, does not resemble benzenoid hybridization in that non-aromatic conjugation retards radiation at frequencies of 5 mc or more whereas benzenoid hybridization accelerates it relative to the equivalent non-conjugated and non-aromatic unsaturation. The two effects may thus be antagonistic as has been noted (10) by contrasting tetraphenylethylene and tetraphenylcyclobutane (12) (P_{E+A} are respectively 12 cc and 8 cc less than additive MR_D) with the tetraphenylated allene, butatriene, and hexyne (items 55–57) of Table I, ref. 10. Likewise the positive exaltation (P_{E+A} = 70.2 cc vs. MR_D = 67.4 cc) of 2.8 cc for 1,4-diphenylbutadiene (12) may be contrasted to a negative exaltation (P_{E+A} = 110.7 cc vs. MR_D = 116.6 cc) of −5.9 cc for 1,1,4,4-tetraphenylbutadiene. Of interest in this connection is 2,3,4,5-tetraphenylpyrrole. The exaltation of 3.5 cc is negative (P_{E+A} = 114.7 cc vs. MR_D = 118.2 cc) but one might have expected the negative value

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to be larger in view of the known negative exaltation of pyrrole (22). However it is probable that pyrroles behave in the same manner as furans, where it has been found (24) that unsaturated substituents reverse the negative exaltation of furan itself to positive values in substituted furans. If the same effect is operative in 2,3,4,5-tetraphenylpyrrole the relatively small negative exaltation may be considered to be a consequence of counteraction between positive exaltation and the "phenyl effect".

We have used the term "phenyl effect" to describe less-than-expected reactance at 5 mc but the term is not limited to benzene and its substituents. The dielectric constants of an appreciable number of crystalline polynuclear aromatic substances have been measured and found to be low (10, 12) but definite correlation must await a larger number of such results as well as a precise method of measuring the concomitant electronic polarization of these solid substances. These studies are in progress.

EXPERIMENTAL

Spectral Studies

Both benzene solutions and polyethylene wax wafers containing diphenylmercury were used for studies with the Beckman IR-4 spectrometer but only the wafers were used in the Perkin–Elmer 301 spectrometer. These wafers were prepared according to the method already outlined (11) but reference wafers were made from the same weight rather than the same thickness of polyethylene wax in the sample wafer because of the relatively high percentage of candidate substance required for the low-frequency spectrometer.

The PE-301 spectrometer was maintained dry by a positive pressure of gas from a liquid nitrogen container. Samples were examined by use of both globar and mercury-arc energy sources with appropriate gratings and restrahlen filters and with scanning rates from 2.75 cm^{-1} per min (grating No. 20) to 1 cm^{-1} per min (grating No. 8).

The spectral intensities were obtained by summation of the 1 cm^{-1} increments on the chart and also by weight-integration of the graph paper.

Densities and Refractive Indices

The refractive indices of solutions of pure diphenylmercury, m.p. 124°, in pure, peroxide-free dioxane at 40 °C and at $\lambda = 5893$ mμ were measured in an Abbe refractometer of precision ± 0.00004. The densities of these solutions were determined by pycnometer in a bath constant to ± 0.02 °C. The experimental data are shown in Fig. 1.

The densities were determined in like manner for 2-butane-bis-mercury at 40° (1.779), 2-butylmercuric chloride at 40° (2.547), and 2-butylmercuric bromide at 50° (2.846). Also the refractive indices were determined at the respective temperatures and from them the molar refractions have been calculated for the several wavelengths and recorded in Table II.

TABLE II

Substituted Tetramethylcyclobutanes

The three cyclobutanes used in the study were obtained from the Tennessee Eastman Company and were crystallized to constant melting point from ethanol. Pure A melted at 105–105.5 °C while pure B melted at 141–141.8 °C.

The apparent dielectric constant of various thicknesses of wafers made from N,N′-diphenyl-2,2,4,4-tetramethyl-1,3-cyclobutanediimine, B, and 6,6,12,12-tetramethyl-1,4,8,11-tetroxadispiro-[4,1-4,1]-dodecane, A, have been plotted against wafer thickness to give the extrapolated values 2.317 and 2.486 respectively, shown in Fig. 3. Densities of B and A have been found by flotation to be 1.089 and 1.200 respectively (20 °C). The maintenance of purity during the preparation and measurement of the compressed wafers of the dispirane, A, is shown by the measurement before and after the determination of the X-ray diffraction pattern using Cu (Ni filtered) radiation. The six largest d spacings in angstrom units at intensities I/I_1 for

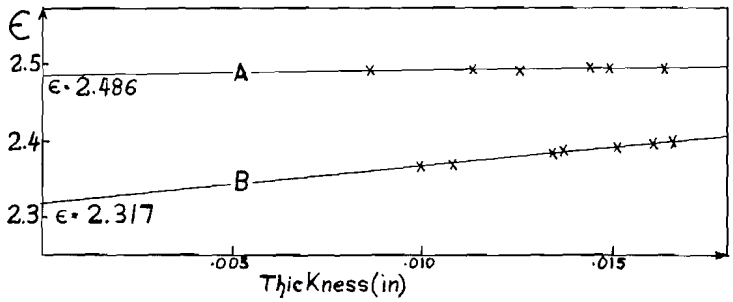

FIG. 3. Apparent dielectric constants vs. wafer thickness: (A) 6,6,12,12-tetramethyl-1,4,8,11-tetroxadispiro-[4,1-4,1]-dodecane, (B) N,N′-diphenyl-2,2,4,4-tetramethyl-1,3-cyclobutanediimine.

the dispirane, A, are: [10] 5.29, [9] 6.19, [8] 6.29, [7] 4.73, [6] 3.23, [5] 5.79, and are the same for both samples, before and after measurement of dielectric constant.

Conjugated Dienes

The melting points of the 1,1,4,4-tetraphenyl-1,3-butadiene and the 2,3,4,5-tetraphenylpyrrole used for determination of solid dielectric constant were 202.3–202.9 °C and 214.3–215.0 °C respectively. The density (flotation) of the tetraphenylbutadiene was 1.2386 at 20° and the extrapolated dielectric constant was 2.863 from which the distortion polarization is calculated to be 110.7 cc. The density (flotation) of the tetraphenylpyrrole at 20° was 1.247 and the extrapolated dielectric constant was 2.883 from which the distortion polarization is calculated as 114.7 cc. The extrapolation plots of apparent dielectric constant versus thickness were as linear as those shown in Fig. 3.

We are grateful to the Defence Research Board for financial support of this investigation and to the Tennessee Eastman Company for ample supplies of the cyclobutanes used in this study. Thanks are due to Drs. E. Whalley and J. Bertie of the National Research Council for use of the PE-301 spectrometer.

SUR LES ÉTHERS ÉNOLIQUES DÉRIVÉS DU FORMYL-3 CAMPHRE*

JEAN-CLAUDE RICHER ET REGINALD CLARKE
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 5 mars 1964

RÉSUMÉ

Les spectres r.m.n. d'éthers énoliques dérivés du formyl-3 camphre (I) ont été examinés. L'isomérie *cis–trans* (formes *a* et *b*) autour de la double liaison hydroxyméthylénique a été observée. Des résultats expérimentaux indiquant la présence de la forme aldéhydo-énolique (forme I*c*) dans les solutions éthérées du formyl-3 camphre sont présentés.

INTRODUCTION

Au cours d'une étude récente des spectres de résonance magnétique nucléaire (r.m.n.) des formyl-2 cyclanones, Garbisch (1) a observé que le formyl-3 camphre (I) en solution existe à l'état d'équilibre entre les diverses formes I, I*a* et I*b*. La présence de la forme aldéhydo-énolique I*c* n'a toutefois pas été décelée.

L'examen des spectres r.m.n. des éthers *O*-méthyliques (II), *O*-éthyliques (III), *O*-butylique (IV) et *S*-butyliques (V) dérivés du formyl-3 camphre a permis de confirmer l'existence des isomères *trans* (forme *a*) et *cis* (forme *b*) dans ces éthers. Les travaux que nous rapportons ici ont aussi permis de mettre en évidence des éthers (forme *c*) dérivés de la forme aldéhydo-énolique (I*c*).

RÉSULTATS ET DISCUSSION

La réaction du formyl-3 camphre (I) avec le diazométhane, le diazoéthane, le méthanol, l'éthanol, le butanol-1 ou le butanethiol-1 (2) conduit aux éthers *O*-méthyliques (II), *O*-éthyliques (III), *O*-butylique (IV) ou *S*-butyliques (V) qui peuvent théoriquement exister sous les formes *a*, *b* ou *c*. La chromatographie de ces éthers sur plaques minces (3) montre d'ailleurs que les dérivés ne sont pas homogènes. Les résultats de ces chromatographies, rapportés dans le Tableau I, seront donc interprétés en fonction de la présence des formes *a*, *b* ou *c* dans les produits.

**Les résultats rapportés dans cette communication sont extraits du mémoire soumis par R. Clarke à la Faculté des Sciences de l'Université de Montréal en vue de l'obtention du grade de Maître ès Sciences. Ces travaux ont été présentés en partie devant le 31ème congrès annuel de l'Association Canadienne-Française pour l'Avancement des Sciences tenu à Québec, Québec, en novembre 1963.*

Afin de déterminer la nature des divers produits composant ces mélanges, les spectres r.m.n. de ces éthers ont été déterminés et les résultats les plus significatifs sont présentés dans le Tableau II.

TABLEAU I

Chromatographie sur plaques minces*

Éther	Mode de préparation	Nombre de taches	R_f
II	Méthanol	2	0.88 0.75
II	Diazométhane	3	0.88 0.75 0.25
III	Éthanol	1	0.88
III	Diazoéthane	3	0.88 0.75 0.25
IV	Butanol-1	1	0.63
V	Butanethiol-1	2	0.56 0.35

*Ces chromatographies sont réalisées à l'aide de couches de 250 microns de Silica Gel G. Les éthers examinés sont appliqués sous forme de solution dans l'éther de pétrole, et les chromatogrammes sont développés au moyen d'une solution méthanol et benzène 2:98. Les produits sont révélés sous forme de taches bleues sous l'action d'une solution à 2% de chlorure ferrique dans le *n*-butanol.

TABLEAU II

Spectres de résonance magnétique nucléaire*

Produits	Préparation	Protons oléfiniques		Aldéhydiques,	Groupes méthoxyles	
		Forme *a*	Forme *b*	forme *c*	Formes *a*, *b*	Forme *c*
I†	—	7.35 (50)	6.78 (41)	9.58 (6) 9.63 (3)

III	Éthanol	6.83 (100)				
III	Diazoéthane	6.80 (80)	6.60 (10)	9.50 (10)		
IV	Butanol-1	6.80 (100)				
V	Butanethiol-1	6.85 (58)	6.27 (42)			

*Les spectres r.m.n. ont été mesurés à l'aide d'un appareil Varian A-60 pour des solutions dans CCl_4 à moins d'indications contraires. La position des bandes (échelle δ) en p.p.m. se réfère au tétraméthylsilane utilisé comme standard interne. Les valeurs entre parenthèses indiquent la proportion de chacune des formes dans le mélange considéré.
†Ce spectre a été mesuré à l'aide d'une solution à 10% dans l'éthoxyéthane.

SUR L'ISOMÉRIE *cis–trans* DANS LES DÉRIVÉS HYDROXYMÉTHYLÉNIQUES

Les résultats rapportés dans le présent travail nous permettent de constater que les produits isomères (I*a* et I*b*) dérivés du formyl-3 camphre (I) existent en solution dans l'éthoxyéthane dans la proportion 55/45. Ces résultats complémentent ceux de Garbisch (1) qui a observé que la proportion relative d'isomères *cis/trans* (I*b*/I*a*) varie de 95/5 pour une solution à 10% dans le CCl_4 jusqu'à 22/78 pour une solution à 14% dans du CCl_4 contenant 8% de diméthylsulfoxyde.

L'isomérie *cis–trans* autour de la double liaison hydroxyméthylénique est aussi observée dans les éthers énoliques préparés (II–V). La proportion de formes *cis* (*b*) et *trans* (*a*) dans ces éthers varie suivant le mode de préparation et le substituant introduit. Les résultats suivants montrent l'influence du mode de préparation: dans l'éther méthylique (II) préparé selon un procédé où le contrôle de la réaction est cinétique (réaction de I en solution dans l'éthoxyéthane avec le diazométhane) on note que la proportion d'isomères *cis/trans* (II*b*/II*a*) est de 56/44 alors que cette proportion est de 8/92 dans l'éther préparé dans des conditions où le contrôle de la réaction est thermodynamique. Dans le cas de l'éther éthylique (III) les proportions d'isomères *cis/trans* (III*b*/III*a*) sont respectivement de 11/89 et 0/100 pour des réactions où le contrôle est cinétique et thermodynamique.

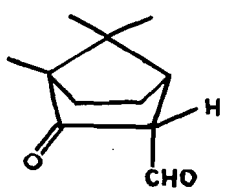
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Lorsque des conditions expérimentales favorisant un équilibre thermodynamique des produits sont employées pour préparer les éthers, on note chez les éthers *O*-alcoylés que les deux isomères stable (forme *a*) et instable (forme *b*) ne se forment que dans le cas des dérivés méthylés (II) où le substituant est peu volumineux. Seul l'isomère thermodynamiquement le plus stable (III*a* ou IV*a*) se forme lorsque le substituant devient plus volumineux. Le fait que les deux isomères *cis* (V*b*) et *trans* (V*a*) soient présents dans l'éther *S*-butylique (V) alors que seul l'isomère le plus stable (*trans*, IV *a*) est présent dans l'éther *O*-butylique, s'explique grâce à la différence de longueur des liens C–S (1.80 Å) et C–O (1.40 Å) (4). Le lien C–S plus long éloignerait le groupe butyle du carbonyle avec lequel il interfère et permettrait une accommodation plus facile de ce radical volumineux. Une explication de ce type est avancée par Eliel (5) pour rendre compte du fait que les dérivés sulfurés occupent plus facilement les configurations axiales que les dérivés oxygénés.

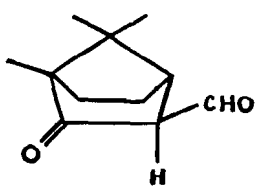
SUR LA PRÉSENCE DE LA FORME ALDEHYDO-ÉNOLIQUE (I*c*) DANS LES SOLUTIONS ÉTHÉRÉES DU FORMYL-3 CAMPHRE

Le traitement d'une solution éthérée de formyl-3 camphre (I) par un excès de diazométhane conduit à l'éther méthylique (II) dont le spectre r.m.n. montre une bande aldéhydique à 9.42 p.p.m. Ce résultat indique que l'éther II*c* est présent dans le produit et cette conclusion est confirmée grâce aux observations suivantes: l'éther méthylique (II) préparé par réaction du formyl-3 camphre (I) avec du méthanol consiste en un mélange de produits II*a* et II*b* (voir plus haut); alors que le spectre r.m.n. de ce produit ne montre qu'un pic à 3.70 p.p.m. dans la région des groupes méthoxyles celui de l'éther méthylique II obtenu par l'action du diazométhane montre en plus du pic à 3.70 p.p.m. une bande à 4.00 p.p.m. Cette dernière bande serait due au groupe méthoxyle présent dans la forme II*c*. La présence de cet éther aldéhydo-énolique (II*c*) dans le produit réactionnel implique que la forme aldéhydo-énolique I*c* est présente en quantité finie en solution éthérée. Les pics aldéhydiques dans le spectre r.m.n. du formyl-3 camphre (I) représentent un maximum de 9% du produit total; on peut donc conclure que cette valeur indique une limite supérieure à la quantité possible de la forme I*c* dans la solution.

Le spectre r.m.n. du formyl-3 camphre (I) en solution dans l'éthoxyéthane montre des bandes à 9.58 et 9.63 p.p.m. Ces pics correspondant à ceux (9.62 et 9.68 p.p.m.) observés par Garbisch (1) pour des solutions de I dans le CCl_4 indiquent la présence d'aldéhydes dans le milieu et ont été attribués (1) aux formes exo (I exo) et endo (I endo) du formyl-3 camphre non énolisé.



I endo



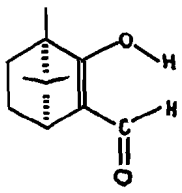
I exo

Deux explications alternatives à celle de Garbisch (1) pourraient être avancées pour rendre compte de la présence de deux bandes aldéhydiques dans le spectre r.m.n. du formyl-3 camphre (I) en solution:

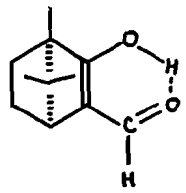
(A) Une des bandes serait due au proton aldéhydique du formyl-3 camphre (I) non énolisé alors que l'autre serait due à la forme aldéhydo-énolique (I*c*).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(B) Les deux bandes pourraient être dues aux formes aldéhydo-énoliques libre (I*c* libre) et liée (I*c* liée).



I*c* libre



I*c* liée

Ces deux explications alternatives rendraient compte du fait que la forme aldéhydo-énolique (I*c*) est présente dans la solution et d'autre part que le pic aldéhydique de l'éther II*c* est unique. Les résultats récents de Anet (6) sur l'énergie d'activation nécessaire pour la rotation du groupe aldéhydique rendent l'alternative B moins plausible que l'alternative A; les faits connus actuellement ne nous permettent toutefois pas de faire un choix définitif entre ces diverses alternatives.

PARTIE EXPÉRIMENTALE

Les points de fusion ont été déterminés en tubes capillaires ouverts au moyen d'un thermomètre étalonné avec des substances pures de p.f. connus. Les spectres infrarouges ont été mesurés sur un appareil Perkin–Elmer modèle 21, prisme NaCl. Les indices de réfraction ont été déterminés à l'aide d'un réfractomètre Abbé 60. Les indices de rotation ont été mesurés au moyen d'un polarimètre Bellingham et Stanley, modèle A; à moins d'indication contraire, ces indices ont été déterminés pour des solutions à 4% dans de l'éthanol 95%. Les analyses élémentaires sont de C. Daesslé, Organic Microanalysis, Montréal. Les spectres ultraviolet ont été déterminés en solution éthanolique à l'aide d'un spectrophotomètre Perkin–Elmer, modèle 4000-A.

1. Synthèse du formyl-3 camphre

Le formyl-3 camphre, obtenu par réaction du formiate d'éthyle sur le sodio-3 camphre, fond à 78–80° (litt. (7) 80–81°) et présente un indice de rotation de +204.1° (litt. (7) +198°).

2. Préparation des dérivés du formyl-3 camphre

2.1. Éther méthylique dérivé du formyl-3 camphre

2.11. Action du méthanol.—Une solution de 3 g (17 moles) de formyl-3 camphre, 2 ml de méthanol et 50 mg d'acide *p*-toluènesulfonique dans 30 ml de benzène anhydre est chauffée à reflux sous atmosphère d'azote. L'eau formée au cours de la réaction est éliminée à l'aide d'un décanteur du type Dean–Stark. Lorsqu'il n'y a plus d'eau qui se forme le benzène est éliminé et le produit repris par de l'éther. La solution éthérée est lavée avec une solution aqueuse de soude 10%, lavée avec de l'eau jusqu'à neutralité, séchée sur du sulfate de sodium anhydre, et évaporée au travers d'une colonne Widmer (30 cm).

L'éther méthylique (II) purifié par distillation présente les caractéristiques suivantes: p.é. 86° à 0.6 mm Hg (litt. (8) 143.5° à 17 mm); $[\alpha]_D^{26}$ +201.6°; n_D^{26} 1.5082 (litt. (8) n_D^{25} 1.509). Spectre r.m.n.: protons éthyléniques à 6.75 p.p.m. et 6.57 p.p.m.; groupe méthoxyle à 3.70 p.p.m.

2.12. Action du diazométhane.—À 2 g de formyl-3 camphre en solution dans 10 ml d'éther anhydre, on ajoute une solution éthérée de diazométhane préparée selon Vogel (9). Le produit isolé à la manière habituelle est purifié par distillation et présente les caractéristiques suivantes: p.é. 90° à 1 mm; $[\alpha]_D^{26.5}$ +200.6°; n_D^{26} 1.5091. Spectre r.m.n.: proton aldéhydique à 9.42 p.p.m.; protons éthyléniques à 6.73 p.p.m. et 6.58 p.p.m.; groupes méthoxyles à 4.00 p.p.m. et 3.70 p.p.m.

2.2. Éther éthylique (III) dérivé du formyl-3 camphre

2.21. Action d'éthanol.—L'action de 2 ml d'éthanol sur 3.0 g de formyl-3 camphre dans les conditions décrites à la section 2.11 fournit l'éther éthylique III avec un rendement de 80%. Le produit purifié par distillation présente les caractéristiques suivantes: p.é. 91° à 0.6 mm (litt. (10) 147° à 17 mm); $[\alpha]_D^{26}$ +196.5°; n_D^{26} 1.5015 (litt. (10) n_D^{17} 1.5047). Spectre r.m.n.: proton éthylénique à 6.80 p.p.m.

2.22. Action du diazométhane.—La réaction du formyl-3 camphre avec une solution éthérée de diazoéthane préparée selon la méthode de Adamson (11) conduit à l'éther éthylique (III) qui, après purification par distillation, présente les caractéristiques suivantes: p.é. 95° à 1 mm; $[\alpha]_D^{26}$ +195.8°; n_D^{25} 1.5049. Spectre r.m.n.: proton aldéhydique à 9.50 p.p.m.; protons éthyléniques à 6.80 p.p.m. et 6.60 p.p.m.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

2.3. Éther butylique (IV) dérivé du formyl-3 camphre

L'action de 5 ml de butanol-1 sur 6.0 g de formyl-3 camphre dans des conditions semblables à celles décrites à la section 2.11 conduit à l'éther butylique (IV) avec un rendement de 78%. Une fraction analytique présente les caractéristiques suivantes: p.é. 103° à 0.2 mm; $[\alpha]_D^{25}$ +173.2°; n_D^{26} 1.4942. Spectre ultraviolet: λ_{max} 268 mμ, log ε 4.14. Spectre r.m.n.: proton éthylénique à 6.80 p.p.m. Anal. Calc. pour $C_{15}H_{24}O_2$: C, 76.22; H, 10.23. Trouvé: C, 76.37; H, 10.08.

2.4. Éther thiobutylique (V) dérivé du formyl-3 camphre

L'action de 9.0 g (0.1 mole) de butanethiol-1 sur 10 g (0.056 mole) de formyl-3 camphre dans des conditions semblables à celles décrites par Ireland (2) a conduit à 9.5 g (67.5% du rendement théorique) de l'éther désiré (V). Une fraction analytique présente les caractéristiques suivantes: p.é. 127° à 1 mm; $[\alpha]_D^{26}$ +236.7°; n_D^{26} 1.5362. Spectre ultraviolet: λ_{max} 315 mμ, log ε 4.18. Spectre r.m.n.: protons éthyléniques à 6.85 et 6.27 p.p.m. Anal. Calc. pour $C_{15}H_{24}OS$: C, 71.38; H, 9.58; S, 12.70%. Trouvé: C, 71.22; H, 9.40; S, 12.82%.

REMERCIEMENTS

Les auteurs remercient le Conseil National de Recherches pour l'aide financière apportée sous forme d'octroi de recherches.

LA DÉTERMINATION DU RAYON DE GIRATION DES MACROMOLÉCULES EN CHAÎNES DANS LES BONS SOLVANTS PAR DIFFUSION DE LA LUMIÈRE[1]

JACQUES PRUD'HOMME ET YVON SICOTTE
Laboratoire de Chimie Physique, Université de Montréal, Montréal, Québec

Reçu le 20 avril 1964

RÉSUMÉ

L'approximation de Zimm pour la détermination des rayons de giration des macromolécules en chaînes en solution par diffusion de la lumière a des limites d'utilisation très étroites. D'une façon presque générale, il faut connaître à priori la forme de la distribution angulaire d'intensité de diffusion pour en tirer la valeur du rayon de giration. Dans le cas des bons solvants, la fonction approchée de Peterlin–Benoît–Ptitsyn semble très bien représenter les données expérimentales.

INTRODUCTION

Debye (1) et Zimm (2) ont montré comment on pouvait déterminer les dimensions des macromolécules en solution par l'étude de la fonction $P(\theta)$, c'est à dire la variation angulaire de l'intensité de diffusion. En particulier, on sait que près de l'origine la fonction $P(\theta)$ ne dépend que du rayon de giration S de la molécule par rapport à son centre de masse. Guinier (3) a montré en effet que l'éq. [1]:

$$P(\theta) = e^{-u/3} \qquad [1]$$

constitue une approximation excellente près de l'origine pour n'importe quelle forme de particules, où u représente $4\pi^2\sigma^2S^2$, σ est la quantité $(2/\lambda)\sin(\theta/2)$ et λ est la longueur d'onde de la lumière incidente mesurée dans le milieu. Zimm a utilisé (2) une expression analogue:

$$P^{-1}(\theta) = 1 + u/3 \qquad [2]$$

pour calculer le rayon de giration à partir de la pente à l'origine. L'équation [2] est contituée en fait des deux premiers termes du développement en série de n'importe quelle fonction $P(\theta)$. Cette approximation ne sera utilisable par conséquent que pour des valeurs relativement faibles de u. L'intervalle de la variable expérimentale σ qui est accessible à l'aide d'un appareil donné est fixé par la longueur d'onde de la radiation utilisée et par l'intervalle angulaire exploré. Par contre la région de u étudiée sera fonction du rayon de giration. Par conséquent si le rayon de giration est assez grand, la pente à l'origine ne sera pas accessible directement: c'est-là une chose connue depuis très longtemps. Par ailleurs la région d'utilisation de l'approximation de Zimm variera suivant la forme de la fonction $P(\theta)$. Pour chaque forme de particule, il faut donc étudier le domaine d'utilisation de cette approximation.

Lorsque la pente à l'origine n'est pas accessible directement, on doit choisir à priori une fonction $P(\theta)$ pour évaluer le rayon de giration. Pour un certain nombre de cas particuliers, la fonction $P(\theta)$ est connue. Par exemple on sait que pour une macromolécule en chaîne en solvant Θ, c'est à dire quand les interactions entre chaînons éloignés s'annulent, on obtient, comme loi de probabilité caractérisant la répartition des distances

[1]*Les résultats utilisés dans le présent travail sont tirés du mémoire de Maîtrise ès Sciences en Chimie présenté par l'un de nous (J. P.) à la Faculté des Sciences de l'Université de Montréal (1964).*

entre deux chaînons, une loi de Gauss. Debye (4) a calculé la fonction $P(\theta)$ pour cette chaîne gaussienne:

$$P(\theta) = 2(e^{-u} - 1 + u)/u^2. \quad [3]$$

En solvant non Θ, on sait que la chaîne n'est plus gaussienne, et pour obtenir le $P(\theta)$ dans ce cas, il faudrait tenir compte de la perturbation introduite par l'effet de solvant dans la configuration de la molécule. Cet effet de solvant, ou effet de volume exclu, a fait l'objet récemment d'un grand nombre de travaux théoriques: voir à ce sujet les revues de Ptitsyn (5) et de Kurata et Stockmayer (6). Malheureusement les résultats obtenus à date sont sous forme de séries à convergence très lente dont on n'a réussi à évaluer que les premiers termes (7), de sorte qu'on ne peut les utiliser que pour des solvants très voisins des solvants Θ. La fonction $P(\theta)$ a d'ailleurs été calculée rigoureusement dans ces conditions (8, 9) où elle se confond en pratique avec l'éq. [3].

Dans le cas des bons solvants, Peterlin (10) a donné une solution qui tient compte au moins partiellement du caractère non gaussien de la chaîne. Expérimentalement on sait que, quelque soit le solvant, la relation entre le carré moyen de la distance entre les bouts de la chaîne et la masse moléculaire peut s'écrire sous la forme:

$$\langle L^2 \rangle \simeq M^{\mu}. \quad [4]$$

Une des façons d'obtenir l'éq. [4] est de supposer que le carré moyen de la distance entre le chaînon i et le chaînon $i + p$ est donné par $p^{\mu}b^2$, quelque soit p; b et μ sont des paramètres caractérisant un système polymère—solvant donné. En solvant Θ, μ serait égal à l'unité. Si on admet que la loi de distribution des distances n'est pas sérieusement perturbée par l'effet de solvant et qu'on peut toujours la considérer comme gaussienne, on obtient la fonction approchée suivante (10–12):

$$P(\theta) = \frac{2}{N^2} \int_{p=0}^{N} (N - p) \exp\{-2\pi^2\sigma^2 b^2 p^{\mu}/3\} dp, \quad [5]$$

ce qui donne pour le rayon de giration:

$$\langle S^2 \rangle = \frac{b^2 N^{\mu}}{(1 + \mu)(2 + \mu)}. \quad [6]$$

N est le nombre de chaînons. Benoît (11) et Ptitsyn (12) ont montré comment évaluer par des séries l'intégrale [5]. Elle a d'ailleurs été calculée directement à l'aide d'un calculateur numérique (13). Cette fonction $P(\theta)$ approchée a été utilisée par de nombreux chercheurs (voir par exemple les références 10 à 19), mais en général la polydispersité des échantillons utilisés ne permettait pas de vérification critique de cette fonction, sauf aux grandes valeurs de u où l'effet de la polydispersité est beaucoup moins important.

Par ailleurs plusieurs études récentes du problème de volume exclu, faites à l'aide de calculateurs numériques (20–25) semblent indiquer clairement que la loi de distribution des distances est fortement perturbée par l'effet de volume exclu, contrairement à l'hypothèse sous laquelle l'éq. [5] a été obtenue. Cette perturbation, si vraiment elle est importante, devrait évidemment se faire sentir, au moins dans une région du $P(\theta)$, et une comparaison entre l'éq. [5] (obtenue sans tenir compte de cet effet) et les résultats expérimentaux devrait nous permettre d'évaluer l'importance de cette perturbation de la loi de distribution des distances.

Puisqu'il semble que pour les hautes valeurs de u l'éq. [5] représente très bien les

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

résultats expérimentaux, (13–16), nous avons voulu étendre cette vérification vers les basses valeurs de u, c'est à dire jusqu'à la région près de l'origine où l'éq. [2] devient valide. Pour cela nous avons entrepris l'étude d'une série de fractions de polystyrène les plus monodispersées possibles.

PARTIE EXPÉRIMENTALE

Le polymère brut a été obtenu de la maison Dow Corning (échantillon B-25). Les fractions ont été obtenues d'une solution à 1% dans la butanone par addition de quantités croissantes de méthanol. Les fractions ainsi obtenues ont été redissoutes par élévation de température puis reprécipitées par retour lent à la température initiale. Douze fractions ont ainsi été obtenues dont six ont été utilisées pour le présent travail. Les solvants utilisés étaient de qualité "Reagent" et ont été redistillés dans une colonne de 2 mètres de hauteur, garnie d'hélices de verre, sous un rapport de reflux de un à dix.

Pour chaque fraction, on a préparé une solution mère par pesée. Les autres solutions ont été préparées par dilution volumétrique. Les mesures ont été prises pour cinq concentrations dans chaque cas. Toutes les solutions ont été dépoussiérées par centrifugation dans un appareil Lourdes (LCA 1–37 000 g) durant 1 heure.

Les mesures de diffusion de la lumière ont été effectuées à l'aide du photogoniodiffusomètre de Wippler et Scheibling (26) fabriqué par SOFICA. Le benzène a été utilisé comme standard pour calibrer l'appareil en prenant comme valeur du rapport de Rayleigh pour ce liquide, à 5461 Å, 17.2×10^{-6} (27).

RÉSULTATS ET DISCUSSION

Pour chaque fraction, les résultats expérimentaux, $c/I(\theta)$, ont été extrapolés à concentration nulle pour chaque angle d'observation par la méthode des moindres carrés: c est la concentration en grammes de soluté par millilitre de solution, et $I(\theta)$ est l'intensité de diffusion normée. Pour retrouver le rayon de giration et la masse moléculaire, on trace alors une courbe de log $P(\theta)$ en fonction de log u et on superpose par translation $x - y$ la courbe log $[c/I(\theta)]_{c=0}$ en fonction de log σ^2. La superposition des abcisses expérimentales (en σ^2) et théoriques (en u) donne log $4\pi^2S^2$. La superposition des ordonnées donne log M. Cette méthode (28) donne évidemment les mêmes résultats que la méthode maintenant classique de Zimm (2) dans les cas où la pente à l'origine est directement accessible à l'expérience. Il importe cependant de noter que le fait que cette dernière condition ne soit pas remplie ne se traduit pas nécessairement par l'apparition d'une courbure évidente dans le diagramme de Zimm. En effet, sur un intervalle de u donné, les erreurs expérimentales normales peuvent noyer complètement l'effet de courbure, et si on prend alors la pente moyenne sur cet intervalle comme une mesure du rayon de giration, éq. [2], on fait une erreur qui peut être importante. La Fig. 1 montre un exemple de diagramme de Zimm obtenu. Aux erreurs d'expérience près, il n'y a pas de courbure évidente, et pourtant on n'est certainement pas dans la région où l'éq. [2] peut s'appliquer. La pente à l'origine obtenue par la méthode décrite plus haut est également tracée sur la Fig. 1: elle conduit à attribuer au rayon de giration une valeur de 530 Å, alors que la pente moyenne de la "droite" expérimentale conduirait à 575 Å. Zimm a d'ailleurs proposé une méthode (2) pour corriger point par point les résultats expérimentaux, dans le cas de la chaîne gaussienne, et les ramener sur la "tangente limite" équivalente, donnée par l'éq. [2].

Dans le cas qui nous intéresse de la chaîne en bon solvant, si on admet au moins à titre d'hypothèse de travail la validité de l'éq. [5], il n'est pas étonnant que les résultats expérimentaux semblent donner une droite. En effet nous avons tracé à la Fig. 2 le $P^{-1}(\theta)$ obtenu pour $\mu = 1.17$. La concavité de cette courbe dans la région étudiée est toujours très faible. Elle est nulle près de l'origine où l'éq. [2] s'applique pour donner la pente à l'origine (prolongée en pointillés). La concavité est ensuite dirigée vers le haut, puis repasse par zéro pour être ensuite dirigée vers le bas. Il en résulte qu'une droite peut constituer une excellente approximation à cette courbe si on admet une incertitude de

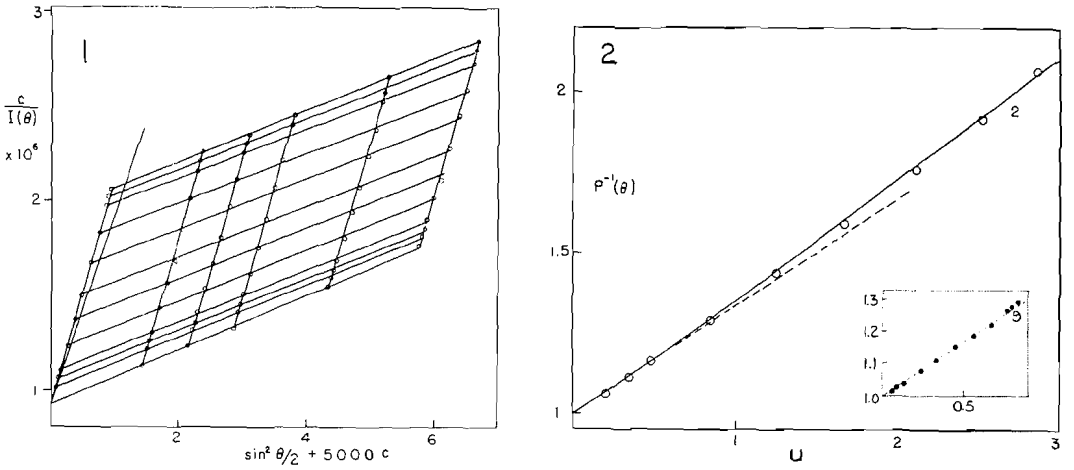

FIG. 1. Diagramme de Zimm pour la fraction B-25-2 en solution dans le toluène, à 25 °C, à 5461 Å.
FIG. 2. Comparaison des données de diffusion à dilution infinie de la fraction B-25-2 et de la courbe théorique (éq. [5] pour $\mu = 1.17$). En médaillon, la fraction B-25-9.

1 ou 2%. Et de fait, comme on le voit, les résultats expérimentaux se superposent aussi bien à la courbe de la Fig. 2 qu'à la droite de la Fig. 1. L'équation [2] a donc des limites d'utilisation assez étroites et nous avons préféré procéder systématiquement par superposition des données expérimentales aux courbes théoriques.

Il faut évidemment pour tracer la courbe théorique choisir une valeur pour le paramètre μ. Théoriquement on pourrait tirer la valeur de ce paramètre des données de diffusion de la lumière elles-mêmes. Particulièrement à haute valeur de u, le $P(\theta)$ est très sensible à la valeur de μ (13, 14). Par contre, puisque nous sommes dans la région des basses valeurs de u, région qui se prête moins bien à la détermination de μ, nous avons préféré suivre la suggestion de Loucheux, Weill et Benoît (14, 15) et tirer μ de la relation empirique entre viscosité intrinsèque et masse moléculaire:

$$[\eta] = KM^a. \qquad [7]$$

En effet, si on admet la relation de Flory (29):

$$[\eta] = \phi \frac{\langle L_0^2 \rangle^{3/2}}{M} \alpha^3, \qquad [8]$$

où ϕ est une constante universelle, $\langle L_0^2 \rangle$ est le carré moyen de la distance entre les bouts de la chaîne en solvant Θ, et $\alpha^2 = \langle L^2 \rangle / \langle L_0^2 \rangle$, on obtient:

$$\mu = [2(a + 1)]/3. \qquad [9]$$

Si on utilise plutôt la relation de Kurata et Yamakawa (30),

$$[\eta] = \phi \frac{\langle L_0^2 \rangle^{3/2}}{M} \alpha^{2.43}, \qquad [10]$$

on obtient:

$$\mu = [2(a + 0.715)]/2.43. \qquad [11]$$

En pratique les deux relations entre a et μ diffèrent très peu. En utilisant pour a la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

valeur 0.72 (31), on obtient pour μ 1.15 ou 1.18. Puisque les $P(\theta)$ correspondant à ces deux valeurs seront très peu différents, nous avons choisis d'utiliser 1.17.

Sur la Fig. 3, nous avons représenté l'ensemble des points expérimentaux, superposés à la courbe tirée de l'éq. [5], pour les six fractions étudiées. Pour plus de clarté nous avons pour chaque fraction successivement décalé la courbe et les points expérimentaux vers le bas. Sur la Fig. 3, les différentes courbes sont identifiées par le numéro de la fraction.

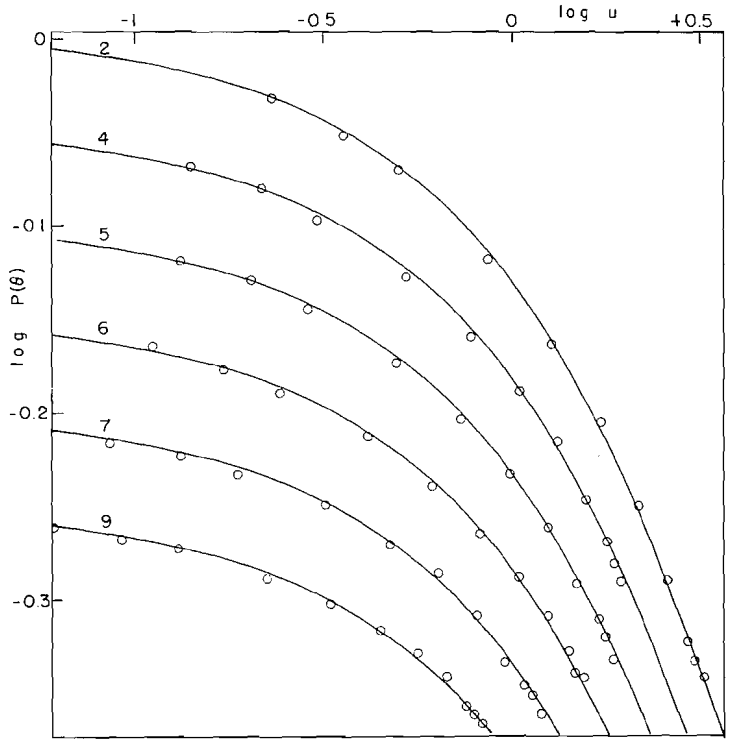

FIG. 3. Superposition de l'ensemble des résultats à la courbe théorique (éq. [5] pour μ = 1.17).

De la superposition des données expérimentales et de la courbe théorique, nous avons obtenu les valeurs de masses moléculaires et de rayons de giration rapportés au Tableau I. Nous avons également rapporté au Tableau I les valeurs de masses moléculaires et de rayons de giration obtenues à l'aide d'un diagramme de Zimm (éq. [2]).

TABLEAU I

Masses moléculaires et rayons de giration obtenus

	Masse moléculaire ($\times 10^{-5}$)		Rayon de giration (Å)		
Fraction	Éq. [5]	Éq. [2]	Éq. [5]	Éq. [2]	Éq. [3]
2	10.6	10.8	530	575	516
4	7.4	7.5	425	444	413
5	7.0	7.0	414	435	404
6	6.1	6.1	373	385	364
7	4.9	4.9	324	336	326
9	3.9	3.9	275	279	272

For personal use only.

On voit donc, comme il fallait s'y attendre, que l'utilisation de l'éq. [2] peut amener des erreurs importantes pour les hautes valeurs de rayons de giration, erreurs par contre qui ne sont pas apparentes à l'examen du diagramme de Zimm. Evidemment lorsque le rayon de giration est assez petit, les deux méthodes, éq. [2] et éq. [5], donnent des résultats identiques. A titre d'exemple, nous avons tracé à la Fig. 2, en médaillon, les données correspondant à la fraction 9. On voit que dans ce cas, avec les mêmes angles d'observation, la pente à l'origine se dessine très nettement, contrairement au cas de la fraction 2.

Plusieurs des déterminations apparaissant au Tableau I ont été reprises deux ou trois fois. Les résultats de rayon de giration obtenus de cette façon, pour une même fraction, en utilisant une fonction $P(\theta)$ donnée, sont cohérents à 1 ou 2% près; mais ceci ne peut évidemment pas être interprété comme étant la précision des mesures, puisqu'il peut se produire des erreurs systématiques.

On voit également au Tableau I que les masses moléculaires obtenues à l'aide de l'éq. [2] ou de l'éq. [5] ne diffèrent pas d'une façon significative.

Pour fins de comparaison, nous avons également déterminé les rayons de giration par superposition des données expérimentales à la fonction $P(\theta)$ de Debye (éq. [3]). On voit que la différence entre les résultats obtenus à l'aide de l'éq. [3] et à l'aide de l'éq. [5] sont faibles dans la région de u où nous sommes: la différence maximum est de 3% (fraction 2) ce qui dépasse à peine la cohérence des mesures. Cette faible différence n'est pas surprenante. En effet Debye a montré récemment (32) que l'éq. [3] se superpose aux données de diffusion en bons solvants, aux erreurs d'expérience près (5% près dans son cas), dans cette région de u où nous sommes. Nous pouvons reprendre la même affirmation, avec cette fois une précision de l'ordre de 1% sur les intensités de diffusion. Cette affirmation, et il faut le souligner, ne vaut évidemment que pour la région de u où nous avons travaillé. Aux plus hautes valeurs de u (11–19), on sait que l'équation de Debye (éq. [3]) ne se superpose plus aux données expérimentales, alors que l'équation de Péterlin (éq. [5]) semble être valide jusqu'à des valeurs de u très élevées.

CONCLUSION

La région d'utilisation de l'approximation de Zimm (éq. [2]) apparait comme étant très étroite. Dans le cas des macromolécules en chaînes, dès que le rayon de giration atteint quelques centaines d'angstroms, la pente à l'origine de la distribution angulaire d'intensité de diffusion n'est plus accessible directement avec les appareils courants, et ceci se produit bien avant que n'apparaisse une courbure évidente dans le diagramme de Zimm. En effet, pour les macromolécules en chaînes, spécialement en bons solvants, il semble que la fonction $P(\theta)$ soit telle que, dans une région assez étendue de u, on obtienne pratiquement des droites dont la pente cependant n'est pas nécessairement celle de l'éq. [2]. En conséquence, sauf pour les molécules relativement petites, il faut se donner à priori une fonction $P(\theta)$ pour pouvoir déterminer la rayon de giration des macromolécules en chaînes.

Dans le cas des bons solvants, il semble, aux erreurs d'expérience près, que l'approximation de Peterlin pour cette fonction $P(\theta)$, développée par Benoît et Ptitsyn, soit superposable aux données expérimentales. Evidemment cette fonction n'est qu'approchée en ce sens qu'elle ne tient pas compte de la perturbation qu'amène l'effet de solvant dans la loi statistique de distribution des distances entre chaînons, bien qu'elle tienne compte évidemment, et suivant une loi qui semble correcte, de l'allongement des distances moyennes sous l'influence du solvant. Mais comme on peut le voir à la Fig. 3, les résultats expérimentaux se superposent très bien à cette fonction $P(\theta)$, et il faut conclure que la précision des résultats ne permet pas de mettre en évidence cette perturbation, pas plus

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

dans la région de u où nous sommes que pour des valeurs de u plus élevées où ceci avait déjà été vérifié (13–16). Par ailleurs, non seulement cette perturbation n'apparait pas, mais le caractère non gaussien de la chaîne lui-même, qui apparait nettement aux valeurs élevées de u, ne semble pas se refléter appréciablement dans la forme de la fonction $P(\theta)$ dans la région étudiée. En effet l'équation de Debye et l'équation de Peterlin donnent des résultats presqu'identiques, alors que l'équation de Debye suppose une chaîne gaussienne et que l'équation de Peterlin tient compte, au moins partiellement, de l'écart au comportement gaussien.

D'autre part puisque, dans le présent travail, nous n'avons exploré pour chaque fraction qu'une zone relativement étroite de valeurs de u, il ne faut pas éliminer la possibilité d'erreurs systématiques introduites par l'utilisation de l'une ou l'autre fonctions $P(\theta)$. Pour le vérifier, nous nous proposons d'effectuer des mesures encore plus fines de variation angulaire d'intensité de diffusion et ce dans des intervalles de u plus étendus. Nous nous proposons également d'étudier l'effet de la polydispersité résiduelle de nos fractions sur la fonction $P(\theta)$. Pour le présent travail, nous avons en effet pris pour acquis que cette polydispersité était assez faible pour ne pas modifier appréciablement la fonction $P(\theta)$. Il ne s'agissait évidemment-là que l'une première approximation que nous nous proposons maintenant de vérifier.

REMERCIEMENTS

Nous tenons à exprimer nos remerciements au Docteur H. W. McCormick et à la maison Dow Chemical pour nous avoir fourni des échantillons de polystyrène. Nous remercions également le Conseil National des Recherches du Canada pour l'octroi d'une subvention de recherche (Y. S.) et d'une bourse (J. P.).

THE ANALYSIS OF THE VOLATILE OILS OF THE LEAVES OF ARTEMISIA MEXICANA AND ARTEMISIA KLOTZCHIANA[1]

A. MANJARREZ AND F. MEDINA
Instituto de Química, Universidad Nacional Autónoma de México, México, D.F.

Received March 23, 1964

ABSTRACT

The analysis of neutral and phenolic fractions of the essential oils from *A. mexicana* and *A. klotzchiana* by means of gas–liquid chromatography was attempted. The mixtures of neutral fractions were resolved using preparative g.l.c., and identification of components was made by chemical, spectrophotometric, and n.m.r. methods. The phenolic components were identified by means of relative retention ratios and addition methods. From *A. mexicana* (−) α-phellandrene, (+) limonene, (−) β-phellandrene, (−) camphor, (−) borneol, thymol, carvacrol, and eugenol were identified. From *A. klotzchiana* (−) α-phellandrene, (+) limonene, 1,8-cineole, (+) β-thujone, (−) camphor, (−) borneol, carvacrol, and eugenol were isolated.

INTRODUCTION

The study of the composition of the essential oils from numerous species of genus *Artemisia* have been described widely in the literature. So far as we are aware, the composition of essential oils from *A. mexicana* and *A. klotzchiana* has not yet been reported.

With the advent of preparative g.l.c. and its many attractive possibilities, we were provided with an analytical tool well suited to the separation and identification of the components of such essential oils.

It is difficult to resolve complex mixtures, as essential oils are, by direct analysis; therefore we separated the phenolic fraction (no acidic fraction was present) from the neutral portion for each oil and analyzed these fractions separately.

Successful separation of terpenoid compounds has been described in the literature. Among the most notable of these investigations were those of von Rudloff (1, 2, 3), Zubyk and Conner (4), Bernhard (5), and Cvrkal and Janák (6). From the data contained in the above communications and the nature of components isolated from another *Artemisia* species, it was concluded that for preparative g.l.c. of neutral fractions, the most promising stationary liquid phase would be ethyleneglycol adipate (APEG). Dimethyl polysiloxane has been reported by Navés and Grampoloff (7), as well as Janák and Komers (8) among others, to give good separation of phenolic mixtures. We choose Silicone D.C. 200 as the silicone type of stationary liquid phase for analysis of phenolic fractions of oils from both artemisias.

APPARATUS

An Aerograph Autoprep A-700 chromatograph (Wilkens Instrument and Research Inc.) was used in conjunction with a Leeds and Northrup, model H recorder (0–1 mV scale). The chart speed was 1.2 cm/min, and the flow rate of helium carrier gas was measured at the exit by the soap bubble method.

Samples of the neutral fractions were introduced on the column automatically without solvent, and phenolic samples were introduced on the column with a Walls liquid sampler (9). The column exhaust was at atmospheric pressure (750–752 mm), whereas the pressure at the column inlet was varied to give the desired flow rates.

[1]*Contribution No. 170 of Instituto de Química, Universidad Nacional de México.*
We are indebted to Dr. J. Valdéz Gutiérrez, from Jardín Botánico, U.N.A.M. for the classication of the Artemisia species.

Preparation of columns.—The solid support used in this work was Chromosorb W (Johns Manville Co.). This type of support is manufactured specifically for gas chromatography and was used without treatment except for removal of fines by water washing. Column packings were prepared by the usual method (4), using methylene chloride as solvent for both chemicals. Aluminum tubing 3/8 in. × 20 ft and 3/16 in. × 20 ft was filled with the dry, free-flowing packings (prepared as described above) by the vibrating-vacuum method (10). After the insertion of glass wool plugs in each end of the tubing, the columns were coiled to fit the Autoprep chromatograph. Conditioning was carried out by passing a stream of nitrogen through the columns while heating for several hours at 200 °C.

EXPERIMENTAL

Samples of *Artemisia* oils were obtained by steam distillation of the leaves and terminal branches of locally grown plants. Oils were dissolved in ether and extracted with 10% sodium bicarbonate solution and 10% sodium hydroxide solution to isolate the acidic and phenolic fractions respectively. The characteristics of essential oils are given in Table I.

TABLE I

Characteristics of essential oils

	A. mexicana	*A. klotzchiana*

Analysis of Neutral Fractions

Samples of neutral fractions were chromatographed on APEG under the following conditions.

Column—20 ft × 3/8 in. aluminum.
Packing—30% APEG on 60/80 Chromosorb W.
Column temperature—180 °C.
Gas flow rate—200 ml/min.
Injection—on column.
Sample size—200 μl.

The Autoprep was automated to repeat the cycle every 30 minutes.

After a small sample (5 μl) of every component had been injected to prove its purity and whether or not it had suffered thermal decomposition, tentative identification of the components was made by infrared and n.m.r.[2] determinations and checked by chemical derivatives, following directions reported in the literature (see Table II.)

Analysis of Phenolic Fractions

Samples of phenolic fractions were chromatographed on Silicone 200 D.C. under the following conditions.

Column—20 ft × 3/16 in. aluminum.
Packing—30% Silicone 200 D.C. on 60/80 Chromosorb W.
Column temperature—190 °C.
Gas flow rate—200 ml/min.
Injection—on column.
Sample size—10 μl.

Components were identified tentatively by relative retention times. These were checked by adding a synthetic mixture of phenols of approximately the same composition (11); comparison of the recorder-tracing with that of the sample mixture showed identical peaks and retention times.

[2]*Infrared spectra were determined on film with a Perkin–Elmer model 21 spectrophotometer, and the n.m.r. spectra were determined with a Varian A-60 instrument.*

*Retention time of limonene = 1.

RESULTS AND DISCUSSION

Results obtained from the analysis of the neutral fractions are given in Table II and those obtained from phenolic portions in Table III.

However, most essential oils, including those from *Artemisia* species, include, in addition to monoterpenes, components such as lactones, coumarins, sesquiterpenes, etc. (12). It is possible that higher-boiling components have not eluted and therefore are not considered as part of neutral or phenolic portions of either oil. From these considerations it appears that the composition area percentages in the tables listed above are relative and not absolute quantitative values. The areas under each peak were determined with a planimeter and not by weighing the different components separated. The reason for this procedure is that in order to obtain pure components, regions near the base line were not collected ("heart cutting"). There is another possible source of error in the weighing method: since a certain amount of carrier gas passes through the collector bottle during sample collection, it is bound to sweep away some component vapors (13).

TABLE III

Analysis of phenolic fraction from essential oils of *A. mexicana* and *A. klotzchiana*

milligram amounts permitted chemical and spectroscopic identification. (−) Camphor was found to be the main constituent of both oils, but the oil of *A. klotzchiana* also contained substantial amounts of (+) β-thujone. Phenolic fractions were very small, and components were identified by means of relative retention times and addition methods.

SYNTHESIS OF 1-PHENYLPROPYNE-2,3-$^{13}C_2$[1]

R. N. RENAUD AND L. C. LEITCH
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received April 9, 1964

ABSTRACT

A method of preparing the title compound from methyl-^{13}C iodide through acetophenone-2-^{13}C, 1-phenylethanol-2-^{13}C, styrene-2-^{13}C, styrene-2-^{13}C dibromide, and 1-phenylacetylene-2-^{13}C is described. The overall yield based on methyl-^{13}C iodide was 24%.

In connection with the measurement of the spin–spin coupling constants of certain C–C linkages by Bernstein and Frei (1), 1-phenylpropyne-2,3-$^{13}C_2$ with an isotopic abundance of 55% above normal in the marked positions was synthesized.

In a review of the literature up to 1958, Hurd and Tockman (2) record no suitable method for the preparation of 1-phenylpropyne labelled as indicated above. The synthesis reported in that paper is also inconvenient because it would involve the preparation of 1-phenylacetone-2,3-$^{13}C_2$. The method of Tripett and Gough (3), employing the pyrolysis of α-phenylacetonylidenetriphenylphosphorane, gave 1-phenylpropyne which was very impure and difficult to purify on a small scale.

For these reasons, 1-phenylpropyne-2,3-$^{13}C_2$ was synthesized by the reactions shown below.

$$C_6H_5MgBr + {}^{13}CH_3CN \rightarrow C_6H_5CO{}^{13}CH_3 \rightarrow C_6H_5CH(OH){}^{13}CH_3$$
$$C_6H_5CH(OH){}^{13}CH_3 \rightarrow C_6H_5CH{=}{}^{13}CH_2 \rightarrow C_6H_5CHBr{}^{13}CH_2Br$$
$$C_6H_5CHBr{}^{13}CH_2Br \rightarrow C_6H_5C{\equiv}{}^{13}CH \rightarrow C_6H_5C{\equiv}{}^{13}C{}^{13}CH_3$$

The preparation of the intermediates up to and including styrene dibromide by methods already reported requires no special comment.

We attempted initially to prepare 1-phenylpropyne from styrene dibromide in one step, by dehydrobromination with lithium amide in liquid ammonia followed by methylation of the phenylacetylene formed. The product was, however, contaminated with an appreciable amount of styrene. When the reaction was carried out in boiling tetrahydrofuran with only a slight excess of lithium amide the product then contained bromostyrene. However, in the presence of excess lithium amide and only a catalytic amount of ammonia in boiling tetrahydrofuran, a 60% yield of 1-phenylpropyne (98.5% pure as determined by vapor phase chromatography) was obtained, provided an excess of methyl iodide was employed. While this is a satisfactory method of preparing 1-phenylpropyne in one step from styrene dibromide, a rather large amount of expensive methyl-^{13}C iodide would be required to prepare the labelled compound. In other words the yield based on methyl iodide is quite low. Consequently, attempts to prepare 1-phenylpropyne in one step were abandoned and attention was directed to the preparation of phenylacetylene.

According to Vaughn, Vogt, and Nieuwland (6) phenylacetylene is obtained in 64% yield by dehydrobromination of styrene dibromide with sodamide in liquid ammonia. Campbell and Campbell (7) report yields of 47–52% in this same preparation. We have repeated the experiments of the authors cited above and observe the formation of appreciable amounts of styrene in this reaction. The similarity in boiling point and refractive

For personal use only.

index of phenylacetylene and styrene prevents the use of these physical constants as criteria of the purity of the phenylacetylene. The presence of styrene in the product was established by vapor phase chromatography of a sample in a Perkin–Elmer Fractometer on a type "O" column at 147°; styrene and phenylacetylene had retention times of 3.5 and 4 min respectively, with good resolution. The formation of olefins in this type of reaction had in fact been reported by Vaughn, Vogt, and Nieuwland (6), who found that stilbene dibromide gave an 83% yield of stilbene rather than diphenylacetylene. It seemed that the preparation of phenylacetylene might best be achieved in good yield by dehydrobromination with excess sodamide in anhydrous ether (or tetrahydrofuran) in the presence of traces of ammonia as described earlier. Phenylacetylene of 96% purity was in fact isolated in 90% yield by this method.

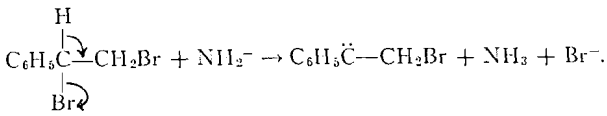
The cobaltous chloride catalyzed reaction between phenylethynyl bromide and methylmagnesium bromide is reported by Kharasch, Lambert, and Urry (4) to give a 62% yield of 1-phenylpropyne, but Black, Horn, and Weedon (5) obtained at best only a 34% yield. Our results agreed with those of Weedon and co-workers and this method was therefore abandoned. The methylation was then carried out with lithium amide in liquid ammonia, and methyl iodide in anhydrous ether. An 80% yield of 1-phenylpropyne, 97% pure, was obtained.

1-Phenylacetylene-2-^{13}C and 1-phenylpropyne-2,3-$^{13}C_2$ were prepared in exactly the same way from styrene-2-^{13}C dibromide and methyl-^{13}C iodide.

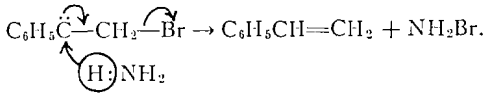
DISCUSSION

Conventional elimination mechanisms readily explain the formation of phenylacetylene from styrene dibromide and sodium amide but, to our knowledge, the formation of styrene in this reaction has not been explained. To rationalize this with both sodium amide and ammonia as reagents we suggest the following reactions.

(1) Proton abstraction to yield a methylene (9):



(2) In the absence of ammonia the methylene undergoes dehydrobromination to phenylacetylene, but in its presence addition of a hydride ion takes place and styrene is formed:



EXPERIMENTAL

Methyl-^{13}C Cyanide

The nitrile was prepared by the method of Cox, Warner, and Turner reported in *Organic Synthesis with Isotopes* (8, p. 40). Yield: 95%.

Acetophenone-2-^{13}C

The ketone was prepared as described by Brown, Cerwonka, and Anderson in *Organic Synthesis with Isotopes* (8, p. 664). Yield: 60%.

1-Phenylethanol-2-^{13}C

The alcohol was prepared by reducing the ketone with aluminum isopropoxide. Yield: 85%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Styrene-2-^{13}C

The alcohol was dehydrated as described by Berstein, Bennett, and Fields (8, p. 1686). Yield: 75%.

Styrene-2-^{13}C Dibromide

Styrene-2-^{13}C (1.2 g; 0.011 mole) was dissolved in 25 ml of chloroform, and a solution of 1.95 g of bromine, also dissolved in chloroform, was added. The dibromide, 3.0 g (93%), was recovered by distilling off the solvent.

1-Phenylpropyne

1. From Styrene Dibromide and Excess $LiNH_2$ in Liquid Ammonia

Lithium amide was prepared in the usual manner from 0.295 g of lithium and 10 ml of liquid ammonia in a flask equipped with a cold finger condenser, which was packed with dry ice and protected from moisture by a drying tube filled with Drierite. After the mixture had been stirred for 15 min, a solution of 3.7 g (0.014 mole) of styrene dibromide in 20 ml of anhydrous ether was added dropwise. The reaction mixture, which turned dark brown, was stirred for 3 h. Methyl iodide (2.3 g; 0.016 mole) in 20 ml of dry ether was added dropwise and the reaction mixture was stirred 2 h under reflux and allowed to stand overnight. In the morning it was decomposed with water. The ether solution was separated, dried over $MgSO_4$, and evaporated. The residue was distilled on the vacuum line and analyzed by vapor phase chromatography. The yield of 1-phenylpropyne was 38%, that of styrene 40%, and that of phenylacetylene 22.

A run with a 5 mole excess of lithium amide on the same scale gave an oil which analyzed 22% styrene, 50% phenylacetylene, and only 16% 1-phenylpropyne.

2. From Styrene Dibromide with an Equivalent Amount of $LiNH_2$ in Tetrahydrofuran (THF)

Styrene dibromide (3.58 g; 0.013 mole) was added in portions to 1.1 g (0.05 mole) of lithium amide in tetrahydrofuran and the reaction mixture was heated overnight under reflux with stirring. Methyl iodide (0.5 mole excess) was added to the reaction mixture at ambient temperature. Stirring was continued for 12 h, and then for 1 h under reflux. The tetrahydrofuran was distilled off on the steam bath, and the residue was taken up in ether before adding water. The reaction product was isolated as described in the preceding experiment. The main fraction of material distilled on the vacuum line contained 28.6% monobromostyrene and 27.4% styrene in addition to 33.4% 1-phenylpropyne.

3. From Styrene Dibromide with Excess $LiNH_2$ in Tetrahydrofuran, Traces of Ammonia, and Excess CH_3I

Lithium amide (1.7 g; 0.074 mole), prepared in the usual manner from lithium and liquid ammonia, was freed of solvent, and 40 ml of dry tetrahydrofuran was added. A trace of dry ammonia was bubbled through the mixture. Styrene dibromide (3.9 g; 0.015 mole) was added in portions over a period of 3 min. The reaction mixture was heated with stirring under reflux overnight. Dry methyl iodide (6.3 g; 0.045 mole) in dry tetrahydrofuran was added, and the reaction mixture was stirred at room temperature for 2 days. The solvent was distilled off on the steam bath, the residue was taken up in ether and worked up as described before. The yield of product, 98.5% pure, was 1.1 g (65%).

Anal. Calc. for C_9H_8: C, 93.1; H, 6.85. Found: C, 92.99; H, 6.83. There were traces of styrene and phenylacetylene in the product.

Phenylacetylene

Sodamide was prepared in the usual manner from 1.3 g of sodium (0.06 mole). The ammonia was removed by pumping the flask on the vacuum line. Anhydrous ether (50 ml) was added, and a trace of dry ammonia was bubbled through the mixture followed by a solution of 3.7 g (0.012 mole) of styrene dibromide dissolved in 10 ml of ether. The reaction mixture became reddish, turned dark brown, and then turned light brown. White solid LiBr was formed. After the mixture had stood overnight, 4.0 g of ammonium chloride in water was added. The phenylacetylene was isolated in the usual manner. The yield was 1.3 g (90%) of phenylacetylene, which analyzed 96% by vapor phase chomatography. A small amount of styrene was present as an impurity.

1-Phenylacetylene-2-^{13}C was prepared in exactly the same way.

1-Phenylpropyne

Lithium amide was prepared from 0.16 g (0.023 mole) of lithium (100% excess), 10 ml of liquid ammonia, and a trace of ferric nitrate. After the mixture had been stirred for 30 min, a solution of 1.0 g of phenylacetylene in 50 ml of absolute ether was added with stirring. This was followed by 1.6 g (0.011 mole) of methyl iodide in 25 ml of ether. The ammonia was allowed to evaporate overnight, and the reaction mixture was worked up as before. The yield of 1-phenylpropyne, 97% pure as determined by vapor phase chromatography, was 1.1 ml (80%) after purification by distillation on the vacuum line.

1-Phenylpropyne-2,3-$^{13}C_2$ was prepared in exactly the same way from 1-phenylacetylene-2-^{13}C. The overall yield based on methyl-^{13}C iodide was 24%.

ACKNOWLEDGMENTS

The authors are indebted to Dr. O. E. Edwards of this Division for suggesting the mechanism mentioned in the discussion.

ISOLATION AND SOME STRUCTURAL FEATURES OF A POLYSACCHARIDE FROM BIRCH SAP[1]

B. URBAS,[2] G. A. ADAMS, AND C. T. BISHOP
Division of Biosciences, National Research Council, Ottawa, Canada

Received April 29, 1964

ABSTRACT

A polysaccharide, precipitated by cetyltrimethylammonium hydroxide from the non-dialyzable portion of birch xylem sap, contained D-galactose, D-mannose, and D-glucose in a molar ratio of 2:1.4:1 and small amounts of D-glucuronic acid. Periodate oxidation studies indicated that the polysaccharide was branched and contained a high proportion of periodate-resistant monosaccharides. This was confirmed by methylation and hydrolysis which yielded 2,3,4,6-tetra-*O*-methyl-D-glucose (2.0 moles); 2,4,6-tri-*O*-methyl-D-mannose (0.9 mole); 2,4,6-tri-*O*-methyl-D-galactose (3.8 moles); unidentified tri-*O*-methyl hexose (1.2 moles); and 3,5-di-*O*-methyl-D-mannose (1.8 moles). The latter, a new di-*O*-methyl-D-mannose, showed the presence of D-mannofuranose units in the polysaccharide. This, together with the $1 \rightarrow 3$ linked α-D-mannopyranose units, makes this polysaccharide unique among plant products. Immunochemical tests with antipneumococcal and antiparatyphoid B horse sera confirmed the presence of D-glucuronic acid and D-glucopyranose non-reducing end groups and supported the other structural conclusions by showing that there were few, if any, $1 \rightarrow 4$ and $1 \rightarrow 6$ linked D-mannopyranose units or D-galactopyranose non-reducing end groups.

Until recently very little was known about the chemistry of wood saps, apart from the sucrose content of maple sap and the glucose and fructose contents of birch sap (1). Interest in the other constituents of these saps arose because it seemed possible that wood sap might contain intermediates or precursors in the synthesis of wood polysaccharides. Previous papers from this laboratory have described the isolation and structural investigation of a polysaccharide from maple sap (2, 3), analyses of the oligosaccharides present in birch (1) and maple (4) saps, and a study of the glycoside hydrolase activity in the xylem saps of birch and maple (5).

The present paper reports the isolation and structural investigation of a polysaccharide from the xylem sap of white birch (*Betula papyrifera* Marsh).

The polysaccharides, isolated from the non-dialyzable sap constituents by precipitation with ethanol, showed several peaks on moving-boundary electrophoresis (6) and yielded galactose, glucose, mannose, xylose, arabinose, rhamnose, and a uronic acid on acid hydrolysis. A polysaccharide that was homogeneous by electrophoresis and ultracentrifugation was obtained from this mixture by precipitation with cetyltrimethylammonium hydroxide (7). This polysaccharide, which made up 27% of the non-dialyzable material, contained D-galactose, D-mannose, and D-glucose in a molar ratio of 2:1.4:1 and 20% of hexuronic acid as estimated by the carbazole method (8). The small amount of hexuronic acid obtained by hydrolysis of the polysaccharide was converted to its parent monosaccharide by successive reduction and hydrolysis of its methyl ester, methyl glycoside. The chromatographic identification of glucose from this procedure indicated that the hexuronic acid was D-glucuronic acid, and this was confirmed by the immunological tests discussed below. In a similar way an aldobio- and aldotrio-uronic acid were partially characterized as a glucuronosylgalactose and a glucuronosylgalactosylmannose. The low yields of these uronic acid derivatives precluded more definitive characterizations.

[1]*Issued as N.R.C. No. 8047.*
[2]*National Research Council Postdoctoral Fellow 1961–1963.*

When the polysaccharide was oxidized by periodate, the moles of oxidant consumed and of formic acid produced per mole of anhydrohexose were 0.818 and 0.365 respectively. The oxidized polysaccharide was reduced and hydrolyzed (9); the hydrolysis products were reduced again to yield a mixture of sugar alcohols which were analyzed by gas–liquid chromatography (10, 11). The results, given in Table I, provide some

TABLE I

	% composition	
	Column 1*	Column 2†
Glycerol	33.1	36.5
Erythritol	6.2	6.0
Glucitol	2.7	2.6
Galactitol }	58.0	33.4
Mannitol }		21.4

*Gas–liquid chromatography of acetates on 8 ft × 1/4 in. column, 10% DCQF-1 (a fluorosilicone polymer) on acid-washed Chromosorb W, 100–120 mesh, 200 °C, 80 ml He/min.

†Gas–liquid chromatography of acetates on 4 ft × 1/4 in. column, 10% of ethylene glycol isophthalate polyester on Gas-Chrom Z, 100–120 mesh, 190 °C, 60 ml A/min.

information about the structure of the polysaccharide. Thus glycerol could arise from non-reducing terminal units or 1 → 2 or 1 → 6 linked units within the polysaccharide chains. However, of these three possibilities, only the 1 → 2 linked units would yield glycerol without also producing a mole of formic acid. The excellent agreement between the glycerol (0.365 mole per mole) and formic acid produced (0.365 mole per mole) strongly suggests that the glycerol was formed by oxidation and reduction of non-reducing terminal units or 1 → 6 linked residues. The oxidation of each such unit requires 2 moles of periodate, and the oxidation of a 1 → 4 linked hexose to yield erythritol in this procedure would require 1 mole of periodate. The amount of oxidant required by the products in Table I is therefore 0.790 mole, a value in good agreement with the 0.818 mole found experimentally. The small amount of glucitol present in these products (Table I) indicated that most of the glucose in the polysaccharide was linked through positions that permitted its oxidation by periodate. The converse was true for galactose and mannose: the large amounts of galactitol and mannitol indicated that most, if not all, of the parent monosaccharides were linked in the polysaccharide through positions which made them resistant to attack by periodate. These conclusions were supported and amplified by the results of methylation and hydrolysis which yielded the following neutral sugars; no acidic derivatives could be isolated.

2,3,4,6-Tetra-*O*-methyl-D-glucose	(2.0 moles)
2,4,6-Tri-*O*-methyl-D-mannose	(0.9 mole)
2,4,6-Tri-*O*-methyl-D-galactose	(3.8 moles)
Unidentified tri-*O*-methyl hexoses	(1.2 moles)
3,5-Di-*O*-methyl-D-mannose	(1.8 moles)

The only derivative of glucose found was the tetramethyl ether; the amount (20.6 mole %) was not sufficient to account for all of the glycerol produced on periodate

oxidation and reduction, but some of the very volatile tetramethyl ether may have been lost during evaporation. Glucose was the only tetra-*O*-methyl sugar found, and hence this sugar formed all of the non-reducing terminal units in the polysaccharide. The small amounts of $1 \rightarrow 4$ linked hexoses indicated by erythritol in Table I and the small amount of unoxidized glucose, indicated by glucitol, may possibly be accounted for in the unidentified tri-*O*-methyl fraction. The remaining *O*-methyl hexoses were derived from units that would resist periodate oxidation, and the total amount of such units (70 mole %) is not greatly different from that found by periodate oxidation (55–58 mole %), particularly since the former value is probably high because of the loss of tetra-*O*-methyl-D-glucose. The 2,4,6-tri-*O*-methyl-D-mannose and 2,4,6-tri-*O*-methyl-D-galactose represented the unbranched portions of the polysaccharide. The polysaccharide therefore consisted largely of $1 \rightarrow 3$ linked D-manno- and D-galacto-pyranose units, probably in the α-configuration because of the high positive specific rotation of the polysaccharide (+173°). The 3,5-di-*O*-methyl-D-mannose represented a branch point with a D-mannose unit substituted in positions 1, 2, and 6, *in the furanose ring form*. As far as the authors are aware, this is the first time that mannose has been found in the furanose form in a polysaccharide. 3,5-Di-*O*-methyl-D-mannose also does not appear to have been reported before. It is a crystalline product having melting point 126–127 °C and $[\alpha]_D^{21}$ +14.5° (*c*, 1.50% in water) and was characterized by successive reduction and periodate oxidation to yield 2,4-di-*O*-methyl-D-arabinose, identified as its crystalline anilide.

The results of cross-reactions of the birch sap polysaccharide in antipneumococcal and antiparatyphoid B horse sera (12) fully supported the structural features given above. Thus, reactions in types II and V antipneumococcal sera provided further evidence for the identity of the hexuronic acid as D-glucuronic and indicated that these units were present as non-reducing end groups. Reaction in type I antipneumococcal serum indicated the presence of either D-galacturonic acid or D-galactose; the latter is preferred because there was no chemical evidence of D-galacturonic acid in the polysaccharide. The weak reaction in type XIV antipneumococcal serum indicated few if any non-reducing end groups of D-galactose, and the weak reaction in antiparatyphoid B sera showed that the D-mannose is probably not linked by $1 \rightarrow 4$ and $1 \rightarrow 6$ glycosidic bonds. In fact, no non-reducing end groups of D-galactose could be found, nor was there any chemical evidence for $1 \rightarrow 4$ or $1 \rightarrow 6$ linked D-mannose units.

The results of periodate oxidation, methylation studies, and immunochemical tests revealed the main structural features of the birch sap polysaccharide. It consists of basic chains of $1 \rightarrow 3$ linked α-D-manno- and α-D-galacto-pyranose units. Branch points occur at mannofuranose units by linkages through the C-1, C-2, and C-6 positions. Some chains are terminated at the non-reducing end by D-glucuronic acid units linked to galactose units which are in turn linked to mannose units. All other non-reducing terminal units consist of D-glucose residues. Several of these features are unique among plant polysaccharides; thus, while $1 \rightarrow 3$ linked D-galactopyranose units form the basic structure of a large number of plant gums (13), neither D-mannofuranose units nor $1 \rightarrow 3$ linked α-D-mannopyranose units have been found in polysaccharides from plants. It is apparent, therefore, that this polysaccharide bears no resemblance whatsoever to the polysaccharides of birch wood or bark (14–16). The only possible way in which it could serve as a precursor or intermediate in the synthesis of wood or bark polysaccharides would be as a donor of monosaccharide residues in a transferase system.

The glucuronoglucomannogalactan that has been described formed 27% of the non-dialyzable material in birch sap. The remaining 73% was a complex mixture from which a small amount of an arabinogalactan has been isolated; it is not yet known if this resembles the rhamnoarabinogalactan isolated from maple sap (3).

EXPERIMENTAL

Paper chromatograms were run by the descending method on Whatman No. 1 paper in the following solvent systems (v/v ratio).

(A) Butan-1-ol:ethanol:water = 40:11:19.
(B) Pyridine:ethyl acetate:water = 1:2.5:2.5.
(C) Ethyl acetate:acetic acid:formic acid:water = 18:3:1:4.
(D) Butanone saturated with water.
(E) Benzene:ethanol:water:ammonia = 200:47:14:1.
(F) Butan-1-ol:pyridine:water = 10:3:3.

Paper electrophoreses were done on Whatman 3MM paper in 0.1 *M* sodium tetraborate at a potential gradient of 25 V/cm for 2 h. Sugars were detected on papers by *p*-anisidine hydrochloride (17) or alkaline silver nitrate (18) spray reagents. Evaporations were done at 35 °C under diminished pressure, melting points are corrected, and specific rotations are equilibrium values unless otherwise stated.

Isolation of Polysaccharide

Sap (620 l) was collected from white birch trees (*Betula papyrifera* Marsh) by tapping the xylem and was concentrated to 20 l before being poured into ethanol (80 l) with vigorous stirring. The precipitate which formed was centrifuged, washed with 80% ethanol, redissolved in water, and dialyzed against tap water for 48 h. The solution of non-dialyzable material was freeze-dried to yield the crude sap polysaccharides as a cream-colored powder (30 g; ash, 39.6%; N, 0.57%). Chromatographic examination (solvents B, C, and F) of an acid hydrolysate of this material showed the presence of galactose, glucose, mannose, xylose, arabinose, rhamnose, and a uronic acid. The crude polysaccharide preparation, which showed several peaks on moving-boundary electrophoresis (6), was passed over Amberlite IR-120 (H^+) exchange resin. Cetyltrimethylammonium hydroxide was added to the acidic solution until precipitation was complete (7). The sticky precipitate was centrifuged, washed thrice with water, dissolved in 1 *M* sodium chloride, and dialyzed against tap water for 18 h. The solution of non-dialyzable material was concentrated to a small volume, and the polysaccharide was precipitated by the addition of ethanol to a concentration of 70%. The polysaccharide (4.86 g; ash, 0.34%; N, nil) showed $[\alpha]_D^{22}$ +173° (*c*, 1.34% in 1% sodium hydroxide) and gave a single, sharp peak on moving-boundary electrophoresis in 0.5 *M* sodium tetraborate and on ultracentrifugation in the same solution or in 0.5 *M* sodium acetate. Acid hydrolysis of the purified polysaccharide yielded galactose, glucose, mannose, and uronic acid as shown by paper chromatography in solvents B, C, and F.

Neutral Sugars

The polysaccharide (250 mg) was hydrolyzed by 1 *N* sulphuric acid in a sealed tube at 100 °C for 15 h. The hydrolysate was deionized by Amberlite IR-120 (H^+) and Duolite A-4 (OH^-) exchange resins, and neutral sugars in the solution were separated by preparative paper chromatography in solvent B.

(a) D-*Glucose.*—The sirup (35 mg) showed $[\alpha]_D^{22}$ +51° (*c*, 1.2% in water) and yielded crystalline *N*(*p*-nitrophenyl)α-D-glucopyranosylamine, m.p. 182–184 °C (19).

(b) D-*Mannose.*—The sirup (38 mg) showed $[\alpha]_D^{22}$ +12° (*c*, 1% in water) and was converted to crystalline D-mannose phenylhydrazone, m.p. 194–196 °C (20).

(c) D-*Galactose.*—The sirup (60 mg) crystallized and was recrystallized from 80% ethanol to yield a product with m.p. 164–166 °C and $[\alpha]_D^{22}$ +80° (*c*, 1.9% in water).

Mixtures of each of these crystalline compounds with corresponding authentic samples had melting points that were not depressed.

For quantitative estimation the polysaccharide was hydrolyzed as described above, and the neutral sugars in the deionized hydrolysate were separated by paper strip chromatography in solvent B. The separated sugars were eluted from the paper with water and estimated colorimetrically (21, 22). The polysaccharide (15 mg) yielded glucose (3.119 mg), mannose (4.182 mg), and galactose (6.102 mg).

Uronic Acids

The purified birch sap polysaccharide contained 20% of hexuronic acid as determined by the carbazole method (8). Preliminary experiments showed that hydrolysis of the polysaccharide for periods longer than 6 h gave only traces of oligouronides. Two sets of hydrolysis conditions were therefore selected for preparation of the uronic acid and of the oligouronides.

(1) Uronic acid.—Polysaccharide (200 mg) was heated with 1 *N* sulphuric acid (10 ml) in a sealed tube at 100 °C for 15 h.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(2) Oligouronides.—Polysaccharide (200 mg) was heated with 1 *N* sulphuric acid (10 ml) under reflux at 97 °C for 6 h.

Both hydrolysates were adjusted to pH 6.0 by additions first of barium hydroxide and then barium carbonate. Barium sulphate was removed by filtration, and cations in the filtrate were adsorbed on a column of Amberlite IR-120 (H^+) exchange resin. Uronic acids were then adsorbed on Dowex 1-X4 (OH^-) exchange resin after which the resin was washed with water until a negative anthrone test showed that all sugars had been removed. Uronic acids were then eluted from the resin by 1 *N* sodium hydroxide and converted to the free acid form by removal of sodium ions on Amberlite IR-120 (H^+) exchange resin. Paper chromatography in solvent C showed that both hydrolysates contained a mixture of the same three components but in different amounts.

Hydrolysate	Component 1 *R*(glucose) = 0.83	Component 2, *R*(glucose) = 0.68	Component 3, *R*(glucose) = 0.28
1	++++	+	+
2	Trace	+++	+++

The three components were isolated by preparative paper chromatography in solvent C.

Component 1

The acid (19 mg), which had the same *R*(glucose) value in solvent C as glucuronic acid, was converted to its parent monosaccharide by successive methanolysis, reduction with lithium aluminum hydride, and hydrolysis. This procedure yielded only glucose, which was identified by its chromatographic properties.

Component 2

This acid appeared to be an aldobiouronic acid on the basis of its paper electrophoretic mobility in 0.025 *N* sodium bicarbonate in comparison with known oligouronides. Hydrolysis with 2 *N* sulphuric acid at 100 °C for 15 h yielded a uronic acid and galactose as shown by paper chromatography (solvent C). The aldobiouronic acid (12 mg) was converted to its methyl ester, methyl glycoside, and reduced to the neutral disaccharide glycoside by lithium aluminum hydride. Hydrolysis with 1 *N* sulphuric acid yielded glucose and galactose as shown by paper chromatography in solvent B. The aldobiouronic acid must therefore have been a glucuronosylgalactose.

Component 3

Acid hydrolysis of this product yielded a uronic acid and approximately equal amounts of galactose and mannose. Paper electrophoretic mobility indicated that this component was an aldotriouronic acid. Reduction of the methyl ester, methyl glycoside, by lithium aluminum hydride yielded the glycoside of a neutral trisaccharide which on hydrolysis gave galactose, mannose, and glucose in equal amounts. Reduction of the original aldotriouronic with sodium borohydride followed by acid hydrolysis yielded mannitol, galactose, an aldobiouronic acid, and glucuronic acid. These results showed that component 3 was a glucuronosylgalactosylmannose.

Periodate Oxidation

The purified birch sap polysaccharide (100 mg) was oxidized by 0.33 *M* sodium metaperiodate (10 ml) at 5 °C in the dark. Aliquots were removed at intervals for estimation of periodate (23) and formic acid (24). The results are given below in moles per anhydrohexose unit.

Time (h)	24	48	72	96	120
Periodate	0.618	0.748	0.787	0.794	0.818
Formic acid	0.172	0.265	0.321	0.346	0.365

In a separate experiment a sample (100 mg) of the polysaccharide was oxidized as above, excess periodate was destroyed by ethylene glycol, and the mixture was dialyzed. The non-dialyzable material was then reduced with sodium borohydride and hydrolyzed by 1 *N* sulphuric acid (9). The neutralized hydrolysate was evaporated to a sirup which was again reduced with sodium borohydride. Examination of the reduced products by paper chromatography (solvent A) revealed the presence of galactitol, mannitol, erythritol, glycerol, and traces of glucitol and uronic acid. The mixture of alcohols was acetylated and examined by gas–liquid chromatography (10, 11) on two different liquid phases; the results are shown in Table I. Quantitative estimations were made from the areas under the peaks given by the individual components. The results from the two ion-exchange columns were in reasonable agreement, although column 1 failed to give a separation of galactitol from mannitol.

Methylation

The polysaccharide (4.0 g) was methylated eight times with dimethyl sulphate and 45% sodium hydroxide (25), then a further four times with the same reagents but in 80% dioxane solution. The product was recovered by extraction into chloroform, and the extract was dried (anhydrous sodium sulphate) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

evaporated. The oily residue was dissolved in methanol (100 ml), the solution was poured into an ethereal solution (150 ml) of diazomethane (prepared from 12 g of nitrosomethylurea), and the mixture was kept at 5 °C for 18 h. The precipitate which formed was filtered off, washed with ether, and dried (2.09 g). Anal. Calc. OCH_3: 45.6%. Found: 44.5%. The methylated polysaccharide had $[\alpha]_D^{24}$ +138° (*c*, 0.80% in chloroform) and showed no hydroxyl absorption in the infrared.

The methylated polysaccharide (2.0 g) was dissolved in 72% sulphuric acid (10 ml) and left for 1 h (26). The reaction mixture was diluted with water (90 ml) and heated for 20 h at 100 °C. The solution was neutralized with barium carbonate, filtered, and passed first through a column of Amberlite IR-120 (H^+) exchange resin and then through one of Duolite A-4 (OH^-). The eluate was evaporated to give the neutral *O*-methyl monosaccharides as a sirup (1.4 g).

Products recovered from the Duolite A-4 (OH^-) resin were shown to contain the same partially methylated sugars as were found in the neutral fraction, and no acidic components could be isolated or distinguished.

Hydrolysis Products from Methylated Polysaccharide

The mixture of *O*-methyl monosaccharides (1.4 g) was resolved by chromatography on a cellulose column (6 × 50 cm) with solvent D as eluant. Fractions (15 ml) were collected automatically every 15 min and were analyzed by paper strip chromatography; the results are shown in Table II.

TABLE II

Hydrolysis products from methylated polysaccharide

Fraction	Tube No.	Yield (mg)	Components identified
1	20–34	243.2	2,3,4,6-Tetra-*O*-methyl-D-glucose
2	39–59	250.2	2,4,6-Tri-*O*-methyl-D-mannose
3	67–91	417.1	2,4,6-Tri-*O*-methyl-D-galactose
4	102–134	184.7	3,5-Di-*O*-methyl-D-mannose

Fraction 1

This product (243.2 mg) crystallized spontaneously and had m.p. 88–92 °C and $[\alpha]_D^{23}$ +79° (*c*, 1.24% in water). Demethylation with boron trichloride (27) gave glucose. It was chromatographically identical, in solvents A, D, and E, with 2,3,4,6-tetra-*O*-methyl-D-glucose and after recrystallization from ether:light petroleum (1:1) had m.p. 92–95° and $[\alpha]_D^{23}$ +85° (*c*, 1.53% in water). The derived *N*-phenyl 2,3,4,6-tetra-*O*-methyl-D-glucosylamine had m.p. 136–137 °C in agreement with the reported value (28).

Fraction 2

This fraction (250.2 mg) yielded glucose and mannose with minor amounts of galactose when demethylated. Paper chromatography in solvent F revealed two components with R_f 0.64 and 0.55; these were separated by preparative paper chromatography in the same solvent. The first component (R_f 0.64, 132 mg) yielded glucose, mannose, and galactose on demethylation and attempts to resolve the mixture further by paper, thin-layer, or gas–liquid chromatography were unsuccessful.

The second component (R_f 0.55, 100 mg) had the same chromatographic properties in solvents A, D, and E as an authentic sample of 2,4,6-tri-*O*-methyl-D-mannose. The sirup crystallized spontaneously and after recrystallization from ether had m.p. 62–65 °C and $[\alpha]_D^{21}$ +17° (*c*, 1% in water). These values are the same as those reported (29), and the melting point of a mixture with an authentic sample was not depressed. Oxidation of the tri-*O*-methyl-D-mannose with bromine and distillation of the product yielded 2,4,6-tri-*O*-methyl-D-mannonolactone, m.p. 95–97 °C. This lactone, on successive treatments with methanolic hydrogen chloride and methanolic ammonia, gave crystalline 2,4,6-tri-*O*-methyl-D-mannonamide (30), m.p. 145 °C and $[\alpha]_D^{22}$ +6° (*c*, 1.0% in water).

Fraction 3

This product (417.1 mg) had the same chromatographic properties as an authentic sample of 2,4,6-tri-*O*-methyl-D-galactose in solvents A and D. Methyl glycosides of this component showed the same retention times as methyl 2,4,6-tri-*O*-methyl α,β-D-galactoside, and demethylation (27) yielded only galactose. The tri-*O*-methyl-D-galactose crystallized spontaneously, m.p. 90–98 °C, and recrystallization from ether yielded colorless needles of 2,4,6-tri-*O*-methyl-D-galactose (31), m.p. 102–104 °C, $[\alpha]_D^{23}$ +92.5° (*c*, 1.88% in water). The derived *N*-phenyl 2,4,6-tri-*O*-methyl-D-galactosylamine (32, 33) had m.p. 172–174 °C, undepressed on admixture with an authentic sample.

Fraction 4

This component (184.7 mg) yielded only mannose on demethylation. It was homogeneous by paper chromatography (solvents A, D, and E) and by paper electrophoresis in borate buffer (34), having an *M*(glucose) value in the latter of 0.56. The compound gave a reddish-brown color with the *p*-anisidine spray reagent. Anal. Calc. for a di-*O*-methyl hexose OCH_3: 29.8%. Found: 30.1%. The di-*O*-methyl-D-mannose crystallized and after recrystallization from ethyl acetate had m.p. 126–127 °C and $[\alpha]_D^{21}$ +14.5° (*c*, 1.58% in water).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The di-*O*-methyl mannose (30 mg) was reduced with sodium borohydride (35), and the sirupy di-*O*-methyl-D-mannitol was oxidized by sodium metaperiodate. The oxidation was complete after 6 h, with an oxidant consumption of 0.93 moles per mole di-*O*-methyl-D-mannitol. The mixture was deionized by exchange resins and evaporated to a sirup (16.8 mg) which showed the same chromatographic behavior in solvents A, D, and E as an authentic sample of 2,4-di-*O*-methyl-L-arabinose. The specific rotation of this product, −87.5° (*c*, 1.68% in methanol) was of the same magnitude, but of opposite sign, as that reported for 2,4-di-*O*-methyl-L-arabinose (36). The derived *N*-phenyl 2,4-di-*O*-methyl-D-arabinosylamine had m.p. 134–135 °C after recrystallization from ethanol. The reported melting points for the L-enantiomorph of this compound are 145 °C (36) and 126 °C (37). The X-ray diffraction pattern of the unknown was identical with that of an authentic specimen (38) of the L-enantiomorph having m.p. 142–144 °C.

Immunochemical Tests

The purified birch sap polysaccharide was tested for cross-reactions in antipneumococcal horse sera types I, II, V, and XIV and in antiparatyphoid B horse serum (12). Portions of sera (1 ml) were mixed in the cold with 0.05 mg of polysaccharide in 0.9% sodium chloride (1 mg of polysaccharide per ml of 0.9% sodium chloride). First readings were taken after 6–7 days; second readings were taken a further 6–7 days after addition of another 0.15 mg of polysaccharide. The results are shown in Table III.

MAGNETIC SUSCEPTIBILITIES OF SOME COMPOUNDS OF SILICON

M. W. Lister and R. Marson
Department of Chemistry, University of Toronto, Toronto, Ontario
Received April 17, 1964

ABSTRACT

Magnetic susceptibility measurements are reported for a number of derivatives of silicon of general formula $SiR_aH_bX_c$, where R is an alkyl group and X is a halogen. The results are compared with earlier measurements on similar compounds of carbon and show deviations from additivity that can be interpreted in terms of bond interactions. The interactions, in general, are less for compounds of silicon than they are for compounds of carbon.

The magnetic susceptibilities of halogenated methanes have been examined in detail by Lacher, Scruby, and Park (1), who showed that the susceptibilities deviated somewhat from additivity in terms of the atoms contained in the compound. They obtained reasonable agreement with experiment if they included terms in their calculated susceptibilities arising from the interactions of various pairs of bonds. These terms were, in general, paramagnetic and they associated them with the paramagnetic term in Van Vleck's equation for diamagnetic susceptibility (2).

A more rigorous derivation of essentially the same equation as used by Lacher was given by Hameka (3). Hameka's equation may be most briefly written as follows:

$$\chi_M = \Sigma\chi(\text{atoms}) + \Sigma\chi(\text{bonds}) + \Sigma\chi(\text{bond interactions}).$$

Here χ_M is the molar susceptibility of the compound, and this is made up from terms for (i) each atom, (ii) each bond, and (iii) each interaction between any two bonds starting from the same atom. Of course, the sizes of the terms depend on the atoms involved. The interaction term is in general paramagnetic and, though introduced somewhat differently, is in effect the same as Lacher's paramagnetic term.

Lacher *et al.* observed that interactions between halogens increased with their size, as would be expected if large neighboring atoms modified each other's electron clouds. The present work is concerned with the susceptibilities of a similar series of compounds of silicon, the silicon being attached to various combinations of hydrogen, chlorine, bromine, iodine, or alkyl groups. Since silicon is a larger atom, it would be expected that the interactions would be less. However, it is well known that silicon–halogen distances are shorter than the sums of the covalent radii, to an extent not found in carbon compounds, the deviation being least for silicon–iodine bonds. If this is caused by partial double bonding, it should decrease the magnetic susceptibilities. The susceptibilities of the silicon compounds were compared with the carbon compounds to see whether such an effect could be detected.

As a knowledge of the molar volumes is required to convert the initially measured volume susceptibilities to molar susceptibilities, the densities of a number of silicon compounds were also measured.

EXPERIMENTAL

Preparation of Compounds

Silicon tetrachloride was fractionally distilled in a stream of nitrogen, and the middle fraction (20 ml out of an initial 150 ml) was used. This boiled at 57.3 °C, in agreement with previous values (4).

Silicon tetrabromide was prepared by passing a mixture of bromine vapor and nitrogen over heated ferrosilicon. The product was refluxed over mercury and then fractionally distilled to give a colorless middle fraction boiling at 152.5 °C. The freezing point, 5.6 °C, remained constant after recrystallization. Ferrosilicon was used, as it was found that pure silicon was not attacked under these conditions.

Silicon tetraiodide was similarly prepared by passing iodine vapor and nitrogen over ferrosilicon at a dull-red heat. The product was dissolved in carbon disulphide, shaken with mercury, and then fractionally distilled at low pressure. The middle fraction was very pale pink and melted at 122.5 °C, in agreement with earlier values (4) ranging from 120 to 123.8 °C.

Trichlorosilane, from the Anderson Chemical Co., was fractionally distilled in nitrogen, and the middle fraction (20 ml out of 300 ml) was used. It boiled at 32 °C. McKenzie, Mills, and Scott (5) give 31.8 °C.

Methyldichlorosilane, from the Anderson Chemical Co., was fractionated under vacuum, and the middle fraction (20 ml out of 300 ml) boiled at 40.9 °C. Gmelin (6) gives 40.7 °C.

Ethyldichlorosilane, from the Anderson Chemical Co., was fractionated under vacuum, and the middle fraction (20 ml out of 250 ml) boiled at 75.2 °C. McKenzie *et al.* (5) give 74.9 °C.

Dimethyldichlorosilane, from the Anderson Chemical Co., was fractionally distilled, and the middle fraction (20 ml out of 400 ml) boiled at 70 °C, in agreement with previous values (6).

Trimethylchlorosilane, from the Anderson Chemical Co., was fractionally distilled to give a middle fraction (20 ml out of 600 ml) boiling at 57.5 °C, in agreement with previous results (6).

Triethylchlorosilane was prepared by treating tetraethyl orthosilicate with ethyl magnesium bromide in ether in the molar ratio of 1 to 3. This was found to give a better yield than with excess Grignard reagent as recommended by di Giorgio *et al.* (7). The mixture was refluxed until it no longer gave the Gilman test for a Grignard reagent. The ether was distilled off, and the solid residue heated for 2 days on a steam bath.

$$Si(OC_2H_5)_4 + 3C_2H_5MgBr \rightarrow SiOC_2H_5(C_2H_5)_3 + 3C_2H_5OMgBr.$$

The residue is triethylethoxysilane, and it was added to dilute sulphuric acid at 0 °C to give hexaethyldisiloxane, $(C_2H_5)_3SiOSi(C_2H_5)_3$. This was extracted with ether, dried over calcium chloride, and fractionally distilled under vacuum. It was then dissolved in concentrated sulphuric acid, and ammonium chloride was added in the molar ratio of 1 to 2. The triethylchlorosilane so formed was extracted with hexane and distilled. It was finally distilled under vacuum to give a product boiling at 145 °C (Gmelin (6) gives 143 to 145 °C). This was fractionally distilled once more to give the final sample.

Trimethylbromosilane was prepared from trimethylchlorosilane, which was first hydrolyzed in boiling water under reflux. The hexamethyldisiloxane so formed was separated, dried over calcium chloride, and distilled. It was sealed into a wide pyrex tube with phosphorus tribromide in the molar ratio of 1 to 1.7, with 0.25 g of ferric chloride as catalyst (8). The mixture stood for 1 day and was then fractionally distilled under vacuum. The product boiled at 79.5 to 80 °C (Gmelin (6) gives 79.5 °C) and was used after one more fractional distillation.

Methyltribromosilane was prepared by McCusker and Reilly's method (9) from silicon tetrabromide and methyl magnesium iodide. The product was distilled several times to give a main fraction boiling at 132–134 °C (Gmelin (6) gives 133.5 °C), which, after one more fractionation, was used for magnetic measurements.

Ethyltribromosilane was prepared by the same method using ethyl magnesium bromide. Repeated fractional distillation gave a product with a constant boiling point of 157 °C.

Trimethyliodosilane. Attempts to prepare this from hexamethyldisiloxane, potassium iodide, and phosphoric acid were unsuccessful, though other halosilanes can be prepared by analogous reactions (10). The method used was a modification of that of Voronkov and Khudobin (11), who refluxed hexamethyldisiloxane with iodine and aluminum granules. It was found that amalgamated aluminum was much more effective, and that it was better to add the iodine gradually in small portions. The molar ratios used were 1.0 of disiloxane, 1.1 of aluminum and 1.5 of iodine. Reflux distillation was continued until the condensate was colorless, and the mixture was then distilled. The product was redistilled over copper filings, in the absence of light which caused decomposition.

Another method, similar to that of Eaborn (12) was also used. Tetramethylsilane and iodine in equimolar amounts were refluxed together for 10 h. Small amounts of amalgamated aluminum were added at intervals to produce aluminum iodide, which acts as a catalyst. Traces of unreacted iodine were then removed by copper filings, and the product was distilled.

The combined products of both methods were fractionally distilled under vacuum to give a colorless middle fraction, boiling at 107–108 °C (Gmelin (6) gives 107 °C).

Triethyliodosilane. Hexaethyldisiloxane, prepared by di Giorgio's method (7), was refluxed under nitrogen with iodine, in a molar ratio of 2 to 3. Freshly amalgamated aluminum was added in the ratio of 1.1 g-atom per g-mole of disiloxane, the method being a modification of that of Voronkov and Khudobin (11). After refluxing, the product was distilled off under vacuum and redistilled over copper filings to give a crude product boiling at 190–195 °C.

Since the yield was only moderate, a preparation similar to that of Eaborn (12), above, was carried out using silicon tetraethyl. The combined products were twice fractionally distilled to give a middle fraction boiling at 192–193 °C (Anderson (13) gives the b.p. as 193 ± 1 °C).

For personal use only.

Dimethyldiiodosilane was prepared by refluxing trimethyliodosilane with equimolar amounts of iodine in an atmosphere of nitrogen (12).

$$(CH_3)_3SiI + I_2 \rightarrow (CH_3)_2SiI_2 + CH_3I.$$

Amalgamated aluminum was again added as a catalyst. The product was distilled, decolorized by copper filings, and redistilled under nitrogen in the absence of light. Redistillation gave a constant boiling product of b.p. 167 °C. This is a little lower than the previously reported value of 170–171 °C. A further vacuum distillation was carried out, and the middle fraction used.

Ethyltriiodosilane was prepared by Anderson's method (13) from ethyltrichlorosilane. The resulting solution was treated with copper filings and distilled under vacuum. The product was redistilled in a nitrogen atmosphere to give a middle fraction with a constant b.p. of 246 °C (Anderson gives 250 ± 1 °C). It was redistilled under vacuum and the middle fraction used.

Tetramethylsilane, from the Anderson Chemical Co., was distilled to give a middle fraction, b.p. 26 °C (Gmelin (6) gives 26.2 °C).

Tetraethylsilane was obtained similarly, and gave a middle fraction, b.p. 154.5 °C.

Density Measurements

These were made by weighing pycnometers of conventional design, with precautions against evaporation. The results are given in Table I. In other cases reliable values were available in the literature, as noted in Table I, and these were used.

TABLE I

Compound	Density, g/ml at 25 °C	Molar susceptibility[a] Obs.	Calc.

Magnetic Susceptibility Measurements

These were made as outlined in a previous paper (14). The standard substance was benzene, carefully freed from oxygen. It was assumed to have a volume susceptibility of -0.6187×10^{-6} e.m.u. per ml, as determined by Eggleston, Evans, and Richards (15).

In every case the susceptibility tube was filled by vacuum distillation, and, when full, nitrogen was admitted up to 1 atm.

The results are given in Table I.

DISCUSSION OF RESULTS

Relevant values for other compounds in the literature are: $(C_2H_5)_2SiCl_2$, 105.8; CH_3SiCl_3, 87.45; $C_2H_5SiCl_3$, 98.84 (20); SiH_4, 20.4 (21).

The equation of Hameka (3) quoted above can be expressed in terms of the following parameters for a compound of formula $SiR_aH_bX_c$, where R is an alkyl group and X is a halogen.

$$\chi_M = aA + bB + cC + abU + acV + bcW.$$

Here a, b, and c are the numbers of the atoms or groups present, and A, B, C, U, V, and W are parameters related to Hameka's various terms as explained below.

The parameter A is given by:

$$A = 0.25\chi(\mathrm{Si}) + \chi(\mathrm{R}) + \chi(\mathrm{Si—R}) + 1.5\chi\left(\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{R}\\ \diagdown\mathrm{R}\end{smallmatrix}\right)$$

where $\chi(\mathrm{Si})$ and $\chi(\mathrm{R})$ are the contributions of the silicon atom and the group R, $\chi(\mathrm{Si—R})$ is the contribution of the Si—R bond, and $\chi\left(\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{R}\\ \diagdown\mathrm{R}\end{smallmatrix}\right)$ is the term due to the interactions of two Si—R bonds to the same silicon. In the same notation,

$$B = 0.25\chi(\mathrm{Si}) + \chi(\mathrm{H}) + \chi(\mathrm{Si—H}) + 1.5\chi\left(\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{H}\\ \diagdown\mathrm{H}\end{smallmatrix}\right),$$

$$C = 0.25\chi(\mathrm{Si}) + \chi(\mathrm{X}) + \chi(\mathrm{Si—X}) + 1.5\chi\left(\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{X}\\ \diagdown\mathrm{X}\end{smallmatrix}\right),$$

$$U = \chi\left(\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{R}\\ \diagdown\mathrm{H}\end{smallmatrix}\right) - 0.5\chi\left(\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{R}\\ \diagdown\mathrm{R}\end{smallmatrix}\right) - 0.5\chi\left(\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{H}\\ \diagdown\mathrm{H}\end{smallmatrix}\right),$$

$$V = \chi\left(\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{R}\\ \diagdown\mathrm{X}\end{smallmatrix}\right) - 0.5\chi\left(\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{R}\\ \diagdown\mathrm{R}\end{smallmatrix}\right) - 0.5\chi\left(\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{X}\\ \diagdown\mathrm{X}\end{smallmatrix}\right),$$

$$W = \chi\left(\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{H}\\ \diagdown\mathrm{X}\end{smallmatrix}\right) - 0.5\chi\left(\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{H}\\ \diagdown\mathrm{H}\end{smallmatrix}\right) - 0.5\chi\left(\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{X}\\ \diagdown\mathrm{X}\end{smallmatrix}\right).$$

As regards the difference between methyl and ethyl compounds, the same treatment leads to the conclusion that there will be a certain increment in susceptibility on replacing a methyl by an ethyl group, but none of the other parameters will be altered. In effect A is increased, but U and V are unchanged.

The data in Table I give an average value of 11.5 for this increment from methyl to ethyl, and this makes $A = 18.6$ for methyl groups. The susceptibility of silane quoted above (21) makes $B = 5.1$, and if we take C from the various tetrahalides we can calculate average values for the other parameters. The results are:

Halogen	C	V
Cl	21.85	0.6
Br	30.85	1.5
I	46.55	0.6

In addition $SiHCl_3$ makes W for chlorine approximately zero, and the two compounds $SiRHCl_2$ make $U = -1.4$. These numbers are used to calculate the susceptibilities given in the last column of Table I; and for the compounds quoted above from the literature, the values are: $(C_2H_5)_2SiCl_2$ obs. 105.8, calc. 106.3; CH_3SiCl_3, obs. 87.45, calc. 86.0; $C_2H_5SiCl_3$ obs. 98.85, calc. 97.5. The average deviation between calculated and observed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

values is 0.52 or 0.47%. It cannot be claimed that the results demonstrate that the silicon compounds follow Hameka's equation; but if they do, the various parameters have the value given above.

Corresponding measurements on carbon compounds (1, 21, 22) fit the following constants: $A = 15.75$, $B = 4.35$, $U = 0.50$, and values of C and W for various halogens are:

Halogen	C	W
F	9.8	−1.65
Cl	16.7	1.1
Br	23.4	2.4
I	33.9	3.8

These are larger interaction parameters than for silicon compounds, especially when it is borne in mind that W values are for interactions between hydrogen and halogen.

Lacher, Scruby, and Park (1) deduce the individual interaction terms by calculating atomic susceptibilities using Slater-type orbitals, with some correction for the effect of bonding. These, coupled with the observed susceptibilities, enable them to obtain values for the interaction terms, such as $\chi(C\langle^{H}_{H})$, and they note that these are all negative (or paramagnetic). Their results depend on a value of 12.7 for the susceptibility of methane and more recent work (21) has given a higher value of 17.4, which would considerably change the estimate of $\chi(C\langle^{H}_{H})$.

However, some comparison can be made. If we take the atomic susceptibility for carbon, 7.84, as calculated by Angus' method (23), and use Lacher, Scruby, and Park's values for halogens (with bond depressions), the interaction terms are found to be $\chi(C\langle^{Cl}_{Cl}) = -3.0$, $\chi(C\langle^{Br}_{Br}) = -6.0$, and $\chi(C\langle^{I}_{I}) = -8.9$, in the expected order. From the W values, if we assume $\chi(C\langle^{H}_{H})$ to be negligibly small, we get $\chi(C\langle^{H}_{Cl}) = -0.4$, $\chi(C\langle^{H}_{Br}) = -0.6$, and $\chi(C\langle^{H}_{I}) = -0.7$, again forming a reasonable sequence. Similarly for silicon, Angus' method gives an atomic susceptibility of 22.3, and using the same halogen values we get: $\chi(Si\langle^{Cl}_{Cl}) = -2.0$, $\chi(Si\langle^{Br}_{Br}) = -3.5$, and $\chi(Si\langle^{I}_{I}) = -2.9$. These are less than the carbon series but the iodine term seems unduly low. The V values only enable us to determine $\chi(Si\langle^{CH_3}_{X}) - \chi(Si\langle^{CH_3}_{CH_3})$, which for various halogens has the values: Cl, −0.4; Br, −0.3; I, −0.9. Presumably $\chi(Si\langle^{CH_3}_{CH_3})$ is less than $\chi(Si\langle^{Cl}_{Cl})$ as the atoms are smaller, and this would make the $\chi(Si\langle^{CH^3}_{X})$ values also fairly small. Consequently these comparisons support the idea that interactions are less if the central atom is relatively large. There is no indication of possible double bonding between a halogen and the central silicon atom, which presumably would lead to relatively large paramagnetic terms with chlorine.

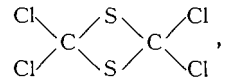
FAR INFRARED AND RAMAN SPECTRA AND STRUCTURE OF DITHIOPHOSGENE[1]

W. K. BUSFIELD,[2] M. J. TAYLOR,[3] AND E. WHALLEY
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received April 2, 1964

ABSTRACT

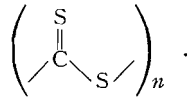
The infrared spectrum in the range 3000–50 cm^{-1} and the Raman spectrum of solutions of dithiophosgene have been obtained. There are no coincidences in the infrared and Raman spectra, and the only structure consistent with this and approximately tetrahedral carbon valencies is



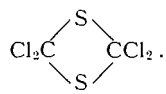
that is tetrachloro-1,3-dithietane, in which the ring is planar or nearly planar. A tentative assignment of the observed bands is given on the basis of D_{2h} symmetry.

1. INTRODUCTION

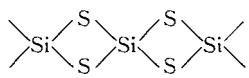
Carbon disulphide polymerizes under high pressure to a black substance (1) that has essentially the structure (2)



Thiophosgene Cl_2CS might be expected to form a similar polymer, and attempts have been made in this laboratory to polymerize it at pressures up to 20 kbar. No polymer was obtained, the thiophosgene being converted to the dimer, which had previously been made (3) by irradiation of thiophosgene with ultraviolet light. Although direct evidence was lacking, it was suggested (3) that the dimer had the structure



Silicon disulphide has a polymeric chain structure



in which alternate four-membered rings are at right angles to one another. It seems likely that carbon disulphide can exist in a similar structure and might be converted to it by applying a high enough pressure. When the work reported in this paper was done, no unambiguous proof of structure of a ring  had been obtained, and only an incomplete investigation of the infrared spectrum of dithiophosgene (4) without a detailed discussion had been made. An attempt has been made therefore to verify the structure by

[1]*N.R.C. No. 8048.*
[2]*N.R.C. Postdoctoral Fellow 1960–62.*
[3]*N.R.C. Postdoctoral Fellow 1961–62.*

investigating the infrared and Raman spectra. Since this work was completed, the infrared and Raman spectra of the fluorinated analogue of dithiophosgene have been reported (5) and its structure confirmed.

2. EXPERIMENTAL METHODS AND RESULTS

Dithiophosgene was prepared as colorless crystals by the action of ultraviolet light on thiophosgene, and was purified by repeated vacuum sublimation.

The Raman spectrum was obtained by examination of approximately 5 ml samples of saturated solutions in carbon tetrachloride, chloroform, and benzene. By use of these three solvents the possibility of any additional lines being masked by solvent frequencies was eliminated. The exciting line was Hg 4358 Å from a Toronto-type mercury arc, isolated by a filter of saturated aqueous sodium nitrite solution. The spectra were recorded photographically by means of a Hilger E612 two-prism spectrograph with an E614 f/5.7 camera (dispersion about 95 cm^{-1}/mm in the region of 4358 Å). Kodak 103a-G plates were used, and the spectra were recorded with a wide range of exposure times. Frequencies were determined using the well-defined Raman lines of the solvents as reference, and the limits of error are about ± 2 cm^{-1}. States of polarization were measured qualitatively by the method of polarized incident light. The frequencies, polarizations, and rough relative intensities are summarized in Table I.

TABLE I

Raman spectrum of dithiophosgene in saturated solution in carbon tetrachloride, chloroform, and benzene

ν/cm^{-1}	Relative intensity	Polarization	Tentative assignment
876	vw	p?	A_g CCl_2 sym. stretching and ring breathing
755	vw	dp	B_{2g} CCl_2 antisym. stretching
714	w	dp	B_{1g} ring in-plane stretching
494	vs	p	A_g CCl_2 sym. stretching and ring breathing
366	s	p	A_g CCl_2 sym. bending and ring in-plane bending
321	w	dp	B_{1g} CCl_2 wagging
253	w	dp	B_{2g} CCl_2 rocking
199	m	p	A_g CCl_2 sym. bending and ring in-plane bending

Abbreviations: v, very; s, strong; m, medium; w, weak; p, polarized; dp, depolarized.

Infrared spectra of solutions of various concentrations in benzene, cyclohexane, carbon disulphide, carbon tetrachloride, and tetrachloroethylene were recorded between 3000 and 650 cm^{-1} using a Perkin–Elmer Model 21 spectrophotometer with a sodium chloride prism, between 800 and 250 cm^{-1} with a Beckman IR-7 prism-grating spectrophotometer, and between 320 and 50 cm^{-1} with a Perkin–Elmer Model 301 double-beam filter-grating spectrophotometer. For calibration, polystyrene (for the Model 21), carbon dioxide, and water vapor were employed. Above 800 cm^{-1} the accuracy is about ± 2 cm^{-1} and below 800 cm^{-1} about ± 1 cm^{-1}. The infrared spectrum is shown in Fig. 1 and summarized in Table II. The band shown at 220 cm^{-1} is the band of a mull of dithiophosgene in Nujol. In benzene solution the band is very broad.

Some dissociation of the dimer occurred in the solutions, particularly when the Raman spectrum was being taken, and the solution became brown. The strongest Raman line of thiophosgene (1140 cm^{-1} (6)) could then be observed faintly in the spectrum of the solution. When this occurred the solution was purified by distilling off the solvent and the thiophosgene in vacuum, and dissolving the dimer in fresh solvent.

220	m	B_{1u} ring out-of-plane bending

Abbreviations: w, weak; m, medium; s, strong; b, broad; sh, shoulder.

3. DISCUSSION

There are a number of possible structures of the dithiophosgene molecule which conform to the usual valencies. A structure containing a four-membered ring of alternate carbon and sulphur atoms has D_{2h} symmetry if the ring is planar, but only C_{2v} symmetry if it is bent about either the S—S or C—C axes. If the structure is

$$\begin{array}{ccc} & & Cl_2C\text{—}S \\ & & | \quad | \\ Cl_2C\text{—}S & & \end{array}$$

the symmetry is C_{2v}. The open-chain structures $Cl_3CSCCl{=}S$ and $Cl_2C{=}CClSSCl$, and all structures with three-membered rings, have a maximum symmetry C_s.

For D_{2h} symmetry, the 18 normal vibrations are divided into symmetry species as follows: $4A_g + 1A_u + 2B_{1g} + 3B_{1u} + 2B_{2g} + 2B_{2u} + 1B_{3g} + 3B_{3u}$. The nine vibrations symmetric to the center of symmetry are Raman active, with the four totally symmetric vibrations giving rise to polarized Raman lines. The vibrations of species B_{1u}, B_{2u}, and B_{3u} are infrared active. The one vibration of species A_u is inactive in both spectra. Under the lower symmetries C_{2v} or C_S all 18 normal vibrations are Raman active, and all are infrared active except for the few A_2 vibrations that occur under C_{2v} symmetry.

In the observed spectra (Tables I and II) there are no coincidences between infrared and Raman bands. There are only eight Raman lines, and only about eight infrared bands appear to be strong enough to be fundamentals. The number of polarized Raman lines is certainly three and possibly four. It appears therefore that the spectrum is close to that expected for D_{2h} symmetry, but is far too sparse for the lower symmetries mentioned, and we can conclude that the structure of dithiophosgene is  , that is tetrachloro-1,3-dithietane. The symmetry requires the ring to be planar but not rectangular; however, a small departure from planarity may not of course be detected spectroscopically.

A detailed unambiguous assignment of the fundamentals is not possible without more work. Nevertheless an attempt is expected and has been made, although the results are on much less firm ground than the conclusion in the preceding paragraph. For ease of reference, the vibrations are described in terms of localized vibrations. This is of course a very crude approximation, and because the chlorine and sulphur atoms have nearly the same mass there will be considerable coupling of their motions except as forbidden by symmetry. Drawings of the approximate forms of the vibrations are given in ref. 7. The assignment is attempted using internal evidence, the assignment of the Raman-active vibrations of the aluminum halides based on a vibrational analysis (7, 8), and the assignment of the vibrations of the fluoro analogue, tetrafluoro-1,3-dithietane (5), for which vapor infrared spectra were obtained and band contours used to determine the symmetry species.

The assignment of the frequencies is best started from the Raman spectrum. The three polarized lines 494, 366, and 199 cm^{-1} must be due to A_g vibrations, and the weak line of uncertain polarization at 876 cm^{-1} is a likely candidate for the fourth A_g vibration. Two of these lines are due to C—Cl and C—S stretching vibrations, and two to bending vibrations. Uncoupled C—Cl and C—S stretching frequencies are usually about 700 cm^{-1}. The A_g C—Cl stretching and ring breathing vibrations are therefore probably strongly coupled to give the 876 and 494 cm^{-1} bands. The A_g CCl_2 symmetric bending and ring in-plane bending vibrations are also probably coupled to give the 366 and 199 cm^{-1} bands. The two high-frequency depolarized bands at 755 cm^{-1} and 714 cm^{-1} are to be assigned to the two remaining Raman-active stretching vibrations, the B_{2g} CCl_2 antisymmetric stretching and the B_{1g} ring in-plane (C—S) stretching vibrations. The best guess at the present time is that the 755 cm^{-1} line is due to the B_{2g} vibration and the 714 cm^{-1} line is due to the B_{1g} vibration. Three Raman-active vibrations remain, the B_{1g} CCl_2 wagging, B_{2g} CCl_2 rocking, and B_{3g} CCl_2 twisting vibrations. One is missing which, by analogy with the aluminum halides (7), may be the B_{3g} vibration. The 321 and 253 cm^{-1} bands are to be assigned to the remaining two, and by analogy with the aluminum halides (7) are probably due to the B_{1g} and B_{2g} vibrations respectively.

We turn next to the infrared spectrum. Eight fundamental bands are expected. On the grounds of intensity the obvious choice is 811, 761, 745, 699, 445, 314, 274, and 220 cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

There are four infrared-active mainly stretching vibrations to be assigned. These are the B_{1u} CCl_2 antisymmetric stretching, the B_{3u} CCl_2 symmetric stretching, and the B_{2u} and B_{3u} ring in-plane stretching vibrations. Since C—Cl stretching vibrations are usually stronger in absorption than C—S stretching vibrations, the very strong pair 761 and 745 cm^{-1}, which are close to the Raman-active B_{2g} CCl_2 antisymmetric stretching vibration at 755 (or 714) cm^{-1}, are probably the B_{1u} antisymmetric and B_{3u} symmetric CCl_2 stretching vibrations, but it is not certain which is which. In the fluoro analogue the B_{1u} vibration has the higher frequency, and this may also be true for dithiophosgene. The 811 cm^{-1} band is probably due to either the B_{2u} or the B_{3u} ring in-plane stretching vibration, the B_{3u} vibration being perhaps more likely than the B_{2u}. The B_{2u} ring in-plane stretching must be of reasonably high frequency, and the band at 699 cm^{-1}, which is close to the Raman-active B_{1g} ring in-plane stretching frequency at 714 (or 755) cm^{-1}, is an obvious choice. In the fluoro analogue the B_{3u} vibration has the higher frequency, which provides some support for this choice.

The B_{1u} ring out-of-plane bending has only a small harmonic restoring force in simple rings (7, 9). However, in dithiophosgene, coupling with the B_{1u} CCl_2 rocking motion is expected because the sulphur and chlorine atoms have about the same mass. The lowest frequency vibration observed, 220 cm^{-1}, is the most likely candidate for this vibration. In the fluoro analogue the corresponding vibration was at 60 cm^{-1}. It is higher in dithiophosgene presumably because coupling with the rocking vibration is greater. The B_{1u} CCl_2 rocking vibration is probably at 274 cm^{-1}. If this assignment is correct, the similarity of the frequency of these two B_{1u} vibrations indicates that the motions are very mixed.

The infrared-active vibrations remaining to be assigned frequencies are the B_{2u} CCl_2 wagging and the B_{3u} CCl_2 symmetric bending. The remaining apparently fundamental frequencies are 445 and 314 cm^{-1}. The 314 cm^{-1} band is probably due to the bending and the 445 cm^{-1} to the wagging vibration. The assignment of the fundamental bands is summarized in Table III.

The infrared-active combination bands can be assigned satisfactorily on the basis of observed bands, except for the 988 and the 904 cm^{-1} bands. The 988 cm^{-1} band could be

TABLE III

Symmetry species, activity, approximate description, and tentative assignments of the fundamental frequencies of dithiophosgene under symmetry D_{2h}

Symmetry species	Activity	Approximate description	ν/cm^{-1}

THE RELATIVE EASE OF REDUCTIVE CLEAVAGE OF 1,3-DIOXOLANES AND 1,3-DIOXANES IN ETHER SOLUTION BY $LiAlH_4$–$AlCl_3$[1]

B. E. Leggetter, U. E. Diner, and R. K. Brown
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received April 27, 1964

ABSTRACT

In ether solution, 1,3-dioxolanes are hydrogenolyzed faster by $LiAlH_4$–$AlCl_3$ than are the corresponding 1,3-dioxanes. This difference is attributed to the relative ease of oxocarbonium ion formation in the rate-determining step of the reaction. The results obtained have been utilized to explain the selective cleavage of the five- and six-membered acetal structures found in the polyacetals of hexitols.

INTRODUCTION

It is known that, in general, acetals and ketals are stable to the action of lithium aluminum hydride and advantage has been taken of this fact to protect certain carbonyl groups from reduction by this hydride (1). However, in the presence of Lewis acids, these acetals and ketals are hydrogenolized by lithium aluminum hydride to the corresponding ethers. Cyclic acetals and ketals under these conditions yield hydroxy ethers (2, 3, 4).

Of the two mechanisms suggested for this reaction (2), hydride attack on the carbonium ion resulting from the complex formed between the Lewis acid and the acetal *or* reduction of an α-halo ether formed by reaction of the Lewis acid with the acetal, the former is preferred on the basis of results obtained from hydrogenolysis of 1,3-oxathiolanes by $LiAlH_4$–$AlCl_3$ (5). Additional evidence in support of a mechanism involving carbonium ion formation in the rate-determining step of the $LiAlH_4$–$AlCl_3$ hydrogenolysis of 1,3-dioxolanes has been given in a recent study of the influence of substituents on the ease and direction of ring-opening during hydride reductive cleavage of 1,3-dioxolanes (6). In this work it was found that electron donor substituents on C_2 enhance while electron-withdrawing groups retard the rate of hydrogenolysis, a situation quite similar to that found for the hydrolysis of acetals and ketals, which is believed to proceed via carbonium ion formation in the rate-determining step (7). A similar, but much less pronounced effect occurs because of substituents on C_4 of the 1,3-dioxolane system. However, in addition, C_4 substituents have a marked control on the *direction* of ring-opening during the reductive cleavage (6).

During work in this laboratory on the reductive cleavage of cyclic acetals and ketals, a marked difference was noted in the ease of reduction of the five-membered ring structures, the 1,3-dioxolanes, and the six-membered ring structures, the 1,3-dioxanes. This paper presents the results of comparative hydrogenolysis of these two types of compounds in ether solution by lithium aluminum hydride in the presence of aluminum chloride.

RESULTS AND DISCUSSION

Reductions and analyses of products were carried out according to the general procedure described previously (6). Care was taken to ensure that the reductions of each of

[1]*Taken in part from the thesis of B. E. Leggetter, submitted to the Faculty of Graduate Studies, University of Alberta, Edmonton, Alberta, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*

the pairs of compounds, the 1,3-dioxolane and the 1,3-dioxane, were carried out identically. The results of the experiments are shown in Table I.

TABLE I

Comparative ease of reduction of 1,3-dioxolanes and 1,3-dioxanes by $LiAlH_4$–$AlCl_3$ in ether solution

Expt. No.	Dioxane or dioxolane	Reduction* time	Total† recovery, %	Yield of‡ starting material, %	Yield of‡ reduction product, %
1	1,3-Dioxolane	24 h	55§	40	60
2	1,3-Dioxane	24 h	75	72	28
3	4-Methyl-1,3-dioxolane	1.5 h	85	8	92
4	4-Methyl-1,3-dioxane	48 h	86	66	34

8	2-Phenyl-1,3-dioxane	15 min	98	7‖	93‖
9	2,2,4-Trimethyl-1,3-dioxolane	1.5 h	86	0	100
10	2,2,4-Trimethyl-1,3-dioxane	1.5 h	84	0	100
11	2,2,4-Trimethyl-1,3-dioxolane	15 min	93	0	100
12	2,2,4-Trimethyl-1,3-dioxane	15 min	96	0	100

*This includes the time taken for addition of the Lewis acid as well as the length of stirring following the addition of reagents.
†Includes both reduction products and starting material.
‡Based upon total recovery.
§Total recovery was low. From experience it was found that the reduction product rather than initial material was absorbed preferentially on the aluminum salts and required exhaustive extraction for removal. Here only two extractions were made, but further extraction would no doubt give more of the reduced product and intensify the differences found for expts. 1 and 2.
Exhaustive extraction was done for expts. 7, 8 and 11, 12 giving the high recovery noted.
‖This was measured using CH_3CH_2—O—CH_2—CH_2—O—CH_2—CH_2—O—CH_2CH_3 as internal standard.

It is clearly seen that 1,3-dioxanes reduce at a rate slower than that for the analogous 1,3-dioxolanes. For those pairs of compounds which possess a phenyl substituent on C_2 (expts. 5–8) or a methyl substituent (expts. 9–12), the usual reaction time of 1 h or more gave complete hydrogenolysis of both the five- and six-membered rings. However, the difference in rates for one of these did show up when the total time of reduction was reduced to 15 min.

The difference in rates of reduction can be explained on the basis of ease of formation of the intermediate oxocarbonium ion. Oxocarbonium ion formation requires that the atoms of the C_2—O_3—C_4 group attain coplanarity for optimum stabilization.* This is more readily achieved in the five-membered ring because it is more nearly coplanar initially (8) than is the 1,3-dioxane whose ideal conformation approaches that of the chair form of cyclohexane. In the six-membered ring there must first occur a distortion to the half chair form to allow the overlap of the *p*-orbital of the oxygen atom with the developing empty *p*-orbital of the C_2 atom (Fig. 1). The greater distortion required for the six-membered ring would thus retard oxocarbonium ion formation and hence reduction.

Recently Bishop and Cooper (9) have shown that the anomerization of five-membered ring glycosides is considerably faster than that of the six-membered ring glycosides and have suggested that the difference in rate is due to the more facile formation of the intermediate carbonium ion transition state of the five-membered ring.

**During the attainment of the transition state, before the ring is actually broken, there must occur an approximation to coplanarity to permit stabilization of the carbonium ion and thus allow further advance in the breaking of the* C_2—O_1 *bond. That the "greater strain of a five-membered ring" is not the controlling factor is shown by the much slower reductive cleavage of 2,2,4,4,5,5-hexamethyl-1,3-dioxolane versus either 2,2,4,4-tetramethyl-1,3-dioxolane or 2,4,4-trimethyl-1,3-dioxolane (B. E. Leggetter and R. K. Brown. Can. J. Chem. 42, 1005 (1964)).*

For personal use only.

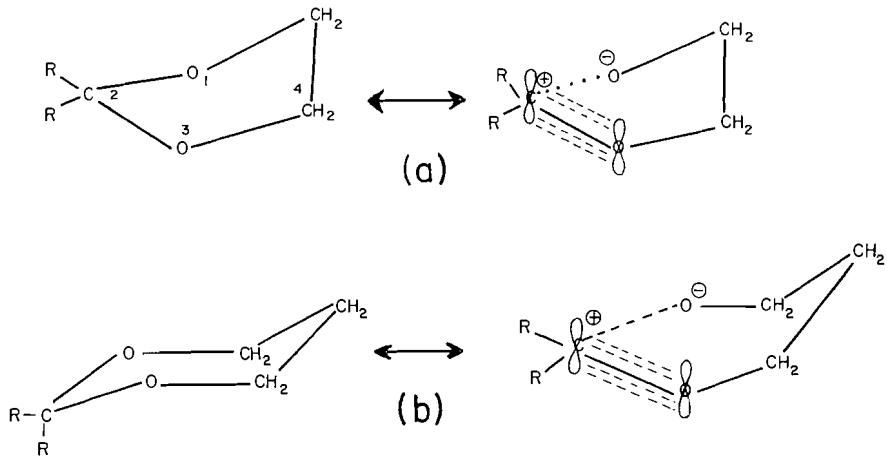

FIG. 1. (*a*) 1,3-Dioxolane—little distortion required; (*b*) 1,3-dioxane—more distortion required.

The discovery by Doukas and Fontaine (10) that when diosgenin was hydrogenolyzed by lithium aluminum hydride in the presence of acids, only the six-membered ring was cleaved (Fig. 2) while the five-membered ring remained intact can be explained on the same basis.

Carbonium ion formation by cleavage of the six-membered ring is preferred because of the more facile overlap of the *p*-orbital of the oxygen atom of the five-membered ring with the developing empty *p*-orbital of the carbon atom common to both rings (Fig. 3).

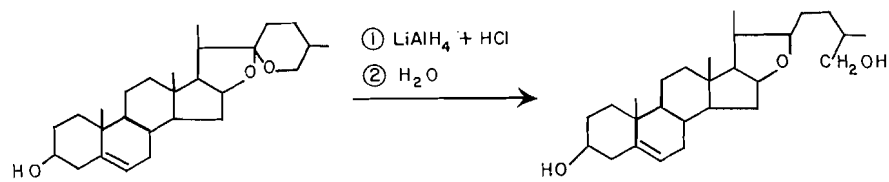

FIG. 2.

Because of the similarity between the acid-catalyzed hydrolysis of acetals and their Lewis acid catalyzed hydrogenolysis with lithium aluminum hydride, in that the rate-controlling step is the formation of the oxocarbonium ion, the results of this work and that describing the effects of substituents on the ease and direction of ring-opening (6) offer an explanation for the anomalous selective acid-catalyzed cleavage of the acetals of a number of hexitols.

The stability of the 2,4-O-methylene ring in 1,3:2,4:5,6-tri-*O*-methylene-D-sorbitol to aqueous acid (11), to acetolysis (12), to acetyl trifluoracetate (13), and to boron trifluoride in methylene chloride (14) can be due to (*a*) its six-membered ring structure, (*b*) the presence of hydroxymethyl groupings on each of the carbon atoms C_4 and C_6, whose *inductive effect* retards carbonium ion formation (6), and (*c*) the greater difficulty of attaining the necessary coplanarity for carbonium ion stabilization because of the large

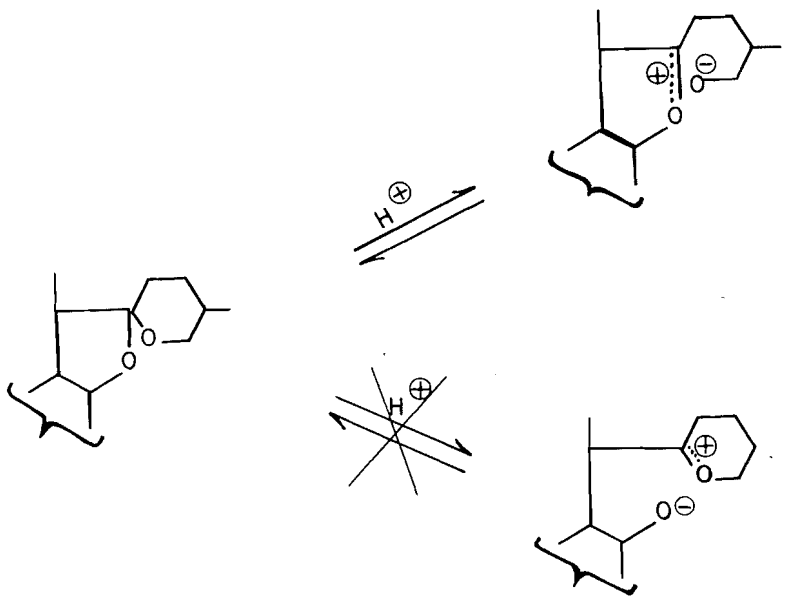

FIG. 3.

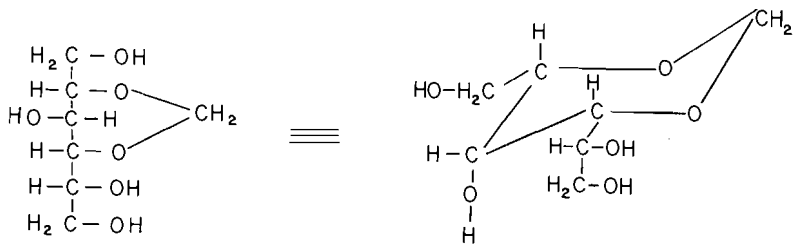
equatorial groups on C_4 and C_6 which in the transition state would tend towards the more restricted axial conformation (15).



The 5,6-O-methylene ring of this compound, being a five-membered cyclic acetal, is expected to (and does) hydrolyze more readily than do either the 1,3 or the 2,5 rings (ref. 15, p. 186).

EXPERIMENTAL

Procedure for the Reduction of 1,3-Dioxolanes and 1,3-Dioxanes

Details of the procedure followed those previously described (6).

Preparation of Compounds

Synthesis of the *1,3-dioxolanes* and *their reduction products* has been reported elsewhere (6).

A. 1,3-Dioxanes

2-Phenyl-1,3-dioxane was prepared by a modification of Salmi's procedure (16). A mixture of benzaldehyde (60 g, 0.57 mole), 1,3-propanediol (38 g, 0.5 mole, Eastman Kodak Co.), *p*-toluenesulphonic acid (1 g), and toluene (150 ml) was heated under reflux in an apparatus equipped with a Dean–Stark water separator (17) until the requisite amount of water (9 ml) was removed. The cooled reaction mixture was poured into saturated aqueous sodium bicarbonate solution and the organic layer separated, washed with water, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

dried (Na_2CO_3). Fractional distillation afforded 55 g (67%) of material boiling at 95–96°/12 mm. This oil solidified when cooled, and after crystallization from Skellysolve B melted at 45–46°. Lit. m.p. 49–51° (18).

1,3-Dioxane was prepared by the directions used for the preparation of 1,3-dioxolane (6), starting with 1,3-propanediol. B.p. 101°/700 mm. Lit. b.p. 105°/755 mm (19).

2,2,4-Trimethyl-1,3-dioxane was prepared by the procedure of Fischer and Pfahler (20) modified as follows.

A mixture of 1,3-butanediol (1.09 mole, Eastman Kodak Co.), anhydrous magnesium sulphate (40 g), *p*-toluenesulphonic acid (1 g), and acetone (600 ml) stood at 25° for 60 h. The filtrate from this mixture was concentrated and the residue poured into saturated aqueous sodium carbonate. The ether extract from this was dried (magnesium sulphate), freed from solvent, and the residue distilled yielding the required dioxane. B.p. 125°/700 mm. Lit b.p. 131–132° (21).

4-Methyl-1,3-dioxane was prepared according to published directions (22).

B. Reduction Products

3-Methoxy-1-propanol was synthesized by a modification of the procedure described by Henze and Rogers (23).

Sodium (5.0 g, 0.22 mole) was dissolved in 120 ml of methanol and the resulting solution was stirred under reflux while 3-chloro-1-propanol (19.0 g, 0.2 mole, Eastman Kodak Co.) was added dropwise. The mixture was then stirred for 3 h, cooled, and poured into cold water. The ether extract was dried ($MgSO_4$), freed from solvent, and distilled affording 3.8 g (21%) of material boiling at 144–146°/700 mm. Lit. b.p. 148–149° (24).

3-Benzyloxy-1-propanol was prepared by modification of a published procedure (25). Sodium metal (2.7 g, 0.12 mole) was dissolved in 30 ml of hot 1,3-propanediol. To the resulting solution was added slowly 15.0 g (0.12 mole) of benzyl chloride. The mixture was heated at 120° for 2 h, then cooled, and poured into water. The dried ether extract ($MgSO_4$) was freed from solvent and the residue distilled giving 7.2 g (37%) of the alcohol boiling at 107°/1.5 mm. Lit. b.p. 155°/23 mm (25).

4-Isopropoxy-2-butanol was prepared by the procedure used for the synthesis of 3-benzyloxy-1-propanol above, starting with 1,3-butanediol and 2-bromopropane. B.p. 94°/45 mm; η_D^{25}, 1.4518. Calc. for $C_7H_{16}O_2$: C, 63.64; H, 12.12. Found: C, 63.96; H, 12.37.

4-Methoxy-2-butanol was prepared according to the above procedure, starting with 1,3-butanediol and methyl iodide. B.p. 85°/62 mm. Lit. b.p. 145° (26).

3-Methoxy-1-butanol was prepared according to the literature (27).

3-Isopropoxy-1-butanol was prepared by the reduction of isopropyl β-isopropoxybutyrate with lithium aluminum hydride according to standard procedure (28). B.p. 93°/35 mm; η_D^{25}, 1.4156. Calc. for $C_7H_{16}O_2$: C, 63.64; H, 12.12. Found: C, 64.04; H, 12.17.

The precursor, isopropyl β-isopropoxybutyrate, was prepared from isopropyl crotonate (29) and isopropyl alcohol by the procedure of Doering and Young (27). Yield, 43% of material boiling at 47°/1.5 mm. Calc. for $C_{10}H_{20}O_3$: C, 63.83; H, 10.64. Found: C, 63.45; H, 10.85.

ACKNOWLEDGMENT

The authors express their appreciation to the National Research Council of Canada whose financial assistance made this work possible.

A STUDY OF HINDERED ROTATION IN SOME PROTONATED BENZYLAMINES

W. F. REYNOLDS* AND T. SCHAEFER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received May 11, 1964

ABSTRACT

The effect of hindered rotation upon methylene and ammonio proton shifts and coupling constants of eight protonated benzylamines has been determined. It is shown that the necessary and sufficient condition for methylene proton asymmetry in protonated benzylamines is the absence of a plane of symmetry along the $C_6H_5CH_2$—N bond axis. It is established that the maximum value of the *gauche* H—C—N—H^+ coupling constant is 3.15 c/s and that the minimum value of the *trans* H—C—N—H^+ coupling constant is 9.45 c/s. From the relative values of the rotationally averaged coupling constants, it is established that the steric effect of the substituent decreases in the following order: isopropyl, phenyl > benzyl ≈ ethyl > methyl. It cannot be decided from the available evidence whether the phenyl group or the isopropyl group causes greater steric hindrance.

INTRODUCTION

Considerable work has been done on the problem of configurational isomerism of substituted ethanes with high resolution nuclear magnetic resonance (1–10). There was some misunderstanding in the early literature about the roles of asymmetry and conformational populations in producing magnetic non-equivalence of nuclei (4, 5). This confusion has lately been cleared up (11–13).

From the temperature dependence of coupling constants involved (7), or from an observed averaged coupling constant at one temperature and a value of energy differences between isomers obtained from vibrational spectra (8), values of vicinal coupling constants have been estimated as 10 to 18 c/s for *trans* coupling constants and 1 to 3.5 c/s for *gauche* coupling constants of protons attached to saturated carbon atoms in substituted ethanes.

While investigating a series of protonated anilines and related compounds, we noted that the methylene protons of certain protonated benzylamines were non-equivalent. Protonated benzylamines (ϕH_2C—$NHRS)^+$ are analogous to triply substituted ethanes (XH_2C—CHYX). We have investigated a series of substituted benzylamines and dibenzylamines in a protonating solvent in an attempt to determine the magnitudes of coupling constants, asymmetry shifts, and isomer population differences for this type of compound.

The equivalence or non-equivalence of rotamer population was established for the series of compounds studied. The predictions of Gutowsky (13) about the effect of substitution upon methylene proton asymmetry were confirmed. Maximum values of the *gauche* coupling constants and minimum values of the *trans* coupling constants were established. A qualitative estimate of the relative steric hindrance caused by several substituents was made. There were not sufficient data available to determine exact values of the vicinal coupling constants and the energy differences between the various isomers.

(A) Effect of Energy Levels upon Rotation Rates about Single Bonds and upon Relative Populations of Rotational Isomers

Steric hindrance of rotation about single bonds in saturated hydrocarbons has often been considered to be due to van der Waals' forces of repulsion between substituents (14).

**Holder of a National Research Council of Canada Studentship*, 1962–1963.

Since this repulsion will generally be greatest when substituents are in eclipsed positions, it is usually assumed that substituted ethanes exist in their three possible staggered configurations (rotamers). The relative populations of rotamers depend upon their relative energy levels. The relative populations are given by the Boltzmann factors. An increase in temperature will cause the relative populations to approach equality.

The rotation rate about a single bond depends upon the heights of the energy barriers and the temperature. If one of the energy barriers is very high, a rocking motion will occur instead of rotation. Since this normally will have the same effect upon the proton spectrum as rotation, further discussion will be based upon the assumption that rotation occurs about the single bond. If two of the barriers are much higher than the other barrier, then this assumption will no longer be justified.

(B) Effect of Rotation Rate and Rotamer Population upon Methylene Proton Asymmetry

Concerning the conditions which cause methylene proton asymmetry, Waugh and Cotton (11), and Bishop (12) pointed out a fundamental error in the reasoning of previous workers. Gutowsky has established the minimum substitution required to cause non-equivalence of methylene protons in compounds of the substituted ethane type (13). His treatment will be applied here to the methylene groups of protonated benzylamines.

(1) Type 1

Consider a compound of the general type $XH_2C—(NRSH_X)^+$. The possible rotational configurations are shown in Fig. 1. There are three more possible rotamers which are mirror images of the three shown.

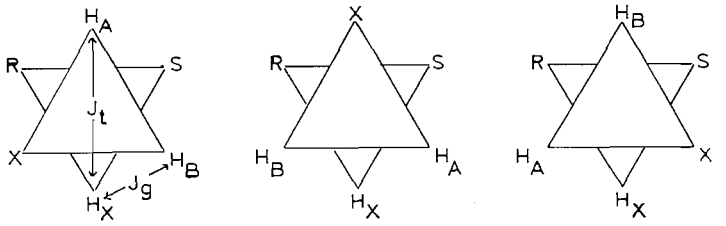

FIG. 1. The three possible rotamers for a protonated compound of the type $XCH_2—(NRSH)^+$ (type 1). The methylene carbon atom lies above the plane of the diagram and the nitrogen atom lies below this plane.

The rotationally averaged proton shifts are

[1] $$\bar{\nu}_A = \sum_n x_n \nu_n^A \quad \text{and} \quad \bar{\nu}_B = \sum_n x_n \nu_n^B$$

or in general,

[2] $$\bar{\nu}_i = \sum_n x_n \nu_n^i,$$

where x_n = mole fraction of rotamer n and ν_n^i = the chemical shift of the ith nucleus of rotamer n. The shift of proton H_X is not considered for reasons outlined in the section on results. It can be seen from the configuration diagrams that all three rotamers are identical if X = H. Therefore,

[3] $$\bar{\nu}_A = \bar{\nu}_B = \sum_n \tfrac{1}{3}\nu_n^A = \sum_n \tfrac{1}{3}\nu_n^B,$$

i.e., $$(\overline{\nu_A - \nu_B}) = 0.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

All A and B protons are equivalent only if rapid rotation occurs about the C—N bond axis. Equation [3] is obtained by noting that $\nu_1^A = \nu_3^B$, etc. However, there is still an intrinsic asymmetry which would be observed if rotation were stopped, since $\nu_1^A \neq \nu_2^A \neq \nu_3^A$, etc.

If X ≠ H, then three different rotamers are present. The presence of X changes all six proton shifts ν_n^A and ν_n^B. The net result is a chemical shift between H_A and H_B

$$[4] \qquad \Delta\bar{\nu}_A = \sum_n x_n(\nu_n^A - \nu_n^B) = (\overline{\nu_A - \nu_B}).$$

This may be rewritten as

$$[5] \qquad \Delta\bar{\nu}_A = \sum_n x_n(\Delta\nu_n^0 + \delta\nu_n),$$

where $\Delta\nu_n^0$ = the shift between the protons of rotamer n of the parent compound (where X = H) and $\delta\nu_n$ = the change in $\Delta\nu_n^0$ caused by the substitution of X for H. But from eq. [3] we find that

$$[6] \qquad \sum_n \tfrac{1}{3}\Delta\nu_n^0 = 0.$$

Substitution of this result in eq. [5] yields

$$[7] \qquad \Delta\bar{\nu}_A = \sum_n (x_n - \tfrac{1}{3})\Delta\nu_n^0 + \sum_n [(x_n - \tfrac{1}{3})\delta\nu_n + \tfrac{1}{3}\delta\nu_n],$$

which was derived by Gutowsky (13).
Equation [7] can be rearranged in terms of eq. [4] to give

$$[8] \qquad \Delta\bar{\nu}_A = \sum_n (x_n - \tfrac{1}{3})(\nu_n^A - \nu_n^B) + \sum_n \tfrac{1}{3}\delta\nu_n.$$

The first term depends upon relative populations and upon differences in chemical shifts in the three rotamers. The second term depends solely upon the additional shifts caused by the substitution of X for H. This additional shift has been referred to as the asymmetry effect (13).

Equations [1] to [8] can be used to predict the types of spectra that would be expected for type 1 compounds for different populations of rotamers and for different rates of rotation about the C—N bond. There are three basic situations which must be considered. These are (1) no rotation – slow rotation, (2) rapid rotation with equal rotamer population, and (3) rapid rotation with unequal rotamer populations. If the compound does not rotate about the C—N bond, the spectra of the individual rotamers will be obtained, if they are sufficiently populated to be observed. As the rotation rate increases, the spectra of the individual rotamers collapse to a single, averaged spectrum. Collapse is complete when the rotation rate exceeds $2\pi(\nu_1^A - \nu_2^A)$ s^{-1}, etc. Since none of the compounds studied showed evidence of slow rotation about the C—N bond, there will be no further discussion of this possibility.

Equation [8] indicates that the methylene protons of type 1 compounds are non-equivalent even when rapid rotation occurs about the C—N bond. The averaged shift will alter with changing temperature until the populations of the three rotamers are equal. At this point a small shift will remain which will not alter with increasing temperature. This asymmetry shift is a second-order effect, which results from different interactions between the various substituent groups. It is very difficult, if not impossible, to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

predict the expected value of the asymmetry effect. It is also difficult to obtain experimentally, because equalized populations normally are obtained only at very high temperatures.

(2) Type 2

Type 2 compounds are those with two identical groups bonded to the nitrogen (other than the benzyl group). There are two possibilities: $XH_2C—(NR_2H)^+$ (type 2*a*) and $XH_2C—(NRH_2)^+$ (type 2*b*). In terms of the asymmetry of the methylene group they are both of the general type $XH_2C—(NRS_2)^+$ and therefore may be considered together. The diagrams in Fig. 2 represent the type 2*a* rotamers. These can be considered as a *trans*

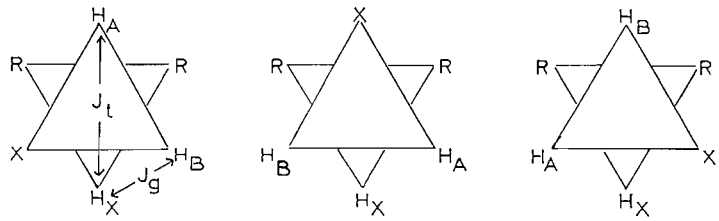

FIG. 2. The three possible rotamers for a protonated compound of the type $XCH_2—(NR_2H)^+$ (type 2*a*).

form (2), referring to X and H_X, and two *gauche* forms (1 and 3). It can be seen that $\nu_1^A = \nu_3^B$, $\nu_3^A = \nu_1^B$, $\nu_2^A = \nu_2^B$, and $x_1 = x_3$, since rotamers 1 and 3 are sterically equivalent. Substitution of the above relations into eq. [1] yields

$$\bar{\nu}_A = \bar{\nu}_B = x_2\nu_2^A + 2x_1(\nu_1^A + \nu_1^B) \quad [9]$$

or

$$\bar{\nu}_A = \bar{\nu}_B = x_t\nu_2^A + x_g(\nu_1^A + \nu_1^B) \quad [10]$$

where $x_g = x_1 + x_3$. Equations [9] and [10] predict that protons H_A and H_B are equivalent, regardless of the relative populations of the *trans* and *gauche* rotamers, if rotation is rapid enough to average chemical shifts. The averaged shifts will vary with temperature until rotamer populations are equal, and then will remain constant.

(3) Type 3

If the $(NRS_2)^+$group is changed to $(NH_3)^+$ (type 3), it can easily be shown that all rotamers are equivalent and that no shift differences will be found, regardless of the rate of rotation about the C—N bond.

From the above discussion it can be seen that only type 1 compounds show methylene proton asymmetry when rapid rotation occurs about the C—N bond. This asymmetry persists even for free rotation (equal populations). The methylene protons of type 2 and type 3 compounds are always equivalent when rotation is rapid enough to average the differences in shift of the individual rotamers. Therefore, methylene proton asymmetry occurs when three different groups, other than the benzyl group under observation, are bonded to the nitrogen atom. In other words, the necessary condition for methylene proton asymmetry is the absence of a plane of symmetry along the C—N bond axis. Complete nitrogen asymmetry is a sufficient but not a necessary condition since some substituted dibenzylamines should show methylene proton asymmetry. For example, protonated *N*-methyldibenzylamine should show methylene proton asymmetry because

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

it has three different groups, other than the benzyl group under consideration, bonded to the nitrogen: C_6H_5—CH_2—$N(CH_3)(C_6H_5CH_2)(H^+)$. There is no plane of symmetry along the $C_6H_5CH_2$—N bond. Thus the methylene protons will be asymmetric even though the nitrogen atom is not asymmetric.

(C) Effect of Rotamer Population and Rotation Rate upon Proton Coupling Constants

There are two basic types of coupling constants between methylene protons and ammonio protons of molecules in staggered configurations: J_{gauche} (J_g) and J_{trans} (J_t). The values of J_g and J_t will vary slightly for the different rotamers for the same reason that there is an asymmetry effect. It is normally assumed that all values of each type of coupling constants within a given molecule are equal (15). It is known that *trans* and *gauche* F–F coupling constants can vary by as much as 4 c/s within a given molecule (10, 16). The constancy of the different *trans* and *gauche* H–H coupling constants within a given ethane-type molecule has apparently never been proved. It has been suggested that F–C–C–F coupling constants are affected also by a "through space" mechanism which principally involves non-bonded F–F interactions (17, 18). On the other hand, H–H coupling constants are believed to depend upon the electron distribution in the intervening bonds (19). If these theories are correct, then vicinal H–H coupling constants should be altered by the electronegativity of the substituents while vicinal F–F coupling constants should be sensitive to steric effects which alter the separation of the fluorine atoms. Since steric factors probably cause different F–F distances in the various rotamers, it is quite possible that vicinal fluorine coupling constants vary more within a given molecule than the corresponding proton coupling constants. In any case, it will be assumed that the values of J_g and J_t are the same for all the rotamers of a given molecule. It is necessary to make this assumption, since without knowledge of the energy levels of the three rotamers, it is impossible to determine the constance of J_g and J_t (10)*.

From the previous equations and diagrams, it is possible to predict the effect of population changes upon proton coupling constants.

(1) Type 1

This type of compound is expected to give an ABX spectrum for the methylene protons and the ammonio proton with the methylene protons being A and B. The AB coupling constant is measurable. The possible values of J_{AX} and J_{BX} can be obtained from the rotamers illustrated in Fig. 1. For fast rotation, the averaged coupling constants are:

$$\bar{J}_{AX} = x_1\bar{J}_t + (x_2 + x_3)\bar{J}_g, \quad [11]$$

$$\bar{J}_{BX} = (x_1 + x_2)\bar{J}_g + x_3\bar{J}_t. \quad [12]$$

The difference between the two coupling constants depends only upon the mole fractions of rotamers 1 and 3 and the values of J_g and J_t. (We assume $J_t > J_g$.)

$$\bar{J}_{AX} - \bar{J}_{BX} = (x_1 - x_3)(\bar{J}_t - \bar{J}_g). \quad [13]$$

In general, $\bar{J}_{AX} \neq \bar{J}_{BX}$ except by coincidence (when $x_1 = x_3$). If it is assumed that J_g and J_t are constant, then it is possible to determine the relative populations and consequently the relative stability of the two rotamers. As populations approach equality, both $\bar{J}_{AX}$ and $\bar{J}_{BX}$ approach a limiting value of $(2/3\,J_g + 1/3\,J_t)$. Inequality of $\bar{J}_{AX}$ and $\bar{J}_{BX}$ definitely indicates unequal rotamer populations. Equality of $\bar{J}_{AX}$ and $\bar{J}_{BX}$ indicates

**A referee points out that, in principle, if the temperature dependence of $\bar{J}$ could be measured with sufficient accuracy, an experimental check could be made of the constancy of J_g and J_t without a priori knowledge of the rotational potential function.*

that $x_1 = x_3$ and that possibly all populations are equal. The situation where $x_1 = x_3 \neq x_2$ might exist if the steric effects due to R and S were approximately equal, because there would then be little energy difference between rotamers 1 and 3. This corresponds to type 2*a* discussed below.

(2) Type 2a

Compounds of this type should give A_2X spectra when rapid rotation occurs about the C—N bond axis. Since the methylene protons are equivalent, it is impossible to measure the geminal coupling constant (20).

The values of $\bar{J}_{AX}$ and $\bar{J}_{A'X}$ can be obtained from Fig. 2 ($H_{A'} \equiv H_B$ in Fig. 2). The rotationally averaged coupling constants are:

$$\bar{J}_{AX} = x_1 J_t + (x_1 + x_3) J_g = \frac{x_g}{2} J_t + \left(1 - \frac{x_g}{2}\right) J_g, \qquad [14]$$

$$\bar{J}_{BX} = x_3 J_t + (x_1 + x_2) J_g = \frac{x_g}{2} J_t + \left(1 - \frac{x_g}{2}\right) J_g. \qquad [15]$$

The averaged coupling constants are therefore equal. The magnitudes of $\bar{J}_{AX}$ and $\bar{J}_{A'X}$ will vary with relative populations up to a limiting value of $(2/3\, J_g + 1/3\, J_t)$.

(3) Type 2b

The rotamers for compounds of this type are shown in Fig. 3. It can be seen from the

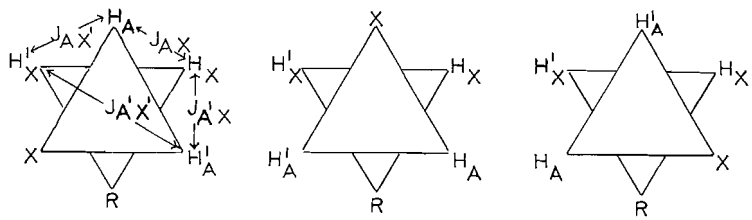

FIG. 3. The three possible rotamers for a compound of the type XCH_2—$(NRH_2)^+$ (type 2*b*).

diagram that $\bar{J}_{AX} \equiv \bar{J}_{A'X'}$ and $\bar{J}_{A'X} \equiv \bar{J}_{AX'}$ since rotamers 1 and 3 are sterically equivalent. If one takes into account that there are two coupling constants of each type per rotamer, the averaged values of the coupling constants are:

$$\bar{J}_{AX} = \frac{(1 + x_2) J_g + (x_1 + x_3) J_t}{2} = \frac{(1 + x_t) J_g + x_g J_t}{2}, \qquad [16]$$

$$\bar{J}_{A'X} = (x_1 + x_3) J_g + x_2 J_t = x_g J_g + x_t J_t. \qquad [17]$$

In general, $\bar{J}_{AX} \neq \bar{J}_{A'X}$. Both will alter with temperature up to a limiting value of $(2/3\, J_g + 1/3\, J_t)$ when populations are equal.

Experimentally, the sums and differences of $\bar{J}_{AX}$ and $\bar{J}_{A'X}$ are measured. These two variables have the following values:

$$\bar{J}_{AX} + \bar{J}_{A'X} = \left(1 + \frac{x_g}{2}\right) J_g + \left(1 - \frac{x_g}{2}\right) J_t, \qquad [18]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[19] $$\bar{J}_{AX} - \bar{J}_{A'X} = \left(x_t - \frac{x_g}{2}\right)(J_t - J_g).$$

If it is assumed that the *gauche* rotamers are sterically less favorable than the *trans* rotamer, then it is found that $(\bar{J}_{AX} - \bar{J}_{A'X})$ varies by $(J_t - J_g)$ when the relative rotamer populations change from $x_t = 1$ to $x_t = 1/2\, x_g$. For the same change in relative populations, $(\bar{J}_{AX} + \bar{J}_{A'X})$ varies by only $1/3(J_t - J_g)$. Consequently the measured difference in coupling constants should be more temperature dependent than the sum of the coupling constants for type 2*b* molecules. The limiting values for the two variables are 0 for $(\bar{J}_{AX} - \bar{J}_{A'X})$ and $(4/3\, J_g + 2/3\, J_t)$ for $(\bar{J}_{AX} + \bar{J}_{A'X})$.

(4) Type 3

Regardless of temperature, rotation rate, etc., a single, averaged value of $(2/3\, J_g + 1/3\, J_t)$ will be obtained for $\bar{J}_{AX}$.

The most notable feature of the effect of temperature upon coupling constants is the constancy of the limiting value of the average coupling constants obtained for the three types of molecules. In type 2 compounds the methylene protons are equivalent and changes in chemical shift can only be measured relative to a reference signal. However, definite values of coupling constants can always be obtained. Definite values of coupling constants are preferable to relative values of chemical shifts since there is always uncertainty whether the reference and (or) the methylene protons may show additional shifts due to factors other than changes in rotamer populations as the temperature changes.

(D) Effect of Proton Exchange upon Methylene Proton Asymmetry and Observed Coupling Constants

Exchange alters the shape of the observed methylene proton spectrum by two mechanisms. Firstly, exchange between the protonated and unprotonated forms of the substituted benzylamine produces an averaged methylene proton spectrum. Experimental evidence* shows that aniline in trifluoracetic acid (TFA) is almost completely protonated. Benzylamines are stronger bases and should be even more completely protonated in solution. Since the concentration of free base is much smaller than that of the protonated base, the observed spectrum should be little different from that of protonated benzylamine in the absence of exchange. Secondly, the exchange of a proton bonded to a nitrogen atom may be accompanied by an inversion of the nitrogen atom valences. This inversion effectively interchanges the A and B protons of the methylene group of a type 1 molecule and the AB spectrum collapses to an A_2 spectrum since the protons become indistinguishable. If the lifetime of unprotonated benzylamine in solution is long compared to the time taken for rearrangement of the nitrogen valences, then every second exchange on an average will invert the nitrogen atom valences.

Exchange will also alter the observed values of $\bar{J}_{AX}$ and $\bar{J}_{BX}$. As the X proton exchanges, there is an increasing uncertainty about the X proton spin alignment. Only every second exchange will result in an interchange of the X proton spin.

(E) Analysis of A_2X, ABX, and A_2X_2 Proton Spectra when the X Proton Spectra are Unmeasurable

The X (ammonio) proton spectra of protonated benzylamines do not yield any useful information, for reasons discussed later. Consequently, the amount of useful information which can be obtained is limited.

**To be published.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(1) A_2X and A_3X Spectra

Only the AX coupling constant can be obtained. When the two protons are equivalent (20), J_{AA} is not observable.

(2) ABX Spectra

The AB part of an ABX spectrum consists of two quartets. The quartets are easily identified since they contain four spacings equal to J_{AB}. Since the X part of the spectrum cannot be measured, the information obtainable is limited. However, if it is assumed that $\bar{J}_{AX}$ and $\bar{J}_{BX}$ have the same sign, then it is possible to obtain the magnitudes of $\bar{J}_{AX}$, $\bar{J}_{BX}$, and the chemical shift. This is a reasonable assumption since it has been shown that the vicinal coupling constants in substituted ethanes have the same sign (7, 9, 21). The values of $1/2|\bar{J}_{AX} + \bar{J}_{BX}|$ and $1/2|\bar{J}_{AX} - \bar{J}_{BX}|$ can be obtained from the spectrum (22). There are two possible values of the latter term, depending upon whether the defined constants $D^+\cos 2\theta^+$ and $D^-\cos 2\theta^-$ (22) have the same or opposite signs. Only one of the two possible values will give $|\bar{J}_{AX} + \bar{J}_{BX}| > |\bar{J}_{AX} - \bar{J}_{BX}|$. This relation must hold if $\bar{J}_{AX}$ and $\bar{J}_{BX}$ have the same sign. The chemical shift can also be obtained from the expressions defining $D^+\cos 2\theta^+$ and $D^-\cos 2\theta^-$. The signs of J_{AB}, $\bar{J}_{AX}$, and $\bar{J}_{BX}$ cannot be obtained. It is also impossible to decide which coupling constant is $\bar{J}_{AX}$ and which is $\bar{J}_{BX}$.

(3) A_2X_2 Spectra

The theory of A_2X_2 spectra has been developed in general (23) and also for the specific case of disubstituted ethanes with unequal rotamer populations (9, 10). The coupling constants are defined as shown in Fig. 3. It is convenient to define the following quantities:

$$K = J_{AA'} + J_{XX'};\ L = \bar{J}_{AX} - \bar{J}_{A'X};\ M = J_{AA'} - J_{XX'};\ N = \bar{J}_{AX} + \bar{J}_{A'X}.$$

If $K \gg L$ and $M = 0$, then the methylene proton spectrum will consist of five peaks: an intense doublet with spacing equal to N and a triplet whose outside peaks are L c/s apart. Both spectral groupings have the same center of gravity. As L increases with respect to K, the central line of the triplet splits into a doublet. If $M \neq 0$, then the outside peaks of the triplet are split into doublets. The spacing from center to center of the two doublets is equal to $(M^2 + L^2)^{1/2}$ and the doublet splitting is equal to M. If L is small or M is large, the total spectrum collapses to a triplet. Only the value of N can definitely be obtained from an A_2X_2 spectrum.

EXPERIMENTAL

Eleven different protonated benzylamines were investigated. In three cases no useful results were obtained. All solutions contained 5 mole percent of the benzylamine being investigated and 2 mole percent of cyclohexane as an internal reference. Trifluoracetic acid was used as a protonating solvent. All chemicals were Eastman White Label grade and were used without further purification.

Proton resonance spectra were measured at 60 Mc/s on a Varian DP-60 spectrometer. Samples were degassed and sealed in thick-walled 5 mm glass sample tubes. Spectra were obtained at different temperatures with the aid of a variable temperature probe manufactured at N.R.C. (24). Sample temperatures were measured by a copper–constantan thermocouple attached to a Varian G-11 recording potentiometer. The temperature measurements are believed accurate to within 2 °K. Peak separations were measured by sideband techniques, using a Hewlett–Packard 521C frequency counter. All results are the average of at least six measurements. The temperature range was limited by the high freezing points of the solutions and by their high volatility.

RESULTS

The calculated chemical shifts and coupling constants are given in Table I. The measured shifts of the centers of gravity of the methylene groups relative to internal cyclohexane are given in Table II. These shifts do not vary in any meaningful manner as temperature changes, and will not be further discussed.

Rapid proton exchange between *N*,*N*-dibenzylethylenediamine and TFA collapsed the methylene proton spectrum below room temperature, preventing the observation of coupling constants. Proton exchange also collapsed the methylene proton spectra of *N*-ethyl-*N*-phenylbenzylamine and *N*-phenyldibenzylamine at temperatures above room temperature.

Separate peaks were observed for the benzyl and ethyl protons of *N*-ethyl-*N*-phenylbenzylamine and 2-benzylamino-6-methylheptanol-6. Presumably, the anisotropy of the phenyl groups caused a low field shift of the benzyl methylene protons relative to the ethyl methylene protons. However, in the spectra of *N*-benzylethanolamine and *N*-benzyldiethanolamine, the ethyl and benzyl methylene protons overlapped, rendering these compounds useless for investigation.

Four main types of methylene proton – ammonio proton spectra were observed. Since the methylene protons resonated at more than 4 p.p.m. to high field of the ammonio protons, the spectra can be classified as A_2X, ABX, A_3X, and A_2X_2. Typical spectra are shown in Figs. 4–7. The analysis of the spectra was complicated by the fact that the ammonio proton spectra always consisted of single broad peaks. A combination of slow proton exchange and ^{14}N quadrupole relaxation effects presumably caused the collapse of the X proton spectra.

The estimated errors in measurements are given in Tables I and II. In the case of ABX spectra, the derived values of chemical shift and coupling constants are not as accurately known as other values of coupling constants since they are obtained by the differences of other derived values.

Two major factors limited the accuracy of the measurements. The individual peaks were quite broad because of the high viscosities of the solutions. Also, the thick-walled sample tubes and the temperature probe reduced the sensitivity of the spectrometer so much that it was difficult to obtain signals. (The sensitivity of the spectrometer has since been increased by a factor of 2 in the signal to noise ratio.) The benzylamine concentration used represented a compromise between too much viscosity broadening and too little signal amplitude. The solution of 2-benzylamino-6-methylheptanol-6 was so viscous that the spectrum could not be accurately measured at room temperature.

DISCUSSION OF RESULTS

(A) Effect of Proton Exchange

Since proton exchange alters the observed coupling constants and chemical shifts, it was considered necessary to determine whether or not appreciable ammonio proton exchange was occurring in the other solutions studied. Since benzylamines are stronger bases than aniline, the activation energies of proton exchange should exceed 25 kcal/mole.*

**To be published.*

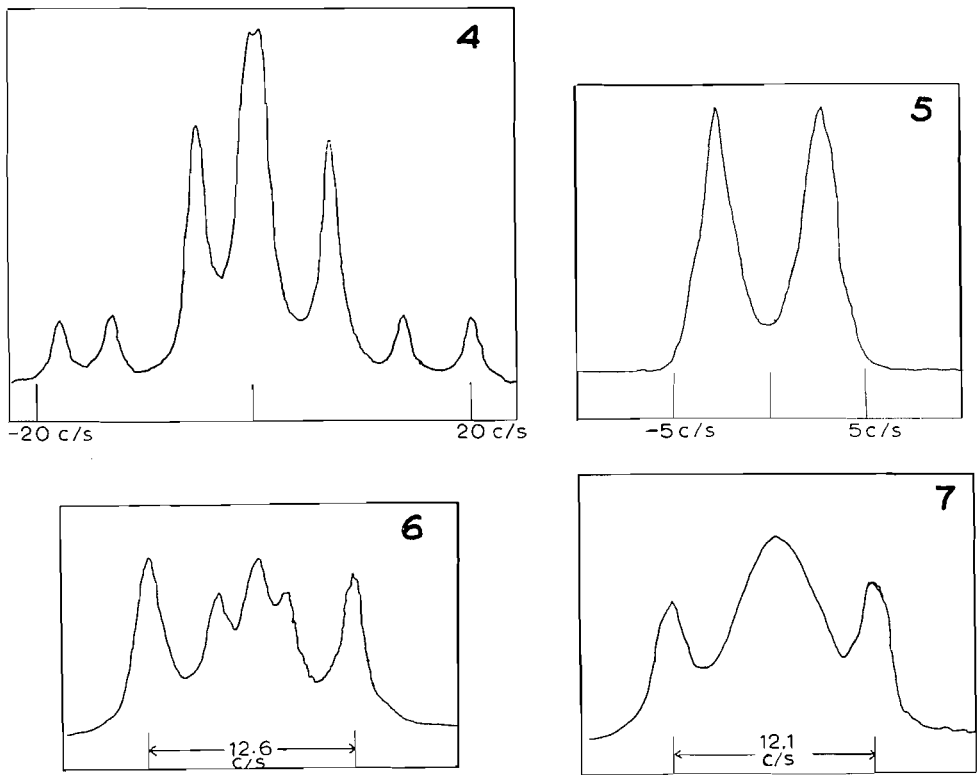

FIG. 4. Reproduction of the methylene proton spectrum of protonated *N*-methyldibenzylamine. This is the AB part of an ABX spectrum (type 1).
FIG. 5. Reproduction of the methylene proton spectrum of protonated *N,N*-dimethylbenzylamine. This is the A_2 part of an A_2X spectrum (type 2*a*).
FIG. 6. Reproduction of the methylene proton spectrum of protonated *N*-isopropylbenzylamine. This is the A_2 part of an A_2X_2 spectrum (type 2*b*).
FIG. 7. Reproduction of the methylene proton spectrum of protonated dibenzylamine. This is the A_2 part of an A_2X_2 spectrum (type 2*b*).

Therefore, the collapse of the methylene proton spectra should occur over a narrow temperature range. Depending upon the peak separations, the spectra will collapse over a temperature range of 15 to 30 °K. This can be shown in the following way: the rate of collapse of a doublet as a result of exchange is approximately given by (25)

$$[20] \qquad \frac{\text{separation of peaks}}{\text{separation of peaks for large } \tau} = \left[1 - \frac{1}{2\pi^2\tau^2(\nu_A - \nu_B)^2}\right]^{\frac{1}{2}}$$

where τ = lifetime of protonated molecule in s. For two peaks 10 c/s apart, the calculated separations are respectively 9.94, 9.75, 8.93, 4.26, and 0.00 c/s for exchange rates of 5.0, 10.0, 20.0, 40.0, and 44.4 exchanges/s. If the activation energy of exchange is 25 kcal/mole and if exchange takes place at a temperature of 330 °K, then the exchange rate will change from 4.4 to 44 exchanges/s over a temperature range of approximately 22 °K.

It is interesting to note that eq. [20] predicts that there is little change in measured peak separations at low exchange rates. Consequently, only the measurements at the highest temperatures are likely to be in error since if appreciable exchange was occurring at lower temperatures, the methylene proton spectra would be completely collapsed at higher temperatures.

Exchange causes a broadening of the spectral peaks as well as a decrease in peak separation. Such behavior was not noticed for any solutions other than the three mentioned, even at the highest temperatures. Additional evidence for the absence of appreciable exchange was provided by the two compounds containing *N*-methyl groups. These formed type 3 groupings because of rotation about the N—CH_3 bonds. In both cases the (H—N--C—H)$^+$ coupling constants were temperature independent, as would be expected for type 3 groupings in the absence of exchange.

Of all the monoamino compounds studied, only those with a phenyl group bonded directly to the nitrogen atom showed evidence of appreciable proton exchange. Presumably, the withdrawal of electrons from the nitrogen atom by the phenyl group increased the acid strength of the ammonio group to such an extent that appreciable proton exchange occurred at higher temperatures. The methylene proton spectra of *N*-ethyl-*N*-phenyldibenzylamine and *N*-phenylbenzylamine were only partly collapsed at 50 °C. Because the collapse occurred over a narrow temperature region and because no evidence of proton exchange at room temperature was noted for either of the two compounds, it is assumed that the room temperature results for protonated *N*-ethyl-*N*-phenylbenzylamine and *N*-phenyldibenzylamine are reliable.

(B) Type I Compounds

The spectra of all three compounds indicate non-equivalent methylene protons. Protonated *N*-phenyldibenzylamine and *N*-methyldibenzylamine contain symmetric nitrogen atoms while protonated *N*-ethyl-*N*-phenylbenzylamine does not. All lack a plane of symmetry along the benzyl–nitrogen bond. This confirms the statement in the introduction that the absence of a plane or axis of symmetry along the bond axis is the sufficient condition for methylene proton asymmetry.

The chemical shifts between the methylene protons are small in all three compounds. In the case of *N*-methyldibenzylamine, the shift decreases when the temperature is increased, but appears to level off at higher temperatures. However, this cannot be true. If rotamer populations are equal at 407 °K, then $\bar{J}_{AX}$ and $\bar{J}_{BX}$ should be equal (see eqs. [11] and [12]). The non-equivalence of $\bar{J}_{AX}$ and $\bar{J}_{BX}$ in all three compounds indicates that the rotamer populations are unequal in all three compounds. Presumably, the asymmetry shift would be found to be quite small if it could be determined. This is not surprising since the asymmetry shift arises from second order effects.

For *N*-ethyl-*N*-phenylbenzylamine, *N*-phenyldibenzylamine, and *N*-methyldibenzylamine, $|J_{AB}|$ has values of 12.75 ± 0.1, 12.95 ± 0.1, and 13.0 ± 0.2 c/s respectively. Thus J_{AB} is essentially constant for the three compounds. Karplus has calculated that $J_{AB} = +12.85$ for H—C—H bonds when the carbon valences are in a tetrahedral configuration (19), although his calculation is probably in error. It is probable that J_{AB} is negative and that $\bar{J}_{AX}$ and $\bar{J}_{BX}$ are positive, since the corresponding coupling constants in substituted ethanes have those signs (26).

As shown by eq. [13], the difference between $\bar{J}_{AX}$ and $\bar{J}_{BX}$ is determined by the difference in mole fractions of rotamers 1 and 3. If it is assumed that J_g and J_t are the same for all three compounds, then it is possible to estimate the relative amounts of steric hindrance caused by the various substituents. It has been shown that the size of vicinal proton coupling constants in polyhaloethanes depends upon the electronegativity of the substituents (10, 27, 28). Since in all three compounds three carbon atoms are bonded to a nitrogen atom, J_g and J_t probably do not alter appreciably from compound to compound. The bonding of a phenyl group to a nitrogen atom may cause some change in J_g and J_t since the bonding carbon atom is trigonally hybridized.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In all three compounds, rotamer 2 would be expected to be energetically least favored since in this rotamer a phenyl group (X) is adjacent to two other bulky substituents (see Fig. 1). The non-equivalence of $\bar{J}_{AX}$ and $\bar{J}_{BX}$ in *N*-methyldibenzylamine is presumably due to the fact that the benzyl groups are bulkier than the methyl group. The non-equivalence of the vicinal coupling constants in the other two type 1 compounds is most reasonably explained by assuming that the phenyl group causes more steric hindrance than either the ethyl or the benzyl group. If it is assumed that the phenyl group causes less steric hindrance than the other two groups, then one must conclude that it also causes less steric hindrance than the methyl group. This does not seem reasonable. Since the coupling constants of *N*-phenyldibenzylamine and *N*-ethyl-*N*-phenylbenzylamine are nearly identical, the ethyl and the benzyl groups must cause approximately the same amount of steric hindrance. Consequently one concludes from the differences between $\bar{J}_{AX}$ and $\bar{J}_{BX}$ for the three compounds that the steric hindrance of the substituents decreases in the following order: phenyl > benzyl ≈ ethyl > methyl. This order seems quite reasonable. This suggests that the assumption that J_g and J_t do not alter from compound to compound is at least approximately correct.

The value of the $H^+—N—CH_3$ coupling constant of *N*-methyldibenzylamine is 5.25 ± 0.15 c/s. The constancy of the coupling constant confirms that no appreciable proton exchange occurs in the temperature range used. Since this is a type 3 grouping, 5.25 c/s should represent the value of $|2/3\,J_g + 1/3\,J_t|$. If the value of another combination of J_g and J_t could be found, then the values of J_g and J_t could be obtained algebraically.

(C) Type 2a Compounds

The value of the vicinal coupling constant of protonated *N*,*N*-dimethylbenzylamine changes very little over a temperature range of 90 °K and is only slightly larger than the expected value when rotamer populations are equal. This indicates that the methyl groups have little effect on the ΔE values of the rotamers. The observed value of the $H^+—N—CH_3$ coupling constant is 5.25 c/s. It is independent of temperature. Therefore, no appreciable ammonio proton exchange can be occurring in the temperature range studied.

The results for tribenzylamine are curious. The vicinal coupling constant is almost temperature independent and is identical, within experimental error, with the two values obtained for $|2/3\,J_g + 1/3\,J_t|$. This indicates that all three rotamers have nearly equal energies and populations. It is difficult to visualize why a phenyl group situated between two benzyl groups should not be in a sterically less favorable position than a phenyl group adjacent to only one benzyl group. However, the results indicate that the two positions are equivalent.

The shifts of the methylene protons, relative to cyclohexane, do not change significantly as the temperature changes. Therefore, no conclusions can be drawn about the effect of changing rotamer population upon chemical shift.

The equivalence of the methylene protons in type 2 compounds confirms that the absence of an axis or plane of symmetry along the C—N bond axis is the necessary condition for methylene proton asymmetry.

(D) Type 2b Compounds

The methylene protons of the three compounds of this type give five line spectra corresponding to the A_2 parts of A_2X_2 spectra. The triplet splitting is measurable only in the spectrum of *N*-isopropylbenzylamine. In the spectra of dibenzylamine and 2-benzylamino-6-methylheptanol-6 the central peaks of the methylene proton spectra are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

broadened rather than split into distinct triplets. The spacing of the outer peaks of the triplet is equal to $M + (M^2 + L^2)^{1/2}$. If $M = 0$, then values of $\bar{J}_{AX}$ and $\bar{J}_{A'X}$ can be obtained from the sums and differences of the two coupling constants. It is not known, but is unlikely, that $M = 0$ in the compounds studied. All that can be stated with certainty is that the value of the triplet splitting represents an upper limit of L. The value of the triplet splitting changes more rapidly with temperature than the value of the doublet splitting. It was shown in the introduction that L should change three times as fast as M as temperature changes.

The value of N for *N*-isopropylbenzylamine appears to be temperature independent. The value of N changes with temperature for dibenzylamine and is, in general, lower than N for *N*-isopropylbenzylamine. This implies that the isopropyl group causes more steric hindrance than the benzyl group. This is not surprising when one notes that the results for type 1 compounds indicated that the benzyl and ethyl groups cause approximately equal amounts of steric hindrance.

The value of N for 2-benzylamino-6-methylheptanol-6 is independent of temperature within the limits of experimental error. It is slightly lower than the corresponding value for *N*-isopropylbenzylamine.

In all cases the rotamer populations must be unequal since N is always smaller than the expected value for equal populations: $|4/3\, J_g + 2/3\, J_t| = 10.5$ c/s.

(E) Possible Values of J_g and J_t

If the energy difference between *trans* and *gauche* rotamers of a type 2*b* compound becomes very large, then most of the compound should exist as the *trans* rotamer (see Fig. 3). If one assumes that protonated *N*-isopropylbenzylamine exists solely as the *trans* rotamer at room temperature, then $|J_g + J_t| = 12.6$ c/s. With this value and the previously obtained value of $|2/3\, J_g + 1/3\, J_t|$, it follows that $|J_g| = 3.15$ c/s and $|J_t| = 9.45$ c/s. These values represent an upper limit of $|J_g|$ and a lower limit of $|J_t|$ since the actual value of $|J_g + J_t|$ may be larger than 12.6 c/s. The values of J_g have been found to be between 1.0 and 3.5 c/s in substituted ethanes, while J_t has values between 10 and 18 c/s (7, 9).

It is possible to use values of J_g and J_t to calculate energy and population differences for the various rotamers. We are presently studying these benzylamines in chlorosulphonic acid. This acid allows us to work over a temperature range of at least 250 °C and, as well, the solutions are much less viscous than the TFA solutions. We hope that the resulting increases in range and accuracy for the J values will allow us to apply the analysis described by Gutowsky (29) to obtain ΔE values and better values for J_g and J_t.

SUMMARY AND CONCLUSIONS

It has been shown that the necessary and sufficient condition for methylene proton asymmetry in protonated benzylamines is the absence of a plane of symmetry along the $C_6H_5CH_2$—N bond axis. Rotamer populations are unequal for all compounds except protonated tribenzylamine. The maximum value of $|J_g|$ in protonated benzylamines is 3.15 c/s. The minimum value of $|J_t|$ is 9.45 c/s. The steric hindrance caused by the various substituents decreases in the following order: isopropyl, phenyl > benzyl ≈ ethyl > methyl. It cannot be decided from the experimental evidence whether the phenyl group or the isopropyl group causes greater steric hindrance.

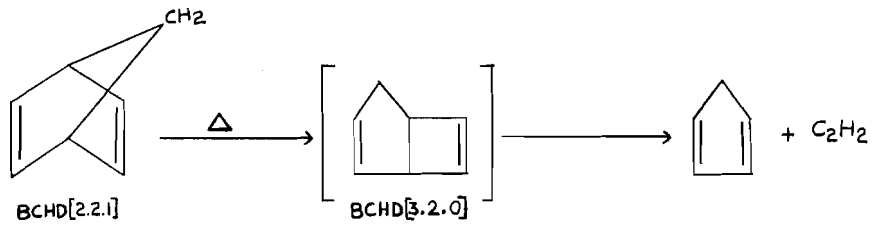
NOTES

THE THERMAL UNIMOLECULAR DECOMPOSITION OF $\Delta^{2,5}$-BICYCLO[2.2.1]HEPTADIENE[1]

B. C. ROQUITTE[2]

The vapor phase thermal decomposition of $\Delta^{2,5}$-bicyclo[2.2.1]heptadiene, BCHD[2.2.1], has received some attention previously (1, 2); recently the kinetic parameters of the thermal decomposition of BCHD have been reported (3). It was found that acetylene, cyclopentadiene, cycloheptatriene, and toluene are the principal products of decomposition. The present investigation on BCHD was undertaken to see whether acetylene and cyclopentadiene could have been formed from the valence tautomer BCHD[3.2.0] as follows:



The decomposition of BCHD[3.2.0] to cycloheptatriene is known (4). However, BCHD[3.2.0] also could decompose to give cyclopentadiene and acetylene in the same fashion as cyclobutane compounds (5). It was hoped that this study would throw some light on the transition state involved in the decomposition of BCHD[2.2.1].

BCHD[2.2.1] supplied by Chemical Intermediate and Research Laboratories, Cuyahoga Falls, Ohio, was subjected to fractional distillation, and a middle cut was further purified by gas chromatography and found to be 99.9% pure. Cyclopentadiene used in the calibration of the gas chromatograph was prepared (6) from dicyclopentadiene (Eastman Kodak Co.) and subsequently purified by gas chromatography. Acetylene (Matheson 99.66%) was used without further purification, except trap-to-trap distillation, for gas chromatographic calibration. Nitric oxide (Matheson 98.7%) was purified by several distillations from −160 to −196°. Oxygen (Matheson 99.5%) was used directly from the cylinder.

The apparatus used and the experimental procedure were in part similar to that described previously (7). Two cylindrical reaction vessels made of pyrex were used in a vertical furnace: (*a*) unpacked vessel, (*b*) vessel packed with thin-walled pyrex tubings to increase the surface:volume ratio by a factor of 25.

After each run the reaction mixture was condensed out of the reaction zone into an

[1]*Issued as N.R.C. No. 8004.*

[2]*N.R.C. Postdoctoral Fellow, 1962–64. Present address: Radiation Research Laboratories, Mellon Institute, Pittsburgh 13, Pennsylvania.*

ampoule at liquid nitrogen temperature and sealed off under vacuum. The reaction mixture was then introduced into the inlet system of an F and M temperature-programmed gas chromatograph model 720 by means of a crushing device developed in this laboratory. The compounds present in the reaction mixture were initially identified by comparison of the retention times of the various products with those of the authentic samples. The individual compounds were separately trapped as they were eluted from the column and subsequently analyzed by a mass spectrometer. The amount of each product was estimated quantitatively by measuring the area under the peak on the chromatogram. The results of the quantitative determination of the products are summarized in Table I.

TABLE I

Decomposition of $\Delta^{2,5}$-bicyclo[2.2.1]heptadiene under various conditions

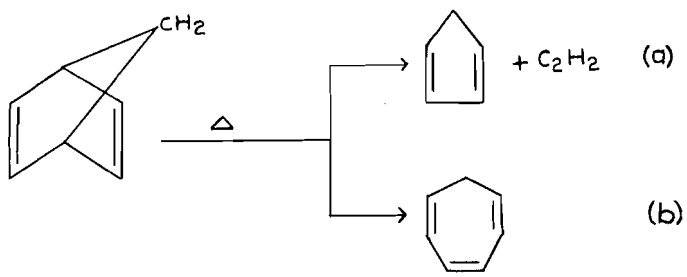
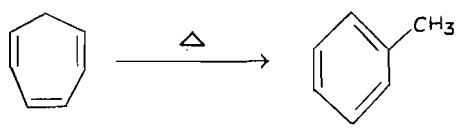
ΔP = increase in pressure corrected for dead space.
P_{CPD} = pressure of cyclopentadiene.
P_{AC} = pressure of acetylene.
Pkd. = packed reaction vessel.

On the basis of product identification, it appears that there are at least two simultaneous reactions occurring in the pyrolysis of BCHD[2.2.1]:



The major portion of toluene (if not all) most probably was produced by the reaction (8):



Three runs were carried out to 100% decomposition. It was observed that the ratio tol/CHT (toluene/cycloheptatriene) had increased in these runs. Moreover, the amount of toluene produced was negligible in experiments in which the decomposition was less

For personal use only.

than 5% but the CHT formed was detected readily. The rate constants of the overall reaction in the pressure range 4–30 mm at temperature 320–360° were calculated from the slope of the straight line obtained from a plot of the left side of the following equation against time t:

$$\log \frac{P_0 L}{(1 - L)P_0 - P_t} = \frac{k}{2.303} t$$

where P_0 is the initial pressure, L is the fraction of BCHD decomposed by step (a), and P_t is the pressure measured at time t; $k = k_a + k_b$. A typical plot is shown in Fig. 1.

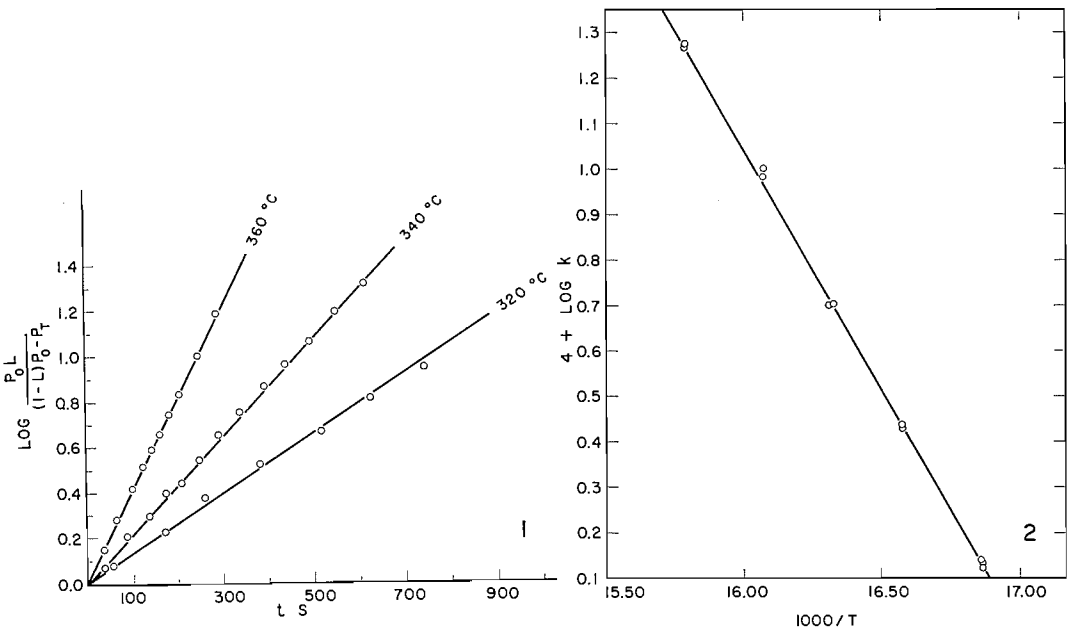

FIG. 1. Unimolecular plot; ordinate scale—for run at 360° to be increased by a factor of 2 and for run at 320° to be decreased by a factor of 2.
FIG. 2. Arrhenius plot for the decomposition of BCHD[2.2.1].

The pressure–time curve has the shape expected for an unimolecular reaction without an induction period. If the lifetime of BCHD[3.2.0] is longer than that of BCHD[2.2.1], then the absence of an induction period would seem to rule out the possibility that decomposition is taking place via an intermediate like BCHD[3.2.0]. This conclusion is further supported by the fact that BCHD[3.2.0] is not a product of the decomposition (confirmed by nuclear magnetic resonance analysis). Since oxygen and nitric oxide did not have an effect on the rate of the overall decomposition, it is safe to conclude that free radicals are not involved in the decomposition of BCHD[2.2.1]. In addition, the change of surface: volume ratio seems to have no effect on the rate of the reaction, which suggests that the decomposition of BCHD is an entirely homogeneous reaction.

The Arrhenius plot for the overall reaction is shown in Fig. 2 and is given by $k = 2.99 \times 10^{14} \exp(-49\,800/RT)\ s^{-1}$. A plot of the ratio of $2C_2H_2/(\text{tol} + \text{CHT})$ ($= k_a/k_b$) vs. temperature (not shown) has a slope of zero although there is some scatter in the plot. This corroborates the fact that there is little or no difference in activation energy between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

the processes (*a*) and (*b*); the individual rate constants are, therefore, $k_a = 2.01 \times 10^{14} \exp(-49\,800/RT)\ s^{-1}$ and $k_b = 0.87 \times 10^{14} \exp(-49\,800/RT)\ s^{-1}$. The entropy of activation of the overall reaction was found to be −2.5 e.u. A small negative entropy usually indicates that the structure of the transition state involved does not differ greatly from that of the original molecule.

FURTHER INVERSE GAMMA-DEUTERIUM ISOTOPE EFFECTS IN SOLVOLYTIC REACTIONS[1]

M. J. Blandamer[2] and R. E. Robertson

The inverse secondary γ-deuterium isotope effect reported by Leffek *et al.* (1, 2) in the hydrolysis of *n*-propyl halides and sulphonates appeared to provide confirmation of the suggestion that there was a loss of torsional freedom coupled with lesser effects on bending and stretching frequencies as a consequence of the close juxtaposition of the terminal methyl group, the nucleophilic water, and the leaving group (3). By extension of this argument, the γ-deuterium isotope effect seemed to provide a means of exploring the arguments advanced by Dostrovsky, Hughes, and Ingold (4) about enhanced steric hindrance to nucleophilic displacement from isobutyl and neopentyl groups. It follows that in these examples the enhanced steric hindrance would lead to a corresponding increase in the inverse γ-deuterium isotope effect. This expectation was not supported by experiment (Table 1). The inverse γ-deuterium isotope effect for the hydrolysis of *n*-propyl halides was reduced for the isobutyl cases and was "normal" for the neopentyl methanesulphonate. The simplest explanation would seem to be that nucleophilic interaction is successively reduced here, as it is in the analogous displacement from the methyl and the isopropyl groups, with a corresponding shift in the α-deuterium isotope effect

from inverse to normal (5). However, this facile explanation must be tempered by the knowledge that even in nucleophilic displacement from the methyl group, the α-deuterium isotope effect has been shown to be "inverse" or "normal" depending on the nucleophile, the leaving group, and the medium. Thus Leffek has shown that displacement of the tosyl ion by a strong nucleophile ($S_2O_3^=$) leads to a "normal" α-deuterium isotope effect, whereas displacement in hydrolysis gives an "inverse" effect (6). These and similar results merely serve to underline the need for the development of a better understanding of the secondary deuterium isotope effects before we can utilize this probe in the exploration of detailed mechanism.

The isobutyl bromide-d_6 and neopentyl alcohol-d_9 were supplied by Merck, Sharp & Dohme and were isotopically better than 95% pure. The former was converted to the corresponding methanesulphonate by exchange with the silver salt (7). The neopentyl methanesulphonate was made by standard methods (7). All were purified to give good first order plots. Rate determinations and attending experimental considerations followed our standard practice (8).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

procedure the solid mixture yields a vapor which condenses at or near the eutectic temperature to a liquid having approximately the eutectic composition, and, at least as a first approximation, this liquid composition is independent of the solid composition. Thus the method is especially effective for the removal of trace impurities.

This sublimation method, one in which the impurity is concentrated in a liquid sublimate and the unsublimed solid becomes more pure, has been applied previously to organic solids at temperatures above room temperature (1). However, the method seems especially promising for systems of organic liquids that are ordinarily difficult to separate by conventional means such as fractional distillation, for in essence what is done is to utilize the invariant equilibrium, solid–solid–vapor–liquid, instead of the more conventional liquid–vapor equilibrium. As an example consider some of the results obtained in working with mixtures of *p*-xylene (major component) – *o*-xylene (impurity).

EXPERIMENTAL

Mixtures of the components were prepared from the highest purity materials available from Eastman Kodak Co. The two compositions used were "99%" and "99.999%" *p*-xylene. These percentages, of course, represent only the nominal compositions of the mixtures since the individual components themselves were not absolutely pure.

These mixtures were frozen completely and the sublimation of the solid mixtures carried out over a ½ h period in a nitrogen atmosphere in a glass sublimation apparatus. The sublimation well was maintained at approximately −33.5° (by using a $Mg(NO_3)_2 \cdot 9H_2O$ – ice eutectic bath) and the condenser at approximately −36° (by using acetone cooled in a $K_2CO_3 \cdot 6H_2O$ – ice eutectic bath). The *p*-xylene – *o*-xylene eutectic temperature is −36.4° (2). The liquid condensates obtained in the sublimations were removed by dissolving in a small volume of 95% ethanol and the resulting solutions were analyzed by vapor phase chromatography.

The gas chromatographic analyses were performed with a Perkin–Elmer Model 154 using 7,8-benzoquinoline on Celite column at 80° and a thermal conductivity detector. An absolute calibration of the response of the column and detector to *p*-xylene – *o*-xylene mixtures was not made, but a standardization experiment was performed. In this experiment (experiment 1, Table I) a mixture of *p*-xylene – *o*-xylene of the eutectic composition was subjected to chromatographic analysis. The results of other experiments were compared to this standard.

TABLE I

Vapor phase chromatography data on *p*-xylene – *o*-xylene mixtures

Expt.	Solution analyzed	Relative peak areas (units)		Remarks
		p-Xylene	*o*-Xylene	
1	Standard eutectic mixture: 27.8% *p*-xylene – 72.2% *o*-xylene	6	15	1 μl of a 1.0% solution of the standard eutectic mixture in ethanol was taken for analysis
2	Liquid condensate from the sublimation of a "99%" *p*-xylene – "1%" *o*-xylene solid mixture	7	11	20 μl of a solution obtained by dissolving the liquid sublimate in 0.07 ml of ethanol
3	A repeat of expt. 2	9	16	Same sampling procedure as in expt. 2
4	Liquid condensate from the sublimation of a "99.999%" *p*-xylene – "0.001%" *o*-xylene solid mixture	5	2	Same sampling procedure as in expts. 2 and 3

RESULTS AND DISCUSSION

From the results in Table I it can be seen that considerable enrichment of the impurity in the liquid condensate was obtained by the sublimation procedure described here. That the condensates obtained did not possess exactly the eutectic composition perhaps can be attributed to the fact that the sublimation was not carried out exactly at the eutectic temperature and also to the fact that equilibrium conditions were probably not attained during the short sublimation period ($\frac{1}{2}$ h). The liquid condensed in experiment 4 contained a ratio of *p*-xylene to *o*-xylene considerably different from the eutectic value, and should have had an equilibrium freezing point of about 0 °C. Quite likely this was a supercooled solution. The formation of supercooled solutions by this sublimation method has been noted previously (3). Despite the fact that the conditions for achieving the maximum degree of separation of *o*-xylene impurity from *p*-xylene were not attained in the experiments described here, it is still quite clear that this sublimation technique can be used to effect the purification of organic substances at low temperatures.

HIGH PRIMARY QUANTUM EFFICIENCY IN THE REACTION OF NEOPENTANE WITH Hg 6($^3P_1$) ATOMS

R. J. NORSTROM, O. P. STRAUSZ, AND H. E. GUNNING

In the determination of the mechanism of energy transfer for collisions between alkane molecules and Hg 6($^3P_1$) atoms (1), the low quantum yield (0.0045) previously reported for the neopentane reaction (2) was thought to have provided important evidence for the role of molecular symmetry in the energy-transfer process. During primary process studies on reactions initiated by Hg 6($^3P_1$) atoms, we have reinvestigated the neopentane reaction and the results are reported below.

EXPERIMENTAL

The neopentane was Phillips Research Grade (stated purity, 99.98%) with *n*-butane the probable impurity. This material was further refined, after thorough degassing, by distillation from methanol slush (−98°) to liquid nitrogen, discarding head and tail fractions. Fractionation from toluene slush (−100°) to *n*-pentane slush (−130°) followed, with continuous pumping, and rejection of the lead fraction. Preliminary experiments indicated that the last traces of impurities could best be removed by photosensitization. After this pre-irradiation, noncondensables were pumped off, and the neopentane was recovered by distillation through a trap at −100°, which retained heavy products. The substrate thus obtained showed no impurities by gas chromatography (g.c.) (6 foot, medium-activity, silica gel column). For the runs reported here a rotating sector technique was used; this has been previously described (3). Absorbed light intensities (I_a) were measured by propane actinometry, taking $\Phi_{H_2} = 0.50$ in the constant $DH_2/\Delta t$ region at propane pressures of

RESULTS AND DISCUSSION

From the results in Table I it can be seen that considerable enrichment of the impurity in the liquid condensate was obtained by the sublimation procedure described here. That the condensates obtained did not possess exactly the eutectic composition perhaps can be attributed to the fact that the sublimation was not carried out exactly at the eutectic temperature and also to the fact that equilibrium conditions were probably not attained during the short sublimation period ($\frac{1}{2}$ h). The liquid condensed in experiment 4 contained a ratio of *p*-xylene to *o*-xylene considerably different from the eutectic value, and should have had an equilibrium freezing point of about 0 °C. Quite likely this was a supercooled solution. The formation of supercooled solutions by this sublimation method has been noted previously (3). Despite the fact that the conditions for achieving the maximum degree of separation of *o*-xylene impurity from *p*-xylene were not attained in the experiments described here, it is still quite clear that this sublimation technique can be used to effect the purification of organic substances at low temperatures.

The neopentane was Phillips Research Grade (stated purity, 99.98%) with *n*-butane the probable impurity. This material was further refined, after thorough degassing, by distillation from methanol slush (−98°) to liquid nitrogen, discarding head and tail fractions. Fractionation from toluene slush (−100°) to *n*-pentane slush (−130°) followed, with continuous pumping, and rejection of the lead fraction. Preliminary experiments indicated that the last traces of impurities could best be removed by photosensitization. After this pre-irradiation, noncondensables were pumped off, and the neopentane was recovered by distillation through a trap at −100°, which retained heavy products. The substrate thus obtained showed no impurities by gas chromatography (g.c.) (6 foot, medium-activity, silica gel column). For the runs reported here a rotating sector technique was used; this has been previously described (3). Absorbed light intensities (I_a) were measured by propane actinometry, taking $\Phi_{H_2} = 0.50$ in the constant $DH_2/\Delta t$ region at propane pressures of

1000 torr. The continuous I_a was 0.358 μeinstein/min, and the sector opening was 9°, resulting in a time-averaged I_a for the intermittent irradiation of 0.00895 μeinstein/min. Noncondensables were measured by gas burette, with analysis by g.l.c. on a molecular sieves column. For the heavy products a high-capacity capillary column was used (Perkin–Elmer, 505U (squalane)) with a helium flow of 45 ml/min. Product characterizations were by nuclear magnetic resonance (n.m.r.) and mass spectrometry.

RESULTS AND DISCUSSION

The major products of the reaction at 25° are hydrogen and a C-10 paraffin. The proton n.m.r. spectrum of the heavy product shows peaks at 8.87 and 9.13 τ in relative intensities of 1:4.4. Hence the product is 2,2,5,5-tetramethylhexane or dineopentyl (DN). The mass spectrum is also consistent with DN. At higher substrate pressures small quantities of a second C-10 product were detected by g.l.c. Quantities obtained by g.l.c. peak isolation were too minute for a complete n.m.r. analysis. However, two uncoupled peaks at 8.8 and 8.9 τ were found which, from intensity ratios, were not methylene protons. These results suggest that the minor heavy product is a mixture of the *cis* and *trans* forms of 2,2,5,5-tetramethylhexene-3.

Under steady illumination (I_a = 0.075 μeinstein/min) the quantum yield (Φ) for hydrogen was 0.60 at substrate pressures exceeding 800 mm. For the rotating sector runs the quantum yield data are given in Table I.

TABLE I

Product quantum yields as a function of substrate pressure and exposure time for the reaction of neopentane with Hg $6(^3P_1)$ atoms

Run No.	Neopentane pressure (torr)	Exposure time (min)	Φ_{H_2}	Φ_{DN}[a]	Δ[b]	Φ_X[c]
1	102	120	0.367	0.342	0.025	—
2	257	120	0.546	0.478	0.068	—
3	478	120	0.656	0.615	0.041	—
4	680	120	0.705	0.670	0.035	—
5	854	120	0.744	0.690	0.054	—
6	1012	61	0.762	0.695	0.067	0.02

[a]Quantum yield of dineopentyl formation.
[b]$\Delta = \Phi_{H_2} - \Phi_{DN}$.
[c]Quantum yield of minor C-10 product.

It should first be noted from Table I that Φ_{H_2} values under intermittent irradiation, at pressures exceeding 800 mm, are higher than that obtained under steady illumination (0.60). Furthermore (Table I) Φ_{H_2} rises with increasing substrate pressure (P_S) and appears to level off at 0.76 for P_S = 1012 torr. Runs 6–10 show that Φ_{H_2} falls off fairly linearly with exposure time (t). The relation between Φ_{H_2} and P_S can best be shown by plotting $1/\Phi_{H_2}$ vs. $1/P_S$ for the 120 min runs, as in Fig. 1. The function is linear, and yields an extrapolated value for Φ_{H_2} at $P_S = \infty$ of 0.87 ($\Phi_{H_2}^{\infty}$). Pertinently, Yang (4) has made some very careful, low-conversion measurements of Φ_{H_2} for a number of paraffins including propane and neopentane. For his actinometric standard he takes $\Phi_{H_2}^{\infty} = 1.00$ for propane from an analogous plot to Fig. 1. On this basis, Yang's data (4) give $\Phi_{H_2}^{\infty} = 0.86$ for neopentane, in excellent agreement with our findings. Of equal interest is the fact that the two actinometric reference values for the propane reaction appear equally valid.

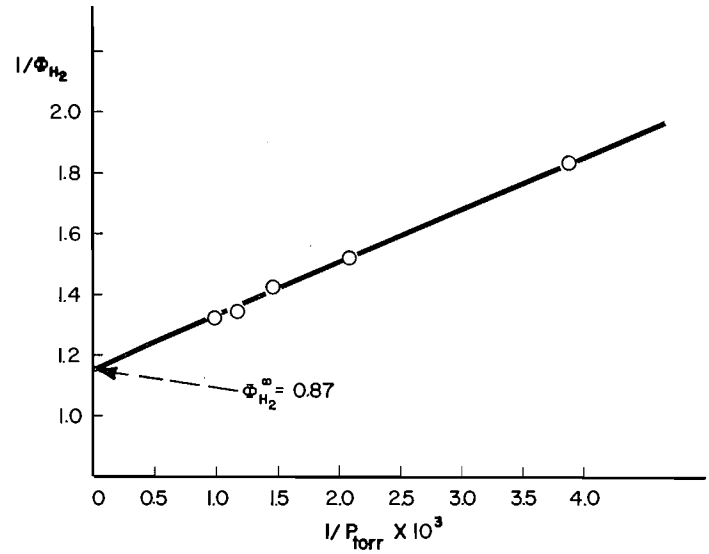

FIG. 1.

If we take R = *t*-butyl, the initial steps in the mechanism are clearly:

[1] $$RCH_3 + Hg\ 6(^3P_1) \rightarrow RCH_2 + H + Hg\ 6(^1S_0)$$

[2] $$H + RCH_3 \rightarrow H_2 + RCH_2$$

[3] $$2RCH_2 \rightarrow RCH_2CH_2R.$$

Since Φ_{H_2} rises with P_S in the complete quenching region, we must add the reaction

[4] $$H + RCH_2 \rightarrow RCH_3.$$

Increasing P_S would favor [2] over [4], and thus both Φ_{H_2} and Φ_{DN} should rise as observed (Table I). Since $\Phi_{H_2}^{\infty}$ is 0.86 and not unity, either [1] is inherently inefficient, or, at the mean I_a used, the linear extrapolation in Fig. 1 to $P_S = \infty$ fails to cancel out the effect of [4].

The above four-step sequence requires that $\Phi_{H_2} = \Phi_{DN}$, whereas, in fact, the difference, Δ, is finite (Table I) and rises with P_S (run 2 excepted) to at least 0.07 at P_S = 1012 torr. This suggests that the heavy DN product is suffering decomposition in the reaction zone, as further indicated by the presence of the minor C-10 olefin detected. Since Δ is constant with increasing t at fixed P_S (runs 6–10, Table I), a steady DN level in the reaction zone is indicated, in which rate of formation and loss by diffusion and reaction are balanced. At constant t the steady DN level would shift upward with P_S, and increased consumption of DN by reaction would result, causing Δ to rise as observed (Table I).

Consumption of DN could arise by three processes:

[5] $$H + RCH_2CH_2R \rightarrow H_2 + R\dot{C}HCH_2R$$

[6] $$RCH_2 + RCH_2CH_2R \rightarrow RCH_3 + R\dot{C}HCH_2R$$

[7] $$Hg\ 6(^3P_1) + RCH_2CH_2R \rightarrow R\dot{C}HCH_2R + H + Hg\ 6(^1S_0)$$

followed by

[8] $$RCH_2 + R\dot{C}HCH_2R \rightarrow RCH_3 + RCH{=}CHR$$

[9] $$RCH_2 + R\dot{C}HCH_2R \rightarrow (RCH_2)_2CHR.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The secondary C—H bonds in DN would render abstraction reactions more facile than in neopentane, and, in addition, markedly increase the quenching cross section. Through [9] DN is lost as a C-15 product which we would not detect. The minor C-10 olefin found likely forms through [8]. This latter product possibly explains why both Φ_{H_2} and Φ_{DN} decrease slowly with t at fixed P_S. By the scavenging reaction

[10] $$H + RCH{=}CHR \rightarrow R\dot{C}HCH_2R$$

competing with [5], Φ_{H_2} and Φ_{DN} would be reduced as found.

From the present study it can be concluded that the alkane, neopentane, shows no exceptional behavior in its primary reaction with Hg $6(^3P_1)$ atoms and closely resembles ethane, since the primary quantum yield is 0.87 and possibly unity.

OBSERVATIONS BY X-RAY DIFFRACTION ON DISCOLORED ZINC OXIDE AFTER HEATING

E. A. Secco

As part of a general program on solid state reactions at temperatures up to 1200 °C, we have studied the effect of temperature on discolored zinc oxide—the discoloration is associated with impurities lodged in the oxide matrix. The discolored zinc oxide was obtained from a melt of varying proportions of ZnO and ZnF_2.

The preparation procedure consisted simply of heating the mixture containing varying proportions of U.S.P. zinc oxide and Technical Grade zinc fluoride, in a graphite or alundum crucible, at 1000 °C for 2–5 hours followed by slow cooling in the furnace. That is, the crucible and contents remained in the cooling furnace until room temperature was attained. With an oxide-rich mixture a green residue was obtained, while with a fluoride-rich mixture a blue residue resulted.

The discolored residue was crushed to a powder in a mortar and prepared for the specimen stage of Model X-86-N high-temperature, high-vacuum attachment (1) to the Norelco wide range goniometer. The specimen stage supplied with the attachment was an elevated surface and the specimen, a suspension in a volatile liquid, was placed on the surface. With this arrangement only a very thin film was available for investigation and there existed the possibility of contamination with constituents other than the specimen. The stage was modified to overcome these potential difficulties by depressing the surface to a depth of 1 mm and enclosing the stage with retaining walls of platinum foil of 1 mm, as shown in Fig. 1. The powder sample was now placed on the stage with a spatula and pressed to

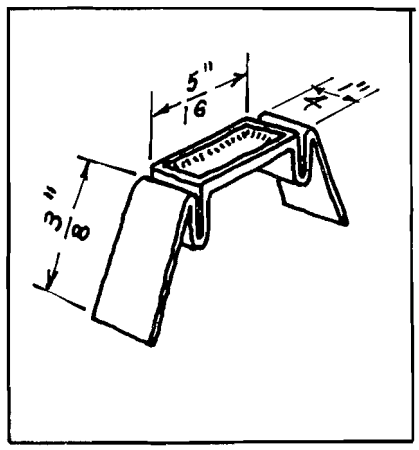

FIG. 1. Modified design of stage for powder specimen.

present a smooth surface to the incident X-ray beam. After the specimen had been positioned and aligned for maximum reflection, the powder was scanned. The diffracted radiation was detected by a Geiger counter and fed to the recorder for a trace of the pattern or diffractogram.

RESULTS AND DISCUSSION

Figure 2 shows a sequence of diffractograms obtained with grey–blue ZnO, I–IV, along with untreated U.S.P. Merck ZnO, V. These traces were obtained under identical operating conditions: angular aperture 1°; receiving slit 0.003 in.; X-radiation, CuK_α, at 45 kV and 15 mA; G.-M. tube voltage, 1550 V; scale factor 16, multiplier 1, time constant 2; scanning speed 1° (2 θ) per min; scan at room temperature (15–20 °C).

During the heating prior to trace II, fumes were observed through the window and a pungent odor was detectable. After the anneal prior to trace IV, the specimen had undergone a significant color change to grey–yellow. Similar annealing of the U.S.P. zinc oxide up to 720 °C did not alter the diffractogram but at 850–875 °C sublimation of the oxide occurred, which reduced all peak intensities proportionately.

No apparent correlation between temperature or time of anneal and the variation in peak intensities was evident, as shown in Fig. 3. Heating in nitrogen or air atmosphere produced the same effects. Similar observations were made on the intensities' variation of the characteristic peaks of crushed natural sphalerite, ZnS, after heating before the onset of oxidation, while such variation was absent with pure ZnS and on crushed natural "red" zincite, ZnO. The qualitative conclusion is that the peak intensity variations are associated with impurities in the host oxide rather than with particle size and (or) the amorphous character of the particles (2).

A possible interpretation of these results is based on impurities incorporated in the oxide. The exact nature of the impurity is not known but fluoride is suspected as the most probable. The radii of $O^=$ and F^- given as 1.40 Å and 1.36 Å respectively (3), suggest that the fluoride ion may be substituted for the oxide ion without distortion of the oxide lattice to yield an anionic substitution compound of composition ZnF_xO_{1-x}, with $x < 0.1$. Since $O^=$ and F^- are isoelectronic their X-ray scattering factors are the same and the supposed ZnF_xO_{1-x} would be expected to give a typical ZnO diffraction pattern. On

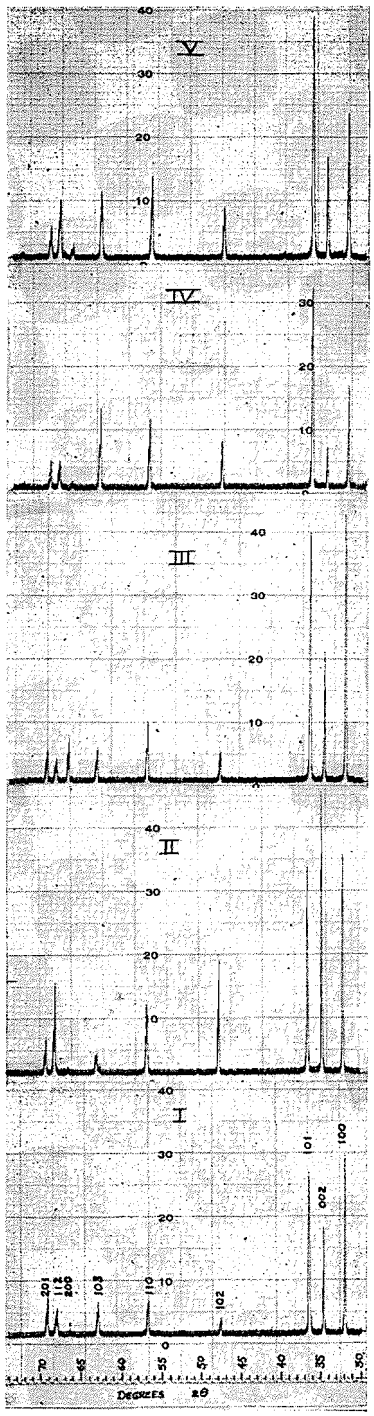

FIG. 2. I, Unannealed grey-blue ZnO; II, same specimen heated in air at 510 °C for 40 min; III, same specimen heated in air at 720 °C for 30 min; IV, same specimen heated in air at 850–875 °C for 183 min; V, Merck, U.S.P. ZnO.

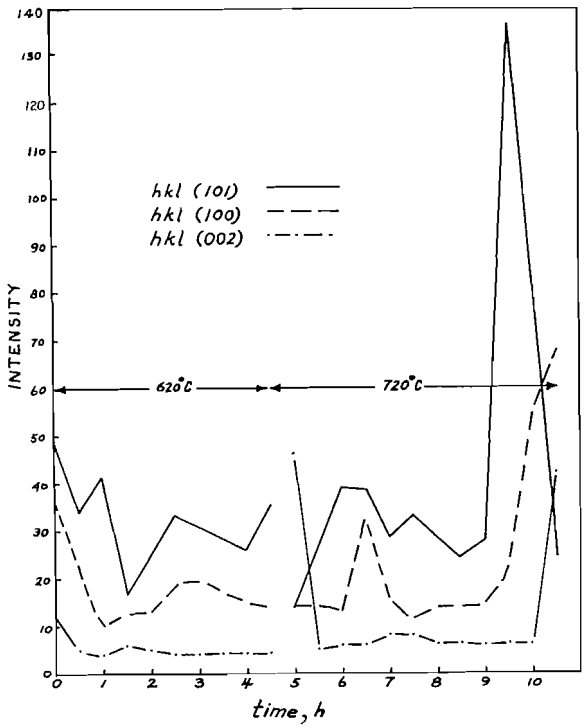

FIG. 3. Variation of peak intensities vs. time of anneal.

heating the presumed compound in air or in nitrogen atmospheres the volatile F^- is expected to move out of the lattice, causing a fractional collapse with subsequent rearrangement of the host ions. The diffractogram after heating would represent the rearranged lattice quenched in a random state of orientation after a loss of a certain fraction of F^-. With sufficient annealing or at sufficiently high temperature, all the effective F^- will have sublimed from the oxide and the diffractogram intensities approach those intensities recorded in A.S.T.M. index No. 5-0664.

A feature which militates against such an interpretation is that the elimination of F^- from the lattice would be expected to be progressive and that such a progression would be reflected in the peak intensities' variation, in contrast to Fig. 3. However, two processes are operative in each anneal, that is, the migration of F^- ions to the particle surface and redistribution of the F^- ions in the particle bulk. These two processes contributing to lattice disruptions and subsequent rearrangements after successive anneals would depend on such factors as F^- ion mobility rate, the stability of the various crystal faces (4), the relative composition of the particles, and the particle-size distribution. The interplay of these factors is beyond the scope of our present understanding.

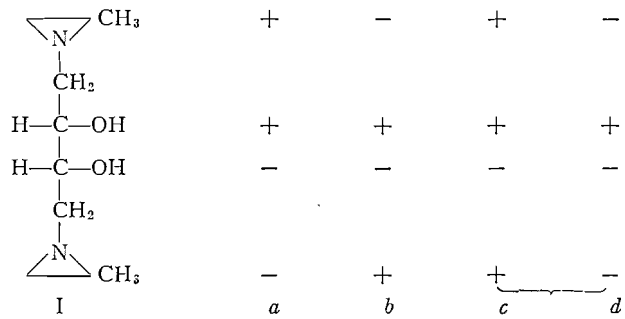
THE REACTION OF DL-PROPYLENIMINE WITH MESO-1,2;3,4-DIEPOXYBUTANE

SANDRA L. HOLTON, JAMES E. CHRISTENSEN, OSBORNE P. CREWS, AND LEON GOODMAN

A previous paper (1) from these laboratories described the preparation of *meso*-1,4-bis(1-aziridinyl)-2,3-butanediol, an interesting anti-tumor agent, from the reaction of ethylenimine and *meso*-1,2;3,4-diepoxybutane. The conversion of that bis-aziridine to the potential anti-radiation drug, 1,4-bis-[(2-mercaptoethyl)amino]-*meso*-2,3-butanediol dihydrochloride, was described in a subsequent manuscript (2). The interesting biological activity of the bis-aziridine and the bis-thiol was the impetus for the preparation of some C-methyl substituted analogues of these compounds. This note reports these studies.

The reaction of DL-propylenimine with *meso*-1,2;3,4-diepoxybutane can give three possible diastereoisomeric products; these are represented as I*a*, I*b*, and I*cd* below. It is apparent that I*a* and I*b* are two optically compensated *meso*-forms and that I*c* and I*d*



constitute a DL-racemate. In practice, reaction of the *meso*-diepoxide with excess DL-propylenimine gave three crystalline solids. The two higher melting materials were easy to obtain as sharply melting solids; the lowest melting material was obtained with some difficulty from the reaction residues. The reaction of D(+)-propylenimine with *meso*-1,2;3,4-diepoxybutane gave a sharply melting crystalline solid which obviously is isomer I*c*. The nuclear magnetic resonance (n.m.r.) spectra, run in deuterium oxide, of the three diastereoisomers from the DL-propylenimine reaction were distinctly different, the major differences appearing in the absorptions due to the six ring protons. The n.m.r. spectrum

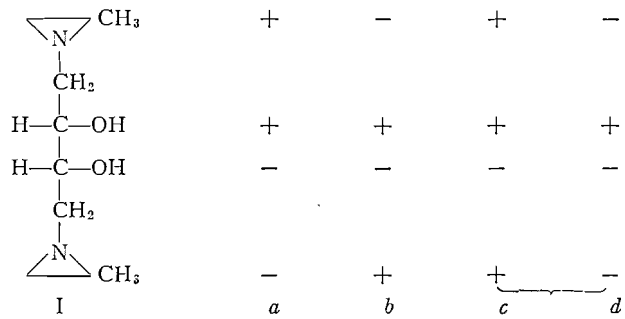
THE REACTION OF DL-PROPYLENIMINE WITH MESO-1,2;3,4-DIEPOXYBUTANE

SANDRA L. HOLTON, JAMES E. CHRISTENSEN, OSBORNE P. CREWS, AND LEON GOODMAN

A previous paper (1) from these laboratories described the preparation of *meso*-1,4-bis(1-aziridinyl)-2,3-butanediol, an interesting anti-tumor agent, from the reaction of ethylenimine and *meso*-1,2;3,4-diepoxybutane. The conversion of that bis-aziridine to the potential anti-radiation drug, 1,4-bis-[(2-mercaptoethyl)amino]-*meso*-2,3-butanediol dihydrochloride, was described in a subsequent manuscript (2). The interesting biological activity of the bis-aziridine and the bis-thiol was the impetus for the preparation of some C-methyl substituted analogues of these compounds. This note reports these studies.

The reaction of DL-propylenimine with *meso*-1,2;3,4-diepoxybutane can give three possible diastereoisomeric products; these are represented as I*a*, I*b*, and I*cd* below. It is apparent that I*a* and I*b* are two optically compensated *meso*-forms and that I*c* and I*d*

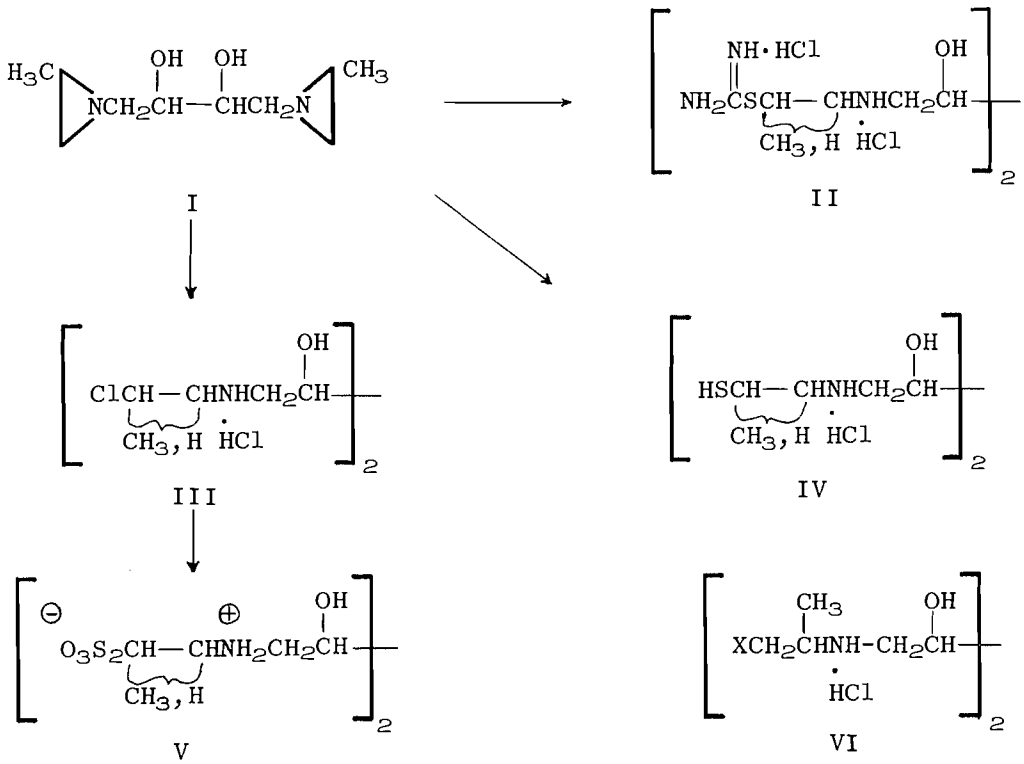


constitute a DL-racemate. In practice, reaction of the *meso*-diepoxide with excess DL-propylenimine gave three crystalline solids. The two higher melting materials were easy to obtain as sharply melting solids; the lowest melting material was obtained with some difficulty from the reaction residues. The reaction of D(+)-propylenimine with *meso*-1,2;3,4-diepoxybutane gave a sharply melting crystalline solid which obviously is isomer I*c*. The nuclear magnetic resonance (n.m.r.) spectra, run in deuterium oxide, of the three diastereoisomers from the DL-propylenimine reaction were distinctly different, the major differences appearing in the absorptions due to the six ring protons. The n.m.r. spectrum

of I*c* was essentially identical with that of the low melting diastereoisomer which is therefore the DL-racemate; the two higher melting isomers are therefore the *meso*-forms I*a* and I*b*.

The three diastereoisomers were converted to a series of potential anti-radiation drugs.

A series—from high melting *meso*-bis-aziridine.
B series—from low melting *meso*-bis-aziridine.
C series—from DL-racemate form of the bis-aziridine.



Thus reaction of the bis-aziridines (I) with hydrogen sulphide followed by reaction of the resulting thiols with hydrogen chloride afforded the bis-mercaptans (IV). Opening of the isomeric compounds I with hydrochloric acid yielded the chloroethylamines (III) that could be converted to the Bunte salts (V) with thallous thiosulphate (3) or, in the case of IIIB, with sodium thiosulphate. The reaction of IA and IB with thiourea and hydrochloric acid (4) gave the bis-isothiuronium salts (IIA and IIB). Compounds II, III, IV, and V are represented as mixtures which result from opening of the aziridine ring at C-2 or C-3; the predominant products would be expected to be those (VI) from attack at the secondary ring carbon.

EXPERIMENTAL

1,4-Bis-(2-methyl-1-aziridinyl)-meso-2,3-butanediol (I)

A stirred mixture of 20.0 g (0.232 mole) of *meso*-1,2;3,4-diepoxybutane, 52.9 g (0.928 mole) of DL-propylenimine and 75 ml of methylal was heated at reflux for 18 h, then cooled to room temperature, and filtered.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

A crystalline precipitate, 8.5 g (18%), m.p. 167–169° (from IA) was isolated. From a previous run a sample of IA was obtained, m.p. 171–172°, and was analyzed. Anal. Calc. for $C_{10}H_{20}N_2O_2$: C, 60.0; H, 10.1; N, 14.0. Found: C, 59.9; H, 10.1; N, 14.3.

The filtrate from IA was chilled (0°) and the solid IB precipitated, 6.6 g (14%), m.p. 107–109°. Recrystallization from ethyl acetate of this solid gave 4.0 g, m.p. 110–113°. From a previous run an analytical sample of the *meso*-compound IB had been obtained by several recrystallizations from Skellysolve C (b.p. 88–99°), m.p. 113–115°. Anal. Found: C, 60.2; H, 10.0; N, 14.2.

The filtrate from IB was evaporated *in vacuo* and the residue recrystallized from ethyl acetate affording 7.9 g of the DL-racemate (IC), m.p. 75–77°. Anal. Found: C, 59.8; H, 10.2; N, 14.2.

The three forms IA, IB, and IC as Nujol mulls gave well-resolved infrared spectra, that were characteristic and reproducible for each compound. Compound IA had a band at 13.0 μ that was absent in the spectra of the other two isomers. Compounds IB and IC had distinctly different infrared spectra, but there were no strong bands in the spectrum of one that were free of absorption in the spectrum of the other. The n.m.r. spectra, determined in deuterium oxide for forms IA, IB, and IC were also different and distinctive for each form. The major differences were found in the patterns for the six aziridine ring protons.

1,4-Bis-[(D(+)-2-methyl-1-aziridinyl)]-meso-2,3-butanediol

A mixture of 0.40 g (4.64 mmoles) of *meso*-butadiene diepoxide, 1.4 g (24 mmoles) of D(+)-propylenimine,* and 1 ml of isopropanol was heated at 50° for 5.5 h then was allowed to stand at room temperature for 48 h. The mixture was evaporated *in vacuo* giving a colorless sirup which slowly crystallized when chilled under 2–3 ml of ether. The crystalline solid, 0.40 g (43%), m.p. 78–84°, was sublimed at 60–70° and 0.4 mm to give the analytical sample, m.p. 83–85°, $[\alpha]_D^{24}$ −56° (0.935% in water). Its n.m.r. spectrum in deuterium oxide was virtually superimposable on that of IC and was distinctly different than those of the two *meso*-forms (IA and IB). Anal. Calc. for $C_{10}H_{20}N_2O_2$: C, 60.0; H, 10.1; N, 14.0. Found: C, 59.7; H, 9.8; N, 14.1.

1,4-Bis-[(meso and DL-2-mercapto-(1)2-methylethyl)amino]-meso-2,3-butanediol (IV)

1. From IA

Hydrogen sulphide gas was bubbled through a suspension of 2.00 g (10.0 mmoles) of IA in 30 ml of methanol for 1 h at room temperature during which time the solid dissolved. Hydrogen chloride was then bubbled through the clear solution until it was distinctly acidic to pH paper (pH ~2). Ether was added to the cloud point and the mixture was chilled. The white, crystalline, nitroprusside-positive solid 1.74 g (57%) was collected, m.p. 170–190° dec. Anal. Calc. for $C_{10}H_{26}Cl_2N_2O_2S_2$: C, 35.2; H, 7.68; Cl, 20.8; N, 8.21; S, 18.8. Found: C, 35.2; H, 7.76; Cl, 20.6; N, 8.07; S, 18.4.

2. From IB

Using the above procedure, starting with 0.41 g of IB, there was obtained 0.20 g (32%) of product, m.p. 162–166° dec. Anal. Found: C, 35.1; H, 7.79; Cl, 21.2; N, 8.22; S, 18.5.

3. From IC

A solution of 0.73 g of IC in 120 ml of methanol was treated with hydrogen sulphide as described above. The solution, which contained undissolved solid, was filtered and treated with a 2% solution of hydrogen chloride in methanol to pH 2 (pH paper), then was evaporated *in vacuo* and the residue thoroughly triturated with ether. A solid formed when the residue was maintained in high vacuum for several hours. The very hygroscopic solid melted with decomposition over a wide range with decomposition more vigorous at 100°. Anal. Found: C, 35.2; H, 7.95; Cl, 20.7; N, 8.24; S, 18.6.

1,4-Bis-[(meso or DL-2-chloro-(1)2-methylethyl)amino]-meso-2,3-butanediol Dihydrochloride (III)

1. From IA

To 50 ml of chilled (0°), stirred, concentrated aqueous hydrochloric acid was added slowly 0.50 g (2.5 mmoles) of IA and the resulting solution was stirred at 0° for 1 h, then evaporated *in vacuo* at room temperature. The solid white residue was washed several times with ether giving 0.86 g (100%) of product. Recrystallization from 20 ml of 95% ethanol afforded 0.41 g (48%) of white crystals, m.p. 215–230° dec. A second crystallization from methanol–ether gave 0.36 g of solid, m.p. 220–228° dec. and a third recrystallization from methanol–ether gave 0.32 g of the analytical sample, m.p. 220–227° dec. Anal. Calc. for $C_{10}H_{24}Cl_4N_2O_2$: C, 34.7; H, 6.99; Cl, 41.0; N, 8.09. Found: C, 35.0; H, 6.95; Cl, 41.0; N, 8.16.

2. From IB

Using the same quantities and the same procedure with IB that was described for IA, there was obtained 0.55 g (64%) of the analytical sample, m.p. 223–229° dec. Anal. Found: C, 34.3; H, 7.38; Cl, 40.6; N, 7.92.

3. From the DL-Racemate, (IC)

Using the same procedure as described for IA, 0.63 g of IC gave 0.27 g (25%) of the analytical sample of III, m.p. 216–223° dec. Anal. Found: C, 34.7; H, 7.30; Cl, 41.0; N, 8.14.

**A generous supply of this compound was provided by Dr. Robert R. Engle, Riker Laboratories, Inc., Northridge, California.*

1,4-Bis-[(meso or DL-*2-mercapto-(1)2-methylethyl)amino]-meso-2,3-butanediol-S,S-disulphate (V)*

1. From IIIA

A suspension of 18.32 g (53 mmoles) of the bis-(2-chloroethyl) amine (IIIA), 57.6 g of thallous thiosulphate (0.247 mole), and 280 ml of water was heated with stirring at 70–80° for 1 h, then a second 57.6-g portion of thallous thiosulphate was added and heating was continued for 18 h. The suspension was cooled to room temperature and filtered, and the filtrate was chilled affording 13.5 g (58%) of white crystals, m.p. 209–213° dec. Recrystallization from 200 ml of boiling water yielded 11.5 g (49%) of the analytical solid, m.p. 211–216° dec. Anal. Calc. for $C_{10}H_{24}N_2O_8S_4 \cdot H_2O$: C, 26.9; H, 5.87; N, 6.27; S, 28.7. Found: C, 26.9; H, 5.46; N, 6.02; S, 28.4.

2. From IIIB

A solution of 2.56 g (7.40 mmoles) of IIIB, 3.66 g (11.5 mmoles) of sodium thiosulphate (pentahydrate), and 40 ml of water was stirred at 80° for 1.5 h, then a second 3.66-g portion of sodium thiosulphate was added and the mixture was heated for 13 h more, then chilled. The white crystalline precipitate, 2.55 g, was collected and recrystallized from 20 ml of hot water affording 2.35 g (74%) of crystals, m.p. 193–200° dec. Anal. Calc. for $C_{10}H_{24}N_2O_8S_4$: C, 28.0; H, 5.64; N, 6.54; S, 29.9. Found: C, 27.7; H, 6.05; N, 6.32; S, 29.9.

3. From IIIC

The reaction of 1.77 g (5.11 mmoles) of IIIC with thallous thiosulphate as described for the preparation of IIIA gave 1.28 g (58%) of the crude bis-Bunte salt. Recrystallization from 5 ml of hot water afforded 0.75 g (34%) of the analytical sample, m.p. 184–192° dec. Anal. Found: C, 27.7; H, 6.09; N, 6.50; S, 29.7.

1,4-Bis[meso-1(2)methyl-2-isothiuroniumethyl]amino-2,3-meso-dihydroxybutane Tetrahydrochloride (II)

1. From IA

To a stirred solution of 4.08 g (53.7 mmoles) of thiourea in 40 ml of methanol containing 9.1 ml of concentrated hydrochloric acid (0.107 mole) was added slowly 5.37 g (26.8 mmoles) of IA. After the addition, the mixture was stirred at room temperature for 0.5 h, then chilled. The white precipitate, 4.68 g (35%), m.p. 205–215° dec., was washed with methanol and ether. A second crop, 4.73 g (36%), m.p. 205–211° dec., was obtained by the addition of ether to the filtrate. Anal. Calc. for $C_{12}H_{32}Cl_4N_6O_2S_2$: C, 28.9; H, 6.48; Cl, 28.5; N, 16.9, S, 12.9. Found (for first crop): C, 29.0; H, 6.64; Cl, 28.4; N, 16.7; S, 12.7; (for second crop): C, 29.1; H, 6.87; Cl, 28.5; N, 16.8; S, 12.7.

2. From IB

The conversion of 0.51 g of IB by the procedure described above for the high melting *meso*-form (IA) gave a low yield of a white crystalline solid that was recrystallized from 1 ml of methanol yielding 0.26 g (20%) of product, m.p. 205–213° dec. Anal. Found: C, 29.1; H, 6.50; Cl, 28.2; N, 16.5; S, 13.2.

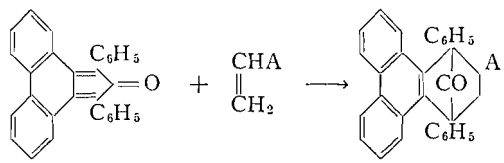
NEW PHENCYCLONE ADDUCTS FROM ETHYLENIC COMPOUNDS

C. F. H. Allen and R. Y. Ning

The formation of adducts from cyclopentadienones ("cyclones") and unsaturated compounds is now well known. Since the extensive literature has appeared in two reviews (1, 2), pertinent references will be given specifically only as needed. It has been reported that adducts are obtained most readily and retained the carbonyl bridge best with phencyclone (I) (3); such a behavior has been confirmed in this laboratory. Since a few investigators have successfully used (1, 2, 4) ethylenic compounds the possibility of using this reaction to identify styrenes and simple non-conjugated olefinic substances, by preparing solid derivatives, was undertaken.

Seven new adducts (II) of phencyclone were prepared. The latter are carbonyl-bridged derivatives of triphenylene, bearing substituents in the 2-position; for example, styrene gives 13-oxo-1,2,4-triphenyl-1,2,3,4-tetrahydro-1,4-methanotriphenylene (II, A = C_6H_5).



I II

The unsaturates employed were 1-hexene, 1-octene, styrene, allyl acetate, butyl acrylate, isopropyl methacrylate, and 2-β-phenethyl methacrylate. Hence, in the adducts, the groups in the 2-position are butyl, hexyl, phenyl, 2-acetoxymethyl, 2-butoxycarbonyl, 2-isopropoxycarbonyl-2-methyl, and 2-methyl-2-β-phenethoxycarbonyl respectively. Oils and gums resulted when vinyl ethers, 2-ethylhexyl acrylate, and 2-methyl- and 4-methylpentenes were employed.

From the limited examples described in this note it appears that phencyclone may be useful in giving solid adducts with styrenes, olefines having terminal unsaturation, allyl compounds, and acrylates, provided no large aliphatic groups are present. Unfortunately, the slow addition, even to the most reactive but difficultly accessible phencyclone, contamination by products of subsequent decarbonylation or other secondary reactions, and reluctance to crystallize, renders this objective discouraging. Active work was discontinued upon the announcement that adducts suitable for the same purpose of identification could be easily obtained by the use of 1,3-dipolar compounds (5); the yields are excellent, but reaction time of 90 hours is rather long. Our results are reported at this time as a contribution to the field of carbonyl bridge compounds.

EXPERIMENTAL

Phencyclone is not easy to prepare. In our hands the best yield (88%) was obtained by modifying the procedure (6) by using propyl alcohol as a solvent and "Triton B" as catalyst. A mixture of 25 g (0.12 mole) of phenanthrenequinone (Eastman Number 1269) and 26 g (0.12 mole) of dibenzyl ketone (Eastman Number P974) is stirred to a thin paste with a little propyl alcohol, and the rest of a total of 1 l of propyl alcohol added. The suspension is stirred and heated to boiling, so that partial solution takes place. The hot mixture is then cooled in ice water to about 60°. While the mixture is cooling, a solution of 5 ml of Triton B (a 40% aqueous solution of benzyltrimethylammonium hydroxide) in 10 ml of propyl alcohol is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

added from a medicine dropper, in small squirts; with each addition, the mixture is vigorously stirred. The rate of addition is timed so that all the base has been added only when the temperature has dropped to 60°. (If too much of the base is admitted without efficient cooling, flocks of a white contaminant become visible.) The temperature is maintained at 60°, and stirring is continued until the orange color of the quinone disappears (5–10 min). The phencyclone is then collected on a filter, rinsed with ethyl alcohol, and dried at about 100°. The average yield was 88%, and the melting point, 245–255°.

Preparation of adducts.—Preliminary exploratory tests showed that addition was rapid (solution decolorized) at about 150° (b.p. of styrene or cumene), but to avoid decarbonylation the temperature must be kept lower. Boiling toluene or dimethylformamide at various temperatures were successfully used; the latter solvent was generally employed, though uniform conditions were not observed. Toluene was preferred with styrene and with butyl acrylate. In all instances a *trace* of concentrated sulphuric acid was added as a catalyst.

A mixture of 4 g of phencyclone and 6 ml of styrene in 60 ml of toluene, with a microtrace of sulphuric acid, was heated to boiling. The initial green color quickly changed to yellow. The solution was cooled in ice water and the adduct was precipitated by addition of an equal volume of hexane. It was recrystallized from toluene–hexane.

A mixture of 6 ml of isopropyl methacrylate and 4 g of phencyclone in 25 ml of dimethylformamide, with a trace of sulphuric acid, was warmed for 2 h at 40° with occasional shaking, and let stand 2 days. The adduct was precipitated by water, and recrystallized from acetone or benzene – petroleum ether. It is light sensitive.

The properties of the new adducts are collected in Table I. The presence of the carbonyl bridge was evident from the analytical figures, and was confirmed by the infrared spectra.

TABLE I

Properties of the adducts (II)

Addend	Group A in 2 position	M.p., °C	Mol. wt.	Analyses

PHOTOCHEMICAL TRANSFORMATIONS OF DIENES[1]

II. THE PHOTOLYSIS OF 3-METHYLCHOLESTA-3,5-DIENE (V)[2]

G. JUST AND V. DI TULLIO[3,4]

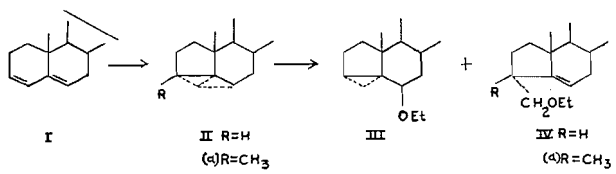
Department of Chemistry, McGill University, Montreal, Quebec

Received December 27, 1963

ABSTRACT

Photolysis of 3-methylcholesta-3,5-diene (V) in ethanol gave 3-methylenecholest-5-ene (VI), 6β-ethoxy-3α-methyl-3β,5-cyclo-5β-cholestane (VII), 3β-ethoxy-3α-methylcholest-5-ene (VIII), and 3α-methylcholesterol (VIII*a*) as well as a number of unidentified hydrocarbons and alcohols. A similar photolysis in pentane, followed by reaction of the resulting 3β,5;4α,6α-bicyclo-5β-cholestane (II*a*) with ethanol, gave the cyclo ether VII as the only isolable product.

Recently, Dauben *et al.* (2) reported that the photolysis of cholesta-3,5-diene (I) in ethanol gave 6-ethoxy-3β,5-cyclo-5β-cholestane (III) accompanied by a minor amount of the A-nor ether IV. These two products were also obtained in identical yields by the reaction of ethanol with the bicyclobutane II, itself obtained by irradiation in pentane



of diene I. Since we were interested in obtaining compounds of type III bearing an alkyl group at C_3, we decided to irradiate 3-methylcholesta-3,5-diene (V).

Cholest-4-en-3-one (3) was treated with methyl magnesium iodide (4). The resulting diene V absorbed in the ultraviolet at 232, 239, and 248 mμ (log ϵ 4.26, 4.29, 4.16).

A solution of diene V in ethanol–pentane (1:9)[5] was irradiated with a 450 W mercury arc lamp until the ultraviolet absorption of the reaction mixture between 220 and 400 mμ was negligible. The solvent was then evaporated and the residue chromatographed on silica gel.

1. Hexane eluted an oil (6.8%) which could not be crystallized. The nuclear magnetic resonance (n.m.r.)[6] indicated the presence of starting material, 3-methylenecholest-5-ene (VI), and other olefins which could not be separated.

[1]*For paper I, see reference 1.*
[2]*Presented in part at the A.C.F.A.S. meetings in Montreal (1962) and Quebec (1963).*
[3]*From part of the thesis presented by V.D.T. in partial fulfillment of the requirements for the Ph.D. degree.*
[4]*Holder of a National Research Council of Canada Studentship 1962–1963.*
[5]*Very similar results were obtained when absolute ethanol was used as solvent.*
[6]*Tetramethylsilane = 0.*

2. Further elution with hexane gave a crystalline diene, ν 3030, 1648, and 888 cm^{-1} ($C{=}CH_2$), δ 4.55 p.p.m. (2H, $C{=}CH_2$) and 5.29 p.p.m. (1H, C=CH—), in approximately 15% yield. The diene VI did not absorb in the ultraviolet between 220 and 400 mμ and was hence not conjugated. Catalytic hydrogenation with platinum oxide in acetic acid gave 3-methylcholestane (IX) (5). Treatment with perchloric acid in dioxane at 70° overnight gave a quantitative yield (by ultraviolet) of 3-methylcholesta-3,5-diene (V). Chemical and spectral properties of the diene were compatible with 3-methylene-cholest-5-ene (VI). However, all attempts to prove the proposed structure by degradation reactions or by synthesis were unsuccessful. An indirect proof of structure was therefore sought. Diene VI was treated with slightly less than one equivalent of diborane in diglyme for 1 h (6). Chromatography gave 3-hydroxymethylcholest-5-ene (X), identical in all respects with a sample prepared by reaction of the Grignard reagent from cholesteryl chloride (XI) in tetrahydrofuran with paraformaldehyde.

3. Elution with benzene and crystallization from hexane gave a compound, $C_{30}H_{52}O$,[7] in 20–30% yield. Its n.m.r. spectrum showed a pair of one proton doublets (J = 4.5 c.p.s.) at −0.47 and 0.45 p.p.m. characteristic for geminal protons (7) on a cyclopropane ring, and a three proton signal in the 3–3.5 p.p.m. region. This signal was very similar to that shown by photoether III. By analogy with Dauben's work (2) on cholesta-3,5-diene (I), this compound was assigned structure VII. Heating under reflux of photoether VII with perchloric acid in dioxane gave 5% (identified by ultraviolet analysis) of 3-methyl-cholesta-3,5-diene (V) and a mixture of alcohols which could not be separated.

Chromatography of the photoether VII on alumina (activity I) resulted in the loss of the elements of ethanol (2*a*) and the formation of olefin XIII, similar to that described by Dauben (2) in the 3-unsubstituted series. The signals for the C_4-cyclopropane protons were now at −0.08 and 0.59 p.p.m. (J = 5 c.p.s.). The olefinic protons at C_6 and C_7 were chemically equivalent and appeared as a singlet at 5.38 p.p.m. Comparison of the n.m.r. spectrum of this olefin with 3β,5-cyclo-5β-cholest-6-ene (XIII*a*) (2*a*) and 3α.5-cyclo-5α-cholest-6-ene (XV) (8, p. 318) supported quite conclusively the stereochemical assignment of the cyclopropane ring (see Table I). In the case of the Δ^6-3β,5-cyclo derivatives, the two olefinic protons appeared essentially as a singlet, whereas in the 3α,5-cyclo compound, the C_6 and C_7 olefinic protons appeared as an evenly spaced (J = 10 c.p.s.) four line system centered at 5.33 p.p.m. Heating olefin XIII under reflux with perchloric acid in aqueous dioxane gave a 24% yield of 3-methylcholestadiene (V). When ethanol was used as a solvent and the solution refluxed overnight, 21% diene V (identified by ultraviolet analysis) and variable yields (5–30%) of 3β-ethoxy-3α-methylcholest-5-ene (VIII) were obtained. Ether VIII was identical in all respects with the photoether described below. These experiments showed that the 3-methyl group influenced markedly the course of the acid-catalyzed reaction of both ether VII and olefin XIII, and probably stabilized a positive charge at C_3 in an intermediate carbonium ion (no formation of cholestadiene or cholesterol was detected in a similar reaction of photoether III).

Catalytic hydrogenation of olefin XIII with platinum oxide in acetic acid at 40° and 60 p.s.i. gave 3α-methyl-3β,5-cyclo-5β-cholestane (XIV), δ 0.44 p.p.m. (1H, doublet, J = 4.45 c.p.s.) and −0.35 p.p.m. (1H, triplet,[8] J = 4.5 c.p.s.).

4. Elution with benzene–ether (4:1) gave an olefinic ether, in 20–30% yield. The n.m.r. spectrum showed low-field signals at 3.45 p.p.m. (2H, quartet, J = 7 c.p.s., OCH_2CH_3) and 5.26 p.p.m. (1H, broad, C=C—H) only. Heating ether VIII under reflux with

[7]*This compound could also be obtained by direct crystallization of the crude photoylsis mixture.*
[8]*Due probably to long-range coupling, which will be discussed in a forthcoming paper.*

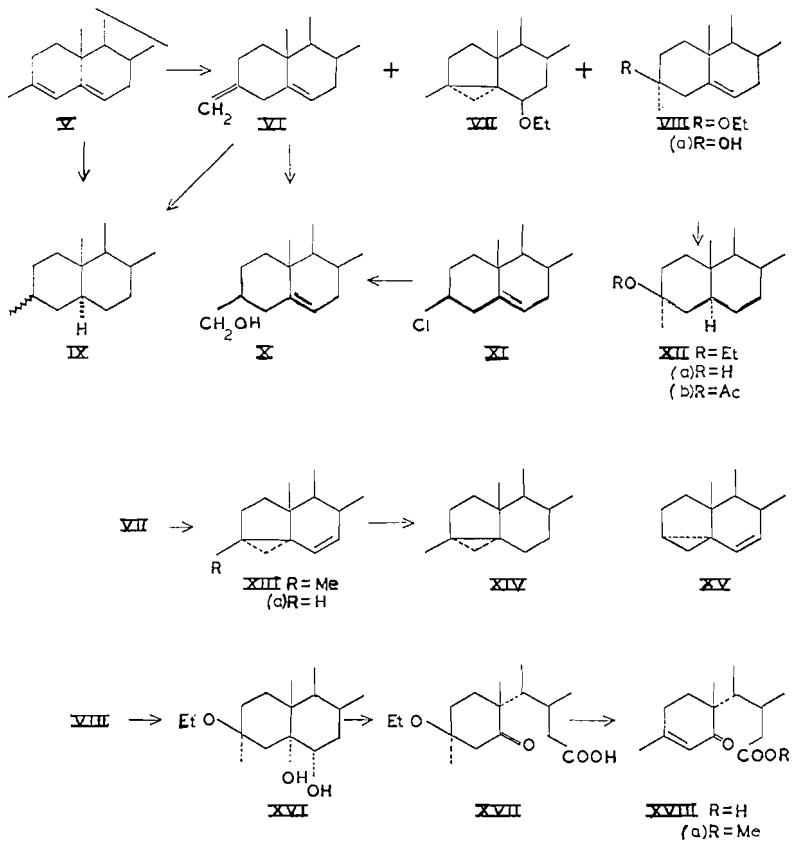
For personal use only.

pyridine hydrochloride in acetic acid gave 3-methylcholesta-3,5-diene (V). Catalytic reduction at 60 p.s.i. and 40° in acetic acid gave 3-methylcholestane (IX) (5) (29%) and 3β-ethoxy-3α-methylcholestane (XII) (51%). The reduced photoether was obtained in 78% yield as the only crystalline product when sodium nitrite was added to the reaction mixture (9). All attempts to hydrolyze the ether function of either VIII or XII failed and resulted either in recovery of starting material or formation of olefins. The reduced photoether XII was oxidized with ruthenium tetroxide in carbon tetrachloride (10) to a



mixture of 3α-methylcholestan-3β-ol (XII*a*) and its acetate XII*b*. Both compounds were identified by comparison with an authentic sample (5*b*, 11), and were distinctly different from the C_3-epimers (5*b*). This proved the stereochemistry at the C_3-position.

Since the reduction of photoether VIII had resulted in hydrogenolysis, when no sodium nitrite had been added, and since molecular rotation increments upon hydrogenation of VIII to XII did not permit unambiguous assignment of the position of the double bond to either the 4- or the 5-position, it was determined in the following way. Reaction with osmium tetroxide gave diol XVI, which was further oxidized to keto acid XVII (3.37 p.p.m., 2H, quartet, $J = 7$ c.p.s.) by chromic acid in aqueous acetic acid at room temperature. When the chromic acid oxidation was carried out at a higher temperature, the dehydroethoxylated keto acid XVIII was obtained. Keto acid XVIII was also obtained by heating XVII with Fehling's solution or with pyridine hydrochloride in acetic acid. Keto acid XVIII, obtained from the three reactions, was amorphous. Its spectral properties were characteristic of an α,β-unsaturated ketone ($\lambda_{max}^{C_6H_{12}}$ 231 mμ, λ_{max}^{EtOH} 236 mμ,

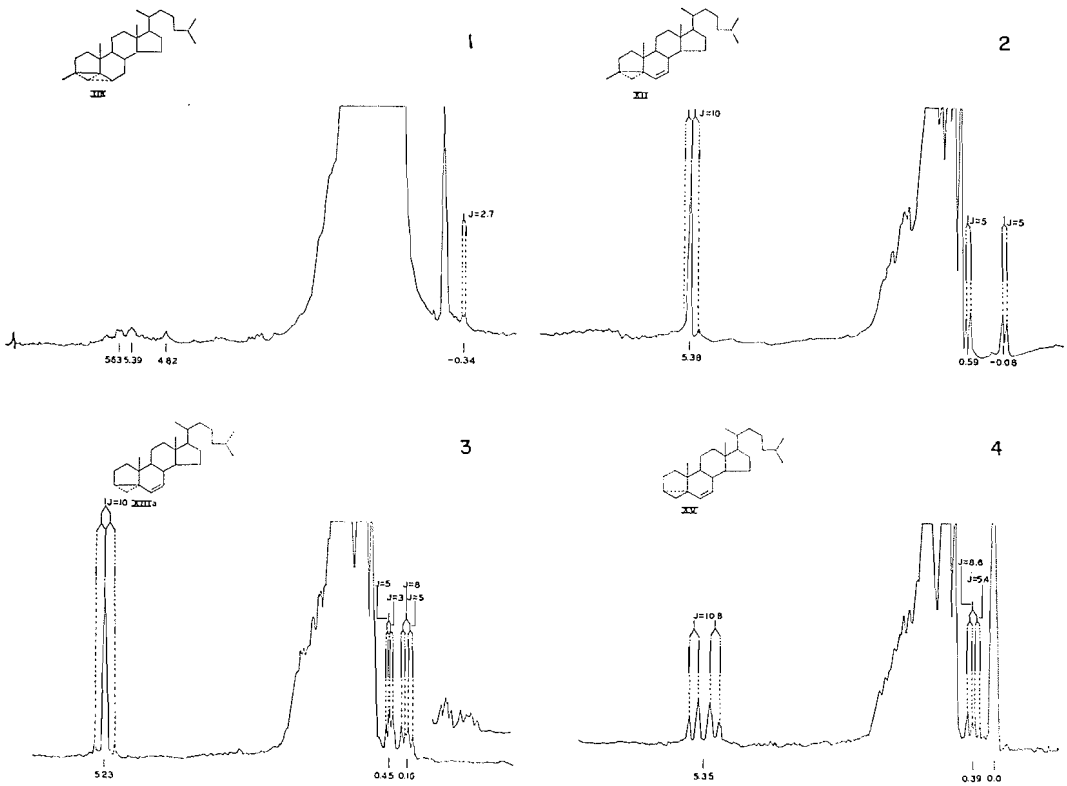
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ν_{CCl_4} 1675 cm^{-1}) and not of an α,β-unsaturated acid. When XVIII was treated with ethereal diazomethane, an amorphous methyl ester was obtained. It absorbed in the ultraviolet at 236 mμ (ethanol) and in the infrared at 1675 cm^{-1} and 1738 cm^{-1}, confirming the assignment of the functional groups in XVIII.

The identity of photoether VIII was further proved by comparison with the ethanolysis product of 3α-methylcholesteryl mesylate (5*b*).

5. Elution with ether gave, in 6.7% yield, an oil from which some 3α-methylcholesterol (5*b*) was isolated.

When the photolysis of 3-methylcholesta-3,5-diene (V) was carried out in pentane, and the solvent evaporated carefully, an oil, $[\alpha]_D$ −85°, δ −0.34 p.p.m. (J = 2.65 c.p.s.) was obtained (see Fig. 1). The high-field n.m.r. signal of the oil was most likely due to a



FIGS. 1–4. Fig. 1, taken in deuterochloroform; Figs. 2–4, taken in carbon tetrachloride.

proton attached to the bicyclobutane ring system in II*a*, which, judging from the intensity of the peak, was present in approximately 30%. Treatment of the oil with boiling ethanol gave photoether VII as the only crystalline product in 20–30% yield. The reaction was repeated a number of times. In no instance was it possible to detect even a trace of VIII either by thin-layer chromatography or by other chromatographic procedures.

The photolysis in ethanol hence gave a different product distribution than the photolysis in pentane, followed by a dark reaction in ethanol. This is in marked contrast to the results described by Dauben for the 3-unsubstituted cholestadiene (I), in which identical products had been obtained in both sets of reactions.

For personal use only.

Further work is in progress to establish the mode of formation of some of the photoproducts described.

EXPERIMENTAL

All melting points were taken in a melting point tube and were uncorrected. Infrared spectra were taken on a Perkin–Elmer 21 spectrophotometer in carbon tetrachloride unless otherwise stated. Ultraviolet spectra were taken on a Bausch and Lomb Spectronic 505 or Beckman DK 1 spectrophotometer. Nuclear magnetic resonance spectra were taken on a Varian HR 60 spectrometer in carbon tetrachloride (tetramethylsilane = 0 p.p.m.). Optical rotations were measured on a C. Zeiss Photoelectric Precision polarimeter (0.005°) in chloroform. The adsorbents used for chromatography were Woelm neutral alumina and Grace No. 923 silica gel. The microanalyses were carried out by Mr. A. Bernhardt, and associates, Mulheim, Germany, and Dr. C. Daessle, 5757 Decelles St., Montreal.

Preparation of 3-Methylcholesta-3,5-diene (V)

Diene V was prepared by slowly adding 15 g of cholest-4-en-3-one, dissolved in 100 ml of absolute ether, to 20 ml of ethereal methyl magnesium iodide, prepared from 2.66 g of magnesium and 7.35 ml of methyl iodide, and the solution was gently refluxed overnight. Aqueous ammonium chloride was added to the cooled mixture. Ether was added and the organic solution was washed neutral with water. After evaporation of the ether, the oily residue was refluxed overnight in 200 ml of ethanol and 20 ml of concentrated hydrochloric acid, diluted with ether, and washed with aqueous sodium bicarbonate and water until neutral. The solvent was then evaporated until crystals began to form. A slow crystallization gave 11.683 g of diene V, m.p. 82–83° (80° (4*a*)); $[\alpha]_D$ −120.4° (*c* 1.4); δ 5.36 p.p.m. (C=C_6—H), 5.78 p.p.m. (C=C_4—H). Calc. for $C_{28}H_{46}$: C, 87.88; H, 12.12. Found: C, 87.80; H, 12.21.

Photolysis of Diene V in Ethanol – n-Pentane[9]

Diene V (10 g) was dissolved in 405 ml of spectrograde *n*-pentane. To the solution was added 45 ml of absolute ethanol. The solution was then irradiated with a 450 W high pressure mercury arc lamp,[10] until there was no absorption in the ultraviolet between 220 and 400 mμ (67 h). The pentane–ethanol was removed by distillation. The oily residue (14.821 g) was dissolved in 50 ml of warm hexane. After the mixture had cooled and had been allowed to stand at room temperature for a few hours, 1.1 g of 6β-ethoxy-3α-methyl-3β,5-cyclo-5β-cholestane (VII), m.p. 129°, was obtained. The mother liquors were chromatographed on 500 g of silica gel.

Elution with 300 ml of hexane gave 0.79 g of a hydrocarbon mixture containing trace amounts of starting material and non-conjugated diene VI, which could not be separated into its components by preparative thin-layer chromatography.

Further elution with 900 ml of hexane gave 1.754 g of crystalline 3-methylenecholest-5-ene (VI), m.p. 109°. Crystallization from ether–acetone raised the melting point to 109–110°; $[\alpha]_D$ −32.4° (*c* 0.344); ν 3030, 1648, 888 cm^{-1} (C=CH_2); δ 4.55 p.p.m. (2H, singlet, C=CH_2), 5.29 p.p.m. (1H, poorly resolved, C=C_6—H). Calc. for $C_{28}H_{46}$: C, 87.88; H, 12.12. Found: C, 87.81; H, 12.03.

Elution with hexane–benzene mixtures gave small amounts (0.138 g) of oil.

Benzene (600 ml) eluted 2.388 g of 6β-ethoxy-3α-methyl-3β,5-cyclo-5β-cholestane (VII), m.p. 120–123°. Two crystallizations from hexane gave 1.22 g of VII, m.p. 130–131°; $[\alpha]_D$ 26.1° (*c* 1.5); ν 3040 cm^{-1} (cyclopropane), 1092, 1102, 1128, 1162 cm^{-1} (C—O—C); δ −0.47 and 0.45 p.p.m. (1H each, doublet, J = 4.5 c.p.s., geminal protons on cyclopropane ring), 3–3.5 p.p.m. (3H, poorly resolved). Calc. for $C_{30}H_{52}O$: C, 84.04; H, 12.23. Found: C, 83.91; H, 12.13.

Further elution with 450 ml of benzene–ether (9:1) gave 0.572 g of a colorless oil.

Elution with 150 and 450 ml of benzene–ether (4:1 and 1:1 respectively) gave 3.111 g of VIII, m.p. 120–121°. Two crystallizations from acetone gave long fine needles, m.p. 125–126°; $[\alpha]_D$ −20.7° (*c*, 1.06); ν 1070, 1110, 1125 cm^{-1} (C—O—C); δ 3.45 p.p.m. (2H, quartet, J = 7 c.p.s. OEt), 5.26 p.p.m. (1H, poorly resolved, C=C_6—H). Calc. for $C_{30}H_{52}O$: C, 84.03; H, 12.22; OEt, 10.5%; molecular weight, 428.7. Found: C, 83.78; H, 11.97; OEt, 9.09%; molecular weight, 411 (Rast).

Elution with ether gave 1.8 g of a yellow oil, ν 3500, 1000–1100 cm^{-1} (broad bands, OH).

When the photolysis was carried out in *n*-pentane until the ultraviolet was clear between 220 and 400 mμ, and the pentane was removed by vacuum distillation at room temperature, an oily residue, $[\alpha]_D$ −85° (*c* 0.8 in $CDCl_3$) was obtained (see Fig. 1 for n.m.r.). The oily residue was refluxed with 100 ml of absolute ethanol for 1 h. The ethanol was distilled off and the semicrystalline residue taken up in hexane. Crystallization gave photoether VII, m.p. 127°. Chromatography of the mother liquors on silica gel gave additional amounts of photoether VII only.

Hydrogenation of 3-Methylenecholest-5-ene (VI)

An acetic acid solution of diene VI (0.196 g) was hydrogenated at room temperature for 20 h using

[9]*The yields obtained in several runs varied considerably.*

[10]*The lamp was cooled by running water in a quartz or vycor jacket, supplied by Hanovia Lamp Division, 100 Chestnut St., Newark, N.J., U.S.A.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

0.15 g of platinum oxide as catalyst. The platinum was filtered off and the filtrate diluted with water and ether. A saturated sodium bicarbonate solution (125 ml) was added slowly until the acetic acid was neutralized. The ether layer was then washed neutral, dried over magnesium sulphate, and evaporated. The crystalline residue, m.p. 91–94°, melted after two recrystallizations from ether–methanol at 100–101° (142 mg), $[\alpha]_D$ 24.8° (*c* 0.55). The melting point was not depressed upon admixture of an authentic sample of 3-methyl-cholestane (IX) (*5b*). Calc. for $C_{28}H_{50}$: C, 86.97; H, 13.03. Found: C, 87.01; H, 13.11.

3-Methylcholesta-3,5-diene from VI

Diene VI (0.18 mg) was dissolved in 10 ml of spectrograde dioxane. To this solution was added 1 drop of 72% perchloric acid. The ultraviolet (u.v.) spectrum was transparent between 220–400 mμ. Upon standing at 70° for 12 h, the solution absorbed at 232, 239, and 248 mμ (log ε 4.26, 4.29, and 4.16).

3-Hydroxymethylcholest-5-ene (X)

1. From 3-methylenecholest-5-ene (VI)

Sodium borohydride (18 mg) was added to 383 mg (1 mmole) of diene VI in 25 ml of diglyme. Boron trifluoride etherate (1 ml) was added to the solution. After the mixture was stirred for 1 h, 10 ml of 30% hydrogen peroxide was added slowly. The solution was diluted with 50 ml of ether and 50 ml of water. The ether layer was washed until neutral, dried over magnesium sulphate, and evaporated. The oily residue (350 mg) was chromatographed on 20 g of silica gel. Hexane eluted 63 mg of oil containing 3-methylcholesta-3,5-diene (V) (u.v.). Further elution with hexane–benzene and benzene–ether mixtures gave oils which were not investigated. Ether eluted 97 mg of 3-hydroxymethylcholest-5-ene (X) (8, p. 33), m.p. 120°. Recrystallizations from acetone gave pure X, m.p. 129–130°; $[\alpha]_D$ −38.4° (*c* 1.0); ν 3630, 975–1050 cm^{-1} (broad band, OH); δ 2.96 p.p.m. (1H, singlet, exchanged in D_2O, OH), 3.4 p.p.m. (2H, poorly resolved signal, CH—CH_2—O) and 5.33 p.p.m. (1H, poorly resolved signal, C=C_6—H). Calc. for $C_{28}H_{48}O$: C, 83.93; H, 12.08. Found: C, 83.72; H, 12.19.

2. From Cholesteryl Magnesium Chloride and Formaldehyde

Cholesteryl chloride (12) was prepared by dissolving cholesterol in thionyl chloride and destroying the excess thionyl chloride by addition to a large excess of water. The water-washed solid residue was recrystallized from ether to give pure cholesteryl chloride, m.p. 97°. Tetrahydrofuran (100 ml) was refluxed over lithium aluminum hydride and distilled directly into a flask containing 2.48 g of magnesium. Methyl iodide (3 ml) was then added and the mixture was heated under reflux for 48 h. After cooling of the mixture, 9.2 g of cholesteryl chloride was added, and the solution was heated under reflux for 48 h. Solid paraformaldehyde (4.6 g) was added to the refluxing solution and the heating continued for another 24 h. A cold aqueous ammonium chloride solution (8 g NH_4Cl in 50 ml of water) was added drop by drop to the cooled reaction mixture. The mixture was taken up in ether, washed neutral with water, dried over magnesium sulphate, and evaporated. The semicrystalline residue (6.4 g) was chromatographed on alumina (II–III, 200 g).

Elution with hexane gave 3.6 g of cholest-5-ene, m.p. 90–91°. Recrystallization from ether gave pure cholest-5-ene, m.p. 92–93°; $[\alpha]_D$ −70.5° (*c* 2.4); δ 5.09 p.p.m. (1H, broad signal, C=C_6—H). Calc. for $C_{27}H_{46}$: C, 87.49; H, 12.51. Found: C, 87.38; H, 12.48.

Cholest-5-ene, on hydrogenation in acetic acid with platinum oxide, gave cholestane, m.p. 78–79°, which was depressed upon admixture of 3-methylcholestane and not depressed upon admixture of authentic cholestane.

Further elution with benzene gave 2.153 g of 3-hydroxymethylcholest-5-ene (X), m.p. 110–115°, which, on two crystallizations from acetone, melted at 129–130°. The infrared spectrum of X was identical with that obtained from the hydroboration of 3-methylenecholest-5-ene (VI) described above.

Further elution with the same solvent gave 0.37 g of cholesterol, m.p. 146–148°, which was not depressed upon admixture of an authentic sample. The reaction was carried out in absolute tetrahydrofuran. Use of dioxane or tetrahydrofuran which was not meticulously dried gave only cholest-5-ene and cholesterol. In "absolute" ether, only cholesterol was isolated.

3α-Methyl-3β,5-cyclo-5β-cholest-6-ene (XIII)

Photoether VII (411 mg) was chromatographed on alumina (I, 20 g). Elution with hexane gave 252 mg of 3α-methyl-3β,5-cyclo-5β-cholest-6-ene (XIII), m.p. 56–61°. Two crystallizations from ethyl acetate raised the melting point to 67–68°, $[\alpha]_D$ 22.8° (*c* 1.0), δ −0.08 and 0.59 p.p.m. (1H each, J = 5 c.p.s., geminal protons on cyclopropane ring), and 5.38 p.p.m. (2H, "singlet"). Calc. for $C_{28}H_{46}$: C, 87.88; H, 12.12. Found: C, 87.78; H, 12.01.

3α-Methyl-3β,5-cyclo-5β-cholestane (XIV)

An acetic acid – ether (4:1, 5 ml) solution of 202 mg of XIII was hydrogenated at atmospheric pressure in the presence of 150 mg of platinum oxide. After 16 h, the platinum was filtered off. The filtrate was diluted with ether and water. The ether layer was washed until neutral, dried over magnesium sulphate, and evaporated. Chromatography of the oily residue on alumina (I, 10 g) gave 3α-methyl-3β,5-cyclo-5β-cholestane (XIV), m.p. 72–74°. Two crystallizations from acetic acid raised the melting point to 77–78°,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$[\alpha]_D$ 32.0° (*c* 1.1), δ 0.44 p.p.m. (1H, doublet, J = 4.45 c.p.s.), and −0.35 p.p.m. (1H, triplet, J = 4.5 c.p.s.). Calc. for $C_{28}H_{48}$: C, 87.42; H, 12.58. Found: C, 87.15; H, 12.75.

Treatment of 3α-Methyl-3β,5-cyclo-5β-cholest-6-ene (XIII) with Perchloric Acid and Ethanol

Perchloric acid (72%, 30 mg) was added to an ethanolic solution (30 ml) of 141 mg of XIII. The solution was heated under reflux overnight, cooled, and diluted with water and ether. The dried ether layer gave, upon evaporation, 155 mg of an oily residue, which had the characteristic ultraviolet absorption pattern of 3-methylcholesta-3,5-diene (V), λ_{max}^{EtOH} 239 mμ (log ε 3.61, i.e. 21% diene V). The oily residue was chromatographed on alumina (I, 10 g). Elution with hexane gave 43 mg of oils. Further elution gave 25 mg of 3-methylcholesta-3,5-diene (V), m.p. 79°. Benzene eluted 48 mg (34%) 3β-ethoxy-3α-methylcholest-5-ene (VIII), m.p. 119–123°. Recrystallization from acetone raised the melting point to 126°. Admixture of an authentic sample did not depress the melting point.

Treatment of 3α-Methyl-3β,5-cyclo-5β-cholest-6-ene (XIII) with Perchloric Acid in Aqueous Dioxane

The reaction described above was carried out in 50 ml of 10% aqueous dioxane containing 1 ml of 72% perchloric acid. Evaporation of the ether gave an oily residue which contained 24% of 3-methylcholesta-3,5-diene (V) (by u.v., λ_{max}^{EtOH} 239 mμ (log ε 3.65)). Chromatography on alumina (I) gave diene V, m.p. 78°, as the only crystalline compound.

3β-Ethoxy-3α-methylcholestane (XII)

Photoether VIII (153 mg) in 40 ml of acetic acid was hydrogenated for 14 h at 40° and 60 p.s.i. with 141 mg of platinum oxide catalyst in a Parr apparatus. The reaction mixture was worked up as described above. The oily residue (152 mg) was chromatographed on alumina (I, 5 g). Elution with hexane gave 44 mg of 3-methylcholestane (IX), m.p. 99°. Crystallization raised the melting point to 99–100°. Admixture of an authentic sample did not depress the melting point. Elution with hexane : benzene (1:1) gave 77 mg of 3β-ethoxy-3α-methylcholestane (XII), m.p. 81–83°. Crystallization from ether–methanol raised the melting point to 89–90°, $[\alpha]_D$ 2° (*c* 0.33), ν 1165, 1100 cm^{-1} (OEt). Calc. for $C_{30}H_{54}O$: C, 83.65; H, 12.64. Found: C, 83.84; H, 12.79.

As was found out later, the hydrogenolysis reaction could be suppressed by the addition of 10% (based on the weight of VIII) sodium nitrite (5*b*, 9). In this case, a 78% yield of XII, m.p. 89–90°, was obtained.

Oxidation of 3β-Ethoxy-3α-methylcholestane (XII) with Ruthenium Tetroxide

Ether XII (55 mg) in 10 ml of carbon tetrachloride was oxidized with 42 mg of ruthenium tetroxide at room temperature, according to the procedure of Bokowicz and Rylander (10). The oily reaction product (161 mg) was chromatographed on alumina (II–III, 2 g). Elution with hexane gave 16 mg of 3β-acetoxy-3α-methylcholestane (XII*b*), m.p. 85–95°. The infrared spectrum was identical with that of an authentic sample and different from that of 3α-acetoxy-3β-methylcholestane (5*b*). Elution with benzene gave 32 mg of 3α-methylcholestan-3β-ol (XII*a*), m.p. 148°. Crystallization from ether–methanol raised the melting point to 149° (150° (11)). Admixture of authentic sample did not depress the melting point. The infrared spectrum was identical with that of an authentic sample and markedly different from its epimer in the 1000–1250 cm^{-1} region (5*b*); $[\alpha]_D$ 36.9° (*c* 0.34), lit. 28° (*c* 1.68) (11). Calc. for $C_{28}H_{50}O$: C, 83.51; H, 12.52. Found: C, 83.38; H, 12.30.

Oxidation of 3β-Ethoxy-3α-methylcholest-5-ene (VIII) with Osmium Tetroxide

Photoether VIII (402 mg) was dissolved in 10 ml of dry ether and 2 ml of pyridine which contained 397 mg of osmium tetroxide (13). The oxidation was carried out in the dark at 33° for 7 days. The solution was worked up according to the procedure given by Woodward *et al.* (13). The oily residue (446 mg) was chromatographed on alumina (IV, 15 g). Elution with hexane gave 315 mg of diol XVI, m.p. 140–141°. Crystallization from hexane raised the melting point to 141–142°, $[\alpha]_D$ 21.6° (*c* 0.44), ν 3475, 3600, 1160 cm^{-1} (OH), δ 2.45 p.p.m. (1H, broad singlet, OH), 3.31 p.p.m. (2H, quartet, J = 6.6 c.p.s., OEt), 4.61 p.p.m. (1H, singlet, OH). It was found that at 18°, 25°, and 33°, the yields of diol XVI were 30, 70, and 74% respectively. Calc. for $C_{30}H_{54}O_3$: C, 77.86; H, 11.76. Found: C, 77.62; H, 11.60.

5,6-Seco-3β-ethoxy-3α-methylcholestan-5-on-6-oic Acid (XVII)

Chromium trioxide (120 mg) in 50% aqueous acetic acid (12 ml) was added slowly to 158 mg of diol XVI in 10 ml of acetic acid. The reaction mixture was kept at 50° overnight. (Under reflux, dehydroethoxylation occurred.) A few drops of methanol were added to destroy excess chromium trioxide. The solvent was removed at 40° under reduced pressure. The keto acid XVII was extracted with ether, and the organic solution washed until neutral, dried over magnesium sulphate, and evaporated. The oily residue (141 mg) was dissolved in a minimum amount of acetic acid, and a slow (3 days) crystallization was permitted to occur after a few drops of water had been added. Recrystallization of keto acid, m.p. 138–139°, gave 14 mg of keto acid XVII, m.p. 152°, $[\alpha]_D$ 66° (*c* 0.46), ν 3000 cm^{-1} and 1705 cm^{-1}, δ 2.26 p.p.m. (2H, poorly resolved peak, CH—CH_2—COOH), 2.67 p.p.m. (2H, singlet, O—C—CH_2—C=O), 3.37 p.p.m. (2H, quartet, J = 7 c.p.s., OEt), 10.63 p.p.m. (1H, poorly resolved singlet, COOH). Calc. for $C_{30}H_{52}O_4$: C, 75.60; H, 11.00. Found: C, 75.74; H, 10.86.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Dehydroethoxylation of Keto Acid XVII

A solution of 182 mg of keto acid XVII in 20 ml acetic acid containing 400 mg of pyridine hydrochloride was refluxed overnight. The solution was diluted with ether and water. The ether layer was washed until neutral, dried over magnesium sulphate, and evaporated. The oily residue was chromatographed on silica gel (7.5 g). Benzene–ether mixtures eluted an oil which could not be crystallized; ν 1705 cm^{-1} (COOH), 1675 cm^{-1} (C=C—C=O), $\lambda_{max}^{cyclohexane}$ 230.5 mμ, λ_{max}^{EtOH} 236 mμ.

In the presence of Fehling solution, the keto acid XVII was also dehydroethoxylated.

Methyl 5,6-seco-3-methylcholest-3-en-5-on-6-oate (XVIIIa)

Ethereal diazomethane was added to 126 mg of amorphous acid XVIII in cold ether containing a few drops of methanol. After 1 h, the excess diazomethane was destroyed by adding a few drops of acetic acid. The solvent was evaporated and the oily residue chromatographed on alumina (II–III, 5 g). Benzene and benzene–ether (95:5) eluted 66 mg of methylester XVIII*a*, which could not be crystallized. The spectral data of XVIII*a* were λ_{max}^{EtOH} 236 mμ (log ϵ 3.91), ν 1738 cm^{-1} ($COOCH_3$), 1675 cm^{-1} (C=C—C=O), δ 1.93 p.p.m. (3H, singlet, C=C—CH_3), 2.2 p.p.m. (2H, doublet, J = 4.1 c.p.s., CH—CH_2—COO), 3.57 p.p.m. (3H, singlet, $COOCH_3$), 5.57 p.p.m. (1H, singlet, C=CH—C=O).

ACKNOWLEDGMENTS

We thank the National Research Council of Canada and Messrs. Ayerst, McKenna and Harrison for financial support. We also thank Dr. C. Stammer of this Department for taking the n.m.r. spectra and Mr. J. Kastner of Ayerst, McKenna and Harrison for high pressure hydrogenations.

COMPLEXES DU GERMANIUM (IV) AVEC LA DICHLORO-2,5 DIHYDROXY-3,6 *p*-BENZOQUINONE[1]

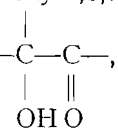
A. BEAUCHAMP[2] ET R. L. BENOIT
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 20 mars 1964

RÉSUMÉ

La formation de complexes entre le germanium (IV) et le ligand dichloro-2,5 dihydroxy-3,6 *p*-benzoquinone (H_2R) a été étudiée en milieu de force ionique 0.49. On a montré par spectrophotométrie que les seuls complexes présents comportent 2 ligands par germanium et que la constante de stabilité apparente est $\beta_2 = 10^{6.16}$ en milieu d'acidité 0.49 *M*. Les constantes d'acidité du ligand, $k_1 = 10^{-0.66}$ et $k_2 = 10^{-2.37}$ ont été déterminées, et la constante de stabilité du complexe $Ge(OH)_2R_2^{2-}$ $\beta_2^0 = 10^{6.57}$ a été obtenue par potentiométrie. On a mis en évidence la présence de deux acidités sur $Ge(OH)_2R_2H_2$, l'une forte, l'autre de constante $\mathcal{K}_2 = 10^{-0.8}$. Des formules sont proposées pour les complexes. On compare la nature et la stabilité des complexes du germanium et du zirconium (IV) et relie leurs spectres d'absorption à ceux des différentes formes H_2R, HR^-, et R^{2-} du ligand.

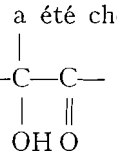
Le germanium (IV) en solution aqueuse forme des complexes avec certains ligands organiques comportant plusieurs atomes d'oxygène donneurs, tels que des polyalcools (1) et polyphénols (2), des acides polycarboxyliques (3), des hydroxy-acides (4), des hydroxy-cétones (5). Des complexes de ce type ont été mis en évidence par des méthodes physico-chimiques et par isolation de composés solides. Toutefois on ne connaît qu'un nombre limité de constantes de stabilité, citons celle du complexe 1 germanium: 2 trihydroxy-2,3,7 phényl-9 fluorone-6 (6, 7), le nature des groupes coordinés dans ce chélate, soit



soit

, prêtant d'ailleurs à discussion (8).

Dans le cadre d'une étude quantitative de complexes du germanium (IV) avec une série de ligands "oxygénés" et "azotés" où l'on se propose de relier la stabilité des complexes à des propriétés des ligands, on présente les résultats obtenus avec la dichloro-2,5 dihydroxy-3,6 *p*-benzoquinone (acide chloranilique). L'acide chloranilique a été choisi pour plusieurs raisons: c'est un composé simple comportant le groupe



qui paraît donner lieu à une réaction avec le germanium (IV) (5), sa solubilité et celle du chélate permettent d'éviter l'emploi de solvant additionnel ou d'agent dispersif, l'utilisation de méthodes d'étude spectrophotométriques et potentiométriques semble a priori possible. Une revue des propriétés et réactions de l'acide chloranilique a été publiée (9) ainsi qu'une étude spectrophotométrique des complexes avec un autre élément du groupe IV, le zirconium (10). Au cours de notre travail Nazarenko & Flyantikova (11) ont fait paraître

[1]*Communication présentée au Congrès de l'A.C.F.A.S. à Québec, P.Q., 1–3 novembre 1963.*
[2]*Boursier du Conseil National de Recherches du Canada 1963–1964.*

un article sur ce même sujet. Certains résultats et l'interprétation de ces auteurs diffèrent essentiellement des nôtres et la critique en sera faite après l'exposé de nos résultats. Place (12) a récemment étudié les réactions de l'acide chloranilique avec le tétrachlorure de germanium en milieu non-aqueux et mis en évidence la formation de complexes comportant deux, trois, et quatre ligands par germanium.

PARTIE EXPÉRIMENTALE

Réactifs

Les solutions de germanium (IV) environ 4×10^{-2} *M* sont préparées par dissolution de dioxyde GeO_2 de haute pureté gracieusement fourni par le Germanium Research Center et dosées par titrage potentiométrique avec de la soude non carbonatée en présence de mannitol.

Les solutions mères d'acide chloranilique 1×10^{-2} *M* sont préparées par pesée du produit Fisher et conservées au maximum 4 jours durant lesquels l'absorption reste constante. Le titrage potentiométrique par NaOH du produit commercial a indiqué une pureté de 99.6 ± 0.3% et le même produit sublimé sous vide n'a donné aucune différence notable. Tous les autres produits chimiques utilisés sont des réactifs purs pour analyse.

Technique expérimentale

L'extinction des solutions est mesurée avec un spectrophotomètre Zeiss (modèle M4-Q11) comportant un chariot thermostaté, en employant une gamme de cuvettes d'épaisseur allant de 0.5 à 50.0 mm.

Une pH mètre Radiometer (modèle 4) est utilisé pour les mesures de pH, avec un système d'électrodes de verre et calomel – KCl saturé. Des solutions d'acide de concentration connue et de force ionique donnée servent à la standardisation, de façon à obtenir directement $-\log [H^+]$, la linéarité de réponse de l'électrode a été vérifiée dans l'intervalle $2 < -\log [H^+] < 4.5$.

L'extinction et l'acidité des solutions de complexes sont mesurées à température constante, 25.0 °C, ces mesures s'avérant sensibles aux variations de température.

RÉSULTATS EXPÉRIMENTAUX

I. Constantes d'acidité de l'acide chloranilique

L'acide chloranilique par ses deux fonctions —OH est un diacide et donne lieu aux équilibres suivants:

$$H_2R \rightleftarrows HR^- + H^+.$$

$$[1] \qquad k_1 = \frac{[H^+][HR^-]}{[H_2R]}.$$

$$HR^- \rightleftarrows R^{2-} + H^+.$$

$$[2] \qquad k_2 = \frac{[H^+][R^{2-}]}{[HR^-]}.$$

Les valeurs de pk_1 et pk_2 données par divers auteurs varient selon les méthodes et les milieux ioniques adoptés: Schwarzenbach (13) 0.85, 3.18; Voigt (14) 1.09, 2.42; Van Rysselberghe (15) 1.22, 3.01; Wallenfels (16) 0.73, 3.08. Ces valeurs concordant mal et ne correspondant pas au milieu de force ionique 0.5 adopté pour ces expériences, la détermination en a été faite en milieu HCl–NaCl 0.484 *M* par deux méthodes. Les constantes d'équilibre sont définies ici à partir des concentrations.

(a) Spectrophotométrie

L'acide chloranilique possède deux bandes d'absorption dans la région 220–800 mμ. Un premier maximum à 302 mμ en milieu acide, se déplace vers 330 mμ à pH > 4.5. Le second maximum à 450 mμ pour des solutions fortement acides ($[H^+] > 2$ *M*), passe à 520 mμ avec élévation du pH.

Définissons ϵ_0, ϵ_1 et ϵ_2 comme étant les coefficients d'extinction molaire de R^{2-}, HR^- et H_2R respectivement, et $\epsilon_L = A_s/C_L$, le coefficient d'extinction molaire moyen, A_s est

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

la densité optique correspondant à une épaisseur de 1.00 cm, et C_L la concentration totale d'acide chloranilique. La fonction $\epsilon_L = f(-\log [H^+])$ (Fig. 1) présentant un maxi-

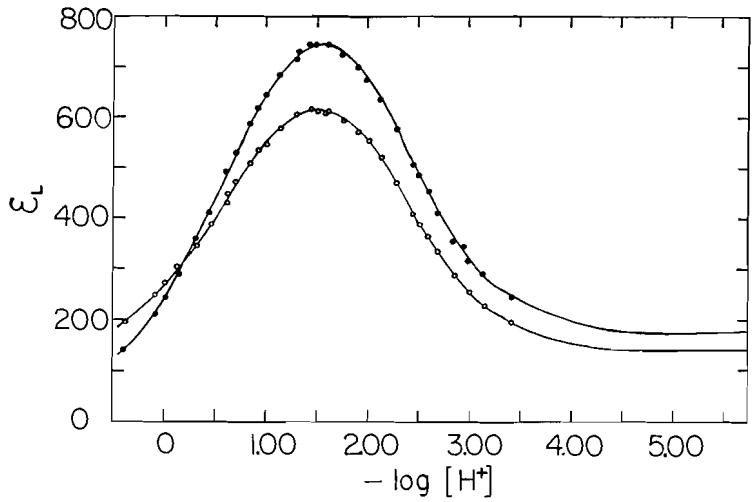


FIG. 1. Coefficient d'extinction molaire moyen ϵ_L de l'acide chloranilique en fonction de $-\log [H^+]$: HCl + NaCl = 0.484 M, T = 25 ± 1 °C, ● 520 mμ, ○ 490 mμ.

mum pour les longueurs d'onde 490 et 520 mμ, on peut appliquer la méthode de Ang (17) pour la détermination des constantes d'acidité.

c_1 et c_2 étant les deux concentrations de H^+ correspondant à une valeur donnée de ϵ_L, on montre que

$$[3] \qquad \epsilon_L = \epsilon_1 - k_2 P \quad \text{où} \quad P = \frac{(\epsilon_L - \epsilon_0)(c_1 + c_2)}{c_1 c_2}$$

$$[4] \qquad \epsilon_L = \epsilon_2 + k_1 Q \quad \text{où} \quad Q = \frac{\epsilon_1 - \epsilon_L}{c_1 + c_2}.$$

On a fait varier la concentration d'acide chloranilique entre 2.38×10^{-3} et 2.03×10^{-4} M; les valeurs de ϵ_0, déterminées dans NH_3 0.5 M (pH 9.97), sont à 490 mμ, 142 ± 2 et à 520 mμ, 177 ± 2. Les valeurs des constantes d'acidité et de ϵ_1 et ϵ_2, obtenues d'après les courbes donnant ϵ_L en fonction de P et Q, (Figs. 2 et 3) sont les suivantes: à 520 mμ: pk_1 0.66 ± 0.03; pk_2 2.37 ± 0.02; ϵ_1 915 ± 10; ϵ_2 94 ± 7; à 490 mμ: pk_1 0.66 ± 0.03; pk_2 2.37 ± 0.03; ϵ_1 755 ± 9; ϵ_2 158 ± 6.

(b) Potentiométrie

La courbe de titrage potentiométrique de l'acide chloranilique (Fig. 14) par NaOH a été utilisée pour déterminer la constante d'acidité k_2. Les relations suivantes sont vérifiées en tout point de la courbe, $[Na^+]$ étant la concentration de NaOH ajoutée,

$$[5] \qquad [H^+] + [Na^+] = [HR^-] + 2[R^{2-}]$$

$$[6] \qquad C_L = [H_2R] + [HR^-] + [R^{2-}].$$

Soit $\bar{n}' = ([HR^-] + 2[H_2R])/C_L$, le nombre moyen de H^+ non dissociés par molécule d'acide chloranilique, en portant dans cette expression les équations [1], [2], [5], et [6] et en réarrangeant, on obtient l'équation suivante de type $Y = 1/k_1k_2 + X/k_2$.

FIG. 3. Détermination de la constante d'acidité k_2 de l'acide chloranilique: ○ 520 mμ, ● 490 mμ.

[7] $$\frac{\bar{n}'}{(2-\bar{n}')[H^+]^2} = \frac{1}{k_1k_2} + \frac{1}{k_2}\frac{(1-\bar{n}')}{(2-\bar{n}')[H^+]}.$$

La courbe donnant Y en fonction de X est représentée sur la Fig. 4, les valeurs correspondant au titrage de 100.0 ml d'acide chloranilique 1.002×10^{-2} M par NaOH 0.2352 M en milieu NaCl 0.484 M. La valeur pk_2 2.37 ± 0.03 calculée à partir de la pente de la droite concorde parfaitement avec les résultats des mesures spectrophotométriques. La valeur de l'ordonnée à l'origine $pk_1k_2 = 3.6 \pm 0.9$ est obtenue avec une mauvaise précision, la première dissociation de H_2R étant pratiquement complète au point initial du titrage ($\bar{n}' = 0.91$).

II. Constante de stabilité du complexe germanium (IV) – acide chloranilique

La formation de complexes entre l'acide chloranilique et le germanium (IV) est mise en évidence par un accroissement de la solubilité du ligand (18) ainsi que par une modification des bandes d'absorption du ligand. Les maxima à 450 mμ pour $[H^+] = 2$ M et 490 mμ pour $[H^+] = 0.50$ M passent à 520 mμ en présence de germanium (IV) et la densité optique augmente considérablement (Fig. 5); dans l'ultraviolet, le maximum est déplacé de 302 mμ à 315–320 mμ (Fig. 6). Les points isobestiques observés à 271 et 312 mμ suggèrent la présence de deux séries d'espèces absorbantes seulement. Le complexe a été étudié par plusieurs méthodes spectrophotométriques.

(a) Méthode de variations continues

La méthode de variations continues (19) permet dans les cas simples de déterminer la composition de complexes. Des expériences ont été effectuées à différentes acidités en utilisant des solutions de $HClO_4$ et des solutions-tampons chloracétate et acétate, les mesures d'absorption ont été faites à plusieurs longueurs d'onde. Les courbes donnant $A_s - \epsilon_L C_L$ en fonction de $C_L/(C_M + C_L)$ sont représentées sur la Fig. 7; C_M est la

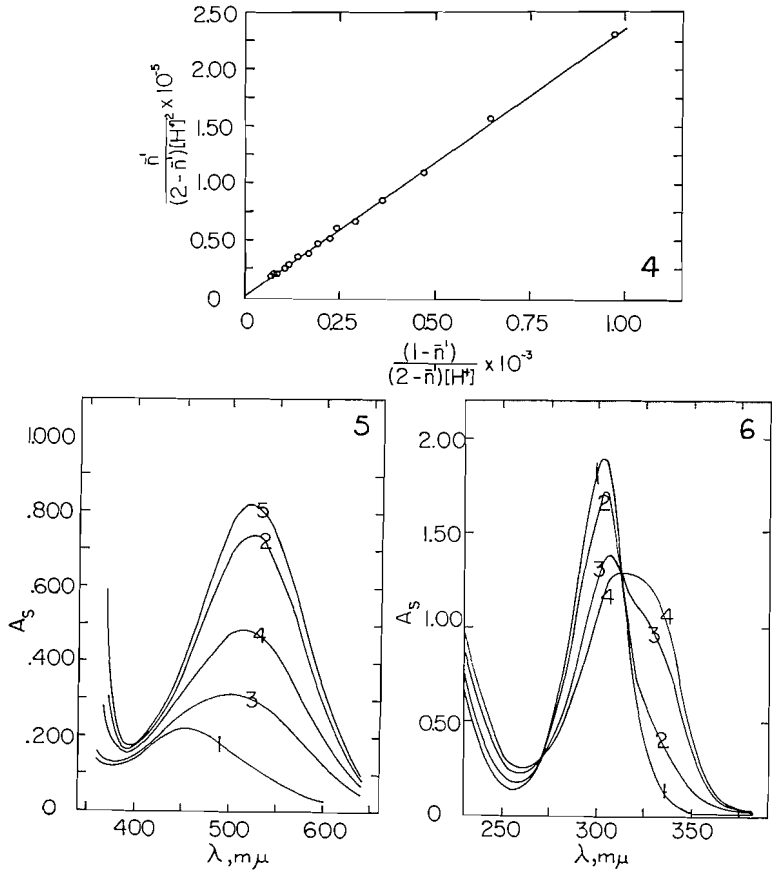

FIG. 4. Détermination des constantes d'acidité k_1 et k_2 de l'acide chloranilique: NaCl 0.484 M, $T = 25 \pm 0.5$ °C.

FIG. 5. Spectre visible de l'acide chloranilique 1.007×10^{-3} M en présence de germanium (IV): (1) $HClO_4$ 2.006 M, $C_M = 0$; (2) $HClO_4$ 2.006 M, $C_M = 2.96 \times 10^{-2}$ M; (3) $HClO_4$ 0.502 M, $C_M = 0$; (4) $HClO_4$ 0.502 M, $C_M = 3.15 \times 10^{-4}$ M; (5) $HClO_4$ 0.502 M, $C_M = 3.60 \times 10^{-2}$ M. Cuvette 1.00 cm.

FIG. 6. Spectre ultraviolet de l'acide chloranilique 1.006×10^{-4} M en présence de germanium (IV), HCl = 0.484 M: (1) $C_M = 0$, (2) $C_M = 1.043 \times 10^{-3}$ M, (3) $C_M = 1.043 \times 10^{-2}$ M, (4) $C_M = 3.55 \times 10^{-2}$ M. Cuvette 1.00 cm.

concentration totale du germanium (IV). Ces courbes présentent toutes un maximum pour un rapport $C_L/(C_M + C_L)$ voisin de 0.67, toutefois à pH 4.65 le maximum est mal défini. Ces résultats indiquent que l'acide chloranilique ne forme avec le germanium que des complexes de type M_mL_{2m} c'est-à-dire comportant 2 ligands par germanium.

(b) Détermination de la constante de stabilité du complexe

Deux méthodes indépendantes ont été utilisées pour montrer que les complexes M_mL_{2m} sont mononucléaires et déterminer la constante de stabilité β_2 du complexe ML_2 en milieu d'acidité 0.484 M. β_{2m} est une constante de stabilité apparente telle que

$$[8] \qquad \beta_{2m} = \frac{[M_mL_{2m}]}{[M]^m[L]^{2m}},$$

où [M] est la concentration du germanium (IV) libre, $[M_mL_{2m}]$ et [L] respectivement les concentrations du complexe et de l'acide chloranilique libre sous leurs différentes formes.

Courbes de variations continues: ▽ $HClO_4$ 2.02 M, 520 mμ, $C_M + C_L = 2.03 \times 10^{-3}$ M, cuvette 1.00 cm; △ $HClO_4$ 0.502 M, 520 mμ, $C_M + C_L = 2.20 \times 10^{-3}$ M, cuvette 1.00 cm; ● $HClO_4$ 0.502 M, 350 mμ, $C_M + C_L = 2.20 \times 10^{-3}$ M, cuvette 0.200 cm; ○ $HClO_4$ 0.502 M, 340 mμ, $C_M + C_L = 2.20 \times 10^{-3}$ M, cuvette 0.200 cm; ▲ pH 2.64, 520 mμ, $C_M + C_L = 1.10 \times 10^{-2}$ M, cuvette 0.200 cm; ▼ pH 3.54, 520 mμ, $C_M + C_L = 1.10 \times 10^{-2}$ M, cuvette 0.200 cm.

1. Méthode de dilution.—Dans cette méthode on mesure l'extinction d'une série de solutions où les concentrations C_M et C_L sont maintenues dans le rapport stoechiométrique du complexe $C_M/C_L = 1/2$. On calcule $(A_s - \epsilon_L C_L)/C_M$ et on trace ensuite la courbe représentative de la fonction $\epsilon_c' = a - bx$ telle que:

$$[9] \qquad \epsilon_c' = \frac{A_s - \epsilon_L C_L}{C_M} = \frac{(\epsilon_c - 2m\epsilon_L)}{m} - \frac{(\epsilon_c - 2m\epsilon_L)^{(1-1/3m)}}{2^{2/3}(\beta_{2m})^{1/3m} m} \frac{(A_s - \epsilon_L C_L)^{1/3m}}{C_M},$$

où $x = (A_s - \epsilon_L C_L)^{1/3m}/C_M$, ϵ_c est le coefficient d'extinction molaire du complexe. La valeur de β_{2m} est calculable à partir des valeurs trouvées pour les coefficients a et b.

On a fait varier C_M entre 0.417×10^{-4} et 8.34×10^{-4} M. L'acidité a été maintenue à 0.484 M au moyen de HCl, à cette concentration d'acide il n'y a pas formation de complexes chlorogermaniques (20).

On a représenté sur la Fig. 8 les fonctions ϵ_c' pour $m = 1$, $m = 2$ et $m = 3$ à 345 mμ. On n'obtient une ligne droite que pour $m = 1$ ce qui démontre l'absence d'espèces polynucléaires. Les fonctions ϵ_c' pour $m = 1$ à 325 et 335 mμ sont aussi portées sur cette même figure. Les valeurs de β_2 obtenues pour les différentes longueurs d'onde sont résumées dans le Tableau I.

2. Méthode applicable aux complexes peu stables.—Cette méthode dérivée de celle de McConnell et Davidson (21) est applicable lorsque le complexe est relativement peu stable puisqu'elle repose sur l'approximation $[M] \sim C_M$. On mesure l'extinction d'une série de solutions où C_L est constant et C_M variable. On trace alors la courbe représentative de la fonction suivante dérivée pour le complexe ML_2

$$[10] \quad (\epsilon_c')^{1/2} = \left(\frac{A_s - \epsilon_L C_L}{C_M}\right)^{1/2} = \beta_2^{1/2} C_L(\epsilon_c - 2\epsilon_L)^{1/2} - \frac{2\beta_2^{1/2}}{(\epsilon_c - 2\epsilon_L)^{1/2}}(A_s - \epsilon_L C_L).$$

Cette fonction est du type $(\epsilon_c')^{1/2} = c - dx$ où $x = (A_s - \epsilon_L C_L)$. Les valeurs des coefficients c et d permettent d'obtenir β_2.

On a fixé la concentration d'acide chloranilique à 1.006×10^{-4} M et fait varier la concentration du germanium (IV) entre 4.17×10^{-4} et 3.56×10^{-2} M. Dans ces conditions, l'approximation $[M] \sim C_M$ est vérifiée à mieux de 99% pour $\beta_2 = 10^{6.2}$. L'acidité a été maintenue à 0.484 M avec HCl. La Fig. 9 reproduit les droites donnant $(\epsilon_c')^{1/2}$ aux différentes longueurs d'onde. Les valeurs de β_2 correspondantes sont portées dans le Tableau I. On a vérifié par ailleurs que les fonctions analogues correspondant aux complexes ML, ML_3 et $M_mL_{2m}(m > 1)$ conduisent à des courbes avec les données expérimentales obtenues.

(c) Méthode des solutions correspondantes

Les deux méthodes de calcul précédentes ne permettent toutefois pas de conclure à l'absence complète d'un complexe ML. Il convenait d'essayer de déterminer une limite pour la constante β_1 d'un tel complexe, c'est dans ce but que la méthode des solutions correspondantes a été utilisée. De plus afin de renforcer nos conclusions les mesures d'extinction ont été faites à 520 mμ au lieu de 325–345 mμ comme dans les méthodes précédentes.

ϵ_c' étant défini comme précédemment, Bjerrum (22) et Fronaeus (23) ont montré que pour une série de solutions ayant une même valeur de ϵ_c', ces solutions étant dites correspondantes, la concentration de ligand libre [L] et $\bar{n}$ le nombre moyen de ligands associés par atome de métal sont les mêmes. En portant ϵ_c' en fonction de C_L pour divers C_M, on détermine pour une valeur donnée de ϵ_c' les concentration C_L et C_M d'une série de solutions correspondantes. Les valeurs de [L] et $\bar{n}$ pour chaque série sont ensuite obtenues graphiquement en portant C_L en fonction de C_M, C_L et C_M étant reliés linéairement par l'équation $C_L = [L] + \bar{n}C_M$. La méthode de Rossotti (24) a ensuite été utilisée pour calculer β_1 et β_2 à partir des valeurs de [L] et $\bar{n}$. On a:

$$[11] \quad \bar{n} = \frac{C_L - [L]}{C_M} = \frac{[ML] + 2[ML_2]}{C_M} = \frac{\beta_1[L] + 2\beta_2[L]^2}{1 + \beta_1[L] + \beta_2[L]^2},$$

d'où

$$\frac{\bar{n}}{(1 - \bar{n})[L]} = \beta_1 + \beta_2 \frac{(\bar{n} - 2)}{(\bar{n} - 1)}[L],$$

une équation du type $y = \beta_1 + \beta_2 x$. Les β_1 et β_2 sont obtenus d'après la droite donnant y en fonction de x. On a fait varier la concentration de germanium (IV) entre 1.15×10^{-4} et 2.29×10^{-3} M et celle de l'acide chloranilique entre 2.09×10^{-4} et 2.00×10^{-3} M, cette dernière valeur étant la limite supérieure imposée par la solubilité; $HClO_4$ a été maintenu constant à 0.502 M. Les fonctions ϵ_c' sont représentées sur la Fig. 10 et les valeurs de $\bar{n}$ et [L] correspondant aux ϵ_c' sont rassemblées dans le Tableau II. Les points expérimentaux donnant $\bar{n}$ en fonction de $-\log [L]$ sont sur la Fig. 11. Les valeurs de $\bar{n}/((1 - \bar{n})[L])$ sont portées en fonction de $((\bar{n} - 2)/(\bar{n} - 1))[L]$ sur la Fig. 12. On trouve $\beta_2 = 10^{6.16 \pm 0.03}$ et $\beta_1 < 10^2$. Au moyen de la valeur de β_2 on a calculé $\bar{n}$ pour différentes valeurs de [L] et tracé la courbe de formation correspondante (Fig. 11). On note un bon accord entre la courbe calculée et les points expérimentaux.

III. Propriétés acides–bases du complexe germanium (IV) – acide chloranilique

Comme les méthodes spectrophotométriques précédentes ne fournissent pour le complexe qu'une constante de stabilité apparente valable en milieu d'acidité 0.49 M, il convenait d'examiner l'influence de l'acidité. Les bandes d'absorption du ligand sont peu affectées par la présence de germanium aux faibles acidités, aussi a-t-on utilisé pour cette étude une méthode potentiométrique.

La courbe de neutralisation de 100.0 ml d'acide chloranilique 9.45 × 10^{-3} M par de la potasse 0.1939 N, représentée par la courbe 1 de la Fig. 13, est modifiée en présence de germanium (IV) 3.83 × 10^{-2} M (courbe 2). Sur cette dernière courbe, un premier point d'inflexion correspond à environ 1 milliéquivalent de base, c'est-à-dire à la neutralisation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

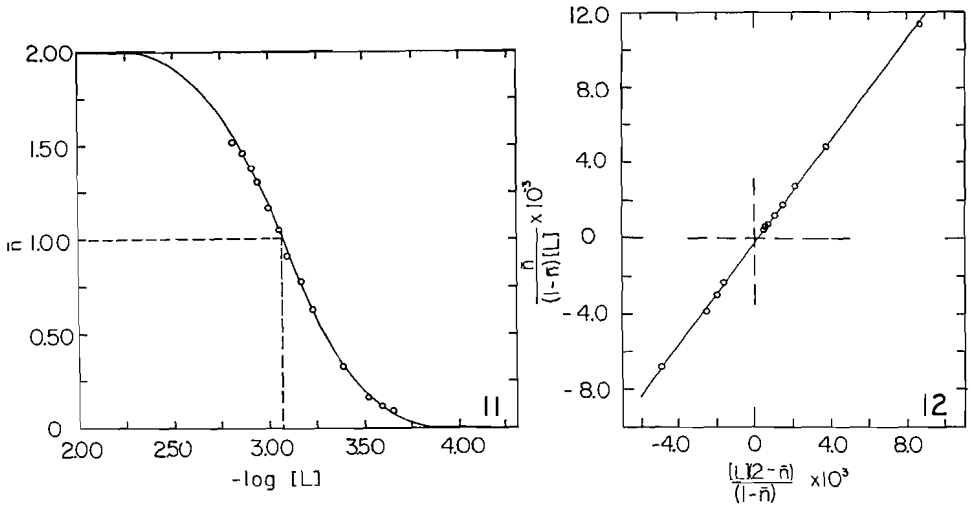

FIG. 11. Courbe de formation des complexes $\bar{n} = f[-\log [L]]$: $HClO_4$ 0.502 M, $T = 25.0 \pm 0.5$ °C.
FIG. 12. Détermination des constantes de stabilité apparentes β_1 et β_2: $HClO_4$ 0.502 M, $T = 25.0 \pm 0.5$ °C.

d'une acidité par ligand. Un deuxième point d'inflexion plus prononcé coincide avec le point équivalent de la courbe 1 et dénote la neutralisation des deux acidités du ligand.

Les réactions suivantes rendent compte qualitativement de l'allure de la courbe 2. Initialement le complexe 1:2 est formé quantitativement,

[a] $$Ge(OH)_4 + 2H_2R \rightarrow Ge(OH)_2R_2H_2 + 2H_2O,$$

jusqu'au premier point d'inflexion, les deux acidités du complexe sont neutralisées,

[b] $$Ge(OH)_2R_2H_2 + 2OH^- \rightarrow Ge(OH)_2R_2^{2-} + 2H_2O,$$

après le premier point d'inflexion le complexe est détruit,

[c] $$Ge(OH)_2R_2^{2-} + 2OH^- \rightarrow Ge(OH)_4 + 2R^{2-},$$

au delà du deuxième point d'inflexion, l'acide germanique de pK 9.2 (25) est neutralisé.

De plus, les positions relatives des débuts des courbes 1 et 2 permettent de conclure que les deux acidités de $Ge(OH)_2R_2H_2$ sont relativement fortes: ainsi initialement la solution environ 10^{-2} M en acide H_2R voit son pH passer de 2.03 à 2.06, en présence de Ge(IV) en excès, c'est-à-dire à une valeur correspondant à la dissociation quasi-totale de $2H^+$ pour le complexe à la concentration approximative 5×10^{-3} M.

La courbe de neutralisation de 150 ml d'une solution 6.52×10^{-3} M du ligand voisin, la dihydroxy-2,5 p-benzoquinone (Fig. 13, courbe 3) par de la potasse 0.2276 N est aussi modifiée en présence de germanium (IV) 6.83×10^{-3} M (courbe 4). L'analyse de cette dernière courbe confirme l'interprétation précédente. Le premier point d'inflexion est cette fois beaucoup plus net, ceci est dû en partie à ce que la dihydroxybenzoquinone est un acide plus faible, $k_1 = 10^{-2.71}$ et $k_2 = 10^{-5.18}$ (13). Pour cette même raison, la courbe 4 débute à des pH plus bas que la courbe 3, la valeur du pH initial sur la courbe 4 indique que les deux acidités du complexe sont aussi essentiellement fortes.

Sur la base de l'interprétation précédente, on a déterminé la deuxième constante d'acidité $\mathcal{K}_2$ du complexe $Ge(OH)_2R_2H_2$ correspondant à l'équilibre

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$Ge(OH)_2R_2H^- \rightleftarrows Ge(OH)_2R_2^{2-} + H^+$$

$$[12] \qquad \mathscr{K}_2 = \frac{[H^+][Ge(OH)_2R_2^{2-}]}{[Ge(OH)_2R_2H^-]},$$

$\mathscr{K}_2$ devant correspondre à une acidité relativement forte, la première acidité de $Ge(OH)_2R_2H_2$ étant elle-même forte.

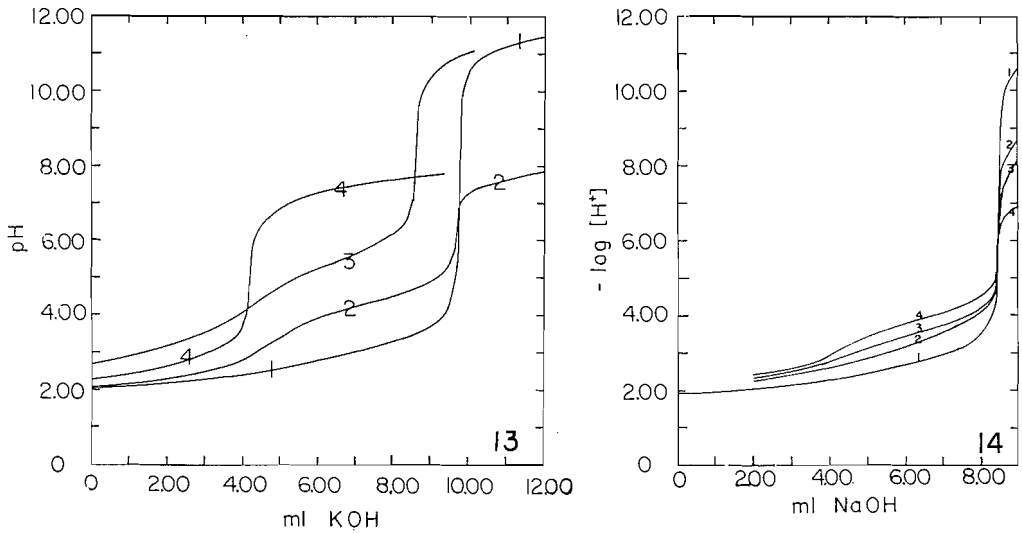

FIG. 13. Courbes de neutralisation de l'acide chloranilique et de la dihydroxy-2,5 *p*-benzoquinone par KOH: (1) acide chloranilique 9.45×10^{-3} *M*, KOH = 0.1939 *M*, $C_M = 0$; (2) acide chloranilique 9.45×10^{-3} *M*, KOH = 0.1939 *M*, $C_M = 3.83 \times 10^{-2}$ *M*; (3) dihydroxy-2,5 *p*-benzoquinone 6.52×10^{-3} *M*, KOH = 0.1138 *M*, $C_M = 0$; (4) D.H.Q. 6.52×10^{-3} *M*, KOH = 0.2276 *M*, $C_M = 6.83 \times 10^{-3}$ *M*.

FIG. 14. Courbes de neutralisation de l'acide chloranilique 1.002×10^{-2} *M* par NaOH 0.2352 *M* en présence de germanium (IV), NaCl = 0.484 *M*: (1) $C_M = 0$, (2) $C_M = 3.51 \times 10^{-3}$ *M*, (3) $C_M = 8.78 \times 10^{-3}$ *M*, (4) $C_M = 3.51 \times 10^{-2}$ *M*.

Dans une première étape, on a calculé la constante de formation du complexe $Ge(OH)_2R_2^{2-}$ telle que:

$$[13] \qquad \beta_2^0 = \frac{[Ge(OH)_2R_2^{2-}]}{[Ge(OH)_4][HR^-]^2}.$$

Pour cela, on a tracé les 3 courbes de neutralisation de 100 ml d'acide chloranilique 1.002×10^{-2} *M* en présence de germanium (IV) respectivement 3.51, 8.18 et 35.1×10^{-3} *M* et en milieu NaCl 0.48 *M* (Fig. 14). On a noté au début de la neutralisation la formation lente d'un précipité pourpre, avec augmentation correspondante du pH, le précipité se redissout quand on poursuit la neutralisation. On a utilisé pour le calcul les portions des courbes situées au delà du premier point équivalent, dans cette région l'espèce $Ge(OH)_2R_2^{2-}$ est la seule forme du complexe présente. Le β_2^0 est obtenu en résolvant le système d'équations [2], [14], [15] et [16].

$$[14] \qquad C_L = 2[Ge(OH)_2R_2^{2-}] + [HR^-] + [R^{2-}].$$

$$[15] \qquad C_M = [Ge(OH)_2R_2^{2-}] + [Ge(OH)_4].$$

$$[16] \qquad [Na^+] + [H^+] = 2[Ge(OH)_2R_2^{2-}] + [HR^-] + 2[R^{2-}].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Les valeurs de β_2^0 ont été calculées pour quelques 8 points de la courbe pour chaque concentration de germanium, les valeurs moyennes sont groupées dans le Tableau III.

TABLEAU III

C_M	Log β_2^0
3.51×10^{-2}	6.61 ± 0.05
8.18×10^{-3}	6.57 ± 0.04
3.51×10^{-3}	6.52 ± 0.07

Dans une deuxième étape, on a déterminé $\mathscr{K}_2$ en reliant β_2^0 à β_2, la constante apparente (équation [8]) dont la valeur est connue en milieu d'acidité 0.49 M.

$$[17]\quad \beta_2 = \frac{[ML_2]}{[M][L]^2} = \frac{[Ge(OH)_2R_2H^-] + [Ge(OH)_2R_2^{2-}]}{[Ge(OH)_4]([H_2R] + [HR^-] + [R^{2-}])^2}$$

$$= \beta_2^0 \frac{1 + ([H^+]/\mathscr{K}_2)}{(([H^+]/k_1) + 1 + (k_2/[H^+]))^2},$$

avec $\beta_2 = 10^{6.16}$ pour $[H^+] = 0.49$ et $\beta_2^0 = 10^{6.57}$, $k_1 = 10^{-0.66}$, $k_2 = 10^{-2.37}$.

La valeur obtenue pour $\mathscr{K}_2$, la deuxième constante d'acidité du complexe $Ge(OH)_2R_2H_2$ est $10^{-0.78\pm0.14}$.

DISCUSSION

La formation des seuls complexes comportant 2 acides chloraniliques par germanium, indiquée par la méthode de variations continues et la présence de points isobestiques a été confirmée par trois méthodes spectrophotométriques indépendantes, qui donnent en outre des valeurs concordantes $10^{6.16\pm0.02}$ pour β_2, la constante de formation apparente du complexe ML_2 en milieu d'acidité 0.49 M. Dans ces méthodes, on a utilisé des longueurs d'onde différentes et l'on a fait varier de façon appréciable le rapport des concentrations C_L/C_M: de 0.0028 à 17.3 ainsi que la concentration C_M: de 4×10^{-5} à 3.5×10^{-2} M. L'absence de complexes ML et ML_3 ainsi que d'espèces polynucléaires M_pL_n stables a été vérifiée.

Les conclusions de Nazarenko et Flyantikova dans leur récent article (11) quant à la présence des trois complexes ML, ML_2 et ML_3 sont donc mises en doute. Ces auteurs ont effectué des mesures spectrophotométriques à 530 mμ dans un domaine d'acidité allant de 1 à 4 M. Leurs courbes de variations continues ayant comme les nôtres, indiqué un complexe ML_2, les conclusions des auteurs reposent uniquement sur une interprétation de la méthode des rapports molaires. L'existence d'un complexe ML est déduite de la non linéarité initiale de la courbe donnant $A_s - \epsilon_L C_L$ en fonction de C_L/C_M. Nous avons confirmé cette courbure (Fig. 10) mais nous avons vérifié par le calcul que le complexe ML_2 suffisait à expliquer cette "anomalie". Quant au complexe ML_3 son existence n'est justifiée que par une cassure de la courbe reposant sur deux points expérimentaux à la seule acidité 1 M. Nos expériences ne nous ont pas conduits à observer de telles cassures comme l'indique la Fig. 10 où l'on a porté $\epsilon_c' = (A_s - \epsilon_L C_L)/C_M$ en fonction de C_L pour des valeurs données de C_M.

L'absence, ou la très faible stabilité, des complexes germanium – acide chloranilique ML et ML_3 est remarquable, d'autant plus que le zirconium (IV) donne avec ce même ligand des complexes ML et ML_2 stables (10). La nature et la stabilité des complexes du germanium (IV) et du zirconium (IV) sont comparées dans le Tableau IV, les constantes apparentes β_n sont calculées pour une acidité 1 M.

TABLEAU IV

	M	ML	ML_2	ML_3
M = Ge	$Ge(OH)_4$ aq.	$\beta_1 < 10^2$	$Ge(OH)_2R_2H^-$, $\beta_2 = 10^{5.9}$	—
M = Zr	Zr^{4+} aq.	ZrR^{2+} aq., $\beta_1 = 10^{5.7}$	ZrR_2 aq., $\beta_2 = 10^{9.5}$	

A l'encontre du complexe ZrR^{2+} aq. stable, l'espèce ML du germanium, soit $Ge(OH)_3R^-$ pentacoordinée, soit $Ge(OH)_3(OH_2)R^-$ ou $Ge(OH)_4R^{2-}$ hexacoordinée, est instable, par rapport à $Ge(OH)_2R_2H^-$ et $Ge(OH)_4$ aq. Le comportement anormal de ce complexe ML semble devoir être relié à la forte "hydratation" du germanium (IV) qui déplace l'équilibre de dismutation $2ML \rightleftarrows M + ML_2$ par stabilisation de M. On a d'ailleurs dans une étude en cours (26) sur les complexes du germanium avec la 8-hydroxyquinoléine, HOx, mis en évidence une seule espèce de composition ML_2, $Ge(OH)_2Ox_2$, en solution aqueuse, alors que la présence d'un complexe ML dans le chloroforme est indiquée. En ce qui concerne l'absence, ou la faible stabilité, du complexe ML_3, elle peut aussi être rapprochée de l'instabilité en solution aqueuse de l'ion complexe $GeOx_3^+$ apparemment présent dans le solide $GeOx_3FeCl_4$ et stable dans certains solvants non hydroxylés (27).

L'absence de polymères est aussi remarquable étant donné que l'acide chloranilique possède deux groupes *o*-hydroxycétones susceptibles de conduire à une chélation. La formation de solides polymériques avec certains ions métalliques, et avec $GeCl_4$ en milieu non-aqueux, a d'ailleurs été signalée (10, 12).

Les complexes du germanium étant nettement moins stables que ceux du zirconium, une méthode d'analyse spectrophotométrique basée sur la réaction avec l'acide chloranilique ne présenterait pas le même intérêt pour le germanium que pour le zirconium (10). D'ailleurs la phénylfluorone est un réactif analytique du germanium supérieur à l'acide chloranilique vue la beaucoup plus grande stabilité du complexe ML_2 correspondant $10^{12.9}$ (6), les valeurs des coefficients d'extinction ϵ_c étant aussi quelque peu favorables à la phénylfluorone, 8.7×10^4 au lieu de 3.3×10^4.

La méthode potentiométrique a permis de préciser les propriétés acides–bases du complexe ML_2, ce dernier possède deux acidités, l'une forte, l'autre de constante $\mathcal{K}_2 = 10^{-0.8}$ et la formule $Ge(OH)_2R_2H_2$ rend compte des propriétés observées. De plus, l'étude du complexe $Ge(OH)_2Ox_2$ précédemment cité, ayant indiqué que les —OH directement liés au germanium sont très faiblement acides (26) on peut conclure que les deux H^+ de $Ge(OH)_2R_2H_2$ proviennent des deux ligands. La formation du chélate a donc renforcé l'acidité du groupe —OH restant libre sur chaque ligand, par rapport aux acidités préexistantes du ligand, $k_1 = 10^{-0.66}$ et $k_2 = 10^{-2.37}$. Un tel effet de la chélation sur l'acidité de groupes libres sur le ligand a été récemment observée par Freiser (28) et Lions (29).

Voigt (10) a aussi montré que la chélation de Zr^{4+} par l'acide chloranilique se faisait avec libération d'environ $2H^+$ par ligand dans un domaine d'acidité allant de 1 à 2 *M*. Le nombre d'H^+ libérés étant d'ailleurs quelque peu inférieur à 2, il est possible que le chélate du zirconium possède des propriétés acides–bases similaires à celles du chélate du germanium.

Une formule, avec le germanium hexacoordiné, est donnée ici pour l'anion complexe $Ge(OH)_2R_2^{2-}$, cette formule est à rapprocher de celle suggérée par Place (12) pour le sel complexe $GeCl_2R_2$ $(pyH)_2 \cdot CH_3NO_2$ préparé à partir de $GeCl_4$ et H_2R en milieu non aqueux.

Cependant, en plus des deux formes résonantes correspondant à cette structure, on doit aussi considérer la possibilité de deux autres structures, où la chélation est effectuée soit par une forme diphénol, soit par une forme dicétone. On est ainsi conduit à envisager une délocalisation probable des électrons; la délocalisation des charges négatives de l'anion complexe pourrait dans une certaine mesure, être à l'origine des propriétés fortement acides de $Ge(OH)_2R_2H_2$.

Il semble probable que la phénylfluorone est coordinée au germanium dans le complexe ML_2 d'une façon analogue plutôt que par le groupe *o*-diphénol en position 2,3, ceci d'autant plus que les ligands comportant ce dernier groupe paraissent conduire à des complexes ML_3 avec le germanium (18). Kanno (5) après avoir étudié un certain nombre de ligands a conclu que ceux qui possèdent un groupe *o*-hydroxycétone réagissent avec le germanium en milieu acide; bien que ce point de vue se trouve confirmé par ce travail, on a observé que certains ligands de cette classe ne donnent pas de réaction (12). Il est ainsi nécessaire de considérer en plus des groupements fonctionnels d'autres propriétés du ligand pour prévoir si celui-ci réagit avec le germanium.

Les caractéristiques des spectres d'absorption des complexes et des différentes formes, H_2R, HR^- et R^{2-} du ligand sont comparées dans le Tableau V. Les valeurs correspondent

TABLEAU V

	λ, mμ	$\epsilon \times 10^{-4}$	λ, mμ	$\epsilon \times 10^{-3}$
ZrR^{2-} (10)	330	1.8	525	
$Ge(OH)_2R_2^{2-}$ et $Ge(OH)_2R_2H^-$	330	3.28	522	1.87
HR^-	307	1.65	525	0.92
H_2R	303	2.0	450	0.22
R^{2-}	334	3.0	525	0.18

aux maxima des deux bandes d'absorption. Les longueurs d'onde sont données à ±5 mμ près et les coefficients ϵ comportent une erreur maximum de ±5%. Les valeurs des coefficients d'extinction molaires du complexe ne sont pas affectées de façon notable par l'acidité entre 0.5 *M* et pH 3.3. On constate que le coefficient ϵ_c du complexe $Ge(OH)_2R_2^{2-}$ comportant 2 ligands R^{2-} est égal à environ 2 fois celui du ligand protoné HR^-, aux deux maxima. Une situation analogue prévaut dans le cas de ZrR^{2+}. On observe souvent des relations telles lorsque les bandes d'absorption des complexes proviennent de modifications des transitions internes des ligands (30) comme dans le cas présent. La bande de HR^- vraisemblablement due à la transition $\pi \rightarrow \pi^*$ (31) est déplacée de 306 à 327 mμ, lors de la chélation du germanium tandis que la bande due à la transition $n \rightarrow \pi^*$ du groupe carbonyle reste inchangée à 525 mμ.

REMERCIEMENTS

Nous exprimons nos remerciements au Conseil National de Recherches du Canada pour une bourse (A. B.) et un octroi de recherches (R. L. B.).

SUMMARY

Complex formation between germanium (IV) and 2,5-dichloro-3,6-dihydroxy-*p*-benzoquinone (H_2R) as ligand is studied at ionic strength 0.49. Spectrophotometric methods are used to show that only complexes with two ligands per germanium atom are present and to calculate the apparent stability constant $\beta_2 = 10^{6.16}$ in 0.49 *M* H^+. The values of the ligand acidity constants are $k_1 = 10^{-0.66}$ and $k_2 = 10^{-2.37}$. The stability constant of $Ge(OH)_2R_2^{2-}$ is found to be $\beta_2^0 = 10^{6.57}$ by potentiometry. The complex $Ge(OH)_2R_2H_2$ is a strong acid in its first dissociation, the constant of the second dissociation is $\mathcal{K}_2 = 10^{-0.8}$. Formulae are suggested for the complexes. The nature and stability of the germanium and zirconium complexes are compared and their absorption spectra are discussed in relation to those of the ligand species H_2R, HR^-, and R^{2-}.

THE HYDROGEN–CHLORINE SYSTEM IN THE MM PRESSURE RANGE

I. ENERGY DISTRIBUTION AMONG VIBRATIONALLY EXCITED STATES

F. D. FINDLAY[1] AND J. C. POLANYI

Department of Chemistry, University of Toronto, Toronto, Ontario

Received April 27, 1964

ABSTRACT

When atomic plus molecular hydrogen coming from a Wood's discharge tube are mixed with molecular chlorine, infrared emission is observed (1). At low reagent pressures, $\sim 10^{-2}$ mm Hg, this emission can be related to the relative rate of the reaction $H + Cl_2 \rightarrow HCl\dagger_v + Cl$ proceeding to form HCl in vibrationally excited states $v = 1$–6, of the ground electronic state. In the present work this system has been investigated for the first time at $\sim 100\times$ the reagent pressure (~ 1 mm Hg). The reaction was shown to proceed by a chain mechanism. The translational–rotational temperature was 1300 ± 100 °K under the experimental conditions normally used. The vibrational distribution was notable for the presence of vibrators in levels $v = 7$ and 8, which are respectively 4 and 10 kcal higher in energy than the exothermicity of the $H + Cl_2$ reaction. The population in these levels appeared to be related to that in the levels with $v \leqslant 6$; it was proposed that vibrational–vibrational exchange among these lower levels was responsible for populating the higher ones. A simple model yielded a collision efficiency for $HCl\dagger_{v=1} + HCl\dagger_{v=6} \rightarrow HCl\dagger_{v=7} + HCl\dagger_{v=0}$, of $Z_{1,6}{}^t = 6 \times 10^3$ collisions per transfer. Addition of HCl to the reaction mixture brought about a redistribution among vibrationally excited states indicative of a fast vibrational transfer, $HCl_{v=0} + HCl\dagger_{v=2} \rightarrow 2\ HCl\dagger_{v=1}$.

At reduced pressure of HCl† the stationary-state distribution among higher vibrational states approximated closely to that observed at 10^{-2} mm Hg total pressure (where collisional deactivation is insignificant), suggesting that collisional deactivation was not of major importance even at the pressure used in the present work. In order to account for the high translational–rotational temperature, in the absence of substantial vibrational deactivation, it was necessary to suppose that the greater part of the energy liberated by the reaction $H + Cl_2$ went *directly* into translational and rotational motion of the products.

INTRODUCTION

When $H_2 + H$ coming from a discharge is mixed with Cl_2, infrared emission (but no visible emission) is observed. This emission (1.5–4.5 μ) was first recorded in experiments conducted at ca. 0.1 mm Hg reagent pressure (1). The objective was to obtain information concerning the vibrational energy distribution in the product of the primary reaction, $H + Cl_2 \rightarrow HCl\dagger + Cl$. The observation of a near-Boltzmann distribution among vibrational states led to the suspicion that the vibrators once formed might be randomizing their energy through rapid vibrational–vibrational transfer. Subsequent experiments (2) were conducted in the 0.01 mm Hg pressure range. At these pressures a markedly non-Boltzmann distribution was observed among the vibrational states of HCl. A steady-state analysis of this distribution led to a series of relative rate constants, k_v, for the $H + Cl_2$ reaction proceeding to form HCl† (vibrationally excited HCl in its ground electronic state) in specified states v.

In the present work we have set out to achieve a qualitative or semi-quantitative understanding of the complicating processes that occur at higher reagent pressure. For this purpose we have gone beyond the original 0.1 mm 'medium' reagent pressure, to a 'high' pressure region of 1–2 mm Hg.

[1]*Present address: National Physical Laboratory, Teddington, Middlesex, England.*

EXPERIMENTAL

A block diagram of the apparatus would be identical to Fig. 1 of ref. 1, with the exception of a second reagent supply running parallel to the first. Experiments were conducted under conditions of continuous flow. Materials (H_2, Cl_2, and HCl) were from the same sources as in ref. 1. However, in order to make possible the much greater flows used in the present work, the gases were delivered directly from cyclinders. Flowmeters consisted of lengths of capillary tubing across which the pressure drop could be measured. These meters were calibrated with the experimental gas at the experimental fore-pressure, either by condensing the material passed in a given time or (for H_2) by measuring a small pressure rise in a closed volume downstream. The pumping facilities consisted of a 2 in. butterfly valve (Edwards QSB-2) directly below the reaction vessel, a liquid-air trap (Edwards NTM-2A), a 4 in. oil booster diffusion pump (NRC QB-4), and a mechanical pump (Edwards ISC-450B; 8.1 liters per second capacity). Only the mechanical pump was used under running conditions, since the reaction vessel pressure was in the range 1–2 mm Hg. Following an experiment, chlorine and hydrogen chloride condensed in the liquid-air trap were distilled into a copper sidearm and removed.

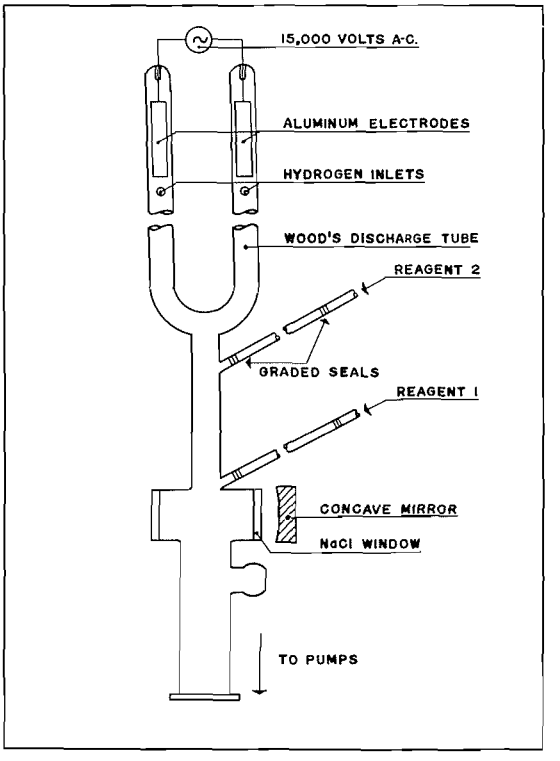

FIG. 1. Reaction vessel assembly.

The reaction vessel assembly (Fig. 1) consisted of a Wood's discharge tube, made from 30 mm pyrex 30 in. long, attached to a cylindrical reaction vessel, 10 cm long by 5 cm diameter, which in turn was attached to a 2 in. diameter by 6 in. long glass tube terminating in a flat flange. The flange was greased and made a vacuum seal either with a flat metal plate or with an O-ring set into a metal plate. In one version the reaction vessel was pyrex with NaCl windows held to either end by glyptal varnish, in another the vessel was made entirely of pyrex with pyrex windows sealed on, and in a third design the vessel was quartz with quartz windows sealed directly to either end. The Wood's tube was poisoned, following a cleaning with 10% hydrofluoric acid, with 30% orthophosphoric acid, to reduce the rate of atom recombination at the walls.

To determine the concentration of hydrogen atoms formed in the discharge, a tungsten-wire probe was inserted through the ball-and-socket joint directly beneath the reaction vessel. The filament (2 cm long by 0.01 cm diameter) formed one arm of an a-c. bridge; it was used as an isothermal calorimeter to measure the heat liberated on H-atom recombination (3). H-atom concentration was only measured in the absence of chlorine. It was found to be constant throughout the cell, to better than ±5%. As the variable transformer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in the primary of the Wood's tube transformer was increased from the 20 to the 100 V setting, the percentage dissociation of H_2 present in the reaction vessel rose almost linearly from 2 to 17%. In most experiments ('normal' conditions) the variable transformer was set at 45 V, resulting in ca. 8% dissociation in the vessel.

Chlorine was normally introduced through reagent inlet tube No. 1, directly above the vessel. The quartz insert between the graded seals on this sidearm was used in experiments where an r.f. discharge was applied to the Cl_2. In experiments where HCl was added, reagent inlet No. 2, located about 5 in. above the vessel, was used.

In normal operation the optics were aligned so that a beam emerging from the spectrometer gave rise to an image of the spectrometer slit (12 mm high) in the center of the front window of the cell; within the cell the beam diverged with a 15° angle. The pressure in the reaction vessel was measured at the ball-and-socket joint 2 in. below the vessel. The flexible metal vacuum tube leading from this joint to the McLeod gauges could be replaced by the tungsten-filament probe.

A spherical mirror with large radius of curvature was placed behind the reaction vessel, giving an increase in intensity of slightly less than a factor of two.

The spectrometer was a Perkin–Elmer 112G double-pass grating instrument, with KBr fore-prism. The detector was a liquid-air-cooled 'Infratron' lead sulphide cell. After an experiment, the spectrometer was calibrated for change in transmissivity with wavelength and, simultaneously, the detector was calibrated for change in sensitivity with wavelength. This was done by making a trace of the emission from a black-body source, recorded at the experimental spectrometer slit width. In correcting line areas for changing efficiency of the instrument, allowance was made for the fact that the dispersion of the grating changes slightly, even within a single order; this affects the signal from the black body used in calibration, but does not affect the areas under the spectral lines.

RESULTS

Infrared emission was recorded in the fundamental, first-overtone, and second-overtone regions of the HCl spectrum. No visible emission was detected.

In preliminary experiments, traces of the first-overtone spectrum were made under very similar flow conditions employing pumps similar to those described in ref. 1 (pressure in the reaction vessel 0.1–0.2 mm, contact time ca. 0.05 s). The gain in intensity on converting to the high-flow system used in the bulk of the present experiments was in the region of 10–100× (pressure in the reaction vessel 1–2 mm, contact time ca. 0.01 s). It may be remarked that Cashion and Polanyi (1) reported a *decrease* in intensity when reagent inflows were increased. In their case, however, an increase in reagent inflow meant a decrease in linear flow rate across the reaction vessel; it appears probable, considering both the gain in intensity referred to above and experiments to be described below (Section 3), that the diminution in intensity in their experiments was due to a displacement of the zone of most intense emission upwards out of the cone-of-sight of their spectrometer.

An actual chart record of a typical fundamental spectrum is shown in Fig. 2. Emission was observed from the $v(1–0)$, $v(2–1)$, $v(3–2)$, and $v(4–3)$ bands. The experimental conditions are recorded in the caption of the figure. A quartz reaction vessel cooled by air jets was used (the transmission of quartz is down to 65% by 3.8 μ). The entire spectrum is not reproduced. The band-head of $v(1–0)$ R-branch (not shown) was observed at $J = 25$.

Part of the first-overtone spectrum, consisting of 130 vibration–rotation lines of $v(2–0)$, $v(3–1)\ldots v(7–5)$, is shown in Fig. 3. The spectrum was recorded using an all-pyrex vessel (transmission 92% in this wavelength region). The reaction $H + Cl_2$ cannot form emitters in levels with $v > 6$; the source of the emission from $v = 7$ will be discussed later.

The second-overtone spectrum shown in Fig. 4 was recorded under the same flow conditions as Fig. 3, but with wide slits owing to the low intensity of the higher overtone. The $v(3–0)$, $v(4–1)\ldots v(8–5)$ can be picked out by their prominent R-branches. Because of the large difference between the rotational constants for the upper and lower vibrational states in these $\Delta v = 3$ transitions, the R-lines converge rapidly and reach a band-head at $J = 10$, giving this spectrum its characteristic appearance. The P-lines diverge rapidly so that the R-branch of any band is overlapped by only three P-lines from the neighboring

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

lower transition. The dotted line at the base of each R-branch indicates the level of intensity from the unresolved P-lines of the neighboring band.

DISCUSSION

In some experiments the Cl_2:HCl ratio in the product was obtained by measuring the pressure over the condensate at various temperatures, in a calibrated volume. It was found that in an experiment with H_2 inflow about 1300 μmoles/s, percentage dissociation about 8%, and Cl_2 inflow 480 μmoles/s, the Cl_2 was at least 90% converted to HCl. This indicates a chain of 4 or 5 links:

[1] $\quad H + Cl_2 \rightarrow HCl + Cl \qquad \Delta H = -45$ kcal/mole

[2] $\quad Cl + H_2 \rightarrow HCl + H \qquad \Delta H = 1$ kcal/mole

The activation energy for reaction [1] is about 2.5 kcal/mole (4), so that there is a total of 47.5 kcal to be distributed among the products. Evidence will be presented in Section 5 below which points to the fact that the major part of this energy is liberated as translation and rotation of the products. The Cl that collides with H_2 in reaction [2] could therefore have excess energy (H_2 is present in excess and is the most likely gas-phase 'coolant'). Even normal thermal collisions, however, would have a high collision efficiency. In Section 1, it will be shown that the translational–rotational temperature of the bulk of the gas is 1250 ± 50 °K. At this temperature reaction [2], which has an activation energy of ca. 6 kcal/mole, would occur every 10–100 collisions (assuming a steric factor of 1–0.1). Since the $v = 1$ level of HCl is 8.25 kcal above $v = 0$, [2] will form HCl primarily in $v = 0$.

The possibility of a chain was demonstrated in an experiment where the discharge through the hydrogen was at first switched off, thus cutting off the supply of atomic H while maintaining normal flows of H_2 and Cl_2 into the reaction vessel. The emission fell to zero. When, however, a radio frequency discharge was applied to the quartz inlet tube carrying the Cl_2, the emission was restored to full intensity, with the normal heating of the vessel walls.

The intensity of a vibration–rotation line in emission, $I_{vJ}^{v'J'}$, is related to the population, $N_{v'J'}$, in the upper state of the transition, by the expression

$$[3] \qquad I_{vJ}^{v'J'} = \frac{64\pi^4 c N_{v'J'}}{3(2J'+1)} \cdot (\omega_{vJ}^{v'J'})^4 \cdot |R_v^{v'}|^2 \cdot S_J \cdot F_{vJ}^{v'J'}$$

where $\omega_{vJ}^{v'J'}$ is the wave-number frequency of the line, $R_v^{v'}$ is the transition moment for the band, S_J is the line strength (J' for an R-branch line, $J' + 1$ for P-branch) and $F_{vJ}^{v'J'}$ is the vibration–rotation interaction factor (2, 5).

1. Rotational Distribution

In considering rotational distribution within a single band we can write,

$$[4] \qquad I_J \propto \frac{N_{J'} \cdot \omega_J{}^4 S_J F_J}{2J'+1}.$$

For a Boltzmann-type distribution

$$[5] \qquad N_{J'} \propto (2J'+1)e^{-J'(J'+1)Bhc/kT}$$

where B is the rotational constant. Substituting into the previous equation and rearranging,

$$[6] \qquad \log \frac{I_J}{\omega_J{}^4 S_J F_J} \propto -J'(J'+1) \cdot Bhc/kT.$$

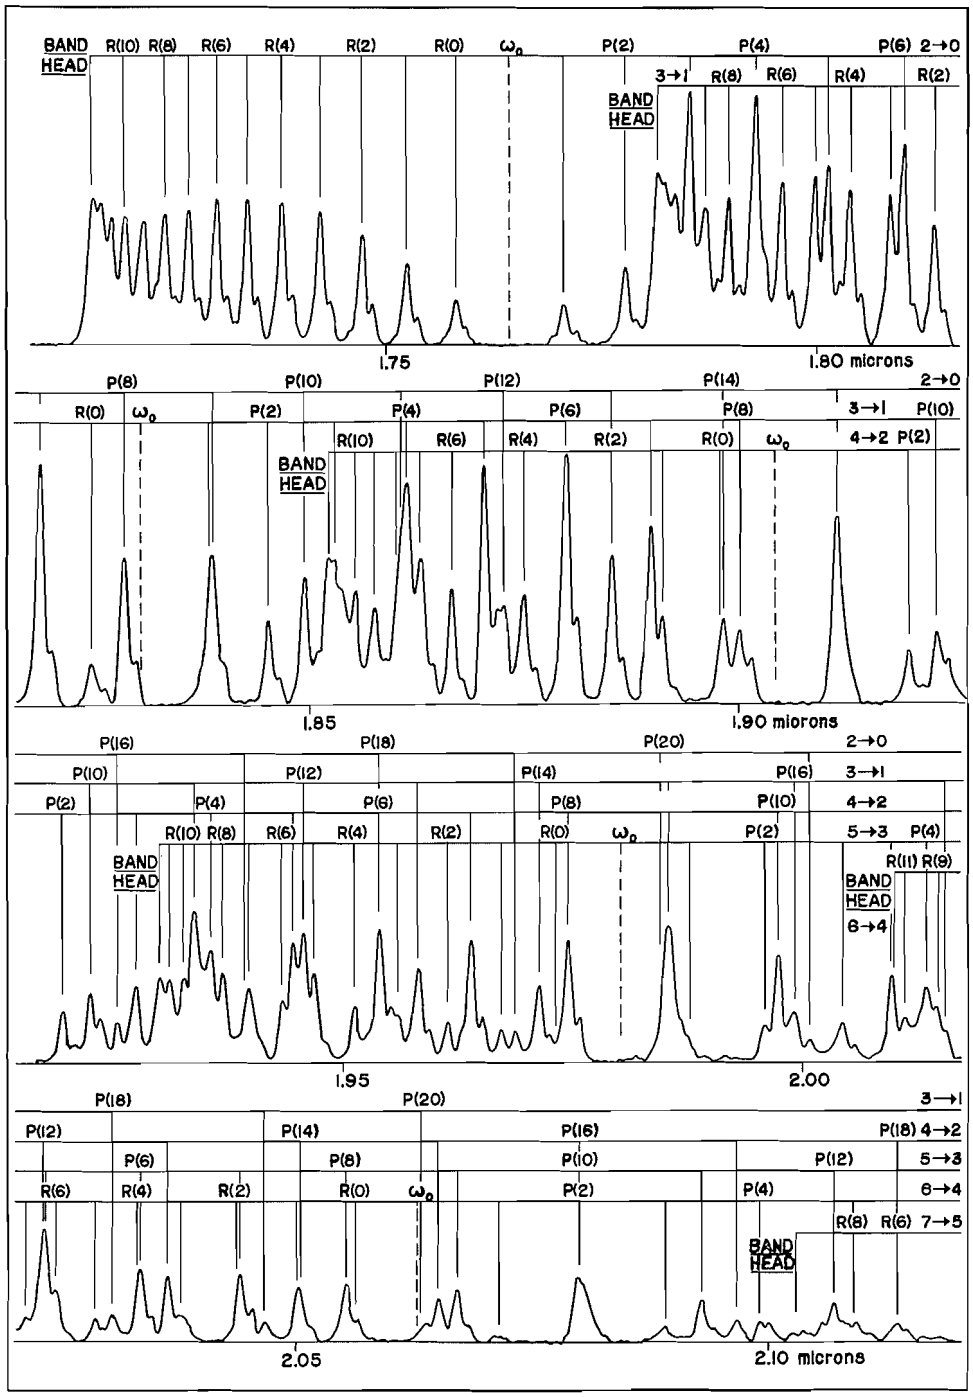

FIG. 3. First-overtone spectrum of HCl. Reagent inflows, 1380 μmoles/s of H_2 + H, 490 μmoles/s Cl_2. Total pressure 1.45 mm Hg. Contact time 0.0084 s. Grating 600 grooves/mm blazed at 1.6 μ, used in the first order. Grating monochromator slit width: 0.250 mm.

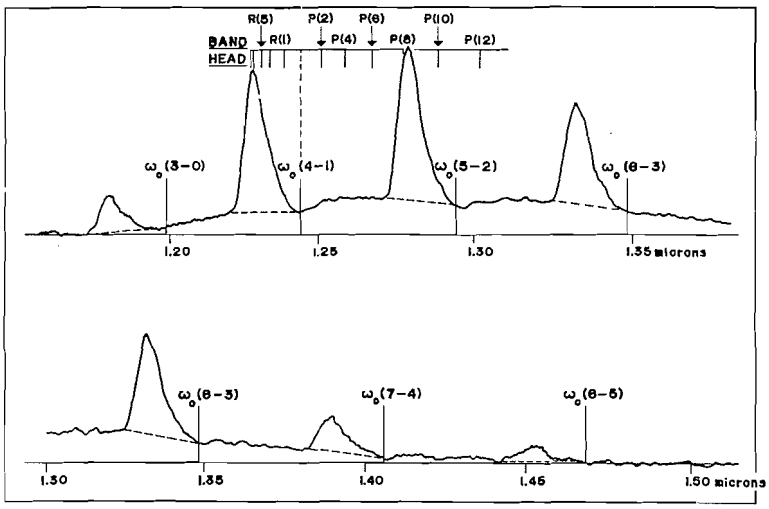

FIG. 4. Second-overtone spectrum of HCl. Reagent inflows, total pressure, and contact time as for Fig. 3. Grating as for Fig. 3, used in the first order. Grating monochromator slit width: 2.0 mm.

Figure 5 shows a plot of log $I_J/\omega_J{}^4 S_J F_J$ for levels $v = 1, 2, 3$, derived from the fundamental spectrum. The plots are linear over the greater part of their length, demonstrating that equilibrium exists within each vibrational state. The exceptions are the states of low J' in $v = 1$ and to a lesser extent $v = 2$, and a few states of very high J', $\geqslant 16$, in $v = 1$ and $v = 2$. The former anomaly will be shown in Part II to be apparent only,

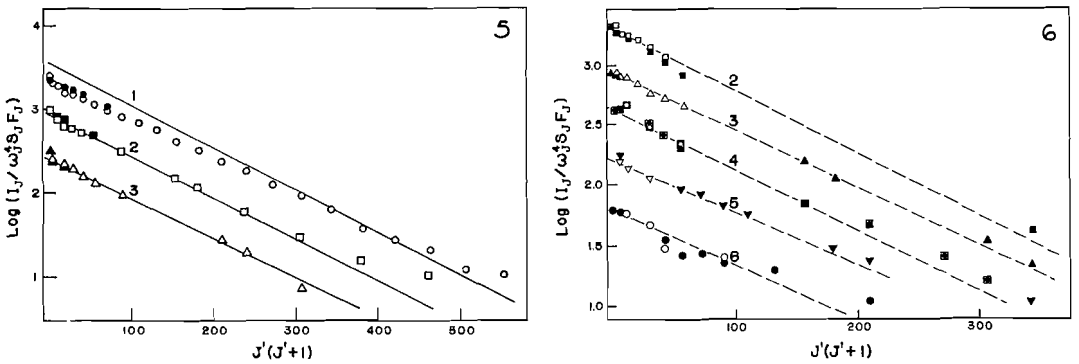

FIG. 5. Rotational distribution in $v = 1, 2, 3$, from the fundamental spectrum. Curve 1 refers to $v = 1$, for which T_{ROT} was *assumed* to be 1250 °K (see Part II); 2 refers to $v = 2$, for which $T_{ROT} = 1270$ °K; 3 refers to $v = 3$ for which $T_{ROT} = 1310$ °K. ● calculated from *P*-branch, ○ from *R*-branch lines.

FIG. 6. Rotational distribution in $v = 2, 3 \ldots 6$, from the first-overtone spectrum. The numbers above the curves give the vibrational quantum number of the level. $T_{ROT} = 1250 \pm 50$ °K for all levels.

being due to self-absorption of the $v(1–0)$ and $v(2–1)$ emissions. This apparent deviation from Boltzmann distribution will be shown to provide a useful clue to the relative and absolute pressures of HCl in the various rotational states of $v = 0$. The deviation among high J' will be discussed later in this section.

The rotational temperatures in $v = 2$ and 3 are the same, 1290 ± 20 °K, within experimental error.

Figure 6 shows rotational plots for the best lines (those not subject to appreciable overlap) in the $v(2–0)$, $v(3–1)\ldots v(6–4)$ bands. Once again, within experimental error there appears to be a Boltzmann rotational distribution within each vibrational state. The rotational temperature is roughly the same in all vibrational states: the dashed lines in the figure have slopes 1250 ± 50 °K.

The constancy of rotational temperature, 1300 ± 100 °K, in all vibrational states $v = 2$ to 6 (with 2 independent estimates for $v = 2$ and 3) can most easily be explained on the hypothesis that the rotators are in equilibrium with a translational heat bath at this temperature. (In Part II it will be shown that $v = 0$ is at a similar elevated rotational temperature.) Since the walls of the vessel are at about 400 °K (estimated from thermocouple measurement of the temperature of the outside surface) this implies the presence of a rotational temperature gradient across the vessel, and also indicates that the HCl has about 2 kcal/mole of rotational energy in excess of the thermal energy available at the wall.

Using a restricted cone-of-acceptance for the spectrometer, experiments were made in which only the R-branch of $v(2–0)$ was recorded, at various points in the reaction vessel. Spectra taken at either side of the vessel close to the wall gave a rotational temperature of about 600 °K. Spectra taken at the top and bottom of the vessel, though differing in intensity by a factor of $10\times$, gave roughly the same rotational temperature at normal H-atom concentration, ca. 1300 °K. It would appear that we are dealing here with rapid streaming flow from top to bottom of the vessel, combined with slower, perhaps diffusive, lateral flow to either side of the normal optical axis. The rapid top-to-bottom flow extended, in depth, along the major part of this optical axis, since the exit pipe, where it met the reaction vessel, encompassed more than half the length of the vessel. (Except for this, Figs. 5 and 6 would show curved rotational plots.)

It appears very probable that this rotational temperature is indicative of a similar translational temperature. Only on this assumption can we plausibly explain the observation of rotational Boltzmann distributions in all vibrational levels. It would be possible for HCl to be formed by the reaction in high states of rotation (9), but, except by far-fetched coincidence, this could not give rise directly to a Boltzmann distribution. If we suppose that rotational excitation is still present in excess of translational, it becomes necessary also to suppose that the non-Boltzmann rotational distributions in each vibrational level relaxed to Boltzmann distributions before losing their excess rotational energy to translation (presumed, for the sake of this argument, to be at 400 °K). It is quite contrary to what we know about energy transfer that (non-resonant) transfer in a quantized degree of freedom (rotation) should be faster than transfer into an unquantized degree of freedom (translation) (7). Moreover, it is hardly to be expected that this type of relaxation would lead by chance to the same rotational temperature in all levels $v = 1$ to 6.

We conclude that the rotational temperature of the excited HCl reflects the rotational and the translational temperature of all the gases in the central part of the reaction vessel. From the fact that the reaction, as evidenced by the emission, is almost complete by the time the vessel has been traversed, and yet the rotational temperature is maintained, we conclude that the loss of heat to the wall is slow. The following rough calculation confirms this.

For simplicity we shall assume a linear temperature gradient of 1000° from the faces of a 1 cm cube at the center of the cell, to the wall. The thermal conductivity of HCl is 3×10^{-5} cal/s deg cm (8), and it follows that 0.09 cal/s will flow from the cube for a 500°/cm gradient at its walls. If we assume, for this order-of-magnitude calculation, that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the entire heat of reaction is available for conduction to the wall and that all 450 μmoles of chlorine entering the reaction vessel per second is converted to HCl (see above) then we have 20 cal/s liberated in the reaction vessel. Reaction takes place more rapidly in a central core of the vessel; we shall suppose that the reaction is completed in 100 cc, one-half the volume of the vessel. Thus the heat liberated is 0.2 cal/s cc. This agrees within a factor of about 2× with the heat loss that must be offset in order to maintain temperatures in the 1000 to 2000° range. (Better agreement than this would be fortuitous, considering the crudity of the model.)

From Figs. 5 and 6, it can be seen that there is some evidence of rotators in excess of the Boltzmann proportion in high rotational states, $J' \geqslant$ ca. 17. In experiments at $10^{-2}\times$ these pressures (2), a similar anomaly was observed for $J' = 9$–18. (Very high rotational levels, $J' > 18$, lay below the limit of detection.) This could reflect a large excess of rotational energy, produced by the reaction $H + Cl_2 \rightarrow HCl + Cl$. Owing to the low moment of inertia of HCl, conservation of angular momentum would not be violated by the presence of large amounts of rotational energy in HCl (9). In the low-pressure experiments with lower collision frequency, some of this rotational excess may survive collisional deactivation even in levels with J' as low as 9. In the present high-pressure experiments the excess in these lower levels has presumably been erased by rotational–translational transfer, and only the residue of an excess in $J' \geqslant 17$ remains. Two reasons might be advanced to explain the greater persistence of the excess in very high J' levels; either the original excess is greater in these levels, or deactivation of the highly rotating molecules is more difficult, owing to wide spacing of the quantum levels.

However, the persistence of even the smallest degree of rotational disequilibrium, under conditions where an emitter suffers an average of 10^5 collisions in the course of a radiative lifetime, is sufficiently unexpected (7) to throw doubt on the reality of the observation. Futher experiments are required before the possibility of a systematic error can be discounted.

2. Vibrational Distribution

For the special case of a molecule having $\theta \approx 1$ ($\theta = M_0/M_1 r_e$, where M_0 and M_1 are the first two coefficients in the Taylor series expansion of the dipole moment) equation [3] reduced to (6)

$$[7] \qquad I_v^{v'} = \frac{64\pi^4 c N_{v'}}{3} \cdot [(\omega_0)_v^{v'}]^4 \cdot |R_v^{v'}|^2.$$

That is to say, the total intensity of a band bears the same relationship to the total number of molecules in the vibrational upper state, whatever the rotational distribution in that upper state. By making the substitution

$$[8] \qquad A_v^{v'} = \frac{64\pi^4[(\omega_0)_v^{v'}]^3}{3h} |R_v^{v'}|^2$$

equation [7] can be abbreviated and rearranged to

$$[9] \qquad N_{v'} = \frac{I_v^{v'}}{hc(\omega_0)_v^{v'} A_v^{v'}}.$$

The Einstein transition probability for HCl, $A_v^{v'}$, has been calculated on the basis of Morse-oscillator eigenfunctions and linear dependence of the dipole moment on internuclear separation and is available in the literature (10).

For the fundamental region of the spectrum, Figs. 2 and 5, $I_v^{v'}$ was calculated only for the R-branches of $v(1–0)$, $v(2–1)$, and $v(3–2)$, by summing line intensities. On the basis of the considerations presented in the preceding sections, the rotational temperature was assumed to be the same in all these levels, and hence $(I_v^{v'})_R$ represented the same fraction of the total $I_v^{v'}$, in each case, to within experimental accuracy. Relative $N_{v'}$ were therefore calculated from relative $(I_v^{v'})_R$. These are shown in Table I. $(I_0^1)_R$ and $(I_1^2)_R$ were corrected

for self-absorption by the methods described in Part II. As a check on [9], $N_{v'J'}$, calculated individually from $I_{vJ}^{v'J'}$ and [3], were summed to give $N_{v'}$. The result agreed to within 1% with that obtained from [9].

In calculating relative stationary-state concentrations in vibrational levels $v = 2$ to 7 inclusive from the first-overtone data of Figs. 3 and 6, sufficient lines were available in both R- and P-branches so that it was unnecessary to resort to the device of comparing $(I_v^{v'})_R$ only. The few non-overlapped lines in $v(7–5)$, not plotted in Fig. 6, indicated $T_{\text{ROT}} = 1200$ °K; the remainder of the $v(7–5)$ lines were interpolated assuming a rotational Boltzmann distribution at this temperature. Populations relative to $N_{v=2}$, and also relative to $N_{v=3}$ for comparison with the second overtone, are listed in Table I.

Relative stationary-state concentrations $N_3/N_{v'}$ for $v' = 3–8$ were calculated from the second overtone, Fig. 4, and are listed in Table I. The procedure in this calculation was to measure the apparent $(I_v^{v'})_R$, correct for the contribution from $(I_v^{v'})_P$ of the next lower band, and then apply [9] to the R-branches only, as for the fundamental.

Examination of Table I shows five ratios of $N_{v'}$, each of which has been obtained from two different bands with different spectrometer transmissivity corrections, different corrections for overlapping lines, different $A_v^{v'}$, etc. The deviations appear to be random; they have a maximum value of 8%.

If the distribution of HCl among vibrational levels were of the Boltzmann type, then

$$[10] \qquad \frac{N_1}{N_{v'}} = \exp\left[-(G_0(1) - G_0(v'))hc/kT\right]$$

$$[11] \qquad \log\frac{N_1}{N_{v'}} = \frac{0.625}{T}\left[G_0(v') - G_0(1)\right]$$

where $G_0(v)$ is the term value, the vibrational energy in units of cm^{-1}. The factor $0.625 = hc/2.303\ k$. Figure 8 shows a plot of $\log N_1/N_{v'}$ versus $G_0(v') - G_0(1)$. Points indicated by open circles refer to an experiment made some months later than that recorded in

Table I. The experimental conditions were similar (rotational temperature was, however, 100° lower: 1200 °K) and are referred to as 'normal' conditions, to distinguish these experiments from others made at very low or high percentage dissociation of H_2 or with added HCl, unusual alignment of the spectrometer, etc.

The 'normal' curve of Fig. 8 was chosen for graphical presentation since it was recorded immediately before the second (added-HCl) curve in the figure. It showed the same main features as the data of Table I (with the exception of a slight upward displacement of N_1/N_2 in the Table I data, which will be discussed in Section 4). The distribution, though much closer to a Boltzmann distribution than in Charters and Polanyi's (2) experiments at 10^{-2} mm pressure, was nevertheless non-Boltzmann, decreasing in vibrational 'temperature' from about 4000 to 3000 °K; this curvature was particularly noticeable starting at about $v = 6$. In the 10^{-2} mm low-pressure experiments the curvature of the Boltzmann plot was in the same sense, but much more extreme; the vibrational temperature, initially 8000 °K, had fallen to 2930 °K by $v = 5$.

A second striking feature of the 'normal' vibrational distribution in these experiments was the presence of detectable concentrations of emitters in levels 7 and 8. Stationary-state concentrations in these levels must have been at least 10× greater here than in Charters and Polanyi's low-pressure experiments.

Levels with $v > 6$ cannot be populated by the reaction $H + Cl_2 \rightarrow HCl + Cl$, which yields 45 kcal/mole exothermicity plus 2.5 kcal activation energy. The most probable explanation of the presence of these vibrators in $v > 6$ is that vibrational–vibrational transfer among HCl molecules, which is of negligible significance when HCl is present at $\leqslant 10^{-2}\times$ the concentration, is promoting HCl from the lower vibrational levels in which it is originally formed to higher levels. Vibrational–vibrational exchange would ultimately randomize the energy in the vibrational degree of freedom producing a Boltzmann distribution characterized by a unique vibrational temperature (not necessarily the same temperature as the translational–rotational temperature). Vibrational–vibrational transfer would account not only for the presence of vibrators in $v = 7$ and 8, but also for the fact that the distribution in levels $v \leqslant 5$ is close to a Boltzmann distribution. Two factors favor vibrational–vibrational exchange in the present work as against that of Charters and Polanyi: increased pressure of vibrationally–excited HCl and increased ambient temperature.

An alternative mechanism for the population of $v = 7$ and 8 which should be considered is 'collisional transfer', that is to say translational-to-vibrational transfer. At 1300 °K, however, collisional excitation from $v = 6$ could only produce a stationary-state concentration in $v = 8$ with less than 0.7% of the population of $v = 6$. (The energy jump is 12.7 kcal, and the rate of removal from $v = 8$ is greater than from $v = 6$.) The observed fraction (Table I) was 8× as great as this upper limit. The same argument appears to rule out the possibility that $v = 8$ might be populated directly by a high-temperature reaction between $H + Cl_2$, for which the minimum activation energy would be 12.7 kcal. In addition it would be expected that the 'intrinsic' efficiency of transfer into $v = 8$ would be less than that into $v = 6$, in the same way as that into $v = 6$ is less than that into $v < 6$ (2), further decreasing the yield in $v = 8$ by this chemical route.

Two further mechanisms which, at the increased stationary-state pressures of H and Cl, might possibly also produce highly vibrating HCl ($v = 7$ and 8) are

$$H + Cl + M \rightarrow HCl\dagger + M, \qquad [12]$$

atomic combination in the gas, where M is some gaseous third body, or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[13] $$H + Cl + W \rightarrow HCl\dagger + W,$$

where W is the wall and HCl† is desorbed into the gas, as a vibrationally-excited species. However, if these were the principal sources of $HCl\dagger_{v=7,8}$, there would be no reason why N_7 and N_8 should always fall on a smooth continuation of the curve (Table I, Fig. 7, and Fig. 8) which passes through N_4, N_5, and N_6. If, however, the body of vibrators are approaching a Boltzmann distribution, some dependence of N_7 and N_8 on $N_{\leqslant 6}$ would be expected. It would, moreover, be predicted that at lower concentrations of $HCl\dagger_{v\leqslant 6}$ the proportion of $HCl\dagger_{v=7,8}$ would decrease. Two methods have been used to decrease $HCl\dagger_{v\leqslant 6}$ (i.e. to decrease the emission intensity, which is directly linked to the stationary-state concentrations of emitters through eq. [3] or [9]); one method is to decrease the percentage dissociation of H_2 (Section 3 below), the other is to add $HCl_{v=0}$ (Section 4). Both these alterations do have the effect of sharply decreasing the proportion of vibrators in $v = 7$ and 8 and, at the same time, increase the degree of disequilibrium among vibrators in the lower states.

The most probable mechanism for the production of $HCl\dagger_{v=7}$ by vibrational–vibrational exchange, both on concentration grounds and on the grounds that the change in vibrational quantum number is a minimum, is

[14] $$HCl\dagger_{v=1} + HCl\dagger_{v=6} \rightarrow HCl\dagger_{v=7} + HCl_{v=0}.$$

This reaction is exothermic by 1.78 kcal. The average number of collisions that $HCl\dagger_{v=6}$ suffers with an $HCl\dagger_{v=1}$ (total pressure in all rotational states, 0.06 mm Hg; see Part II) in the course of transit through the vessel is $\sim 5 \times 10^3$. We conclude that $\sim 5 \times 10^3$ collisions $HCl\dagger_{v=1} + HCl\dagger_{v=6}$ are capable of producing a detectable concentration of $HCl\dagger_{v=7}$. It would be much more valuable to have a figure for the collision efficiency of this process. In the following paragraphs the stationary-state equations which govern the (known) concentration of $HCl\dagger_{v=7}$ will be set up and solved for the rate constant and hence collision efficiency of the transfer process [14].

The general stationary-state equation governing N_v in this system can be written

[15] $$R_v + \sum_{uw} k_{uw}{}^t N_u N_w + \sum_{uu} k_{uu}{}^t N_u{}^2 + \sum_w A_v{}^w N_w + Z \sum_w P_{wv} N_w = [\sum_u k_{vu}{}^t N_u + \sum_w k_{vw}{}^t N_w + k_{vv}{}^t N_v + \sum_u A_u{}^v + Z \sum_u P_{vu} + \tau^{-1}] N_v$$

where $u < v < w$, k is a rate constant, P is probability of deactivation per collision, Z is the collision frequency, and τ is the mean contact time in the vessel. Terms on the left-hand side of [15] give rates of processes forming vibrators in v, while terms on the right-hand side give rates of processes removing vibrators from v. Those on the left, taken in sequence, give rate of chemical reaction directly into v; rates of the vibrational transfer processes $HCl_u + HCl_w \rightarrow HCl_v$ and transfer processes $2HCl_u \rightarrow HCl_{u+1} + HCl_{u-1}$; rates of radiation from all higher levels into v; and rates of collisional transfer from all higher levels into v. Terms on the right give rates of three categories of transfer process out of level v; rates of radiative and collisional transfer out of v; and rate of removal from the reaction vessel by pumping. Wall deactivation can probably be neglected in view of the slow rate of transfer to the wall. (Evidence has already been presented for a reactive 'core' of gas.)

In applying [15] to $v = 7$ we can write $R_7 = 0$. In the light of evidence to be presented in the following section, we shall neglect collisional transfer into and out of v. We shall

make two assumptions: (a) only transfer process [14] is important, since it is favored both by relatively high concentration in $v = 1$ and also by the fact that Δv is a minimum; (b) rates of processes terminating in, or originating from, $v \geqslant 9$ can be ignored. This assumption is acceptable in accounting for $N_{v=7}$ since $A_7^9 < A_7^8$ and $N_9 < N_8$. It will, however, introduce some error into $k_{17}{}^t$ (eq. 17). Fortunately $k_{17}{}^t$ only figures as a correction to $k_{16}{}^t$. From [17], $k_{17}{}^t$ is 2.5×10^{10} cc/mole s. If this is out by a factor of 2, then $k_{16}{}^t$ (eq. 16) is altered by 25%.

The stationary-state equations employed for $v = 7$ and 8 were,

$$[16] \qquad k_{16}{}^t N_1 N_6 + A_{87} N_8 = k_{17}{}^t N_1 N_7 + [\sum_u A_{7u} + \tau^{-1}] N_7$$

$$[17] \qquad k_{17}{}^t N_1 N_7 = [\sum_u A_{8u} + \tau^{-1}] N_8.$$

Using absolute values for N_1, N_6, N_7, and N_8 based on $N_1 = 0.06$ mm Hg, obtained in Part II, we calculated $k_{16}{}^t = 3.4 \times 10^{10}$ cc/mole s. The probability for vibrational transfer per collision is then

$$P_{uw}{}^t = k_{uw}{}^t / Z_{A,B},$$

where $Z_{A,B}$ is the bimolecular collision rate under the standard conditions of 1 mole/cc concentration. For $\sigma_{A,B}$ (mean collision diameter) = 3 Å, $T = 1300$ °K, $Z_{A,B} = 2 \times 10^{14}$ cc/mole s. It follows that $P_{16}{}^t = 1.7 \times 10^{-4}$. The collision efficiency, the average number of collisions per transfer, is therefore $Z_{1,6}{}^t = 5.9 \times 10^3$. Inclusion of collisional deactivation terms (vibration → translation in the collision partner) in [16] and [17], using an experimental upper limit for the deactivation probability (2), decreases $Z_{1,6}{}^t$ by a factor of about 2.5.

$Z_{1,6}{}^t \approx 6 \times 10^3$ obtained here may be compared with the value of 2.5×10^3 yielded by the theory of Schwartz, Slawsky, and Herzfeld (11, 7) for this energy discrepancy ($\Delta\nu = 1.78$ kcal or 620 cm^{-1} and temperature 1300 °K). The depth of the Lennard–Jones minimum in this calculation was, $\epsilon/k = 360$ °K (14). The orientation parameter, Z^0, was taken as 9, in conformity with Callear (11). The force constant in the exponential repulsion was $l = 0.2$ Å (11).

It is instructive to compare $Z_{1,6}{}^t$ calculated for two HCl molecules, with Z^t calculated by Callear for energy transfer between molecules BC, with atomic weights $M_B = M_C = 15$, $\epsilon/k = 90$ °K (14). For $\Delta\nu = 620$ cm^{-1}, Callear, using the Schwartz–Slawsky–Herzfeld (S.S.H.) theory, obtains $Z^t \approx 2 \times 10^6$, at $T = 300$ °K. $Z_{1,6}{}^t$ for transfer between HCl molecules calculated for this same temperature is 1.1×10^5: an order-of-magnitude fewer collisions are required for HCl–HCl vibrational transfer than for BC–BC transfer, despite the fact that the energy discrepancy is the same as in the HCl–HCl case. This apparent anomaly arises from a term $(M_B M_C / M_B{}^2 + M_C{}^2)^2$ in the S.S.H. equation for Z^t; a term which is small for $M_B \ll M_C$.

3. Variation in H-Atom Concentration

The method of measuring H-atom concentration, in the absence of chlorine, has already been described.

The experiments discussed in the two previous sections were performed at a setting of the discharge-tube primary voltage that resulted in approximately 8% dissociation of H_2, in the absence of chlorine. Spectra were also recorded at a number of H-atom concentrations equivalent to 3–17% dissociation of the incoming H_2. The effects of this

sixfold variation in percentage dissociation on total intensity, rotational temperature, and vibrational distribution were explored.

Total intensity from, and hence stationary-state population in, levels $v = 2$–6 rose to a maximum as the percentage dissociation of H_2 increased from 3 to 8%, then fell as the dissociation was further increased from 8 to 17%. These observations were made with the normal spectrometer alignment, viewing a cone in the center of the vessel. When a similar series of experiments were conducted viewing a narrower region close to the top of the vessel, the emission intensity from these same levels rose continuously as the percentage dissociation was increased from 3 to 17%. It appears that the decrease in intensity observed at the center of the vessel at the highest H-atom concentrations was merely due to an upward shift of the main reaction zone. This is in accord with the postulate of streaming flow through the vessel, with a vertical time axis.

Traces were made of the R-branch of $v(2–0)$ with normal optical alignment, over the whole range of H-atom concentrations. Rotational analysis yielded linear Boltzmann plots, with rotational temperatures rising from 590 to 2100 °K as the H-atom concentration was increased. It has already been noted that there existed a rotational-temperature gradient perpendicular to the flow axis. This gradient became steeper at higher H-atom concentrations. Apparently a greater proportion of the reaction was occurring away from the vessel walls.

The effect on vibrational distribution of reduced H-atom concentration, reduced emission intensity, and hence reduced HCl† stationary-state concentration was investigated since it was hoped by this means to decrease the effects of vibrational–vibrational transfer. The intention was to approach the conditions of the low-pressure experiments of Charters and Polanyi, with the single important difference that the low pressure of vibrators would, in the present case, be bathed in a 'high' pressure of gas (~1 mm as against $\sim 10^{-2}$ mm).

To save time in analysis, only second-overtone spectra were recorded over the full range of H-atom concentration. Figure 7 shows the results at the three lowest H-atom

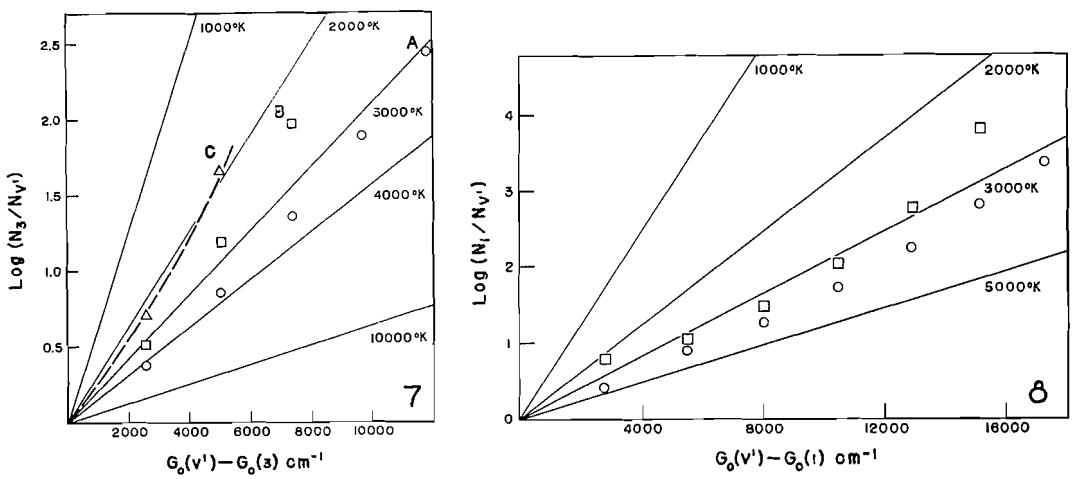

FIG. 7. Vibrational distribution in levels $v = 3, 4\ldots$: A with normal, B with 3/4 normal, and C with 1/2 normal percentage dissociation. Inflows, 1450 μmoles/s of H_2 + H, 520 μmoles/s of Cl_2. The broken curve is taken from the results of Charters and Polanyi (2) at $10^{-2}\times$ this total pressure.

FIG. 8. Vibrational distribution in levels $v = 1, 2\ldots 8$: ○ under normal experimental conditions; □ with added HCl.

concentrations used. The stationary-state distribution for the lowest H-atom concentration is very similar to that obtained in Charters and Polanyi's experiments (2).

The factors governing relative vibrational stationary-state concentrations in Charters and Polanyi's experiments were adjudged to be the rates of chemical reaction into each vibrational level, the rates of radiation into and out of each level, and the rate of removal from the vessel by pumping. These factors were almost the same in the present work (the only difference was a factor of about 2× in residence time in the vessel). Gas-phase collisional deactivation was believed to be unimportant in Charters and Polanyi's experiments, at $\sim 10^{-2}$ mm pressure. Since the low-concentration vibrational distribution in this work, curve C, agrees with Charters and Polanyi's, it would appear that collisional deactivation of the HCl vibrators is not of major importance even at ~1 mm pressure. At this total pressure the average number of collisions per vibrational radiative lifetime was $\sim 10^5$. The ambient temperature, curve C, was roughly 600 °K. A shock-tube study of pure HCl has yielded $Z_{10} \approx 1 \times 10^6$ for vibrational relaxation at this temperature (15).

4. Addition of $HCl_{v=0}$

Two fundamental spectra, $v' = 1, 2, 3$, and two second-overtone spectra, $v' = 3, 4 \ldots 8$, were recorded successively under normal conditions of hydrogen and chlorine flow (approximately 1100 μmoles/s and 450 μmoles/s respectively). In the second of the pair of experiments HCl was introduced, through the second-reagent inlet, at a flow of 600 μmoles/s.

Analysis showed that in the 'normal' spectrum the rotational temperature was ca. 1200 °K in $v = 1$, 2, and 3. (The second overtone could not be sufficiently well resolved to yield rotational temperatures). In the spectrum with added HCl the rotational temperature had dropped to 700–750 °K. This was probably due in part to a decrease in energy release per unit volume, caused by increased likelihood for the thermoneutral reaction

$$H + HCl \rightarrow H_2 + Cl$$

to carry the chain in place of the exothermic

$$H + Cl_2 \rightarrow HCl + Cl$$

reaction. In part it was due simply to the loss of rotational and translational energy from the products of reaction 1 to the room temperature HCl.

If the amount of reaction $H + Cl_2$ in the cone-of-sight decreases, a general decrease in emission intensity from all vibrationally excited states would be expected. Since some of the population observed under normal conditions in the higher vibrational levels appears to be due not to direct reaction into these levels but to vibrational–vibrational transfer, a more marked decrease in intensity and in N_v would be expected from successively higher vibrational levels.

The observed ratios of N_v' recorded in the presence of added HCl, to N_v without added HCl (both corrected for self-absorption, see Part II) were: for $v = 1$, 0.96; $v = 2$, 0.40; $v = 3$, 0.69; $v = 4$, 0.57; $v = 5$, 0.47; $v = 6$, 0.29; $v = 7$, 0.10; $v = 8$ was only detectable in the absence of added HCl. The figures conformed to the expected pattern, with the exception of $v = 2$ and $v = 1$; the decrease in population of $v = 2$ was anomolously large, *greater* than that in the next higher levels, and the decrease in population in $v = 1$ anomolously small. This anomaly can be seen clearly in Fig. 8, which shows a Boltzmann plot of vibrational populations under standard conditions, with added HCl (corrected for self-absorption). The higher vibrational states lie in an upward curve, similar to that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

observed when HCl† concentration is reduced by a small decrease in H-atom concentration. However, N_1'/N_2' is anomolously high[2] in the presence of added $HCl_{v=0}$.

The anomaly provides evidence for a vibrational energy transfer process (12)

[18] $$HCl_{v=0} + HCl_{v=2} \rightarrow 2HCl_{v=1} \qquad -0.3 \text{ kcal/mole}$$

which must proceed more rapidly than the competing vibrational energy transfer processes which involve collisions $HCl_{v=0} + HCl_{v>2}$, for which the energy match is less good. An energy transfer of this type has been postulated in connection with the relaxation of vibrationally excited NO following flash photolysis (13).

5. Energy Distribution Among $H + Cl_2$ Reaction Products

It has been shown in Section 1 of this Discussion that the rotational temperature of the HCl must reflect the translational and rotational temperature of the gas present in the reaction vessel. The maximum rotational temperature recorded, at maximum H-atom concentration, Section 3, was 2100 °K. Under normal conditions $\geqslant 90\%$ of chlorine inflow was converted to HCl; we shall suppose that 100% of the chlorine inflow was converted to HCl under conditions of maximum H-atom concentration. (This supposition received qualitative confirmation from the marked falloff in intensity from the mixing point at the top of the vessel down the flow-axis). The molar inflow rate of hydrogen in this experiment was 900 μmoles/s, that of chlorine 450 μmoles/s; this would form 450 μmoles/s of HCl by way of reaction [1] of the chain, 450 μmoles/s of HCl by way of reaction [2]. 450 μmoles of hydrogen would remain unreacted every second. Thus in the formation of each mole of HCl by reaction [1] we must 'heat up' rotationally and translationally 2 moles of HCl and 1 mole of H_2. The energy required is

$$\Delta H = C_p \Delta T = 7/2\, R\Delta T, \qquad \text{where } \Delta T = 1800 \text{ °K};$$

Therefore $\Delta H = 12.5$ kcal/mole of mixture. If the reaction $H + Cl_2$, which produces only 0.33 of the mixture $2HCl + H_2$, is to cause this amount of heating, it must produce 38 kcal/mole of HCl formed in reaction 1. In addition it must supply 1 kcal to offset the endothermicity of [2], bringing the requirement to roughly 39 kcal/mole of HCl from [1]. (We can neglect the 0.22 kcal which we calculate leaves the system by radiation, for each mole of HCl formed in [1]). This figure is to be compared with $-\Delta H$ for reaction [1], which is 45 kcal/mole.

This crude calculation indicates that the major part of the heat liberated by the reaction [1] is present as translation and rotation in our reaction vessel. In Section 3 evidence was presented which indicated that there is little collisional deactivation of vibrators in this system. If this is correct, it follows that the major part of the heat of reaction [1],

$$H + Cl_2 \rightarrow HCl + Cl,$$

is liberated *directly* as translation and rotation, not as vibration.[3]

[2] *A much smaller effect of qualitatively the same type (i.e. N_1/N_2 high) was discernible in some traces made under optimum conditions without added* HCl. *A graphical record of the data in Table I would show the effect; the 'normal' trace of Fig. 8 does not. Whether or not this small effect is detectable will depend on the ambient temperature and the relative population in $v = 0$; $N_{v=0}$ is variable independently of $N_{v>0}$ since $N_{v=0}$ is populated in part by a different reaction, the reaction* $Cl + H_2$ *that governs chain length.*

[3] *It is instructive to consider the implications of the opposite model, in which the major part of Q would go initially into vibration, forming* $HCl_{v=6}$. *Under normal flow conditions 10–20 cal/s must have entered the rotational plus translational degrees of freedom to maintain the observed temperature (see Section 1). On the model under consideration, this would require that* $\sim 2 \times 10^{20}$ *molecules of* $HCl\dagger_{v=6}$ *are transferred to $v = 0$ per second. Considering the observed stationary-state concentration of* $HCl\dagger_{v=6}$ *and the low total pressure, this transfer would only be possible if about 1 in 20 collisions were successful in deactivating $v = 6 \rightarrow v = 0$. This is roughly $10^5\times$ the efficiency to be expected on the basis of recent experimental evidence (15).*

This qualitative conclusion is of interest in view of the lack of information on this topic. Such information as exists (2) is concerned with the relative rate of reaction directly into the various accessible vibrationally-excited states of the product, without reference to the question of how the sum of these rates compares with the total rate. (The method described in Part II of this paper will, however, permit the rate into $v = 0$ to be measured in future.)

THE HYDROGEN–CHLORINE SYSTEM IN THE MM PRESSURE RANGE

II. THE VIBRATIONAL GROUND STATE STUDIED BY SELF-ABSORPTION

J. R. Airey, F. D. Findlay,[1] and J. C. Polanyi
Department of Chemistry, University of Toronto, Toronto, Ontario

Received April 27, 1964

ABSTRACT

Studies of energy distribution among reaction products, through the agency of infrared chemiluminescence, have previously only yielded information concerning the distribution among vibrationally excited states. In the work described here it was shown that self-absorption of the infrared emission could be used as a measure both of the relative and the absolute amount of product present in the vibrational ground state, $v = 0$. Two independent methods were used to measure the extent of self-absorption. The first method relied on measurements of an apparent deviation from Boltzmann-type rotational intensity distribution within the $v(1–0)$ and $v(2–1)$ bands. The second method depended on measurements of an apparent deviation of the relative intensity of corresponding $H^{35}Cl$ and $H^{37}Cl$ isotopic lines from the natural abundance ratio. (It was shown, at the same time, that the isotopic reactions $H + {}^{35}Cl_2 \rightarrow H^{35}Cl + {}^{35}Cl$ and $H + {}^{37}Cl_2 \rightarrow H^{37}Cl + {}^{37}Cl$ have the same rate constant, within $\pm 10\%$). A third method of measuring the extent of self-absorption, which depends on the detection of an anomaly in the relative intensity of *P*- and *R*-branch emission lines is discussed.

The self-absorption method was applied to the study of the hydrogen–chlorine system in the 1–2 mm Hg pressure range (see also Part I). Mean partial pressures of $HCl_{v=0} \sim 10^{-2}$ mm Hg were measured in individual rotational states to an accuracy of ca. $\pm 10\%$, using an optical path length of 20 cm. The rotational distribution in $v = 0$ corresponded to a temperature of 1150 ± 150 °K (the uncertainty in this figure encompasses two independent methods of estimating the self-absorption), as compared with 1300 ± 100 °K for all vibrationally excited states (Part I).

INTRODUCTION

In the preceding paper (Part I) an account was given of an investigation of the infrared emission arising from the hydrogen–chlorine reaction at 1–2 mm Hg total pressure. This work formed part of a wider study, conducted in this laboratory, of the infrared emission from the same reaction at 10^{-1} and 10^{-2} mm pressures.

An obvious and serious limitation of these infrared emission studies is that they fail to give information concerning the vibrational state, $v = 0$. Infrared absorption measurements would, in principle, eliminate this difficulty. With one exception, however, infrared absorption is impractical as a means of detecting very low pressures of absorbing species. The exception is the case where a sharp infrared line source is available that matches the sharp line spectrum of the absorber; under these circumstances very low pressures can be detected in absorption.

This naturally suggests the possibility of using the emitting material itself as the infrared source, that is to say, of studying the self-absorption. In the work described here a simple model for the self-absorption in this system is proposed and tested. The technique is used to measure 10^{-2} mm pressure of HCl absorber in a 20 cm path length and is capable of detecting 10^{-3} mm pressure. With the increased path lengths used in other experiments currently under way, it will be possible to measure 10^{-4} mm, and detect 10^{-5} mm, pressures of absorbing material.

THEORY

An exothermic gas-phase chain reaction giving rise to visible luminescence is commonly termed a flame. We are dealing in this work (1–2 mm reagent pressure) with a low-pressure flame which is evidenced exclusively by infrared luminescence.[2] In the interpretation of self-absorption in low-pressure flames it is commonly assumed that the 'excitation ratio', n_e/n_a, the ratio of the number of emitters to the number of absorbers in each elementary volume, is a constant throughout the volume under observation (1). The same assumption will be made here. This does not require that the emission intensity shall be constant throughout the region observed. It does require that the processes which affect the concentration of emitters and the processes which affect the concentration of absorbers shall be closely coupled.

In the present case emitters ($HCl_{v=1,2}$ are the emitters relevant to the self-absorption studies) are formed by a chemical reaction involving one set of reagents ($H + Cl_2$), whereas the absorbers are partly formed by this same reaction and partly by a reaction involving a different set of reagents ($Cl + H_2$). One of the latter reagents (Cl) is, moreover, formed only as a product of the first reaction. As long, therefore, as we are operating under conditions of combined streaming and diffusive flow, we must expect some degree of spatial separation between the regions of maximum rate for the two reactions, $H + Cl_2$ and $Cl + H_2$, with a consequent spatial variation in n_e/n_a.

We have nonetheless used the 'uniform excitation' model (constant excitation ratio) as a first approximation. The model gives reasonable figures for relative and absolute pressures of HCl in the rotational levels of $v = 0$. (For both of these quantities we have approximate values obtained by means independent of self-absorption.) This result is particularly gratifying since we are anxious to use the self-absorption technique in experiments at total pressure two orders of magnitude lower (with correspondingly increased optical path length) where the complications arising from chain reaction in conjunction with streaming and diffusive flow will be insignificant in comparison with the present work.

In addition to a spatial distribution for absorbers and emitters, the model must establish a functional dependence of the transition probability on the frequency, ω (cm^{-1}), to either side of the center, ω_0, of each line. There is little question that a Doppler line shape of half-width

$$\delta = [\ln 2(2\,kT\omega_0^2/m)]^{1/2} \qquad [1]$$

(m is the mass of the molecule) is appropriate to the temperatures and pressures encountered in the present work.

Cowan and Dieke (1) have calculated the fractional transmission for a source with uniform excitation and Doppler line shape, to be

$$\frac{I}{I_0} = \sum_{n=0}^{\infty} \frac{(-2p)^n}{(n+1)!(n+1)^{1/2}} \qquad [2]$$

Here n is an integer, and p is the 'absorption parameter' which brings together:

B, the absolute Einstein transition probability of absorption or stimulated emission for the line as a whole;

$P(\omega_0)$, the relative transition probability for absorption at ω_0 ($P(\omega)$ is normalized to unity, $\int P(\omega).\mathrm{d}\omega = 1$);

[2] *In very low-pressure studies, $\sim 10^{-2}$ mm total pressure (6) the luminescence can be characterized as 'chemiluminescence'. In the present work, as in conventional flame studies, physical processes (energy transfer) also contribute to the excitation, and hence to the subsequent luminescence.*

and $\bar{N}_a.x$, the total number of absorbers in the optical path, where $\bar{N}_a$ is the mean density of absorbers and $\bar{N}_e$ that of emitters along the optical path, and x is the optical path length.

[3] $$p = h\omega_0 P(\omega_0)(B_a\bar{N}_a - B_e\bar{N}_e)x.$$

Since the line shape is known, $P(\omega_0)$ in [3] can be expressed in terms of the half-width (1)

[4] $$P(\omega_0) = \left[\frac{\ln 2}{\pi\delta^2}\right]^{1/2}.$$

Introducing [1],

[5] $$P(\omega_0) = \frac{1}{\omega_0}\left[\frac{m}{2\pi kT}\right]^{1/2}.$$

Substituting into [3],

[6] $$p = h(B_a\bar{N}_a - B_e\bar{N}_e)\left[\frac{m}{2\pi kT}\right]^{1/2}x.$$

Introducing quantum numbers appropriate to the present case, and recognizing that $B_a/B_e = (2J' + 1)/(2J + 1)$,

[7] $$p_{vJ}^{v'J'} = h(B_{vJ}^{v'J'})_a(2J + 1)\left(\frac{\bar{N}_{vJ}}{2J + 1} - \frac{\bar{N}_{v'J'}}{2J' + 1}\right)x\left[\frac{m}{2\pi kT}\right]^{1/2}.$$

Since (3)

[8] $$\left(B_{vJ}^{v'J'}\right)_a = \frac{8\pi^3}{3h^2}\frac{|R_v^{v'}|^2.S_J.F_{vJ}^{v'J'}}{(2J + 1)},$$

therefore

[9] $$\frac{\bar{N}_{vJ}}{(2J + 1)} - \frac{\bar{N}_{v'J'}}{(2J' + 1)} = \frac{3hp_{vJ}^{v'J'}}{8\pi^3 x}\frac{1}{|R_v^{v'}|^2.S_J.F_{vJ}^{v'J'}}.\left[\frac{2\pi kT}{m}\right]^{1/2}.$$

To calculate $\bar{N}_{vJ} - \bar{N}_{v'J'}$ from the observed fractional transmission, I/I_0, the right-hand side of [2] was summed for trial values of p, the best value of p being chosen and inserted into [9]. A sum of the form required for [2] has been tabulated by Ladenburg and Levy (2).

RESULTS AND DISCUSSION

In all the experiments reported here, the apparatus and materials were identical to those described in Part I.

Three methods for the estimation of the fractional transmission, I/I_0, will be discussed. They are based on three types of abnormality which may appear in vibrational–rotational bands subjected to self-absorption.

1. Anomalous Rotational Distribution

In Part I there was noted an apparent deviation of the rotational distribution in the low rotational states of $v = 1$, from a Boltzmann-type distribution (see Fig. 5 of Part I, recorded under normal flow conditions). This deviation was of a sort that would imply an underpopulation of the low rotational states in $v = 1$. Significantly this apparent underpopulation of $v = 1$ was most marked for those transitions within the v(1–0) band, that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

terminated in the most highly populated rotational levels of $v = 0$. It seemed probable that this anomaly could be accounted for by self-absorption.

Qualitative support for this view came from experiments in which these lines were traced with and without a plane mirror behind the reaction vessel: the gain in intensity which resulted from the presence of the mirror was found to be consistently less for the low rotational lines of $v(1–0)$ than for lines in $v(2–0)$. The $v(2–0)$ band did not show evidence of the low-J anomaly (see Fig. 6 in Part I). All these findings are consistent with the postulate of self-absorption in $v(1–0)$, no self-absorption in $v(2–0)$ (in this frequency range the intrinsic probability of first-overtone absorption, $v(2 \leftarrow 0)$ is two orders of magnitude less than for fundamental absorption, $v(1 \leftarrow 0)$).

Additional confirmation came from experiments with added HCl. Fig. 1 of this paper shows the apparent rotational distribution of HCl in level $v = 1$ when HCl is injected through the second-reagent inlet with a flow-rate comparable to that of $H_2 + H$ and of Cl_2 (see caption). The uncorrected $v = 1$ points show a systematic deviation from the linear plot characteristic of a Boltzmann distribution. No such deviation is detectable in the $v = 2$ and 3 points; the lines passing through these points have slopes corresponding to rotational temperatures of 700 °K and 750 °K. A line joining the points of highest J in $v = 1$ has a slope corresponding to 760 °K. The fact that this rotational temperature agrees quite well with the rotational temperatures from the higher vibrational states is an indication that this is the true slope of the $v = 1$ plot, since there is good reason to suppose that the rotational temperature in every vibrational state is the same (see Part I). The line passes through the points of high J since these spectral lines terminate in J levels of $v = 0$ with negligible population. On this view I/I_0 for the self-absorbed lines of $v = 1$, can be obtained from Fig. 1 by taking the difference in height between an 'unabsorbed' intensity (corresponding to a point on the line) and the self-absorbed value.

This has been done for the small anomaly in the $v = 1$ curve recorded under normal flow conditions, without added HCl (Fig. 5 of Part I), since these are the conditions of greatest interest. The best line of slope corresponding to 1300 °K (mean rotational

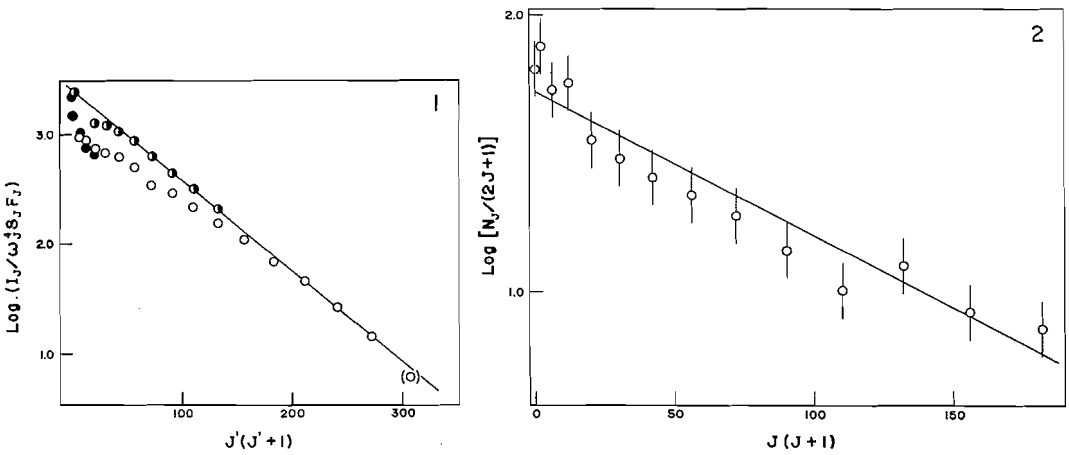

FIG. 1. Apparent rotational distribution of HCl among levels $v = 1$, taken from a fundamental spectrum with normal hydrogen and chlorine flows (1100 μmoles per sec and 450 μmoles per sec, respectively) with, in addition, 600 μmoles per sec of HCl entering through the second-reagent inlet. For personal use only.

temperature in the higher vibrational states) was drawn through points of high J. The anomaly is detectable up to $J' = 14$ of the R-branch; that is to say, the self-absorption is appreciable up to $J = 13$. I/I_0 for each of these Js was converted into a value for N_J in $v = 0$. The anomaly in rotational distribution being very small, these $\bar{N}_J$ s are very approximate. However, they are sufficiently accurate to have some meaning, as evidenced by Fig. 2 of this paper, in which they are seen to conform to an approximately Boltzmann-like distribution for $v = 0$.

2. Anomalous Isotopic Ratios

The abundance ratio of $^{35}Cl_2$:$^{37}Cl_2$ in natural chlorine is 3.065:1. Provided that the H + Cl_2 reactions, which produces vibrationally-excited HCl, proceeds with the same rate whatever the isotope of chlorine, the relative stationary-state concentration of $H^{35}Cl$:$H^{37}Cl$ should also be 3.065:1. (Radiation, collisional deactivation, and flow are other processes which could in principle disturb this ratio of concentrations; in practice they are insufficiently selective to be significant here.) The expected intensity ratio I_{35}/I_{37} is very close to N_{35}/N_{37}, being given by

$$\frac{[I_{vJ}^{v'J'}]_{35}}{[I_{vJ}^{v'J'}]_{37}} = \frac{[N_{v'J'}\omega_{vJ}^{v'J'}|R_v^{v'}|^2 F_{vJ}^{v'J'}]_{35}}{[N_{v'J'}\omega_{vJ}^{v'J'}|R_v^{v'}|^2 F_{vJ}^{v'J'}]_{37}} \approx 1.004 \frac{[N_{v'J'}]_{35}}{[N_{v'J'}]_{37}}.$$

Twelve lines of the $v(2\text{–}0)$ and $v(3\text{–}1)$ overtone bands were recorded at 0.1 mm spectrometer slit width and slow tracing speed. Resolution of the isotopic lines was comparable to that shown in Fig. 3. The ratios I_{35}/I_{37} were found to fluctuate in a random fashion

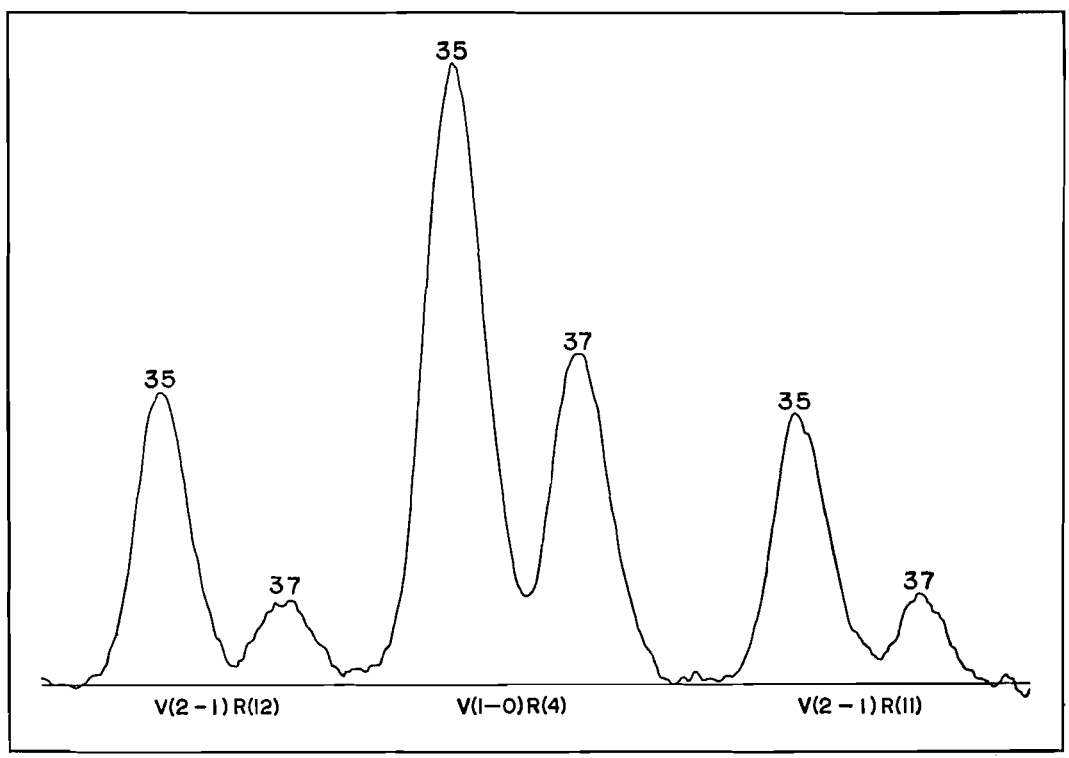

FIG. 3. Resolved isotopic lines in $v(1\text{–}0)$ and $v(2\text{–}1)$ of the fundamental. Actual trace recorded at 0.1 mm spectrometer slit width. The symbol $R(12)$ identifies an R-branch emission line terminating in $J = 12$.

For personal use only.

in the range 3.02 ± 0.30. We conclude that the rate constants for the isotopic reactions

$$H + {}^{35}Cl_2 \rightarrow H^{35}Cl + {}^{35}Cl$$

and

$$H + {}^{37}Cl_2 \rightarrow H^{37}Cl + {}^{37}Cl$$

are the same, to within $\pm 10\%$.

Isotopic intensity ratios were recorded for six R-branch lines of $v(1\text{–}0)$ and three R-branch lines of $v(2\text{–}1)$, chosen for the fact that they were free from overlap by any other lines. Some of these lines are shown in Fig. 3. All are listed in Table I. It is apparent that

TABLE I

Partial pressures of HCl in some rotational levels of $v = 0$ and $v = 1$, as calculated from isotopic ratio data

Line	I_{35}/I_{37}	P_{37}	$[HCl]_{vJ}$ (mm Hg)
			$v = 0$
$v(1\text{–}0)$ $R(1)$*	2.37	0.211	0.017
" $R(4)$	1.86	0.535	0.060
" $R(10)$	2.36_5	0.214	0.035
" $R(11)$	2.56_5	0.140	0.025
" $R(12)$	2.74	0.086	0.016
" $R(13)$	2.80	0.069	0.013
			$v = 1$
$v(2\text{–}1)$ $R(5)$	2.80	0.069	0.0044
" $R(7)$	2.76	0.080	0.0058
" $R(8)$	2.84	0.058	0.0044

*$R(1)$ is the R-branch emission line terminating in $J = 1$.

for these lines the isotopic intensity ratio is significantly less than the theoretical ratio of 3.08. This we ascribe to self-absorption; the more abundant species being more self-absorbed than the less abundant, the intensity ratio I_{35}/I_{37} is reduced. In the language of the previous section we would say that the fractional transmission for $H^{35}Cl$ emission, I_{35}/I_{35_0}, is less than I_{37}/I_{37_0}, owing to the fact that the absorption parameter p_{35} is greater than p_{37}. To a good approximation $p_{35}/p_{37} = 2.98$. Representing the right-hand side of [2] as $f(2p)$ we have,

$$[10] \qquad \frac{I_{35}/I_{35_0}}{I_{37}/I_{37_0}} = \frac{f(5.96\, p_{37})}{f(2p_{37})}$$

$$[11] \qquad \frac{I_{35}}{I_{37}} = g(p_{37})$$

The function g includes a multiple, $I_{35_0}/I_{37_0} = 3.08$. I_{35}/I_{37} is the observed isotopic intensity ratio. Equation [11] was solved for a number of trial values of p_{37}, and the best value was chosen by interpolation (Table I). By equation [9], p_{37} yields $\bar{N}_{37}$; $\bar{N}_{37} + 3.065\, \bar{N}_{37} = \bar{N}_{vJ}$, which is listed as a partial pressure, $[HCl]_{vJ}$ mm Hg, in Table I. Figure 4 presents the derived populations in $v = 0$ and $v = 1$ in the form of Boltzmann plots.

The calculation from distorted isotopic ratios is more dependable than that from distortion in the Boltzmann plot, since it avoids the necessity for the advance assignment of a rotational temperature to the upper state of the transition and also the necessity of designating certain lines as 'unabsorbed'. (This designation is further complicated by the fact that at the highest J-numbers there is a second region of deviation from Boltzmann

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

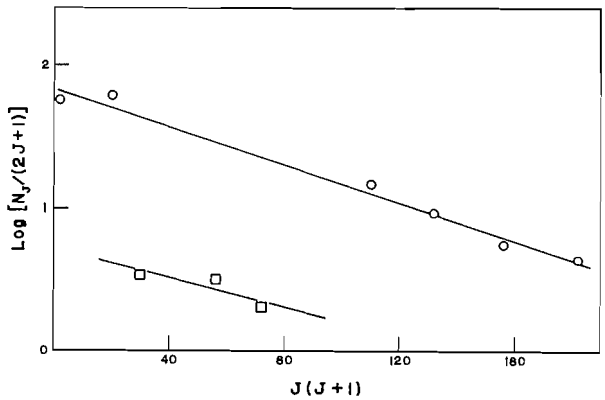

FIG. 4. Rotational distribution in $v = 0$, ○, and v = 1, □, calculated from the apparent deviation of the v (1–0) and v(2–1) isotopic ratios from the natural ratio. $T_{ROT} \approx 1000 \pm 100$ °K for $v = 0$; 1200 ± 200 °K for $v = 1$.

distribution—see Part I.) The method based on distortion of the Boltzmann distribution has, on the other hand, the advantage of versatility; it can be applied in cases where isotopic lines cannot be resolved, or are absent. (It would, however, be possible in such a case to add a known proportion of isotope, or other reagent whose competing reaction rate could be measured and which gave rise to product for which the constants of [9] were known.)

Strongly self-absorbed lines recorded in the presence of added HCl (Fig. 1) provided the best check on the degree of equivalence between methods 1 and 2. Pairs of isotopic lines were analyzed to yield I/I_0 for particular transitions, and this ratio was applied as a correction to the points in Fig. 1; the corrected points are seen to lie close to the line that describes the true Boltzmann curve, underlying method 1.

The rotational temperature of 1200 ± 200 °K for $v = 1$, calculated from v(2–1) self-absorption, is in fair agreement with the temperature of the 'heat bath' (translation + rotation) which is believed to be at 1300 ± 100 °K (Part I). The rotational temperature of 1000 ± 100 °K obtained by the isotopic-ratio method for $v = 0$ is somewhat lower than the temperature of the heat bath. This discrepancy could be caused by the fact that a greater proportion of $HCl_{v=0}$ than $HCl_{v>0}$ lies close to the vessel walls, in the path of the emitted radiation. (It may be permissible to draw this qualitative conclusion, even though the model used here is no longer strictly applicable once this complicating effect becomes significant.)

The partial pressures in the rotational states of $v = 0$ and $v = 1$ (Table I) were summed with the aid of the Boltzmann curves of Fig. 4 to give a pressure of 0.48 mm Hg for $v = 0$, 0.06 mm Hg for $v = 1$; $N_0/N_1 = 8.0$. This partial pressure of HCl (in all levels v) corresponds to about 80% conversion of Cl_2 to HCl. Since from an analysis of the products (Part I) we know that conversion is $\geqslant 90\%$, this is a reasonable result.

The absolute pressure of $HCl_{v=1}$, 6×10^{-2} mm, can be compared with an estimated pressure of roughly 10^{-3} mm $HCl_{v=1}$, based on absolute intensity measurements (4, 5) made under conditions of hydrogen and chlorine flow which would be expected to yield 10^{-1} to 10^{-2} times the intensity, i.e. 10^{-1} to 10^{-2} times the mean pressure of vibrationally excited HCl in the cone-of-sight (see Part I). In the light of this earlier estimate, the figure of 6×10^{-2} mm for $HCl_{v=1}$ appears reasonable.

3. Anomalous Intensity Ratio, I_P/I_R

A molecule in any upper state, $v'J'$, has a known relative probability of transfer by a P-branch transition to v, $J = J' + 1$, or by R-branch transition to v, $J = J' - 1$:

$$\frac{I_P}{I_R} = \frac{[(\omega_{vJ}^{v'J'})^4 . S_J . F_{vJ}^{v'J'}]_P}{[(\omega_{vJ}^{v'J'})^4 . S_J . F_{vJ}^{v'J'}]_R}$$

In the $v(1\text{–}0)$ band of HCl this ratio is 2.0 for $J' = 1$ decreasing to 1.2 for $J' = 5$. The effect of self-absorption will parallel that described under Section 2 above; there will be a reduction in I_P/I_R, since the P-branch emission will be more self-absorbed than the R. From the extent of the reduction in I_P/I_R, provided the rotational temperature in the lower vibrational level is known, it would be possible to calculate the absorption parameter for P (or for R) and hence the absolute concentration $\bar{N}_{vJ}$ for the appropriate lower state.

However, the closer I_P/I_R, before self-absorption, is to unity, the smaller will be the distortion in this ratio for any given value of $B_a\bar{N}_a . x$ (more precisely, $(B_a\bar{N}_a - B_e\bar{N}_e)x$). For HCl the effect is small and has not, until now, been detected with any degree of certainty.

ORGANIC COMPLEXES OF URANIUM

PART I. THE SYNTHESIS AND SPECTRUM OF URANYL PHTHALOCYANINE

J. E. BLOOR,[1] J. SCHLABITZ, C. C. WALDEN, AND (IN PART) A. DEMERDACHE
British Columbia Research Council, Vancouver, British Columbia

Received March 13, 1964

ABSTRACT

The preparation of uranyl phthalocyanine from uranyl chloride and dilithium phthalocyanine is described. The infrared and electronic spectra of the complex are quite different from that previously reported for uranyl phthalocyanine and it is suggested that previous workers obtained mainly a mixture of phthalocyanine (PcH_2) and inorganic uranyl compounds. The infrared spectra of α- and β-PcH_2, β-PcCu, $PcLi_2$, and $PcUO_2$ from 4000 to 300 cm^{-1}; the far infrared spectra of β-PcH_2, β-PcCu, and $PcUO_2$ from 300 to 100 cm^{-1}; and the electronic spectrum from 3500 to 10 000 Å of $PcUO_2$ in 1-chloronaphthalene are recorded. A tentative assignment of a band at 278 cm^{-1} to the O—U—O bending frequency is made. The electronic spectrum of $PcUO_2$ differs from previous spectra of metal phthalocyanines in that it possesses no strong absorption in the 6000–7000 Å region. It does, however, have a strong band at 9145 Å, $\epsilon = 4.15 \times 10^4$.

INTRODUCTION

Although many metal porphyrins have been prepared (1) no record of a uranyl phthalocyanine could be found when this work was started (2). The properties of such a compound might be expected to provide information about the structure of the uranyl group and, because the U—O bonds are very sensitive to their environment (3), a study of their spectra may provide information about the interaction of uranium with the porphyrin ring. Recently, two reports of the synthesis of uranyl phthalocyanine have appeared (4, 5). Since, however, we have been unable to prepare uranyl phthalocyanine by either of the two methods previously described* (4, 5) and since the spectroscopic properties of our compound differ considerably from those reported by others (5, 6) we report here our work in some detail, together with a discussion of the previous work.

EXPERIMENTAL

Preparation of Uranyl Phthalocyanine

Anhydrous uranyl chloride (1.51 g) was added to dried dimethyl formamide (2 ml) and the mixture heated until the uranyl chloride had dissolved. To the hot solution, phthalonitrile (1.16 g) was added and the solution refluxed under nitrogen for 30 min. The dark solution then turned green and precipitation of a dark green solid occurred. The mixture was allowed to cool to room temperature and ethanol (30 ml) added. The precipitate was filtered off and washed with ethanol. The precipitate was a mixture of reddish crystals of phthalocyanine, deep blue–black feather-like crystals of uranyl phthalocyanine, and inorganic and organic by-products, total dry weight 0.676 g. Purification of the uranyl phthalocyanine was achieved by extracting the precipitate with 1,2,4-trichlorobenzene until the extracting solution turned from deep green to light blue. The trichlorobenzene was reduced in bulk to 2 ml by distillation. The uranyl phthalocyanine recrystallized as bluish green leaflets (yield 0.21 g) (11.6% theoretical on phthalonitrile). Further purification was carried out by vacuum sublimation below 0.01 mm pressure at 400–450 °C. Anal. Calc. for $C_{32}H_{16}N_8O_2U$: C, 49.11; H, 2.06; U, 30.42. Found: C, 49.6; H, 2.07; U, 28.3.

**Dr. Frigerio in private communication has informed us that to prepare uranyl phthalocyanine from uranyl nitrate dimethyl formamide complex and dilithium phthalocyanine in dimethyl formamide (DMF) solvent extreme precautions must be taken to remove the last traces of water from the solvent by repeated fractional distillation. In our attempts to prepare $PcUO_2$ by this method we dried our DMF over Linde's 5A molecular sieve and distilled until our gas chromatograph failed to detect water (less than 50 p.p.m.).*

INFRARED SPECTRA

(a) Phthalocyanine and Metal Phthalocyanines

The infrared spectra of the α- and β-polymorphic forms of the parent phthalocyanine (9) and many of their metal derivatives have previously been recorded between 4000 cm^{-1} and 400 cm^{-1} (8, and references cited therein, 9). In the extensive study of Sidorov and Kotlyar the spectra were measured on samples deposited directly on sodium chloride or potassium bromide plates. Our spectra (Fig. 1 and Table I) were recorded on a Perkin–

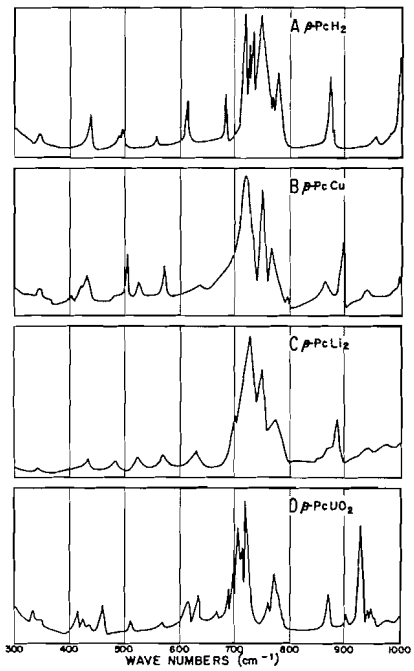

FIG. 1. Infrared spectra (Nujol mulls) of: A, β-phthalocyanine; B, β-copper phthalocyanine; C, lithium phthalocyanine; D, uranyl phthalocyanine.

Elmer 521 infrared spectrophotometer from 4000 cm^{-1} to 300 cm^{-1} using finely ground mulls of the relevant phthalocyanines. Comparison of our spectra of phthalocyanine and that in (9) shows only minor differences between the two spectra on changing from a thin film to a dispersed sample. The chief changes were in the relative intensities of different bands. We have therefore adopted the numbering system of (9) in Table I. We have also used an additional letter subscript, to introduce bands not numbered in the Table I of (9) although most are evident in the actual spectra (Fig. 2 of (9)). Our phthalocyanine (β-PcH_2) spectra differ from (9) mainly in: the resolution of band 32 into two quite sharp bands at 1615 and 1605 cm^{-1}; the presence of a band at 1530 cm^{-1}, which is present in the curve given in (9); the presence of a shoulder corresponding to band 19 in the metal derivatives at 1112 cm^{-1}; and the presence of weak bands at 1040 cm^{-1} and 480 cm^{-1}, probably due to the extra resolution of our grating instrument. We have also found a band at 340 cm^{-1} beyond the range of the spectrophotometer used in (9).

The spectra of the copper and magnesium phthalocyanine, PcCu and PcMg, are also very similar to those reported in (9). We do however find extra bands at 1312 cm^{-1} and

532 cm^{-1} in PcCu. We have labelled the first one as corresponding to band 25 although this is not listed in (9) as appearing in any of the other PcM spectra. The second one at 532 cm^{-1}, if not due to contamination, is probably due to one of the Cu—N vibrations which might be expected in this region (10). In the PcMg we find a new band at 1134 cm^{-1} not recorded in (9) and which appears to come from a splitting of band 20*b*. The spectrum of the dilithium phthalocyanine was not recorded in (9) and is reported here for the first

For personal use only.

time. It is very similar to the other phthalocyanines except for an extra band at 1635 cm^{-1}.

The metal phthalocyanine spectra are in general very similar to those of the parent. The main differences are:

1. The disappearance on metal formation of the weak band at 3280 cm^{-1}, which is probably due to the N—H frequency (11). Our result and that given in (9) differ from those given by Frigerio (12) and Tyler and Ehrhardt (13) for PcCu. These workers report a band in the 3200 cm^{-1} region for PcCu and in (12) it is stated that the deuterated phthalocyanine also has a band at 3298 cm^{-1} but no N—D band in the 2000–2500 cm^{-1} region. This result differs from that reported in (9) where they report an N—D frequency at 2456 cm^{-1} for the (D_2) compound and at 2467 cm^{-1} for the mono deuterated (DH) compound. The Russian workers also claim to find the other expected changes on deuteration, whereas Frigerio (12) found no other changes. We are at the present time unable to explain these differences in experimental findings, therefore our assignment of the frequency at 3280 cm^{-1} to an N—H vibration must be regarded as tentative.

2. The spectra of the parent and the metal derivatives differ in that the 1250 cm^{-1} and 1321 cm^{-1} bands, 23*b* and 25, appear to be missing in the metal complexes except for the band found by us in PcCu.

3. A quite strong band 17*b* is found in the metal complexes in the 1060–1080 cm^{-1} region. It could however correspond to a weak one found by us in the parent. The strong band 16 appearing at 1002 cm^{-1} in the parent becomes either extremely weak or vanishes altogether in the metal complexes.

4. The major change in the infrared spectrum on substituting a metal into the phthalocyanine ring occurs in the 700–800 cm^{-1} region. In the β-PcH_2 this region has six clearly defined bands. These are reduced to three in all the metal phthalocyanines discussed in (9) and in the dilithium compound. Between 700–300 cm^{-1} little change occurs on metal formation although the frequency, at which band 2*b* appears, seems sensitive to the nature of the metal.

(b) Uranyl Phthalocyanine

The main evidence cited in (6) for the successful preparation of a uranyl phthalocyanine is the infrared spectrum of the sample. The spectra reported in (9) were taken as a standard in (6) although the spectra compared were not measured under the same conditions. If however we compare the spectrum reported in (6) with those of α-PcH_2 and β-PcH_2 measured under comparable conditions, i.e. in Nujol mulls, we find that most of the bands attributed to metal complex formation can be related, with some confidence, to bands in the parent phthalocyanine. This is demonstrated by comparison of the spectral data assembled in Table I. Our data for α- and β-PcH_2 are in columns 2 and 9 respectively and for the metal phthalocyanines in columns 3 to 6 inclusive. Data for the $PcUO_2$ reported by Lyalin and Kobyshev (6) are in column 7 and for α-PcH_2 (9) in column 8. Thus, for example, the band at 1530 cm^{-1} is found in the parent phthalocyanines. The fairly strong band at 1006 cm^{-1} reported by Lyalin for $PcUO_2$ clearly corresponds to band 16 observed in the parent molecules at 1002 cm^{-1} and found to be absent or extremely weak in other metal phthalocyanines. The very weak shoulders reported in (6) at 1055 and 1068 cm^{-1} can be related to weak bands observed in the parent phthalocyanine at 1040 cm^{-1} and 1070 cm^{-1}. The bands at 1095, 1120, and 1158 cm^{-1} reported in (6) can be related to bands 18, 20*b*, and 21 of the parent respectively. Between 700 cm^{-1} and 800 cm^{-1} the spectrum reported in (6) is most unusual since it has only one main peak at 732 cm^{-1} corresponding to band 6. If however we assume that either the resolution was poor in this region, or the sample

For personal use only.

was not sufficiently well mulled to produce sharp bands,* we can match the shoulders to the peaks found in our spectrum of α-PcH_2. The remaining two bands are at 868 cm^{-1} and 920 cm^{-1}. The former can be related to band 11 or 12† whereas the latter is almost certainly due to the uranyl group. In the examination of 20 uranyl–organic complexes we have found in every case that the strong band in the 900–950 cm^{-1} region which is due to the O—U—O assymetric stretch is always extremely sharp. On the occasions where we have observed a broad band in this region similar to that shown in (6), we have always been able to trace it to a uranyl inorganic impurity. In particular in our early attempts to prepare uranyl phthalocyanine from phthalic anhydride and urea, we often obtained a blue solid giving a spectrum similar to that given in Fig. 1 of (6). On solvent extraction of the reaction product we isolated an inorganic insoluble residue and α-PcH_2.

From the above discussion of the properties of the substance reported in (6) we must conclude that it consists largely of unchanged α-phthalocyanine contaminated by inorganic uranyl substances.

Applying the method of preparation described in the experimental section we obtained a greenish-blue solid with a very different spectra from that reported in (6). This spectrum is compared with that of β-PcH_2 in Fig. 1 for the region 1000–300 cm^{-1}. All the observed bands from 4000–300 cm^{-1} are listed in Table I, column 6. No band could be found in the 3300 cm^{-1} region. Between 1650 and 1000 cm^{-1} the spectrum is very much like that of other metal phthalocyanines except that there was no trace of the weak band 19, and band 16 was about as strong as in the parent phthalocyanine but shifted from 1002 cm^{-1} to 1020 cm^{-1}. In the 800–700 cm^{-1} region the spectrum was more complicated than in other metal phthalocyanines but corresponded quite well to that of the parent with irregular shifts to lower frequencies of the order of 30 cm^{-1} for the six bands of the parent in this region. Below 700 cm^{-1} the uranyl phthalocyanine differs considerably from the parent phthalocyanine and other metal phthalocyanines. Thus band 1 appears as two bands, either of which could correspond to U—N stretching frequencies which are expected in this region.

In the 900–950 cm^{-1} region the very strong sharp peak which experience has led us to associate with organic uranyl chelates appears at 930 cm^{-1} together with a band of much lower intensity at 900 cm^{-1} which we have also found in many uranyl compounds. No trace of the O—U—O symmetric stretching frequency often assigned in the 800–900 cm^{-1} region could be found. This can be regarded as evidence that the UO_2 group is linear in $PcUO_2$ with very little distortion.

Thus we have prepared a compound possessing an infrared spectra considerably different from either the parent phthalocyanines or that of other metal phthalocyanines and which possesses the characteristics expected of a uranyl complex. That the phthalocyanine ring is present in the compound is clearly shown by the fact that on stirring the uranyl compound in concentrated sulphuric acid for 1 h at −4 °C, precipitating, and drying, we obtained a compound which gave an infrared spectrum identical with that of α-phthalocyanine (Table I, column 9).

FAR INFRARED SPECTRA (with A. Demerdache)

Metal–ligand stretching and bending frequencies are usually assumed to be low frequencies and very few, especially those below 300 cm^{-1}, have been assigned (14). In an

We occasionally experienced this phenomenon but achieved considerable sharpening on increasing the mulling time. Spectra measured in KBr *pellets also gave ill-defined spectra.*

†*There appears to be no justification for allotting two numbers 11 and 12 to the band appearing in this region, as in no compound studied in (9) do both occur simultaneously.*

attempt to identify the O—U—O bending frequency and possibly the frequencies due to the uranium–nitrogen bands we have recorded the infrared spectrum between polyethylene plates of finely ground Nujol mulls of β-PcH_2, β-PcCu, and $PcUO_2$ between 300 cm^{-1} and 100 cm^{-1}, using a Perkin–Elmer 301 instrument. The spectra, which are the first to be taken in this region for phthalocyanines, are given in Fig. 2 and tabulated in Table II.

‡The 280 cm^{-1} band is probably hidden by the UO_2 bending frequency.

The suggested correspondencies in this table are purely speculative. The only assignment we can make with any degree of certainty is to assign the band observed in uranyl phthalocyanine at 278 cm^{-1} to the O—U—O bending frequency.

The only previous direct observation of this bending frequency appears to be by Raman measurements of aqueous solutions of uranyl compounds where a band at 210 cm^{-1} was found, although the bending frequency should be Raman inactive (15, 16). In a study of the

far infrared of a number of inorganic and organic uranyl compounds we have always found a band in the 240–280 cm^{-1} region, but only rarely have we found a weak band in the 200–220 cm^{-1} region. Frequencies in the higher range have also been previously found in the vibrational fine structure of the electronic emission spectra of uranyl compounds (17, 18). We prefer therefore to assign the O—U—O bending frequency to the 240–280 cm^{-1} region since this bending frequency should be active only in the infrared and should not be observed by Raman measurements. The 210 cm^{-1} frequency may be due to either a lattice vibration (19) or to a splitting of the degenerate bending frequency of the linear UO_2 group by crystal field perturbations of the environment of the uranyl group.

ELECTRONIC SPECTRA

The electronic absorption spectrum of our $PcUO_2$ was measured in 1-chloronaphthalene solvent from 3500 Å to 11 000 Å, the result is shown in Fig. 3. The outstanding features

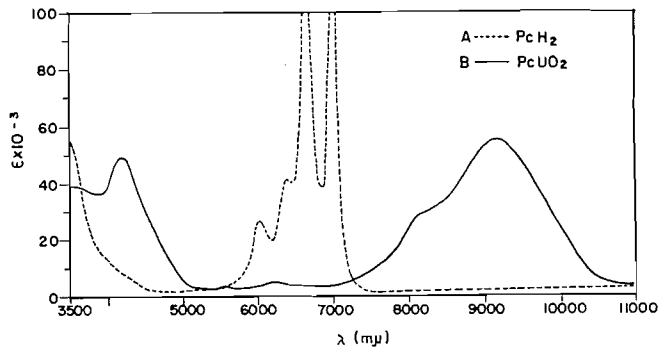

FIG. 3. Electronic spectra in 1-chloronaphthalene of: A, phthalocyanine - - - - and B, uranyl phthalocyanine ———.

of this spectrum are the absence of any strong bands in the 6000–7000 Å region and the presence of a strong band at 9145 Å ($\epsilon = 4.15 \times 10^4$) with a shoulder at 8100 Å. The spectra of many metal phthalocyanines and metal porphyrins have been recorded (20, and references cited therein, 21) and in no other case has it been found that there were no strong bands in the 6000–7000 Å. The only other example of a phthalocyanine with bands in the near infrared is that of manganese phthalocyanine (II) (22) which in pyridine solution has bands at 8800 Å and 8350 Å. The nature of the transitions responsible for these absorption bands is at the present a matter only of conjecture. In both cases the near infrared bands are unlikely to be due to localized transitions confined to the metal atoms. The intensity is too high and the frequency too low. Also we have not been able to observe such bands in other uranyl complexes, e.g. in UO_2 complexes of β-diketones and hydroxyarylazo compounds (23). We have also been unable to find any near infrared bands in either PcH_2 or PcCu. One must conclude therefore that the near infrared absorption bands in the Mn (II) and the UO_2 phthalocyanines must be due to interactions between the metal atomic orbitals and molecular orbitals of the Pc ring. In the former case the band is probably a charge transfer band in which in the ground state there is very little mixing of the Pc and manganese molecular orbitals. In the case of the uranyl phthalocyanine the considerable difference between the electronic spectra of the metal complex and the PcH_2 parent indicate considerable interaction between the UO_2 and Pc molecular orbitals. Since the absence of any band in the infrared spectra which can be assigned to the

For personal use only.

symmetric stretching frequency of the UO_2 group implies that the UO_2 group has kept its linearity in the phthalocyanine, we can either consider $PcUO_2$ to be either an example of very strong perpendicular conjugation (24) of the oxygen atoms, with the Pc ring through the uranium, or a case of unusually strong interaction of the uranium atomic orbitals with the Pc ring. Both the asymmetric stretching frequency at 930 cm^{-1} and the bending frequency at 278 cm^{-1} are quite normal for uranyl chelates such as uranyl acetylacetonate and therefore do not support the first hypothesis that considerable ground state interaction exists between the oxygens and the Pc ring. The Pc ring is apparently still intact since on removing the UO_2 group with acid the resulting compound possesses the visible spectra characteristic of the parent phthalocyanine. The general problem of the nature of the bonding of the UO_2 group with organic ligands will be discussed in more detail elsewhere after we have reported the results (23) of our studies on other uranyl organic compounds.

ACKNOWLEDGMENTS

We wish to acknowledge gratefully the financial support of the Canadian Uranium Research Foundation, under whose auspices this work was undertaken. We wish to thank Dr. R. H. Wright for kind permission to measure far infrared spectra on the Perkin–Elmer 301 spectrophotometer (purchased under Contract No. DA-49-193-MD-2391 with the U.S. Army Medical R & D Commission).

MEASUREMENT OF ELECTRON SPIN RESONANCE DIFFERENCE SPECTRA AT 77 °K

APPLICATIONS OF THE METHOD IN LOW-TEMPERATURE RADIATION CHEMISTRY[1]

D. R. SMITH AND J. J. PIERONI

Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario

Received May 29, 1964

ABSTRACT

The technique of measuring e.s.r. difference spectra has been extended to 77 °K. This enables elimination of the main signal due to irradiated silica sample tubes and of about 90% of the hydrogen atom signal from the same source. Under certain conditions, e.g. when the e.s.r. spectrum due to one species can be photochemically bleached, the method permits resolution of two superimposed spectra. This has been demonstrated by measurements which resolve the e.s.r. singlet due to trapped electrons in irradiated tetrahydro-2-methylfuran from the underlying septet. These developments have rendered the e.s.r. difference method very useful for the study of paramagnetic species formed in systems which have been γ-irradiated at 77 °K.

INTRODUCTION

Smith and Wilmshurst (1) have reported a method whereby, using a TE_{103} cavity containing two samples at room temperature, the difference between their electron spin resonance (e.s.r.) spectra was automatically obtained as the spectrometer output to a strip-chart recorder. The basis of the method is that the magnetic field modulation at one sample position be of equal frequency and amplitude but independent of, and 180° out of phase with respect to, the field modulation at the other sample position. The two samples (of identical dimensions) should be at equivalent positions (i.e. at antinodes) in the cavity and they should be subjected to identical d-c. magnetic fields.

We have extended the method by using a TE_{104} X-band cavity, Varian Associates dual cavity accessory (2), containing two Varian Associates liquid nitrogen dewars. A Varian 12 in. electromagnet enables both sample positions to be subjected to the same d-c. magnetic field without difficulty. This enables the e.s.r. difference spectrum of two samples at 77 °K to be obtained. Our modification of the method renders it useful to low-temperature radiation-chemical studies because it permits elimination of the e.s.r. signal due to irradiated silica sample tubes, it permits 90% elimination of the hydrogen atom signal due to adsorbed water in irradiated sample tubes, and in special cases it enables resolution of superimposed e.s.r. spectra due to irradiated samples. These applications and some results to illustrate them are discussed below.

EXPERIMENTAL

(a) The Electron Spin Resonance Difference Spectrum Technique

A Varian V-4502-04 X-band e.s.r. spectrometer with dual cavity and two liquid nitrogen dewar accessories was used. A field modulation of 100 kc/s was used, and it was first passed through a switch box so that the field could be modulated at either sample position separately or at both sample positions simultaneously, but 180° out of phase. First derivative spectra ($d\chi''H_1/dH$ vs. H) are shown in the figures.

Pairs of Spectrosil (British Thermal Syndicate) sample tubes, 0.100 in. I.D., whose I.D. and O.D. were equal within less than ± 0.00025 in. over the vertical dimension of the cavity were used. This accurate matching of the sample tubes reduces the difference (from this source of error) in the total number of unpaired spins in each tube to $\pm 0.5\%$.

[1]*Issued as AECL No. 2047.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The following precautions were taken to ensure that the 100 kc magnetic field modulation at each sample position conformed to the requirements for this technique. A "pick-up" probe, consisting of an 80 turn (A.W.G. 38 copper wire) coil elongated to go into a sample tube, was placed first in one and then the other cavity sample position. By displaying the signal, induced by the 100 kc/s field modulation, on an oscilloscope it was verified that (*a*) the field modulation amplitudes were equal within 1% at both sample positions (a 240 mV signal was obtained when the amplitude was about 2.5 gauss); (*b*) at the back sample position field modulation due to the front pair of modulation coils was less than 0.5% of the detected amplitude at the front sample position, and vice versa; (*c*) at either sample position, for modulation amplitudes of 2.5 gauss or less, the modulation amplitude did not decrease by more than 1% when the modulation signal was fed to both pairs of modulation coils simultaneously, compared to feeding it to only one of the pairs of coils. Higher amplitudes were never used.

The relative phase of the magnetic field modulation at the two sample positions was determined by an oscilloscope. The X and Y inputs to the oscilloscope were obtained from "pick-up" probes located at the two sample positions. From the pattern observed it was concluded that the magnetic field modulations at the two sample positions were $180 \pm 3°$ out of phase with respect to each other. When phase sensitive detection is used, a 3° error in the relative phase of the field modulation at each position only introduces an error equal to $\pm(1 - \cos 3°) \times 100$ or $\pm 0.14\%$ in the subtraction of spectra.

It was observed that the phase of the field modulation depended on the load on the field modulation power supply. When there was a sample in one cavity position and the other position was empty, the intensity of the spectrum decreased by one-third when the modulation signal was fed to both pairs of modulation coils. The original intensity was restored by a simple adjustment of the phase of the 100 kc/s reference signal going to the phase sensitive detector. Consequently, the phase of the reference signal was always adjusted to maximize the intensity of the e.s.r. spectrum.

(b) Sample Preparation

Eastman tetrahydro-2-methylfuran was dried over a sodium mirror. After drying and degassing, samples were distilled into Spectrosil tubes (joined to quartz-to-pyrex graded seals) and sealed off, under vacuum, at a constriction. No grease or mercury was present in the vacuum system. Hoke TY440 valves (stainless steel with Teflon seats) and Edwards O-ring (Teflon) connectors were used instead of greased stopcocks, cones, and sockets (3).

RESULTS AND DISCUSSION

1. Subtraction of Identical Spectra

Figure 1A and B shows the room-temperature spectra of solutions of 2,2-diphenyl-1-picryl-hydrazyl (DPPH) in benzene (having identical concentrations) in tubes of inner diameter matched to $\pm 0.25\%$. Figure 1C, the measured difference between A and B, illustrates that about 98% accuracy in the subtraction can be achieved.

2a. Elimination of the Spectrum due to Irradiation of Silica Tubes

Samples are often irradiated and studied (at 77 °K) in Spectrosil silica tubes. Frequently, but not always, the e.s.r. spectrum due to the irradiated silica is negligible in intensity compared to the free radical spectrum. Silica tubes of lower purity (Suprasil) have been used (6), and the resultant e.s.r. spectrum was distorted by the sample tube signal.

There are techniques for avoiding the spectrum of the irradiated silica sample tube. Sometimes the sample is frozen on the bottom of the cavity (7). Other workers solidify a sample by dropping it into liquid nitrogen; the sample is then irradiated, and a few pieces are transferred at 77 °K into a dewar in the spectrometer cavity (8). However, these methods render it difficult to estimate free radical concentration because they do not facilitate reproduction of sample size and shape.

The subtraction technique described here eliminates the spectrum due to the irradiated silica tube. Consequently there is no objection to containing samples in these tubes. This reduces the problem of reproducing sample geometry to one of calibrating the inner diameter of the sample tube. The procedure is as follows: by placing an irradiated sample and tube in the dewar at one cavity position and an empty irradiated tube which has identical dimensions and which has received the same radiation dose in the dewar at the second cavity position, the e.s.r. difference spectrum automatically yields the spectrum of

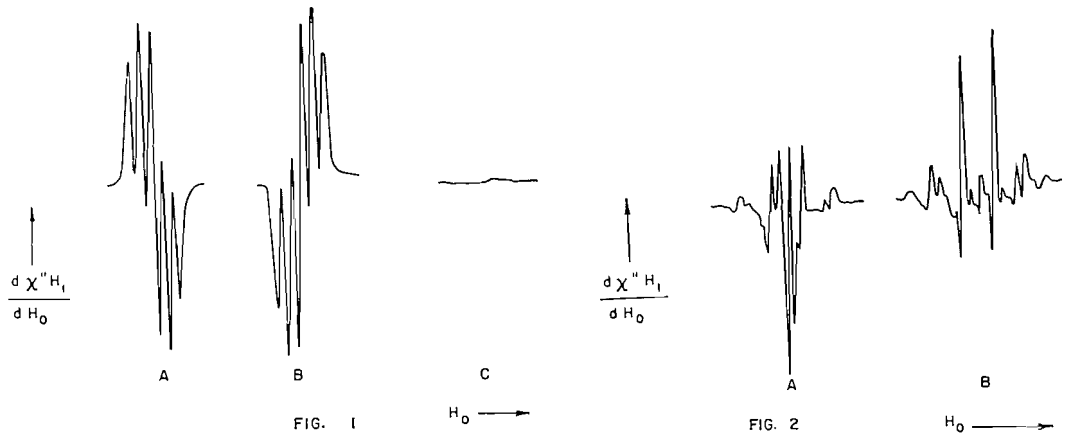

FIG. 1. A, DPPH solution in the front cavity position; B, DPPH solution in the rear cavity position; C, difference between A and B.

FIG. 2. A, Ethyl radical plus sample tube spectrum, ×100; B, difference between A and the spectrum of an empty irradiated tube, ×250.

the irradiated sample undistorted by a sample tube signal. The subtraction of the sample tube spectrum is illustrated in Fig. 2. An irradiated mixture of 15% ethane in krypton* in a Spectrosil tube at 77 °K was in one cavity position, and at the same time an empty irradiated Spectrosil sample tube was in the other position. Figure 2A was obtained by modulating the magnetic field at the sample position only. Figure 2B was obtained by modulating the magnetic field at both the sample and the empty irradiated tube simultaneously but in anti-phase. The spectrum in Fig. 2B is the same as that obtained for the ethyl radical by other workers (4, 5) in systems where the ethyl radical spectrum was intense enough to render the sample tube signal insignificant.

2b. Subtraction of the Sample Tube Hydrogen Atom Signals

The intensities of the hydrogen atom signals in two irradiated Spectrosil tubes, which had been previously flamed and sealed off under vacuum, differed by 10%. Thus the difference spectrum only achieved a 90% reduction in the hydrogen atom signal. To achieve this, narrow modulation amplitude (0.4 gauss) and extremely careful positioning of the cavity in the magnet gap were required, because the line widths are only 0.5 gauss between derivative maxima.

To study hydrogen atom formation in ice containing inorganic salts, Kevan *et al.* (9) made cylinders of ice 2 mm in diameter. They could not contain the ice in sample tubes because these develop hydrogen atom signals when irradiated. The large reduction in the intensity of the unwanted hydrogen atom signals, achieved by the subtraction technique, should enable the use of sample tubes in hydrogen atom studies such as the above-mentioned.

3. Resolution of Superimposed Spectra

Observations on trapped electrons in γ-irradiated systems have been complicated by the fact that their e.s.r. singlet is superimposed on the multiline spectrum due to another paramagnetic species (10–13). The technique of obtaining difference spectra enables the trapped electron singlet to be resolved. To demonstrate this, some results obtained in a

*Unpublished experiment with Dr. J. A. Stone.

study of irradiated tetrahydro-2-methylfuran (MTHF) are presented. These may be compared to those obtained by Salmon (13) using conventional methods.

To study MTHF a dimensionally matched pair of samples in Spectrosil tubes was prepared, slowly immersed in liquid nitrogen (MTHF forms a clear colorless glass), and ^{60}Co γ-irradiated at a dose rate of 6.46×10^{15} eV ml^{-1} s^{-1} for 2 hours. The samples developed a strong blue color. One member of the pair was then photochemically bleached by tungsten light transmitted by a Corning 2403 filter until the sample was again colorless. Both samples were then placed in the dual cavity at 77 °K, and their difference spectrum was recorded at 0.2 mW cavity input power and a modulation amplitude of 2.3 gauss. The e.s.r. spectra obtained are shown in Figs. 3 and 4. The results show that irradiation of

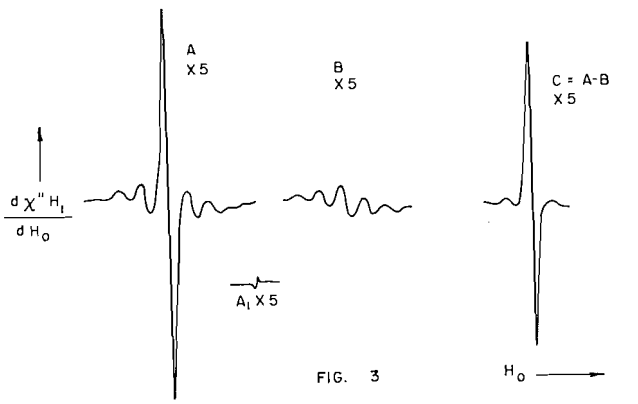

FIG. 3. A, Unbleached MTHF; A_1, difference between two unbleached MTHF samples; B, bleached MTHF; C, difference between unbleached and bleached MTHF.

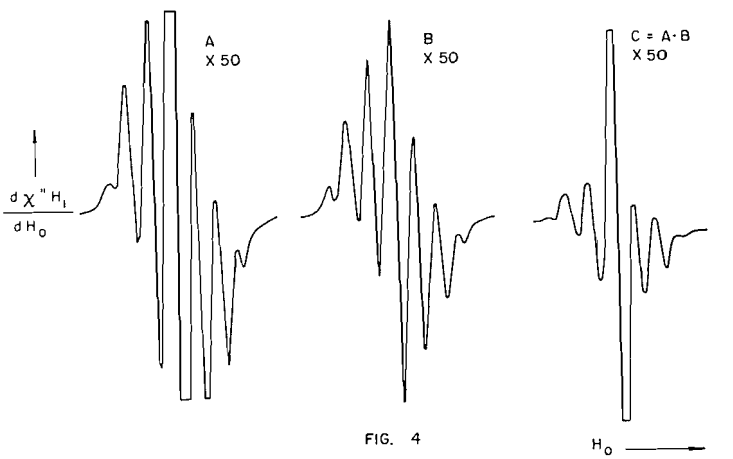

FIG. 4. A, B, and C are the same as A, B, and C in Fig. 3 except they are measured using a ten times greater sensitivity.

MTHF yields a narrow intense singlet superimposed on the center line of a septet spectrum. Bleaching causes the singlet and about 30% of the septet to disappear. These spectra do not give a true indication of the relative intensities of the singlet and septet. They are both saturated to a different extent at this power level. Their microwave satura-

tion curves differ such that, at a power level of 2.5 μW, the difference spectrum only reveals the electron singlet. Figure 5 shows the relative intensities of the singlet superimposed on the septet and of the resolved singlet at a power level of 2.5 μW. Neither of the spectra in Fig. 5 are saturated to a detectable extent.

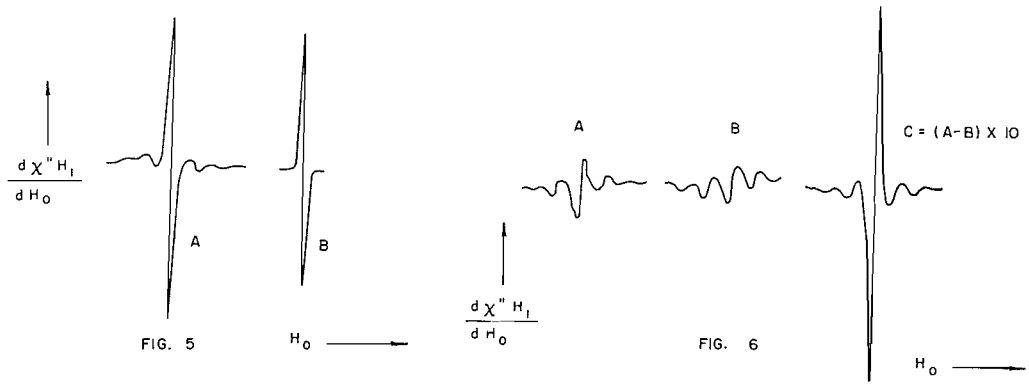

FIG. 5. Cavity input power 2.5 μW. A, unbleached MTHF; B, difference between unbleached and bleached MTHF.

FIG. 6. A, MTHF bleached until very pale blue; B, MTHF bleached until colorless; C, difference between A and B using a ten times greater sensitivity.

An experiment which illustrates the sensitivity of the technique is shown in Fig. 6. One irradiated MTHF sample was bleached until a very pale blue color remained, and the other was bleached until colorless. The spectrum of each and their difference spectrum (the latter at a sensitivity setting ten times greater than the former) was then recorded. Figure 6C clearly reveals the presence of trapped electrons while Fig. 6A only hints at their presence.

SUMMARY

The MTHF data have been presented to illustrate the difference technique. These data, together with data on trapped electrons in other systems, will be discussed in a subsequent paper. In particular, the technique is being used to measure the radiation-chemical *G*-values of trapped electrons with greater accuracy than is otherwise possible.

The technique could be used as a routine procedure to eliminate the central spectrum of the irradiated Spectrosil tube. This is valuable in systems where the radical yield is low and significant distortion of the free radical spectrum can occur.

In more specialized applications, the technique is limited to systems in which radiation-chemical yields can be reproduced fairly well. It is important to be able to produce pairs of samples having the same concentrations of the same paramagnetic species. Otherwise it is difficult to deduce, from the e.s.r. difference spectrum, chemical reactions resulting from an operation on one member of the pair, such as photochemical bleaching. We have encountered no trouble from this factor in several organic glasses studied. However, in polycrystalline systems, which may have a phase transition at a temperature above 77 °K, very careful annealing at the transition temperature will be necessary before one can even hope to succeed in reproducing radiation-induced yields of free radicals. This is because the free radical yield apparently depends on the structure of the crystal lattice. Plunging a sample rapidly into liquid nitrogen freezes a significant amount of the material in the form of the high-temperature phase. If the sample is first annealed at the phase transition tem-

perature and then cooled to 77 °K, the low-temperature phase structure is formed. In cyclohexane, Bensasson *et al.* (14) measured the yield of cyclohexyl radicals. The rapid-freezing procedure yielded $G(C_6H_{11}\cdot)$ equal to 3 or 4. Samples which were annealed at 193 °K (the phase transition temperature) for 15 hours before cooling to 77 °K yielded $G(C_6H_{11}\cdot)$ equal to about 1.2. Similar treatment of cyclopentane samples yielded $G(C_5H_9\cdot)$ equal to 2 and 0.3, respectively.

ACKNOWLEDGMENTS

We wish to thank Dr. J. S. Geiger for valuable advice and Mr. J. C. Tole for his assistance in checking the amplitude and phase of the 100 kc/s field modulation. Dr. R. H. Betts deserves thanks for his continuous encouragement and critical discussion.

THERMODYNAMICS OF TERNARY UNIVARIANT SYSTEMS OF THE TYPE: WATER – METAL SALT – ACID

J. W. LORIMER
Department of Chemistry, University of Western Ontario, London, Ontario
Received February 4, 1964

ABSTRACT

Thermodynamic equations for the variation of vapor pressure and composition with temperature along ternary univariant lines on phase diagrams of systems typified by H_2O–$ZnSO_4$–H_2SO_4 are developed. The usefulness of these equations in testing the consistency of experimental data, in estimating invariant points, and in obtaining thermodynamic data is discussed.

Quantitative thermodynamic treatments of phase diagrams are recognized as being valuable in "checking, extrapolation, interpolation, prediction" (1), and such treatments for binary systems and a number of types of ternary systems have been summarized (1, 2, 3). Ternary phase diagrams which describe, for example, the effect of addition of sulphuric acid on the solubility of a metal sulphate and its hydrates in water do not appear to have been subjected to systematic thermodynamic analysis. Ternary univariant lines are conspicuous features of diagrams of this type, and general equations for these lines are discussed in this paper.

Experimental data from the literature on the system H_2O–$ZnSO_4$–H_2SO_4 are used to illustrate the application of the theoretical analysis. Three hydrates, three incongruent binary transitions, and a ternary quintuple point are involved in the known equilibria in this system.

1. GENERAL EQUATIONS FOR THE TERNARY UNIVARIANT EQUILIBRIA

On the schematic isothermal ternary diagram shown in Fig. 1, A is a volatile component

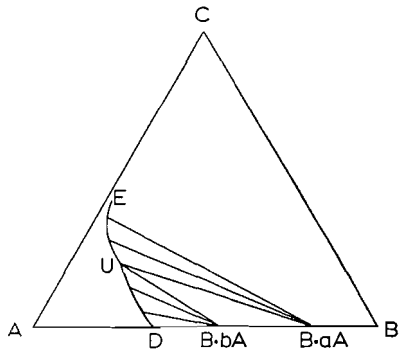

FIG. 1. Schematic isothermal ternary diagram (see text).

(e.g. H_2O) while B and C are nonvolatile (e.g. $ZnSO_4$, H_2SO_4, respectively). Components A and B form the binary compounds $B.aA$ and $B.bA$ ($b > a \geqslant 0$), which may melt either congruently or incongruently. The solubility curves UE, DU of these binary compounds intersect at the ternary univariant point U, at which the phases solid α (compound $B.aA$),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

solid β (compound B.bA), solution saturated with respect to the two binary compounds, and vapor A are mutually in equilibrium. As the temperature is increased, point U moves towards the binary AB axis to become eventually a binary invariant point (either a eutectic or a transition point) or even a ternary invariant, or quintuple point.*

In principle, two cases must be distinguished in the analysis. (*a*) The total pressure P on the system is equal to the vapor pressure π of component A. This case is important for the comparison of the vapor pressure of the solution with the dissociation pressure of one solid phase. (*b*) The system is kept at a fixed total pressure P by addition of an indifferent gas; $dP = 0$, $d\pi \neq 0$. This is the condition under which most experimental composition–temperature data have been obtained. Strictly speaking, admission of air to the system introduces another component, and the system is divariant (cf. ref. 2, p. 148). The analysis is thus indeterminate unless the total pressure is kept constant.

At thermodynamic equilibrium, the conditions for chemical equilibrium are:

$$[1] \qquad d\mu^{\alpha} = a\, d\mu_1' + d\mu_2';\ d\mu^{\beta} = b\, d\mu_1' + d\mu_2';\ d\mu_1' = d\mu_1'',$$

where the superscripts α, β, $'$, $''$ refer to the two solid phases, solution, and vapor, respectively. Expansion of these equations as functions of temperature and pressure leads readily to the general vapor pressure equation:

$$[2] \qquad \Delta H_{tr}\, dT/T - \Delta V_{tr}\, dP = (b - a)(d\mu_1'')_{T,P}$$

and

$$[3] \qquad (d\mu_1')_{T,P} = RT\, d \ln f_i' x_i' = dk_i(T, P), \qquad i = 1, 2,$$

where

$$[4] \qquad \begin{cases} dk_1(T, P) = -\Delta H_v\, dT/T - v_1'\, dP + RT\, d \ln \pi, \\ dk_2(T, P) = (a\Delta H_v + \Delta H_s^{\alpha})\, dT/T - (a\Delta V_v + \Delta V_s^{\alpha})\, dP - aRT\, d \ln x_1'' \\ \qquad\qquad = (b\Delta H_v + \Delta H_s^{\beta})\, dT/T - (b\Delta V_v + \Delta V_s^{\beta})\, dP - bRT\, d \ln x_1'', \end{cases}$$

$$[5] \qquad x_3'(d\mu_3')_{T,P} = -x_1'(d\mu_1')_{T,P} - x_2'(d\mu_2')_{T,P}.$$

Subscripts 1, 2, 3 refer to compounds A, B, C, respectively. ΔH_{tr} is the enthalpy of dissociation of compound β into α plus A vapor, ΔH_v is the enthalpy of vaporization from the saturated solution, $\Delta H_s^{\alpha,\beta}$ are the enthalpies of solution of α and β, v_1' is the partial molal volume of A in solution, π is the partial pressure of A in the vapor, and f_i' is the mole fractional activity coefficient of i. The volume terms are in each case defined analogously to the enthalpies.

2. THE VAPOR PRESSURE CURVES

Case (a) $P = \pi$

Equation [2] gives rigorously

$$[6] \qquad d\pi/dT = \Delta H_{tr}/T\Delta V_{tr},$$

the ternary univariant Clapeyron equation, which has been deduced by other methods (3, 4). The volume term may be written

$$[7] \qquad \Delta V_{tr}/(b - a) = (V^{\alpha} - V^{\beta})/(b - a) + RT/\pi + B,$$

where $B \sim 31$ cm^3 mole^{-1} is the van der Waals' covolume for water vapor. The molal

**Univariant systems involving ternary compounds (such as the hydrate of a metal acid sulphate) do not always have a dissociation pressure and are excluded specifically from this analysis.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

volumes of the hydrates of zinc sulphate are (5): $7H_2O$, 146; $6H_2O$, 130; H_2O, 58 cm^3 $mole^{-1}$. The term $V^\alpha - V^\beta$ is thus negative, and partially cancels B, making the approximation

$$\Delta V_{tr} = (b - a)RT/\pi \quad [8]$$

good to at least 0.03% for vapor pressures of 0.5 atm and lower and temperatures between 0 and 90 °C. The approximation gives

$$d \ln \pi/d(1/T) = -\Delta H_{tr}/R(b - a). \quad [9]$$

Equation [9] can be deduced without any reference to the solution phase, and is therefore also valid for the binary univariant system with phases solid B.aA, solid B.bA, and A vapor. The vapor pressure of the volatile component is the "dissociation pressure" for B.bA. Dissociation pressures for the system $ZnSO_4$–H_2O have been reviewed recently (6, 7), and values of the heat of transition per mole of water are given in Table I as

TABLE I

*All quantities are in kcal $mole^{-1}$, except where noted. B ≡ $ZnSO_4$.

$\Delta H_{tr}/(b - a)$. The variation of the heat of transition with temperature is negligibly small. For example, over the range of coexistence of the hepta- and hexa-hydrates (21–39 °C), heat capacity data (2, 7) indicate that ΔH_{tr} changes by only 30 cal $mole^{-1}$.

Case (b) P = Constant

Equation [2] again gives eq. [9]; i.e., the partial vapor pressure of A is essentially unaffected by addition of an indifferent gas to a total pressure of at least 1 atm. At a given temperature,

$$d \ln \pi/dP = (V^\beta - V^\alpha)/(b - a)RT \quad [10]$$

or, approximately

$$\Delta\pi/\pi_0 = (V^\beta - V^\alpha)(P - \pi_0)/(b - a)RT, \quad [11]$$

where π_0 is the vapor pressure with no indifferent gas present. At 0 °C and 1 atm, $\Delta\pi/\pi_0 \sim$ 0.06%, a negligible amount. The standard Gibbs' free energy of transition is

$$\Delta G_{tr}^0 = -\int_{1\text{ atm}}^{\pi\text{ atm}} \Delta V_{tr}\, dP = -(b - a)RT \ln \pi\text{ atm}, \quad [12]$$

values of which are given for 298 °K in Table I.

One further quantity may be calculated from the vapor pressures. If it is taken that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$a_1' = 1$ when $\pi = P_0$, the vapor pressure of pure component A at temperature T, the activity of component A in solution is, according to eqs. [1] and [3],

$$[13] \qquad (a_1')_{T,\pi} = \pi/P_0.$$

The quantity of interest here, however, is the variation of the activity of component A with temperature, which is discussed below.

3. THE COMPOSITION CURVES

Case (a) $P = \pi$

If, as in [8], the volume of the condensed phases is neglected in comparison with that of the vapor, and the vapor is ideal, eq. [4] becomes

$$[14] \qquad T\,\mathrm{d}k_1(T)/\mathrm{d}T = \Delta H_{tr}'/(b-a) \equiv R\lambda_1,$$

$$[15] \qquad \begin{aligned} T\,\mathrm{d}k_2(T)/\mathrm{d}T &= \Delta H_s^{\alpha} - a\Delta H_{tr}'/(b-a) \\ &= \Delta H_s^{\beta} - b\Delta H_{tr}'/(b-a) \\ &= (b\Delta H_s^{\alpha} - a\Delta H_s^{\beta})/(b-a) \equiv R\lambda_2, \end{aligned}$$

where

$$[16] \qquad \Delta H_{tr}' = \Delta H_{tr} - (b-a)\Delta H_v = \Delta H_s^{\beta} - \Delta H_s^{\alpha}$$

is the heat of transition (negative of the "enthalpy of hydration" (6)) for the process

$$\mathrm{B}.b\mathrm{A(s)} = \mathrm{B}.a\mathrm{A(s)} + (b-a)\mathrm{A(sat.\ soln.)}$$

and $R\lambda_1$, $R\lambda_2$ are abbreviations for the appropriate enthalpy terms. The heats of vaporization for the solution and for pure water differ by the relative partial molal heat content of water in the saturated solution, which in general is negligibly small compared to ΔH_v (see ref. 11, p. 541 for relevant data). Table I lists values of $\Delta H_{tr}'/(b-a)$ where average values of ΔH_v for pure water over the temperature range of stable existence of the various hydrates have been used (5). A substitution of [14] and [15] into [3] gives:

$$[17] \qquad \mathrm{d}\ln f_i' x_i'/\mathrm{d}(1/T) = -\lambda_i, \qquad i = 1, 2,$$

or

$$[18] \qquad \mathrm{d}\ln x_i'/\mathrm{d}(1/T) = -\mathrm{d}\ln f_i'/\mathrm{d}(1/T) - \lambda_i \equiv -\beta_i, \qquad i = 1, 2.$$

If the λ_i and β_i are independent of temperature, [37] and [38] integrate to

$$[19] \qquad f_i' x_i' = f_i'^{*} x_i'^{*} \exp\{\lambda_i(1/T^* - 1/T)\}, \qquad i = 1, 2,$$

and

$$[20] \qquad x_i' = x_i'^{*} \exp\{\beta_i(1/T^* - 1/T)\},$$

where $T = T^*$ at $x_i = x_i^*$, a reference temperature and mole fraction. Equations [18] and [5] give

$$[21] \qquad \begin{aligned} \mathrm{d}x_3'/\mathrm{d}(1/T) &= \beta_1 x_1' + \beta_2 x_2' \\ &= \lambda_1 x_1' + \lambda_2 x_2' - x_3'\,\mathrm{d}\ln f_3'/\mathrm{d}(1/T). \end{aligned}$$

Introduction of [20] into [21] and subsequent integration gives

$$[22] \qquad x_3' = x_3'^{*} + x_1'^{*}[1 - \exp\{\beta_1(1/T^* - 1/T)\}] + x_2'^{*}[1 - \exp\{\beta_2(1/T^* - 1/T)\}].$$

For personal use only.

Case (b) P = Constant

Equation [4] again gives [14] and [15], if the volume of the condensed phases is neglected in comparison with that of the vapor; i.e., the composition curves are essentially unaffected by addition of an indifferent gas to a total pressure of, for example, 1 atm, the condition under which most solubility data have been obtained.

From eqs. [2] and [4], the explicit dependence of composition on pressure at a given temperature is

$$[23] \qquad \mathrm{d} \ln f_1' x_1' / \mathrm{d}P = -\Delta V_{tr} / RT(b - a),$$

$$[24] \qquad \mathrm{d} \ln f_2' x_2' / \mathrm{d}P = -(b\Delta V_s^{\alpha} - a\Delta V_s^{\beta}) / RT(b - a),$$

where $\Delta V_{tr}'$ is defined analogously to $\Delta H_{tr}'$. From the values for the molal volumes of the zinc sulphate hydrates, $v_1' \sim 18$ cm^3 mole^{-1} and $v_2' \sim 10$–20 cm^3 mole^{-1}, [23] and [24] indicate that the variation of activity with pressure will not exceed 0.1% per atm. Equations [17] through [22] may now be applied to experimental composition data. In systems such as H_2O–$ZnSO_4$–H_2SO_4, it is customary to analyze equilibrium systems for zinc and sulphate to obtain the number of moles of $ZnSO_4$ and H_2SO_4. The moles of H_2O are found by difference. Under these conditions,

$$\Delta n_i'/n_i' = \Delta x_i'/x_i', \qquad i = 2, 3,$$

that is, a relative error in the number of moles of $ZnSO_4$ or H_2SO_4 will give rise to the same relative error in the mole fractions of these two components. The mole fraction of H_2O, however, reflects errors in analyses of both of the other two components.

Figure 2 contains plots of log x_1' against $1/T$, which appear to be linear; that is, β_1 is

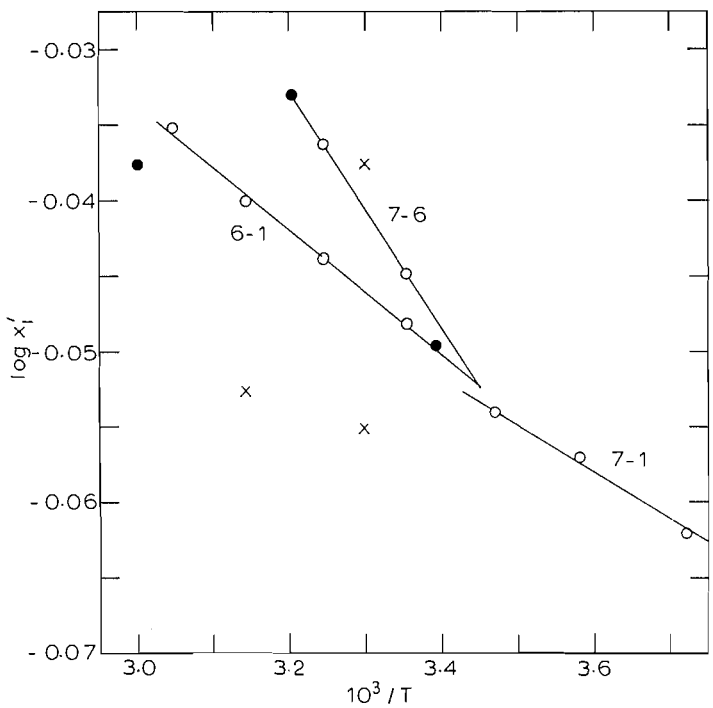

FIG. 2. Log (mole fraction of water) vs. reciprocal temperature plot for H_2O–$ZnSO_4$–H_2SO_4 ternary univariant solutions: ○ Copeland and Short (8); × Joshi and Devadatta (10); ● invariant points of Copeland and Short. The numbers 7–1, 7–6, 6–1 identify the solid hydrates present.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

constant. Estimated invariant points (8) are also included on the plot. Since the vapor pressure data indicate that λ_1 is also constant, it follows that d ln f_1'/d$(1/T)$ is also constant to within experimental error. These plots are consistent with a quintuple point at 21 °C, $x_1' = 0.892$ (8), only if there is marked curvature of the 7–6 and 7–1 lines near this point, or if the experimental errors are large. The experimental data (8) indicate that the error in the mole fraction of H_2O can be as large as 3%. Since x_1' is close to unity, this error is magnified greatly on the logarithmic plot, and the plot is thus unsuitable for extrapolation or interpolation purposes. It is preferable, therefore, to note that x_1' is constant for any given transition to within 1%, and that eq. [18] may be written

$$[25] \qquad d(x_2' + x_3')/d(1/T) = \beta_1 x_1'.$$

Plots of $x_2' + x_3'$ against $1/T$ are shown in Fig. 3. While it is difficult to decide from the

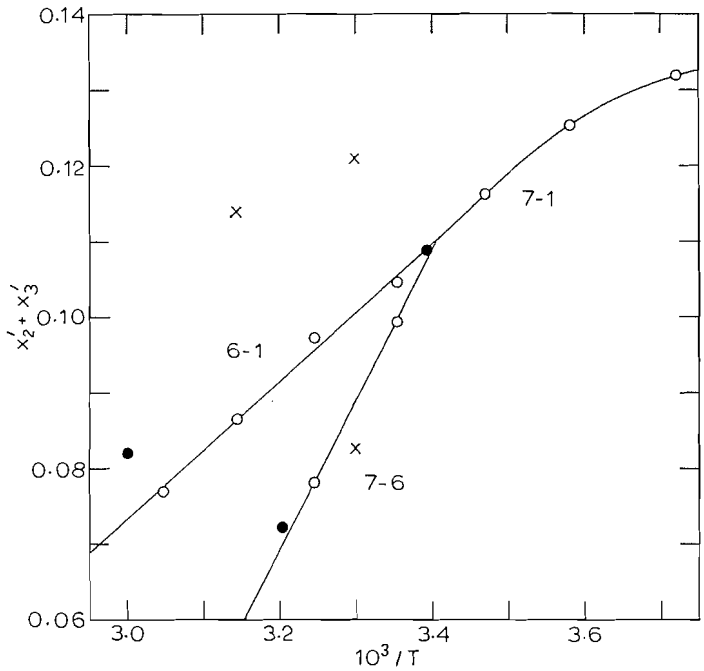

FIG. 3. Total mole fraction of $ZnSO_4$ and H_2SO_4 vs. reciprocal temperature plot for H_2O–$ZnSO_4$–H_2SO_4 ternary univariant solutions. The points correspond to those in Fig. 1.

available data whether or not these plots are curved (except for the low temperature portion of the $7H_2O$–H_2O transition line), best straight lines extrapolate to a quintuple point at 20 °C, $x_1' = 0.890$, in good agreement with other estimates (6, 8). The composition at the $7H_2O$–$6H_2O$ binary transition point appears to be slightly in error, since vapor pressure data (6) substantiate the transition temperature of 39 °C. There appears to be no support for the contention of Copeland and Short (8) that their data indicate a $6H_2O$–H_2O binary transition at 60 °C rather than at 70 °C (6). Table I lists the values of β_1 and d ln f_1'/d$(1/T)$ derived from these plots.

Figure 4 shows plots of log x_2' vs. $1/T$, including estimated invariant points (8). The plots are linear (with the exception of the high temperature portion of the $6H_2O$–H_2O transition line), and give a quintuple point at 21 °C, $x_2' = 0.0396$, in good agreement with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

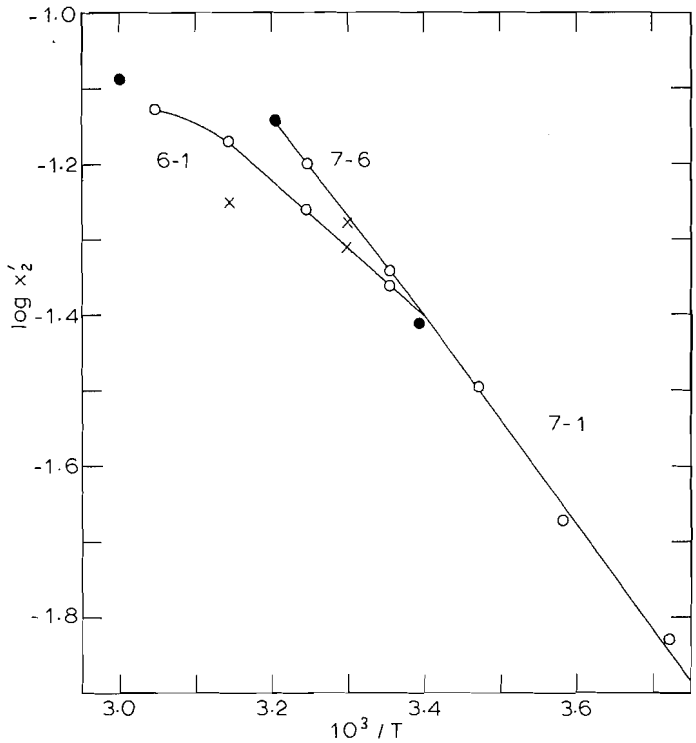

FIG. 4. Log (mole fraction of $ZnSO_4$) vs. reciprocal temperature plot for H_2O–$ZnSO_4$–H_2SO_4 ternary univariant solutions. The points correspond to those in Fig. 1.

other estimates ((6, 8) $x_2' = 0.0388$). Again, the composition at the $7H_2O$–$6H_2O$ binary transition appears to be slightly in error, and there is no support for a $6H_2O$–H_2O binary transition at 60 °C.

Unfortunately, no data are available which permit an estimate of the variation of the activity of $ZnSO_4$ along these univariant lines. However, it would appear that $d \ln f_2'/d(1/T)$ is constant along the linear portions of the plots in Fig. 4, since λ_2 should be almost independent of temperature. Values of β_2 from these plots are given in Table I.

Figure 5 shows plots of x_3' against $1/T$, including estimated invariant points (8). The solid lines in Fig. 5 have been calculated from eq. [22] using values of β_1 and β_2 from Table I and the quintuple point data from Figs. 3 and 4. ($10^3/T = 3.405$, $x_2' = 0.0395$, $x_3' = 0.0705$.) The broken lines are based on the same values of β_1 and β_2 and the quintuple point data estimated by Copeland and Short (8). From [18] and [21],

$$d^2x_3'/d(1/T)^2 = -(\beta_1^2 + \beta_2^2),$$

so that the x_3' vs. $1/T$ plots are always convex upwards.

The lines based on the quintuple point estimated by the above methods represent the experimental points better on the whole than the line based on the Copeland and Short quintuple point. The solid lines extrapolate to $x_3' = 0$ to give a $7H_2O$–$6H_2O$ binary transition at 38.9 °C, compared to the precisely known value 38.12 °C (7, 9). The $6H_2O$–H_2O transition point is, by extrapolation, 52.5 °C, in bad agreement with the value 70 °C from vapor pressure data (6). It is noteworthy that the $7H_2O$–H_2O binary transition from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

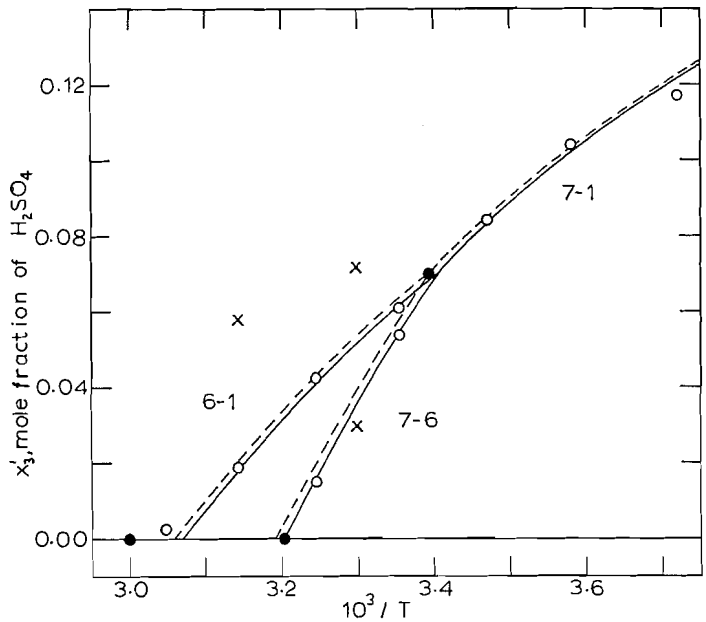

FIG. 5. Mole fraction of H_2SO_4 vs. reciprocal temperature plot for H_2O–$ZnSO_4$–H_2SO_4 ternary univariant solutions. The points correspond to those of Fig. 1; — and - - - are calculated lines based on quintuple points of this paper and of Copeland and Short (8), respectively.

vapor pressure data is 55 °C (6), which suggests that the higher temperature data for the $6H_2O$–H_2O equilibria may actually be for $7H_2O$–H_2O equilibria.

Two points for $6H_2O$–H_2O equilibria and one for $7H_2O$–$6H_2O$ determined by Joshi and Devadatta (10) are included in each of Figs. 2–5. The $7H_2O$–$6H_2O$ point agrees reasonably well with the Copeland and Short data, but the $6H_2O$–H_2O points are evidently greatly in error, except for one x_2' value.

Finally, the apparent insensitivity of the activity coefficients of H_2O and $ZnSO_4$ along the univariant lines must be considered. These activity coefficients are presumably determined by temperature, ionic strength, and total molality. It is difficult to estimate the ionic strength because of the significant ion-pair formation in $ZnSO_4$ solutions (11, p. 190) and the considerable variation of the second dissociation constant of H_2SO_4 with temperature (12). However, if it is assumed that the only ionic species present are H^+ and HSO_4^- (from H_2SO_4) and Zn^{2+} and SO_4^{2-} (from $ZnSO_4$), the ionic strength is simply

$$I = 55.5(2x_2' + x_3')/x_1'.$$

From the experimental data, it is found that this ionic strength varies less than 5% along the $7H_2O$–H_2O univariant lines and about 10% along the $7H_2O$–$6H_2O$ line. The total molality is given to a good approximation by $x_2' + x_3'$ (Fig. 3), and varies 30–40% along the univariant lines. Apparently the relatively small variation in ionic strength is the main reason that the variation of the activity coefficients with composition along the univariant lines is of little importance for the present analysis.

It should be noted that if the activity coefficients do vary with composition, the β_i in eq. [18] will in general no longer be constant, and the equations for the composition curves will take on a much more complex form.

Received May 28, 1964

ABSTRACT

trans-3-Hexadecenoic acid was found to be a component of the glyceride oil of seeds of *Helenium bigelowii* A. Gr. It constituted about 10% of the total fatty acids. The acid was isolated and identified by oxidative cleavage and by its infrared and nuclear magnetic resonance (n.m.r.) spectra. Reaction with alkaline permanganate gave 3-hydroxypalmito-γ-lactone. Mild alkaline treatment of methyl *trans*-3-hexadecenoate caused a shift of the double bond to the 2-position. A sample of *Helenium hoopesii* seed oil did not contain any *trans*-unsaturated acid.

Glyceride acids with unsaturation in the 3-position were not known to occur in seed oils until very recently. Two such acids were reported in 1964, viz. a 3,9,12,15-tetraene acid, found by Hopkins and Chisholm in a species of *Tecoma* (Bignoniaceae) (1), and a 3,9,12-triene acid, found by Bagby and co-workers in a species of *Calea* (Compositae) (2). Both of these are C_{18} acids.

In the present work, the seed oil of *Helenium bigelowii* A. Gr. (family Compositae) was found to contain a substantial amount of a *trans*-monoene acid which proved to be *trans*-3-hexadecenoic acid. This species of *Helenium* is a herbaceous plant, native to North America, and is grown as a flowering perennial. A sample of a related species, *H. hoopesii* A. Gr., did not contain any *trans* fatty acid.

The seed oil of *H. bigelowii* had no conjugated unsaturation but its infrared spectrum revealed the presence of isolated *trans* olefinic unsaturation (υ_{max} = 960 cm^{-1}, C—H out-of-plane bending mode (3)). The oil was converted to methyl esters and submitted to gas–liquid chromatography (g.l.c.). The chromatogram indicated the presence of 12% of hexadecenoic acid.

The mixed acids were crystallized fractionally from acetone at low temperatures and the fractions were examined by g.l.c. and by infrared absorption. It was evident that the component responsible for *trans* absorption was in the hexadecenoic acid fraction. Repeated crystallization of this fraction from acetone at low temperatures gave a pure acid, m.p. 53–54°. Its methyl ester had an infrared maximum at 962 cm^{-1}, equal in intensity to the same peak in the spectrum of methyl elaidate, confirming the presence of one *trans* double bond.

Hydrogenation of the acid gave palmitic acid, establishing its structure as a straight chain, C_{16} acid. Oxidative cleavage gave tridecanoic acid, showing that the double bond is at the 3-position. The compound is therefore *trans*-3-hexadecenoic acid (I). The melting point is in agreement with recorded data (3). The structure was confirmed by the n.m.r. spectrum, which had the following bands (tetramethylsilane = 0):

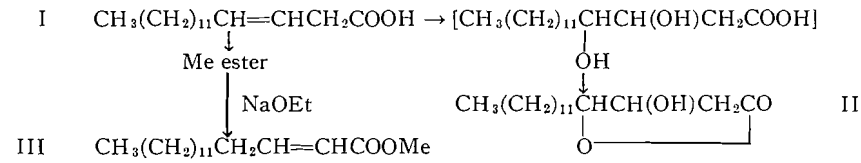
Chem. shift, δ	Type of band	No. protons	Assignment
5.56	Quintuplet	2	CH=CH
3.07	Essentially doublet	2	=CHCH_2CO
2.04	Multiplet	2	CH_2CH=
0.89	Multiplet	3	CH_3

$CH_3(CH_2)_{11}CH{=}CHCH_2COOH$

[1]*Issued as N.R.C. No. 8065.*

The band at $\delta = 3.07$ is assigned to the methylene protons in the grouping $=CHCH_2CO$ on the basis of its chemical shift and its essentially doublet structure. This is supported by the absence of the band characteristic of the ordinary methylene group adjacent to carboxyl, which would appear at $\delta = 2.3$ (4). Furthermore, the band given by methylene protons adjacent to an isolated double bond ($\delta = 2.04$) represents only two protons.

Hydroxylation of the acid by alkaline permanganate gave a lactone, judged to be 3-hydroxypalmito-γ-lactone (II), because of the known ease of formation of γ-lactones from hydroxy acids. It had infrared maxima at 3540s (OH stretching) and 1763, 1785vs (C=O stretching in γ-lactone (5)).



The ester of *trans*-3-hexadecenoic acid was heated with ethanol containing sodium ethoxide according to the procedure of Linstead and Noble (6). This caused a shift of the double bond to the 2-position (III), as shown by the infrared and n.m.r. spectra. A strong C=C stretching band appeared at 1653 cm^{-1} in the infrared (αβ-unsaturated ester (7)). This bond shift, produced under relatively mild conditions, is further proof that the original double bond is at Δ^3. The n.m.r. spectrum of the product had a typical ABX_2 pattern with multiplets centered at $\delta = 5.7$ and 7.0, representing the two olefinic protons. The coupling constant, J_{AB}, was 16 c.p.s., showing that the double bond is *trans* (8).

The amount of *trans*-3-hexadecenoic acid was about 10% of the total fatty acids of the oil. There was some evidence of a *trans* polyenoic acid.

EXPERIMENTAL

Infrared spectra were determined in carbon disulphide in a Perkin–Elmer model 21 spectrophotometer with sodium chloride prism. Nuclear magnetic resonance spectra were measured at 60 Mc/s on a Varian model A-60 spectrometer in deuterochloroform solution with tetramethylsilane as internal standard. Gas–liquid chromatography was carried out with a diethylene glycol – succinic acid polyester as liquid phase, on Celite, and a thermal conductivity detector. Petroleum ether refers to the fraction of b.p. 30–60°. Melting points were determined in capillary tubes and are corrected.

Helenium bigelowii Seed Oil

Seed of *Helenium bigelowii* A. Gr. was obtained from a reliable commercial source. Extraction of the ground seed with petroleum ether yielded 15% of oil. The oil had an infrared absorption peak at 960 cm^{-1} with intensity equivalent to a content of about 14% of *trans*-monoene fatty acid. There was no peak in the region 980–995 cm^{-1} (no conjugated unsaturation). A portion was converted to methyl esters. The mixed esters were analyzed by g.l.c. at 185°. The percentages of the various acids were (mean of three determinations): palmitic 10, hexadecenoic 12, octadecenoic 8, octadecadienoic 65, octadecatrienoic 5. There were no acids in the C_{20}–C_{22} region.

Isolation of the Acid

The oil was hydrolyzed by refluxing for 30 min with 6% ethanolic potassium hydroxide and the unsaponifiable matter was removed. The acids (31.2 g) were dissolved in 280 ml of acetone and the solution was cooled to −17° and then to −37°. Fatty acid crystals were filtered off at each stage and were examined by g.l.c. and by infrared absorption.

Fraction	Crystallizing temp., °C	Yield, g	Main component
F1	−17	3	Palmitic acid
F2	−37	4	*trans*-Hexadecenoic acid
F3	Filtrate	23	Octadecadienoic acid

Most of the *trans* acid was in fraction F2, which was solid. This fraction was crystallized from 30 ml of acetone at −20°. The crystals (2.55 g) consisted of 85% hexadecenoic acid and 15% palmitic acid, determined by g.l.c. One gram of this product, crystallized twice from acetone at −5°, yielded 118 mg of pure *trans*-3-hexadecenoic acid, m.p. 53–54° [lit. 53.5–55.0° (3)].

Anal. Calcd. for $C_{16}H_{30}O_2$: C, 75.5; H, 11.9. Found: C, 75.7; H, 12.25. Its n.m.r. spectrum is described above.

The methyl ester was prepared. It had υ_{max} = 962vs cm^{-1}, with intensity equivalent to one *trans* double bond.

Hydrogenation and Oxidative Cleavage

A portion of the acid (0.1 g) was hydrogenated in methanol with Adams platinum catalyst. It gave palmitic acid in quantitative yield, m.p. 62.0–62.5° alone and mixed with palmitic acid.

The monoenoic acid (0.06 g) was treated with permanganate–periodate by von Rudloff's procedure (9). On acidification, the reaction mixture gave a precipitate which was collected and crystallized once from acetone and once from pentane. It was tridecanoic acid, m.p. 38–39° alone and mixed with an authentic sample. The other products were extracted from the filtrate, esterified, and examined by g.l.c. There was no appreciable amount of any other monobasic acid.

3-Hydroxypalmito-γ-lactone

trans-3-Hexadecenoic acid (0.5 g) was dissolved in 500 ml of water containing 0.5 g of sodium hydroxide, mixed with 50 ml of 1% aqueous potassium permanganate, and allowed to stand at 20° for 6 min. The excess permanganate was destroyed, the solution was acidified and cooled in ice, and the precipitate was filtered off, dried, and washed with pentane to remove non-hydroxylic by-products. The residual product (0.14 g) was crystallized three times from ethanol at −20°, giving 3-hydroxypalmito-γ-lactone, m.p. 71–72°.

Anal. Calcd. for $C_{16}H_{30}O_3$: C, 71.1; H, 11.2. Found: C, 70.8; H, 11.0.

It formed glistening white flakes, moderately soluble in ethanol but insoluble in petroleum ether. It had υ_{max} = 3540s (OH), 1763, and 1785vs (γ-lactone). There was no peak in the region of acid carbonyl (ca. 1705 cm^{-1}).

Isomerization of the Ester

Methyl *trans*-3-hexadecenoate (0.3 g) was dissolved in 50 ml of absolute ethanol to which 0.035 g of sodium metal had been added. The solution was refluxed for 12 h, diluted with water, acidified, and extracted with petroleum ether. The extract contained some free acid. It was reesterified by methanol – hydrogen chloride. The liquid product (0.22 g) had υ_{max} 1653s (αβ-unsaturated ester). A model compound, methyl *trans*-2-octadecenoate, had a similar strong band at 1653 cm^{-1}.

Helenium hoopesii Seed Oil

Seed of *H. hoopesii* A. Gr. yielded 16% of oil, n_D^{25} 1.4753. Its ultraviolet spectrum had no maxima in the region 230–320 mμ (no conjugated diene or triene). The infrared spectrum showed much unsaturation (υ_{max} = 3000 cm^{-1}) but no *trans* double bonds (ca. 962 cm^{-1}). Analysis by g.l.c. showed the following percentages of fatty acids: palmitic 9; hexadecenoic, less than 1; octadecenoic 8; octadecadienoic 83.

DISCUSSION

Occurrence of a mono-unsaturated Δ^3 acid in seed oil fatty acids has not been observed previously. However, *trans*-3-hexadecenoic acid was detected by Debuch in 1961 in the leaves of two plant species (10) (not Compositae) and the same acid was isolated from an alga by Klenk and Knipprath in 1962 (3). Two polyenoic acids with unsaturation at Δ^3 are known to occur in seed oils (1, 2). The Δ^3 double bond in these three natural acids has the *trans* configuration. The 5-octadecenoic acid of *Thalictrum* seed oil is also *trans* (11). It is possible that ethylenic groupings near the carboxyl end of the chain tend to form in the *trans* configuration.

Natural monoenoic fatty acids include a group with various chain lengths in which the double bond is at position 3, 5, 9, 11, or 13, counting from the carboxyl end. This series, complete except for a Δ^7 acid, may be of significance in relation to the mechanism of biosynthesis. There is a strong likelihood that the longer chain monoenoic acids are formed by the addition of a 2-carbon unit at the carboxyl end of a shorter chain acid, e.g. 11-octadecenoic acid from 9-hexadecenoic acid (12), and 5-octadecenoic acid from 3-hexadecenoic acid.

THE REDISTRIBUTION REACTION OF BIS-MERCURIALS

W. E. French, N. Inamoto, and George F Wright
Department of Chemistry, University of Toronto, Toronto, Ontario
Received April 27, 1964

ABSTRACT

The demetalation of diorganosubstituted mercury compounds is catalyzed by peroxides. When organomercuric salts are present this demetalation leads to formation of mercurous salt plus mercury. This latter combination has been found to be a catalyst for the redistribution reaction of bis-mercurials. It is suggested that all previously reported catalysts for this reaction operate by formation of the mercurous salt – mercury combination. Equilibration studies with this combination as catalyst indicate that random exchange is not general for the redistribution reaction of mercury compounds.

The equilibration of organic substituent groups among mixtures of bis-organolead, organotin, and organomercurials has been summarized (1) by Calingaert, who coined the name "redistribution reaction" originally for the equilibration of tetraalkyllead compounds in which the substituents were homologous or structurally isomeric (2). He applied the name also to the simpler equilibration of bis-mercurials (3).

$$2R'—Hg—R \rightleftarrows R'—Hg—R' + R—Hg—R.$$

Obviously these reactions are, at most, "distributions"; the redundancy was unfortunate but at least it accentuated Calingaert's discovery that the "redistribution" was statistically random and unrelated to the structure of the substituent groups. Also, he demonstrated that the redistribution was catalyzed by metal halides and organometallic halides, including those related to the organometallic compounds that he was "redistributing".

Despite the mass of evidence relating to the redistribution reaction and its catalysis, we have found that for bis-mercurials it is quite erratic. For example, 4-cyclohexylmercuritoluene is recovered unchanged when it is treated in solvents such as methanol, petroleum ether, benzene, or dioxane with 1–5 mole % of the recommended (3) catalysts: boron fluoride etherate, aluminum chloride, magnesium bromide hydrate, zinc chloride, and cyclohexylmercuric chloride at room temperature. On the other hand, a moderately pure sample decomposes when heated without either solvent or any of the recommended catalysts, giving bis-4-tolylmercury. Likewise, for one operator, 2-butylmercuri-4-toluene in methanol or petroleum ether has been heated under reflux for 15 h without alteration in presence of mercuric bromide or 2-butylmercuric bromide. For another, a methanol solution of the substance has reacted in 8 h under reflux without added catalyst to give a 42% yield of bis-4-tolylmercury and a 47% yield of bis-2-butylmercury. Similar anomalies have been found for benzylmercuriethane.

Part of the reason for this lack of reliability has become evident during our attempts to isolate and preserve bis-cyclohexylmercury in a pure state for determination of its dielectric constant (4). The instability of this substance is apparent in its use (5) as a catalyst in the homopolar polymerization of vinyl acetate. We find that the recently crystallized white substance turns grey within an hour in air. If it is vacuum distilled immediately after crystallization, some decomposition occurs during the process, but the distillate is somewhat more stable than the crystalline material before distillation. However, it too begins to turn grey within a few hours. However, if the fresh distillate is

treated with alkali to decompose any contaminating mercurous salt and then is vacuum distilled, a product is obtained which is quite stable under vacuum or under pure nitrogen so long as it does not contain any peroxide.

It is evident that bis-cyclohexylmercury is very sensitive to oxygen. Indeed, we have been able to measure the dielectric constant in air only after addition of antioxidants. Among those tried the best is 2,5-di-*tert*-butylhydroquinone. Therefore, the oxygen seems to be acting as a source of organic peroxide.

In general, thermal stability of organomercurials (like other organometallic compounds) increases from tertiary to primary with respect to the substituent groups. Therefore, it is not unexpected that bis-benzylmercury, unlike bis-cyclohexylmercury, is stable in air at room temperature.

$$R—Hg—R' \rightleftarrows R—R' + Hg^0.$$

However, bis-benzylmercury without solvent decomposes slowly at 120–130° to metallic mercury and 1,2-diphenylethane. In benzene solution this decomposition is much slower but, as may be seen in Table I, it is accelerated by peroxidic catalysts.

TABLE I

Catalyzed decomposition of bis-benzylmercury in benzene (1:2 by weight)

Catalyst				
Name	Mole %	Temp., °C	Time, h	% Hg^0
None	0	85–105	9	1
t-Butylperoxide	5	Same	Same	6
t-Butylhydroperoxide	5	Same	Same	8
Ascaridole	5	Same	Same	40[a]
None	0	105–110	3	6
Mercurous chloride	5	Same	Same	8
Acetone peroxide	3	Same	Same	19
t-Butylperoxide	50	130	6	93[b]

[a]41% of 1,2-diphenylethane.
[b]69% of 1,2-diphenylethane, of preparative interest.

It would seem that a highly stable peroxide such as ascaridole is especially effective, as might be expected for a slow reaction such as this decomposition. It should be noted that mercurous chloride alone is relatively ineffective.

The catalysis demonstrated according to Table I explains why a comparatively stable unsymmetrical bis-mercurial, 2-butylmercuri-4-toluene, precipitates 55–60% of its mercury content as the metal during 4 h of reflux in the peroxidizable solvent dioxane. Similarly, a boiling methanol solution of the same mercurial to which 0.01% of conc. nitric acid has been added to generate peroxide (6) produces during 6 h *p*-bitolyl, of which 15% precipitates together with 88% of the original mercury in the form of the metal.

We knew that the bis-mercurials mentioned above contained traces of halogen, evidently as the organomercuric halides. Acting on the possibility that the redistribution proceeded via these salts, we have treated benzylmercuric chloride and cyclohexylmercuric chloride under the same conditions and with the same set of peroxidic catalysts as were used with the bis-mercurials. In every instance these salts have been recovered almost unchanged. However, a small amount (2–9%) of mercury and also of mercurous chloride is formed in presence of the peroxides. Thus the organomercuric salts are not catalytically redistributed by peroxides but their decomposition products might be involved.

With a knowledge of these contaminants in mind, we have now reviewed the redistribution reaction using 2-butylmercuri-4-toluene and benzylmercuriethane as typical disubstituted mercurials. The halogen-containing impurities have been removed from these mercurials by treating them with hydrazine hydrate at room temperature and then distilling them. No redistribution has been detected during distillation.

[1] $$4R—Hg—Cl + 5N_2H_4H_2O \rightarrow 2R—Hg—R + 4N_2H_5Cl + 5H_2O + N_2.$$

The examination of 2-butylmercuri-4-toluene has been made quantitatively with respect to the products, mercury and bis-4-tolylmercury, but only qualitatively with respect to the bis-2-butylmercury because of the tendency for this substance to decompose under some of the reaction conditions. The experiments (with magnetic stirring) have been carried out either in high boiling peroxide-free petroleum ether (S) or else neat (N, without solvent). Temperature, time, catalyst, and supernatant atmosphere (air or nitrogen) have been varied as shown in Table II.

It is evident from expts. 1 and 2 that the uncatalyzed reaction is impracticably slow. Moreover, substances like alkylmercuric halides (expts. 3, 5) are not effective catalysts, with or without peroxides, which themselves (expts. 4, 6, and 7) are of very low activity. In fact, the first substance which shows a significant effect is mercuric chloride (expt. 9), but the enhancement achieved by addition to it of metallic mercury (itself ineffective) shows (expt. 10) that a lower valence state is functioning. Involvement with mercurous chloride is indeed shown by the effectiveness of this substance with or without metallic mercury (expts. 11 and 12).

In fact, the effectiveness of these salts explains some of the erratic behavior characteristic of the redistribution reaction of bis-mercurials. Although Calingaert and his co-workers (3) do not mention any nonhomogeneity of their reacting systems, we have always observed that when redistribution occurs, a dirty second phase is present. Nor from the present findings would the system be expected to be clean. One may expect the following reactions to occur:

[2] $$RHgR \xrightarrow[\text{peroxide}]{\Delta} RR + Hg$$

[3] $$RHgX \rightarrow RX + Hg$$

[4] $$2RHgX \rightleftarrows R_2Hg + HgX_2$$

[5] $$HgX_2 + Hg \rightleftarrows Hg_2X_2.$$

Reaction [2] has been demonstrated in the present report (reaction [3] has been discovered, though not yet reported) from this laboratory. The equilibrium of reaction [4] will be strongly to the left, if RHgX is present only as a slight contaminant of R_2Hg. However, this equilibrium is a source of mercuric chloride which enters into the well-known equilibrium of reaction [5]. Thus, a proper combination of these four reactions will furnish some mercurous salt.

Because of a tendency for RHgCl to co-distill and co-crystallize with RHgR, it is very difficult to obtain halogen-free organodisubstituted mercury compounds. We believe that the seemingly spontaneous redistributions reported in the past were due to halogen contamination (and this belief includes our own work before we adopted the purification with hydrazine hydrate). Either because halogen is inadvertently present or else because it is introduced in ostensible catalysts such as Calingaert used, the presence of halogen will give rise to mercurous halide according to reactions [2]–[5]. Therefore, the actual catalyst may, in the past, have been synthesized *in situ*, more or less effectively. If, indeed,

32	Mercurous nitrite + mercury, 1:1	2	N_2	S	2	80	59.2	10

[a]The same results were obtained under nitrogen.

mercurous salt – mercury is the true catalyst, obviously it is better to add it deliberately.

Because of the reversibility of reactions [4]–[5], the effectiveness of additional mercurous salt as a redistribution reaction catalyst is not simply related. Thus, when diethylmercury is heated in acetone with 50 mole % of mercurous chloride, most of the latter is converted to metallic mercury, and ethylmercuric chloride is formed.

[6] $$R_2Hg + Hg_2Cl_2 \rightarrow 2RHgCl + Hg.$$

Similarly the reaction of benzylmercuri-2-butane with mercurous chloride yields mercury as well as benzylmercuric chloride and, qualitatively, 2-butylmercuric chloride. However, this heterogeneous reaction [6] is slower in the presence of a nonpolar solvent, or without solvent, than it is in acetone.

The participation of reactions [4]–[5] (i.e. reaction [6]) is quite apparent by the darkening of the surface of a white mercurous salt when it is added to a bis-mercurial either neat or in solvent. But this darkening does not proceed rapidly and only at the end of the reaction period may the mercurous salt largely or completely disappear. That is to say, the presence of mercury seems to retard reaction [4] when it is heterogeneous. This may be simply a mechanical inhibition or, more likely, it may involve a metal-rich intermediate.

[7] $$Hg + X—Hg—Hg—X \rightleftarrows X—Hg—(Hg)_n—HgX.$$

The enhancement of redistribution when metallic mercury is included initially by mortar-grinding with mercurous chloride, as shown by expt. 11 vs. 12 and elsewhere in Table II, seems to indicate this involvement. The same effect is observed when twice the amount of catalyst is treated with a half equivalent of hydrazine hydrate.

Among other mercurous salts the acetate (expt. 17) is less effective than mercurous chloride, but the sulphate (expts. 18–20) and the oxalate (expts. 21–23) are more active catalysts. The effect of either is enhanced by inclusion of metallic mercury.

The most effective catalyst is mercurous nitrate (expts. 24–30), but the rate is unaltered by inclusion of metallic mercury. Although mercurous nitrite is less effective than the nitrate, its effectiveness also is unaltered appreciably by added mercury metal which enhances the effect of the chloride, sulphate, and oxalate. This apparent contradiction is resolved by the observation that the nitrite and nitrate generate metal according to reaction [6] from the solution of bis-mercurial much more rapidly than does the chloride, sulphate, or oxalate. Thus sufficient mercury to satisfy eq. [7] is soon present and added metal is superfluous. The ready evolution of the metal may be due to the peroxide-forming tendency of nitrate (and nitrite) salts.

The catalysts that are mentioned in Table II are nominally heterogeneous. There is visual evidence of reaction at the catalyst surface in an unstirred system in which bis-4-tolylmercury or bis-benzylmercury appears as a crystalline solid because the crystals seem to be growing from the mass of darkened mercurous salt. Of course the catalysis might actually be homogeneous despite this appearance. We have found difficulty in making a firm decision because systems which are strictly homogeneous cause reaction alternative to redistribution. The inclusion of acid to bring about homogeneity causes demetalation.

Since mercurous nitrate is somewhat soluble in methanol, a solution has been refluxed containing 1 equivalent of 2-butylmercuri-4-toluene, 0.02 equivalent of mercurous nitrate, and a small amount of nitric acid sufficient to make a clear solution. After 6 h, 0.9 equivalent of the mercury precipitated as the metal and no bis-4-tolylmercury was isolable. Instead *p*-bitolyl was found. Elimination of the nitric acid from the system reduces metal formation markedly and a 19% yield of the symmetrical bis-4-tolylmercury was obtained, but the system was cloudy (heterogeneous) in absence of the nitric acid. A relatively

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

clearer solution is obtained without acid when the 2-butylmercuri-4-toluene and 0.02 equivalent of mercurous nitrate are refluxed 4 h in peroxide-free dioxane under nitrogen, but redistribution, as exemplified by bis-4-tolylmercury, occurs only by a few percent despite precipitation of about 0.02 equivalent of metallic mercury. In summation, the catalysis does not seem to be homogeneous but our proof is equivocal.

Likewise, it might be doubted whether our redistribution catalyst is alternative to those reported by Calingaert *et al.* or whether the substances that they used for catalysis actually generated mercury plus mercurous salt. They do not describe their reaction systems in sufficient detail to disclose whether a nondescript second phase is present. We have attempted to simulate their systems by comparing the effectiveness of mercurous chloride plus mercury on the one hand with aluminium chloride, and on the other at room temperature with four bis-mercurial combinations: benzylmercuriethane, bis-ethylmercury plus bis-*p*-tolylmercury, 2-butylmercuri-4-toluene and bis-2-butylmercury plus bis-4-tolylmercury. With either of the two catalysts the systems did not come to equilibrium even after 140 h, but they are about equally effective. Moreover, the two catalysts resemble each other in appearance while the reactions are proceeding. It is our opinion that aluminium chloride is effective as a catalyst for redistribution because it reacts with bis-mercurials that are present to give mercurous chloride and mercury.

The evidence for this opinion is the presence of metallic mercury among the final products. Although mercurous chloride could not be identified, its presence may be expected during the reaction if the following equations are valid.

$$R_2Hg + AlX_3 \leftrightarrows RHgX + RAlX_2 \quad [8]$$

$$RHgX + AlX_3 \leftrightarrows RHg^+(AlX_4)^- \quad [9]$$

$$RHg^+ \rightarrow R^+ + Hg^0 \quad [10]$$

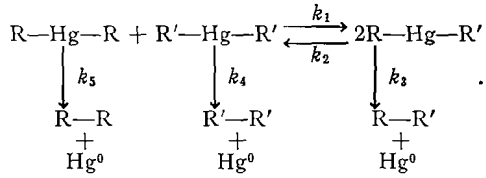
$$R^+(AlX_4) \rightarrow RX + AlX_3. \quad [11]$$

Equation [8] is well known; indeed Calingaert invoked it (1) in his mechanism according to which he would consider RHgX to be the catalyst. Since the present study excludes this type as the direct catalyst, we suggest that metallic mercury is formed according to [9]–[11] because the RHg^+ cation will be unstable (7). Since mercuric halide is potentially available from the equilibrium [4], the initial presence of mercurous halide may be expected in view of [5]. Therefore the catalyst combination, mercurous salt plus mercury, can arise from aluminium chloride and bis-mercurial.

Of course, a reaction which is accelerated by a material catalyst should proceed satisfactorily without that catalyst, if the temperature is sufficiently raised, providing of course that the system (or part of it) is otherwise stable. Rausch has reported (8) that methylmercuribenzene, as well as bis-methylmercury plus bis-phenylmercury, undergoes the redistribution reaction cleanly and to almost the same equilibrium. Evidently, no metallic mercury is formed. This is a necessary condition since if one of the three bis-mercurials in the system were thermally more or less stable than the others a false equilibrium value might be observed, depending on the relative rates of the redistribution versus the demetalation reaction. The error would not necessarily be detected by the alternative directions of approach to equilibrium. Since Rausch did not report any metallic mercury in his redistribution reaction, it would seem that bis-methylmercury, bis-phenylmercury, and methylmercuribenzene all are equally stable at 150°. But this circumstance may not prevail with other substituent groups.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The error would easily be detectable if R—Hg—R or R′—Hg—R′ were much less stable than R—Hg—R′, especially if the redistribution rate were slow, i.e., if k_4 or $k_5 \gg k_2 > k_3$,



This circumstance is apparent in the following two examples. When 2-butylmercuri-4-toluene on the one hand, and an equimolar mixture of bis-2-butylmercury and bis-4-tolylmercury on the other, are heated at 140–150° under nitrogen for 4.5 h the amounts of mercury precipitated are 7% and 30% respectively. The system initially containing the mixed bis-mercurial yields 45% of the bis-4-tolylmercury expected if the distribution were random, while the system initially two-component yields 167% of the bis-4-tolylmercury expected upon random distribution. Clearly, in this case, the bis-2-butylmercury has demetalated at a rate faster than redistribution equilibrium can be established.

An extreme case where redistribution is impossible at high temperatures is shown by an initially equivalent mixture of bis-ethylmercury and bis-benzylmercury. When this mixture is heated to 140–150° for 4.5 h, 50% of the total mercury is precipitated as the metal. Except for traces, all that is left is bis-ethylmercury, the dibenzylmercury having been demetalated completely.

From these results it is apparent that thermal redistribution equilibration is impractical when secondary alkyl, aralkyl, and other electropositive substituents are involved.

It is apparent that if one disregards the obvious basis of error, i.e. appearance of metallic mercury, a false value for equilibrium will be obtained if $k_3 >$ or $= k_2 > k_4 = k_5$ because the equal amounts of bis-mercurials in the product will be misleading. Perhaps it is fortuitous that unsymmetrically disubstituted mercury is frequently more stable thermally than the bis-mercurials to which redistribution would convert it, so that this error will be unlikely. However, one cannot be certain that this rule is unequivocal and circumstances where k_1–k_5 are all of the same order of magnitude may exist and lead to erroneous conclusions. When secondary or tertiary alkyl, aralkyl, or other electropositive substituents are present, the precipitated metal may be expected during high-temperature redistribution. In this circumstance an equilibrium value is unreliable.

At lower temperatures in hydrocarbon solvent one may with some bis-mercurials get a meaningful value for equilibrium by use of catalyst such as mercurous nitrate. Table III shows how the value is chosen for the benzyl–ethyl–mercury system. Comparison of uncatalyzed expts. 1 and 5 of Table III shows that neither represents a state of equilibrium, but it does indicate that k_2 is larger than k_1. These magnitudes are reflected in the approximate constant k_1/k_2 of about 0.24 which may be derived from the data of expts. 2 and 3 where the region of equilibrium seems to be established. The value should be accepted with some reservation in view of the amount of metallic mercury which is evolved. However, it may be noted that expt. 4 at room temperature produces about the same amount of metal, although equilibrium seems not to have been attained. It would seem from expt. 4 that the production of metal is not due to a high-temperature demetalation.

[a]Magnetically stirred.

Attempts to find the redistribution equilibrium for the system bis-2-butylmercury plus bis-4-tolylmercury $\rightleftarrows$ 2-butylmercuri-4-toluene have not been so satisfactory according to Table IV. Evidently the difficulty is due to the instability of bis-2-butylmercury as may be seen by comparison of expts. 1 and 2 where a catalyst is not involved and of expts. 2 and 7 where bis-2-butylmercury is present initially. The same disparity between the unstable secondary bis-mercurial and the aromatic bis-mercurial is seen in expts. 3–4. As may be seen in expt. 6 the instability problem may be compensated by low temperature and long duration, but it is doubtful whether equilibrium has been reached. Actually expt. 5 in which the system is stirred gives values which may be close to equilibrium, in which case k_1/k_2 is about 0.17. Whether or not expts. 6 and 5 approach or reach equilibrium, the direction is such that the equilibrium constant cannot equal four.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

If the redistribution reaction of organodisubstituted mercury were a random exchange process regardless of the polarity of the substituents as Calingaert *et al.* have tried to demonstrate, then the equilibrium constant ought to be four. As may be seen from the results of Tables IV and V, the observed equilibria, even if they are in error, could never conform to the Calingaert condition. We suggest that the small difference in polarity among the lower alkyl groups that form the basis for Calingaert's postulation are not sufficiently different in polarity to warrant a generalization about the redistribution reaction. If the term "redistribution" has become associated with randomization then this association ought to be discontinued.

TABLE V

Attempted equilibration by means of aluminium chloride

Expt. No.	Disubstituted mercury, mmole			Time, h	Hg^0, mg
	Bis-2-butyl	Bis-4-tolyl	2-Butyl, 4-tolyl		
1 Initial	3.92	3.92	None	137	30
Final	2.96	3.36	0.53		
	Bis-2-butyl	Bis-4-tolyl	2-Butyl, 4-tolyl		
2 Initial	None	None	4.33	139	50
Final	0.14	0.23	3.58		
	Bis-ethyl	Bis-benzyl	Ethyl, benzyl		
3 Initial	3.92	3.92	None	141	110
Final	2.08	3.30	0.73		
	Bis-ethyl	Bis-benzyl	Ethyl, benzyl		
4 Initial	None	None	3.90	117	45
Final	0.21	0.26	2.56		

It follows also that if randomization is not characteristic of the redistribution reaction then the correlative concept that redistribution occurs via free radical transfer likewise has no experimental basis.

EXPERIMENTAL*

Bis-cyclohexylmercury, Halogen and Peroxide Free

The stirred Grignard reagent prepared in 85% yield, 0.34 mole, from cyclohexyl bromide (9), b.p. 88° (76 mm), n_D^{14} 1.49572, m.p. −49 to −48, was treated slowly under nitrogen with 50.4 g (0.14 mole) of dry mercuric bromide during 9 h at 25° and then was poured onto crushed ice. After acidification of the system with 30 ml of acetic acid the nonaqueous layer, dried with magnesium sulphate, was evaporated, leaving 44 g (86%) melting above 70°. This crude product in 15 ml of diethyl ether was treated with 10 ml of 99–100% hydrazine hydrate in the dark during a minimum time of 20 h. After addition of 10 ml of water and separation of the aqueous phase the latter was twice extracted with ether which was added to the nonaqueous phase. The combined ether solution, washed once with water, was dried with magnesium sulphate, and distilled at 125° (1 mm). The distillate, m.p. 76–78°, which contained some mercury, was crystallized from absolute ethanol, m.p. 78–79°. This product will begin to decompose in air after several hours, but will remain white for long periods under nitrogen or in vacuum. It may be stabilized for 24 h in air, if it is dissolved in acetone containing 2% of 2,5-di-*tert*-butylhydroquinone and the resulting solution evaporated to dryness *in vacuo*. A portion heated to 170 °C *in vacuo* (2.43 mmole) liberated cyclohexene according to infrared absorption at 3.32 and 5.92 μ. The thermal stability of this bis-mercurial at 25° was not decreased by contamination with mercurous chloride.

Benzylmercuriethane, Halogen and Peroxide Free

The Grignard reagent from 0.09 g-atom of magnesium and 0.09 mole of ethyl bromide in 150 ml of diethyl ether was stirred under nitrogen at +4 °C while 11.7 g (35.8 mole) of benzylmercuric chloride, m.p. 105.5–106°, (10) was added in small portions during 15 min. After 30 min subsequent stirring the system was poured into a mixture of ice plus 1% aqueous sulphuric acid. The aqueous layer was twice extracted with peroxide-free diethyl ether and the entire nonaqueous portion, dried with magnesium sulphate, was distilled finally at 0.04 mm to give 10.9 g (70%) of benzylmercuriethane, b.p. 89–91°. The distillation residue yielded 0.6 g of bis-benzylmercury, m.p. 108–110.

**Melting points have been corrected against reliable standards.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The crude product in 10 ml of diethyl ether was treated with 10 ml of 95–100% hydrazine hydrate. After the mixture was stirred for at least 24 h, 10 ml of water was added and the aqueous layer was extracted with peroxide-free ether. The combined ether solution, twice washed with water and dried with magnesium sulphate, was distilled at 0.01 mm, b.p. 85–90 °C, in 78% recovery.

2-Butylmercuri-4-toluene, Halogen and Peroxide Free

The Grignard reagent, from 0.156 g-atom of magnesium and 0.155 mole of *p*-bromotoluene, in 270 ml of diethyl ether was stirred at −11 °C while a solution of 31.15 g (0.092 mole) of 2-butylmercuric bromide (11), m.p. 42.5–43 °C, in 260 ml of diethyl ether was added during 35 min. After 30 min stirring at the same temperature the whole was poured into a mixture of ice and 1% aqueous sulphuric acid. The aqueous layer was extracted with peroxide-free ether. The combination of nonaqueous parts was washed with water and then was stirred with 20 ml of 99–100% hydrazine hydrate for 24 h. The nonaqueous layer was separated, dried with magnesium sulphate, and distilled finally at 95–100° (0.01 mm) to yield 30.1 g (94%).

When (+)2-butylmercuric bromide, $[\alpha]_D^{28} = +3.24°$ in acetone, was used in this preparation the resulting 2-butylmercuri-4-toluene gave 2-butylmercuric bromide, m.p. 34–35°, $[\alpha]_D^{28} = +2.80°$ in acetone, when it was treated with 1 equivalent of mercuric bromide in methanol.

Benzylmercuric Chloride with Peroxides

A solution of benzylmercuric chloride (0.5 g) in benzene containing 4.3 mole % of ascaridole, *tert*-butyl hydroperoxide, or di-*tert*-butyl peroxide in 2 ml of benzene was heated to 110° for 3.5 h. The rest was taken up in benzene to leave 10–15 mg of mercurous chloride (black with alkal, positive for chlorine upon elemental analyses). The benzene solution upon evaporation left 410 mg (82%) unchanged chloromercurial, m.p. 105.5–106°.

Preparation of Mercurous Salts

Mercurous oxalate monohydrate was prepared in 99% yield by treating (12) a solution of 1.12 g of mercurous nitrate dihydrate in 3 ml of water containing 10 mg of conc. nitric acid with 0.5 g of oxalic acid with shaking. The precipitate was filtered, washed with water, acetone, and ether, and dried *in vacuo*. The salt did not lose water at 60° *in vacuo* for 22 h.

Mercurous sulphate was prepared in 33% yield (13) by treatment of 1.12 g of mercurous nitrate dihydrate in 3 ml of water plus 10 mg of conc. nitric acid with 2 ml of 30% aqueous sulphuric acid. The precipitate was washed with water and vacuum dried.

Mercurous nitrite was prepared by treating a solution of 5 ml conc. nitric acid and 15 ml of water with 20 g of metallic mercury at 30–35° for 5 h and then at 25° for 3 days. The filtrate from this sytem when cooled gave white crystals instead of yellow ones (14). They gave a positive Liebermann test. According to the mercurous chloride obtained from 300 mg, this salt is the dihydrate of the monomeric species.

Redistribution with Aluminium Chloride

The experiments summarized in Table V were effected in petroleum ether (b.p. 40–60, 3 ml for the unsymmetrical and 6 ml for the symmetrical mercurials) at 20–25° and were processed after reaction by filtration; the filtrate was treated with water, then dried and distilled. The initial precipitate was extracted with benzene, leaving dirty metallic mercury. Evaporation of the benzene left the petroleum ether insoluble bis-mercurial.

Preparation of Mercurous Salt – Mercury Metal Systems

Generally the ingredients were ground in a mortar until the metal was no longer visible. In one instance 1.12 g of mercurous nitrate was suspended in 1 ml of water to which 39 mg of 100% hydrazine hydrate was added. The suspension was filtered after 10 min and washed with water and acetone, then vacuum dried.

Bis-ethylmercury with Mercurous Chloride

A system comprised of 1.61 g (3.42 mmole) of mercurous chloride and 1.77 g (6.84 mmole) of bis-ethylmercury in 30 ml of acetone was heated for 1 h. The mercurous chloride gradually was converted to metallic mercury. After 15 h the metal was filtered off, 0.675 g (97%). The filtrate was evaporated and the residue (1.95 g) was washed with petroleum ether, b.p. 40–60°, leaving 0.80 g (88%) of ethylmercuric chloride, m.p. 190–192°.

Redistribution Reaction, Heterogeneous Catalyst

Reactions were carried out in 25 ml Erlenmeyer flasks under a reflux condenser in a temperature-regulated bath. When stirring was desired a glass-covered Kovar bar was used with magnet drive. Some reactions were carried out under air and some under nitrogen. When petroleum ether (b.p. 90–100°) was used it was dry, free from unsaturated impurities, and peroxide free.

Upon completion, the insoluble part was filtered off and washed with petroleum ether (b.p. 40–60°), dried, and weighed. Then it was extracted with benzene if bis-4-tolylmercury was to be removed or with acetone if it contained bis-benzylmercury. The spent catalyst (principally metal) was then weighed to obtain by difference the yield of bis-benzylmercury or bis-4-tolylmercury. The extracts were vacuum evaporated at room temperature via a dry ice cooled trap, and the weighed residue was distilled. The boiling points of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

several products are: bis-ethylmercury, b.p. 72–74° (35 mm); bis-2-butylmercury, 45–48° (0.8 mm); benzylmercuriethane, b.p. 85–88° (0.01 mm); benzylmercuri-2-butane, b.p. 90–94° (0.02 mm); 2-butylmercuri-4-toluene, b.p. 105–110° (0.06 mm). Since the first two of these products tended to co-distill with the solvent the cold-trap content was treated with an amount of mercuric bromide in acetone, which was equivalent to the difference between the theoretical yield and the amount obtained by distillation. After 1 h this system was vacuum evaporated. From the increased weight the additional dialkylmercury could be calculated. The distilled dialkylmercury was also dissolved in acetone or methanol and treated with an equivalent amount of mercuric bromide, to identify the distillate by the melting point of the corresponding alkylmercuric bromide.

The residues in the flasks after distillation were dissolved in benzene or acetone, filtered, vacuum evaporated, washed with petroleum ether, b.p. 40–60, and dried before weighing as bis-4-tolylmercury (m.p. 243–245°) or bis-benzylmercury (m.p. 110–111°).

Redistribution Reaction, "Homogeneous Catalyst"

A cloudy system of 0.5 g (1.43 mmole) of 2-butylmercuri-4-toluene and 16 mg (0.029 mmole) of mercurous nitrate in 15 ml each of water and methanol plus 25 ml of acetone was heated for 6 h under reflux at a bath temperature of 83–90°. Subsequently 70 ml of water was added and the remaining precipitate was filtered off, weight 220 mg containing mercury. Extraction with benzene left 150 mg, largely mercury. Evaporation of the benzene solution left 70 mg (19%) of bis-4-tolylmercury, m.p. 241–243°. Similar results were obtained when the reaction medium was methanol alone, but the yield, m.p. 240–242°, was only 5 mg when dioxane was the medium.

When 5 mg of conc. nitric acid was included in the system where methanol alone was used, the precipitation of metal was very large (250 mg) and the isolable product was 4,4′-ditolyl, m.p. 115–118°. These products were the same in type and yield when mercurous nitrate was not included in the system.

PHOTO-INITIATED REACTIONS OF THIOLS AND OLEFINS

I. THE THIYL RADICAL CATALYZED ISOMERIZATION OF BUTENE-2 AND 1,2-ETHYLENE-d_2

D. M. GRAHAM, R. L. MIEVILLE, AND C. SIVERTZ
Department of Chemistry, University of Western Ontario, London, Ontario

Received February 21, 1964

ABSTRACT

Kinetic studies have been made of the isomerization of butene-2 and 1,2-ethylene-d_2 catalyzed by thiyl radicals produced from the photolysis of methanethiol. The rate of isomerization was found to be first order with respect to both the olefin and $CH_3\dot{S}$ concentrations. The lack of influence of pressure on the reaction rate, at pressures above about 4 mm, leads to a simple mechanism in which isomerization is considered to occur as a result of thermal decomposition of the collisionally stabilized adduct radical produced in the reaction $CH_3\dot{S} + RCH{=}CHR + M \rightarrow CH_3SCH(R)\dot{C}HR + M$. The rate constants for this attack step were found to be 2×10^7 and 4.8×10^6 l mole^{-1} s^{-1} for butene-2 and ethylene-d_2, respectively. In both cases the activation energy for isomerization was found to be close to zero. From a kinetic study of the isomerization of *cis*-butene-2 in the presence of butadiene-1,3, which acts as a retarder, the attack constant for butadiene at 25 °C was found to be 4.5×10^8 l mole^{-1} s^{-1}.

INTRODUCTION

The addition of thiols to olefins has been extensively studied in solution. The reaction was found to be a comparatively fast chain reaction of considerable chain length. Because of this latter fact, a simple kinetic analysis of the system could be made and the rate constants for the individual steps in the chain sequence could be readily determined. These results have been summarized in a number of review articles (1, 2). When an attempt to extend the measurements to the gas phase was made, it was found that, for unconjugated olefins, the overall activation energy which was observed to be of the order of 3 kcal in solution became negative by about 8 kcal (3). In addition, it was observed that in the case of *cis*-butene-2, the addition reaction was accompanied by a much faster isomerization reaction (4). These results may be explained by assuming that the attack of the thiyl radical on a double bond is reversible.

The work reported here was undertaken to determine the detailed mechanism for this reverse reaction and its role in isomerization and addition, the latter to be discussed in Part II (5).

EXPERIMENTAL

Chemicals

All of the hydrocarbons used were Phillips "Pure Grade" and, with the exception of ethylene, were purified by gas chromatography on a 50 ft diethylformamide column. The compounds, *cis*- and *trans*-ethylene-d_2, were prepared by reduction of acetylene-d_2 with copper-activated zinc and chromous chloride, respectively (6). Sulphur hexafluoride (Matheson, 98.0%) and carbon dioxide (Matheson, 99.99%) were used after six successive trap-to-trap distillations at 10^{-6} mm. Methanethiol (Eastman Reagent Grade) was purified in a similar manner; no impurities could be detected by gas chromatography.

Apparatus

The reaction cell consisted of a cylindrical quartz vessel, 5 cm in diameter and 10 cm long, with plane windows, and was connected to a grease-free vacuum manifold by means of Springham diaphragm valves in such a way that the "dead volume" was restricted to less than 1% of the total. The cell was housed in an aluminium block thermostat with quartz windows which could be regulated to ±0.1 °C. The light source was a Hanovia SH 616A high-pressure mercury arc operated at 1.2 A and 127 V d-c. using a regulated power supply. A system of quartz lenses was used to focus and collimate the light. Most of the work was carried out using a 10 mm thick solution filter of 2,7-dimethyl-3,6-diazocyclohepta-1,6-diene iodide (10% in water) to isolate the 2537 Å region.

Analysis

The isomerization of *cis*- and *trans*-butene-2 was followed by gas chromatography using a 300 ft polypropylene glycol capillary column and a hydrogen flame ionization detector. The isomerization of *trans*-

ethylene-d_2 was determined using the bands at 842 cm^{-1} (*cis*) and 987 cm^{-1} (*trans*) by means of a Beckman IR-7 infrared spectrophotometer.

Rate of Initiation

Photolysis of methanethiol produces hydrogen and methyl disulphide with a quantum yield approaching 1 (7). In the presence of olefin both of the primary products, $CH_3\dot{S}$ and H, are very reactive and will be capable of initiating a chain. There will arise some uncertainty about the details of the initiating reaction under widely varying concentration conditions because of the competition for H between thiol and olefin. However, provided the chain length is sufficiently long, this information is not required and it is only necessary to know the number of initiating radicals produced in unit time. Therefore, since the chain lengths observed were about 100, the reasonable assumption has been made that the rate of initiation in the presence of olefin is twice the rate of hydrogen production in its absence.

The rate of formation of hydrogen was measured as a function of the thiol concentration by means of a mass spectrometer. A known amount of helium was added to the reaction cell initially and was used as an internal reference.

Since, even at low thiol pressures, an appreciable fraction of the total light is absorbed by the reacting mixture, the rate of primary radical production is not uniform throughout the cell. The mean rate of isomerization (or addition) is therefore proportional to the square root of the initiation rate averaged over the length of the cell, assuming biradical termination. A procedure by which $\overline{r_i^{1/2}}$ may be calculated has been developed by Burns and Dainton for a system in which monochromatic light is used to initiate reaction (8). Unfortunately it proved impossible to isolate one single active spectral line from the lamp used, and it was necessary to modify the averaging procedure to allow for the different absorption characteristics of the various wavelengths present.

The rate of initiation in a layer of depth dl, at a distance l from the illuminated face of the cell, will depend on the number of quanta absorbed in unit time, I_a, and the quantum yield for primary radical formation. Therefore, for polychromatic light,

$$[1] \qquad r_i\,(\text{local}) = \sum_\lambda (\phi I_a)_\lambda = \frac{d}{dl}\sum_\lambda (\phi I_0)_\lambda[1 - e^{-\epsilon_\lambda c l}] = \sum_\lambda (\phi I_0)_\lambda \epsilon_\lambda c\, e^{-\epsilon_\lambda c l},$$

where I_0 is the light intensity of wavelength λ entering the illuminated face of the cell and c is the concentration of absorbing substance whose extinction coefficient is ϵ_λ.

The mean rate of initiation in a cell of path length L is

$$[2] \qquad \overline{r_i} = \frac{1}{L}\int_0^L r_i\,(\text{local})\,dl = \frac{1}{L}\sum_\lambda (\phi I_0)_\lambda[1 - e^{-\epsilon_\lambda c L}].$$

The mean square root rate of initiation is

$$[3] \qquad \overline{r_i^{1/2}} = \frac{1}{L}\int_0^L r_i^{1/2}\,(\text{local})\,dl = (\phi I_0)_{\lambda_1}^{1/2} g,$$

where

$$g = \left(\frac{\epsilon_{\lambda_1} c}{L}\right)^{1/2}\int_0^L G^{1/2}(c, l)\,dl,$$

$$G(c, l) = \sum_\lambda \frac{(\phi I_0)_\lambda \epsilon_\lambda}{(\phi I_0)_{\lambda_1}\epsilon_{\lambda_1}} e^{-\epsilon_\lambda c l},$$

and ϕ_{λ_1}, $I_{0\lambda_1}$, and ϵ_{λ_1} are, respectively, the quantum efficiency, the incident light intensity, and the extinction coefficient for one specific wavelength.

These equations were readily applied since it was possible to attribute the initiation to three lines at 254, 257, and 265 mμ on the basis of the transmission characteristics of the filter and of methanethiol, and the spectral distribution of the lamp. Using the measured extinction coefficients of methanethiol at these wavelengths and the variation in rate of hydrogen production with thiol concentration in the absence of olefin, one can obtain an equation of the form of [2]. The relation obtained for the 10 cm cell was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$$[2'] \qquad r_i \times 10^{10} = 48.6(1 - e^{-1431c}) + 25.0(1 - e^{-699c}) + 143(1 - e^{-168c}).$$

A comparison of the initiation rate calculated from this equation with the experimentally observed rates is given in Fig. 1.

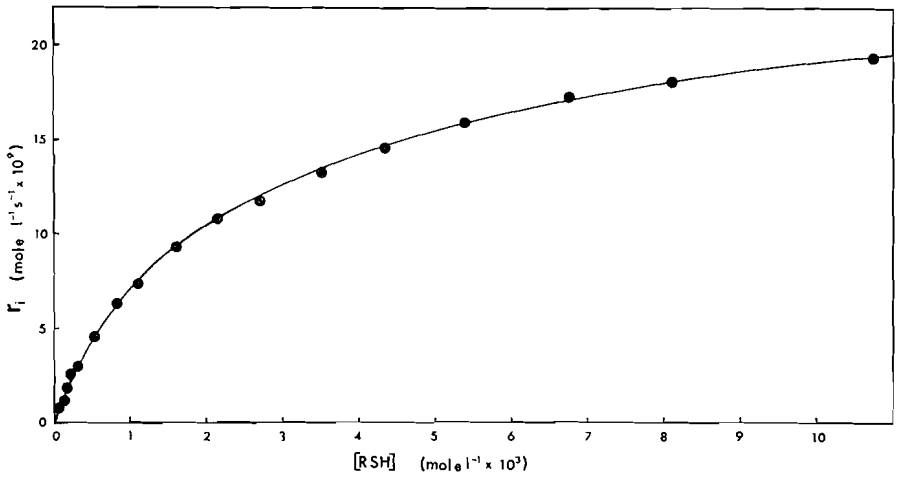

FIG. 1. Rate of initiation: the curve is calculated from eq. [2']; the points were obtained from the rates of hydrogen production in the absence of olefin.

$G(c, l)$ can therefore be determined as a function of path length and concentration; g may be evaluated for different thiol concentrations by numerical integration of $G^{1/2}(c, l)$; and the mean square root initiation evaluated.

The rate of isomerization of a standard mixture of reactants was determined several times during the course of the hydrogen evolution measurements. The isomerization rate of this mixture was used during the subsequent experimental work to correct for variations in light intensity. It has, however, been assumed that the relative intensities of the three spectral lines remained the same, i.e., that g remains constant. This assumption is not unreasonable since the transmission characteristics of the filter solution was found to be unchanged over the period in which this work was carried out and, since the operating conditions of the lamp were maintained constant, it is unlikely that the spectral distribution of the lamp should change appreciably.

RESULTS AND DISCUSSION

The Mechanism

The main features of the gas phase reaction may be explained in terms of the formation of an adduct radical, $\dot{X}^*$, which contains initially the exothermic heat of reaction. Dissociation of $\dot{X}^*$ to produce *cis* or *trans* olefin occurs after a short time interval which depends upon the way in which the energy is initially distributed. Competing with the reverse reaction is collisional de-energization to $\dot{X}$. This stabilized radical then may either dehydrogenate thiol or undergo collisional re-energization to the state $\dot{X}^0$, which may then dissociate to *cis* or *trans* olefin and $R\dot{S}$. The distinction between the species $\dot{X}^*$ and $\dot{X}^0$ is necessary since the former arises from chemical energization whereas the latter is produced thermally and will thus belong to a much broader energy distribution. For a large exothermic heat of reaction, all $\dot{X}^*$ will have approximately the same energy. The proposed mechanism is shown in Fig. 2.

Application of the steady state approximation to this mechanism yields the following expression for the initial rate of isomerization, R_1, in this case the initial rate of formation of *trans* from pure *cis* olefin.†

†*For consistency the probability factor* ρ_{-1}^0 *has been rewritten* ρ_3 *in eq. [4].*

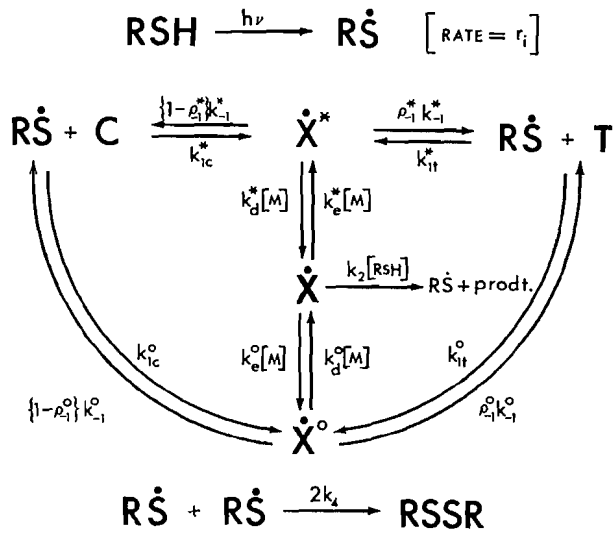

FIG. 2. The reaction mechanism: C and T represent the *cis* and *trans* forms of the olefin; $\dot{X}^*$, $\dot{X}$, $\dot{X}^0$ represent the chemically energized, the de-energized, and the re-energized adduct radicals, respectively; ρ is the probability that a decomposition reaction produces the *trans* isomer.

[4] $$R_1 = \left[\frac{d[T]}{dt}\right]_0 = \rho_{-1}{}^*k_{-1}{}^*[\dot{X}^*] + \rho_{-1}{}^0k_{-1}{}^0[\dot{X}^0]$$

$$= \left[\frac{r_i}{2k_4}\right]^{1/2} \phi^* k_{1c}[C]\left\{\frac{\rho_{-1}{}^*k_{-1}{}^*}{k_d{}^*[M]} + \frac{\rho_3 k_3}{k_3 + k_2[RSH]}\right\}.$$

where

$$\phi = k_d[M]/[k_d[M] + k_{-1}],$$

$$k_3 = \phi^0 k_{-1}{}^0 k_e{}^0[M]/k_d{}^0[M].$$

k_3 represents a mean effective rate constant for the thermal decomposition of $\dot{X}$, the stabilized intermediate. It will depend on pressure in the same way as the quenching coefficient ϕ^0, and at high pressures, as $\phi^0 \rightarrow 1$, k_3 will become independent of pressure.

Isomerization of Butene-2

According to eq. [4], if isomerization occurs by dissociation of $\dot{X}^*$, there will be an inverse relation between isomerization and pressure. On the other hand, the isomerization path through the thermal decomposition of $\dot{X}$ should be independent of pressure at sufficiently high pressures. To distinguish between these two paths, isomerization rates were measured as a function of total pressure in the presence of an inert gas. It was found that, below about 4 mm total pressure of reactants, addition of SF_6 or CO_2 increased the rate of isomerization. The increase was linearly dependent on the amount of gas added at low pressures, and at higher pressures of inert gas the rate approached a maximum value. This pressure effect is just the opposite of what might be expected on the basis of eq. [4]. It can be explained, however, in terms of wall termination. Whereas the high-pressure rate was found to be proportional to the square root of the incident light intensity, I_0, and of the initial thiol concentration (Fig. 3), the low-pressure rate was almost first order with respect to both of these variables. Since at low thiol concentrations $r_i = kI_0[RSH]$, these results indicate second order termination at high pressures and predominantly first

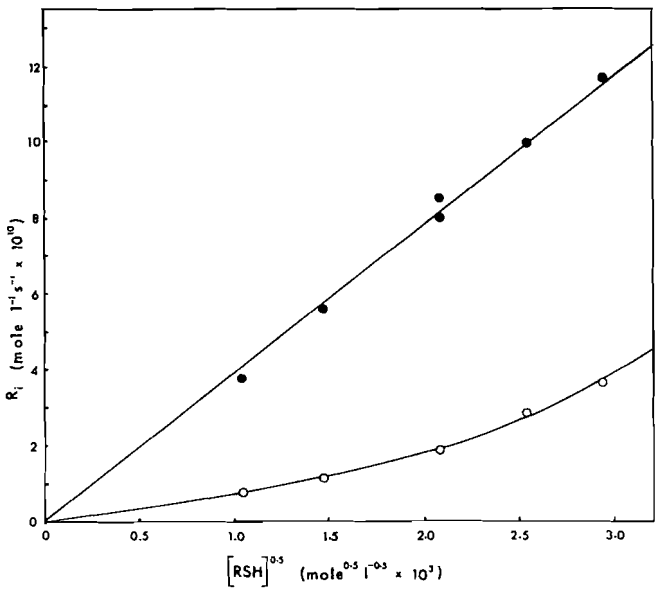

FIG. 3. Dependence of the initial rate of isomerization on thiol concentration at 25 °C, [C] = 5.38×10^{-6}: ● [SF_6] = 50 mm; ○ [SF_6] = 0.

order at low pressures. The dependence on inert gas pressure is also what might be expected for first order wall termination.

It may be concluded therefore that isomerization is due to thermal decomposition of the energized radical $\dot{X}$, and the rate becomes independent of pressure for homogeneous termination.

$$[5] \qquad R_1 = \left[\frac{d[T]}{dt}\right]_0 = \left[\frac{r_i}{2k_4}\right]^{1/2} \frac{\rho_3 k_3 k_{1c}[C]}{k_3 + k_2[RSH]}.$$

From the results given in Fig. 4 and Table I, it is seen that the initial rate of isomerization is first order with respect to olefin and zero order with respect to thiol. This is consistent with eq. [5] if, at 25 °C and [RSH] $< 3 \times 10^{-3}$ mole l^{-1}, $k_3 \gg k_2$ [RSH].

These conclusions are also consistent with the observations on the temperature dependence of the isomerization rate given in Fig. 5. At low thiol concentrations (2×10^{-4} mole l^{-1}) the isomerization rate is independent of temperature ($E_a = 0.050 \pm 0.046$ kcal), whereas at higher thiol concentrations a small positive activation energy of 1.9 ± 0.7 kcal (90% confidence limits) appears. The activation energy for the thermal decomposition of $\dot{X}$, E_3, should be of the same order of magnitude as the exothermic heat of reaction for the attack step. The heats of formation of the thiyl radical and the adduct radicals, $\dot{X}$, have been estimated according to Franklin's method (9), and from these the estimated heats of reaction are about 15 kcal for ethylene and 18 kcal for butene. At low [RSH], $k_3 \gg k_2$ [RSH] and the overall activation energy will be $E_{1c} + E_{\rho_3} - \frac{1}{2}E_4$. The second term might be expected to be small and negative and may to a certain extent compensate for the small activation energy possible in the attack step. At high thiol concentrations the term k_2[RSH] begins to contribute to the denominator and E_3 begins to contribute to the total activation energy.

Thus far in the discussion it has been assumed that chain termination occurs primarily by combination of two thiyl radicals. It may be readily shown that if either $\dot{X} + R\dot{S}$ or $\dot{X} + \dot{X}$ termination predominated, the rate of isomerization would be either one-half or zero order, respectively, with respect to *cis*-olefin concentration. Since first order dependence on olefin was observed over a wide concentration range of both olefin and thiol it may be concluded that $R\dot{S} + R\dot{S}$ termination does indeed predominate. This is also confirmed by the kinetics of the addition reaction and by the fact that the termination rate constant, determined by applying the method of intermittent illumination to the addition reaction, was the same within experimental error for ethylene, propylene, butene-2, and isobutene (5, 10).

For the concentration region where $k_3 \gg k_2[\mathrm{RSH}]$ the rate equation may be integrated to give

$$[6] \qquad -\ln\left\{1 - \left(\frac{1+K}{K}\right)\alpha\right\} = \left(\frac{r_i}{2k_4}\right)^{1/2}\left(\frac{1+K}{K}\right)\rho_3 k_{1c} t,$$

where α is the fractional conversion of *cis* to *trans* and the equilibrium constant K is defined as

$$[7] \qquad K = \frac{[\mathrm{T}]_{eq}}{[\mathrm{C}]_{eq}} = \frac{k_{1c}\rho_3}{k_{1t}(1-\rho_3)}.$$

The rate constant $\rho_3 k_{1c}$ may be evaluated either from eq. [5] using initial rates or from eq. [6] if α is determined as a function of time. The results obtained by both methods from data of the form given in Fig. 4 and from integrated plots of the type shown in Fig. 6 were

found to be in good agreement. Some of the former results are given in Table I. It is apparent from these that eq. [5] with $k_3 \gg k_2[RSH]$ is valid over a wide range of butene and thiol concentrations, and that the relation between $\overline{r_i^{1/2}}$ and thiol concentration determined from hydrogen evolution measurements is also valid over a wide concentration range.

*In the presence of 50 mm SF_6.

For $K = 3.2$ at 25 °C (11) and $k_4 = (2.5 \pm 0.7) \times 10^{10}$ l mole^{-1} s^{-1} (5), it is found that $\rho_3 k_{1c} = 1.6 \times 10^7$ l mole^{-1} s^{-1}. The corresponding rate constant for the isomerization of the *trans* form may be determined from equations equivalent to [5] and [6]. However, the experimental difficulties in measuring the very small conversions necessary do not permit precise estimates to be made in this way. Rather eq. [7] has been used to calculate $(1 - \rho_3)k_{1t} = 4.9 \times 10^6$ l mole^{-1} s^{-1}. The probability factor ρ_3 is likely greater than 0.5, thus making k_{1c} and k_{1t} approximately of the same magnitude and of the order of 2×10^7 l mole^{-1} s^{-1}.

Isomerization of trans-Ethylene-d_2

The rate of isomerization was determined both in the presence and the absence of 100 mm carbon dioxide; the results are plotted in the integrated form in Fig. 7. In spite of

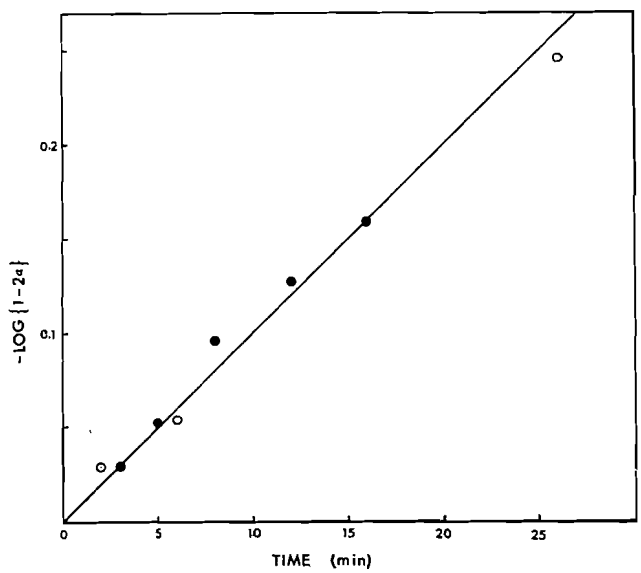

FIG. 7. Isomerization of *trans*-ethylene-d_2 at 25 °C: [RSH] = 1.07×10^{-4} mole l^{-1}, [T] = 3.96×10^{-4} mole l^{-1}, $\overline{r_i^{1/2}} = 2.15 \times 10^{-9}$ mole$^{1/2}$ $l^{-1/2}$ $s^{-1/2}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

an appreciable amount of scatter, it may be concluded that the rate of isomerization is independent of pressure down to at least 10 mm. By means of eq. [6] with $K = 1$, $\rho_3 = 0.5$, $k_{1c} = k_{1t} = k_1$, the attack constant for ethylene is found to be $k_1 = 4.8 \times 10^6$ l mole^{-1} s^{-1} at 25 °C. No measurable change in rate was observed on increasing the temperature to 75 °C, and it would appear likely that, as with butene, the activation energy for isomerization is close to zero; although further work is necessary to establish this more rigorously.

Thus butene-2 is roughly four times as reactive as ethylene. This increase in reactivity on alkyl substitution of the double bond is consistent with the electrophilic nature of the thiyl radical and is similar to, although much smaller than, that observed for atomic oxygen which may also be considered an electrophilic reagent (12). Steric restrictions are undoubtedly more important for $CH_3\dot{S}$ than for O attack and these will tend to diminish the increase in rate resulting from the increase in p-character of the olefinic carbons brought about by alkyl substitution.

Isomerization of Butene-2 in the Presence of Butadiene

The results obtained in the early stages of this work exhibited complex kinetics which could not be reconciled with any reasonable mechanism. The observed variation of the rate of isomerization with *cis*-butene-2 concentration is shown in Fig. 4. Although simple first order kinetics were observed at low butene pressures, the initial rate fell off more rapidly at higher pressures, and in the limit became practically independent of the olefin concentration. This behavior is just what might be expected if the termination mechanism changes from $R\dot{S} + R\dot{S}$ at low olefin concentrations, through $R\dot{S} + \dot{X}$, to $\dot{X} + \dot{X}$ as the concentration of olefin is increased. The rate equations derived on this basis however were not consistent with the kinetics of the addition reaction. This explanation may also be eliminated by consideration of the dependence of the isomerization rate on the thiol concentration. At low thiol concentrations, the rate of initiation is directly proportional to the concentration and hence the rate of isomerization should be proportional to the square root of the thiol concentration provided mutual termination of thiyl radicals predominates. The results shown in Fig. 8 indicate however that the rate of isomerization is first order with respect to thiol and therefore linearly proportional to the rate of initiation. This can occur only if chain termination results from a first order reaction involving the chain carriers. Since wall termination should be negligible at these pressures, it appears likely that at high olefin concentrations chain termination occurs as a result of the reaction of $R\dot{S}$ with a reactive impurity which acts as a retarder.‡ The subsequent results, which were reported in the previous sections, obtained using butene-2 purified by gas chromatography, show none of these kinetic anomalies and tend to confirm the presence of a reactive contaminant.

Since conjugated olefins are known to act as efficient inhibitors for the addition of thiols to olefins in solution (1), it appeared likely that the observed retardation of isomerization was due to the presence of trace quantities of butadiene-1,3. This was further suggested by the fact that the retardation could be reduced (but not completely eliminated) by bubbling the *cis*-butene-2 through a refluxing solution of maleic anhydride in benzene. Confirmation of the presence of butadiene was obtained by gas chromatography. In order to reduce the tail of the *cis*-butene-2 peak which completely masked the butadiene, about 80% of the *cis*-butene-2 was first removed by fractionation on a dimethylsulpholane column (diameter 3/8 in., length 25 ft) at 0 °C. (The difference in retention times of *cis*-butene-2 and butadiene on this column was 26 min.) This sample was then analyzed

‡*Phillips "Research Grade" cis-butene-2 appeared to contain a slightly higher amount of the retarder.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

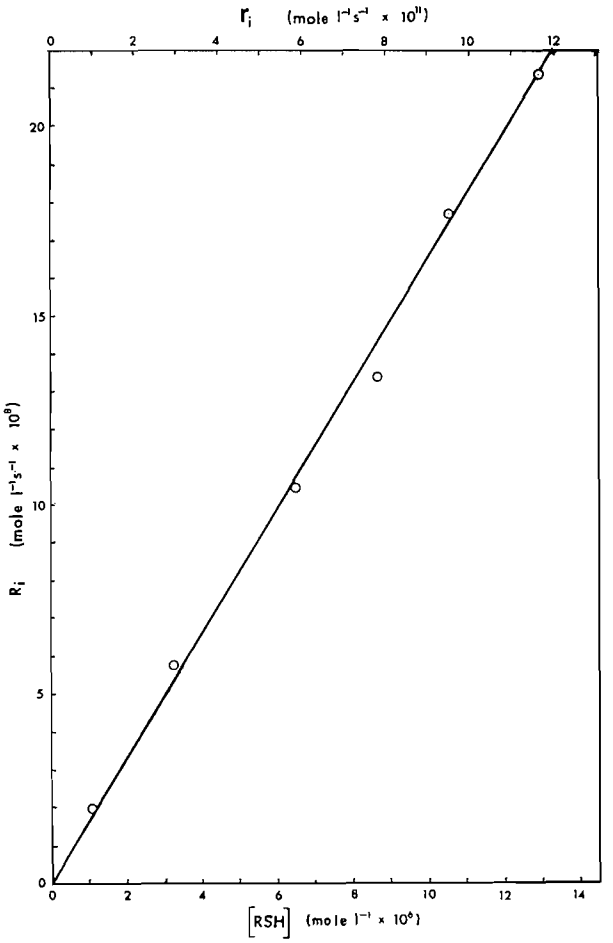

FIG. 8. Dependence of the isomerization rate on the thiol concentration or initiation rate at low pressures at 25 °C: [C] = 4.84×10^{-3} mole l^{-1}.

on a 200 ft dimethylsulpholane capillary column. Tailing of the remaining *cis*-butene interfered with the quantitative analysis but it could be estimated that there was 0.0019 ± 0.0009 mole % butadiene in the original sample. This agrees reasonably well with an estimate of 0.003% made spectrophotometrically at 220 mμ, assuming all of the absorption at this wavelength to be due to butadiene. That the retardation was due specifically to this impurity was shown by removing only the material with retention time in the immediate neighborhood of that of butadiene on the 3/8 in. diameter column. The resulting *cis*-butene-2 exhibited no retardation.

The addition of $\dot{RS}$ to butadiene (B) would produce a stable allylic radical ($\dot{Y}$) which would dehydrogenate thiol relatively slowly. It may therefore be assumed that, in the presence of butadiene, the termination reaction [4] (Fig. 2) may be replaced by

$$\dot{RS} + B \xrightarrow{k_7} \dot{Y},$$

$$\dot{Y} + \dot{RS} \xrightarrow{k_8} \text{product},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$$\dot{Y} + \dot{Y} \xrightarrow{k_9} \text{product.}$$

When $[\dot{Y}] \gg [R\dot{S}]$, termination reaction [8] will predominate and the initial rate of isomerization of *cis* will be

[8] $$R_1 = r_1\rho_3 k_{1c}[C]/k_7[B].$$

At lower concentrations of $\dot{Y}$, when reaction [8] becomes the main mode of termination, a factor of 2 will appear in the denominator of eq. [8].

Thus for a constant ratio of olefin to butadiene, the rate of isomerization should be independent of olefin concentration for high olefin and hence high butadiene concentrations, and at low rates of generation of $R\dot{S}$. This is consistent with the observations presented in Fig. 4. The rate constant k_7 (or $2k_7$) may be evaluated from the limiting rate of isomerization from Fig. 4 (4.3×10^8 l mole^{-1} s^{-1}) and from the slope of Fig. 8 (4.7×10^8 l mole^{-1} s^{-1}). The results are in good agreement and the average is k_7 (or $2k_7$) $= 4.5 \times 10^8$ l mole^{-1} s^{-1}. This result compares well with the result reported for styrene in solution where $k_1 = 8 \times 10^8$ l mole^{-1} s^{-1} (1).

Further work on butadiene is now in progress and this mechanism and result must be considered as tentative at present. It would appear perhaps surprising that butadiene, which is only about 15 times as reactive as butene-2 should have such a profound effect on the rate of isomerization at such a slow concentration. This behavior however must be due to the fact that attack of $R\dot{S}$ on butadiene is not reversible at 25 °C because of the formation of a stable allylic radical and because of the long chain length of the isomerization reaction, this irreversible removal of $R\dot{S}$ results in a large decrease in reaction rate.

PHOTO-INITIATED REACTIONS OF THIOLS AND OLEFINS

II. THE ADDITION OF METHANETHIOL TO UNCONJUGATED OLEFINS

D. M. GRAHAM, R. L. MIEVILLE, R. H. PALLEN, AND C. SIVERTZ
Department of Chemistry, University of Western Ontario, London, Ontario

Received February 21, 1964

ABSTRACT

Kinetic studies have been made of the addition of methanethiol to ethylene, propylene, and butene-2. The results obtained are consistent with the mechanism postulated for the isomerization reaction (1). The overall activation energy was found to be negative and could be explained in terms of two competing reactions of the adduct radical: thermal decomposition leading to $CH_3\dot{S}$ and olefin and dehydrogenation of thiol yielding addition product. Only the ratio of the rate constants for these two reactions could be determined. The method of intermittent illumination was used to evaluate the termination rate constant for the combination of two $CH_3\dot{S}$ radicals which was found to be $(2.5 \pm 0.7) \times 10^{10}$ l mole^{-1} s^{-1}.

INTRODUCTION

In Part I(1) it was shown that the thiyl radical catalyzed isomerization of butene-2 and 1,2-ethylene-d_2 could be explained at pressures above 4 mm by the reaction sequence shown in Fig. 1. To investigate further the results of the reversibility of the attack step [1]

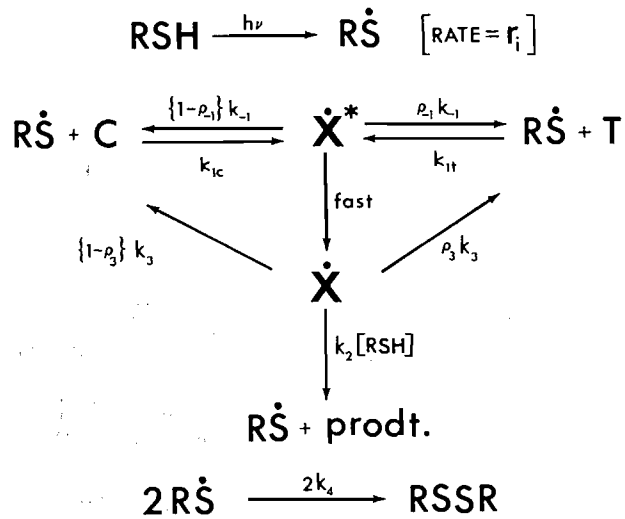

FIG. 1. The reaction mechanism. As was explained in Part I, because of the observed lack of pressure dependence of the rate of isomerization, decomposition of the adduct radical may be represented by a simple first order reaction (reaction [3]) which is the high-pressure limit of the more complicated unimolecular sequence given previously. Superscripts on the rate constants are no longer necessary to distinguish between the two possible decomposition paths, and have been dropped. C and T represent the *cis* and *trans* forms of the olefin; $\dot{X}^*$ and $\dot{X}$ represent the chemically energized and the de-energized adduct radicals, respectively; ρ is the probability that a decomposition reaction produces the *trans* isomer.

and to test the validity of the proposed mechanism, the kinetics of the addition reaction have been studied.

EXPERIMENTAL

Purification of the chemicals used and a description of the apparatus have been given in Part I. For the intermittent illumination experiments, the optical system was modified by the addition of a light stop with an opening of about 5 mm and a rotation sector at the focal point of one of the lenses. The sector motor was

operated from a thyratron-controlled d-c. power supply, and the ratio of light to dark period was 1:1. It was established using a photometer that the apparatus produced reasonably good square wave modulation.

The pressure change arising from the addition reaction was followed using a differential manometer. In the early stages of the work a wide-bore mercury manometer was used; reliable pressure measurements could be made to ±0.1 mm using a cathetometer. In the later stages a Wallace–Tiernan differential manometer in which the sensing element is a beryllium–copper capsule 2 cc in volume was used; this gauge permitted pressure measurements accurate to ±0.01 mm.

RESULTS AND DISCUSSION

The Termination Rate Constant

The isomerization kinetics discussed in Part I indicate that chain termination occurs exclusively by thiyl radical combination even at high olefin concentrations. The addition kinetics to be reported here confirm this. The method of intermittent illumination allows the mean lifetime of the chain carrier $CH_3\dot{S}$ to be determined. However the application of this technique was complicated by the experimental conditions under which addition rates could be measured. In order to obtain measurable rates, it was necessary to work at relatively high thiol pressures resulting in a large radical concentration gradient along the length of the cell because of strong absorption of light by the thiol. A procedure for applying the method of intermittent illumination in such cases has been developed by Burns and Dainton (2) for a system in which monochromatic light is used. With the system used to initiate the reactions of methanethiol, it proved impossible to isolate one single active spectral line and it was necessary to modify this procedure to account for the different absorption characteristics of the various wavelengths present.

On the basis of measurements of the rate of hydrogen production from the photochemical decomposition of methanethiol, it was shown in Part I that the rate of initiation in a layer of depth dl at a distance l from the illuminated face of the cell may be described by an equation of the form

$$[1] \qquad r_i\,(\text{local}) = \sum_{\lambda} (\phi I_0)_\lambda \epsilon_\lambda c\, e^{-\epsilon_\lambda c l}$$

The summation is taken over the three active wavelengths found to be present, 254, 257, and 265 mμ, with molar extinction coefficients ϵ_λ = 143, 69.9, and 16.8, respectively. ϕ_λ is the quantum efficiency for primary radical production and I_{0_λ} is the incident light intensity at wavelength λ; this product may be evaluated from the hydrogen production measurements. The concentration of thiol is c.

For a sector producing light and dark periods of the same duration the significant ratio is

$$[2] \qquad \rho = \sqrt{2}\,\frac{\text{sectored rate}}{\text{rate for continuous illumination}}.$$

Under conditions of non-uniform illumination this ratio must be averaged over the length of the cell, L, and it is readily shown that

$$[3] \qquad \bar{\rho} = \frac{\int_0^L r_i^{1/2}(\text{local}) f[t_l k_t^{1/2} r_i^{1/2}(\text{local})]\, dl}{\int_0^L r_i^{1/2}(\text{local})\, dl} = \frac{\int_0^L G^{1/2}(c, l) f[m' G^{1/2}(c, l)]\, dl}{\int_0^L G^{1/2}(c, l)\, dl},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where

$$G(c, l) = \sum_{\lambda} \frac{(\phi I_0)_\lambda \epsilon_\lambda}{(\phi I_0)_{\lambda_1} \epsilon_{\lambda_1}} e^{-\epsilon_\lambda c l}.$$

The subscript λ_1 refers to one specific wavelength; in this case the 254 mμ line was chosen. t_l is the duration of the flash and k_t is the rate constant for the termination reaction. The form of the function $f[m'G^{1/2}(c,l)]$ is identical with that obtained for $f(m)$ for the case of uniform illumination (3) and $\bar{\rho}$ may be evaluated by numerical integration for different values of the dimensionless parameter $m' = t_l[k_t(\phi I_0)_{\lambda_1} \epsilon_{\lambda_1} c]^{1/2}$. The curve calculated in this manner is then compared with the experimental curve obtained from [2] for $\bar{\rho}$ as a function of t_l and the termination constant determined in the usual way.

The experimental results and the theoretical curve are shown in Fig. 2. Although there

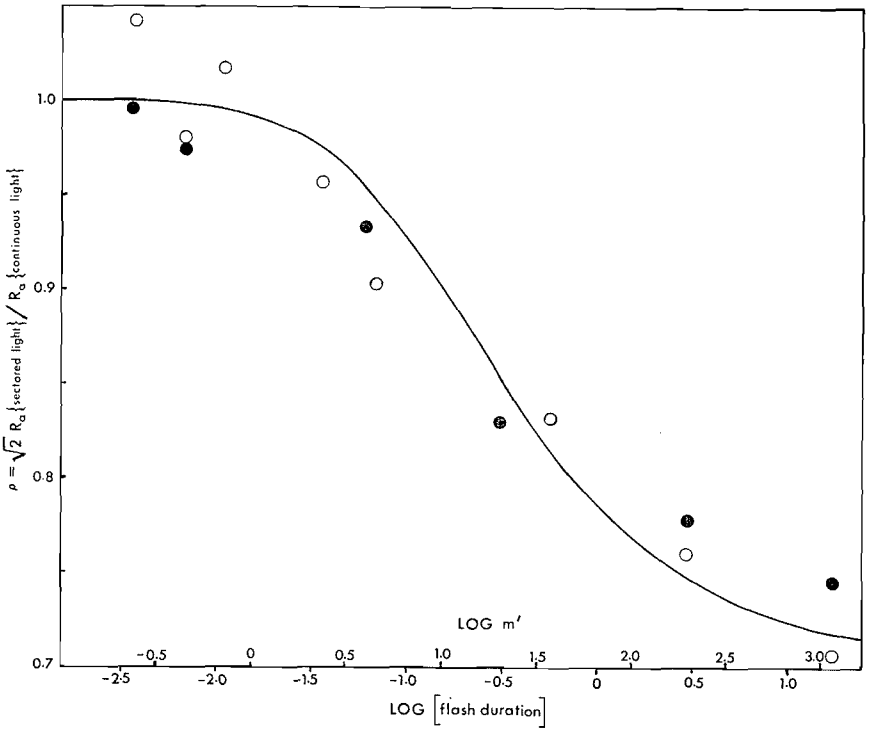

FIG. 2. Rotating sector curve: ● butene-2; ○ ethylene.

is an appreciable amount of scatter in the points, it is apparent that the termination constant is the same under these conditions for the butene-2 and ethylene systems. This is consistent with the kinetic evidence that termination occurs in both cases by combination of thiyl radicals. The rate constant for reaction [4] is found to be $k_4 = k_t/2 = (2.5 \pm 0.7) \times 10^{10}$ l mole^{-1} s^{-1}. The limits quoted indicate the maximum range over which the calculated and experimental curves may be fitted. It is hoped that a considerably better estimate of k_4 will be obtained by applying this technique to the isomerization rate. These measurements may be made more accurately and at very much lower thiol concentrations where the correction for non-uniform illumination will be small.

Kinetics of the Addition Reaction

The isomerization results indicated that, at pressures above 4 mm, collisional de-energization of the adduct radical $\dot{X}^*$, which contains the exothermic heat of reaction [1], is very fast and the rate of reaction should be independent of the total pressure. The rate of addition under these conditions is found to be

$$[4] \qquad R_a = -\frac{d[RSH]}{dt} = \left(\frac{r_i}{2k_4}\right)^{1/2} \frac{k_2[RSH](k_{1c}[C] + k_{1t}[T])}{k_3 + k_2[RSH]}.$$

Since isomerization is very much more rapid than addition, the isomers are in their equilibrium concentrations during the period in which addition rate measurements are made. It is therefore convenient to use a mean attack constant, k_1, which is averaged over the equilibrium concentrations, and to represent the total olefin concentration as [A]. Then [4] becomes

$$[5] \qquad R_a = \left(\frac{r_i}{2k_4}\right)^{1/2} \frac{k_1 k_2[RSH][A]}{k_3 + k_2[RSH]}$$

where

$$k_1 = \frac{k_{1c} + Kk_{1t}}{1 + K}$$

and

$$K = [T]_{eq}/[C]_{eq}.$$

The pressure–time plots for ethylene were linear over the range of conversion ($< 5\%$) used to determine R_a. For butene-2, however, a short non-reproducible inhibition period was observed, during which time almost no pressure decrease was observed. When the butene was purified by gas chromatography, the inhibition period disappeared and the rate of addition became greater. A similar effect was observed for the isomerization reaction and the retarder was identified as butadiene-1,3 (1). Because the chain length for addition is much less than that for isomerization, initial inhibition rather than retardation, as in the case of the isomerization reaction, occurs. The subsequent retardation of the addition rate is likely due to the products of the inhibition reaction. With unpurified butene the rate was less than first order with respect to olefin, which is consistent with the retardation mechanism postulated for the isomerization reaction.

Equation [5] predicts a first order dependence on olefin which is in agreement with the experimental observations for ethylene and butene-2 over the wide concentration ranges shown in Figs. 3 and 5. The results given in Figs. 4 and 5 show that after the rate is divided by $\overline{r_i^{1/2}}$, it is directly proportional to the thiol concentration. This will follow from eq. [4] only if $k_3 \gg k_2[RSH]$, which was also concluded from the observed isomerization kinetics.

The Rate Constants

It is possible therefore to obtain from these results the ratio $k_1k_2k_3^{-1}$ since k_4 has been determined. Some of the values obtained are given in Table I. The propylene results were calculated assuming identical kinetic behavior. The temperature dependence of the ratio is shown in Fig. 6, and from these results, $E_1 + E_2 - E_3$ may be evaluated assuming E_4 to be zero; these activation energies are also given in Table I. The estimated values of $k_2k_3^{-1}$ given were calculated using the attack constant (k_1) values obtained from the isomerization studies and assuming that $E_1 \simeq 0$ (1).

Unfortunately it is at present impossible to draw any general conclusions from the

Addition rate constants. The propylene results are interpolated values from Fig. 6. For ethylene $k_1 = 4.8 \times 10^6$ l mole^{-1} s^{-1}, and it is assumed that for butene $k_{1c} = k_{1t} = k_1 = 2.1 \times 10^7$ l mole^{-1} s^{-1} (1)

†Units: l mole^{-1}.

values obtained for the rate constant ratios or the activation energy differences. The rate constant at 30 °C and the activation energy for methyl radical dehydrogenation of methanethiol (corresponding to reaction [2]) have been roughly estimated to be 2×10^4 l mole^{-1} s^{-1} and 5 kcal. If it is assumed that k_2 and E_2 have approximately these values for all olefins, the results obtained are intuitively unreasonable. For example a greater k_3 value is obtained for butene than for ethylene even though the corresponding activation energies bear the opposite relation. It must be concluded therefore that the rates of both reactions [2] and [3] are dependent upon the structure of the adduct radical.

The rate constants k_2 and k_3 could be separated if rate measurements could be carried out at sufficiently high concentrations of $\dot{X}$ (i.e., at high olefin and low thiol concentrations and at low temperatures) that a termination reaction other than [4] would predominate. This appears to be beyond the technique reported here but further investigation of this possibility is planned.

The complexity of eq. [5] for the rate of addition emphasizes the danger inherent in obtaining "relative reactivities" from relative rates of addition (4). This procedure can be valid only for cases in which the attack step is not reversible or for reaction systems in which the thiol concentration is chosen such that $k_2[\mathrm{RSH}] \gg k_3$.

IONIZATION POTENTIALS OF METHYL-SUBSTITUTED BENZENES AND CYCLOPENTADIENES

F. MEYER AND A. G. HARRISON[1]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received June 4, 1964

ABSTRACT

The ionization potentials of a number of methyl-substituted benzenes and cyclopentadienes have been measured by electron impact. The experimental results are compared to calculations based on a group orbital method.

INTRODUCTION

The relation between structure and ionization potentials of organic compounds has been the subject of a considerable number of investigations, both experimental and theoretical. It has become evident that more series of related compounds are needed to test the semi-empirical methods of calculation and to widen the field of their applicability. We have recently measured the electron-impact ionization potentials of a number of methyl-substituted benzenes and cyclopentadienes. We have compared the results obtained for these two series with calculations based on a group orbital method.

The group orbital method is a simplification of the equivalent orbital method developed by Lennard-Jones and Hall (1, 2). They showed that the total wave function of a molecule can be considered either as a set of equivalent orbitals or as a set of molecular orbitals. The two sets can be derived from each other by a unitary transformation. The energy to remove an electron from a molecular orbital can be calculated starting from an equivalent orbital description which refers to bonds and lone pairs of electrons in the molecule. Hall (3) showed for planar molecules, in the case where the observed ionization potential is for removal of an electron from an orbital antisymmetric in the plane of the molecule, that only the antisymmetric combinations of the equivalent orbitals need to be considered.

In such a case the ionization potentials can be calculated from certain group parameters. The ionization potentials, E, are the roots of the secular equation

$$|e_{m,n} - E\delta_{m,n}| = 0, \qquad [1]$$

where m and n refer to the various groups in the molecule. To a good approximation, $e_{m,n}(m = n)$ can be taken as the ionization potential of the hydride of group m, and the interaction factors $e_{m,n}$ $(m \neq n)$ can be calculated from experimental data. For $m = n$, $\delta_{m,n} = 1$, and for $m \neq n$, $\delta_{m,n} = 0$. The group orbital method has been extensively applied in this form to the calculation of ionization potentials by Franklin (4).

EXPERIMENTAL

The ionization potentials were measured with an A.E.I. MS-2 mass spectrometer previously described (5). The ionization potentials were determined in the usual manner (6) using xenon to calibrate the voltage scale. The methylbenzenes were commercial samples, while the methylcyclopentadienes were very kindly supplied by Mr. P. Haynes and Professor S. McLean of this Department. Details of the synthesis and proof of structure of the cyclopentadienes will be published elsewhere (7) as will a detailed consideration of the mass spectra (8). The methylcyclopentadienes were purified by gas chromatography and kept at dry-ice temperature until used.

[1]*Alfred P. Sloan Fellow 1962–1964.*

RESULTS AND DISCUSSION

The measured ionization potentials for cyclopentadiene and a number of methyl-substituted cyclopentadienes are compared with calculations based on the group orbital method in Table I. The details of the calculations will be discussed below. Our value of

8.93 eV for cyclopentadiene is in good agreement with previous electron-impact values of 9.00 eV (9) and 8.9 eV (10) and the calculated value of 8.91 eV (11). The ionization potentials of the methylcyclopentadienes have not been measured previously.

It is interesting to note that the ionization potentials of the positional isomers in the cyclopentadienes are identical, within experimental error, although the ring positions are not identical. This is even true for the 5,5-disubstituted cyclopentadienes where one might have expected the interaction between the methyl groups and the π-electron system to be reduced. It does not appear that this lack of structural effect can be due to thermal isomerization in the ion chamber prior to ionization. It has been reported (12) that 1,5,5-trimethylcyclopentadiene undergoes rearrangement to 1,2,3-trimethylcyclopentadiene when the compound at 400 °C is passed through a 60 cm tube partially filled with glass wool. However, the ion source temperature is only 20–30 °C above room temperature, as measured with a thermocouple under operating conditions, and any rearrangement of the 5,5-disubstituted compounds will be very slow at this temperature. The 1- and 2-methylcyclopentadienes do isomerize by an alpha hydrogen shift in the liquid phase giving an equilibrium mixture (13), but the rate is slow compared to the residence time in the ion source. Furthermore, no appreciable rearrangements of the compounds studied were observed on separation in a gas chromatograph with an inlet temperature of 200 °C and a column temperature of 75 °C. Significant differences were noted in the mass spectra of the 5,5-disubstituted compounds compared to the isomers with methyl groups in other positions (8). On the other hand, 5-monomethylcyclopentadiene rearranges very rapidly at room temperature and has not been included in this study.

The ionization potentials of a number of methyl-substituted benzenes are compared in Table II with calculations based on the group orbital method and with previous electron-impact results (14). The ionization potentials measured in the present work are in reasonable agreement with previous values, although the present values for the xylenes and

trimethylbenzenes are slightly lower. The ionization potentials of the tetramethylbenzenes and pentamethylbenzene do not appear to have been measured previously by electron impact.

Calculation of Ionization Potentials

Franklin (4) calculated the ionization potential of cyclopentadiene using one methane and two ethene groups to build up the molecule. The interaction factor, a, between a methane and an ethene was calculated from the ionization potential of propene; the interaction factor, b, between two ethene groups was obtained from the ionization potential of butadiene. Both these factors can be obtained by solving equation [1]. The ionization potentials of methane and ethene were taken as 13.31 eV and 10.50 eV respectively. The secular equation for cyclopentadiene can be written as:

$$\begin{vmatrix} 13.31 - E & a & a \\ a & 10.50 - E & b \\ a & b & 10.50 - E \end{vmatrix} = 0$$

where the lowest root for E corresponds to the ionization potential which is measured experimentally. The determinant factorizes into

$$(10.50 - b - E)\{(13.31 - E)(10.50 + b - E) - 2a^2\} = 0,$$

which gives as the lowest root $E = 10.50 - b$. This is, however, identical with the ionization potential of butadiene since from the method of calculation of b,

$$10.50 - I(\text{butadiene}) = b.$$

This implies that there is no interaction between the methane part of the molecule and the butadiene part of the molecule as far as the lowest ionization potential is concerned and obviously leads to the conclusion that substitution in the 5 position will have no effect on the ionization potential. This is clearly not in agreement with the results for the 5,5-disubstituted compounds and indicates that this method of building up the cyclopentadiene molecule cannot be used[2].

[2]*In this regard it might be pointed out that if cyclopropane is built up from three methane groups with an interaction factor derived from the ionization potential of ethane, the calculated I(cyclopropane) is the same as I(ethane), expressing the fact that on this model no interaction is possible between the methane and ethane parts of the molecule. Similarly, if cyclopentane is built up from a methane and two ethane groups, I(cyclopentane) equals I(butane) since I(butane) is used to calculate the interaction between the two ethane groups.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

It seems justified, however, in these substituted ring compounds to consider the ring nucleus as one group and the substituents as separate groups. Calculation of the ionization potential for an n-methyl substituted ring compound then requires the solution of the following determinant, where H is the ionization potential of the unsubstituted ring compound, 13.31 eV is the ionization potential of methane[3], $a_1, a_2, a_3 \ldots a_n$ are the interaction factors of the methyl groups with the ring, and $b_1, b_2, b_3 \ldots b_n$ are the interaction factors between the methyl groups.

$$\begin{vmatrix} H-E & a_1 & a_2 & a_3 & \ldots \\ a_1 & 13.31-E & b_1 & b_2 & \ldots \\ a_2 & b_1 & 13.31-E & b_3 & \ldots \\ a_3 & b_2 & b_3 & 13.31-E & \ldots \\ \cdot & \cdot & \cdot & & \\ \cdot & \cdot & \cdot & & \\ \cdot & \cdot & \cdot & & \end{vmatrix} = 0$$

In the cyclopentadiene series there is no observable difference between the different methyl-substituted isomers; this suggests that all a factors are the same and also that all b factors are the same. For the case where $a_1 = a_2 = a_3$, etc. and $b_1 = b_2 = b_3$, etc. $\neq 0$ the determinant factorizes into

$$(H - a^2/b - E)(13.31 - b - E)^{n-1}(13.31 + (n-1)b - E) + a^2/b(13.31 - b - E)^n = 0.$$

It appears that $n - 1$ roots are equal to $13.31 - b$, and the lowest root can be calculated from the resulting quadratic equation.

For the cyclopentadiene series values of $a = 1.53$ eV and $b = 1.15$ eV yield calculated ionization potentials (column 3, Table I) in agreement with measured values within experimental error for the whole series. For comparison we give in the final column of Table I a set of values calculated assuming $a = 1.53$ eV but $b = 0$, that is, assuming no methyl–methyl interaction. In this case the discrepancies between measured and calculated values become very large for the polysubstituted members of the series. The introduction of the factor b has the effect of slowing down the decrease in ionization potential with increasing number of methyl substituents. Attempts were made to fit the series with $b = 0$ by adjusting the ring–methyl interaction factor, a, but no satisfactory agreement could be obtained for the whole series.

In the benzene series there are small differences in the ionization potentials of positional isomers, suggesting that all the interaction factors are not identical. If these small differences are neglected as a first approximation, one can calculate ionization potentials in reasonable agreement with the mean value for each group, using $a = 1.32$ eV and $b = 0.40$ eV as shown in column 4 of Table II. In this case the secondary interaction factor, b, has little effect, and agreement which is almost as good can be obtained using $b = 0$ and adjusting the other parameters. This is shown by the calculations due to Franklin (4) which are reproduced in column 5 of Table II.

The small differences between positional isomers such as that observed for the isomeric dimethyl and trimethyl compounds cannot be reproduced using only one set of interaction parameters. An explanation for the observed differences in ionization potentials for positional isomers has been presented in terms of simple molecular orbital theory by Bralsford *et al.* (15) and discussed with reference to the xylenes by Streitwieser (16). The

[3]*We have taken 13.31 eV as the ionization potential of ethane to correspond to the value used in previous calculations by Franklin (4).*

methyl substitution is considered as a perturbation of benzene. The two highest occupied molecular orbitals in benzene are shown schematically in Fig. 1, both orbitals having the

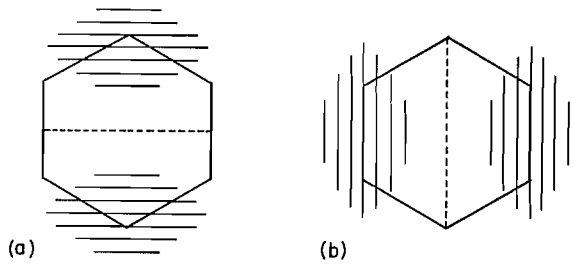

FIG. 1. Molecular orbitals of benzene.

same energy. The interaction of the methyl substituent is considered to depend on the magnitude of the wave function at the point of substitution and, since a methyl group has the highest possible interaction in the 1 position of the molecular orbital in Fig. 1(*a*), this orbital becomes the highest occupied orbital with the lowest ionization potential. The interaction in the 4 position is the same, while the interactions in the 2, 3, 5, and 6 positions are less. Thus paraxylene has two methyls capable of strong methyl–ring interaction and, therefore, a lower ionization potential than either the ortho- or meta-xylene, each of which only have one methyl in a position to interact strongly.

This model suggests that at least two methyl–ring interaction parameters should be used in the calculation of the ionization potentials of methylbenzenes by the group orbital methods. One of these parameters, a_1, should express the strong interaction possible in the 1 and 4 position of Fig. 1(*a*), while the second parameter, a_2, expresses the weaker interaction in the other positions. The final column of Table II shows the results obtained using $a_1 = 1.265$ eV and $a_2 = 1.09$ eV, with the combinations of a_1 and a_2 factors used for each molecule given in brackets after the calculated value. In these calculations the methyl–methyl interaction factor, b, was zero. The calculated values agree quite well with the experimental values and, in addition, correctly reproduce the differences between structural isomers. A better fit for the dimethyl and trimethyl cases would probably require the introduction of one or more methyl–methyl interaction factors.

It is clear from the present work that the group orbital method can be used satisfactorily to reproduce the ionization potentials of a homologous series of compounds. However, the fact that a second interaction parameter, b, must be introduced, as for the cyclopentadienes, seriously limits the usefulness of the method since this parameter cannot be estimated without a knowledge of the ionization potential of higher members of the series. In addition, to reproduce small differences among isomers, different substituent–ring interactions which cannot be estimated without experimental guides must be used.

PHOTOLYSE DE L'IODURE DE VINYLE EN SOLUTION DANS LE TETRACHLORURE DE CARBONE

PIERRE C. ROBERGE ET JAN A. HERMAN
Département de Chimie, Université Laval, Québec, Québec

Reçu le 29 avril 1964

ABSTRACT

The photolysis of vinyl iodide in carbon tetrachloride solutions gives several products among which the most important are: acetylene, hydrogen iodide, iodine, ethylene, and vinyl chloride. A mechanism based on diffusion-controlled disproportionation of geminate radicals, as first proposed by Hamill, agrees well with the observed phenomena. To explain the diminishing production of ethylene and iodine with increasing concentration of the monomer, it is necessary to postulate a telomerization of the vinyl iodide.

INTRODUCTION

La polymérisation photochimique (ou radiochimique) des halogénures de vinyle, liquides purs ou en solution, ne présente pas de difficultés à l'exception de celle de l'iodure de vinyle. Toutefois, nous avons réussi à le polymériser (1) par l'action des rayons X, en solution dans les solvants chlorés tels que CH_2Cl_2, $CHCl_3$ et CCl_4.

Les espèces primaires actives produites sous l'influence du rayonnement ionisant étant très nombreuses, l'étude du mécanisme de la radiolyse s'avère très complexe. C'est pourquoi nous avons décidé d'étudier le mécanisme photochimique, en espérant en tirer des indications utiles pour la radiolyse.

Emschwiller (2), dans une étude sur la photochimie de l'iodure de vinyle liquide, a trouvé de l'éthylène, de l'acétylène et de l'iode comme produits de décomposition. Son interprétation des résultats fait intervenir deux molécules d'iodure de vinyle: (*a*) celle qui a subi l'action de la lumière perd à la fois son atome d'iode et un atome d'hydrogène, le groupement restant se transpose en acétylène; (*b*) les atomes d'hydrogène et d'iode concourent alors avec une deuxième molécule de monomère à la production de l'éthylène et de l'iode moléculaire. Emschwiller trouve un rapport C_2H_2/C_2H_4 de 1.25 et un rapport gaz en C_2/atome d'iode de 1.55. Il explique ce déficit de l'éthylène par rapport à l'acétylène et de l'iode relativement aux gaz en C_2 par une fixation de l'iode sur l'acétylène et surtout sur l'éthylène. Le ΔH^0 de réaction (calculé) étant de -6.4 kcal/mole pour la fixation d'iode sur l'acétylène et de $+7.3$ kcal/mole pour la fixation sur l'éthylène, on voit immédiatement que cet argument ne saurait tenir.

A la suite des travaux plus récents de Hamill (3, 4) sur la photolyse des iodures et en particulier de l'iodure d'éthyle, il nous est permis d'imaginer une production d'acide iodhydrique dans le système et son importance pour les réactions secondaires. A la lumière de ces faits, nous avons entrepris l'étude de la photolyse de l'iodure de vinyle dans le tétrachlorure parce que, d'une part, la polymérisation radiochimique est maximum (1) et, d'autre part, en cas de réaction entre ce monomère et le solvant, les produits formés seraient marqués par les atomes de chlore.

PARTIE EXPÉRIMENTALE

Réactifs

L'iodure de vinyle est préparé par la méthode de Spence (5). On le distille sur une colonne à 30 plateaux théoriques, à un taux de reflux très grand. On recueille la fraction correspondant à une concentration en impureté inférieure à 0.01%, tel que vérifié par chromatographie en phase gazeuse. L'iodure ainsi obtenu est

finalement distillé plusieurs fois sous haut vide, de piège en piège maintenus à une température de −76 °C. Il est conservé sous haut vide à l'obscurité et dans ces conditions s'avère stable.

Le tétrachlorure de carbone "pour analyse" et l'acide chlorhydrique de Matheson Co. sont dégazéifiés par distillation de piège en piège à −185 °C. L'acide iodhydrique est préparé suivant la méthode usuelle de déshydratation d'une solution aqueuse de HI et est débarassé de l'iode par distillation à très basse température et est ensuite dégazéifié par les procédés habituels.

Dispositif d'irradiation

La source lumineuse utilisée est une lampe à mercure Hanovia à haute pression (Utility Model, No. 30600), dont l'intensité est beaucoup plus grande dans le visible et le proche ultraviolet que dans l'ultraviolet lointain. Le système optique est choisi de façon à obtenir un faisceau lumineux presque parallèle et d'intensité maximum. La cellule d'irradiation, en quartz à fenêtres optiquement polies, est soudée par l'intermédiaire d'un joint gradé à une cellule en pyrex s'adaptant directement à la place des cellules d'absorption des spectrophotomètres Beckman DU et DKA. La partie en pyrex de cette cellule d'irradiation est pourvue d'une pointe cassable sous vide. La cellule est nettoyée à l'acide sulfurique concentré, bouillant et dégazéifiée sous haut vide en chauffant à environ 300 °C avant chaque irradiation. L'espace occupé par la vapeur au-dessus du liquide est recouvert de papier d'aluminium de façon à éliminer la photolyse en phase gazeuse.

L'iodure de vinyle absorbe très fortement entre 2000 et 3500 Å (11) alors que le tétrachlorure de carbone n'absorbe practiquement plus au-dessus de 2400 Å (6, 7). Comme le système optique coupe environ 80% de l'intensité lumineuse sous 2500 Å et que l'intensité de la lampe, également sous 2500 Å, n'est que d'environ 15% de la lumière émise entre 2500 et 3500 Å (8), on peut assumer que la lumière n'est pratiquement absorbée que par l'iodure. La photolyse du solvant peut donc être considérée comme négligeable, si elle se produit.

Pour faire varier l'intensité d'irradiation, on emploie un filtre optique approprié qui réduit de 8.3 fois l'intensité du spectre de la lampe nue. Les irradiations sont faites à température ambiante, soit à 23° ± 2 °C.

Préparation des échantillons

Les solutions d'un volume total d'environ 5 ml sont préparées par distillation séparée de CCl_4 et de C_2H_3I à travers un mélange de chaux sodée et de sulfate de magnésium, de façon à sécher et à éliminer toute trace de chlore et d'acide iodhydrique ou d'iode suivant le cas; cette distillation est suivie de distillations successives de piège en piège à −80 °C, sous haut vide. Les poids du solvant et de l'iodure de vinyle sont obtenus par pesées successives. Finalement, les deux substances sont distillées ensemble dans la cellule qui est scellée sous vide. Ces cycles de dégazéification sont très longs mais absolument essentiels si l'on veut obtenir des résultats reproductibles. En effet, on doit éliminer avec grand soin toute trace d'oxygène dont l'influence sur la photolyse des iodures organiques (9, 10) est énorme.

Analyse

Dans chacune des irradiations, on suit la formation d'iode par la mesure de la densité optique à 500 mμ. Une calibration spectrophotométrique préalable d'iode dans des solutions de diverses concentrations en C_2H_3I et CCl_4 à 500 mμ permet de transposer les lectures des densités optiques en fractions molaires d'iode dans l'échantillon irradié. Après irradiation, la cellule est soudée à un dispositif d'extraction des gaz que nous avons mis au point (Fig. 1). La cellule est soudée en A et, lorsque le vide est bon dans l'appareil, on brise la pointe et l'on distille le contenu de la cellule en B. On ajoute alors environ 10 ml d'eau, préalablement dégazéifiée en C, de façon à retenir l'acide iodhydrique, le tout est congelé à l'air liquide. Le serpentin D est maintenu à 0 °C pour qu'il y ait le moins possible de distillation d'eau vers le diverticule E, froid et tenu à −80 °C. Une pompe Toepler pompe continuellement les gaz. Dans ces conditions, on peut recueillir très facilement et totalement C_2H_2 et C_2H_4, ainsi qu'une partie de C_2H_3Cl et C_4H_6 contenus dans la solution.

Une fois cette première fraction recueillie à −80 °C, on ramène la température du diverticule E à 0° et collecte une deuxième fraction contenant, cette fois, le reste de C_2H_3Cl et C_4H_6 et une bonne quantité d'iodure de vinyle, dont la tension de vapeur à cette température est d'environ 5 cm. Les gas ainsi collectés sont analysés par chromatographie à gaz. Une fois les gas recueillis, on récupère la solution en la congelant en B, dans l'azote liquide. Cette solution est décantée et la phase aqueuse contenant l'acide iodhydrique est lavée au cyclohexane pour extraire CCl_4 et l'iode demeurés en solution. L'analyse de HI est alors faite à partir de cette solution aqueuse en mesurant l'absorption de l'acide iodhydrique à 2260 Å. Lorsque la concentration de HI est suffisamment élevée, on peut vérifier les résultats spectrophotométriques par titrage avec une solution diluée de NaOH.

RÉSULTATS ET INTERPRETATION

Nous avons pu distinguer et analyser quantitativement les produits de photolyse suivants: C_2H_2, C_2H_4, HI, I_2, C_2H_3Cl et C_4H_6. Pour éviter l'intervention des réactions secondaires qui pourraient brouiller l'aspect cinétique du problème, nous n'avons jamais poussé la conversion au-delà de 1%, travaillant en général à un pourcentage de conversion de l'ordre de 0.1%.

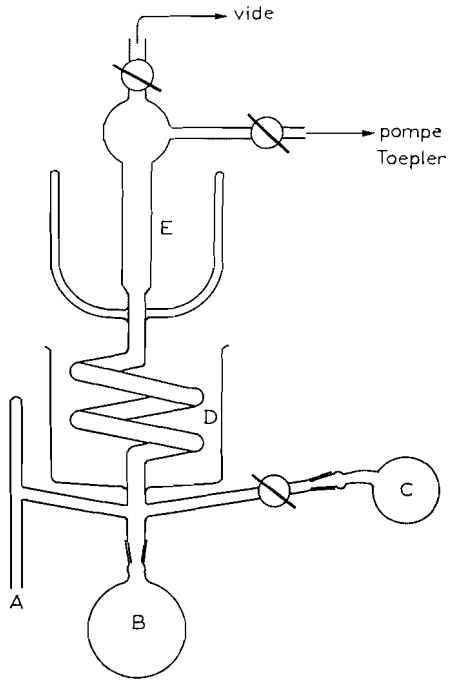

FIG. 1. Dispositif d'extraction des gaz des échantillons irradiés.

Formation de l'acétylène et de l'acide iodhydrique

En ce qui concerne la formation de l'acétylène, on trouve les faits suivants. (*a*) Sa formation est proportionnelle au temps d'irradiation (Fig. 2), du moins jusqu'à des conversion de l'ordre de 1%. (*b*) La production de C_2H_2 est indépendante de la concentration en monomère (Fig. 3). Dans les conditions de nos expériences, la vitesse de formation est de 6.6×10^{-9} mole ml^{-1} min^{-1}. (*c*) Il n'y a pas d'effet d'intensité de la lumière sur la vitesse de formation de C_2H_2, comme le montre le Tableau I où l'on voit que le rapport des productions pour un même temps d'irradiation est égal au rapport des intensités. Pour cette raison nous avons utilisé la production d'acétylène comme étalon interne pour les effets d'intensité des autres produits de photolyse. (*d*) L'addition de HI ou de HCl, jusqu'à des concentrations de 0.1 mole/l, n'affecte pas la quantité d'acétylène produite (Tableau II). Toutefois, l'addition d'oxygène en concentration de l'ordre de 0.03 mole/l entraîne une réduction d'environ 40% de la production de C_2H_2 (Tableau II). En présence d'oxygène, cette expérience doit être menée à basse concentration en C_2H_3I (environ 2% mole) car à plus haute concentration l'oxydation thermique est de loin trop rapide et, comme elle mène aussi à la formation d'acétylène (11), on ne peut guère en tirer de conclusions.

La formation de l'acide iodhydrique (Fig. 2) est caractérisée par les faits suivants. (*a*) Elle est proportionnelle à l'énergie absorbée jusqu'à des conversions de l'ordre de 1%. (*b*) Le taux de production est indépendant de la concentration en monomère, tout au moins jusqu'à des concentrations de l'ordre de 25% en C_2H_3I (Fig. 4), la vitesse de formation est d'environ 5.2×10^{-9} mole ml^{-1} min^{-1}. (*c*) Il n'y a pratiquement pas d'effet d'intensité sur la production de HI (Tableau I). On voit qu'à intensité réduite, la vitesse de formation de HI est 1.22 fois plus grande.

Il existe un parallèlisme frappant entre la formation de l'acétylène et de l'acide iodhydrique: dans les deux cas, l'influence du temps d'irradiation et de la concentration en iodure de vinyle est la même. De plus, les vitesses de formation de ces substances sont du même ordre de grandeur. Il faut, en outre, mentionner que l'on ne retrouve pas d'hydrogène, même pour des temps d'irradiation de l'ordre de 1200 min. Ces diverses constatations peuvent s'expliquer par le processus de "dismutation controlée par diffusion" tel que proposé d'abord par Hamill (3, 12) et repris par Willard (13) et Wijnen (14, 15) dans la photolyse de l'iodure d'éthyle liquide. L'absorption de photons dans l'acte primaire conduirait à une situation représentée symboliquement par la réaction [1],

$$[1] \qquad C_2H_3I \xrightarrow{h\nu} (C_2H_3 + I),$$

où les particules entre parenthèses, appelées radicaux jumelés (16), sont sujettes à une interaction par diffusion: soit la dismutation,

$$[2] \qquad (C_2H_3 + I) \rightarrow C_2H_2 + HI,$$

soit des réactions en compétition avec la dismutation,

$$[3] \qquad (C_2H_3 + I) \rightarrow C_2H_3\cdot + I\cdot$$

$$[1a] \qquad (C_2H_3 + I) \rightarrow C_2H_3I.$$

L'étape [3] représente la transition de la cinétique de diffusion à la cinétique en état stationnaire. L'effet cage, traditionnelement évoqué pour expliquer une décroissance du rendement photochimique en raison de la réaction du type [1*a*], peut expliquer ici un phénomène inverse en raison de la réaction [2]. Ce schéma a l'avantage d'expliquer, à partir d'un même acte primaire, la production de radicaux soumis à une cinétique en état stationnaire et la production directe de fragments moléculaires C_2H_2 et HI.

La formation de l'acétylène et de l'acide iodhydrique par la dismutation contrôlée par diffusion est formellement équivalente au processus de détachement moléculaire directe,

$$[A] \qquad C_2H_3I \xrightarrow{h\nu} C_2H_2 + HI,$$

sauf en ce qui concerne les effets d'intercepteurs de radicaux. Dans le cas de détachement moléculaire directe, l'effet d'intercepteurs devrait être nul, alors que dans le cas de la dismutation contrôlée par diffusion, l'effet sur la production de C_2H_2 devrait être assez important, à condition que la concentration des intercepteurs soit suffisamment grande pour qu'ils puissent s'introduire dans les cages. Or, nous l'avons vu, l'oxygène affecte très fortement la production de l'acétylène, ce qui plaide en faveur du mécanisme [1].

Formation de l'iode

La formation de l'iode donne des résultats peu reproductibles; nous soupçonnons que les traces d'impuretés et d'oxygène en sont la cause. De façon générale, nous avons constaté que la quantité d'iode formée croît avec le temps (mais non de façon linéaire). La Fig. 5 illustre cet effet; nous y avons présenté, choisies parmi les nombreux résultats, quelques courbes typiques de production d'iode en fonction du temps pour diverses concentrations en monomère. Par ailleurs, la vitesse de formation décroît avec l'augmentation de la concentration en iodure de vinyle. Cette diminution de vitesse (Fig. 4) est rapide pour les basses concentrations de C_2H_3I et devient lente à mesure que la solution est plus concentrée.

La réaction majeure qui conduit à l'apparition de l'iode moléculaire est la recombinaison des atomes d'iode:

$$[4] \qquad I\cdot + I\cdot \rightarrow I_2.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

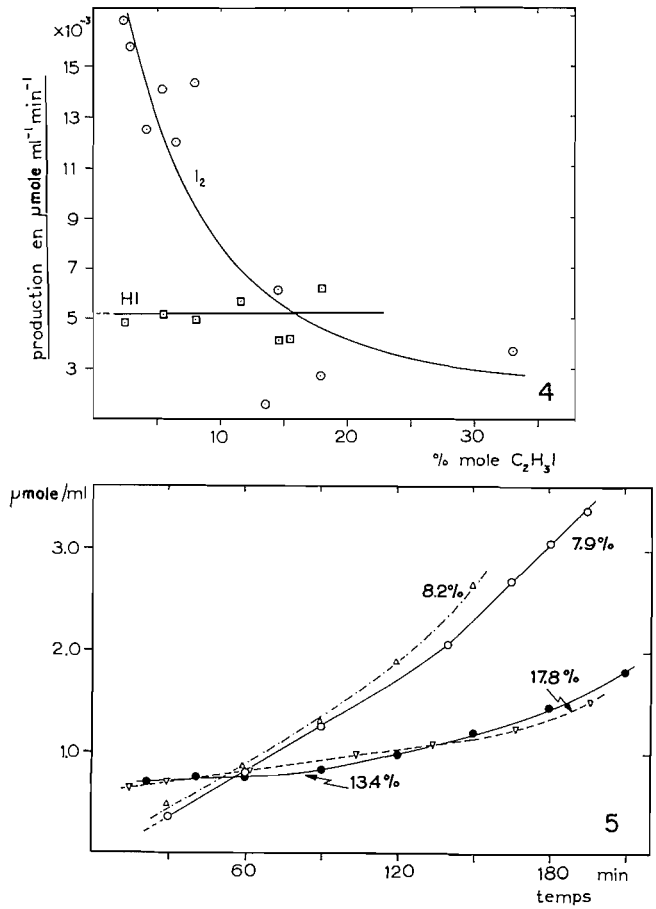

FIG. 4. Vitesse de formation de l'acide iodhydrique (□) et de l'iode (○) en fonction de la concentration en C_2H_3I. La courbe de l'iode est pour 180 min d'irradiation.

FIG. 5. Formation de l'iode en fonction du temps pour différentes concentrations (% mole) en iodure de vinyle.

La réaction de formation de l'iode moléculaire par l'action de l'iode atomique sur l'iodure de vinyle:

[4*a*] $$C_2H_3I + I\cdot \rightarrow C_2H_3\cdot + I_2$$

ne peut être importante, car elle conduirait à un accroissement de la production de C_2H_4 en fonction de la concentration en monomère, ce que l'on n'observe pas expérimentalement.

Formation de l'éthylène

La formation de l'éthylène suit des lois complexes. (*a*) Elle est fonction du carré du temps d'irradiation (Fig. 6) pour des périodes inférieures à 600 min. L'allure des courbes expérimentales peut être décrite par l'équation [B],

[B] $$[C_2H_4] = Kt^2,$$

où K est fonction de la concentration en iodure de vinyle. (*b*) La Fig. 3 montre la vitesse de formation de C_2H_4 en fonction de la concentration en monomère pour une même dose d'énergie absorbée. En comparant les valeurs des vitesses de production de l'éthylène et

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

celles de l'acétylène, on constate que les premières sont environ 10 fois plus faibles pour 180 min d'irradiation. (*c*) L'addition d'acide iodhydrique avant irradiation entraîne un accroissement de la formation d'éthylène, d'un facteur de huit, comme en témoigne les chiffres du Tableau II. (*d*) Le Tableau III indique qu'il y a un effet d'intensité très net sur la vitesse de formation de l'éthylène. Dans ce tableau les vitesses de production de l'éthylène sont rapportées à celles de l'acétylène que nous savons indépendantes de l'effet d'intensité. Les rapports sont calculés pour un même temps d'irradiation.

TABLEAU III

Effet de l'intensité sur la production de l'éthylène et du chlorure de vinyle

C_2H_3I (% mole)	Temps (min)	$R_{C_2H_2}/R_{C_2H_4}$ pour intensité relative de		$R_{C_2H_2}/R_{C_2H_3Cl}$ pour intensité relative de	
		1.0	0.12	1.0	0.12
2.0	420	2.2	16	—	—
8.3	300	4.3	40	—	—
11.7	480	3.3	35	—	—
13.5	1380	1.1	7.5	—	—
14.0	180	—	—	9.0	10.0
25.0	420	5.2	55	—	—

La production d'éthylène étant proportionnelle au carré du temps et au carré de l'intensité, ce gaz doit donc être produit à partir de deux produits de photolyse, dont l'un s'accumule avec le temps d'irradiation. Ce fait nous pousse à rejeter une réaction de type classique, c'est-à-dire l'abstraction par un radical vinyle d'un atome d'hydrogène sur une molécule de vinyle, réaction qui serait d'ailleurs défavorisée thermodynamiquement.

Un premier type de réaction conduisant à la formation de C_2H_4 et faisant intervenir deux produits de photolyse est la dismutation de deux radicaux vinyles. Ce mécanisme, déjà proposé par Tickner et Le Roy (17), a été évoqué par Herman et Hupin (18) pour interpréter la formation d'éthylène dans la radiolyse du chlorure de vinyle gazeux. Dans ce cas l'expression de la formation de l'éthylène devrait être une fonction linéaire du temps, ce qui n'est pas vérifié expérimentalement. Par conséquent, s'il y a participation de ce mécanisme à la formation d'éthylène, elle ne peut être importante. Exprimé en d'autres termes, cela revient à dire qu'en phase liquide le rapport dismutation–recombinaison des radicaux vinyles est très petit.

On doit donc penser à la réaction suivante:

[5] $$C_2H_3\cdot + HI \rightarrow C_2H_4 + I\cdot.$$

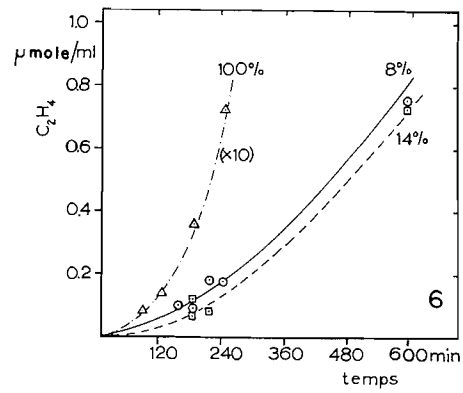
Ce genre de réaction entre un radical et l'acide iodhydrique a déjà été évoqué par Hamill (3), Willard (14) et Wijnen (15) dans la photolyse de divers iodures organiques. Une telle réaction serait très favorisée thermodynamiquement ($\Delta H^0 \sim -40$ kcal/mole). On peut voir, sur la Fig. 2, que la concentration en HI croît linéairement en fonction du temps d'irradiation. L'éthylène produit à partir de la réaction [5] devrait alors afficher une dépendance du carré du temps et une influence de l'intensité lumineuse d'ordre un, ce qui correspond bien aux résultats expérimentaux.

Ce mécanisme est aussi vérifié par le fait qu'une addition d'acide iodhydrique entraîne un accroissement de la quantité d'éthylène. Toutefois, cette quantité d'éthylène (Tableau II) est inférieure de 25% à la quantité calculée à partir de la concentration en acide (valeur calculée, 1.0×10^{-6} mole/ml). Mais on peut expliquer cet écart: (*a*) soit par le fait que

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

l'on atteint la limite de solubilité de HI dans CCl_4, (*b*) soit par le fait que tous les radicaux disponibles sont déjà captés à une plus faible concentration en acide iodhydrique.

La réaction [5] peut donc expliquer toute la production de l'éthylène et, si les deux autres réactions mentionnées y participent, leur participation ne serait que de l'ordre de quelques pourcents, soit la précision sur les mesures de l'éthylène.



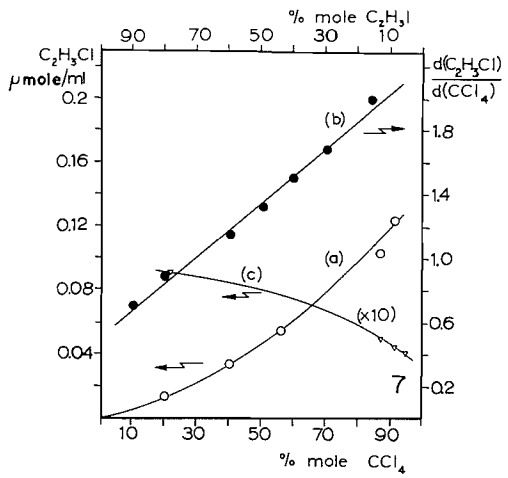


FIG. 6. Formation de l'éthylène en fonction du temps pour différentes concentrations (% mole) en iodure de vinyle.

FIG. 7. Formation du chlorure de vinyle (courbe *a*) et du butadiène (courbe *c*) en fonction de la concentration pour 180 min d'irradiation. La courbe *b* représente la dérivée, $d(C_2H_3Cl)/d(CCl_4)$, de la courbe *a*.

Formation du chlorure de vinyle

Dans le cas du chlorure de vinyle, nous constatons les faits expérimentaux suivants: (*a*) sa formation croît linéairement en fonction du temps, puis ralentit à mesure que le temps augmente (Fig. 2); (*b*) la formation de C_2H_3Cl est fonction du carré de la concentration en CCl_4 (Fig. 7, courbe *a*), comme en témoigne la linéarité de la dérivée (Fig. 7, courbe *b*); (*c*) l'addition de l'acide iodhydrique au système diminue la production de C_2H_3Cl mais ne l'inhibe pas complètement (Tableau II); (*d*) la vitesse de formation de C_2H_3Cl ne montre pas d'effet d'intensité (Tableau III).

La réaction suivante permet d'interpréter la formation du chlorure de vinyle:

[6] $$C_2H_3^{\cdot} + CCl_4 \rightarrow C_2H_3Cl + CCl_3^{\cdot}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Cette réaction, favorisée thermodynamiquement ($\Delta H^0 \sim -17$ kcal/mole) en raison de la grande stabilité relative du radical $CCl_3^{\cdot}$, ne montre pas d'effet d'intensité, ce qui est conforme à l'expérience. L'effet du temps sur la formation de C_2H_3Cl se comprend aussi si l'on songe qu'avec l'accroissement du temps de photolyse il y a augmentation de la concentration en intercepteurs de radicaux, HI et I_2, et que leurs effets entrent en compétition avec la réaction [6]. Dans la discussion nous reviendrons sur l'effet de concentration.

Par contre, les réactions des atomes de chlore, formés à partir de CCl_4, avec les radicaux vinyles ou avec le monomère lui-même ne peuvent être prises en considération pour les raisons suivantes. Cette réaction d'atomes de chlore avec les radicaux vinyles devrait présenter une dépendance linéaire de l'intensité, ce qui n'est pas le cas; nous pouvons donc l'éliminer. D'autre part, la réaction d'échange atome de chlore–monomère, favorisée thermodynamiquement, ne devrait aucunement présenter une dépendance du carré de la concentration en CCl_4, elle peut donc être également éliminée. Comme nous l'avons vu au début de cet exposé, ces faits vérifient bien que le dispositif expérimental peut assurer une photolyse négligeable du solvant.

Formation du butadiene

La Fig. 2 montre que le butadiène se forme surtout au début de la photolyse; après 180 min, la production devient très faible. Mais il existe un léger accroissement dans la formation de C_4H_6 en fonction de la concentration en monomère (Fig. 7, courbe *c*). Signalons de plus que l'addition de l'acide iodhydrique inhibe complètement la production du butadiène.

Comme source majeure de formation du butadiène, on peut admettre une réaction de recombinaison des radicaux vinyles,

[7] $$C_2H_3^{\cdot} + C_2H_3^{\cdot} \rightarrow C_4H_6,$$

réaction qui permet d'expliquer l'effet du temps: au cours de la photolyse, la concentration en intercepteurs, HI et I_2, croît également et l'on doit s'attendre à un effet d'inhibition encore plus prononcé que dans le cas de la réaction [6]. L'effet de concentration peut aussi s'expliquer par le fait qu'au fur et à mesure que la concentration en iodure de vinyle augmente, l'absorption de la lumière se fait en couches de plus en plus minces, favorisant ainsi la recombinaison de deux radicaux vinyles par suite de leur grande concentration locale.

Si l'on considère néanmoins l'effet de concentration en monomère sur la formation du butadiène, on peut imaginer les réactions suivantes:

[8] $$C_2H_3^{\cdot} + C_2H_3I \rightarrow C_4H_6 + I^{\cdot}$$

ou (et)

[8*a*] $$C_2H_3I^* + C_2H_3I \rightarrow C_4H_6 + 2I^{\cdot}.$$

Une telle réaction a déjà été proposée par West et Fitelson (19, 20) dans la photolyse de l'iodure d'éthyle. Cependant, un tel mécanisme devrait conduire à une production de butadiène sensiblement proportionnelle au temps de photolyse, et l'on ne voit pas pourquoi il serait plus sensible à l'action des intercepteurs que la réaction de production du chlorure de vinyle [7].

Il semble donc que la formation du butadiène doit être attribuée surtout à la réaction [7], sans toutefois rejeter totalement une participation de la réaction [8] en raison de l'effet de concentration.

DISCUSSION

Avant d'établir un schéma cinétique qui rendrait compte dans les grandes lignes des phénomènes observés, nous devons porter notre attention sur deux faits expérimentaux qui n'ont pas reçu d'explication dans le chapitre précédent: les productions du chlorure de vinyle et de l'éthylène en fonction de la concentration en iodure de vinyle.

En admettant la réaction [6] pour la formation du chlorure de vinyle, on devrait trouver une dépendance linéaire de la concentration en CCl_4. En fait, on trouve une dépendance du carré de la concentration (Fig. 6). La seule manière d'expliquer ce fait est d'admettre une dépendance de la concentration des radicaux vinyles vis-à-vis de la concentration en CCl_4 ou, vice versa, vis-à-vis de la concentration en C_2H_3I.

Considérons maintenant la formation de l'éthylène. Si l'on admet que la concentration en HI ne varie pas sensiblement avec la concentration en C_2H_3I, ce qui semble être le cas du moins dans la région entre 0 et 25% (Fig. 4), la seule façon d'expliquer la diminution de formation de l'éthylène en fonction de la concentration en iodure de vinyle est de postuler une variation de la concentration des radicaux vinyles.

Or, une réaction d'amorçage de chaîne polymériques par les radicaux vinyles pourrait bien être l'explication des phénomènes observés.

[9] $$C_2H_3^{\cdot} + C_2H_3I \rightarrow C_4H_6I^{\cdot}.$$

On ne peut, ici, parler véritablement de polymérisation mais plutôt de télomérisation, la présence d'inhibiteurs dans le système, HI et I_2, limitant la propagation d'une chaîne probablement à deux ou trois unités de monomère:

[10] $$(C_2H_3I)_n^{\cdot} + HI \rightarrow (C_2H_3I)_n + I$$

[11] $$(C_2H_3I)_n^{\cdot} + I_2 \rightarrow (C_2H_3I)_n + I.$$

Cette réaction n'a rien de surprenant si l'on considère que les composés éthyléniques sont des intercepteurs de radicaux et que tous les halogénures de vinyle polymérisent facilement. La réaction d'amorçage [9] est en principe favorisée par la concentration croissante du monomère et ceci justifie, dans une certaine mesure, l'allure des courbes de formation du chlorure de vinyle et de l'éthylène.

Mais les réactions [6] et [9] sont compétitives; on peut alors expliquer que la formation du chlorure de vinyle dépende du carré de la concentration en iodure de vinyle. Dans le cas de l'éthylène, la dépendance de la concentration n'est pas aussi simple (Fig. 3); ce qui peut s'expliquer par le fait que la vitesse de formation de l'éthylène dépend à la fois des vitesses des réactions [6] et [9], alors que celle du chlorure de vinyle ne dépend que de la vitesse de la réaction [9].

Les réactions [5] et [10] sont fonction de l'intensité lumineuse et rendent compte de l'effet d'intensité sur la production de l'acide iodhydrique; la quantité produite par unité de dose absorbée est légèrement plus grande à plus faible intensité. En outre, par la nature même des réactions [5] et [10], on peut admettre que les constantes de vitesse k_5 et k_{10} sont du même ordre de grandeur. Or, le fait que la production d'acide iodhydrique est sensiblement constante quelle que soit la concentration en iodure de vinyle corrobore cette constatation car, si seule la réaction [5] existait, on devrait s'attendre à une variation de la quantité d'acide iodhydrique formée en fonction de la concentration. Puisque ce n'est pas, c'est—d'une certaine façon—une preuve de l'existence de la réaction [10] avec une constante de vitesse comparable à k_5.

Toutefois, les tentatives pour retrouver le télomère ont été vaines parce que la quantité formée est trop faible pour être détectée par les méthodes usuelles. Néanmoins, après des

irradiations prolongées, on constate la présence d'un résidu huileux qui distille plus lentement que le monomère, mais dans lequel on n'a pu identifier avec certitude des télomères.

La consommation d'acide iodhydrique par la réaction [5] n'est que de 3 à 4% de la quantité totale produite. Comme la précision du dosage de HI est d'environ 10%, on peut donc comprendre que, pour toute fin pratique, on ne puisse distinguer l'influence de la formation de l'éthylène sur la formation de l'acide iodhydrique. Par conséquent, le déficit en HI par rapport à C_2H_2 doit avoir une autre origine: soit l'addition de HI à la double liaison du monomère, soit l'absorption de HI sur les parois, soit, encore, une autre cause qui nous échappe actuellement.

L'ensemble des réactions [1] à [11] ainsi que la réaction [12] rendent compte des phénomènes observés.

[12] $$C_2H_3\cdot + I_2 \rightarrow C_2H_3I + I\cdot$$

En appliquant l'hypothèse de stationnarité et en négligeant la réaction [8] (dont la contribution est faible), les réactions de terminaison des télomères [10] et [11] (dont nous ne saurions tenir compte), ainsi que la réaction [7] (qui n'est importante qu'au tout début de l'irradiation), on trouve les expressions suivantes pour la production de l'éthylène et du chlorure de vinyle:

[C] $$\frac{d[C_2H_4]}{dt} = R_{C_2H_4} = \frac{\phi_3 k_5[HI]}{k_5[HI] + k_6[CCl_4] + k_9[C_2H_3I] + k_{12}[I_2]}$$

[D] $$\frac{d[C_2H_3Cl]}{dt} = R_{C_2H_3Cl} = \frac{\phi_3 k_6[CCl_4]}{k_5[HI] + k_6[CCl_4] + k_9[C_2H_3I] + k_{12}[I_2]}$$

où ϕ_3 est égal au rendement quantique de la réaction [3]. On voit que:

[E] $$R_{C_2H_4}/R_{C_2H_3Cl} = \frac{k_5[HI]}{k_6[CCl_4]}.$$

Cette expression devrait être vérifiée pour des périodes supérieures à 120 min, alors que la production du butadiène est déjà terminée; la Fig. 8 prouve qu'il en est bien ainsi. La pente de la droite donne un rapport $k_5/k_6 = 1.2 \times 10^4$.

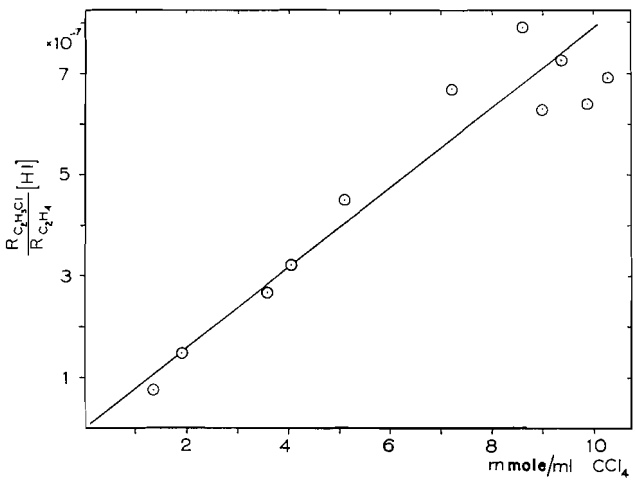

FIG. 8. $(R_{C_2H_3Cl}/R_{C_2H_4})[HI]$ en fonction de la concentration en CCl_4.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

A partir de ces expressions cinétiques, on peut calculer le rapport des constantes de vitesses; on trouve $k_{12}/k_5 = 1.5 \pm 1$ et $k_9/k_6 = 5 \pm 3$. En ce qui concerne le rapport k_{12}/k_5, l'incertitude des résultats significatifs pour la formation de l'iode peut conférer une erreur importante à la valeur trouvée.

Si l'on compare les rapports de vitesse ainsi obtenus et si l'on tient compte de l'aptitude de la double liaison vinylique à intercepter les radicaux, nous voyons immédiatement que l'efficacité du radical $C_2H_3^{\cdot}$ dans l'amorçage des chaînes polymériques est réellement faible; conclusion à laquelle sont arrivés Melville (21) de même que Herman et Hupin (18), le premier en étudiant la photopolymérisation du chlorure de vinyle, les seconds en étudiant la radiolyse de ce même chlorure.

Le rapport des vitesses $R_{C_2H_2}/R_{C_2H_4}$ permet d'estimer celui des rendements quantiques ϕ_2/ϕ_3, qui à l'aide de l'hypothèse de l'état stationnaire peut s'exprimer par l'équation suivante:

[F] $$\frac{R_{C_2H_2}}{R_{C_2H_4}} = \frac{\phi_2}{\phi_3} + \left[\frac{\phi_2}{\phi_3}\frac{k_9}{k_5[HI]}\left(1 + \frac{k_6[CCl_4]}{k_9[C_2H_3I]} + \frac{k_{12}[I_2]}{k_9[C_2H_3I]}\right)\right][C_2H_3I].$$

Une extrapolation à concentration nulle en monomère devrait donner la valeur de ϕ_2/ϕ_3; on trouve ainsi $\phi_2/\phi_3 = 1.2 \pm 0.3$. Il est à remarquer que pour la photolyse de l'iodure d'éthyle dans le cyclohexane (3), le rapport des rendement quantiques des réaction correspondant aux réactions [2] et [3] est égal à 1.8. Si l'on admet une analogie entre la photolyse de C_2H_5I et celle de C_2H_3I, $\phi_2/\phi_3 > 1$ indiquerait que la réaction [6] peut se passer à l'intérieur de la cage soumise à la diffusion:

[6a] $$(C_2H_3 + I + CCl_4) \rightarrow C_2H_3Cl + (I + CCl_3).$$

Cette réaction devrait normalement diminuer le rendement ϕ_3. Il n'est toutefois pas exclus que ce type de réaction nécessite des radicaux chauds, comme il semble que ce soit le cas pour l'iodure d'éthyle en solution dans le cyclohexane (3). Mais, d'autre part, pour les conditions de nos expériences, la non-concurrence de réactions telles que:

[13] $$C_2H_3^{\cdot} + C_2H_3I \rightarrow C_2H_4 + C_2H_2I^{\cdot},$$

possibles à partir de radicaux chauds, laisse prévoir que peut de radicaux formés réagissent en tant que radicaux chauds. Ceci correspond d'ailleurs aux conclusions de Wijnen (14) sur la photolyse de l'iodure d'éthyle. Tout un problème reste donc à résoudre, qui fera l'objet d'une prochaine publication.

CONCLUSIONS

Les conclusions que nous pouvons tirer de ce travail sont les suivantes: (1) le mécanisme de la "dismutation contrôlée par diffusion" explique bien les phénomènes observés; (2) l'éthylène est principalement formé par la réaction de radicaux vinyliques thermalisés par HI; (3) nous devons postuler une réaction de télomérisation pour expliquer la diminution de la production d'éthylène et de l'iode avec l'augmentation de la concentration en iodure de vinyle; (4) l'efficacité d'amorçage des chaînes polymériques par le radical $C_2H_3^{\cdot}$ est faible comparée aux autres réactions compétitives de disparition de ce radical.

REMERCIEMENTS

Nous remercions le Dr. W. Forst pour les judicieux commentaires qu'il nous a faits durant ce travail. Nos remerciements vont également au Conseil National de Recherche du Canada pour une bourse accordée à l'un de nous (P. C. R.) et pour l'aide matérielle qui nous a permis de mener à bien cette étude.

COMMENTS ON N.M.R. SPECTRA OF THE $X_nAA'X_n'$ TYPE

R. K. HARRIS[1]
Mellon Institute, Pittsburgh, Pennsylvania
Received May 15, 1964

ABSTRACT

General expressions are derived for line positions and relative intensities in the X spectrum for an $X_nAA'X_n'$ nuclear magnetic system in the case when $J_X = 0$. It is shown that in most cases it is possible to obtain the coupling constants involved by direct measurement of the spectrum using simple equations, but that this is not possible in certain limiting cases where the spectrum is deceptively simple.

I. INTRODUCTION

The development of nuclear magnetic resonance (n.m.r.) theory in the analysis of spectra has led to the extensive use of computers for the more complex nuclear magnetic systems. On the other hand, as the magnetic field strength has been increased in modern spectrometers, more spectra may be classified as first order (1), and the coupling constants and chemical shifts can be obtained by direct measurement. There exist, however, types of nuclear magnetic system for which the spectra are never first order but which yield the n.m.r. parameters by direct measurement, using appropriate formulae. This is so for all nuclear magnetic systems in which there are nuclei which are chemically (or structurally) equivalent but not magnetically equivalent (2). We shall distinguish such nuclei by a prime, as in the notation of Corio (3). The direct measurement of parameters from spectra is of course a more convenient and less costly procedure than the use of computers, but there have been few instances in the literature where the formulae have been presented. The XAA'X' system is, of course, well known (1), and several papers have dealt with cases of $X_2AA'X_2'$ (4) and $X_3AA'X_3'$ (5, 6) spectra. However, it is not generally realized that many of the formulae developed for these spectra are appropriate also for the more general $X_nAA'X_n'$ case. This paper presents these general formulae for the $X_nAA'X_n'$ system subject to three limitations: (i) only expressions for resonances of the X nucleus will be presented, (ii) it will be assumed that coupling J_X between nuclei of types X and X' is zero, and (iii) only nuclei of spin 1/2 will be considered. The theory was developed for the analysis of the proton spectra of $(CH_3)_2P(:S)P(:S)(CH_3)_2$ and $(CH_3)_2PP(CH_3)_2$, which are examples of $X_6AA'X_6'$ systems (7) for which these conditions are valid and for which the correspondingly high-resolution ^{31}P spectra were unobtainable in this laboratory. However, the formulae will be applicable to a range of symmetrical methyl compounds.

II. TRANSITION ENERGIES OF THE X NUCLEI

Since we are assuming that $J_X = 0$ and also that the chemical shift between the A and X nuclei is large with respect to all other coupling constants in the system (this assumption is implicit in the nomenclature (1, 3)), there are only three nuclear magnetic parameters that affect the spectrum (5, 6). These are the coupling constant J_A between the A and A' nuclei, and the two types of coupling constant between an A or A' nucleus and an X or X' nucleus, $J_{AX} = J_{A'X'}$ and $J_{AX'} = J_{A'X}$. These latter parameters will be written J_{AX} and $J_{AX'}$ respectively, and will be referred to as the short-range and long-range (A, X) coupling

constants. It will, however, prove to be more convenient (1) to use combinations L and N of these coupling constants defined by $L = |J_{AX} - J_{AX}'|$ and $N = |J_{AX} + J_{AX}'|$. Since the n nuclei of type X are magnetically equivalent, coupling between them does not affect the spectrum and can be ignored (1). Similarly we can neglect coupling between the n nuclei of type X′. The basic spin functions, α and β, will be used to describe the spin states of the A and A′ nuclei, while the total spin (in the direction of the magnetic field) of the X_n and X_n' groups of nuclei will be given by $I_z(X_n) = p$ and $I_z(X_n') = m$, the overall spin state being denoted by (p, m).

Because of the assumptions listed above, there are no off-diagonal elements of the spin Hamiltonian between states differing in $I_z(A) + I_z(A')$. Therefore we may separate the total matrix representation of the Hamiltonian into three sub-matrices appropriate for (i) the $\alpha\alpha$, (ii) the $\beta\beta$, and (iii) the $\alpha\beta$ and $\beta\alpha$ spin states. There will be mixing between states differing only by an interchange of spins between the A and A′ nuclei (that is, in sub-matrix (iii)), due to J_A. However, sub-matrix (i) may be further divided into symmetric and antisymmetric parts (see ref. 1) and when $J_X = 0$, there are no off-diagonal elements in either part. Consequently, transitions within these parts all occur at the same frequency, namely $(\nu_X + \frac{1}{2}N)$, where ν_X is the unperturbed resonance frequency of the X and X′ nuclei. Similarly from sub-matrix (ii) a single line is obtained at $(\nu_X - \frac{1}{2}N)$. Here we have assumed for the sake of convenience that the absolute sign of $(J_{AX} + J_{AX}')$ is positive, but in fact this sign does not affect the final result that sub-matrices (i) and (ii) together give an intense doublet symmetrically disposed about ν_X, with a splitting of N.

The sub-matrix (iii) gives rise to a more complex series of lines. However, the only off-diagonal elements are those between $\alpha\beta$ and $\beta\alpha$ states of the AA′ nuclei, and these elements all have the value $\frac{1}{2}J_A$. The sub-matrix therefore reduces to a series of 2×2 sub-sub-matrices. The diagonal elements are given in general form for a single sub-sub-matrix as follows,

[1]
$$\begin{array}{ll} (p, m)\alpha\beta \text{ state} & \frac{1}{2}(p - m)L \\ (p, m)\beta\alpha \text{ state} & -\frac{1}{2}(p - m)L. \end{array}$$

In these expressions terms in ν_X have been omitted, since ν_X occurs in all the X and X′ transition energies. Diagonalization of the sub-sub-matrix results in eigenvalues ϵ given by

[2]
$$\epsilon(p, m) = \pm\tfrac{1}{2}[(p - m)^2L^2 + J_A^2]^{\frac{1}{2}},$$

where $(p - m)$ may take any integral value between n and $-n$ inclusive. Obviously these eigenvalues are independent of the sign of $(p - m)$, so that all allowed X transition energies may be expressed relative to ν_X by a single equation:

[3]
$$(\epsilon_\chi - \epsilon_{\chi-1}) = \pm\tfrac{1}{2}\{[\chi^2L^2 + J_A^2]^{\frac{1}{2}} \pm [(\chi - 1)^2L^2 + J_A^2]^{\frac{1}{2}}\},$$

where χ (which is $|p - m|$ for the upper state) may be any integer between 1 and n inclusive. These lines are symmetrically situated about ν_X and may be divided into two types. The pair with a plus sign between the square root terms, here referred to as the outer lines, has a separation $S_o(\chi)$ given by

[4]
$$S_o(\chi) = \{\chi^2L^2 + J_A^2\}^{\frac{1}{2}} + \{(\chi - 1)^2L^2 + J_A^2\}^{\frac{1}{2}},$$

whereas the lines with a minus sign between the square root terms (the inner lines) have a separation $S_i(\chi)$:

[5]
$$S_i(\chi) = \{\chi^2L^2 + J_A^2\}^{\frac{1}{2}} - \{(\chi - 1)^2L^2 + J_A^2\}^{\frac{1}{2}}.$$

Since X and X′ are chemically equivalent, the expressions [3] to [5] apply to both X transitions ($\Delta p = 1$) and X′ transitions ($\Delta m = 1$).

III. RELATIVE INTENSITIES

The values are initially calculated (before normalization) with unit intensity for an allowed transition between two of the basis states. Thus for a molecule with k magnetic nuclei the total intensity will be $k2^{k-1}$, while for an $X_nAA'X_n'$ system the sum of the intensity of the X and X′ transitions will be $2n2^{2n+1}$. The doublet of separation N will comprise half of this value, since it originates from half of the A and A′ spin states. The situation is again much more complex for sub-matrix (iii). Each sub-sub-matrix has a degeneracy of ${}^nC_{(n/2)+p} \times {}^nC_{(n/2)+m}$ for the number of ways of obtaining $I_z(X_n) = p$ and $I_z(X_n') = m$ from n nuclei of spin 1/2. When we consider the number of X transitions, we must multiply by $(n/2 + p)$ for the number of ways of changing p by $+1$ for a single wave function. For a given transition we must then sum over all possible values of p, keeping $p - m = \chi$ constant with $n/2 \geqslant m \geqslant -n/2$ and $n/2 \geqslant p \geqslant -n/2 + 1$. The limits set by these conditions for positive χ are $n/2$ and $\chi - n/2$, and expression [6] is obtained.

$$[6] \qquad \sum_{p=\chi-(n/2)}^{p=n/2} \left(\frac{n}{2} + p\right) {}^nC_{(n/2)+p}\, {}^nC_{(n/2)+p-\chi}.$$

However, the transition energy for $p - 1 \rightarrow p$ is the same as that for $-p \rightarrow -p - 1$, so [6] must be multiplied by 2 and two further factors of 2 are necessary to include (a) the X′ transitions and (b) both $\alpha\beta$ and $\beta\alpha$ AA′ spin states. This gives the total relative intensity for the four lines with energies given by [3] for a single value of X. In the absence of mixing between the $\alpha\beta$ and $\beta\alpha$ spin states (that is $J_A = 0$), the outer lines [4] are forbidden and thus have zero intensity while the inner lines [5] will each have intensity

$$4\sum_{r=\chi}^{n} r^nC_r\, {}^nC_{r-\chi},$$

where $r = n/2 + p$. For the weakest pair of inner lines ($\chi = n$), the above expression gives intensity $4n$, so that if we normalize to these lines, the relative intensities are given by [7]:

$$[7] \qquad \frac{1}{n}\sum_{r=\chi}^{n} r^nC_r\, {}^nC_{r-\chi}.$$

This will be referred to as the limiting intensity of each line. On this scale each line of the doublet of separation N will have intensity $2^{2(n-1)}$.

However, when J_A becomes appreciable, the outer lines acquire energy from the inner lines. The perturbations of intensities introduced may be calculated as in ref. 1. For the sub-sub-matrix [2] the parameter (1), $\tan 2\theta$, is $J_A/(p - m)L$ and the eigenstates are $\cos\theta|(p, m)\alpha\beta > +\sin\theta|(p, m)\beta\alpha) >$ and $-\sin\theta|(p, m)\alpha\beta > +\cos\theta|(p, m)\beta\alpha >$. The relative transition intensities for the outer and inner lines may be found by multiplying the appropriate coefficients $\sin\theta$ and $\cos\theta$, summing over allowed transitions between the basis functions, and taking the square of the result. Thus for the inner lines we must weight [7] by the factor $\frac{1}{2}(1 + g)$, where $g = [\chi(\chi - 1)L^2 + J_A^2]/\{[\chi^2L^2 + J_A^2][(\chi - 1)^2L^2 + J_A^2]\}^{\frac{1}{2}}$.

Therefore the inner lines each have intensity $Z_1(\chi)$ given by [8]:

$$[8] \qquad Z_1(\chi) = \frac{1}{2n}(1 + g)\sum_{r=\chi}^{n} r^nC_r\, {}^nC_{r-\chi}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The outer lines will each have intensity $Z_0(\chi)$ given by [9]:

$$[9] \qquad Z_0(\chi) = \frac{1}{2n}(1 - g)\sum_{r=\chi}^{n} r^nC_r{}^nC_{r-\chi}.$$

The expression for g may easily be put in terms of $(L/J_A)^2$ alone (or, alternatively, in terms of $(J_A/L)^2$). The intensities then depend only on the relative magnitude of the two coupling constants L and J_A. It can be shown that g falls off as χ increases, and that for each value of χ there is a minimum in g (and therefore a maximum in $Z_0(\chi)$) when $(L/J_A)^2 = 1/\chi(\chi - 1)$. For $\chi = 2$ this minimum value of g is as large as 0.943, and it increases with χ. Consequently the outer lines for $\chi \geqslant 2$ are always very weak and will usually be unobservable (7).

IV. CHARACTERISTICS OF THE X SPECTRUM

There may be a total of $(2n + 1)$ pairs of lines symmetrically placed about ν_X. Half the total intensity (that is, relative intensity 2^{2n-1}) lies in the doublet of separation N, whereas the remaining intensity is spread over the $2n$ pairs of lines which are completely defined by eqs. [4], [5], [8], and [9]. The only nuclear magnetic parameters occurring in these equations are L and J_A, and the line positions and intensities (apart from a scaling factor) depend only on the ratio $L/|J_A|$. A typical spectrum, excluding the N doublet, is listed in Table I for $L/|J_A| = 1$ and values of χ up to 6. This shows several general features.

TABLE I

The X lines of an $X_6AA'X_6'$ nuclear magnetic system with $L/|J_A| = 1$

	Doublet separations[a]			
χ	Inner pair	Outer pair	Limiting intensity[b]	g
1	0.414	2.414	462	0.7073
2	0.822	3.650	330	0.9489
3	0.926	5.398	165	0.9898
4	0.961	7.285	55	0.9971
5	0.976	9.222	11	0.9992
6	0.984	11.182	1	0.9994

[a]In units of L.
[b]Given for each line by eq. [7]. Each line of the N doublet will have relative intensity 1024.

1. The doublet separations of the inner lines increase monotonically with χ, but they converge to the value L as $\chi \to \infty$. This fact can be used to obtain an approximate value of L by inspection of the spectrum. The doublet separation of the outer lines also increases with χ but diverges towards a constant increment of $2L$.

2. If any of the inner lines fall outside the N doublet, it immediately follows that J_{AX} and J_{AX}' are opposite in sign.

3. It can be anticipated that the inner pairs of lines will become difficult to resolve from one another for values of χ greater than about 3.

4. The limiting intensities fall off very rapidly as χ increases.

5. The value of g increases towards unity as χ increases. When considered together with feature 4, this fact means that it will usually not be possible to see outer lines with $\chi > 1$.

6. The inner and outer lines are usually well separated, for $S_i(\chi)$ must be less than L, as noted above, whereas the separation of a pair of outer lines $S_0(\chi)$ must be greater than L.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

All three parameters, N, L, and $|J_A|$, may be obtained directly from the spectrum using only the separations of the three most intense lines. It is always easy to pick out the N doublet and this should then be mentally discarded from the spectrum. The separations of the first two pairs of inner lines (which are therefore the next most intense features of the spectrum) then give $S_1(1) = [L^2 + J_A^2]^{\frac{1}{2}} - |J_A|$ and $S_1(2) = [4L^2 + J_A^2]^{\frac{1}{2}} - [L^2+J_A^2]^{\frac{1}{2}}$. Equations [10] and [11] may then be used.

$$[10] \qquad |J_A| = [3S_1(1) + S_1(2)][S_1(1) - S_1(2)]/2[3S_1(1) - S_1(2)].$$

$$[11] \qquad L^2 = S_1(1)\cdot S_1(2)\cdot[S_1(1) + S_1(2)]/[3S_1(1) - S_1(2)].$$

However, if the first pair of *outer* lines is visible it becomes more convenient to measure the separation between one of these and the corresponding inner line, giving J_A directly (see Fig. 1). The separation $S_1(1)$ between the first pair of inner lines is then needed to

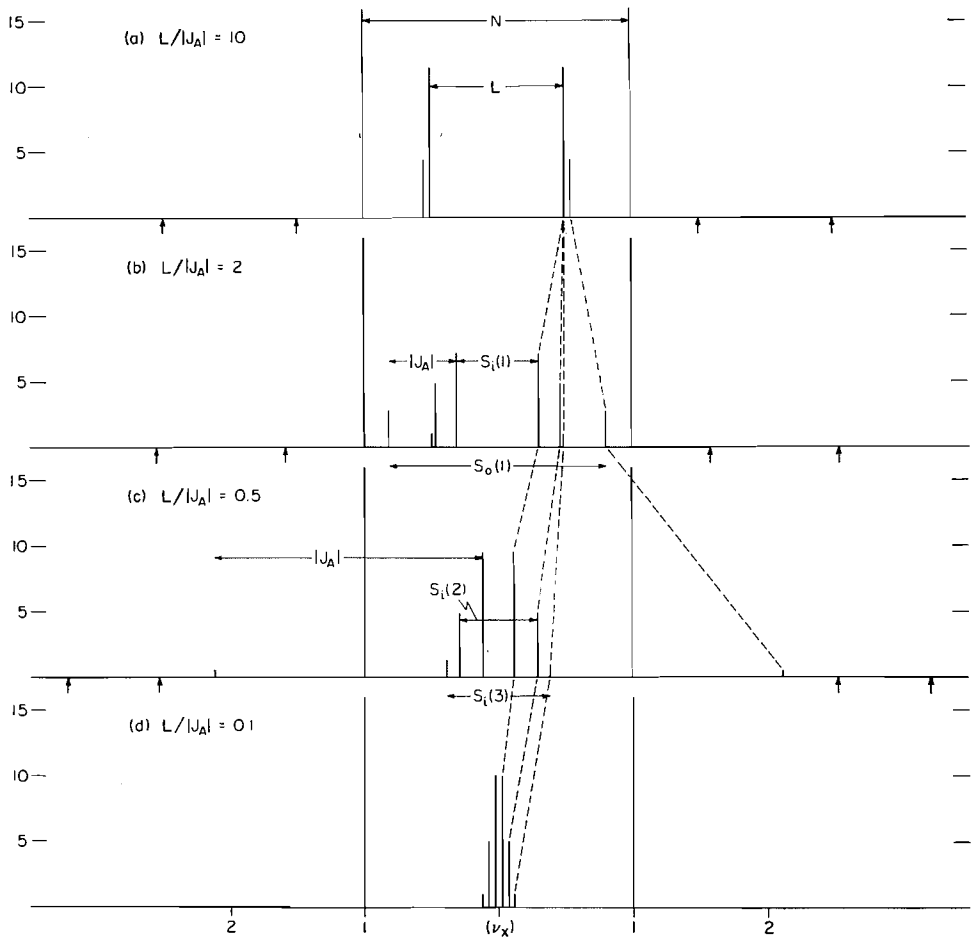

FIG. 1. Diagram to illustrate the variation of the X spectrum of $X_3AA'X_3'$ systems with changes in $L/|J_A|$. The relative intensities (as explained in the text) are plotted along the ordinates. The abscissae give line positions in units of L. The value of N is taken to be $2L$ (therefore J_{AX} and $J_{AX'}$ have the same sign). The small vertical arrows mark the positions of outer lines, which have negligible intensity (< 0.06), for $x = 2$ and 3. In (*d*) all three outer lines lie between 10 and 10.5 units of L from the center ($\simeq J_A$) and their total intensity is less than 0.04. Spectra (*a*) and (*d*) approach limiting cases B and A discussed in the text.

For personal use only.

give L from the expression above. Since the spectrum in general yields L and N, it is usually possible to obtain the relative signs of J_{AX} and J_{AX}'. It is not possible, however, to determine the sign of J_A relative to these, nor is it possible to make any distinction between J_{AX} and J_{AX}', and so they cannot be assigned to actual couplings in the molecule (that is, we cannot tell which is the "long-range" coupling constant).

It is important to realize the relation between X spectra of systems of the $X_nAA'X_n'$ type. If the number of X and X′ nuclei are increased by 1 to $(n+1)$—while N, L, and J_A are left constant—the only spectral changes are (i) the addition of two very weak pairs of lines with $\chi = (n+1)$ and (ii) corresponding slight alterations in the relative intensities of other lines. Consequently it is usually possible to recognize the most intense lines as typical of a simple XAA′X′ system (with $J_X = 0$), or at any rate an $X_2AA'X'_2$ system. This type of relation also exists between spectra of the AB_{2n} type (8).

V. LIMITING CASES

The general description above may be considerably simplified in certain cases, giving rise to "deceptively simple" spectra (9). There are two possible extreme types, which are indicated in Fig. 1 for the $X_3AA'X_3'$ system.

(A) $|J_A| \gg L$, giving approximately an A_2X_{2n} spectrum (see Fig. 1d).—In this case the outer lines have negligible intensity ($g \approx 1$) and to a first approximation the separations $S_o(\chi)$ are all $2J_A$. The inner lines, with a total intensity of 2^{2n-1}, fall very close to ν_X, and therefore the whole X spectrum, including the N doublet, has the appearance of a 1:2:1 triplet. This is, of course, the spectrum that would be given if $J_{AX} = J_{AX}'$ but, as pointed out by Abraham and Bernstein (9), it is not necessary that L be identically zero (see also ref. 10). Only a single peak will be seen at ν_X if the separation of the first inner doublet is less than the effective resolution of the spectrometer, that is, the full width at half-height, $\Delta\nu_{\frac{1}{2}}$, of a single line. However, when $|J_A| \gg L$, then $S_1(1) = [L^2 + J_A^2]^{\frac{1}{2}} - J_A \approx \frac{1}{2}(L^2/|J_A|)$; therefore the condition for a deceptively simple spectrum reduces to [12]:

$$L^2 < 2|J_A|\Delta\nu_{\frac{1}{2}}. \qquad [12]$$

Such a spectrum may frequently be distinguished from that expected if A and A′ were magnetically equivalent by observation of peak heights (or widths). If L is small, but not zero, the central "line" of the triplet may appear broader than the two outer ones even when condition [12] is obeyed. Then the height of the central line will be less than twice that of the N doublet lines. The only information that may be derived from these deceptively simple spectra is the value N from the separation of the outer lines of the triplet and an upper limit to the value of $L^2/|J_A|$ from the width of the central line. It may be noted that the above discussion is only strictly valid for low values of χ (since the simplifying condition is really $|J_A| \gg \chi L$), but since these values give the most intense lines, they are the only ones that need to be considered. However, it is still true that for high values of χ (which necessitates high n), $S_1(\chi)$ tends to L, so the central line of the deceptively simple triplet may appear to tail off abnormally slowly on both sides.

In cases near the extreme discussed above, where $L < |J_A|$ but expression [12] is not obeyed, the separation of the inner pairs of lines simplifies to $S_1(\chi) = L^2(2\chi - 1)/2|J_A|$, except for high values of χ.

(B) $J_A \to 0$, giving approximately an X_nAM spectrum (see Fig. 1a).—Here $g = 0$ for $\chi = 1$, and consequently the inner and outer lines for this value of χ have the same intensity, and they also have the same separation, L. All the other inner lines also have separations $S_1(\chi) = L$, while the outer lines are separated by $S_o(\chi) = (2\chi - 1)L$ but have negligible

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

intensities because $g \simeq 1$. Thus the whole X spectrum consists of four lines with spacings N and L (see Fig. 1). An alternative choice of spacings for this case would be $|J_{AX}|$ and $|J_{AX}'|$, as expected for the X spectrum of an X_nAM system. Thus it is not possible to obtain J_A in this case nor is it possible to obtain the relative signs of the coupling constants. However, $|J_{AX}|$ and $|J_{AX}'|$ can be evaluated, in contrast to case A above. Also these conclusions are valid however large χ may become. This type of spectrum will frequently be encountered when the "long-range" coupling constant J_{AX}' is small, while the short-range one is large (coupling constants normally fall off rapidly as the number of bonds separating the coupled nuclei increases). In such cases it may become impossible to resolve the L doublet from the N doublet. We then have two effectively uncoupled X_nA systems giving a single doublet in the X spectrum.

When $L \gg |J_A|$ but $|J_A|$ is greater than the resolution of the instrument, the six lines of Fig. 1*a* may be seen. Whenever this is possible $|J_A|$ may be measured and the relative signs of J_{AX} and J_{AX}' obtained. When $L > |J_A|$ but more than six lines can still be resolved, the inner lines will have separations given approximately by the simplified formula $S_1(\chi) = L - (J_A^2/2\chi(\chi - 1)L)$.

NUCLEAR MAGNETIC RESONANCE STUDIES OF COMPOUNDS RELATED TO TETRAMETHYLDIPHOSPHINE DISULPHIDE

R. K. HARRIS[1] AND R. G. HAYTER[2]
Mellon Institute, Pittsburgh, Pennsylvania

Received May 15, 1964

ABSTRACT

The proton n.m.r. spectra of tetramethyldiphosphine disulphide and a number of related compounds have been obtained, yielding values for the nuclear magnetic parameters. Brief comments are made on these parameters. Double resonance experiments yielded the relative signs of the coupling constants for tetramethyldiphosphine sulphide and spectral analysis provided similar information for the disulphide. Comparisons are made with published data.

INTRODUCTION

Although nuclear magnetic resonance (n.m.r.) studies have been carried out on quite a large number of phosphorus-containing compounds, many of these studies have consisted in obtaining chemical shifts for ^{31}P resonance. Consequently accurate values of (H, P) coupling constants were not obtained. Most of the proton resonance investigations of phosphorus-containing compounds have been carried out with acids, esters, and salts. The french group of Mavel, Martin, and their co-workers (1) have reported studies on a greater variety of compounds but much of their work is carried out at 25 Mc/s, which puts limitations on their results. Consequently there is a scarcity in the literature of accurate values for (P, H) coupling constants. Recently, relative signs have been reported (2–7) for a number of such coupling constants, but these signs have not been linked directly to that for the (^{13}C, H) coupling through one bond, which is commonly taken as a reference. Further investigations seemed warranted. This relative lack of data is much more pronounced for the case of (P, P) coupling. Only a few values have been reported (2, 8, 9), and of these only the results of Lynden-Bell (2) and Callis *et al.* (9) are for compounds with a direct P—P bond. On the other hand, there is, at the present time, a continued interest in the theoretical interpretation of coupling constants. For this purpose accurate experimental data are of great importance, and in particular there is need for values of coupling constants between directly bonded nuclei. Consequently it seemed worth while to study a series of substituted diphosphines and related compounds to obtain the nuclear magnetic parameters.

EXPERIMENTAL PROCEDURE

The proton spectra were taken using a Varian A60 spectrometer operating at 60 Mc/s and a sample temperature of 37 °C. Chloroform-*d* was used as a solvent for most of the compounds, with a small amount of tetramethylsilane added to serve as an internal reference. However, tetramethyldiphosphine, $(CH_3)_2P\cdot P(CH_3)_2$, (I), was examined as a neat liquid plus tetramethylsilane;* in particular because the ^{13}C satellites were observed. The sample tubes were 5 mm in outside diameter and were degassed and sealed under a vacuum before use. In some instances small peaks appeared in the proton resonance spectrum because of impurities, but these were always easily recognized as such.

The samples of tetramethyldiphosphine and dimethylchlorophosphine, $(CH_3)_2PCl$, (II), were prepared as

**We are very grateful to Dr. G. W. Parshall for informing us of his work on tetramethyldiphosphine and for sending his n.m.r. spectra of the compound.*

[1]*Permanent address: School of Chemical Sciences, Wilberforce Road, Norwich, England.*
[2]*Present address: Shell Development Co., Emeryville, California.*

described by Parshall in refs. 10 and 11 respectively. The method of Niebergall and Langenfeld (12) was used for tetramethyldiphosphine disulphide, $(CH_3)_2P(:S)P(:S)(CH_3)_2$, (III), and resulted in a product with melting point 233–235 °C (lit. 228–229).

The results of elemental analysis were C, 26.0; H, 6.55 (calculated values for $C_4H_{12}P_2S_2$ are C, 25.7; H, 6.5).

The n.m.r. spectrum was identical with that of a sample supplied by Dr. T. Shryne of Shell Development Co., Emeryville, California. Tetramethyldiphosphinesulphide, $(CH_3)_2P(:S)\cdot P(CH_3)_2$, (IV), was prepared by heating a 1:1 mixture of (III) with (I) in a sealed tube at ≈ 220 °C for 16 h (13). It was sublimed twice in a vacuum at 45–50 °C to obtain the analytical sample. The n.m.r. spectrum of the analytical sample was essentially identical with that taken directly with the reaction products. Consequently, since the compound is very air-sensitive, the ^{31}P spectra were obtained (using a nonspinning tube of 15 mm outside diameter) from the reaction products themselves.

Elemental analysis gave P, 37.8; S, 19.0; ratio P/S = 2.06/1 (calculated values for $C_4H_{12}P_2S$ are P, 40.2; S, 20.8).

Dimethyl(dimethylarsino)phosphine sulphide, $(CH_3)_2P(:S)As(CH_3)_2$, (V), was prepared in an analogous manner by heating a 1:1 mixture of (III) with cacodyl, tetramethyldiarsine, $(CH_3)_2As\cdot As(CH_3)_2$, (VI), in a sealed tube at ≈ 220 °C for 16 h. The reaction product was dissolved in $CDCl_3$ for the n.m.r. spectrum without analysis or purification. The method of Auger (14) was used to prepare (VI). Trimethylphosphine sulphide, $(CH_3)_3P:S$, (VII), was obtained from $PSCl_3$ and the Grignard reagent, CH_3MgBr (15).

Elemental analysis results were C, 32.1; H, 8.5; P, 28.5; S, 29.6 (calculated values for C_3H_9PS are C, 33.3; H, 8.4; P, 28.6; S, 29.65).

The double resonance experiments on (IV) were also performed on an A60 spectrometer, using the modifications and apparatus recently developed by N.M.R. Specialities Inc. Instabilities in the system could be attributed mainly to drift of the 5 kc/s signal of the spectrometer. The experiments reported here were not very sensitive to drifts of the order of 10 c/s and no difficulties were encountered during operation of the equipment. We are very grateful to N.M.R. Specialities Inc. for allowing us to perform these experiments at their New Kensington, Pa. laboratory.

ANALYSIS OF THE SPECTRA

The coupling constant notation of Musher and Corey (16) will be used here to designate by a numerical prefix the number of chemical bonds through which coupling occurs. In the compounds studied here, there are two such types of (H, P) coupling constants, coupling occurring through two and three chemical bonds. These two types of coupling constants will be written $^2J_{HP}$ and $^3J_{HP}$ and will be referred to as short-range and long-range (H, P) coupling respectively. A further division of the (H, P) coupling constants may be made since the phosphorus atom involved is trivalent or pentavalent. This will be indicated by a roman superscript as in $^2J_{HPIII}$. For the symmetrical molecules tetramethyldiphosphine and tetramethyldiphosphine disulphide, more convenient parameters than $^2J_{HP}$ and $^3J_{HP}$ can be shown to be $L = |^2J_{HP} - {}^3J_{HP}|$ and $N = |^2J_{HP} + {}^3J_{HP}|$, and so these latter will normally be used. The only (H, H) coupling between protons that are not magnetically equivalent occurs through five bonds and is negligibly small in the present instances. The only (P, P) coupling is between directly bonded phosphorus atoms, and will be designated simply J_{PP}. Further division into J_{PIIIPV}, $J_{PIIIPIII}$, and J_{PVPV} will occasionally be used.

The proton spectrum of cacodyl, (VI), consisted of a single, rather broad line. The samples of (II) and (VII) each gave rise to a doublet, as expected, and the nuclear magnetic parameters could be obtained directly. Two doublets were obtained from (V), $(CH_3)_2P(:S)As(CH_3)_2$, and these were assigned to the two types of methyl groups by comparing the chemical shifts and coupling constants with those for related compounds (see Table I).

The spectrum of tetramethyldiphosphine (I) was deceptively simple (17, 18), being a 1:2:1 triplet. Consequently only the sum of the two (P, H) coupling constants could be obtained, $N = 14.2$ c/s. However, the central line was distinctly broader than the outer lines (the ratio of line heights for the central:outer lines is 1.3:1 instead of the usual 2:1), showing that the methyl groups were not all magnetically equivalent. An estimate of $L^2/|J_{PP}|$

can be made using eq. [12] of ref. 18. This equation is the condition for observation of a deceptively simple spectrum. If $J_{PP} \approx 100$ c/s (as in diphosphine) a value of $L < 11$ c/s is obtained, indicating that $^2J_{HP^{III}}$ and $^3J_{HP^{III}}$ have the same sign in this compound (see Table II for comparisons with other phosphorus-containing molecules). If L is appreciable, the satellites in the proton spectrum due to molecules containing a ^{13}C atom should appear as quartets (19). However, they still have triplet structure, although the height of the central line is but barely greater than the heights of the outer lines. It is concluded that $L \leqslant 0.8$ c/s, giving the coupling constants shown in Table I. It is not possible to distinguish the "long-range" value, $^3J_{HP}$, from the "short-range" coupling, $^2J_{HP}$.

The spectrum of (IV), $(CH_3)_2P(:S)P(CH_3)_2$, consists of four doublets which may be grouped into two pairs. By comparison of chemical shift values with the other compounds it can be seen that the two doublets at lower field are due to the protons of the methyl groups attached to the pentavalent phosphorus atom, whereas the high-field pair of doublets belong to the protons of the $P^{III}(CH_3)_2$ group. Consequently it is possible to distinguish $^2J_{HP^V}$ and $^3J_{HP^{III}}$ from $^2J_{HP^{III}}$ and $^3J_{HP^V}$. However, it is not possible by this evidence alone to distinguish $^2J_{HP^V}$ from $^3J_{HP^{III}}$ or $^2J_{HP^{III}}$ from $^3J_{HP^V}$. The ^{31}P spectrum of this compound at 15.1 Mc/s consists of four very broad bands in an AB type of pattern with a chemical shift between P_{III} and P_V of 94.5 ± 0.4 p.p.m. and a coupling constant $J_{PP} \approx 220$ c/s. The P_V resonance is considered to occur to low field of the P_{III} resonance (20). The breadth of the bands is due to unresolved coupling to the large number of methyl protons. It is noticeable that the two P_V bands are broader than the P_{III} lines, indicating that the average of the two (H, P^V) couplings is larger than the average of the (H, P^{III}) couplings.

A complete assignment was made and the relative signs of the coupling constants were obtained by double resonance techniques (21, 22). Because of the large band separations in the ^{31}P spectrum there was insufficient power available to decouple completely either of the phosphorus nuclei from the methyl protons. However, each of the four ^{31}P bands (that is, the centers of multiplets due to coupling with the methyl protons) were selectively irradiated at low power (23) in turn, and the effects on the proton spectrum noted (Fig. 1). In each case irradiation of the P^V bands caused the larger splittings in the proton spectrum to collapse, while irradiation of the P^{III} bands caused the collapse of the smaller splittings for both the $(CH_3)_2P^{III}$ quartet and the $(CH_3)_2P^V$ quartet. It was thus demonstrated that $^2J_{HP^V} > {}^3J_{HP^{III}}$ and $^3J_{HP^V} > {}^2J_{HP^{III}}$, and a complete assignment was established (Table I). Low-power irradiation (23) of the P^{III} band at highest field caused the *high*-field proton doublet of the $(CH_3)_2P^V$ group and the *low*-field doublet of the $(CH_3)_2P^{III}$ group to collapse (Fig. 1). This shows that J_{PP} and $^2J_{HP^V}$ have the same sign, while $^3J_{HP^V}$ is of the opposite sign (21, 33). Similar information regarding relative signs was obtained for the (H, P^{III}) coupling constants by irradiation of one of the P^V bands (Table II). In this case, however, collapse of two lines was not so marked, presumably because the (H, P^V) coupling constants are sufficiently large that the irradiating power necessary to cause selective collapse of lines in the proton spectrum also causes spectral side-effects to become noticeable (22, 23). However, it is clear (Fig. 1) that only two lines of the four for each type of methyl proton have been affected. Irradiation of the remaining ^{31}P bands confirmed the correctness of the deductions but provided no new information. In the above double-irradiation work it should be noted that the two types of methyl protons are treated completely independently, giving double resonance spectra typical for the X_6 nuclei of ABX_6 nuclear magnetic systems.

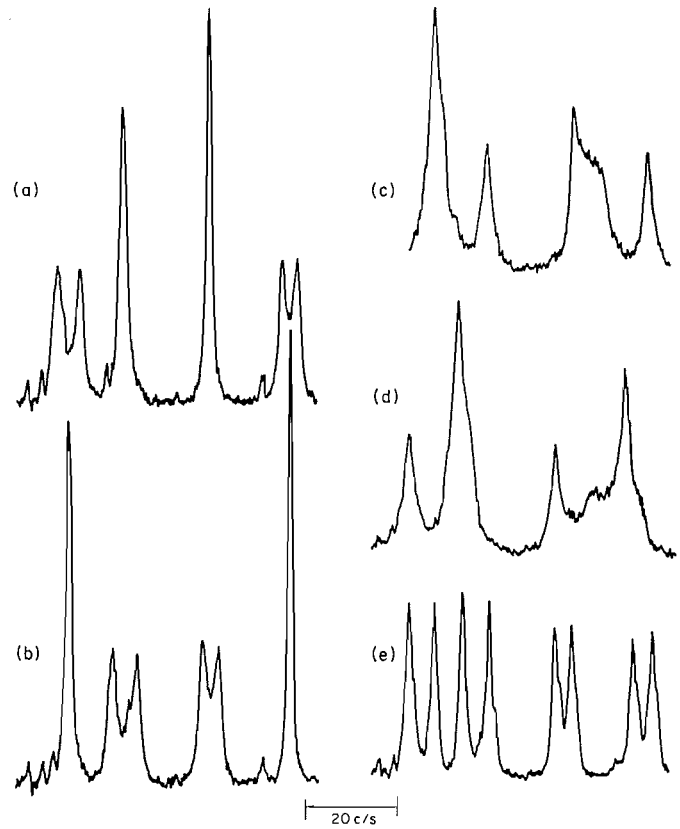

FIG. 1. Proton spectra of tetramethyldiphosphine sulphide, $(CH_3)_2P(:S)P(CH_3)_2$, in solution in chloroform-*d* during irradiation at low power in the region of the ^{31}P resonance. Spectra (*a*) to (*d*) correspond to irradiation of each of the four bands of the phosphorus spectrum in order of decreasing field-strength. Thus (*a*) and (*b*) are recorded for irradiation at P^{III} resonance frequencies, while for (*c*) and (*d*) irradiation is occurring at P^{V} frequencies. Trace (*e*) is the normal spectrum obtained while irradiating well to low field of any of the ^{31}P resonances of the compound. A few weak lines due to impurities may be seen in the spectra. The magnetic field strength increases from left to right for these spectra.

Tetramethyldiphosphine disulphide (III) was actually the first compound studied in this work (18). The structure of this molecule has been said to be $(CH_3)_2P(:S)P(:S)(CH_3)_2$ by Goubeau, Reinhardt, and Bianchi (24) and by Christen, Van der Linde, and Hooge (25). This compound gave a spectrum which is an excellent example of the $X_nAA'X_n'$ nuclear magnetic system, discussed in the previous paper (18), with $n = 6$. The two most intense lines are, as expected, those given by molecules with the $\alpha\alpha$ and $\beta\beta$ phosphorus spin states. The separation of this doublet immediately gives us $N = 5.48$ c/s. The fact that all the other lines lie outside this doublet is an indication that $^2J_{HP}$ and $^3J_{HP}$ are of opposite sign. The inner pairs of lines (see ref. 18) with $\chi = 1$ and $\chi = 2$ are resolved, but the pairs with $\chi = 3$, 4, 5, and 6 form two broad, weak bands. A calculation using the separations $S_1(1) = 8.49$ c/s and $S_1(2) = 16.73$ c/s with eq. [11] of ref. 18 gives the value $L = 20.24$ c/s. However, the first pair of *outer* lines ($\chi = 1$) are visible in the spectrum and this gives $|J_{PP}| = |J_A| = \frac{1}{2}[S_0(1) - S_1(1)] = 18.7 \pm 0.05$ c/s. A recalculation of L using this value of $|J_A|$ and the observed $S_1(1) = [L^2 + J_{PP}^2]^{1/2} - |J_{PP}|$ results in $L = 19.87$ c/s. This is considered good agreement with the value above since the lines are weak (the compound

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

is not highly soluble in $CDCl_3$), somewhat broad, and partly overlapped. The value of L which gives the best fit to the spectrum (Fig. 2) is 20.0 ± 0.15 c/s. The spectral charac-

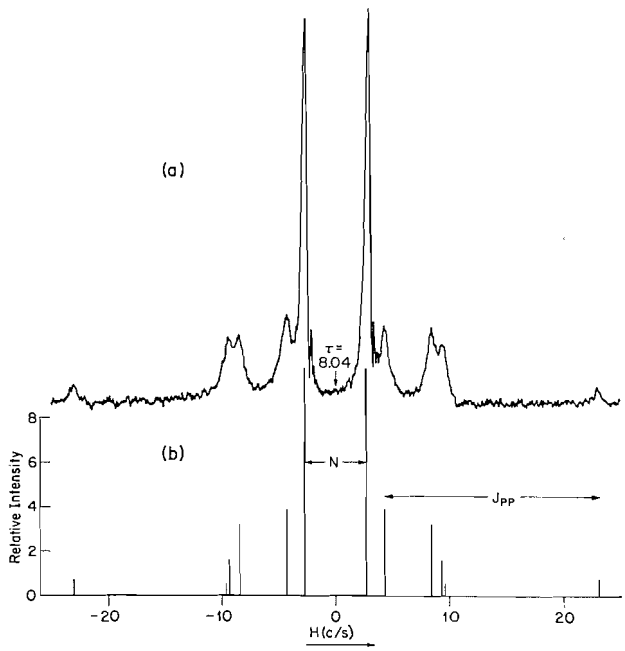

FIG. 2. Observed (*a*) and calculated (*b*) proton spectra of tetramethyldiphosphine disulphide, $(CH_3)_2P(:S)P(:S)(CH_3)_2$, in solution in chloroform-*d*. Spectrum (*b*) has been calculated using the parameters ${}^5J_{HH} = 0$, ${}^1J_{PP} = 18.7$, $L = |{}^2J_{HP} - {}^3J_{HP}| = 20.0$, and $N = |{}^2J_{HP} + {}^3J_{HP}| = 5.48$. Inner lines $S_i(5)$ and $S_i(6)$ are too weak and too close to $S_i(4)$ to be seen on this scale. Outer lines for $x > 1$ are too weak and too widely spaced to be observed. For nomenclature and the definition of the intensity scale see ref. 18.

teristics mentioned in ref. 18 are clearly shown by this example. It is not possible to obtain the sign of J_{PP} relative to the (H, P) coupling constants, nor is it possible to distinguish between ${}^2J_{HP}$ and ${}^3J_{HP}$. Table I therefore gives an arbitrary assignment—the other compounds listed are not sufficiently closely related to be of help here.

DISCUSSION

(a) The Nuclear Magnetic Parameters (Table I)

The pattern which emerges from the values of Table I is not simple. Moreover, it is complicated by the ambiguities in the assignment of the (P, H) coupling constants of (I) and (III). It is clear that (P, H) coupling constants across three bonds are of the same order of magnitude as those across two bonds, and indeed the former may be the larger. It seems that ${}^2J_{HP\,III}$ can be relatively small, but it has been reported as 24 c/s in methyl dibromophosphine (20). Consequently these coupling constants are of little use in structural determinations where decisions must be made between groupings of the type H—C—P^{III}, H—C—X—P^{III}, H—C—X—P^{V}, and H—C—P^{V} unless a very closely related series of molecules is considered. It seems from Table I that the chemical shift values may be of more diagnostic importance than the coupling constants, since the resonance of a methyl group attached to a trivalent phosphorus atom usually occurs approximately 0.6 p.p.m. to high field of that for a similar compound in which the phosphorus

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

atom is pentavalent. Replacement of P^{III} by As^{III} seems to cause only a very small shift in the resonance position. It is worth noting that proton resonances for methyl groups attached to arsenic have line widths ($\approx$ 1 c/s) greater than normal, presumably because of incomplete elimination of the effects of (As, H) coupling via the arsenic quadrupole moment.

(b) Tetramethyldiphosphine Disulphide, (III): J_{PP} and Structure

The value obtained for J_{PP} in (III) is very low in comparison to that of the monosulphide (IV) and diphosphine itself (2). This is probably not due to the absence of any trivalent phosphorus atoms in the disulphide, since the reported value (9) for the diphosphite ion $(P^{V}O_3P^{V}HO_2)^{3-}$ is much higher (480 c/s), whereas for anions containing the P^{V}—O—P^{V} linkage (9), it falls to $\approx$ 17 c/s, remarkably close to the present value. The contrast in values is so startling that it raises the question of whether the accepted structure (24, 25) is correct. The value of J_{PP} would be more reasonable if no direct bond existed between the two phosphorus atoms.* The evidence for the structure $(CH_3)_2P(:S)P(:S)(CH_3)_2$ seems to consist (24, 25) mainly in the observed mutual exclusion of infrared-active and Raman-active vibrational modes, which indicates that the molecule possesses a center of symmetry. Consequently the authors reject the structure $(CH_3)_2P$—S—S—$P(CH_3)_2$— although even in this case it is not impossible to pick a rotamer that has the desired symmetry. Moreover, the structure $(CH_3)_2P(:S)P(:S)(CH_3)_2$ is centrosymmetric only if the P=S bonds are in a transoid relation. The authors did not consider other possible structures. One possibility in accord both with the vibrational spectra and with the low value of J_{PP} is a four-membered P_2S_2 ring system. This is unlikely chemically, although four-membered ring systems containing two phosphorus atoms and two metal atoms are well known (26). Moreover, some support for the accepted structure $(CH_3)_2P(:S)P(:S)(CH_3)_2$, is provided by the fact that the two (H, P^{V}) coupling constants are of opposite sign, as they are for the analogous values in IV. It is interesting that recently the molecule $(CH_3)_4As_2S_2$ has been shown (27) to possess the structure $(CH_3)_2As(:S)$—S—$As(CH_3)_2$. The evidence of the vibrational spectra precludes such a possibility for (III). It must be noted that if (III) does not possess the accepted (24, 25) structure, then the nomenclature $^2J_{HP}$ and $^3J_{HP}$ used in Table I for this molecule is incorrect. On the other hand, if the accepted structure is correct the varying magnitudes of the (P, P) coupling constant for directly bonded phosphorus nuclei in the few known cases are rather puzzling. It must be concluded that it is not possible on the basis of present evidence to be certain of the structure of tetramethyldiphosphine disulphide. Further speculation should await the result of attempts to determine the structure by X-ray methods.

(c) The Relative Signs of the Coupling Constants (Table II)

Until very recently absolute signs of spin–spin coupling constants were unknown. Theoretical predictions are most likely to be accurate for coupling between directly bonded atoms, and Karplus (28) suggested that the sign of $^1J_{H^{13}C}$ be regarded as positive (in the sense that an antiparallel nuclear spin orientation corresponds to a more stable state than the parallel orientation) and that signs of other coupling constants should be related to that of $J_{H^{13}C}$. Recent work with the electric-field effect (29) has confirmed this hypothesis. Considerable progress has been made in placing the signs of (H, H) coupling constants on this scale (30, 31), but values for other situations are scarce. Consequently it is difficult to relate the signs of Table II unequivocally to the $^1J_{H^{13}C}$ scale. No measure-

**However, considerable variations in $^1J_{PP}$ have recently been reported (35) for some polyphosphine heterocycles.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ments have been reported linking the signs of $^1J_{PP}$, $^1J_{HP}$, $^2J_{HP}$, or $^3J_{HP}$ directly to that of $^1J_{H^{13}C}$. However, it has been shown that the signs of coupling constants across two bonds, ^2J, are more variable than those for coupling across three bonds, ^3J (30). The latter are normally positive, certainly for the (H, H) case. Table II has been arranged as far as is possible so that the upper sign in each case is related to a positive sign for a ^3J in the same molecule. Thus the upper sign is considered the more reasonable, although the argument is not strong, especially when the comparison is to $^3J_{HCPH}$ or $^3J_{HPPH}$. The relation for trivinyl phosphine (VIII), that is all coupling constants positive (5), appears the most certain because the comparison is to the well-known vinyl $^3J_{HC=CH}$ values. The above procedure could not of course be followed for (IX), (XIV), and case (ii) for (XV) because there are no ^3J values for (XIV) and (XV) and the sign of ^3J for (IX) was not reported. However, (IX) and (X) are sufficiently similar that comparison is good in this case.

The assumption that ^3J values are all positive gives a fairly consistent picture, with the exception of the ambiguous (XIV) (2, 9). The values of $^2J_{HCPV}$ are then all negative (four cases) while $^2J_{HCPIII}$ is normally positive (five cases) except for the small negative value reported (6) for (XI). The single case of $^2J_{HPPIII}$ is also positive (2). The three values for $^1J_{HPIII}$ are all positive under these conditions. The results for compound (XIV) are anomalous whatever the absolute signs are, but it should be noted that both $^1J_{HP}$ and $^2J_{HXP}$ for this compound are of a unique type in the table. The most perturbing feature about this analysis is that both values for $^1J_{PP}$ appear to be negative, which is unexpected although this has already been proposed tentatively by Lynden-Bell (2) for XV. There is of course no fundamental reason why coupling between directly bonded nuclei should be positive; indeed it has been shown (32) that $^1J_{F^{13}C}$ is negative with respect to $^1J_{H^{13}C}$, but it is generally felt that fluorine may be unique in this respect. It is, of course, quite possible that the lower signs are correct for some of the compounds of Table II, that is that some ^3J values are negative. It therefore appears unprofitable to base too many conclusions on this table until more of the signs are directly related to that of $^1J_{H^{13}C}$. It should be noted that compound III gives relative signs consistent with the pattern of Table II when the accepted (24, 25) structure is assumed.

Finally it is perhaps instructive to convert the values of J_{PP} to the units proposed by Lynden-Bell and Sheppard (33) by dividing by the square of the magnetogyric ratio for phosphorus ($\gamma_P = 2.2610$). For tetramethyldiphosphine sulphide this yields the value $J_{PP} \approx 43$ coupling units. This compares with the value $J_{CC} = 17.54$ coupling units for ethane (33). The value for (III) is $J_{PP} = 3.7$ coupling units.

PROTONATION SITE IN ORGANIC BASES FROM INFRARED X—H DEFORMATION MODES[1,2]

DENYS COOK
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received June 1, 1964

ABSTRACT

The infrared absorption bands due to X—H stretching modes in protonated bases are diagnostically of little value in determining the protonation site. However, the deformation mode, δ_{XH}, shows promise of becoming a useful group frequency whose value is characteristic of the type of atom protonated. The following values, which have been confirmed by deuterium substitution of the sensitive hydrogen atom, are typical:

RNH_3^+	($\delta_{NH_3}^{as}$)	1580 cm^{-1};	($\delta_{NH_3}^{s}$)	1500 cm^{-1};	(ρ_{NH_3})	1155 cm^{-1}.	
$R_2NH_2^+$	(δ_{NH_2})	1585 cm^{-1};	(ω_{NH_2})	1415 cm^{-1}.			
R_3NH^+	(δ_{NH})	1402 cm^{-1}.		$R_2C{=}OH^+$	(δ_{OH})	1257 cm^{-1}.	
R_3NOH^+	(δ_{OH})	1463 cm^{-1}.		$R_2C{=}SH^+$	(δ_{SH})	968 cm^{-1}.	
$\rangle NH^+$	(δ_{NH})	1258 cm^{-1}.		R_2OH^+	(δ_{OH})	1072 cm^{-1}.	

Occasionally splittings occur so that two components of the bending mode are observed. These have been attributed in many cases to correlation field coupling in the solid state.

INTRODUCTION

The infrared spectra of protonated organic bases have one feature in common, a broad, strong band in the range 2000–3500 cm^{-1}, the position of which depends on the hydrogen-bonded distance $X^+—H \ldots Y^-$ and on the nature of the anion Y^- of the protonating acid.

It should be emphasized that, with the possible exception of primary and secondary amines, there is little in the shape or position of the X—H stretching absorption band for a particular acid HY which gives information on the nature of the atom protonated. The band contours will certainly vary slightly, but not in any pattern which can be related to the type of protonation site.

Some feature of the infrared spectrum of a protonated base which would give such information on the protonation site would obviously be valuable. Such information would have many applications including

(1) the determination of donor sites in a polyfunctional molecule where a choice of sites is possible;

(2) the ability to determine sites in stepwise protonation, and therefore to determine what functionality exists at different pH;

(3) the ability to determine whether a protonated function was capable of hydrogen bonding before protonation, and therefore whether protonation would disrupt such hydrogen bonding (of importance in biological systems);

(4) the ability to determine whether a particular site is protonated already (e.g. a zwitterion), and therefore not available for coordination (of importance in chelating systems).

Such a feature seems to be the X—H bending mode in protonated functional groups since it has been found to be quite characteristic of the type of atom protonated. This feature will be described below.

[1]*Contribution No. 105.*
[2]*Presented in part at the XIXth International Congress of Pure and Applied Chemistry, London, England, July 15, 1963.*

Previous literature references quoting substantiated values (i.e. those shown to shift on deuteration) of the deformation modes are extensive for primary amines (1–5), less so for secondary amines (3, 6, 7), and singular for tertiary amines (3). Until recently little information was available about XH deformation modes in other protonated bases.

RESULTS AND DISCUSSION

1. *Carbonyl Compounds*

The in-plane hydrogen-deformation mode, δ_{OH}, in compounds containing a protonated carbonyl group has been observed close to 1265 cm^{-1} (8–11). The slightly different values of δ_{OH} depending on the anion in these and other salts have been averaged. The out-of-plane hydrogen-bending mode, γ_{OH}, is near 750 cm^{-1}, but is much more variable in frequency, and in some compounds is not visible in the rock salt region. Some regularities have been

TABLE I

observed in this band and will be discussed elsewhere. Table I shows the experimental results obtained for many carbonyl compounds. They include straight-chain* and cyclic amides, $\alpha\beta,\alpha'\beta'$-unsaturated ketones ($\gamma$-pyrones and γ-pyridones), or other nitrogen heterocycles containing a carbonyl group. The value of δ_{OH} shown is, in many cases, an average value of two components, and the splitting between these two components is shown under the heading $\Delta\delta_{OH}$. This splitting of the deformation mode is attributed to correlation field coupling (12, 13); in one case where the crystallographic data is known, namely 2,6-dimethyl-4-pyrone·HBr (14), the doubling of the in-plane hydrogen-bending mode is quite in accord with the selection rules (9). To prove that the splitting is due to correlation field coupling, the technique of dilute isotopic solid solutions (15, 16) can be used. This requires replacement of the protonating H atom by randomly distributed D atoms. The force field around these D atoms is identical with that around the H atom, but because of the doubled mass, the vibration of the OD group is uncoupled from those of the OH groups. The OD group should, in this condition, have an absorption frequency which is the average of all the correlation field components. When the H_2SnBr_6 salt of 2,6-dimethyl-4-pyrone is exchanged with water containing 5% D_2O, a moderate enhancement of a very weak band at 962 cm^{-1} is observed. This is the uncoupled OD in-plane bending

**The n.m.r. spectra of amide salts first showed conclusively that the oxygen atom was the protonation site. Many details and references to earlier work can be found in the paper by R. J. Gillespie and T. Birchall. Can. J. Chem. 41, 148 (1963).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

mode, and is quite close to the average of the two coupled vibrations, 992 and 935 cm^{-1}, which were not observed in this spectrum. Similarly the uncoupled OH group deformation mode can be obtained as a weak band at 1251 cm^{-1} (close to the average of 1296 and 1202 cm^{-1}) in the solid derived from exchange with D_2O containing 5% H_2O.

2. Thiocarbonyl Compounds

Table II shows the values determined for the in-plane bending mode in thiocarbonyl compounds. The average value is near 968 cm^{-1}, and splittings are not observed.

TABLE II

SH deformation frequencies in protonated thiocarbonyl compounds

Compound	δ_{SH}	δ_{SD}	δ_{SH}/δ_{SD}
2,6-Dimethyl-4-thiopyrone	978	781	1.25
1,2,6-Trimethyl-4-thiopyridone	978	699	1.39
1-Methyl-4-thiopyridone	957	711	1.35
Thiourea (19)	981		
Thioacetamide (19)	948		
Average	968	730	

Protonation of thiocarbonyl groups has been described infrequently in the literature. Spinner (17) and Janssen (18) have made some assignments in some thioamide salts, but with insufficient detail to establish the absorptions of the SH bending modes. Kutzelnigg and Mecke (19) studied thiourea and thioacetamide salts, noting a band near 970 cm^{-1} as a likely candidate for δ_{SH}, but did not examine isotopically substituted salts. The reasons for preferring protonation of the C=S group in thiocarbonyl compounds are quite as valid for this group of compounds as they were for the carbonyl compounds shown in Table I. Thus the absence of a band near 1420 cm^{-1} in protonated 4-thiopyridones and thioamides rules out N protonation.

The much lower value of δ_{SH} for the protonated thiocarbonyl compounds (as well as the much lower value of ν_{SH}) compared with the OH values for carbonyl compounds has to do with the strength of the SH bond. In mercaptans the SH stretching frequency and bond energy are both lower than the corresponding OH compound.

3. Heterocyclic Nitrogen Compounds

Previously published work (20) has established that the in-plane hydrogen-bending mode in pyridinium salts gives rise to an absorption band near 1240 cm^{-1}. No splitting was observed in the HCl salt (or others), which is in accordance with the selection rules using the details of the crystal structure determined by Rérat (21). Spinner (22) assigned a band near 1250 cm^{-1} in the infrared spectra of the hydrochlorides of several 2-, 3-, and 4-substituted pyridines to the NH in-plane bending mode, though this assignment was not confirmed by deuterium substitution.

In the early stages of this work, 1240–1260 cm^{-1} seemed a reasonable range for δ_{NH}. As more salts were studied, however, it became obvious that this would have to be enlarged to about 1225–1300 cm^{-1}. This naturally raised the question of the correctness of the assignment. Correlation of all the bands having an isotopic shift showed no band to be more suited than the 1225–1300 cm^{-1} band, leading to the conclusion that there may be good reasons why there should be a wider variation in δ_{NH} in these bases than in other salts. This will be amplified in a later section.

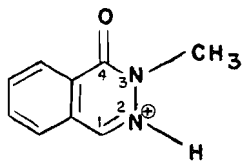
TABLE III

NH deformation frequencies in protonated heterocyclic nitrogen compounds

Compound	δ_{NH}	δ_{ND}	δ_{NH}/δ_{ND}
Pyridine (20)	1242	932	1.33
11 Substituted pyridine HCl salts (22)	1248		
Benzothiazole	1240	991	1.25
N-Methylphthalazone	1261	897	1.40
Pyrazine	1250	916?	
2,6-Dimethylpyrazine	1250	980	1.28
N-Methylimidazole	1298	1082/852	
Caffeine	1295	935	1.38
Quinaldine	1298	950	1.36
2,2′-Bipyridyl	1228		
1,4,6-Trimethyl-2-oxopyrimidine	1231	953	1.30
Average	1258	944	

Other nitrogen heterocycles are listed in Table III. Benzothiazole is very similar to pyridine in that the deformation mode absorbs at 1240 cm^{-1}. N-Methylphthalazone shows two components in the bending mode, at 1300 and 1222 cm^{-1}. The splitting seems due to correlation field effects and dilute isotopic solid solutions studies are projected. In this compound O protonation can be discounted because of the following evidence. There is a rise in frequency of $\sim$ 38 cm^{-1} in the band which is found at 1640 cm^{-1} in the neutral compound and which is obviously associated with the carbonyl group. This seems about the right order of magnitude for the inductive effect of a positive charge on N_2. A positive charge on a nitrogen atom adjacent to a carbonyl group raises its frequency by over 140 cm^{-1} (8).



Generally, O protonation would result in the appearance of a new, fairly intense band near 1500 cm^{-1} associated with $\nu_{C=\overset{+}{O}H}$ (11), with little or no isotope shift. In fact, there is only a moderately strong band near 1529 cm^{-1} in the salt, which is not in the neutral base, and which moves to 1325 cm^{-1} on deuteration. This is strongly reminiscent of the behavior of pyridine salts and supports N protonation (20).

4. Tertiary sp^3 Amines

Protonated tertiary sp^3 amines occur widely. Since there is only one NH bond in an approximately tetrahedral arrangement with the other three NC bonds, there is only one non-degenerate NH deformation mode. Its average frequency is near 1402 cm^{-1}. Splitting is exceptional but no X-ray structures have been determined for any of the compounds listed in table IV, so that it is not possible to correlate splitting with structure. The spectra, apart from those of $(CH_3)_3NH^+$ salts, are quite complicated with several bands showing deuteration shifts. It is likely that some coupling of the ND mode with other modes occurs, the low δ_{NH}/δ_{ND} ratio of 1.19 in $(C_2H_5)_3NH^+$ salts being an indication of this.

TABLE IV

NH deformation frequencies in protonated tertiary sp^3 amines

Compound	δ_{NH}	$\Delta\delta_{NH}$	δ_{ND}	$\Delta\delta_{ND}$	δ_{NH}/δ_{ND}
$(CH_3)_3N$(3, 30)	1420	0		0	
$(C_2H_5)_3N$*	1420	0	1190	0	1.19
N-Methylpiperidine	1398	0		0	
Aminopyrine	1383	0	985	0	1.40
$(C_6H_5)_3N$†	1427	86	1093	140	1.31
Hexamethylenetetramine	1396	0	1085	0	1.29
Triethanolamine	1410	0	1118	0	1.26
1,4-Diazabicyclo[2.2.2]octane	1380	0	1045	0	1.32
Nicotine (mono H^+)	1390	0	975	0	1.42
Average	1402		1062		

*See also ref. 31.
†See also ref. 30.

An example of protonation of a tertiary sp^3 amine when two possible sites are present occurs in the case of nicotine. The spectrum of nicotine monohydrobromide in $CHBr_3$ solution shows clearly a band at 1390 cm^{-1} which is absent, but replaced by one at 975 cm^{-1}, in the monodeuterobromide. There is no evidence of a band near 1240 cm^{-1} which moves in the deuterated salt. This is adequate proof that in nicotine monoprotonated salts the pyrrolidine ring nitrogen atom is more basic than the pyridine ring.

5. Secondary Amines

Apart from the data of Heacock and Marion (6) and Stone *et al.* (7), information on secondary amines is sparse and needs augmenting. The figures shown in Table V seem to be consistent. A deformation (scissors) mode appears at about 1580 cm^{-1}, in roughly the same place as the asymmetric NH deformation in protonated primary amines. The wagging mode causes absorption near 1410 cm^{-1}, which is close to the deformation mode in tertiary (sp^3) amine salts. The rocking mode is not well characterized and may be subject to more perturbations than the scissors or wagging mode.

TABLE V

NH deformation frequencies in protonated secondary amines

Compound	δ_{NH_2}			ω_{NH_2}			ρ_{NH_2}		
$(CH_3)_2NH$(3)	1582	1157	1.37	1421	1035	1.35	878	689	1.27
Piperidine*	1580			1407			917

Average	1585	1178		1415	1035		898	689	

*See also ref. 32.
†For some compounds where the presence of two absorptions suggested crystal splittings, the mean value of the two components was taken.

6. Primary Amines

The protonated primary amine group, RNH_3^+, should have an asymmetric and a symmetric deformation mode and a rocking mode. Table VI shows the asymmetric deformation to be near 1600 cm^{-1}. The symmetric deformation is not as well defined but is near 1500 cm^{-1}. Extensive observations of the NH deformation bands of this group in amino acids (2, 5) and in other primary amines (1, 3, 4) have been reported. Smaller cations with higher symmetry such as the methylammonium cation seem to have slightly non-typical values.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Two components seem to be present for the rocking mode. If there is a plane of symmetry in the molecule, then an in-plane and an out-of-plane rocking mode will be expected. Table VI shows average values for the two components. The $CH_3NH_3^+$ ion again seems to have a divergent value of the rocking modes.

TABLE VI

Deformation and rocking modes in protonated primary amines

Compound	$\delta_{NH_3}^{as}$			$\delta_{NH_3}^{s}$			ρ_{NH_3}		
CH_3NH_2(1, 2)	1580	1190	1.33	1538	1180	1.30	1265	1144*	1.11

Average	1580	1182		1500	1135		1201 1110		

*But see ref. 5 for different assignment.
†See also ref. 33.

7. Amine Oxides

Table VII shows the compounds for which adequate data are known. Two deformation modes should be observed for the protonated oxygen function, an in-plane and an out-of-plane hydrogen bending. In $(CH_3)_3NO$ salts the in-plane bending mode is split into two components near 1505 and 1425 cm^{-1}. This is quite in accordance (23) with the selection rules derived from the known structure of $(CH_3)_3NO \cdot HCl$ (24). In pyridine-1-oxide salts no splitting is observed, and one absorption near 1450 cm^{-1} on deuteration gives rise to a band at 1108 cm^{-1} having a normal isotopic shift. The analysis of the structure of pyridine-1-oxide hydrochloride (25, 26) seems to be in agreement with this behavior.

TABLE VII

OH deformation frequencies in protonated amine oxides

Compound	δ_{OH}	$\Delta\delta_{OH}$	δ_{OD}	$\Delta\delta_{OD}$	δ_{OH}/δ_{OD}
$(CH_3)_3NO$(23)	1465	80	1090	103	1.34
C_5H_5NO	1450	0	1108	0	1.31
4-Methoxypyridine-1-oxide	1496	0	1083	0	1.38
4-Benzyloxypyridine-1-oxide	1449	0	1056	0	1.37
2,6-Dimethylpyridine-1-oxide	1455	0	1083	0	1.34
Average	1463		1084		

8. Ethers

Protonation of ethers has been postulated in the very early chemical literature. Very few examples of solid salts from ethers and protonating acids have been substantiated. Cineole, a cyclic ether derived from menthol, forms salts with halogen acids (27) but their constitution is unknown. The HBr salt is tractable, though low melting, and as indicated in Table VIII there are two bands in the spectrum near 1140 and 1040 cm^{-1} which move to lower frequency on deuteration. These compare favorably with bands near 1150 and 1060 cm^{-1} in the spectrum of oxonium salts, attributed to the symmetric OH bending vibration (28) in H_3O^+. The cause of the doubling is not explained.

In the Raman and infrared spectra of ether solutions of HCl, Vidale and Taylor (29)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

recorded a band near 1200 cm^{-1} and attributed this to the OH deformation mode of the protonated base. When DCl was used the band was observed near 800 cm^{-1}, the ratio of the two frequencies being close to $\sqrt{2}$.

TABLE VIII

OH deformation frequencies in protonated ethers

Compound	δ_{OH}	δ_{OD}	δ_{OH}/δ_{OD}
Cineole	1140 1038	900 792	1.27 1.31
H_3O^+(28)	1150 1060	785	1.35
Average	1072		

CONCLUSIONS

The average values quoted above for the deformation modes constitute useful group frequencies, helpful in the diagnosis of functional groups in organic molecules. The limits of variation are not wide at present but could possibly increase as more compounds are studied.

That there should be such constant values of δ_{XH} is to be expected. In the case of protonated carbonyl, thiocarbonyl, and N-oxide groups, at least two other atoms supervene between the proton and any other group which by an alteration in mass or electronic function could cause variation in the deformation mode. In amine and ether salts there is only one such supervening atom, but the stereochemical arrangement around it is constant and it is probably little affected by electronic influences. Compounds with heterocyclic (sp^2) nitrogen atoms would be expected to, and actually do, show the largest variation in δ_{XH}. In these compounds electronic influences are very easily transmitted through the π-electrons in the ring, and the effect of these and the size of the ring may have an effect on the σ-electrons in the X—H bond.

This is not to deny that systematic trends may be present within the boundaries of a group frequency. (The carbonyl frequency, a group frequency par excellence, has been the subject of countless efforts to correlate frequency with other parameters.) Not enough data have been collected at present to test this possibility, though Stone *et al.* have described a correlation between δ_{NH_2} and σ^*-values (7) for some secondary amines.

The existence of group frequencies for different X—H bonds must be due both to real variations in k_{XH}, the bending force constant, and non-bonded interactions between the X—H bond and its neighbors. While it is impossible to comment on the force constant aspect, two conclusions seem warranted about non-bonded interactions. Thus tetrahedrally arranged bonds have higher bending frequencies than those with a trigonal planar arrangement; and for the same spatial arrangement, δ_{XH} is lower when X is from a lower row of the periodic table.

Detailed assignments of the spectra of many of the salts described here will be published later.

EXPERIMENTAL

Materials

Organic compounds were purchased from commercial sources or synthesized in this laboratory. All were of high purity. Salts were made by standard methods previously described (8–11, 20, 23). Deuterium replacements were usually made with D_2O, though DBr and DCl were used occasionally to make some salts.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Spectra

The infrared spectra of emulsions of the finely ground solids in Nujol and Fluorolube were recorded on a Perkin–Elmer model 221 prism-grating spectrometer between 4000 and 650 cm^{-1}. Hygroscopic and deuterated salts were handled in a dry box.

ACKNOWLEDGMENT

The assistance of Mrs. R. H. Veach (C. D. Anderson) in preparing some of the materials and recording their spectra is gratefully acknowledged.

DIFFUSION COEFFICIENTS OF O AND N ATOMS IN INERT GASES*

J. E. MORGAN AND H. I. SCHIFF
Upper Atmosphere Chemistry Group, McGill University, Montreal, Quebec
Received April 23, 1964

ABSTRACT

The diffusion coefficients of atomic oxygen in O_2, N_2, Ar, and He, and of atomic nitrogen in N_2, have been measured as a function of pressure and temperature, using a previously described method.

The rigid sphere collision diameters of atomic oxygen and atomic nitrogen at 280 °K were calculated as 2.65 Å and 2.75 Å respectively. The temperature dependence of the diffusion coefficients of O in O_2 and N in N_2 yielded the following Lennard-Jones parameters:

$$\epsilon/k(O/O_2) = 154° \ (\sigma_O)_{L\text{-}J} = 2.33 \text{ Å},$$

$$\epsilon/k(N/N_2) = 78° \ (\sigma_N)_{L\text{-}J} = 2.94 \text{ Å}.$$

INTRODUCTION

In a previous communication from this laboratory (1), a method was described for determining the diffusion coefficients of atomic species in essentially inert atmospheres.

The basis of the method is to place an extremely efficient atom sink in a rapidly streaming, partially dissociated gas. If all of the atomic species can be removed without affecting the flow of inert carrier gas, a very steep concentration gradient will be produced in the vicinity of the sink. The slope of this concentration gradient will be governed almost entirely by the diffusion coefficient of the atomic species and the linear velocity of the carrier gas.

A simple analysis (1) shows that, in the absence of any localized sink, the concentration of the dilute atomic species as a function of distance, x, measured in the flow direction, is given by the following expression:

$$[1] \qquad C = C_0 \exp (V/2D - R)x,$$

where C_0 = atom concentration at an arbitrary origin ($x = 0$), V = linear velocity of carrier gas, D = binary diffusion coefficient, $R = (V^2 + 4kD)^{\frac{1}{2}}/2D$, k = composite first-order rate constant for homogeneous and heterogeneous recombination. This expression is valid for flow through an infinitely long reaction vessel under conditions of first-order atom removal. Implicit in the expression is the assumption of one-dimensional flow, i.e. negligible radial concentration gradients. Atoms are removed in such a system only by gas phase and wall recombination processes.

If a localized atom sink is now placed at $x = L$ with efficiency great enough to satisfy the condition that $C = 0$ at $x = L$, the expression becomes

$$[2] \qquad C' = \frac{[1 - \exp (-2R(L - x))]}{[1 - \exp (-2RL)]} C_0 \exp (V/2D - R)x,$$

where C' is now the *perturbed* atom concentration at any position $x(\leqslant L)$.

This work was supported in part by the U.S.A.F. Cambridge Research Laboratories and in part by the Defence Research Board of Canada.

Thus, at any given x in the flow stream, when the sink is situated downstream at L, the ratio of the perturbed to the unperturbed concentration will be given by

$$[3] \qquad C'/C = \frac{1 - \exp(-2R(L - x))}{1 - \exp(-2RL)}.$$

Provided the product $2RL$ is not too small (in the present experiments never less than 10), the denominator of [3] can be set equal to unity and the expression written as

$$\ln(1 - C'/C) = -2R(L - x).$$

A plot of $\ln(1 - C'/C)$ against $(L - x)$ should therefore yield a straight line of slope $-2R$.

The evaluation of the diffusion coefficient from R requires a knowledge of both k and the linear velocity V. However, if $V^2 \gg 4kD$, the influence of k will be small and it need not be known with great accuracy. For example, under typical operating conditions (V = 500–1000 cm s^{-1}, $k \simeq 5$ s^{-1}), the effect of neglecting the 'normal' recombination reactions completely ($k = 0$) and writing $D = V/2R$ is to introduce less than 1% error into the calculation of the diffusion coefficient.

This is the biggest single advantage of the method, since the accuracy of the diffusion coefficient measurement is governed almost completely by the accuracy of R and V, both of which can be measured with considerable precision. Also, provided $4D\ \mathrm{d}\ln C/\mathrm{d}x \ll V$, the restriction of overall first-order recombination can be removed, thus extending the applicability of the method.

EXPERIMENTAL

The procedure adopted to measure R has been outlined previously (1).

Essentially, a dilute atom stream is allowed to flow with relatively high velocity through a cylindrical reaction tube. Situated in the tube is a 0.4 mm thick disc of 40 mesh platinum gauze placed perpendicularly to the flow stream and with a diameter of 21 mm, only slightly less than that of the reaction vessel. For systems involving atomic oxygen, the disc was plated with silver which was rapidly converted to silver oxide on exposure to atoms. This disc acted as a very efficient localized atom sink.

It will be noted that R can be measured by two alternate procedures: (*a*) by measuring C' and C at varying x with L constant, and (*b*) by measuring C' and C at constant x as L is varied. In method *a* both C and C' are variable, although the variation of C with x is very much less than that of C' in the region of interest. Method *b* is considerably simpler and is preferable, since C at a given x is constant and only C' varies with L.

For atomic oxygen systems, the relative concentration at a fixed position in the reaction tube was measured by adding a trace of nitric oxide (2) through a fixed upstream inlet and viewing the resulting emission with a collimated 1P21 phototube. The net effect of the nitric oxide is to produce a catalyzed first-order recombination. This does not affect the diffusion coefficient measurement, provided the overall recombination rate satisfies the criterion given above.

With the atom sink sufficiently far downstream, the phototube output is proportional to the unperturbed concentration, C. The relative light intensity was then recorded on a Speedomax recorder as the atom sink was moved upstream in equal increments of 1.67 mm. From these data, C'/C at constant x was obtained as a function of $(L - x)$. Typical plots of the relative atom concentration and of $\ln(1 - C'/C)$ against $(L - x)$ were shown in the previous paper (1).

An approximate value of k was obtained for each experiment by withdrawing the sink and scanning the reaction vessel with the phototube.

For systems involving atomic nitrogen, the associated Lewis–Rayleigh afterglow provided the monitoring reaction. The atom sink in this case was plated with cobalt (3).

The following systems were studied: (1) atomic oxygen in O_2, (2) atomic oxygen in N_2, (3) atomic oxygen in Ar, (4) atomic oxygen in He, and (5) atomic nitrogen in N_2. System 1 was obtained by partially dissociating molecular oxygen, using a microwave generator. A trace of nitric oxide was added below the discharge to provide the monitoring emission. System 2 was obtained by slightly overtitrating discharged nitrogen with nitric oxide (4). The slight excess of nitric oxide again provided the monitoring emission. Systems 3 and 4 were obtained by dissociating a mixture of oxygen and inert gas (2–3% O_2, 97–98% inert gas), while system 5 was simply discharged nitrogen.

Diffusion coefficients of the atomic species in these systems were measured over a range of pressures (0.25–2.5 mm Hg) and temperatures (4–95 °C).

RESULTS AND DISCUSSION

Some of the diffusion coefficients are shown as a function of pressure at constant temperature (4–7 °C) in Fig. 1. The systems, O/N_2 and N/N_2, have not been reproduced in this figure, since they lie between those of O/Ar and O/O_2. The slopes, D^0, of these curves are shown in Table I.

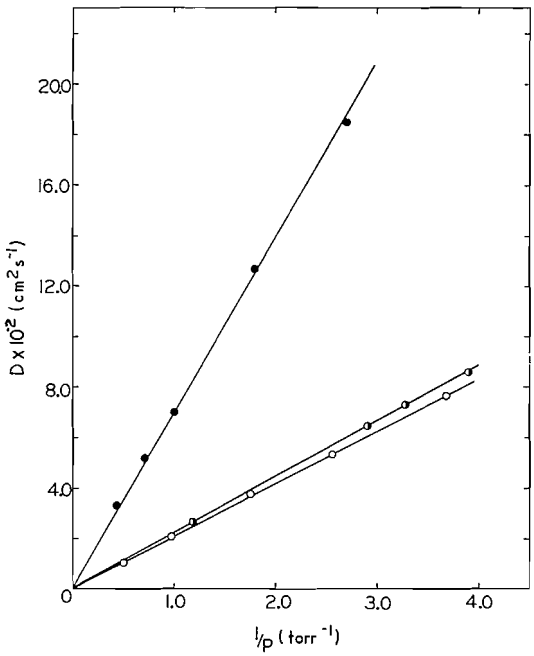

FIG. 1. Atom diffusion coefficients as a function of pressure at 280 °K: (●) O, He; (◑) O, O_2; (○) O, Ar.

TABLE I

Values of the diffusion coefficient, D^0, at 1 torr pressure and temperature 280 °K

System	$D^0 \times 10^{-2}$ (cm² s⁻¹)
O/He	7.0
O/Ar	2.09
O/N_2	2.18
O/O_2	2.22
N/N_2	2.21

It can be assumed that these diffusion coefficients are essentially those involving ground state atoms and molecules. Excited species, although undoubtedly present (5), will be in low concentration and will vary in amount depending upon the pressure conditions and the elapsed time to the point of measurement. Since constant values of $D \times P$ were obtained under a variety of flow conditions, it seems probable that the presence of excited species did not have any significant effect on the measured diffusion coefficients.

There are few published data for atomic diffusion coefficients with which the present results can be compared.

Krongelb and Strandberg (6) made two measurements of D_{O,O_2} at 1.0 and 1.5 mm Hg pressure. These were obtained by following the rate of change of atomic oxygen concentration in a closed sidearm when the concentration at the open end was suddenly reduced to zero. This time-dependent concentration is a complex function of both the diffusion coefficient and the recombination rate. The two isolated measurements yielded values of 2.40×10^2 and 2.25×10^2 cm^2 s^{-1} for D^0.

Young (7) measured D_{N,N_2} over a range of pressures by following the rate of decay of atomic nitrogen in a static system. In this method a long, closed sidearm was attached to a spherical reservoir. The time constant for the decay of atoms in the reservoir was measured as a function of the position of a catalyst situated in the sidearm. From these measurements both the diffusion coefficient and the recombination coefficient of the catalyst were obtained. The experimental data showed considerable scatter, yielding an average value of 5.6×10^2 cm^2 s^{-1} for $D_{N,N_2}{}^0$. Young indicates that this value could be reduced by as much as a factor of two if a reactive species is generated at the catalytic surface, but the argument appears unconvincing.

The method employed by Walker (8) makes use of eq. [1], D and k being evaluated by determining the exponent in this equation for two different values of V (V finite and zero respectively). This involves two separate experiments under markedly different flow conditions and any variation in the composite recombination rate constant will be reflected as an error in D. Over the pressure range 1.05–2.17 mm Hg, Walker obtained a value for $D_{O,O_2}{}^0$ at 298 °K of $2.3 \pm 0.1 \times 10^2$ cm^2 s^{-1}, in good agreement with the present work.

Collision Diameters from Diffusion Coefficients

Accurate diffusion coefficient data are useful in calculating collision parameters. If the colliding particles are regarded as incompressible rigid spheres, the binary diffusion coefficient is given by (9)

$$[4] \qquad D_{AB} = \frac{2.63 \times 10^{-3}}{P(\sigma_{AB})_{r.s.}{}^2}\left(\frac{T^3(M_A + M_B)}{2M_AM_B}\right)^{\frac{1}{2}},$$

where $(\sigma_{AB})_{r.s.}$ = rigid sphere collision diameter of particles A and B in Å, P = pressure in atm, and M_A, M_B = molecular weights of A and B.

The rigid sphere collision diameters of atomic oxygen and atomic nitrogen were calculated using this expression and are shown in Table II.

TABLE II

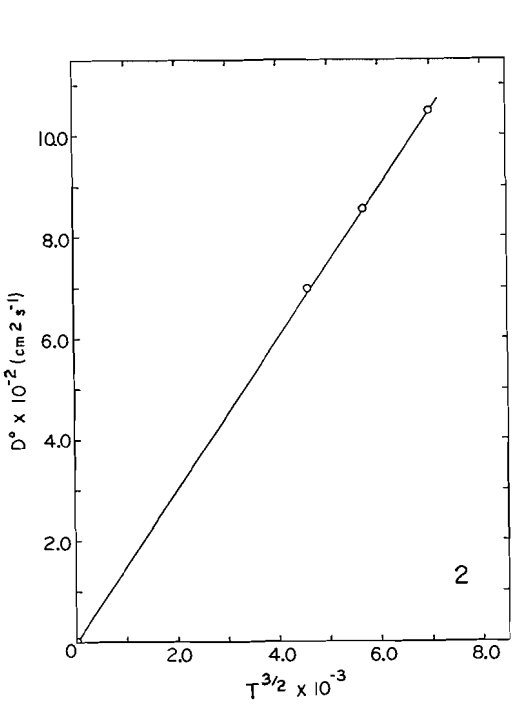
Rigid sphere collision diameters for atomic oxygen and nitrogen

A	B	$(\sigma_{AB})_{r.s.}{}^a$ (Å)	$(\sigma_B)_{r.s.}{}^b$ (Å)	$(\sigma_A)_{r.s.}$ (Å)
O	Ar	3.06_1	3.45	2.67
O	N_2	3.08_4	3.55	2.62
O	O_2	3.03_6	3.40	2.67
O	He	2.34_5	2.04	2.65
N	N_2	3.15_0	3.55	2.75

[a]Calculated from eq. [4] and the experimentally determined diffusion coefficient.
[b]Calculated from the Lennard-Jones parameters [tables IA and IM of ref. 9] using $(\sigma_B)_{r.s.}{}^2 = (\sigma_B)_{L\text{-}J}{}^2\Omega^{(1,1)*}$.

The consistent collision diameter of atomic oxygen in such diverse systems is rather surprising, and this could be regarded as a measure of the validity of the rigid sphere model. However, consistent measurements at a single temperature do not completely

justify this conclusion. The dependence of the collision diameter on temperature provides a more rigorous criterion since the inadequacy of the model will appear as a temperature-dependent collision cross section. The rigid sphere model requires the binary diffusion coefficient to be proportional to $T^{3/2}$. For the systems O/He, O/Ar, and O/N_2, a good linear dependence was found between $D_{AB}{}^0$ and $T^{3/2}$. This is illustrated by the data for $D_{O,He}{}^0$ shown in Fig. 2. For these systems the rigid sphere model appears to be an accurate description.



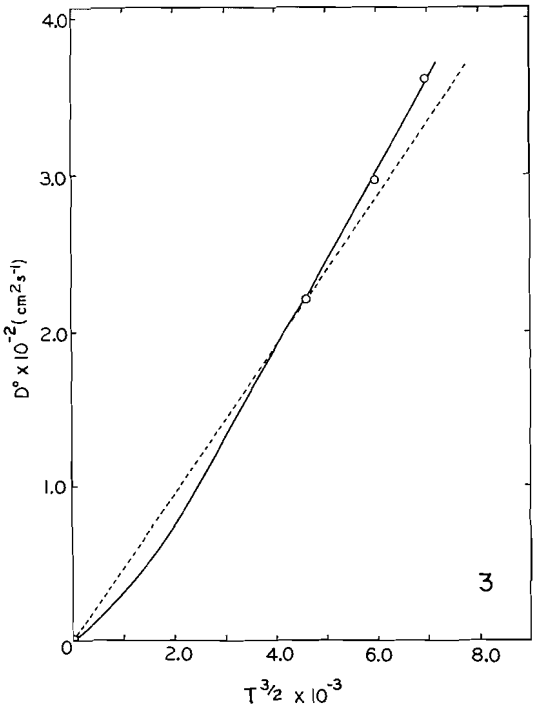


FIG. 2. Diffusion coefficient of atomic oxygen in helium as a function of temperature at 1 torr pressure.
FIG. 3. Diffusion coefficient of atomic oxygen in O_2 as a function of temperature at 1 torr pressure: O experimental results; – – – rigid sphere model; — Lennard-Jones model (ϵ/k = 154°).

However, the diffusion coefficient of O in O_2 showed a definite deviation from linearity and the rigid sphere model is inapplicable.

For more realistic potentials, such as the Lennard-Jones 12.6 potential, the binary diffusion coefficient can be written (9) in the form

$$[5] \qquad D_{AB} = \frac{2.63 \times 10^{-3}}{P(\sigma_{AB})_{L\text{-}J}{}^2\,\Omega^{(1,1)*}}\left(\frac{T^3(M_A + M_B)}{2M_AM_B}\right)^{\frac{1}{2}},$$

where $(\sigma_{AB})_{L\text{-}J}$ = temperature *independent* Lennard-Jones collision diameter and $\Omega^{(1,1)*}$ = temperature *dependent* collision integral.

The collision integral, $\Omega^{(1,1)*}$, can be calculated independently as a function of the reduced temperature T^* ($= kT/\epsilon$) where ϵ is the depth of the Lennard-Jones potential well.

From tabulated values of $\Omega^{(1,1)*}$ as a function of T^*, it should be possible to fit the experimental results by a suitable choice of ϵ. Thus the deviation of the experimentally determined diffusion coefficients from the $T^{3/2}$ dependence can be used to derive the Lennard-Jones parameters, ϵ and $(\sigma_{AB})_{L\text{-}J}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The data for $D_{O,O_2}{}^0$ as a function of temperature are shown in Fig. 3. The best Lennard-Jones fit to the experimental points (full line in Fig. 3) was obtained with $\epsilon/k = 154°$. If $(\sigma_{O_2})_{L\text{-}J}$ is taken equal to 3.43 Å (9), a value of 2.33 Å for $(\sigma_O)_{L\text{-}J}$ is obtained.

It should be pointed out that the shape of the Lennard-Jones plot is not very sensitive to changes in its parameters. For example, values of ϵ/k lying between 110° and 190° all give fits that are within the experimental uncertainty of the results. (The derived value of $(\sigma_O)_{L\text{-}J}$ of course will also change as ϵ/k is varied.)

A similar though slightly less pronounced deviation was obtained for N in N_2. For this system, a best fit was found with $\epsilon/k = 78°$, $(\sigma_{N_2})_{L\text{-}J} = 3.68$ Å (9) and $(\sigma_N)_{L\text{-}J} = 2.94$ Å.

An interesting comparison can be made between our experimental results and the theoretical considerations of Yun *et al.* (10), who have calculated the diffusion coefficients of partially dissociated oxygen and nitrogen as a function of temperature in the range 1000 – 10 000 °K. These authors point out that their calculated diffusion coefficients cannot be reliably extrapolated to room temperature since their force laws do not include the long-range dispersion forces which make an appreciable contribution at low temperature. However, they have calculated these dispersion forces independently and added them to their extrapolated short-range interactions and fitted the resulting potentials to a modified Buckingham (exp −6) potential of the form

$$\phi(r) = \frac{\epsilon}{1 - 6/\alpha}\left[\frac{6}{\alpha}\exp\left(\alpha[1 - r/r_m]\right) - (r_m/r)^6\right]$$

where ϵ, α, and r_m are adjustable constants.

From these parameters the diffusion coefficients at low temperature can be calculated and are shown in Table III.

[a] Calculated using a Lennard-Jones potential $\phi(r) = 4\epsilon[(\sigma/r)^{12} - (\sigma/r)^6]$ with $\sigma = [(\sigma_N)_{L\text{-}J} + (\sigma_N)_{L\text{-}J}]/2 = 3.31$ Å and $\epsilon/k = 78°$.
[b] Calculated using exp −6 potential with $\alpha = 13$, $\epsilon/k = 12.3°$, and $r_m = 4.74$ Å (Yun *et al.* (10)).
[c] Calculated using a Lennard-Jones potential with $\epsilon/k = 154°$ and $\sigma = [(\sigma_O)_{L\text{-}J} + (\sigma_{O_2})_{L\text{-}J}]/2 = 2.88$ Å.
[d] Calculated using exp −6 potential with $\alpha = 15$, $\epsilon/k = 167°$, and $r_m = 3.19$ Å.
[e] Calculated using exp −6 potential with $\alpha = 15$, $\epsilon/k = 16.0$ °K, and $r_m = 4.20$ Å (Yun *et al.* (10)).
[f] Low-temperature limit of the high-temperature calculations of Yun *et al.* (10).

Columns II and IV in this table were calculated using the Lennard–Jones potentials which gave the best fit to the experimental results in the 280–365 °K range.

For the N–N_2 system (column II) this calculation grafts onto the high temperature calculated results quite satisfactorily. The exp −6 calculation, using Yun's parameters,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

differs from the experimental results by only 3.5%, an agreement which is well within the combined uncertainty of the calculated and experimental values (column III).

The Lennard-Jones calculation for $D_{O,O_2}{}^0$ (column IV) does not match the high-temperature calculations as satisfactorily, being high by about 15% at 1000 °K. A fit of the experimental results with an exp -6 potential (column V) yields a similar discrepancy. It will be noted that both plots require values for ϵ/k which are much greater than predicted by Yun *et al.* The exp -6 calculation, using Yun's parameters, accurately predicts the experimental value at 280 °K, but the predicted rate of increase of D_{O,O_2} is less than that observed experimentally (column VI). This deviation (or alternatively the large value of ϵ/k) found for $D_{O,O_2}{}^0$ may possibly reflect the additional valence interaction between O and O_2. Further experimental work to extend the temperature range would be valuable in clarifying this point.

THE SYNTHESIS OF β-GALACTO- AND β-GLUCO-PYRANOSYL DISACCHARIDES BY SPOROBOLOMYCES SINGULARIS[1]

P. A. J. GORIN, J. F. T. SPENCER, AND H. J. PHAFF[2]
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received June 1, 1964

ABSTRACT

Synthesis of β-D-galactopyranosyl disaccharides takes place in growing cultures of *Sporobolomyces singularis* containing lactose and a sugar acceptor. The products of galactosyl transfer using various acceptors arise mainly from substitution of secondary rather than primary hydroxyl groups. The minimal structural requirement for reaction with the acceptor appears to be a hydroxyl vicinal to the substituted hydroxyl group. A mechanism that accounts for the formation of secondary disaccharides is postulated.

The organism also contains a β-glucosidase which transfers *O*-β-D-glucopyranosyl groups from cellobiose to sugar acceptors. The positions of the glycosidic linkages in the disaccharide products are identical with those formed in the corresponding galactosyl transfer reaction.

INTRODUCTION

Sporobolomyces singularis, when grown on a medium containing lactose at an initial pH of 3.7, utilizes the glucose portion of the disaccharide as an energy source and transfers the galactose moiety to unused lactose to form a trisaccharide. This sugar has been characterized as *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 4)-D-glucose. By an additional galactosyl transfer reaction, part of the trisaccharide was converted to a tetrasaccharide containing three β-1,4 linkages (1). The yeast shows a high selectivity in carbohydrate utilization studies, and of 28 compounds examined it only utilized glucose, mannose, fructose, D-mannitol, D-sorbitol, cellobiose, and lactose (2). This small number of sugars utilized suggested that growth of the yeast on a medium containing lactose and an additional sugar would promote the transfer of galactose to the additive to give a β-galactosyl disaccharide.

A number of β-galactopyranosyl disaccharides of hexoses and pentoses were prepared by using this organism (Table I). Some experiments gave more than one disaccharide, but the major component could generally be isolated by crystallization after chromatography. The fractionation was necessary since the disaccharide(s) was generally contaminated with unused acceptor and trisaccharide formed by transfer of galactose to the synthesized disaccharide. For example, with L-arabinose as acceptor, trisaccharide was formed which contained an *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl unit attached to the 3-position of L-arabinose. Very little galactosyl lactose was obtained since L-arabinose competed successfully with lactose as an acceptor. The β-galactosidase responsible for the reaction was associated with the cells since culture filtrates had no detectable activity. In addition to this enzyme, a β-glucosidase was present, since β-glucopyranosyl disaccharides could be synthesized by growing *Sporobolomyces singularis* in a mixture of cellobiose and a carbohydrate acceptor.

Disaccharides synthesized by the growing organism were mostly formed by substitution of a secondary rather than a primary hydroxyl in the acceptor molecule. Most acceptors

[a]Synthesized by Pazur using yeast lactase enzyme from *o*-nitrophenyl-D-galactopyranoside and galactose (7).
[b]Synthesized by action of enzyme from *Lactobacillus bifidus* var. Penn on lactose and *N*-acetyl-D-glucosamine (20).
[c]Synthesized from cellobiose and D-xylose using cell free extracts of *Aspergillus niger* (21).
[d]Synthesized by disproportionation of lactose using an enzyme from *Saccharomyces fragilis* (22).

were substituted in only one position, thus rendering the method superior to conventional chemical synthetic methods which generally give secondary disaccharides in much lower yields.

Control of the substitution position could be achieved by modification of the acceptor molecule. For example, in the glucose series 2-, 4-, or 5-substituted β-galactopyranosyl glucose derivatives can be synthesized using benzyl-α-D-glucopyranoside, methyl-α-D-glucopyranoside, and 1,2-*O*-isopropylidene-D-glucofuranose, respectively, as starting materials. The enzyme system obtained by disintegration of cells of *Sporobolomyces singularis* could be used to obtain a mixture of 3-*O*- and 6-*O*-β-D-galactopyranosyl-D-glucose from lactose, the former (63%) being obtainable by crystallization. This system, unlike the growing organism, did not assimilate glucose.

Enzyme extracted from cells converted lactose and an acceptor to the same disaccharides as growing cells in the four instances examined. However, contamination with 3-*O*- and 6-*O*-β-D-galactopyranosyl-D-glucose always took place. These similarities in disaccharide structures suggest that sugar transport across the cell membrane is not a factor in determining the structures of the transglycosylation products.

Experiments with the cell extract showed that transglycosylation took place readily at pH values of 4.0 to 8.2 but was most rapid at pH 6.5.

Mechanism of Sugar Transfer

Wallenfels and co-workers (3) have studied extensively the β-galactosidases of *E. coli* and calf intestine, and have interpreted galactosyl transfer reactions in terms of active sites in the enzymes. The reaction is depicted in Fig. 1, substantially by the route visualized

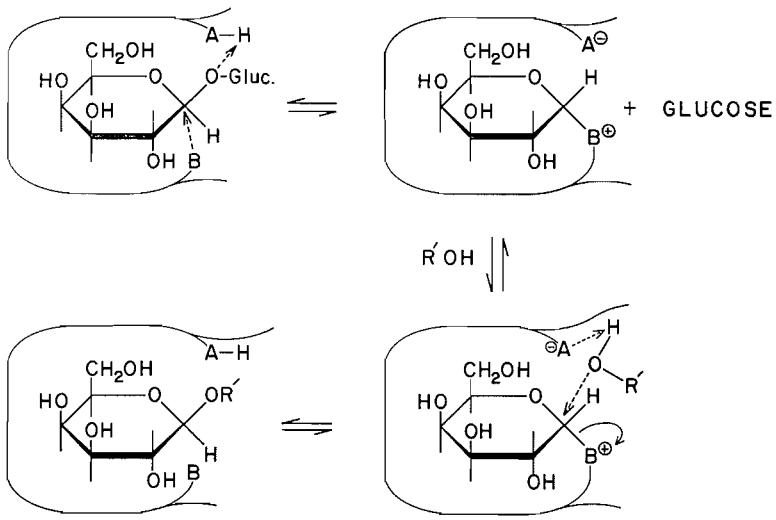

FIG. 1. Mechanism of β-galactosyl transfer.

by Wallenfels. After induction (4) of the β-galactosidase by the lactose molecule simultaneous protonation of the glycosidic oxygen by —A—H and nucleophilic attack by —B at C-1 takes place. The intermediate α-galactose–enzyme complex formed can react with a new alcohol to give a new β-galactoside. The intermediate complex in this reaction differs from that postulated by Wallenfels and Malhotra, who prefer a β-configuration (3). However, Koshland (5) has concluded that in an enzymic reaction in which a β-configuration is retained, the sugar–enzyme intermediate has an α-configuration. The latter theory appears to be more plausible on the basis of energy requirements in chemical replacement reactions at anomeric sugar centers.

A mechanistic description of disaccharide synthesis in the *Sporobolomyces singularis* system must answer two main questions. (*a*) Why are disaccharides formed in preference to galactose, which would arise by decomposition of the intermediate enzyme complex by the excess water present? (*b*) Why does the intermediate enzyme complex react with secondary rather than the more chemically active primary hydroxyl group of an acceptor?

Before these questions can be considered it is necessary to show that the relative rates of hydrolysis of the various products of β-galactosyl transfer are small. Hydrolysis rates have been shown to be important in the work of Wallenfels and Beck (6), who reported the transfer of *O*-α-L-arabopyranosyl residues from *o*-nitrophenyl-α-L-arabopyranoside to glucose using *E. coli* β-galactosidase. Over long periods of time this reaction gave mainly 6-*O*- and 4-*O*-α-L-arabopyranosyl-D-glucose. Although the 3-isomer was formed initially it eventually disappeared since it was hydrolyzed relatively rapidly. However, in growing cultures of *Sporobolomyces singularis* in two instances relatively little hydrolysis of disaccharides took place during disaccharide synthesis. For example, during the formation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of 3-*O*-β-D-galactopyranosyl-D-galactose from lactose and galactose only 1% of 6-*O*-β-D-galactopyranosyl-D-galactose (introduced in trace amounts labelled with ^{14}C in the reducing end unit) was hydrolyzed to galactose. Similarly, only 16% of 5-*O*-β-D-galactopyranosyl-L-arabinose-^{14}C was hydrolyzed in a culture containing lactose and arabinose, a reaction that gives mainly 3-*O*-β-D-galactopyranosyl-L-arabinose with smaller amounts of the 5-isomer. This figure compares with 20% hydrolysis noted when 3-*O*-β-D-galactopyranosyl-L-arabinose-^{14}C was introduced into a similar system.

Examination of the products of β-hexosyl transfer reactions listed in Table I shows that the substituted secondary hydroxyl group invariably has nearby hydroxyl groups. *N*-Acetyl-D-glucosamine and 1,2-*O*-isopropylidene-D-glucofuranose could be substituted on the 4- and 5-position respectively, whereas methyl-3-deoxy-α-D-glucopyranose did not function as an acceptor molecule. It appears that two vicinal hydroxyl groups are necessary for β-galactosyl transfer to take place. As an example the 6-position of 1,2-*O*-isopropylidene-D-glucofuranose should be bound to the galactose–enzyme complex prior to reaction of the 5-hydroxyl. This reaction is depicted in Fig. 2, in which the enzyme is represented as a

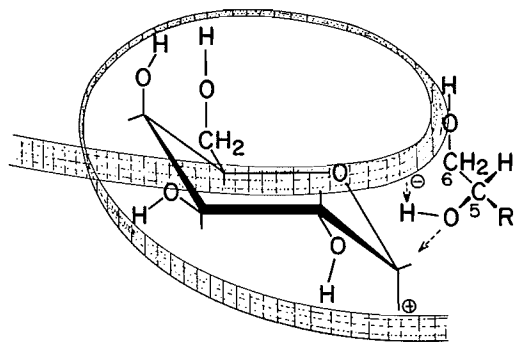

FIG. 2. Intermediate in transfer of galactose to 1,2-*O*-isopropylidene-D-glucofuranose.

spiral to which the sugar hydroxyl groups are bound, presumably by hydrogen bonds. This process would successfully explain the relative lack of reactivity of the monofunctional water hydroxyl group or the isolated primary hydroxyl group of a sugar.

In the acceptor molecule the presence of hydroxyl groups other than that vicinal to the reacting hydroxyl group may have a role in the reaction, since they also could be bound to the enzyme. This longer range effect is evident from the β-galactosyl transfer experiments carried out with L-arabinose, D-galactose, and their derived methyl pyranosides. Whereas the reducing sugars were substituted on the 3-position the glycosides gave 4-substituted disaccharides. It would be interesting to characterize the product from a similar experiment with methyl-α-D-galactopyranoside in the presence of *o*-nitrophenyl-D-galactopyranoside and the yeast lactase enzyme of Pazur (7) since the enzyme system from various yeasts may be similar. This author showed that when D-galactose was used as an acceptor substitution took place on the 3- or 6-position, and concluded that three vicinal secondary hydroxyl groups were necessary for substitution of the middle hydroxyl group.

Characterization of Transglycosylation Products

β-Galactopyranosyl and β-glucopyranosyl disaccharides with pentose reducing ends were characterized by following their lead tetraacetate oxidation kinetics (8) and by paper

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

chromatographic examination of the sodium borohydride reduction product of the oxidized sugars. These could be characterized by their R_F values on paper chromatograms depending on whether they were 2-*O*-β-hexopyranosyl pentitols, tetritols, or glycerol, derived from 2-, 3-, or 4-linked β-hexopyranosyl pentoses respectively. The products could in turn be distinguished from 1-*O*-β-hexopyranosyl glycerols, which would be formed from a 5-linked disaccharide.

The β-galactopyranosyl disaccharide fraction formed from L-arabinose contained a mixture of 3- and 5-links, the former predominating. Similarly linked disaccharides were obtained from D-ribose. The yields of the D-arabinose and D-ribose disaccharides were poor, but from L-arabinose 3-*O*-β-D-gluco- and 3-*O*-β-D-galactopyranosyl-L-arabinose could be readily prepared in crystalline form in good yield (21% and 25% respectively). The reaction of lactose with L-arabinose also gave a trisaccharide. This was shown to have a 3-linked reducing end by its lead tetraacetate oxidation characteristics. The oxidation product was reduced with sodium borohydride to give a galactobiosyl erythritol. This consumed 4 moles of sodium periodate with concomitant production of 1 mole of acid. The periodate oxidation product, when reduced with sodium borohydride and hydrolyzed, gave glycerol and erythritol thus characterizing the product as *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 2)-L-erythritol. The trisaccharide was, therefore, formed by transfer of D-galactose to the 4-position of the galactose portion of 3-*O*-β-D-galactopyranosyl-L-arabinose. By a similar procedure the characterization of a trisaccharide fraction from cellobiose and L-arabinose was attempted. This was unsuccessful since it appeared to contain two or more components.

Starting with D-xylose, 2-*O*- and 3-*O*-β-D-galactopyranosyl-D-xylose were prepared giving 9% and 18% yields respectively. The latter material crystallized, and the 2-linked disaccharide was isolated from the mother liquor after modification of the 3-linked disaccharide with lead tetraacetate. The 2- and 3-linked β-glucopyranosyl analogs could be synthesized from cellobiose and D-xylose.

O-β-D-Galactopyranosyl hexoses were characterized by techniques identical with those used for the pentose disaccharides. When grown on a mixture of lactose and galactose *Sporobolomyces singularis* provided a mixture, which was chromatographed to yield crystalline 3-*O*-β-D-galactopyranosyl-D-galactose and a lesser amount of the 4-linked disaccharide. Formation of the 3-linked disaccharide indicates that the corresponding 3-linked L-arabinose disaccharide arose from the pyranose and not the furanose form. D-Allose provided mainly crystalline 4-*O*-β-D-galactopyranosyl-D-allose and a smaller proportion of the 3-isomer.

It was shown that 6-deoxy-D-glucose and D-fucose (6-deoxy-D-galactose) were good acceptors in the hexosyl transfer reaction and were substituted in their 3-positions. On the other hand L-fucose could not participate as an acceptor in the reaction. This parallels the reactivity of arabinose, which reacted in the L-form, but not the D-form. Another methyl pentose, L-rhamnose, was substituted in the 2- and 3-positions.

2-Acetamido-2-deoxy-4-*O*-(β-galactopyranosyl)-D-glucose (*N*-acetyllactosamine) was synthesized from lactose and *N*-acetyl-D-glucosamine, giving a poor yield since glucosamine was utilized by the yeast. The disaccharide was identified by comparison with an authentic specimen. The 3-isomer was not obtained on seeding the mother liquor.

The product from lactose and 1,2-*O*-isopropylidene-D-glucose was shown to be substituted in the 5-position. Hydrolysis of the isopropylidene group yielded 5-*O*-β-D-galactopyranosyl-D-glucose, which was converted to 2-*O*-β-D-galactopyranosyl-L-erythritol by lead tetraacetate oxidation followed by sodium borohydride reduction. The product was identified

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

by its characteristics towards sodium periodate and by being distinguishable from 2-*O*-β-D-galactopyranosyl-D-erythritol (9).

Characterization of the products formed by transfer from lactose to methyl-α- and benzyl-α-D-glucopyranose and methyl-α-D-galactopyranoside was carried out by measurement of their sodium periodate uptakes. To distinguish between 2- and 4- linked disaccharide glycosides their oxidation products were reduced with sodium borohydride. Hydrolysis to erythritol and glycerol showed that the methyl-α-D-gluco- and galactopyranoside disaccharides were 4-linked. Since only glycerol was obtained from *O*-β-D-galactopyranosyl-(benzyl-α-D-glucopyranoside) it contained a 2-linkage. This method was not applicable in identification of the product from methyl-β-L-arabopyranoside. Instead it was methylated and the product then hydrolyzed. The mixture of methyl sugars was shown to be inert to lead tetraacetate, which indicated the presence of a 2-substituted dimethyl arabinose. The disaccharide consumed 3 moles of sodium periodate with formation of 1 mole of acid, and was therefore 4-*O*-β-D-galactopyranosyl-(methyl-β-L-arabopyranoside).

The β-galactosyl transfer reaction was highly specific when erythritol and D-arabitol were used as acceptors. The products were 2-*O*-β-D-galactopyranosyl-D-erythritol and 4-*O*-β-D-galactopyranosyl-D-arabitol respectively.

EXPERIMENTAL

Production of Oligosaccharides

The organism was grown on a medium containing 5% lactose (or cellobiose), 2.5% sugar acceptor, and 0.75% Difco yeast extract. Growth took place in 250 ml Erlenmeyer flasks containing 25 ml medium at 20 °C incubated on a New Brunswick shaker (240 r.p.m., 1 inch eccentricity). Other runs on varying scales were carried out in 125 ml Erlenmeyer flasks (12.5 ml medium) and 500 ml flasks (50 ml medium). Inoculation was directly from slants (yeast–nitrogen base agar containing 3% lactose). The mixture of lactose and yeast extract was adjusted to pH 3.7 and autoclaved. The acceptor solution was then sterilized by passage through a filter, pore size 0.45 μ, and added just before inoculation. The progress of the hexosyl transfer was followed by means of paper chromatography using ethyl acetate–acetic acid–water (9:2:2 v/v) as solvent and *p*-anisidine hydrochloride (10) as spray reagent in experiments in which the products were reducing di- or tri-saccharides. For nonreducing products *n*-butanol–ethanol–water (40:11:19 v/v) (solvent A) and the ammoniacal silver nitrate spray (11) were used. The lactose and cellobiose reactions were generally complete after 8 and 6 days respectively.

Isolation of Oligosaccharides

The products from the hexosyl transfer reactions were isolated using cellulose chromatography. The following abbreviations for column eluants are used in the text. Solvent B: acetone–water (10:1 v/v); solvent C: acetone–water (7:1 v/v); solvent D: acetone–water (5:1 v/v); solvent E: benzene–ethanol–water (500:50:1 v/v); solvent F: *n*-butanol, saturated with water; solvent G: *n*-butanol, one-half saturated with water.

Oligosaccharide Synthesis from Lactose and Acceptors Using the Intact Organism

(i) L-Arabinose Acceptor

The product from 25 ml of medium, when chromatographed on cellulose using solvent B, yielded L-arabinose (322 mg). Solvent C eluted the disaccharide fraction (752 mg) and solvent D the trisaccharide fraction (324 mg).

The disaccharide portion consumed 1.30, 1.33, and 1.34 moles of lead tetraacetate after 2, 5, and 15 min respectively. After addition of oxalic acid to remove excess oxidant, the oxidized sugar was reduced with sodium borohydride as described in the previous paper on galactosyl transfer reactions (1). The product was examined by paper chromatography in solvent A using the ammoniacal silver nitrate spray. It was shown to contain an *O*-β-galactopyranosyl erythritol and an *O*-β-galactopyranosyl glycerol. Since the consumption of lead tetraacetate oxidation did not increase appreciably with time, 1,4-linked disaccharides were absent (8). The data indicated that 3-*O*-β-D-galactopyranosyl-L-arabinose (70%) and the 5-linked disaccharide (30%) were present in the mixture.

The 3-linked disaccharide crystallized from 3 ml of methanol. The amorphous 5-isomer (12) remained in the mother liquor and had $[\alpha]_D$ +85° (*c*, 1.0, H_2O). A further recrystallization from methanol yielded 3-*O*-β-D-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

galactopyranosyl-L-arabinose with m.p. 177–178 °C and $[\alpha]_D$ +30° → +45° (*c*, 1.0, H_2O). Aspinall, Auret, and Hirst (13) reported m.p. 202–203 °C and $[\alpha]_D$ +80° → +62° for the β-anomer.

Calcd. for $C_{11}H_{20}O_{10}$: C, 42.3; H, 6.5. Found: C, 42.1; H, 6.5.

When this experiment was repeated using 150 ml of medium, 1.42 g of the 3-linked and 1.35 g of the 5-linked disaccharides were isolated.

A portion (300 mg) of the trisaccharide fraction (1.20 g) was oxidized with 1 mole of lead tetraacetate and the oxidized sugar reduced with sodium borohydride. The product consisted of two materials and the major component (139 mg) ran on a paper chromatogram at the same speed as lactose in solvent D. The minor component (60 mg) had a slightly higher mobility. The former product was recrystallized twice from methanol to give material with m.p. 137–138 °C and $[\alpha]_D$ +4° (*c*, 1.0, H_2O). Acid hydrolysis yielded galactose and erythritol.

Calcd. for $C_{16}H_{30}O_{14}\cdot CH_3OH$: C, 42.7; H, 7.2. Found: C, 42.4; H, 7.05.

The material consumed 3.8 and 4.0 moles of sodium periodate after 6 and 25 h, yielding 0.9 and 1.0 moles of acid respectively. The resulting oxidation product was reduced with sodium borohydride and then hydrolyzed with acid. The presence of glycerol and erythritol in the hydrolysate and the lead tetraacetate and periodate data characterized the material as *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 2)-L-erythritol.

(ii) D-*Arabinose*

Procedures and amounts of reactants were identical with those used in section (*i*). The yield of β-galactopyranosyl-D-arabinose disaccharides was only 5% and characterization was not carried out.

(iii) D-*Xylose*

Identical isolation procedures as in the L-arabinose experiment were used. From 25 ml of medium xylose (219 mg), two disaccharide fractions, one (168 mg) being chromatographically pure and the other a mixture (181 mg), and a trisaccharide fraction (324 mg) were obtained. The chromatographically pure fraction consumed 0.90, 0.94, and 0.98 moles of lead tetraacetate after 2, 5, and 15 min respectively and was therefore 3-linked. It was recrystallized twice from methanol to give 3-*O*-β-D-galactopyranosyl-D-xylose with m.p. 196–200 °C and $[\alpha]_D$ +27° → +10° (*c*, 1.0, H_2O).

Calcd. for $C_{11}H_{20}O_{10}$: C, 42.3; H, 6.5. Found: C, 42.4; H, 6.7.

The mixed disaccharide fraction consumed 0.37, 0.40, and 0.46 moles of lead tetraacetate after 2, 5, and 15 min respectively. Oxidation of a portion (120 mg) with 0.40 moles of lead tetraacetate yielded a mixture which was fractionated on cellulose using solvent C. The resulting 2-*O*-β-D-galactopyranosyl-D-xylose was recrystallized twice from methanol to give material with m.p. 159–160 °C and $[\alpha]_D$ +25° (constant, *c*, 1.4, H_2O).

Calcd. for $C_{11}H_{20}O_{10}\cdot CH_3OH$: C, 41.9; H, 7.0. Found: C, 41.6; H, 6.9.

The results indicated that the β-galactosyl transfer product consisted of 66% of 3-*O*-β-D-galactopyranosyl-D-xylose and 34% of the 2-linked disaccharide.

(iv) D-*Ribose*

The mixture from 25 ml of medium yielded 420 mg of ribose and 138 mg of a disaccharide fraction after cellulose chromatography using solvent C. The latter consumed 0.85, 0.90, 0.95, and 1.02 moles of lead tetraacetate after 2, 5, 10, and 20 min respectively. The lead tetraacetate oxidation product, when reduced with sodium borohydride, was converted to galactopyranosyl erythritol and a smaller proportion of galactopyranosyl glycerol. The product therefore consisted of 3-*O*-β-galactopyranosyl-D-ribose and a smaller quantity of the 5-isomer.

(v) D-*Galactose*

The mixture obtained from 200 ml of medium was fractionated on cellulose using solvent C. The first disaccharide fraction (250 mg), which ran at a slightly faster rate than the main component on paper chromatograms, was twice recrystallized from methanol to give 4-*O*-β-D-galactopyranosyl-D-galactose (130 mg) with m.p. 195–198 °C and $[\alpha]_D$ + 85° → +67° (*c*, 1.0, H_2O). The disaccharide gave an X-ray diffraction pattern identical with an authentic specimen (14).

Calcd. for $C_{12}H_{22}O_{11}$: C, 42.1; H, 6.4. Found: C, 41.7; H, 6.45.

The second disaccharide fraction (1.57 g) was eluted and of this 1.32 g was recrystallized twice from methanol to yield 3-*O*-β-D-galactopyranosyl-D-galactose (7) (0.70 g) with m.p. 204–206 °C and $[\alpha]_D$ +56° (constant, *c*, 1.3, H_2O).

Calcd. for $C_{12}H_{22}O_{11}$: C, 42.1; H, 6.4. Found: C, 41.9; H, 6.5.

The remainder of the disaccharide fraction (0.25 g) was oxidized with lead tetraacetate and the product reduced with sodium periodate. Examination of the product on a paper chromatogram showed predominantly galactopyranosyl pentitol and two recrystallizations from methanol–ethanol yielded 4-*O*-β-D-galactopyranosyl-D-arabitol with m.p. 180–182 °C. It gave an X-ray diffraction pattern identical with an authentic specimen (15).

Calcd. for $C_{11}H_{22}O_{10}$: C, 42.0; H, 7.1. Found: C, 42.0; H, 7.0.

(vi) D-*Allose*

The product from 25 ml of medium was fractionated on a cellulose column using solvent C. The disaccharide fraction (0.53 g) consumed 1.40, 1.55, and 1.71 moles of lead tetraacetate after 2, 5, and 15 min respec-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

tively. The oxidation product was reduced with sodium borohydride and examination of the reduction product on a paper chromatogram showed that a galactopyranosyl pentitol was the main product together with a smaller proportion of galactopyranosyl-erythritol. Two recrystallizations of the disaccharide fraction from methanol yielded 4-*O*-β-D-galactopyranosyl-D-allose with m.p. 112–113 °C and $[\alpha]_D$ +29° (constant, *c*, 1.0, H_2O). It consumed 1.09, 1.52, and 1.92 moles of lead tetraacetate after 2, 5, and 15 min respectively.

Calcd. for $C_{12}H_{22}O_{11}$: C, 42.1; H, 6.4. Found: C, 41.75; H, 6.8.

(vii) 6-Deoxy-D-glucose

Fractionation of the product, obtained from 25 ml of medium, on cellulose column using solvent C yielded a disaccharide fraction (0.40 g). Two recrystallizations from ethanol–methanol yielded 3-*O*-β-D-galactopyranosyl-6-deoxy-D-glucose (0.26 g), having m.p. 246–248 °C and $[\alpha]_D$ +25° (constant, *c*, 1.0, H_2O). It consumed 0.77, 0.97, and 1.05 moles of lead tetraacetate after 2, 5, and 15 min respectively.

Calcd. for $C_{12}H_{22}O_{10}$: C, 44.2; H, 6.8. Found: C, 44.0; H, 6.8.

(viii) D-Fucose

Cellulose column chromatography of the product from 25 ml of medium yielded, on elution with solvent B, D-fucose. A disaccharide fraction (0.38 g) was obtained using solvent C. One crystallization from methanol gave crystals (0.28 g) which on recrystallization from methanol had m.p. 245–246 °C and $[\alpha]_D$ +78° (constant, *c*, 1.0, H_2O).

Calcd. for $C_{12}H_{22}O_{10}$: C, 44.2; H, 6.8. Found: C, 44.25; H, 6.9.

The disaccharide was 3-linked since it consumed 1.00, 1.09, and 1.12 moles of lead tetraacetate after 2, 5, and 15 min respectively. The product obtained directly from the column consumed 0.91, 1.12, and 1.19 moles of oxidant after identical times and therefore consisted mainly of the 3-linked disaccharide.

(ix) L-Fucose

Only minute traces of disaccharide could be detected when the yeast was grown on a L-fucose–lactose mixture, using procedures and amounts identical with those described in section (*viii*).

(x) L-Rhamnose

Fractionation of the product from 25 ml of medium on a cellulose column gave rhamnose (518 mg) using solvent B. Solvent C eluted a disaccharide (227 mg), which appeared to contain 55% of 3-links and 45% of 2-links since 0.52, 0.57, and 0.68 moles of lead tetraacetate were consumed after 2, 5, and 15 min respectively.

(xi) N-Acetyl-D-glucosamine

From 75 ml of medium 220 mg of a disaccharide fraction was obtained by cellulose chromatography using solvent C. Crystallization from methanol gave 4-*O*-β-D-galactopyranosyl-*N*-acetyl-D-glucosamine (72 mg) with m.p. 176–178 °C. Its identity was established by comparison of its X-ray diffraction pattern with that of an authentic specimen (16).

(xii) 1,2-O-Isopropylidene-D-glucofuranose

The product from 25 ml of medium, by chromatography on cellulose using solvent E, yielded unchanged monoacetone glucose. Elution with solvent F gave a sirupy isopropylidene disaccharide (372 mg) which had $[\alpha]_D$ +15° (*c*, 1.2, MeOH). Partial hydrolysis on heating at 100 °C for 1 h in 0.01 *N* sulphuric acid gave the free disaccharide.The solution was then neutralized ($BaCO_3$), filtered, and evaporated. Oxidation of the product with 2.2 moles of lead tetraacetate followed by reduction with sodium borohydride gave a mixture of products. Chromatography on cellulose using solvent C yielded mainly a galactosyl erythritol with a smaller amount of a galactosyl glycerol. The erythritol derivative was recrystallized twice from ethanol and had m.p. 168–169 °C and $[\alpha]_D$ −6° (*c*, 1.0, H_2O).

Calcd. for $C_{10}H_{20}O_9$: C, 42.25; H, 7.1. Found: C, 42.15; H, 7.1.

It was characterized as 2-*O*-β-D-galactopyranosyl-L-erythritol, derived from 5-*O*-β-D-galactopyranosyl-D-glucose, since it consumed 3.0 moles of sodium periodate with production of 1.0 mole of acid after 25 h. The X-ray diffraction pattern differed from that of 2-*O*-β-D-galactopyranosyl-D-erythritol (9).

(xiii) Methyl-α-D-glucopyranoside

The product from 25 ml of medium was fractionated on a cellulose column using solvent G and unchanged glycoside (0.25 g) was eluted. The disaccharide glycoside (0.45 g) was obtained using solvent F. Crystallization from methanol–ethanol gave 0.36 g of crystals and a further crystallization from the same solvent yielded material which melted partly at 183 °C and partly at 220–230 °C and had $[\alpha]_D$ +102° (*c*, 1.0, H_2O). The product, which appeared to be a mixture, consumed 3.0 moles of sodium periodate with concomitant formation of 1.0 mole of acid after 6 to 25 h. The oxidized glycoside was reduced with sodium borohydride and the product hydrolyzed with acid. Formation of glycerol and erythritol indicated that the glycoside mixture contained 4-*O*-β-D-galactopyranosyl-methyl-α-D-glucopyranoside.

(xiv) Benzyl-α-D-glucopyranoside

Little galactosyl transfer took place on growth of the yeast in 16 ml of medium. Cellulose chromatography using solvent E eluted unchanged glycoside and solvent G provided the disaccharide glycoside (153 mg). Crystallization from ethyl acetate gave a product (68 mg) and a further crystallization from the same solvent yielded 2-*O*-β-D-galactopyranosyl-benzyl-α-D-glucopyranoside with m.p. 185–189 °C and $[\alpha]_D$ +78° (*c*, 0.9, H_2O).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Calcd. for $C_{19}H_{28}O_{11}$: C, 52.8; H, 6.5. Found: C, 52.9; H, 6.3.

It was characterized by sodium periodate oxidation which resulted in the consumption of 2.8 and 2.8 moles of oxidant with formation of 0.8 and 0.9 moles of acid after 6 and 25 h respectively. The oxidation product, on treatment with sodium borohydride followed by hydrolysis, gave glycerol, thus showing a 2-linkage.

(xv) Methyl-α-D-galactopyranoside

Using a procedure similar to that in the methyl-α-D-glucopyranoside experiment a methyl galactobioside (452 mg) was obtained. Recrystallization from methanol–ethanol gave crystals (0.36 g), which were recrystallized from the same solvent. The product had m.p. 207–208 °C and $[\alpha]_D$ +102° (*c*, 1.0, H_2O). Examination using the techniques described in section (*xiv*) characterized the product as 4-*O*-β-D-galactopyranosyl-methyl-α-D-galactopyranoside.

Calcd. for $C_{13}H_{24}O_{11}$: C, 43.8; H, 6.8. Found: C, 44.0; H, 6.7.

(xvi) Methyl-β-L-arabopyranoside

Chromatography of the contents of 25 ml of medium on cellulose using solvent F provided methyl-β-L-arabopyranoside (0.24 g) and a disaccharide glycoside (0.56 g). Recrystallization of the latter from ethanol gave material (0.37 g) which was recrystallized from the same solvent. The product had m.p. 216–218 °C and $[\alpha]_D$ +163° (*c*, 1.1, H_2O). The glycoside consumed 3.2 and 3.1 moles of sodium periodate releasing 1.0 and 1.1 moles of acid after 6 and 25 h respectively.

Calcd. for $C_{12}H_{22}O_{10}$: C, 44.2; H, 6.8. Found: C, 44.3; H, 6.7.

To ascertain whether the linkage was at the 2- or 4-position the glycoside was methylated by the aqueous sodium hydroxide–methyl sulphate method. Extraction of the neutralized solution with chloroform yielded a partially methylated material which was fully methylated by the silver oxide–methyl iodide method. The product was hydrolyzed in *N* hydrochloric acid at 100 °C for 18 h. Neutralization (Ag_2CO_3) and evaporation provided a sirup which contained 2,3,4,6-tetra-*O*-methyl-D-galactose and a di-*O*-methyl-L-arabinose. Paper chromatograms showed that the dimethyl sugar was not oxidized by lead tetraacetate indicating that it was substituted in the 2-position. These experiments characterized the glycoside as 4-*O*-β-D-galactopyranosyl-methyl-β-L-arabopyranoside.

(xvii) Methyl-α-D-mannopyranoside

Only 60 mg of disaccharide glycoside was obtained from 25 ml of medium using the same procedure as for methyl-α-D-glucopyranoside. Most of the mixture consisted of unchanged glycoside. The disaccharide glycoside was recrystallized twice from ethanol–methanol to give material (30 mg) with m.p. 168–170 °C and $[\alpha]_D$ +51° (*c*, 0.7, H_2O).

Calcd. for $C_{13}H_{24}O_{11}$: C, 43.8; H, 6.8. Found: C, 43.8; H, 6.9.

(xviii) D-Arabitol and D-Erythritol

The products from these polyols were fractionated on cellulose using solvent F.

From 50 ml of D-arabitol medium, galactosyl arabitol (125 mg) was obtained. Two recrystallizations from methanol gave 4-*O*-β-D-galactopyranosyl-D-arabitol with m.p. 178–181 °C. It gave an X-ray diffraction pattern identical with that of an authentic specimen (15).

Calcd. for $C_{11}H_{22}O_{10}$: C, 42.0; H, 7.1. Found: C, 42.0; H, 7.1.

Galactosyl erythritol (276 mg) was isolated from 25 ml of medium and was recrystallized twice from methanol–ethanol. It had m.p. 182–184 °C and gave an X-ray diffraction pattern corresponding to that of 2-*O*-β-D-galactopyranosyl-D-erythritol (9).

Calcd. for $C_{10}H_{20}O_9$: C, 42.25; H, 7.1. Found: C, 42.1; H, 6.9.

(xix) Methyl-3-deoxy-α-D-glucopyranoside

Cellulose fractionation of the mixture from 25 ml of medium using benzene–ethanol–water (200:50:1 v/v) eluted unchanged glycoside. No disaccharide glycoside was obtained on elution with solvent G.

Oligosaccharide Synthesis from Cellobiose and Acceptors Using the Intact Organism

The isolation procedures, column eluants, and characterization methods are similar to those using the corresponding acceptor in the lactose series.

(i) L-Arabinose Acceptor

The product from 150 ml medium contained disaccharides (2.16 g), trisaccharides (0.35 g), and a mixed fraction (0.50 g). The disaccharide contained 26% of 5-*O*-β-D-glucopyranosyl-L-arabinose and 74% of the 3-isomer. Fractional crystallization from methanol–ethanol gave the 3-linked disaccharide (0.81 g) and a further recrystallization provided material with m.p. 199–201 °C and $[\alpha]_D$ +70° (constant, *c*, 1.0, H_2O).

Calcd. for $C_{11}H_{20}O_{10}$: C, 42.3; H, 6.5. Found: C, 42.0; H, 6.6.

(ii) D-Xylose

The product (25 ml) provided di- (167 mg) and tri-saccharides (276 mg). The disaccharide fraction contained 76% 1,3- and 24% 1,2-links. From the mixture only 2-*O*-β-D-glucopyranosyl-D-xylose was obtained in crystalline form subsequent to oxidation of the 3-linked disaccharide with lead tetraacetate. It had m.p. 202–206 °C and $[\alpha]_D$ +7° (constant, *c*, 1.0, H_2O). Jones and Reid (17) report m.p. 200–202 °C and $[\alpha]_D$ 0° or this disaccharide.

Calcd. for $C_{11}H_{20}O_{10}$: C, 42.3; H, 6.5. Found: C, 42.6; H, 6.4.

(iii) D-*Ribose*

Only a small amount (136 mg) was obtainable from 25 ml of medium. The product appeared to contain mainly 1,3-links and a smaller proportion of 1,5-links.

(iv) D-*Fucose*

This substrate was efficiently converted to the disaccharide (0.65 g). It contained mainly 1,3-links since one recrystallization from methanol provided 3-*O*-β-D-glucopyranosyl-D-fucose (0.52 g). Recrystallization provided material with m.p. 250–252 °C and $[\alpha]_D$ +45° (constant, *c*, 1.0, H_2O).

Calcd. for $C_{12}H_{22}O_{10}$: C, 44.2; H, 6.8. Found: C, 44.0; H, 6.7.

Reaction Reversibility Studies Using ^{14}C*-Labelled Disaccharides*

(i) Lactose to L-*Arabinose Transfer Reaction*

3-*O*- and 5-*O*-β-D-galactopyranosyl-L-arabinose labelled with ^{14}C in the pentose portion were prepared by transglycosidation.

Two systems, each containing one of the labelled disaccharides (50 mg), L-arabinose (625 mg), lactose (1.25 g), and 0.75% Difco yeast extract in water (25 ml) were inoculated with *Sporobolomyces singularis*, which was allowed to grow for 8 days. The resulting L-arabinose was isolated by cellulose column chromatography using solvent F and its specific activity measured. During the course of the reaction 20% of the 3-*O*-β-D-galactopyranosyl-L-arabinose and 16% of the 5-isomer were hydrolyzed to arabinose.

(ii) Lactose to D-*Galactose Transfer Reaction*

A fermentation was carried out on a mixture containing 6-*O*-β-D-galactopyranosyl-D-galactose-^{14}C (18) (labelled in the reducing end-unit) (31.5 mg), lactose (625 mg), and D-galactose (312 mg). After 8 days D-galactose was isolated and its specific activity measured. The result indicated that only 1% of the radioactive disaccharide was hydrolyzed during the β-galactosyl transfer reaction.

Preparation of Cell Extracts

Sporobolomyces singularis (60–79) was grown in a medium containing 7.5% lactose and 0.75% Difco yeast extract. In a 500 ml Erlenmeyer flask 50 ml of medium was inoculated from a slant and incubated at 24 °C on a Gump rotary shaker (230 r.p.m., eccentricity 1 inch). The cells (15–20 g) from 10 flasks (500 ml of culture) were recovered by centrifugation and washed twice with cold water. The cells were disrupted in a modified Hughes press (19). The paste from the press was divided into four parts, mixed with buffers of the desired pH values, allowed to thaw, and centrifuged at high speed to remove cells and debris. The supernatant liquid, about 25 ml per portion, was returned and the pH determined and adjusted if necessary. The sugars, 0.25 g of L-arabinose and 0.5 g of lactose or cellobiose, were dissolved directly in about 12 ml of enzyme extract. The reaction was followed by chromatography on Whatman No. 1 paper, using as solvent ethyl acetate – acetic acid – water (8:2:2 v/v). The resulting glycosyl arabinoses were detected with the *p*-anisidine hydrochloride spray.

Effect of pH on β-Hexosyl Transfer Reactions

β-Hexosyl transfer took place readily at pH values 4.0, 6.5, and 8.2, the most rapid reaction occurring at about pH 6.5. The rate of reaction was greatly reduced at pH 2.5. The rate of glucose transfer to L-arabinose to give disaccharides, as shown on paper chromatograms, was appreciably greater than that of galactose transfer to the same acceptor.

(i) Oligosaccharides from Lactose Using Cell Extract

The product formed after 18 h incubation of lactose (1.50 g) with cell extract (25 ml) at pH 4.0 for 24 h was fractionated on a cellulose column using solvent C. Initially glucose (0.53 g) was eluted followed by a disaccharide fraction (172 mg) moving slightly faster than lactose on a paper chromatogram in the ethyl acetate – acetic acid – water (9:2:2 v/v) solvent. Two crystallizations from methanol gave 3-*O*-β-D-galactopyranosyl-D-glucose (54 mg) with m.p. 167–169 °C and $[\alpha]_D$ +37° (*c*, 0.8, H_2O).

Calcd. for $C_{12}H_{22}O_{11}$: C, 42.1; H, 6.5. Found: C, 40.8; H, 6.4.

It consumed 0.72, 0.98, and 1.05 moles of lead tetraacetate after 2, 5, and 15 min respectively. The product from the mother liquor consumed 1.34, 1.54, and 1.88 moles of oxidant after identical intervals. Reduction of the latter oxidized product with sodium borohydride gave products corresponding mainly to 4-*O*-β-D-galactopyranosyl-D-erythritol and 4-*O*-β-D-galactopyranosyl-D-arabitol on paper chromatograms. A trace of 6-*O*-β-D-galactopyranosyl-D-glucitol was also detected. These data indicated that 63% of 3-links, 37% of 6-links, and a trace of 2-links were present in the disaccharide fraction.

The next fractions consisted of the above disaccharides and lactose (227 mg) and lactose (251 mg). Two trisaccharides were eluted with solvent D, the first (0.12 g) was unidentified and the second (0.25 g) was characterized as *O*-β-D-galactopyranosyl-(1 → 4)-*O*-β-D-galactopyranosyl-(1 → 4)-D-glucose. After two recrystallizations from aqueous methanol it had a melting point and a mixed melting point of 225–228 °C.

(ii) Oligosaccharides from Lactose and Acceptors Using Cell Extract

The disaccharide fractions obtained on disproportionation of lactose (1.50 g) for 18 h in the presence of L-arabinose and D-galactose (0.75 g) and cell enzyme extract (25 ml) were isolated. Examination of the products was carried out by techniques described previously in the section on transglycosylation using intact cells. Other than 3-*O*- and 6-*O*-β-D-galactopyranosyl-D-glucose the disaccharide linkages formed by the cell

For personal use only.

extract and intact cells were identical. The products were 3-*O*- and 5-*O*-β-D-galactopyranosyl-L-arabinose from L-arabinose and 4-*O*- (trace) and 3-*O*-β-D-galactopyranosyl-D-galactose from galactose.

(iii) Oligosaccharides from Cellobiose and L-*Arabinose Using Cell Extract*

The products obtained from cellobiose (1.50 g), L-arabinose (0.75 g), and enzyme extract (25 ml) were 3-*O*- and 5-*O*-β-D-glucopyranosyl-L-arabinose, as indicated by the lead tetraacetate oxidation characteristics and products obtained by sodium borohydride reduction of the oxidized material.

AN APPLICATION OF SOME ELECTRON DENSITY, ELECTRIC DIPOLE, AND MAGNETIC DIPOLE MODELS TO THE GAS PHASE PROTON SHIFTS OF SOME SUBSTITUTED ETHYLENES

T. SCHAEFER AND T. YONEMOTO[1]
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received April 29, 1964

ABSTRACT

Measurements in the gas phase of the proton shifts relative to ethylene of methyl vinyl ether, of vinyl chloride, and of the three dichloroethylenes are reported. It is suggested that available molecular orbital calculations somewhat overestimate delocalization in the chloroethylenes. If this is so, then a model involving electrostatic fields arising from excess π-electron densities and from electric dipoles originating from the substituents, as well as magnetic fields from a point dipole representing the anisotropy of the substituents, predicts shifts in reasonable agreement with experiment for β-protons. The agreement for α-protons is not as good. The gas phase measurements are compared to measurements in the inert solvents, tetramethylsilane or cyclohexane.

INTRODUCTION

Considerable data exists supporting a linear correlation of proton magnetic resonance shifts with π-electron densities on neighboring carbon atoms in aromatic systems (1–8). In the empirical relation $\Delta\sigma_\pi = k\Delta q$, where Δq is the deviation from 1 of the π-electron density on the carbon atom and $\Delta\sigma_\pi$ is the corrected shift relative to benzene of the bonded proton, it appears that k has a value near 10 p.p.m./electron (5), although estimated values have a range from about 9–13 p.p.m./electron (9). It is known that simple molecular orbital calculations overemphasize the charge differences at various points in a molecule (5) and the measured shifts do suggest a more uniform distribution of π-electrons. Corrections to the experimental shifts have to be applied for the magnetic anisotropy of the substituents including ring current effects, ion association, and solvent effects (5), and for electric fields arising from bond dipoles due to substituents (6).

In an attempt to extend such a correlation to some simple aliphatic systems like substituted ethylenes, it became apparent that some of the available molecular orbital calculations are perhaps not reliable in their estimation of π-densities. We report some measurements here in support of this suggestion. We chose methyl vinyl ether, vinyl chloride, and the three dichloroethylenes. These could be measured in the gaseous phase without great difficulty, thus eliminating all sizeable corrections except those of magnetic anisotropy and electric dipole effects of the substituent. Also, these compounds were some of the few for which molecular orbital calculations were available. The reference substance in these cases is ethylene.

THE MODEL

We assume that replacement of a hydrogen atom in ethylene by oxygen or chlorine will affect the shielding of the remaining protons in three ways: (1) electrostatic fields from a delocalization of π-electrons into the double bond of ethylene polarize the C—H bonds and lead to changes in shielding; (2) electrostatic fields arising from the polar sigma bonds between carbon and oxygen or chlorine also polarize the C—H bonds; (3) the

[1]*N.R.C. Postdoctoral Fellow, 1963–64.*

C—O and C—Cl bonds introduce additional bond magnetic anisotropy leading to para- or dia-magnetic fields at the protons (10). Details of how these three effects were estimated are now described.

1. Effect of the π-Electrons

The π-electron densities of methyl vinyl ether were taken from the results of an improved LCAO–MO calculation by Julg and Bonnet (11). This calculation introduced a mutual deformation of the sigma orbitals between carbon and oxygen and gave excellent agreement with the experimental value of the first N → V transition. The π-densities for the chloroethylenes were derived from the calculations of Goldstein (12) and of Howe and Muirhead (13). These were simple MO approximations including overlap and the results were given in terms of a π-electron density matrix. To reduce these to the Coulson definition (14) we traced their calculations using Coulomb exchange and overlap integral values which they adopted as most adequate. Molecular orbitals and π-densities were then calculated in the usual way. Values of Δq are given in Table I.

TABLE I

Calculated values of charge densities, electric field shifts, and geometric factors for the magnetic anisotropy shifts in substituted ethylenes

Compound		Δq^a	u^b	$\Delta\sigma_E(1)^c$	$\Delta\sigma_E(2)^d$	$f_1(r,\theta)^e$	$f_2(r,\theta)^f$
	A	−0.11		−0.51	−0.73	0.075	0.046
	B	0.15	1.33	−0.12	−0.17	0.024	0.010
	C	0.15		−0.20	−0.28	−0.021	0.002
	A	−0.03		−0.53	−0.75	0.067	0.043
	B	0.08	1.79	−0.13	−0.19	0.022	0.012
	C	0.08		−0.19	−0.28	−0.009	0.006
		0.04	1.79	−0.66	−0.94	0.058	0.049
		0.04	1.79	−0.72	−1.02	0.089	0.055
		0.15	1.79	−0.32	−0.45	0.013	0.018

[a]Excess π-electron densities obtained as discussed in text.
[b]Group moment in Debyes obtained from ref. 17.
[c]Shift in p.p.m. using $a = -2.0 \times 10^{-12}$ and $b = 10^{-18}$ in eq. [1].
[d]Shift in p.p.m. using $a = -3.0 \times 10^{-12}$ and $b = 7.4 \times 10^{-19}$ in eq. [1].
[e]Geometrical factor of eq. [2] with the point dipole placed at the midpoints of the C—O and C—Cl bonds.
[f]As in footnote *e* with the point dipole placed at the oxygen or chlorine atoms.

We then use the relation $\Delta\sigma_\pi = k\Delta q$, with $k = 10$ p.p.m./electron to estimate values of $\Delta\sigma_\pi$. A more sophisticated treatment would take into account the polarization of the C—H bonds by excess charge densities on the other atoms (8), as well as including a term in the square of the field arising from the excess charges (8, 9). Buckingham's equation (15),

$$\Delta\sigma = aE_z - bE^2, \qquad [1]$$

where E_z is the electric field along the C—H bond direction and E is the field at the proton in question, can be rewritten in terms of Δq and interatomic distances, as has

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

been done by Schweizer *et al.* (8). However, in view of the uncertainties in Δq and of the range in accepted values of a and b in eq. [1], we retain the relation $\Delta\sigma_\pi = k\Delta q$.

2. Effect of the Electric Dipole from the C—O or C—Cl Bonds

The effect of the intramolecular electric field from the C—O or C—Cl dipoles was estimated using a point dipole model and eq. [1]. The question arose of the magnitude of the dipole and of where and in what direction to place it. One could use the experimental dipole moment of the molecule and place it on the midpoint of the line connecting the substituent to the midpoint of the C=C double bond, as has been suggested by some microwave studies (16). Or one could place it somewhere along the C—O or C—Cl bond and pointing along it.

We decided, however, to use a group moment and to place it on the Cl or O atom in the direction of the =C—X bond.* The magnitude of the group moment can be taken from the tables of Smyth (17). Goldstein *et al.* (18) had considerable success in correlating the chemical shifts of protons in substituted uracils using a group dipole moment and Musher (19) later showed that these correlations lead to reasonable values of a in eq. [1]. Values of the group dipole are given in Table I.

Another question concerns the values of the coefficients a and b in eq. [1]. Musher (9) quotes theoretical and experimental values ranging from -2 to -3.4×10^{-12} electrostatic units (e.s.u.) for a and suggests 7.38×10^{-19} e.s.u. for b, while Buckingham (15) estimated 1×10^{-18} e.s.u. for b. In Table I we have tabulated the values obtained for $\Delta\sigma_E$ using $a = -2 \times 10^{-12}$ and $b = 1 \times 10^{-18}$, as suggested originally by Buckingham (15); as well, $\Delta\sigma_E$ values using $a = -3.0 \times 10^{-12}$ and $b = 7.4 \times 10^{-19}$. It seems to us that these values of a and b give a reasonable estimate of the range of $\Delta\sigma_E$ values.

It must be remembered that the dipole model is a "long-range" model and that errors as large as about 50% may be expected in the calculations of $\Delta\sigma_E$ for protons on the α-carbon. For protons on the β-carbon the error should be considerably less.

3. Effect of the Magnetic Anisotropy of the C—O or C—Cl Bonds

The polar substituents are considered to be magnetically anisotropic. In the absence of a knowledge of the magnitude of this *neighbor anisotropy effect*, we assume (10) that the Cl or O susceptibility is axially symmetric about the C—Cl or C—O bond direction; and that, therefore, the neighbor anisotropy effect can be calculated by a point dipole approximation as

$$\Delta\sigma_M = \tfrac{1}{3}\Delta\chi(1-3\cos^2\theta)/|\boldsymbol{R}|^3, \qquad [2]$$

where $\boldsymbol{R}$ is the vector between the dipole and the proton, θ is the angle which $\boldsymbol{R}$ makes with the C—X bond, and $\Delta\chi = \chi_\parallel - \chi_\perp$. However, $\Delta\chi$ is unknown and must be different for each molecule, but it appears that in our compounds $\Delta\chi$ is such that a high-field shift will result for the α-protons (10, 20).

It must be decided where to place the point dipole. For the chloroethylenes we have placed it on the chlorine as well as midway along the C—Cl bond and have calculated the geometrical factors in eq. [2] for the two cases. These factors are given in Table I.

For methyl vinyl ether, the conformation of the molecule is important since there are two C—O bonds giving rise to magnetic anisotropy effects. Owen and Sheppard (24) have shown that in the gas phase the planar *cis* conformation is more stable by 1150 ± 250 cal/mole than a (probably) nonplanar *trans* form. Because of the approximate nature of our estimates we have considered the two forms I and II only.

**Placing the dipole at the midpoint of the C—X bond leads to much larger effects at the α-protons, as would be expected.*

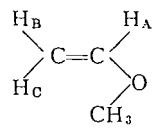
I
trans-planar



II
cis-planar

We assume that at 100 °C, where our measurements were carried out, it is sufficiently accurate to take the populations of isomers as 2/3 *cis* and 1/3 *trans*. The point dipole was placed at the oxygen as well as midway along the C—O bonds for the two conformations. The geometrical factors are given in Table I.

4. Geometry

For methyl vinyl ether we approximated bond angles about the double bond by 120°; the ∠ =C—O—CH_3 was taken as 105°; bond lengths: C=C 1.34 Å, C—O 1.4 Å, C—H 1.08 Å.

For vinyl chloride the more precise bond angle data in ref. 16 were used for the angles involving chlorine: ∠ Cl—C=C 122° 18′; ∠ Cl—C—H 113° 53′. All H—C=C angles were taken as 120°. These same values were taken for the dichloroethylenes. Bond lengths: C=C 1.32 Å, C—Cl 1.72 Å, C—H 1.08 Å.

EXPERIMENTAL

Samples were condensed into pyrex 5 mm outside diameter tubes on a vacuum line using liquid nitrogen. Each sample contained about 10% ethylene as a reference. The pressures at elevated temperatures were estimated on the basis of the ideal gas law and vapor pressure data. Temperatures and total pressures at which the spectra were taken ranged from 100 to 110 °C and 5 to 15 atm. The proton spectra were measured at 60 Mc.p.s. on a Varian DP60 spectrometer. The spectrum for *cis*-1,2-dichloroethylene was obtained by rapid passage techniques because the signal was very easily saturated. Signal-to-noise problems were not negligible for any compound but by repeated calibrations the reproducibility of the measured line positions was found to be ±0.4 c.p.s. for all except *gem*-dichloroethylene, for which it was ±1 c.p.s.

The spectra of the vinyl compounds were analyzed as ABC systems (14). The fit obtained was about ±0.3 c.p.s. or better and the shift values were estimated to be accurate to 0.3 c/s, which is sufficiently good for our purposes. The proton shifts relative to ethylene are given in Table II.

The proton shifts have been measured a number of times in solution. In Table II are given the shifts in solvents expected to be inert.

DISCUSSION

To predict the shifts we need values of $\Delta\chi$. For the C—C bond an average value* is about 5×10^{-30} cm^3 $molecule^{-1}$ (21). From Goldstein's estimate (20) of a 0.25 p.p.m. high-field shift due to magnetic anisotropy for proton A in vinyl chloride, we calculate $\Delta\chi = 4\text{–}6 \times 10^{-30}$ cm^3 $molecule^{-1}$ for the C—Cl bond. In the absence of a better value we will take $\Delta\chi = 5 \times 10^{-30}$ cm^3 $molecule^{-1}$ for both the C—O and C—Cl bonds. We realize that this value may be wrong by a factor of 2 or more.

1. Methyl Vinyl Ether

We calculate the various shifts in Table II. They represent the various combinations of the different estimates of $\Delta\sigma_E$ and $\Delta\sigma_M$ with 10 Δq. We cannot decide which calculated value is most reasonable but the simple average agrees reasonably well with experiment, when one considers the possible errors in the calculation of all three effects. It is interesting to note that the shift between protons B and C is predicted to be of the correct sign. Both $\Delta\sigma_E$ and $\Delta\sigma_M$ contribute to this shift. The largest error in our model would be expected for proton A, as is the case.

**Suggested values of $\Delta\chi$ range from about 2 to 8 $\times$ 10^{-30} cm^3 $molecule^{-1}$ (21–23).*

[g]Experimental proton shift in gas phase relative to internal ethylene.
[h]Proton shifts in solution. The methyl ether shifts were taken in 10% volume solution in tetramethylsilane (25). The chloroethylene shifts were taken in tetramethylsilane or cyclohexane and extrapolated to infinite dilution (20). We have converted the shifts to values relative to ethylene by taking −5.29 p.p.m. as the shift of ethylene relative to tetramethylsilane (20).

2. *Vinyl Chloride*

It is clear from Table I that agreement of experimental with the calculated Δq values is not very good. If we arbitrarily reduce Δq values in Table I to −0.015 and 0.02 the calculated values in Table II agree well with experiment for protons B and C. For proton A, however, the agreement is worse, perhaps indicating an underestimation of the electric field from the C—Cl dipole and (or) that the point dipole approximation is poor for such a near proton. Moving the dipole down along the C—Cl bond would improve the agreement at proton A but not at protons B and C. Decreasing Δq at carbon A to −0.03 improves agreement with experiment. In view of the uncertainty in Δq values, our model may be considered reasonably successful.

3. *The Dichloroethylenes*

Even if we reduce the Δq values to 0.01 in the *cis* and *trans* compounds, agreement with experiment is not too good, as seen in Table II. This is expected in view of the results for proton A in vinyl chloride. It is very hard to say where the error lies since none of the three contributions is small. If $\Delta\sigma_M$ were set equal to zero for these two molecules the calculated average shifts become −0.70 and −0.84 p.p.m. respectively for the *trans* and *cis* compounds. This is very much closer to the experimental values. If we take Δq = 0.04 for the *gem*-dichloroethylene as indicated by the values of Δq taken for vinyl chloride, the calculated shift in Table II is in reasonable agreement with experiment. We might attribute this to the fact that the protons lie relatively far from the chlorines.

CONCLUSIONS

In view of the fair agreement between calculated and experimental shifts for protons farther removed from the substituent and in view of the poorer agreement for protons

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

attached to the same carbon as the substituents, we suggest that point dipole models have to be used with caution. We suggest also that the available molecular orbital calculations for the chloroethylenes somewhat overestimate the delocalization of electrons into the double bond, and that the values we have used for Δq are more reasonable, although arbitrary. We do not suggest that our results and calculations can be taken as supporting the value of $\Delta\chi$ we used for the C—O or C—Cl bonds.

Comparison of Proton Shifts in Gaseous Phase and in Solution

In the last column of Table II the proton shifts in the inert solvents, tetramethylsilane or cyclohexane, are presented. The differences between these and the gaseous shifts are not large in general. However, they are large enough to influence the consideration of small corrections like magnetic anisotropy effects appreciably in some cases. One large difference is the methyl proton shift in the methyl vinyl ether. The reason for the 0.36 p.p.m. shift to low field in the gas phase is not clear, but it may arise from a difference in conformation of the ether in the gas phase and in solvents. Owen and Sheppard (24) found that the stability of the planar *cis* form relative to the *trans* form decreased in polar solvents. In the planar *cis* form the CH_3 protons will be closer to the ethylenic double bond and may experience a greater low-field shift due to its anisotropy than in the *trans* form. Such an effect would explain the low-field shift in the gas phase, where a greater proportion of the molecules have the *cis* conformation.

ACKNOWLEDGMENTS

We are grateful to a referee for suggesting the additivity of the three effects we considered. We thank the National Research Council for financial assistance.

THE KINETICS OF THE INHIBITED AUTOXIDATION OF TETRALIN[1]

J. A. HOWARD AND K. U. INGOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received May 22, 1964

ABSTRACT

The kinetics of the inhibition of the autoxidation of tetralin by 2,6-di-*t*-butyl-4-methylphenol, phenol, and 4-methoxyphenol have been investigated at 65 °C. The highly hindered 2,6-di-*t*-butyl-4-methylphenol follows simple first order kinetics and exhibits a normal deuterium isotope effect ($k_H/k_D = 10$). The kinetics with phenol are complicated by the fact that the phenoxy radical can abstract a hydrogen atom from both tetralin and its hydroperoxide. This leads to oxidation rates which are inversely proportional to the square root of the phenol concentration. The deuterium isotope effect has about the value to be expected in view of this square root relation. The kinetics with 4-methoxyphenol result from chain transfer and from chain termination by the coupling of 4-methoxyphenoxy radicals. The isotope effect varies between zero and a value that approaches the upper limit of about 10 at low inhibitor concentrations.

INTRODUCTION

The inhibition of the autoxidation of styrene by phenols has been described in considerable detail in a recent series of papers from this laboratory (1). The overall process can be represented by the following simplified reaction scheme:

[1] $$I_2 \rightarrow 2I\cdot$$

[2] $$R\cdot(I\cdot) + O_2 \rightarrow RO_2\cdot$$

[3] $$RO_2\cdot + RH \rightarrow ROOR\cdot H$$

[5] $$RO_2\cdot + RO_2\cdot \rightarrow \text{inactive products}$$

[6] $$RO_2\cdot + AH \rightarrow ROOH + A\cdot$$

[7] $$RO_2\cdot + A\cdot \rightarrow \text{inactive products.}$$

I_2 represents α,α'-azo-bis-isobutyronitrile (AIBN) which was used to initiate the oxidations. RH represents the styrene and AH the phenolic inhibitor. The radical R· in reaction [2] represents the poly(peroxy-styryl) radical. Our experimental conditions were such that chain termination occurred predominantly by reaction [7], so that the bimolecular self-termination reaction could be ignored. Under these conditions, the theoretical rate of oxidation of the styrene is given by

[I] $$P = \rho - (2e - 1)k_1[I_2] = \frac{ek_1k_3[RH][I_2]}{k_6[AH]},$$

where ρ is the measured inhibited rate and e is the efficiency with which the AIBN initiates reaction chains. The correction factor $(2e - 1)k_1[I_2]$ allows for oxygen absorption and nitrogen evolution by the AIBN. This equation describes the kinetics of the inhibition process with a variety of phenols at low concentrations where self-association of the phenol by hydrogen bonding and hydrogen bonding between the phenol and the initiator were unimportant.

These results in styrene differ in two important respects from the results reported by several other workers using basically the same technique but employing different hydrocarbon substrates. Firstly, a deuterium isotope effect $(k_6)_H/(k_6)_D \simeq 10.6$ at 65 °C was

[1]*Issued as N.R.C. No. 8097.*

obtained in styrene on deuterating the phenolic hydrogen of phenol, 4-*t*-amylphenol, 2,6-di-*t*-butylphenol, and 2,6-di-*t*-butyl-4-methylphenol (1). In contrast, previous workers did not observe an isotope effect in the N-methylaniline and diphenylamine inhibited oxidation of cumene and tetralin (2, 3) nor in the 2,6-di-*t*-butyl-4-methylphenol inhibited oxidation of 9,10-dihydroanthracene (4). The absence of an isotope effect with diphenylamine is reportedly not due to the loss of deuterium from the inhibitor by exchange since the addition of heavy water has no effect on the reaction rate (5).

Secondly, the simple kinetics which apply to the inhibition of the autoxidation of styrene by phenols are by no means universally obeyed.* Failure to follow these kinetics will occur when the self-termination process (reaction [5]) is not completely suppressed by the inhibitor (1). However, eq. [I] frequently fails to account for the kinetics even under conditions where reaction [5] can be neglected. Thus, Hammond *et al.* (3) have reported that the rate of the phenol and N-methylaniline inhibited oxidation of tetralin in chlorobenzene can be represented by

$$[II] \qquad P \propto \frac{[I_2]^{1/2}}{[AH]^{1/2}}.$$

Similar kinetics have also been found for the diphenylamine inhibited oxidation of cumene (9). Hammond *et al.* suggested that these kinetics resulted from the reversible formation of a peroxy radical – inhibitor complex, followed by decomposition of the complex by reaction with a second peroxy radical.

$$[6a] \qquad RO_2\cdot + AH \rightleftarrows (RO_2\cdot AH)$$

$$[7a] \qquad RO_2\cdot + (RO_2\cdot AH) \rightarrow \text{inactive products.}$$

Direct attempts to establish the existence of such complexes by electron spin resonance have been unsuccessful in themselves (9, 10), but they have led to three independent reinvestigations of the kinetics of these systems.† Two of these investigations provide simple alternative explanations for eq. [II].

Firstly, Thomas (11) has shown that cumene hydroperoxide increases the rate of the phenol-inhibited oxidation of cumene, the increase in rate being proportional to the square root of the initial peroxide concentration. This result is in contrast to a previous report that cumene hydroperoxide reduced the rate (5), and it implies that reaction [6] is reversible, i.e.,

$$[-6] \qquad A\cdot + ROOH \rightarrow AH + RO_2\cdot.$$

Hence,

$$[III] \qquad P = \frac{ek_1k_3[RH][I_2]}{2k_6[AH]}\left(1 + \left\{1 + \frac{4k_6k_{-6}[AH][ROOH]}{ek_1k_7[I_2]}\right\}^{1/2}\right),$$

which for large [ROOH] has the same form as eq. [II], but which calls for an inverse first order dependence of P on [AH] at zero initial hydroperoxide concentration. The fact that this was not observed was attributed to the hydroperoxide formed during the determination of the initial rate, but it can also be explained by chain transfer to the substrate (see below).

**Although previous workers have shown that these kinetics apply to the inhibition of the oxidation of ethyl linoleate by hydroquinone and other very active phenols (6) and to the inhibition of the oxidation of 9,10-dihydroanthracene by 2,6-di-t-butyl-4-methylphenol and 2,4,6-tri-t-butylphenol (7) and by N-phenyl-α- and N-phenyl-β-naphthylamine (8).*

†Incidentally, the effect of inert solvents on the rates of hydrocarbon autoxidation indicates that peroxy radicals do not complex very readily with aromatic hydrocarbons (1). This tends to argue against the formation of complexes by reaction [6a] but does not specifically preclude such an inhibition process.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Secondly, Mahoney and Ferris (12) showed that the rate of the phenol inhibited oxidation of tetralin and of 9,10-dihydroanthracene was 1.5 order with respect to hydrocarbon. This was explained by including the chain transfer reaction,

[8] $$A\cdot + RH \rightarrow AH + R\cdot,$$

instead of reaction [−6] in the kinetic analysis. With the assumptions (which are not necessarily justified) that $k_3[RH] \gg k_6[AH]$ and $k_8[RH] \gg k_7[RO_2\cdot]$, the following simplified expression was obtained.

[IV] $$P = k_3\left(\frac{ek_1k_8}{k_6k_7}\right)^{1/2}\frac{[RH]^{3/2}[I_2]^{1/2}}{[AH]^{1/2}}.$$

Another similar equation with $P \propto [RH]^{3/2}[I_2]^{1/2}[AH]^{-1/2}$ has been recently proposed by Lloyd and Lange (13). Their equation was derived as a limiting case for the condition that the phenol reacted solely with the radicals derived from the initiator (i.e., I· radicals, which were suggested to be 2-cyano-2-propoxy radicals)* with chain termination by reaction [5]. Because of the rapidity with which 2-cyano-2-propyl radicals react with oxygen to give the corresponding *peroxy* radicals,† it seems extremely unlikely that the low concentrations of phenol used in inhibition studies can seriously compete with oxygen for the propyl radicals.

By including both reactions [−6] and [8] in the kinetic analysis the following expression is obtained,

[V] $$P = \frac{ek_1k_3[RH][I_2]\alpha}{2k_6[AH]} + \frac{ek_1k_6k_8[RH][I_2][AH]\alpha}{2k_6[AH](k_{-6}[ROOH] + k_8[RH]) + ek_1k_7[I_2]\alpha},$$

where

$$\alpha = 1 + \left(1 + \frac{4k_6[AH](k_{-6}[ROOH] + k_8[RH])}{ek_1k_7[I_2]}\right)^{1/2}.$$

This equation would account for the dependence of P on $[AH]^{1/2}$ reported by Thomas (11) at zero initial hydroperoxide concentration.

Equation [IV] had been derived previously by Waters and Wickam-Jones (16) as a part of their broad theoretical treatment of inhibited oxidations. These authors point out that an inhibitor which undergoes a chain transfer reaction with the substrate will persist in a reaction medium for a longer time and may not reduce the rate to as great an extent as an equal concentration of an inhibitor which does not undergo chain transfer. When reactions [−6] or [8] are of any importance AH should be called a retarder rather than an inhibitor.

Equation [IV] had also been derived in a somewhat different form by Bickel and Kooyman (7), who showed that it accounted qualitatively for the inhibition of the oxidation of 9,10-dihydroanthracene by 2,4-di-*t*-butyl-6-methylphenol, 2,6-dimethyl-4-*t*-butylphenol (7), and N-methylaniline and aniline (8). These workers also tentatively identified the reaction,

[9] $$A\cdot + A\cdot \rightarrow A_2,$$

as the sole chain termination process with 4-*t*-butylphenol and 2-*t*-butyl-4-methylphenol

The existence of significant amounts of the propoxy radical in these systems, which contain a readily oxidizable substrate, would seem highly improbable.

†*This conclusion is drawn from the identification of 1-methyl-1-(2-cyano-2-propylperoxy)-3,5-di-t-butyl-2,5-cyclohexadienone-4 as the main product produced from 2,6-di-t-butyl-4-methylphenol by the decomposition of AIBN in the presence of oxygen (14, 15).*

(7). With this chain-terminating process and with chain transfer by reaction [8] the correct expression for the rate is

$$[VI] \qquad P = \frac{2ek_1k_3[RH][I_2]}{k_6[AH]}\left(1 + \frac{k_8[RH]}{2(ek_1k_9[I_2])^{1/2}}\right) + k_8[RH]\left(\frac{ek_1[I_2]}{k_9}\right)^{1/2}.$$

In the absence of chain transfer (i.e., $k_8 = 0$) this expression simplifies to its first term. It is therefore not possible to distinguish by means of rate measurements between termination by reaction [7] and [9] unless chain transfer is important. The distinction can, however, be made in the absence of chain transfer from the length of the induction period at low inhibitor concentrations.

A situation that probably occurs fairly commonly and which demonstrates the complexity of the kinetic expressions which are derived from quite simple elementary reactions arises when chain transfer by reaction [8] and chain termination by reactions [7] and [9] all take place. Equation [IV] is obtained if $k_7[RO_2\cdot] \gg 2k_9[A\cdot]$. The opposite condition that $k_7[RO_2\cdot] \ll 2k_9[A\cdot]$ leads to

$$[VII] \qquad P = k_3[RH][RO_2\cdot] + \frac{k_8[RH]}{4k_9}\left(4(ek_1k_9[I_2])^{1/2} - k_7[RO_2\cdot]\right),$$

where

$$[RO_2\cdot] = \frac{8ek_1k_9[I_2] + 4k_8[RH](ek_1k_9[I_2])^{1/2}}{4k_6k_9[AH] + k_7k_8[RH] + 4k_7(ek_1k_9[I_2])^{1/2}}.$$

Even more complicated expressions arise when additional elementary reactions are introduced into the kinetic scheme (see, for example, refs. 16, 17).

It is clear from the foregoing discussion that nonintegral and variable orders in [RH], [I_2], and [AH] will frequently be encountered in inhibited oxidation studies and that eq. [I] describes a highly idealized system. Because of the considerable differences between our data for phenolic inhibitors in styrene and much of the published literature, we decided to extend our study to a substrate containing a readily abstractable hydrogen atom. Tetralin was chosen as the substrate since it is readily oxidized and has been the substrate in many other inhibition studies. Three typical phenolic inhibitors were examined. (1) 2,6-Di-*t*-butyl-4-methylphenol as a representative highly hindered phenol; (2) phenol itself, in order to investigate the various theories as to the origin of eq. [II]; (3) 4-methoxyphenol as a representative very efficient but unhindered inhibitor.

EXPERIMENTAL

Fisher tetralin was purified by the usual procedure which involved washing with sulphuric acid and distillation. It was stored in the dark under nitrogen and the required amount was always passed through a 3 ft column of fresh chromatographic alumina immediately before each run to remove all traces of tetralin hydroperoxide. Samples as large as 150 ml were used for the very slow reactions. The reagents were preheated to 65 °C (the temperature at which all the present experiments were performed) before the addition of the AIBN initiator.

The rates of inhibited oxidations with 2,6-di-*t*-butyl-4-methylphenol, phenol, and 4-methoxyphenol are all independent of the oxygen pressure in the range 300–750 mm.

RESULTS AND DISCUSSION

The inhibition by 2,6-di-*t*-butyl-4-methylphenol (BMP) of the AIBN-initiated autoxidation of tetralin is accurately described by eq. [I]. That is, the inhibited rate is directly proportional to the tetralin concentration* and to the AIBN concentration and is inversely

**At concentrations below 3.0 mole/l upon further dilution with chlorobenzene or o-dichlorobenzene.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

proportional to the BMP concentration. If we take $e = 0.60$ and $k_1 = 1.8 \times 10^{-5}$ s^{-1} at 65 °C, then

$$k_3/k_6 = 6.66 \times 10^{-4}.$$

Therefore, if we take $k_3 = 13.6$ l/mole s (18), then $k_6 = 2.0 \times 10^4$ l/mole s. This value can be compared with the redetermined k_6 value of 2.7×10^4 l/mole s (18) for the reaction between styryl peroxy radicals and BMP at 65 °C. The fairly close agreement between the two values indicates that the rate of reaction [6] with a given phenol is, to a first approximation, independent of the nature of the peroxy radical.

The oxygen absorption curves show no evidence of autocatalysis, i.e., oxygen uptake is linear with time until a significant fraction of the initiator or BMP is consumed. The rate is almost unaffected by added hydroperoxide (see Fig. 1), which suggests that reaction [−6] is very slow with a hindered phenoxy radical (11, 19).

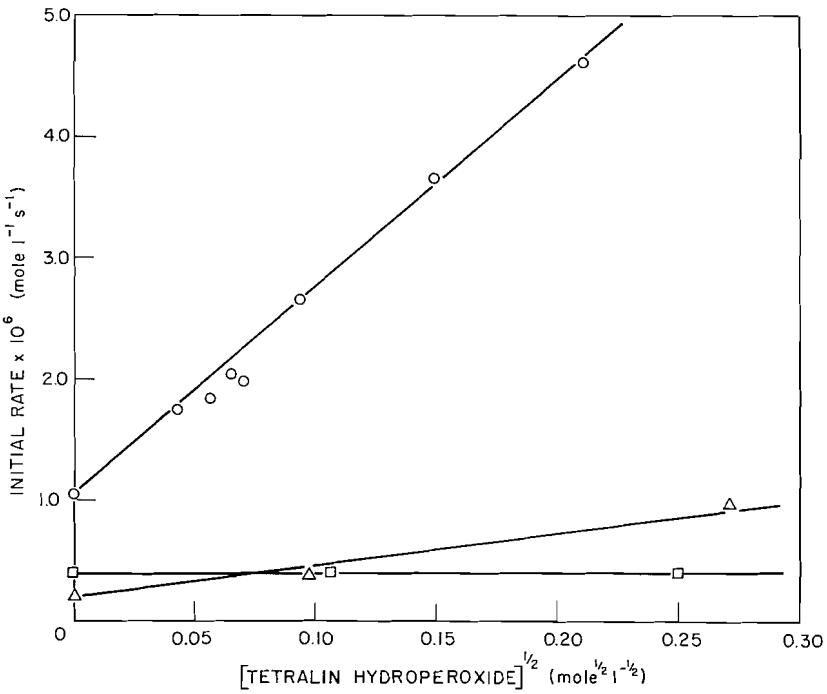

FIG. 1. The variation of the initial rate with the square root of the added tetralin hydroperoxide concentration. ○ Phenol (4.92×10^{-3} mole/l), AIBN (1.23×10^{-3} mole/l); □ BMP (4.98×10^{-5} mole/l), AIBN (4.92×10^{-4} mole/l); △ 4-methoxyphenol (1.73×10^{-4} mole/l), AIBN (9.76×10^{-4} mole/l).

The deuterium isotope effect in reaction [6] was measured by the technique we have previously employed in which the rates of inhibited oxidations in the presence of light and heavy water are compared (1). With BMP in tetralin the isotope effect was 9.7 at 65 °C, i.e., $(k_6)_H/(k_6)_D = 9.7$. This value is in good agreement with the value of 10.6 obtained previously with this inhibitor in styrene at 65 °C (1).

The oxygen absorption curves with phenol as the inhibitor show significant autocatalysis after the absorption of as little as 1×10^{-4} mole $[O_2]$ per liter of tetralin. The hydroperoxide formed in the oxidation is responsible for this autocatalysis since the same rate is obtained when the hydroperoxide is formed *in situ* during an oxidation as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

when the same amount of hydroperoxide is added at the start of the reaction.* To obtain rates which are not affected by hydroperoxide it is necessary to work with large volumes of very pure tetralin and to measure only the initial rates. Figure 1 shows that the increase in the initial rate is proportional to the square root of the initial hydroperoxide concentration, a result which is the same as that reported by Thomas for the phenol-inhibited oxidation of cumene (11). Reaction [−6] is probably mainly responsible for this increase but hydrogen bonding between the phenol and the hydroperoxide may also contribute to the rate enhancement.

Figure 2 shows that, at a given phenol concentration, the rate is proportional to the square root of the initiator concentration. This relation is used in Fig. 3 to show that the rate is inversely proportional to the square root of the phenol concentration, provided the phenol concentration is below about 5×10^{-3} mole/l. That is, these two figures reconfirm the kinetics originally reported by Hammond *et al.* (3). At concentrations above 5×10^{-3} mole/l the order in [phenol] decreases. This is not entirely unexpected as the phenol will hydrogen bond with itself and with the initiator at these high concentrations, so that its activity decreases (1). Certain other factors which may also contribute to the decrease in kinetic order at high phenol concentrations are mentioned below.

In a recent paper from this laboratory we showed that apparently inert solvents can have a very pronounced influence on the rates of both uninhibited and inhibited oxidations (1). Their effect on inhibited oxidations seems to be related to the strength of the hydrogen bond between the inhibitor and the solvent, i.e., as the hydrogen bond strength increases the activity of the inhibitor decreases. This factor means that great care must be exercised in interpreting inhibited rates in solvents of varying composition such as must always be involved in any dilution experiments aimed at determining the kinetic order in [RH]. For this reason, two solvents were used in the dilution experiments with phenol as the inhibitor. One solvent, chlorobenzene, appears to depress the inhibited rate compared with its value in pure tetralin and the other, nitromethane, appears to enhance the rate (see Fig. 4). To minimize the effect of the changing solvent composition, the kinetic order in [RH] was determined from measurements at tetralin concentrations of 3.67 mole/l (50%) and less. In the absence of any initial hydroperoxide the measured orders in [RH] are 1.3 in chlorobenzene and 1.5 in nitromethane ([AH] = 2×10^{-3} mole/l, $[I_2] = 5.0 \times 10^{-4}$ mole/l). In the presence of 1×10^{-2} mole/l $[ROOH]_0$ the measured orders decreased to 1.0_4 and 1.0_8 respectively. The fact that the order is 1.5 in only one case tends to argue against the importance of reaction [8] as a general cause of the observed dependence of P on $[I_2]^{1/2}/[AH]^{1/2}$. Moreover, even if reaction [8] is of primary importance in the complete absence of hydroperoxide it is rapidly suppressed by the hydroperoxide formed in the reaction. That is, the lower kinetic orders observed in the presence of 10^{-2} mole/l $[ROOH]_0$ can be readily explained if reaction [−6] is much faster than reaction [8], i.e., this added peroxide reduces the phenoxy radical concentration sufficiently to reduce the rate of reaction [8] by a very large amount. Since it is impossible to be certain that any rate is completely uninfluenced by hydroperoxide, it is possible that the kinetic order of 1.3 in chlorobenzene in the *apparent* absence of hydroperoxide has been reduced from a somewhat higher value by traces of hydroperoxide.

On the whole, the phenol inhibition data can probably be best represented by eq. [V]. However, it must be remembered that reaction [8], although probably quite important in determining the kinetic orders for [RH], $[I_2]$, and [AH] in the absence of hydroperoxide, is

**Preliminary results with N-methylaniline suggest that its behavior in tetralin is very similar to the behavior of phenol.*

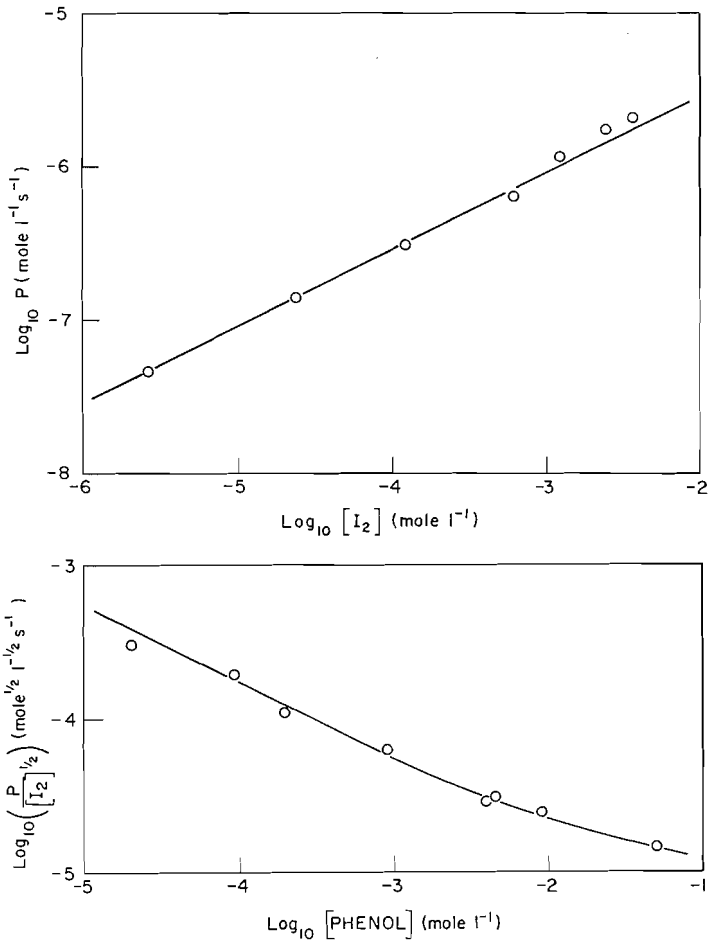

FIG. 2. Rate of oxidation of tetralin inhibited by 4.92×10^{-3} mole/l [phenol] as a function of AIBN concentration. The line in this figure has a slope of 0.5.

FIG. 3. $\text{Log}_{10}\ (P/[I_2]^{1/2})$ as a function of the phenol concentration. The linear region has a slope of 0.5.

rapidly suppressed by quite small concentrations of hydroperoxide and the data can then be represented by eq. [III]. Both equations predict that the rate will be proportional to $[I_2]^{1/2}/[AH]^{1/2}$ only over a comparatively small range of concentrations. At low [AH] or large $[I_2]$ both equations simplify to $P \propto [RH][I_2]/[AH]$ (i.e., eq. [I]). Such kinetics were not observed, but these particular limiting conditions were purposely avoided since self-termination between peroxy radicals (reaction [5]) also becomes important in this region. Equation [V] (but not eq. [III]) predicts that the rate will become proportional to $[RH]^{1/2}[I_2]^{1/2}[AH]^{1/2}$ as [AH] becomes very large. That is, this equation predicts that there will be a minimum in a plot of log P or of log $(P/[I_2]^{1/2})$ against log [AH], this minimum being followed by an increase in rate as [AH] is further increased. The slight curvature in Fig. 3 at high phenol concentrations may perhaps arise partly from this factor.

The deuterium isotope effect for the phenol-inhibited oxidation was measured at an AIBN concentration of 1.97×10^{-5} mole/l and a phenol concentration of 4.92×10^{-3} mole/l. In the absence of hydroperoxide the rate is 1.3×10^{-7} mole/l s (see Fig. 2). In

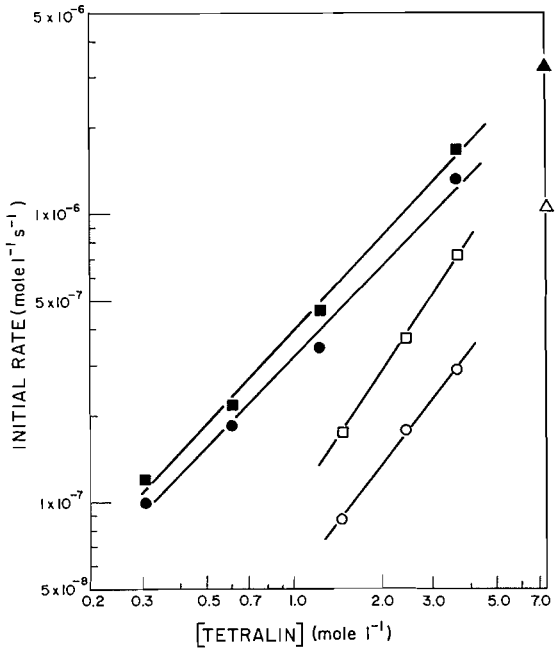

FIG. 4. The rate of oxidation of tetralin inhibited by 2.0×10^{-3} mole/l [phenol] and initiated by 5.0×10^{-4} mole/l [AIBN] as a function of the tetralin concentration. In the initial absence of hydroperoxide; ○ chlorobenzene as diluent, □ nitromethane as diluent, △ pure tetralin. In presence of 1×10^{-2} mole/l [tetralin hydroperoxide]; ● chlorobenzene as diluent, ■ nitromethane as diluent, ▲ pure tetralin.

the presence of H_2O and D_2O the rates were 2.2 and 6.8 $\times 10^{-7}$ mole/l s, respectively,* giving a directly measured isotope effect of 3.1. However, since the rate is proportional to $[AH]^{-1/2}$, the true isotope effect for the inhibition reaction is given by

$$(k_6)_H/(k_6)_D = (3.1)^2 = 9.6,$$

in excellent agreement with the value obtained with BMP.

The isotope effect was also measured under the same conditions of concentration but with the addition of 1×10^{-2} mole/l of hydroperoxide before the start of the reaction. Deuteration of the hydroperoxide would be expected to reduce the rate of reaction [−6]. This will tend to reduce the measured isotope effect since P will be decreased by a decrease in k_{-6} (see eq. [III]). In the absence of water the hydroperoxide increased the rate to 4.5×10^{-7} mole/l s. The addition of H_2O decreased the rate very slightly to 4.4×10^{-7} mole/l s† and the addition of D_2O raised the rate to only 7.2×10^{-7} mole/l s. These rates give an apparent isotope effect of 1.64, which is significantly less than the value in the absence of hydroperoxide.

4-Methoxyphenol appears to be a much more efficient inhibitor than phenol. The oxygen absorption curves show no evidence of autocatalysis and the comparative unimportance of reaction [−6] is further emphasized in Fig. 1. There is a very unusual relation between

*The higher rate in the presence of water is probably due to the loss of some of the added phenol into the aqueous phase. In the calculation of the isotope effect it is assumed that such physical effects of light and heavy water will be equal.

†The small effect of H_2O may be due to a compensation between the expected increase in rate produced by the loss of phenol into the aqueous phase and a decrease in rate resulting from a decrease in the rate of chain transfer because of hydrogen bonding between the hydroperoxide and H_2O.

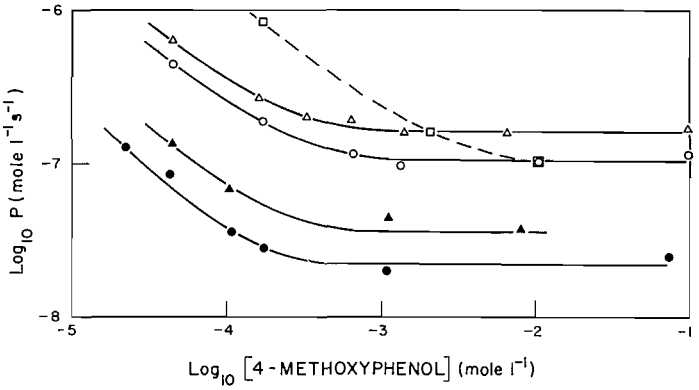

FIG. 5. The rate of oxidation of tetralin as a function of the 4-methoxyphenol concentration. △ 7.35 mole/l [RH], 1.95×10^{-3} mole/l [AIBN]; ○ 7.35 mole/l [RH], 9.76×10^{-4} mole/l [AIBN]; □ 7.35 mole/l [RH], 9.76×10^{-4} mole/l [AIBN] inhibited by 4-methoxyphenol O-*D*; ▲ 1.22 mole/l [RH] in chlorobenzene, 1.95×10^{-3} mole/l [AIBN]; ● 1.22 mole/l [RH] in chlorobenzene, 9.76×10^{-4} mole/l [AIBN].

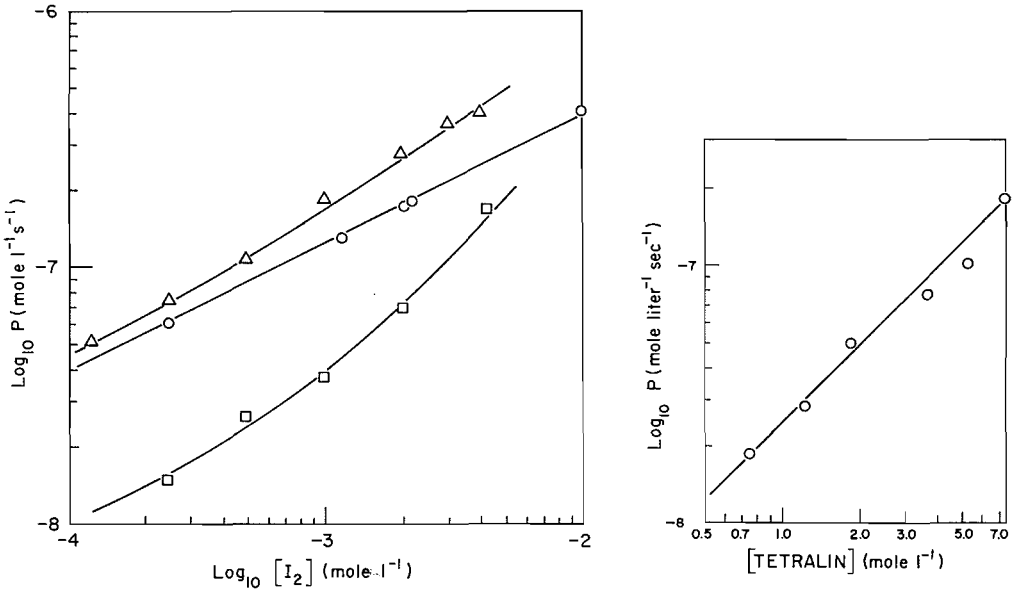

FIG. 6. The rate of oxidation of tetralin as a function of the AIBN concentration. ○ 7.35 mole/l [RH], 6.68×10^{-3} mole/l [4-methoxyphenol], this line has a slope of 0.5; △ 7.35 mole/l [RH], 1.66×10^{-4} mole/l [4-methoxyphenol]; □ 1.22 mole/l [RH] in chlorobenzene, 1.06×10^{-4} mole/l [4-methoxyphenol].

FIG. 7. Rate of oxidation of tetralin in chlorobenzene at an AIBN concentration of 9.76×10^{-4} mole/l and a 4-methoxyphenol concentration of 1.73×10^{-4} mole/l. The line has a slope of 1.0.

the rate and the 4-methoxyphenol concentration which is shown in Fig. 5. The data for this phenol can be most readily accounted for on the basis of eq. [VI]. At high phenol concentrations this equation predicts that only the last term will be important and therefore the rate will be independent of [AH] but will be proportional to $[RH][I_2]^{1/2}$. The limiting rate at high 4-methoxyphenol concentrations does indeed follow these predictions (see Figs. 5 and 6). At lower inhibitor concentrations the rate retains its direct proportionality to [RH] (Figs. 5 and 7) but the order in $[I_2]$ increases from 0.5 towards 1.0

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

as the initiator concentration is increased (see Fig. 6). Furthermore, at a given [AH], the order in $[I_2]$ increases as [RH] is reduced (Fig. 6). The order in [AH] increases from 0 to a value which definitely appears to exceed 0.5 and therefore, presumably, approaches 1.0 as the inhibitor concentration is reduced. All these changes in order are in agreement with the predictions of eq. [VI], which suggests that reaction[7] is relatively unimportant with 4-methoxyphenol.* Incidentally, some of the deviation of the phenol-inhibited rates at high phenol concentrations (Fig. 3) might also be connected with this limiting rate effect.

The most interesting feature of this type of inhibition is that the deuterium isotope effect varies from zero in the limiting rate region to a much larger value, which probably approaches a limit of about 10 at very low 4-methoxyphenol concentrations (see Fig. 5).

In conclusion, the different inhibition kinetics exhibited by the three phenols studied in this work provide an obvious explanation for the well-known empirical observation that the relative efficiencies of different phenols vary markedly from substrate to substrate.† The measured oxidation rates with different inhibitors can only be used to calculate relative k_6 values under ideal conditions where eq. [I] applies. More generally, the measured oxidation rates under a standard set of conditions reflect the individual values of so many different rate constants that comparisons of inhibitor efficiencies are almost meaningless when applied outside the actual substrate employed.

**There appears to be a very slight increase in the rate at very high 4-methoxyphenol concentrations. This would suggest that there may perhaps be a very slight contribution from reaction [7], i.e., from a term similar to the second term in eq. [V].*

†A secondary cause of this variation which is related to the strength of the hydrogen bond between the phenol and the substrate has been discussed in a previous publication from this laboratory (1).

GAS–SOLID EXCHANGE STUDIES BY THE FLOW METHOD: Zn–ZnS AND Zn–ZnO REACTIONS

ALLAN J. MACKINNON, RONALD R. MARTIN, AND E. A. SECCO
Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia
Received May 4, 1964

ABSTRACT

The initial exchange of zinc vapor with polycrystalline zinc oxide and zinc sulphide has been studied by a flow method under different conditions of zinc vapor flow rates and temperature. The exchange rate was found to be independent of flow rate. Kinetic and mechanism interpretations of these results along with existing data from exchange studies by the static method are discussed.

INTRODUCTION

Recent studies (1, 2) on gas–solid exchange reactions by the static method have revealed two processes involved in the exchange reaction. The rapid initial rate interpreted as a simple exchange process was followed by a slower rate which appeared to be a diffusion-controlled process. The initial rate was not restricted to the surface but persisted to ca. one-half the particle radius, and the depth of penetration increased with temperature. The question now arises as to the exact nature of this initial exchange process. That is, the exchange rate may be determined by an adsorption or desorption step, by a direct exchange step, or by some partial combination of any two of these steps. The present investigation was undertaken to elucidate the initial exchange process in the Zn–ZnS and Zn–ZnO systems by studying their exchange rates by the flow method.

EXPERIMENTAL PROCEDURE

The polycrystalline ZnS and ZnO used in this work were from the sources previously reported (1, 2). The method of preparation of the zinc metal carrying the radioactive component, ^{65}Zn, and the counting technique have already been described (1).

The exchange runs were carried out by a flow method with use of the reaction chamber shown in Fig. 1. For each run, about 50 mg of the solid oxide or sulphide was placed on a fritted quartz disc holder fitted with a 18/9 ground-quartz ball joint. The fritted disc had to be of coarse porosity grade to permit passage of the vapor. The ball joint was fitted into a 18/9 ground-quartz socket joint of the quartz flow reactor. A weighed amount of radiozinc was placed in the quartz bucket suspended about 5 cm above the fritted disc holder. After installation of the holder and bucket with their contents in the flow reactor, the reactor was connected by a 24/40 ground taper to an oxygen-free nitrogen supply. The nitrogen (Matheson Prepurified Grade with a stated impurity of 0.003% oxygen and metered through a Fischer and Porter flowmeter), was allowed to flush the chamber for 25–45 min at room temperature, followed by flushing at 150 °C for an additional 20–25 min at the requisite flow rates to ensure complete purging. After the flushing was completed, the tubular furnace, set on tracks, was raised mechanically to a predetermined height to enclose the reactor. The furance thermocouple tip was located at the site of the ground socket joint.

The stream of nitrogen transported the radiozinc vapor through the fritted disc carrying the solid. The vapor was condensed and collected in a trap at the reactor's exhaust.

After the solid had been annealed for a definite time interval at a constant nitrogen flow rate, the furnace was lowered and the nitrogen flow was continued until the reactor attained room temperature, ca. 20 min. The bucket and holder were withdrawn, weighed, and counted. The amount of radiozinc metal used was determined by the loss in weight from the bucket and by the residual activity: these two measurements checked within limits of their operation errors. The activity uptake by the solid in the holder was a measure of the exchange reaction.

The positive pressure of the nitrogen above the fritted-disc holder ensured a leak-proof fit at the ball-and-socket joint. Tests made with water and with fritted discs of fine porosity grade confirmed a leak-proof fit during flow experiments.

Blank runs, i.e. without the solid component, were carried out with radiozinc and nitrogen passing through the fritted disc to check the possibility of trapped ^{65}Zn in the disc pores. No activity uptake by the disc was discernible.

The temperature profile of the tubular resistance furnace was determined using a platinum vs. platinum–rhodium thermocouple (Leeds and Northrup) calibrated at the National Bureau of Standards, Washington, D.C. (test No. 147033).

RESULTS

Zn–ZnS Reaction

Figure 2 shows the reaction fraction as a function of time for 760 °C at the various nitrogen flow rates. The rate of exchange is independent of the flow rate within the limit

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

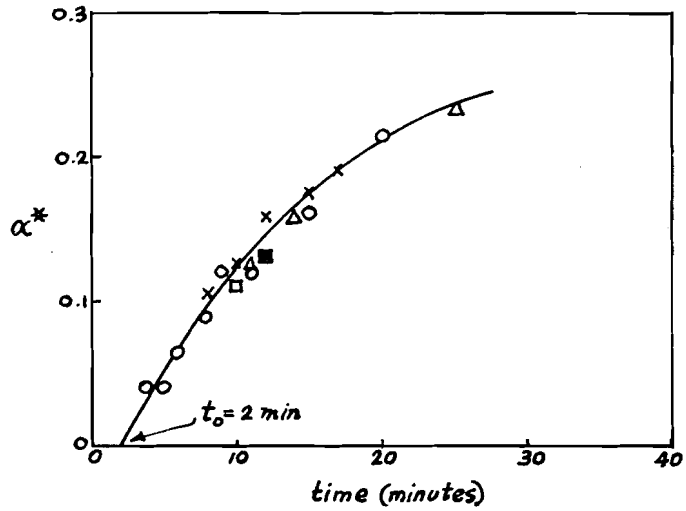

FIG. 2. Reaction fraction, α^*, vs. time for the Zn–ZnS reaction for △ 680, × 320, ○ 160, □ 80, and ■ 40 ml/min.

40–680 ml/min. The positive time intercept of 2 min is interpreted as the induction period for the evaporation of zinc metal.

The logarithms of the exchange rate constants are plotted against the reciprocals of the absolute temperature in Fig. 3. The exchange rate data are fitted to a first-order rate law with the Arrhenius expression given by

$$k_e = 1.7 \times 10^3 \exp(-30.5 \text{ kcal}/RT) \text{ s}^{-1}.$$

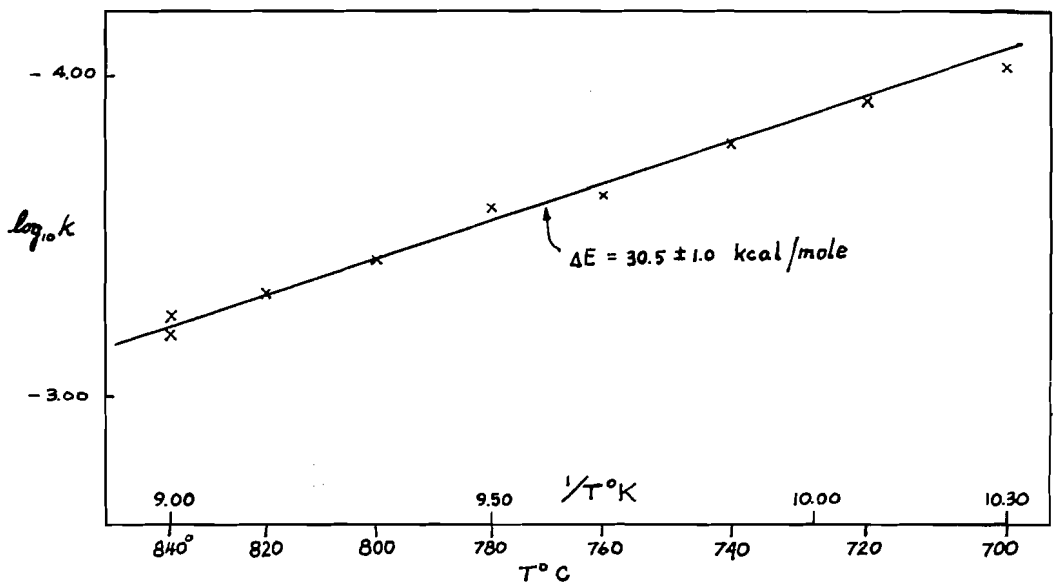

FIG. 3. Logarithm of exchange rate constant vs. reciprocal of absolute temperature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

It is evident that the rate constant obtained by the flow method is one-half the value obtained by the static method, i.e.

$$k_e \text{ (flow)} = \tfrac{1}{2} k_e \text{ (static)}.$$

Zn–ZnO Reaction

Figure 4 shows the reaction fraction as a function of time for 760 °C and 850 °C at a flow of 200 ml/min. The scatter of the exchange data in Fig. 4*a* is in striking contrast to

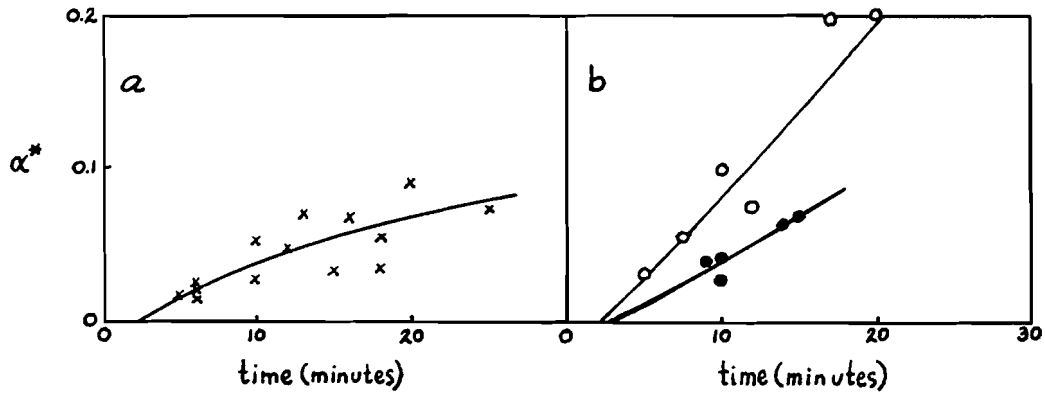

FIG. 4. Reaction fraction, α^*, vs. time for the Zn–ZnO reaction: (a) ZnO at 760 °C; (b) ZnO at 850 °C, ○ untreated, ● pretreated.

the high degree of reproducibility in the Zn–ZnS case. The more significant feature of Fig. 4*a* is the low reaction fraction, i.e. 0.07, as compared to that fraction, 0.60, observed in the static system at the same temperature. The constant value of ca. 0.07 corresponds very closely to the surface area of the oxide, 3.52 m^2/g, as determined by krypton adsorption measurements. The exchange data cannot be fitted to a first-order rate law with sufficient degree of confidence.

Figure 4*b* gives the exchange data at 850 °C for untreated oxide and for oxide pretreated in the flow reactor with inactive zinc vapor at the same temperature for 20 min at 200 ml/min nitrogen flow.

ANALYSIS OF DATA AND DISCUSSION

We consider the case of gas flowing through solid powder in the form of a porous wafer and assume that during the passage of a small increment of the gas the solid remains in a steady state. Let t_c be the time taken for the increment of gas to pass from the initial contact with the solid to a point at which the gas composition has changed from c_0 to c. Then, if the first-order kinetics obtain during the reaction,

$$[1] \qquad \frac{-dc}{dt} = kc.$$

If the constant term k is allowed to include parameters due to powder compactness and surface activity, eq. [1] may be integrated between the limits $t = 0$ and $t = t_c$, the "residence" time when the final composition is c_t, to yield

$$[2] \qquad \ln \frac{c_0}{c_t} = kt_c.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The rate equation for the uptake of radioactivity by a solid from the active vapor in a static system is given by

$$[3] \qquad \ln\left(1 - \frac{\alpha_t{}^s}{\alpha_\infty{}^s}\right) = -k_e t,$$

where k_e is the exchange rate constant. For a flow system with a fresh supply of vapor of specific activity $\alpha_0{}^g$ passing over the solid, the equilibrium specific activity of the solid, $\alpha_\infty{}^s$, will equal $\alpha_0{}^g$ so that eq. [3] reads,

$$[4] \qquad \ln\left(1 - \frac{\alpha_t{}^s}{\alpha_0{}^g}\right) = -k_e t,$$

which is the limiting case of the static system for the condition

$$n^g \gg n^s \text{ or } S = 0,$$

where

$$S = n^s/(n^s + n^g) \text{ and } \alpha_\infty{}^s = \alpha_0{}^g\,(1 - S);$$

α^g and α^s are activities of the gas and solid phases, while n^g and n^s are moles in the gas and solid phases respectively.

Replacing c_0/c_t by $1/(1 - \alpha^*)$, where α^* is the fraction of exchange $\alpha_t{}^s/\alpha_0{}^g$, we have

$$[5] \qquad k_e = \frac{2.303}{t_c} \log\,(1 - \alpha^*)\cdot$$

Theoretically, for a constant flow rate of vapor at a constant temperature, a plot of reaction fraction vs. the duration time of the experiment should be a plateau if direct exchange were the sole rate-determining step, since the flow rate determines the residence time. The longest residence time in these flow experiments was evaluated to be ca. 20 s, and for such a time interval the expected reaction fraction is ca. 1% as obtained from the static system. Furthermore, the exchange rate data were found to be independent of the gas flow rates.

In view of these facts and the zinc – zinc sulphide exchange data given in Fig. 2, we conclude that the direct exchange step is not the only step in the initial exchange process. The important step in the zinc – zinc sulphide exchange must be, therefore, the adsorption of zinc vapor on the sulphide surface. We visualize an adsorption–desorption equilibrium which precedes the actual exchange step of the type

$$Zn^*_{(g)} + ZnS_{(s)} \underset{k_1}{\overset{k_2}{\rightleftharpoons}} ZnS_{(s)} \ldots Zn^*_{(ads)} \xrightarrow{k_3} Zn^*S_{(s)} + Zn_{(g)}.$$

The observed exchange rate constant is then a product of an actual rate constant for the rate-determining process and the equilibrium constant of the preceding equilibrium. The difference in the exchange rate constant, i.e.

$$2k_e \text{ (flow)} = k_e \text{ (static)},$$

by the factor of 2 between the flow and static systems represents, therefore, the ratio of the adsorbed species $ZnS_{(s)} \ldots Zn^*_{(ads)}$ in the two systems.

The activation energy of 30.5 kcal as obtained from Fig. 3 is a composite quantity since it may include not only the true activation energy of the exchange reaction but also the heat of adsorption of zinc vapor.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The zinc – zinc oxide data from the flow system are in strong contrast to the exchange data obtained in the static system. The scatter of the exchange data indicates a sensitivity of the rate to the parameter suspected to be surface adsorption. The correspondence of the low exchange fraction with surface area does suggest a major role for adsorption in the exchange reaction. The reduction of the reaction fraction as a result of the pretreatment in zinc vapor at 850 °C, Fig. 4*b*, prior to exchange is consistent with the prominent role of the surface. Here again, the difference in the exchange rate constant, i.e.

$$10k_e \text{ (flow)} = k_e \text{ (static)},$$

by the factor of 10 represents the ratio of adsorbed species $ZnO_{(s)} \ldots Zn^*_{(ads)}$ in the two systems.

A very significant interpretation of these results is that the oxide and sulphide surfaces present adsorption sites of varying degrees of activity. The most active sites are occupied very readily, that is within the contact time of the flow method, whereas other sites require longer contact times which prevail in the static method. The fact that the exchange rate and adsorption was observed to be independent of the flow rates in the zinc – zinc sulphide militates against the above interpretation. However, if the adsorption sites show a discontinuous variation of adsorbing power, very strong and very weak, and if the flow conditions were varied within a particular band of activity, no effect on adsorption would be expected. We incline towards this discontinuous model for activity.

ADDENDUM: Since submitting the manuscript we tested our adsorption hypothesis by a fairly critical experiment. In addition to the contact time the dynamic method differs from the static method by the presence of the N_2 carrier gas. It was speculated that adsorbed N_2 can reduce the zinc adsorption and hence the exchange rate. Using the static method we injected sufficient N_2 to give 1 atm pressure at the exchange temperature. That is, the static study was followed in a manner similar to that previously described except that the solid was bathed in an ambient of zinc vapor and N_2 gas. The exchange results are given below.

	Static system		*Dynamic system*
Zn–ZnS reaction at 800 °C at constant time:			
	Zn, 39%	Zn + N_2, 41%	Zn + N_2, 20%
Zn–ZnO reaction at 760 °C at constant time:			
	Zn, 60%	Zn + N_2, 30%	Zn + N_2, 7%

We interpret these results as further support of our adsorption hypothesis.

ADSORPTIVE AND GAS CHROMATOGRAPHIC PROPERTIES OF VARIOUS CATIONIC FORMS OF ZEOLITE X[1]

H. W. HABGOOD
Fuels Branch, Research Council of Alberta, Edmonton, Alberta

Received June 1, 1964

ABSTRACT

Gas chromatographic retention volumes for O_2, N_2, CH_4, C_2H_6, C_3H_8, C_4H_{10}, C_2H_4, and C_3H_6 have been measured over a range of temperatures between 25 and 400 °C, on columns of the following ion-exchanged forms of zeolite X: Li^+, Na^+, K^+, Mg^{++}, Ca^{++}, Ba^{++}, and Ag^+. In addition, for AgX zeolite, full isotherms have been determined for O_2, N_2, C_2H_6, and C_2H_4; and for NaX zeolite, isotherms for C_2H_6 and C_2H_4. The gas chromatographic retention volumes agree well with the isotherms in the case of NaX but are significantly low for AgX, presumably as the result of at least a portion of the adsorption process being slow. The heats of adsorption on NaX agree well with literature values for O_2, N_2, CH_4, and C_2H_6 but are low for C_3H_8 and C_4H_{10}; further indication of slow processes and hence of a limitation of the g.c. technique. The observations can be correlated qualitatively in terms of the interplay of the following effects: (*a*) cationic field increases with decreasing ionic radius; (*b*) shielding of smaller cations is greater—at least in the six-membered oxygen-ring sites; (*c*) divalent cations, while having greater fields, are only half the number of monovalent cations and tend to be found in less exposed sites; and (*d*) the polarizing power of silver ion, which also occupies all types of exposed sites, is very strong. The most intense interactions were found with AgX; with ethylene a much stronger complex is formed than has been reported for any other silver compound. The significance of molecular quadrupole interactions on these heteroionic surfaces is shown by the much weaker cationic effects observed with O_2 (which has negligible quadrupole moment) than with nitrogen.

INTRODUCTION

Following the earlier measurements of Barrer and Sutherland (1) and of Barrer Bultitude, and Sutherland (2) on the adsorption of various gases and vapors by NaX zeolite (synthetic near-faujasite), the important contribution of the exchangeable cations to the sorption process has been demonstrated by the measurements of Barrer and Stuart (3) on the adsorption of argon and of nitrogen by the Li, Na, and K forms of zeolite X (and of argon by the Ca, Sr, and Ba forms of the zeolite). The measurements with argon showed that the polarizing power of the cation contributed substantially to the energy of adsorption, and a comparison between argon and nitrogen showed a strong contribution, increasing from K^+ to Li^+, due to the interaction of the nitrogen electric quadrupole moment with the field gradient. The importance of quadrupole interactions to account for the greater adsorption of nitrogen than of either oxygen or argon was first pointed out in detail by Drain (4) and has also been analyzed by Kington and Macleod (5). Such interactions, which depend on the intensity of the electric field gradient, are expected to be particularly intense on the zeolite surfaces where the cations occupy positions of an unusually low degree of screening yet immediately adjacent to the oxygen anions of the alumino-silicate framework. The maximum effects, moreover, should be found at low adsorbate concentrations and, although Barrer and Sutherland found relatively little concentration dependence for NaX, Barrer and Stuart found that the heats of adsorption of nitrogen on LiX increased markedly at lower coverages. Their measurements, however, did not explore the region of lowest sorbate concentrations and for the most part involved concentrations greater than one molecule per cavity.

Gas chromatography offers a very convenient technique for the rapid measurement of

[1]*Contribution No. 269 from the Research Council of Alberta. Presented in part to the Western Regional Meeting of the Chemical Institute of Canada, Regina, 1960.*

the limiting low-pressure adsorption behavior. Kiselev, Khrapova, and Shcherbakova (6) have determined gas chromatographically the heats of adsorption of the lower hydrocarbons on type 5A (i.e. CaA) zeolites. Eberly (7), also using gas chromatography, has examined the adsorptive properties of cationic forms of zeolite X towards *n*-hexane and benzene. In general, the trends in cationic effects that he observed were more complex than those found by Barrer and Stuart; e.g., while the heats of adsorption on NaX were lower than on LiX, they were also lower than on KX, indicating an interplay of two opposing tendencies. However, there is also the question of whether, particularly with larger molecules, kinetic effects might become important so that the gas chromatographic values are low as compared with the equilibrium measurements.

The present work includes gas chromatographic measurements for O_2, N_2, CH_4, C_2H_6, C_3H_8, C_4H_{10}, C_2H_4, and C_3H_6 on the following cationic forms of zeolite X: Li^+, Na^+, K^+, Mg^{++}, Ca^{++}, Ba^{++}, and Ag^+. While oxygen has a small but finite quadrupole moment and therefore is less satisfactory than argon for comparison with nitrogen to indicate quadrupole energies, the difference between the adsorption of oxygen and of argon appears to be small. These observations therefore may be considered as extending the measurements of Barrer and Stuart to limiting low-pressure conditions as well as to a greater range of cations. They complement the gas chromatographic studies of Eberly by covering a greater range of adsorbates.

For the silver form of the zeolite a number of complete isotherms are also reported.

EXPERIMENTAL

For the gas chromatographic measurements, commercial zeolite in pellet form was used.[2] This contains approximately 20% clay binder which was assumed to have negligible adsorptive properties. From the parent sodium form, various cationic forms were prepared by ion exchange using 5% solutions of LiCl, KCl, $MgCl_2$, $CaCl_2$, and $BaCl_2$ percolated at 90 °C through 5 or 10 g samples of crushed pellets, 28–48 mesh. Two different samples of AgX pellets were prepared: AgX I by successive treatments with five portions of 1% $AgNO_3$ solution in the dark at room temperature and AgX II by treatments with 2% $AgNO_3$ followed by 3 treatments with 15% $AgNO_3$ solution at 60° also in the dark. The samples were washed with water to remove all salts, and the last washings were adjusted to pH 9.5 with the appropriate hydroxide to minimize any hydrolysis. The degree of exchange was confirmed by analysis to be over 90% in all cases. Except for AgX I for which no determination was made, the sorptive capacities of the various samples after activation in vacuum at 450° as measured by nitrogen adsorption at liquid nitrogen temperatures are included in Table I. These values indicate that there was negligible degradation of the material during preparation except for the magnesium species, which has an unusually low capacity and might on this basis be assumed to have lost some 35% of its crystallinity. The variations among the other forms are roughly consistent with the expected changes in cation volume.

The gas chromatographic measurements were carried out as previously described (8) but using this time a glass column 5 mm I.D. by 25 cm long which contained roughly 3.7 g (dry weight) of zeolite. The gas sample volume was 0.14 ml and the pressure of the sample could be varied as desired. The usual gas flow rate was 50 ml/min and retention volumes could be reproduced within ±1 ml, although the absolute accuracy was probably poorer than this. The columns were activated by heating in flowing helium up to 450°. The temperature range covered by the measurements was room temperature to 400°.

Helium was used as carrier gas and the dead space was determined with hydrogen. At room temperature it was necessary to extrapolate from higher temperatures since hydrogen itself is significantly retained. Because hydrogen reacts with the silver zeolite, dead space values for this column were estimated from the values for the other columns.

As pointed out previously (8) the numerical value of the net retention volume in ml of carrier gas per g of column packing expressed at 0 °C and in terms of effective mean column pressure approaches the value of the initial slope of the adsorption isotherm expressed in ml (s.t.p.) g^{-1}, atm^{-1}. A derivation of this relation has recently been presented by Gale and Beebe (9). This net retention volume per g may, in conformity with recommended nomenclature (10), be designated by V_g. The fact that V_g, which is called the specific retention volume, was originally defined to refer to 1 g of liquid phase in gas–liquid chromatography should cause no confusion when reference is to the adsorbent solid in gas–solid chromatography. For convenience in comparing the various cationic forms, all V_g's are further expressed in terms of 1 g of the parent dehydrated

[2] *Molecular Sieve 13X, 1/16 in. pellets, Linde Division, Union Carbide Corp.*

sodium pellet form. The actual retention volumes per g of the exchanged zeolite may be calculated with good approximation from the numbers given by applying a factor calculated on the basis of complete exchange and an initial sodium content of 12.5% in the anhydrous commercial material.

A sample of silver zeolite X in powder form was prepared by several successive treatments of pure NaX powder[3] with 5% $AgNO_3$ solution followed by the usual washings. Adsorption isotherms were determined for this material using a standard volumetric apparatus. Volumes of gas adsorbed are given in terms of 1 g of the pure NaX using the factor 1 g $AgX_{(anh)} \equiv 0.64$ g $NaX_{(anh)}$.

The oxygen used for isotherm measurements was chemically prepared by heating potassium permanganate; the nitrogen was commercial purified grade; and the hydrocarbons were either pure grade or research grade.

The silver form of the zeolite was somewhat unstable to light, and precautions were taken to shield it from bright light during transfer operations. In the dehydrated state it was found also to be reducible by hydrogen, turning black due to the formation of metallic silver. Separate experiments showed that the reduction could be carried quantitatively to completion, in some cases at room temperature, but the rate appeared to vary from one sample to another. This may have been due to variations in the amount of residual water but was not investigated further in detail.

Chromatographic measurements with the reduced silver pellet material gave retention volumes similar to those for NaX but only about one-third as great, indicating a partial loss of crystallinity. X-ray diffraction measurements on the reduced AgX powder confirmed this and also showed the presence of metallic silver. This latter observation indicates a significant migration of the atomic silver to form crystallites large enough to give coherent scattering of X rays.

RESULTS

Retention volumes were determined for each of the gases on the various columns over as wide a temperature range as possible between room temperature and an arbitrary upper temperature limit of 400°, chosen to minimize any possibilities for decomposition of the zeolite or cracking of the hydrocarbons. Within this range measurements were made at 8 to 10 separate temperatures in random order. With this particular choice of column size and flow rate it was possible to obtain conveniently measurements for ethane over nearly the whole temperature range. With oxygen, the most weakly retained adsorbate, the maximum convenient temperature was around 150°; above this the observed net retention volumes fell below 3 or 4 ml and the uncertainties became proportionately larger. For the most strongly retained gases the measurements were limited to temperatures above 250 or 300° to keep the observed retention volumes below around 1000 ml. Consequently the number of separate temperature points for each solute varied between 3 (occasionally only 2) and 6 or 8.

The elution peaks were all nearly symmetrical with only a slight tendency towards tailing. The peak widths, calculated in the recommended manner (10), corresponded to plate heights of approximately 1 mm, indicating efficient chromatographic processes. The variation of retention volume with sample pressure was small; two or three sample pressures between 0.5 and 15 cm (i.e. 0.4–12 μmoles) were usually used, and linear extrapolation to zero pressure involved at most a few tenths of a milliliter in V_g. Column AgX I was an exception to this and showed significantly more peak asymmetry, greater peak broadening, and greater dependence of retention volume on sample size. Some very extreme behavior of this sort was also observed in preliminary experiments with other species less completely exchanged than the ones described here. However, more extensive percolation of the hot exchanging solution and the final washings with the dilute hydroxide solution eliminated these features.

Plots of log V_g against reciprocal of the absolute temperature gave straight lines within the accuracy of the measurements, although there was sometimes a suggestion of a decrease in slope towards higher temperatures. Some curvature would be expected on theoretical grounds because of a temperature dependence of ΔH (11, 12), but most workers usually find similar linearity. The scatter of the experimental points about these lines led

[3]*Kindly provided by Dr. D. W. Breck of the Linde Division, Union Carbide Corp.*

to maximum uncertainties in the slope which varied with the solute. Expressed in terms of ΔH, these uncertainties ranged from ± 0.7 kcal/mole for O_2, where the relative scatter was quite high and the temperature range relatively short, down to ± 0.1 kcal/mole for C_2H_6, for which good measurements could be made over a wide temperature range, and increased again to as much as ± 1 kcal/mole for more strongly adsorbing gases such as butane and propylene, which could only be measured over short temperature ranges.

*V_g is given in ml corrected to 0 °C and effective mean column pressure per g of dehydrated NaX pellets or equivalent.
†ΔH is given in kcal/mole.
‡Zeolite capacity given in ml N_2/g at 77 °K.
§Data for argon from Barrer and Stuart (3) extrapolated from 5 ml/g to zero coverage.
‖Estimated by extrapolation of curves of Barrer and Stuart (3) from 260 to 298 °K and from 10 ml/g to zero coverage.
¶Estimated by extrapolation of data of Barrer and Sutherland (1) to zero coverage.

The best fit straight lines to the measurements are summarized in Table I, which gives the value of V_g at a specified temperature and the heat of adsorption as obtained from the slope of the line. Values for the two separate AgX preparations are given, and it is interesting that although the V_g values differ by a factor of 2, the heats of adsorption are approximately the same. As noted above, AgX I did show evidence of slow adsorption and surface heterogeneity. Both preparations were shown by analyses to be nearly 100% exchanged, and while the low temperature sorptive capacity was not determined for AgX I, the value for AgX II as given in the table is normal. Even for AgX II, however, the V_g's are significantly lower than would be expected from the equilibrium isotherms, although here there was no excessive band broadening as might be expected for high transfer resistances. This puzzling behavior is further discussed later.

Table I also includes, for comparison, limiting isosteric heats of adsorption for argon and nitrogen on the alkali metal zeolites derived from Barrer and Stuart (3) and for the normal alkanes on NaX from Barrer and Sutherland (1). Argon and oxygen might reasonably be expected to show similar adsorptive behavior, and a few chromatographic measurements with argon gave V_g's close to those for oxygen. The agreement of the heats of adsorption and the isosteric heats is within experimental error. For nitrogen on NaX Barrer and Stuart found a 1 kcal/mole range in isosteric heats between 170 and 260 °K, whereas the chromatographic heats over the range 298–480 °K appear to be roughly constant and to agree with the estimated limiting isosteric value at 298°. A further comparison may be made between the observed initial slope of Barrer and Stuart's 273° isotherm for nitrogen on NaX and an extrapolated retention volume. The initial slope of the isotherm was estimated as 16 ml (s.t.p.) atm^{-1} g^{-1} hydrated zeolite or 21 ml (s.t.p.) atm^{-1} g^{-1} dehydrated zeolite; extrapolation of the retention volumes to 273 °K gives 16 ml/g of pelletized zeolite equivalent to approximately 20 ml/g of the binder-free material.

The initial heats of adsorption of the alkanes on NaX show good agreement with the estimated limiting isosteric values in the case of methane and ethane, but are significantly lower for propane and butane. There is some uncertainty concerning these last two comparisons because the isosteric values refer to coverages of 30 ml/g or higher. There is, however, no significant variation with coverage to suggest that the zero coverage limit should be much different, so that the discrepancy may well be real.

The gas chromatographic heats of adsorption reported by Kiselev *et al.* (6) for the adsorption of hydrocarbons on CaA zeolite are compared in Table II with the present

TABLE II

Gas chromatographic heats of adsorption on CaA and CaX zeolites

	Heat of adsorption, kcal/mole

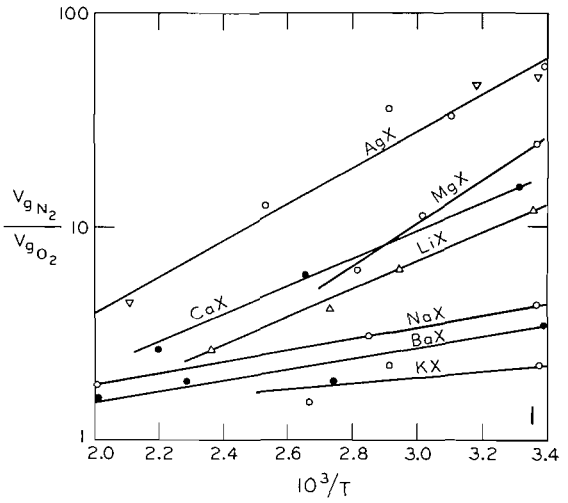
C_2H_4	9.0	(19)
C_3H_6	10.7	(23)

*Kiselev, Khrapova, and Shcherbakova (6).

results for CaX. Apart from the cases of ethylene and propylene where the present measurements are highly uncertain, the values for CaA are regularly 2–3 kcal/mole lower than those for CaX. There is, however, a suggestion from a comparison with a calorimetric result in Kiselev's work that their chromatographic values may be low by around 1 kcal/mole. Accessibility to the surface is more difficult through the smaller pores of CaA, and any temperature dependence here will give an apparently low heat of adsorption. Such a possibility is suggested by calculations of the plate heights from the chromatograms shown for ethane by Kiselev *et al.* which give values decreasing from around 3.6 mm at 30° to 1.5 mm at 100°. It would seem, therefore, that there is little conclusive evidence for any difference in heats of adsorption on X and on A zeolites, and from the similarities of their surfaces this is hardly surprising.

With further reference to the significance of quadrupole interactions as exemplified in

the comparison of nitrogen and oxygen, the ratio of the retention volumes of these two gases is of interest and is shown in Fig. 1 plotted against $1/T$. These values are, in effect,



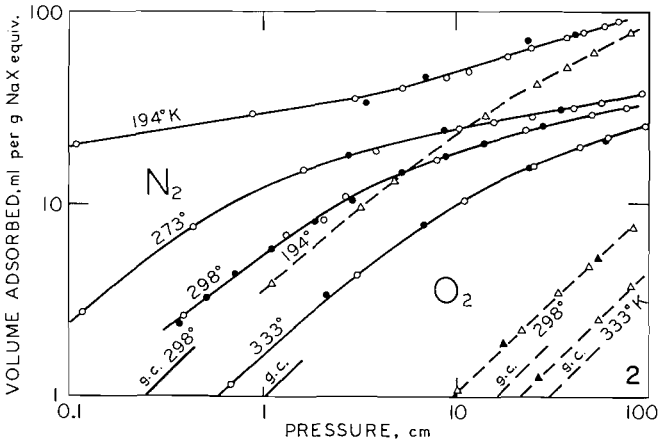


FIG. 1. Ratio of the specific retention volumes of nitrogen and oxygen as a function of temperature for various cationic forms of zeolite X. For AgX the circles refer to AgX I and the triangles to AgX II.

FIG. 2. Isotherm for the adsorption of nitrogen and oxygen by AgX powder. The lines labelled g.c. are the limiting isotherm slopes corresponding to the gas chromatographic results of AgX II.

the limiting separation factors that might be approached in the adsorption of nitrogen–oxygen mixtures at low coverage. The selectivity for nitrogen, particularly for the silver, calcium, and magnesium zeolites, approaches very high values—considerably larger than have been reported for other adsorbents at these temperatures. Such selectivity, of course, is also of interest from considerations of practical chromatography or of selective adsorption.

To investigate the extent of this high degree of preference for nitrogen, full isotherms were measured for nitrogen and oxygen on AgX, the species exhibiting the most extreme behavior. The results are shown in Fig. 2 and the corresponding isosteric heats in Fig. 3. Comparison is possible with the gas chromatographic measurements, and in Fig. 2 are

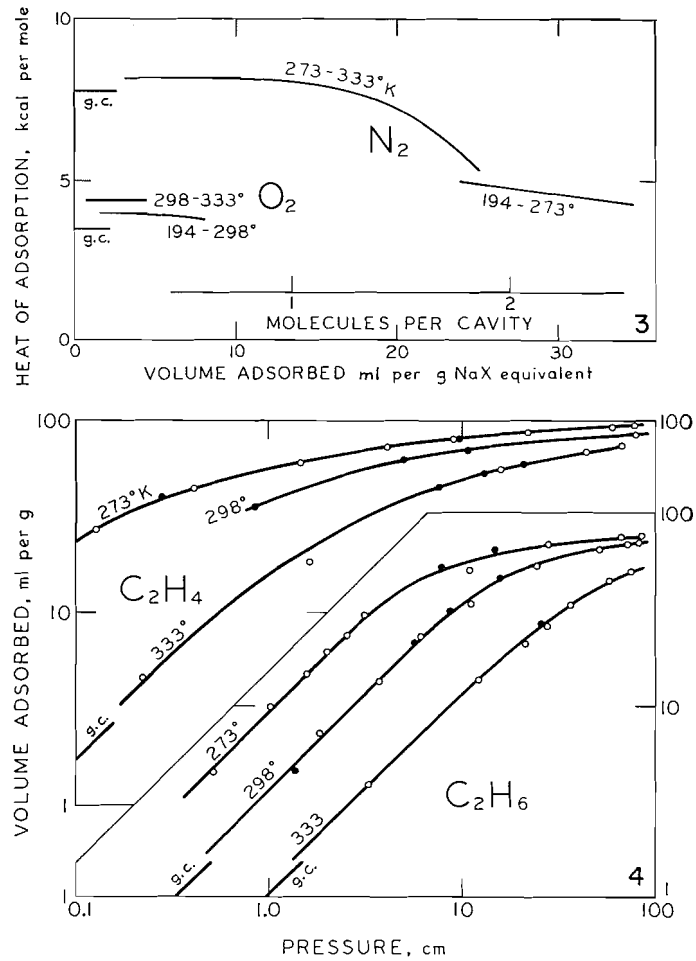

FIG. 3. Heats of adsorption of nitrogen and oxygen on AgX.
FIG. 4. Isotherms for the adsorption of ethane and ethylene on NaX powder.

shown the limiting portions of the isotherms at 25 and 60 °C (assumed linear) corresponding to the gas chromatographic retention volumes for AgX II increased by 25% to allow for the presence of binder in the pellets. Even these gas chromatographic values, the higher of the two columns measured, are only about two-thirds of the equilibrium isotherm measurements, although the heats of adsorption are in good agreement.

The data of Figs. 2 and 3 indicate clearly that the relatively strong adsorption of nitrogen is limited to low coverages—around 1 molecule per cavity or less. Such an effect was indicated by the work of Barrer and Stuart, but their measurements did not extend to the very lowest coverages and did not show any stepwise change in ΔH, as is indicated in Fig. 3.

Isotherms were also determined for ethane and ethylene on AgX and, for comparison, on NaX as well. These are shown in Figs. 4 and 5 and the isosteric heats of absorption in Fig. 6. The comparison with the limiting isotherms indicated by gas chromatography is seen to be fairly good for NaX, but the chromatographic values for AgX are significantly low, as was the case with the nitrogen and oxygen. It was very noticeable with AgX that

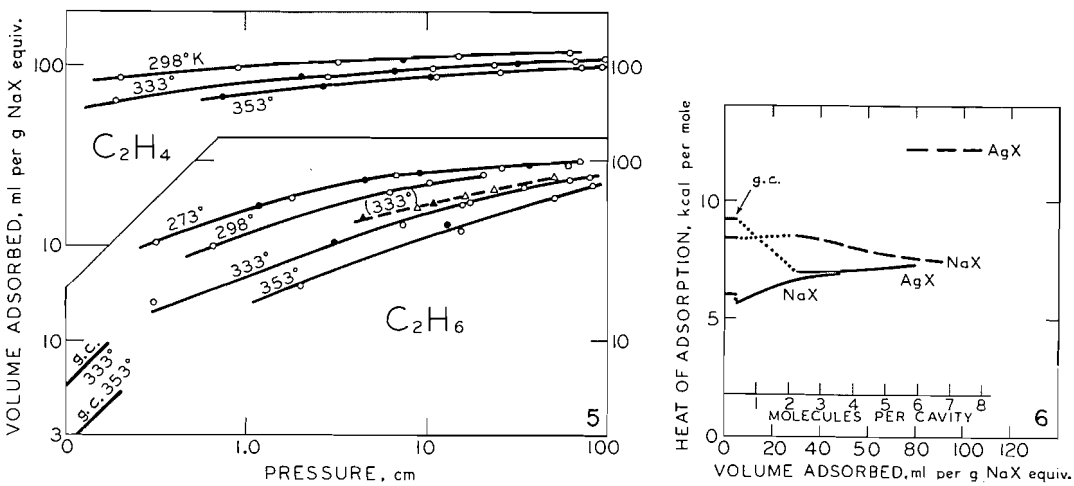

FIG. 5. Isotherms for the adsorption of ethane and ethylene on AgX powder. The broken line for ethane at 333° corresponds to the total ethane + ethylene when ethane is added to a sample containing 39 ml of ethylene/g NaX equivalent preadsorbed.

FIG. 6. Heats of adsorption of ethane (solid lines) and ethylene (broken lines) on NaX and AgX.

adsorption of all gases was much slower than for NaX, and with ethane and ethylene 2 to 3 h was necessary at every point to reach equilibrium. It would thus seem that while the total adsorptive capacity of the AgX pellets was not diminished as compared with the parent NaX, at least part of this capacity is only slowly accessible and not able to participate in the rapid adsorption and desorption processes involved in gas chromatography.

The behavior of ethylene on AgX requires additional comment. Ethylene was never eluted from the gas chromatographic columns, and during the isotherm measurements a portion of the ethylene resisted prolonged pumping into a liquid-nitrogen-cooled trap. This amount of residual ethylene varied from approximately 36 ml/g at 373 °K to 49 ml/g at 298 °K. Excessive heating led to some decomposition of the ethylene and apparently also some reduction of silver ion. This firmly held ethylene could, however, be completely displaced by water vapor.

The complexing of olefins with silver ions is well known and has been discussed by Dewar (13) in terms of combined d–π^* and s–π orbital interactions between Ag^+ and the double bond, but such complex formation is seldom very pronounced with the lower olefins and usually cannot be detected with ethylene. Quinn and Glew (14) recently reported studies of the complexing of olefins with anhydrous silver fluoborate to give the strongest complexes then reported for the lower olefins. Their 1:1 complex with ethylene, for example, had a vapor pressure at 25° of 12.75 mm. At least part of the ethylene adsorbed on AgX is much more strongly held; the 40 ml/g (approximately 3 molecules per cavity) which is not removable by pumping into a liquid-nitrogen-cooled trap must have a vapor pressure less than 2μ.

DISCUSSION

Because of some apparently real discrepancies between gas chromatographic and isotherm measurements, this work raises questions concerning the limitations of the gas chromatographic technique for studying the limiting low-pressure adsorption properties. The general validity and usefulness of the technique seems to have been clearly established

in previously reported studies (8, 9, 10) and is confirmed by at least a portion of the measurements reported here. However, in the case of systems involving either very active adsorbents such as AgX or relatively large adsorbate molecules such as propane and butane there is a clear suggestion that the gas chromatographic retention volumes and heats of adsorption may be low as compared with the equilibrium values. This would be expected if the adsorption processes are slow as compared to the time scale of the chromatographic process. The retention volumes would be smaller than the values corresponding to the initial slopes of the isotherms, and the discrepancy would be expected to be more serious the lower the temperature, thus giving too low a slope to the log V_g vs. $1/T$ plot and hence too low a value of ΔH. Such an effect might also just compensate for the expected curvature in the log V_g vs. $1/T$ plot to give the high degree of linearity often observed. Under these conditions the V_g's and ΔH's obtained by chromatography would tend to be minimum values, and this must be borne in mind in their application and interpretation.

It must be emphasized that except for column AgX I no *chromatographic* evidence of slow adsorption–desorption processes has been obtained in this work—such as excessively broad bands or an increase in retention volume with decrease in flow rate—but only limited attempts were made to look for such effects. Within the normal range of chromatographic conditions, however, processes slower by more than approximately two orders of magnitude than the dynamic transfer steps involved in elution simply would not be seen at all. For example, chromatography of carbon dioxide on NaX yielded reasonably symmetrical peaks corresponding to the rapid adsorption processes but showed no evidence of the slow chemisorption processes that have been demonstrated to occur (15). Such chemisorption processes are extreme examples. Slow adsorption such as observed for oxygen, nitrogen, or ethane on AgX may be the result of the presence of structural faults in the crystal which restrict access to some interior cavities. Alternatively, it may indicate merely slowness of redistribution after an initially high concentration is achieved in the outer cavities of a crystal. This redistribution process would be expected to have an activation energy comparable to the heat of adsorption and hence to vary significantly over the temperature range of the experiments. It should therefore result in heats of adsorption being too low and also be detectable chromatographically as a significant mass transfer resistance contribution to the plate height. Structural blockages might be relatively insensitive to temperature and therefore yield low V_g's but reasonably correct ΔH's, as appeared to be the case with the silver zeolite. It remains puzzling that there was so little evidence of band broadening in some of the other cases of low ΔH such as the measurements with propane and butane. Studies of mass transfer resistances in gas–solid chromatography of zeolites would be worthwhile.

In general, therefore, the gas chromatographic results must be considered as conservative, tending to be low rather than high both in retention volume and in heat of adsorption. Even with this degree of uncertainty, the present results clearly confirm the very pronounced contributions pointed out by Barrer and Stuart (3) of the exchangeable cations to the adsorptive properties of zeolite X. These authors discussed the various energy terms, dispersion, polarization, repulsion, and quadrupole interaction energies, contributing to the adsorption process, and in the light of their analyses it is pertinent to make some comments concerning the present results.

From the available knowledge of the crystal structure of zeolite X (16) it is clear that the exchangeable cations occupy positions of a very low degree of shielding. In each large cavity there are approximately eight univalent cations. Four of these have been located

in the six-membered oxygen rings which form the windows of the sodalite cages, and while a small cation such as lithium might be stable within the plane of the ring, the sodium and, even more so, potassium cations will probably project significantly into the adsorption cavity. This lower degree of screening of the larger cations in this site would tend to compensate for their weaker field. The other four cations have not been definitely located by crystallographic studies but probably occupy sites on the cavity surface, most probably adjacent to four-membered oxygen rings. These positions are much more exposed than the six-membered ring sites and would correspondingly have more intense fields and field gradients associated with them.

In the case of divalent cations it has not been demonstrated which sites are occupied, but it would be expected that the six-membered ring sites would be the more stable. Thus, the enhancement of adsorptive properties due to the higher charge density on the cations would not be as great as if these cations occupied the less shielded positions on the cavity surface.

A further factor relevant to the adsorption processes under discussion is the difference between silver ion and the others studied. The alkali and alkaline earth cations are all of a stable noble gas electronic configuration whereas the d orbitals of silver ion give it much more intense directional properties. Silver ion has a much stronger polarizing power than, say, sodium ion which is of the same total charge and very similar size. Furthermore, because Ag^+ is monovalent, half of these ions will be in the exposed positions on the cavity surface where this polarizing power can be most forcefully exerted.

As Barrer and Stuart have already shown, quadrupole interactions are the main reasons for the strong adsorption of nitrogen as compared with oxygen. From Fig. 1 it is seen that the selectivity increases in the order K, Na, Li and Ba, Ca, Mg, increasing with decreasing ionic size and hence with increasing charge density (charge density is used here in the sense that it applies to the individual ion and is proportional to the charge divided by the ionic radius squared). However, the difference between the two series is less marked than might be expected and this is probably because of the absence of the divalent cations from the exposed sites. The strongest effect of all is with silver ion which must occupy these sites. The limitation of the high selectivity in AgX to the first one or two molecules adsorbed per cavity suggests that the field around these exposed cationic sites is very sensitive to the perturbations of neighboring molecules.

Of the remaining adsorbates, only the olefins are likely to have significant quadrupole contributions to the energy of adsorption; methane has no quadrupole moment and the higher alkanes probably only have very small moments (17). With these substances it is more likely that polarization energies make significant contributions in addition to the usual dispersion and repulsion terms. Barrer and Stuart pointed out that adsorption on completely unscreened cations would yield ion-induced dipole polarization energies equal to or larger than the total observed heats of adsorption. Some screening must be present for the ions on any solid surface but, as already noted, it is probably minimal for the zeolites. Consequently it is considered probable that polarization effects are a major contributor to the increased heats of adsorption found with the more strongly polarizing cations.

Finally, one secondary effect should be mentioned. This is a tendency with larger adsorbate molecules for the adsorption on KX to be stronger than on NaX in opposition to the trend $Li^+ > Na^+ > K^+$. This same effect was evident in the measurements of Eberly (7) for the C_6 hydrocarbons. While this difference may be an accidental result of incomplete equilibration as mentioned earlier, it may also be explained as being due to the

greater ease with which a larger and somewhat more flexible molecule can fit against a large ion than against a small ion. In this way a greater total area of close adsorptive contact is obtained, even though the local field intensities are less. This enhancement of adsorption on KX relative to NaX is evident for ethane but not for the more rigid ethylene.

The observations reported herein have some practical significance for improved gas chromatographic resolutions through appropriate choice of the cationic species. These results are also felt to be relevant and useful in terms of conventional equilibrium adsorption processes, but kinetic limitations and the limitations of low coverage mean that great care must be taken in extending the conclusions of gas chromatography. Additional careful comparisons of gas chromatographic and equilibrium data would be worthwhile.

ACKNOWLEDGMENTS

The author thanks E. Dutcher and A. Vilonyay for carrying out most of the experimental work of the paper. Helpful discussions with Dr. F. Birss of the University of Alberta are gratefully acknowledged.

NOTES

ON THE EFFECT OF AN ATTRACTIVE MORSE POTENTIAL ON THE VIBRATIONAL ENERGY TRANSFER

H. SHIN

The effect of an attractive potential on the vibrational energy exchange, which has recently attracted considerable attention, is an important subject because of its significance in the general field of inelastic collisional processes (1–4). The importance is due to the argument that the attractive part is present in the true interaction in which the approaching molecules are "speeded up" in a potential well of depth D. Though such a physical argument is suggestive, there are some doubts regarding the exact forms of the D-dependent correction terms and their importance in the exponential part of the de-excitation probabilities per unit time (3–5).

In this note we shall point out that using the W.K.B. semiclassical approach (4, 6) we can formulate the D-dependent correction terms in different forms from the originally suggested form D/kT in the exponent of the de-excitation probability (1). For this study the assumed form of the interaction energy between an oscillator and an incident particle is the Morse type

$$w(x) = D(e^{-x/a} - 2e^{-x/2a}).$$

We also briefly discuss the de-excitation probability for a Lennard-Jones (L-J) potential.

If we omit the coefficient of the exponential factor, the de-excitation probability per unit time can be written in terms of the W.K.B. wave functions

$$[1] \quad P \sim \int_0^\infty \exp\left\{-\frac{2\sqrt{2\mu}}{\hbar}\left[\int_{x_2}^{x_0}\sqrt{w(x)-E'}\,dx - \int_{x_1}^{x_0}\sqrt{w(x)-E}\,dx\right] - \frac{E}{kT}\right\}dE,$$

where μ is the reduced mass of the collision partners, x_1, x_2 are the turning points, and $x_0 \to -\infty$, i.e., $w(x) \to \infty$, in the asymptotic limit. For the purely repulsive exponential interaction $w(x) = Ae^{-x/a}$, it has been shown that equation [1] gives (4)

$$P \sim \exp\left\{-\frac{3\chi}{kT} + \frac{\Delta}{2kT}\right\},$$

where

$$\chi = \left(\sqrt{\frac{\mu}{2}}\frac{\pi a \Delta kT}{\hbar}\right)^{2/3}$$

and $\Delta = E' - E$, the magnitude of the change in the oscillator's energy due to the collision.

Since the terms in the square brackets in equation [1] are proportional to the reciprocal of energy E, the integrand posesses a sharp maximum value at some energy E^*. An estimate of this energy which is the most probable value for energy transfer is obtained by minimizing the exponent of equation [1], i.e., the solution of

$$[2] \qquad \int_{x_2}^{x_0}\frac{dx}{\sqrt{w(x)-E'}} - \int_{x_1}^{x_0}\frac{dx}{\sqrt{w(x)-E}} = \frac{\hbar}{\sqrt{2\mu kT}}.$$

By changing $dx = (dx/dw)dw$ and by obtaining dx/dw in the region of strong repulsion as

$$\frac{dx}{dw} = -\frac{a}{w}\left[1 + \sqrt{\frac{D}{w}} - \frac{1}{2}\left(\frac{D}{w}\right)^{3/2} - \left(\frac{D}{w}\right)^{2} + \dots\right],$$

the l.h.s. of equation [2] can be expanded in a binomial series to obtain

$$[3] \qquad \sum_{i=0}^{\infty}\sum_{n=1}^{\infty}\left[(-1)^{n-1}\frac{\Gamma(n+i+\frac{1}{2})}{\Gamma(i+1)n!}\Delta^n a_i (E^*)^{-\frac{1}{2}-i-n}\right] = \frac{\hbar}{\sqrt{2\pi\mu kT}},$$

with $n = 1, 2, 3, \dots$

$i = 0, 1/2, 1, 3/2, 2, \dots$

$\alpha_0 = a$, $\alpha_{1/2} = a\sqrt{D}$, $\alpha_1 = 0$, $\alpha_{3/2} = -aD^{3/2}$. . . .

The solution of equation [3] is

$$[4] \qquad E^* = \chi + \frac{8\sqrt{D\chi}}{3\pi} - \frac{\Delta}{2}.$$

On the other hand, if the purely repulsive interaction $w(x) = Ae^{-x/a}$ is assumed, $E^* = \chi - \Delta/2$, so that the term $8\sqrt{D\chi}/3\pi$ characterizes the effect of the attractive part in $w(x)$.

In terms of the energy E^*, the de-excitation probability, equation [1] can now be written

$$[5] \qquad P \sim \exp\left\{\frac{\sqrt{2\pi\mu}}{\hbar}\sum_{i=0}^{\infty}\sum_{n=1}^{\infty}\left[(-1)^n\frac{\Gamma(n+i-\frac{1}{2})}{\Gamma(i+1)n!}\Delta^n a_i (E^*)^{\frac{1}{2}-n-i}\right] - \frac{E^*}{kT}\right\}.$$

When we calculate each term of the double-sum with respect to a set of i and n, the exponent in equation [5] becomes

$$[6] \qquad -\frac{\pi a\Delta}{\hbar}\sqrt{\frac{\mu}{2E^*}}\left[1 + \frac{8}{3\pi}\sqrt{\frac{D}{E^*}} - \frac{3}{4}\left(\frac{\Delta}{E^*}\right) - \frac{4}{3\pi}\frac{\Delta}{E^*}\sqrt{\frac{D}{E^*}} + 0\left(\frac{1}{E^{*2}}\right)\right] - \frac{E^*}{kT}.$$

By substituting equation [4] into [6], the final expression for the de-excitation probability, in the asymptotic limit, is

$$[7] \qquad P \sim \exp\left\{-\frac{3\chi}{kT} + \frac{4\sqrt{D\chi}}{\pi kT} + \frac{16D}{3\pi^2 kT} + \frac{\Delta}{2kT}\right\}.$$

The first term in the exponent is the leading term, the Landau–Teller term (7), and the same form also appears in the case of the purely repulsive interaction. The last term, $\Delta/2kT$, is a small correction which is quite independent of the exact form of $w(x)$, because symmetrization yielding this term affects only the leading term. The two intermediate (D-dependent) terms, which resulted from the i-summation in equations [3] and [5], are the corrections due to the presence of the attractive part $-2De^{-x/2a}$ in $w(x)$. Since both terms are positive, this additional part in $w(x)$ leads to more effective energy transfers, as it must.

Obviously, the presence of the first correction term $4\sqrt{D\chi}/\pi kT$, which is the geometric mean of the leading term and the second correction term $16D/3\pi^2 kT$, is important. In previous approaches, the existence of this term has not been reported (2, 8). Since at

For personal use only.

ordinary temperatures χ/kT is 5–10 and D/kT is close to unity, the first correction significantly contributes to the overall value of P. The contribution of the second correction term is small, but it is important to note its existence, in view of Schwartz and Herzfeld's purely physical argument (1, 9), in obtaining a similar term D/kT. Numerically, therefore, the second correction is half of Schwartz and Herzfeld's term. While the latter workers have considered D/kT as the only term responsible for an attractive force between the collision partners, we have found an important D-dependent correction term $4\sqrt{D\chi}/\pi kT$ for a realistic Morse potential.

The present result may be compared to Nikitin's work (3) for a L-J potential. Using first-order perturbation theory he has obtained

$$P \sim \exp\,(-\,3\chi/kT + 4\sqrt{D\chi}/\pi kT + \Delta/2kT),$$

which is very similar to the expression obtained above. It should be noted, however, that he has neglected the attractive part of $w(x)$ in the formulation of dw/dq, where q is the vibrational coordinate, while he has included it in the calculation of the classical integral of motion. Therefore, it is not possible to compare the two results quantitatively, but the importance of the D-dependent correction terms is seen in both cases. Note that Nikitin's expression shows no term proportional to D/kT.

Since the nature of repulsive part in a L-J potential is somewhat different from that of the exponential case, its leading term in the exponent of P cannot be the Landau–Teller form for exponential interactions. In fact, for the 12–6 L-J potential,

$$w(x) = 4D[(a'/x)^{12} - (a'/x)^{6}],$$

the present method gives the leading term

$$\frac{19}{7}\left[7\frac{\Gamma(7/12)}{\Gamma(1/12)}\frac{\sqrt{2\pi\mu}a_0'\Delta kT}{\hbar}\right]^{12/19}\frac{1}{kT}$$

where $a_0' = a'(4D)^{1/12}/12$. This expression is entirely different from the Landau–Teller term given above for exponential interactions. However, this leading term can be closely related to the Landau–Teller term either by equating the leading terms of the double-sum in equation [5] for the two potentials, or by properly fitting the L-J potential to the Morse potential such that magnitudes are equal for $x = x_c$ and $x = x_1$, where x_c is the distance between molecular centers at the classical turning point and x_1 is the corresponding value for the energy zero of the L-J potential (1).

QUANTITATIVE DECARBOXYLATIONS OF ELECTRONEGATIVELY SUBSTITUTED BENZOIC ACIDS VIA THE SCHMIDT REACTION

A. J. McNamara and J. B. Stothers

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Reaction mechanism studies involving isotopic carbon frequently require the isolation, for isotopic analysis, of a particular carbon atom in a molecule. If the atom of interest is bonded to an aromatic ring, a common approach to its isolation involves an oxidation to the substituted aromatic carboxylic acid followed by decarboxylation to furnish carbon dioxide for mass spectrometric analysis or radio assay. While it is always desirable that this degradation to carbon dioxide be accomplished in high overall yield, for isotope effect studies it is essential. The most frequently employed methods for the decarboxylation step include the Schmidt reaction, the Hunsdiecker silver salt degradation, and the copper chromite – quinoline reaction. The relative merits of these methods have been discussed recently (1) and a thorough review of the Schmidt reaction has appeared (2). The major deficiency of the Schmidt reaction for this purpose was shown to be the poor yields obtained with aromatic acids bearing electronegative substituents (1), the presence of which so lowers the yield of carbon dioxide that the method is of little use for isotope effect studies. To our knowledge, however, most of the previous results have been obtained using *concentrated* sulphuric acid, either as the reaction medium or as a catalyst in a heterogeneous reaction mixture. While Newman and Gildenhorn (3) have reported the use of 100% sulphuric acid for the decarboxylation of 2,6-dimethyl substituted benzoic and terephthalic acids and Briggs, de Ath, and Ellis (4) noted the adverse effects of water on yields from this reaction, no studies of the Schmidt reaction on *m*- and *p*-substituted benzoic acids in anhydrous sulphuric acid appear in the literature. We have found that the yield of carbon dioxide from these acids is dramatically increased, if "100% sulphuric acid"* is used as the reaction medium.

Virtually quantitative yields of carbon dioxide, together with high yields of the appropriately substituted aniline, have been obtained for a series of meta- and para-substituted benzoic acids bearing a variety of electron-withdrawing groups. Typical data are listed in Table I in which the results for benzoic and *p*-anisic acids are included for comparison. The yields noted for the various anilines represent *lower* limits for the method, since these data represent the quantity of material actually isolated after recrystallization either as the aniline or as a derivative. The yields of carbon dioxide were obtained by precipitation as barium carbonate in the usual way (5). It is clear from these results that sulphonation is not an important side reaction for those acids having electron-withdrawing substituents although the presence of electron-releasing groups may lead to significant quantities of sulphonated products, as indicated by the reduced yields of the aniline from *p*-anisic and benzoic acids. No attempt was made to isolate sulphonated products from these reactions.

The reaction conditions (2 h at 40 °C) were chosen for convenience and to allow comparison with previous results using concentrated sulphuric acid (1, 6). These conditions are not particularly drastic and the reaction proceeds smoothly at even lower temperatures. Furthermore, Deno and his co-workers (7) have demonstrated that much more reactive species can be treated with, and recovered from, sulphuric acid solutions

without serious decomposition. While it would appear that the Schmidt reaction is complete in a shorter period of time, no quantitative kinetic data have been obtained to date. Each experiment was allowed to continue for 2 h to ensure that all of the evolved carbon dioxide was collected in the gas absorption trap.

Clearly the use of "100% sulphuric acid" in the Schmidt reaction affords sufficiently high yields of carbon dioxide for isotope work, but it is also interesting that the substituted aniline is formed in high yield. It appears, therefore, that this slight modification of the standard method may offer a straightforward route to certain substituted anilines which may be difficult and (or) tedious to prepare by other methods. All except one of those substituents in the present series are unaffected by the reagents. The lone exception, the cyano group, is hydrolyzed readily to the amido grouping in sulphuric acid producing a good yield of *p*-aminobenzamide. Our survey included 3,5-dinitrobenzoic acid to examine the effect of two strongly electron-withdrawing substituents on the yield of the reaction products. While reaction in "100% sulphuric acid" was negligible, the use of 20% oleum afforded a quantitative yield of carbon dioxide and an 82% yield of 3,5-dinitroaniline.

EXPERIMENTAL

The general procedure was similar to that described previously (6). An absorption train was set up, following the method of Phares (8), and to a cold (0°) solution of 1–2 mmole of the benzoic acid in 5 ml of sulphuric acid of the appropriate concentration was added sodium azide (15% excess over a 1:1 mole ratio, NaN_3:RCOOH). After connection to the absorption traps, the temperature of the reaction mixture was maintained at 40 ± 1° for 2 h while the evolved carbon dioxide was swept into 0.2 *M* carbonate free sodium hydroxide by a slow stream of purified nitrogen. The carbon dioxide was precipitated as barium carbonate in the usual way (5). Great care was taken in all operations to avoid contamination with extraneous carbon dioxide and suitable blanks were run at regular intervals to check the operations. To isolate the aniline, the reaction mixture was poured into cold water, sufficient alkali was added to make the solution definitely basic, and the product removed by ether extraction. Removal of the ether was followed by recrystallization of the residue in the case of the solid anilines; otherwise a suitable solid derivative was prepared and recrystallized. In the case of *p*-aminobenzamide (from *p*-cyanobenzoic acid), the reaction mixture was poured onto 15 g of ice and, with external cooling, was neutralized with concentrated NH_4OH (just basic to litmus); the insoluble amide was filtered off and recrystallized from $EtOH/H_2O$.

All of the starting materials, except *p*-trifluoromethylbenzoic acid which was kindly supplied by Prof.

LA RÉACTION DU SULFURE DE BORE AVEC LES ALCOOLS

J. M. LALANCETTE

Moissan (1) rapporte que le sulfure de bore réagit avec certaines molécules organiques sans toutefois préciser le mode d'action du sulfure ou la nature des produits ainsi obtenus. Au cours d'une étude systématique de l'interaction de B_2S_3 avec différents types de composés organiques (2) la réaction de ce sulfure avec les alcools a été étudiée.

On a constaté que les alcools, tant aliphatiques qu'aromatiques, conduisent aux esters orthoboriques correspondants, avec de bons rendements, la réaction s'accompagnant d'un dégagement de H_2S.

$$6ROH + B_2S_3 \rightarrow 2(RO)_3B + 3H_2S,$$

où R = CH_3, C_2H_5, *n*-C_3H_7, *n*-C_6H_{13}, *n*-C_7H_{15}, C_6H_5, α-$C_{10}H_7$.

Cependant, certains phénols nitrés demeurent complètement inertes vis-à-vis le sulfure. Cette absence de réaction ne peut se justifier par une inhibition simple due au groupe nitro car le phénol donne une réaction avec B_2S_3 même en présence d'une quantité équimoléculaire de nitrobenzène. Cette réaction demeure à l'étude afin d'en préciser, si possible, le mécanisme.

PARTIE EXPÉRIMENTALE

Réaction du sulfure de bore avec les alcools

A une suspension de 12 g (0.10 mole) de sulfure de bore, préparé selon le mode usuel (2), dans le benzène anhydre, on ajoute 61 g (0.60 mole) d'hexanol normal redistillé. L'addition s'accompagne d'un échauffement prononcé et d'un fort dégagement de H_2S, ce gaz étant capté sous forme de sulfure de plomb. On isole ainsi 0.26 mole de gaz sulfhydrique. Après un reflux de 3 h, la masse réactionnelle est filtrée. Le résidu

A. N. Bourns, are commercially available and the purity of each was checked by a melting point determination. The compounds were purified by recrystallization before use if the melting point indicated the presence of impurities.

LA RÉACTION DU SULFURE DE BORE AVEC LES ALCOOLS

J. M. LALANCETTE

Moissan (1) rapporte que le sulfure de bore réagit avec certaines molécules organiques sans toutefois préciser le mode d'action du sulfure ou la nature des produits ainsi obtenus. Au cours d'une étude systématique de l'interaction de B_2S_3 avec différents types de composés organiques (2) la réaction de ce sulfure avec les alcools a été étudiée.

On a constaté que les alcools, tant aliphatiques qu'aromatiques, conduisent aux esters orthoboriques correspondants, avec de bons rendements, la réaction s'accompagnant d'un dégagement de H_2S.

$$6ROH + B_2S_3 \rightarrow 2(RO)_3B + 3H_2S,$$

où R = CH_3, C_2H_5, *n*-C_3H_7, *n*-C_6H_{13}, *n*-C_7H_{15}, C_6H_5, α-$C_{10}H_7$.

Cependant, certains phénols nitrés demeurent complètement inertes vis-à-vis le sulfure. Cette absence de réaction ne peut se justifier par une inhibition simple due au groupe nitro car le phénol donne une réaction avec B_2S_3 même en présence d'une quantité équimoléculaire de nitrobenzène. Cette réaction demeure à l'étude afin d'en préciser, si possible, le mécanisme.

PARTIE EXPÉRIMENTALE

Réaction du sulfure de bore avec les alcools

A une suspension de 12 g (0.10 mole) de sulfure de bore, préparé selon le mode usuel (2), dans le benzène anhydre, on ajoute 61 g (0.60 mole) d'hexanol normal redistillé. L'addition s'accompagne d'un échauffement prononcé et d'un fort dégagement de H_2S, ce gaz étant capté sous forme de sulfure de plomb. On isole ainsi 0.26 mole de gaz sulfhydrique. Après un reflux de 3 h, la masse réactionnelle est filtrée. Le résidu

solide ne renferme plus de sulfure de bore et la portion liquide est distillée après évaporation du benzène. On retrouve ainsi 52 g (0.16 mole) d'orthoborate de *n*-hexyle: p.éb. 182° à 12 mm; n_D^{25} 1.4250. Décrit (3): p.éb. 185° à 15 mm; n_D^{23} 1.4250. Spectre infrarouge: absence de bandes dans la région de 3500 cm^{-1}, bandes à 1470 cm^{-1} (moyenne), 1410 cm^{-1} (forte), 1335 cm^{-1} (très forte), 1080 cm^{-1} (moyenne). Ce spectre est identique à celui donné par un échantillon authentique d'orthoborate d'hexyle préparé à partir de l'alcool correspondant et de l'acide borique. En appliquant la même méthode avec l'alcool propylique normal et l'alcool heptylique normal, on retrouve les orthoborates correspondants.

Avec des alcools volatils (méthanol, éthanol), la réaction peut être réalisée sans diluant (benzène) et en utilisant un léger excès de sulfure de bore. De cette façon, les orthoborates correspondants sont produits et recueillis directement par distillation, sans nécessiter une séparation de l'azéotrope de l'ester borique d'un excès d'alcool ou de diluant. Les esters ainsi obtenus présentent les constantes suivantes, orthoborate de méthyle: p.éb. 67.5° à 750 mm; n_D^{25} 1.3612. Orthoborate d'éthyle: p.éb. 116° à 750 mm; n_D^{23} 1.3742. Décrit (3): orthoborate de méthyle: p.éb. 68.7° à 760 mm; n_D^{20} 1.3610. Orthoborate d'éthyle: p.éb. 117.3° à 760 mm; n_D^{20} 1.3741.

Le phénol et l'α-naphtol réagissent également bien. Utilisant le procédé décrit plus haut pour la préparation de l'orthoborate d'hexyle, on retrouve, à partir du phénol, l'orthoborate de phényle, p.f. 90–91°, avec un rendement de 76%. Par la même méthode l'orthoborate d'α-naphtyle est produit, p.f. 107°. En utilisant toujours la même technique mais portant la durée de reflux à 24 h, il s'est avéré impossible de faire réagir le *p*-nitrophénol dont on retrouve 96% de la quantité initialement mise en expérience. Le sulfure de bore est retrouvé également intact et de façon quantitative, par filtration de la masse réactionnelle, au terme du reflux. Un comportement similaire est noté avec le *m*-nitrophénol. Cependant le phénol (0.15 mole) en présence de nitrobenzène (0.15 mole) et de sulfure de bore (0.03 mole) donne, par la méthode usuelle, l'orthoborate de phényle, p.f. 90–91°, avec rendement de 72%.

PROTON MAGNETIC RESONANCE CHEMICAL SHIFTS OF THE S-METHYL GROUP

George R. Pettit, Irwin B. Douglass, and Ralph A. Hill

Among organosulphur compounds, the proton magnetic resonance (p.m.r.) signals exhibited by certain thiols (1), sulphides (2), hemithioketals (3), sulphonium salts (4), and sulphites (5) have received major study. Although a variety of other H—C—S group responses have been included in several useful collections of p.m.r. data (6) only a few examples (cf. refs. 6 and 7) of S-methyl proton resonance have been recorded. The need[1] for a more extensive p.m.r. survey of the methyl group influenced by an adjacent sulphur atom has led to the present investigation. In Table I we have summarized the p.m.r. chemical shifts of 17 S-methyl compounds containing divalent sulphur. Tables II and III contain an additional 12 substances bearing S-methyl sulphur atoms in higher valence states. A small number of related sulphur compounds have been included in each table.

[1]*Required as part of a general program (for example, see ref. 8) involving the chemistry of organosulphur compounds.*

De cette façon, les orthoborates correspondants sont produits et recueillis directement par distillation, sans nécessiter une séparation de l'azéotrope de l'ester borique d'un excès d'alcool ou de diluant. Les esters ainsi obtenus présentent les constantes suivantes, orthoborate de méthyle: p.éb. 67.5° à 750 mm; n_D^{25} 1.3612. Orthoborate d'éthyle: p.éb. 116° à 750 mm; n_D^{23} 1.3742. Décrit (3): orthoborate de méthyle: p.éb. 68.7° à 760 mm; n_D^{20} 1.3610. Orthoborate d'éthyle: p.éb. 117.3° à 760 mm; n_D^{20} 1.3741.

Le phénol et l'α-naphtol réagissent également bien. Utilisant le procédé décrit plus haut pour la préparation de l'orthoborate d'hexyle, on retrouve, à partir du phénol, l'orthoborate de phényle, p.f. 90–91°, avec un rendement de 76%. Par la même méthode l'orthoborate d'α-naphtyle est produit, p.f. 107°. En utilisant toujours la même technique mais portant la durée de reflux à 24 h, il s'est avéré impossible de faire réagir le *p*-nitrophénol dont on retrouve 96% de la quantité initialement mise en expérience. Le sulfure de bore est retrouvé également intact et de façon quantitative, par filtration de la masse réactionnelle, au terme du reflux. Un comportement similaire est noté avec le *m*-nitrophénol. Cependant le phénol (0.15 mole) en présence de nitrobenzène (0.15 mole) et de sulfure de bore (0.03 mole) donne, par la méthode usuelle, l'orthoborate de phényle, p.f. 90–91°, avec rendement de 72%.

PROTON MAGNETIC RESONANCE CHEMICAL SHIFTS OF THE S-METHYL GROUP

George R. Pettit, Irwin B. Douglass, and Ralph A. Hill

Among organosulphur compounds, the proton magnetic resonance (p.m.r.) signals exhibited by certain thiols (1), sulphides (2), hemithioketals (3), sulphonium salts (4), and sulphites (5) have received major study. Although a variety of other H—C—S group responses have been included in several useful collections of p.m.r. data (6) only a few examples (cf. refs. 6 and 7) of S-methyl proton resonance have been recorded. The need[1] for a more extensive p.m.r. survey of the methyl group influenced by an adjacent sulphur atom has led to the present investigation. In Table I we have summarized the p.m.r. chemical shifts of 17 S-methyl compounds containing divalent sulphur. Tables II and III contain an additional 12 substances bearing S-methyl sulphur atoms in higher valence states. A small number of related sulphur compounds have been included in each table.

[1]*Required as part of a general program (for example, see ref. 8) involving the chemistry of organosulphur compounds.*

TABLE I

Proton magnetic resonance chemical shifts (δ units) of divalent sulphur compounds[a]

Substance (ref.)	—C—H[e]	—C—CH_3	—SH	S —COCH$_3$	—SCH_3	—$SSCH_3$	S—CH_2—S	S—CH_2—O	S—CH_2—Cl
CH_3SH			0.91, 1.17[e] (J = 7.0 c.p.s.)		1.95, 2.05				
CH_3COSH		2.29	4.47						
CH_3SCH_3					2.0				
CH_3S—SCH_3					2.30				
CH_3S—S—SCH_3 (11)					2.43				
CH_3S—S—S—SCH_3 (12)[b]					2.55				
$CH_3CO_2CH_2SCH_3$ (13)		2.15			1.98			4.86	
$(CH_3)_2C(SCH_3)_2$ (14)		1.49			1.95				
$CH_3CH(SCH_3)_2$ (15)	3.50, 3.73 (J = 7.0 c.p.s.)	1.44, 1.55			2.0				
$CH_3SCH_2SCH_3$ (16)					2.05		3.45		
$CH_3\overset{O}{\overset{\|}{C}}SCH_3$		2.20			2.24				
$CH_3S\overset{O}{\overset{\|}{C}}$—NH⟨⟩[c] (17)					2.28				
$CH_3S\overset{O}{\overset{\|}{C}}SCH_3$ (18)					2.32				
$CH_3SS\overset{O}{\overset{\|}{C}}SCH_3$ (8*a*)					2.35	2.48			
$CH_3S\overset{O}{\overset{\|}{C}}Cl$[d]					2.40				
$CH_3O\overset{S}{\overset{\|}{C}}SCH_3$ (8*a*)				4.05	2.46				
CH_3SCN					2.50				
$CH_3S\overset{O}{\overset{\|}{S}}CH_3$ (19)					2.60				
$ClCH_2S\overset{O}{\overset{\|}{C}}CH_2Cl$ (20)									4.70

[a]Unless otherwise noted, the sample was studied in carbon tetrachloride solution.
[b]The specimen of tetrasulphide used here contained detectable (by p.m.r.) amounts of impurities which appeared to represent somewhat longer-chain sulphides.
[c]Acetonitrile as solvent.
[d]Stauffer Chemical Co.
[e]The chemical shifts presented correspond to quartets.

TABLE II

Proton magnetic resonance chemical shifts (δ units) of tricovalent sulphur compounds[a]

Substance (ref.)	O —SCH_3	O —$SOCH_3$
CH_3SCH_3[b]	2.43	
CH_3SOCH_3 (21)	2.46	3.56
CH_3SCl (22)	3.22	
 (13)		3.25
CH_3OSOCH_3 (23)		3.45

[a]Each substance was studied in carbon tetrachloride.
[b]Identical responses were observed when acetonitrile or carbon tetrachloride was used as solvent.

Several noteworthy observations were made during this study. First, a potentially useful property of multiple sulphur bonding was revealed while we were studying a series of methyl sulphides (Table I). Proton magnetic resonance signals exhibited by the methyl mono-, di-, tri-, and tetra-sulphides were separated by at least 0.1 p.p.m., and shielding of the methyl protons decreased at a decreasing rate with extension of the sulphur chain. The p.m.r. response arising from further lengthening of the sulphur chain will most probably reach a limiting value at ca. 6–8 sulphur units. However, the present results suggest that an appropriate p.m.r. study may provide a valuable method for rapidly assessing the length of relatively small sulphur chains in both symmetrical and unsymmetrical methyl sulphides.

The spectrum of N-bis(2-fluoroethyl)methanesulphonamide (Table III) also deserves comment. In addition to an S-methyl signal at 2.82δ, the spectrum exhibited a series of four triplets (J = 5.0 in each case), of nearly equal intensity, centered at 3.25, 3.65, 4.05, and 4.82δ. The two triplets at higher field most probably correspond to both protons adjacent to nitrogen, and the two at lower field to protons next to fluorine. Therefore, the triplets at 3.65 and 4.82δ provide an interesting example of spin–spin coupling involving fluorine (cf. ref. 9).

In general, the present data indicate that deshielding of the S-methyl protons increases in the order thiol $\cong$ sulphide < sulphoxide < sulphinate < sulphone < sulphonamide < sulphinyl halide < sulphonyl halide. As expected, the increasing chemical shift from tetramethylsilane appears related to the number and magnitude of electronegative atoms bonded to sulphur.

EXPERIMENTAL

The p.m.r. spectra were obtained by the use of a Varian Associates Model A-60 n.m.r. spectrometer. In each case, a 10% (by weight) solution of the specimen in spectro grade carbon tetrachloride or redistilled acetonitrile was prepared and diluted with enough tetramethylsilane to standardize the instrument. Scanning was performed from low to high field at a rate of 120 c.p.s./min. Measurements (at 20 °C) are reported (10) in terms of the frequency-independent unit δ (p.p.m.) with respect to tetramethylsilane.

Each (with exception of dimethyl sulphone from Crown Zellerbach Co.) of the organosulphur compounds studied was prepared and (or) purified in this laboratory.

AN ALTERNATIVE SYNTHESIS OF 5-CARBOXYVANILLIN[1]

Hirokazu Morita

This report deals with the synthesis of 5-carboxyvanillin from commercially available materials and by a method which is more direct than those previously reported.

5-Carboxyvanillin has been prepared by a four-step synthesis starting from orthovanillic acid, the terminal conversion requiring an autoclave (1). The directions outlined

[1]*Soil Research Institute, Contribution No. 110.*

For personal use only.

below give somewhat poorer yields, but this is offset by the decided advantage in the simplicity of the procedure and by the easy accessibility of the reagents.

The experiment described here is based on the formylation of vanillic acid by hexamethylenetetramine in hot glacial acetic acid (2). The application of this reaction to orthovanillic acid readily affords 5-carboxyvanillin, which in turn can be oxidized cleanly to 5-carboxyvanillic acid. Oxidation of the 5-formylvanillic acid prepared according to Seshardi and Thiruvengadam (2) gave the identical acid.

EXPERIMENTAL

All melting points were determined on a calibrated Fischer–Johns apparatus.

X-ray powder diffraction patterns were obtained on a Norelco X-ray diffractometer unit using Cu Kα radiation. Line intensities were estimated visually from photographs of the Debye–Scherrer type.

5-Carboxyvanillin

Practical grade 2-hydroxy-3-methoxybenzaldehyde (Monsanto Chemical Company) was oxidized with silver oxide to orthovanillic acid (m.p. 147–148°) in 70% yield (3). Orthovanillic acid (10.1 g, 0.06 mole), hexamethylenetetramine (British Drug Houses; 42 g, 0.30 mole), and glacial acetic acid (80 ml) were heated on a boiling water bath for 7 h. Then hot (90°) 6 *N* hydrochloric acid (110 ml) was added, and the heating resumed for another 10 min. Upon cooling of the reaction mixture in the cold overnight, light cream-colored crystals of 5-carboxyvanillin were obtained. The crystals were collected by filtration, washed with water, and recrystallized from 40% ethanol in water (600 ml) to give colorless crystals, yield 3.5 g (26%), m.p. 256–258° (lit. 256–257°).

Analysis for $C_9H_8O_5$: Calcd.: C, 55.09; H, 4.11; CH_3O, 15.82. Found: C, 55.12; H, 4.10; CH_3O, 15.81.

The ultraviolet absorption spectrum in 95% ethanol showed maxima at 230 mμ (ϵ 18 000), 290 mμ (ϵ 10 700), and 320 mμ (ϵ 11 600). The X-ray powder diffraction pattern of the crystals showed prominent lines at *d*, 7.66 Å (I/I_1 70); *d*, 7.25 Å (I/I_1 80); *d*, 5.28 Å (I/I_1 70); *d*, 4.09 Å (I/I_1 80); *d*, 3.83 Å (I/I_1 50); *d*, 3.42 Å (I/I_1 80); *d*, 3.35 Å (I/I_1 100); *d*, 3.12 Å (I/I_1 60); *d*, 2.71 Å (I/I_1 50); *d*, 2.51 Å (I/I_1 50); *d*, 2.41 Å (I/I_1 50); *d*, 2.04 Å (I/I_1 50); *d*, 1.70 Å (I/I_1 50).

5-Carboxyvanillic Acid

Oxidation of 5-carboxyvanillin with silver oxide according to the procedure outlined by Pearl and Beyer (1) gave a product which, after repeated recrystallization from water, melted at 282.5–284°. This product was confirmed as 5-carboxyvanillic acid by comparison of its physical properties (mixed melting point, ultraviolet spectrum, and crystallographic features) with those observed for the dicarboxylic acid obtained from 5-formylvanillic acid.

5-Formylvanillic acid (m.p. 224–225°) was obtained in 25% yield by the formylation of vanillic acid as described by Seshardi and Thiruvengadam (2). Oxidation of this acid with alkaline silver oxide gave a quantitative yield of 5-carboxyvanillic acid, m.p. 283–284° (after repeated recrystallization from water) (lit. m.p. 276° (4); 283–284° (1), 271–272° (1)).

Analysis for $C_9H_8O_6$: Calcd.: C, 50.93; H, 3.80; CH_3O, 14.63. Found: C, 50.89; H, 4.02; CH_3O, 14.58.

The ultraviolet absorption spectrum in 95% ethanol showed maxima at 227 mμ (ϵ 27 400), 267 mμ (ϵ 7400), and 310 mμ (ϵ 3800). The X-ray powder diffraction pattern of the acid showed prominent lines at *d*, 10.66 Å (I/I_1 40); *d*, 9.03 Å (I/I_1 70); *d*, 6.97 Å (I/I_1 80); *d*, 4.61 Å (I/I_1 30); *d*, 4.51 Å (I/I_1 30); *d*, 4.03 Å (I/I_1 30); *d*, 3.86 Å (I/I_1 50); *d*, 3.23 Å (I/I_1 100); *d*, 3.14 Å (I/I_1 30).

RING CONTRACTION DURING THE LEAD TETRAACETATE OXIDATION OF REDUCING SUGARS[1]

A. S. PERLIN

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received June 12, 1964

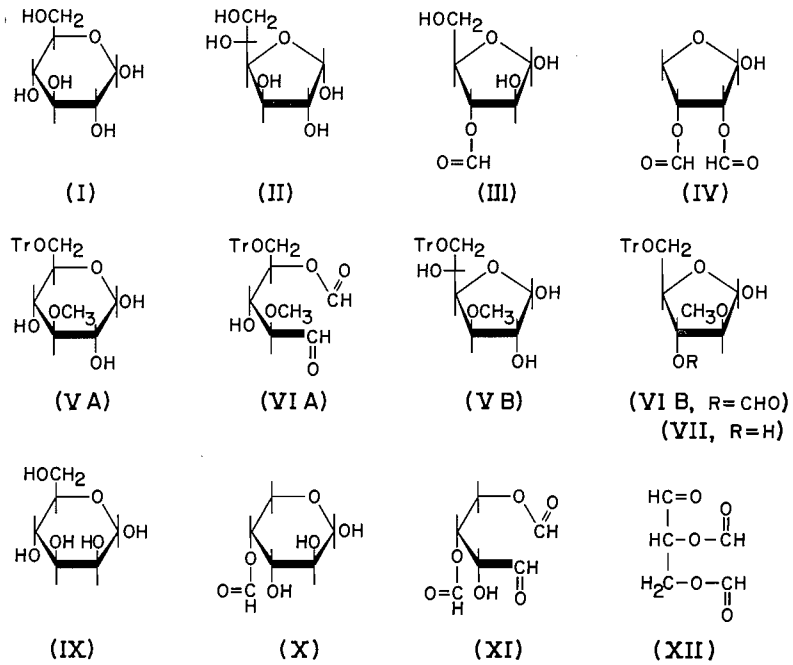
ABSTRACT

The rate of oxidation of D-glucose by lead tetraacetate in acetic acid is affected little by a large change in concentration of reactants, showing that the glycol cleavage step is not rate-controlling. Oxidation of 3-*O*-methyl-6-*O*-trityl-D-glucose yields 3-*O*-formyl-2-*O*-methyl-5-*O*-trityl-D-arabinose; the latter is not derived by production initially of a 4-*O*-formyl derivative that undergoes acyl migration. It is probable that the oxidation of D-glucose proceeds with conversion of the pyranose sugar into a furanose intermediate. By contrast, D-mannose appears to be oxidized mainly in the pyranose form, as shown by the oxidation patterns of D-mannose-1- and -2-^{14}C and 5-*O*-methyl-D-mannofuranose, and the effects of concentration change on the reaction of D-mannose and derivatives. The proximity of the ring oxygen atom to the 1,2-diol group may contribute to the unusually high reactivity of D-mannopyranose as compared with other types of monocyclic six-membered ring *vic*-diols.

Intermediate proportions of furanose and pyranose pathways characterize the lead tetraacetate oxidation of the other six aldohexoses. Similarities in the behavior of glucose and idose, gulose and mannose, and allose and talose may originate in steric similarities between these pairs of sugars.

The lead tetraacetate oxidation (1, 2) of reducing sugars in acetic acid involves primarily the cleavage of α-hydroxy hemiacetal glycol groups, and results in a stepwise shortening of the carbon chain (3, 4, 5). However, the uptake of oxidant in these reactions is lower than might be anticipated. For example, D-glucose (I) consumes only 2 moles of lead tetraacetate per mole rather than the 3 moles theoretically possible for the 1,2,3,4-tetrol grouping of the pyranose sugar (I), yielding a diformate ester of D-erythrose rather than of D-glycerose. A possible explanation for these results is to assume that a complex (6) between the tetravalent lead and the 1,2-diol group of α-D-glucofuranose (II) is an intermediate in the reaction. This complex could be formed directly from the pyranose sugar, by analogy with the formation of D-glucofuranose 1,2-acetals and borate complexes (7, 8), or from the furanose sugar if present in solution even as a minor constituent. Dissociation of the complex would give 3-*O*-formyl-D-arabinose, which, oxidized as a furanose sugar (III), would yield 2,3-di-*O*-formyl-D-erythrose (IV). Thus, involvement of a reactive structure such as II accounts for the high rate of the reaction (5, 9), as well as the consumption of only 2 moles of oxidant per mole. Consistent with these possibilities is the fact that derivatives of D-glucose that are prevented from going over to a furanose form by substituents at C-4 are oxidized much more slowly than D-glucose itself, whereas the rate is essentially unaltered by a substituent at C-3 or C-6 (10).

[1]*Issued as N.R.C. No. 8101.*



In the oxidation route depicted above, the initial product is a 3-, rather than a 4-, formate ester. Support for this step is provided by examining the oxidation of 3-*O*-methyl-6-*O*-trityl-D-glucose to mono-*O*-formyl-2-*O*-methyl-5-*O*-trityl-D-arabinose. If the pyranose sugar (VA) were to be degraded directly, the product should be a 4-formate of the *aldehydo*-pentose (VIA), whereas a furanose intermediate (involving VB) should yield a 3-formate of the pentofuranose (VIB). Nuclear magnetic resonance (n.m.r.) spectral evidence strongly favors the latter formulation for the oxidation product. Its spectrum (Fig. 1*a*) is affected little by deacylation (Fig. 1*b*), aside from the expected shift towards

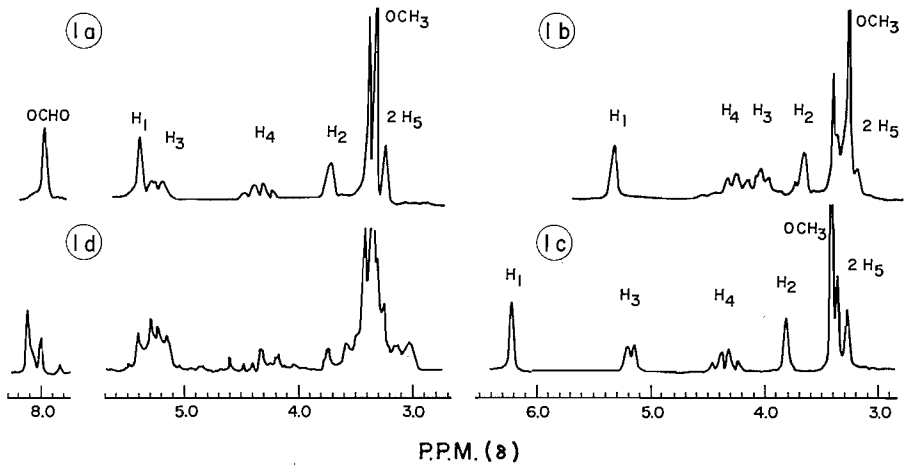


FIG. 1. The n.m.r. spectra of (*a*) 3-*O*-formyl-2-*O*-methyl-5-*O*-trityl-D-arabinose (VIB); (*b*) 2-*O*-methyl-5-*O*-trityl-D-arabinose (VII); (*c*) 1,3-di-*O*-acetyl-2-*O*-methyl-5-*O*-trityl-D-arabinose (signals for the acetyl protons are not shown); (*d*) the product (VIII) formed by oxidation with lead tetraacetate in benzene solution of 3-*O*-methyl-6-*O*-trityl-D-glucose.

higher field for the signal of the proton α to the formate group. If the oxidation product were acyclic (VIA), the gross conformational change inherent in its conversion into 2-*O*-methyl-5-*O*-trityl-D-arabinofuranose (VII) should surely be accompanied by greater differences than found between the spectra of these compounds. By contrast, the changes actually observed are those to be expected on simple deacylation of VI B to yield VII. Steric similarities between these latter two are emphasized further by acetylating VII. A n.m.r. spectrum is then obtained (Fig. 1*c*) that closely simulates the original spectrum (Fig. 1*a*), except that the H_1 signal has been shifted to lower field by the presence of the 1-acetoxy group.

Proton–proton coupling in Fig. 1*a* leads to the conclusion that H_3 of the oxidation product is located α to the formate group. The singlet at low field (5.4 p.p.m.) may be ascribed to H_1 (11)[2] and the singlet at 3.75 p.p.m. to its neighbor H_2, which appears at relatively high field because of the adjacent methoxyl group (12). Since H_2 is not coupled with H_3, the latter is undoubtedly the doublet at 5.25 p.p.m. which is split by coupling with H_4. Also, a proton situated at position-4 most readily accounts for the quartet at 4.40 p.p.m., since coupling is then permitted both with H_3 and the H_5 protons. Therefore, these data strongly support the conclusion that the product formed initially on oxidation of D-glucose is the 3-formate (III).

The oxidation of D-glucose to IV can be accounted for also by an alternative route whereby D-glucopyranose yields 4-*O*-formyl-D-arabinose, which then is converted into the 3-formate (III) by acyl migration (4).[3] This possibility could be favored even more with the trityl derivative (V), since migration of the formate from position-4 to position-3 (VIA $\rightarrow$ VIB) would permit ring closure. However, it is unlikely that such a transformation takes place, as shown by the following experiment in which V was treated with lead tetraacetate in benzene solution.

Since oxidations are much more rapid in benzene than in acetic acid (6), the pyranose form (VA) might itself be attacked in benzene with sufficient vigor to offset the displacement towards a furanose pathway, as presumably occurs in acetic acid. In fact, the product of oxidation in benzene (VIII) differs notably from the 3-formate (VIB), as seen in the contrast between its n.m.r. spectrum (Fig. 1*d*) and spectrum 1*a*. The major signal due to the formate proton is at slightly lower field in Fig. 1*d*; other signals are poorly resolved, with the broad multiplet at 3.3 p.p.m. accounting for about 7 of the remaining 10 protons. Relatively weak signals at 8.0, 5.4, 4.3, and 3.7 p.p.m., respectively (Fig. 1*d*), indicate that the 3-formate (VIB) is a minor constituent (about 25%) of this oxidation product. On deacylation, VIII yielded the same product as obtained from the 3-formate, i.e., VII (identified by chromatography and by the close identity of its n.m.r. spectrum with that shown in Fig. 1*b*). It is probable that VIII consists mainly of the 4-formate (VIA). Although VIII was not prepared in acetic acid, it was found to be quite stable in this solvent, showing that, if VIA had been produced by oxidation in acetic acid, it would not have rearranged readily to VIB. Therefore, a 3-formate must be derived from the D-glucose ether (V) and, undoubtedly, also from D-glucose itself by the initial cleavage of the α-hydroxy hemiacetal group in acetic acid.

Further evidence that D-glucose is oxidized in acetic acid via a reactive intermediate such as II is provided by examining the effect of dilution on the rates of cleavage of different *vic*-diols (Table I). The rate for the acyclic 3,4-diol group of 1,2:5,6-di-*O*-isopropylidene-D-mannitol is lowered by a factor of about 100 on dilution of the reaction mixture

[2]*This is supported by the effect of acetylation on the original (Fig. 1c) (12).*
[3]*This alternative has been regarded as highly likely (13).*

4,6-*O*-Ethylidene-D-mannose	8.5	0.2	42

*Time required for uptake of 0.5 mole of lead tetraacetate per mole.
†Concentration of diol; the lead tetraacetate was present in 20% molar excess.
‡min^{-1} $mole^{-1}$ l; measured under the more dilute conditions.

100-fold. Similarly, a large decrease in rate is shown for D-glucopyranose when a change of ring size is prohibited, as with maltose or cellobiose (the reducing end-unit of which is oxidized preferentially (10)). By contrast, the rate of scission of the 1,2-diol group of 3-*O*-methyl-D-glucose is lowered by a factor of only 3.5 upon dilution.[4] This latter oxidation is controlled, not by the glycol cleavage step, but by the availability of some reactive species formed in an equilibrium displacement. That D-glucofuranose could function as such a species is suggested by the extreme reactivity of 3,5-di-*O*-methyl-D-glucofuranose compared with pyranose derivatives, its second-order rate constant being about 60 times that of even the 3-*O*-methyl derivative. With reactivity of this order, there need only be a small proportion of D-glucofuranose in the sugar solution to ensure its preferential oxidation in the presence of the dominant pyranose form. The ensuing equilibrium displacement step should be much less sensitive to a change in concentration than is the bimolecular oxidation step.

The reaction of D-mannose (IX) with lead tetraacetate contrasts sharply with that of D-glucose. Oxidation proceeds rapidly to a value of 2.8 moles per mole (4) and the product is chiefly di-*O*-formyl-D-glycerose (XII), with D-erythrose diformate (XI) being only a minor product. The oxidation is initiated primarily at the α-hydroxy hemiacetal group, as shown by the high yield of D-arabinose monoformate produced by limited oxidation (4). In addition, when D-mannose-1-^{14}C or -2-^{14}C is treated with 2.7 moles of lead tetraacetate per mole, products XI and XII account for almost all of the carbon-14, i.e.,

D-Mannose-1-^{14}C → products XI and XII,
(77 mμc/mmole CO_2) (76 mμc/mmole CO_2)

D-Mannose-2-^{14}C → products XI and XII.
(133 mμc/mmole CO_2) (126 mμc/mmole CO_2)

These results are readily explicable if the major reaction pathway proceeds in stepwise fashion, yielding at first 4-*O*-formyl-D-arabinose (X),[5] then 3,4-di-*O*-formyl-D-erythrose (XI), and finally the triose diformate (XII). Carbon-1 and carbon-2 of the original

[4]*Although not strictly comparable because of the overall greater uptake of oxidant involved, the reaction of* D-*glucose itself illustrates this same behavior. Thus, the time required for an uptake of 0.5 mole/mole is extended, on dilution, by a factor of only five.*

[5]*It was concluded earlier that 4-O-formyl-*D-*arabinose (X) cannot be the product formed initially in the oxidation of* D-*glucose. This is consistent with the oxidative behavior of* D-*mannose, for otherwise the two epimeric sugars should show the same overall reaction pattern.*

hexose are then retained in XII and carbon-3 is liberated.[6]

According to these data, a furanose pathway plays only a minor role in the oxidation of D-mannose. Nevertheless, D-mannofuranose should be highly reactive because it contains a *cis*-2,3-diol group on a five-membered ring, in addition to that potentially available at C-1 and C-2. As a model compound, 5-*O*-methyl-D-mannofuranose (14) was found to consume 1 mole of lead tetraacetate per mole very rapidly (k_{27} for this stage in dilute solution was estimated to be about 65 000) and additional oxidant much more slowly. Although acetal formation (15) and borate complexing (8) favor the 2,3- over the 1,2-diol group of D-mannofuranose, oxidation occurred chiefly at the 1,2-positions, since a pentose derivative was produced in 60% yield. Almost identical behavior was shown by 5-*O*-methyl-D-glucofuranose, in which the 2,3-diol group is *trans*. Clearly, then, the oxidation behavior of D-mannose itself cannot be reconciled with a high proportion of a furanose pathway, for the overall reaction should resemble more closely that of D-glucose.

Two other observations are consistent with a pyranose pathway predominantly for the D-mannose oxidation: the effect on reaction rates of (*a*) substitution at C-4, and (*b*) dilution. 4,6-*O*-Ethylidene-D-mannose[7] is oxidized at a rate comparable with that of the parent hexose both at low and high dilution, in marked contrast to the strong retarding effect of the same type of bicyclic system in the D-glucose series (Table I). In addition, a 100-fold dilution of the reaction mixture lowers the oxidation rate of D-mannose much more than that of D-glucose, showing that different types of pathways are operative for the two sugars.

The effect of a large change in concentration is seen in yet another way. The rapid uptake of 2.8 moles per mole by D-mannose (reported earlier) was measured at the higher concentration (ca. 10^{-2} *M*). Although this level of oxidation is reached with the more dilute reaction mixture (10^{-4} *M*), there is a marked decrease in rate after about 2 moles per mole have been taken up (Fig. 2). With the 4,6-*O*-ethylidene derivative there is also a sharp break in the curve, but this occurs at a level of 1 mole per mole. The 6-deoxy sugar (L-rhamnose) has been shown to consume rapidly about the same proportion of oxidant as does D-mannose (4). In dilute solution, its behavior is more akin to that of the *O*-ethylidene derivative. It is probable that the more rapid phases of these reactions involve cyclic forms of the sugars, and that the slower oxidations involve acyclic products (16). Thus, D-mannose and 4-*O*-formyl-D-arabinose (X) could together account for the rapid uptake of 2 moles per mole, whereas the resulting α-hydroxy aldehyde 3,4-di-*O*-formyl-D-erythrose (XI)[8] would be oxidized in the slow step. Similarly, *aldehydo* derivatives are produced by the initial degradation of 4,6-*O*-ethylidene-D-mannose to 3,5-*O*-ethylidene-4-*O*-formyl-D-arabinose (chromatographic evidence confirms a pentose product exclusively in this reaction) and of L-rhamnose to a 4-formate of 5-deoxy-L-lyxose. This could account for the rapid uptake of only 1 mole per mole by these latter sugars. By contrast, well-defined stages of this kind are not observed in the oxidation of D-glucose or of 6-substituted derivatives of it under the same conditions; however, no oxidizable acyclic products are expected in these reactions. D-Glucofuranose 5,6-carbonate, which initially should yield a 3,4,5-trisubstituted *aldehydo*-pentose,[9] is characterized by a two-

[6]*If the total reaction proceeds in this way, the product should actually be slightly more radioactive than the original hexose, since one unlabelled carbon atom would be lost as formic acid in the formation of XII.*

[7]*This derivative was kindly provided by Dr. D. M. Ball.*

[8]*At this stage, in fact, degradation has produced mainly tetrose formate, and very little triose formate has appeared. This was shown by chromatographic examination of the product formed on treating* D-*mannose with only 2 molar equivalents of lead tetraacetate under these dilute conditions.*

[9]*By oxidation of the hexose carbonate with 1 molar equivalent of lead tetraacetate,* D-*arabinose carbonate is obtained in high yield (17).*

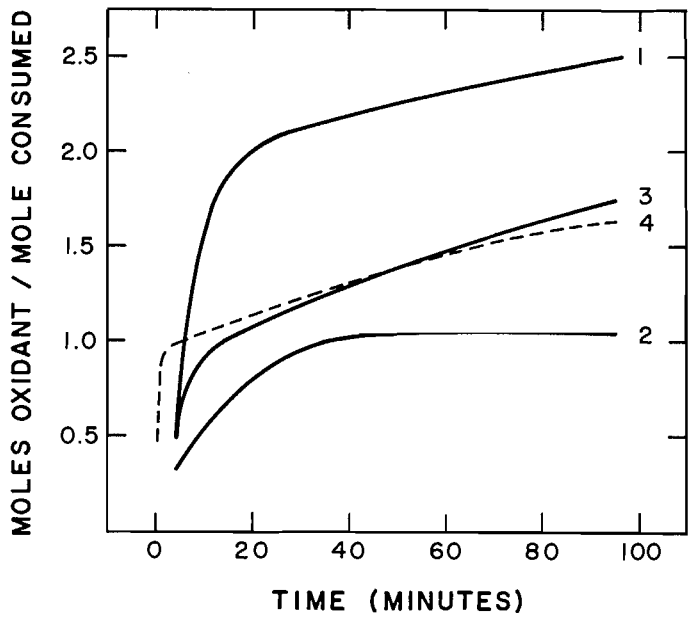

FIG. 2. Rates of lead tetraacetate consumption at high dilution (ca. 10^{-4} *M*) of (1) D-mannose; (2) 4,6-*O*-ethylidene-D-mannose; (3) 6-deoxy-L-mannose; (4) D-glucofuranose 5,6-carbonate (closely similar curves are given by D-erythrose and D-threose).

stage reaction. It is noteworthy that this latter curve is closely paralleled by those for D-erythrose and D-threose, each of which should afford an α-hydroxy aldehyde, viz. 3-*O*-formyl-D-glycerose.

The overall consistency of these different types of data leads to the conclusion that the oxidation of D-glucose in acetic acid involves preferential attack on D-glucofuranose or formation of a furanose intermediate, whereas, in the oxidation of D-mannose a pyranose form is involved chiefly. Apparently, the relative inertness of D-glucopyranose permits an equilibrium displacement in favor of the furanose pathway. However, even glucopyranose can be relatively reactive as compared with other kinds of monocyclic six-membered ring compounds; for example, the reducing unit of maltose or cellobiose is oxidized far more rapidly than is the nonreducing end-unit (10). D-Mannopyranose is a remarkably reactive monocyclic six-membered ring diol. This property of reducing sugars would not be predicted on steric grounds by comparing molecular models of pyranose forms with those of glycopyranosides and related cyclic polyhydric alcohols. In a free sugar, however, the unshared electron pair of the ring oxygen atom could aid materially in attracting the strongly electrophilic tetravalent lead atom towards the 1,2-diol group, increasing the effective concentration of oxidant about this region of the molecule. The models suggest that an orienting influence of this kind should be particularly noticeable with β-D-mannopyranose, the 1- and 2-oxygen atoms of which lie relatively close to the ring oxygen atom, but less so with α-D-glucopyranose (in accord with the higher reactivity of D-mannose).

Oxidation of Other Aldohexoses

The six other aldohexoses rapidly consume lead tetraacetate in proportions ranging between the values for D-glucose and D-mannose (4, 5) (Table II). Their oxidations have not been examined as extensively as those of the latter two sugars. A high yield of pentose

formate obtained by partial oxidation of D-galactose, D-allose, or D-altrose (4, 5) shows that these sugars are degraded preferentially in stepwise fashion from the reducing end. Di-*O*-formyl-D-threose is the major product obtained from D-galactose, consistent with a lead tetraacetate uptake of slightly over 2 moles per mole, whereas D-altrose, which consumes 2.5 moles per mole, affords about equimolar amounts of triose and tetrose formates.

The amounts of lead tetraacetate consumed in the oxidation of these aldohexoses may be interpreted in terms of the proportions of furanose and pyranose forms that have reacted. For example, D-idose consumes 2.1 moles of lead tetraacetate per mole, only slightly more than does D-glucose, so that its oxidation pathway probably involves chiefly a furanose form. It is noteworthy that the relative orientation of the 1-, 2-, and 3-hydroxyl groups and of C-5 in β-D-idofuranose is the same as in α-D-glucofuranose. This marked steric resemblance was emphasized by Isbell (19) in noting that these forms may be assigned the α-L-*xylo* and α-D-*xylo* configurations, respectively. Since there is little effective competition from a pyranose route in the oxidation of idose, the relative unreactivity of α-D-idopyranose is analogous to that of α-D-glucopyranose.[10] There are some notable steric similarities between these two forms. For example, in the two chair conformations (20) considered, the orientation of all substituents other than that of the C-6 carbinol groups is the same. On balance, free-energy changes accompanying the formation of the activated complexes could be lower by approximately the same amount for each furanose pathway than for each pyranose pathway, thus favoring the same oxidation pattern for the two aldohexoses.

This type of comparison, based on similar oxidation patterns and configurational resemblance, permits pairing of D-gulose with D-mannose. D-Allose and D-talose constitute a third pair for which there is good agreement, but the analogy does not hold as closely for the pair D-galactose and D-altrose.

The pyranose conformation listed for each sugar in Table II is chosen to emphasize similarities, and does not necessarily represent the most stable ground state of the individual compounds (20–24). Probably, this factor is not significant in some of the oxidations, since energy barriers separating conformers (23, 24) are small relative to, for example,

[10]*It is assumed that 1,2-cis-anomers of pyranose or furanose sugars are more likely to be attacked in these oxidations than are 1,2-trans-anomers.*

heats of reaction of lead tetraacetate oxidations (25, 26, 27). However, in an instance where both furanose and pyranose pathways are prominent (most notably, the oxidation of D-altrose), it could substantially affect the outcome, since this is dependent on the *difference* between overall free-energy changes for the competing pathways.

EXPERIMENTAL

Lead tetraacetate uptake was measured iodometrically (1, 2) with reaction mixtures in which the concentration of reactants was about 10^{-2} *M*, and spectrophotometrically (28) with reaction mixtures in which the concentration of reactants was about 10^{-4} *M*.

Proton magnetic resonance (n.m.r.) spectra were measured with a Varian A-60 high-resolution spectrometer, using chloroform or deuterochloroform as solvent and tetramethylsilane as internal standard. When the compound to be examined contained a free hydroxyl group, a preliminary deuterium exchange was carried out by shaking the chloroform solution twice with deuterium oxide.

Specific activity measurements were made by combustion analysis according to the procedure of Buchanan and Nakao (29).

Solutions were concentrated *in vacuo* at 40–45 °C.

*3-O-Methyl-6-O-trityl-*D*-glucose (V)*

3-*O*-Methyl-D-glucose (2.0 g) in pyridine (20 ml) was treated with chlorotriphenylmethane (3.4 g) at 3 °C for 18 h. Ice water was added, the syrupy deposit was extracted into chloroform, and the chloroform layer was washed well with water, dried, and concentrated. After being dried thoroughly in a high vacuum, the syrupy product was applied in chloroform solution (25 ml) to a column of dry silicic acid (4 cm × 40 cm). The column was developed with chloroform, fractions of the eluate being examined by thin-layer chromatography (solvent—benzene:methanol (9:1); spray—30% sulphuric acid; all products containing the trityl group gave a bright yellow color, whereas that also containing the sugar residue charred when the chromatogram was heated). Chromatographically pure material isolated was extracted into benzene, and the extract was concentrated, yielding a white solid (3.3 g); $[\alpha]_D$ 35° (*c*, 2, benzene).

Calcd. for $C_{26}H_{28}O_6$: C, 71.54; H, 6.47. Found: C, 71.81; H, 6.34.

*1,2,4-Tri-O-acetyl-3-O-methyl-6-O-trityl-β-*D*-glucose*

In a second preparation of V, on twice the scale above, additional pyridine (20 ml) and acetic anhydride (20 ml) were added to the reaction mixture at 48 h, and the solution was stored at 3 °C for a further 48 h. Ice water was added; the syrupy deposit was extracted into benzene; and the benzene extract was washed successively with cold sodium bicarbonate solution, cold tartaric acid solution, and water; then dried, and concentrated. The residue afforded crystalline material (2.8 g) from ethanol; m.p. 173–175 °C, $[\alpha]_D$ 18° (*c*, 2, chloroform.

Calcd. for $C_{32}H_{34}O_9$: C, 68.31; H, 6.09. Found: C, 68.57; H, 6.20.

*Lead Tetraacetate Oxidation of 3-O-Methyl-6-O-trityl-*D*-glucose (V)*

(*A*) To a solution of V in acetic acid (165 mg, 5 ml) was added an acetic acid solution of lead tetraacetate (7 ml; 160 mg (0.95 molar equivalents)). After 10 min reaction time, when a negative test was given for tetravalent lead, the solution was concentrated and the residue was extracted with benzene. The extract was washed three times with ice water, dried, and concentrated to a syrup (120 mg); $[\alpha]_D$ 20.6° (*c*, 3.3, methanol). The syrupy product (VI) absorbed strongly in the infrared region at 1725 and 1175 cm^{-1}, characteristic of a formate ester group; the n.m.r. spectrum is reproduced in Fig. 1*a*.

The oxidation product was taken up in methanol and treated with a slight excess of sodium methoxide; the calculated $[\alpha]_D$ of the deacylated product (VII) was 17.9°. Absorption bands in the infrared region due to a formate group were no longer detectable; otherwise, the spectra of VI and VII were virtually indistinguishable. The n.m.r. spectrum of VII is reproduced in Fig. 1*b*.

(*B*) A solution of V in dry benzene (100 mg; 5 ml) was treated with lead tetraacetate (92 mg) in dry benzene containing 2% of acetic acid (4 ml). A precipitate formed immediately, and a negative test for tetravalent lead was obtained within 30 s. The filtrate from the suspension was concentrated to yield a syrup (VIII) (80 mg), $[\alpha]_D$ − 4.0° (*c*, 3.7, chloroform), which was shown by infrared spectroscopy to contain a formate ester group; the n.m.r. spectrum is reproduced in Fig. 1*d*. After deacylation with sodium methoxide, the product gave an n.m.r. spectrum essentially the same as that shown in Fig. 1*b*. In another experiment, product VIII was stored for several hours as a solution in acetic acid. After removal of the solvent, the n.m.r. spectrum was indistinguishable from that shown in Fig. 1*d*.

*1,3-Di-O-acetyl-2-O-methyl-5-O-trityl-*D*-arabinose*

The deacylated oxidation product (VII) was taken up in a mixed solvent of pyridine and acetic anhydride (3 vol.:2 vol.), the solution was stored at 3 °C for 48 h and then poured into ice water. The syrupy deposit was extracted into benzene, the extract was washed with cold sodium bicarbonate solution, cold tartaric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

acid solution, and ice water, and dried. Removal of the benzene afforded a colorless syrup, $[\alpha]_D$ 46° (*c*, 2.2, acetone).

Calcd. for $C_{29}H_{30}O_7$: C, 71.00; H, 6.16. Found: C, 71.19; H, 6.21.

*3,4-O-Isopropylidene-2-O-methyl-*D*-arabinose (30)*

2-*O*-Methyl-5-*O*-trityl-D-arabinose (VII) (120 mg; about one-half of this sample was derived from VIB and one-half from VIII) was taken up in acetone (5 ml), one drop of concentrated hydrochloric acid was added, and the solution was stored at 3 °C for 72 h. Excess lead carbonate was added, followed by water (10 ml); the neutral suspension was filtered, the filtrate was concentrated, and the residue was extracted with acetone. The acetone-soluble product (52 mg) solidified; m.p. 116–119 °C; $[\alpha]_D$ −107° (*c*, 2.5, methanol; no mutarotation observed).

D-*Mannose-2-*^{14}*C*

D-Mannose-2-^{14}C was prepared from D-mannono-1,4-lactone-2-^{14}C (kindly furnished by A. C. Neish) by reduction with sodium borohydride in the presence of Amberlite-IR-120 (H^+), according to the procedure of Frush and Isbell (31).

Lead Tetraacetate Oxidation of D-*Mannose or* D-*Mannose-*^{14}*C*

In a typical experiment, D-mannose (250 mg) in water (0.3 ml) was taken up in acetic acid (15 ml). A solution of lead tetraacetate (1.7 g; 2.7 molar equivalents) in acetic acid (50 ml) was added to the sugar solution over a period of 15 min, and this was followed 10 min later by a solution of oxalic acid (0.3 g) in acetic acid (5 ml). The precipitate of lead oxalate was filtered off through Celite, the filtrate was concentrated, and the residue was extracted with ethyl acetate. On being concentrated, the extract yielded a syrup which was purified by distillation (bath temp. 140 °C at 0.05 mm).

Samples of the syrup, after reduction with excess sodium borohydride, gave a mixture consisting mainly of erythritol and glyceritol (paper chromatographic evidence). These products were estimated, after elution from the chromatograms, by treatment with periodate, followed by analysis of the formaldehyde produced on oxidation (32). The ratio of erythritol to glyceritol was 6.8 to 3.2.

In experiments with D-mannose-^{14}C, the distilled oxidation product was used for the specific activity measurements.

*5-O-Methyl-*D*-glucose and 5-O-Methyl-*D*-mannose (2,5-dichlorophenyl) Hydrazones*

The 5-*O*-methyl sugars were prepared as chromatographically pure syrups by procedures described elsewhere (14, 33). By treatment with a methanolic solution of (2,5-dichlorophenyl) hydrazine (34), each sugar yielded a solid product that was recrystallized from ethyl acetate – benzene.

The substituted hydrazone of 5-*O*-methyl-D-glucose had m.p. 140–142 °C.

Calcd. for $C_{13}H_{18}Cl_3N_2O_5$: C, 44.20; H, 5.10. Found: C, 44.00; H, 5.31.

An attempt to prepare the dichlorophenylosazone by use of excess reagent and a longer reflux period, as with D-erythrose (35), was unsuccessful, only the substituted hydrazone being obtained in this experiment.

The substituted hydrazone of 5-*O*-methyl-D-mannose, m.p. 129–130 °C, contained benzene as solvent of crystallization (its presence being detected by gas–liquid chromatographic analysis of a concentrated solution of the hydrazone in methyl sulphoxide).

Calcd. for $C_{13}H_{18}Cl_2N_2O_5 \cdot O \cdot 5C_6H_6$: C, 48.99; H, 5.40; Cl, 18.08. Found: C, 49.00; H, 5.75; Cl, 18.47.

*Lead Tetraacetate Oxidation of 5-O-Methyl-*D*-glucose and -mannose*

The sugar derivative (10 mg) in acetic acid (1 ml) was treated with lead tetraacetate (22 mg) in acetic acid (1 ml) for 10 min; a negative test for tetravalent lead was given within this period. Water (5 ml) was added to the reaction mixture followed by excess of Amberlite-IR-120 (H^+), and the solution was warmed on the steam bath for 0.5 h, concentrated, and examined chromatographically. Three products were detected, the major component being indistinguishable from 4-*O* methyl-D-arabinose (unpublished preparation). Based on the intensity of color developed by the latter with the orcinol ferric chloride reagent for pentose (36), the yield of 4-*O*-methyl-D-arabinose produced in the oxidation of each 5-*O*-methyl hexose was estimated to be 57% (D-gluco isomer) and 60% (D-manno isomer).

When the sugar was treated at high dilution with 2 molar equivalents of lead tetraacetate, the uptake of oxidant (moles/mole) was as follows:

Time (min)	2	5	10	15	25
5-*O*-Methyl-D-glucose	0.83	1.00	1.18	1.27	1.36
5-*O*-Methyl-D-mannose	0.95	1.10	1.20	1.30	1.40

Measurement of lead tetraacetate uptake by 5-*O*-methyl-D-mannose at the outset of the reaction gave the following data, calculated as second-order rate constants (min^{-1} $mole^{-1}$ l) at 27 °C: 67 900 (0.20 min); 70 900 (0.25 min); 64 100 (0.30 min); 54 100 (0.40 min).

THE REARRANGEMENT OF 2,4-DIMETHYLTHIAZOLE 3-OXIDE WITH ACETIC ANHYDRIDE

HUGH J. ANDERSON, DOUGLAS J. BARNES, AND (IN PART) ZAHIR M. KHAN
Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received May 28, 1964

ABSTRACT

The rearrangement in acetic anhydride of 2,4-dimethylthiazole 3-oxide has been found to produce 2-acetoxymethyl-4-methylthiazole and 4-acetoxymethyl-2-methylthiazole in the ratio of about 4.5 to 1. The same type of rearrangement with 4-methylthiazole 3-oxide gave both 4-acetoxymethylthiazole and 2-acetoxy-4-methylthiazole, but in poor yields. The structure of the sulphate salt of 2,4-dimethylthiazole 3-oxide has been established.

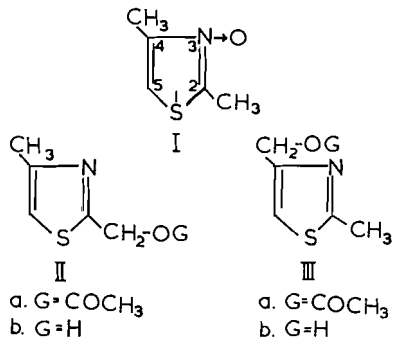
The rearrangement in acetic anhydride of 2- and 4-picoline 1-oxide (1) to the corresponding acetoxymethylpyridine has been used widely for the synthesis of oxygenated side chains. It has also been used extensively with more highly substituted pyridine 1-oxides as well as with the N-oxides of the other six-membered ring heterocycles (2). Rearrangements to form a heterocycle with an acetoxyl group in an open 2- or 3-position also take place readily with these heterocycles (2, 3).

Although several N-oxides have been prepared in the thiazole series (4), no previous investigation has been reported of their behavior in the acetic anhydride rearrangement. 2,4-Dimethylthiazole 3-oxide (I) rearranges with *p*-toluenesulphonyl chloride to give a good yield of 2-chloromethyl-4-methylthiazole (5). This agrees with other observations of the much greater activity of the 2-methyl than of the 4-methyl group in thiazoles. Bond fixation and variation of the degree of conjugation have been suggested as the cause (6).

While various 2-substituted thiazoles may be synthesized from available 2-aminothiazoles through diazonium and other reactions, none leads easily to compounds containing oxygenated side chains in the 2-position. It was hoped that the acetic anhydride rearrangement of the 3-oxide of the commercially available 2,4-dimethylthiazole might provide a satisfactory path to these compounds. The behavior of 4-methylthiazole 3-oxide under these conditions was also investigated.

By use of the standard preparative procedure (7) 2,4-dimethylthiazole 3-oxide (I) could be prepared in good yield and vacuum distilled to give a white, crystalline, but very hygroscopic solid of low melting point. If the crude product was left standing for some time a white solid of higher melting point could be obtained. This proved to be a sulphate salt of the N-oxide, whose structure is discussed below. Partial oxidative destruction of the ring must have produced a small amount of sulphuric acid to form this salt.

The crude N-oxide could be rearranged to give about the same overall yield of product as the distilled material. Distillation often gave extensive decomposition, so most rearrangements were carried out directly from the crude product. Vacuum distillation of the product gave a colorless oil which showed two peaks on gas–liquid partition chromatography of area ratio about 4.5 to 1. Similarly the nuclear magnetic resonance (n.m.r.) spectrum of the mixture, on integration, showed about 17% of the minor isomer to be present and no other impurities.



Chemical shifts (Table I) were consistent with the assignment of the structure of the major isomer as 2-acetoxymethyl-4-methylthiazole (II*a*) and the minor as 4-acetoxymethyl-2-methylthiazole (III*a*). It was possible to isolate the picrate of the major isomer directly from the mixture. Column chromatography on neutral alumina enabled concentration of the minor isomer. A second chromatography of the concentrate produced a small amount of the minor isomer showing less than 10% of the major isomer by gas chromatography and by n.m.r. Although a picrate was obtained, it could not be recrystallized without some decomposition, consequently its analysis was close, but unsatisfactory. Attempts to prepare other derivatives were also unsuccessful. Thus positive identification is based on the n.m.r. spectrum.

Hydrolysis of the acetoxymethyl mixture provided a good yield of a mixture of roughly the same proportions of the corresponding hydroxymethyl isomers II*b* and III*b*. Again n.m.r. supported the assigned structures. The picrate of the major isomer, the known 2-hydroxymethyl-4-methylthiazole (8), was prepared from the mixture. Oxidation of the mixture of hydroxymethyl isomers with alkaline permanganate gave a poor yield of the known 4-methyl-2-thiazolecarboxylic acid. Milder oxidation gave the corresponding 4-methyl-2-thiazolecarboxaldehyde, identified through its known thiosemicarbazone and *p*-nitrophenylhydrazone. A second N-oxidation followed by rearrangement has been found useful in the picoline series (1), but our attempts led to a complex mixture of compounds from which no recognizable pure substance could be isolated.

The usual as well as a wide variation of oxidation conditions gave a low yield of the known 4-methylthiazole 3-oxide (3). Rearrangement in acetic anhydride produced a mixture of products containing both 4-acetoxymethylthiazole and 2-acetoxy-4-methylthiazole. Gas–liquid partition chromatography showed only two peaks. Hydrolysis of the mixture produced a small amount of the known 2-hydroxy-4-methylthiazole, while careful oxidation of the residual hydrolysis product gave some of the known 4-thiazolecarboxylic acid. Because of the low yields throughout we abandoned further investigation.

The white solid by-product from the preparation of 2,4-dimethylthiazole 3-oxide analyzed correctly for $(C_5H_7NOS)_2.H_2SO_4$. It dissolved in water and gave a white precipitate with barium chloride solution in dilute nitric acid. The acetic anhydride rearrangement proceeded from this sulphate. It also gave the picrate of 2,4-dimethylthiazole 3-oxide.

N-Oxides in the pyridine series form two types of salts with monobasic acids, having structures which may be symbolized as

$$(\text{Het.}\overset{+}{\text{N}}\text{—O—H})\ \text{An}^- \qquad (\text{Het.N—O}\cdots\text{H}\cdots\text{O—NHet.})^+\ \text{An}^-$$

TABLE II

Chemical shifts in dimethyl sulphoxide

Compound	2 – CH_3	4 – CH_3	5 – H
2,4-Dimethylthiazole	2.68	2.39	7.12
Sulphate salt	2.91	2.50	7.64
I	2.50	2.28	7.51
I sulphate salt	2.67	2.33	7.70

characterized by both infrared and n.m.r spectra (9, 10, 11). Although our sulphate is the salt of a dibasic acid and could form structures of either type:

$$(\mathrm{Thz.\overset{+}{N}—O—H)_2SO_4^{=}} \quad \text{or} \quad (\mathrm{Thz.N—O\cdots H\cdots O—NThz.)^{+}HSO_4^{-}},$$

Va Vb

it has been possible to assign to it structure V*a*. A very wide and intense band from 1800 to 2300 cm^{-1}, characteristic of the IV*a* type in the solid state (9, 10), was found in the infrared. This is the O—H stretching frequency found to be dependent on the anion of the salt. Although there are no recorded spectra of sulphate salts of N-oxides in the pyridine series the absorption pattern lies close to that of a bromide of the IV*a* type. The medium N—O band at 1249 cm^{-1} in the free 2,4-dimethylthiazole 3-oxide was diminished to a weak one at 1260 cm^{-1} in the sulphate salt.

In the pyridine series the strongest acids, such as perchloric and hydriodic, form salts of the IV*b* type while weaker acids, such as hydrochloric and hydrobromic, tend to form type IV*a*.

Infrared spectra indicate that type IV*b* salts are converted into IV*a* type in polar solvents. This is especially true for the strong proton acceptor dimethyl sulphoxide (DMSO) (10). The n.m.r. spectrum in $CDCl_3$ of a type IV*b* salt shows two different sets of signals for the picoline nuclear and methyl protons, indicating that the proton is not shared equally in this solvent. Because of the insolubility of the salt its n.m.r. spectrum was determined in DMSO (Table II). Only one set of signals was found where the acidic protons shifted strongly with dilution while the rest changed only slightly. For comparison, 2,4-dimethylthiazole 3-oxide was run in DMSO as well as 2,4-dimethylthiazole and its sulphate salt. Salt formation caused changes in chemical shifts qualitatively similar in the two compounds but about twice as large for the thiazole as for its N-oxide. Thus oxygen aids in dispersing the positive charge. There is a remarkably specific deshielding effect on the 5-proton in DMSO compared to carbon tetrachloride for both 2,4-dimethylthiazole and its 3-oxide. It has been pointed out before that the 5-proton of thiazole is the most susceptible to solvent effects (12).

EXPERIMENTAL

General

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Infrared spectra were recorded by a Unicam SP100 spectrophotometer using the potassium chloride disk technique (2 mg of sample in 200 mg KCl) or as capillary films.

The nuclear magnetic resonance spectra were determined at 60 Mc/s. The chemical shifts are in p.p.m. from tetramethylsilane as internal reference in carbon tetrachloride. In dimethyl sulphoxide the solvent peak was taken as 2.62 p.p.m. and used as internal reference.

Elemental analyses were determined by Alfred Bernhardt, Mulheim (Ruhr), Germany.

2,4-Dimethylthiazole 3-Oxide (I)

A mixture of 2,4-dimethylthiazole (22.5 g, 0.02 mole), 140 ml glacial acetic acid, and 25 ml hydrogen peroxide solution (30% w/v) was heated at 75–80° for 4 h in an oil bath. A further 20 ml of hydrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

peroxide solution was added and heating continued for 17 h. The mixture was concentrated in a flash evaporator to about 50 ml, an equal volume of water was added, and the solution again was concentrated to a yellow syrup containing white crystalline material. This was taken up in 150 ml chloroform and was neutralized with a saturated aqueous solution of potassium carbonate. The chloroform layer was removed and dried with anhydrous sodium sulphate. The chloroform was then removed under vacuum. The residual oil was vacuum distilled, b.p. 104–105° at 1.0 mm; yield 14 g (55%) of oily, white solid with a melting point below 45° (from pentane) and very hygroscopic. Picrate (from ethanol); m.p. 151–152°, literature m.p. 149–152° (4).

Sulphate of I

A sample of crude N-oxide which had stood for some time contained a solid which was insoluble in dioxane and which could be recrystallized from isopropyl alcohol or pentane to colorless crystals, m.p. 124–125°. The solid was very soluble in water giving an acidic solution.

Anal. Calcd. for $C_{10}H_{16}N_2O_6S_3$: C, 33.70; H, 4.53; N, 7.87; S, 26.99. Found: C, 33.92; H, 4.35; N, 7.77; S, 27.04.

Rearrangement of 2,4-Dimethylthiazole 3-Oxide

The crude 2,4-dimethylthiazole 3-oxide (14.0 g) was added slowly to gently boiling acetic anhydride (40 ml). As soon as the reaction began, external heat was removed and the reaction proceeded vigorously. After addition was complete, the solution was refluxed for a further 20 min. Vacuum distillation gave a forerun of acetic anhydride followed by 15.0 g of a pale yellow oil, b.p. 80–82° at 1.5 mm. Gas–liquid partition chromatography of the product was carried out on a 30 in. column (Beckman No. 70 007) of Carbowax 4000 dioleate on firebrick operated at 190° with helium as the carrier gas at inlet pressure of 30 p.s.i.g. This showed two peaks in area ratio of 80–84% and 16–20%. The nuclear magnetic resonance spectrum showed, by integration, about 17% of the minor isomer present in the mixture. Chemical shifts were consistent with assignment of structures (see Table I). The major isomer was 2-acetoxymethyl-4-methylthiazole (II*a*). Picrate (from methanol): m.p. 84–85° was made from the mixed oil.

Anal. Calcd. for $C_{13}H_{12}N_4O_9S$: C, 39.10; H, 2.78; N, 14.03; S, 8.03. Found: C, 39.21; H, 2.96; N, 13.85; S, 8.09.

The minor isomer was 4-acetoxymethyl-2-methylthiazole (III*a*). It was concentrated by column chromatography of the mixture on neutral alumina (Woelm, activity grade I) to about 90% purity. From this mixture a picrate was obtained; m.p. 74–79° (from methanol), decomposed by recrystallization.

Hydrolysis of Rearrangement Product

The mixture of acetoxymethyl compounds (15 g) was dissolved in 100 ml 6 *N* hydrochloric acid, refluxed 1 h, cooled, and neutralized with 6 *N* sodium hydroxide solution. It was extracted with ether and the extract dried over sodium sulphate. After distillation of the ether, a pale yellow oil (8.0 g, 70%) was vacuum distilled at 92–93° and 1.0 mm. Literature boiling point for 2-hydroxymethyl-4-methylthiazole (II*b*) is 86° at 1 mm (8) and for 4-hydroxymethyl-2-methylthiazole (III*b*), 104° at 5 mm (13). Nuclear magnetic resonance spectrum (see Table I) showed, by integration, about 85% II*b* and 15% III*b*. Chemical shifts agreed with assigned structures. Picrate of the major isomer, 2-hydroxymethyl-4-methylthiazole, (from ethanol); m.p. 126–127°, literature m.p. 132° (11).

Anal. Calcd. for $C_{11}H_{10}N_4O_8S$: C, 36.98; H, 2.84; N, 15.69; S, 8.89. Found: C, 37.13; H, 2.78; N, 15.55; S, 8.82.

4-Methyl-2-thiazolecarboxylic Acid

To a suspension of the above mixture of hydroxymethyl isomers (II*b* and III*b*) in 20 ml 2.5% aqueous sodium carbonate solution was added slowly 40 ml 5% aqueous potassium permanganate solution during continuous shaking of the suspension at room temperature over 25 min. After a further 15 min the solution was filtered and the pH adjusted to 2 by addition of 10% hydrochloric acid (14). From a chloroform extract of the solution about 8% yield of 4-methyl-2-thiazolecarboxylic acid was obtained; m.p. 95–95.5° (pentane), literature m.p. 99° (15). The acid decarboxylated easily to an oil whose picrate was undepressed in mixed melting point with an authentic specimen of the picrate of 4-methylthiazole.

4-Methyl-2-thiazolecarboxaldehyde

Sodium dichromate (4 g) was dissolved in a solution of the mixture (5 g) of hydroxymethyl isomers (II*b* and III*b*) in 32 ml 6 *N* acetic acid. After 1 h at 75° the reaction mixture was cooled and, after addition of 10 g ice, neutralized with 10% aqueous sodium hydroxide. The solution was extracted with ether, the extract was dried, and the ether was removed. A liquid was vacuum distilled giving 2 g of oil; b.p. 64° at 17 mm, n_D^{25} 1.5018. Thiosemicarbazone of 4-methyl-2-thiazolecarboxaldehyde; m.p. 223° (decomp.), literature m.p. 224° (decomp.) (14). *p*-Nitrophenylhydrazone of 4-methyl-2-thiazolecarboxaldehyde (from ethanol); m.p. 195–196°, literature m.p. 195° (15).

Anal. Calcd. for $C_{11}H_{10}N_4O_2S$: C, 50.37; H, 3.81; S, 12.23. Found: C, 50.48; H, 3.78; S, 11.92.

4-Methylthiazole 3-Oxide

Following the procedure of Whitman (17) for pyridine N-oxide, 10 ml 35% hydrogen peroxide solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was added to a vigorously stirred mixture of 4-methylthiazole (1g) (16), glacial acetic acid (35 ml), and tungstic acid (2.5 g) at a temperature of 55°. After the mixture was stirred for 5 h at 60–65°, the product was filtered and worked up. A yield of 2.5 g crude 4-methylthiazole N-oxide was obtained. Attempted vacuum distillation led to rapid decomposition. Picrate (from methanol); m.p. 127–129°, literature m.p. 130–132° (4).

Rearrangement of 4-Methylthiazole 3-Oxide

4-Methylthiazole 3-oxide (3.5 g) was refluxed in 18 ml acetic anhydride for 10 min. After removal of lower boiling material, an oil (2.7 g), b.p. 76° at 1 mm, was obtained. From this a picrate was obtained (from methanol), m.p. 123–124°. Literature m.p. for picrate of 4-acetoxymethylthiazole is 129–131° (18).

Anal. Calcd. for $C_{12}H_{10}N_4O_9S$: C, 37.31; H, 2.61; N, 14.50; S, 8.30. Found: C, 37.26; H, 2.89; N, 14.38; S, 8.15.

Hydrolysis of Rearrangement Product

The product from the above rearrangement (4 g) was refluxed in 10% hydrochloric acid (30 ml) for 1 h (much hydrogen sulphide evolved) cooled, neutralized with 6 *N* sodium hydroxide solution, and extracted with ether. On evaporation a small amount of crystalline solid, m.p. 99–100° (from hexane), was obtained. Literature melting point for 2-hydroxy-4-methylthiazole is 102° (19).

Anal. Calcd. for C_4H_5NOS: C, 41.72; H, 4.38; N, 12.16; S, 27.85. Found: C, 41.82; H, 4.61; N, 11.94; S, 27.45.

Oxidation of Hydrolysis Product

The residual oil from the above hydrolysis (about 1 g) was added to 5% potassium carbonate solution (20 ml). A 5% potassium permanganate solution (40 ml) was then added. The solution, shaken frequently, was allowed to stand 30 min at room temperature. A 10% hydrochloric acid solution was then added to lower the pH to 2. From the dried ether extract, crystals were obtained, m.p. 188° (decomp.). Literature m.p. from 4-thiazolecarboxylic acid is 194° (20).

ACKNOWLEDGMENTS

The authors are grateful to the Research Corporation for a Frederick Gardner Cottrell grant-in-aid which made this research project possible. They also thank professors F. A. L. Anet, L. Bauer, and E. Bullock for aid in the determination of n.m.r. spectra.

RING MIGRATION IN ALKYLATED FERROCENES

DONALD E. BUBLITZ
Western Division Research Laboratories, Dow Chemical Company, Walnut Creek, California
Received April 30, 1964

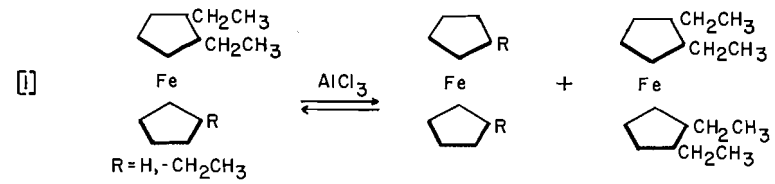
ABSTRACT

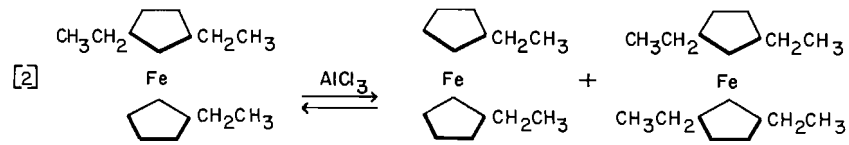
Alkylferrocenes have been found to undergo disproportionation to ferrocene and 1,1′-dialkylferrocenes in the presence of aluminium or gallium chloride. The mechanistic pathway has been shown to involve (π-ligand)–(π-ligand) exchange as opposed to the usual carbon–carbon cleavage found in benzene chemistry.

Aluminium chloride is the most widely used catalyst for Friedel–Crafts alkylation and acylation of ferrocene. The numerous compounds which have been prepared by these methods are, in part, the subjects of recent reviews (1, 2, 3). The stability of ferrocene under the conditions of these reactions has never been questioned, for the yields of acyl materials are generally quite good. The yield of any one particular alkylferrocene is generally low, however, since a complex mixture of mono- and isomeric di-, tri-, and polyalkylated materials is obtained. Recently various workers have reported that ferrocene undergoes decomposition after prolonged heating in different solvents in the presence of aluminium chloride to give various products (4–7).

In a study of the Friedel–Crafts acylation of *n*-propylferrocene in methylene chloride, we observed, by gas–liquid chromatography (g.l.c.) analysis of the products, the presence of two minor components identified as ferrocene and 1,1′-di-(*n*-propyl) ferrocene. Neither of these components was present in the starting material, as shown by g.l.c. analysis. It was subsequently shown that *n*-propylferrocene could be disproportionated to a mixture of ferrocene, *n*-propylferrocene, and 1,1′-di-(*n*-propyl)ferrocene in the presence of aluminium chloride in refluxing methylene chloride. The amount of isopropylated ferrocenes formed, if any, was less than 0.5%, as determined by the nuclear magnetic resonance (n.m.r.) spectrum of the reaction mixture. The lack of alkyl group isomerization was clearly demonstrated by the use of isobutylferrocene in the disproportionation reaction. The presence of less than 0.1%, if any, *t*-butylated ferrocenes was confirmed by n.m.r. analysis of the reaction products. This lack of alkyl group isomerization was a further indication that the reaction mechanism did not involve ring – alkyl group cleavage.

Proof that the mechanistic pathway proceeds via ring–metal scission has been obtained. When 1,1′,2-triethylferrocene was subjected to the conditions of the disproportionation, the only products present, as shown by g.l.c. of the mixture, were 1,1′-diethyl-, 1,1′-2-triethyl-, and 1,1′,2,2′-tetraethyl-ferrocene (eq. [1], R = CH_2CH_3). In addition, trace amounts of ethylferrocene formed by concomitant dealkylation were observed. Corresponding results were obtained when either 1,2-diethyl-, or 1,1′,3-triethyl-ferrocene was utilized (eq. [1], R = H; eq. 2). In both instances, trace amounts of ethylferrocene were again observed. A trace amount of 1,1′,2-triethylferrocene in the disproportionation products of 1,2-diethylferrocene was attributed to the dealkylation of the tetraalkylated product present. Dealkylation has been substantiated by treatment of 1,1′-diethylferrocene with aluminium chloride in refluxing methylene chloride. After 2 hours the reaction mixture was found to comprise 1,1′-diethylferrocene (93.4%), ethylferrocene (3.88%), and 1,1′,2-triethylferrocene (2.70%). The relative amounts of the last two products show realkylation occurs to an even lesser extent.





The structural assignments of 1,1′,2,2′- and 1,1′,3,3′-tetraethylferrocene were based on two facts. First, no 1,3-disubstitution products were generated from starting materials of a 1,2-disposition. Alternatively, when the substituents in the starting material were of a 1,3-nature, no 1,2-disubstitution products were observed. The conditions of the g.l.c. analysis permit such a distinction between these isomers if they are present. Thus, alkyl substituents do not migrate. Second, certain characteristic peaks in the infrared spectra of 1,3-diethyl-, and 1,1′,3-triethyl-ferrocene are present in 1,1′,3,3′-tetraethyl-ferrocene and are absent in their 1,2-counterparts. Similarly, certain characteristic infrared peaks common to the 1,2-family are absent in its 1,3-counterparts (8). Various workers have made similar observations with other 1,2- and 1,3-disubstituted ferrocene systems (9–11).

The equilibrium nature of the reaction has been shown by the appearance of ethyl-ferrocene in a mixture of ferrocene and 1,1′-diethylferrocene in the presence of aluminium chloride. A similar reaction of 1,1′-diethylferrocene with either ruthenocene (12) or methylcyclopentadienylmanganese tricarbonyl* was attempted but no synproportion-ation products were observed. The result for ruthenocene is parallel to earlier observations that its ring–metal bond is stronger than the ring–metal bond in ferrocene (13–16).

Aluminium chloride is not functionally unique in causing this disproportionation, gallium(III) chloride behaves in an identical fashion. No disproportionation is observed when antimony(III, V), arsenic(III), bismuth(III), indium(III), or tin(IV) chloride is used.

The recent observations of Nesmeyanov and co-workers (17, 18) concerning the exchange of a cyclopentadienyl or substituted cyclopentadienyl moiety for an aromatic moiety such as benzene or mesitylene, in the presence of aluminium chloride, agree with our observations of ring–metal cleavage. While the same mechanistic pathway is doubtless common to both reactions, the presence of excess benzene, or other solvents capable of forming π-complexes, evidently precludes the reverse combination of ferrocene fragments. In methylene chloride, a solvent not capable of such complex formation, the reverse reaction of recombination of ferrocene fragments is found to occur as we have shown.

Nesmeyanov *et al.* have shown acetylferrocene capable of cleavage by aluminium chloride in mesitylene. In agreement with the report of Rosenblum *et al.* (19), we found no evidence whatsoever for its disproportionation in refluxing methylene chloride. Analysis by g.l.c. demonstrated conclusively the absence of ferrocene even when 4 molar

equivalents of aluminium chloride were utilized. These results are in accord with the reported inhibitory effect of the acetyl group upon the ligand exchange reaction (17, 18).

EXPERIMENTAL

Gas–liquid chromatographic analyses were performed on an Aerograph Autoprep model A-700 equipped with a $\frac{3}{8}$ in. × 20 ft aluminium column packed with Apiezon L (20%) on 60/80 Chromasorb P. Nuclear magnetic resonance spectra of preparative g.l.c. samples were obtained on a Varian A-60 spectrometer. Boiling points were obtained for 1–2 mg samples on a DuPont model 900 differential thermal analyzer at 764.5 mm.

Preparation of 1,2-Diethylferrocene

A solution of 0.50 g 1-acetyl-2-ethylferrocene (9) in 20 ml ether was added dropwise to a stirred solution of 0.5 g lithium aluminium hydride and 1.5 g aluminium chloride in 100 ml ether at reflux (20). The solution was maintained at reflux temperature for 30 min and allowed to cool. The reaction mixture was then carefully hydrolyzed with water. The ether layer was separated, dried over anhydrous magnesium sulphate, and filtered. Evaporation of the ether left 0.48 g 1,2-diethylferrocene, n_D^{25} 1.5765, b.p. 287 °C.

Found: C, 69.27; H, 7.35. Calcd. for $C_{14}H_{18}Fe$: C, 69.43; H, 7.50.

Gas–liquid chromatographic analysis of this material showed it to be a single component, thus demonstrating the reducing reagent incapable of causing disproportionation.

Preparation of 1,1′,2- and 1,1′,3-Triethylferrocene

To a stirred solution of 5.5 g 1,1′-diethylferrocene (9) in 300 ml dry methylene chloride at reflux temperature was added dropwise under nitrogen a solution of 2.3 g acetic anhydride and 3.0 g aluminium chloride in 100 ml dry methylene chloride. The solution was maintained at reflux for a period of 4 h and then allowed to cool. The reaction mixture was then hydrolyzed with ice water. The organic layer was separated, dried over anhydrous magnesium sulphate, filtered, and evaporated to dryness. The residual oil was taken up in hexane and placed on a column of alumina (Alcoa Grade F-20) which had been deactivated to activity grade III (21).

Elution with hexane removed unchanged 1,1′-diethylferrocene (1.92 g) while 1% ether–hexane removed 1-acetyl-1′,2-diethylferrocene (0.57 g). When the eluent was changed to 10% ether–hexane, 1-acetyl-1′,3-diethylferrocene (1.48 g) was removed.

The structures of the clearly separated acetyl isomers, each a viscous liquid, were conclusively established by their n.m.r. spectra in carbon tetrachloride solution (22–24). In the ring proton region 1-acetyl-1′,2-diethylferrocene exhibits a single proton multiplet centered at 5.60 τ and a two proton multiplet centered at 5.85 τ. The spectrum of 1-acetyl-1′,3-diethylferrocene has a two proton multiplet centered at 5.53 τ and a single proton multiplet centered at 5.80 τ. In addition the spectrum of 1-acetyl-1′,2-diethylferrocene exhibits two quartets characteristic of ethyl group methylenes centered at 7.30 τ and 7.80 τ. The lower field group is assigned to the methylene of the 2-ethyl group and is attributed to magnetic anisotropy effects of the adjacent carbonyl group. This deshielding is not observed in the case of the 1,1′,3-disposed isomer.

Each of the pure acetyl-diethylferrocene isomers was reduced by means of lithium aluminium hydride/aluminium chloride in a manner identical with that given above for 1-acetyl-2-ethylferrocene. In each instance g.l.c. analysis demonstrated the reaction product to be a single component. The isomeric products were shown to be triethylated ferrocenes on the basis of their n.m.r. spectra and microanalytical data.

Found (1,1′,3-isomer): C, 70.99; H, 8.09; b.p. 299 °C. Found (1,1′,2-isomer): C, 71.24; H, 7.95; b.p. 302 °C. Calcd. for $C_{16}H_{22}Fe$: C, 71.12; H, 8.21.

Disproportionation of Ethylferrocene

A mixture of 1.00 g of ethylferrocene and 0.44 g of aluminium chloride in 150 ml of dry methylene chloride was stirred at reflux temperature for 2 h in an atmosphere of prepurified nitrogen. The mixture was then cooled and poured into ice water containing 0.1 g of ascorbic acid. The organic layer was separated, dried over anhydrous magnesium sulphate, filtered, and evaporated. The residue was analyzed by preparative g.l.c. and found to be a mixture composed of ferrocene, ethylferrocene (b.p. 263 °C), and 1,1′-diethylferrocene (b.p. 283 °C). The identities of the three components were proved by comparison of their infrared and n.m.r. spectra with those of authentic compounds.

Corresponding results were obtained without exception when methyl-, *n*-propyl-, *n*-butyl-, or *i*-butylferrocene was substituted for ethylferrocene in the reaction with aluminium chloride. The reaction product was composed of three components, as shown by g.l.c. analysis. The components were identified as ferrocene, starting alkylferrocene, and 1,1′-dialkylferrocene by their infrared and n.m.r. spectra. When acetylferrocene was substituted for ethylferrocene in the reaction with aluminium chloride, no disproportionation was observed.

The n.m.r. spectrum of *t*-butylferrocene has a sharp singlet at 8.80 τ in carbon tetrachloride solution while *i*-propylferrocene has a sharp doublet at 8.70 τ. Close examination of the n.m.r. spectra of the disproportionation products from *n*-propyl- and *i*-butyl-ferrocene failed to reveal any peaks in these locations, thus demonstrating the lack of alkyl group isomerization. The limits of detection were set at 0.1% for *t*-butyl groupings and 0.5% for *i*-propyl groupings.

For personal use only.

Disproportionation of 1,1',2-Triethylferrocene

A solution of 0.30 g 1,1',2-triethylferrocene and 0.17 g aluminium chloride in 50 ml dry methylene chloride was stirred at reflux temperature in an atmosphere of prepurified nitrogen for 2 h. It was then cooled, poured into ice water containing 0.1 g ascorbic acid, and the organic phase was separated. The organic layer was dried over anhydrous magnesium sulphate, filtered, and evaporated to dryness. Analysis of the residue indicated the presence of three major components and a trace of a fourth. Two of the major components were identified as 1,1'-diethylferrocene and starting material by their infrared and n.m.r. spectra. The remaining major component was identified as a tetraethylated ferrocene (found: C, 72.04; H, 9.02; b.p. 319 °C; calcd. for $C_{18}H_{26}Fe$: C, 72.48; H, 8.79) and assigned the structure 1,1',2,2'-tetraethylferrocene. The trace material was identified as ethylferrocene by its infrared and n.m.r. spectra.

Similar treatment of 1,1',3-triethylferrocene gave correspondingly similar results. The tetraethylated product obtained in this latter reaction was assigned the structure 1,1',3,3'-tetraethylferrocene. (Found: C, 72.51; H, 8.52; b.p. 307 °C.)

When 1,2-diethylferrocene was utilized in place of 1,1',2-triethylferrocene, the major reaction products were ferrocene, starting material, and 1,1',2,2'-tetraethylferrocene. This tetraethylated derivative was identical in all respects with that obtained from the disproportionation of 1,1',2-triethylferrocene. In addition, traces of ethyl- and 1,1',2-triethylferrocene were detected.

The Synproportionation of Ferrocene and 1,1'-Diethylferrocene

A mixture of 0.42 g 1,1'-diethylferrocene, 0.32 g ferrocene, and 0.16 g aluminium chloride in 100 ml dry methylene chloride was stirred at reflux temperature in an atmosphere of dry argon for 2 h and worked up in the usual manner. Analysis of the reaction product indicated the presence of ethylferrocene in addition to the starting materials.

Similar reactions with ruthenocene (12) or methylcyclopentadienylmanganese tricarbonyl* in place of ferrocene were investigated. Analyses of the reaction products showed only the presence of starting materials.

ION–MOLECULE REACTIONS STUDIED BY TIME-OF-FLIGHT MASS SPECTROMETRY

II. REACTIONS IN CO–D_2 AND CH_4–D_2 MIXTURES[1]

CLIFFORD W. HAND[2] AND HANNS VON WEYSSENHOFF[3]

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California

Received April 20, 1964

ABSTRACT

The pulsed operation capability of the time-of-flight mass spectrometer has been used for the study of ion–molecule reaction kinetics. Reactions take place in a high-pressure (up to 0.08 Torr) region free from external electric fields, and time is used as a direct kinetic variable. The following reactions were studied.

$$CO^+ + D_2 \xrightarrow{k_3} DCO^+ + D,\ k_3 = 7.1_6 \times 10^{-10}\ cm^3/molecule\ s;$$

$$D_2^+ + CH_4 \xrightarrow{k_7} CH_4D^+ + D,\ k_7 \sim 2 \times 10^{-10}\ cm^3/molecule\ s.$$

In CH_4–D_2 mixtures a reaction in addition to $CH_4^+ + CH_4 \rightarrow CH_5^+ + CH_3$ leads to the formation of an ion of m/e 17. Various possibilities for this reaction are discussed.

INTRODUCTION

Gas phase reactions between ions and molecules have been studied in a variety of ways, usually involving more or less energetic ions as reactants. The most common technique has been the operation of a mass spectrometer at relatively high source pressures. The theory, experimental techniques, and results of such investigations have been reviewed (1, 2). The rate constants of ion–molecule reactions have been observed to depend on ion energy (velocity) and hence on the strength of the electric field in the reaction chamber; moreover, the form of the field dependence is not completely understood for all reactions (1). In view of the increasing interest in the role of ions in combustion processes (3), it is desirable to have available kinetic data which are obtained with ions reacting at thermal velocities in the absence of external electric fields. These conditions are met in a new method which has been briefly reported (4). An additional advantage of this method is that the measured kinetic variable is time, rather than the less direct variables of reservoir pressure or electric field.

EXPERIMENTAL

A description of the apparatus has been published (4), but for completeness will be summarized here. A Bendix Model 14 time-of-flight mass spectrometer (t.o.f.)* was modified to permit operation at relatively high pressures. The ion source region was enclosed in a stainless steel box with appropriate orifices provided for electron beam entrance and exit, ion exit, sample inlet, and pressure measurement. Source pressure was measured with a McLeod gauge and (or) a CEC micromanometer. The region around the source box was pumped by a 6″ CVC oil diffusion pump, and source pressures up to 0.080 torr could be attained without increasing the flight-tube pressure above 2×10^{-5} torr.

The gas temperature in the source was 15–20 deg above room temperature; an average value of 310 °K was used in all kinetic calculations. The gases were introduced into the vacuum rack through cold traps and had the following nominal purities: CO, Matheson C.P. (99.5%); CH_4, Phillips Research Grade (99.59%); D_2, Biorad (99.5%) or Matheson (99.5%). Semiquantitative mass spectral observation showed no significant impurities. Gas mixtures were prepared manometrically and allowed to stand at least 12 h before use.

[1]*This paper presents results of one phase of research carried out at the Jet Propulsion Laboratory, California Institute of Technology, under Contract No. NAS-7-100, sponsored by the National Aeronautics and Space Administration.*

[3]*Present address: Chemistry Department, Northwestern University, Evanston, Ill.*

**The operating principles of the t.o.f. are well described elsewhere. See, for example, D. B. Harrington. In Encyclopedia of spectroscopy. Editor, G. L. Clark. Reinhold, New York. 1960. p. 628.*

A time delay, variable and accurately known, was introduced between the ionizing electron beam pulse and the pulse which withdraws the ions for analysis. During this delay period the source region was free from external electric fields. Unless otherwise stated, the ionizing voltage was 70 V. The ionizing current was kept low to avoid overloading the detector and varied somewhat with pressure.

In a typical experiment a continuous flow of sample was introduced into the ion source through a Granville-Phillips variable leak. When observations of source pressure indicated that steady flow had been achieved, the intensities of the relevant mass peaks were measured as a function of delay time. These data were obtained for eight or nine different delay times in random sequence to minimize the effect of slow variations in operating parameters.

It was found necessary to keep the source and detector electrodes as clean and free from carbonaceous deposits as possible. Dirt on the electrodes showed up primarily as periodic fluctuations in the gain of the detector. Whenever this condition became intolerable the mass spectrometer was disassembled and cleaned.

RESULTS AND DISCUSSION

As a general check on the method we have reinvestigated (4) the reaction

[1] $$CH_4^+ + CH_4 \xrightarrow{k_1} CH_5^+ + CH_3.$$

With the usual assumptions of no important competing or consecutive reactions and equal ion collection efficiencies for all species, the kinetic equations may be integrated to yield

[2] $$\log_{10}\frac{I_{16} + I_{17}}{I_{16}} = \frac{k_1[CH_4]t}{2.303},$$

where I_N refers to the observed detector output due to the ions of m/e N. The plots of log $[(I_{16} + I_{17})/I_{16}]$ vs. delay time were linear up to approximately 75% reaction, and from them an average value of $k_1 = 12.6 \times 10^{-10}$ cm^3/molecule s was obtained.* This agreed well with the published (5, 6) values of 8.9×10^{-10} and 11.6×10^{-10} and confirmed that the method gave reliable results.

The System CO–D_2

It has been reported (7) that the species DCO^+ is a product of an ion–molecule reaction in a CO–D_2 mixture and suggested that CO^+ is the ionic reactant. Since the species D_2^+ is also a possible reactant, it was of interest to ascertain whether CO^+ or D_2^+ is the reactant and also to obtain an independent measure of the rate constant. A mixture of 1:1 CO–D_2 was used for all experiments. Preliminary experiments revealed a large peak at m/e 30, the intensity of which increased with pressure and delay time. Therefore the peak was identified as the secondary species DCO^+, arising from either of the ion–molecule reactions:

[3] $$CO^+ + D_2 \xrightarrow{k_3} DCO^+ + D$$

or

[4] $$CO + D_2^+ \xrightarrow{k_4} DCO^+ + D.$$

The only other species observed were D^+, D_2^+, D_3^+, C^+, O^+, and CO^+. The ionization efficiency curve of the species DCO^+ was found to be identical with that of CO^+; in particular there was no structure in the DCO^+ curve corresponding to the onset of D_2^+. Thus we conclude that under the conditions of our experiment the reactant ion is CO^+, and that [4] does not contribute appreciably to the formation of DCO^+. With the reaction system thus simplified, the kinetic equations may again be integrated to

[5] $$\log_{10}\left[\frac{I_{28} + I_{30}}{I_{28}}\right] = \frac{k_3[D_2]t}{2.303}.$$

**The value given in ref. 4 (11.1×10^{-10}) was not corrected for temperature. The true value is 12.6×10^{-10}, as above.*

is plotted vs. delay time. That the lines in Fig. 1 do not pass through the origin is a reflection of the arbitrary zero of time, due to the finite rise times and widths of the several electronic pulses, and the finite transit time of the ions emerging from the reaction chamber. The *differences* in delay times, hence the slopes and rate constants, are accurately known. Note that in Fig. 1 the lines produced meet at a common point on the time axis. In Table I each rate constant was obtained by a least squares treatment of the data. The least squares error in the slope was of the order of 3–4%, and did not vary widely from one run to the next. The average of the values in Table I is $7.1_6 \pm 0.12 \times 10^{-10}$ cm^3/molecule s, with a standard deviation of 1.6%. This may be compared with the published value (7) of 16.3×10^{-10} cm^3/molecule s. The difference between our value and the literature value cannot be explained, except to note that the latter is the result of a single determination at non-zero electric field in the reaction chamber.

The System CH_4–D_2

There are several recent papers (8–10) which mention the reaction

[6] $$[CH_4 + H_2]^+ \longrightarrow CH_5^+ + H$$

or its deuterated variations. The brackets indicate that either species may be the ionic reactant. Lampe and Field (8, 10) could not observe this reaction and were thus able to assign a rather low upper limit to the reaction rate, namely $k < 5 \times 10^{-12}$ cm^3/molecule s (10). On the other hand, Talrose and Frankevitch (9), although they did not measure its rate, observed the reaction without difficulty and used their results to calculate the proton affinity of methane.

We have investigated the charged species existing in an ionized mixture of methane and deuterium (5% methane). A small peak was observed at m/e 18, which, however, was significantly larger than the combined contributions of background and $^{13}CH_5^+$. This peak was identified as CH_4D^+, on the basis of the following evidence. The intensity of CH_4D^+ (relative to any of the primary ionic species) increased with delay time, as expected for a

product ion. The ionization efficiency data for some of the species present in the mixture are shown in Fig. 2, where the detector signal (normalized to 40 V ionizing energy) is plotted vs. ionizing energy. For ease of comparison, all three species shown are secondary ions. It is seen that the ionization efficiency curve of CH_4D^+ very closely approximates that of D_3^+, and the conclusion may be drawn that both species are formed in reactions of the same precursor ion, namely D_2^+.* Thus in our system reaction [6] is readily observable; the ionization efficiency data allow us to identify the ionic reactant, and write

$$[7] \qquad CH_4 + D_2^+ \xrightarrow{k_7} CH_4D^+ + D.$$

Our own preliminary observations as well as the dispute in the literature indicated that the rate constant k_7 is quite low; its determination is complicated by competing reactions such as

$$[8] \qquad D_2^+ + D_2 \xrightarrow{k_8} D_3^+ + D.$$

This difficulty can be overcome by changing the experimental procedure to work only at low percent reaction. Under these conditions the exponential form of eq. [2] or [5] may be expanded and higher terms dropped to yield, in the case of reaction [7],

$$[9] \qquad \frac{I_{18}}{I_4} = k_7[CH_4]t.$$

**It is well established that D_3^+ is formed in the reaction $D_2^+ + D_2 \rightarrow D_3^+ + D$. See ref. 1, for example.*

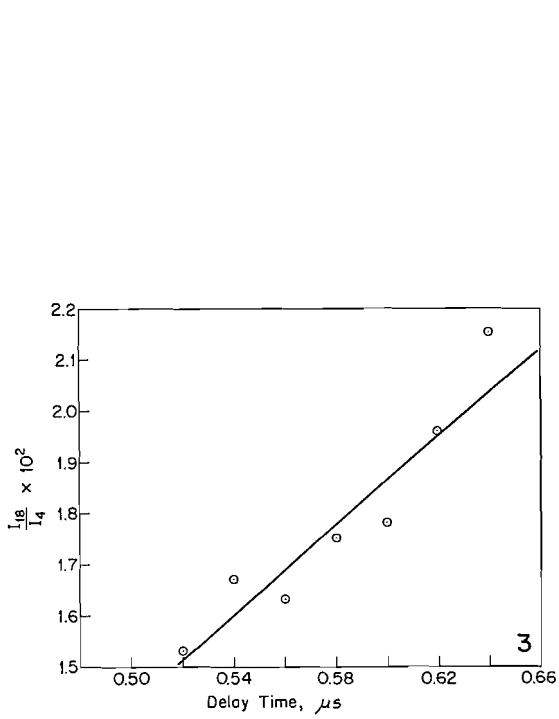
It can be shown (1) that this form of the kinetic equations is valid even in the presence of competing reactions, so long as the percentage conversion is low.

Experimentally this technique is less accurate than the method used to obtain k_1 and k_3: the measurement of larger concentration ratios is inherently less accurate than smaller, and moreover, in our apparatus the measurement of small time delays is less accurate than large. The result of this experimental difficulty is illustrated in Fig. 3, where I_{18}/I_4 is plotted vs. delay time [arbitrary zero] for run C of Table II. It is seen that the scatter greatly exceeds that of Fig. 1 and that quantitative conclusions drawn from such plots must be regarded as estimates. The determination of the rate constant k_7 from the slope of the line in Fig. 3 is further complicated by a difficulty which does not arise in the case of reactions [1] or [3]. This difficulty is that the assumption of equal collection efficiencies for reactant and product ions is no longer valid when the species are as different as CH_4D^+ and D_2^+. The breakdown of this assumption has two causes. Firstly, the focussing properties of the t.o.f. mass spectrometer are not wholly mass independent, and secondly, the sensitivity of the electron multiplier detector is not the same for all ions. This latter effect is better known in terms of γ, the secondary electron emission coefficient. The variation of γ with experimental parameters has been discussed by many authors (11–16). Many of the experiments have yielded conflicting results, and the theoretical treatments (11–13) must be cautiously applied to real experiments. The results of Sternglass (12) may be used to predict that γ will increase with the square root of ionic mass in the t.o.f. spectrometer, but not all experiments support this. We do not feel confident in basing any rate constant corrections on either theoretical values of γ or on experimental values obtained under rather different conditions, but prefer to determine a correction factor of our own, as follows.



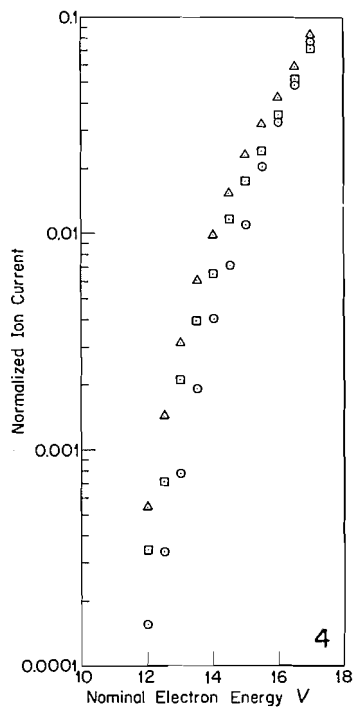


FIG. 3. Formation of CH_4D^+ vs. delay time in CH_4–D_2. 0.011_5 torr.
FIG. 4. Ionization efficiency in CH_4–D_2. (○) mass 15, (△) mass 16, (□) mass 17.

The results with reaction [1] indicate that the equal collection efficiency assumption is valid when applied to the species CH_4^+ and CH_5^+; CH_4D^+ may be expected to behave as CH_5^+, and hence the same as CH_4^+. Further the relative ionization efficiencies for D_2^+ from D_2 and CH_4^+ from CH_4 are known (17). Thus for a known mixture of CH_4 and D_2 one can calculate the relative concentrations of CH_4^+ and D_2^+ in the ion source immediately following ionization by 70 V electrons. Comparison of this calculated ratio with that obtained from the detector signals yields the relative collection efficiencies of CH_4^+ and D_2^+, hence those of CH_4D^+ and D_2^+. In our mixture of CH_4 (5%) and D_2 (95%) the experimental ratio D_2^+/CH_4^+ was 0.53, whereas the ratio calculated on the basis of known relative ionization efficiencies (17) is 9.56.* Thus in our mass spectrometer CH_4^+ and CH_4D^+ are collected 18 times as efficiently as D_2^+. Our experiments do not allow us to determine how much of this factor is due to difference in focussing efficiency and how much to difference in γ.

This correction was applied to the raw data of six runs in CH_4 (5%) – D_2 (95%) and the results are shown in Table II. The last column gives the corrected estimate of the rate constant. The average, $\sim 2 \times 10^{-10}$ cm^3/molecule s, may be compared to the upper limit of 5×10^{-12} set by Lampe and Field (8*b*).

Other Reactions in CH_4–D_2 Mixtures

During the course of preliminary experiments it was observed that the rate of reaction [1] measured in the CH_4–D_2 mixture considerably exceeded that measured in pure CH_4. This enhancement of k_1 was observed under conditions where the exponential approximation to eq. [2] was expected to hold, and was quite reproducible. A series of seven runs at varying pressures gave for the enhanced rate constant $k_1' = 59.7 \pm 7.1 \times 10^{-10}$ cm^3/molecule s. Compared to the pure methane value of $k_1 = 12.6 \times 10^{-10}$ cm^3/molecule s, this is an increase of a factor of almost 5.

A possible reason for this enhancement lies in some unspecified "mass effect" due to the high dilution with a low molecular weight species, perhaps related to differential effusion from the source chamber. This possibility was checked by measuring k_1 in mixtures of 5% CH_4 in He. If a "mass effect" is causing the enhancement, the substitution of He for D_2 in the mixture should have no effect. Five determinations in the CH_4–He mixture yielded $k_1'' = 27.6 \pm 3.6 \times 10^{-10}$ cm^3/molecule s, larger than the true value by a factor of 2.2. Thus a "mass effect" is not entirely responsible for the enhancement in D_2, and some other ion–molecule reaction producing a species of m/e 17 is taking place.

In the CH_4–D_2 system there are only two possibilities for increased intensity at m/e 17; these are CH_3D^+ and CHD_2^+. It might be expected that ionization efficiency data would

*This calculated ratio is itself subject to the errors of conventional mass spectrometry and may be in error by 50–100%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

provide a means of deciding between these two species, but further consideration shows this not to be the case. At least part of the intensity at m/e 17 is due to reaction [1]; if the other contributing reaction had the same precursor (CH_4^+), the ionization efficiency of m/e 17 would coincide with that of CH_4^+ and a positive identification could be made. If, however, the contributing reaction has some precursor X^+ different from CH_4^+, the ionization efficiency of m/e 17 will be intermediate between that of CH_4^+ and X^+, and no positive conclusion can be drawn. That the latter situation obtains is shown in Fig. 4, which shows the ionization efficiencies for m/e 15, 16, 17 in the CH_4–D_2 system. The curve for m/e 17 is *not* coincident with that of CH_4^+. From this, one can conclude that some other reaction is supplying part of m/e 17, and that this other ionic reactant has an appearance potential greater than that of CH_4^+. The curve for m/e 15, CH_3^+, is included in Fig. 4 for comparison.* There are several possible reactions in the CH_4–D_2 system which satisfy the requirements that they (i) be not endothermic, (ii) produce either CH_3D^+ or CHD_2^+, and (iii) involve an ionic reactant which has an appearance potential greater than that of CH_4^+.

TABLE III

Possible sources of m/e 17 from CH_4–D_2 mixtures

$CH_4 + D_2^+ \rightarrow CH_3D^+ + HD$
$CH_4 + D_2^+ \rightarrow CHD_2^+ + H_2 + H$
$CH_4 + D^+ \rightarrow CH_3D^+ + H$
$D_2 + CH_2^+ \rightarrow CHD_2^+ + H$
$D_2 + CH_3^+ \rightarrow CHD_2^+ + H_2$

Table III lists the possible reactions, but in the absence of further evidence we cannot draw any definite conclusions. However, if we assume that any one of these reactions is involved, an estimate of its rate constant can be made.

For example, if reaction [10]

[10] $$CH_4 + D^+ \xrightarrow{k_{10}} CH_3D^+ + H$$

is solely responsible,† a straightforward treatment of the kinetic equations leads to the expression

[11] $$k_1' = k_1 + \frac{[D^+]}{[CH_4^+]} k_{10},$$

where k_1 and k_{10} have their usual meanings, and k_1' is the enhanced rate constant measured in the presence of D_2 [for the moment we are ignoring the "mass effect" discussed above]. The ratio $[D^+]/[CH_4^+]$ can be obtained from the known mixture composition and the relative mass spectral sensitivities of D^+ and CH_4^+ given in the A.P.I. tables (17), and is equal to 0.16_5. Inserting this value and k_1', k_1 into eq. [11] we obtain $k_{10} = 280 \times 10^{-10}$ cm³/molecule s. This must be regarded as an upper limit to k_{10}, since it was obtained by ignoring the "mass effect".

**Some relevant appearance potentials from CH_4 and D_2 are CH_4^+, 13.1 V; CH_3^+, 14.4 V; CH_2^+, 20.1 V; D_2^+, 15.4 V; D^+, 18.2 V. Values taken from F. H. Field and J. L. Franklin. Electron impact phenomena. Academic Press, New York. 1957.*

†Reaction [10] is the simplest of the possibilities and therefore a likely secondary contributor to m/e 17. It may be regarded as either an S_E2 reaction or as a proton (deuteron) transfer reaction; the latter class of reaction is known for its high rate constants (1).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

It will be recalled that the enhancement in the presence of helium yielded a rate constant k_1'' larger than k_1 by a factor of 2.2. If the enhancement in D_2 is regarded as a combination of "mass" and "chemical" effects, the value of k_1' must be adjusted by dividing it by 2.2. The new estimate of k_{10} can then be obtained as above, and is $k_{10} = 86 \times 10^{-10}$ cm^3/molecule s. The true value probably lies somewhere between these limits.

SYNTHESIS OF THIOHYDROXIMATES

THE ADDITION OF THIOLS TO NITRILE OXIDES

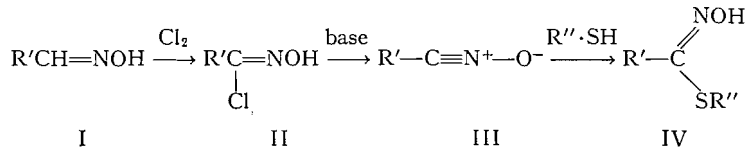
M. H. BENN
Department of Chemistry, University of Alberta, Calgary, Alberta
Received February 3, 1964

ABSTRACT

The addition of thiols to nitrile oxides is shown to constitute a general synthesis of thiohydroximates.

In a consideration of routes for the synthesis of mustard oil glucosides, the addition of thiols to nitrile oxides appeared to us to represent an attractively direct and simple method of constructing the thiohydroximate system characteristic of these compounds.

The only examples of the realization of this reaction which appear to be reported in the literature are the preparation by Alemagna and Bacchetti (1) of some benzothiohydroximates, e.g. IV (R′ = phenyl, R″ = benzyl).



Before attempting the synthesis of a mustard oil glucoside, we carried out some model studies with aryl and alkyl nitrile oxides and thiols. We report here the results of these experiments, which demonstrate that the reaction is a general and excellent method for the synthesis of thiohydroximates.

Nitrile oxides are commonly prepared by treating a hydroxamoyl chloride (α-chlorooxime) (II) with base (2, 3, 4), the hydroxamoyl chloride having been prepared by chlorination of the corresponding aldoxime (I). The procedure which we usually followed was to generate the nitrile oxide *in situ* by treating a cold ethereal solution of the thiol and hydroxamoyl chloride with excess triethylamine. After about 30 minutes at room temperature the reaction was worked up to give the thiohydroximate, which usually crystallized spontaneously in a high state of purity. In this way we prepared a series of alkyl and aryl thiohydroximates (IV, R′ = alkyl or aryl, R″ = alkyl or aryl).

Proof that the products are indeed thiohydroximates with the structure IV includes comparison with thiohydroximates prepared by alternative routes (1, 5) and from their infrared and proton magnetic resonance (p.m.r.) spectra. The infrared spectra[1] show broad, strong intensity OH (stretch) absorption around 3300 cm^{-1} and a sharp, medium intensity band at 1625 $\pm$ 10 cm^{-1} corresponding to the C=N (stretch) absorption. The p.m.r. spectra[2] show a signal around $\tau = 0.3 \pm 0.2$, of intensity corresponding to one hydrogen, in the same position as the signal for hydrogen in the oxime function of ketoximes and aldoximes; the remaining features of the p.m.r. spectra are in accord with the structure IV.

Nitrile oxides formed *in situ* by the addition of triethylamine to an ethereal solution

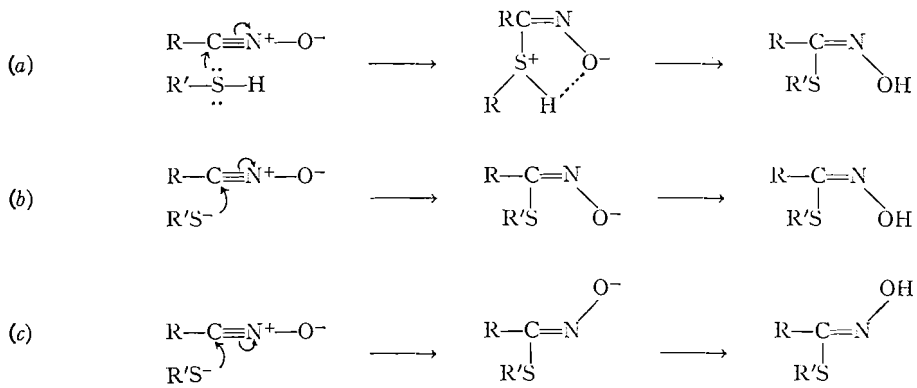
[1]*Potassium bromide discs.*
[2]*Measured in chloroform and deuterochloroform at 60 Mc/s with tetramethylsilane as an internal standard.*

of the appropriate hydroxamoyl chloride have been trapped by addition to a variety of unsaturated compounds, reactions in which the nitrile oxide behaves as a 1,3-dipolar ion (4). Direct evidence that nitrile oxides are involved as intermediates[3] under our conditions for the thiohydroximate synthesis may be summarized as follows.

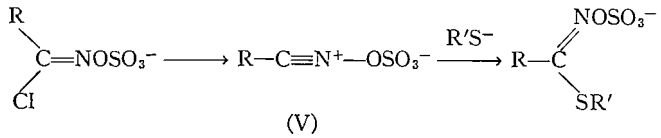
Thiols did not react with hydroxamoyl chlorides at an appreciable rate, under the conditions which we employed, if no triethylamine was added. Addition of triethylamine to a cold ethereal solution of hydroxamoyl chloride resulted in immediate precipitation of triethylamine hydrochloride and the filtered solution exhibited intense absorption at 2320 cm^{-1}, characteristic of nitrile oxides[4] (3). Addition of thiol to this solution resulted in extremely rapid disappearance of this absorption band, and evaporation of the solution yielded the thiohydroximate.

It is significant that, under the usual conditions which we employed for the thiohydroximate synthesis, *t*-butyl mercaptan gave a poor yield of benzothiohydroximate, the major product being the furoxan produced by dimerization of the initially formed benzonitrile oxide. Presumably here the rate of dimerization of benzonitrile oxide is competitive with the rate of reaction with the hindered thiol.

Various mechanisms can be written for the reaction of thiols with nitrile oxides which lead to either of the two possible configurations about the carbon–nitrogen double bond. Thus (*a*) attack of un-ionized thiol on the nitrile oxide leads to the *anti* (R, OH) configuration in a process reminiscent of the 1,3-dipolar addition of nitrile oxides to olefins (2, 4); (*b*) attack by thiolate anion leads to the same, *anti*, configuration; and (*c*) attack also by thiolate anion leads to the opposite, *syn*, configuration. Mechanism (*b*) represents a *trans* addition in which the lone pair of electrons develops on the nitrogen *trans* to the attacking thiolate anion, whilst in (*c*) the geometry of the transition state is such as to minimize repulsion between the formal charges on the thiolate nucleophile and the oxygen of the nitrile oxide.



[3]*Ettlinger and Dateo have discovered (6) that O-sulphonated hydroxamoyl chlorides react with thiolate salts, forming thiohydroximates. In these cases nitrile oxide formation is blocked, and it appears that the thiolate species displace halide from these hydroxamoyl chlorides. However, the reaction may well proceed via an intermediate (V), closely related to a nitrile oxide.*



(V)

[4]*For spectroscopic purposes, it was more convenient to use carbon tetrachloride as solvent. The filtered solution then exhibited intense absorption at 2300 cm^{-1}, which as before disappeared upon addition of thiol.*

Whilst we do not have the rate data which would permit a definite decision, on the basis that yields of thiohydroximates appear to be higher when excess base is present, we favor a mechanism involving thiolate anion as the nucleophilic species. Discrimination between (*b*) and (*c*) is not possible on the basis of the results which we have obtained, but the stereochemistry about the carbon–nitrogen double bond may be deduced by the following argument.

The mustard oil sinigrin, a naturally occurring thiohydroximate, has been shown by X-ray crystallography (7) to have the *anti* configuration, and it is reasonable to assume that the other mustard oil glucosides have a similar configuration.

We have been able to use the addition of thiols to nitrile oxides in the synthesis of compounds identical with the natural mustard oil glucosides (5) under conditions which were most unlikely to result in change in configuration about the carbon–nitrogen double bond. We conclude therefore that the addition of thiols to nitrile oxides results in formation of thiohydroximates with the *anti* configuration.[5]

The thiohydroximates synthesized were stable, well crystallized solids and yields were, with the exception of the *S-t*-butyl thiohydroximate, good; in fact, the reaction of thiols with phenylacetonitrile oxide appears suitable for their characterization.

Selenols react analogously to yield selenohydroximates.

EXPERIMENTAL

Preparation of Hydroxamoyl Chlorides

Isobutyrohydroxamoyl Chloride

(II, R = isopropyl.) Isobutyraldoxime (3.0 g) was dissolved in chloroform (30 ml), the solution was cooled to 0° in an ice–salt bath, and a fairly slow stream of dry chlorine was bubbled through the solution for 30 minutes. The blue solution was concentrated under reduced pressure (bath $T \not> 40°$) to an almost colorless oil containing a little crystalline material, presumably a hydrochloride. The oil was dissolved in ether and the solvent again removed under reduced pressure (bath $T \not> 40°$). The residual oily isobutyrohydroxamoyl chloride was sufficiently pure for the subsequent reactions.

The following hydroxamoyl chlorides were obtained by the same procedure.

Acetohydroxamoyl Chloride

(II, R = methyl.) Oil. Lit. (8) oil.

Benzohydroxamoyl Chloride

(II, R = phenyl.) Cryst., m.p. 49° from petroleum ether. Lit. (9) m.p. 49°.

Phenylacetohydroxamoyl Chloride

(II, R = benzyl.) Cryst. m.p. 89–91° (5).

Preparation of Thiohydroximates by Method A

S-p-Tolyl Isobutyrothiohydroximate

(IV, R′ = isopropyl, R″ = *p*-tolyl.) Crude isobutyrohydroxamoyl chloride (1.50 g) and *p*-toluenethiol (1.20 g) were dissolved in ether (100 ml), and to the gently stirred solution was added triethylamine (2.5 g) in ether (10 ml) in one portion. There was an immediate copious precipitate of triethylamine hydrochloride. After 30 min at room temperature, the reaction mixture was poured into cold ca. 0.5 *N* aqueous sulphuric acid. The ether layer separated and the aqueous phase was re-extracted with ether (2 × 50 ml). The combined ether extracts were dried ($MgSO_4$) and evaporated to yield *S-p*-tolyl isobutyrothiohydroximate, which crystallized spontaneously from the concentrated ethereal solution in colorless laths; 1.33 g (66%), m.p. 155–159°, raised to 158–159° on recrystallization from ether – petroleum ether.

Anal. Calcd. for $C_{11}H_{15}NOS$: C, 63.12; H, 7.22; N, 6.69; S, 15.32. Found: C, 63.34; H, 7.46; N, 6.83; S, 15.03.

The following thiohydroximates were similarly prepared.

S-p-Tolyl Acetothiohydroximate

(IV, R′ = methyl, R″ = *p*-tolyl.) Colorless laths from ether – petroleum ether, m.p. 132–134° (61%).

Anal. Calcd. for $C_9H_{11}NOS$: C, 59.61; H, 6.11; N, 7.73; S, 17.68. Found: C, 59.37; H, 6.01; N, 8.35; S, 18.07.

[5]*This conclusion is opposite to the one which we gave initially (5). The structures given in these earlier communications should be amended to the anti configuration.*

For personal use only.

S-Methyl Benzothiohydroximate

(IV, R′ = phenyl, R″ = methyl.) Colorless spars from ether – petroleum ether, m.p. 85° (50%).

Anal. Calcd. for C_8H_9NOS: C, 57.40; H, 5.43; N, 8.38; S, 19.18. Found: C, 57.60; H, 5.48; N, 8.20; S, 18.93.

S-Ethyl Benzothiohydroximate

(IV, R′ = phenyl, R″ = ethyl.) Colorless prisms from ether – petroleum ether, m.p. 90–91° (87%).

Anal. Calcd. for $C_9H_{11}NOS$: C, 59.63; H, 6.11; N, 7.73; S, 17.69. Found: C, 59.78; H, 6.26; N, 7.55; S, 17.72.

S-t-Butyl Benzothiohydroximate

(IV, R′ = phenyl, R″ = *t*-butyl.) Colorless spars from ether – light petroleum, m.p. 55–56° (12%).

Anal. Calcd. for $C_{11}H_{15}NOS$: C, 63.12; H, 7.22; N, 6.69; S, 15.32. Found: C, 63.36; H, 7.07; N, 6.83; S, 15.21.

In this preparation, the major product isolated was the furoxan (67%), formed by dimerization of the benzonitrile oxide, which crystallized first from ether – petroleum ether, m.p. 115–116°. Lit. (10) m.p. 114–115°.

S-(2-Carboxyethyl) Benzothiohydroximate

(IV, R′ = phenyl, R″ = CH_2CH_2COOH.) Prepared in ice-cold methanol solution and obtained as fine colorless prisms from ethanol, m.p. 146° (50%).

Anal. Calcd. for $C_{10}H_{11}NO_3S$: C, 53.30; H, 4.92; N, 6.22; S, 14.25. Found: C, 53.38; H, 5.10; N, 6.10; S, 14.24.

S-Benzyl Benzothiohydroximate

(IV, R′ = phenyl, R″ = benzyl.) Colorless laths from ether – petroleum ether, m.p. 121–122° (91%). Lit. (1) m.p. 121–122°.

S-Phenyl Benzothiohydroximate

(IV, R′ = phenyl, R″ = phenyl.) Colorless prisms from ethanol, m.p. 142–143° (91%).

Anal. Calcd. for $C_{13}H_{11}NOS$: C, 68.09; H, 4.84; N, 6.11; S, 13.99. Found: C, 68.04, H, 4.93; N, 6.34; S, 13.72.

S-p-Tolyl Benzothiohydroximate

(IV, R′ = phenyl, R″ = *p*-tolyl.) Colorless plates from ether – petroleum ether, m.p. 134–135° (84%).

Anal. Calcd. for $C_{15}N_{15}NOS$: C, 69.98; H, 5.87; N, 5.44; S, 12.46. Found: C, 70.25, H, 6.20; N, 5.78; S, 12.90.

S-Methyl Phenylacetothiohydroximate

(IV, R′ = benzyl, R″ = methyl.) Long spars from ether – petroleum ether, m.p. 85° (65%).

Anal. Calcd. for C_8H_9NOS: C, 57.40; H, 5.43; N, 8.38; S, 19.18. Found: C, 57.60; H, 5.48; N, 8.20; S, 18.93.

S-p-Tolyl Phenylacetothiohydroximate

(IV, R′ = benzyl, R″ = *p*-tolyl.) Colorless, flat plates from ether – petroleum ether, m.p. 134–135 (70%).

Anal. Calcd. for $C_{15}H_{15}NOS$: C, 69.98; H, 5.87; N, 5.44; S, 12.46. Found: C, 70.25; H, 6.20; N, 5.78; S, 12.90.

Se-Phenyl Benzoselenohydroximate

(IV, R′ = Ph, R″S = PhSe.) Colorless plates from ether – petroleum ether, m.p. 165–166° (35%).

Anal. Calcd. for $C_{13}H_{11}NOSe$: C, 56.53; H, 4.02; N, 5.07; Se, 28.59. Found: C, 56.45; H, 4.25; N, 5.17; Se, 28.44.

Preparation of Thiohydroximates by Method B

Isobutyrohydroxamoyl chloride (1.0 g) was dissolved in carbon tetrachloride (20 ml), and the solution was cooled to 0° and stirred whilst a solution of triethylamine (0.85 g) in carbon tetrachloride (5 ml) was added. The reaction mixture became pasty. The triethylamine hydrochloride was filtered off and washed with a little carbon tetrachloride, and the pale-yellow solution was refiltered. The solution exhibited intense absorption at 2300 cm^{-1}. Addition of *p*-toluenethiol (0.50 g) to this solution resulted in very rapid disappearance of this absorption band. (The band had completely disappeared by the time that the solution was reintroduced into the cell and the spectrum at 2300 cm^{-1} re-examined, ca. 1 min). Evaporation of the solution gave a yellow oil which crystallized from ether as the *thiohydroximate*, m.p. 156–158°, undepressed on admixture with the material prepared by method A. Better yields of the thiohydroximate were obtained by working with more dilute solutions of the hydroxamoyl chloride in ether.

The crystalline phenylacetohydroxamoyl and benzohydroxamoyl chlorides behaved similarly.

ACKNOWLEDGMENTS

We wish to thank Dr. M. G. Ettlinger of Rice University, Houston, Texas, for drawing our attention to the syntheses of mustard oil glucosides described in ref. 6 and for his helpful comments on the stereochemical aspects of the thiohydroximate synthesis.

We also wish to thank Evans Chemetics Inc., 250 East 43rd St., New York 17, N.Y.,

PRÉPARATION DU *tert*-BUTYL-5 DIMÉTHYL-3,3 CYCLOHEXÈNE ET DE QUELQUES ISOMÈRES[1]

JEAN-CLAUDE RICHER ET PATRICE BÉLANGER[2]
Département de Chimie, Université de Montréal, Montréal, Québec
Reçu le 19 mai 1964

RÉSUMÉ

Les hydrocarbures isomères (III, X, XI, XII et XV) ont été préparés par des méthodes standards et ont été caractérisés grâce à leurs propriétés physiques et à leur temps de rétention en c.p.g.

Au cours d'une étude connexe sur la solvolyse des tosylates dérivés des *tert*-butyl-4 diméthyl-2,2 cyclohexanols (I), la formation des hydrocarbures III, X, XI, XII et XV comme produits réactionnels pouvait être envisagée. Le présent travail a été entrepris afin de réaliser la synthèse de ces hydrocarbures par des méthodes non ambigües. Les schémas réactionnels utilisés pour ces synthèses sont présentés dans le Diagramme I.

La pyrolyse du xanthogénate de méthyle (II) dérivé du *tert*-butyl-4 diméthyl-2,2 cyclohexanol-*trans* (I) selon la méthode de Tchougaeff (1) conduit à l'hydrocarbure III dont la pureté est confirmée par chromatographie en phase gazeuse (c.p.g.) analytique.

L'action du réactif de Grignard (iso-PrMgI) sur la *tert*-butyl-3 cyclopentanone (VII) conduit à un mélange de *tert*-butyl-3 isopropyl-1 cyclopentanols VIII et d'un solide dont la constitution n'a pas été établie mais qui est probablement la (*tert*-butyl-3 cyclopentylydène)-2 *tert*-butyl-4 cyclopentanone IX. La formation de composés semblables à ce dernier serait due à l'action aldolisante du dérivé magnésien (2) et a déjà été observée par plusieurs auteurs (3, 4, 5). Les acétates des alcools tertiaires isomères sont pyrolysées à 450° selon la méthode de DePuy (6). Les trois hydrocarbures (X, XI et XII), dont on peut théoriquement prévoir la formation, sont isolés à l'état pur par c.p.g. préparative. La structure X est assignée à l'hydrocarbure (n_D^{22}: 1.4640) qui donne naissance à la *tert*-butyl-3 cyclopentanone (VII) par ozonolyse oxydante. Les structures XI et XII sont attribuées respectivement aux hydrocarbures (n_D^{22} 1.4478 et 1.4522) dont le proton vinylique apparait dans le spectre r.m.n. sous forme de doublet (5.20 p.p.m.) et de triplet (5.28 p.p.m.).

Les *tert*-butyl-4 diméthyl-1,2 cyclohexanols isomères (XIV) obtenus par addition de l'iodure de méthylmagnésium sur la *tert*-butyl-4 méthyl-2 cyclohexanone (XIII) sont deshydratés à l'aide de l'iode selon les indications de Hammond et Nevitt (7). Une analyse du produit réactionnel par c.p.g. analytique indique la présence de cinq produits. Le produit majeur de la réaction (XV) est isolé à l'état pur par c.p.g. préparative. La structure XV attribuée à cet hydrocarbure est supportée par les spectres infrarouge et r.m.n. et est confirmée par ozonolyse oxydante du produit suivie d'une réaction haloformique qui conduit à de l'acide *tert*-butyl-3 adipique (VI*a*).

Les propriétés physiques des hydrocarbures obtenus ainsi que leurs temps de rétention en c.p.g. sont résumés dans le Tableau I. Il est à noter que par c.p.g. chacun de ces hydrocarbures présents dans un mélange peut être détecté.

PARTIE EXPÉRIMENTALE

Les spectres infrarouge ont été mesurés à l'aide d'un spectrophotomètre "Perkin–Elmer" modèle 21 à double faisceau avec prismes de chlorure de sodium. Les analyses par c.p.g. sont effectués sur un appareil Kromo-Tog, modéle K-2 de la compagnie Burrell. Les points de fusion ont été déterminés dans des tubes capillaires dans un appareil dont le thermomètre avait été calibré avec des standards du Bureau des Standards de Washington. Les spectres de résonance magnétique nucléaire ont été enregistrés à l'aide d'un spectromètre modèle A-60 de Varian. Les déplacements chimiques, δ, sont exprimés en parties par million (p.p.m.) du champs total. Le tétraméthylsilane est utilisé comme standard interne. Les analyses élémentaires sont de C. Daesslé, Montréal.

Par extraction à la manière habituelle, on entend que le produit est extrait trois fois par de l'éther et que les solutions éthérées, lavées successivement par uns solution à 5% de bicarbonate de sodium et par de l'eau distillée jusqu'à neutralité, sont séchées sur du sulfate de sodium anhydre et évaporées au travers d'une colonne Widmer 30 cm.

1. Synthèse du tert-butyl-5 diméthyl-3,3 cyclohexène, III

1.1. Préparation du xanthogénate de méthyle (II) du tert-butyl-4 diméthyl-2,2 cyclohexanol trans, I

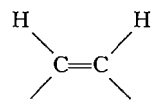
Une solution de 1 g de l'alcool I dans 15 ml de toluène anhydre est mise en contact avec 1 g de sodium et le tout est refluë durant 24 h. Après le reflux, l'excès de sodium est enlevé mécaniquement, 5 ml de sulfure de carbone est ajoutés et le mélange est agité à la température de la pièce durant 1 h. On ajoute alors 14 ml d'iodure de méthyle au mélange réactionnel qui est chauffé à reflux durant 4 h avant d'être laissé à la température de la pièce pour la nuit. Par extraction à la manière habituelle et distillation à 125–126° à 1 mm Hg, le xanthogénate désiré (II) est obtenu.

Un échantillon analytique, $n_D^{25} = 1.5262$, montre dans l'infrarouge des bandes caractéristiques à 1225 cm^{-1} et 1050 cm^{-1}.

Anal. Calc. pour $C_{14}H_{26}OS_2$: S, 10.71. Trouvé: S, 10.56.

1.2. Pyrolyse du xanthogénate, II

Dans un appareil à distillation contenant des morceaux de verre maintenus à une température de 300° à l'aide d'un bain de sable, on ajoute goutte à goutte 1 g de xanthogénate II. L'hydrocarbure brut distille au fur et à mesure de sa formation. Par redistillation, 0.54 g (90% du rendement théorique) de l'hydrocarbure désiré III sont obtenus. Un échantillon analytique du *tert*-butyl-5 diméthyl-3,3 cyclohexène (III) distille à 69–70° à 41 mm Hg, et son indice de réfraction est 1.4452 à 22°. La c.p.g. à l'aide d'une colonne de Carbowax 20% à 130° révèle la présence d'un seul produit. Le spectre infrarouge montre une bande à 1650 cm^{-1}.



Les bandes principales apparaissant dans le spectre r.m.n. de cet hydrocarbure sont à 0.87 p.p.m. (9 protons dûs au groupe *tert*-butyle), 0.95 (6 protons, du groupe *gem*-diméthyle) at à 5.40 p.p.m. (2 protons dûs aux hydrogènes éthyléniques).

2. Synthèse des tert-butyl isopropyl cyclopentènes

2.1. Préparation de l'acide tert-butyl-3 adipique, VIa

2.11. Par l'intermédiaire de l'acétate énolique, V, de la tert-butyl-4 cyclohexanone

(a) Préparation de l'acétate énolique, V.—Dans un ballon à fond rond adéquat, 23 g de *tert*-butyl-4 cyclohexanone (IV) sont placés avec 72 ml d'acétate d'isopropényle et 0.5 ml d'acide sulfurique concentré. Sous une atmosphère d'azote, le mélange est maintenu à reflux durant 1 h puis 50 ml de solvant est distillé sous une pression réduite de 60 mm Hg. Le mélange réactionnel est alors extrait à la manière habituelle et le produit purifié par distillation à 112° à 25 mm Hg.

Une échantillon analytique, n_D^{25} 1.4638, montre dans l'infrarouge les bandes caractéristiques aux acétates énoliques à 1755 cm^{-1} et 1697 cm^{-1}.

Anal. Calc. pour $C_{12}H_{20}O_2$: C, 73.42; H, 10.27. Trouvé: C, 73.31; H, 10.50.

(b) Ozonolyse.—Une solution de 5 g de l'acétate énolique (V) en solution dans 100 ml d'éther de pétrole sans doubles liaisons est soumise à l'action d'un courant d'ozone dans l'oxygène. Lorsque la coloration bleue de l'ozone apparaît, l'éther de pétrole est évaporé sous un jet d'azote. On ajoute alors 50 ml d'acétate d'éthyle, 50 ml de peroxyde d'hydrogène 30% et 100 ml d'eau et on laisse le mélange réactionnel à la température de la pièce pour la nuit. Par extraction à la manière habituelle, l'acide *tert*-butyl-3 adipique, p.f. 117–118° (litt. (8) 118 °C), est obtenu.

L'estérification de cet acide par le diazométhane conduit au diesther méthylique (VI*b*), n_D^{23} 1.4425, ne montrant qu'un seul pic en c.p.g. analytique.

2.12. Oxydation de la tert-butyl-4 cyclohexanone, IV, par le permanganate de potassium

Dans un ballon de 5 l, on introduit 100 g de *tert*-butyl-4 cyclohexanone (IV), 80 g d'hydroxyde de potassium, 300 g de permanganate de potassium et 3000 ml d'eau. La température du mélange réactionnel est maintenue près de 50° grâce à un bain d'eau. Lorsque toute la cétone IV est passée en solution indiquant que la réaction est terminée, le mélange réactionnel est porté à son point d'ébullition pendant quelques instants. Après avoir refroidi le tout, le bioxyde de manganèse est éliminé par filtration et le filtrat est décoloré par addition de bisulfite de sodium. La solution est alors concentrée sous vide et acidifiée par de l'acide chlorhydrique concentré. L'acide *tert*-butyl-3 adipique se sépare sous forme de solide blanc que l'on récupère par filtration. Après recristallisation dans l'eau, l'acide VI*a* fond à 117–118° (litt. (8) 118°).

2.2. Tert-butyl-3 cyclopentanone, VII

Un mélange formé de 60 g d'acide *tert*-butyl-3 adipique (VI*a*) et de 200 ml d'anhydride acétique est chauffé à reflux dans un appareil à distiller du type Claisen; l'acide acétique distille au fur et à mesure de sa formation. Lorsque la réaction est terminée, l'anhydride acétique en excès est éliminé par distillation et l'anhydride de l'acide VI*a* est chauffé sur un bain de sable à une température de 300°; un liquide jaunâtre distillant à 208° est recueilli. Le produit brut est versé sur une solution d'hydroxyde de sodium 20%, laissé en contact pendant 15 min et finalement extrait à la manière habituelle. La *tert*-butyl-3 cyclopentanone (VII) purifiée par distillation à 74–75° à 15 mm Hg (litt. (8) 202° à 760 mm Hg) possède un indice de réfraction de 1.4482 (litt. (8) 1.4505 à 22°.

La semicarbazone de cette cétone fond à 203–204° (litt. (8) 194°) alors que sa dinitro-2,4 phénylhydrazone fond à 140° (litt. (8) 139°).

2.3. Tert-butyl-3 isopropyl-1 cyclopentanols et leurs acétates

2.31. Synthèse des tert-butyl-3 isopropyl-1 cyclopentanols, VIIIa

Dans un ballon adéquat, on place 15 g de magnésium et 25 ml d'éther anhydre. A cette suspension, 100 g d'iodure d'isopropyle dilués à l'aide de 200 ml d'éther anhydre sont ajoutés; le mélange réactionnel est porté à reflux durant 4 h puis refroidi. Une solution de 35 g de *tert*-butyl-3 cyclopentanone (VII) dans 50 ml d'éther anhydre est ajoutée lentement; lorsque l'addition est terminée, le mélange réactionnel est chauffé à reflux pour la nuit. De l'eau glacée est alors ajoutée lentement et la masse solide est dissoute par addition d'acide tartrique 1 *M*. La fraction éthérée est alors lavée à la manière habituelle et le produit brut est purifié par distillation sous vide.

La première fraction, de point d'ébullition 80° à 150 mm Hg, pèse 6.94 g (15% du rendement théorique). Un spectre infrarouge montre la présence d'une bande à 3400 cm^{-1} et une bande faible à 1745 cm^{-1}; cette dernière bande est attribuée à la cétone de départ qui n'a pas réagit et celle-ci est éliminée par des lavages à l'aide d'une solution saturée de bisulfite de sodium. Le produit obtenu (VIII*a*) ne montre alors qu'un seul pic par c.p.g. sur Carbowax 20%.

La seconde fraction, point d'ébullition 180° à 2.5 mm Hg, pèse 38.4 g (85% du rendement théorique) et se présente sous forme de liquide fortement coloré et très visqueux qui se solidifie après quelques semaines. Le spectre infrarouge montre de larges bandes carbonyles à 1735 et 1710 cm^{-1} et n'indique aucune bande dans le voisinage de 3400 cm^{-1}. Ce produit pour lequel la structure IX a été proposée n'a pas eté étudié plus à fond.

2.32. Acétylation des tert-butyl-3 isopropyl-1 cyclopentanols, VIIIa

Une solution formée de 5 g d'alcools VIII*a*, 5 g de chlorure d'acétyle et de 50 ml de diméthylaniline est portée à reflux pendant 2 h. Après refroidissement, le mélange est versé dans une solution glacée d'hydroxyde de sodium 20% et extrait à la manière habituelle. La redistillation du produit brut conduit aux acétates VIII*b*, p.é. 88° à 125 mm Hg n_D^{23} 1.4759, dont le spectre infrarouge montre une bande à 1740 cm^{-1}, caractéristique aux acétates.

2.4. Pyrolyse des acétates, VIIIb

Dans un appareil à distillation contenant des morceaux de verre dont la température est maintenue à 450°, on introduit 3 g des acétates VIII*b*. Le produit brut distille au fur et à mesure de sa formation et est ensuite extrait à la manière habituelle. Le produit obtenu est analysé par c.p.g. sur Carbowax 20% à 130°; cette méthode montre la présence de trois composants.

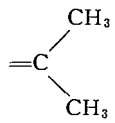
La c.p.g. est effectuée sur le mélange dans les conditions suivantes.

Appareil: Fisher Prep-partitionner.
Colonnes: 8 colonnes de Polyester de Craig 15%.
Températures: colonne 100 °C,
flash evaporator 290 °C,
cellule 200 °C.
Débit d'azote: 15 lbs/p.c.

De cette manière, le mélange est séparé en trois fractions. La première fraction, formée du *tert*-butyl-3 isopropyl-1 cyclopentène (XI), p.é. 66° à 32 mm Hg et n_D^{22} 1.4478, montre une bande à 1645 cm^{-1} dans l'infrarouge. Dans le spectre r.m.n. on note des bandes à 0.85 p.p.m. (9 protons du *tert*-butyle), 1.00 p.p.m. (doublet, $J = 7$ c.p.s.; 6 protons des méthyles du groupe isopropyle) et 5.20 p.p.m. (doublet mal défini; 1 proton éthylénique). La deuxième fraction, composée du *tert*-butyl-4 isopropyl-2 cyclopentène (XII),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

p.é. 65° à 32 mm Hg et n_D^{22} = 1.4522, montre une bande à 1650 cm^{-1} dans l'infrarouge. Dans le spectre r.m.n. de cet hydrocarbure, on note des bandes à 0.85 p.p.m. (9 protons du *tert*-butyle), 1.04 p.p.m. (doublet, J = 7 c.p.s.; 6 protons des méthyles du groupe isopropyle) et 5.28 p.p.m. (triplet, J = 2.6 c.p.s.; 1 proton éthylénique). Pour des composés similaires à XI et XII Smith et Trotter (9) observent des pics à 5.13 et 5.23 p.p.m. respectivement. La troisième fraction, composé de *tert*-butyl-3 isopropylydènecyclopentane (X) p.é. 67° à 32 mm Hg et n_D^{22} 1.4640, ne montre aucune bande vers 1650 cm^{-1}, ce qui suggère une double liaison tétrasubstituée. Une ozonolyze oxydante de cet hydrocarbure (X), effectuée dans les conditions expérimentales décrites à la section 2.11, fournit de la *tert*-butyl-3 cyclopentanone (VII) décelée par c.p.g. sur une colonne de Carbowax 20% à 130°. Dans le spectre r.m.n. de cet hydrocarbure, aucune bande n'est notée dans la région de 5.25 p.p.m.; le groupe *tert*-butyle apparaît à 0.88 p.p.m. alors qu'un signal correspondant à 6 protons est noté à 1.57 p.p.m.



Il est à noter que la c.p.g. analytique de chacun des produits décrits ici ne montre qu'un pic.

3. Synthèse du tert-butyl-4 diméthyl-1,2 cyclohexène

3.1. Préparation des tert-butyl-4 diméthyl-1,2 cyclohexanols

Dans un ballon à fond rond de 500 ml surmonté d'un réfrigérant Vigreux, d'une ampoule à addition et d'un tube à chlorure de calcium on introduit 4.6 g de magnésium et 25 ml d'éther anhydre. A cette suspension, 25.4 g d'iodure de méthyle sont additionnés à une vitesse telle que l'éther reflue doucement. Après l'addition, le mélange est porté à reflux pendant 3 h puis refroidi. Au dérivé magnésien ainsi formé, 25 g de *tert*-butyl-4 méthyl-2 cyclohexanone (XIII, préparé suivant les indications de ref. 10) en solution dans 50 ml d'éther anhydre sont ajoutés lentement et le mélange réactionnel est laissé à la température de la pièce pour la nuit. Le dérivé magnésien en excès est détruit par addition d'eau glacée et la masse solide est dissoute par addition d'une solution d'acide chlorhydrique 10%. Après extractions à la manière habituelle, les alcools désirés (XIV) sont recueillis et purifiés par distillation.

Un échantillon analytique, p.é. 105° à 50 mm Hg et n_D^{22} = 1.4662, montre dan l'infrarouge une large bande hydroxyle à 3400 cm^{-1}. Par chromatographie en phase gazeuse analytique sur Carbowax 20%, on note la présence de deux produits différents du produit de départ.

Anal. Calc. pour $C_{12}H_{24}O$: C, 78.19; H, 13.13. Trouvé: C, 78.34; H, 12.97.

3.2. Deshydratation des tert-butyl-4 diméthyl-1,2 cyclohexanols, XIV

Dans un appareil à distillation Vigreux, la deshydratation est effectuée en chauffant 5 g de *tert*-butyl-4 diméthyl-1,2 cyclohexanols (XIV) en présence de 0.25 g d'iode à 170°. Un mélange d'eau et d'hydrocarbures distille à 140°. Le distillat ainsi formé est extrait à la manière habituelle et le produit brut obtenu, analysé par c.p.g. sur Carbowax 20% à 130°, est formé de cinq composants.

Par c.p.g. préparative dans des conditions semblables à celles décrites à la section 2.4, le *tert*-butyl-4 diméthyl-1,2 cyclohexène (XV) est obtenu à l'état pur. Le produit purifié, p.é. 67–68° à 35 mm et n_D^{22} 1.4658, ne montre aucune bande dans le voisinage de 1650 cm^{-1}. La structure de l'hydrocarbure est confirmée par son spectre r.m.n. qui montre des bandes à 0.86 p.p.m. (9 protons du *tert*-butyle) et 1.57 p.p.m. (6 protons des deux méthyles attachés à la double liaison).

3.3. Ozonolyse oxydante de tert-butyl-4 diméthyl-1,2 cyclohexène

Une solution de 500 mg de l'hydrocarbure XV dans 50 ml d'éther de pétrole libre de doubles liaisons est ozonolysée en suivant les indications décrites à la section 2.11. Après extraction à la manière habituelle, le produit obtenu est ajouté à une solution d'hypoiodite de sodium, formée par l'addition de 5 g d'iode à une solution d'hydroxyde de sodium 20%. Un précipité d'iodoforme se forme immédiatement et est éliminé par filtration. Le filtrat est acidifié par de l'acide chlorhydrique concentré et extrait à la manière habituelle. Après évaporation du solvant d'extraction, le résidu est dissous dans 50 ml d'éther anhydre et une solution de diazométhane est ajoutée jusqu'à persistance de la coloration jaune. L'éther est alors évaporé et le produit brut est chromatographié en phase gazeuse sur une colonne de Carbowax 20% à 150°. Un pic qui se superpose avec celui de l'ester méthylique (VI*b*) de l'acide *tert*-butyl-3 adipique est obtenu.

REMERCIEMENTS

Les auteurs remercient sincèrement le Conseil National de Recherches du Canada pour l'aide financière apportée sous forme de subvention de recherche (A-1295), le Ministère de la Jeunesse de la province de Québec pour la bourse de perfectionnement attribuée à P. Bélanger, la compagnie Dow Chemicals of Canada Ltd. pour un généreux échantillon de *tert*-butyl-4 cyclohexanone et la compagnie Pitt-Consol Chemical Company, Library, Pennsylvania, pour un généreux échantillon de *tert*-butyl-4 méthyl-2 phénol.

KINETICS OF THE CATALYZED HYDROLYSIS OF *p*-NITROPHENYL ACETATE

E. SACHER[1] AND K. J. LAIDLER
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received May 28, 1964

ABSTRACT

Catalytic constants have been determined for the hydrolysis at 20 °C of *p*-nitrophenyl acetate in 9.56% (w/w) dioxane–water mixtures; catalysts used were hydroxide ions, imidazole and 2-methylimidazole, various substituted pyridines, serine, histidine and histidylhistidine. In the case of hydroxide ion catalysis, the rate constant falls off at high catalyst concentrations, and this is attributed to the establishment of an equilibrium involving the anion of the substrate. The results with the various catalysts indicate that there is no simple correlation between catalytic efficiency and pK or nucleophilicity. In the imidazole series there is evidence of steric hindrance when a group is present in a position next to the functional group. There is an indication of bifunctional catalysis in the hydrolysis by 2-(β-hydroxyethyl)pyridine and 4-(γ-hydroxypropyl)pyridine, both of which are much more effective than pyridine.

INTRODUCTION

The factors influencing the effectiveness of a catalyst are still by no means understood. The Brønsted relationships indicate that the ease with which a proton is transferred plays a very important role, but there are cases where there is serious interference by other effects. Because of these gaps in our knowledge the very high catalytic efficiencies of enzymes have still received no satisfactory explanation. Enzyme mechanisms involving bifunctional catalysis have been proposed for several systems (e.g. chymotrypsin (1, 2), acetylcholinesterase (3), the dehydrogenases (4), and ribonuclease (5)). Up to the present time, however, bifunctional catalysis has only been clearly established for the catalysis by 2-hydroxypyridine of mutarotation reactions (6). Since this work was done in benzene solution it does not offer a good analogy to an enzyme system.

The present work, carried out on *p*-nitrophenyl acetate with a series of catalysts, was done with the object of learning more about the factors influencing catalytic efficiency. It was also hoped to obtain clear-cut examples of bifunctional catalysis in aqueous solution, and it appears that these were found in the case of two hydroxyalkyl pyridines.

EXPERIMENTAL

Materials

All of the work was carried out in 9.56% (w/w) dioxane–water mixtures. The dioxane was purified by the method of Fieser (7) and was stored in pyrex and Teflon apparatus under nitrogen: precautions were taken to prevent the solvent from coming into contact with the atmosphere, so as to avoid the formation of peroxide impurities which are known to have a very strong catalytic effect.

The *p*-nitrophenyl acetate was prepared by the method of Chattaway (8), and was purified by several recrystallizations from an acetone–water mixture. The catalysts were pure commercial products which were carefully repurified either by vacuum sublimation or by fractional distillation.

The titrant used to follow the course of the reaction was 0.02 N sodium hydroxide solution, prepared from the Fisher Certified reagent.

Procedure

The reactions were followed using a pH-stat, the sodium hydroxide solution being continuously and automatically added so as to maintain a constant pH. The pH-stat equipment was that supplied by the Radiometer Company of Copenhagen (TTT1c titrator, TTA3 titration assembly, SBU1 burette and SBR2

[1]*Present address: Film Department, Research and Development Division, E. I. du Pont de Nemours and Company, Wilmington 98, Delaware, U.S.A.*

recorder). The pH values reported in this paper are those measured using this equipment; no solvent corrections have been made.

The reactions were carried out in 10 ml of 9.56% (w/w) dioxane–water mixture containing 2 meq of potassium chloride and maintained at 20.0 °C in a thermostatically controlled bath. Stock solutions of ester and catalysts were made up in dioxane, except for the amino acids and hystidylhistidine, for which water solvent was used. The concentration of the stock solutions was 0.2 *M*, or as close to 0.2 *M* as solubility allowed, and the reactions were carried out with the catalysts at a concentration of approximately 10^{-3} *M*.

The reactions were followed to about 5% completion, and rates were obtained from the initial slopes of the records.

RESULTS

Hydroxide Ion Catalysis

The catalysis by hydroxide ions was carried out from pH 8.4 to 10.7. A plot of rate against hydroxide ion concentration showed a marked deviation from linearity at high hydroxide ion concentrations, as shown in Fig. 1*a*. This behavior suggested that a law of the form

$$[1] \qquad v = \frac{a[\mathrm{S}][\mathrm{OH}^-]}{1 + b[\mathrm{OH}^-]}$$

was being obeyed. This was tested by making plots of $v/[\mathrm{OH}^-]$ against v (Fig. 1*b*) and of $1/v$ against $1/[\mathrm{OH}^-]$. From these plots the values obtained for the constants were

$$a = 21.5 \text{ l mole}^{-1} \text{ s}^{-1}$$

and

$$b = 6140 \text{ l mole}^{-1}.$$

The value of a, the second-order rate constant at low hydroxide ion concentrations, is consistent with the results of previous studies (9–12) carried out in different solvents. The previous investigations were not carried out over such a wide range of hydroxide ion concentrations, and did not reveal the falloff at high pH values.

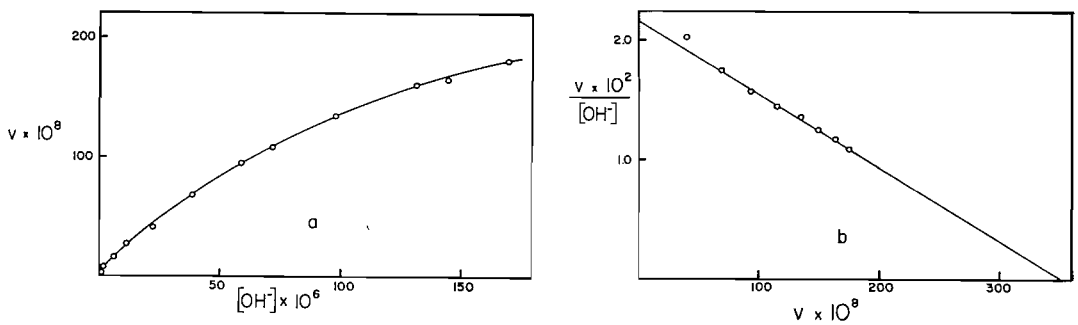

FIG. 1. Plot of v against $[\mathrm{OH}^-]$ (*a*) and of $v/[\mathrm{OH}^-]$ against v (*b*) for the alkaline hydrolysis of *p*-nitrophenyl acetate. The units of velocity are moles l^{-1} s^{-1}, while $[\mathrm{OH}^-]$ is in moles l^{-1}.

Catalysis by Imidazole and Its Derivatives

The hydrolysis of *p*-nitrophenyl acetate catalyzed by imidazole has previously been studied in various solvents (9, 12, 13), and the rate was found to be proportional to the concentrations of both substrate and catalyst. The same result was found in the present work, but the rate constant was significantly smaller, as shown in Table I. This difference is believed to be due to the presence in the previous work[2] of peroxides, as

[2]*This possibility is referred to in footnote 16 of ref. 13; unpurified dioxane has a marked catalytic effect on the reactions.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

contaminants in the dioxane solvent; peroxides are known to have a powerful catalytic effect. The previous study in dioxane (9) also showed excessive hydroxide ion catalysis, attributed to the same cause.

The hydrolysis catalyzed by 2-methylimidazole was also stated by previous investigators (14) to be first order in both catalyst and substrate, with a rate constant of 7.0×10^{-2} l mole^{-1} s^{-1}. The solvent was 28.5% (v/v) ethanol–water, and the temperature was 30.0 °C. No catalysis could be detected in the present investigation, from which it is concluded that the rate constant is less than 10^{-4} l mole^{-1} s^{-1}. The discrepancy is again attributed to peroxide catalysis in the previous investigation.

TABLE I

Rate constants for the catalysis of the hydrolysis of *p*-nitrophenyl acetate by imidazole

Solvent	Temperature (°C)	Rate constant (l mole^{-1} s^{-1})	Reference
Ethanol–water 1.90% (v/v)	25.0	0.425	Koltum *et al.* (11)
Dioxane–water 5.0% (v/v)	26.0	0.47*	Bender and Turnquest (13)
Ethanol–water 28.5% (v/v)	25.0	0.233	Bruice and Schmir (14)
Ethanol–water 28.5% (v/v)	30.0	0.355	Bruice and Schmir (14)
Dioxane–water 9.56% (w/w)	20.0	0.058±0.002	Present work

*This high value is suspect, as noted in footnote 16 of ref. 13; imidazole is reported to have a higher catalytic effect in 5% dioxane than in 1.9% ethanol, whereas the opposite is expected.

TABLE II

Rate constants for the catalysis of the hydrolysis of *p*-nitrophenyl acetate by pyridine and derivatives

Catalyst	Solvent	Temperature (°C)	Rate constant (l mole^{-1} s^{-1})	Reference
Pyridine	Water	25.0	16.7×10^{-4}	Jencks and Carriuolo (12)
Pyridine	Ethanol–water 28.5% (v/v)	30.0	14.7×10^{-4}	Bruice and Schmir (14)
Pyridine	Dioxane–water 5.0% (v/v)	26.0	5.3×10^{-4}	Bender and Turnquest (9)
Pyridine	Dioxane–water 9.56% (w/w)	20.0	0	Present work
2-Methylpyridine	Dioxane–water 9.56% (w/w)	20.0	0	Present work
4-Methylpyridine	Dioxane–water 5.0% (w/w)	26.0	7.95×10^{-3}	Bender and Turnquest (9)
4-Methylpyridine	Ethanol–water 28.5% (v/v)	30.0	8.2×10^{-3}	Bruice and Schmir (14)
4-Methylpyridine	Dioxane–water 9.56% (w/w)	20.0	$(4.6\pm0.15)\times10^{-3}$	Present work

Catalysis by Pyridine and Its Derivatives

The results of the present work, and of previous investigations, are summarized in Table II. In all cases the reaction was first order in both substrate and catalyst.

Catalysis by Amino Acids

The rate law was again of the same form; the rate constants are summarized in Table III. It is to be noted that hystidylhistidine has about the same effectiveness as imidazole, when the presence of two groups is allowed for.

TABLE III

Rate constants for the catalysis of the hydrolysis of *p*-nitrophenyl acetate by amino acids

Catalyst	Solvent	Temperature (°C)	Rate constant (l mole^{-1} s^{-1})	Reference
Serine	Dioxane–water 9.56% (w/w)	20.0	$(2.4\pm0.1)\times10^{-2}$	Present work
Histidine	Dioxane–water 9.56% (w/w)	20.0	$(1.24\pm0.09)\times10^{-1}$	Present work
Histidylhistidine	Water	20.0	4.67×10^{-2}*	Jencks and Carriuolo (12)
Histidylhistidine	Dioxane–water 9.56% (w/w)	20.0	$(5.6\pm0.3)\times10^{-2}$*	Present work

*These rate constants have been divided by 2, to allow for the presence of two catalytic groups on each molecule.

TABLE IV

Catalytic constants for the hydrolysis of *p*-nitrophenyl acetate (solvent, 9.56% (w/w) dioxane–water; *T*, 25.0 °C)

Catalyst	Rate constant (l mole^{-1} s^{-1})	pK_a
Hydroxide ion	21.5	15.7

Chymotrypsin	1.63×10^{2}*	—
Trypsin	71†	—

*At pH 8.0.
†In 20% (v/v) isopropyl alcohol, pH 7.0, 25 °C.

GENERAL DISCUSSION

The catalytic constants obtained in the present work, and the pK_a's of the acids conjugate to the basic catalysts, are summarized in Table IV. Included in addition are the second-order constants (at low substrate concentrations) for the hydrolysis by the enzymes chymotrypsin and trypsin. The value for chymotrypsin was obtained in these laboratories by Kaplan (15) using the same dioxane–water solvent and at pH 8.0; that for trypsin was obtained by Stewart and Ouellet (16) in 20% (v/v) isopropyl alcohol at 25 °C and pH 7.0.

It was found in the present work that the rate of the reaction catalyzed by hydroxide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ions rises to a limiting value as the catalyst concentration is increased. This result is of interest in connection with a study on anilide hydrolysis by Biechler and Taft (17), who found a similar dependence on hydroxide ion concentration in the case of trifluoroacetanilide, $C_6H_5CONHCF_3$. They attribute the fall off of rate constant at high hydroxide ion concentrations to the establishment of the equilibrium

$$C_6H_5CONHCF_3 + OH^- \rightleftarrows C_6H_5CON^-CF_3 + H_2O.$$

This proton extraction is favored by the strongly electron-attracting character of the CF_3 group. In *p*-nitrophenyl acetate the strongly electron-attracting power of the *p*-nitrophenyl group will similarly lead to the establishment of the equilibrium

$$CH_3\overset{\overset{O}{\|}}{C}OC_6H_4NO_2 + OH^- \rightleftarrows {}^-CH_2\overset{\overset{O}{\|}}{C}OC_6H_4NO_2 + H_2O,$$

and the ion will be stabilized by resonance involving the structure

$$CH_2{=}\overset{\overset{O^-}{|}}{C}OC_6H_4NO_2.$$

The kinetics of the hydrolysis by hydroxide ions may thus be formulated as follows:

$$SH + OH^- \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} S^- + H_2O$$

$$H_2O + S^- \xrightarrow{k_2} OH^- + \text{products.}$$

Application of the steady-state treatment gives

$$[2] \qquad k_1([SH]_0 - [S^-])[OH^-] - (k_{-1} + k_2)[S^-] = 0$$

where $[SH]_0$ is the total concentration of substrate: the water concentration is incorporated in the rate constants k_{-1} and k_2. The rate is then

$$[3] \qquad v = \frac{k_1k_2[SH]_0[OH^-]}{k_{-1} + k_2 + k_1[OH^-]},$$

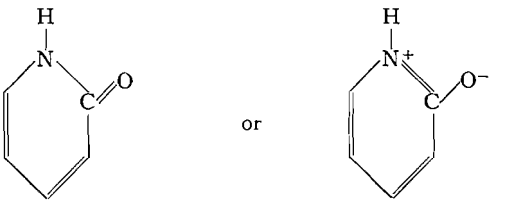
which is of the same form as eq. [1]. If this interpretation is correct, it follows that

$$k_2 = a/b = 3.5 \times 10^{-3}\ s^{-1}.$$

The results obtained with the various catalysts are not capable of any simple interpretation. There is no apparent correlation between catalytic efficiency and either pK or nucleophilicity. There is evidence for steric hindrance, in that 2-methylimidazole is less effective than imidazole in spite of being more basic. Clear-cut evidence for steric hindrance in catalysis has been obtained by Butler and Gold (18) in the hydrolysis of acetic anhydride, for which pyridine is a catalyst whereas 2-methylpyridine and 2,6-lutidine are not. More recently Feather and Gold (19) have noted steric hindrance in the iodination of ketones, reactions in which the rate-determining step is a proton transfer; again there was hindrance when substituents were introduced into the 2 and 6 positions of pyridine.

At first sight it might appear that evidence for bifunctional catalysis was provided by the fact that 2-hydroxypyridine, although a weaker base than pyridine, is a more powerful catalyst. This conclusion is not, however, valid, since it is known (20–24) that 2-hydroxypyridine exists largely as the pyridone tautomer:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



The nucleophilic group responsible for catalysis is therefore the carbonyl oxygen atom. An indication of bifunctional catalysis is, however, given by the fact that 2-(β-hydroxyethyl)pyridine and 4-(γ-hydroxypropyl)pyridine are much more effective than pyridine, in spite of the fact that they have approximately the same basicities. At the pH's of the present investigation these compounds exist in the forms in which the =N— and —OH groups are free. It therefore seems reasonable to suppose that catalysis is brought about by a nucleophilic attack by the nitrogen atom and a simultaneous proton transfer from the alcoholic hydroxyl group.

AN ATTEMPT TO STUDY COMPLEX FORMATION BETWEEN 1,3,5-TRINITROBENZENE AND OLEFINS BY GAS CHROMATOGRAPHY[1]

R. J. CVETANOVIĆ, F. J. DUNCAN,[2] and W. E. FALCONER[3]
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received June 12, 1964

ABSTRACT

An attempt has been made to study complex formation between 1,3,5-trinitrobenzene (TNB) and olefins by a gas chromatographic technique. A particular interpretation of the data indicates that the TNB – olefin complexes exhibit progressive increases in stability with increasing double-bond substitution. Steric effects are less pronounced than for olefin complexes with silver nitrate or molecular iodine. Olefins are well separated by carbon number, and differences in retention times among the structural isomers of each molecular weight are sufficiently characteristic to provide a basis for assigning major structural features.

Molecular complexes, or electron donor–acceptor complexes, have received much attention during the past 15 years, and have been the subject of a recent book (1) and several reviews (2–5). The quantum mechanical description of the interaction of electron donors and electron acceptors developed by Mulliken and his co-workers (5, 6) has gained general acceptance and satisfactorily explains the observed features of charge-transfer spectra. The association constants of 1:1 molecular complexes have been most frequently determined by the spectrophotometric methods recently evaluated by Hayman (7), who compared their reliability with the more classical partition method. DeMaine (8) has pointed out the need for additional nonspectrophotometric methods for determining complex stabilities which can provide data for comparison with the copious spectrophotometric data. Gas chromatography can potentially provide one such method.

Gas chromatography has for some time exploited the phenomenon of electron donor–acceptor complex formation to separate olefins selectively using silver nitrate – ethylene glycol – firebrick mixtures (9). Specific retentions of individual olefins are affected by their solubility in the ethylene glycol solvent, as well as by the strength of their interaction with the Ag^+ ions. Muhs and Weiss (10), and independently Gil-Av and Herling (11), have proposed methods for separating the two effects. An extensive list of equilibrium constants for the reaction

$$\text{olefin} + AgNO_3 \rightleftarrows \text{olefin} \cdot AgNO_3,$$

with all species dissolved in ethylene glycol, has been published (10).

The chromatographic approach to determining the stability of electron donor–acceptor complexes has been extended to include interactions with the following electron acceptors: solid silver nitrate (12), some complexes of the transition metals (13, 14), iodine (15), and in this paper 1,3,5-trinitrobenzene (TNB). Although TNB is among the most-studied electron acceptors, data concerning its interactions with simple olefins are sparse, undoubtedly because these olefin complexes are much weaker than those with aromatic molecules which have commonly been the object of spectrophotometric investigations (16).

EXPERIMENTAL

Column packings were prepared in the following manner.

Packing 1.—8.0 g TNB (Eastman Organic Chemicals) dissolved in 100 ml benzene was mixed with 32.0 g 30–60 mesh firebrick (Johns–Manville Chromosorb P) and the benzene was slowly evaporated under reduced pressure.

Packing 2.—29.9 g of the same firebrick was precoated by first mixing the firebrick with 0.69 g NaOH dissolved in 100 ml water and then evaporating the water under reduced pressure. When dry, the pretreated firebrick was mixed with 5.2 g TNB dissolved in 75 ml acetone. The mixture immediately turned a deep purple–red color (cf. ref. 17), which persisted when the acetone was slowly evaporated under reduced pressure.

Packing 3.—30.0 g of the same firebrick was precoated by mixing the firebrick with 0.73 g H_3PO_4 dissolved in 50 ml water and then evaporating the water as before. When dry, the pretreated firebrick was mixed with 5.3 g TNB dissolved in 75 ml acetone. There was no evidence of chemical reaction. The acetone was slowly evaporated under reduced pressure.

Packing 4.—8.0 g of TNB dissolved in 75 ml benzene was mixed with 32.0 g 60–80 mesh celite (Johns–Manville Chromosorb W) and the benzene was slowly evaporated under reduced pressure.

All packings were dry, had a uniform appearance, and flowed easily. Columns were prepared in 16 ft lengths of 4 mm I.D. Pyrex tubing and maintained at 0 °C in an ice bath. Samples[4] were flushed onto the columns from a U-shaped bypass injector, volume ~2 cc. Helium was used as the carrier gas, and linear flows through the columns were ~4 cm s^{-1}. A 6:1 bypass system was inserted between the injection system and the column to reduce the effective injection time to a few tenths of a second. Detection was with a flame ionization detector (18) and recorder chart speeds of either 1 or 2 in. per min were used.

Most samples used were Phillips Petroleum Company pure grade or A.P.I. research hydrocarbons. The purity of any others was predetermined by gas chromatography.

Attempts to obtain retention data using a 400 ft length of 0.015 in. I.D. type 316 stainless steel capillary tubing coated with TNB at 0, −20, and −78 °C were unsuccessful. No attempt was made to use TNB solutions as liquid phases, as has been found successful in studying $AgNO_3$ complexes (9–11, 19).

RESULTS

The adjusted retentions (20) of all olefins and paraffins studied relative to 1-pentene are listed in Tables I and II, respectively. From these values, plus the retention data in Table III, actual retention times under typical experimental conditions can be obtained. The relative retentions in Tables I and II are reproducible to within the larger of ±0.01 units or ±2% for columns 1 and 2, but are somewhat less reproducible for columns 3 and 4 on which retention times were shorter.

Column efficiencies were measured for all peaks for columns 2, 3, and 4. On column 2 (TNB on firebrick pretreated with NaOH), efficiencies dropped from about 300 theoretical plates per foot for early peaks to less than 250 theoretical plates per foot for those compounds retained ~30 min. On column 3 (TNB on firebrick pretreated with H_3PO_4), a similar decline in efficiency with retention time was observed, the range being approximately 300–200 theoretical plates per foot. For column 4 (TNB on untreated celite), a variation in efficiency with compound type was superimposed upon the decrease observed with retention time. Efficiencies, which dropped from 300 to 15 theoretical plates per foot, were notably lower for cyclic olefins, cyclic paraffins, and nonterminal olefins. For column 1 (TNB on untreated firebrick), only a few random efficiencies were measured but their trend and order of magnitude appeared to be similar to columns 2 and 3.

Figure 1 shows that good linear plots of log r against number of carbon atoms present in the molecule are obtained for any given structural type using TNB on NaOH pretreated firebrick columns. Similar plots are obtained with the other three columns. Retention times increase fourfold with each additional carbon atom, and hence all compounds are well grouped by the carbon atom content of the molecules. Differences within each group

[4]*Small samples (~10^{-3} micromole) were used throughout this investigation to minimize peak asymmetry due to concentration effects. Larger samples can be used if necessary, subject to limitations similar to those for conventional packed columns.*

are determined by structural changes and are sufficiently characteristic and reproducible that major structural features could be assigned from a measurement of the retention time of an unknown olefin.

It is instructive to consider the numbers obtained when the retention times of olefins (t_{ol}) are normalized by dividing by the retention times of the structurally analogous

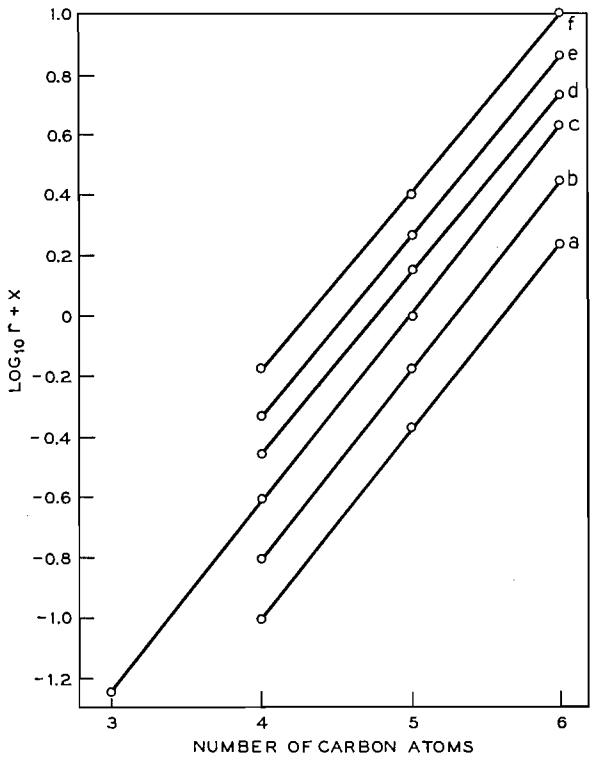

FIG. 1. Variation of $\log_{10} r$ with number of carbon atoms for column 2—(*a*) 2-methyl paraffins ($x = -0.2$), (*b*) *n*-paraffins ($x = -0.1$), (*c*) linear terminal olefins ($x = 0$), (*d*) 2-substituted terminal olefins ($x = 0.1$) (*e*) linear *trans*-2-olefins ($x = 0.2$), (*f*) linear *cis*-2-olefins ($x = 0.3$).

paraffins (t_p). Since paraffins do not complex and $RT \ln (t_{ol}/t_p) = -(\Delta F_{ol} - \Delta F_p)$, it can be assumed that, to a first approximation, this procedure removes the purely physical effect of surface condensation and the "normalized retention times" ($t_n = t_{ol}/t_p$) are determined by the free energies of complexing of olefins with TNB. Inasmuch as this assumption is correct, they should show the effects of increasing basicity of the double bond caused by electron donation from alkyl groups situated on the olefinic carbon atoms.[5]

Normalized retention times are listed in Table IV, grouped for each column by the number of carbon atoms in the olefin and the degree of double bond substitution. Mean

[5]*As might be expected, good correlations are also obtained by plotting log t_R against the boiling points. Distinct plots are obtained for different classes of compounds and these correlations are therefore of analytical value. However, they do not reveal the specific effect of complexing. For example, cycloolefins and cycloparaffins are retained very much less than might be expected from their boiling points. Nevertheless, the normalized retention times are close to those of other olefins. It appears that entropy requirements for surface condensation are similar for the structurally analogous olefins and paraffins, but differ from those for condensation into bulk liquids.*

*As defined in text.

deviations are given when more than one compound of a type has been studied. Only a relatively small decline is found with increasing carbon number. In the last column of Table IV average values for each degree of substitution are listed. Cyclic olefins have been omitted from these calculations, as their inclusion as disubstituted olefins increases the scatter. 2-Ethyl-1-butene has been omitted because the presence of an unsaturated group in the side chain is unique in the group of compounds studied, and a comparison with 3-methylpentane is not strictly analogous with the other normalizations. However, the inclusion of these compounds does not significantly affect the observed trends.

TABLE V

Ratios of mean normalized retention times* for unit increments in double bond substitution

Ratio	Column				Mean
	1	2	3	4	
Di-/mono-	1.42	1.27	1.21	1.31	1.30
Tri-/di-	1.38	1.29	1.15	1.28	1.27
Tetra-/tri-	1.34	1.26	1.25	1.34	1.30
					1.29

*As defined in text.

Effects of the increase in basicity of the double bond with alkyl substitution on the olefinic carbon atoms are reflected in the ratios of the mean normalized retention times for unit increments in the degree of substitution. Such ratios are listed in Table V; their mean value is about 1.3. (Very similar mean ratios are also obtained if the ratios for each carbon number first are evaluated and then are averaged for each of the four columns.) The results

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in Table V show that the increase is independent of the extent of substitution, and depends only slightly on the column support. This provides strong evidence that the effect is due to complexing with TNB and that complications due to interaction with the solid support are largely eliminated in the ratios listed in Table V. These ratios are therefore believed to represent approximate ratios of the corresponding equilibrium constants for complex formation.[6]

Two major differences were observed in column behavior using different column packings. The absolute retention times were considerably greater in columns 1 and 2 than in columns 3 and 4. In addition, the difference in retention between olefins and paraffins decreased going from column 1 to column 4. These differences are probably caused by uneven covering of the solid support by TNB and perhaps also by variations in the basic properties of the different support materials used in the four columns.

DISCUSSION

The observed decrease in column efficiency with increasing retention time is contrary to the trend usually observed with packed columns (21). It is probably indicative of slower rates of complex formation and breakdown for the more strongly retained compounds. The low efficiencies observed with the TNB on celite support column for cyclic olefins, cyclic paraffins, and nonterminal olefins are probably also a result of slow equilibration processes. Pronounced differences in apparent efficiency have been observed in a parallel investigation of complex formation between iodine and olefins. The peak broadening effects of differences in the rates of equilibration will be discussed in greater detail separately (15).

In contrast to silver nitrate – olefin (19) and iodine–olefin (15) interactions, where the complexes are considerably strengthened by substitution of deuterium atoms for hydrogen atoms at the olefinic bond (22), deuterium substitution had no significant effect on the TNB – olefin complexes. The small effect that was observed showed a slight reduction in retention time, such as is observed in partition chromatography where separation is according to boiling point only (23). Furthermore, retention times generally increased with increasing substitution at the double bond, indicating that for TNB complexes the increase in basicity from double-bond substitution outweighs the opposing effect of steric hindrance which frequently predominates. Both these effects suggest that the role of steric changes in the olefins plays a lesser part in TNB – olefin complexes than in the other systems similarly investigated (9–12, 14, 15, 19, 22).[7]

The specific nature of the interactions of hydrocarbons with TNB may prove especially useful for specific analytical separations, complementing the usual columns for olefin separations and analyses (silver nitrate, etc.). The regular dependence on the carbon number (or the boiling point) within a structural group should prove a distinct advantage in some cases and may provide a method of characterizing the carbon content and structural features of unknown olefinic reaction products. Although quantitative values of the association constants for TNB complexes with individual olefins have not been obtained, the technique provides a rapid source of the relative strengths of these complexes. These results may be used to corroborate data acquired by conventional spectrophotometric techniques.

[6] *A mathematical treatment which is related to the case considered here will be given in ref. 15.*

[7] *Although steric effects do not appear to play too important a role in the olefin – TNB complexes, the gradual decline in t_n values with carbon number, shown in Table IV, suggests that they are not altogether negligible. Quantitative limitations of the data preclude any detailed conclusions in this respect.*

NEW NITROCHALCONES. VII[1,2]

T. SZELL[3] AND A. M. EASTHAM

AND
GY. SIPOS
University of Szeged, Szeged, Hungary
Received April 8, 1964

SUMMARY

A number of new nitrohydroxychalcones have been synthesized using sodium hydroxide and hydrogen chloride as catalysts. It has been found that with substituents which increase the acidity of acetophenones or the electrophilic character of benzaldehydes (e.g. NO_2, halogen, CN), sodium hydroxide is the better condensing agent, while with those substituents which increase the basic strength of the carbonyl, hydrogen chloride is satisfactory.

Since the pioneer work of Kostanecki (1), Wurtz (2), and Claisen (3) numerous examples in the literature have described the use of either sodium hydroxide or hydrogen chloride as the condensing agent in aldol condensations, without providing much guidance as to the choice of catalyst for any particular condensation. This work was undertaken to correlate the choice of catalyst with the structure of the reactants, using substituted benzaldehydes and acetophenones as the model compounds.

RESULTS

Table I lists the new chalcones and some of their properties; Table II records the results of experiments carried out with sodium hydroxide as the condensing agent and Table III the experiments carried out in the presence of hydrogen chloride. Reaction times are considered to be well below those required for the reactions to reach equilibrium but, nevertheless, all experiments in which precipitation of the product, its sodium salt, or its HCl adduct occurred have been excluded from the tables.

In alkaline catalysis, the substituents on the aldehyde component accelerate the rate of chalcone formation in aqueous ethanol in the following way: 2,4-dichloro- > 4-NO_2 > halogeno-* and 4-CN- > H ≈ 2-CH_3O- and 2-C_2H_5O- > α-naphthaldehyde > 3,4-methylenedioxy- > *p*-isopropyl- > 3,4-dimethoxy- and 3,4-diethoxy- > 4-hydroxy-3-methoxy- > 2-hydroxy- and 4-hydroxy-. In earlier work (4–7) the effect of benzaldehyde substituents was found to be 4-NO_2 > 4-Cl > 4-H and 3-OH > 4-OH; the acetophenone substituents were in the order 2-NO_2 > 4-NO_2 > 3-NO_2, 3-OH > 2- and 4-OH, 6-NO_2-3-OH > 4-NO_2-2-OH > 5-NO_2-2-OH > 3-NO_2-4-OH.

In acid catalysis the effect on the rate of substituents on the benzaldehyde component has been found to be in the following order: 4-hydroxy-3-methoxy- ⩾ 3,4-dimethoxy- ⩾ 4-hydroxy ≈ 4-methoxy- ⩾ H > halogeno- > 4-NO_2. Earlier work (8, 9) had shown the 4-hydroxy derivative to be more reactive than 4-nitro-benzaldehyde and had also shown

**The order within the halogens (o-, p-, and m-; F, Cl, Br) is not clear. In part this is because some of the reaction mixtures were not homogeneous but it also appears that the order of reactivity of the o-, p-, and m-compounds is not the same for the different halogens. In general, the m-isomers seem more reactive than the p-isomers.*

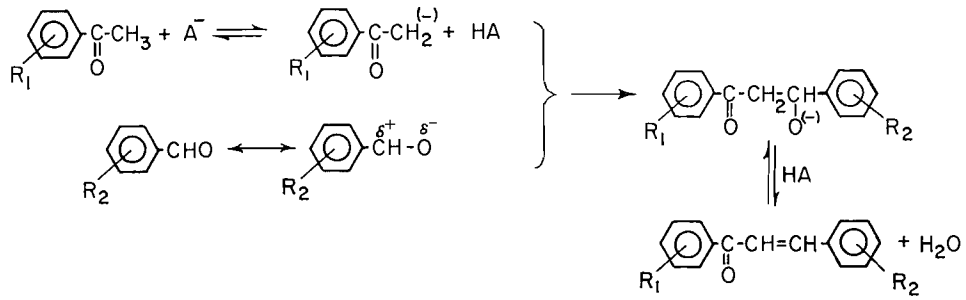
the following order for acetophenone substituents: 4-hydroxy-3-NO_2- > 2-hydroxy-4-NO_2- > 4-NO_2.

DISCUSSION

The pK_a values of substituted benzoic acids increase (10, 11), and the Hammett substituent constants decrease in the order 4-NO_2 > 3-NO_2 > 4-CN > halogeno >

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

H ≈ 3-OH > 3-CH_3 ≈ 4-CH_3 > 4-CH_3O > 4-OH > 3,4-dimethoxy. The pK_{BH+} values for a number of substituted benzaldehydes (12, 13) increase in the order 4-NO_2 > 3-Cl > 4-Cl > H > α-naphthaldehyde > 4-CH_3 > 4-CH_3O > trialkyl, while those for substituted acetophenones (14) increase in the order 4-NO_2 > 3-NO_2 > 3-hydroxy- > H > 4-hydroxy-. There is thus a close parallel between the effectiveness of the substituents in increasing the rate of the alkali-catalyzed condensation, in increasing the acidity of the benzoic acids, and in increasing the electrophilicity of the benzaldehyde (assuming that pK_{BH+} is directly related to electrophilicity). Such a correlation is not surprising, since the generally accepted mechanism for this condensation involves attack at the aldehyde carbon by a carbanion formed by removal of a proton from the acetophenone (15).



Since the mechanism of the acid-catalyzed condensation is less clear and more complex than the alkali-catalyzed, it is difficult to provide a satisfactory explanation for the effect of substituents on the rate (15). In general, the more basic the aldehyde the more rapid the rate, which suggests that the extent of protonation of the aldehyde is important, in accordance with the views of Noyce (15).

In general, the results suggest that for reactants having electron-withdrawing groups sodium hydroxide is the better condensing agent and that those containing electron-releasing groups can be satisfactorily condensed with hydrogen chloride. However, in many cases either catalyst seems effective and the choice may be governed by other factors. For example, ethanol–HCl is often particularly useful in preparing the 4′-nitrochalcones (9, 19) and, because the product precipitates, aqueous sodium hydroxide often gives good yields of the chalcones from mononitro-2- or mononitro-4-hydroxyacetophenones. On the other hand, a number of workers have reported difficulties in synthesizing hydroxychalcones in the presence of alkali (1, 7, 17). The alkaline condensation is simpler to use and can be applied even to those reactants having electron-releasing groups, if they will tolerate the longer reaction time; solvents of high dielectric constant such as water or aqueous alcohols are advantageous (4, 17). High concentrations of alkali should be avoided because of the possibility of Cannizzaro or other side reactions, especially with 2- or 4-nitro compounds (5, 7, 15, 16). Side reactions seem less important in acid solution but can occur (8, 16, 19).

Many specific deviations from these qualifications are known. Electron-withdrawing groups usually increase the yield in alkaline condensations (4, 6, 16, 20), but *p*-nitrobenzaldehyde does not always do so (9) and conversely, this same aldehyde sometimes improves the yields of acid-catalyzed condensations over those obtained with benzaldehyde (9, 19, 21, 22, 23). However, in some of these cases the improved yields may be due to precipitation and the poor yields due to the resinification of the product.

With *o*-hydroxybenzaldehyde in HCl, secondary or side reactions always occur; with the meta isomer and with *m*-hydroxyacetophenone they sometimes occur. Actually, *o*-hydroxybenzaldehyde condenses readily with acetophenones, but the products could not be identified (cf. Schraufstätter (16)). No difficulties were encountered in preparations with nitro-2- and nitro-4-hydroxyacetophenones but the preparation of 3′-hydroxychalcones in HCl was accompanied by considerable resinification. Many of these difficulties with phenolic compounds could probably be eliminated by acetylating or otherwise protecting the hydroxyl group (16, 22, 23). Perhaps for this reason as well as for its high electron-releasing power, the 4-methoxyl group gives satisfactory reactions in both acid and alkaline condensations and when present in either reactant (21); the duality of its reactivity is usually attributed to resonance effects (10, 12, 14, 24). Noyce has interpreted the effect of 4-methoxy and 4-nitro substituents as due to two counterbalancing factors, a change in basicity of the aldehyde and a change in the ease of bond formation between the reactants (15).

In acid solution the *p*-methyl group was found to give poorer yields than the ethyl, propyl, or butyl groups (19).

Under conditions of the present experiments 5-nitro-2-hydroxyacetophenone did not react with 4-hydroxybenzaldehyde, but reaction will occur under more drastic conditions (18); even 2,4-dihydroxyacetophenone will react, albeit in poor yield, with vanillin under sufficiently drastic conditions (7).

Clearly, with so many anomalies and because the experiments reported in the literature have been run under a wide variety of conditions, often with precipitation of the product and without correction for solubility of the product, sometimes in heterogeneous solution, and so on, any generalization other than the very broad one given above would be presumptuous.

EXPERIMENTAL

Materials

(a) Aldehydes

Halogeno- and cyano-benzaldehydes were obtained from Aldrich Chem. Co. Inc., the rest from Distillation Products, and all were used without further purification. A 13.58 mmole per 100 ml ethanolic solution was prepared from them.

(b) Acetophenones

5-Nitro-2-hydroxy-, 4-nitro-2-hydroxy, and 3-nitro-4-hydroxy-acetophenones were prepared by the Fries reaction from 4-, 3-, and 2-nitrophenylacetates, respectively (6, 25) and 6-nitro-3-hydroxyacetophenone was prepared according to Klinke's method (26), m.p. 103°, 65.5°, 133°, and 150°, respectively. A 4.92 g per 200 ml ethanolic solution was prepared from them.

(a) Synthesis of chalcones in the presence of *NaOH* was carried out as follows. To 4 ml of aldehyde solution 4 ml of ketone solution was added, the mixture was kept in a thermostat for 20 min at 30 °C then was mixed with 2 (or 4) ml of aqueous NaOH solution (96 g NaOH and 100 g H_2O). The reaction was stopped by acidifying the solution with 10 ml of an acetic acid solution. For 2-hydroxy ketones the acetic acid solution was prepared from 70 ml of acetic acid in 200 ml of water and 1800 ml of ethanol; for 3- and 4-hydroxy ketones the solution was prepared from 40 ml of acetic acid in 960 ml of water. On acidification, the chalcones precipitated and the starting materials remained in solution. Acidification was carried out in the same way even when the yellow or red sodium salt precipitated during the course of the run. After the mixture was cooled, the chalcones were filtered, washed with 2 ml of ethanol and 2 × 2 ml water, dried at 100°, and weighed. This weight was corrected for the solubility of chalcones which was determined for each run. In case of experiments 28 and 56 (Table I) oily material separated on acidifying the solution, but slowly solidified in the refrigerator.

(b) The syntheses in the presence of *HCl* were carried out by adding 4 ml of ketone solution to 4 ml of aldehyde solution and saturating the mixture with dry hydrogen chloride while cooling in ice. This was always accompanied by a change of color. Reactions were stopped by diluting the solutions with water and making them up to 20 ml, and the mixtures were then left overnight in the refrigerator. The chalcones were filtered off, weighed, and the weight corrected for the solubility. The product obtained from 4-isopropyl-benzaldehyde and 3-nitro-4-hydroxyacetophenone separated as an oil which could not be crystallized.

Recrystallization

Solvents used for recrystallization are given in Table I. Ethyl acetate – ethanol (EtOAc–EtOH), ethanol – acetic acid (EtOH–AcOH) were mixtures of 2:1 and 1:2, respectively. Recrystallization from ethanol–water was carried out by dissolving the raw products in as little boiling ethanol as possible, adding hot water until slightly turbid, and allowing the solution to cool slowly.

ACKNOWLEDGMENTS

We are grateful to Mrs. C. Lakos, Mrs. G. Bartok (University of Szeged, Hungary), and Mr. H. Seguin (N.R.C. Division of Pure Chemistry, Ottawa) for the microanalyses and to Mr. E. Gyurki and Mr. F. Kiszely (University of Szeged) for preparing the starting acetophenones.

THE METAL-CATALYZED AUTOXIDATION OF TETRALIN

IV. THE EFFECT OF SOLVENT AND TEMPERATURE[1]

Y. KAMIYA[2] AND K. U. INGOLD

Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received July 3, 1964

ABSTRACT

The limiting rate of oxidation of tetralin catalyzed by cobalt, manganese, and copper decanoates has been measured in 12 solvents at 65 °C. This rate is generally determined by the kinetic condition that the hydroperoxide reaches a steady-state concentration but the experimental rates are smaller than expected in some solvents. Both cobalt and manganese are able to terminate reaction chains and they therefore act as inhibitors of the oxidation at high concentrations. The ratio of the propagation rate constant (k_3) to the square root of the termination rate constant (k_6) for the oxidation of tetralin in acetic acid solution is given by

$$k_3/k_6^{1/2} = 300 \exp(-6\,900/RT) \text{ (l/mole s)}^{1/2}.$$

INTRODUCTION

In previous papers in this series it was shown that the rates of autoxidation of tetralin at 50 °C catalyzed by the acetates in acetic acid (1, 2) and the decanoates in pure tetralin (1, 3) of cobalt, manganese, copper, nickel, and iron tended to limiting values at high catalyst concentrations. In the case of cobalt, both in acetic acid (2) and, after applying a correction for tetralin consumption, in pure tetralin (3), it was shown that this limiting rate was in fairly good agreement with the theoretical predictions of Tobolsky (4). However, the rates for the other four metals were smaller than the theoretical limit both in acetic acid and in pure tetralin (1). These low rates were tentatively attributed to the low solubilities of the catalysts, since dilution with inert solvents gave rates that were in fairly close agreement with the theoretical value.

When the limiting rate is due to the production of a steady-state concentration of hydroperoxide (4), the kinetic scheme describing the overall reaction can be represented by (2, 5)

[1] $$\text{ROOH} + n\text{M} \xrightarrow{k_1'} \text{radical} \xrightarrow{\text{RH}} \text{R}\cdot$$

[2] $$\text{R}\cdot + \text{O}_2 \xrightarrow{k_2} \text{RO}_2\cdot$$

[3] $$\text{RO}_2\cdot + \text{RH} \xrightarrow{k_3} \text{ROOH} + \text{R}\cdot$$

[4] $$\text{RO}_2\cdot + \text{RO}_2\cdot \xrightarrow{k_6} \text{inactive products} + \text{O}_2.$$

When the rate of hydroperoxide decomposition is negligible compared with its rate of formation, the overall rate of oxidation is given by

[2] $$-\frac{\text{d}[\text{O}_2]}{\text{d}t} = k_3\left(\frac{k_1'}{2k_6}\right)^{1/2}[\text{RH}][\text{ROOH}]^{1/2}[\text{M}]^{n/2}.$$

[1] *Issued as N.R.C. No. 8118.*

[2] *N.R.C. Postdoctoral Fellow, 1962–1964. Present address: Department of Fuel, University of Tokyo, Tokyo, Japan.*

When the rate of hydroperoxide decomposition equals its rate of formation, this steady-state concentration is given by

$$[3] \qquad [\mathrm{ROOH}]_\infty = \frac{k_3^2[\mathrm{RH}]^2}{2k_1' k_6[\mathrm{M}]^n}$$

and, therefore, the limiting rate of oxidation is given by

$$[4] \qquad \left(-\frac{\mathrm{d}[\mathrm{O_2}]}{\mathrm{d}t}\right)_\infty = \frac{k_3^2[\mathrm{RH}]^2}{2k_6}.$$

A recent publication from this laboratory (6) lists values of $k_3/k_6^{1/2}$ at 65 °C for several hydrocarbons, including tetralin, in a variety of oxidation resistant solvents. These values were obtained from the oxidation of 1 ml of hydrocarbon in 20 ml of solvent initiated with 7×10^{-2} mole/l of α,α' azo-bis-isobutyronitrile (AIBN). They show a small but significant variation with the dielectric constant of the solvent. Now provided the limiting rate of a metal-catalyzed oxidation is controlled by the formation of a steady-state hydroperoxide concentration, it can be represented by eq. [4]. A comparison of the values of $k_3/k_6^{1/2}$ for tetralin derived from limiting rates in different solvents with the values obtained using AIBN as the initiator should provide a very sensitive test of Tobolsky's hydroperoxide steady-state theory, since the rate will be less sensitive to catalyst solubilities in dilute tetralin solutions. Moreover, the results should give some information as to whether or not peroxy radicals can complex with transition metal catalysts and still undergo the same propagation and termination reactions as uncomplexed "free" radicals. That is, it has been tentatively suggested by several authors (7, 8) that the formation of complexes between transition metal catalysts and peroxy radicals could affect metal-catalyzed oxidation rates by altering the rates of propagation and termination. A comparison of the $k_3/k_6^{1/2}$ values derived from metal-catalyzed limiting rates with the values obtained using AIBN should provide a fairly sensitive test for the existence of such complexes.

The present work describes the oxidation of tetralin in a variety of solvents at 65 °C catalyzed by the decanoates (or acetates in acetic acid solution) of cobalt, manganese, and copper since these three metals were the most active catalysts in pure tetralin (1). The effect of temperature on the limiting rates produced with these three metals, plus nickel and iron, has also been examined both in pure tetralin and in a 1:1 by volume solution of tetralin in acetic acid. The experimental technique has been described previously (2, 3).

RESULTS AND DISCUSSION

1. Solvent Effects

In a series of preliminary experiments the maximum rates of oxidation of 0.35 mole/l of tetralin (1 ml in 20 ml solvent) catalyzed by 5×10^{-2} mole/l of cobalt, manganese, and copper were measured in 12 solvents at 65 °C. The initial hydroperoxide concentration ($[\mathrm{ROOH}]_0$) was 5×10^{-2} mole/l in each experiment. This peroxide was added to eliminate the induction period which would otherwise be observed in the manganese-catalyzed oxidations because of the rapid chain-terminating process involving divalent manganese (1). It was also added to the cobalt- and copper-catalyzed reactions to keep all the experiments on a comparable basis. In nine experiments (noted in Table 1) no oxygen absorption took place in 3 000 – 5 000 s. In certain other experiments the rate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

decreased very rapidly after achieving its maximum value right at the beginning of the reaction. Those cases where the rate fell to half its maximum value before 1 ml O_2 at s.t.p. had been absorbed are also noted in Table I. When the rate decreases this rapidly its maximum value can be obtained from only the first two or three readings and is therefore subject to considerable error. Moreover, a steady-state hydroperoxide concentration will not exist and therefore $k_3/k_6^{1/2}$ values cannot be derived from this rate.

The complete inhibition of oxidation with cobalt and manganese in several solvents led us to study one such system in considerable detail, namely, the cobalt decanoate catalyzed oxidation of tetralin in chlorobenzene. The measured maximum rates of oxidation at five tetralin concentrations (including pure tetralin) at 65 °C have been plotted against the cobalt concentration in Fig. 1. It is clear that at any particular tetralin concentration the rate tends to increase as the catalyst concentration is increased. This continues until the catalyst reaches a critical concentration ($[M]_c$) whereupon, with further small increases in catalyst concentration, the oxidation is inhibited and the rate (measured over the first few thousand seconds) suffers a catastrophic decline. That is, the cobalt functions as a catalyst below the critical concentration and as an inhibitor above it. Since the critical concentration decreases as the tetralin concentration is decreased the rate at any given catalyst concentration will drop to zero upon dilution of the tetralin past a certain critical point. That is, the curves in Fig. 1 show that at a given tetralin concentration there is a critical catalyst concentration and at a given catalyst concentration there is a critical tetralin concentration. The failure to obtain any oxidation with 0.35 mole/l tetralin catalyzed by 5×10^{-2} mole/l Co was obviously a specific aspect of a very general effect.

[a]Determined in this work.
[b]No oxidation in 3 000 – 5 000 s with 0.35 mole/l of tetralin catalyzed by 5×10^{-2} mole/l metal decanoate with $[ROOH]_0 = 5 \times 10^{-2}$ mole/l.
[c]The rate of oxygen absorption decreased to less than half its maximum value after the absorption of less than 1 cc O_2 at s.t.p. per cc tetralin with 0.35 mole/l tetralin catalyzed by 5×10^{-2} mole/l metal decanoate and with $[ROOH]_0 = 5 \times 10^{-2}$ mole/l.

Critical metal catalyst concentrations have occasionally been observed by other workers* and have been attributed to the chain termination process,

[8] $$RO_2\cdot + M \rightarrow RO_2M.$$

The limiting rate with this additional reaction is given by (1),

[4a] $$\left(-\frac{d[O_2]}{dt}\right)_\infty = \frac{k_3[RH]}{2k_6}(k_3[RH] - k_8[M]),$$

which predicts that the critical concentration should be directly proportional to [RH]. The values of $[M]_c$ from Fig. 1 (defined as the cobalt concentration at which the rate over the first few thousand seconds has declined to one tenth of its maximum value) have been plotted against [RH] in Fig. 2. The points appear to fall on a curve which shows the expected first-order dependence of $[M]_c$ on [RH] only at high [RH]. The apparent order in [RH] increases as [RH] decreases, the overall average order being about 1.5. This variable order suggests the occurrence of a third chain ending process which is first order in $[RO_2\cdot]$ and less than first order in [M] (i.e., probably zero or one-half order in [M]). If the chain ending step (11),

[10] $$RO_2\cdot \rightarrow \text{inactive products},$$

is introduced into the reaction scheme, the limiting rate is given by

[4b] $$\left(-\frac{d[O_2]}{dt}\right)_\infty = \frac{k_3[RH]}{2k_6}(k_3[RH] - k_8[M] - k_{10})$$

**For example, cupric stearate increases the maximum rate of oxidation of n-decane and causes small induction periods at concentrations below 0.06 mole %, but above this concentration the induction period is very greatly prolonged (9). In contrast, the sudden inhibition of the cobalt stearate catalyzed oxidation of butane upon dilution with benzene has been attributed to the chain terminating process (10):*

$$RO_2\cdot + C_6H_6 \rightarrow (RO_2\cdot C_6H_6) \rightarrow \text{inactive products}.$$

However, since the cobalt concentration was kept constant in these experiments, it seems more likely that chain termination by reaction [8] was responsible for the inhibition.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The experimental critical concentrations are in moderately good agreement with this equation, but the oxidation rates decrease more rapidly on approaching $[M]_c$ than is predicted. However, this may be due to the failure of the assumption that the occurrence of a steady-state hydroperoxide concentration still determines the kinetics when the catalyst concentration approaches $[M]_c$. Values of $[M]_c$ at 35 and 95° are also included in Fig. 2.

The measured rates of oxidation of 1.22 mole/l of tetralin in chlorobenzene at 65 °C are shown in Fig. 3 for catalysis by cobalt stearate and pivalate and by the decanoates of manganese and copper. The heavy line in this figure is the cobalt decanoate line from Fig. 1. Cobalt stearate and pivalate give a slightly larger maximum rate than was obtained with the decanoate but this rate is still well below the theoretical limit of 9.84×10^{-5} mole/l s calculated from the AIBN data. The critical catalyst concentration is greater for the stearate than for the decanoate (as was found previously in pure tetralin at 50 °C (3)) and is slightly greater again for the pivalate. The effect of the anion on $[M]_c$ probably results mainly from steric factors, i.e., the greater the steric protection of the coordination sites on the metal the slower will be reaction [8]. Solvent effects on $[M]_c$ (see Table I) may also be connected with steric factors resulting from the association of the solvent with the catalyst. However, the probable absence of critical concentrations in the more polar media which are good solvents for the catalyst suggests that this critical effect may be connected with some heterogeneous process on the surface of the undissolved catalyst. On the other hand, the critical cobalt decanoate concentration in chlorobenzene was unaffected by the addition of relatively large concentrations of cobalt phthalate or oxalate (both of which are very insoluble and are therefore very inactive catalysts). This rather argues against the importance of any surface reaction in determining $[M]_c$. The critical concentration was also unaffected by a threefold increase in the surface:volume ratio of the reaction vessel.

It can be seen from Fig. 3 that the cation has an even more profound effect on $[M]_c$

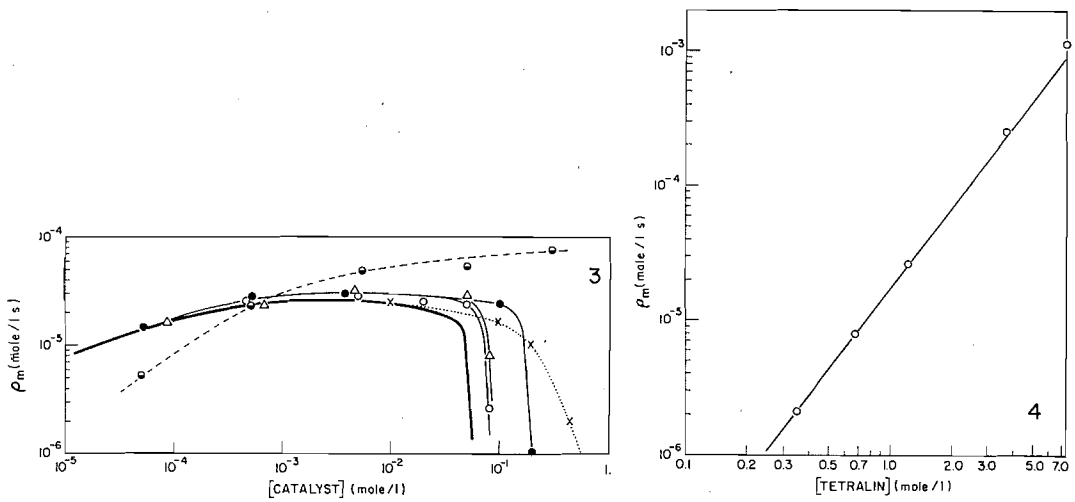

FIG. 3. The measured rate of oxidation of 1.22 mole/l of tetralin in chlorobenzene at 65 °C as a function of the catalyst concentration; ○ cobalt stearate, △ cobalt pivalate, ● manganese decanoate, ◒ copper decanoate, × cobalt decanoate together with 3×10^{-2} mole/l AIBN. The heavy line on the figure is the same as the line in Fig. 1 for the cobalt decanoate catalyzed oxidation of tetralin at this concentration. The theoretical limiting rate is 9.84×10^{-5} mole/l s.

FIG. 4. The measured maximum rate of oxidation of tetralin in chlorobenzene at 65 °C. The line on the figure has a slope of 2.0.

For personal use only.

than the anion. That is, $[M]_c$ for manganese decanoate is four times as large as for cobalt decanoate although the limiting rates are about the same. The critical copper decanoate concentration must be quite large since the rate approaches the theoretical limit and this limit was easily reached at lower tetralin concentrations.

The fact that cobalt is a true inhibitor of the oxidation was further demonstrated by adding 3×10^{-2} mole/l AIBN to 1.22 molar tetralin in chlorobenzene. The critical cobalt decanoate concentration was increased and became less sharply defined (see Fig. 3), but at high cobalt concentrations the rate did decrease below the value found with AIBN alone (7.7×10^{-6} mole/l s). Incidentally, in the limiting rate region cobalt and AIBN appear to have an additive effect on the rate. For example, with 1.22 molar tetralin in chlorobenzene ρ_m is 2.4×10^{-5} mole/l s with 1×10^{-2} mole/l $CoDe_2$ or with 2×10^{-1} mole/l AIBN. Both catalysts together should therefore give a rate of $\sqrt{2} \times 2.4 \times 10^{-5} = 3.4 \times 10^{-5}$ mole/l s (bimolecular chain termination), which is in good agreement with the measured value of 3.3×10^{-5} mole/l s.

Values of $k_3/k_6^{1/2}$ at 65 °C calculated from the maximum rates of oxidation of dilute tetralin solutions (1.22 mole/l or less) catalyzed by the decanoates (or acetates in acetic acid) of cobalt, manganese, and copper at their optimum concentrations and with the optimum initial hydroperoxide concentrations* are given in Table I together with the values reported previously for the AIBN-initiated oxidation (6). The measured rates have been corrected for tetralin consumption where necessary. For example, the measured limiting rate with 0.35 molar tetralin in chlorobenzene is 2.15×10^{-6} mole/l s (Fig. 1) but this rate is not reached until a certain amount of oxygen has been absorbed. With the assumption that two molecules of oxygen oxidize three molecules of tetralin (2) the correction factor is found to be 1.2. Hence, $k_3/k_6^{1/2} = 6.5 \times 10^{-3}$ l$^{1/2}$mole$^{-1/2}$ s$^{-1/2}$. This value is considerably smaller than the value obtained previously with AIBN (6) (see Table I), i.e., the oxidation rate is smaller than would be predicted by eq. [4]. Similarly, in pure tetralin the corrected rate is 1.65×10^{-3} mole/l s (corresponding to $k_3/k_6^{1/2} = 7.8 \times 10^{-3}$ l$^{1/2}$ mole$^{-1/2}$ s$^{-1/2}$) which is considerably below the theoretical rate of 2.65×10^{-3} mole/l s obtained with AIBN.†

In many cases the agreement between AIBN and metal-catalyzed $k_3/k_6^{1/2}$ values is excellent. In these cases, it must be concluded that the metals have no significant effect on k_3 or k_6 and therefore metal-complexed peroxy radicals do not play any important role in the oxidation of tetralin in these solvents. This conclusion does not necessarily apply in those solvents where the $k_3/k_6^{1/2}$ values obtained from the metal-catalyzed oxidations are smaller than the values obtained with AIBN. However, these small values may also be due to the decomposition of some of the hydroperoxide to non-radical products or to radicals which are destroyed before they enter into reaction [3]. If the rate constant for all such processes is denoted by k_1^*, the limiting rate is reduced by the factor $k_1/(k_1 + k_1^*)$ but still has the correct dependence on $[RH]^2$, i.e.,

$$\left(-\frac{d[O_2]}{dt}\right)_\infty = \frac{k_3^2[RH]^2}{2k_6} \cdot \frac{k_1}{k_1 + k_1^*} \cdot \qquad [4c]$$

Only small amounts of peroxide were added to the copper-catalyzed oxidations since large amounts produced high initial rates which obviously did not correspond to the steady-state conditions from which values of $k_3/k_6^{1/2}$ could be derived.

†*The corrections for catalyst deactivation (3) and for the diluting effect of the catalyst are negligible. The correction factor of 1.45 for tetralin consumption is the same as at 50 °C (3). In our original work at 50 °C we included a correction for the diluting effect of the catalyst which gave a corrected rate approximately equal to the theoretical value (3). It now seems likely that this correction should not be applied since the catalyst is not completely soluble at high concentrations where this correction could become significant.*

On the other hand, the curves in Fig. 1 suggest that the limiting rates may be determined by the inhibiting action of the catalyst. That is, inhibition appears to become important at each tetralin concentration shortly before the limiting rate is reached. However, eq. [4*b*] does not account for the fact that these low limiting rates are often obtained over nearly a one hundredfold change in catalyst concentration nor will it account for the fact that these rates are exactly proportional to $[RH]^2$ (at tetralin concentrations below 1.22 mole/l where changes in the solvent composition cease to affect the rate (6), see Fig. 4). The chain terminating reactions

[8′] $$RO_2\cdot + M \rightleftarrows ROOM$$

[9] $$RO_2\cdot + ROOM \rightarrow \text{inactive products}$$

give

[4*d*] $$\left(-\frac{d[O_2]}{dt}\right)_\infty = \frac{k_3^2[RH]^2}{2k_6 + 2K_8' k_9[M]}$$

and might therefore contribute to the low limiting rates although they will not account for the detailed shape of the rate against catalyst concentration curves in Figs. 1 and 3. However, it must be remembered in relation to eqs. [4*a*], [4*b*], and [4*d*] that the basic assumption that there is a steady-state hydroperoxide concentration which determines the rate may not apply in the region where chain termination by the metal catalyst becomes important. At the present time, it does not seem possible to decide on the exact cause of the low $k_3/k_6^{1/2}$ values which are obtained with some metal catalysts in some solvents.

2. Temperature Effects

The rates of oxidation of pure tetralin and of 3.67 mole/l of tetralin in acetic acid were measured with all five metal catalysts over a temperature range from 26 to 95 °C. The rates in acetic acid were obtained with 5×10^{-1} mole/l of the metal acetate together with an equal initial concentration of tetralin hydroperoxide (see Fig. 5). Under these conditions the maximum rate occurs at or near the beginning of the reaction and there is no necessity to correct the measured rates for tetralin consumption. Furthermore, with the exception of the ferric acetate catalyzed reaction, the rates are fairly easily measured (except at 95 °C) since they decrease only as the tetralin is consumed, there being no deactivation of the catalyst (2, 3). The rates obtained with cobalt acetate at 35, 50, and 65 °C are equal, within the limits of experimental accuracy, to the theoretical rates derived from the AIBN-initiated oxidation of pure tetralin. Over the entire temperature range cobalt acetate gives an overall activation energy of 13.8 ± 0.4 kcal/mole. That is, from eq. [4]

$$E_3 - \tfrac{1}{2}E_6 = 6.9 \pm 0.2 \text{ kcal/mole}$$

and

$$k_3/k_6^{1/2} = 300 \exp(-6\,900/RT) \text{ (l/mole s)}^{1/2}.$$

These values are quite accurate because of the large temperature range that can be covered by this technique. The activation energy is smaller than the value of 8.2 ± 0.6 kcal/mole reported by Woodward and Mesrobian (5) from similar experiments over a smaller temperature range (50–81 °C). The difference almost certainly arises from the fact that Woodward and Mesrobian did not use a sufficiently large cobalt acetate concentration to reach the limiting rate at 50 °C (2). That is, E_1, the activation energy for the cobalt-catalyzed decomposition of tetralin hydroperoxide in acetic acid (21.2 ± 0.9 kcal/mole

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(5)), is greater than E_3, the activation energy for the propagation reaction. Therefore, the rate of chain initiation by a given small concentration of cobalt acetate will increase more rapidly than the rate of the propagation reaction as the temperature is raised. This means that with insufficient catalyst the measured oxidation rate will approach the limiting rate as the temperature is raised, thus giving an anomalously high activation energy. The high temperature coefficients obtained in this work with manganese, nickel, and copper acetates arise from the same factor.

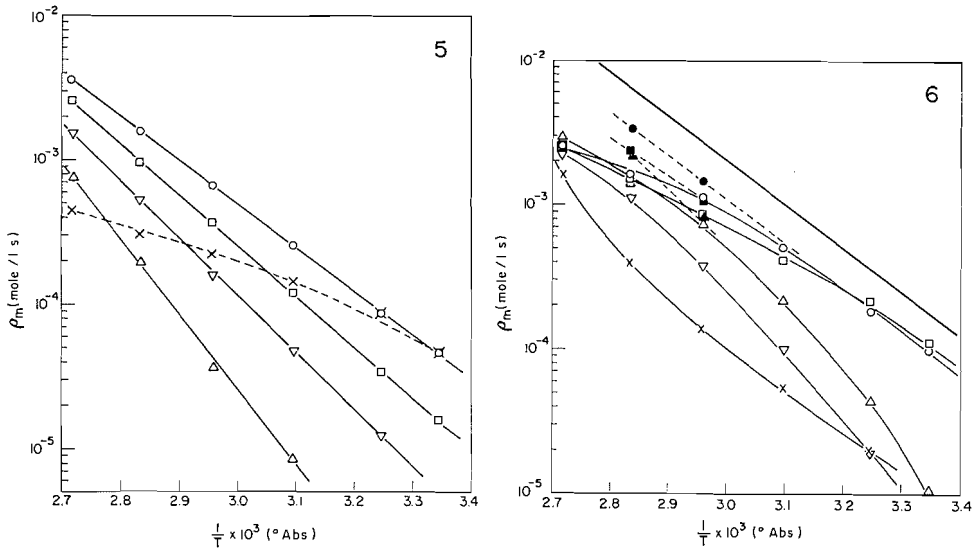

FIG. 5. Measured rates of oxidation of 3.67 mole/l of tetralin in acetic acid catalyzed by 5×10^{-1} mole/l of the following metal acetates; ○ cobalt, □ manganese, △ copper, ▽ nickel, and × iron. $[ROOH]_0 = 5 \times 10^{-1}$ mole/l.

FIG. 6. Measured rates of oxidation of pure tetralin catalyzed by 0.1 mole/l of manganese □, copper △, nickel ▽, and iron × decanoates. Maximum rates have been plotted for cobalt decanoate ○. The solid points represent the rates obtained with oxygen circulating continuously above the tetralin.

The rates obtained with ferric acetate are much less meaningful than the rates obtained with the other metal acetates. This is because oxidation only occurs to a very limited extent right at the beginning of the reaction, the rate quickly decreasing to a very small value as the iron is precipitated. As was pointed out above, such rates are not only difficult to measure but they also bear no relation to eq. [4] since a steady concentration of hydroperoxide is not set up.

The measured rates of oxidation of pure tetralin, catalyzed by 0.1 mole/l of manganese, copper, nickel, and iron decanoates, are shown in Fig. 6 as a function of the temperature. The initial hydroperoxide concentrations were 0.1 mole/l for manganese and 0.3 mole/l for the other three metals.* The points for cobalt decanoate represent the maximum rates obtained from curves of the rate against cobalt concentration at each temperature ($[ROOH]_0 \approx 10^{-3}$ mole/l). These rates are 10–20% larger than the rates obtained with 0.1 mole/l of cobalt (see Fig. 1). The heavy line in Fig. 6 represents the theoretical limiting rate of oxidation of pure tetralin.

The curvature and convergence at high temperatures of the Arrhenius plots for the

different metals is due to several factors. Firstly, the maximum rates are difficult to measure above 80 °C even with 1 ml samples, since the rate maintains its very high maximum value for only a short time at the beginning of the reaction. The tetralin in the reaction vessel therefore does not have time to come into temperature equilibrium with the surrounding oil bath. Secondly, the water formed in reaction [1] cannot be neglected at high temperatures. This water will produce a diminution in the apparent rate of oxygen absorption because one molecule of water vapor will be formed from two molecules of oxygen, i.e.,

$$2RH + 2O_2 \rightarrow 2ROOH \xrightarrow{M} RO\cdot + RO_2\cdot + H_2O\uparrow$$

and also because the oxygen will have increased difficulty in diffusing through this vapor into the tetralin. At high temperatures the measured oxidation rates therefore reflect the rate at which oxygen can diffuse into the tetralin rather than the rate at which it can react with the tetralin.* This was confirmed by a few experiments with Co, Mn, and Cu decanoate in which the oxygen was circulated continuously above the tetralin and through an air-cooled condenser to remove the water vapor as soon as it was formed. The rates obtained at 65 and 80 °C are increased (see solid points in Fig. 6) and the curvature of the Arrhenius plots is reduced or eliminated (dotted lines in Fig. 6). At 95 °C the rates were too great to measure. The correction to the measured maximum rate for tetralin consumption is about 40–45% for cobalt at all temperatures i.e., the corrected rate is smaller than the theoretical value by roughly the same amount at all temperatures. This correction is smaller for the other metals probably because of the higher initial peroxide concentrations that were used with these other metals (1). The small rates obtained with Cu, Ni, and Fe at the lower temperatures are probably due to the low solubilities of these rather inactive catalysts.

The present results illustrate the inherent dangers involved in assigning measured activation energies to specific elementary reactions unless independent evidence is available that the measured rates are related to the same elementary reactions over the entire temperature range. With the exception of the cobalt data in acetic acid, the temperature coefficients obtained from Figs. 5 and 6 cannot be assigned to any particular elementary reactions. That is, the measured rates are influenced to a different extent at each temperature by such factors as the catalyst concentration, the catalyst solubility, diffusion phenomena, the relative rates of hydroperoxide decomposition to radical and non-radical products, chain termination by the catalyst, etc. Many or all of these factors can influence the experimentally determined limiting rate at high metal-catalyst concentrations. However, Tobolsky's theory (4) that the steady-state hydroperoxide concentration determines the maximum possible value of the rate provides a unifying concept that clarifies the whole subject of metal-catalyzed oxidations.

**The very low activation energy (6.5 kcal/mole) reported by George, Rideal, and Robertson (12) for the ferric stearate (4×10^{-3} mole/l) catalyzed oxidation of tetralin between 90 and 120° is also consistent with a reaction which is mainly diffusion-controlled at these high temperatures. These authors actually claimed that their reaction was not diffusion-controlled because the measured rate at 110 °C did not increase when the sample size was reduced from 2 ml to 0.5 ml. However, this test will be rather insensitive at temperatures where all the water produced in reaction [1] is evolved as steam. Incidentally, the rate obtained in our work with 0.1 mole/l of ferric decanoate at 95 °C falls on their Arrhenius plot but our value at 80° is very much less than would be expected from their data.*

AMMONOLYSIS OF URONIC ESTER GROUPS IN BIRCH XYLAN[1]

PAUL Y. WANG, H. I. BOLKER,[2] AND C. B. PURVES

Wood Chemistry Division, Pulp and Paper Research Institute of Canada and Department of Chemistry, McGill University, Montreal, Quebec

Received June 10, 1964

ABSTRACT

Solvent-extracted white birch, kept near 20° in liquid ammonia under pressure for 72 h and then extracted with methanol to remove acetamide, retained 0.25% of amide nitrogen. Extraction of the very finely ground residual wood with hot water yielded 21% as a 4-O-methylglucuronoxylan containing 0.53% of amide nitrogen. Alkaline hydrolysis removed the amide absorption in the infrared and restored the normal xylan spectrum. These results, supported by various control experiments, showed that amide groups in the ammonia-treated wood were derived from lactone or ester groups in the original 4-O-methylglucuronoxylan. Some of the uronic acid groups in the native wood presumably existed as ester cross-links.

INTRODUCTION

It has long been known (1, 2) that the hardwoods in aqueous suspension are nearly neutral in reaction despite the 3–5% of uronic acid groups they contain (3). Yet, even if their ash content of 0.2–0.4% (3) is attributed entirely to calcium oxide, it is enough to neutralize only 25–80% of the uronic acid; the rest is presumably present as an ester or a lactone. Until now, the only ester linkages positively established in wood have been acetyl groups in the hemicellulose components (4) and possibly a few formyl groups (5). Nevertheless, some authors have inferred the presence of other esters from various experimental results (2), while others (1, 6) have particularly noted that non-extractable nitrogenous compounds analyzed as amides, remained in wood meals which had been immersed in liquid ammonia under pressure at room temperature. Ammonia, of course, yields ammonium salts from free carboxylic acid groups and only slowly cleaves esters at atmospheric pressure (−33°) (7). However, at room temperature ammonolysis of esters occurs in a reasonable time and produces acid amides. Such amides, other than acetamide, have never actually been recovered from the ammonolysis products of wood, and it was the object of the present research to isolate them from ammonia-treated birch wood meal.

By use of the procedure developed with other woods (1), birch wood meal was treated with a large excess of nearly anhydrous liquid ammonia under pressure (about 150 p.s.i.), washed several times with fresh liquid ammonia, and extracted with hot methanol in a Soxhlet apparatus to remove acetamide. As in the previous work, the quantitative differentiation of amide from ammonium nitrogen was based on the selective expulsion of ammonia from the latter by boiling with an aqueous suspension of magnesium oxide (8); control experiments with known mixtures of pure acetamide and ammonium acetate showed the method to be reliable. The Kjeldahl nitrogen content of the untreated wood was 0.06% and of this, 0.03% which responded as amide could probably be ascribed to nitrogen in the wood protein (9).

Table I shows that the amide nitrogen content of the wood increased with time of ammonolysis until a maximum value of 0.25% was reached after 24 h; a period of 72 h was chosen in subsequent experiments. Prior extraction of the wood with strong aqueous

[e]Recovered from the potassium hydroxide extract.

potassium hydroxide yielded a residual wood B and an extracted "xylan" C both of which were practically devoid of amide nitrogen, presumably because the potassium hydroxide had hydrolyzed all ester or lactone groups originally present. Ammonolysis caused the ammonium nitrogen content of the wood to attain its final, constant value of 0.11 ± 0.03% within an hour. The assumption that this value corresponded to carboxylic acid present originally as inorganic salt gave a salt:ester mole ratio (0.11:0.25) of about 3:7, and the sum of the ammonium and amide nitrogen, 0.36% was equivalent to 4.5% as uronic acid. Although birch wood was reported (3) to contain 4.6% of uronic acid, this excellent agreement was possibly fortuitous because the ammonium contents of the highly swollen wood residue B and of the extracted "xylan" C had no obvious connection with their content of uronic acid. The significance of the values for "ammonium" nitrogen after ammonolysis requires further study.

Confirmation of the presence of amides in ammonolyzed wood, freed of acetamide, was obtained by infrared spectroscopy. In earlier work (10) differential spectroscopy had been applied to determine the spectra of lignins in whole woods and pulps; in the present work the technique was altered, and the differential spectrum of holocellulose was determined by using wood in the sample beam and precisely calculated quantities of dioxane lignin, from the same wood, in the reference beam of the double-beam spectrometer. As shown in Fig. 1, the holocellulose differential spectrum (I) corresponds fairly well to the spectrum (against air) of isolated Tappi holocellulose (II). In the differential spectrum there are slight, but seemingly unavoidable, shifts of some of the principal bands, and also slight residues of the lignin spectrum, particularly at 1 500 and 1 600 cm^{-1}. However, these defects are not significant when the differential spectrum of the holocellulose in ammonia-treated wood (III) is observed. Here, as expected, the absorption bands at 1 730 cm^{-1} (C=O) and at 1 250 cm^{-1} (C—O), characteristic of acetyl groups, are absent, but a new, very strong band has appeared at 1 680 cm^{-1}. This band corresponds to the amide I band of α-D-glucuronamide (Fig. 2, V; IV is the spectrum of glucuronolactone for comparison), although the latter is found at a somewhat lower wave number (1 655 cm^{-1}). The amide II

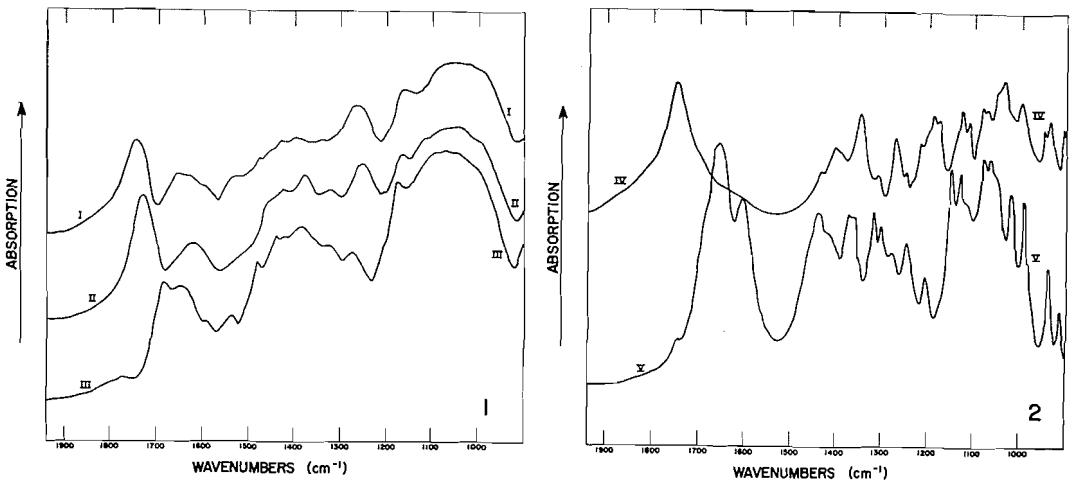

FIG. 1. Infrared spectra: (I) differential spectrum of holocellulose in untreated birch wood, (II) spectrum of birch (Tappi) holocellulose, (III) differential spectrum of holocellulose in ammonia-treated birch wood.
FIG. 2. Infrared spectra: (IV) glucuronolactone, (V) α-D-glucuronamide.

band at 1 608 cm^{-1} cannot be seen in the holocellulose spectrum, probably because of overlapping.

After the ammonia treatment and preliminary spectroscopic analysis, attempts were made to extract the "amide xylan" from the wood with dimethyl sulphoxide. Although the extraction was tried for 42 h under nitrogen, both at room temperature and at 80° with solids:liquor ratios varying from 1:15 to 1:100, and with the addition of up to 60% of water to the dimethyl sulphoxide, only about 1% of the wood substance was dissolved in each case. Pure water at room temperature yielded 1.5% of soluble material. Experiments then showed that if untreated wood meals of several species were first ground to almost colloidal size in a vibratory mill, hot water under neutral conditions extracted good yields of the hemicellulose fractions. When applied to the birch wood residue from ammonolysis, this procedure removed much of the hemicellulose and with it up to 75% of the original nitrogen. A larger scale preparation recovered 21% of the wood as a polysaccharide containing 0.53% of amide nitrogen (almost half the original amount) and only 1.7% of lignin. Acid hydrolysis followed by paper chromatography showed this polysaccharide to be nearly pure 4-O-methylglucuronoxylan.

The infrared spectrum of the above 4-O-methylglucuronoxylan (Fig. 3, VI) retained the prominent amide I absorption band near 1 680 cm^{-1} already noted in the differential spectrum of the ammonolyzed wood from which the xylan had been extracted (Fig. 1, III). Moreover, when this xylan was treated with 5% aqueous potassium hydroxide the amide band disappeared (VII) and the spectrum became identical with that of the xylan (VIII) extracted by 24% aqueous potassium hydroxide from untreated wood meal. These results showed that the 4-O-methylglucuronoxylan had been isolated from the ammonolyzed wood as an amide.

There is evidence that liquid ammonia yields amines from some reducing sugars (11), amides from acetylated disaccharides (12), and in appropriate conditions amides even from carboxylic acids (13). However, in the present research, control experiments produced no "aldose amide" from a fully acetylated cotton cellulose of DP_n, 395. When 4-O-methylglucuronoxylan plus added acetamide was immersed for 72 h in liquid ammonia

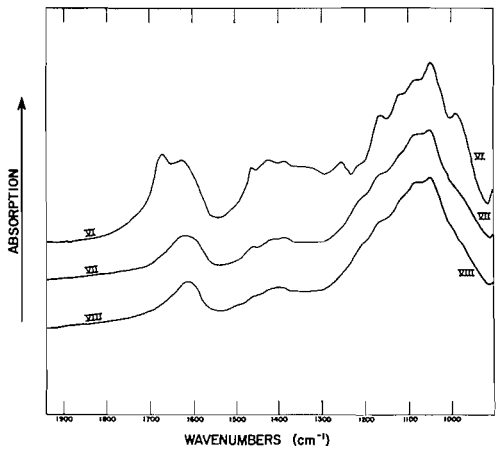

FIG. 3. Infrared spectra: (VI) "xylan amide" from ammonia-treated birch wood, (VII) "xylan amide" after hydrolysis in alkali, (VIII) alkali-extracted birch xylan.

under pressure at room temperature, the product was free of amide groups; hence a transfer reaction between acetamide and uronic acid or aldehyde groups in the xylan did not occur. These negative results minimized the possibility that the amide groups in the 4-O-methylglucuronoxylan from ammonolyzed birch wood originated in some unsuspected side reaction and strengthened the conclusion that many of the carboxyl groups in the untreated wood must have existed in the form of either lactone or ester groups, the latter as cross-links within the xylan itself or between xylan and other wood constituents.

EXPERIMENTAL

Materials

Wood meal, 60–80 mesh, from white birch (*Betula papyrifera*) was thoroughly extracted with ethanol–benzene, and was air-dried. After being screened again the meal was stored in screw-capped amber bottles. A published method (14) was used to extract 4-O-methylglucuronoxylan with 24% aqueous potassium hydroxide from some of the wood meal; yield: 24.3%. Acid hydrolysis followed by paper chromatography (15, 16) indicated the presence of much xylose and only traces of other sugars. The "xylan poor" wood residue (75.2%) was washed with distilled water until neutral to universal indicator paper, next with 0.02 *N* hydrochloric acid, then with distilled water again to neutrality, and, finally, air-dried.

Commercial liquid ammonia of 99.9% purity was used.

The acetylated raw Coastland cotton used in control experiments was described by Timell (17).

Analytical Methods

Klason lignin determinations were by TAPPI method (18).

A standard method (8) was adapted as follows for the determination, first of ammonium and then of amide nitrogen. An air dry, 1 g sample was placed in a 300 ml, 3-necked round-bottom flask equipped with 250 ml dropping funnel and a U-shaped splash-head connected to a condenser; the third neck was stoppered. The lower, distal end of the condenser was immersed in 25 ml of 1% aqueous boric acid containing 2 drops of a methyl purple indicator and just enough 0.02 *N* hydrochloric acid to make the solution purple. A suspension of 5 g of magnesium oxide (A.R. grade) in 150 ml of water was added through the dropping funnel, and the mixture was heated until about 80 ml, containing all of the liberated ammonia, had distilled into the boric acid solution. The latter was then titrated with 0.02 *N* hydrochloric acid, and the percentage of ammonium nitrogen was calculated. After providing a fresh 25 ml volume of the boric acid, with the indicator and of the proper pH, 150 ml of 60% aqueous potassium hydroxide was added through the dropping funnel and the third neck of the flask was equipped for a steam distillation; an ordinary distillation caused excessive "bumping". About 80 ml of distillate was collected in the boric acid solution which was then titrated as before. The result corresponded to the content of amide nitrogen, when correction was made for the small blank.

Found for pure acetamide, m.p. 81.5°: amide N, 23.2, 23.6; calcd.: 23.8. Found for pure ammonium acetate: ammonium N, 17.8, 17.8; calcd.: 18.2. Found for a mixture containing 0.30 g of acetamide and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

0.63 g of ammonium acetate: amide N, 7.6; ammonium N, 11.6; calcd.: amide N, 7.7; ammonium N, 12.3. For a mixture containing 0.51 g of acetamide and 0.46 g of ammonium acetate, found: amide N, 11.9; ammonium N, 8.3; calcd.: amide N, 12.1; ammonium N, 8.4.

A Unicam S.P. 100 prism-grating spectrophotometer was used to determine infrared spectra, the finely ground samples being suspended in clear pressed discs of potassium bromide 16 mm in diameter. Differential spectra were determined on wood samples of known Klason lignin content which had been ball-milled in a stainless steel vial for 5 min. The method for incorporating a precise weight (about 5 mg) of sample into a 400 mg potassium bromide disc was described previously (10). An amount of birch dioxane lignin (19) corresponding to the Klason lignin content of the wood samples was incorporated in a similar disc for use in the reference beam.

Small-Scale Ammonolyses

In a typical experiment, 10 g samples of the solvent-extracted birch wood meal plus 15 ml of liquid ammonia for each 1 g of sample, were sealed in steel bombs equipped as described elsewhere (6). After being kept at room temperature for various times, the liquid ammonia was siphoned through a fine sintered-glass filter stick. The wood was then washed with more liquid ammonia, and the combined liquors on evaporation yielded a small residue. A 1 h ammonolysis extracted 3.9% of the wood, and a 100 h treatment removed only 4.6%.

The ammonia remaining in the wood was removed by keeping the sample under vacuum for 12 h. Then the wood was extracted in a Soxhlet apparatus with methanol for 2 h. After drying in air, the sample was analyzed. The results shown in Table I were the means of concordant duplicates.

Amide of 4-O-Methylglucuronoxylan

A larger steel bomb (6) made it possible to extract 300 g of the birch wood meal in 50 g batches for 72 h at room temperature by the method already described, but in this case the liquid ammonia:wood ratio was reduced to 5:1 (vol:wt.). The moisture in the wood amounted to about 1% of the volume of the liquid ammonia.

After the residual wood had been extracted with methanol and dried in the air, 20 g was ground, with no addition of liquid, in a vibrating ball mill (20) for 30 h at 4°. The extremely finely divided product was then boiled for 1 h under reflux with 2 l of water. Without cooling, the suspension was filtered through a medium porosity, sintered-glass funnel, and the residue was washed with three 500 ml volumes of boiling water, then with 500 ml of cold water. The combined liquors were concentrated at 50° under reduced pressure to about 70 ml, the concentrate was poured into 1 l of ethanol, and the mixture was kept overnight near 4°. The precipitate of hemicellulose was then recovered on a filter, solvent-exchanged through ethanol and petroleum ether (b.p. 30–60°), and dried *in vacuo*. Yield of the gray, white powder, 4.1 g (21%).

Found: amide N, 0.53; Klason lignin 1.7.

A small sample was hydrolyzed in acid (15) and the hydrolysate was chromatographed on paper with ethyl acetate – acetic acid – water (9:2:2 v/v) and with *n*-butanol–pyridine–water (10:3:3 v/v) as eluents (16). The R_f values of the major spots corresponded to those observed in control experiments with xylose, 4-O-methylglucuronic acid, and 2-O-[4-O-methyl-α-D-glucopyranosyluronic acid]-D-xylopyranose; only traces of galactose, glucose, mannose, and arabinose were found.

In a smaller-scale experiment, 1.0 g of the residual wood from the ammonolysis was extracted as before with hot water, the amide nitrogen contents of the extract and the residue were 0.15% and 0.05%, respectively, on the wood basis. That is, hot water had extracted 75% of the amide nitrogen from the wood, and it was in the xylan.

To hydrolyze the amide group in the above hemicellulose, 100 mg was boiled under reflux and in a nitrogen atmosphere for 3 h with 10 ml of 5% potassium hydroxide. Precipitation of the liquor in ethanol yielded 92 mg of the hemicellulose as the potassium salt.

α-D-Glucuronamide

In a modification of methods described in the literature (21, 22), 5 g α-D-glucuronamide was prepared in a crude yield of 48%. After purification by ion-exchange and five recrystallizations from water–isopropanol, yield 37%; m.p. 153–154° (decomp.); reported 150° and 158°; $[\alpha]_D^{20}$ (2% in water), +46° (10 min), +31° (90 min), +29.3° (22 h); reported (21) +78° (3 min), +31.6° (22 h).

Calcd. for $C_6H_{11}O_6N.H_2O$: N, 6.63. Found: N, 6.47, 6.51.

CHEMICAL SCAVENGER PROBE STUDIES OF ATOM AND EXCITED MOLECULE REACTIVITY IN ACTIVE NITROGEN FROM A SUPERSONIC STREAM

A. FONTIJN, D. E. ROSNER, AND S. C. KURZIUS
AeroChem Research Laboratories, Inc., Princeton, New Jersey, U.S.A.

Received December 12, 1963

ABSTRACT

A quartz chemical scavenger probe has been developed to study the local composition of supersonic electrically discharged gas streams. The probe samples the central portion of a nonequilibrium jet and allows direct comparison with other local measurement techniques (e.g. differential catalytic detectors) for determining active species concentrations. Active nitrogen from a Mach 3 stream was sampled and reacted inside the probe with one of the scavenger gases NO, NH_3, or C_2H_4 at 18.8 mm Hg and at an average temperature of 500 °K. Limiting values of the NO destruction rate and the HCN production rate were observed; however, NH_3 destruction exhibited no plateau. The observed maximum rate of NO destruction was 2.1 times as large as the NO flow rate at the light titration end-point. This difference is attributed to a reaction of NO, added in excess of the titration end-point flow, with metastable electronically excited molecules formed within the discharge zone. The converging–diverging supersonic nozzle-glow discharge source used in these experiments apparently delivers metastable excited molecules to the reaction zone in a higher relative concentration than do the more conventional subsonic electrical discharge flow systems used for most previous active nitrogen studies.

INTRODUCTION

The chemistry of active nitrogen has received much attention in recent years and has been put on a sounder basis with the aid of spectroscopic and mass spectrometric techniques. While it is known that ground state, (^4S), nitrogen atoms are a major active component, interesting differences in the ratio of excited molecules to ground state atoms have been observed using active nitrogen from various sources. Thus a microwave discharge produces large quantities of vibrationally excited ground state, $X^1\sum_g^+$ (probably mainly $v = 1$), molecules (1–3), a species not observed in condensed (4) or radio-frequency (5) discharges. However, condensed discharges can apparently produce considerable amounts of electronically excited molecules (6). Since most of these observations have been made with nitrogen of similar purity under similar flow conditions, it appears that these differences are inherent to the type of discharge used, although the importance of other discharge parameters should be kept in mind.

Because of the advantages for certain experimental studies in nonequilibrium aerodynamics and chemical kinetics, a new type of high flow rate electrical discharge system has been in use in this laboratory for some time. In this apparatus (cf. Fig. 1) the products of a "high" pressure (usually above 20 mm Hg) continuous glow discharge are expanded through a converging–diverging nozzle-shaped electrode into an evacuated test section, resulting in a supersonic, activated gas jet at a translational static temperature of about 300 °K. The diameter of the jet is about equal to that of the nozzle exit diameter and its composition, in general, varies with radial position. To study active species concentrations in this environment, differential catalytic probes have been used (7). However, since every current technique for quantitative determination of the active species present in a discharged gas stream has its own inherent limitations, in practice it is necessary to apply fundamentally different techniques and to correlate the results. To this end a "chemical

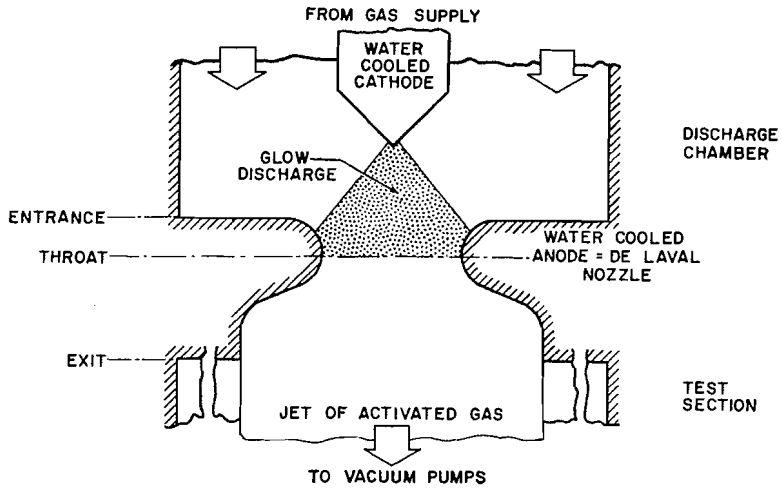

FIG. 1. Schematic of discharge apparatus.

scavenger probe" was developed which, like the catalytic probe methods used previously, allows measurement of *local* active species concentrations in the gas stream.

A chemical scavenger probe can be defined as a device which samples a gas stream containing active species (atoms, free radicals, excited species, or ions), and in which the sampled gas reacts rapidly with a "scavenger" gas to form stable products.[a] The concentration of the active species can be calculated from the amount of reaction.

This paper describes the scavenger probe and discusses the probe reactions of active nitrogen with NO, NH_3, and C_2H_4. The behavior of these reactants is relatively well known from previous studies[b] using subsonic Wood–Bonhoeffer type discharge flow systems (hereafter referred to as conventional flow systems) and they can be used to distinguish between atom and excited molecule reactivity. This work thus allows comparison of the reactivity of active nitrogen from the present electrical discharge source with that of more conventional discharges.

EXPERIMENTAL[c]

Chemical Scavenger Probe

It was undesirable to operate with high velocities within the probe, since this would have caused trapping difficulties and spatially extended reaction zones. A detached shock inlet probe (11), which consisted of a 30 mm outer diameter quartz tube (wall thickness 2 mm) with a 90° angle (cf. Fig. 2), was therefore designed. The end of the 8 cm long vertical section, the probe head, was partly blanked off, leaving an 8 mm diameter entrance orifice through which the active nitrogen jet was sampled. Immediately downstream of the probe entrance orifice was a 1 mm wide annular opening through which the secondary gas, consisting of a helium – scavenger gas mixture, was introduced. The helium served as a coolant and allowed measurement of the actual scavenger gas flow rate through the probe as described below. A thorough mixing of helium and titrant gas was obtained by passing the combined flow of these gases through a column packed with $\frac{1}{4}$ inch Berl saddles before introduction into the probe. The downstream portion of the 50 cm long horizontal section of the scavenger probe was brought outside the plasma jet test section through a vacuum tight O-ring connection. With an asbestos sleeve contained within a brass collar whose position could be closely controlled, it was possible to center the probe head with respect to the active nitrogen jet. The horizontal section of the probe ended in a 29/42 ground joint connected directly to a pyrex gas flow and analysis system.

The diameter of the supersonic jet (about 1.4 cm) was smaller than that of the flat face of the probe but

[a] *R. M. Fristrom has concurrently developed a scavenger probe of different design to study combustion flame intermediates, see refs. 8 and 9.*

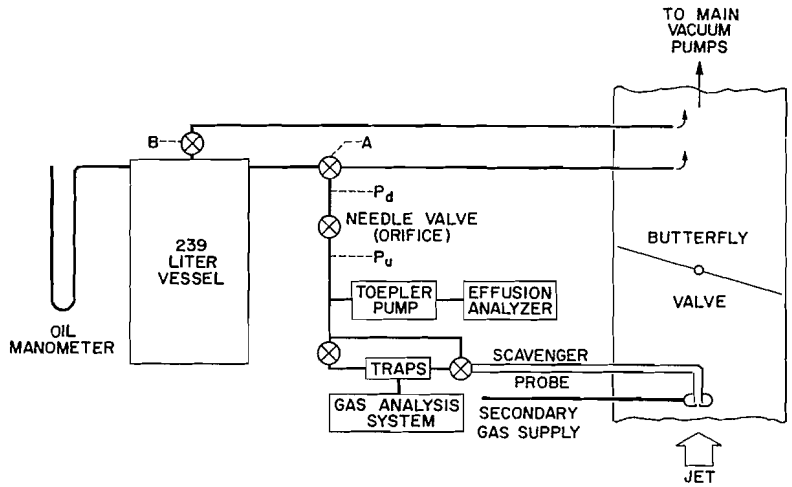

FIG. 2. Chemical scavenger probe flow system.

larger than that of the probe inlet orifice diameter by a factor of 1.7. The jet was thus stagnated by the probe and diffusely filled the test section downstream of the probe. Because of the deceleration of the gas behind the detached shock the actual region of the undisturbed jet sampled was smaller than the probe inlet opening (11) and corresponded to a central stream tube of about 2.4 mm diameter (i.e. some 3% of the jet). The probe was placed about 5 mm downstream of the nozzle exit and centered by visual observation of the nitrogen afterglow within the probe. The probe was considered properly centered when the afterglow filled the probe head. Small deviations from the centered position resulted in an unequal filling of the probe head, i.e. a beam of afterglow radiation was directed against a portion of the probe walls. During the centering operation the secondary gas used was helium without added titrant.

A 0.6 cm outside diameter stainless steel tube could be moved along the center of the scavenger probe downstream of the 90° bend through a vacuum tight O-ring packing. It contained the leads of a chromel–alumel thermocouple and was also connected to a pressure gauge. The tube was partially closed at the sensing end by a piece of quartz tubing which had a small hole, opening to the pressure tap, downstream from the thermocouple junction. The quartz served to hinder direct recombination or de-excitation on the junction. While the gas samples were taken this P,T probe was drawn out of the gas flow path.

Scavenger Probe Flow System

The scavenger probe flow system is shown schematically in Fig. 2. The effluent probe gases entering the analysis system consisted of N_2, He, unreacted scavenger gas, and reaction products. The condensables could be trapped by two consecutive cold traps and thence transferred in the conventional manner to a number of known volumes for PV measurement (using a silicone oil filled manometer) or to a demountable analysis flask. Liquid air traps were used which, for the NO experiments, were pumped down. A small coil of cobalt plated platinum wire was placed ahead of the traps to recombine O atoms formed in the reaction with NO. This procedure prevented ozone formation in the traps.

The flow rates of N_2 and He through the probe were calculated from the N_2/He ratio as determined by an effusion analyzer (see below) and the combined N_2 + He flow as determined by collection through a sonic orifice (see below) into a 239 l volume. The flow rate of scavenger gas through the probe before reaction in an active nitrogen experiment could then be calculated directly from the known scavenger–helium ratio. The difference between this flow rate and that determined by actual trapping gave the amount of scavenger destroyed by the active nitrogen. The scavenger–helium ratio was calculated from their individual metered flow rates and checked in blank experiments with the active nitrogen stream shut off.

The molecular effusion analyzer was submerged in a constant temperature water bath. It consisted of a fixed (≈250 cc) volume, out of which the gas mixture to be analyzed could effuse through a small hole into a continuously evacuated line. The pressure drop from a constant initial pressure (40 mm Hg) in the fixed volume after a certain time interval (30 min) was calibrated in terms of the N_2/He ratio. A Toepler pump was employed to fill the effusion analyzer. Gases analyzed by the effusion analyzer also contained uncondensable reaction products; however, these formed only a small fraction of the total flow and had an effect well within the limits of accuracy of the N_2/He ratio determinations (cf. Table I).

Upstream from the 239 l volume was a needle valve with which the flow rate through the probe could be adjusted (cf. Fig. 2). The pressure upstream, P_u, and downstream, P_d, from this "valve orifice" could be measured. With stopcock A open to the vacuum pump line the relation between P_u and P_d was such that

the flow through the valve orifice was sonic. When stopcock A was turned so that the gas streamed into the previously evacuated calibrated 239 l volume, the flow rate through the valve orifice remained the same as before, as long as the flow through it was sonic. Before P_d reached a value for which this condition was no longer fulfilled, stopcock A was turned back again to the pump line. Measurement of the final pressure in the 239 l vessel and of the collection time gave the flow rate. At the flow rates used, the collection times were about 1 to 5 min. Stopcock B allowed the vessel to be re-evacuated for succeeding measurements.

General Apparatus

A Stokes model 1712 mechanical booster – vacuum pump combination of nominal capacity 2500 c.f.m. was used. Static pressures were measured with Bourdon type absolute pressure gauges. Flow rates of nitrogen and helium were measured with sonic orifice meters and titrant flows were measured by rotameters. The axisymmetric water-cooled copper nozzle, which served as the anode of the glow discharge, had an exit diameter of 1.36 cm and a throat diameter 0.657 cm (cf. Fig. 1). For a specific heat ratio $c_p/c_v = 1.4$ the design exit Mach number was about 3. The distance between the tip of the glow discharge cathode (a coaxial copper rod) and the nozzle entrance was 6.8 cm.

Materials

Airco prepurified nitrogen, U.S. welding helium, Matheson c.p. ethylene, and anhydrous ammonia were used without further purification. Matheson nitric oxide was freed of NO_2 by passage through a column of 8–20 mesh Fisher Caroxite. The oil manometers were filled with Dow-Corning 702 silicone oil. Reagent grade chemicals were used.

Experimental Conditions

The N_2 flow rate into the system was 7.74×10^{-3} mole s^{-1}; an electrical discharge through it was operated at a potential of 930 V and a current of 630 mA. The pressure in the discharge region was 38.5 ± 0.5 mm Hg and the test section pressure, which was approximately that of the undisturbed jet, was 1.00 ± 0.02 mm Hg. The He (secondary gas) flow into the probe was 2.45×10^{-3} mole s^{-1}. From Table I it may be seen that 3.4% of the total N_2 flow was sampled and that 18.8% of the premixed secondary gas – titrant flow went through the probe to the trapping system, the rest spilling out around the probe periphery, thereby minimizing any thermal problems which might have been associated with the direct impingement of the active nitrogen jet upon the otherwise uncooled probe. Possible errors associated with this spillage are discussed below. The interior probe walls were poisoned with phosphoric acid, and the whole flow system downstream from the sonic orifice meters in the N_2 and He lines was pumped out for periods of at least 16 h before an experiment. Measurements were made after discharge stabilization periods of at least 30 min.

Active nitrogen sucked in at the probe entrance orifice must initially have been at a temperature close to that of the shocked gas; i.e. $\approx$ 900 °K. The secondary gas entered the probe at a temperature somewhat above room temperature, since heat must have been absorbed from the inlet region heated by the shocked gas. Reaction occurred when primary and secondary gas mixed. The probe temperature given in Table I was measured at the 90° bend in the probe and thus represents an average temperature, which may be somewhat lower than the actual average reaction temperature since most of the reaction occurred in the probe head upstream from the 90° bend. Downstream from the 90° bend the gas temperature dropped to about 300 °K within a few cm. The average gas velocity in the probe at 503 °K was 2.4 m s^{-1}.
