favoring attack at carbon is the great facility of $^-OSO_2Cl$ as a leaving group (cf. ref. 9). This is no doubt due in the main to the fact that $^-OSO_2Cl$ is the conjugate base of one of the strongest acids, but it may also result from the possibility of multiple bond fission (4). However, another pertinent factor may well be that the competing nucleophilic attack at sulfur will be discouraged, relatively, by the negative field effect of the sulfonyl oxygens (10, 11). A further electronic effect which will have the same influence is back-donation from an occupied p-orbital of chlorine to a vacant d-orbital of sulfur. The relevance of such p_π–d_π bonding to chlorosulfate reactivity will be further discussed at a later date (12).

Experimental

n-Propyl chlorosulfate was prepared according to the procedure of Binkley (13) and had physical properties as previously described (8). Di-*n*-propyl sulfate was prepared by the method of Nef (14) and had the following physical properties: b.p. 114–115°/15 mm, density 1.114 (22.5°), refractive index 1.4140 (25°), in close agreement with the literature values (14).

The reactions between *n*-propyl chlorosulfate and *n*-propanol were run in a thermostatted bath at 25° to completion. Product analysis was performed directly on aliquots of the reaction mixture. The ionic products (total acid, chloride ion, and propyl hydrogen sulfate by difference) were determined by volumetric procedures given previously (8). The volatile products were determined by quantitative g.l.c. using a Beckman G.C.2 chromatograph with a column of neopentylglycol sebacate, 10% on Embacel, and helium as carrier gas (40 p.s.i.). For analysis of di-*n*-propyl ether, *n*-propyl chloride, and isopropyl chloride, the column temperature was 70°, while for di-*n*-propyl sulfate the temperature was 190°. The yields of these products were determined by means of calibration curves (*n*-propanol solvent), constructed using the authentic compounds.

Electron spin resonance studies of radicals condensed from irradiated water vapor: reactions of the radicals[1,2]

P. WARDMAN[3] AND W. A. SEDDON

Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario

Received November 26, 1968

Electrons and hydroperoxyl radicals are trapped in polycrystalline ice after irradiation of water vapor and rapid condensation to 77 °K. Using higher sample flow rates than in the earlier work of Seddon, Smith, and Bindner, the electron spin resonance spectra of the trapped electrons (e_t^-) were obtained in both H_2O and D_2O ice with negligible interference from the underlying $HO_2\cdot$ ($DO_2\cdot$) radicals. Addition of $C(NO_2)_4$, H_2O_2, $(CH_3)_2SO$, and O_2 as radical scavengers confirmed the earlier prediction that reactions with the radicals do not occur in the vapor phase in this system. The results with $C(NO_2)_4$ and H_2O_2 also provided chemical evidence consistent with the spectroscopic assignment for $HO_2\cdot$ ($DO_2\cdot$) radicals. Experiments with added isobutylene suggested that hydrogen atoms are formed (possibly in a post-irradiation reaction during condensation) and are also produced on photobleaching e_t^- at 77 °K.

Canadian Journal of Chemistry, 47, 2149 (1969)

Introduction

Gamma irradiation of many glassy solids produces electrons which are trapped in the matrix with high efficiency. Typically, the yield (G) of trapped electrons (e_t^-) at 77 °K is in the range 0.5–3 per 100 eV energy absorbed (1, 2). In contrast, electrons produced by irradiation of the same materials in polycrystalline or single crystal forms are generally trapped with very low efficiency or not at all (e.g. in solute-free ice, $G(e_t^-) \simeq 2 \times 10^{-4}$ at 77 °K (3)). The observation by Marx, Leach, and Horani (4) and Seddon, Smith, and Bindner (5) that electrons could be efficiently trapped in polycrystalline ice when water vapor was irradiated and rapidly condensed to 77 °K, was therefore of considerable interest.

Further study of e_t^- in solute-free ice was made difficult by the presence of the underlying $HO_2\cdot$ electron spin resonance (e.s.r.) absorption, which entirely masked the e_t^- resonance in H_2O ice (4, 5). We have found that increasing the sample flow rate increased the ratio of e_t^- to $HO_2\cdot$ in the deposit and this permitted an extension of the earlier work (5). Hydrogen atoms and hydroxyl radicals are expected to be formed during irradiation in the vapor phase and reactive solutes have been added to the water vapor in an attempt to study the formation and reactivity of $HO_2\cdot$ and other radicals in this system.

Experimental

Materials

Dimethylsulfoxide-d_6 was supplied by Stohler Isotope Chemicals (99.5% D). Isobutylene was Phillips Research Grade, 99.84%. Nitric oxide (Matheson) was fractionally distilled several times in vacuo. Sodium deuteroxide was prepared by dissolving sodium in D_2O. Tetranitromethane (K and K Laboratories) was shaken with 0.1 *M* HCl ten times (6), degassed, and stored in vacuo at 77 °K. Water (H_2O and D_2O) was quadruply distilled and preirradiated as described previously (7). D_2O was 99.75% D, low tritium, high grade material supplied by A.E.C.L. All other chemicals were of reagent or spectroscopic grade.

Preparation of Samples

All samples were deaerated on a grease and mercury-free vacuum system by bulb-to-bulb distillation where appropriate. Samples of pure H_2O and D_2O (0.2 to 0.4 g) were distilled directly from the liquid into the target chamber but mixtures (0.1 g) were admitted from a 5 l bulb. After preliminary washing, glassware was cleaned by baking in an air oven for 12 h at 550 °C.

Irradiations

A 100 μA, 1 MeV He^+ ion beam was used for crossed-beam irradiations as described previously (5, 8). The sample introduction system was constructed entirely of stainless steel and the needle valve used in the previous work (5, 8) was omitted.

Preliminary experiments had shown that increasing the sample flow rate over that used in the earlier work (5, 8) increased the ratio of electrons to other radicals in the deposit and in all the experiments described below, the flow rates were up to five times greater than those used earlier. The pressure in the radiation zone was therefore slightly different from that measured previously (5). Pure water samples were introduced at a rate of about 0.1 g in 3 min and mixtures at about 0.1 g in 15 min. In the latter

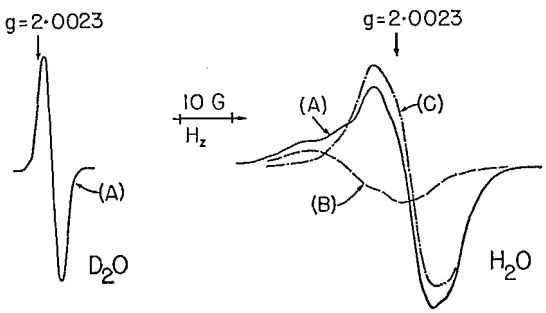

FIG. 1. Electron spin resonance absorption spectra of H_2O and D_2O at 77 °K after condensing irradiated water vapor. (A), before photobleaching (no saturation); (B), after photo bleaching; (C), calculated for e_t^-, i.e. (A) − (B).

case most of the sample was deposited in the first 5 min. Samples were then isolated under vacuum; light was excluded during irradiation and examination of samples.

Electron Spin Resonance Spectroscopy

A Varian V-4502 X-band spectrometer was used with the Fieldial and the TE_{104} cavity. Resonances exhibiting g-factor anisotropy were analyzed using Kneubühl's method (9). Frequency measurements were made with a Hewlett–Packard microwave frequency converter and electronic counter.

Deposits of ice on the cold finger were warmed by passing a stream of cold helium through the finger, displacing the liquid nitrogen. The temperature was measured with a thermocouple in the gas stream and was varied by controlling the helium flow rate.

Samples in the e.s.r. cavity were photobleached using a focussed 150 W tungsten filament lamp and Corning glass filters ($440 < \lambda < 740$ mμ).

Results and Discussion

(i) Pure Water Vapor

The e.s.r. absorption spectra of the deep blue colored deposit at 77 °K from irradiated D_2O and H_2O vapor are shown in Fig. 1. In D_2O at low microwave powers (3×10^{-8} to 10^{-6} W) only the singlet (A) of e_t^- was observed, but at higher powers, saturation of the e_t^- signal permitted the observation of an underlying radical, and the spectra were similar to those found earlier (5) for deposits containing fewer trapped electrons. In H_2O the singlet of e_t^- was four times broader than in D_2O and was slightly distorted by an underlying resonance even at low microwave powers (spectrum (A)). The absorption of e_t^- in H_2O was obtained (C) by photobleaching e_t^- completely and subtracting the underlying resonance (spectrum (B)) remaining after photobleaching. It was verified that the concentration of the underlying radicals (spectrum (B)) did not change during photobleaching e_t^-. The lines of e_t^- in D_2O and H_2O were closely Gaussian, with line widths between derivative maxima $\Delta H_{ms} = 2.7 \pm 0.3$ and 10.6 ± 1.5 G, respectively and both had $g = 2.0008 \pm 0.0003$.

Although ȮD was expected to be observed in the deposit (5), no evidence for the characteristic splitting of ȮD was observed in D_2O. The underlying resonance observed after removal of e_t^- by photobleaching was similar to that observed previously and assigned to the hydroperoxyl radical (5): cf. Fig. 2 (below). In H_2O, $g_{\parallel} = 2.034 \pm 0.001$ and $g_{\perp} = 2.0024 \pm 0.0008$; in D_2O, $g_{\parallel} = 2.034 \pm 0.001$ and $g_{\perp} = 2.004 \pm 0.001$, all at 77 °K. Splitting of the parallel feature was always observed in H_2O ($A_{\parallel} = 15 \pm 3$ G at 77 °K) but never in D_2O. An almost negligible splitting of the perpendicular feature was often seen in both H_2O and D_2O (similar to that observed in Fig. 2). In H_2O this may in part be attributable to proton hyperfine interaction, but there is a small difference between g_x and g_y for $HO_2\cdot$ or $DO_2\cdot$ in ice at 77 °K. These parameters are in good agreement with those well established for the hydroperoxyl radical (10, 11).

Warming the deposit without photobleaching resulted in the disappearance of both e_t^- and $HO_2\cdot$ ($DO_2\cdot$). The e_t^- signal began to decay at about 120 °K and the first half-life was 20 ± 2 min at 130 ± 5 °K in D_2O. The decay could not be followed to an extent sufficient to determine the kinetic order because of the underlying resonance. The $HO_2\cdot$ ($DO_2\cdot$) radicals were also decaying in this temperature region and decayed rapidly at 140 °K. The small splitting of the perpendicular feature of the $DO_2\cdot$ radical disappeared on warming to 110 °K.

The probable fate of e_t^- during thermal bleaching at about 130 °K is by reaction [1] rather than by the alternative reaction [2], because Bennett *et al.* (12) have shown that the electrons trapped in a similar ice matrix in the absence of solvated protons were observable at temperatures up to at least 170 °K. This

$$[1a] \qquad e_t^- + kT \rightarrow e_m^-$$

$$[1b] \qquad e_m^- + [(H_2O)_nH]^+ \rightarrow nH_2O + H\cdot$$

$$[2] \qquad 2\,e_m^- \rightarrow 2OH^- + H_2$$

comparison is justified because the ice matrix is produced in a very similar manner in both systems and the e.s.r. parameters for e_t^- in ice at 77 °K obtained in this work are closely similar to those obtained by Bennett *et al.* (12). It is very probable that the ice in these experiments is polycrystalline since vitreous ice is produced to a maximum thickness of 0.06 mm when wet nitrogen impinges slowly on a cold surface (13, 14).

(ii) The Line Shape of e_t^- in Ice

Our results confirm the suggestion of Bennett *et al.* (12) that the alkali metal ions do not broaden the e.s.r. line of e_t^- prepared by depositing sodium atoms and water vapor on a rotating drum at 77 °K. These authors observed 7 hyperfine lines ($A_H = 5.5 \pm 0.5$ G) in the e.s.r. spectrum of e_t^- in H_2O at 170 °K. If the spin density on the D atoms is the same for e_t^- in D_2O ice as it is on the H atoms in H_2O ice, then *F* center theory (15) predicts $\Delta H_{ms}(H_2O) = 4\,\Delta H_{ms}(D_2O)$; such a ratio was experimentally observed. However, computer simulation of the spectrum expected for e_t^- in D_2O at 77 °K assuming six equivalent D atoms and $A_D = 0.85 \pm 0.09$ G indicated that the minimum linewidth of the singlet would be $\Delta H_{ms} \simeq 4$ G. Thus either the 6 protons are not all equivalent or the spin density distribution is different in H_2O and D_2O.

(iii) The Effects of H_2O_2 and $C(NO_2)_4$

The e.s.r. spectrum of the deposit obtained from 7.5 mole % H_2O_2 in H_2O is shown in Fig. 2(A); no electrons were trapped in the deposit. The spectrum was closely similar to that obtained from pure H_2O after bleaching e_t^- and had $g_{\|} = 2.034 \pm 0.001$, $g_{\perp} = 2.0030 \pm 0.0006$, and $A_{\|} = 15 \pm 2$ G at 77 °K. A sample of D_2O containing 0.18% H_2O_2 gave the spectrum shown in Fig. 2(B) at 77 °K with $g_{\|} = 2.033 \pm 0.001$ and $g_{\perp} = 2.004 \pm 0.001$. (Since H_2O_2 exchanges in D_2O (16), a dilute solution of H_2O_2 in D_2O may be treated as D_2O_2 in D_2O.) On warming, the parallel feature became more prominent and at 130 °K (Fig. 2(C)), $g_{\|} = 2.032 \pm 0.001$ and $g_{\perp} = 2.0072 \pm 0.0005$. We conclude from the spectroscopic data that the addition of sufficient hydrogen peroxide prevents the trapping of electrons in the deposit and that the only remaining paramagnetic species is the hydroperoxyl radical.

It was found that the addition of hydrogen peroxide approximately doubled the concentration of $HO_2\cdot$ ($DO_2\cdot$) radicals in the deposit relative to that observed in the absence of this scavenger. This is expected if $\dot{O}H$ radicals produced during condensation by reaction [3] are converted to $HO_2\cdot$ in reaction [4] in preference to the dimerization reaction [5], which is important in the absence of H_2O_2.

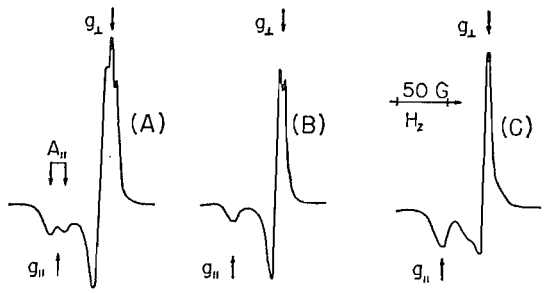

FIG. 2. Electron spin resonance absorption spectra of the deposit condensed from irradiated water vapor containing hydrogen peroxide. (A), 7.5 mole % H_2O_2 in H_2O at 77 °K; (B), 0.18 mole % D_2O_2 (see text) in D_2O at 77 °K; (C), sample (B) at 130 °K.

[3] $$e_m^- + H_2O_2 \rightarrow \dot{O}H + OH^-$$

[4] $$\dot{O}H + H_2O_2 \rightarrow H_2O + HO_2\cdot$$

[5] $$2\,\dot{O}H + M \rightarrow H_2O_2 + M$$

The ratio of $[e_t^-]/[DO_2\cdot]$ was measured in pure D_2O and found to be ~ 2.1, about 5 times higher than that measured in the earlier work (5). The increase in this ratio arose from about a doubling in the number of electrons trapped in the deposit and a halving of the concentration of $DO_2\cdot$ radicals with the increased sample flow rate. The reasons for this marked effect of deposition rate are not known.

Tetranitromethane reacts with both electrons and hydroperoxyl radicals to produce $C(NO_2)_3^-$ and NO_2 (6, 17). No trapped electrons were observed in the deposit condensed from an irradiated mixture of D_2O and 0.005 mole % $C(NO_2)_4$. The e.s.r. spectrum of the deposit is shown in Fig. 3(A) and is very similar to that ascribed by Symons *et al.* (18) to NO_2 in ice at 77 °K. The 3 hyperfine lines overlap to a negligible extent and were integrated to ascertain whether the $DO_2\cdot$ radical (which underlies only the central line of NO_2) was present. The integrated area under the central line was only about 10–15% higher than the outer lines (of the same

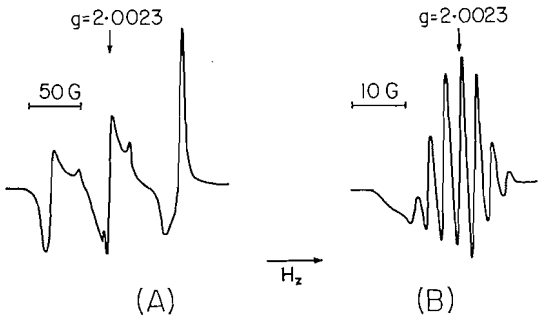

FIG. 3. Electron spin resonance absorption spectra of the deposit at 77 °K condensed from irradiated D_2O vapor containing: (A), 0.005 mole % $C(NO_2)_4$; (B), 0.5 mole % $(CD_3)_2SO$.

order of magnitude as the experimental error) even at $[C(NO_2)_4] = 0.1$ mole %.

The ratio of electrons to $DO_2\cdot$ radicals condensed in the deposit from pure D_2O is less than 2.1 under the conditions used for the samples containing solutes. If $C(NO_2)_4$ scavenged only the electrons and not the $DO_2\cdot$ radicals, the integrated area under the central line of the NO_2 triplet would be at least twice as great as the outer lines. No such difference was observed. This may indicate that $C(NO_2)_4$ was also reacting with $DO_2\cdot$ and is additional chemical evidence supporting our confirmation of the assignment (4, 5) of the underlying radical in pure water to the hydroperoxyl radical. An alternative explanation of the apparent absence of $DO_2\cdot$ upon the addition of $C(NO_2)_4$ is that the number of electrons reacting with $C(NO_2)_4$ is considerably greater than the number trapped in the absence of scavengers (see below).

(iv) Effects of $(CH_3)_2SO$, O_2, and NO

Earlier calculations (5) had predicted that only extremely rapid reactions with the major component of the vapor (such as ion–molecule reactions) could occur in the vapor phase in the time between irradiation and hitting the surface of the cold finger (ca. 10 μs). If this is correct then the efficiency of scavenging electrons and other radicals might depend on the efficiency with which the scavenger is condensed. Dimethylsulfoxide reacts with e_{aq}^- very slowly

$$k(e_{aq}^- + (CH_3)_2SO) = 1.7 \times 10^6\ M^{-1}\ s^{-1}$$

at ~ 20 °C in H_2O (19) but like $C(NO_2)_4$ has a melting point close to room temperature. Oxygen and nitric oxide have a reactivity towards e_{aq}^- similar to that of $C(NO_2)_4$ but the condensing efficiency will be much lower.

The e.s.r. spectrum of the deposit condensed from an irradiated mixture of 0.5% $(CD_3)_2SO$ in D_2O is shown in Fig. 3(B). The 7 lines of $CD_3\cdot$ ($A_D = 3.6 \pm 0.1$ G) are superimposed on a broad underlying resonance. No trapped electrons were observed, but at $[(CD_3)_2SO] = 0.01\%$, a small fraction of the electrons was not scavenged and e_t^- was observed in low yield. Hydroxyl radicals may also react with dimethylsulfoxide to produce methyl radicals (19, 20).

Even 0.7% O_2 had little or no effect on the radicals trapped in the deposit. When oxygen was admitted to the surface of the deposit whilst under e.s.r. examination, no change in the concentration of electrons was observed after several minutes exposure. A similar lack of effect of oxygen on $CD_3\cdot$ radicals trapped in the deposit suggested that oxygen could not diffuse through the ice at 77 °K, since the formation of alkyl peroxy radicals is known to be rapid even at low temperatures (11).

The deposit condensed from irradiated 0.2% NO in D_2O contained a very low concentration of NO_2 radicals in addition to $DO_2\cdot$ and a much lower concentration of electrons than normal. Blank experiments without irradiation produced an identical concentration of NO_2; admission of oxygen to the surface of the deposit at 77 °K had no effect on the e.s.r. spectrum.

The absence of an effect with O_2 may be contrasted with the effectiveness of $C(NO_2)_4$ and $(CD_3)_2SO$ at concentrations three orders of magnitude less. It seems likely that reaction of the electron with the solute must only occur either in the transient liquid phase during condensation or in the solid condensate at temperatures where the electrons are still mobile.

(v) Effect of $(CH_3)_2C{=}CH_2$: Photobleaching of e_t^-

Isobutylene (0.2%) in H_2O did not prevent the trapping of electrons in the deposit and the e.s.r. spectrum of the $(CH_3)_3C\cdot$ radical was observed ($A_H = 22.7 \pm 0.5$ G) superimposed on the e_t^- and $HO_2\cdot$ signals (Fig. 4(A)). The concentration of $(CH_3)_3C\cdot$ radicals was increased by 25% on photobleaching e_t^- at 77 °K (Fig. 4(B)). When 0.5% CO_2 (an electron scavenger) was added in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

addition to 0.2% isobutylene, the contribution of $(CH_3)_3C\cdot$ to the total concentration of radicals was much less, the blue coloration of e_t^- was considerably diminished, and no increase in the $(CH_3)_3C\cdot$ radical concentration was observed on photobleaching the remaining e_t^- absorption.

The observation of *t*-butyl radicals upon the addition of isobutylene suggests that hydrogen atoms are produced. The effects of electron scavengers suggest that a major fraction of the alkyl radicals observed arise not from the hydrogen atoms produced in primary events during radiolysis (which would probably condense with low efficiency), but from hydrogen atoms produced during post-radiolysis events in the deposit. Electrons are mobile in ice at temperatures above about 130 °K and hydrogen atoms are expected to be produced in the deposit during cooling in the post-irradiation reaction [1*b*]. If reaction [1*b*] is indeed important during condensation, added scavengers would react with a much greater number of electrons than could be trapped in the absence of scavenger.

The increase in the $(CH_3)_3C\cdot$ radical signal observed on *photobleaching* e_t^- *in ice* condensed from H_2O containing $(CH_3)_2C{=}CH_2$ suggests that hydrogen atoms are produced during this process. It is experimentally difficult to determine whether a major fraction of spins is converted from e_t^- to $(CH_3)_3C\cdot$ during photobleaching, and it is impossible from this evidence alone to be sure that a reaction producing $H\cdot$ is the major photobleaching process. Ionic reactions such as [6] followed by [7] are also a possible explanation of the observations

$$[6] \quad H_3O^+ + (CH_3)_2C{=}CH_2 \rightarrow H_2O + (CH_3)_3C^+$$

$$[7] \quad (CH_3)_3C^+ + e_m^- \rightarrow (CH_3)_3C\cdot$$

and from the available thermochemical data (21) we cannot exclude this possibility.

Conclusions

The electrons trapped in polycrystalline ice after condensing irradiated water vapor have similar chemical properties to those trapped in glassy matrices. Chemical evidence to support the spectroscopic identification of the hydroperoxyl radical in the deposit has been obtained but only indirect evidence is available that the precursor

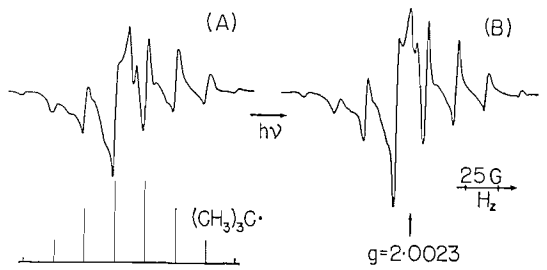

FIG. 4. Electron spin resonance absorption spectra of the deposit at 77 °K condensed from irradiated H_2O vapor containing 0.2 mole % $(CH_3)_2C{=}CH_2$; (A), before photobleaching e_t^- ($H_1 = 2 \times 10^{-2}$ G, e_t^- strongly saturated); (B), after photobleaching.

of $HO_2\cdot$ is[4] $\dot{O}H$. The $HO_2\cdot$ radical is also observed when water containing $\dot{O}H$ radicals, produced by a microwave discharge, is condensed and the problem is discussed in some detail elsewhere (22, 23). Recent work (24) indicates that reaction [4] has a surprisingly low activation energy (1.2 kcal mole^{-1}).

The disadvantages of this technique are that post-irradiation reactions may occur during condensation and the choice of scavengers is restricted. The absence of an effect of a scavenger (such as that with O_2) does not necessarily indicate that the species of interest are absent. Relative primary yields may not be deduced from an examination of the condensate.

Acknowledgments

Most of the apparatus and techniques used in this work were developed by Dr. D. R. Smith and co-workers (5, 25) and we thank Dr. Smith for helpful discussions. We thank Mr. G. A. Sims for his expert operation of the accelerator and Mr. P. E. Bindner for technical assistance.

[4]The addition of 0.2 mole% isopropanol did not prevent the trapping of electrons in the deposit and $(CH_3)_2\dot{C}OH$ radicals were observed together with $HO_2\cdot$ and e_t^-. It is possible that the $(CH_3)_2\dot{C}OH$ radicals arose from reaction with $H\cdot$ atoms rather than $\dot{O}H$, although no increase in the concentration of $(CH_3)_2\dot{C}OH$ was observed on photobleaching e_t^- (unpublished work by Wardman).

Electron spin resonance studies of radicals condensed from irradiated water vapor: paramagnetic relaxation of trapped electrons in ice[1,2]

P. WARDMAN[3] AND W. A. SEDDON

Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario

Received November 26, 1968

The spin–lattice relaxation time T_1 of electrons (e_t^-) trapped in several ice matrices at 77 °K has been estimated to be of the order of 10^{-2} s by observation of the electron spin resonance (e.s.r.) dispersion signal under fast passage conditions. These studies, together with measurements of the microwave power saturation of the e.s.r. absorption signal indicate that there is little difference in T_1 at 77 °K for e_t^- in solute-free polycrystalline H_2O or D_2O ice, γ-irradiated 8 *M* $NaOH/H_2O$ or $NaOD/D_2O$ glassy ices, and in 8 *M* $NaOD/D_2O$ glasses in which the electrons were produced by photoionization of ferrocyanide ion. This indicates that the predominant spin–lattice relaxation mechanism is not cross relaxation, and that correlations between T_1 and line width or trap depth are inappropriate.

Canadian Journal of Chemistry, 47, 2155 (1969)

Introduction

Electrons trapped in solute-free ice (e_t^-) by condensation of irradiated water vapor appear to have similar chemical properties to those trapped in ice containing high concentrations of electrolytes (1). It was of interest to compare some of the e.s.r. characteristics of e_t^- in solute-free, polycrystalline ice with those trapped in glassy ice containing high concentrations of solute. The close similarity of the small, negative *g*-shift for e_t^- in both types of system suggested similar interaction with the matrix via (weak) spin–orbit coupling, and by means of microwave power saturation characteristics we have investigated the interaction of e_t^- with the matrix to see whether any differences could be detected. A study has been published (2) of the saturation characteristics of e_t^- in γ-irradiated glassy ice containing ca. 8 *M* NaOH or NaOD, and we have, therefore, compared e_t^- in solute-free ice with those in γ-irradiated alkaline ice. In the latter case, enhanced spin–spin interaction due to the inhomogeneous spatial distribution of e_t^- could complicate the study, and hence we also compared the saturation behavior of e_t^- produced (presumably homogeneously) by photoionization of a dilute solution of ferrocyanide ion (3) in an identical glassy alkaline ice matrix.

Theory

During an e.s.r. experiment, the magnitude of the external magnetic field H_z is given by the expression

$$H_z = H_0(t) + H_m \cos(\omega_m t)$$

where $H_0(t)$ represents the direct current magnetic field, H_m is one half the peak-to-peak amplitude of the modulating field, ω_m the modulation frequency, and t the time. When $dH_0/dt \ll \omega_m H_m$ (as in this work), $dH_z/dt \simeq -\omega_m H_m \sin(\omega_m t)$ and the rate of passage through resonance is restricted by ω_m and H_m. The e.s.r. dispersion ($d\chi' H_1/dH_z$) and absorption ($d\chi'' H_1/dH_z$) signals depend both on the spin system (the spin–lattice and spin–spin relaxation times T_1 and T_2 and the width-at-half-height of the line envelope ΔH_{env}) and on the experimental parameters ω_m, H_m, and H_1 (the mean value at the sample of the circularly polarized magnetic component of the microwave field). The saturation behavior expected under several conditions of passage through resonance has been described at length (4–7). The important conditions are

(*a*) slow passage

$$(\gamma H_1)^{-1} \ll (T_1 T_2)^{1/2} \ll H_1 (dH_z/dt)^{-1}$$
$$H_m \ll \Delta H_{env}$$

(*b*) rapid passage: $H_1 (dH_z/dt)^{-1} \ll (T_1 T_2)^{1/2}$

(*c*) fast passage: $\omega_m T_1 \gg 1$, and

(*d*) adiabatic condition: $\gamma H_1^2 \gg dH_z/dt$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where γ is the gyromagnetic ratio of the electron. The validity of a particular restriction may vary throughout the modulation cycle, but since most of the signal arises near the extrema of the modulation cycle, for many purposes dH_z/dt may be replaced by $\omega_m H_m$. True slow passage, adiabatic conditions are a requirement for the treatment of progressive microwave power saturation data to obtain T_1 and T_2 using the Portis (8) and Castner (9) methods. Smith and Pieroni (10) developed these methods to demonstrate the spatial inhomogeneity of e_t^- and radicals in γ-irradiated 2-methyltetrahydrofuran glass, and Zimbrick and Kevan (2) later extended them to glassy alkaline ice. Progressive saturation under fast passage conditions is theoretically less satisfactory but may be used to compare relaxation characteristics under similar experimental conditions. By observation of the effects of fast passage on the dispersion signal, Bullock and Sutcliffe (7) estimated T_1 for a free radical in a solid matrix and we have also used this approach.

Experimental

Most of the experimental techniques have been described earlier (1).

Estimation of H_1 and H_m[4]

The microwave power P (W) incident at the cavity was measured using a Hewlett–Packard power meter, thermistor mount, and a 3 dB directional coupler. For powers less than 10^{-6} W the height of the diphenylpicrylhydrazyl (DPPH) standard was used to estimate H_1. For the V4531 TE_{102} cavity the maximum value of the microwave field H_1 at the sample is given by $H_1 = 1.41 \times 10^{-2} (Q_L P)^{1/2}$ G (12) where Q_L is the loaded Q (typically 4500), measured from the oscilloscope mode sweep pattern to $\pm 10\%$ as $f/\Delta f_{1/2}$ (9). For the TE_{104} cavity, $H_1 \simeq 1.0 \times 10^{-2} (Q_L P)^{1/2}$ G and this expression was taken to be the mean value of H_1 at the sample (variation of H_1 along a line sample may be neglected for our purposes using 100 kHz modulation (12)). The peak-to-peak modulation amplitude $2H_m$ was estimated (to $\pm 25\%$) from the effects of modulation broadening on signals from the $(SO_3)_2NO^{2-}$ and *p*-benzosemiquinone anion radicals (14).

Photoionization of Ferrocyanide Ion in Alkaline Ice

Samples contained ca. 1 m*M* $K_4Fe(CN)_6$ and were photolyzed at 77 °K with light from a low pressure mercury resonance lamp (Oriel Optics C-13-61) in conjunction with a Corning CS 7-54 glass filter, which together provide light of about 89% 254 mμ, 7% 313 mμ, and 4% 366 mμ.

Results

(i) Progressive Microwave Power Saturation of e_t^- in Ice

The effects of increasing microwave power on the e.s.r. absorption signal of e_t^- were investigated in two systems. System I was e_t^- in solute-free, polycrystalline D_2O ice at 77 °K (the deposit condensed from irradiated D_2O vapor) and system II was e_t^- in glassy 8 *M* NaOD in D_2O at 77 °K (after photoionization of ferrocyanide ion). In both systems, $[e_t^-] = 5 \times 10^{16}$ spins cm^{-3}, very approximately. The saturation factor Z was determined at several values of H_1 by measuring

$$Z_{H_1} = \chi''_{H_1}/\chi''_{\lim H_1 \to 0}$$

the ratio of the height of the first derivative absorption signal of e_t^- to that of a solid DPPH standard in the TE_{104} dual cavity (DPPH does not saturate under these conditions). Neither the shape nor the linewidth between derivative maxima ΔH_{ms} of the e_t^- resonance changed over the values of H_1 used. The underlying radical ($DO_2\cdot$) in system I did not interfere with the experiments; in system II there is no resonance underlying e_t^-.

The conditions used were $\omega_m = 2\pi \times 10^5$ rad s^{-1}, $H_m = 1.1 \pm 0.3$ G, $H_1 = 10^{-4}$ to 10^{-2} G, $dH_0/dt \simeq 0.5$ G s^{-1} (a value used throughout this work). Preliminary experiments (observation of passage effects on the dispersion signal, see below) had shown that $T_1 \gg 10^{-5}$ s in both systems and since $dH_0/dt \ll \omega_m H_m$, fast passage, strongly non-adiabatic conditions applied throughout most of the modulation cycle. The results are shown in Fig. 1; saturation of e_t^- ($Z < 1$) began at $H_1 \simeq 10^{-3}$ G and the dependence of Z on H_1 was

[4]Apparent discrepancies in published work often arise from the use of different equations for H_1. For example Smith and Pieroni (10) erroneously used Ingram's equation (11) for a TE_{102} cavity

$$H_1 = 5.7 \times 10^{-2} (Q_L P)^{1/2}$$

Using Hyde's equation (12) modified for a TE_{104} cavity

$$H_1 = 1.0 \times 10^{-2} (Q_L P)^{1/2}$$

lowers all of Smith's values of H_1 by a factor of 5.7. Since $T_1 T_2 = \gamma H_1^2$, Smith's T_1 is too short by a factor of $(5.7)^2 = 32.5$; the corrected value of T_1 is $7.5 \times 10^{-5} \times 32.5 = 2.4 \times 10^{-3}$ s. T_2 is unaffected by the error since it was obtained from the ratio of two H_1 values. The values of Williams *et al.* (13) may be compared to Smith's (10) by recalculation of Williams' data using Smith's measured $Q_L = 4440$ rather than Williams' assumed $Q_L = 6900$. This reduces the discrepancy with Smith's data still further. Williams' values of H_1 then become only a factor of 1.24 lower than Smith's. Such a small difference may arise in different laboratories from the use of quartz Dewars having different wall thicknesses. (Private communication from D. R. Smith.)

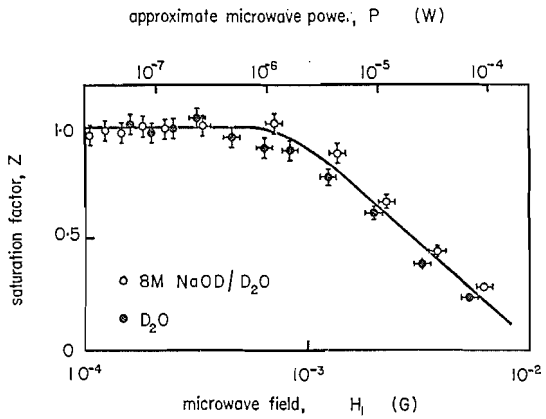

FIG. 1. Fast passage progressive microwave power saturation of the e.s.r. absorption of e_t^- at 77 °K. System I (●): solute-free, polycrystalline ice; system II (○): photolyzed glassy 8 *M* NaOD in D_2O containing $Fe(CN)_6^{4-}$.

similar for both systems. The difference in Z at a particular value of H_1 was only slightly outside the experimental precision in estimating Q_L and P as shown in Fig. 1 as error limits on H_1. Since different sample geometries were used in the two systems, the mean value of H_1 at the sample is expected to be slightly different for the same $Q_L P$.

(ii) Effects of Fast Passage on the Dispersion Signal

(a) Using 100 kHz Field Modulation

Figure 2 shows the effect on the dispersion signal of e_t^- of varying H_m under non-adiabatic fast passage conditions. The conditions used were $\omega_m = 2\pi \times 10^5$ rad s^{-1}, $H_1 = 2.0 \times 10^{-3}$ G and the signal was observed in phase with the modulating field. Figure 2 actually refers to e_t^- produced by photoionization of ferrocyanide ion in 8 *M* $NaOD/D_2O$ at 77 °K, but similar effects were observed with slightly different values of H_1 and H_m for e_t^- trapped in solute-free H_2O or D_2O ice and in γ-irradiated 8 *M* $NaOH/H_2O$ or $NaOD/D_2O$ glassy alkaline ice.

The first derivative dispersion signal was of the usual form (as observed for DPPH under these conditions) at $H_m > 4$ G but as H_m was reduced, the signal decreased and changed quite suddenly into a bell-shaped (approximately Gaussian) curve. This signal at first increased in size as H_m was reduced further, went through a maximum at $H_m \simeq 0.06$ G and then decreased approximately linearly with H_m. Below $H_m \simeq 0.2$ G the signal did not change in shape appreciably and

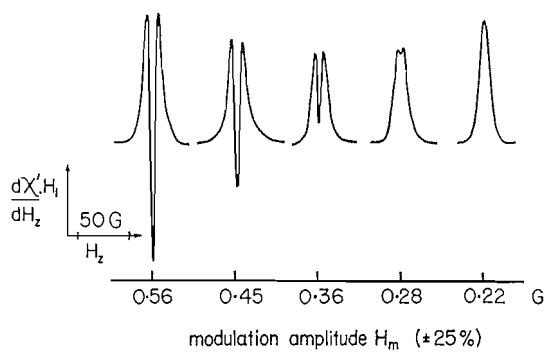

FIG. 2. Fast passage e.s.r. dispersion signal of e_t^- at 77 °K in the region of $2\gamma H_1^2 T_1/\pi H_m \sim 1$.

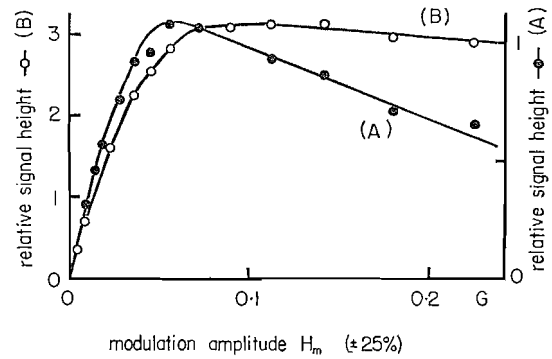

FIG. 3. Dependence of the height of the fast passage e.s.r. dispersion signal on H_m when $H_m < 2\gamma H_1^2 T_1/\pi$. Curve (A) (●): $H_1 = 2.0 \times 10^{-3}$ G; curve (B) (○): $H_1 = 6.6 \times 10^{-3}$ G.

the height of this "bell-shaped" signal is plotted as a function of H_m in Fig. 3, curve (A), for the same $NaOD/D_2O/Fe(CN)_6^{4-}$ sample. The form of the variation of the height of the "bell-shaped" signal with H_m depended on H_1 and in Fig. 3, curve (B), this variation is shown for the identical sample used for curve (A) but using a value of H_1 only three times as great. At the higher power, hardly any decrease in the height of the signal at high H_m was observable. At higher H_m than that shown in Fig. 3 the signal shape began to show the changes illustrated in Fig. 2.

The variations in the dispersion signal of e_t^- with H_m shown in Figs. 2 and 3 are qualitatively *identical* to the effects observed by Bugai (6) and Hyde (15) for *F* centers in potassium chloride crystals. Bullock and Sutcliffe (7) show that the overall change in signal form shown in Fig. 2 is expected to occur when

[1] $$2\gamma H_1^2 T_1/\pi H_m \sim 1$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and one might therefore expect that for the same system (same T_1), identical "intermediate" shapes such as that observed at $H_m \simeq 0.4$ G in Fig. 2 would be observed at identical values of H_1^2/H_m. Fast passage dispersion effects were therefore investigated for the sample of photolyzed $Fe(CN)_6^{4-}$ in alkaline D_2O ice at several values of H_1 ($H_1^2 = 1.0$, 4.0, 14.5, 44, and 170×10^{-6} G^2). As expected, the values of H_m over which the change in form of the dispersion signal occurred did vary with H_1, but at no value of H_1^2/H_m could a constant intermediate shape be observed at the various values of H_1, contrary to what one expects from eq. [1]. This may be explained by the fact that at high H_1 the magnitude of the bell-shaped dispersion signal does not change rapidly with increasing H_m, whilst at lower values of H_1 the bell-shaped signal decreases very rapidly as H_m is increased. It is therefore not surprising that, as observed, the change in the form of the signal occurs rather more sharply at the lower values of H_1 and no "intermediate" shape of signal is found at a constant value of H_1^2/H_m.

These observations preclude reliable comparison between widely different systems unless the differences in T_1 are of orders of magnitude, but should not invalidate approximate comparison between the systems of interest in this work. We arbitrarily defined the signal shape corresponding to eq. [1] as that intermediate between those shown for $H_m = 0.45$ and 0.36 G in Fig. 2. We then compared the values of T_1 obtained from eq. [1] at similar values of H_1. Values of T_1 obtained were all in the range 7×10^{-3} to 4×10^{-2} s for e_t^- in solute-free, polycrystalline H_2O or D_2O ice, γ-irradiated 8 *M* NaOH/H_2O (NaOD/D_2O) glassy ice (dose ca. 1 Mrad), and photolyzed $Fe(CN)_6^{4-}$ in 8 *M* NaOD/D_2O glassy ice, all at 77 °K.

(b) Using Field Modulation at Audio Frequencies

Results using 100 kHz field modulation suggested that $T_1 \simeq 10^{-2}$ s and hence fast passage conditions should still be observable at modulation frequencies of about 10^2 Hz. (In fact one may obtain an estimate of T_1 simply by reducing ω_m until passage effects are not observed, although since the restrictions vary throughout the modulation cycle, this method is unsuitable for detecting small differences.) Working at $\omega_m = 2\pi \times 200$ rad s^{-1} also had the advantage that values of H_1 could be used such that approximately adiabatic conditions were obtained, and the results could be compared with those observed under strongly non-adiabatic conditions at $\omega_m = 2\pi \times 10^5$ rad s^{-1}.

The dispersion signal in phase with the modulating field for γ-irradiated NaOD/D_2O ice was investigated as a function of H_m at $H_1 = 10^{-2}$ G, $\omega_m = 2\pi \times 200$ rad s^{-1}, and $H_m = 0.2$–2 G ($\gamma H_1^2 \simeq dH_z/dt$). Results qualitatively similar to those shown in Fig. 2 were obtained and at the same value of H_1, the change in form of the signal with H_m was identical at $\omega_m = 2\pi \times 200$ and $2\pi \times 10^5$ rad s^{-1}, within the precision of comparing H_m ($\pm 15\%$).

(c) The Phase Lag of the Fast Passage Dispersion Signal

Hyde (5, 16) has shown that for *F* centers in LiF crystals, the phase of the rapid-passage (bell-shaped) dispersion signal lags the modulating field by 90° (i.e. the signal is in quadrature) when $\omega_m T_1 < 1$. It is expected that when $\omega_m T_1$ is of the order of unity, a rapid-passage dispersion signal will be observed of about equal intensity both in phase and in quadrature with the modulating field. The dispersion signals at these two settings of the reference phase in the phase sensitive detector were examined for e_t^- in polycrystalline D_2O using $H_1 = 1.9 \times 10^{-3}$ G and $\omega_m = 2\pi \times 200$ rad s^{-1}. The in phase signal (an approximately Gaussian, bell-shaped curve) was about one-sixth the intensity of the similarly shaped in quadrature signal. It is impossible to place quantitative significance on these ratios because of the variation of passage conditions during the modulation cycle but these results do confirm the prediction above that T_1 is of the order of 10^{-2} to 10^{-3} s.

Discussion

The theoretical treatment of the fast passage dispersion experiments used to derive eq. [1] applies to inhomogeneously broadened lines. Whilst an important source of broadening is in fact inhomogeneous (the presence of unresolved hyperfine lines), in γ-irradiated samples homogeneous contributions are also important (2, 10) because of the non-uniform distribution of the electrons. The e.s.r. absorption of electrons trapped with different local concentrations even in the same matrix will have different spin packet width and since the behavior observed is in part a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

function of this quantity (6), meaningful interpretation of small apparent differences is impossible. We may draw no comparison, for example, between our estimate of $T_1 \simeq 10^{-2}$ s in ice at 77 °K and the value of 5×10^{-3} s estimated by Tsujikawa *et al.* (17) for e_t^- in triethylamine glass at 77 °K in a brief application of the same technique. Kevan's estimates (2) of $(T_1T_2)^{1/2}$ and T_2 for γ-irradiated alkaline ice gave a value of T_1 in agreement with our estimates.

For fast passage progressive saturation of an inhomogeneously broadened line under adiabatic conditions, T_1 may be estimated from eq. [2] (7)

$$[2] \qquad Z = [1 + (2\gamma H_1^2 T_1/\pi H_m)]^{-1}$$

In fact the line drawn through the points in Fig. 1 gives $Z = 0.5$ at $H_1 = 3.0 \times 10^{-3}$ G and using eq. [2], $T_1 = 1 \times 10^{-2}$ s. Such agreement with the dispersion data may be fortuitous because of the disturbance of adiabaticity (7). Variation of Z with H_1 may also be used under slow passage, adiabatic conditions to distinguish between homogeneous and inhomogeneous line broadening mechanisms (8, 9). Such a treatment of the data in Fig. 1 suggested that the line broadening mechanism was entirely inhomogeneous. Much less homogeneous broadening is expected in the two systems presented in Fig. 1 than in the γ-irradiated case, because of the lower value of the spin packet width compared to the line envelope width in the former systems (a higher local concentration of electrons increases the spin packet width (10)). However, it is apparent from earlier work (7) that the large disturbance from adiabaticity under these conditions may have entirely masked any homogeneous contribution. The absence of an increased e.s.r. absorption line width with increasing H_1 for electrons trapped in solute-free ice and glassy alkaline ice after photoionization of $Fe(CN)_6^{4-}$ is in accord with the expected major contribution of inhomogeneous broadening to the line width and supports our use of the fast passage effects to estimate T_1.

The fast passage saturation characteristics of the e.s.r. absorption signal of e_t^- in solute-free or glassy ice shown in Fig. 1 confirm our conclusion from the dispersion studies that T_1 is similar in both systems. It is important to realize that even if relaxation times are determined under the theoretically better understood slow passage, adiabati cconditions, the results obtained are probably quantitatively no more reliable than our estimates. Recent comparisons of relaxation data obtained by the Castner and Portis methods with more direct spin-echo or pulse measurements confirm this conclusion (18). The precise estimation of H_1 is very difficult because of the distortion of radio-frequency fields by the quartz. When T_1 is as long as in this case it is experimentally very difficult to obtain true slow passage adiabatic conditions over the whole range of H_1 required. The important conclusion from slow passage studies as applied by Smith and Pieroni (10) is the estimate of T_2 and hence the local concentration of electrons.

Conclusions

We have estimated the spin–lattice relaxation time for electrons trapped at 77 °K in solute-free, polycrystalline ice and glassy alkaline ice (for both H_2O and D_2O matrices) to be 10^{-2} s *within an order of magnitude*. The absence of significant variation in T_1 indicates that the interaction of the electron with the environment via spin–lattice relaxation is similar in the various ices. Cross relaxation processes (2) are probably excluded since in addition to e_t^-, hydroperoxyl radicals are present in the polycrystalline ice, O^- radical-ions in the γ-irradiated alkaline ice (with a different spatial distribution to $HO_2\cdot$ in the former case), and neither of these latter species are present after photolysis of alkaline ice containing ferrocyanide. Further discussion of the relaxation mechanism is unjustified. The results also indicate that correlations between T_1 and line width or trap depth (17) are inappropriate.

The value of T_1 obtained is of interest in: (*i*) the possible application of the slow passage saturation technique (10) to determine T_2 and the spatial distribution of e_t^- generated photolytically in alkaline ice and in the ice condensed from irradiated water vapor; (*ii*) the choice of H_1 to avoid saturation effects in the routine observation of e_t^- in ice under fast passage conditions; (*iii*) distinguishing between e_t^- and other species with similar e.s.r. absorptions but different T_1's; and (*iv*) in the application of electron nuclear double resonance to investigate the hyperfine interactions of e_t^- in ice (a knowledge of saturation and passage conditions is required).

Translational freezing in free jet expansions, with special reference to molecular beam formation[1]

RODNEY L. LEROY[2] AND JACQUES M. DECKERS
Lash Miller Chemical Laboratories, University of Toronto, Toronto 5, Ontario

Received November 15, 1968

A theoretical model is described which can be used to calculate the velocity distribution function in the transition region of a free jet expansion. It makes use of a simple mechanism to account for the way in which collisions "perturb" the distribution function which would apply in the absence of collisions. The results are compared with experimental studies of argon beams isolated from free jet sources. If the collision frequency is calculated using a hard sphere collision cross section of (25 ± 5) Å^2, good agreement with experimental beam intensity profiles is obtained. In the transition region computed values of the bulk mass velocity, and of the parallel and perpendicular temperatures, are intermediate between the values which would be found if the flow were collision-dominated or free molecular. In particular the perpendicular temperature varies slowly from a dependence on the $-4/3$ power of the distance from the source, approaching monotonically a -2 power dependence at large distances.

Canadian Journal of Chemistry, 47, 2161 (1969)

Introduction

Following the suggestion of Kantrowitz and Grey (1), free jets are now used in many laboratories as molecular beam sources. In this application the core of the jet must be "skimmed" at a point where the local mean free path is considerably greater than the diameter of the skimming orifice (2). This condition usually[3] requires that the skimmer sample the free jet in the transition region of the expansion, where the flow is no longer "collision-dominated".

Brook and Oman (4) attempted the first study of this transition region by solution of the Boltzmann equation, and their approach was extended and improved upon by Edwards and Cheng (5) and by Hamel and Willis (6). These latter two groups arrived at equivalent results. Their work constitutes an essentially complete theoretical description of source flow expansions. Hamel and Willis (6) examined their solution by fitting it to an ellipsoidal (two-temperature) function superimposed on the bulk mass velocity. Although the resulting predictions of the terminal value of the parallel temperature ($T_\parallel$) were in reasonable agreement with experimental measurements (7–10), those of the perpendicular temperature ($T_\perp$) were not. The theory predicts that at large distances from the source, $T_\perp$ approaches a direct dependence on the inverse of the nozzle–skimmer separation s. This may be compared with the $T \propto s^{-4/3}$ dependence which applies in the collision dominated region, or with the $T_\perp \propto s^{-2}$ dependence which applies in the limit of free molecular flow. Values of $T_\perp$ deduced from measurements of beam profiles downstream of the skimmer (9, 10), and of beam intensities as a function of skimmer area (11, 12), always show a dependence on s which is intermediate between the results expected in the collision dominated and free molecular limits.

The discrepancy between theory and experiment was clarified by Edwards and Cheng's analysis (13) of the asymptotic solution which they had obtained previously (5). They found that it can be represented by a bimodal function — the sum of an ellipsoidal function corresponding to a low value of $T_\perp \propto s^{-2}$, and a broad function (high $T_\perp$) which describes those molecules whose trajectories in the transition region are affected by collisions. Molecules contributing to this broader distribution likely make a negligible contribution to experimental beam intensities downstream of the skimmer on or near the centerline. In fact such molecules can be considered to have been self-scattered out of the beam for purposes of predicting centerline molecular beam intensities (14).

Thus the discrepancy is only apparent. Experimental determinations of $T_\perp$ which are carried out by fitting beam profiles to a Maxwellian distribution are quite insensitive to the "tails" of the profile. In fact the signal is generally

lost in noise when the beam intensities are measured more than a few degrees from the centerline. Hence it is likely that if the distribution functions obtained by solution of the Boltzmann equation were used directly to predict beam intensity profiles downstream of a skimmer, they could reasonably reproduce the experimental measurements

In the calculation outlined below we make use of a simple model to approximate the way in which collisions affect the distribution of molecular speeds in the transition region of a free jet expansion. Throughout the calculation distribution functions are truncated quite near the centerline, at angles which are scaled so that they adequately cover the experimental profiles at the skimmer. Several approximations are made: near its centerline the expansion is assumed to have spherical symmetry about the source; a hard sphere collision model is used to calculate collision probabilities in the transition region, although the formalism is not restricted to such a model; and collisions in the transition region are assumed to take place only on a series of well defined surfaces. By varying the separation between such surfaces, this latter approximation was shown to introduce a negligible error. The collision cross section in the transition region is used as a fitting parameter, and is derived by comparison with typical experimental beam profiles.

The description of the expansion which results is neither rigorous nor complete, but the distributions obtained are in good agreement with experimental measurements of molecular beam intensities.

Theory

The velocity distribution function in the collision dominated region of the expansion is well known, so we start the calculation in this region at a distance s_q from the nozzle throat. The distribution function downstream of s_q is evaluated on a series of spheres which are so spaced that the collision probability between any two is much less than unity (a typical value being 0.2). The velocity distribution function on a given sphere of radius $R + \Delta R, f'(v,\theta)$, is derived from the known function $f(v,\theta)$ on the sphere of radius R, using the relation

$$[1]\quad f'(v,\theta) = [1 - P(v,\theta)]f_{geom}(v,\theta) + P(v,\theta)f_{coll}(v,\theta)$$

Here $P(v,\theta)$ is the probability that a particle with a trajectory defined by v and θ suffers a collision between the two spheres, $f_{geom}(v,\theta)$ is a geometrically altered function describing those particles which do not suffer a collision, and $f_{coll}(v,\theta)$ is a function which describes those particles which do suffer a collision. All three functions are defined with respect to the space element $dvd\theta$. Because of the assumed spherical symmetry of the expansion, they are independent of the azimuthal angle ϕ.

The probability that a particle (1 say) collides between the two spheres of radius R and $(R + \Delta R)$ is

$$[2]\quad P(v_1,\theta_1) = 4\frac{n(R')d_1}{v_1}\int_0^{2\pi}\int_0^{\pi}\int_0^{\infty} g_r Q(g_r) \times f(v,\theta)\, dv\, d\theta\, d\phi$$

where

$$d_1 = -R\cos\theta_1 + [R^2\cos^2\theta_1 + \Delta R(2R + \Delta R)]^{1/2}$$

The number density n is taken as its value on an intermediate sphere of radius $R' = [R(R + \Delta R)]^{1/2}$, chosen such that $n(R)/n(R') = n(R')/n(R + \Delta R)$. g_r is the relative velocity of collision between particles with velocities $\boldsymbol{v}_1(v_1,\theta_1,\phi_1 = 0)$ and $\boldsymbol{v}(v,\theta,\phi)$, and it may be derived in analytical form if we consider collisions between R and $(R + \Delta R)$ to occur at R'. The result is

$$g_r = [v_1^2 + v^2 - 2v_1v(\cos\alpha\cos\beta + \sin\alpha\sin\beta\cos\phi)]^{1/2}$$

where $\alpha = \arcsin(R\sin\theta_1/R')$ and $\beta = \arcsin(R\sin\theta/R')$, $Q(g_r)$ is the collision cross section.

In the absence of collisions, a particle which crosses the sphere of radius R at an angle θ_1 with respect to the radial direction will cross the sphere of radius $(R + \Delta R)$ at an angle $\theta = \arcsin[R\sin\theta_1/(R + \Delta R)]$. Thus $f_{geom}(v,\theta)$ can be derived directly from the known function $f(v,\theta_1)$

$$[3]\quad f_{geom}(v,\theta) = \left[\left(\frac{R + \Delta R}{R}\right)^2 - \sin^2\theta_1\right]^{1/2} \times \frac{f(v,\theta_1)}{\cos\theta_1}$$

To construct an appropriate collisionally altered distribution function, we equipartition the available energy at R' among the three transla-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

tional degrees of freedom. The appropriate conservation law (see, for example, ref. 10) is

$$[4] \quad mv_b^2/2 + 3kT_{\parallel}/2 + kT_{\perp} = 5kT_0/2$$

where m is the molecular mass, k is the Boltzmann constant, and T_0 is the source temperature. v_b is the bulk mass velocity, evaluated at R' from[4]

$$[5] \quad v_b = \langle v \cos\theta \rangle$$

The "collisional distribution function" at R' in (v,θ') space is thus

$$[6] \quad f_{coll}(v,\theta') = \left(\frac{m}{2\pi kT}\right)^{3/2} \exp\left[-\frac{m}{2kT} \times (v^2 + v_b^2 - 2vv_b\cos\theta')\right] 2\pi v^2 \sin\theta'$$

where[5]

$$T = T_0 - \frac{mv_b^2}{5k}$$

A geometric correction (cf. eq [3]) is applied to obtain $f_{coll}(v,\theta)$ at $(R + \Delta R)$.

The distribution function on a new sphere may thus be evaluated from eq. [1]. A computation is started with the known function in the collision dominated region on the sphere of radius s_q, and $f(v,\theta)$ is computed on successive spheres until the skimmer plane is reached.

Results and Comparison with Experiment

It is apparent that the terms on the right hand side of eq. [1] cannot be obtained in analytical form, and hence that $f(v,\theta)$ must be carried through the computation as a two-dimensional table of numbers. The numerical techniques which we use are detailed elsewhere (15).

The computed distribution function at the skimmer may be compared with experimental measurements of the beam intensity profile downstream of the skimmer. Suitable flux measurements were published by Anderson and Fenn[6] (7) and are reproduced in Fig. 1. These data

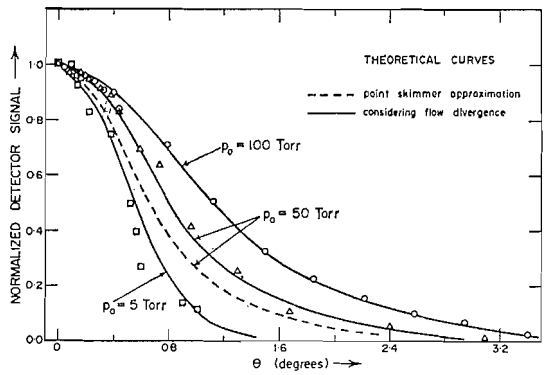

FIG. 1. Experimental and theoretical profiles of a nozzle beam downstream of an 0.35 mm skimmer. Source pressure, 50 Torr; nozzle exit diameter, 0.33 mm; nozzle–skimmer separation, 2.1 cm.

were obtained by moving an ionization gauge perpendicular to the beam axis, 63 cm downstream of an 0.35 mm skimmer. The nozzle diameter was 0.33 mm and the nozzle–skimmer separation was 2.1 cm. To make comparison with these data, the flux distribution $vf(v,\theta)$ was determined at the skimmer for each pressure. In each case the distance s_q from the nozzle was taken rather arbitrarily from Anderson and Fenn's empirical correlation for the value of the terminal mach number (7).

The solid curves in Fig. 1 were obtained by suitable integration of the flux distribution at the skimmer over velocity, and over the dimensions of the skimmer orifice (15). The broken curve illustrates the effect of ignoring the finite divergence of the flow at the skimmer. A hard sphere cross section of 25 Å^2 was used to compute collision frequencies in the calculations summarized in Fig. 1. Profiles were also computed using cross sections of 15 and 35 Å^2, and in both cases the agreement with experiment was poor. The larger cross section broadened the computed profiles, while the smaller cross section narrowed them. We conclude that the effective collision cross section for argon is (25 ± 5) Å^2. This is comparable to the values determined by Knuth and Fisher (10, 16) in their study of a similar free jet expansion, although we should emphasize that the cross section is a function of the local temperature, and thus of the source conditions (see ref. 16).

Finally we examine the variation of v_b, $T_{\perp}$, and $T_{\parallel}$ in the expansion downstream of the "quitting"

[4]The nomenclature

$$\langle \psi(v,\theta) \rangle = \int_0^{\infty} \int_0^{\pi} \psi(v,\theta)\, f(v,\theta)\, d\theta\, dv$$

is introduced here.

[5]Using this expression our considerations are restricted to gases for which the heat capacity ratio is 5/3.

[6]We are grateful to Professor Anderson for providing us with the original data which were used in the plotting of Fig. 11 of ref. 7.

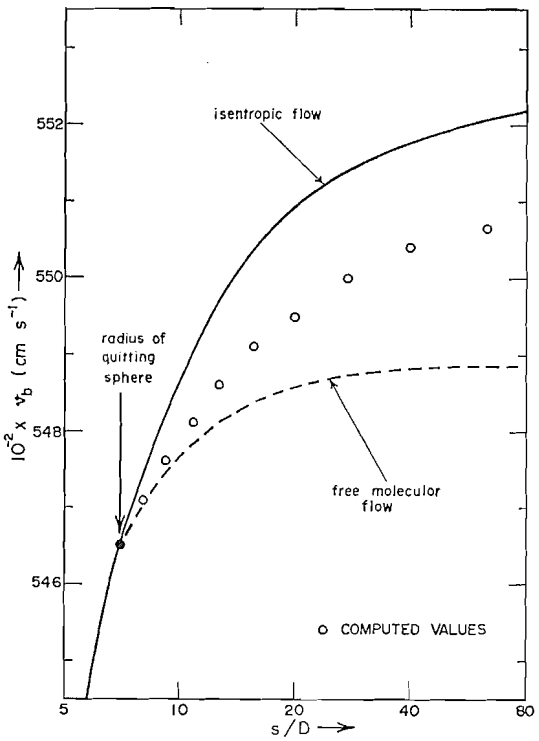

FIG. 2. Variation of the bulk mass velocity v_b with distance downstream of s_q. The computed results are compared with the variation which would be found in the limits of collision dominated and free molecular flow.

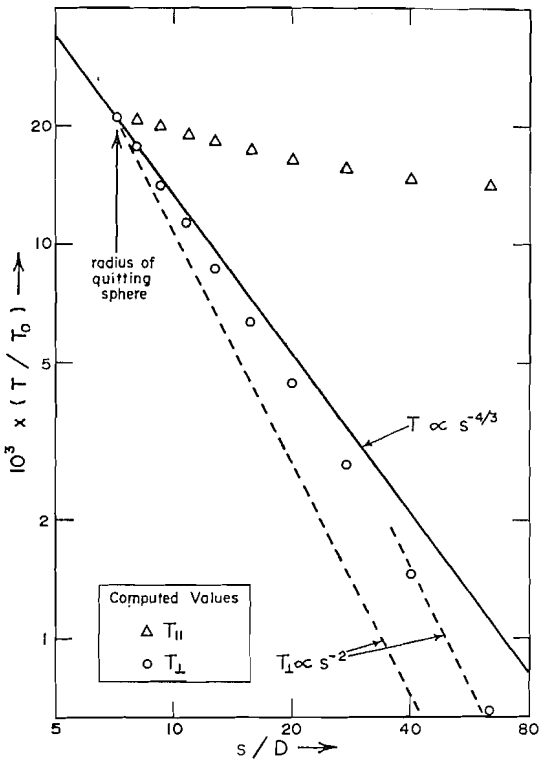

FIG. 3. Variation of the perpendicular temperature $T_\perp$ and the parallel temperature $T_{||}$ with distance downstream of s_q.

surface. These quantities are computed on each sphere from eq. [5] and the relations

$$[7] \qquad T_\perp = \frac{m}{2k}\langle(v \sin\theta)^2\rangle$$

and

$$[8] \qquad T_{||} = \frac{m}{2k}\langle(v \cos\theta - v_b)^2\rangle$$

The specific results presented correspond to a source pressure of 50 Torr and $Q = 25$ Å^2.

In Fig. 2, the solid curve illustrates the increase of bulk mass velocity with distance in an isentropic expansion, while the broken curve indicates the variation which would be observed if the flow became suddenly free molecular at s_q (15). The computed velocities (eq. [5]) are intermediate between these two limits. Increasing Q increases v_b, while decreasing it has the opposite effect. Values of $T_\perp$ and $T_{||}$ (eqs. [7] and [8]) are plotted as a function of the distance from the nozzle in Fig. 3. The solid line represents the local temperature in an isentropic expansion, and the broken line illustrates the variation of $T_\perp$ with distance which would be observed in the absence of collisions downstream of s_q. The computed variation is intermediate, and falls off slowly from $T_\perp \propto s^{-4/3}$ to approach $T_\perp \propto s^{-2}$, 50 diameters downstream of the source. This is not unlike the experimental dependence of $T_\perp$ on s which Abuaf *et al.* (9) report for similar source conditions. In fact our calculations seem to agree with the experiments of Scoles and his co-workers (11, 12) and of Abuaf *et al.* (9) in indicating that the $s^{-4/3}$ dependence persists far downstream of a "quitting" surface whose position is calculated from the terminal mach number. As we might expect, increasing Q causes the $s^{-4/3}$ dependence to persist to larger distances, and decreasing it has the opposite effect.

Conclusions

We have outlined above a simple method which is capable of predicting velocity distribution

functions in the transition region of a free jet expansion. The results are in good agreement with molecular beam measurements. A simple model is used to account for the way in which collisions redistribute translational energy. The approach is essentially equivalent to a solution of the Boltzmann equation, although its success may reflect the fact that our distribution functions are tabulated near the centerline, at angles which are scaled so that they adequately cover the experimental profiles at the skimmer. In this way the calculation exhibits the same prejudice as a molecular beam experiment; it is relatively insensitive to the broad tails of the distribution function.

Acknowledgments

The authors are deeply indebted to Professor J. P. Valleau for his assistance throughout this work. Also we are grateful for stimulating discussions with many people, especially Miss Wong Wan Yin, Dr. R. G. Albright, Professors G. Scoles, R. P. Andres and J. B. Anderson, and Mr. T. R. Govers. Nuclear magnetic relaxation of 1,2-dichloroethane in deuterated benzene and carbon disulfide solution at 20 °C

E. Bock
Parker Chemistry Laboratory, University of Manitoba, Winnipeg, Manitoba

AND

E. Tomchuk
Department of Physics, University of Winnipeg, Winnipeg, Manitoba

Received January 10, 1969

The molecular rotational relaxation time of the 1,2-dichloroethane molecule in deuterated benzene and carbon disulfide solution was determined by pulsed nuclear magnetic resonance techniques. It was found that the rotational relaxation time, τ_r, in infinitely dilute deuterated benzene solution and in infinitely dilute carbon disulfide solution was 1.3×10^{-12} and 0.6×10^{-12} s, respectively. Both values are in fair agreement with the dielectric molecular relaxation time for 1,2-dichloroethane in dilute benzene, *p*-xylene, and *n*-hexane solution reported by Chitoku and Higasi (1).

Canadian Journal of Chemistry, 47, 2167 (1969)

Introduction

Chitoku and Higasi (1) found that 1,2-dichloroethane exhibits an exceptionally high electric dipole moment and dielectric relaxation time in dilute benzene and *p*-xylene solution as compared to other non-polar, non-aromatic solvents, viz. 1.80 D and 3.69×10^{-12} s in benzene as compared to 1.35 D and 1.31×10^{-12} s in hexane. The above authors attributed the exceptional behavior of 1,2-dichloroethane in benzene solution to the existence of a particular conformer of the molecule in solution, the *gauche* form, and to the formation of a weak complex between the solute and solvent molecules. On the other hand, other workers who investigated the same problem have interpreted the anomalous behavior of 1,2-dichloroethane molecule in benzene solution in terms of different conformations of the molecule (2), formations of definite complexes (3), or different types of interaction between solvent and solute molecules (4). In order to shed some new light on this problem we have determined the nuclear magnetic spin–lattice relaxation of the protons of the 1,2-dichloroethane molecule in two different non-magnetic solvents, viz. perdeutero benzene and carbon disulfide. Although perdeutero benzene is not really an entirely non-magnetic solvent, we nevertheless chose this solvent because the efficiency of the deuteron nucleus in causing nuclear relaxation as compared to that of the proton is only 1/24 of the latter and because all the other properties of perdeutero benzene closely resemble those of ordinary benzene.

Experimental

Solvents

The benzene-d_6, 99.5 atom % D, was obtained from Merck, Sharp, and Dohme of Canada Ltd., and was used without further purification. The carbon disulfide, Fisher certified reagent, was deodorized by prolonged shaking, ~ 12 h, with mercury and saturated mercuric chloride and potassium permanganate solutions, in that order, and distilled from P_2O_5.

Solute

The 1,2-dichloroethane was obtained from Eastman Organic Chemicals and was used without further purification.

Apparatus and Procedure

The spin–lattice relaxation time of pure 1,2-dichloroethane and of 4 different solutions of progressively lower concentration of 1,2-dichloroethane in heavy benzene and carbon disulfide was determined at 20 °C on a PS-60A NMR Specialities pulsed nuclear magnetic resonance (n.m.r.) spectrometer using a 180–90° pulse sequence (5). The experimental solutions were carefully degassed by repeated freeze–pump–thaw cycles to remove dissolved oxygen and were sealed under vacuum. To minimize vaporization from the liquid phase the experimental glass sample tubes, 8 mm in diameter, were provided with a restriction leading to the vapor space as suggested by Green and Powles (6).

Results and Discussion

The experimental results are shown graphically in Fig. 1 in a form of a graph of T_1^{-1} vs. the mole fraction of 1,2-dichloroethane in solution. In

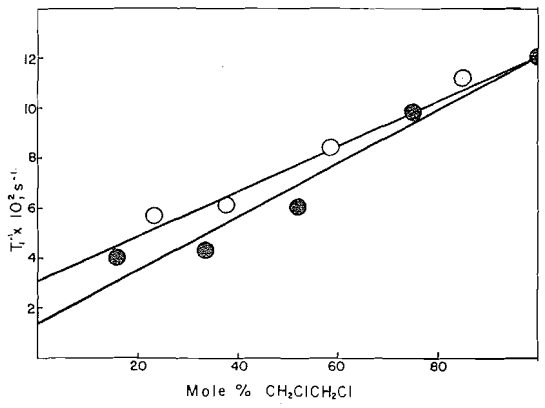

FIG. 1. Graph of T_1^{-1} vs. mole % 1,2-dichloroethane in solution. ○, heavy benzene; ●, carbon disulfide.

each case the experimental points were fitted to a straight-line plot by a least squares fitting procedure; the average deviation from the straight line was, in the case of heavy benzene, 0.34 T_1^{-1} units and in the case of carbon disulfide, 0.66 T_1^{-1} units. The rotational relaxation time, τ_r, was calculated using the extrapolated value of T_1^{-1} and the following relationship between the intramolecular relaxation time, i.e. the extrapolated value of T_1, and the rotational relaxation time, τ_r (7).

$$[1] \qquad T_1^{-1}\,(\text{intra}) = A\tau_r$$

$$[2] \qquad A = \frac{\hbar^2\gamma^4}{n}\sum_i\sum_j \beta_{ij} d_{ij}^{-6}$$

Here n is the number of protons in the molecule, β_{ij} is a constant factor equal to 3/2 for equivalent protons and 1 for nonequivalent protons, γ is the magnetogyric ratio of the proton, and d_{ij} is the distance between proton i and proton j. The necessary data for the calculation of the constant A in eq. [2] were taken from the literature (8). In the calculation it was assumed, following the suggestion of Chitoku and Higasi (1), that the solute molecules exist in two conformations only, viz. the *gauche* and *trans* conformation respectively. The resulting value for the molecular rotational relaxation time, τ_r was found to be 1.31×10^{-12} and 0.57×10^{-12} s for heavy benzene and carbon disulfide solvents, respectively. Both values are in reasonable agreement with the dielectric relaxation values reported by Chitoku and Higasi (1), viz. 3.69×10^{-12} s in benzene, 4.53×10^{-12} s in *p*-xylene, and 1.31×10^{-12} s in hexane solution, see Table I. In making the above comparison it should be remembered that on theoretical grounds (9) it is expected that the n.m.r. relaxation time, τ_r, is 1/3 of the dielectric relaxation time, τ_D, and that according to the Debye relationship, the rotational relaxation time for a sphere rotating in a viscous medium is proportional to the viscosity of that medium. This means that our value of 1.31×10^{-12} s for benzene should be compared with one third of the value obtained by Chitoku and Higasi (1) for benzene and *p*-xylene solutions, i.e. 1.23×10^{-12} s and 1.51×10^{-12} s respectively. Also our value for carbon disulfide should be compared with one third of their value obtained in hexane solution, but, corrected for the different viscosities of the two solvents. The viscosity of hexane and carbon disulfide at 20 °C is 0.308 cP (1) and 0.367 cP (10), respectively. If our value of 0.57×10^{-12} s is multiplied by the ratio of the viscosities for hexane and carbon disulfide and the result is multiplied by 3, there results a relaxation time of 1.44×10^{-12} s, which compares favorably with the dielectric value for hexane solution reported by Chitoku and Higasi (1), viz. 1.31×10^{-12} s. The reason we chose hexane for our comparison from the 5 different solvents studied by Chitoku and Higasi (1) was that the viscosity, and hence also the macro hydrodynamical properties of this solvent, most closely resemble the viscosity and the hydrodynamical properties of carbon disulfide.

Although there is fair agreement between our values and those found by Chitoku and Higasi (1), which argues in favor of their interpretation that the "situation may possibly be described in the first approximation by a picture of rotating *gauche* molecules in a viscous medium", it will be noticed that in each case our values are larger than the values found by Chitoku and Higasi. We

believe that this discrepancy is due to either spin–rotation and/or spin – internal rotation interaction. It is well known that if parts of a molecular structure are capable of rotating about some internal molecular axis, then, depending on the relative speeds of rotation of the over all, end-for-end tumbling motion of the molecule and the internal rotary motion, the measured value of τ_r will be decreased by a certain factor which in the limit, when the speed of the internal rotary motion far exceeds the speed of the tumbling motion, assumes a value of 1/4 (11). In our case we evaluated the rotational relaxation time, i.e. the relaxation time for the tumbling motion, on the assumption that the molecule was rigid; the internal rotation of the two chloromethyl groups was neglected. Now as a first approximation the total intra molecular spin–lattice relaxation rate, T_1^{-1} may be written as a sum of two parts, one corresponding to the tumbling motion and the other to the internal rotation, viz.

$$[3] \quad T_1^{-1}(\text{intra}) = T_1^{-1}(\text{tumb}) + T_1^{-1}(\text{int rot})$$

From eqs. [3] and [1] it is obvious that the neglect of the internal rotation contribution to T_1^{-1} (intra) will result in a larger calculated value for τ_r. Chitoku and Higasi (1) noted that the Cole–Cole parameter for benzene and *p*-xylene solution was 0.11–0.14 and 0.17–0.21, respectively, suggesting the existence of two or more polar molecular species. However, the above authors did not think that the accuracy of their data warranted an analysis of their measurements into two or more different absorption peaks. We, too, think that the precision of our data does not permit a more elaborate analysis of our data, but, the fact that our values in both cases are larger than those of Chikotu and Higasi, values which reflect the tumbling motion of the molecule only, does suggest that the tumbling motion of the molecule is accompanied to some, albeit small, degree by an internal rotation of the two chloromethyl groups.

Acknowledgments

We thank Mr. R. Long for some of the experimental measurements and Dr. T. Schaefer for helpful discussions. The financial assistance of the National Research Council of Canada is very much appreciated.

Electrochemical reactions at PbO_2 electrodes. Part IV. Electrochemical behavior of α-PbO_2 in acid perchlorate electrolytes

N. A. HAMPSON, P. C. JONES[1], AND R. F. PHILLIPS
Department of Chemistry, Loughborough University of Technology, Leicestershire, England

Received May 27, 1968

The cathodic passivation and the exchange reactions at α-PbO_2 electrodes in acid perchlorate electrolytes have been investigated using the galvanostatic technique. The results are generally closely similar to those previously reported for β-PbO_2 but some differences occur and these are explained in terms of an α–β-PbO_2 equilibration process.

Canadian Journal of Chemistry, 47, 2171 (1969)

Introduction

Lead dioxide exists in two polymorphic states, known as the α and the β forms. As usually produced, both forms exist together, but under controlled experimental conditions either may be prepared substantially free of the other. In general, the less reactive β-modification is obtained from acid solutions, and the α-modification from alkaline solutions, but precise control of temperature and, in anodic deposition, current density is necessary. The electrochemical behavior of β-PbO_2 electrodes in acid lead perchlorate electrolytes has been described in previous papers (1–3). The present paper describes similar studies at α-PbO_2 electrodes.

Experimental

The electrolytic cell, electrical circuit, electrolyte purification procedure, and electrode geometry and construction have been described (1).

Deposition of α-PbO_2 on Platinum

Counter, test, and reference electrodes were prepared by electrodeposition of α-PbO_2 from alkaline sodium plumbite (2 *M* NaOH, saturated with PbO) at a rate of 0.8 mA cm^{-2} at 30 °C on etched (1:1, HNO_3:H_2SO_4) platinum, (see ref. 4). Comparative X-ray diffraction measurements were made to establish the initial freedom of the preformed α-PbO_2 deposits from β-PbO_2.

Electrolytes

Two series of acidified $Pb(ClO_4)_2$ electrolytes were used, the first at constant $[H^+]$ and variable $[Pb^{2+}]$ and the second at constant $[Pb^{2+}]$ and variable $[H^+]$. The total perchlorate concentration was maintained (added $NaClO_4$) at 6.85 *M* throughout.

Electrometric Measurements

After allowing 10 min for stabilization of the electrode–electrolyte system, measurements were made of transition time and overpotential in the same manner as previously reported (1).

Results

The Galvanostatic (Cathodic) Passivation of α-PbO_2 in Acid Perchlorate Electrolytes

During the cathodic polarization of α-PbO_2 in acid perchlorate electrolytes, two abrupt changes in potential were recorded corresponding to transitions respectively between the following reactions

[1] $$\alpha\text{-}PbO_2 + 4H^+ + 2e \rightarrow Pb^{2+} + 2H_2O$$

[2] $$Pb^{2+} + 2e \rightarrow Pb$$

[3] $$2H^+ + 2e \rightarrow H_2$$

Subsequent ex situ examination of the electrode after stage [3], however, showed only a reddish-brown film containing Pb(II) with no evidence of metallic lead (no amalgamation when the film was treated with Hg). The non-appearance of elemental Pb contrasts with that observed when using β-PbO_2 electrodes (1).

For each electrolyte system the equation

[4] $$(i - i_l)t_p^{\frac{1}{2}} = k_p$$

was obeyed, where t_p (< 20 s) is the time taken to reach the first transition at the current density, i, and k_p and i_l are constants for a given solution. Both k_p and i_l vary with $[H^+]$. The dependence of k_p on $[H^+]$ calculated using the method of least squares is (at 23 °C)

[5] $$k_p = 0.197\ [H^+] + 0.015$$

From eq. [5], using the theory developed in Part I (1), values of δ, the thickness of the diffusion layer, have been calculated and these are shown in Table I.

Overpotential – Current Density Data

Double Layer Capacitances

Double layer capacitances calculated (2) from the rise of electrode potential during the very early stages of galvanostatic polarization are shown in Table II.

Lower Overpotential Region (η_D < 10 mV)

Linear plots were obtained of charge transfer overpotential, η_D, vs. current density. The exchange current, i_0, was calculated from the slope of these plots at the origin, using

$$[6] \qquad \left(\frac{\partial \eta_D}{\partial i}\right)_{\eta_D=0} = -\frac{RT}{2F}\cdot\frac{1}{i_0}$$

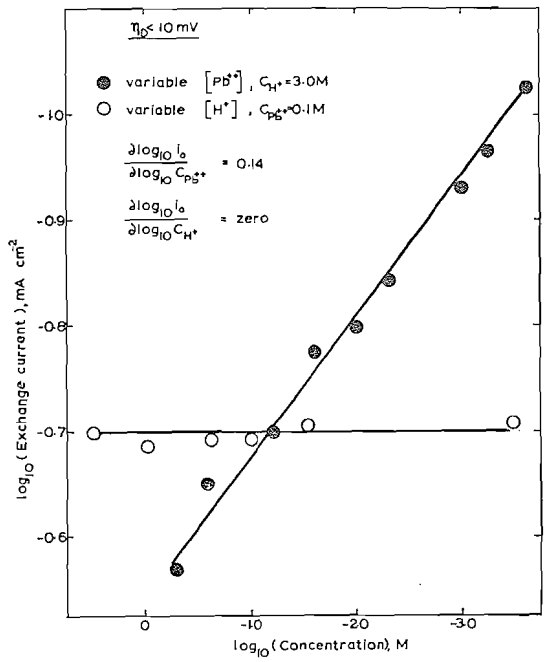

FIG. 1. Variation of exchange current with $[Pb^{2+}]$ and $[H^+]$ α-PbO_2 electrode; total $[ClO_4^-]$, 6.85 M (with $NaClO_4$) at 23 °C.

Satisfactory agreement was obtained (Table III) between these values of i_0 and those obtained using the iterative technique (5). The charge transfer coefficients derived by the iterative method also agree with the value calculated from the dependence of i_0 on $[Pb^{2+}]$ (Fig. 1). The dependence of i_0 on $[H^+]$, also shown in Fig. 1, suggests an abnormally high value for the charge transfer coefficient and possibly indicates some adsorption of H^+ (2).

The effect of temperature on current density – overpotential relationships is shown in Fig. 2*a*. $\log_{10} i$ vs. $1/T$ °K Arrhenius plots (Fig. 2*b*) suggest two approximately linear parts, corresponding to activation enthalpies of ~ 3 kcal mole^{-1} in the low temperature range and ~ 10 kcal mole^{-1} in the higher temperature range. Figure 2*b* was typical of all the electrolytes investigated.

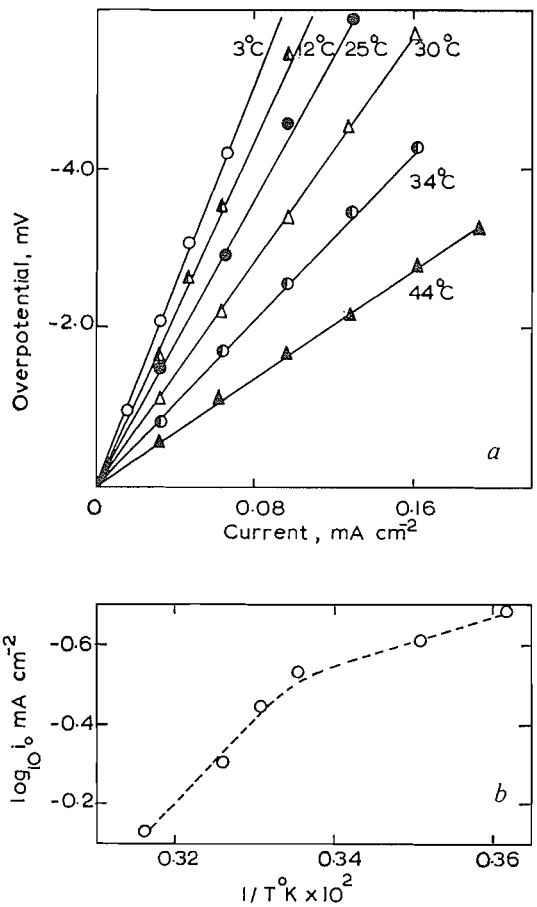

FIG. 2. Temperature dependence of current–overpotential curves for α-PbO_2. Electrolyte: 0.025 *M* Pb^{2+} plus 3.0 *M* H^+, total $[ClO_4^-]$, 6.85 *M*.

High Overpotential Region ($\eta_D > 10$ mV)

Figure 3 shows Tafel plots ($\log_{10} i$ vs. η_D) for different $[Pb^{2+}]$ at constant $[H^+]$. Potentials $E_{3M}{}^{\alpha}$ refer to the α-PbO_2/3.0 *M* H^+, 1.0 *M* Pb^{2+} system as the reference potential.

Figure 4 shows Tafel plots for electrolytes of constant $[Pb^{2+}]$ and variable $[H^+]$. The potentials $E_{M'}{}^{\alpha}$ refer to the α-PbO_2/0.1 *M* Pb^{2+}, 1.0 *M* H^+ system as a similar arbitrary standard. In both series of experiments the reference electrode was connected using saturated sodium perchlorate electrolyte through a tap and sintered frits of low porosity. Over the concentration ranges investigated experimental values of the equilibrium potential agreed with calculated values, confirming that the liquid junction potential had been eliminated.

TABLE IV

Potential limits of constant αZ. Potential region (about the equilibrium) in which the reaction conforms to a simultaneous two-electron transfer process

Concentration, *M*	Potential region, ± 5 mV
1. Pb^{2+} concentration at constant $[H^+] = 3.0$ *M*, $[ClO_4^-] = 6.85$ *M*	
0.025	−22 mV to +13 mV
0.0098	−32 mV to +12 mV
0.0050	−38 mV to +14 mV
2. H^+ concentration at constant $[Pb^{2+}] = 0.1$ *M*, $[ClO_4^-] = 6.85$ *M*	
0.94	−35 mV to + 9 mV
0.24	−39 mV to +13 mV
0.027	−25 mV to +10 mV

Following the procedure adopted in Part III (3) the effect of increases in $|\eta_{D_{max}}|$ (the maximum numerical value of the overpotential) on "αZ" was examined, where "αZ" is part of the exponent in the charge transfer equation

$$[7] \quad i = i_0\left[\exp -\frac{\alpha ZF}{RT}\eta_D - \exp\frac{(1-\alpha)ZF}{RT}\eta_D\right]$$

Table IV shows the limits within which "αZ" remained constant.

Discussion

Galvanostatic Passivation of α-PbO_2

For a given electrolyte the similarity of k_p, i_l, and δ for both α- and β-PbO_2 indicates that for the first transition point, which is controlled by mass transport in the electrolyte phase, the effective surface area of each modification involved in this diffusion controlled process is substantially the same.

The absence of detectable lead and the presence of Pb(II) on the electrode when the latter, polarized to the point of hydrogen evolution, is removed from the electrolyte and examined chemically, represents a notable difference from the behavior of the β-electrode. This difference might be attributed to a greater oxidizing power of α-PbO_2 promoting the reaction

$$[8] \quad \text{Pb(IV)} + \text{Pb} \rightarrow \text{Pb(II)}$$

and so chemically converting metallic lead to Pb(II) as it forms at the electrode. An alternative

explanation may be obtained by analogy with the work of Mark (7) who found that, in the discharge of α- and β-PbO_2 in dilute H_2SO_4, the final $PbSO_4$ product in the case of α-PbO_2 remains as a tightly adherent film on the surface of the undischarged PbO_2, whereas in the case of β-PbO_2, the $PbSO_4$ film is much less adherent. This might suggest in our experiments the initial formation of an adherent Pb(II) film, which on further reduction produces Pb in close contact with the PbO_2 electrode with which it simultaneously reacts chemically to form PbO (8) or some corresponding salt of perchloric acid. The lead product film in the case of β-PbO_2, however, being in less perfect physical contact with the underlying electrode, would on this evidence be expected to react at a much slower or even negligibly slow rate.

Overpotential – Current Density Measurements

The mean value of the double layer capacitance (138 μF cm^{-2}) is substantially higher than that found for β-PbO_2 (78 μF cm^{-2}). This might suggest a greater degree of electrode surface roughness in the case of α-PbO_2.

Low Overpotential Region

The equality respectively of the anodic and cathodic exchange currents and of the charge transfer coefficients, in the low overpotential region, indicates that in this region the rate controlling reaction is the same for both the anodic and cathodic processes, and for reasons adduced in the closely similar case of β-PbO_2 (2, 3) is a simultaneous two-electron transfer process.

The observation that the activation enthalpy increases with temperature (Figs. 2*a* and 2*b*) was confirmed in a number of replicate experiments. Such changes were not observed with β-PbO_2 (3). It is interesting to report that Angstadt, Venuto, and Ruetschi (9) in their investigations of PbO_2 in H_2SO_4 in the same temperature range as reported here, found a pronounced change in slope of the electrode potential versus temperature curve in the case of α-PbO_2 but not in the case of β-PbO_2.

High Overpotential Region

Figure 3 shows a family of anodic and cathodic $\log_{10} i$ vs. η_D curves, corresponding to varying $[Pb^{2+}]$ at constant $[H^+]$. The *cathodic branch* of this family of curves is of particular interest.

For the exchange reaction

$$[9] \qquad PbO_2 + 4H^+ + 2e = Pb^{2+} + 2H_2O$$

we can write for constant potential conditions

$$[10] \qquad i_C = k_C a_{PbO_2} a_{H^+}{}^m$$

$$[11] \qquad i_A = k_A a_{Pb(II)} a_{H^+}{}^n$$

where i_C and i_A are cathodic and anodic current, respectively, k_C and k_A are potential dependent rate constants, m and n are the numbers of H^+ involved in the rate determining step in the cathodic and anodic directions respectively, and a is the activity[2].

The faradaic current ($i = i_C - i_A$) reduces to i_C at sufficiently high cathodic potentials since i_A becomes negligibly small. At these high cathodic potentials i would be expected to follow eq. [10] and to be dependent on a_{PbO_2} and $a_{H^+}{}^m$ but to be independent of $a_{Pb(II)}$. For β-PbO_2 only one cathodic Tafel line was observed, as expected under these conditions. For α-PbO_2, however, Fig. 3 shows a closely spaced set of cathodic Tafel lines indicating a reduction in reaction rate with increased [Pb(II)]. That is, at constant potential in the cathodic Tafel region, the current flowing decreases with increased [Pb(II)]. Reference to eq. [10] indicates that at constant pH and potential, the cathodic current is reduced only by a decrease in PbO_2 activity. This reduction must therefore be brought about by increased [Pb(II)].

To explain these results, one must either assume direct participation of Pb^{2+} in the cathodic reaction, or consider the possibility of a change in the activity of the PbO_2 electrode, in the direction of a decrease of PbO_2 activity with increase in $[Pb^{2+}]$. The appearance of a single cathodic Tafel line in the β-PbO_2 experiments must rule out the first of these hypotheses, and focus attention on PbO_2 as the only difference in the two series of experiments.

The key observation from Fig. 3 is the shift of the cathodic Tafel line towards the β-PbO_2 cathodic Tafel line with increase in $[Pb^{2+}]$. At

---

[2] a_{H^+} occurs in both eqs. [10] and [11] since eq. [9] may be balanced in other ways with respect to H^+ (or OH^-), e.g. in a reaction such as

$$PbO_2 + 3H^+ + 2e = Pb^{2+} + H_2O + OH^-$$

m would be 3 and n would be −1.

TABLE V

Characteristics of Tafel plots. α-PbO_2 electrode: total [ClO_4^-] 6.85 *M* (with added $NaClO_4$) at 23 °C

Concentration, *M*		Cathodic coefficient $-2.3\frac{RT}{F}\cdot\frac{\partial \log_{10} i_c}{\partial \eta_D}$	Anodic coefficient $2.3\frac{RT}{F}\cdot\frac{\partial \log_{10} i_A}{\partial \eta_D}$	Intercepts at $\eta_D = 0$ mA cm^{-2}

0.0050	3.0	0.94	0.18	0.0417	0.407
0.0010	3.0	0.92	0.18	0.0141	0.355
0.098	0.24	0.98	0.20	0.0955	0.531
0.10	0.027	1.00	0.18	0.100	0.569
0.10	0.0001	0.84	0.18	0.123	0.501

equilibrium the extent of the exchange reaction [9] is governed by the activities of the electroactive species H^+, Pb(II), and PbO_2. Increases in activities of the electroactive species increase the rate of exchange between Pb(II) in the solution and PbO_2 in the electrode surface. If this is linked with the known higher stability of β-PbO_2 in acid media, the effect of increasing the [Pb^{2+}] is to be seen to progressively alter the electrode surface from α- to β-PbO_2. The resultant equilibrium situation would be controlled by the [Pb^{2+}] and be established by the exchange current (i_0) during the interval (10 min) preceding the polarization measurements (< 80 ms duration). Schematically we have

$$\alpha\text{-}PbO_2 \overset{Pb^{2+}}{\rightleftharpoons} \binom{Pb^{2+}}{H^+} \overset{Pb^{2+}}{\rightleftharpoons} \beta\text{-}PbO_2$$

The results reported in Fig. 3 are the overpotential values extrapolated to time $t = 0$, and thus refer to the electrode in its initial (Pb^{2+} controlled) equilibrium state.

Coming next to the anodic polarization curves of Fig. 3, the results are virtually identical with the similar family of curves reported (3) for β-PbO_2. This is in agreement with the fact that the PbO_2 (whether α or β) is not involved as a reactant in this anodic process. The situation is precisely similar for the anodic family of curves shown for constant [Pb^{2+}] but varying [H^+] (Fig. 4).

When we come to consider the cathodic family of curves of Fig. 4, similar arguments for an equilibrated α/β-PbO_2 electrode surface would apply, following the scheme

$$\alpha\text{-}PbO_2 \overset{H^+}{\rightleftharpoons} \binom{Pb^{2+}}{H^+} \overset{H^+}{\rightleftharpoons} \beta\text{-}PbO_2$$

The equilibrium proportion of β-PbO_2 would thus be expected to increase in proportion to some power of the [H^+].

The corresponding rate eq. [10] now becomes

$$[12] \qquad i_C = k_C' \, a_{H^+}^{(m+x)}$$

x, reflecting the dependence of the α/β equilibrium process of [H^+]. From this we deduce

$$(\partial \log i_C/\partial \log[H^+]) = m + x$$

If our value of 2.0 is now compared to the value of 1.5 reported for $\partial \log i/\partial \log[H^+]$ for β-PbO_2, the increase represents the effect of [H^+] on the α/β-PbO_2 equilibration process.

Characteristics of Tafel Plots

The results in the present series of experiments (see Figs. 3 and 4) provide the same evidence as reported for β-PbO_2 (3), for a change of the charge transfer mechanism from a simultaneous two-electron transfer to two consecutive single-electron transfer steps with increase in overpotential. This follows from

(*a*) the sum of the cathodic and anodic coefficients

$$\left[-\left(\frac{RT}{F}\right)\cdot \partial \log_e i_C/\partial \eta_D \quad \text{and} \quad \left(\frac{RT}{F}\right)\cdot \partial \log_e i_A/\partial \eta_D\right]$$

is significantly less than two (Table V).

(*b*) The anodic and cathodic exchange currents, i_{0a} and i_{0b}, obtained by extrapolating Tafel plots to η_D equals zero, are both appreciably different from each other (Table V).

(*c*) The charge transfer resistances, R_D, observed in the low overpotential region differ

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

TABLE VI

Charge transfer resistances. Comparison of experimental charge transfer resistance (for $\eta_D <$ 10 mV) with those calculated for $\eta_D >$ 50 mV

Concentration, M		Charge transfer resistance, Ω cm^2	
Pb^{2+}	H^+	Experimental	Calculated
0.005	3.0	93.3	340.0
0.0098	3.0	80.0	212.8
0.063	3.0	65.8	158.8
0.50	3.0	48.0	121.0
0.098	0.24	61.8	157.0
0.100	0.027	61.0	150.1

from those calculated from high overpotential measurements (Table VI) using

$$[13] \qquad R_D = \frac{RT}{4F} \cdot \left(\frac{1}{i_{0a}} + \frac{1}{i_{0b}} \right)$$

(*d*) Two distinct rectilinear regions are identifiable in the cathodic branch of Fig. 3; Fig. 5, which gives the full range of results for the 0.005 M Pb^{2+} case, shows this in greater detail.

In these terms, the reaction sequence (written for the reduction process) at overpotentials greater than $\sim$ 80 mV is

$$[14] \qquad PbO_2 \xrightarrow{i_{0a},\ \alpha_a} Pb(III)$$

followed by

$$[15] \qquad Pb(III) \xrightarrow{i_{0b},\ \alpha_b} Pb(II)$$

Following the procedure outlined in Part III, the rate determining step in the cathodic reduction of PbO_2 and also in the anodic oxidation of Pb^{2+} is the step leading to the formation of the Pb(III) intermediate. The experimental parameters calculated from the slope of cathodic and anodic Tafel plots

$$-2.3 \frac{RT}{F} \cdot \left(\frac{\partial \log_{10} i_C}{\partial \eta_D} \right) = \alpha_a$$

$$2.3 \frac{RT}{F} \cdot \left(\frac{\partial \log_{10} i_A}{\partial \eta_D} \right) = (1 - \alpha_b)$$

and intercepts ($2i_{0a}$ and $2i_{0b}$) are shown in Table V and are of similar order to the corresponding parameters observed for β-PbO_2.

Comparison of α- *and* β-PbO_2

Passivation (discharge) data are very similar for electrodeposited α- and β-PbO_2, although

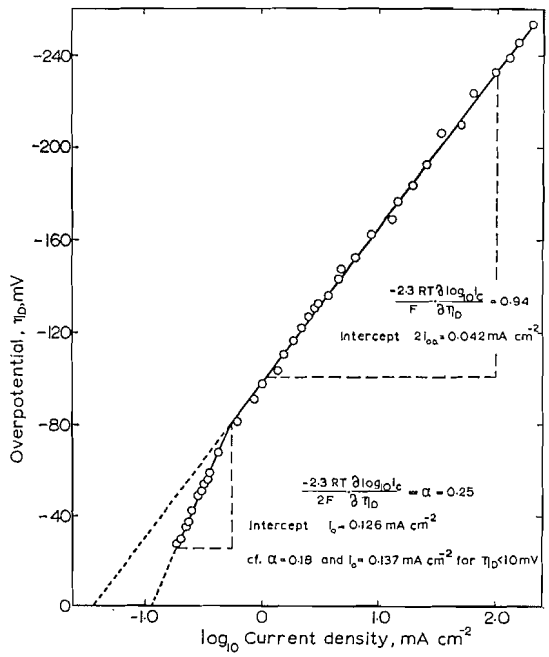

FIG. 5. Cathodic Tafel plot for α-PbO_2. Electrolyte: 0.005 M Pb^{2+} plus 3.0 M H^+; total [ClO_4^-], 6.85 M at 23 °C.

capacitance results indicate a greater true surface area in the case of the α-modification. This is to be expected since on the time scale of the passivation experiments, the diffusion layer is thick and reflects the apparent area of the electrodes, whereas electrode capacitances calculated in the first few milliseconds of electrode polarization when the diffusion layer is thin, reflect the true surface area.

The charge transfer process is similar for both α- and β-PbO_2. It is desirable to compare the numerical magnitude of characteristic thermodynamic and kinetic data for α- and β-PbO_2. Comparative data concerning oxidizing power, enthalpy of activation, exchange current density, and transfer coefficients would be particularly interesting. However, it is clear that experiments with α-PbO_2 in acid solutions have certain limitations which preclude a quantitative interpretation of the results. The isolation therefore of exact kinetic data for α-PbO_2 in acid perchlorate electrolytes has not proved possible. As suggested earlier in the paper, the reason for this is likely to be the formation of β-PbO_2 in addition to α-PbO_2 as products of the exchange reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

which occurs from the instant the PbO_2 electrode comes into contact with the electrolyte.

Qualitatively it can nevertheless be concluded that the exchange current density for α-PbO_2 in perchlorate electrolytes is approximately twice as large as that for β-PbO_2, the charge transfer coefficients being approximately the same.

Studies on metal hydroxy compounds. VI. Kinetics of thermal decomposition of zinc and cadmium halide (Cl, F) derivatives

P. RAMAMURTHY AND E. A. SECCO
Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia

Received October 31, 1968

Kinetics of thermal decomposition of zinc and cadmium hydroxides along with their halide (Cl, F) derivatives are reported. The kinetic results are discussed in terms of the appropriate reaction mechanism. The rates are also discussed using activated complex theory in a manner outlined by Cordes (9) where the effect of molecular rotation in both the reactants and the activated complex is considered. Furthermore, the abnormally high preexponential factors are speculated to have their origin in an active translational mode on the surface.

Canadian Journal of Chemistry, 47, 2181 (1969)

Introduction

The observed rates of solid-state decompositions are extremely difficult to interpret in terms of elementary steps, in contrast to gas-phase and liquid-phase reactions, because the rate is not controlled by the molecularity or chemistry alone, but is also controlled by the geometry of the solid, i.e. its topochemistry.

The purpose of this research is to study in detail a series of compounds within a certain restricted class in order to obtain a better understanding of the fundamental chemical aspect of solid-state decomposition reactions. The class of metal hydroxy compounds present, to our view, the requisite features which would allow a systematic investigation of the structural and substituent parameters on their reaction kinetics.

This communication, representing the first part of a systematic program of study on solid-state decomposition kinetics, reports on the kinetics of thermal decomposition of cadmium and zinc hydroxides and their halide (Cl, F) derivatives. Details of these decomposition reactions and analyses have already been reported (1–3).

Experimental

All compounds used in this study were prepared in this laboratory using procedures already described (1, 2).

The decomposition kinetics were determined gravimetrically, i.e. weight loss vs. time, using a duPont TGA-950 plug-in module for the duPont DTA-900 thermal analyzer console. To do kinetic studies with this unit the *x*-axis drive for the recorder must be accurately calibrated for time and temperature.

The time base calibration was done by switching the "Program Mode" selector to "Isothermal" and setting the appropriate controls on the 900 console and 950 module as recommended in the manufacturer's manual. The time intervals for a number of trial scans were checked against a stop watch; periodic checks were also made during the course of a reaction.

The temperature was calibrated by determining the relation between "Starting Temperature" dial setting and the "Isothermal" temperature. A plot of this relationship allowed us to choose the "Isothermal" experimental temperature from the "Starting Temperature" dial setting.

The recorded weight loss vs. time trace was converted to yield decomposition fraction, α, vs. time plot. The kinetic data were further processed to obtain the best straight line or linear fit with the known rate expressions.

All decomposition runs were done in nitrogen gas atmosphere. A current of nitrogen (Matheson Prepurified Grade with a stated impurity of 0.003% oxygen) was passed through the assembly at a constant flow rate of 2SCFH.

Results and Discussion

The kinetic data for the decomposition reactions occurring according to the following general reaction equations

$$[1]\quad Me(OH)_{2(s)} \rightarrow MeO_{(s)} + H_2O_{(g)}$$

$$[2]\quad 2MeOHX_{(s)} \rightarrow MeO_{(s)} + MeX_{2(s)} + H_2O_{(g)}$$

where Me represents the metal (Cd, Zn) and X the halogen (Cl, F), are presented in Table I.

The experimental α, t data were processed through a large number of kinetic equations. The best fit between the experimental data and the known rate expressions over the maximum reaction fraction $\alpha \geqslant 0.8$ and over the temperature ranges studied is given in Table I. In all cases, except CdOHF, the fitting of the data to a particular rate expression was straight-forward and clear-cut. On the other hand, the CdOHF data are fitted equally well to three known rate equations: (*i*) Avrami–Erofeyev (A–E) type with $n = 3/2$, (*ii*) the contracting formula or Roginskii–Todes–Mampel (R–T–M) equation, and (*iii*)

TABLE I

Kinetic data for decomposition reactions

Compound	Temperature range (°C)	Number of temperatures	Rate expression	Activation energy E_a (kcal)	log A	Heat of reaction ΔH (kcal)
ε-$Zn(OH)_2$	110–145	5	First order	10.2±1.5	4.4	11.6
β-ZnOHCl	250–290	6	First order	67.3±4.1	25.6	5.6
ZnOHF	370–400	4	First order	70.6±5.2	21.9	4.7
$Cd(OH)_2$	170–210	5	First order	26.3±2.1	10.9	12.1
CdOHCl	300–350	5	$1/(1-\alpha) = 1+kt$	54.3±3.4	9.2	9.8
CdOHF	290–330	5	$\ln(1-\alpha) = kt^{3/2}$	18.3±1.8		
			$1-(1-\alpha)^{1/3} = kt$	18.8±2.0	4.7	9.0
			$\log(\alpha/1-\alpha) = k \log t + c$	8.0±4.0		

modified Prout–Tompkins (P–T) in the order of listing in Table I.

The values of the preexponential factor A in the Arrhenius equation indicate a dependence on the E_a values. However, there is no dependence of E_a on ΔH indicated. The contents of Table I are grouped on the basis of their kinetic behavior and discussed under three categories: (*a*) zinc compounds and $Cd(OH)_2$, (*b*) CdOHCl, and (*c*) CdOHF.

(a) Zinc Compounds and $Cd(OH)_2$

The simple first-order kinetics obeyed by this group of compounds suggests the absence of a nucleation-controlled mechanism with the solid particle presenting a reaction zone or reactant/product interface where each molecule possesses an equal probability for decomposition. The low activation energies for the two hydroxides are in sharp contrast to the high E_a values for ZnOHCl and ZnOHF. In the latter reactions, one of the decomposition products, that is, $ZnCl_2$ or ZnF_2, is known to be hygroscopic. It thus presents the strong possibility of the decomposition water becoming chemisorbed at the reactant/product interface. The chemisorbed water could hinder the reaction by stabilizing the reaction interface. The above mode of action is in accord with the higher E_a values and lower rates observed, i.e. factor of 10^3, in ZnOHCl and ZnOHF relative to $Zn(OH)_2$. Zhabrova and his co-workers (4) have reported similar retardation effects with ambient gases (O_2, N_2, H_2O) on the dehydration kinetics of $Mg(OH)_2$ and $Al(OH)_3$.

(b) CdOHCl

The decomposition data for CdOHCl fit the second-order rate law represented in its integrated form by

$$1/(1 - \alpha) = 1 + kt$$

The integrated form of the second-order rate law is considered in solid state kinetics as a special case of the treatment given by Avrami (5), which was cast into a second-order rate expression by Honig *et al.* (6) at sufficiently large t to yield

$$[3a] \qquad 1/(1 - \alpha) = 1 + \sigma N_g G t$$

where σ is a shape factor, G is the lineal growth rate of the new phase, N_g is the initial density of germ nuclei, and t is the time. The composite quantity $\sigma G N_g$ is taken to be the formal rate constant k.

With σ and N_g effectively constant, the rate constant dependence on temperature originates with the term G in the composite rate constant, i.e. $\sigma N_g G$. The observed activation energy appears, therefore, to represent the rate of growth of the new phase or in this case, the advancement of the product/reactant interface.

In this reaction, as in the case of ZnOHCl and ZnOHF, one of the products $CdCl_2$ has a strong affinity for water. The action of chemisorbed water on a product retarding the progressive movement of the product/reactant interface is again in evidence resulting in a high activation energy for the reaction.

(c) CdOHF

The kinetics of CdOHF decomposition are quite well described by three rate expressions, which illustrates that the kinetics analysis, while a necessary one, is not sufficient alone to define the nature of the decomposition reaction. However, there is justification in disregarding the modified P–T equation on grounds of the low E_a value relative to the higher E_a value obtained for the other two equations. Furthermore, since no theoretical justification accompanies the A–E

type equation with $n = 3/2$, we are left with the contracting formula

$$1 - (1 - \alpha)^{1/3} = kt$$

The contracting formula is valid where the rate of advance in directions parallel to the surface is very fast compared with the rate perpendicular thereto, and—provided the surface is reasonably well nucleated—the surface then rapidly becomes covered with a layer of product which consumes the particle at a constant linear rate; the interface retains the shape of the original solid particle. The equation

$$1 - (1 - \alpha)^{1/3} = kt$$

applies specifically to spherical particles but in general to any isodimensional particles.

Attempts to analyze and interpret the pre-exponential factors of solid-state decomposition reactions in terms of fundamental molecular kinetic steps have been unsuccessful. The first such effort (7) made use of the Polanyi–Wigner equation, i.e. rate $= C.\nu.e^{-E_a/RT}$, and applied to decomposition of salt hydrates, where C is a constant computed from the number of water molecules per unit area of the interface and ν is the vibration frequency responsible for initiating decomposition with an expected order of magnitude of $5 \times 10^{12}\ s^{-1}$. The main hurdle encountered in this type of analysis was to reconcile experimental values of ν that differed by a factor as much as 10^{10}, e.g. $\nu \sim 10^5$–10^{22}.

Several applications have been made of the theory of the activated complex to solid decompositions with the most recent treatments embracing monomolecular and bimolecular cases given by Shannon (8) and Cordes (9) respectively. The treatment hinges on the critical parameter of the number of active degrees of freedom in the reactant and the complex contributing to their respective partition functions in the equation of absolute rate theory

$$k_r = A \exp\left(-E_a/kT\right) = \left[\frac{kT}{h}\cdot\frac{Q^*}{Q}\right] \exp\left(-E_a/kT\right)$$

where Q^* and Q represent the complete partition functions of the activated complex, excluding the reaction coordinate, and of the reactant, respectively, with the remaining terms following the conventional notation of rate theory.

The association is made between the experimental A term and the theoretical composite term

$$\left[\frac{kT}{h}\cdot\frac{Q^*}{Q}\right]$$

so that we have

$$\left[10^{13}\cdot\frac{Q^*}{Q}\right] = A$$

leading to three distinct limiting cases:

(i) $Q^* > Q$ yielding $A > 10^{13}$,
(ii) $Q^* < Q$ yielding $A < 10^{13}$, and
(iii) $Q^* = Q$ yielding $A = 10^{13}$.

Case (*i*) is visualized for a complex located on the surface exercising a larger number of active degrees of freedom relative to the reactant incorporated or locked in the crystal interior. Case (*ii*) is the converse, that is, the complex is more restricted in its freedom on the surface or in the bulk relative to the reactant. Case (*iii*) obviously refers to the situation where the complex and the reactant resemble each other within the limits of absolute rate theory.

Unfortunately, it is not possible now to make a rigorous test for the kinetics of the reactions reported here in terms of absolute rate theory, owing to the lack of the complete infrared spectrum for the reactant, that is, data on lattice vibrations, torsional oscillations, etc. We can, however, speculate on the nature of these reactions using Cordes' general analysis considering only rotational freedom for empirical first-order preexponential factors.

Following Cordes' treatment we envisage a reaction scheme for decomposition as follows

(a) Hydroxides

[1] HO—Me—OH → [HO--Me--OH]*
→ Me—OH + OH

[2] OH + Me—OH → [Me—OH---OH]*
→ MeO + H_2O

(b) Basic Halides

[1] X—Me—OH → Me—X + OH

[2] OH + X—Me—OH → [X—Me—OH---OH]*
→ X—Me—O + H_2O

[3] Me—X + X—Me—O → [X—Me---X---Me—O]*
→ MeX_2 + MeO

We further envisage the rate determining steps to be reaction [1] or [2]. Although an activated

complex is shown in reaction [3] to represent an intermediate species prior to the stable products, we cannot appreciate this reaction since this step is not accompanied by a weight loss and is therefore unobservable in our experiments.

In the case of hydroxides with reaction [1] as the slow step, the overall decomposition rate will be monomolecular first-order. If the limiting aspect of this reaction is a surface one, a surface regression rate which is pseudo-first-order is observed. The activated complex formed is highly restricted in rotation with a very low preexponential factor $\sim 10^5$ predicted. This predicted value agrees very well with the observed value for ε-$Zn(OH)_2$. On the other hand, if the complex enjoys a "freer" condition on the surface, then the predicted factor of 10^9 is again in fair agreement with the observed value for $Cd(OH)_2$. Alternatively for $Cd(OH)_2$, if reaction [2] is the limiting step, the reaction will be bimolecular first-order with a predicted preexponential factor range 10^9–10^{11}. This situation includes the case where the bond length between the two parts of the complex, i.e. —(OH---OH), is such to permit free rotation.

The preexponential factors observed for ZnOHCl and ZnOHF rates are more difficult to interpret from Cordes' analysis because these rates are complicated by the intervention of H_2O vapor giving rise to extremely high preexponential values. However, we can imagine the adsorbed H_2O to provide a mobile layer on the reactant/product surface to permit the complex to execute one or two translational modes of freedom where these modes are absent in the reactant. The contribution to the overall partition function by one additional translational mode in the complex is ca. 10^8, yielding a predicted A value of ca. 10^{21} which is within the order of magnitude observed experimentally.

Studies on metal hydroxy compounds. VII. Thermal analyses of copper derivatives

P. RAMAMURTHY AND E. A. SECCO
Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia

Received November 15, 1968

Copper basic halide compounds have been studied by thermogravimetric and differential thermal analyses. This study reveals the general pattern of thermal stability observed for cadmium and zinc basic halides.

The initial mode of decomposition varied within the copper group. The iodides, bromides, and chlorides all decomposed via dehydroxylation and in this way resembled the Cd and Zn basic halides. The copper basic fluorides, on the other hand, decomposed by simultaneous dehydroxylation and dehydrofluorination which is in distinct contrast to the Cd and Zn basic fluorides.

Canadian Journal of Chemistry, 47, 2185 (1969)

Introduction

A program of research on metal basic halides was initiated in our laboratory with studies on Zn and Cd compounds reported earlier (1, 2). Since other transition metals, such as Cu, Ni, Co, and Fe form two types of basic halides, i.e. MeOHX and $Me_2(OH)_3X$, it was considered worthwhile to extend our studies to include this group of compounds. In this communication we report on the differential thermal analysis (d.t.a.) and thermogravimetric analysis (t.g.a.) of copper basic halides.

Wheeler and Handler (3) studied the decomposition of $CuF_2 \cdot 2H_2O$ and CuOHF by d.t.a. and proposed the following reactions

$$[1a] \quad 2Cu_2F \cdot 2H_2O \xrightarrow{130\text{–}150\ ^\circ C} Cu_2(OH)F_3 + HF + 3H_2O$$

$$[1b] \quad Cu_2(OH)F_3 \xrightarrow{420\ ^\circ C} CuO + CuF_2 + HF$$

$$[2a] \quad 4CuOHF \xrightarrow{370\ ^\circ C} Cu_2(OH)F_3 + 2CuO + HF + H_2O$$

$$[2b] \quad Cu_2(OH)F_3 \xrightarrow{420\ ^\circ C} CuO + CuF_2 + HF$$

Recently, Le Van My and co-workers (4) reported $CuF_2 \cdot 2H_2O$ to decompose in vacuum as follows

$$[3a] \quad CuF_2 \cdot 2H_2O \xrightarrow{130\ ^\circ C} CuOHF + H_2O + HF$$

$$[3b] \quad 4CuOHF \xrightarrow{350\ ^\circ C} Cu_2(OH)F_3 + 2CuO + H_2O + HF$$

$$[3c] \quad Cu_2(OH)F_3 \xrightarrow{420\ ^\circ C} CuO + CuF_2 + HF$$

When our study was nearing completion a report by Ball and Coultard (5) appeared on the t.g.a. of a number of copper basic halides conducted in air. This latter report contained results which were in disagreement with the already published decomposition reactions and, therefore, added to the existing controversy.

The purpose of this communication is to clarify the growing controversy on the modes of decomposition of copper basic halides and to contrast these modes of decomposition with those of their zinc and cadmium analogues.

Experimental

All the compounds used in this study were prepared in this laboratory by following known methods with slight modification of the procedures. Brief descriptions of the procedures are given below; all chemicals used in these preparations were of reagent grade.

(i) CuOHCl

This was prepared by heating a mixture of $CuCl_2 \cdot 2H_2O$ and CuO at 110 °C for one week in a sealed Pyrex tube (6, 7).

(ii) α-$Cu_2(OH)_3Cl$

This was prepared by reacting $3Cu(OH)_2 \cdot CuSO_4$ with

TABLE I

‡Observed with all fluorides except $Cu_2(OH)_3F$.

saturated aqueous solution of NaCl at room temperature for 48 h (8).

(iii) β-*$Cu_2(OH)_3Cl$*

This was prepared by digesting CuO with medium concentrated aqueous solution of $CuCl_2$ at 110 °C for one week (7).

(iv) γ-*$Cu_2(OH)_3Cl$*

This was prepared by the oxidation of Cu_2Cl_2 in solution of $CuCl_2$ with oxygen (8).

(v) δ-*$Cu_2(OH)_3Cl$*

This was prepared by adding excess NH_3 to 1 *M* $CuCl_2$ solution with slow evaporation of NH_3 at 50 °C (8).

(vi) $Cu_2(OH)_3Br$

This was prepared by digesting CuO with medium concentrated aqueous solution of $CuBr_2$ at 110 °C for one week (9).

(vii) $Cu_2(OH)_3I$

This was prepared by heating aqueous solution of cupric acetate with KI at 60–70 °C overnight (10).

All preparations involving the basic fluorides were carried out in polyethylene or platinum containers.

(viii) $CuF_2 \cdot 2H_2O$

This was prepared by the action of aqueous HF on $CuCO_3$ (3). This compound was used immediately after preparation.

(ix) $Cu_2(OH)F_3$

This was prepared by heating $CuF_2 \cdot 2H_2O$ for 2 h in N_2 atmosphere (3) at 160 °C.

(x) CuOHF

This was prepared by the hydrolysis of $CuF_2 \cdot 2H_2O$ in air at 100 °C for 10 h (3).

(xi) $Cu_2(OH)_3F$

This was prepared by dissolving $CuCO_3$ in aqueous HF and then adding concentrated NH_3 until the blue color of the ammonium complex appeared. The resulting solution was diluted with distilled H_2O and hydrolyzed slowly (11).

The identity and purity of the compounds were confirmed by the available infrared (i.r.) spectra and X-ray diffraction patterns (9, 12).

The thermograms were recorded on a DuPont Thermal Analyzer, DTA-900 and TGA-950, and DuPont 1200 °C DTA cell, as previously described (1). In the case of the fluorides, only the 1200 °C d.t.a. cell equipped with platinum cups and liners was used; experiments with the fluorides in the 850 °C cell equipped with quartz sample holders were complicated by reaction of the quartz with the fluoride compound.

The heating rate used for most thermograms was 20 °C/min. In the case of overlapping processes, slow heating rates of 4 and 2 °C/min were used in an attempt to resolve the processes. An ambient atmosphere of dry N_2 (Matheson Prepurified Grade with a stated impurity of 0.003% oxygen) was maintained during both the d.t.a. and t.g.a. measurements unless otherwise specified.

Results and Discussion

Thermogravimetric Analysis

The results of t.g.a. are presented in Table I and each compound is discussed in sequence. The proposed reactions for each compound are those which best fit the observed weight loss; the intermediate and final products were further identified by X-ray diffraction and correlated with d.t.a. thermograms.

(I) CuOHCl

The first step is the dehydroxylation to the oxide and halide according to

[I*a*] $$2CuOHCl \rightarrow CuO + CuCl_2 + H_2O$$

which was followed by disproportionation of the halide, i.e.

[I*b*] $$2CuCl_2 \rightarrow Cu_2Cl_2 + Cl_2$$

The third step involves the volatilization of Cu_2Cl_2 leaving CuO which itself disproportionates above 800 °C to yield a residue of Cu_2O.

The observed weight loss values assigned to reaction [I*b*] in all cases of basic chlorides are lower than their calculated values. This discrepancy arises from the overlap of $CuCl_2$ disproportionation with Cu_2Cl_2 volatilization as shown graphically in Fig. 1.

In all cases of the basic chlorides, i.e. CuOHCl and $Cu_2(OH)_3Cl$, it was observed that the weight loss up to the CuO product stage was always greater than calculated. This discrepancy was interpreted in terms of chlorination of CuO to form the volatile Cu_2Cl_2, i.e.

[I*c*] $$2CuO + Cl_2 \rightarrow Cu_2Cl_2 + O_2$$

which contributes to the higher weight losses observed. This interpretation was confirmed with 2:1 mole ratio physical mixture of CuO:$CuCl_2$ which showed a loss of 56.33%, whereas the predicted value, in the absence of the chlorination step, is 45.80%.

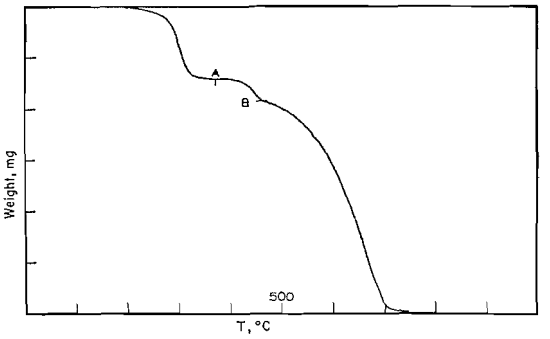

FIG. 1. Thermogravimetric analysis curve for α-$Cu_2(OH)_3Cl$ illustrating the initial dehydroxylation step followed by the disproportionation of $CuCl_2$ overlapping with Cu_2Cl_2 volatilization. A, represents weight value used to calculate weight loss for dehydroxylation; B, represents the weight value used to calculate weight loss for $CuCl_2$ disproportionation.

(II) α-, β-, γ-, and δ-$Cu_2(OH)_3Cl$

All four forms of this basic chloride undergo decomposition in the same manner, namely, dehydroxylation, similar to reaction [I*a*] accompanied by a slight variation in the temperature range. The subsequent processes of disproportionation of $CuCl_2$ and volatilization of Cu_2Cl_2, along with the partial chlorination and disproportionation of CuO, are observed as described above for CuOHCl.

Ball and Coultard in their experiments done in air observed Cu_2Cl_2 as an intermediate only in the decomposition of $CuCl_2 \cdot 2H_2O$. Their claim that the basic chlorides undergo only dehydroxylation with direct oxidation of $CuCl_2$ to CuO is in contrast to our observations. In view of the possibility that the course of the reaction is determined by the experimental conditions, particularly the nature of the atmosphere in contact with the compound, we carried out the decomposition in our instrument using air instead of N_2. The formation of Cu_2Cl_2 was confirmed consistently as identified by X-ray diffraction and supported by d.t.a. thermograms.

(III) $Cu_2(OH)_3Br$

The initial step corresponds to simultaneous dehydroxylation and disproportionation of $CuBr_2$, i.e.

[III*a*] $$2Cu_2(OH)_3Br \rightarrow 3CuO + \tfrac{1}{2}Cu_2Br_2 + \tfrac{1}{2}Br_2 + 3H_2O$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

On the premise that disproportionation should follow the formation of $CuBr_2$ from dehydroxylation, several unsuccessful attempts were made at low heating rates to resolve these two processes. From the d.t.a. measurements, it is obvious that $CuBr_2$ disproportionates at the same temperature as dehydroxylation occurs. The second step in the thermogram corresponds to volatilization of Cu_2Br_2 which is followed by disproportionation of CuO.

Ball and Coultard reported the mode of decomposition in air as follows

$$[IIIb]\quad 2Cu_2(OH)_3Br + \tfrac{1}{2}O_2 \rightarrow 3Cu(OH)_2,CuO + Br_2$$

and

$$[IIIc]\quad 3Cu(OH)_2, CuO \xrightarrow{370\text{–}435\ ^\circ C} 4CuO + 3H_2O$$

Since these reactions appeared unreasonable on the basis that it demands the copper hydroxide be stable up to 400 °C, compared to its experimentally determined value of 200 °C, the thermogravimetry of $Cu_2(OH)_3Br$ was repeated by us in air and at the same heating rate given by Ball and Coultard. The thermogram clearly displayed two steps, with slight overlap, corresponding to 24.96 and 38.00% weight loss, respectively. These observed weight losses are fitted to the following reactions

$$2Cu_2(OH)_3Br \rightarrow 3CuO + \tfrac{1}{2}Cu_2Br_2 + \tfrac{1}{2}Br_2 + 3H_2O$$

and

$$Cu_2Br_2 + O_2 \rightarrow 2CuO + Br_2$$

which predict weight losses of 25.96 and 38.33%, respectively.

The slight discrepancy between our observed and predicted values is attributed to the overlap. Furthermore, an X-ray diffractogram of the residue after heating $Cu_2(OH)_3Br$ in air up to 320 °C showed peaks characteristic of Cu_2Br_2 and CuO.

(IV) $Cu_2(OH)_3I$

In common with the basic bromide, the initial step corresponds to simultaneous dehydroxylation and disproportionation of CuI_2, i.e. reaction [III*a*]; the second step involves volatilization of Cu_2I_2 which is followed by disproportionation of CuO at high temperatures.

The decomposition of $Cu_2(OH)_3I$ in air for the first two steps leaving CuO as the product shows weight losses of 46.55 and 50.00%, respectively; the predicted weight loss after the second step is 50.49%. The high value of 46.55% in air relative to 28.46% in N_2 must include partial oxidation of Cu_2I_2; a thermogram of pure Cu_2I_2 carried out in air revealed almost complete oxidation between 280–350 °C.

(V) $CuF_2 \cdot 2H_2O$

The mode of decomposition involves dehydroxylation and dehydrofluorination forming a basic fluoride which in turn breaks down by further dehydrofluorination, yielding the oxide and fluoride in the residue, i.e.

$$[Va]\quad 2CuF_2 \cdot 2H_2O \rightarrow Cu_2(OH)F_3 + HF + 3H_2O$$

and

$$[Vb]\quad Cu_2(OH)F_3 \rightarrow CuO + CuF_2 + HF$$

These steps are followed by volatilization of CuF_2 and disproportionation of CuO at high temperatures. The mode of decomposition represented by reactions [V*a*] and [V*b*] is in agreement with Wheeler and Handler (3).

(VI) $Cu_2(OH)F_3$

The initial step is dehydrofluorination as described by reaction [V*b*].

(VII) CuOHF

Our results are best fitted to a dehydroxylation and dehydrofluorination and the formation of $Cu_2(OH)F_3$ with its subsequent decomposition overlapping, i.e.

$$[VIIa]\quad 4CuOHF \rightarrow Cu_2(OH)F_3 + 2CuO + HF + H_2O$$

and

$$[VIIb]\quad Cu_2(OH)F_3 \rightarrow CuO + CuF_2 + HF$$

Attempts to resolve these reaction processes at low heating rates, 1.4 °C/min, were unsuccessful.

(VIII) $Cu_2(OH)_3F$

Decomposition occurs via dehydroxylation and dehydrofluorination to yield only CuO in the residue, i.e.

$$[VIIIa]\quad Cu_2(OH)_3F \rightarrow 2CuO + H_2O + HF$$

Differential Thermal Analysis

The results of d.t.a. measurements are presented in Table II and each compound is discussed in sequence to accompany the t.g.a. results.

(I) CuOHCl

Four endotherms are observed on heating to 1200 °C; these endotherms are identified with (*a*) dehydroxylation, (*b*) disproportionation of $CuCl_2$, (*c*) volatilization of Cu_2Cl_2, and (*d*) dis-

proportionation of CuO, respectively. Cooling the thermogram from 700 °C revealed two exotherms at 460 and 422 °C, identified with freezing of Cu_2Cl_2 and structural transition, respectively (13). The heating and cooling thermograms of pure Cu_2Cl_2 reveal the corresponding endo- and exotherms.

(II) α-, β-, γ-, δ-$Cu_2(OH)_3Cl$

All four forms of $Cu_2(OH)_3Cl$ show the same thermogram pattern with slight variation only in the peak temperatures of the first endotherm. The endotherms are identified with similar processes described above for CuOHCl.

(III) $Cu_2(OH)_3Br$

The thermogram revealed five endotherms associated with (*a*) dehydroxylation and disproportionation of $CuBr_2$, (*b*) (γ → β), (*c*) (β → α) structural transitions (14), (*d*) fusion of Cu_2Br_2, and (*e*) disproportionation of CuO accompanied by volatilization of Cu_2Br_2, respectively. The endotherms associated with reversible processes (*b*), (*c*), and (*d*) as expected appeared as exotherms on cooling from 700 °C.

The heating thermograms of pure $CuBr_2$ confirmed the endotherms identified above involving $CuBr_2$ and Cu_2Br_2.

(IV) $Cu_2(OH)_3I$

Five endotherms were observed on heating to 1200 °C identified with (*a*) dehydroxylation and disproportionation of CuI_2, (*b*) (γ → β), (*c*) (β → α) structural transformations of Cu_2I_2 (15), (*d*) fusion of Cu_2I_2, and (*e*) volatilization of Cu_2I_2 along with disproportionation of CuO, respectively. The endotherms associated with reversible processes (*b*), (*c*), and (*d*) as expected appeared as exotherms on cooling from 700 °C. The solidification exotherm, however, appeared as a doublet, 620 and 605 °C. The doublet only occurs when

CuO is present with Cu_2I_2 as confirmed with 3:1 mole ratio $CuO:Cu_2I_2$ mixture. The origin of the doublet, which will be a subject for further study, is speculated to arise from a compound or a solid solution of partial miscibility.

(V) $CuF_2 \cdot 2H_2O$

The thermogram showed three endotherms associated with (*a*) decomposition of dihydrate, (*b*) decomposition of the intermediate species $Cu_2(OH)F_3$, and (*c*) disproportionation of CuO. These observations agree with Wheeler and Handler (3) up to 500 °C. In a later study by Handler and co-workers (16) on d.t.a. of CuF_2 in CaF_2 and quartz matrix, they reported an endotherm at 770 °C, an exotherm at 780 °C, and a strong endothermic effect at 870–900 °C. In all our basic fluorides where CuF_2 was a product, corresponding peaks were not observed except for a very weak exotherm at 715 °C.

(VI) $Cu_2(OH)F_3$

Two endotherms were observed and identified with processes (*b*) and (*c*) stated above under (V).

(VII) CuOHF

The three endotherms in this thermogram are identified with decomposition and the subsequent two processes (*b*) and (*c*) characteristic of $Cu_2(OH)F_3$ which forms in the initial step.

(VIII) $Cu_2(OH)_3F$

The thermogram consisted of two endotherms which were associated with decomposition and subsequent disproportionation of CuO.

Conclusions

The thermal analyses of copper basic halides reveal the general pattern of thermal stability observed for Cd and Zn compounds, i.e. $Me(OH)_2 < Me(OH)I < Me(OH)Br < Me(OH)Cl < Me(OH)F$. The initial mode of decomposition varied within the copper group. The iodides, bromides, and chlorides all decomposed via dehydroxylation and in this way resembled the Cd and Zn halide derivatives. The copper basic fluorides, on the other hand, decomposed by simultaneous dehydroxylation and dehydrofluorination which is in distinct contrast to the Cd and Zn basic fluorides.

The work confirms the results by Wheeler and Handler (3) and therefore disagrees with Le Van My and co-workers (4) on the mode of decomposition of $CuF_2 \cdot 2H_2O$, namely the formation of CuOHF instead of $Cu_2(OH)F_3$, i.e. reactions [1*a*] and [3*a*]. Since CuOHF is formed by the action of H_2O vapor on $Cu_2(OH)F_3$, as reported earlier (3) and confirmed in this laboratory, we conclude that sufficient H_2O vapor is accumulated during the experiments of Le Van My to effect the formation of Cu(OH)F from the primary product $Cu_2(OH)F_3$.

The identification of Cu_2Cl_2 and Cu_2Br_2 as secondary products in the decomposition of $Cu_2(OH)_3Cl$ and $Cu_2(OH)_3Br$, respectively, in this work is at variance with the results of Ball and Coultard (5). There is a further inconsistency in the latters reporting of Cu_2Cl_2 as a secondary product in the dehydration of $CuCl_2 \cdot 2H_2O$ in air.

Behavior of lead electrodes in sulfuric acid solutions. II[1]

E. TARTER AND K. EKLER[2]
Department of Chemistry, Loyola College, Montreal, Quebec

Received September 26, 1968

An attempt was made to clarify the question whether the variation in the length of the "first discharge plateau" with change in H_2SO_4 concentration was caused by a change in the efficiency of PbO_2 formation or by a variation in its discharge rate. The relationships between acid concentration, "passivation time", amount of $PbSO_4$ formed during passivation, and the quantity of PbO_2 derived therefrom during charging were investigated. The amount of $PbSO_4$ on the anode increased with a decrease in passivating acid concentration. More PbO_2 was formed at lower charging acid concentrations. The higher the discharge acid concentration, the greater was its stabilizing effect on PbO_2 discharge. The combination of two factors, i.e. a decrease of the amount of PbO_2 formed at higher acid concentrations together with an increase in the PbO_2 stability, gave rise to the maximum 10.5 *N* H_2SO_4.

Canadian Journal of Chemistry, 47, 2191 (1969)

Introduction

In a previous publication the conversion of $PbSO_4$ to PbO_2 in H_2SO_4 solutions and the reverse reaction were studied by the galvanostatic method and by making potential–time records during charging and self-discharge of the lead anode (1).

Since the behavior of the anode was sensitive to the "immersion time", i.e. the time during which the anode had been in contact with the H_2SO_4 before polarization, the results are here reported for anodes which were immersed in the electrolyte for the shortest possible time ("short immersion").

When the current was turned off and the electrode allowed to self-discharge on open-circuit, there was a drop of about 300 mV from the "charging-plateau" to a level that was termed the "first discharge plateau" (Fig. 1). The duration of the latter was dependent on acid concentration, with a particularly long first discharge plateau being observed in 10.5 *N* H_2SO_4.

An attempt was made to investigate the relationships between acid concentration and "passivation time" (Fig. 1, A to C), amount of $PbSO_4$ formed during passivation, and quantity of PbO_2 derived therefrom during charging, as well as the stability of PbO_2 in various acid concentrations.

Experimental

Procedure

The galvanostatic method was used for the polarization of the anode and has been described in an earlier paper (1). The cell was immersed in a constant temperature bath (Lauda Ultra Kryostat, UK 40 SD) in which temperatures between +30 and −50 °C could be controlled to ±0.02 °C. The coolant was methanol. The direct current was supplied by a Harrison power-supply (881-A, 1.0 A capacity). The preparation of the anodes was identical to that reported previously.

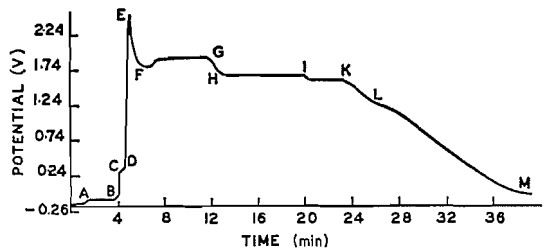

FIG. 1. Typical potential–time recording for short-immersion electrode. A to G, charging; G to N, discharging; A, $Pb/PbSO_4$ potential; F to G, "charging plateau" (PbO_2/O_2 potential); H to K, "first discharge plateau" ($PbSO_4/PbO_2$ potential); L, mixed potentials.

In experiments where an anode was transferred from one acid to another of a different concentration, the electrode was allowed to drain for 3 s before it was immersed in the second acid and was then drawn back and forth through the electrolyte for about 10 s to insure mixing.

When an anode was force-discharged by applying a current in the reverse direction, resistors ranging from 7 to 30 kΩ, depending on the discharge current used, were incorporated into the circuit to avoid short-circuiting the anode and cathode through the low-impedance power-supply while force-discharge was taking place. The method of Rüetchi and Cahan (2) was employed to obtain the maximum anodic charge by force-discharging at successively higher current densities (i) and extrapolating the product $i \times t$ to zero time, where t is the discharge time in s.

Analytical Methods

The quantity of $PbSO_4$ formed on the anode during

the passivation time was determined polarographically (Radiometer, Polariter P O 4). The passivated electrode was thoroughly rinsed with distilled H_2O and immersed for 3 min with constant agitation in 18.0 ml 4.0 *N* CH_3COONa. When solution of the $PbSO_4$ had taken place the electrode was removed, drained, the liquid mixed with 18.0 ml 4.0 *N* CH_3COOH, and the polarogram taken. A calibration curve was established using 1.0 to 10.0 mg samples of $PbSO_4$. A blank in which a freshly etched electrode was agitated in H_2SO_4 for 3 min showed a negligible amount of Pb.

The PbO_2 formed on the anode on charging was determined by a semi-micro titration adapted from a standard method (3). To minimize self-discharge the charged anode was rinsed with distilled water as rapidly as possible and then submerged in an excess (40.0 ml) of 0.004 *N* As_2O_3. The unreacted As_2O_3 was back-titrated (in the presence of 1.5 *N* HCl and 0.5 g KBr) with 0.004 *N* $KBrO_3$, using one drop of 0.1% methyl orange as indicator. A blank had shown that 0.70 ml $KBrO_3$ was required to oxidize the indicator. Near the end-point the $KBrO_3$ was added at intervals of 20 s or more. The method was tested with 5.0–10.0 mg samples of PbO_2, in the presence and absence of finely divided Pb-powder, and was capable of detecting 96–98% of the PbO_2. Analyses were unaffected by digestion of the PbO_2 in H_2SO_4 and were reproducible to ± 0.05 mg PbO_2.

Materials

During the earlier part of the investigation the 2.5 cm × 10.0 cm electrodes were cut from $\frac{1}{4}$ in. rolled Pb-sheet (Canada Metal Co., Montreal) identical to that used in the previous paper. Later, 0.025 in. sheet was used (International Nickel Co., Sheridan Park, Ontario) of the following analysis: Sn, <0.0001%; Sb, 0.0001%; As, 0.0001%; Ag, 0.0003%; Cu, 0.0002%; Bi, 0.0008%; Fe, 0.0001%; Zn, 0.0001%. The following reagent grade chemicals were used: H_2SO_4 and CH_3COOH (Nicholls), As_2O_3, $KBrO_3$, and KBr (J. T. Baker), NH_2SO_3H and $CH_3COONa \cdot 3H_2O$ (Anachemia), and PbO_2 (Fisher). The H_2O was doubly distilled from KOH.

Results and Discussion

To obtain first discharge plateaux which were long enough to minimize self-discharge during force-discharging and to yield $PbSO_4$ and PbO_2 in sufficient quantity to allow a quantitative determination with the required precision, the influence of temperature on the length of the plateaux was investigated in the range −40 to +70 °C. The plateau for an electrode charged at 5.0 °C and 0.5 mA/cm² for 14 min showed a several-fold increase in length relative to that at 25.0 °C and 1 mA/cm², the latter having been reported previously (1), and therefore most of the experiments were made at the lower temperature and current density. The plateau lengths for various acid concentrations again showed the peculiar maximum in 10.5 *N* H_2SO_4 (Fig. 2).

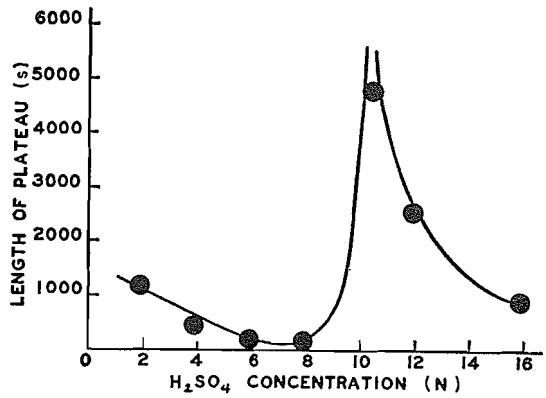

FIG. 2. Acid-dependence of "first discharge plateau" for electrodes charged at 5.0 °C and 0.5 mA/cm² for 14 min (self-discharge).

(a) $PbSO_4$ Formation

The passivation time was recorded for anodes in acids ranging from 1.0–14.0 *N* at 5.0 °C and 0.5 mA/cm² and found to increase with a decrease in H_2SO_4 concentration in a similar manner to that reported before for 25.0 °C and 1.0 mA/cm² (1).

A difference in the character of the $PbSO_4$ layer seems to be involved, since the coating formed in 2.0 *N* H_2SO_4 had a dull grey appearance, whereas at higher acid concentrations it was transparent. This is in agreement with the findings of Kabanov *et al.* (4) who found that $PbSO_4$ formed in concentrated acid crystallizes in a denser layer than in dilute solution. The cause for this is probably the decrease of the diffusion coefficient of $PbSO_4$ at higher H_2SO_4 concentrations.

The polarographic determination of the amounts of anodic $PbSO_4$ indicated that the longer passivation times in more dilute acids corresponded to progressively larger amounts of $PbSO_4$ (Fig. 3).

(b) PbO_2 Formation

(i) Passivating and Charging, Acid Concentration Constant

To correlate the amounts of $PbSO_4$ and PbO_2 formed during passivation and charging, respectively, anodes were passivated and charged in the same acid ranging in concentration from 1.0 to 16.0 *N* and, immediately after the charging current was turned off, the PbO_2 was determined by titration (Fig. 4*b*). The amount of PbO_2 formed,

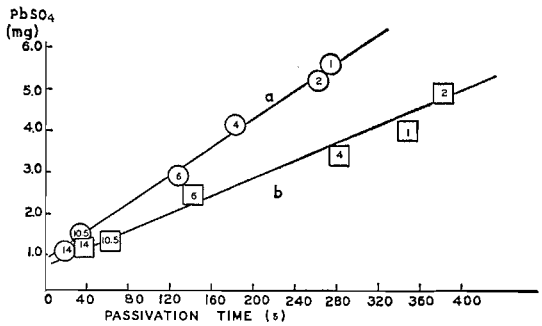

FIG. 3. Dependence of $PbSO_4$ formation on passivation time. (*a*) current density = 1.0 mA/cm², temperature = 25.0 °C; (*b*) current density = 0.5 mA/cm², temperature = 5.0 °C. The numbers inside circles and squares refer to acid concentrations.

similar to that of $PbSO_4$, increased with a decrease in acid concentration. This, however, could be anticipated, as it is well recognized that the amount of PbO_2 formed, for short charging periods in strongly acidic solutions, is approximately equivalent to the $PbSO_4$ deposited on the electrode during passivation (5, 6)

$$PbSO_4 + 2H_2O \rightarrow \beta\text{-}PbO_2 + 2H^+ + H_2SO_4 + 2e$$

(ii) Passivating, Acid Concentration Constant—Charging, Acid Concentration Variable

In a series of experiments in which anodes were passivated in one acid and transferred to be charged in a second acid of a different concentration, the results indicated that a given quantity of $PbSO_4$ on the anode is less completely oxidized to PbO_2 the higher the charging acid concentration. The amount of PbO_2 was determined by titration.

(iii) Passivating and Discharging, Acid Concentration Constant—Charging, Acid Concentration Variable

The observations were supported by another set of experiments in which the anodes were passivated in one acid, transferred and charged in a second acid, as before, but then were returned to the first acid to be force-discharged (Fig. 5). The shortening of the plateaux with an increase in charging acid concentration reflects the lesser amounts of PbO_2 formed on the anodes with an increase in the passivating and/or charging acid concentration.

Similar evidence was obtained with anodes which were passivated in one acid (2.0 *N*), transferred for charging to progressively more concentrated solutions (2.0–14.0 *N*), and then returned to the first acid (2.0 *N*) for self-discharging. The continuous decrease of plateau length (Table I) for charging acid concentrations between 2.0 and 14.0 *N* was attributed to incomplete oxidation of $PbSO_4$ to PbO_2 during charging.

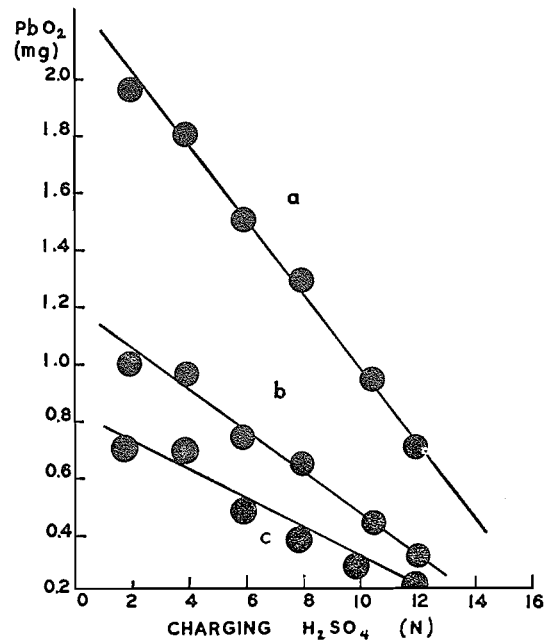

FIG. 4. PbO_2-determinations by (*a*) extrapolation; (*b*) titration; and (*c*) "inert PbO_2". Electrodes charged at 5.0 °C and 0.5 mA/cm² for 14 min.

others, at the PbO_2/O_2 potential during anodization, i.e. the conversion of $PbSO_4$ to β-PbO_2 at the $PbSO_4$–electrolyte interface and secondly the oxidation of the underlying Pb to α-PbO_2, due to the basic conditions possibly prevailing there. According to Burbank (7) "the rate of formation of α-PbO_2 is controlled by the rate of penetration of the oxygen species through the β-PbO_2 layer." Presumably, the rate of penetration would be increased in more dilute acids. This would give rise to an amount of α-PbO_2 at the metal boundary in addition to the β-PbO_2 obtained at the electrolyte interface, thus causing more PbO_2 (α + β) to be formed in more dilute solutions.

Electrochemical reduction (Fig. 6) was used as an alternative method for the determination of "initial PbO_2" (the quantity of PbO_2 formed during anodization), Rüetchi and Cahan (8) having reported that "the titration of the absolute amount of PbO_2 in a freshly formed oxide-layer was inconclusive because of self-discharge effects

TABLE II

Quantity of PbO_2 by extrapolation method

... a much smaller error might be anticipated when discharged layers were titrated." The product $i \times t$ was extrapolated to zero time, converted to mg PbO_2 to which was added the value for "inert PbO_2" (electrochemically undischargeable PbO_2), determined by titration after force-discharging (Table II). Voss and Freundlich (9) have postulated several reasons for the existence of "inert PbO_2" with reference to battery plates, e.g. the electrical isolation of PbO_2 crystallites by $PbSO_4$. The amount of "inert PbO_2" in the present case was essentially independent of the force discharge current density.

A comparison of the results obtained by the extrapolation and titration methods together with the "inert PbO_2" is given in Fig. 4. Although self-discharge took place to a considerable degree when the titration-method was used, the trend was similar for both curves. Both methods indicated the fact that in higher charging acid concentrations, less PbO_2 was formed for a given quantity of charge passed.

(c) Stability of PbO_2

(i) Passivating and Charging, Acid Concentration Constant—Discharge, Acid Concentration Variable

To examine the question of whether different acid concentrations caused a variation in the discharge-rate of a given quantity of PbO_2, electrodes were both passivated and charged in one acid, transferred to a second acid of a different concentration, and allowed to self-discharge. The lengths of the plateaux were dependent on two factors, firstly the amount of "initial PbO_2" and secondly the self-discharge acid concentration (Table III). Anodes which were both passivated and charged in successively more concentrated acids and were then self-discharged in one particular acid, yielded pro-

gressively shorter plateaux, reflecting the lesser amounts of "initial PbO_2". On the other hand, the lengths of the plateaux underwent a very large increase when anodes, passivated as well as charged in one particular acid, were transferred to be discharged in an acid varying from 2.0–16.0 N. Since the quantity of "initial PbO_2" was maintained constant, it can be concluded that the higher the discharge acid concentration, the greater is its stabilizing effect on the PbO_2 discharge.

The peculiar maximum observed for the self-discharge plateau in 10.5 N H_2SO_4 (Fig. 2) can be explained in terms of the above data. Experiment Nos. 1, 6, 11, and 16 (Table III) correspond to some of the key points of Fig. 2. A gradual decrease in the amount of PbO_2 formed, coupled with a simultaneous increase in discharge acid concentration are opposing factors, giving rise to the maximum in 10.5 N H_2SO_4. Thus for anodes which were both passivated and charged in the same acid, the lengths of the self-discharge plateaux depended on both "initial PbO_2" and the self-discharge acid concentration.

(ii) Passivating, Acid Concentration Constant—Charging and Discharging, Acid Concentration Variable

The plateau lengths again passed through a maximum when anodes were passivated in one

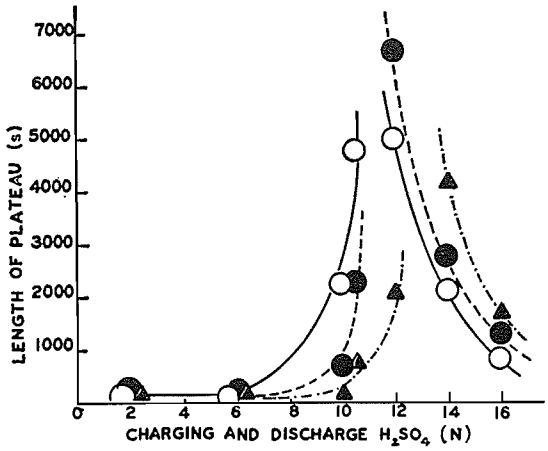

FIG. 7. Dependence of "first discharge plateau" on charging and/or discharge acid concentration for electrodes charged at 25.0 °C and 1 mA/cm² for 7 min (self-discharge). Passivating acid concentration: ○, 2 N; ●, 6 N; △, 10.5 N.

acid, and transferred to a second acid ranging from 2.0–16.0 N for charging as well as self-discharging (Fig. 7). This also was probably due to the fact that a given passivating acid concentration controlled the amount of $PbSO_4$ formed during passivation. The $PbSO_4$ was less completely oxidized when transferred to greater charging acid concentrations. Nevertheless, the lengths of the plateaux increased because of the stabilizing effect of the second acid.

The greater stability of PbO_2 in more concentrated H_2SO_4 solutions (Table III) is in accordance with the work of Rüetchi and Cahan (2) who reported a similar behavior with PbO_x electrodes (where x has a value from 1.4–1.6): "Potential measurements in H_2SO_4 more dilute than specific gravity 1.225 indicated that self-discharge strongly increased with decreasing acid concentration." Rüetchi and Angstadt (10) formulated a self-discharge mechanism as follows: "At the surface of the film nearest the electrolyte β-PbO_2 is electrochemically reduced in acid medium according to

$$[1]\quad 2e + \beta\text{-}PbO_2 + HSO_4^- + 3H^+ \rightarrow PbSO_4 + 2H_2O$$

and

$$[2]\quad 2e + \beta\text{-}PbO_2 + SO_4^{2-} + 4H^+ \rightarrow PbSO_4 + 2H_2O$$

As the surface becomes covered with $PbSO_4$, further reduction of β-PbO_2 and underlying α-PbO_2 to $PbSO_4$ is inhibited because of slow diffusion of H_2SO_4 into the film." They reported

further that electrons for these reactions are supplied during self-discharge by reactions such as

[3] $$H_2O \rightarrow \tfrac{1}{2}O_2 + 2H^+ + 2e$$

[4] $$Pb + SO_4^{2-} \rightarrow PbSO_4 + 2e$$

[5] $$Pb + 2OH^- \rightarrow PbO + H_2O + 2e$$

and that [4] would proceed faster and with less restrictions than the other reactions. Referring to Table III it seems that the greater self-discharge rate in lower acid concentrations is governed by increased solubility of $PbSO_4$ in the acid, allowing reaction [4] to proceed at a higher rate. The solubility of $PbSO_4$ in H_2SO_4 was determined by Kameyama and Fukumoto (11) from 0.5–10.5 *N* H_2SO_4 and by Craig and Vinal (12) to 14.2 *N* and shows a maximum in 2.0 *N* where PbO_2 is the least stable.

Conclusions

The present study showed that the longer passivation times in dilute acids correspond to increased yields of $PbSO_4$ on the electrodes, that the efficiency of oxidation to PbO_2 of the $PbSO_4$ thus formed is higher the more dilute the acid, and that the stability of the PbO_2 in turn is greater the more concentrated the acid. The maximum length of the self-discharge plateau in 10.5 *N* H_2SO_4 can be explained in terms of the influence of two opposing factors, i.e. a decrease of the amount of PbO_2 formed on the anode and a simultaneous increase in PbO_2 stability with an increase in acid concentration.

Diffusivity measurements of the argon–mercury vapor system

H. B. SPENCER, J. M. TOGURI, AND J. A. KURTIS
Department of Metallurgy and Materials Science, University of Toronto, Toronto 5, Ontario
Received November 18, 1968

An experimental method for the determination of the diffusivities of metal vapor – gas mixtures has been examined. An investigation of the mercury vapor – argon system in the temperature range 180–340 °C indicated that the experimental diffusivities agreed well with the diffusivities calculated from the kinetic theory of gases. The temperature dependence of the diffusivity was found to vary with the absolute temperature to the 1.7 power.

Introduction

In reactions involving condensed systems with gaseous components, molecular diffusion in the gas phase can often be a rate-controlling step. Consequently, a knowledge of diffusivities is essential to the analysis of such processes. For high temperature systems, however, data on the diffusivities of metal vapor – gas mixtures are scarce.

Predictions of vapor and gas diffusivities can be obtained from the Chapman and Cowling (1) approximation (eq. [1]) of the rigorous theory developed by Enskog and Chapman for monoatomic gases

$$[1] \qquad D_{12} = \frac{0.0018583 T^{1.5}(1/M_1 + 1/M_2)^{1/2}}{P C r_{12}^{\,2}}$$

where D_{12} is the binary diffusivity in cm^2/s, T the absolute temperature in °K, M_1 and M_2 the molecular weights of the species 1 and 2 respectively, P the pressure in atm, C the collision integral, and r_{12} the arithmetic mean of the diameters of the colliding molecules in Å.

The derivation of eq. [1] is based on nonreacting systems of monatomic gases which are nonpolar and spherically symmetric. Furthermore, the gas densities must be low enough to allow collisions involving only two molecules to dominate.

The Lennard–Jones (12-6) model of intermolecular forces can be used as the basis for a numerical evaluation of the collision integral and collision diameter. The collision integral accounts for the dynamics of molecular interaction including the speeds, the masses, and the angles involved in the collisions. The values of this complex function based on the Lennard–Jones (12-6) model have been tabulated by Hirschfelder *et al.* (2) in terms of a reduced temperature, T_R, where $T_R = (k/\varepsilon)T$, and ε/k is the force constant.

For many gases and vapors, the force constants for the individual species are available from viscosity data or from calculations involving the second virial coefficient. However, for most metal vapors these sources of information are not available and, hence, empirical relationships based on the law of corresponding states are useful to determine the force constants. Hirschfelder *et al.* (2) showed that force constants for the Lennard–Jones (12-6) model, the reduced temperature T_R, and other reduced properties approximate to universal constants at critical points.

Based on these empirical relations, force constants and collision diameters may be estimated from the following expressions

$$[2] \qquad \varepsilon/k = 0.77\, T_c \quad \text{in °K}$$

$$[3] \qquad \varepsilon/k = 1.15\, T_b \quad \text{in °K}$$

$$[4] \qquad r = 0.841\, (V_c)^{1/3} \quad \text{in Å}$$

$$[5] \qquad r = 1.166\, (V_b)^{1/3} \quad \text{in Å}$$

The subscripts b and c refer to the boiling and critical temperatures respectively. V_b and V_c are the respective molar volumes of the liquid at the boiling and critical temperatures in $cm^3\ mole^{-1}$.

For mercury, the necessary parameters have been determined experimentally from viscosity measurements of mercury vapors. For the calculations in this paper, the data for mercury and argon cited by Hirschfelder are used. As shown in Table I, the mercury–argon system showed good correlation between the force constants obtained from the empirical equations and those calculated from viscosity data. The calculations also demonstrate that the calculated diffusivities

TABLE I

Comparison of force constants and diffusivities based on viscosity data and on empirical relationships for the argon–mercury vapor system

	Viscosity			Empirical	
	Ar	Hg	Ar–Hg	Hg	Ar–Hg
r (Å)	3.46	2.90	3.18	2.92*	3.19‡

§Calculated from $(\varepsilon_{Hg} \cdot \varepsilon_{Ar})^{1/2}$.

for the mercury–argon system were relatively insensitive to changes in the force constants. Hence, eqs. [2]–[5] appear to be satisfactory approximations in the determination of diffusivities of systems involving metal vapors for which no viscosity data are available. This view is also supported by Turkdogen (3).

The cumbersome nature of eq. [1] and the apparent deviation of experimental diffusivities from the theoretical values have led to many attempts to develop relationships with improved predictive powers. Generally these relationships have tended to be empirical. Two notable examples are the relationships developed by Chen and Othmer (4) and by Wilke and Lee (5).

The expression of Wilke and Lee is a modification of eq. [1] and is expressed as follows

$$[6] \qquad D_{12} = \frac{2BT^{3/2}\left(\frac{1}{M_1} + \frac{1}{M_2}\right)^{1/2}}{PCr_{12}^{\,2}}$$

where

$$B = 10.7 - 2.46\left(\frac{1}{M_1} + \frac{1}{M_2}\right)^{1/2}$$

The diffusivity becomes more dependent upon the molecular weights. The expression for B is determined empirically.

The Chen–Othmer approach is more rigorous. The lengthy collision integral table is eliminated by relating the collision integral to an expression containing the force constant, ε/k, and the absolute temperature. The force constants are then replaced by expressions involving critical temperatures and critical volumes. These relationships are then incorporated into the equation derived from the kinetic theory of gases. The various parameters required in the development of the relationship are determined by fitting the expression to the experimental data. The resulting equation is presented below

$$[7] \qquad D_{12} = \frac{0.43\left(\frac{T}{100}\right)^{1.81}\left(\frac{1}{M_1} + \frac{1}{M_2}\right)^{1/2}}{P\left(\frac{T_{C1}\,T_{C2}}{10\,000}\right)^{0.1405}\left[\left(\frac{V_{C1}}{100}\right)^{0.4} + \left(\frac{V_{C2}}{100}\right)^{0.4}\right]^2}$$

where C refers to the critical points.

The expression proves to be effective in predicting diffusivities of many systems. However, some difficulty can be expected in metal vapor systems where reliable critical data are scarce. This lack of data for metal vapor systems has prevented the estimation of reliable diffusivities for metal vapor – gas mixtures.

The present study was therefore carried out to examine a method of determining experimental values for the diffusivities of metal vapors in non-reacting atmospheres. The experimental technique is a modified version of the Stefan method (6). This method has been used by many investigators (7, 8) for measuring rates of evaporation of organic liquids near room temperature. In this investigation the technique was modified to examine the mercury–argon system in the temperature range 180–340 °C. The mercury–argon system was selected since the experimental

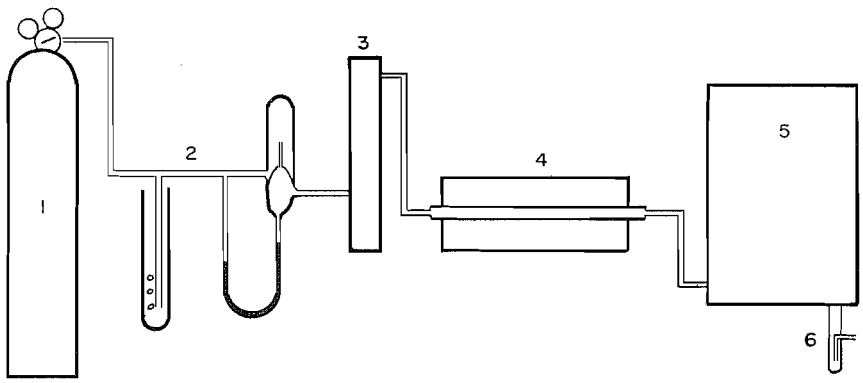

FIG. 1. Diagram of apparatus.

diffusivities could be compared with those calculated from the kinetic theory and from certain empirical relationships.

Experimental

(1) Theoretical Basis

Based on the Stefan method, a gas stream was passed over a vertical open mouth tube which was partially filled with the condensed phase of one of the components. A measure of the mass flux or the change in height of the column of the condensed phase allowed the determination of the diffusivity of the system.

The diffusion of the mercury vapor through the argon is accompanied by a bulk flow in the same direction, i.e. away from the surface of the condensed phase. At the same time, the corresponding upward bulk flow of argon is much smaller and is balanced by the downward molecular diffusion of the argon. Therefore, the argon gas above the mercury in the diffusion tube is considered to be a stagnant layer. The general expression for the molecular flux in a binary gas mixture is as follows

$$[8] \qquad N_1 = \frac{-D_{12}}{RT}\frac{dP_1}{dx} + \frac{P_1}{P_T}(N_1 + N_2)$$

where N_1 is the molar flux in g mole/cm² s, R the gas constant in mm Hg cc/g-mole °K, P_T the total pressure of system in mm Hg, and P_1 the partial pressure of species 1.

For the system under investigation, i.e. steady state diffusion of mercury vapor through stagnant argon, integration of eq. [8] and application of the condition $N_{Ar} = 0$ results in the following expression.

$$[9] \qquad N_{Hg} = \frac{D_{12} \cdot P_T \cdot (p_0 - p_s)}{R \cdot T \cdot L \cdot p_{lm}}$$

where L is the diffusion length in cm and p_0, p_s, and p_{lm} are partial pressures at the mouth of the diffusion tube, at the surface of the condensed phase, and the logarithmic mean of argon pressures, respectively.

Further reduction of the terms and conversion to c.g.s. units of mass flux produces the expression which was used in the present calculations

$$[10] \qquad D_{12} = 0.1757 \frac{T}{\alpha} \cdot \frac{w}{t} \cdot L$$

where w is the weight of condensed vapor in grams, t is the duration of the run in hours, and

$$\alpha = P_T \cdot \ln\left(\frac{P_T - p_0}{P_T - p_s}\right)$$

In this development, the diffusion length, L, is assumed to remain constant. This condition is approximated by keeping the change in length during a run to a small percentage of the overall diffusion length.

(2) Apparatus and Procedure

A schematic diagram of the apparatus is presented in Fig. 1. The copper gettering furnace, operated at 600 °C, reduced the oxygen pressure of the argon carrier gas to less than 10^{-10} mm Hg. The low oxygen pressure prevented the formation of an oxide film on the liquid mercury and also eliminated any chance of enhanced vaporization due to the formation of an oxide fog above the liquid (9). Calcium sulfate was used as the drying agent.

Figure 2 shows the arrangement of the diffusion and condensation cell with the furnace. In order to minimize temperature gradients along the vertical length of the diffusion cell, a graphite block was placed around the cell. The cell temperature was controlled to within ±1 °C. The gas entering the furnace was pre-heated in the vertical column filled with glass beads before passing over the diffusion cell.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

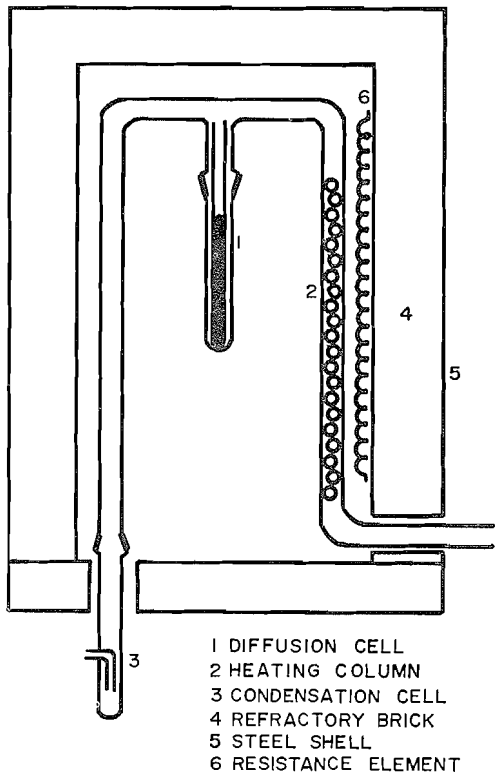

FIG. 2. Arrangement of diffusion and condensation cell.

The diffusion cell contained the Pyrex diffusion tube which was 15 cm in height and 0.792 ± 0.001 cm in internal diameter (i.d.). After passing over the diffusion cell and sweeping the mercury vapor away, the carrier gas entered the condensation cell. As the gas left the furnace and cooled, the mercury vapor condensed. The condensation cell extended into the furnace to insure that all condensation occurred within the cell. The lower 3 in. of the cell were immersed in an ice – water mixture to maintain a constant temperature for the effluent gas and to minimize vapor losses. The temperature of the effluent gas was 22 °C.

Before each run, the system was completely evacuated and then flushed with argon gas. This procedure eliminated an "incubation period" during the initial stages of the experiment. If air was left in the system, in particular in the stagnant gas layer above the condensed phase, molecular diffusion of oxygen and nitrogen was found to interfere with the diffusion of the mercury vapor for periods of 20–24 h.

The flow rate of the argon gas was 2.4 cc/s, a rate suggested by the earlier work of Kurtis (10). When the furnace had been at thermal equilibrium for 1 h, the condensation cell was inserted into the gas train. At the end of the run, the cell was removed. To prevent vapor losses from the cell as it cooled, the hot end of the condensation cell was stoppered. When the furnace had cooled to room temperature, the mercury level in the diffusion tube was measured. The final diffusion path length and the weight of condensed material collected provided the data necessary for the determination of the interdiffusivity of the system.

Runs lasted from 10–24 h depending on the initial height of mercury in the diffusion tube and on the temperature. Doubly distilled mercury was used throughout this study.

(3) Treatment of Data

At the end of each run, the distance from the top of the diffusion tube to the point of contact between the liquid mercury and the glass was measured. The change in height during the experiment was determined in the following manner

$$\text{Volume} = \frac{\text{weight}}{\text{density}}$$

$$\frac{\pi}{4} d^2 \Delta h = \frac{w}{\rho_{RT}}$$

$$[11] \qquad \Delta h = 0.150\, w$$

where d = i.d. of the diffusion tube in cm, Δh = the change in height in cm of the mercury column during the run, and ρ_{RT} = the density of mercury at room temperature in g/cc.

Two other corrections were necessary. Some factor was required to account for the meniscus, the top of which in the present case was 0.14 cm above the measured point at room temperature. In addition, when the furnace was cooled after the run, some diffusion still occurred. The resulting change in height combined with the effect of the meniscus was determined as 0.10 cm.

To estimate the effective diffusion length at operating conditions, the thermal expansion of the mercury column was considered. Neglecting the relatively small thermal expansion of the Pyrex tube, the correction took the following form

$$[12] \qquad L_T = (\rho_{RT}/\rho_T - 1) L_{Hg}$$

where L_T = change due to thermal expansion in cm, ρ_T = the density of mercury in g/cc at operating temperature, and L_{Hg} = the length of the mercury column at room temperature in cm.

The expression for the average diffusion length, L, is

$$[13] \qquad L = \frac{(2L_f - \Delta h)}{2} - 0.10 - L_T$$

where L_f = the measured length at the end of the run in cm.

The mercury vapor pressure at the mouth of the diffusion tube (p_0) can be assumed to be zero only if a high flow rate of carrier gas is used. The magnitude of p_0 was determined by assuming ideal behavior of the mercury vapor and by considering the flow rate and mass flux of the vapor. Thus

$$[14] \qquad p_0 = 0.0352 T \frac{w}{t}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

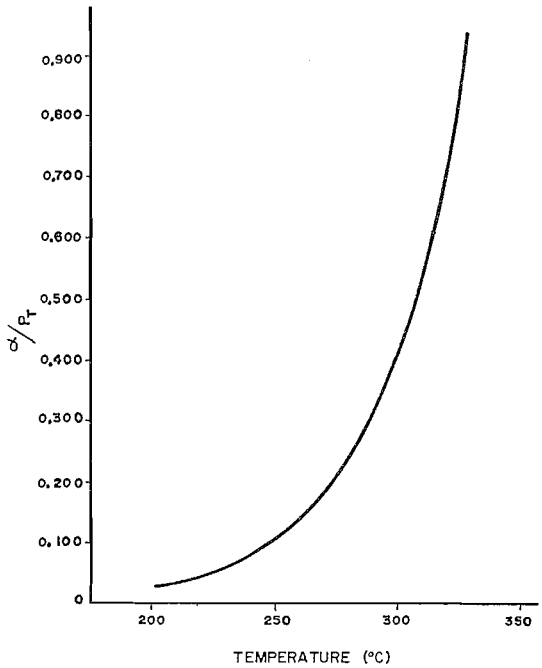

FIG. 3. Temperature dependence of α.

This correction was incorporated in the present calculations.

With the two quantities, p_0 and L, determined, the calculation of the diffusivity from eq. [10] is straightforward.

Results and Discussion

The temperature dependence of the diffusivity in eq. [10] centers on the absolute temperature, T, and the inverse of the function α. As shown in Fig. 3, the latter dependence was critical in the experimental analysis. Because of the strong dependence of this function on temperature, particularly above 280 °C, isothermal conditions were essential. A temperature profile study of the diffusion tube revealed that the temperature at the mouth of the tube was slightly higher (about 1 °C) than the temperature at a point 12 cm lower in the tube. This temperature gradient combined with the small diameter of the tube effectively eliminated any convection effects.

Wilke and Lee (8) have investigated the inherent errors in the Stefan tube technique. The turbulence effect at the mouth of the tube is of primary importance since it shortens the effective diffusion length. If turbulence occurs, the measured or apparent diffusion length is greater than the true length. The error introduced by this condition is calculated by plotting the inverse of the apparent diffusivities, all at the same temperature, against the inverse of the corresponding apparent diffusion lengths. A similar study was undertaken to determine the effect of turbulence in this experiment. At 278 °C, experimental values of 0.386 ± 0.024 and 0.389 ± 0.024 cm^2/s had diffusion lengths of 5.87 and 12.30 cm, respectively. Since the experimental uncertainty was greater than the difference between the two values and since the diffusivity with a shorter diffusion length was the smaller of the two, this quantitative study indicated that the turbulence effect was negligible. Accordingly, the effect was neglected in the calculations.

The experimental results are presented in Table II. A comparison of experimental and theoretical values found from eq. [1], using force constants and collision diameters estimated from viscosity data, is shown in Fig. 4. Data from other metal vapor – inert gas systems (3) are also included.

In Fig. 5, a comparison of the experimental diffusivities and the diffusivities calculated from eqs. [1], [6], and [7] are shown. At the higher

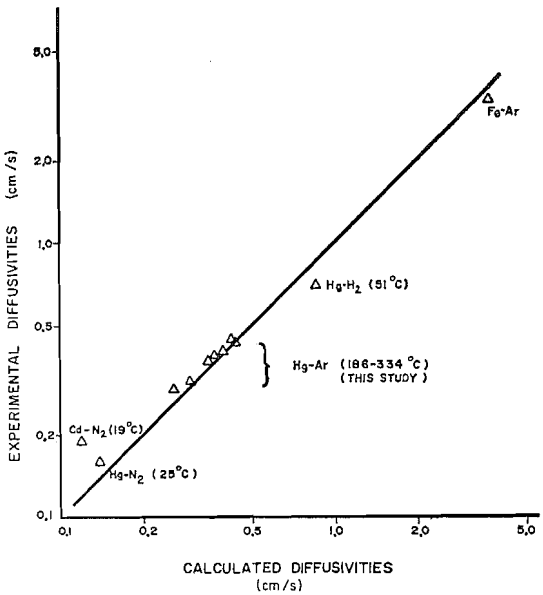

FIG. 4. Comparison of experimental and calculated diffusivities for various metal vapor – vapor systems.

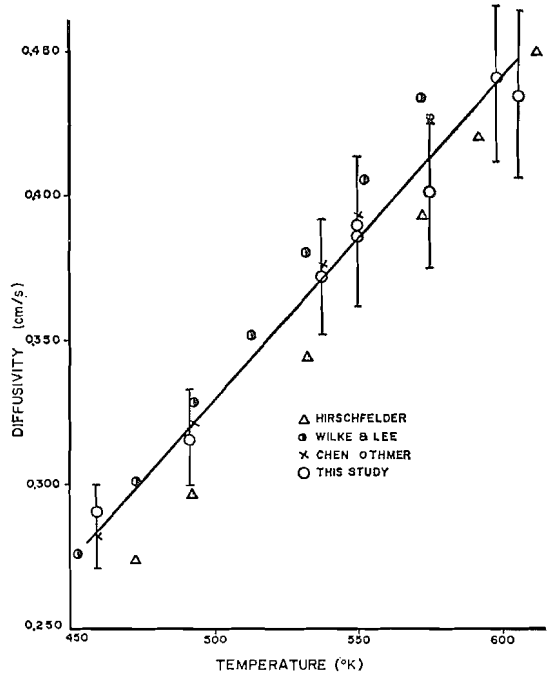

FIG. 5. Diffusivities for the Hg–Ar system as a function of temperature.

temperatures, the results tend to deviate from the trend established at the lower temperatures. The sensitivity of the function α accounts for a good part of the discrepancy, and for the large error limits in this range. The error limits of the value at 186 °C represent effects of a temperature decrease of 3 °C during part of the run.

Examination of Fig. 5 reveals good correlation of the data with the empirical relationships of eqs. [6] and [7], particularly with the Chen–Othmer relationship. Considering that the empirical expressions for diffusivities are based on studies of systems involving gases and organic vapors, the correlation obtained for this metal vapor system is excellent.

The experimental values of the diffusivities were consistently higher than the theoretical values found from eq. [1]. This may be due to the inadequacy of the Lennard–Jones (12-6) model and to the empirical rules for combining collision diameters and force constants to describe the binary mixtures. A further possible explanation for the high results depends on the existence of a more pronounced turbulence effect than that determined in the investigation of this condition. Turbulence to a depth of 1 cm in the diffusion tube would bring the experimental data into very good agreement with the theoretical values. However, a study of the turbulence effect did not justify a correction of this magnitude to the effective diffusion length.

As shown in eq. [1], the kinetic theory predicts that the temperature dependence of the diffusivity is the absolute temperature to the 3/2 power. A least mean squares analysis of the data from the runs between 180 and 326 °C inclusive produced a value of 1.70. This value is in good agreement with the results of similar analyses of other monatomic systems (11).

Conclusions

The results of this study demonstrated that the proposed technique can be useful in the investigation of the diffusivities of metal vapors. The experimental results for the mercury vapor – argon system were found to be in reasonably good agreement with values predicted by both the kinetic theory and other empirical relationships.

The effect of temperature on the diffusivity of mercury vapor – argon has been found to vary as $T^{1.7}$.

The temperature range over which the Stefan

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

tube technique can be usefully employed is somewhat restricted. At low temperatures, the small vapor pressures make it increasingly difficult to obtain suitably large samples in a reasonable period of time. At high temperatures, the increased sensitivity of the function α to temperature becomes important. Furthermore, this technique can not be used above the boiling point of the metal under consideration.

Oxidative addition of silicon hydrides to hydridocarbonyltris(triphenylphosphine)iridium(I)

J. F. HARROD, D. F. R. GILSON, AND R. CHARLES
Chemistry Department, McGill University, Montreal, Quebec

Received November 12, 1968

Complexes have been prepared by oxidation of hydridocarbonyltris(triphenylphosphine)iridium(I) with a variety of silicon hydrides. The complexes were very stable with respect to thermal loss of either silicon hydride or molecular hydrogen.

An unequivocal assignment of stereochemistry of the complexes was obtained from a combination of infrared and proton nuclear magnetic resonance (n.m.r.) techniques. Addition of the silicon hydride to the iridium complex was found to be stereospecifically *cis*.

Canadian Journal of Chemistry, 47, 2205 (1969)

Introduction

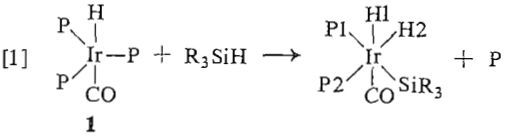
The oxidative addition of silicon hydrides to chlorocarbonylbis(triphenylphosphine)iridium(I) was previously studied as part of an investigation of the mechanism of metal ion catalyzed olefin hydrosilation (1). The complexes formed in this reaction were not suitable for an intensive investigation of structure and physical properties, because of their instability in solution and because the reaction was limited to silicon hydrides bearing electronegative substituents.

The present study was undertaken after it was established that hydridocarbonyltris(triphenylphosphine)iridium(I), **1**, reacted readily with silicon hydrides, and that even triaryl and trialkylsilanes yielded relatively stable adducts. These reactions were of particular interest because, on the one hand, there existed the possibility of an unequivocal assignment of stereochemistry using proton n.m.r. and infrared spectroscopies, and on the other hand, it was expected that reductive elimination of hydrogen from the adducts would provide a synthetic route to the hitherto unknown silylcarbonylbis(triphenylphosphine)iridium(I) complexes.

In the course of the present investigation the addition of some chloro-substituted silicon hydrides to tris(triphenylphosphine)chlororhodium(I) was reported by de Charentenay *et al.* (2). The presence of Rh—H in the adducts was detected by n.m.r., but a complete assignment of stereochemistry was not possible.

Results and Discussion

A variety of silicon hydrides was found to react rapidly with **1** to yield adducts according to [1]



1

where P = $(C_6H_5)_3P$.

Chemical analyses were obtained for the crystalline products resulting from additions of $(C_6H_5)_3SiH$, $(C_2H_5O)_3SiH$, and Cl_3SiH. Although difficulties were experienced in obtaining adducts with other silicon hydrides that were sufficiently pure for chemical analysis, the similarity of the infrared or n.m.r. spectra of all of the adducts leaves little doubt that they were isostructural.

All of the adducts exhibited a strong and weak band in the region of 2100 cm^{-1} in the infrared. These bands are assigned to the symmetric and antisymmetric Ir—H vibrations. In addition all complexes exhibited a band at ca. 1950 cm^{-1} due to the carbonyl group. Infrared data on all of the complexes prepared are summarized in Table I.

Proton n.m.r. spectra in the high field region, characteristic of protons directly bonded to transition metals, were obtained with the adducts derived from $(C_2H_5O)_3SiH$, $(C_6H_5)_3SiH$, and $(C_6H_5)(CH_3)_2SiH$. Each of these complexes gave a complicated splitting pattern interpreted as a 16 line spectrum, according to the correlation diagram illustrated in Fig. 1 for the triethoxysilyl derivative. The chemical shifts and coupling constants for all 3 complexes are listed in Table II. The 16 line spectrum is in accord with the stereochemistry depicted for the product in reaction [1], with regard to the relative positions of the protons and the phosphines, but does not

give any unequivocal indication of the relative position of the silicon and carbonyl groups. The insensitivity of the chemical shift values to variation of the substituents on the silicon suggested that the structure as in reaction [1] was in fact the correct one.

In order to prove the latter conclusion, a reaction was carried out between triethoxysilane and deuteridocarbonyltris(triphenylphosphine)-iridium(I) in equimolar amounts. The product of this reaction exhibited two carbonyl bands at 1965 and 2000 cm^{-1} and gave an n.m.r. spectrum identical to that shown in Fig. 1 except that the H–H coupling was no longer evident. These results find a ready interpretation in terms of the structure shown in Fig. 1, if it is assumed that the deuterium is equally distributed between the hydride positions. The carbonyl band at 2000 cm^{-1} may be assigned to CO *trans* to deuterium (3).

Some Properties of the Dihydridosilyliridium(III) Complexes

The adducts synthesized in the present work are of considerably greater stability than those formed from chlorocarbonylbis(triphenylphosphine)iridium(I), as evidenced by the ready formation of complexes with trialkyl and triarylsilanes. The order of stability, however, seems to be similar, since the trimethyl- and phenyl-dimethylsilyl derivatives were only completely formed in the presence of excess silane, whilst silanes containing a chloro- or ethoxy substituent gave an essentially complete reaction with equimolar quantities of reactants. This enhanced stability is in accord with the currently held belief that oxidative addition is promoted by the presence of electron releasing ligands on the reactant complex (4), hydride being more electron releasing than chloride.

The remarkable stability of the adducts with respect to loss of molecular hydrogen, may also be understood in terms of the above hypothesis. Pure samples of the triethoxy- and triphenylsilyl derivatives could be heated up to temperatures where charring occurred without loss of hydrogen or silicon hydride. Since silyl ligands seem to be very strong σ-donors (5), it would be expected (at least with the benefit of hindsight) that the hydrogen adduct of a silylcarbonylbis(triphenylphosphine)iridium complex would be extremely

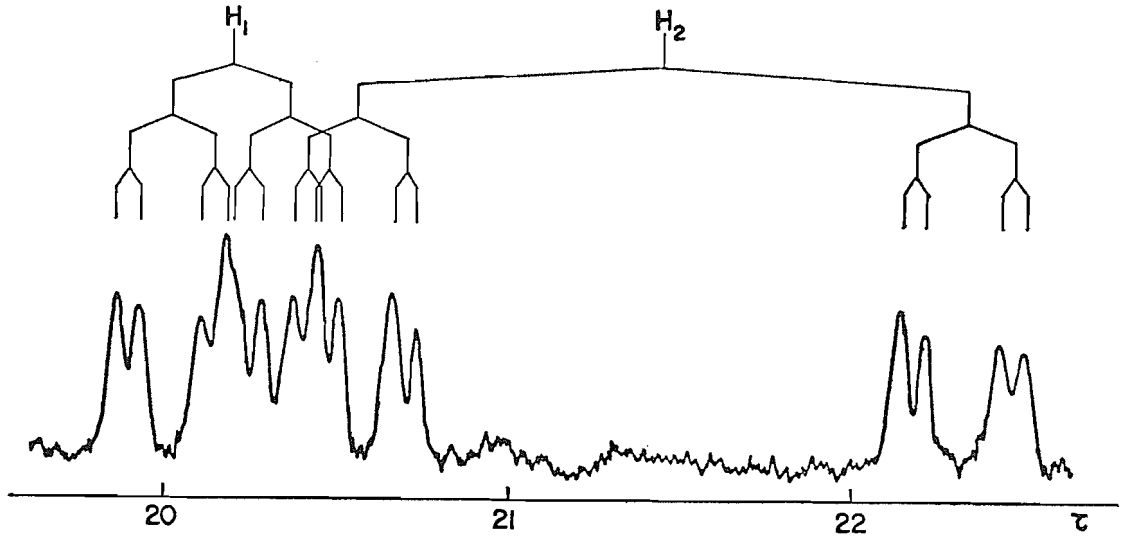

FIG. 1. Proton n.m.r. spectrum of dihydridotriethoxysilylcarbonylbis(triphenylphosphine)iridium(III) in the high field region (the coupling constants for this complex are given in Table II).

stable, and that our objective of preparing the latter by dehydrogenation of the former would not be realized.

At the time we obtained our results, we were surprised to find that the structure of our adducts was one in which the phosphine ligands were *cis* to each other, since all other analogous bisphosphine complexes for which structures had been reported contained the phosphines in the *trans* position. We could find no evidence for isomerization occurring, even though spectra could be run within a very short time of mixing the reactants.

Since we obtained these results, the addition of allyl halides to chlorocarbonylbis(phenyldimethylphosphine)iridium(I) to yield products with mutually *cis* phosphines has been reported by Deeming and Shaw (6). The similarity of the above reaction to the silicon hydride additions studied by us (at least from the point of view of stereochemistry) suggests a possible similarity in mechanism. Such an analogy would require a predissociation of the 5-coordinate complex **1** to a square planar intermediate as depicted in reaction [2]. Approach of the addend along the axis perpendicular to the plane of the molecule, accompanied by a simultaneous migration of the phosphine ligands in a direction away from the approaching addend, would give the required stereochemistry as in reaction [3].

A serious objection to such a simple scheme is

[2] 
1 **2**

[3] 
that the results of the experiment, where triethyoxysilane was added to the deuterido analogue of **1**, indicated that either of the hydrogen ligands in the product may originate from the silicon hydride. The fact that Deeming and Shaw obtained a mixture of isomers from the addition of allyl chloride to *trans* bromocarbonylbis(phenyldimethylphosphine)iridium (I), indicates that a similar lack of stereospecificity may also arise in that reaction.

The catalysis of SiH–SiD exchange by chlorocarbonylbis(triphenylphosphine)iridium(I) has been reported by Sommer and Lyons (7). We have found that hydridodeuteridotriethoxysilylcarbonylbis(triphenylphosphine)iridium(III) undergoes exchange with triethoxysilane. In principle such an exchange could occur, if reaction [1] was a rapid equilibrium, by repetitive oxidative addition and reductive elimination. Such a possibility does not, however, exist for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

chloro complex. In view of the extreme stability of the triethoxy derivative with respect to loss of silicon hydride, it seems more probable that these exchange reactions occur by a concerted bimolecular process. A kinetic investigation of such exchange reactions is in progress to test the validity of this hypothesis.

Experimental

Iridium trichloride trihydrate was obtained from Engelhard Industries Ltd. Chlorocarbonylbis(triphenylphosphine)iridium(I) was prepared by the method of Collman and Kang (8). Hydridocarbonyltris(triphenylphosphine)iridium(I) was prepared by the method of Vaska and Bath (9) in the initial stages of this work, but subsequently we obtained much better yields by the dehydrochlorination of chlorodihydrocarbonylbis(triphenylphosphine)iridium(III) with KOH in ethanol (10). Deuteridocarbonyltris(triphenylphosphine)iridium(I) was prepared according to Vaska (11).

Triphenyl-, trimethyl-, triethoxy-, and trichloro-silanes were obtained from Penninsular Chemresearch Ltd. Methyldichlorosilane and phenyldimethylsilane were gifts from the General Electric Co.

Preparation of Dihydrido(triethoxysilyl)bis(triphenylphosphine)iridium(III)

A sample of **1** (0.3 g) was dissolved in dry benzene (5 ml) and placed on a vacuum transfer line. After the solution had been thoroughly degassed, triethoxysilane (1.0 g) was distilled onto it and the reactants were then left at room temperature for 1 h. During this time the initially yellow solution became almost colorless. All volatile material was pumped off by prolonged evacuation at room temperature to yield a yellow oil. Trituration of this oil with a small amount of hexane yielded pale yellow crystals, which on recrystallization from hexane became white. Yield (after recrystallization): 0.24 g (78%), melting point 152–154 °C.

Anal. Calcd. for $IrC_{45}H_{47}O_4P_2Si$: C, 56.72; H, 5.17; Si, 3.08; P, 6.80. Found: C, 56.68; H, 5.35; Si, 2.84; P, 6.63.

The phenyldimethylsilane adduct was prepared by the same procedure, but the complex underwent dissociation during attempts to recrystallize. An impure sample of the phenyldimethyl adduct was found to undergo loss of silane on heating to ca. 120 °C.

Preparation of the Trichlorosilane and Methyldichlorosilane Adducts

A sample of **1** was dissolved in dry dichloromethane (0.3 g in 10 ml) and attached to a vacuum transfer line. Trichlorosilane (0.6 g) was distilled onto the solution and the mixture was allowed to warm to room temperature. On reducing the volume of the solution, white crystals of the product were obtained. The product was filtered in nitrogen, washed with a little dry dichloromethane, and dried *in vacuo*. The product neither melted nor decomposed below 300 °C. Yield: 0.24 g (88%).

Anal. Calcd. for $C_{37}H_{32}OP_2Cl_3SiIr$: C, 50.4; H, 3.64; Si, 3.2; P, 7.04. Found: C, 51.0; H, 3.83; Si, 3.76; P, 6.90.

The methyldichlorosilane adduct was prepared by the same procedure and had physical properties virtually identical to the trichlorosilane adduct.

Anal. Calcd. for $C_{38}H_{35}OP_2Cl_2SiIr$: C, 53.0; H, 4.1; Si, 3.3; P, 7.2. Found: C, 57.0; H, 4.9; Si, 3.3; P, 7.5.

The very high values for C, H, and P in this analysis indicate incomplete separation of the product from uncomplexed triphenylphosphine.

Preparation of the Triphenylsilane Adduct

A mixture of **1** (0.22 g) and triphenylsilane (0.06 g) was dissolved in dry benzene (10 ml). The solution was evaporated to dryness on a vacuum transfer line and the residue was redissolved in benzene. Careful addition of hexane to this solution caused the product to precipitate free of triphenylphosphine. The precipitate was filtered and washed with hexane. Yield: 0.20 g (90%), decomposing at 160 °C.

Anal. Calcd. for $C_{55}H_{47}OP_2SiIr$: C, 65.68; H, 4.71; Si, 2.79; P, 6.17. Found: C, 65.87; H, 4.9; Si, 3.08; P, 6.09.

The Trimethylsilane Adduct

Excess trimethylsilane was distilled directly from the cylinder onto a solution of **1** in benzene at 0 °C. On warming the solution to room temperature the intense yellow color characteristic of **1** faded considerably, indicating rapid formation of the adduct. All attempts to isolate the adduct, either by solvent removal, or by precipitation, resulted in the decomposition of the adduct by loss of silane.

Spectroscopic Measurements

Infrared spectra were measured on a Perkin–Elmer model 257 spectrometer.

Proton n.m.r spectra were measured with a Varian A60 spectrometer coupled to a Varian C1024 averaging computer. Generally about 50 scans at 250 s were required for spectra such as those illustrated in Fig. 1. Samples were saturated solutions in dichloromethane.

Complexes of Group IV halides with mercuric thiocyanate and mercuric cyanide as ligands

S. C. JAIN AND R. RIVEST
Department of Chemistry, University of Montreal, Montreal 3, Quebec

Received October 21, 1968

Coordination compounds between mercuric thiocyanate and mercuric cyanide as ligands and the Group IV halides as Lewis acids have been prepared and their infrared (i.r.) spectra (4000–200 cm^{-1}) examined. Two types of compounds, $MX_4 \cdot L$ and $MX_4 \cdot 2L$ where M = Ti, Sn; X = Cl, Br; and L = $Hg(SCN)_2$ or $Hg(CN)_2$ were characterized. On the basis of i.r. spectral results, possible coordination through the thiocyanato and cyano groups has been discussed.

Les composés de coordination entre le thiocyanate mercurique et le cyanure mercurique comme ligands et les halogénures des éléments du Groupe IV comme acides de Lewis ont été préparés et leurs spectres infrarouges mesurés de 4000 à 200 cm^{-1}. Deux genres de composés ont été obtenus soit: $MX_4 \cdot L$ et $MX_4 \cdot 2L$ où M = Ti, Sn; X = Cl, Br; et L = $Hg(SCN)_2$ ou $Hg(CN)_2$. D'après les résultats obtenus dans l'infrarouge on discute de la coordination possible par l'intermédiaire du groupe thiocyanato et cyano.

Canadian Journal of Chemistry, 47, 2209 (1969)

Introduction

We have previously reported the formation of coordination complexes between organic cyanides (nitriles) (1) or organic thiocyanates (2) and Group IV halides. Since Jones (3) and Lewis *et al.* (4) have concluded that the Hg—C bond in $Hg(CN)_2$ and Hg—S bond in $Hg(SCN)_2$ are strong covalent bonds, it was considered interesting to use $Hg(CN)_2$ and $Hg(SCN)_2$ as ligands towards Group IV halides and compare their donor behavior with those of organic cyanides and thiocyanates.

Experimental

Since the Group IV halides are highly hygroscopic, all the experimental manipulations were carried out in a dry box continuously flushed with dry nitrogen. The experimental set up and the method of preparation of the complexes were similar to the ones discussed previously (1, 5). Lewis acids used were purified by suitable methods (1) and the solvent methylene chloride was dried over phosphorus pentoxide and fractionally distilled before use. Mercury thiocyanate and cyanide (purified) were obtained from the City Chemical Corporation, New York, and used as such after drying in vacuo.

Since the mercury compounds were found insoluble in common organic inert solvents, the reactions were performed in large excesses of Lewis acids by taking the ligands in suspension (6). The reactants were normally allowed to react for 4–6 days with magnetic stirring at room temperature. In each case solid powdery compounds were obtained which were filtered, washed with the solvent, and dried in vacuo at room temperature.

The analyses for titanium and mercury were made gravimetrically by weighing as TiO_2 and $[Cuen_2][HgI_4]$ (7) respectively. Sulfur, nitrogen, and halogens were determined by Organic Micro-analyses, 5757 Decelles Ave., Montreal. The analytical results are included in Table I.

The i.r. spectra were recorded on a Perkin–Elmer spectrophotometer model 621 in Nujol mull. In the case of mercuric cyanide compounds, cesium iodide disks were used over the range 4000–200 cm^{-1}. In the case of mercuric thiocyanate coumpounds, however, where cesium iodide seems to interact, sodium chloride disks were used over the range of 4000-600 cm^{-1} and polyethylene disks were used for the range 600–200 cm^{-1}. The i.r. spectral results are reported in Table II.

Results and Discussion

The analytical results (Table I) indicate that Group IV halides form two types of adducts with $Hg(SCN)_2$ and $Hg(CN)_2$ i.e. 1:1 and 1:2. It is well known (1, 8, 9) that as a result of coordination through the electron pair on nitrogen of the cyano group, the cyano stretching frequency, ν(CN) shows a hypsochromic effect. A coordination through the π electrons of the triple bond, on the other hand, would result in the appearance of a bathochromic effect on the CN stretching frequency (10–12).

The i.r. spectral results in the cyano stretching region (Table II) for the 1:1 adducts show the ν(CN) shifted to higher positions, whereas for the 1:2 adducts both shifted and unshifted bands are observed (Fig. 1). The increase in ν(CN) for the compounds may be attributed to a change in CN force constant, or may be due to bridging between two metal atoms. Since the 1:2 adducts display both shifted and unshifted ν(CN) bands and the 1:1 adducts display only shifted ν(CN) bands, it seems more likely that the increase in

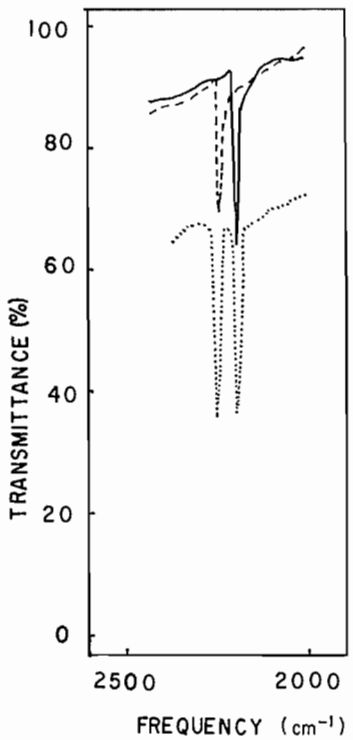

FIG. 1. Infrared spectra in ν(CN) region; —, $Hg(CN)_2$; - - -, $TiCl_4 \cdot Hg(CN)_2$; · · ·, $SnCl_4 \cdot 2Hg(CN)_2$.

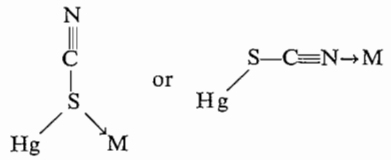
ν(CN) is mainly due to bridging between two metal atoms. ν(CN) is known (13) to appear at a higher position for a bridging cyano group than for a non-bridging one. Mitchell and Williams (14) reached a similar conclusion with regard to the cyanide stretching frequency for a bridging thiocyanate group. Such a group has two possibilities for bridging, i.e. either through the sulfur atom or through the nitrogen atom as shown below.



On the basis of X-ray crystallography Chatt and Hart (15) have concluded that in the great majority of bridged complex thiocyanates, bridging takes place through both the sulfur and the nitrogen atoms. In fact, AgSCN in the pure state consists of infinite chains of structure (16) ··Ag—S—C—N→Ag··· in which the thiocyanato bridge is also formed through both the sulfur and the nitrogen atoms. In the pure state mercuric thiocyanate is also likely to consist of bridging thiocyanate groups similar to AgSCN.

In our 1:1 adducts, it seems that both the cyano groups of $Hg(CN)_2$ or $Hg(SCN)_2$ coordinate to the Group IV metal atoms but in the 1:2 adducts only one of the functional group coordinates, while the other one remains unaffected. The i.r. spectrum shows two ν(CN) peaks corresponding to the two types of thiocyanato or cyano groups (14). The fact that these compounds are not soluble in commonly used organic inert solvents makes it rather difficult to study further their physico-chemical nature in support of their structure. Since the cyano (17) and the thiocyanato groups are almost linear in nature, it is reasonable to believe that in the 1:1 adducts both the functional groups coordinate to different metal atoms forming compounds polymeric in nature. On the other hand, in the 1:2 adducts, the unshifted ν(CN) bands may be due to terminal CN or SCN groups or to bridging functional groups between two mercury atoms. Since the position of these bands is almost the same in the complexes and in pure $Hg(CN)_2$, where the CN groups are known to be bridging between two mercury atoms (13), it is quite sure that the same type of bridging still exists in the complexes with Group IV halides. As a result of this, these compounds also are probably polymeric in nature.

Another important feature of the i.r. results is that in the compounds formed, the cyano or thiocyano groups are not completely ionic, because a free ionic CN^- group displays a ν(CN) band at a much lower region (18) than the ones observed in the present case. Moreover, $Hg(CN)_2$, being a covalent molecule (3), is less likely to ionize in a nonpolar solvent like CH_2Cl_2 to give CN^- ions.

A comparison of $Hg(CN)_2$ or $Hg(SCN)_2$ with organic cyanides or thiocyanates (1, 2) as ligands towards Group IV halides, is difficult to make. $Hg(SCN)_2$ or $Hg(CN)_2$ as solids are said to contain SCN or CN bridging between neighboring Hg atoms (13). So the shift or increase in ν(CN) on coordination with Group IV metals is not necessarily the difference between the ν(CN) of the terminal cyano group and the bridging cyano group.

To obtain the position of terminal ν(CN) and ν(SCN) bands we recorded i.r. spectra of $Hg(CN)_2$ and $Hg(SCN)_2$ in Nujol mulls and compared them with those taken in tetrahydrofuran solution. In the case of $Hg(CN)_2$ the i.r. spectrum recorded in solution showed the ν(CN) band 8 cm^{-1} lower than the one observed in the spectrum taken in Nujol, while in the case of $Hg(SCN)_2$, the ν(SCN) band position remained unchanged. This would suggest that there is only very weak bridging interaction between two $Hg(SCN)_2$ or two $Hg(CN)_2$ molecules. The fact that the N—Hg distance in solid $Hg(CN)_2$ is 2.70 Å as compared to 1.99 Å for Hg—C (19) strongly indicates that the bridging effect in the ligands in the pure state is very weak. Actually a fairly strong N—Hg bond would be needed to effect the ν(CN) vibration. If one considers the magnitude of the positive shift, Δν(CN) as the measure of basicity of the CN or S—CN groups in an organic or inorganic ligand and takes 2195 and 2116 cm^{-1} as the terminal ν(CN) bands for $Hg(CN)_2$ and $Hg(SCN)_2$, respectively, then it is interesting to note that in organic cyanides and thiocyanates (1, 2), cyanide seems to be a better donor than the corresponding thio compound as shown below

Compound	Δν(CN) (cm^{-1})	Reference
$TiCl_4(—CH_2CN)_2$	53	1
$TiCl_4(—CH_2SCN)_2$	30	2
$2TiCl_4(—CH_2CN)_2$	56	1
$2TiCl_4(—CH_2SCN)_2$	40	2
$TiCl_4 \cdot Hg(CN)_2$	46	This work
$TiCl_4 \cdot Hg(SCN)_2$	55	This work

but in the case of $Hg(CN)_2$ and $Hg(SCN)_2$, the thiocyanate molecule shows a larger Δν(CN) on coordination with titanium.

Far Infrared Spectral Studies

(a) MX_4 and $Hg(CN)_2$ Compounds

In addition to the metal–halogen and the metal–ligand stretching bands, these compounds would exhibit Hg—C stretching, and Hg—CN and C—Hg—C bending bands in the low frequency region. Since the C—Hg—C bending band appears below the 200 cm^{-1} range (20) we will discuss only the ν(M—X), ν(Hg—C), and δ(Hg—CN) bands.

ν(M—X) bands

The ν(M—X) bands are usually strong bands and their identification can be made easily by comparing the positions of ν(M—Cl) and ν(M—Br) bands in identical compounds. ν(M—Br) bands normally appear in a much lower region than the ν(M—Cl) bands. Our assignments of the ν(M—X) bands are given in Table II and the results are in good agreement with the

values reported previously (6, 21, 22), and correspond to the value for which the central metal atom exhibits a coordination number six (23).

ν(Hg—C) bands

The bands at 411 and 422 cm^{-1} for $Hg(CN)_2$ are assigned to ν(Hg—C) (3). In the 1:1 adduct $TiCl_4 \cdot Hg(CN)_2$ these bands disappear and new medium bands appear at 502 and 495 cm^{-1} which probably are shifted ν(Hg—C) bands. Shifting of the ν(Hg—C) bands to a higher frequency region may be due to coupling of the ν(Hg—C) with the ν(CN) in the Hg—CN part of the molecule. Since the ν(CN) shifts to a higher position on coordination, the ν(Hg—C) should show a similar effect. It is interesting to note that in the $MX_4 \cdot 2Hg(CN)_2$ compounds the i.r. spectra show both the shifted ν(Hg—C) bands due to coordinated (bridged) cyano group and the unshifted bands due to the CN groups which remain unaffected. In fact a similar effect in the ν(CN) region further supports our interpretation that in the 1:2 adducts we have two types of cyano groups, one bridging between mercury and titanium, and another probably bridging between mercury and mercury.

δ(Hg—CN) bands

In the spectrum of $Hg(CN)_2$ we observed δ(Hg—CN) at 338 cm^{-1} as a weak band. In the literature (3) the value reported for this band is 341 cm^{-1}. In the complexes of Group IV halides this band seems to remain almost unchanged. Since strong ν(Ti—Br) and ν(Sn—Cl) bands also appear in the same region, in the spectra of the complexes $TiBr_4 \cdot 2Hg(CN)_2$ and $SnCl_4 \cdot 2Hg(CN)_2$ most probably the δ(Hg—CN) bands are hidden under the strong ν(M—X) bands.

(b) MX_4 and $Hg(SCN)_2$ Compounds

ν(M—X) bands

Assignment of the ν(M—X) bands in these compounds is in good agreement to the corresponding bands already discussed in the previous section. In these compounds also the Group IV metals seem to exhibit a coordination number of six.

ν(C—S) bands (4, 24, 25)

For a thiocyanato group the ν(C—S) occurs between 690 and 720 cm^{-1} (24, 25). In the i.r. spectrum of $Hg(SCN)_2$ we assign a band at 722 cm^{-1} to the ν(C—S) vibration. As a result of coordination, the ν(C—S) shifts to a higher position. Clark and Williams (24) also observed that both the ν(C—N) and ν(C—S) stretching frequencies increase on coordination of the thiocyanate ion to the metal.

The Thiocyanato Bending Mode δ(S—C≡N) (4, 25)

The behavior of N—C≡S bending vibration has been discussed by Sabatini and Bertini (25) on the basis of its bonding to the metal atom through the sulfur or nitrogen. The S-bonded thiocyanato compounds absorb at a lower frequency region than the N-bonded ones. The S-bonded groups also show more than one δ(SCN) band. In the case of S-bonded $Hg(SCN)_2$ we observe two bands in the δ(SCN) range, Table II. The spectra of complexes with Group IV halides show 3–4 bands in this region which appear at higher positions than the bands for pure $Hg(SCN)_2$. In a system where S—C≡N is bridging between two different metals Hg—S—C≡T—Ti, there are both S-bonded and N-bonded groups at the same time; thus an increase in the number and the positions of δ(SCN) is not surprising.

Mercury–Sulfur Stretching Band: ν(Hg—S)

Sabatini *et al.* (25) report the ν(Hg—S) band at 285 cm^{-1} for $K_2[Hg(SCN)]_4$ compound. The spectrum of $Hg(SCN)_2$ shows a strong band at 306 cm^{-1} which could be associated with the ν(Hg—S) vibration. Since a number of ν(M—X) bands also appear in this region (Table II), it is not safe to comment on the effect of coordination of $Hg(SCN)_2$ to MX_4 on the ν(Hg—S) vibration. However, a band at 301 cm^{-1} for $TiCl_4 \cdot Hg(SCN)_2$ where the ν(Ti—Cl) are expected to appear at a higher position than 300 cm^{-1} shows that the ν(Hg—S) is not much affected when the SCN groups of $Hg(SCN)_2$ coordinate to titanium through the nitrogen atom. Clark (24) also noticed the very small effect that bridging of the NCS group has on the (M—NCS) stretching mode.

Crystal structure of $\beta'Mn_3(PO_4)_2$

J. S. STEPHENS[1] AND C. CALVO

Department of Physics and Institute for Materials Research, McMaster University, Hamilton, Ontario

Received March 19, 1968

$\beta'Mn_3(PO_4)_2$ crystallizes as a monoclinic crystal with lattice parameters $a = 8.94(3)$ Å, $b = 10.04(2)$ Å, $c = 24.12(12)$ Å, $\beta = 120.8(1)°$, and $Z = 12$. The diffraction pattern shows a pronounced superlattice phenomenon with reflections generally weak if their l index $\neq 0$ mod 3. The conventional R value for a total of 3516 reflections, of which 1637 were strong enough to be measured,was reduced to 0.09 by full matrix least squares procedures. This structure is related to that of $\beta Zn_3(PO_4)_2$ whose unit cell dimensions are comparable save for a tripled c axis in $\beta'Mn_3(PO_4)_2$. In addition, the latter compound is isostructural with the low temperature form of $Cd_3(PO_4)_2$. The PO_4^{3-} groups are slightly irregular tetrahedra with a mean P—O bond distance of 1.54 ± 0.01 Å. The coordination numbers of the cations have increased on the average in comparison to $\beta Zn_3(PO_4)_2$ where they are 4, 5, and 5 for the three unique cations. In $\beta'Mn_3(PO_4)_2$ each cation shows 5 strong Mn—O bonds and most cations have one additional bond of intermediate strength. The metal–oxygen atom bond distances in $\beta'Mn_3(PO_4)_2$ range from 2.03 to 2.31 Å although there are some additional long ones ranging from 2.4 to 3.0 Å which can be correlated with normal bond lengths in $\beta Zn_3(PO_4)_2$.

Introduction

Two crystalline modifications of $Mn_3(PO_4)$ are known (1). One has a structure similar to that of the mineral graftonite, a solid solution represented as $(Fe,Mn,Ca)_3(PO_4)_2$ (2). The second has a Debye–Scherrer pattern very similar to that of $\beta Zn_3(PO_4)_2$. Further, the pattern of $Cd_3(PO_4)_2$ (3) also appeared closely related to that of $\beta Zn_3(PO_4)_2$ and therefore a structural similarity was anticipated. The close structural relationship between $Cd_3(PO_4)_2$ and $\beta Zn_3(PO_4)_2$ was confirmed in that single crystal data from the former phase were used in elucidating the crystal structure of $\beta Zn_3(PO_4)_2$ (4). The structure of this phase of $Mn_3(PO_4)_2$ was examined in detail in order to consider further the question of direct cation substitution of Mn^{2+} in $\beta Zn_3(PO_4)_2$.

This and related crystallographic studies on the $M_3(XO_4)_2$ systems, where the XO_4^{3-} group has a tetrahedral configuration and M is a divalent ion of moderately small radius ($\leqslant 1$ Å), show a surprising number of crystallographically distinct phases. Even among those phases of a common structural type, the cations coordination numbers vary as the composition of a given cation site is changed (5). A comparison of the structures of $\beta Zn_3(PO_4)_2$ and $\beta'Mn_3(PO_4)_2$ indicates that similar changes occur here, resulting in slightly different structures for these phases.

Katnack and Hummel (6) have studied the phase diagram of the $ZnO - MnO - P_2O_5$ system. Above 900 °C the β form of $Zn_3(PO_4)_2$ appears to be stable up to a composition of about 30 mole % of Mn^{2+}. Beyond this composition $\beta Zn_3(PO_4)_2$ is no longer the stable phase although this instability might be due to the oxidation of Mn (6). Below 900 °C and above 5% $Mn_3(PO_4)_2$ a solid solution, commonly called "γ" $Zn_3(PO_4)_2$, is stable. The structure of this phase has been reported previously (7).

The structural similarity between $\beta Zn_3(PO_4)_2$ and $Cd_3(PO_4)_2$ and this phase of $Mn_3(PO_4)_2$ can be implied by labelling these phases as $\beta'Cd_3(PO_4)_2$ and $\beta'Mn_3(PO_4)_2$. $\beta'Cd_3(PO_4)_2$ has a high temperature phase transition necessarily involving small atomic displacements (8) and therefore may transform to a phase like that of $\beta Zn_3(PO_4)_2$ but not identical with it.

Experimental

$Mn_3(PO)_2 \cdot 7H_2O$, obtained from Fisher Scientific Co., was dried to remove the water and then fused in a sealed evacuated Vycor tube with an oxygen-gas flame. Crystals were grown upon slowly removing the flame and allowing the sample to cool across its melting temperature, reported to be 1119 °C (9). The crystals, whose color varied from dirty brown to nearly colorless, had plate-like morphologies. Preliminary X-ray photographs showed that they were monoclinic with the space group $P2_1/c$, since the systematic extinctions were the l odd reflections of $h0l$ set and k odd reflections of $0k0$ set. Also it was

[1]Present address: Chemistry Department, University of Manchester Institute of Science and Technology, Manchester 1, England.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

apparent, particularly at low angles, that the structure showed a pronounced superstructure. This indicated that the c axis was tripled, because of small displacements of the atoms from an average structure, since all strong reflections had their l Miller index equal to 0 mod 3.

A small fragment, broken from one of the less colored single crystals, was mounted on a glass fiber and aligned so as to rotate around the b axis. The crystal had dimensions $0.07 \times 0.15 \times 0.10$ mm^3 with the long axis parallel to the axis of rotation. Intensity data of the $h0l$ and the $h1l$ planes were recorded with a Weissenberg camera using MoKα radiation while the [100] and [001] zones were photographed on a precession camera with the same radiation. The intensities of these reflections were estimated visually and corrected for Lorentz and polarization effects but not for absorption.

The lattice parameters were determined with the same crystal. The b axis length was determined from a rotation photograph calibrated by a superimposed TiO_2 pattern. The lattice parameters of the rutile crystals, which had been grown by the Verneuil technique, were taken to be $a = 4.5929(5)$ Å and $c = 2.9591(3)$ Å, after Cromer and Herrington (10).

The lengths of the reciprocal axes, a^* and c^*, were determined from the films of the [100] and [001] zones calibrated by the previously determined b axis. The β angle was determined from the spindle readings on the precession camera when the [100] and [001] zones were photographed. The density was measured with a pycnometer. The crystal data are recorded in Table I.

In addition to forming the β′ structure, $Mn_3(PO_4)_2$ can be crystallized with the graftonite structure. The conditions which determine the formation of each of these phases are uncertain. Although the graftonite-like phase appears with greater frequency than the β′ phase and can be produced at will, both phases have been obtained a number of times. An effort was made to determine the systematics for the formation of the β′ phase. An analysis of Fisher's "$Mn_3(PO_4)_2 \cdot 7H_2O$" showed it contained a substantial amount of $MnHPO_4$. Thus, it was postulated that the β′ structure formed in the presence of $Mn_2P_2O_7$, which is the decomposition product of $MnHPO_4$. This can be understood if graftonite is regarded as the stable phase at the melting temperature, the β′ phase is stable at lower temperatures, and if the transformation between the phases is irreversible and sluggish. The β′ phase would then result if the melting temperature of $Mn_3(PO_4)_2$ could be reduced by adding a compound like $Mn_2P_2O_7$ to the liquid phase. Attempts to prove this hypothesis by obtaining the β′ phase from $Mn_3(PO_4)_2$ – $Mn_2P_2O_7$ mixtures proved unsuccessful since only the graftonite form could be detected.

Structure Solution

The structure was solved by taking advantage of the fact that both $\beta Zn_3(PO_4)_2$ and $\beta' Cd_3(PO_4)_2$ have structures similar to that of $\beta' Mn_3(PO_4)$. The average cation positions in $Cd_3(PO_4)_2$ were determined from Patterson projections prepared with the $l = 0$ mod 3 reflections. These were used to elucidate the cation positions in $\beta Zn_3(PO_4)_2$ and eventually the entire structure of this compound (4). The final atomic coordinates of $\beta Zn_3(PO_4)_2$ were used to find the "average" positions of the atoms in $Cd_3(PO_4)_2$ and $Mn_3(PO_4)_2$ using the $l = 0$ mod 3 data only. By "average" or "average structure" is meant the positions r_j where the position of the jth atom in the nth sub-cell along the c axis is given by $R_{jn} = r_j + \varepsilon_{jn} + nc/3$ and $n (= 0, 1, 2)$ is the index defining the sub-cell. The average positions are chosen so that the displacements from these positions, ε_{jn}, average to zero, i.e. $\sum_{n=0} \varepsilon_{jn} = 0$. The structure factor for these $l = 0$ mod 3 reflections is

$$[1] \quad F(H) = \sum_n \sum_j f_j(H)\, e^{2\pi i H\cdot(r_j+\varepsilon_{jn}+nc/3)} = \sum_n \sum_j f_j(H)\, e^{2\pi i H\cdot(r_j+\varepsilon_{jn})} = \sum_j f_j(H)\, e^{2\pi i H\cdot r_j} \sum_n (1 + 2\pi i H\cdot\varepsilon_{jn} + \ldots)$$

If the ε_{jn}'s are small and/or if only low order reflections are used, the structure factor

$$[2] \quad F(H) = \sum_j f_j(H)\, e^{2\pi i H\cdot r_j}$$

is that corresponding to the average structure only. The "average" β′ structure was refined by difference synthesis and least squares refinement until the value of

$$R_2 = \left[\frac{(\sum\omega||F_o| - |F_c||)^2}{\sum\omega|F_o|^2}\right]^{\frac{1}{2}}$$

had reached a minimum for $Cd_3(PO_4)_2$ first. These coordinates were then used as those of the average structure of $\beta' Mn_3(PO_4)_2$. Refinement was continued until no further improvement in the agreement was noted. At this point R_2 was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

0.2 but the PO_4^{3-} groups were unrealistically distorted and the isotropic temperature factors for the oxygen atoms ranged from moderate negative values to large positive values.

The values for the ε_{jn} were now determined. Since the average intensity of the $l \neq 0$ mod 3 reflections relative to that of the $l = 0$ mod 3 reflections was larger in β′$Mn_3(PO_4)_2$ than in β′$Cd_3(PO_4)_2$, the data of the former were used to obtain the trial structure for the proper unit cell.

The signs of 15 reflections of the type $h0l$ with $l \neq 0$ mod 3 were determined using inequality relationships amongst the unitary structure factors (11). Of these 15 signs, 13 were related to a parameter p, which could be + or −; the remaining two signs were predicted to be +, independent of the choice of sign for p.

Subsequent electron density sections were calculated in the region of the average cation positions using these 15 reflections for both $p = -$ and +. These sections were treated as though they were difference density maps, and the displacements, ε_{jn}, for the cations estimated from the density gradients at their average positions. Subsequent structure factor calculations using all the $h0l$ data yielded slightly better agreement for the choice $p = +$. The refinement was continued with the set of displacements resulting from this choice, but the $h1l$ data were excluded, so that it could be used as an independent check on the validity of the displacements at a later stage. Scattering factors were obtained from the International tables for X-ray crystallography (12).

The phosphorus and oxygen atoms were placed close to their average positions such that the PO_4^{3-} groups became regular tetrahedra and their coordinates refined by least squares. A full matrix least squares program, written by one of the authors (J.S.S.) for the I.B.M. 7040, was employed. The temperature factors were not varied during the initial stages, and approximate tetrahedral geometry was enforced on the phosphate groups by shifting the oxygen atoms radially to give P—O bond lengths of 1.54 Å whenever these distances departed by more than 0.05 Å from this value.

After several cycles of refinement, the $|F_c|$ (calculated structure factors), seemed to be too small for the $l \neq 0$ mod 3 reflections. The weighing scheme was changed from unit weights on all reflections to one where the weights of $l \neq 0$ mod 3 reflections were gradually reduced to 0.75 over several least squares cycles. The least squares residues, which had previously been 0.10 and 0.23 for the $l = 0$ mod 3 and $l \neq 0$ mod 3 data respectively, fell to 0.09 and 0.13.

The choice of $p = +$ was then confirmed by calculating structure factors for the unused $h1l$ data, first with the ε_{jn} just determined, and then with the inverse of these displacements. By eq. [2], this reversal is equivalent to changing the signs of the $l \neq 0$ mod 3 reflections while leaving the average structure unchanged. This latter calculation yielded very poor agreement between $|F_o|$ and $|F_c|$ while the original set of displacements gave a value for R_2 with $h1l$ data of 0.13 after a cycle of least squares. The choice of $p = +$ was then considered to be correct.

An additional three cycles of least squares refinement were carried out using all the data measured to this point, isotropic temperature factors for all the atoms, and with weights chosen, as suggested by Cruickshank *et al.* (13). The oxygen atoms were no longer shifted between cycles. Unobserved reflections were given zero weight if $|F_c| < |F_{min}|$, and $|F_o|$ the observed structure factor was taken as 0.85 $|F_{min}|$ when the calculated structure factor, $|F_c|$, exceeded the minimum observable structure factor $|F_{min}|$. Although the R value was 0.089 at this point, only 821 reflections out of 1289 recorded reflections were intense enough to be measured. Since there were 160 variables, including 4 scale constants, in the least squares refinement an honest skepticism concerning the validity of the structure could persist.

The intensity of the hnl ($n = 2, 3, 4, 5$) reflections were then measured by visual comparison from Weissenberg photographs taken with MoKα radiation. In addition, the intensities of the [10$\bar{3}$] zone again taken with MoKα radiation, were measured with a Joyce–Loebl densitometer from integrated precession photographs. This yielded an additional 2500 reflections of which 816 has measurable intensity. The amount of data now exceeded the mount conveniently handled by our IBM 7040 computer. Therefore, only those unobserved reflections whose $|F_c| > 0.85\ |F_{min}|$ on a previous refinement cycle were included in subsequent cycles. The final cycles used 1679 reflections with 177 positional parameters, 39 isotropic temperature factors, and 9 independent scale constants. Of this total about one-third were observed $l \neq 0$ mod 3 reflections.

TABLE II

*Estimated standard deviations in parentheses.

The weights were chosen as indicated above with ω given by $[30 + 0.25F_o + 0.0075F_o^2]^{-1}$. The measured structure factors of common reflections were averaged and randomly assigned to the possible scale constant groups. The final atomic parameters are listed in Table II, where the atoms are labelled with letters A, B, or C denoting the particular sub-cell to which they belong (n = 0, 1, or 2 respectively.) The final least square residues are $R = 0.096$ and $R_2 = 0.123$. The observed and calculated structure factors are found in Table III[2].

[2]Table III has been placed in the Depository of Unpublished Data. Photocopies may be obtained free of charge, upon request, from: Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada.

Description of the Structure

A strong similarity between the structures of $\beta'Mn_3(PO_4)_2$ and that of $\beta Zn_3(PO_4)_2$ has been noted. Therefore, the rather complex structure of $\beta'Mn_3(PO_4)_2$ will be described in terms of similarities and differences between these structures. Each phosphorus atom is surrounded, roughly tetrahedrally, by 4 oxygen atoms. The average value of the P—O bond distances is 1.54 Å with the value for any individual tetrahedra deviating by no more than 0.01 Å. These distances have not been corrected for the effects of thermal motion. The range of the phosphorus–oxygen bond distances about any phosphorus atom does not exceed 0.08 Å. Since the extremes lie within two standards of the mean values, the deviations of the tetrahedra from regularity do not appear

*Estimated standard deviations in parentheses.

significant by this criterion. On the other hand, the O—P—O bond angles, also found in Table IV, suggests that the tetrahedron about P(2) may be irregular.

These tetrahedra connect sheets of cation polyhedra extended parallel to the ($\bar{1}$13) plane with those related by the 2_1 axes extended parallel to the ($\bar{1}\bar{1}$3) plane. Although the major bonding between the oxygen atom polyhedra surrounding the cations lies in the sheet, there are some bonds involving shared oxygen atom between sheets often involving long cation–oxygen atom bond lengths. In β′$Mn_3(PO_4)_2$ these sheets, shown in Fig. 1, are composed of three sub-units each similar to the ($\bar{1}$11) planes in β$Zn_3(PO_4)_2$, seen in Fig. 2. In the latter case, this unit has a center of symmetry in the sheets while in β′$Mn_3(PO_4)_2$, two of the sub-units are related by the center of symmetry lying at the center of the third.

In the structure of β$Zn_3(PO_4)_2$ a pair of cations of type 1, related by a center of symmetry, share a common edge. These cations show four-fold coordination with oxygen atoms. A fifth oxygen atom, O(4), lies 2.55 Å from this cation. This group shares an oxygen atom, O(8), on each side with an edge-shared pair of five-fold coordinated Zn ions involving cations 2 and 3. These latter cations then share an oxygen atom with the centro-symmetrically related cation pair. Bonding between sheets is propagated through long cation–oxygen bonds, involving O(6) between Zn(2) and Zn(1), and O(4) between Zn(3) and Zn(1). In addition, there are strong bonds between sheets involving O(7), Zn(2), and Zn(3).

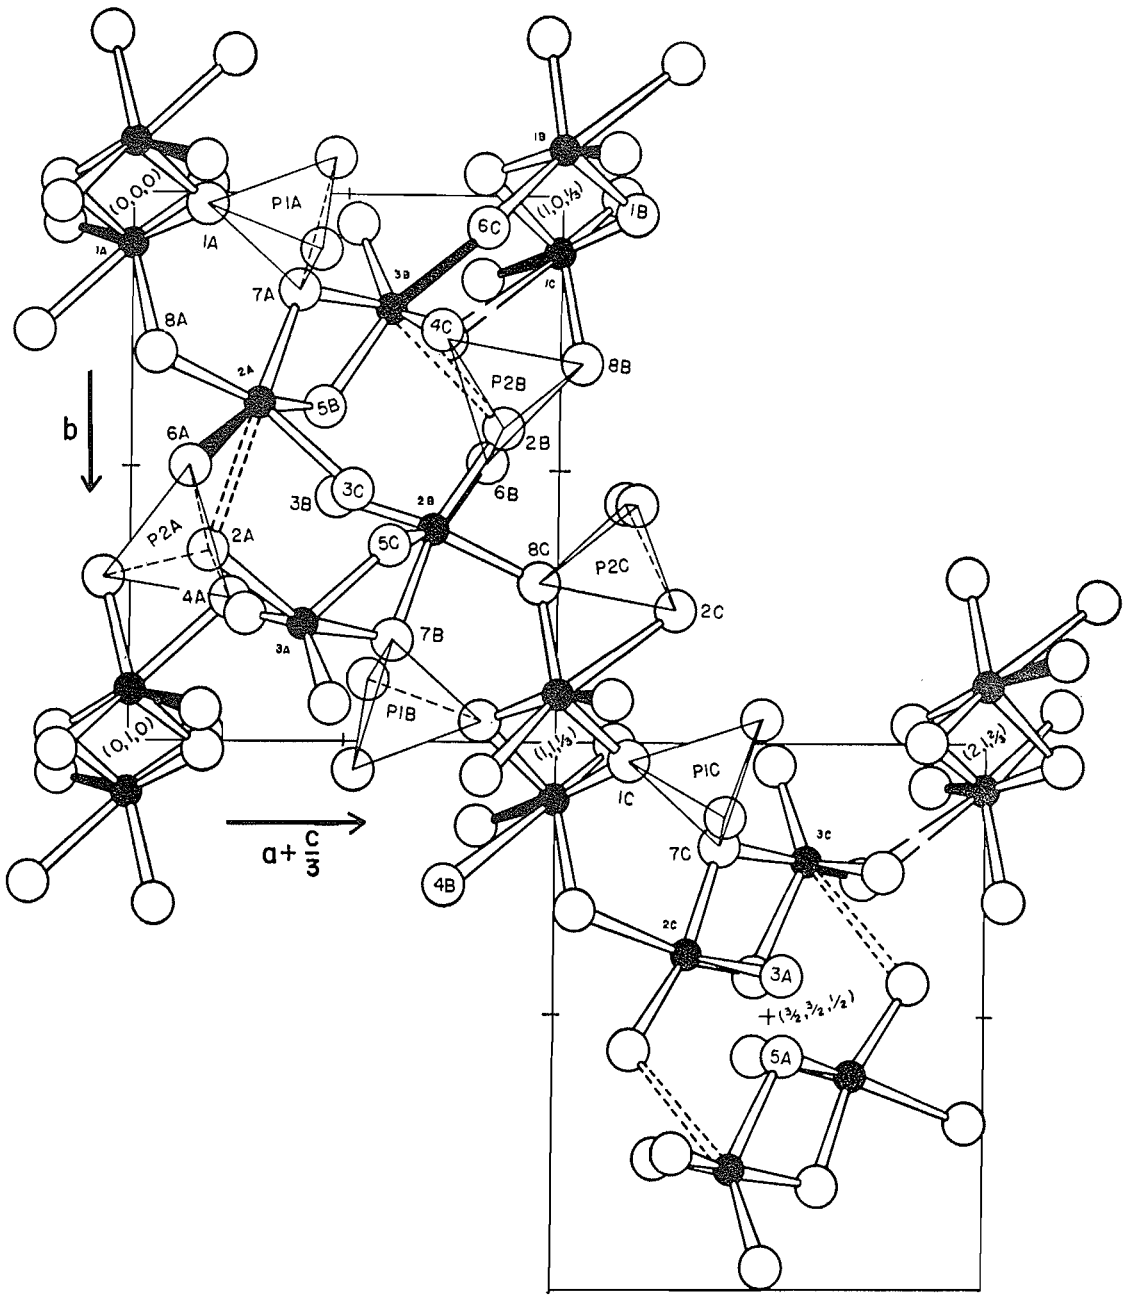

FIG. 1. The structure of $\beta'Mn_3(PO_4)_2$ near the $(\bar{1}13)$ plane is shown. The large open circles represent oxygen atoms while the filled ones depict the cations. The 4 oxygen atoms comprising the PO_4^{3-} tetrahedra are connected outlining this group. The filled bonds represent new bonds with respect to the $\beta Zn_3(PO_4)_2$ structure while the dotted bonds have been broken in comparison to that structure.

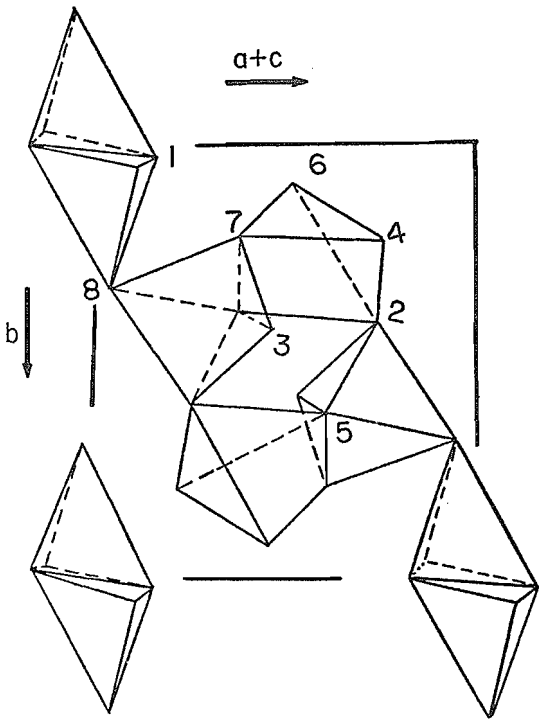

FIG. 2. The cation polyhedra in plane in $\beta Zn_3(PO_4)_2$ analogous to that of β′$Mn_3(PO_4)_2$ seen in Fig. 1 are shown. The oxygen atoms are labelled by analogy to that of β′$Mn_3(PO_4)_2$.

In β′$Mn_3(PO_4)_2$ each sub-unit consists of a pair of a polyhedra of oxygen atoms, each containing a cation of type 1, sharing an edge and lying at the corner of each of the reduced cells. This group then shares an oxygen atom, O(8), with the edge-shared polyhedral group containing cations 2 and 3. Cations 2 and 3 "share" a pair of oxygen atoms with a similar cation pair (3 and 2) but in this structure, in contrast to $\beta Zn_3(PO_4)_2$, these bonds are long. These bonds are shown dotted in Fig. 1.

We now turn to a detailed examination of the difference between the three sub-cells in β′$Mn_3(PO_4)_2$. All the cations show at least 5 acceptable Mn—O bonds. Mn(1A) has a sixth near neighbor oxygen atom, O(4A), at 2.45 Å; Mn(3B) has its sixth oxygen atom, O(6C) which lies 2.39 Å away; and Mn(2B) has its sixth neighbor, O(6B), at 2.49 Å from the cation. Each of the remaining cations, except Mn(2C), has a sixth oxygen atom within 3.0 Å of the cation but at distances greater than 2.6 Å. The detailed cation–oxygen atom bond lengths are compared with the analogous bonds in $\beta Zn_3(PO_4)_2$ in Table V. The average length of the 5 nearest Mn—O bonds, also included in Table V, shows values ranging from 2.13 to 2.19 Å.

Mn(1A) shares the O(1A) – O(1Ā′) edge across the center of symmetry at the origin. The cation–oxygen atom bond lengths about Mn(1A) range from 2.08 to 2.45 Å, with an average of 2.19 Å for the 5 shortest. The 4 shortest bond lengths involve the same oxygen atoms as in $\beta Zn_3(PO_4)_2$ while in each structure there is a long bond involving O(4). There are 5 short bonds about Mn(1B), with an average cation–oxygen atom bond length of 2.14 Å, while the sixth oxygen atom, O(4C), lies at 2.72 Å from the cation. Oxygen atoms O(1B) and O(1C) are shared between cation Mn(1B) and Mn(1C). The environment of Mn(1C) is similar to Mn(1B) with O(4B), the long sixth oxygen atom bond, lying at 2.62 Å. The five shorter cation–oxygen lengths range from 2.09 to 2.23Å with an average of 2.16 Å. All the individual cation–oxygen atom bond lengths about cation site 1 in the three sub-cells are insignificantly different except those to O(4). O(2), which lies more than 3.0 Å away from cation site 1 in $\beta Zn_3(PO_4)_2$, shows a modest deviation of ±0.08 Å from the average value of 2.23 Å in this structure.

In $\beta Zn_3(PO_4)_2$ cation site 2 shows five-fold coordination with an average Zn—O bond length of 2.09 Å and an additional oxygen atom, O(6), displaced by 2.51 Å from this cation. In β′$Mn_3(PO_4)_2$, Mn(2A) shows five-fold coordination with an average Mn—O bond length of 2.18 Å but the sixth oxygen atom, O(2A), is removed by 2.79 Å. Mn(2B) again has 5 strong bonds with an average value of 2.17 Å and a sixth, involving O(6), subtending a length of 2.49 Å. Oxygen atom, O(6C), lies more than 3.0 Å away from Mn(2C) and, therefore, this cation has only 5 cation–oxygen atom bonds. In both sub-cell B and C, O(2) forms a normal bond to the cation in contrast to the long bond in sub-cell A.

Of the three cation types, cation 3 shows the greatest variation in bonding amongst the sub-cells. Two of these cations, Mn(3A) and Mn(3C) clearly show five-fold coordination involving, however, oxygen atoms of different types. Mn(3B) has 5 bonds in the range 2.10 to 2.26 Å with the sixth, O(6C), at 2.39 Å. O(2B) lies more than 3 Å from this cation. O(6) lies about 2.96 Å from Mn(3A) while O(2A) is bonded normally

*The average atomic coordinates of the final structure are enclosed in square brackets and the estimated standard deviations obtained the $l = 0$ mod 3 data.

at 2.25 Å and O(4A) is unbonded. In the case of Mn(3C), it is O(6A) which lies more than 3 Å from the cation while O(2C) lies 2.93 Å away. The average Mn(3)—O bonds are 2.16, 2.18, and 2.13 Å for sub-cells A, B, and C, respectively. In β$Zn_3(PO_4)_2$, O(6) and O(4) lie beyond the primary coordination sphere around cation 3.

In summary, Mn(1), in comparison with β$Zn_3(PO_4)_2$, takes O(2) as its fifth strong oxygen atom bond. Cation 2 retains O(7), O(8), O(5), and O(3) as strong bonds in all sub-cells. There are strong bonds to O(2) in two of the sub-cells. In the remaining sub-cell the fifth strong bond is formed with O(6). Cation 3 shows strong bonds to O(4), O(3), O(5), and O(7). In one sub-cell cation 3 retains the strong bond to O(2), analogous to β$Zn_3(PO_4)_2$. The remaining sub-cells adopt O(4), as the fifth strong bond.

The values of the ε_{jn}'s, the deviations from the average structure, are of some interest. Therefore, the final values of the atomic coordinates using only the $l = 0$ mod 3 reflections are tabulated in Table VI. From these the values of ε_{jn} can easily be obtained. The average parameters obtained from the final β′$Mn_3(PO_4)_2$ atomic parameters are also shown. These indicate that the two average values almost always differ insignificantly. They differ most for the y coordinates of O(7) and O(6), and the z coordinates of O(4).

Discussion

The mean P—O bond length at 1537 ± 0.005 Å agrees well with the accepted value for this bond in PO_4^{3-} groups. The temperature factors of the cations and the phosphorus atoms show modest variation. The mean value (1.03 $Å^2$) and the variation in these values for the oxygen atoms exceeds that of the cations, but there does not appear to be any correlation among those expected

to be sensitive to positional disorder. The standard deviations of these thermal parameters seem to be about 25% too small since 4 lie more than 2 standard deviations from the mean. This likely results from the lack of adsorption corrections.

The mean displacement of the cations, and P(1) from the positions determined from the $l = 0$ mod 3 reflections is about 0.1 Å while that of oxygen atoms about this phosphorus atom is about 0.2 Å. The displacements about P(2) are about twice as great. Although the major component of this displacement is along the c axis for the cations, this is not necessarily the case for the phosphorus and oxygen atoms. The largest displacement found, that of O(2A), is about 0.6 Å. An examination of Table V shows that it is exclusively the oxygen atoms about P(2) that are involved in the difference in bonding between the β and β′ structure and the sub units of the latter phase.

The studies of Pearson, Turkdogan, and Fenn (9) suggest, in agreement with the present studies, that the stable phase of $Mn_3(PO_4)_2$ at the melting temperature is the graftonite form since the density they report agrees with that of the mineral. The value for the density of $\beta'Mn_3(PO_4)_2$ is substantially larger, 3.92 g/cm^3 compared to graftonite 3.756 g/cm^3. Further, the value of specific volume versus composition in the range between $Mn_3(PO_4)_2$ and MnO is linear with MnO composition, suggesting that the graftonite phase remains stable down to the eutectic temperature of 1044 °C. The field stability of $\beta'Mn_3(PO_4)_2$ is unknown and the variables leading to the stability cannot be ascertained without a more careful study. Finally, $\beta'Cd_3(PO_4)_2$ shows a phase transformation at high temperatures apparently removing the superstructure, but $\beta Zn_3(PO_4)_2$ down to at least −100 °C does not manifest a superstructure. Whether $\beta'Mn_3(PO_4)_2$ shows a transformation analagous to $\beta'Cd_3(PO_4)_2$ is unknown.

It is difficult to avoid some remarks concerning the driving force which generates the superstructure of the β′ structure. Divalent Mn can be regarded as unstable if coordinated to less than 5 oxygen atoms and will seek higher coordination numbers if possible. Thus, $Mn_3(PO_4)_2$, in the hypothetical β structure, would distort in such a manner as to increase the coordination number of site 1 to at least 5. The most obvious mode, shortening of the cation 1 – O(4) bond length, is not favored since as a result this Mn would share an edge involving two strong oxygen atom bonds with the PO_4^{3-} about P(1). In fact, in both the $\beta Zn_3(PO_4)_2$ and $\beta'Mn_3(PO_4)_2$ structures when an edge is shared with a PO_4^{3-} group, one of the cation–oxygen atom bonds is significantly longer than normal. An apparently more favorable change involves the acquisition of O(2) by Mn(1) from the adjacent sheet. In order to tolerate this change, one of the strong bonds between this oxygen atom and a cation, either 2 or 3, is broken. Mn(2A) exchanges the weak bond to O(6A) and strong bond to (2A) of the β structure for a strong bond to O(6A) and a weak one to O(2A). Mn(2B) maintains the status quo while Mn(2C) ignores O(6C) entirely. The bond to O(2) in the latter two cases is broken at cation 3 i.e. Mn(3B) and Mn(3C). These latter cations complete their coordination requirements by bonding both O(4B) and O(6C) to Mn(3B) and only O(4C) to Mn(3C).

Although the assumption of the desire of Mn for coordination numbers of 5 or greater while not sharing an edge strongly with the PO_4^{3-} group yields a plausible explanation for the difference between the β and β′ structures, other structures can not easily be excluded. In particular, that of $Cu_3(AsO_4)_2$ (14) shows all 5 cation ligand bonds in sheets paralleling (100) planes. Further, one would hope to derive a justification for the superstructure rather than just a structure having the β phase unit cell dimensions but with a higher coordination number for Mn(1). In fact, an examination of the sub-cell about the center of symmetry at 3/2 3/2 1/2 in Fig. 1 shows that the requirements assumed to be desirable can be fulfilled with a structure with this sub-cell as the unit cell, provided that the Mn(1)—O(8) bond is made long while the Mn(1)—O(4) bond is assumed normal. Each cation would then show 5 strong bonds and avoid sharing a strongly bound edge with any phosphorus tetrahedra. Under these circumstances O(4) would be tightly bonded to three cations while O(6) would be bonded to only one. This can be regarded as unfavorable. Since there is no convenient way, under our assumptions, to bond O(6) to cation 3 it does not appear that one can easily find a β-like analogue of $Mn_3(PO_4)_2$.

In considering the role of the structure on the energy levels of Mn^{2+} in doped compounds such

as $\beta Zn_3(PO_4)_2$, one has to know the detailed environment of the impurity. The levels involved in transition near the visible range of the spectrum seem to be particularly sensitive to the "cubic" components of the electric field and these would be dominated by the near neighbors. Mn^{2+} in $\beta Zn_3(PO_4)_2$ will adopt an environment which will be a compromise between that found for the cation in the β′ structure and that in the β structure. It is not at all certain that this compromise will be dominated by the host lattice. Therefore, it cannot be concluded what will be the detailed environment of the Mn^{2+} in $\beta Zn_3(PO_4)_2$.

Electron paramagnetic resonance spectroscopic study of nitroxide radicals formed from oximes[1]

P. SMITH AND W. M. FOX
Department of Chemistry, Duke University, Durham, North Carolina 27706

Received September 13, 1968

The addition of hydroxyl radicals to each of the oximes, acetaldoxime, acetoxime, and 2,3-butanedione monoxime, has been studied by mixing titanous chloride, hydrogen peroxide, and the oxime in an aqueous continuous-flow system. In each case a β-hydroxy nitroxide (functional structure $\rangle C(OH)—NH—O\cdot$) is formed. In confirmation of these results, amino and hydroxymethyl radicals were added to the oximes using similar procedures to give in each case the radicals of functional structure $\rangle C(NH_2)—NH—O\cdot$ and $\rangle C(CH_2OH)—NH—O\cdot$, respectively. Attempts to add methyl radicals, prepared by the reaction between titanous chloride and *t*-butyl hydroperoxide, to these oximes gave no observable products save the methyl radicals. However, use of titanous chloride and peracetic acid gave results consistent with the addition of hydroxyl radicals. The addition of hydroxyl radicals to the oxime-*O*-methyl ethers of acetaldehyde and acetone gave radicals of functional structure $\rangle C(OH)—\dot{N}—O—CH_3$ ($|a_N|$, ca. 14 G; $|a_H^{OCH_3}|$, ca. 3 G) which have not previously been identified unambiguously. On the assumption that $|Q_N| = |Q_H^{NH}| = 23$ G in all these radicals, ρ_N^π has been calculated and used to obtain a value for $|Q_H^{OCH_3}|$ of ca. 11 G which is within the range of other estimates in the literature.

Canadian Journal of Chemistry, 47, 2227 (1969)

Introduction

The reaction between titanous chloride and hydrogen peroxide in the presence of an organic substrate within an aqueous flow system has been shown (1) to be an effective method for the generation of transient free radicals for the purpose of electron paramagnetic resonance (e.p.r.) observations. A number of investigations using this generative method have been reported already from this laboratory (2–6). The present investigation concerns an extension of this method to a range of simple oximes. All aliphatic oximes proved to be highly reactive and underwent hydroxyl-radical addition to the carbon of the C=N bond. The few aromatic oximes studied were unreactive. In addition, some of these substrates were successfully investigated with the use of other radical-generating methods similar to that involving titanous chloride and hydrogen peroxide.

The results obtained from this present investigation confirm and considerably extend those of a recent study of Adams (7) which came to our attention after this work was complete.

[1]This work was supported by National Science Foundation Grant GP 7534.

Experimental

The experimental arrangement and procedures were essentially as described before (5).

The acetaldoxime, acetoxime, and 2,3-butanedione monoxime were all Eastman White Label. The other substrates were prepared with the use of reagent-grade materials. Of these other substrates, the simple oximes examined were prepared by the reaction between hydroxylamine and the carbonyl compound in alkaline solution, following which they were recrystallized from methanol until satisfactory melting points were obtained. In addition, acetaldoxime-*O*-methyl ether and acetoxime-*O*-methyl ether were prepared by mixing the carbonyl compound with an equivalent amount of methoxyamine hydrochloride in alkaline solution, and were used without further purification.

The following reaction conditions were employed: total flow rate, 2–9 ml s^{-1}, divided equally between the two streams; the reaction temperature, 25 ± 2 °C; the titanous chloride concentration in the reducing stream, 0.01–0.005 *M*; the hydrogen peroxide concentration in the oxidizing stream, 0.05 *M*; unless otherwise stated, the only acid present was that originating in the Fischer (2–6) titanous chloride solution[2] used in making up the reducing stream; similarly, except where specified to the contrary, the oxime was included only in the oxidizing stream, its concentration being about 0.02 *M*. When it was hoped to add methyl radicals to the oxime, the above

[2]A typical analysis of this solution (20% titanium trichloride) provided by the supplier gives: titanous chloride, titanic chloride, zinc chloride, hydrochloric acid, and phosphoric acid, 20.0, 0–5.0, 15.6, 7–9, and 3 wt./wt. %, respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

conditions were modified so as to use as the oxidizing stream 0.1 *M* peracetic acid (1) (Pflatz and Bauer, Inc., 40% wt./wt. solution) or saturated *t*-butyl hydroperoxide (1, 6, 8–10) (Borden Chemical Co.) instead of 0.05 *M* hydrogen peroxide. When the addition of amino radicals was to be studied, the hydrogen peroxide in the oxidizing stream was replaced by hydroxylamine hydrochloride (11, 12) (Eastman White Label) at a concentration of 0.1 *M*. The reaction between titanous chloride and hydrogen peroxide was conducted with both reactant streams 25 v/v % with respect to methanol (Baker and Adamson reagent grade) when the addition of hydroxymethyl radicals, $\cdot CH_2OH$, was to be investigated (11). It was found that both sulfuric acid and titanous chloride broadened the lines of the radical spectra, and consequently the best results were obtained when their concentrations were kept as low as possible.

When Fenton's reagent (1, 13, 14) was used, the titanous chloride normally present in the reducing stream was omitted and, instead, this stream was made 0.01 *M* in ferrous sulfate (Fischer Certified Reagent) and 0.05 *M* in ethylenediamine tetra-acetic acid, EDTA (G. Frederick Smith Chemical Co.).

All *g* values were measured with the use of peroxylamine disulfonate, the maximum uncertainty of the results being ±0.0002. In most instances the method followed was that described before (5), where the peroxylamine disulfonate was dissolved in the oxidizing stream. However, when hydroxylamine hydrochloride and oxime were present in this stream, it was found that the peroxylamine disulfonate tended to be particularly unstable. Consequently, for those cases, it was preferable to omit the peroxylamine disulfonate from the oxidizing stream and to utilize instead a solution of the peroxylamine disulfonate within an external, thin-walled Pyrex capillary held to the side of the mix-and-flow cell (both methods give the same results).

Results

It was found that the reaction between titanous chloride, hydrogen peroxide, and acetoxime, $(CH_3)_2C{=}NOH$, with the use of the flow system, gave rise to a spectrum of four equally-spaced lines of relative intensity 1:2:2:1 separated by 13.3 G. This pattern of absorption is characteristic of equal coupling to a nitrogen nucleus and a proton, and the coupling constants are similar to those reported by Gutch and Waters (15) for hydroxylamine radicals (nitroxides) of functional structure

$$\rangle C{-}NH{-}O\cdot$$

produced by oxidation of the corresponding hydroxylamine. It is assumed that the basic reactions which took place may be represented (1) as follows

[1] $\quad Ti(III) + H_2O_2 \rightarrow Ti(IV) + OH^- + \cdot OH$

[2] $\cdot OH + (CH_3)_2C{=}N{-}OH \rightarrow (CH_3)_2C(OH){-}\dot{N}{-}OH$

[3] $(CH_3)_2C(OH){-}N{-}OH \rightarrow (CH_3)_2C(OH){-}NH{-}O\cdot$

1

although there is some question (16) about the mechanistic details of the titanous chloride – hydrogen peroxide radical-generating system. The titanous chloride and hydrogen peroxide react to give a hydroxyl radical which adds exclusively to the carbon of the C=N bond of the oxime. Addition of a hydroxyl radical to the nitrogen end of the double bond would have been expected to have given an iminoxy radical

[4] $(CH_3)_2C{=}N{-}OH + \cdot OH \rightarrow (CH_3)_2\dot{C}{-}N(OH)_2$

[5] $(CH_3)_2\dot{C}{-}N(OH)_2 \rightarrow (CH_3)_2\dot{C}{-}N{=}O + H_2O$

[6] $\quad (CH_3)_2\dot{C}{-}N{=}O \leftrightarrow (CH_3)_2C{=}N{-}O\cdot$

Iminoxy radicals have been well characterized by e.p.r. spectroscopy (17) but none was observed in this investigation.

The presence of the $(CH_3)_2C(OH)$— group in radical **1** is difficult to establish as none of the protons in this group interact appreciably with the unpaired electron. However, the addition of hydroxyl radicals to acetaldoxime, $CH_3CH{=}NOH$, should give rise to the radical $CH_3CH(OH)$-$NHO\cdot$ with an interacting β-CH proton[3]. Furthermore, amino radicals from the reaction between titanous chloride and hydroxylamine hydrochloride would be expected (11, 12) to give with acetoxime the radical $(CH_3)_2C(NH_2)NHO\cdot$. The nitrogen of the amino group in this radical would be expected to have an appreciable interaction (11) identifying the position of radical attack. Both of these species were readily detected and the expected splittings observed. It was felt that these results adequately confirmed the position of radical addition. A typical spectrum obtained by adding amino radicals to acetoxime is shown in Fig. 1.

The addition of hydroxyl radicals to 2,3-butanedione monoxime, $CH_3COC(=NOH)CH_3$, produced a spectrum consistent with the formation of the expected product $CH_3COC(CH_3)$-$(OH)NHO\cdot$. This spectrum was sufficiently intense for carbon-13 satellites ($a_{^{13}C}$ equal to 6.0 G) to be relatively easily observed. However, these satellite lines were not sufficiently well resolved

[3]The sites in radicals of this type are labelled with respect to the nitrogen atom, i.e.

$$\begin{matrix}\gamma & \beta & \alpha\end{matrix}$$
$$—C—C—NH—O\cdot$$

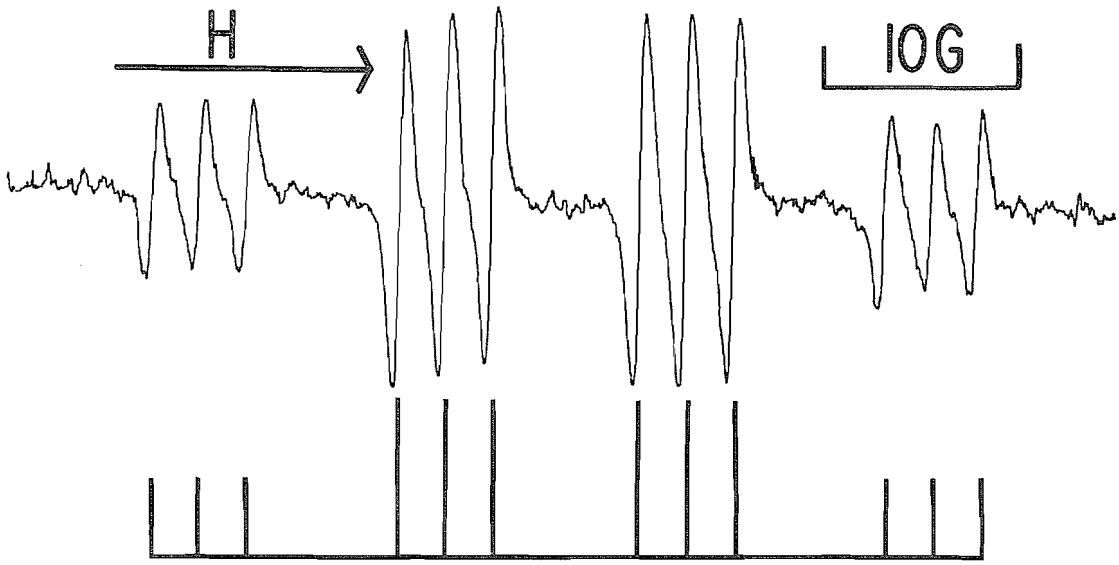

FIG. 1. First-derivative plot of the e.p.r. spectrum for the addition of amino radicals to acetoxime: temperature 25 °C; no sulfuric acid added to either stream; [$TiCl_3$] in the reducing stream, 0.005 *M*; [$NH_2OH{\cdot}HCl$] and [acetoxime] in the oxidizing stream, 0.1 and 0.02 *M*, respectively; total flow rate, 9.5 ml s^{-1} equally divided between both streams. The stick plot shows the positions and theoretical intensity distribution of the lines for the radical $(CH_3)_2C(NH_2)$—NH—O·, a quartet (1:2:2:1) of triplets (1:1:1).

for the number of interacting nuclei to be determined.

Hydroxyl radicals also added to the *O*-methyl ethers of acetoxime and acetaldoxime, $(CH_3)_2C{=}NOCH_3$ and $CH_3CH{=}NOCH_3$, respectively. In the former case, a rather broad-line spectrum (linewidth, between points of maximum slope, ca. 1.0–1.5 G) was observed, showing a 3.2 G interaction with a methyl group and a 13.7 G interaction with a nitrogen nucleus. No interaction was observed which could be due to a proton bonded directly to the nitrogen, hence the radical was thought to be $(CH_3)_2C(OH)$—$\dot{N}$—O—CH_3. A more clearly defined spectrum was obtained using acetaldoxime-*O*-methyl ether. It exhibited an interaction with the aldehyde CH-group proton in addition to the nitrogen and methyl-group proton hyperfine couplings, i.e., consistent with the expected structure, $CH_3CH(OH)$—$\dot{N}$—O—CH_3. Figure 2 shows a typical spectrum obtained by adding hydroxyl radicals to acetaldehyde-*O*-methyl ether.

The reaction between oximes, titanous chloride, and hydrogen peroxide in aqueous solutions 25 v/v % with respect to methanol did not produce the same radical as these reactants gave in the absence of methanol. The interacting nuclei were the same in the two cases but the magnitudes of the hyperfine couplings were different. The following reaction scheme is suggested by analogy with recent work (11) on vinyl compounds under comparable conditions

[1] $Ti(III) + H_2O_2 \rightarrow Ti(IV) + OH^- + {\cdot}OH$

[7] ${\cdot}OH + CH_3OH \rightarrow {\cdot}CH_2OH + H_2O$

[8] ${\cdot}CH_2OH + \rangle C{=}N{-}OH \rightarrow R_2C(CH_2OH){-}NH{-}O{\cdot}$

where $\rangle C{=}N{-}OH$ denotes the oxime.

Methyl-radical addition to oximes was investigated by mixing titanous chloride and either peracetic acid or *t*-butyl hydroperoxide in the presence of the three oximes, acetaldoxime, acetoxime, and 2,3-butanedione monoxime. Both these radical-generating systems produce two radicals by way of two-step reactions (1, 6, 8–10), viz.,

[9] $Ti(III) + CH_3CO(OOH) \rightarrow Ti(IV) + CH_3CO(O{\cdot}) + OH^-$

[10] $CH_3CO(O{\cdot}) \rightarrow {\cdot}CH_3 + CO_2$

or

[11] $Ti(III) + (CH_3)_3C{-}O{-}OH \rightarrow Ti(IV) + (CH_3)_3C{-}O{\cdot} + OH^-$

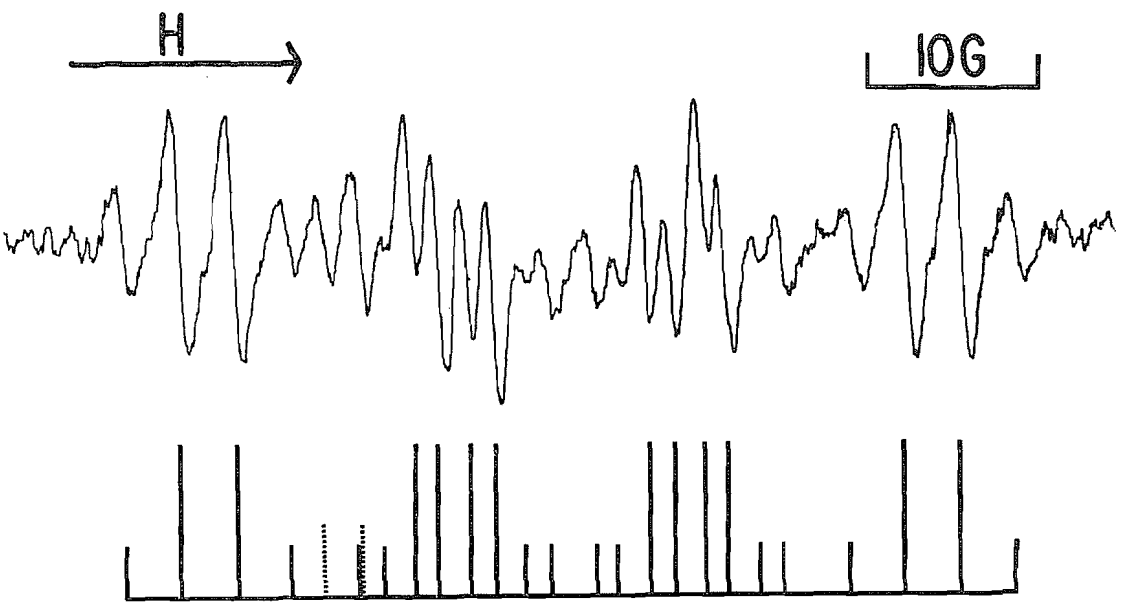

FIG. 2. First-derivative plot of the e.p.r. spectrum for the addition of hydroxyl radicals to acetaldoxime-*O*-methylether: temperature, 25 °C; no sulfuric acid added to either stream; [$TiCl_3$] in the reducing stream, 0.005 *M*; [H_2O_2] and [acetaldoxime-*O*-methylether] in the oxidizing stream, 0.05 and 0.02 *M*, respectively; total flow rate, 9.5 ml s^{-1} equally divided between both streams. The stick plot shows the positions and theoretical intensity distribution of the lines for the radical $CH_3CH(OH)—\dot{N}—O—CH_3$, a doublet (1:1) of triplets (1:1:1) of quartets (1:3:3:1); the two broken sticks indicate lines which arise from inorganic reaction products with *g* values estimated in this present work to equal about 2.0119 and 2.0132 (16).

[12] $(CH_3)_3C—O\cdot \rightarrow \cdot CH_3 + (CH_3)_2CO$

and, consequently, their use is attended by an element of ambiguity in that a suitably reactive substrate may perhaps react with the unstable radical precurser of the methyl radical, $(CH_3)_3CO(O\cdot)$ or $(CH_3)_3C—O\cdot$. No clear evidence for this sort of complication was found even in the case of the substrate acetaldoxime, for which such evidence might be the most easily discerned on account of the likely presence of an interacting β-CH group proton in the radicals expected from this substrate (see above). Another kind of complication was noticed, however. This appears to be the more relevant to the present work and hence it will be taken up in detail. In all instances where peracetic acid was used, the spectrum of the methyl radical was observed superimposed on a nitroxide spectrum of comparable intensity. It was found that the nitroxide radicals observed under these conditions had the same hyperfine interactions as the corresponding species formed by hydroxyl-radical addition with the use of the regular titanous chloride – hydrogen peroxide system. This may indicate that the radicals $\rangle C(OH)NHO\cdot$ and $\rangle C(CH_3)NHO\cdot$ formed by hydroxyl- and methyl-radical addition to oximes, happen to have the same magnetic properties. Alternatively, hydroxyl radicals may be formed from the hydrogen peroxide in equilibrium with the peracetic acid by way of the reaction

[13] $CH_3CO(OOH) + H_2O \leftrightharpoons CH_3CO(OH) + H_2O_2$

which has an equilibrium constant at 25 °C of ca. 4 (18), and the hydroxyl radicals so formed attack the oxime while the methyl radicals are relatively unreactive. In all cases where *t*-butyl hydroperoxide was used, the methyl-radical spectrum was observed but the nitroxide spectrum was absent. This suggests that methyl radicals are indeed relatively unreactive towards oximes, and that the radical formed in the presence of peracetic acid is the result of hydroxyl-radical addition.

The reaction between the ferrous–EDTA complex and hydrogen peroxide also gives rise to the $\rangle C(OH)NHO\cdot$ radical. No differences were observed between the splittings obtained with the use

*Throughout this paper, signs of a and Q parameters are omitted. Of the a values from this present investigation and reported in this table, those cited to two decimal places have a maximum uncertainty of ca. 0.05 G and the rest have a maximum uncertainty of ca. 0.1 G. Numbers in parentheses are taken from ref. 7.

†$a_N^{NH} = a_H^{NH}$.

‡Obtained with the use of Ti(III) – H_2O_2; Fe(II) – EDTA – H_2O_2 gave the same result.

§Obtained with the use of Ti(III) – $CH_3CO(OOH)$.

‖$a_{^{13}C} = 6.0$ G.

¶This radical was prepared from $CH_3COC(CH_3)$=NOH in the presence of NH_2OH, and hence, may perhaps be derived from the corresponding dioxime, i.e., it may be $CH_3C(=NOH)$-$C(CH_3)(NH_2)NHO\cdot$.

**a_N only.

of this system and those found with the use of the titanous chloride – hydrogen peroxide system.

The reaction between titanous chloride and hydrogen peroxide was performed in the presence of two oximes having aromatic substituents (benzophenone oxime, $(C_6H_5)_2C$=NOH and benzaldoxime, C_6H_5CH=NOH) but no signals from free radicals derived from these oximes were observed. This suggests that conjugation with the aromatic ring reduces the reactivity of the oxime group towards hydroxyl-radical addition.

To summarize, hydroxyl, hydroxymethyl, and amino radicals were successfully added to all three oximes, acetaldoxime, acetoxime, and 2,3-butanedione monoxime, but attempts to add methyl radicals to these same oximes failed; hydroxyl radicals were successfully added to the oxime-*O*-methyl ethers of acetoxime and acetaldoxime, but attempts to add hydroxyl radicals to benzophenone oxime and benzaldoxime failed. Table I lists all the hyperfine coupling constants obtained.

The g values for the β-hydroxy and β-hydroxymethyl nitroxides were equal to 2.0059; those for the β-amino nitroxides were 2.0062. The g values for the radicals formed by hydroxyl-radical addition to the oxime-*O*-methyl ethers were found to be 2.0047. It can be seen that g values for disubstituted radicals of structure R—$\dot{N}$—O—CH_3, where R is a substituted alkyl group, are lower than those for monosubstituted radicals of structure R—NH—O·. The g values for the dialkyl nitroxides $(CH_3)_2$N—O· and $(C_2H_5)_2$N—O· have been recently reported (19) to be 2.0055 and 2.0054, respectively. These results also are less than those found in this present work for monosubstituted nitroxide radicals.

Discussion

Adams (7) has recently reported the results of an e.p.r. study of the radicals formed from formaldoxime, acetaldoxime, and acetoxime with the use of the chemical reaction of titanous chloride with hydrogen peroxide in dilute aqueous sulfuric acid solution within a continuous-flow system. These results show that hydroxyl radicals

add to the carbon end of the C=N bond in each case to give a β-hydroxy nitroxide radical and reveal the presence of hindered internal rotation about the C—N bond in these species

$$>C(OH)—NHO\cdot$$

The results in this present work partly overlap with, and considerably extend, those reported by Adams (7) and serve to confirm the identity of the radicals thought (7) to be formed by aliphatic oximes in this reaction system. In addition, in this present work the reactivity of aliphatic oximes has been investigated under other conditions and with other radicals (section I).

The addition of hydroxyl radicals to oxime-*O*-methyl ethers and the relevance of the products to the structure of other species are discussed in section II, while the estimation of spin densities from isotropic hyperfine splittings is considered in section III.

I. The Specificity of Radical Attack on Oximes

Shiga and co-workers (13, 14) have compared the reactivity of Fenton's reagent and the titanous chloride – hydrogen peroxide system to a variety of organic substrates. They conclude that in most cases the two systems give rise to a different distribution of products. In the present work these two systems are found to give the same products in the presence of an oxime; however, this possibly reflects only the favorability of producing a nitroxide from an oxime, but does not necessarily prove that it was formed by the same reaction in both cases.

Adams (7) has suggested that, in the case of the titanous chloride – hydrogen peroxide system, the specificity of hydroxyl-radical addition is due to the protonation of the nitrogen atom of the C=N bond of the oxime. In a similar fashion with this same radical-generating system, the protonation of the nitrogen atom of the amino group of a saturated aliphatic amine deactivates the amine with respect to hydrogen-atom abstraction (20). Attempts to confirm this were made with the use of the ferrous – EDTA – hydrogen peroxide system. In these attempts the oxime was included only in the reducing stream and this stream was made progressively less acidic and eventually alkaline by addition of reagent grade sodium hydroxide. Thus, the deprotonated oxime should be attacked when the oxidizing stream containing the hydrogen peroxide is mixed with the reducing stream. The only noticeable effect was to reduce the intensity of the β-hydroxy nitroxide spectrum until it finally disappeared when the mixed streams were of pH 8–9.

The radicals $\cdot OH$, $\cdot NH_2$, $\cdot CH_2OH$, and $\cdot CH_3$ were prepared in the presence of the aliphatic oximes (see Table I) and all except the methyl radical seemed to react[4]. The low reactivity of methyl radicals with respect to addition to a C=N bond under these conditions is paralleled by the work of Smith and Wood (6) on radical attack on allyl alcohol under reaction conditions similar to those of the present investigation. In this latter work (6), with the use of the titanous chloride – hydrogen peroxide system, the two species formed by addition of hydroxyl radicals to either end of the C=C bond of the allyl alcohol were more readily observed than that formed by hydrogen-atom abstraction from the 1 position, viz. the allylic radical CH_2-$=CH\dot{C}HOH$. But the reverse was true with the use of the titanous chloride – *t*-butyl hydroperoxide system, i.e. the allylic radical was the chief radical product observed. Further support for the idea that methyl-radical addition by way of the titanous chloride – *t*-butyl hydroperoxide system is less effective than hydroxyl-radical addition by way of the titanous chloride – hydrogen peroxide system is provided by recent studies with the use of these systems and the substrate acrylic acid (10). These show that methyl-radical addition is more selective than hydroxyl-radical addition. At present, it seems hardly worthwhile to speculate here on the reasons for the differences in the effectiveness of these two radical-generating systems until more is known about their reaction kinetics and mechanisms (8, 16)[5] and the factors which determine the orientation of free-radical addition to double bonds (23). Similar considerations apply to the other radical-generating systems where related questions arise.

[4]For the sake of simplicity of language, this statement and similar ones elsewhere in the text rest on the assumption that the operating mechanism of the Ti(III) – H_2O_2 system is as represented in eqs. [1]–[3]. A similar comment applies to the other radical-generating systems employed.

[5]A complication worth consideration in the case of the titanous chloride – *t*-butyl hydroperoxide system stems from formation of the *t*-butoxyl radical, $(CH_3)_3CO\cdot$, as a precursor of the methyl radical (see eqs. [11] and [12]). This radical is particularly effective in hydrogen-atom abstraction processes (21, 22).

II. Radicals Formulated as R—Ṅ—O—R′

The azobisisobutyronitrile-initiated oxidation of liquid aniline (24) has been shown to give a stable radical which was thought to be a time average of the structures C_6H_5—Ṅ—O—H and C_6H_5—NH—O·. Subsequently, this species has been prepared in aqueous solution by reduction of nitrosobenzene with sodium dithionite (25) and by the oxidation of *N*-phenyl hydroxylamine and triphenylhydrazine (26), and the radical was assigned the structure C_6H_5—Ṅ—O—H (25, 26). Russell and co-workers (27) have suggested that a more likely general structure is

[14] 
2

where X is an unspecified group.

Until now no radical of the type R—Ṅ—O—R′, where R and R′ are hydrocarbon or substituted hydrocarbon groups, has been prepared, and hence, it has been difficult to predict the magnetic properties of C_6H_5—Ṅ—O—H. However, assuming $(CH_3)_2C(OH)$—Ṅ—O—CH_3 has magnetic properties similar to those of $(CH_3)_2C(OH)$—Ṅ—O—H, we are able in this present work to assess the properties of R—Ṅ—O—H radicals.

The results of this present investigation show that

(*a*) radicals of the type R—Ṅ—O—R′ do exist even in acid solution and are not observed as the protonated species R—$\dot{N}\overset{+}{H}$—O—R′,

(*b*) the nitrogen hyperfine splittings of R—NH—O·, R—Ṅ—O—R′, and hence probably R—Ṅ—O—H, are very similar, and

(*c*) as R—Ṅ—O—CH_3 shows a methyl-group proton hyperfine interaction of 3.2 G, so R—Ṅ—O—H should also possess a hydroxyl-proton splitting of approximately the same value. None is observed in the spectrum attributed (25, 26) to C_6H_5—Ṅ—O—H, although the resolution is sufficient to reveal the 0.9 G interaction of the *meta*-protons in the phenyl group. Of these three observations, the first two suggest that it is possible for the radical observed (24–26) by earlier workers to be C_6H_5—Ṅ—O—H. The third observation suggests that it is not.

It should be possible to distinguish between C_6H_5—Ṅ—O—H and $C_6H_5\dot{N}O_2X$ (**2**) purely on the magnetic properties resulting from restricted rotation about the C—N bond. Both the nitrosobenzene radical anion, $C_6H_5NO^-$, and C_6H_5—NH—O· exhibit this restricted rotation (27, 28) which holds the —NO group and the benzene ring coplanar for a time longer than ca. 10^{-6} s for the former, or for a time comparable to 10^{-6} s for the latter. This results in unsymmetrical coupling to the protons of the benzene ring. Thus, the two *ortho* protons have hyperfine couplings which differ by 0.3 G or more depending on the solvent. Protonation of the oxygen should not obliterate either the restricted rotation or the assymetry of the hyperfine couplings of the protons in the benzene ring. This has been confirmed experimentally, for example, in the case of the benzaldehyde radical anion, $C_6H_5CHO^-$ (29), and $C_6H_5\dot{C}HOH$ (30). In contrast, $C_6H_5\dot{N}O_2X$ would be expected to show symmetrical couplings to the protons in the benzene ring by analogy with the recently reported results for similar radicals (31).

III. Q-Parameter Values for the Isotropic Interaction of Protons in N—H and N—CH_3 Groups

Attempts to relate the spin-density distribution in an organic radical to the observed hyperfine interactions using predictable constants have been made on several levels of sophistication. The Karplus and Fraenkel equation (32) assumes that the isotropic hyperfine coupling constant of a nucleus results from the polarization of electron pairs by spin density in an orbital on that nucleus and also in orbitals on adjacent nuclei. The equation was first proposed to account for the isotropic hyperfine interaction of an sp^2-hybridized carbon atom that is bonded to three other atoms and was used with some success (32, 33). However, attempts to extend its use to nitrogen-containing radicals have been less profitable, and no unique, universally acceptable set of ρ–π or Q parameters has emerged (34–36). The equation yields self-consistent parameters for a series of closely related radicals, but it has been suggested that the greater variations of charge and hybridization of nitrogen compared with carbon in organic radicals prevents simple correlation between different series. Thus, no attempt was made to use this equation to estimate the spin-density

distribution in the nitroxide radicals presented here.

A more simple approach postulates that the proton hyperfine interaction of a proton or of a methyl group bonded to an sp^2-hybridized carbon, a_H^{CH} or $a_H^{CCH_3}$, respectively, is an indication of the spin density in the $2p_z$ orbital on that carbon, ρ_C^π, using eq. [15] or [16]

$$[15] \qquad a_H^{CH} = Q_H^{CH}\rho_C^\pi$$

$$[16] \qquad a_H^{CCH_3} = Q_H^{CCH_3}\rho_C^\pi$$

However, even here there is uncertainty as to which of the two ρ–π parameters, Q_H^{CH} or $Q_H^{CCH_3}$, if either, has a generally applicable value. Fessenden and Schuler (37) have estimated a value of $Q_H^{CCH_3}$ equal to 29.3 G from a study of a series of alkyl radicals and suggested that this parameter is more likely than Q_H^{CH} to be a universal constant. Fischer (38) has shown that, if this is true, Q_H^{CH} is strongly dependent upon the substituents at the trigonal carbon atom in aliphatic radicals. His values of Q_H^{CH} varied between 18.3 and 26.2 G. Consequently, it may be possible to determine the spin density on a nitrogen atom in an organic radical in an analogous fashion from any of the following equations

$$[17] \qquad a_H^{NH} = Q_H^{NH}\rho_N^\pi$$

$$[18] \qquad a_H^{NCH_3} = Q_H^{NCH_3}\rho_N^\pi$$

$$[19] \qquad a_N = Q_N\rho_N^\pi$$

Tables II and III give representative data for radicals bearing N—H and N—CH_3 groups. These data show that the ratios a_N/a_H^{NH} and $a_N/a_H^{NCH_3}$ vary considerably between different types of radical or even within an apparently similar group of radicals, e.g., radicals containing functional groups —NHO· or —CONHO·. Thus, all three equations cannot be valid simultaneously. Furthermore, the few estimates for the three Q values in eqs. [17]–[19] given in Tables II and III suggest that these too, vary appreciably (Q_N, 20–35 G; Q_H^{NH}, 21–36 G; $Q_H^{NCH_3}$, 20–36 G).

*For di-*t*-butyl nitroxide a_N has been reported (50*a*) to equal 15.4 G and sufficient anisotropic hyperfine coupling constant data are presented (50*a*) to enable ρ_N^π to be calculated. The value of ρ_N^π obtained is ca. 0.61 and is based on the assumption that unit spin density in a $2p_z$ orbital on nitrogen gives an interaction of ca. 17 G (50*b*). This information and the assumption that $a_N((CH_3)_2NO\cdot)$: $a_N((t\text{-}C_4H_9)_2NO\cdot)$ equals $\rho_N^\pi((CH_3)_2NO\cdot)$: $\rho_N^\pi((t\text{-}C_4H_9)_2NO\cdot)$ lead to an estimate for $\rho_N^\pi((CH_3)_2NO\cdot)$ of ca. 0.60 from which the Q values of this present work were deduced.

†Calculated in this present work on the assumption, analogous to that originally made in the case of alkyl radicals (37), that each α-methyl group removes 8.1% of the unpaired spin density from the $2p_z$ orbital of the adjacent unsaturated nucleus, i.e., ρ_N^π equals 0.776.

‡This radical was prepared at 25 °C from $C_6H_5CON(CH_3)OH$ with the use of aqueous ceric ammonium sulfate ca. 0.1 *M* with respect to sulfuric acid and the procedures are described in the main text. The $C_6H_5CON(CH_3)OH$ was prepared from $C_6H_5COOC_2H_5$ and CH_3NHOH (48).

Since there appears to be no simple generally applicable method of determining the spin density on nitrogen in the nitroxides discussed in this paper, it was thought that the most appropriate method was to choose values of Q_H^{NH} and Q_N and assume the validity of eqs. [17] and [19] for this limited range of radicals. The values $Q_N = Q_H^{NH} = 23$ G derived from the hydrazine radical cation, $[NH_2NH_2]^+$ (39), have been chosen because of the similarity between the hyperfine interactions of this radical and those of the simplest nitroxide radical $NH_2O\cdot$ (34). Both of the above radicals and the monoalkyl nitroxides, $RNHO\cdot$ (15, 32), are unusual in that their nitrogen and proton hyperfine interactions are about equal (see Tables I and II).

The values of ρ_N^π obtained in this way for the radicals listed in Table I vary between 0.62 for $(CH_3)_2C(OH)\dot{N}OCH_3$ and 0.52 for $CH_3COCCH_3(NH_2)\dot{N}HO\cdot$. The value of ρ_N^π equal to 0.62 for $(CH_3)_2C(OH)\dot{N}OCH_3$ would indicate ρ_O^π to be between 0.25 and 0.35, by analogy with work on alkyl radicals (37) which suggests that an α-alkyl group withdraws about 8% of the unpaired spin density from the $2p_z$ orbital of the adjacent unsaturated carbon atom. Hence, a value of $Q_H^{OCH_3}$ equal to 12.4–8.9 G can be estimated. If the highest value of Q_N given in Tables II and III, viz., 35 G, is used, the apparent spin density on oxygen increases and $Q_H^{OCH_3}$ decreases to between 5.5 and 6.7 G. The coupling constant data for $CH_3CH(OH)\dot{N}OCH_3$ are similar to those for $(CH_3)_2C(OH)\dot{N}OCH_4$ and yield estimates of $Q_H^{OCH_3}$ of about the same size. Values of $Q_H^{OCH_3}$ found by other workers vary between 5.6 and 19 G, while values of Q_H^{OH} are in the range 7 to 21 G (55–57).

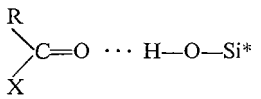
Infrared spectroscopic studies of adsorption and catalysis. Part 3. Carboxylic acids and their derivatives adsorbed on silica

R. P. YOUNG[1]

School of Chemical Sciences, University of East Anglia, Norwich, England

Received February 20, 1969

Infrared spectra in the region 4000–1300 cm^{-1} have been obtained of acetic acid, acetyl chloride, acetic anhydride, propionic acid, and propionyl chloride adsorbed on discs of pressed silica powder. In all cases the spectra showed the presence of both the simple hydrogen-bonded species



where X = OH, Cl, or O.CO.R and Si* represents a surface silicon atom, and also chemisorbed surface ester groups R.CO.O—Si*. The latter were characterized by a $\nu_{C=O}$ frequency in the 1760–1740 cm^{-1} region, whereas in the case of hydrogen-bonded physical adsorption, the $\nu_{C=O}$ frequency was about 20–30 cm^{-1} lower than that of the same molecule in the vapor phase. At high temperatures (150–200 °C) the water or hydrogen chloride eliminated in the surface esterification reaction was desorbed, and high conversions of surface OH to surface ester groups were observed. Under these conditions the carboxylic acid was formed from both the chloride and the anhydride; the latter was also produced at room temperature from the acid chloride. A scheme is suggested for the equilibration of these compounds on hydroxylated silica surfaces. The chemisorbed ester groups were susceptible to hydrolysis by water vapor, thus regenerating the original silanol OH groups.

Canadian Journal of Chemistry, 47, 2237 (1969)

Introduction

In continuation of recent spectroscopic studies of the adsorption of organic carbonyl compounds, the adsorption of a range of carboxylic acids and their derivatives at various temperatures on pressed discs prepared from pure silica powder has been examined. The adsorption of these compounds has not previously been investigated in very much detail by infrared (i.r.) spectroscopy, although formic acid was studied by Hirota (1) on silica and alumina, and by Clarke and Pullin (2) on silica-supported nickel. Noto *et al.* (3) have recently examined the decomposition of formic acid over alumina and silica and concluded that on the latter at 180 °C the adsorbate was stable, although deuterium exchange occurred with the hydrogen atom of the surface hydroxyl groups. Eischens (4) showed that acetic acid interacted with a silica – magnesium oxide surface to form chemisorbed surface acetyl groups. The adsorption of acetyl chloride and acetic anhydride on solid aluminium chloride was studied by Bertoluzza and co-workers (5, 6).

This paper describes the i.r. spectra obtained from acetic acid, acetic anhydride and acetyl chloride, and propionic acid and propionyl chloride adsorbed on Cab-O-Sil powder at temperatures between 25 and 200 °C. In each case the spectra show that several surface species are formed, indicating that an equilibrium is established on the surface between the acid, the chloride, and the anhydride, whereby they may be interconverted one with another. Chemisorbed surface ester groups R.CO.OSi* were observed as a predominant species, although in the presence of water vapor they were found to be easily hydrolyzed, thus regenerating the original surface hydroxyl groups.

Experimental

The adsorbates were distilled under dry nitrogen immediately before use, and thoroughly degassed by repeated freeze–thaw–pumping cycles just prior to admission of the pure vapor to the adsorption cell at 25 °C. Spectra were taken before and after sample admission, and again after various intervals of standing and/or heating. The adsorption cell and the spectrometer have been described before (7). The silica used was Cab-O-Sil HS powder (kindly donated by the Cabot Corporation, Boston, Mass.), which was ignited for 12 h at 600 °C, and then pressed for 2 min at 5 tons/sq in. into thin discs 1 in. diameter and weighing about 100 mg.

---

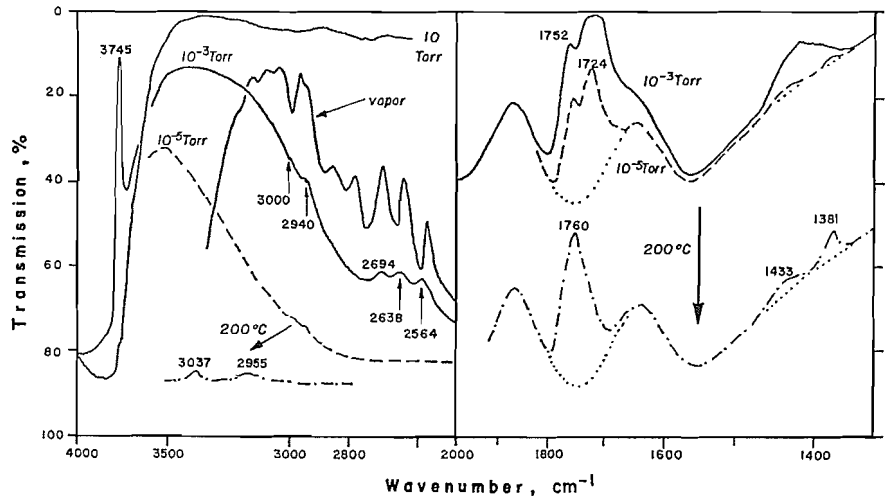

FIG. 1. Acetic acid adsorbed on Cab-O-Sil powder. 25 °C at 10, 10^{-3}, and 10^{-5} Torr (dashed); 200 °C at 10 Torr for 15 h and evacuated at 100 °C to 10^{-5} Torr (dot–dashed).

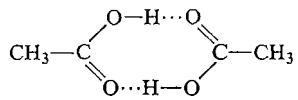
Results

A. *Acetic Acid, Acetyl Chloride, and Acetic Anhydride*

(i) Acetic Acid

Exposure of a Cab-O-Sil sample to acetic acid vapor (10 Torr) resulted in the very highly absorbing spectrum shown as the upper solid line in Fig. 1 (4000–2700 cm^{-1} region). The ν_{O-H} band of free surface hydroxyl groups at 3745 cm^{-1} had completely disappeared and was replaced by the very strong $\nu_{O-H\cdots O}$ band which extended well below 3000 cm^{-1}, and obscured all the detail of the ν_{C-H} bands. The vapor phase spectrum in this region showed the main ν_{O-H} absorption and also the overtone and combination satellite bands characteristic of the hydrogen-bonded cyclic dimer (8)



Similar bands were also seen in the adsorbed phase after evacuation to 10^{-3} Torr, indicating that this species was also present on the surface; the free OH groups of the silica surface were largely restored. At this pressure the $\nu_{C=O}$ region showed a very strong band at 1724 cm^{-1} and a weaker one at 1752 cm^{-1}. On further evacuation to 10^{-5} Torr (dashed line) there was a general loss of intensity in this region of the spectrum, the 1724 cm^{-1} band becoming weaker relative to that at 1752 cm^{-1}. The characteristic overtone and combination bands below 2700 cm^{-1} and the broad band at 1410 cm^{-1} of the dimer were no longer visible, suggesting that at this pressure monomeric acetic acid is the principal physically adsorbed species. When a further sample of acetic acid vapor was admitted and heated overnight at 200 °C, followed by evacuation to 10^{-5} Torr at 100 °C, the spectrum given by the dot–dashed line was obtained. This showed very weak ν_{C-H} bands at 3037 and 2955 cm^{-1}, a single $\nu_{C=O}$ band at 1760 cm^{-1}, and CH deformation bands at 1433 and 1381 cm^{-1} (see also Table I). These new bands were not diminished at all by prolonged evacuation and most probably arose from chemisorbed species formed by reaction between the acid vapor and the surface hydroxyl groups. This residual spectrum is characteristic of the acetyl group, and can reasonably be attributed to a surface acetyl species formed by the esterification reaction

$$CH_3.COOH + HOSi^* \rightarrow CH_3.CO.OSi^* + H_2O$$

As will be described below, the reactions of both acetyl chloride and acetic anhydride give rise to virtually identical residual spectra, suggesting that the chemisorbed product is the same in each case. We may therefore confidently assign the strong band at 1760 cm^{-1} to the $\nu_{C=O}$ mode of chemisorbed surface acetyl groups. The 1724 cm^{-1} band, which was strong initially but was

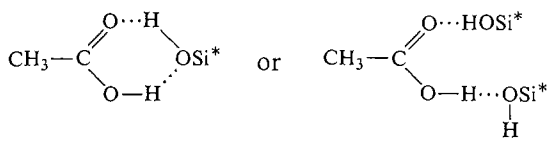
†Monomer.
‡Dimer.

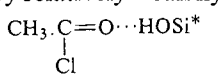
entirely eliminated by evacuation at 100 °C, was attributed to physically adsorbed acetic acid.

The observation by Noto and co-workers (3) that D.CO.OD participated in deuterium exchange with surface OH groups suggests that the hydroxylic hydrogen atom of the acid molecule interacts directly with the surface. The $\nu_{C=O}$ frequency of $\sim 1720\ cm^{-1}$ which we observe for the physically adsorbed acetic acid, indicates that the carbonyl group also is hydrogen-bonded to surface OH groups. However, it is not clear from the i.r. spectra alone, whether the acetic acid molecule is held to the silica surface by one or by two silanol groups, e.g.



(ii) Acetyl Chloride

Figure 2(*a*) shows the spectra obtained immediately after the adsorption of acetyl chloride (10 Torr, solid line; 10^{-5} Torr, dashed line). Of particular note are the two $\nu_{C=O}$ bands; the one at 1795 cm^{-1} was completely removed after brief evacuation (dashed line), and was therefore assigned as the $\nu_{C=O}$ mode of acetyl chloride held to the surface by relatively weak hydrogen-bonds



The 1742 cm^{-1} band, on the other hand, was retained even after evacuation for several hours at 25 °C, and was attributed to chemisorbed surface acetyl groups (the intensity ratio of the ν_{C-H} and $\nu_{C=O}$ bands was similar to that observed above in the case of acetic acid adsorption). The hydrogen chloride liberated in the surface esterification was not observed, presumably because it was removed from the adsorption cell by evacuation before the spectrum was recorded. When a further sample of acetyl chloride vapor (10 Torr) was allowed to stand over the silica surface for 15 h at 25 °C, not only did the ν_{C-H} and $\nu_{C=O}$ bands of the surface ester groups become stronger, but in addition a new weak $\nu_{C=O}$ band appeared at 1842 cm^{-1} (Fig. 2(*b*), solid line). As before, evacuation to 10^{-5} Torr at 25 °C removed all the physically adsorbed acetyl chloride (as shown by the disappearance of bands at 1795 and 1364 cm^{-1}, dashed line) but the new 1842 cm^{-1} band remained, and was only finally removed by evacuation for 30 min at 150 °C (at 10^{-5} Torr). That the adsorption of this new species was physical, and not chemical in nature, was established by the eventual disappearance of the 1842 cm^{-1} band, in contrast to the surface acetyl groups which were retained at 150 °C. The high frequency of the $\nu_{C=O}$ band (1842 cm^{-1}) suggests the possible formation of an acid anhydride; the strong retention on the silica surface is consistent with the relatively high boiling point

(140 °C) of acetic anhydride. The lower frequency component (at ~ 1785 cm^{-1}) of the expected anhydride $\nu_{C=O}$ doublet was obscured by the broad strong band at 1756 cm^{-1} of the surface ester groups still retained at 10^{-5} Torr. This assignment of the 1842 cm^{-1} band was confirmed by experiments with acetic anhydride itself (see following section). A further sample of acetyl chloride (10 Torr) was admitted and heated overnight at 150 °C; subsequent cooling to 25 °C yielded the spectrum shown in Fig. 2(*c*), solid line. In addition to $\nu_{C=O}$ bands characteristic of physically adsorbed acetyl chloride (1790 cm^{-1}), acetic anhydride (1838 cm^{-1}, shoulder), and chemisorbed surface acetyl groups (~ 1765 cm^{-1}, very strong), bands characteristic of physically adsorbed acetic acid dimer were also observed (2800–2600 cm^{-1} region, 1720 and 1410 cm^{-1}). Evacuation at 100 °C removed all these physically adsorbed species, leaving only the surface ester groups which had almost completely replaced the original free hydroxyl groups (Fig. 2(*c*), dashed line). The residual $\nu_{O-H\cdots O}$ band at about 3600 cm^{-1} (dashed) possibly arises from hydrogen-bonding between a small number of surface acetyl groups and unreplaced OH groups

$$CH_3.CO.OSi^*$$
$$\vdots$$
$$HOSi^*$$

The variation of $\nu_{C=O}$ frequency within the 1760–1740 cm^{-1} range is discussed later in terms of hydrogen-bonding to OH groups, either on the silica surface or in vapor phase molecules. The frequencies and optical densities of all the observed bands are listed in Table II.

(iii) Acetic Anhydride

In order to confirm the assignment of the 1842 cm^{-1} band observed with acetyl chloride, spectra were recorded using acetic anhydride itself as adsorbate. In Table III are listed the frequencies of the bands shown in Fig. 3 for the adsorption of acetic anhydride at 3 Torr on Cab-O-Sil. The dashed line represents the spectrum obtained after evacuation to 10^{-5} Torr at 25 °C, and shows both physically adsorbed acetic anhydride (1839 cm^{-1}) and surface acetyl groups (1755 cm^{-1}). After reaction at 200 °C for 12 h the surface OH groups were replaced to a considerable extent by acetyl groups (dot–dashed line), as in the cases of acetic acid and acetyl chloride. The ν_{C-H} region is shown expanded. Because of the low volatility of acetic anhydride, the silica surface was exposed

for several minutes to the saturated vapor pressure (~ 3 Torr at 25 °C). This may account for the breadth of the bands recorded at this pressure, since some condensation may have occurred on the sample. The vapor phase also appeared to contain a small amount of acid (1740 cm^{-1}) although none was observed in the spectrum of the adsorbed phase.

B. Propionic Acid and Propionyl Chloride

(i) Propionic Acid

At room temperature and a pressure of 1 Torr the spectrum shown in Fig. 4(*a*) was obtained; the ν_{C-H} bands were superimposed on the broad $\nu_{O-H\cdots O}$ absorption and the $\nu_{C=O}$ band was broad and unresolved, and centered at about 1720 cm^{-1}. On evacuation to 10^{-5} Torr the maximum shifted to 1745 cm^{-1}, after removal of the low frequency component responsible for the original breadth of the band (although this was still visible as a shoulder at 10^{-5} Torr). By analogy with the case of adsorbed acetic acid, the 1720 cm^{-1} band has been assigned to the $\nu_{C=O}$ mode of physically adsorbed propionic acid; at 1 Torr there was less evidence of the dimer than with acetic acid at 10^{-3} Torr, since the overtone and combination bands below 2700 cm^{-1} were scarcely visible, although a rather broad band was present at 1420 cm^{-1} corresponding to the 1410 cm^{-1} band of acetic acid dimer. The residual

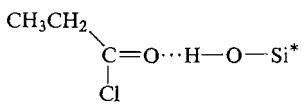
spectrum ($\nu_{C=O}$ at 1745 cm^{-1}, and ν_{C-H} bands as shown) has been taken to represent chemisorbed surface propionyl groups $CH_3CH_2.CO.OSi$*. The frequencies of the bands are listed in Table IV. Virtually identical spectra were observed from the ester groups formed from propionyl chloride (see following section).

(ii) Propionyl Chloride

The spectrum of propionyl chloride adsorbed on silica, shown in Fig. 4(*b*), was analogous to that observed with acetyl chloride. Thus, physically adsorbed propionyl chloride



showed a $\nu_{C=O}$ band at 1786 cm^{-1} which was easily removed by evacuation, and a persistent band at 1828 cm^{-1} attributed to the anhydride. Room temperature evacuation to 10^{-5} Torr removed the acid chloride (dashed line), revealing the $\nu_{C=O}$ band of chemisorbed $CH_3CH_2.CO.OSi$* groups at 1742 cm^{-1}. In the ν_{C-H} region the intensity pattern was very similar to that observed with methyl ethyl ketone (7) and diethyl ketone (9), which also contain the propionyl group. The rather pronounced adsorbed anhydride $\nu_{C=O}$ band may have been slightly enhanced by the possible presence of traces of anhydride impurity in the sample (see the weak high frequency shoulder on the vapor phase $\nu_{C=O}$ band).

When heated overnight at 200 °C in the presence of 10 Torr propionyl chloride, the surface OH groups were replaced almost completely by $CH_3CH_2.CO.OSi$* groups. Considerable amounts of propionic acid were also formed, as shown by the characteristic dimer bands in the 2800–2600 cm^{-1} region, the broad 1427 cm^{-1} band, and the $\nu_{C=O}$ band at 1725 cm^{-1} (Fig. 4(*c*), solid line). All the physically adsorbed acid, acid chloride, and acid anhydride were removed by evacuation to 10^{-5} Torr at 100 °C, leaving on the surface almost exclusively the chemisorbed propionyl groups. The weak band at about 3500 cm^{-1} on the side of the residual $\nu_{O-H\cdots O}$ band (dashed) was assigned as the overtone of the $\nu_{C=O}$ fundamental at 1764 cm^{-1}. The frequencies of all the other observed bands are listed in Table V.

Discussion

It is concluded that the species responsible for the strong absorption band in the 1760–1740 cm^{-1} region is chemisorbed, since prolonged evacuation at elevated temperatures fails to remove it from the surface. Moreover, the similarity observed in these residual spectra, whether the initial adsorbate is the carboxylic acid, the acid chloride, or the acid anhydride, suggests that the same species is formed in each case. There is, in fact, little doubt that the surface silanol groups are esterified to form chemisorbed acetyl and propionyl groups, i.e. $CH_3.CO.OSi$* and $CH_3CH_2.CO.OSi$*. This assignment is fully confirmed, at least in the acetyl case, by a comparison with the vapor phase spectra of silyl acetate reported by Robiette and Thompson (10). There is surprisingly little difference between $CH_3.CO.OSi$*, $CH_3CO.OSiH_3$, and $CH_3.CO.OSiD_3$ in any of the vibrational frequencies, as is shown in Table VI.

The only frequency which is significantly affected by the presence of the silica surface is that

of the carbonyl stretching mode, which is increased by about 15 cm^{-1} relative to silyl acetate. Inspection of Tables I–V and Figs. 1–4 reveals that the observed frequency of the $\nu_{C=O}$ band of the surface ester groups varies within the range 1765–1740 cm^{-1}. There is, however, a consistent trend in every case; the frequency after brief adsorption at 25 °C is always between 1755 and 1740 cm^{-1}, and rises to over 1760 cm^{-1} after long periods at high temperature (note that all the spectra were recorded with the sample at 25 °C). Closely parallelling the frequency rise in the $\nu_{C=O}$ vibration is the intensity decrease of the ν_{O-H} band of the surface OH groups. This strongly suggests that it is the surface OH concentration which influences the behavior of the ester groups replacing them on the surface. It seems not unlikely that at low ester group concentrations, hydrogen-bonding to adjacent, unreplaced, silanol groups may occur. As the

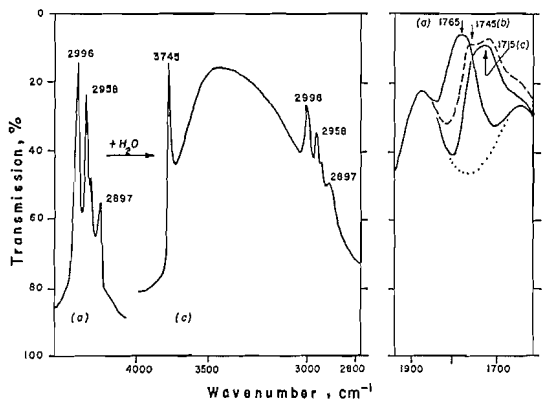

FIG. 5. Hydrolysis of surface propionyl groups by water vapor at 25 °C. (*a*) Surface as in Fig. 4 (*c*-dashed); (*b*) immediately after addition of water vapor (dashed line); (*c*) after standing in water vapor at 10 Torr for 14 h and evacuation to 10^{-4} Torr.

temperature is raised, the conversion of OH to ester groups increases and such neighboring group interactions become less numerous. Such interactions would be expected to cause a shift of about -20 cm^{-1} to the $\nu_{C=O}$ frequency (7, 9). To test the hypothesis that hydrogen-bonding to OH groups can cause a frequency shift from ~ 1760 to ~ 1740 cm^{-1} in the $\nu_{C=O}$ mode of surface carbonyl groups, a fully esterified surface was exposed to water vapor at 25 °C. The propionylated surface represented by the dashed line in Fig. 4(*c*) was used, and the results are shown in Fig. 5. The spectrum before the adsorption is shown in the $\nu_{C=O}$ region as curve (*a*), with a peak intensity at 1765 cm^{-1}. Immediately after the surface was exposed to water vapor the dashed curve (*b*) was observed, with maximum absorption at 1745 cm^{-1}, in support of the view that this lower frequency refers to hydrogen-bonded surface carbonyl groups

$$\mathrm{CH_3CH_2.CO.OSi^*} \quad \text{or} \quad \mathrm{CH_3CH_2.CO.OSi^*}$$
$$\vdots \qquad\qquad\qquad\qquad \vdots$$
$$\mathrm{H{-}O{-}H} \qquad\qquad\qquad \mathrm{H{-}OSi^*}$$

In addition to this change, a band at 1715 cm^{-1} also appeared on addition of water. This was attributed to physically adsorbed propionic acid, formed by the hydrolysis of the surface ester groups by the added water vapor

$$\mathrm{CH_3CH_2.CO.OSi^* + H_2O \rightarrow HOSi^* + CH_3CH_2.COOH}$$

Support for this view was found when, after standing overnight at 25 °C in water vapor (10 Torr), the spectrum of the surface again showed bands in the 2800–2600 cm^{-1} region characteristic of the dimeric acid. Moreover, on evacuation to 10^{-4} Torr, the "free" ν_{O-H} band at 3745 cm^{-1} was partially restored and the ν_{C-H} bands of the $CH_3CH_2.CO.OSi^*$ groups were considerably weaker (Fig. 5, curve (*c*)). These observations are similar to those of Eischens (4) who reported bands at 1747 and 1389 cm^{-1} which he attributed to chemisorbed acetyl groups formed by the interaction of acetic acid with a mixed silica/magnesium oxide surface; however, on pure silica he found these bands to be very weak, and concluded that the ester groups were formed mainly on the magnesium oxide. He also noticed that the addition of water led to a decrease in the concentration of these ester groups, and the appearance of a weak band at 1701 cm^{-1} indicated the regeneration of the free acid.

From the results presented here, it is clear that surface ester groups are readily formed on pure silica and, in addition, that the same chemisorbed ester groups are also formed from acid chlorides and anhydrides. In these cases, however, more than one surface species is usually formed, and these can generally be identified by the $\nu_{C=O}$ frequency. The highest conversions of surface hydroxyl to surface ester groups were achieved at high temperatures, when the water or hydrogen chloride released in the reaction was desorbed from the surface. Under these conditions the carboxylic acid was formed from both the chloride and the anhydride; the latter was also observed during the room temperature adsorption of the acid chloride. It is evident, therefore, that an equilibrium is established on the surface between the acid, the chloride, and the anhydride, whereby they may be interconverted with each other; the actual products obtained depend on the conditions employed. This may be represented schematically as shown below.

In this scheme, † denotes physical adsorption by hydrogen-bonding to surface OH groups; (A) ~ 1720 cm^{-1}; (B) ~ 1840 cm^{-1}; (C) ~ 1790 cm^{-1}; (D) 1760–1740 cm^{-1}, these limits represent "essentially free" and "essentially hydrogen-bonded" surface carbonyl groups respectively.

Finally, it is concluded that the esterification of surface silanol groups by carboxylic acids and their derivatives is reversible with respect to hydrolysis by water vapor, which is consistent with Eischens (4) observations of the behavior

Coefficient of thermal expansion of solid cyclohexane by means of dielectric constant measurements

R. K. CHAN AND H. A. CHEW
Department of Chemistry, University of Western Ontario, London, Ontario

Received February 6, 1969

A method has been devised to measure the coefficient of thermal expansion of solid cyclohexane from −80 to 0 °C by means of dielectric constant measurements in a spring-loaded apparatus. Assuming the Clausius–Mosotti equation to be valid, the coefficient of thermal expansion is given by

$$\alpha = -\frac{3}{(\varepsilon - 1)(\varepsilon + 2)}\left(\frac{\partial \varepsilon}{\partial T}\right)_p$$

$(\partial\varepsilon/\partial T)_p$ for solid cyclohexane is found to be -9.6×10^{-4} °C^{-1}. Therefore, $\alpha = 6.0 \times 10^{-4}$ °C^{-1} at −40 °C and $(\partial\alpha/\partial T)_p = 6.4 \times 10^{-7}$ °C^{-2}.

According to Crowe and Smyth $(\partial\varepsilon/\partial T)_p$ is $+7 \times 10^{-4}$ °C^{-1} because it has been measured with a fixed amount of solid cyclohexane between the electrodes. Using a model calculation based on the equivalent circuit consisting of 3 series capacitors filled alternately with air and sample, it is shown that the apparent value of $(\partial\varepsilon/\partial T)_p$ actually changes sign.

The coefficient of thermal expansion, α, of solids can be calculated simply from the dimensional changes as a function of temperature. For solids with well-defined dimensions such as metals, the measurement of α is straightforward. Various methods have been reviewed by Hidnert and Souder (1). However, these methods are not adaptable to polycrystalline organic or inorganic solids because of their volatility and tendency to fracture upon cooling. These complications have adverse effects on the dimensional stability of the specimen. Garner and Ryder (2) measured the densities of solid fatty acids using the dried air displacement method. Because of the high compressibility of air they had to take extraordinary precautions to maintain a constant temperature and to measure pressures very accurately. A convenient method has been devised to measure the coefficient of thermal expansion of non-polar polycrystalline solids over a considerable temperature range using dielectric constant measurements.

Experimental

The dielectric constant of solid cyclohexane was measured by a General Radio 1615-A transformer ratio arm capacitance bridge capable of 0.01% precision from 1–10 kHz. The signal was supplied by a Hewlett–Packard 200 CD oscillator and the unbalanced signal was amplified by a Rohde–Schwarz UBM tunable indicating amplifier. The temperature was measured to ±0.1 °C by means of a duplex copper–constantan thermocouple with a Leeds and Northrup K-3 universal potentiometer. The thermocouple was calibrated at the freezing point of mercury and the sublimation point of solid carbon dioxide at 1 atm. The spring-loaded 3-terminal dielectric cell is shown in Fig. 1. The tension of the spring equivalent to 10 atm kept the solid sample under an essentially constant pressure. The dielectric cell was made of stainless steel and insulated with teflon and mica. A system of 3-terminal coaxial electrodes similar to that employed by Davidson and Cole (3) was used. The nominal dimension of the inner electrode was 0.5 in. in diameter and the outer electrode was 0.75 in. in diameter by 1.25 in. in length. With the dielectric cell empty, the cell constant was 4.443 ± 0.002 pF independent of frequency from 1–10 kHz. The cyclohexane was Fisher certified spectranalyzed grade which was distilled fractionally from calcium hydride at atmospheric pressure before use. The cyclohexane was frozen by packing the outside of the dielectric cell with a small amount of dry ice. After the spring was loaded the dielectric cell was introduced into a copper tube wound with insulated heater wire, this assembly being placed in the center of a metal can containing polyurethane foam insulation. The entire assembly was placed in a stainless steel Dewar and was cooled by liquid nitrogen. The heater was controlled to ±0.1 °C by a Philips automatic compensator using a thermocouple as the sensing element. The temperature of the solid cyclohexane was cycled between −80 and 0 °C until the dielectric constant in the warming and cooling cycles agreed to within ±0.1% or better. About 4 cycles were required and each cycle took 2 days. The solid sample remained at constant temperature for at least 2 h before the final readings were taken.

Results

The dielectric constants of cyclohexane at 10 kHz are shown in Table I and Fig. 2. The conductance of the sample was approximately $10^{-10}\ \Omega^{-1}\ \text{cm}^{-1}$. According to the Clausius–Mosotti equation the dielectric constant of a

non-polar substance is related to the molar polarization by

$$[1] \qquad \frac{\varepsilon - 1}{\varepsilon + 2}\frac{M}{\rho} = P$$

where ε is the dielectric constant, M is the molecular weight, ρ is the density, and P the molar polarization. If the molar polarization is independent of temperature

$$[2] \quad \alpha = -\left(\frac{\partial \ln \rho}{\partial T}\right)_p = -\frac{3}{(\varepsilon - 1)(\varepsilon + 2)}\left(\frac{\partial \varepsilon}{\partial T}\right)_p$$

where α is the coefficient of thermal expansion. Since α is normally a positive quantity, ε should increase with a decrease of temperature. For liquid cyclohexane the temperature coefficient of dielectric constant is $-1.6 \times 10^{-3}\ °C^{-1}$ and the dielectric constant is 2.023 at 20 °C (4). According to eq. [2], $\alpha = 1.16 \times 10^{-3}\ °C^{-1}$. The densities

of liquid cyclohexane are 0.77855 and 0.77389 g cm^{-3} at 20 and 25 °C respectively (5), $\alpha = 1.20 \times 10^{-3}\ °C^{-1}$. Therefore, the value of α obtained from dielectric constant compares favorably with that obtained from the density for liquid cyclohexane. It is assumed that similar calculations apply to solid cyclohexane. The temperature coefficient of dielectric constant for solid cyclohexane from −80 to 0 °C is $-9.6 \times 10^{-4}\ °C^{-1}$ which is independent of temperature within the experimental error. Values of α for various temperatures are given in Table II. The temperature coefficient of α is $6.4 \times 10^{-7}\ °C^{-2}$. Garner and Ryder (2) quoted the mean α for solid octoic, nonoic, decoic, undecoic, and lauric acids between 0 and 50 °C as $7.7 \times 10^{-4}\ °C^{-1}$ compared to $6.0 \times 10^{-4}\ °C^{-1}$ at −40 °C for solid cyclohexane.

Discussion

The dielectric behavior of cyclohexane has been investigated by Crowe and Smyth (6). They took the precaution of eliminating voids and cracks

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

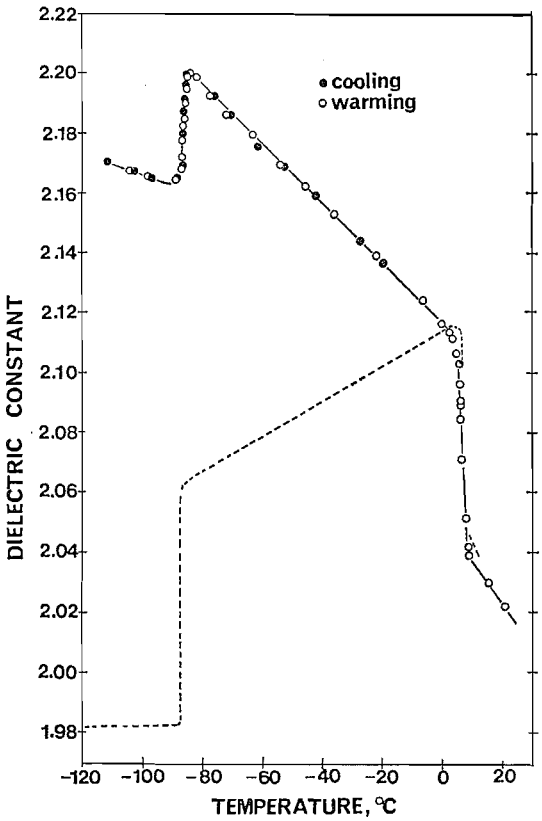

FIG. 2. Dielectric constant of cyclohexane at 10 kHz. The dashed line represents the data of Crowe and Smyth (6).

by freezing and thawing the sample repeatedly. Consequently, the value of the dielectric constant for solid cyclohexane slightly below the freezing point agreed well with the results of this investigation. Their results are represented by a dashed line in Fig. 2. With the use of a spring-loaded dielectric cell, the solid sample always filled the space between the electrodes. Increase in density as the temperature was decreased inevitably resulted in an increase of dielectric constant according to eq. [1], provided the molar polarization remained constant. The decrease of dielectric constant of solid cyclohexane observed by Crowe and Smyth can be explained if air gaps were present when the sample was cooled below the freezing point. Consequently, their measurements were most probably made on the solid–vapor equilibrium line. Since the amount of solid material between the electrodes was constant, shrinkage at low temperature could cause cracks

TABLE II

Variation of coefficient of thermal expansion of solid cyclohexane from −80 to 0 °C

Temperature (°C)	$\alpha(10^4\,°C^{-1})$

to appear. It was demonstrated conclusively by Auty and Cole (7) that air gaps parallel to the electrodes caused a decrease in dielectric constant of ice. Consider two parallel electrodes with area A and separation d. The capacitance in pF is given by

$$[3] \qquad C = \frac{\varepsilon A}{4\pi d}$$

where ε is the dielectric constant of the medium. If a parallel air gap of fractional width $\delta/2$ separates each electrode from the solid dielectric, the apparent capacitance of this compound capacitor, which is equivalent to 3 capacitors in series with the solid dielectric sandwiched between 2 air capacitors, is

$$[4] \qquad \frac{1}{C_{app}} = \frac{1}{C_{air}} + \frac{1}{C_{solid}} + \frac{1}{C_{air}}$$

Combining eqs. [3] and [4], one gets

$$[5] \qquad \frac{1}{\varepsilon_{app}} = \frac{\delta}{2} + \frac{1-\delta}{\varepsilon_{solid}} + \frac{\delta}{2}$$

or

$$\varepsilon_{app} = \frac{\varepsilon_{solid}}{1 + \delta(\varepsilon_{solid} - 1)}$$

In order to account for the result of Crowe and Smyth with ε_{app} being 2.07 at −80 °C, the fractional width of the air gaps, δ, must be 5.0%. In other words, the sample has to contract 5.0% in a direction perpendicular to the electrodes. The volume contraction of the sample from the freezing point to −80 °C is 5.2%. If the sample contracts uniformly, the fractional width of air gaps should be approximately one third of volume contraction, i.e. 1.7%, which is substantially below the predicted value of 5.0%. At least the prediction is in the right direction even though the quantitative agreement is poor. On the other hand, if the contraction is not uniform, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

extreme case would give rise to a value of 5.2% for the fractional width of air gaps. Granting such a case, the apparent dielectric constant of solid cyclohexane would be represented almost exactly by the dashed line in Fig. 2. It is worthwhile to point out that the apparent dielectric constant at −80 °C is only 0.13 less than the true value. For most dielectric constant measurements this is within the experimental error. Therefore, the slight error due to incomplete filling of the space between the electrodes will not show under normal circumstances.

Dielectric properties of hexafluoroacetone and hexachloroacetone

R. K. CHAN
Department of Chemistry, University of Western Ontario, London, Ontario
Received February 7, 1969

The dielectric constants of hexafluoro- and hexachloro-acetone are measured in the solid and liquid state. They show negligible association in the liquid state. The dipole moments are 0.648 D measured in the gaseous state and 0.63 D in pure liquid for hexafluoroacetone, and 1.24 D in carbon tetrachloride solution and 1.34 D in pure liquid for hexachloroacetone. If the differences between inductive effects due to CX_3 and C=O groups can be ignored, the vector addition of bond moments gives values of dipole moment which are compatible with the experimental values.

Recently Plaush and Pace (1) studied the thermodynamic properties of hexafluoroacetone from 12 °K to its normal boiling point. A survey of the literature revealed that the dielectric properties of hexafluoroacetone and hexachloroacetone had never been investigated. The objectives of this work were to measure their dielectric constants in the gas, liquid, and solid state and in solution.

Experimental

The chemically pure grade of hexafluoroacetone was supplied by the Matheson Co. It was purified by fractional distillation in a standard vacuum apparatus. The melting point was 147.5 °K as determined by the dielectric constant measurements compared to the literature value of 147.70 °K (1). The reagent grade hexachloroacetone was supplied by Aldrich Chemical Co. It was purified by refluxing with calcium hydride and fractionally distilled at 1 atm. The constant boiling fraction of 476–477 °K was retained. The boiling point given in the literature was 475–477 °K (3).

The apparatus for measuring the dielectric constants in the gas phase was constructed according to Shoemaker and Garland (4). It consisted of a General Radio 1304-B beat frequency audio generator, an oscilloscope, and a GR 1422-ME precision variable capacitor. The frequency of the resonance circuits was 200 kHz. The dielectric cell was made of 3 concentric cylinders insulated by quartz separators. The cell constant measured in vacuum after the lead correction was 297 ± 0.5 pF, effectively independent of temperature. The gas dielectric cell was placed in a fiber glass insulated aluminium block which was heated by two embedded calrod elements. After thermal equilibrium was established, a constant voltage was enough to maintain the temperature drift to less than 0.1° per h. For measurements taken below the room temperature, ice water was circulated through a copper coil placed between the aluminium block and the fiber glass insulation. The temperature was measured by a calibrated chromel p-alumel thermocouple with a Leeds and Northrup K-3 universal potentiometer.

The dielectric constants of the sample in the solid and liquid state were measured in a 3-terminal dielectric cell similar to the one used by Gross and Taylor (5). A General Radio 1615-A transformer ratio arm capacitance bridge with a precision of better than 0.01% was used.

The dielectric constants of the solutions at 25 °C were measured by a Dipolmeter type DM01 manufactured by Wissenschaftlich-Technische Werstätten, Germany. It was calibrated with freshly dried and distilled cyclohexane, benzene, and carbon tetrachloride. The refractive indices (n_D) were measured by an Abbe refractometer thermostated at 25 °C.

Results

The dielectric constants of gaseous hexafluoroacetone were measured up to 1 atm from 276–528 °K (Table I). Using the Debye equation the total molar polarization in $cm^3\ mole^{-1}$ was given by

$$[1] \qquad [P] = 17.53 + \frac{2.556 \times 10^3}{T}$$

corresponding to a dipole moment value of 0.64_8 D. The values of the total molar polarization at various temperatures have been corrected for the non-ideal behavior of the gas by means of the Berthelot equation (6) with the critical temperature of 357.25 °K and the critical pressure of 27.97 atm (1). The calculated molar polarization at the sodium D line was 16.82 $cm^3\ mole^{-1}$ based on the bond refraction values of Smyth (7), and was considered to be in satisfactory agreement with the intercept of 17.53 $cm^3\ mole^{-1}$ in eq. [1] in view of the uncertain contribution due to the atomic polarization.

The gaseous hexafluoroacetone was condensed into the dielectric cell and it was cycled three times through the melting point before the measurements for the solid phase were taken. The dielectric constants of solid and liquid hexafluoroacetone at 10 kHz are shown in Fig. 1 and Table II. At 147.5 °K the solid sample melted sharply with only a slight premelting. The

conductance of the liquid was estimated to be $\sim 10^{-10}\ \Omega^{-1}\ \text{cm}^{-1}$ at 200 °K. Using the Onsager equation (8)

$$[2] \qquad \mu^2 = \frac{9kT}{4\pi N}\,\frac{(\varepsilon - n^2)(2\varepsilon + n^2)}{\varepsilon(n^2 + 2)^2}$$

where N is the number of molecules in 1 cm^3 of liquid. The dipole moments were calculated to be 0.61, 0.63, and 0.64 D at 200, 220, and 240 °K, respectively, with an average of 0.63 ± 0.01 D. The density data were taken from Plaush and Pace (1). The refractive index was estimated by means of the Lorenz–Lorentz equation. The molar refraction was taken as the sum of the bond refractions at the sodium D line less 4% contribution due to atomic polarization (7).

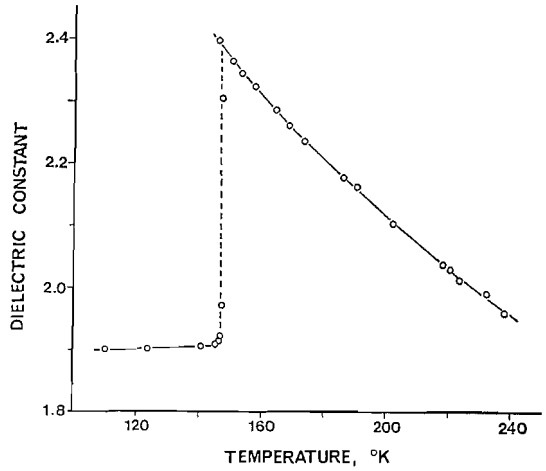

FIG. 1. The dielectric constants of hexafluoroacetone.

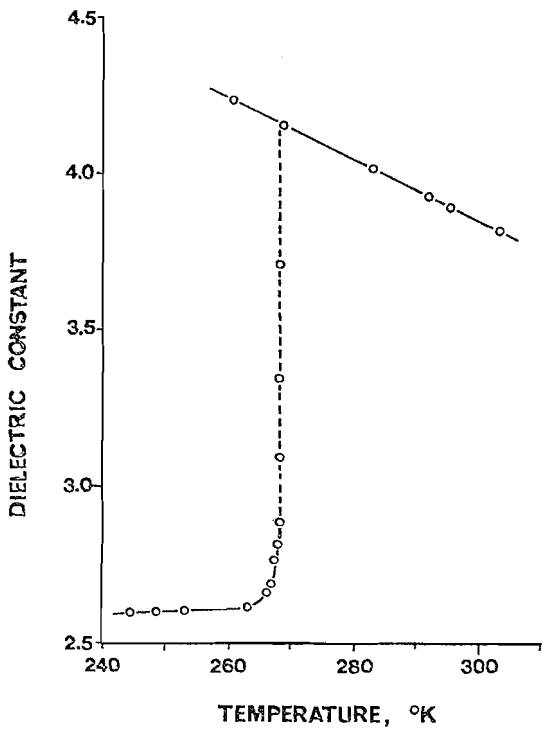

FIG. 2. The dielectric constants of hexachloroacetone.

The dielectric constants of solid and liquid hexachloroacetone at 10 kHz are shown in Fig. 2 and Table III. At 280 °K the conductance of the liquid was $\sim 3 \times 10^{-8}\ \Omega^{-1}\ \text{cm}^{-1}$. With a slight premelting, the solid sample melted sharply at 268.2 °K in fair agreement with the literature value of 269–270 °K (9).

TABLE III

Dielectric constants of hexachloroacetone at 10 kHz

T (°K)	ε	State
244.2	2.594	solid
248.5	2.600	solid
253.0	2.604	solid
263.2	2.612	solid
266.3	2.659	melting
266.8	2.684	melting
267.3	2.767	melting
267.6	2.814	melting
268.2	2.885	melting
268.2	3.090	melting
268.2	3.341	melting
268.2	3.710	melting
260.6	4.234	supercooled liquid
268.7	4.153	liquid
282.8	4.013	liquid
291.9	3.925	liquid
295.2	3.890	liquid
303.3	3.816	liquid

The densities of liquid hexachloroacetone were determined in a 10 cm^3 bicapillary pycnometer calibrated with freshly distilled water in the temperature range of 275 to 315 °K

[3] $d(\text{g cm}^{-3}) = 2.1673 - 0.00145\,T$

the uncertainty being 0.01%. At 285 °K the rather old literature value was 1.744 g cm^{-3} (3) compared to the calculated value of 1.7540 g cm^{-3}. The calculated Onsager dipole moments of liquid hexachloroacetone were 1.32, 1.34, and 1.34 D at 270, 285, and 300 °K, respectively, with an average of 1.33 ± 0.01 D.

The dipole moment of hexachloroacetone was also determined in the carbon tetrachloride solutions at 25 °C. The results were given in Table IV. The dipole moment was calculated according to the Guggenheim method (10). The limiting slopes of the dielectric constants and squares of the refractive index as a function of weight fractions of solute were 1.279 and 0.156, respectively, giving a dipole moment of 1.24 D for the solute.

Discussion

The dielectric constants of solid and liquid hexafluoro- and hexachloro-acetone are normal, both exhibiting a sharp rise at the melting point. The rise of the dielectric constant is three times larger for hexachloroacetone than hexafluoroacetone because the former is considerably more polar. The dipole moments of hexachloroacetone, 1.24 D (solution) and 1.34 D (liquid), are higher than those of hexafluoroacetone, 0.648 D (gas) and 0.63 D (liquid). Since the dipole moment in the liquid state is comparable to that obtained by other means, it implies that neither of the liquids associates to any appreciable extent. Acetone behaves similarly with dipole moments of 2.86 D (gas) and 3.0 D (liquid) (11).

TABLE IV

Weight fraction w, dielectric constant ε, and refractive index n_D of hexachloroacetone in carbon tetrachloride solutions at 25 °C

$w \times 10^2$	ε	n_D
0	2.2263	1.4570
1.269	2.2423	1.4575
1.797	2.2495	1.4579
2.885	2.2634	1.4584
3.237	2.2693	1.4588
4.200	2.2815	1.4591
4.902	2.2923	1.4597
5.353	2.2980	1.4598
6.366	2.3143	1.4605
6.614	2.3166	1.4606
7.960	2.3386	1.4616

TABLE V

Values of dipole moment from McClellan (11)

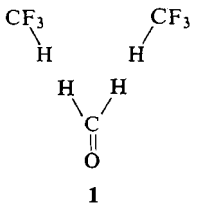
Substance	μ_{gas} (D)
CH_3F	1.83
CHF_3	1.64
CH_3Cl	1.94
$CHCl_3$	1.05
CH_2O	2.32

An attempt is made to calculate the dipole moments of hexafluoro- and hexachloro-acetone by the vector addition of bond moments. Since the C—C—C bond angle is normal (12)

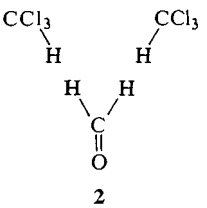
[5] $\mu_{calculated} = \mu_{C=O} - 2\mu_{CX_3} \cos 60°$

Because all 3 halogen atoms are bonded to the same carbon atom, the inductive effect will be considerable (2). Consequently, an effective fractional positive charge is induced in the carbon atom resulting in a reduction of the CX_3 group moment. The difference of dipole moments between CHX_3 and CH_3X is explained usually in this manner since all the bond angles are essentially tetrahedral (see Table V). If it is assumed that the differences between inductive effects on the carbon atom are negligible for CHX_3 and CH_2O, then the vector addition of bond moments

as illustrated in configurations **1** and **2**, will yield dipole moment values of 0.68 D for hexafluoroacetone and 1.27 D for hexachloroacetone.



1



2

Admittedly, the values of dipole moments in Table V are uncertain to the extent of ~0.05 D and, therefore, the calculated dipole moments are probably accurate to ~0.1 D. Their agreement with the experimental values must be considered satisfactory.

Substitution reactions at octahedral centers. IV. Acid and base hydrolysis of chloropentakis(alkylamine)chromium(III) ions

M. PARRIS[1] AND W. J. WALLACE[2]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received November 28, 1968

The compounds $[Cr(RNH_2)_5Cl](ClO_4)_2$, where R = H, CH_3, C_2H_5, n-C_3H_7, and n-C_4H_9, have been prepared and the replacement of chloride by either water or hydroxide ion subjected to kinetic examination. Below about pH 7 the reaction was acid independent, and ΔH_A^* was 22.4 kcal mole^{-1} when ammonia was the inert ligand compared with about 26.4 kcal mole^{-1} when the inert ligand was a primary amine. The corresponding ΔS_A^* values increased continuously with R from H to n-C_4H_9. At higher pH the rate became inversely dependent upon the acidity of the solution, and ΔH_B^* decreased from 26.7 kcal mole^{-1} for ammonia as the inert ligand to 25.4 kcal mole^{-1} for an amine as the inert ligand. For the pH dependent reaction the values obtained for ΔS_B^* were much larger than for the pH independent reaction but the pattern of variation as the inert ligands were changed was quite similar in the two cases. The great similarity in the trends of ΔS^* values for the acid and base hydrolysis reactions has been interpreted in terms of a rate-determining step that is primarily dissociative in both cases.

Canadian Journal of Chemistry, 47, 2257 (1969)

Introduction

There have been a number of investigations of the kinetics of substitution reactions on octahedral chromium and the mechanism of removal of a simple anion and its replacement by water (eq. [1]) seems well understood (1–5). The mechanism of the companion reaction in more

[1] $Cr(NH_3)_5X^{2+} + H_2O \rightarrow Cr(NH_3)_5H_2O^{3+} + X^-$

basic solution where the replacing group is hydroxide (eq. [2]) remains a problem. The interpretation of the kinetics of alkaline hydrolysis of the halopentamminechromium(III) ions (eq. [2])

[2] $Cr(NH_3)_5X^{2+} + OH^- \rightarrow Cr(NH_3)_5OH^{2+} + X^-$

in mechanistic terms is complicated by the presence of labile hydrogen atoms, which give rise to the possibility of reaction through a conjugate base intermediate (6) kinetically indistinguishable from a bimolecular reaction between the complex and hydroxide ions.

The validity of a conjugate base mechanism hinges on the comparative kinetic behavior of otherwise similar complexes at high pH in both the presence and the absence of a moderately acidic proton. A number of aprotic cobalt complexes have been studied and found to hydrolyze at a rate which is independent of hydroxide ion even at high pH (7, 8). However, in each of these studies the change in the inert ligands may have introduced inductive and mesomeric terms that changed the mechanism. Examination of the activation parameters for these systems would reveal such effects, but these data have not been available.

It seemed, then, to be of interest to attempt to prepare a series of complex ions related to the pentammine by progressive substitution of inert groups for the hydrogens on nitrogen. It has been possible to prepare the series of complexes in which aliphatic straight chain primary amines replace ammonia as inert ligands. However, even this limited series of compounds introduces significant variation into the solvation and acidic properties of the complex ions, and these differences are shown to be mechanistically significant.

Experimental

Preparation of Compounds

The chloropentakis(alkylamine)chromium(III) chlorides were prepared by the slow addition of anhydrous chromic chloride to the refluxing amines as described by Rogers and Staples (5). A reaction similar to that occurring in liquid ammonia in the absence of basic catalysts (9) takes place and a suspension of the chloropentakis(alkylamine)chromium(III) chloride is formed. Too high a temperature, produced for example, by rapid addition of the chromic chloride, caused the formation of apparently polymeric products. Excess amine was removed by decanting, washing with ether, and vacuum pumping. Precipitation from aqueous acetone solution with perchloric acid was followed by recrystallization from the same solvent until the product gave no test for ionic chloride.

Chloropentamminechromium(III) Perchlorate

The preparation and properties have been described elsewhere (4).

Chloropenta(methylamine)chromium(III) Perchlorate

This was obtained as carmine red platelets, soluble in water, alcohol, and acetone.

Anal. Calcd. for $C_5H_{25}N_5O_8Cl_3Cr$: Cr, 11.8; N, 15.9; Cl, 24.0. Found: Cr, 12.0; N, 15.9; Cl, 23.5.

Chloropenta(ethylamine)chromium(III) Perchlorates

These were obtained as very dark red platelets very soluble in water, alcohol, and acetone.

Anal. Calcd. for $C_{10}H_{35}N_5O_8Cl_3Cr$: Cr, 10.2; N, 13.7; Cl, 20.8. Found: Cr, 10.1; N, 13.6; Cl, 20.7.

Chloropenta(n-propylamine)chromium(III) Perchlorate

This was obtained as a reddish-purple powder, soluble in water and very soluble in alcohol and acetone.

Anal. Calcd. for $C_{15}H_{45}N_5O_8Cl_3Cr$: Cr, 8.95; N, 12.0; Cl, 18.2. Found: Cr, 8.9; N, 11.9; Cl, 18.2.

Chloropenta(n-butylamine)chromium(III) Perchlorate

This was obtained as a reddish powder with a pronounced purple tinge, slightly soluble in water, but very readily precipitated by perchlorate and soluble in alcohol and acetone.

Anal. Calcd. for $C_{20}H_{55}N_5O_8Cl_3Cr$: Cr, 7.98; N, 10.7; Cl, 16.3. Found: Cr, 7.6; N, 10.3; Cl, 16.1.

Analyses

Analyses were performed by standard methods: nitrogen by the Kjeldahl method, chloride gravimetrically as silver chloride, and chromium by oxidation with alkaline peroxide and back titration with ferrous sulfate.

n-Amylamine and *n*-hexylamine gave tacky, apparently polymeric products, tenaciously retaining excess amine and difficultly soluble in acetone. Secondary and tertiary amines even in the presence of sodamide gave no reaction upon heating for prolonged periods in sealed tubes.

Upon heating and occasionally upon concussion, the dry perchlorates explode, but the reaction becomes less violent as the size of the alkyl group is increased.

Kinetic Studies

Solutions were made up to 10^{-3} *M* in complex ion at a selected pH, controlled by amine–perchlorate buffers and adjusted to ionic strength $\mu = 0.2$, as described previously (4). By adjustment of the buffering amine and/or the buffer ratio the pH could be controlled to any value over the range shown in Fig. 1. The solutions were then thermostated at the desired temperature and the reaction allowed to proceed. The extent of reaction was followed by removing an aliquot, quenching, either by cooling or lowering the pH or both, and determining the liberated chloride polarographically. Pseudo first order plots were obtained over the first two half lives of the reaction. No attempt was made to isolate the liberated aquo complex because loss of chloride was followed by rapid loss of amine.

Results

The data plotted in Fig. 1 show that, on the basis of its pH dependence, the process leading to the hydrolytic removal of chloride from all the chloropentamminechromium(III) complexes can be divided into the same two parts.

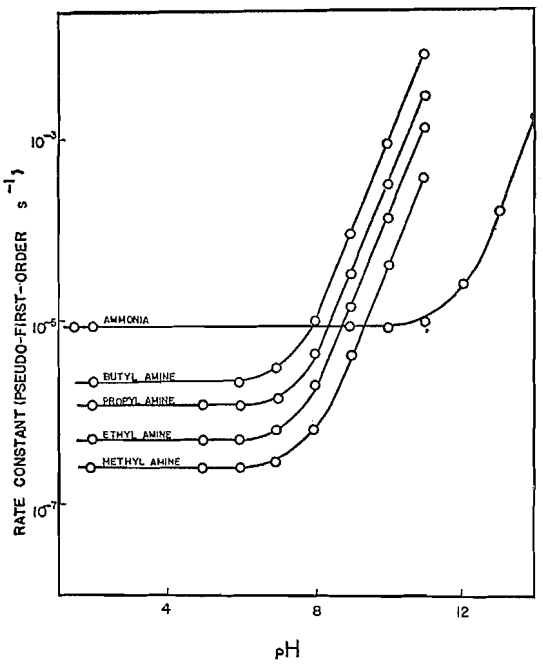

FIG. 1. pH profiles for the hydrolysis of some chloropentamminechromium(III) complex ions at 25 °C.

Over the entire pH range the rate law is given by

$$\text{Rate} = k_A[\text{complex}] + k_B[\text{complex}][OH^-]$$

However, when the pH of the reaction mixture is not controlled by buffering, the scatter of the data is much greater and a superimposed pH dependence of the type reported by Rogers and Staples (5) is observed (11).

The rate constants for acid hydrolysis are sensitive to the amount and kind of electrolyte present in the reaction system. Such electrolyte effects must be taken into account in making comparisons among published rate data for the pentamminechromium(III) complexes (4, 5, 10).

The data in Table I show the variation of the rate constants as a function of temperature for both the acid and base hydrolysis. These data have been used to calculate the activation parameters reported in Table II. Individual chloride determinations were within $\pm 3\%$ of the true value and 6 points obtained over two half lives of the reaction gave rate constants with an average deviation over 5 values at 25° of $\pm 1\%$. Some replicate values are given in Table I to illustrate the quality of the data but in general the values reported are averages obtained from three indi-

Discussion

The patterns exhibited by the pH profiles of the rate constants (Fig. 1) suggest that there are two distinct mechanistic processes operating in this series of complexes.

In acid hydrolysis ΔH^* increases from 22.3 to 26.3 kcal/mole when the inert ligand is changed from ammonia to methyl amine, but lengthening of the carbon chain produces no further increase. By contrast the same changes in the inert ligand produce, for the base hydrolysis, an initial ΔH^* decrease from 26.7 to 25.4 kcal/mole then no further change. For both the acid and base hydrolyses, the pattern of entropy changes is very nearly the same. The initial increase, $\delta\Delta S^*$, of about 7 e.u. when the inert ligand is changed from ammonia to methyl amine is followed by progressive increases of about 2 e.u. per carbon increase in the chain length. These observations are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

most easily rationalized in terms of models which allow a progressive but similar loosening of the molecular constraints in the transition state for both acid and base hydrolyses but which require opposite enthalpy effects.

An explanation for the entropy variation which is compatible with the experimental observations can be drawn from the picture of ion–solvent interaction painted by Frank and Evans (12), and modified and expanded by Nemethy and Scheraga (13). In this view of aqueous solutions, a non-polar solute molecule induces solvent molecules in its near vicinity to interact with each other in such a way that, on the average, these molecules are more ordered than are those of the bulk solvent. By contrast, specific interaction between polar solutes and the solvent tends to destroy the "iceberg" structure by reorienting the water molecules so that they are no longer favorably disposed to fit such a configuration.

The complex ions studied in this work have large radii so that despite their charge they should orient but not polarize the solvent, and their effect upon the solvent should be analogous to alkali metal ions of the same charge density. Consequently, the data of Frank and Evans (12) for the alkali metal ions have been used to produce a charge density–structural entropy calibration curve. Then, using this calibration curve together with estimates of the sizes of the complex ions involved in this study, it is possible to estimate the entropy change produced in the solvent as a function of ion size and ion charge. The estimates obtained in this way are given in Table III.

The hydrolysis reaction illustrated in reaction [1] represents an actual case in which the ion charge is increased from 2+ to 3+ in proceeding from reactant to product. This should mean that as the reacting ion moves up to and through the transition state, its interaction with the solvent will tend to cause the structural entropy of the ion in solution to decrease progressively, as the breaking bond distorts. It might be expected that if a pair of ions reacts by the same mechanism, there will be a correlation between the change in the structural entropy produced by the increase in ionic charge in the transition state and the change in the activation entropy for the one ion compared with that for the other. If the charge separation in the transition state is the same for the two ions, then the correlation between the change in structural entropy and the change in activation entropy for the two ions may depend only on the relative sizes of the two ions. An attempt to make such a correlation is shown in the last two columns of Table III. Even though the estimates of the structural entropy differences for the various ions are very crude, it is quite clear that there is a real correlation between these two parameters. In fact, the correlation that is obtained would suggest that the change in structural entropy is the principal reason for the change in the activation entropy through the series of complexes.

The obvious, mechanistically distinct, processes involving the hydroxide ion are described as displacement, ion pair, and conjugate base mechanisms (14). The first two seem unlikely both in terms of the low concentration of hydroxide at the onset of the base catalyzed reaction, and of the difficulty in fitting them to the observed pattern of activation entropies. The conjugate base mechanism (reactions [3], [4], and [5]) seems better suited to the observations on both counts.

[3] $Cr(NH_3)_5Cl^{2+} \rightleftarrows [Cr(NH_3)_4NH_2Cl]^+ + H^+$

[4] $[Cr(NH_3)_4NH_2Cl]^+ + H_2O \rightarrow Cr(NH_3)_5OH$

[5] $H^+ + OH^- \rightarrow H_2O$

This mechanism is a composite of two acid–base equilibria (reactions [3] and [5]) and a rate determining dissociation (reaction [4]). The observed activation parameters are summations of the appropriate thermodynamic parameters for each of the steps. Within the series of compounds investigated here the hydronium ion – hydroxide ion recombination makes a constant contribution of +19.3 e.u. (15) to the measured entropy of activation. The entropy change in the acid dissociation of the bound amine (reaction [3]) is much more in doubt because there are no direct measurements reported in the literature. However, it may be possible to get some feel for the order of magnitude of this quantity by analogy with the corresponding systems involving water. The acid dissociation of the chromium(III) aquo ion (reaction [6]) involves an entropy change of

[6] $Cr(H_2O)_6^{3+} \rightarrow Cr(H_2O)_5OH^{2+} + H^+$

+24 e.u. (16). This means that there is a difference between the entropy of dissociation of water and that of coordinatively bound water of about +43 e.u. For other trivalent aquo ions the difference is comparable (17). If the assumption is made that this difference is transferable to the

TABLE III

Structural entropies estimated for various pentaminechromium(III) complex ions

Amine	Radius[c]	ΔS_{ST} 2+ Ion	ΔS_{ST} 3+ Ion	$\delta\Delta S_{ST}$[a]	$\delta\Delta S^*$[b]

[a]Change in ΔS_{ST} as the ion charge is increased from +2 to +3 compared with the same change for the ammonia complex.
[b]Change in ΔS^* for the acid hydrolysis reaction compared with that for the ammonia complex (Table I).
[c]Based upon the distance of closest approach of a water molecule to a non-bonding hydrogen on the terminal carbon assuming the most compact configuration for the alkyl chain.

corresponding ammonia systems, it would be expected that the entropy of dissociation would increase from −39.1 e.u. for free ammonia (17) to about +4 e.u. for ammonia bound to chromium(III). Then, a rough order of magnitude value for the entropy change involved in reaction [3] might be 0–10 e.u. Combination of this value with that for step [5] easily accounts for the 25 e.u. which separate the entropies of activation for the acid and base hydrolyses. If it is then assumed that the dissociation of the amines follows the dissociation of the corresponding ammonium salts (18), only small variations in the entropy of dissociation would be expected as the amine is changed through the series. This would mean that the entropy change in reaction [3] is roughly the same for all the amine complexes and that the sum of entropy changes for steps [3] and [5] would remain the same through the series of complexes. Consequently the predissociation steps do not contribute to the differences in the activation entropies between complexes, and the pattern of activation entropies that are observed would be expected to arise in reaction [4].

It is suggested that the similarity in the pattern of activation entropy variation through the series of complexes for the acid and base hydrolyses indicates a mechanistic similarity as well. Thus, the argument presented about the role of solvation in determining the entropy differences as the inert ligands were varied could apply equally well to both acid and base hydrolysis reactions. So, if the acid hydrolysis is primarily dissociative in character, it is at least plausible to propose that the base hydrolysis is also. This is exactly what might be expected for the rate determining step (reaction [4]) in the conjugate base mechanism.

If the conjugate base model is correct, the transition state for the base hydrolysis should differ from that for the acid hydrolysis only in the absence of one proton from one of the nitrogens, and if a similar degree of charge separation is attendant upon the base hydrolysis (as was suggested by the entropy changes) then, by analogy with the acid hydrolysis, the enthalpy of activation might have been expected to increase by about 4 kcal in going from the ammonia complex to the methyl amine complex. The decrease that actually occurred must represent a complication in the system and may have its origin in the pre-equilibrium acid dissociation to produce the conjugate base intermediate. This would have the enthalpy change in the acid dissociation of a bound primary amine less than that of bound ammonia. On the basis of purely electronic effects this is unlikely (19). However, calorimetric measurements of the heats of protonation of alkyl amines in aqueous solution (20, 21) show that replacement of a single hydrogen on ammonia by an alkyl group produces the expected increase, but two alkyl groups produce a decrease of about 1 kcal $mole^{-1}$ and a third alkyl group reduces the binding of the new proton by a further 4 kcal $mole^{-1}$. These changes have been interpreted in terms of the inefficient solvation of the substituted ammonias, making an unbound fully solvated proton increasingly favored as the degree of substitution on ammonia increased (21, 22).

When the alkyl amines are bound in the chromium complex, they are much more restricted in their interaction with the solvent than they would be as free amines in solution. It would not then be surprising that the alkyl substituents would exhibit an unusually large effect in shielding the remaining amino protons from interaction with the solvent. In this case it might be expected

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

that acid dissociation would be energetically favored in an attempt to reduce the positive charge on the metal complex, and distribute it into the bulk solvent (via the proton) where it could be effectively solvated. If this is correct then a decrease of the enthalpy associated with a process involving hydrogen dissociation could be expected. If all other factors were to remain constant a decrease of the activation energy for reaction through the conjugate base path is reasonable.

The experimental results presented here and the arguments which have been drawn from them are consistent with a mechanism for both the acid and base hydrolysis of these complexes which has as its rate determining step a primarily dissociative process.

Protonation of conjugated carbonyl groups in sulfuric acid solutions. II. Protonation and basicity of α,β-unsaturated alicyclic ketones[1, 2]

R. I. ZALEWSKI[3] AND G. E. DUNN
Department of Chemistry, University of Manitoba, Winnipeg 19, Manitoba

Received December 16, 1968

The protonation of 14 α,β-unsaturated alicyclic ketones, B, by sulfuric acid leads to values of log [B]/[BH^+] which, when plotted against the amide acidity function, H_A, give straight lines of unit slope. The pK_{BH^+} values thus obtained show substituent effects which are additive and can be interpreted in terms of polar and resonance effects.

Canadian Journal of Chemistry, 47, 2263 (1969)

The first paper of this series described the use of the amide acidity function, H_A, to study the protonation of the carbonyl group in non-Hammett bases (1). These included some alicyclic α,β-unsaturated ketones. In this paper, data for more compounds of this class of bases are presented.

The protonation of α,β-unsaturated ketones has not been a point of great interest in the past. Deno reported that α,β-unsaturated ketones in concentrated sulfuric acid solutions exist as mesomeric carbonium ions (2), with an absorption maximum near 287 mμ (3). However, no systematic study of the protonation of simple α,β-unsaturated ketones has been undertaken.

Not long ago, Zalewski studied the protonation of α,β-unsaturated ketosteroids and concluded that these compounds do not follow Hammett's H_0 acidity function (4). This investigation also clearly showed an influence of acid strength on the location and shape of the absorption curve in the ultraviolet region (4, 5). The present paper will present protonation data for a set of alicyclic α,β-unsaturated ketones having 5- and 6-membered rings, and show that these are better accommodated by the H_A acidity function than the H_0 function. A correlation between basicity and the electronic effects of substituents attached to the chromophore will be demonstrated.

Experimental

Materials

Compounds[4] used in this study were commercially available except **2** and **3**. Compounds **3**, **4**, **9–13** were used without purification. Compounds **1**, **2**, **5–8** and **14** were purified by the following procedure. About 1 g of ketone was mixed with 1 ml of *n*-heptane, filtered through Al_2O_3, and eluted by *n*-heptane. The eluent was removed by evaporation.

The sulfuric acid solutions were prepared by dilution of Allied Chemical C.P. Reagent sulfuric acid (min. 95.5%) and the concentrations were determined by density measurements for higher concentrations, by titration and density measurements for lower concentrations. The sulfuric acid concentrations were read from density data in the International Critical Tables. The corresponding H_0 or H_A values were read from graphs of acidity function vs. concentration, constructed from the data of Jorgenson and Hartter (6), and Yates *et al.* (7), respectively.

Method

The protonation of several classes of organic compounds has been intensively investigated in recent years, mostly by spectrophotometric methods in sulfuric acid solutions. An organic base may be considered to exist as free base, B, in water or dilute acid solutions, while in strongly acidic solutions it is protonated to its conjugate acid, BH^+. Since B and BH^+ usually have different absorption spectra, a wavelength can be found (often in the ultraviolet region) where the absorbance changes as the compound is protonated. From the absorbance change, it is in general possible to calculate K_{BH^+}, the equilibrium constant for the protonation reaction, in terms of an acidity function H (such as pH, H_0, H_A, etc.), in two ways (10).

(a) A plot of absorbance against H gives a titration curve, at the inflection point of which $H = pK_{BH^+}$.

(b) Absorbances can be used to calculate the quantity

$$[1] \qquad \frac{[B]}{[BH^+]} = \frac{\varepsilon_{BH^+} - \varepsilon}{\varepsilon - \varepsilon_B}$$

[4]The names corresponding to compound numbers are found in Table II.

from which pK_{BH^+} is obtained by the relationship

$$[2] \qquad pK_{BH^+} = H - \log \frac{[B]}{[BH^+]}$$

where B is the organic base, BH^+ is its conjugate acid, ε is the absorptivity of the solution at acidity H, and ε_B, ε_{BH^+} are the absorptivities of the base and conjugate acid, respectively, at the wavelength where ε is measured.

Sometimes it is very difficult to determine the coordinates of the inflection point in the first method, or the values of ε_B and ε_{BH^+} in the second method. We have attempted to overcome these difficulties by the use of a computer program based on the following considerations.

Generally, for the protonation of an organic base, B, under conditions where activities may be approximated by concentrations, the ionization constant is expressed by

$$K_{BH^+} = \frac{[B][H^+]}{[BH^+]}$$

where the quantities in square brackets represent molar concentrations. If the total concentration of base (free and ionized) is [C] then the absorbance, A, measured in a solution where the base is only partly ionized, can be shown (20) to be given by

$$[3] \qquad A = [C] \frac{\varepsilon_B K_{BH^+} + \varepsilon_{BH^+}[H^+]}{K_{BH^+} + [H^+]}$$

Equation [3] is an adequate representation of the titration curve at constant ionic strength in the region of acidity, where $[H^+]$ may be approximated from pH. For use in strong solutions of sulfuric acid, pH is replaced by an acidity function, such as H_0, which expresses the deviation of the system from ideality. Constancy of ε_B and ε_{BH^+} over the necessary range of sulfuric acid concentration is still assumed, of course.

Since A, $[H^+]$, and [C] are observable quantities, eq. [3] contains three unknowns: K_{BH^+}, ε_{BH^+}, and ε_B. In principle ε_B and ε_{BH^+} can be determined experimentally by measurements made in solutions with $[H^+] = pK_{BH^+} + 2$ and $[H^+] = pK_{BH^+} - 2$, respectively. However, in practice, they may not be so readily accessible, because the base is subject to further protolytic or non-protolytic reactions at high or low acidity, because the solvent absorbs at the necessary acidity, or for a variety of other reasons. In moderately concentrated sulfuric acid solutions, it is often observed that ε_B and ε_{BH^+} are not constant, even in the region of acid concentrations where the organic base should be present as a single species, either free base or conjugate acid (8–14). It is therefore probable that ε_B and ε_{BH^+} will vary across the range of acidities where both species contribute to the absorbance. Various methods have been proposed to take account of this variation (10–13), most of them based on extrapolation of ε_B and ε_{BH^+} from regions of acidity outside the titration range. The extrapolation requires that absorbance by the substrate outside the titration range be subject only to medium effects (no protolytic, hydrolytic, or other reactions), and that the medium effects be linear in the acidity function used. For many bases these conditions cannot be satisfied, so in the present work, a procedure was used which makes some allowance for medium effects, even when extrapolation is not possible. Absorbances were measured at 12 or more intervals in the titration range, and used in a least-squares computer program to solve eq. [3] for the 3 disposable parameters K_{BH^+}, ε_B, and ε_{BH^+}. This procedure is an extension of one suggested by Flexser *et al.* (10) and, in effect, gives the best average values of ε_B and ε_{BH^+} over the titration range.

Measurements were made at the wavelength, λ_B, characteristic of the base, and at the wavelength, λ_{BH^+}, characteristic of the conjugate acid, so that two largely independent estimates were obtained for each of the 3 unknowns. Measurements at the 2 wavelengths were also combined by the Stewart–Granger procedure (*8a*), to give a third set of estimates intermediate between the first two.

Absorption Spectra Measurements

Aqueous stock solutions (10^{-3} M) of the ketones were diluted with sulfuric acid solutions to concentrations of about 5×10^{-5} M for absorbance measurement on a Beckman DK-1 spectrophotometer. Three ketones which were not easily soluble were treated differently. Compounds **9** and **10** were dissolved in 10 ml of concentrated sulfuric acid, then diluted to 250 ml with water to give the 10^{-3} M stock solutions. Compounds **5**, **6**, and **7** gave the same spectral and pK data by this procedure and the standard one, so it appears that most α,β-unsaturated ketones are unaffected by concentrated sulfuric acid, except for protonation. For *d*-carvone, which does react with sulfuric acid of more than 70% concentration, 10 ml of methanol was used instead of 10 ml of sulfuric acid to prepare the stock solution.

Results and Discussion

In Fig. 1 are shown spectra from 210 to 265 mμ of 2-cyclopentenone in various concentrations of sulfuric acid, as well as in methanol and in water. These are typical of the spectra obtained from all the α,β-unsaturated ketones examined. It is observed that the $\pi \rightarrow \pi^*$ band shifts bathochromically with increasing solvent polarity, from 218.5 mμ in methanol, to 221.5 mμ in water. A further bathochromic shift occurs in sulfuric acid solution (Figs. 1 and 2).

Figure 2 shows a typical relation between the acidity of the solvent and the location of the $\pi \rightarrow \pi^*$ maximum. The lower part of the curve represents the absorption maximum for the α,β-unsaturated ketone as a base, where the concentration of the conjugate acid is small. The small bathochromic shift in this region can be explained by increasing interaction between the carbonyl group and solvent. The upper part of the curve represents the absorption maximum for the conjugate acid of the ketone, where the concentration of unprotonated ketone is small. Again there is a small bathochromic shift with increasing acid

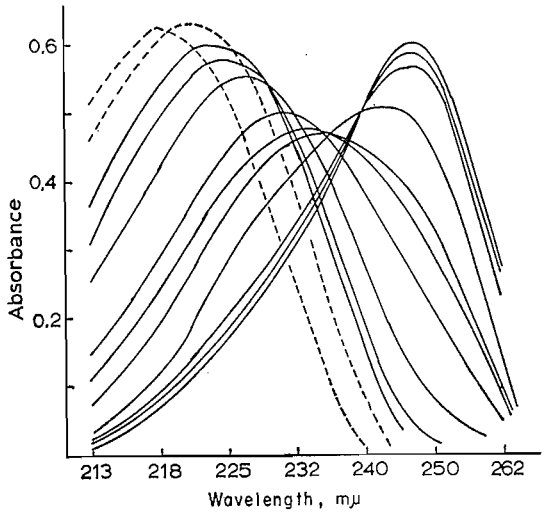

FIG. 1. Absorbance of 2-cyclopentenone as a function of sulfuric acid concentration. Solvent (top to bottom at left-hand margin); methanol, water, sulfuric acid 38.0, 51.0, 57.3, 66.0, 69.1, 71.5, 74.2, 83.9, 94.1, and 96%.

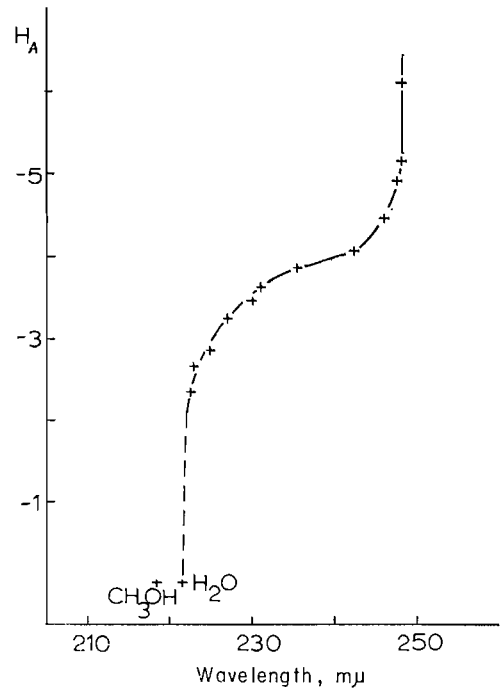

FIG. 2. Effect of sulfuric acid concentration on λ_{max} of 2-cyclopentenone.

concentration as the result of changing interaction between cation and solvent (15). The middle part of the curve represents the broad, irregular maxima, resulting from the overlapping absorptions of mixtures of the 2 species. Curves similar to those in Fig. 2 were observed for all the α,β-unsaturated ketones examined.

The solvent shifts in λ_{max} described above are such that there is no single isosbestic point in Fig. 1. In the region of acidities where the ketone should be present as unionized base (lower vertical part of Fig. 2), the gradual shift in λ_{max} results in the convergence of the absorbance curves into an apparent isosbestic point at 230 mμ. A similar convergence occurs at 240.5 mμ for the conjugate acid (acidities in the upper vertical part of Fig. 2). The true isosbestic point, where $\varepsilon_B = \varepsilon_{BH^+}$, lies at about 236 mμ. Here the approximate convergence of the absorption curves shows that, within the region of acidities corresponding to the non-vertical part of Fig. 2, the variation in ε_B and ε_{BH^+} is not large. It is in this region that pK_{BH^+} measurements were made.

The primary objective of the present investigation was to examine the effect of structural changes on the basicities of α,β-unsaturated ketones. In order to do this, of course, it is necessary to find an acidity function which adequately represents the ability of acid solutions to protonate ketones. Ideally, this requires that the activity coefficient ratio, f_B/f_{BH^+}, must exactly parallel that of the indicator bases used to establish the acidity function through the whole range of acidities from the neutralization point to dilute aqueous solution. Such information is rarely available, so that an organic base is usually considered to obey an acidity function satisfactorily, if the activity coefficient ratio parallels that of the indicators through the titration range of acidities. Tests for this minimum requirement are provided by eqs. [2] and [3]. The pK_{BH^+} values calculated from eq. [2] must be independent of acidity and the plot of log $[B]/[BH^+]$ vs. the acidity function must have a slope of unity. The acidity function which best satisfies eq. [3] is the one which most closely reproduces the experimental absorbances.

Table I presents the numerical data for acidity, H_0 and H_A, of sulfuric acid solutions, the wavelength λ_{max}, and the absorbance A_{max} of the $\pi \rightarrow \pi^*$ transitions of 2-cyclopentenone and its conjugate acid. Also presented, for the wavelength characteristic of the base, λ_B, and that characteristic of the conjugate acid, λ_{BH^+}, are the experimental absorbances ($A = \varepsilon[C]$), and those calculated from eq. [3]. It is seen that the values of A_B, A_{BH^+}, and pK_{BH^+} have a smaller standard

deviation when calculated from H_A than from H_0, and that the values from H_A give much better reproduction of the experimental absorbances than do those from H_0. The last 2 columns of Table I show pK_{BH^+} calculated from eq. [2] at λ_B using the values of A_B and A_{BH^+} from eq. [3]. The values calculated from H_A are approximately constant while those from H_0 show a pronounced drift. Figure 3 shows the plot of log $[B]/[BH^+]$ vs. H_A with slope 1.01 and vs. H_0 with slope 0.52. It is evident that the protonation of 2-cyclopentenone very closely parallels that of the amides used to establish the H_A acidity function. Similar behavior was observed for all the other α,β-unsaturated ketones tested.

Data for all the α,β-unsaturated ketones are presented in abbreviated form in Table II. Spectral data are given for the ketone as base, B, and as conjugate acid, BH^+, together with values for pK_{BH^+} obtained from eq. [3] using the Stewart–Granger procedure, and for the slopes of the lines log $[B]/[BH^+]$ vs. H_A and H_0. It is clear that for all the α,β-unsaturated ketones, the slopes are those to be expected from the H_A acidity function. In the absence of activity data over the whole acidity range, it is not known whether or not the pK_{BH^+} values derived from H_A are thermodynamic ones or not, but they should be satisfactory for interpreting structural effects upon acidity within a single series of bases[5].

The effect of structure on the basicities of α,β-unsaturated ketones may now be considered. In

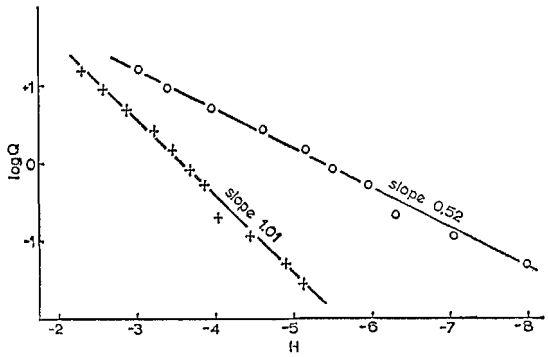

FIG. 3. Plot of log $[B]/[BH^+]$ (= log Q) vs. acidity for 2-cyclopentenone. Crosses represent H_A and circles represent H_0.

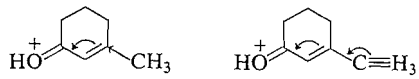
general, the ability of the base to accept a proton depends on factors affecting the electron density at the basic center, in our case the carbonyl group. These are customarily divided into polar, resonance, and steric factors. Polar and resonance effects on the basicities of α,β-unsaturated ketones are easily demonstrated from the pK_{BH^+} data of Table II, but effects specifically attributable to steric factors are not evident. It is noticeable in this connection that similarly substituted 2-cyclopentenones and 2-cyclohexenones (**1** and **5**, **2** and **6**) have almost identical pK_{BH^+} values. Apparently this much variation in ring size does not affect basicity.

Ketones substituted by methyl groups in the β-position (**2**, **6**) are stronger bases than the unsubstituted ones by 0.75 pK_{BH^+} unit. β-Methylene (**9**) has the same acid-strengthening effect as β-methyl. Further methyl substitution in the δ-position (**7**) does not effect the basicity. These facts are all explainable in terms of the +I inductive effect of the methyl group, which stabilizes the conjugate acid more than the ketone. Hyperconjugation will have a similar influence.



α-Methyl substitution (**8**) also makes the base stronger. Unfortunately *d*-carvone is not stable in more concentrated solutions of sulfuric acid so that it is impossible to find λ_{BH^+}. Consequently, pK_{BH^+} was calculated at only one wavelength (λ_B) and for only part of the titration curve. A more reliable demonstration of the base-strengthening effect of α-methyl substitution is obtained by

[5]Bunnett and Olsen (16) and Greig and Johnson (13) prefer to relate the protonation of all bases to the original Hammett acidity function, H_0, by use of the observation that all acidity functions are linearly related to H_0 (12). If

$$H = mH_0 + b$$

then eq. [2] becomes

$$pK_{BH^+} = mH_0 + b - \log([B]/[BH^+])$$

Since all acidity functions must converge in dilute acid, b should be zero. This is observed to be the case except for the amide acidity function (12), where a plot of H_A vs. H_0 deviates from linearity at low acidity, so that in the region of acidities used in most of this work, $H_A = 0.53H_0 + 0.68$. Hence, for a base which fits the H_A scale, a plot of log $[B]/[BH^+]$ vs. H_0 should have a slope of 0.53. Table II shows that this prediction is correct, except for compounds **13** and **14**, where pK_{BH^+} lies on the curved part of the H_A vs. H_0 plot. Except for these 2 compounds, the pK_{BH^+} preferred by the above authors will be obtained by adding 0.68 to the values given in Table II. Without activity data, it is not known whether either set is thermodynamic, and the latter set rests upon the as yet unproved assumption that the H_A scale is incorrectly based, so we have used the set based on H_A and eq. [3].

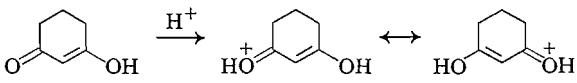
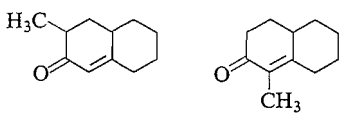
comparing the pK_{BH^+} values of 2,3-dimethylated ketones (**3**, **9**) with those of 3-methylated ones (**2**, **6**). The additional methyl group in the α-position strengthens the base by 0.3 pK_{BH^+} unit.

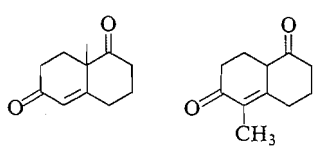
Resonance stabilization may produce much larger changes in basicity, as is illustrated by compounds **13** and **14** which are about 2.6 pK_{BH^+} units more basic than the unsubstituted α,β-unsaturated ketones. Compound **13** is 1,3-cyclohexanedione but this is reported by Schwarzenbach and Felder to be more than 90% enolized in aqueous solution (17). Its high basicity has previously been noted by Eistert *et al.* (18), whose pK value agrees satisfactorily with the one reported here. The very close agreement in basicity between this compound and 3-ethoxy-2-cyclohexenone (**14**) tends to confirm the enol structure. The inductive effect (−I) of hydroxy and alkoxy groups should be base-weakening, so the great basicity of the β-oxy compounds must be the result of resonance stabilization of their conjugate acids. This should be of special importance because of the equivalence of the two main con-



tributing structures. Such resonance stabilization is not possible when the hydroxy group is in the α-position, so the inductive effect should be revealed. Compound **4** illustrates these conclusions. It is 3-methyl-1,2-cyclopentanedione which is also completely enolized in aqueous solution (19). The α-hydroxy group makes the base weaker than the corresponding unsubstituted compound (**2**) by about 0.45 pK_{BH^+} unit. Evidently the inductive effect predominates here. The α-fluoro substituent behaves similarly in α,β-unsaturated ketosteroids (21).



9 **10**



11 **12**

TABLE III

The effects of substituents on basicity of α,β-unsaturated ketones

Substituent	ΔpK_{BH^+}
	0.00
α-CH_3	+0.30
β-CH_3, —CH_2—	+0.75
α-OH	−0.50
β-OH	+2.60
δ′-C=O	−0.75
δ-CH_3	0.00

The basicities of molecules such as **11** and **12**, which contain a second (unenolized) carbonyl group in the δ-position, are smaller than those of the corresponding unsubstituted compounds (**9** and **10**, respectively) by about 0.75 pK_{BH^+} unit. No doubt this is the result of the inductive effect (−I) of the highly polar carbonyl group. A similar result is seen in α,β-unsaturated ketosteroids with a carbonyl group at C-11, which are weaker than the corresponding unsubstituted compounds by about 0.2 pK_{BH^+} unit (5). In these compounds, the substitution is more remote from the basic center, so the effect is smaller.

The effects of substituents on pK_{BH^+} of α,β-unsaturated ketones may be summarized in terms of differences ΔpK_{BH^+} between substituted and unsubstituted molecules, as shown in Table III. Also, ΔpK_{BH^+} values are additive, at least within the series of compounds examined, so that the basicity of an α,β-unsaturated ketone can be calculated by eq. [5], with a maximum error of 0.05 pK_{BH^+} unit.

$$[5] \qquad pK_{BH^+} = -3.57 + \sum \Delta pK_{BH^+}$$

Osmotic and activity coefficients of some simple borates in aqueous solution at 25°

R. F. PLATFORD
Canada Centre for Inland Waters, Burlington, Ontario

Received December 19, 1968

Activity coefficients for sodium tetraborate, potassium tetraborate, sodium metaborate, sodium fluoroborate, and orthoboric acid were derived from isopiestic vapor pressure measurements. The osmotic behavior of sodium tetraborate, at concentrations up to its solubility limit, was the same as that of the more soluble potassium salt. The mean activity coefficients of both tetraborates were quite low: 0.355 at 0.1 *m*; the activity coefficients of sodium metaborate and fluoroborate were less than those of sodium chloride, indicating partial association in solution.

The boric acid results were not very reliable because boric acid apparently volatilized during the measurements, but the results obtained indicated that it behaves like a non-electrolyte at all concentrations up to saturation, with an activity coefficient never less than 0.92.

Canadian Journal of Chemistry, 47, 2271 (1969)

Introduction

Borax ($Na_2B_4O_7 \cdot 10H_2O$) is a common mineral and its osmotic properties in aqueous solution should be of interest to geochemists. It is not, however, very soluble in water and therefore is not very suitable for isopiestic studies, but its analogue, potassium tetraborate, is soluble enough to make such measurements worthwhile, and to provide insight into the behavior of the less soluble borax. The metaborates and fluoroborates are also soluble salts of interest, the latter particularly so because a fluoroborate ion electrode has recently been marketed[1].

Another soluble boron compound worth investigating is boric acid, which, with its pK_a of 9.2 (1), should behave like a non-electrolyte in solution.

The measurements described here are preliminary to a study of multicomponent borate systems of geochemical interest.

Experimental

The reference salt, sodium chloride, was recrystallized from water and dried at 120°.

Sodium tetraborate was recrystallized twice from water at 55° and dried over a saturated solution of sucrose and sodium chloride to give $Na_2B_4O_7 \cdot 10H_2O$ (2). The solubility (reported as molality of the salt at 25°) determined by titration with HCl was 0.158 *m*; the literature value is 0.157 *m* (3). The solubility measured by the isopiestic method described by Scatchard *et al.* (4) was 0.154_3 *m*. This last value refers to an air-free solution at a total pressure of ~ 23 Torr, and the difference in values may be due to the different conditions.

[1]Orion Research Incorporated, Cambridge, Mass., 02139.

Potassium tetraborate was recrystallized twice from water and dried at 60° to give $K_2B_4O_7 \cdot 4H_2O$ (5). The solubility at 25° determined by three different methods, was: by titration, 0.660 *m*; by evaporation at 60°, 0.65 *m*; and by the isopiestic method, 0.648_4 *m* (literature value, 0.65 *m* (5)).

Sodium metaborate was recrystallized from water and dried at 80° to give the dihydrate. Some runs were also done with reagent grade tetrahydrate. The solubility of sodium metaborate determined by titration was 4.29 *m* and by the isopiestic method was 4.423 *m* (literature value, 4.19 *m* (3)).

Sodium fluoroborate was recrystallized from water and dried at 120°. Its solubility, determined by evaporation to dryness at room temperature, was 9.4_6 *m*, and by the isopiestic method was 9.87 *m* (literature value, 9.8 *m* (6)).

Orthoboric acid was recrystallized twice from water and dried at 60°. This sample slowly lost weight, apparently by sublimation, as it always assayed 100 ± 0.5% pure. Volatilization also occurred at the low pressures under which the isopiestic measurements were made, but not to a great enough extent to be readily detectable by analysis of the small volumes (1–2 ml) of final solutions, resulting from the isopiestic measurements. Because of this volatilization, or for some unknown reason, the isopiestic results for boric acid were quite badly scattered, and the concentrations reported (which were usually determined by weighing as described below) may not be better than ±0.005 *m*, even though they are reported to 0.001 *m*. (This difficulty was also observed with the sodium fluoroborate solutions although to a lesser extent than with the boric acid.)

The solubility of boric acid at 25°, determined by titration with $Ba(OH)_2$ in the presence of mannitol (7), was 0.927 *m*. Evaporation of saturated solutions to dryness at room temperature gave a solubility of 0.929_5 *m* and the isopiestic method gave 0.92 *m* (literature value, 0.934 *m* (3)).

Isopiestic comparisons were made either in 7 silver dishes or in 4 platinum dishes (for $NaBF_4$) set in gold plated copper blocks (8). The pure dry salts were weighed into the dishes and a suitable amount of distilled water was added to each. The dishes and block were set in a

*$Na_2B_4O_7$.
†Saturated solution.

desiccator which was then evacuated, and the solutions were equilibrated for 3–5 days in a thermostat at 25.00° before the dishes were reweighed. Some solutions were frozen before evacuation in order to reduce bumping and volatilization. Each set contained 2 or 3 sodium chloride reference solutions. The isopiestic concentrations reported in Table I are averages of 2 or 3 replicates corrected to vacuum. The last figure in each column is the average precision of all the replicate measurements for that salt.

Potassium tetraborate solutions supersaturated so easily that measurements on this salt were extended to concentrations of nearly 1.2 m.

Results and Discussion

The osmotic coefficients were calculated from the equation

$$[1] \qquad \phi = 2m_R\phi_R/\nu m$$

where m_R and ϕ_R are respectively the molality and osmotic coefficient of sodium chloride (9), ν is the number of moles of ions formed per mole of borate, and m is the molality of the borate in equilibrium with the reference solution.

For boric acid, ν was put equal to 1 (H_3BO_3 is the predominant species in solution at all concentrations) and for the two tetraborates it was necessary to put $\nu = 6$, in order that $\phi \to 1$ as $m \to 0$. This value for ν is consistent with the dissociation

$$[2] \quad Na_2B_4O_7 + 7H_2O \rightarrow 2Na^+ + 2B(OH)_4^- + 2H_3BO_3$$

because borax in solution is equivalent to boric acid titrated halfway to the equivalence point with strong base. If the dissociations of sodium metaborate and sodium fluoroborate are given by reactions [3] and [4]

$$[3] \quad NaBO_2 + 2H_2O \rightarrow Na^+ + B(OH)_4^-$$

$$[4] \quad NaBF_4 \rightarrow Na^+ + BF_4^-$$

then $\nu = 2$ for these two salts. The fluoroborate ion hydrolyzes (10) slightly in solution to give H_3BO_3 and HF. This hydrolysis causes some uncertainty in the values of ϕ and $\gamma_\pm$ for $NaBF_4$, which will have to be determined by electrode measurements.

The osmotic coefficients interpolated at round molalities are given in Table II. The sodium and potassium tetraborates have such similar osmotic coefficients over their common concentration range, that any difference is indistinguishable on an ordinary plot. Therefore, the values in Table II refer to either of these salts up to 0.15 m.

The mean activity coefficients were calculated from the standard equation (9)

$$[5] \quad -\ln \gamma_\pm = 1 - \phi + 2\int_0^{m^{\frac{1}{2}}} \frac{(1-\phi)}{m^{\frac{1}{2}}} dm^{\frac{1}{2}}$$

and are reported in Table II. The integral in eq. [5] was evaluated graphically.

The uncertainties in ϕ are about 0.002 for the borates, and because of the uncertainties mentioned earlier, are about 10 times greater for the boric acid. The uncertainties in $\gamma_\pm$ are as much as 0.01 depending on how the integral in eq. [5] is evaluated at low concentrations.

Because borax in solution can be formed by mixing aqueous sodium metaborate and boric acid, it should be possible to calculate changes in

1.0	0.351	0.082	—	—	7.0	—	—	0.686	0.300
1.1	0.341	0.077	—	—	8.0	—	—	0.680	0.286
1.2	0.333	0.072	—	—	9.0	—	—	0.676	0.275

ideality resulting from the reverse of the process in eq. [2]. This is done by comparing ϕ(borax) with the weighted sum of $\phi(NaBO_2)$ and $\phi(H_3BO_3)$. The ϕ values are measures of the colligative properties of solutions, and any difference is directly related to the excess free energy of mixing (11) or change in ideality on mixing.

For example, if 0.3 mole of $NaBO_2$ in 0.667 kg of water is added to 0.3 mole of H_3BO_3 in 0.333 kg of water to give 0.15 mole of $Na_2B_4O_7$ in 1.0081 kg of water, the process will have taken place at a nearly constant νm of 0.9. (The small amount of water required to hydrate the $NaBO_2$ has been ignored.) The change in ideality on mixing is given by

$$\Delta = \phi\,(0.15\,m\,Na_2B_4O_7) - 2/3\,\phi\,(0.45\,m\,NaBO_2) - 1/3\,\phi\,(0.9\,m\,H_3BO_3)$$

where $\Delta \to 0$ as $m \to 0$. For the process above

$$\Delta = 0.60 - 2/3 \times 0.85 - 1/3 \times 0.98 = -0.29$$

This dimensionless quantity is directly related to the excess free energy of mixing, and is fairly large in comparison with the Δ for other mixing processes (11). The actual free energy change cannot be calculated with any confidence from these data alone but if it is relatively large, as the large value of Δ indicates, it shows that borax in solution has behavior more complicated than that represented by eq. [2].

Acknowledgments

Dr. C. L. Christ of the U.S. Geological Survey first suggested to me that I study the tetraborates isopiestically, and he corrected my naïve ideas on what species exist in borate solutions. I am grateful to the Fisheries Research Board of Canada for the loan of the apparatus used in this work, and to Dr. M. E. Thompson for helpful suggestions during the writing of this paper.

Some substituted urea and thiourea complexes of Co(II), Mn(II), and Cr(III)[1]

PAKINAM ASKALANI[2] AND R. A. BAILEY
Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York 12181

Received December 11, 1968

Complexes of Co(II), Mn(II), and Cr(III) with N-butylurea, N-methylthiourea, and N,N′-dimethylthiourea, and Cl^-, Br^-, NO_3^-, and ClO_4^- anions were prepared and characterized using infrared and visible spectroscopy, and magnetic susceptibility. The urea is bonded through oxygen, and the thioureas through sulfur in all cases. The Co–N-butylurea compounds are octahedral, mostly with CoL_6X_2 stoichiometries, but some compounds involving coordinated anions and possibly bridging butylurea ligands were found. The Co–thioureas are tetrahedral. Octahedral Cr(III) compounds of the type CrL_3X_3 and $CrL_6(ClO_4)_3$ were prepared, and the CrS_6 chromophore characterized. Mn(II)–butylureas are octahedral, while the thioureas show MnL_6X_2 and MnL_4X_2 stoichiometries. X-ray diffraction established some of the latter to be isostructural with the analogous tetrahedral Co(II) compounds. Ligand field parameters *Dq* and *B* have been evaluated for the Co(II) and Cr(III) compounds.

Canadian Journal of Chemistry, 47, 2275 (1969)

Introduction

Urea, thiourea, and their N-substituted forms have recently been subject to some investigations due to their ability to behave as oxygen (sulfur in the case of thioureas) or nitrogen coordinating ligands. Much of the attention has been given to the infrared (i.r.) spectra of their coordination compounds to determine the bonding atom of the ligand (which is usually but not always oxygen or sulfur for most of the first row transition elements which have been considered), although some studies on the different structural aspects of their transition metal complexes have been reported. Among these are the studies on Co(II) compounds with thiourea (1); ethylenethiourea and N,N′-diethylthiourea (2); N,N′-diethylthiourea, N,N′-dibutylthiourea, and N,N′-diphenylthiourea (3); and N-methylurea, N-ethylurea, N,N′-dimethylurea, N,N′-diethylurea, and ethyleneurea (4). In general, it has been found that thiourea and its N-substituted forms tend to surround Co(II) ions in a tetrahedral geometry, while urea and its substituted forms give octahedral Co(II) compounds, although exceptions to this generalization have been reported.

Cr(III) compounds with urea and N,N′-dimethylurea are evidently octahedral, (5–7), although only Stonestreet *et al.* (7) have considered properties other than i.r. spectra. Thiourea complexes of this ion have been still less studied; recently Cervone *et al.* (8) obtained octahedral compounds of the sort CrL_3Cl_3 where L = thiourea, N,N′-diethylthiourea, and N,N′-dibutylthiourea, but were unable to obtain species with a CrS_6 chromophore. The C—S bond is difficult to form, and spectral and magnetic properties for such compounds are of interest. While ligand field spectra of the above compounds imply sulfur bonding, no confirming i.r. data are available.

Infrared evidence for sulfur bonding of thiourea with Mn(II), (9, 10) and of oxygen bonding of dimethylurea (7) has been presented, but no structures are known for the thiourea compounds which are of the form $Mn(thiourea)_4X_2$. The hexakis-N-methylurea complex (11) has been shown to be oxygen bonded and octahedral.

The present study was undertaken to fill in some of the gaps in the knowledge of the behavior of Cr(III) and Mn(II) with this class of ligands. Work on Co(II) has been included as well, since this, along with previously published work, provides a series of well characterized complexes with the same ligands for a number of first row transition metal ions. Effects of different anions can be correlated, as can trends in ligand field parameters with changing substituent on the organic ligands.

Experimental

Chemicals

All chemicals used were reagent grade when possible,

and were used without further purification. N-butylurea was obtained from K and K Laboratories, Inc., and the two thioureas from Chemicals Procurement Laboratories. The metal halides were anhydrous, but hydrated perchlorates and nitrates were employed.

Preparations

The compounds were prepared by dissolving the metal salt and ligand in a hot organic solvent (shown for each case in Table I), heating for 30–60 min, and cooling in ice with vigorous stirring to help initiate crystallization. For chromium halide compounds, zinc was used as a catalyst to break the auto-complex. This, along with any unreacted halide, was filtered from the hot reaction mixture. In some cases, ether or benzene was added to induce crystallization. The solvent used was determined by trial, and depended on solubilities. All solid products were recrystallized, usually from the solvent used in the preparation. A number of products could not be obtained as solids, and were characterized as oils. They were thoroughly washed with solvents which would dissolve unreacted starting materials, and dried under vacuum until pure. All analytical data are given in Table I.

For the $Co(NO_3)_2$ – N-butylurea system, the product isolated depended on the ratio of ligand to metal salt, with $Co(BU)_4(NO_3)_2$ being formed if this ratio were much below 6.

Most of these compounds showed color changes in dilute solution, raising the possibility of dissociation or other reaction with the solvent. In these cases, solution data were not considered to be reliable indications of structures of the solid compounds.

Physical Measurements

Magnetic susceptibilities were taken by the Gouy technique, using $[Hg\,Co(NCS)_4]$ as calibrant and measurements were corrected for diamagnetism in the usual manner. Measurements were made at room temperature, and at lower temperatures by surrounding the specimen with a suitable coolant in a Dewar flask. Measurement results were independent of field strength.

Electronic spectra were taken by reflection from finely powdered samples, using a Beckman DU spectrophotometer and $MgCO_3$ as standard. Oils were pressed between quartz plates and measured by transmission on a Beckman DK-2A spectrophotometer. Neither technique can provide extinction coefficients.

Infrared spectra were taken on a Perkin–Elmer 621 spectrophotometer. Solids were pressed in KBr discs and checked in mulls, while oils were pressed between salt plates.

X-ray powder diffraction patterns were taken with a Philips X-ray unit, type 12045B/3 and a Philips high angle goniometer, type 42267/0. Nickel filtered copper radiation was used.

Conductance measurements, when it was felt that these would be significant, were taken at 25 °C on 0.001 *M* solutions using an Industrial Instruments, Inc., model RC 16B2 conductance bridge.

Analyses

Manganese and cobalt were determined by EDTA titration methods, while chromium was found spectrophotometrically as CrO_4^{2-}. Total nitrogen was estimated by the Kjeldahl technique with selenium or copper sulfate as catalyst, while nitrate was determined gravimetrically as nitron nitrate. Halides were analyzed potentiometrically with silver nitrate, and perchlorates were precipitated as tetraphenylarsonium perchlorate. Sulfur was determined as $BaSO_4$ after decomposition by Eschka's mixture.

Results and Discussion

Infrared Spectra

Shifts in the i.r. spectra of the coordinated ligands can be used to indicate the mode of bonding of the organic ligands in these compounds. For N-butylurea, comparison with other substituted ureas (12) suggests that the most distinctive change expected on coordination through oxygen is a decrease in the energy of the C=O stretching band at 1650 cm^{-1}. This is found here at 1625–1640 cm^{-1}. The N—H stretching region near 3400 cm^{-1} shows no shift to lower energy, and other bands behave similarly to those observed in other oxygen-bonded N-butylurea complexes (12).

The bonding criteria of N-methylthiourea have been suggested by Lane *et al.* (13) and Gosavi and Rao (14), and for N,N′-dimethylthiourea by Gosavi and Rao (14). The spectra of the complexes of N-methylthiourea were in good agreement with what is expected for sulfur bonding on the basis of the above, while those of N,N′-dimethylthiourea showed only slight discrepancies from the sulfur-bonding criteria. (The N—H out-of-plane bending mode at 718 cm^{-1} in the free ligand is expected to increase for S-bonding and to decrease for N-bonding. It was found in these complexes at 710–720 cm^{-1}.)

The above conclusions, that all N-butylurea compounds are bonded through oxygen, while all those of the thioureas are sulfur bonded, are in keeping with most of the previous observations on urea and thiourea complexes of the metals of the first transition series. The electronic spectra below provide some further evidence to this point.

Magnetism

The magnetic data for the compounds prepared here are reported in Table II. Measurements were made at three or more temperatures, but only the room temperature data are tabulated; the values given for θ permit the lower temperature data to be recovered. Moments are corrected for diamagnetism and temperature independent paramagnetism when the latter

*Moment decreased with decreasing temperature. Believed to be a packing difficulty.
†μ_{eff} was calculated from the Curie law; θ was not determined.

is significant (Cr(III) and tetrahedral Co(II) compounds).

The Co–N-butylurea compounds all have moments suggesting octahedral geometry (15), 4.88–5.17 B.M. Moments decreased with decreasing temperature, as is characteristic of a $^4T_{1g}$ ground state; plots of $1/\chi_M$ vs. temperature were not linear. Moments of the substituted thiourea complexes with Co, on the other hand, are clearly in the range for tetrahedral symmetry. All obeyed the Curie–Weiss law with relatively small values of θ (Table II). Room temperature moments in the table were calculated from the relation $\mu = 2.84\ (T - \theta)^{\frac{1}{2}}$ B.M., although we make no claims as to the significance of θ.

Moments for all of the chromium compounds are also in the range characteristic of octahedral geometry (15), and behave in a straight-forward manner. Those for the manganese compounds are typical for Mn(II) in a weak ligand field; they are not characteristic of geometry for a d^5 ion. The Curie-Weiss law was obeyed in both cases.

Electronic Spectra

Three spin allowed transitions are predicted for Co(II) in an octahedral ligand field; these are, in order of energy

$$^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)$$

$$^4T_{1g}(F) \rightarrow {}^4A_{2g}(F)$$

$$^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$$

Of these, the second corresponds to a 2-electron jump and is expected to be very weak (16); it is usually obscured by the tail of the more intense third band (4). The five pink Co–N-butylurea compounds which appear to be octahedral on the basis of magnetic data show two major bands; one around 8 000 cm^{-1} and the other at 19 000 – 20 000 cm^{-1} with a shoulder at higher energies (Table III, Fig. 1). It is reasonable to assign these bands to first and third transitions, respectively, with the shoulder on the latter probably due to spin–orbit splitting of the $^4T_{1g}(P)$ state (16). The band listed under the ν_2 transition in Table III is

*For assignments, see text.

rather low in energy, and is almost certainly the spin-forbidden transition to the ^2E_g state which also lies in this region; it was not used in obtaining the ligand field parameters, and does not agree well with the parameters given if it is the $^4A_{2g}$ band. Values of both Dq and B (the Racah parameter, Table III) are comparable to those of other oxygen coordinated ligands with Co(II) (4).

Spectra of the deep blue cobalt – substituted thiourea compounds do not fit an octahedral case, and magnetic results above indicate a tetrahedral geometry. Three ligand field bands are expected in this case, with the lowest energy band (equal to 10 Dq) below the range of measurement. Two bands were observed, near 8 000 and 15 000 cm^{-1} with the latter showing much fine structure which is common for tetrahedral Co(II) (2). The transition energy (Table III) was taken as the center of gravity of this band; the individual peaks (usually three) have not been listed. These bands can be assigned to the transitions $^4A_2(F) \rightarrow {}^4T_1(F)$ and $^4A_2(F) \rightarrow {}^4T_1(P)$, and Dq and B evaluated from the relationships of Underhill and Billings (17). The data are given in Table III. Both parameters are reasonable when compared to other tetrahedral Co(II) systems. In particular, values of B of about 600 cm^{-1} were reported by Cotton *et al.* (1) for other Co(II)–thiourea compounds. Such small values are reasonable only if the ligand is bonded through sulfur, which lies high in the nephelauxetic series.

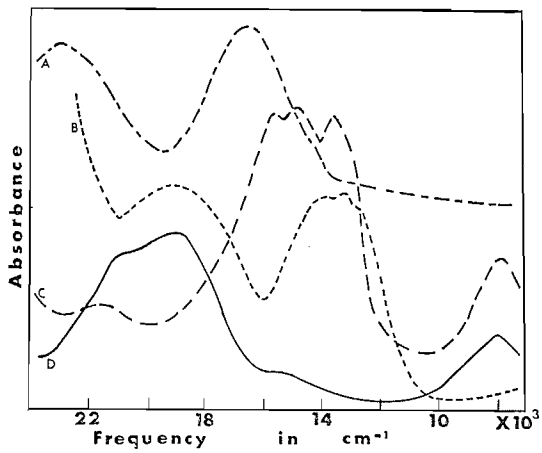

FIG. 1. Representative electronic spectra of Co(II) and Cr(III) complexes. (A), $[Cr(BU)_6](ClO_4)_3$; (B), $[Cr(DMTU)_3Cl_3]$; (C), $[Co(DMTU)_2Br_2]$; (D), $[Co(BU)_6](ClO_4)_2$.

Cr(III) should exhibit three bands in an octahedral field

ν_1: $^4A_{2g}(F) \rightarrow {}^4T_{2g}(F)$

ν_2: $^4A_{2g}(F) \rightarrow {}^4T_{1g}(F)$

ν_3: $^4A_{2g}(F) \rightarrow {}^4T_{1g}(P)$

In addition, spin-forbidden bands may appear.

The chromium–butylurea spectra exhibit two major bands, near 16 400 and 22 700 cm^{-1} (Table III). A small shoulder appears at 14 300 cm^{-1} in the spectra of all these compounds. These band positions are similar to those reported with other oxygen coordinating ligands (7, 18); the major bands can be assigned to the ν_1 and ν_2 transitions. The position of ν_3 can be predicted to be above 35 000 cm^{-1} where it is obscured by charge transfer bands. The weak shoulder, on the other hand, can be attributed to the $^4A_{2g}(F) \rightarrow {}^2E_g(G)$, $^2T_{1g}(G)$ doublet, which has been observed as a single band at this energy in other Cr(III) complexes. (These levels are independent of ligand field.) The methylthiourea and most dimethylthiourea compounds are similar to the above, but B is much smaller, again in keeping with S-bonded organic ligands (19). A value of 1400–1450 cm^{-1} for Dq of the Cr(III)–S_6 chromophore may be compared with that of 1510 cm^{-1} calculated by Cervone *et al.* (8) from average ligand field arguments; this is an average for the three thiourea ligands which they used. Dq for the N,N′-dibutylurea complexes, 1640 cm^{-1}, is slightly greater than the 1540 cm^{-1} of N,N′-dimethylurea given by Stonestreet *et al.* (7). Substitutents on the urea ligands have some effect on the coordination strengths toward Cr(III) as toward Ni(II) (12).

The spectra of the chloride and perchlorate of the chromium dimethylthioureas exhibit three peaks in the region assigned to ν_1. A similar observation on other Cr(III) compounds was explained by Bates (18) on the basis that, in the region where the three energy levels ^2E_g, $^2T_{1g}$, and $^4T_{2g}$ cross, mixing occurs which gives all three levels intermediate doublet–quartet character. Transitions to all should then have comparable probabilities. Since none of these bands can be assigned definitely to the ν_1 transition, the center of this triplet band was used in calculating Dq, and only this is tabulated.

No visible spectra were obtained for compounds of manganese. This is not unexpected, since all bands would be spin-forbidden.

In all of the above compounds, N,N′-dimethlythiourea has a slightly weaker ligand field strength than N-methylthiourea. Both are slightly stronger than Cl^- and considerably weaker than butylurea. Substituted ureas and thioureas are stronger than the unsubstituted ligands, since presumably substitution increases the electron density around the O (or S) atom. The greater tendency for butylurea compounds to be octahedral with cobalt may be related to the greater ligand field stabilization energy associated with the octahedral geometry which is more significant with this ligand than with the weaker thioureas. However, the same observations on structure seem to hold for some of the Mn(II) compounds (see below) where this stabilization energy is zero, so that other factors must be important.

The Co–N-butylurea compounds were shown above to be octahedral, indicating the existence of the $[Co(BU)_6]^{2+}$ cation in the bromide, nitrate, and perchlorate compounds. $Co(BU)_4(NO_3)_2$ may have two coordinated nitrate ions to complete the octahedral geometry. This could not be confirmed. Infrared evidence was inconclusive, as some of the nitrate regions are obscured by bands from the organic ligands; however, nitrate bands at 823 and 1300–1400 cm^{-1} (very broad) best fit ionic nitrate (20). In fact, these regions of the i.r. spectrum match almost exactly those of $[Co(BU)_6](NO_3)_2$ where the nitrates are without doubt ionic. Conductance data were not useful, as a color change in all suitable solvents investigated implied further changes. If the nitrates are ionic, bridging butylurea would be indicated (bridging through the oxygen, based on the i.r. spectrum and the similarity of the ligand field spectrum to that of $[Co(BU)_6](NO_3)_2$).

Octahedral $Co(BU)_2Cl_2$ must also be a bridged structure. Bridging of both butylureas, or both chlorides, or one of each, could lead to an octahedral geometry. Application of the average ligand field rule (21) to the various possibilities leads to the following calculated values for 10 Dq (assuming only O-bonding, as indicated by the i.r. evidence): 4 butylureas and 2 chlorides around each Co(II), 9060 cm^{-1}; 4 chlorides and 2 butylureas around each Co(II), 8130 cm^{-1}; 3 chlorides and 3 butylureas around each Co(II), 8600 cm^{-1}. The observed value is 9500 cm^{-1}. While the rule is only approximate, and will be influenced by bond lengths, it usually holds to within a few hundred wavenumbers in systems similar to this. It seems to rule out bridging chlorides. While bridging of 2 metal ions by the oxygen atom of a urea type ligand has not previously been established, it is known with the sulfur of thiourea systems (22). Clearly, addi-

tional structural data would be valuable in this case. This last compound is the first cobalt urea complex with coordinated anions.

This last compound is very unstable, rapidly but incompletely decomposing on standing to a gummy, deep blue material which exhibits a spectrum characteristic of tetrahedral cobalt, and a reduced magnetic moment (4.6 B.M.). The blue product was soluble in ether, so could be washed away as formed. However, different samples of it varied in composition, and no single product could be isolated. Interestingly, the other possibly bridged compound of this series, $Co(BU)_4(NO_3)_2$, also decomposes readily to a blue, tetrahedral species. A similar decomposition was observed by Costamagna and Levitus (4), who believed the reaction to be

$$ML_{6(oct)} \rightarrow ML_2X_{2(tet)} + 4L$$

in their case. The tetrahedral species could not be isolated and characterized.

The Co – substituted thiourea compounds are tetrahedral. Since $Co(MTU)_2Cl_2$ and $Co(DMTU)_2Cl_2$ are non-electrolytes in nitromethane, the anions are believed to be coordinated. The compounds $CoL_3(NO_3)_2$ may have one coordinated nitrate or a bridged structure; conductance data were again invalid due to changes in color in solution. For the methylthiourea compound, the i.r. spectrum showed bands at 822 and 1350 cm^{-1} attributable to ionic nitrate, but also gave a band at 1025 cm^{-1} which can be assigned to a coordinated nitrate (20). Other possible nitrate bands, and the 1025 cm^{-1} region in the dimethylthiourea compound, were obscured by ligand absorptions. We suggest very tentatively one coordinated NO_3^- group. Meneces *et al.* (23) describe analogous cobalt thiourea halides.

The Cr(III) compounds are all octahedral; this is the usual geometry for this ion. Compounds of the butylurea series contain the $[Cr(BU)_6]^{3+}$ cation, while those of formulas CrL_3X_3 contain coordinated anions, as shown by Cervone *et al.* (8).

No structural data can be obtained for the Mn(II) compounds from magnetic or spectral measurements. It is presumed that those of formula MnL_6X_2 are octahedral. In an attempt to relate structures of the remaining compounds to others of similar formulas and known structures, X-ray powder patterns were examined. Identical powder patterns for two such compounds (except for slight differences in d spacings) can be taken as evidence that the compounds are isostructural and therefore contain units with the same coordination geometry. This is the case, for example, with $[Mn(BU)_6]Br_2$ and $[Co(BU)_6]Br_2$. The compounds $Mn(DMTU)_2Cl_2$, $Mn(DMTU)_2Br_2$, and $Mn(DMTU)_4(ClO_4)_2$ have the same stoichiometries as the analogous cobalt compounds, and the

For personal use only.

first two of these are isostructural with their cobalt analogues as shown in Table IV. Tetrahedral species are thus indicated for these Mn(II)–thiourea systems, while the ureas are octahedral, as for Co(II). The manganese chloride compound was a non-conductor in nitromethane as the proposed structure requires.

$Mn(DMTU)_4(ClO_4)_2$ is not isostructural with its cobalt analogue. Its conductance in nitromethane, ca. 125 Ω^{-1} cm^2, is in the range of a 1:2 electrolyte. $Mn(MTU)_2Cl_2$ is not isostructural with $Co(MTU)_2Cl_2$, $Fe(MTU)_2Cl_2$ (24), or $Ni(MTU)_2Cl_2$ (12). This does not preclude a similar coordination structure to any one of them, but a different crystal structure. It was dissociated in solution.

It is interesting that the stoichiometry of the Mn(II) perchlorate compounds varies with the substituents on the thiourea ligands. The methylthiourea species is evidently octahedral, unlike the thiourea–Co(II) systems. It is likely that compounds of both stoichiometries $MnL_4(ClO_4)_2$ and $MnL_6(ClO_4)_2$ could be formed under proper conditions with these ligands.

An analytical method of calculating thermodynamic data in ternary systems

A. D. PELTON AND S. N. FLENGAS
Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario

Received September 27, 1968

Relationships between the coefficients of series expansions in the composition variables for isothermal partial molar properties of all components, and for the corresponding integral property in a ternary system, have been developed. These relationships allow the calculation of the isothermal partial properties of mixing of all components, from experimental values of this property for one component, or from experimental measurements of the corresponding integral property of mixing. The form of the series expansions is such as to permit the easy fitting of the experimental data by standard least-squares techniques. Experimental data in a binary sub-system or experimentally determined phase boundary positions may easily be used to give end-points for the calculation. The method is faster and more accurate than the older graphical integration techniques. The simplicity of the method depends upon the proper choice of composition variables. Sample calculations have been done for the Cd–Bi–Sn system, using computer programs designed for the purpose.

Introduction

As is well-known, if values of the isothermal excess free energy of mixing of one component in a system are known over a composition range, then values of the excess free energy of mixing of all the other components, and values of the excess integral free energy of mixing, may be calculated by use of the Gibbs–Duhem relation. For binary systems, the calculations may be done by the well-known graphical techniques or by analytical techniques such as that proposed by Margules (1).

For ternary systems, such calculations have only been done by the graphical techniques of Darken (2), Wagner (3), Schuhmann (4), and Gokcen (5). These techniques are long and tedious. They involve several steps such as the graphical determination of slopes of tangent lines. Unless great care is taken, the results can be inaccurate. Quantities are calculated at one composition at a time. The experimental data must be available along simple composition paths (such as quasi-binary lines or constant mole fraction lines) so that interpolations may be made, and slopes and areas may be determined graphically. If the available data points are scattered at random over the composition range, interpolation can be very difficult.

In the present investigation, an analytical method has been developed which overcomes these difficulties. In this method, relationships between the coefficients of series expansions in the composition variables for the isothermal excess partial and integral free energies of mixing, are found. If the coefficients of the expansion for one component are found by a least-squares surface fitting technique to experimental data, then the coefficients of the expansions for the properties of all the other components, and for the integral property, are immediately and exactly determined. The method is readily adaptable for use with a digital computer.

The Analytical Method in Binary Systems

The following modification of the analytical method of Margules (1) for binary systems will serve as a basis for the later extension to ternary systems.

Let f_1 and f_2 be the partial molar excess free energies of mixing of components *1* and *2*, and let f be the excess integral molar free energy of mixing. If f_1, f_2, and f are expressed as power series in X_2, the mole fraction of component *2*, as follows

$$[1] \qquad f_1 = \sum_{j=2}^{j'} a_j X_2^{\,j}$$

$$[2] \qquad f_2 = \sum_{j=0}^{j'} b_j X_2^{\,j}$$

$$[3] \qquad = \sum_{j=1}^{j'} \phi_j X_2^{\,j}$$

then the relationships between the coefficients, as derived by Margules (1) from the Gibbs–Duhem relation, take the following form

$$[4] \qquad b_j = a_j - \left(\frac{j+1}{j}\right) \cdot a_{j+1} \qquad j \geqslant 1$$

$$[5] \qquad \phi_j = a_j/(1-j) \qquad j \geqslant 2$$

The expansion for f_1 must start with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$j = 2$ term. The missing coefficient a_0 is zero because $f_1 = 0$ when $X_2 = 0$, and the fact that the missing coefficient a_1 is zero follows from eq. [5], since ϕ_1 must be finite. In the expansion [3] for f, the missing coefficient ϕ_0 is zero, since $f = 0$ when $X_2 = 0$. If the coefficients a_j have been determined by fitting a curve to the experimental values of f_1 over a composition range, then all the coefficients, b_j and ϕ_j, may be calculated from eqs. [4] and [5] except for b_0 and ϕ_1. The determination of these two coefficients requires the experimental knowledge of one end-point value of f_2 (or f) at the boundary of the composition range studied.

In the simple case when f_1 has been measured over the composition range down to $X_2 = 1$, the boundary conditions that $f_2 = 0$ and $f = 0$ when $X_2 = 1$ may be used, and no independent measurement of f_2 (or f) is required to give end-point values. In this case it may easily be shown that b_0 and ϕ_1 are given by the explicit forms

$$[6] \qquad b_0 = -\sum_{j=1}^{j'} b_j$$

$$[7] \qquad \phi_1 = -\sum_{j=2}^{j'} \phi_j$$

It is well-known that partial molar excess free energies of mixing are well-fitted by an expansion, such as that in eq. [1]. For most systems, a very good fit may be obtained with only three or four terms.

The Form of the Series Expansions for Ternary Systems

The composition variables chosen in this work for the series expansions were designated y and t where

$$[8] \qquad y = (1 - X_1)$$

$$[9] \qquad t = \frac{X_3}{X_2 + X_3}$$

where X_1, X_2, and X_3 are the mole fractions of the three components. The inverse transformations are

$$[10] \qquad \begin{aligned} X_1 &= (1 - y) \\ X_2 &= (1 - t)y \\ X_3 &= ty \end{aligned}$$

In the composition triangle of an isothermal ternary system, t is constant along quasi-binary lines of constant X_3/X_2 ratio. The variable can assume values from $t = 0$ in the *1–2* binary system to $t = 1$ in the *1–3* binary system. The variable y is constant along lines parallel to the *2–3* binary line, and can assume values from $y = 0$ for pure component *1* to $y = 1$ in the *2–3* binary system. This is shown on the ternary composition triangle in Fig. 1. These variables were first suggested by Wagner (3) for his graphical treatment, and have also been found particularly useful for the present analytical method.

The partial and integral excess molar free energies of mixing are expressed as power series in y and t as follows

$$[11] \qquad f_1 = \sum_{j=2}^{j'} \sum_{k=0}^{k'} a_{jk} y^j t^k$$

$$[12] \qquad f_2 = \sum_{j=0}^{j'} \sum_{k=0}^{k'} b_{jk} y^j t^k$$

$$[13] \qquad f_3 = \sum_{j=0}^{j'} \sum_{k=0}^{k'} c_{jk} y^j t^k$$

$$[14] \qquad f = \sum_{j=1}^{j'} \sum_{k=0}^{k'} \phi_{jk} y^j t^k$$

where f_1, f_2, and f_3 are the partial molar excess free energies of mixing of components *1*, *2*, and *3*, respectively, and f is the excess integral molar free energy of mixing.

The upper limits of the summations can be selected in accordance with the number of terms found necessary to fit the data for a particular system. In many cases, it may be expedient for the upper limit k' to be a function of j'. An example of this is given later.

Equation [11] may be written in expanded form as

$$[15] \qquad \begin{aligned} f_1 = {} & (a_{20} + a_{21}t + a_{22}t^2 + \cdots\cdot)y^2 \\ & + (a_{30} + a_{31}t + a_{32}t^2 + \cdots\cdot)y^3 \\ & + \cdots\cdots\cdots\cdots \end{aligned}$$

Along a line of constant t, each of the bracketed factors in eq. [15] becomes constant, and f_1 is simply a power series in $y = (1 - X_1)$ starting with the y^2 term, which is of the same form as eq. [1] for binary systems. In the *1–2* and *1–3* binary sub-systems, y becomes equal to X_2 or X_3, respectively, and eq. [15] reduces exactly to eq. [1]. It is in this sense that the lines of constant t are called quasi-binary lines.

The expansion [11] for f_1 starts with the $j = 2$ term. That the missing coefficients a_{0k} are zero for all values of k follows from the condition that $f_1 = 0$ when $y = 0$. That the missing coefficients a_{1k} are all zero follows from the Gibbs–Duhem relation as will be discussed shortly. In the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

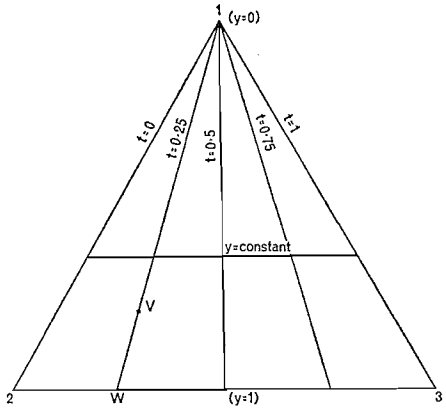

FIG. 1. Quasi-binary lines in a ternary system.

expansion [14] for f, the missing coefficients ϕ_{0k} for $j = 0$ must all be zero because of the condition that $f = 0$ when $y = 0$. The analogy with the binary case is clear.

Calculation of the Excess Integral Molar Free Energy of Mixing

By substituting the inverse transformations [10] into the well-known expression

$$[16] \qquad f = X_1 f_1 + X_2 f_2 + X_3 f_3$$

and into the Gibbs–Duhem equation

$$[17] \qquad X_1 df_1 + X_2 df_2 + X_3 df_3 = 0$$

it may be shown (see Appendix I) that

$$[18] \qquad f - f_1 = y\left(\frac{\partial f}{\partial y}\right)_t$$

Substitution of eqs. [11] and [14] into eq. [18] yields the equation

$$[19] \quad \sum_{j=1}\sum_{k=0}\phi_{jk}y^j t^k - \sum_{j=2}\sum_{k=0}a_{jk}y^j t^k = y\sum_{j=1}\sum_{k=0}\phi_{jk}(j)y^{j-1}t^k$$

By equating coefficients of $y^j t^k$ for each pair of values of j and k, the following relationship is obtained

$$[20] \qquad a_{jk} = (1 - j)\phi_{jk}$$

For $j = 1$, it is seen from eq. [20] that $a_{1k} = 0$ for all values of k, since the coefficients ϕ_{1k} must be finite. This proves the assertion made previously.

From eq. [20], the coefficients ϕ_{jk} in the expression for f, may be found from a knowledge of the coefficients a_{jk} for all values of j and k except for $j = 1$. These coefficients, ϕ_{1k}, must be found from boundary conditions as will be discussed shortly.

Calculation of the Partial Molar Excess Free Energies of Mixing

By taking the partial differentials of f in eq. [16] with respect to t and y, it may be shown (see Appendix II), that

$$[21] \qquad f_2 = f_1 + \left(\frac{\partial f}{\partial y}\right)_t - \frac{t}{y}\left(\frac{\partial f}{\partial t}\right)_y$$

Substituting the expressions for f_1, f_2, and f from eqs. [11], [12], and [14] into eq. [21] and simplifying (see Appendix II) yields the following relationship

$$[22] \quad \sum_{j=0}\sum_{k=0}b_{jk}y^j t^k = \sum_{j=2}\sum_{k=0}a_{jk}y^j t^k + \sum_{j=0}\sum_{k=0}\phi_{(j+1)k}(j + 1 - k)y^j t^k$$

By equating coefficients of $y^j t^k$ for each pair of values of j and k for $j \geqslant 1$, the following relationship is obtained

$$[23] \qquad b_{jk} = a_{jk} + (j + 1 - k)\phi_{(j+1)k} \qquad j \geqslant 1$$

By substitution from eq. [20], it is seen that

$$[24] \qquad b_{jk} = a_{jk} - \left(\frac{j + 1 - k}{j}\right)a_{(j+1)k} \qquad j \geqslant 1$$

The relationship between the coefficients c_{jk} and the coefficients a_{jk} may be derived in a similar manner (see Appendix III). The relationship is

$$[25] \quad c_{jk} = a_{jk} - \left(\frac{j + 1 - k}{j}\right)a_{(j+1)k} - \left(\frac{k + 1}{j}\right)a_{(j+1)(k+1)} \qquad j \geqslant 1$$

In applying eqs. [24] and [25], if j' is the upper summation index, then the coefficients $a_{(j'+1)k}$ must be taken to be zero.

From eqs. [24] and [25], the coefficients b_{jk} and c_{jk} of the expansions for f_2 and f_3 may be determined from a knowledge of the coefficients a_{jk}, except for the case when $j = 0$. These coefficients, b_{0k} and c_{0k}, must be determined from boundary values as discussed in the next section.

The Inclusion of Boundary Values

Equation [12] for f_2 may be expanded as follows

$$[26] \quad f_2 = (\sum_{k=0}b_{0k}t^k) + \sum_{j=1}\sum_{k=0}b_{jk}y^j t^k$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

As stated previously, the coefficients b_{0k} cannot be calculated from eq. [24] and must be found from boundary values of f_2.

The undetermined term, $(\sum_{k=0} b_{0k}t^k)$, in eq. [26], is constant along a quasi-binary line where t is constant. The knowledge of one end-point value of f_2 along a quasi-binary line is thus sufficient to give values of f_2 at any point on that line.

Let $f_{2(y^*,t)}$ be some known end-point value of f_2 at some point where $y = y^*$ along a quasi-binary line where t is constant. Then

$$[27]\quad f_{2(y^*,t)} = (\sum_{k=0} b_{0k}t^k) + \sum_{j=1}\sum_{k=0} b_{jk}y^{*j}t^k$$

Let $f_{2(y,t)}$ be the value of f_2 at any value of y along the same quasi-binary. Substitution of eq. [27] into eq. [26] then gives

$$[28]\quad f_{2(y,t)} = f_{2(y^*,t)} + \sum_{j=1}\sum_{k=0} b_{jk}(y^j - y^{*j})\,t^k$$

In Fig. 1, then, values of $f_{2(y,t)}$ at any point along the quasi-binary line *1*–W are given by a knowledge of $f_{2(y^*,t)}$ at any point on this line, say at point V, which could lie on a phase boundary such as a liquidus. It is thus seen that the use of end-point values permits f_2 to be found in the ternary system, without the explicit determination of the coefficients b_{0k}.

If values of f_1 were measured and fitted down to the *2–3* binary line where $y = 1$, then the experimental value of f_2 at point W, obtained from measurements in the *2–3* binary system, could be used as an end-point. In this case, $y^* = 1$, and eq. [28] takes the simple form

$$[29]\quad f_{2(y,t)} = f_{2(1,t)} + \sum_{j=1}\sum_{k=0} b_{jk}\,(y^j - 1)\,t^k$$

If f_2 has been measured in the *2–3* binary system as a function of concentration, then $f_{2(1,t)}$ may be written as a function of t (where $t = X_3$ in the *2–3* binary system from the definition [9]). The functional form of $f_{2(1,t)}$ would be as in eq. [1]. Equation [29] would then be a complete analytical equation for f_2 in the ternary system.

In the *1–2* binary system, the end-point condition that $f_2 = 0$ when $X_2 = 1$ can be used if values of f_1 are available down to $X_2 = 1$. This determines values of f_2 in this binary system, and in particular it fixes a value of f_2 at $X_1 = 1$ ($y = 0$). From Fig. 1, it may be seen that this value, $f_{2(0,t)}$, could then be used as an end point value in any quasi-binary. No independent measurements of f_2 anywhere would then be required to give values of f_2 at any point in the ternary composition triangle.

In fact, in this case, the boundary condition used, (that $f_2 = 0$ when $X_2 = 1$), could be employed to give explicit equations for the coefficients b_{0k} analogous to eq. [6] for binary systems.

However, this method requires that extremely accurate values of f_1 be known in the region near $X_1 = 1$, since f_2 is usually quite large in this region and, through the Gibbs–Duhem relation, is very sensitive to changes in the partial derivatives of f_1 with y and t. However, f_1 is very small in this region, and it is very difficult to determine the partial derivatives with any accuracy. Attempts to use this technique in the Cd–Bi–Sn system, discussed later, failed completely. Thus, in practice, end-point values obtained from independent measurements of f_2 are always required. All the graphical Gibbs–Duhem integration techniques (2–5) require the knowledge of end-point values for the same reason.

Equations completely analogous to eqs. [28] and [29] may be written for f_3

$$[30]\quad f_{3(y,t)} = f_{3(y^*,t)} + \sum_{j=1}\sum_{k=0} c_{jk}\,(y^j - y^{*j})\,t$$

Or, if values of f_3 in the *2–3* binary system may be used as end points

$$[31]\quad f_{3(y,t)} = f_{3(1,t)} + \sum_{j=1}\sum_{k=0} c_{jk}\,(y^j - 1)\,t^k$$

$f_{3(1,t)}$ could be expressed as a power series in t to give a complete analytical solution for f_3 in the ternary system.

For the excess integral free energy of mixing, f, eq. [14] may be expanded as

$$[32]\quad f = y\sum_{k=0}\phi_{1k}t^k + \sum_{j=2}\sum_{k=0}\phi_{jk}y^jt^k$$

If $f_{(y^*,t)}$ is some known value of f at a point where $y = y^*$ along a quasi-binary line, then

$$[33]\quad f_{(y^*,t)} = y^*\sum_{k=0}\phi_{1k}t^k + \sum_{j=2}\sum_{k=0}\phi_{jk}y^{*j}t^k$$

By substitution of eq. [33] into eq. [32], it may be seen that $f_{(y,t)}$ at any point on the quasi-binary

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

line may then be calculated from the equation

$$[34]\quad f_{(y,t)} = \left(\frac{y}{y^*}\right) f_{(y^*,t)} + \sum_{j=2}\sum_{k=0} \phi_{jk}(y^j - y y^{*(j-1)})t^k$$

And in the simple case where values of f in the *2–3* binary system may be used as end-points

$$[35]\quad f_{(y,t)} = y f_{(1,t)} + \sum_{j=2}\sum_{k=0} \phi_{jk}(y^j - y)\, t^k$$

$f_{(1,t)}$ may be expressed as a power series in t to give a complete analytical solution for f in the ternary system.

Although explicit equations for the coefficients c_{0k} and ϕ_{1k} could be found from the boundary conditions at the corners of the composition triangle, this method fails to give accurate results for the same reasons as discussed previously for the case of f_2, and so in practice, end-point values of f_3 and f from independent measurements are always required.

Summary of Method

Experimental values of f_1 over a composition range of a ternary system are fitted by a least-squares technique to an equation of the form of eq. [11]. The expansions for f_2, f_3, and f are then of the forms of eqs. [28], [30], and [34]. The coefficients b_{jk}, c_{jk}, and ϕ_{jk} are calculated from eqs. [24], [25], and [20]. The terms $f_{2(y^*,t)}$, $f_{3(y^*,t)}$, and $f_{(y^*,t)}$ are end-point values which must be determined at one point ($y = y^*$) on each quasi-binary line (t = constant), along which values of f_2, f_3, and f are to be calculated.

In the simple case in which values of f_1 have been measured and fitted over a composition range which has the *2–3* binary line as a boundary, experimental end-point values $f_{2(1,t)}$, $f_{3(1,t)}$, and $f_{(1,t)}$ obtained from measurements in this binary system, may be used. These could be expressed as power series in t (where $t = X_3$ in this binary system from the definition [9]). Suppose, for instance, that experimental values of $f_{2(1,t)}$ in the *2–3* binary system were available. These values could be fitted to an equation of the form of eq. [1]

$$[36]\quad f_{2(1,t)} = \sum_{j=2}^{j'} a_j t^j$$

Then, $f_{3(1,t)}$ and $f_{(1,t)}$ are given by equations of the form of eqs. [2] and [3]

$$[37]\quad f_{3(1,t)} = \sum_{j=0}^{j'} b_j t^j$$

$$[38]\quad f_{(1,t)} = \sum_{j=1}^{j'} \phi_j t^j$$

where the coefficients b_j and ϕ_j are given by eqs. [4]–[7].

Example of Application

The activities of Cd at several compositions in the Cd–Bi–Sn system have been determined with the aid of e.m.f. measurements at 500 °C by Mellgren (6). Also, the activities of Sn in the Bi–Sn binary system have been measured by Seltz and Dunkerley (7), and were corrected to 500 °C with the aid of the Gibbs–Helmholz equation by Mellgren (6). Using this data, Mellgren (6) applied the graphical Gibbs–Duhem integration techniques of Darken (2) and Wagner (3) to obtain activities of Bi and Sn at several compositions in the ternary system.

In the following discussion, the analytical method is applied to this system, and the results compared to those obtained graphically.

Cd, Bi, and Sn are taken as components *1*, *2*, and *3*, respectively.

A Fortran IV computer program was written to determine the coefficients a_{jk} for f_1 by a least-squares technique. The form of the expansion for f_1 used was as follows

$$[39]\quad \begin{aligned} f_1 = {} & (a_{20} + a_{21}t + a_{22}t^2 + a_{23}t^3 + a_{24}t^4)\, y^2 \\ & + (a_{30} + a_{31}t + a_{32}t^2 + a_{33}t^3)\, y^3 \\ & + (a_{40} + a_{41}t + a_{42}t^2) y^4 \\ & + (a_{50} + a_{51}t)\, y^5 \\ & + (a_{60})\, y^6 \end{aligned}$$

That is, 15 coefficients were used. Since y and t are never greater than unity, terms in $y^j t^k$ become progressively less significant as $(j + k)$ becomes larger. Thus, truncation in this manner with $(j + k) \leqslant 6$ was considered to be the most logical.

Another least-squares fit with $(j + k) \leqslant 5$ (10 coefficients), was done. Results for the 10 and 15 coefficient cases differed very little. The 15 coefficient fit seemed slightly better, however, and is reported here.

Values of the coefficients a_{jk} are listed in Table I. In Fig. 2 the fit between the calculated surface

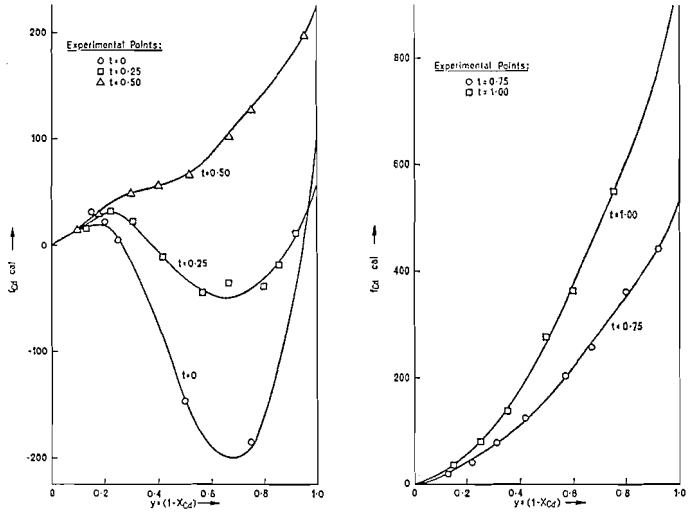

FIG. 2. Least-squares fit to experimental values (6) of the partial molar excess free energy of mixing of Cd along quasi-binary lines in the Cd–Bi–Sn system at 500 °C. Solid lines are the least-squares fit. $t = X_{Sn}/(X_{Bi} + X_{Sn})$.

and the experimental points is illustrated. The standard error of estimate was 6.58 cal.

Since the calculated values of f_2, f_3, and f depend upon the partial slopes of the tangents to the f_1 surface (through the Gibbs–Duhem relation), it is most important, when the analytical method is used, that the least-squares fit to the data be plotted as in Fig. 2 in order to make sure that a smooth fit without "hills and valleys" has been obtained.

The coefficients b_{jk}, c_{jk}, and ϕ_{jk} of the expansions for f_2, f_3, and f were determined, with the aid of a digital computer, from eqs. [24], [25], and [20] and are listed in Table I.

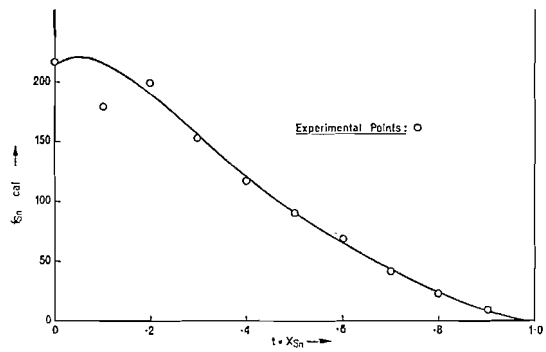

FIG. 3. Least-squares fit to experimental values (6, 7) of the partial molar excess free energy of mixing of Sn in the Bi–Sn system at 500 °C. Solid line is the least-squares fit. (Point at $t = 0.1$ was not included in least-squares fit.)

From the data in the *2–3* binary system, $f_{2(1,t)}$, $f_{3(1,t)}$, and $f_{(1,t)}$ as functions of t were determined by a least-squares fit, followed by an application of eqs. [4]–[7]. A good fit was obtained using 4 coefficients. The coefficients a_j, b_j, and ϕ_j of the expansions [36]–[38] are listed in Table I, and the fit between the calculated curve for $f_{3(1,t)}$ and the experimental points is illustrated in Fig. 3. (The actual method employed was to fit $f_{3(1,t)}$ as a series in X_2, to use eqs. [4]–[7] to obtain the coefficients for $f_{2(1,t)}$ and $f_{(1,t)}$ as series in X_2, and then to apply the relation, $X_2 = (1 - X_3)$, to obtain the coefficients of the expansions in $t = X_3$. Matters would have been facilitated if Sn rather than Bi had been defined as component *2*. However, this makes no difference to the final result.) The standard error of estimate was 3.5 cal.

Complete solutions for f_2, f_3, and f in the form of eqs. [29], [31], and [35] were thus obtained.

Values of f_2 and f_3 at the compositions at which Mellgren graphically determined values, were calculated, and are compared to his results in Table II. The two sets of results compare within the limits of experimental accuracy. Also, graphical plots of f_2 and f_3 over the entire composition range for the ternary system are in agreement with the curves given by Mellgren (6).

Although the two sets of calculations done by Mellgren (Table II) appear to agree more closely with each other than with the analytical calcula-

ϕ_1 = 214.89	ϕ_2 = 123.05	ϕ_3 = −885.04	ϕ_4 = 979.75	ϕ_5 = −432.65

*Cd = *1*, Bi = *2*, Sn = *3*; 500 °C.

tions, it should be noted that Mellgren's calculations are the result of two different graphical integrations, on the same set of smoothed plots of the experimental data. The analytical calculations are the result of treating a slightly different basic interpolation of the data.

Discussion

Although the analytical method should find most application with partial molar excess free energies of mixing as obtained from activity measurements, all the derived equations are valid for any partial molar property of mixing to which the Gibbs–Duhem relationship may be applied, provided that the partial property of every component and the corresponding integral property and their derivatives are continuous and finite functions, in and on the boundary of the entire composition range, so that series expansions as in eqs. [11]–[14] may be written.

*Cd = *1*, Bi = *2*, Sn = *3*; 500 °C.

The enthalpy of mixing and the excess entropy of mixing are examples of properties to which the method may be applied. The method may not be applied to the total free energy of mixing or to the total entropy of mixing, since in these cases the partial property of mixing of a component becomes infinite as the mole fraction of that component approaches zero.

It is also evident that, with slight modification, the present method could be used to calculate partial molar properties of mixing, by fitting an equation of the form of eq. [14] to experimentally available values of the corresponding integral molar property of mixing, such as to calorimetrically measured values of the enthalpy of mixing.

Relationships between the coefficients of series expansions of partial and integral molar properties of mixing in ternary systems have been previously calculated by Wohl (8). Wohl used the mole fractions as composition variables. Nikol'skii (9) has recently generalized and simplified Wohl's equations. The drawback to using Wohl's or Nikol'skii's equations in a Gibbs–Duhem treatment of experimental data, however, is that it is not possible to utilize end-point values as is done in eqs. [28], [30], and [34]. The boundary conditions at the corners of the composition triangle are implicit in the equations. As discussed earlier, the use of these boundary conditions can lead to very serious inaccuracies. Also, the use of these boundary values renders the use of Wohl's and Nikol'skii's equations impossible if experimental data are available only over a restricted region of the composition triangle. Besides this, Wohl's and Nikol'skii's equations are in a form not easily fit by a least-squares technique.

Conclusions

An analytical technique based upon the Gibbs–

For personal use only.

Duhem relation has been developed for calculating isothermal partial molar properties of mixing of the second and third components in a ternary system, when experimental measurements for one component or for the corresponding integral property are available. The method overcomes the problems inherent in graphical integration techniques. Data points may be scattered randomly over the composition range. The technique is not subject to human error. Equations are determined which allow the calculation of the quantities to be quickly made at any composition. The method is thus faster and more accurate than the graphical techniques.

The relationships developed are simple and readily adaptable to solution by a digital computer, and they reduce directly to the equations of Margules for binary systems. The use of quasi-binary lines along which one composition variable is constant makes the method simple, permits the easy utilization of end-point data, and aids in the visualization of the procedure.

Acknowledgments

The authors wish to thank Professor F. G. Smith of the Department of Geology, University of Toronto, for his valuable contribution in writing the computer programs used in this investigation. Financial support from the National Research Council of Canada and a maintenance fellowship for one of the authors (A.D.P.) from Shell Canada, are also gratefully acknowledged.

Appendix I

Substitute eq. [10] into eq. [16] and collect terms

[A-1] $$f = (1 - y)f_1 + y(1 - t)f_2 + tyf_3$$

[A-2] $$f = f_1 + y(f_2 - f_1) + ty(f_3 - f_2)$$

Differentiate eq. [A-2] with respect to y at constant t

[A-3] $$\left(\frac{\partial f}{\partial y}\right)_t = \left[\left(\frac{\partial f_1}{\partial y}\right)_t + y\left(\frac{\partial(f_2 - f_1)}{\partial y}\right)_t + ty\left(\frac{\partial(f_3 - f_2)}{\partial y}\right)_t\right] + [(f_2 - f_1) + t(f_3 - f_2)]$$

Substitute eqs. [10] into eq. [17] and collect terms

[A-4] $$(1 - y)\,df_1 + y(1 - t)\,df_2 + ty\,df_3 = 0$$

[A-5] $$df_1 + y\,d(f_2 - f_1) + ty\,d(f_3 - f_2) = 0$$

Since eq. [A-5] holds everywhere, it also holds along a line where t is constant. Thus, by eq. [A-5], the first term on the right-hand-side of eq. [A-3] is zero. By substitution from eq. [A-2], the second term on the right-hand-side of eq. [A-3] is given, with the result that

[A-6] $$\left(\frac{\partial f}{\partial y}\right)_t = \frac{f - f_1}{y}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Appendix II

Differentiate eq. [A-2] with respect to t at constant y

$$[A\text{-}7] \qquad \left(\frac{\partial f}{\partial t}\right)_y = \left[\left(\frac{\partial f_1}{\partial t}\right)_y + y\left(\frac{\partial(f_2 - f_1)}{\partial t}\right)_y + ty\left(\frac{\partial(f_3 - f_2)}{\partial t}\right)_y\right] + y(f_3 - f_2)$$

From eq. [A-5], it is seen that the first term on the right-hand-side of eq. [A-7] is zero. Multiplying through in eq. [A-3] by y, multiplying through in eq. [A-7] by t, and subtracting the resulting equations, yields the following

$$[A\text{-}8] \qquad y\left(\frac{\partial f}{\partial y}\right)_t - t\left(\frac{\partial f}{\partial t}\right)_y = y(f_2 - f_1)$$

which may be written

$$[A\text{-}9] \qquad f_2 = f_1 + \left(\frac{\partial f}{\partial y}\right)_t - \frac{t}{y}\left(\frac{\partial f}{\partial t}\right)_y$$

Substitute eqs. [11], [12], and [14] into eq. [A-9] and simplify

$$[A\text{-}10] \qquad \sum_{j=0}\sum_{k=0} b_{jk}y^j t^k = \sum_{j=2}\sum_{k=0} a_{jk}y^j t^k + \sum_{j=1}\sum_{k=0} \phi_{jk}(j)y^{j-1}t^k - \frac{t}{y}\sum_{j=1}\sum_{k=0} \phi_{jk}(k)y^j t^{k-1}$$

Whence

$$[A\text{-}11] \qquad \sum_{j=0}\sum_{k=0} b_{jk}y^j t^k = \sum_{j=2}\sum_{k=0} a_{jk}y^j t^k + \sum_{j=1}\sum_{k=0} \phi_{jk}(j-k)\, y^{j-1}t^k$$

Alter the dummy variable j in the second term on the right-hand-side of eq. [A-11]

$$[A\text{-}12] \qquad \sum_{j=0}\sum_{k=0} b_{jk}y^j t^k = \sum_{j=2}\sum_{k=0} a_{jk}y^j t^k + \sum_{j=0}\sum_{k=0} \phi_{(j+1)k}(j+1-k)\, y^j t^k$$

Appendix III

Re-arrange eq. [A-7]

$$[A\text{-}13] \qquad f_3 = f_2 + \frac{1}{y}\left(\frac{\partial f}{\partial t}\right)_y$$

Substitute eqs. [12], [13], and [14] into eq. [A-13]

$$[A\text{-}14] \qquad \sum_{j=0}\sum_{k=0} c_{jk}y^j t^k = \sum_{j=0}\sum_{k=0} b_{jk}y^j t^k + \frac{1}{y}\sum_{j=1}\sum_{k=0} \phi_{jk}(k)y^j t^{k-1}$$

Alter both dummy variables, j and k, in the second term on the right-hand-side of eq. [A-14]

$$[A\text{-}15] \qquad \sum_{j=0}\sum_{k=0} c_{jk}y^j t^k = \sum_{j=0}\sum_{k=0} b_{jk}y^j t^k + \sum_{j=0}\sum_{k=-1} \phi_{(j+1)(k+1)}(k+1)\, y^j t^k$$

Equate coefficients of $y^j t^k$ for each pair of values of j and k for $j \geqslant 1$

$$[A\text{-}16] \qquad c_{jk} = b_{jk} + (k+1)\,\phi_{(j+1)(k+1)} \qquad j \geqslant 1$$

Substitute eqs. [20] and [24] into eq. [A-16]

$$[A\text{-}17] \qquad c_{jk} = a_{jk} - \left(\frac{j+1-k}{j}\right)a_{(j+1)k} - \left(\frac{k+1}{j}\right)a_{(j+1)(k+1)} \qquad j \geqslant 1$$

Reaction of chromyl chloride with donor molecules[1]

R. C. MAKHIJA[2] AND R. A. STAIRS
Chemistry Department, Trent University, Peterborough, Ontario

Received December 11, 1968

Reaction of chromyl chloride with various donor molecules led to solid products of compositions $CrO_2Cl_2.2D$ (D = acetone or dimethylsulfoxide), $2CrO_2Cl_2.3D$ (D = tetrahydrofuran, 1,4-dioxan, or 4-picoline), $CrO_2Cl_2.D$ (D = diethyl ether, triphenylphosphine, or triphenylarsine), and $2CrO_2Cl_2.(C_6H_5)_3N$. Acetonitrile failed to react. Infrared and ultraviolet spectra, X-ray diffraction and magnetic measurements, and the organic products obtained on hydrolysis were interpreted as showing that none of these complexes are Lewis adducts of chromyl chloride, but that all contain chromium(IV).

Introduction

Chromyl chloride, CrO_2Cl_2, has been used as an oxidant for hydrocarbons from time to time for many years, and its reactions with saturated and unsaturated molecules have been extensively studied (1–8). In the course of recent investigations of the structure of the main product of the Etard reaction of chromyl chloride with toluene (9), it was found that this product could react with two molecules of a Lewis base to form complexes containing the elements of the hydrocarbon, chromyl chloride, and the base, in the approximate molar proportions 1:2:2. (We will refer to this as a "ternary complex".) It was considered desirable to investigate the possibility of direct reaction of chromyl chloride as a Lewis acid with the base. Possible Lewis acid character also seemed relevant to the rapid cyclization of tetraphenylethylene by chromyl chloride which has been recently reported (10, 11).

The only past work on Lewis adducts of chromyl chloride is that of Bernard and Camelot (12), who have reported what appear to be 1:1 and 1:2 adducts with pyridine, which are formed only at temperatures below $-30\,^{\circ}C$, and decompose with reduction of the chromium on warming. Necsoiu and co-workers (4) have reported a 1:1 complex with ether which, however, clearly involves oxidation–reduction. Apsit, Sauka, and Blum (13) have reported a complex with hydrogen sulfide, which also probably contains reduced chromium.

Formation of an adduct by chromyl chloride requires that the coordination number of chromium be increased above 4. Unlike molybdenum and tungsten (14–16), chromium does not, on presently available evidence, appear to do this in its hexavalent state. Durrant and Durrant (17) describe the crystal structure of chromium trioxide as having the AlF_3 structure, with six-coordinate chromium, but Bystrom and Wilhelmi (18) describe the structure as made up of chains of CrO_4 tetrahedra.

In this work, chromyl chloride in dilute solution in an inert solvent (carbon tetrachloride or carbon disulfide) was reacted with a variety of molecules containing nitrogen, phosphorus, arsenic, oxygen, and sulfur as potential electron-pair donors. The complexes which were produced were then examined analytically, spectroscopically, by X-ray diffraction, and in one case each, by magnetic susceptibility and by electron spin resonance spectrometry (e.s.r.), for evidence that chromium was still hexavalent and that it was bonded directly to the donor atom.

Experimental

Reagents

Chromyl chloride (Alfa) was distilled, and the middle fraction, b.p. 114.5–115.5 °C used. Carbon tetrachloride, petroleum ether, diethyl ether, dioxan, tetrahydrofuran, 4-picoline, acetone, and acetonitrile were dried and purified as described earlier (9). Triphenylamine (Eastman), triphenylphosphine, and triphenylarsine (Alfa) were used as received.

Preparation and Analysis of Complexes

All operations were performed in a nitrogen atmosphere. Most of the preparations were carried out several times. The same procedure was used for all. Sufficient carbon tetrachloride and chromyl chloride were distilled into a three-necked flask to give an approximately 2% solution of the latter. A 2% solution of the donor substance was added slowly with continuous stirring,

until it was in excess as noted in Table I. Stirring was continued until the color of chromyl chloride was discharged from the solution. This took place within a few minutes, except in the case of acetonitrile, which failed to react not only at room temperature, but also at the boiling point of carbon tetrachloride and at dry-ice temperature. (Prolonged refluxing of acetonitrile and chromyl chloride in carbon tetrachloride led to formation of a metal-free tar, which appeared to be a polymer of acetonitrile.) The precipitate that formed was removed by filtration, washed with several portions of solvent, and dried in vacuum at room temperature for 2–3 days.

Chromium and chlorine were estimated as Cr_2O_3 and as AgCl as described earlier (9). Some determinations of chromium as $BaCrO_4$ were also carried out as a check. Carbon, hydrogen, and nitrogen analyses were performed by a commercial analyst. The results are summarized in Table I, together with the compositions deduced therefrom, and the calculated analyses. Agreement between the analyses found and calculated is moderately good, with the notable exceptions of the results for carbon in the triphenylphosphine and triphenylarsine complexes. The latter figure would be in better accord with an assumed stoichiometry $3CrO_2Cl_2.2(C_6H_5)_3As$, but the analyses for H, Cr, and Cl are inconsistent with this, and are in agreement with the composition noted in the Table.

Physical Measurements

Infrared (i.r.) spectral measurements on the complexes were carried out in the frequency range 4000–200 cm^{-1} using a Perkin–Elmer 621 grating instrument purged with nitrogen. Samples were examined in Nujol or Fluorolube mulls between CsI plates. Ultraviolet (u.v.) spectra were obtained with a Unicam SP.800 spectrophotometer, using dioxan or tetrahydrofuran as solvent. Concentrations were not measured, but were estimated to be 10^{-5}–10^{-6} *M*. The path length of the cells used was 1 cm. Results of spectral measurements are summarized in Tables II, III, and IV.

The apparent oxidation state of chromium in the complexes was determined iodometrically. A weighed sample was added to an acidified aqueous solution of potassium iodide, allowed to stand in the dark in a stoppered flask

for 2–3 min, and the liberated iodine titrated with sodium thiosulfate solution, using starch as indicator. The color change at the end point was sharp, from blue to green. The apparent oxidation numbers found are listed in Table I.

The organic products of hydrolysis were sought in the solutions resulting from addition of 2–3 g of the complexes in water saturated with sulfur dioxide. Chromium was removed by precipitation as hydroxide by ammonia, filtered off, and washed. The filtrate and washings were extracted with carbon tetrachloride, and both layers separately examined. Some products were identified by their i.r. or u.v. spectra only, but those that could be separated by evaporation of their solutions were crystallized where possible, and derivatives prepared. In Table V the results are summarized, including yields where determined (based on the assumed total amount of the organic reactant in the complex), frequencies of identifying u.v. or i.r. absorption bands, and m.p. of crystalline products and derivatives prepared.

X-ray powder diffraction patterns were taken using an 11.46 cm Debye-Scherrer camera with nickel-filtered copper Kα radiation. The magnetic susceptibility was measured by the Gouy method, at temperatures from 143 to 300 °K, on a powdered sample.

Discussion

The products of the reactions studied may be divided roughly into two classes, according to their stoichiometry and their i.r. and u.v. spectra. Class A, which is typified by the products of reaction of chromyl chloride with dioxan and tetrahydrofuran, is characterized by a combining ratio CrO_2Cl_2:D of 2:3 (D is the organic molecule) the presence in the i.r. absorption spectrum of the band assigned to OH, and the absence of the pair at 970–945 cm^{-1} tentatively assigned to O=Cr=O vibrations, as well as the presence of the series of bands in the u.v. from 37.9 to 41.9 kK. The product from 4-picoline lacks one qualification for this class, agreeing in stoichiometry and in the i.r. spectrum, and the product from diethyl ether agrees in the i.r. spectrum alone. The appearance of the OH band in the i.r. spectrum of all these suggests that an Etard-type oxidation has occurred, with transfer of a hydrogen to chromyl chloride at the same time reducing the Cr—O bond order, and therefore shifting the two Cr—O stretching bands to longer wavelengths. The i.r. spectra of the diethyl ether, tetrahydrofuran, and dioxan complexes also show features typical of the coordinated, but not oxidized molecules in the range 1250–200 cm^{-1}; in particular, the peak associated with the C—O—C antisymmetric stretch is split, and shows the expected frequency decrease, in each case (19, 20), i.e. the strong 1070 cm^{-1} band in tetrahydrofuran moves to 1030(m) and 1000(s) cm^{-1}, and the strong 1124 cm^{-1} band of dioxan appears at 1045(m) and 1015(m) cm^{-1}; also the tetrahydrofuran band at 908 cm^{-1} moves to 850 cm^{-1}, and the dioxan band at 878 cm^{-1} splits to give peaks at 868 and 820 cm^{-1}.

The u.v. bands observed in the complexes of dioxan and tetrahydrofuran (the spectra were taken using these same substances as solvents) may be characteristic of chromium(IV) complexed by a cyclic ether, for they also appeared weakly in the spectra of the complexes of triphenylamine and its analogues, which were taken in dioxan as solvent. That they appear only weakly suggests that dioxan is unable to displace extensively the other ligands.

The hydrolysis products from class A consist in each case, including the marginal ones, of some unchanged base and some that has been oxidized. Allowing for the possibility of some further reaction on working up, it appears probable that the reactions in this class can be viewed as a two-step process, viz. an Etard-type reaction of two molecules of chromyl chloride with one molecule of the base at a carbon adjacent to oxygen or the aromatic ring followed

by reaction of two further molecules of the base with the first product, giving rise in effect to a ternary complex like those mentioned above. On hydrolysis two moles of unchanged base and one of oxidized base should be obtained for each mole of the complex $2CrO_2Cl_2.3D$ reacting. We have not succeeded in making a quantitative recovery of the products of hydrolysis but the complexes from 4-picoline, dioxan, and tetrahydrofuran each yielded unchanged base as a major component.

The oxidized products are concordant with the known behavior of chromyl chloride. Attack by chromyl chloride appears to be facilitated by the presence of one single-bonded oxygen on a carbon atom, but hindered by more than one electronegative substituent, whether oxygen or another such as chlorine. There seems to be, also, a strong tendency for chromium(IV) to form binuclear complexes and a lesser tendency to further polymerization. It is probably for both these reasons that the Etard reaction proceeds two steps from toluene to aldehyde, but not further. In certain cases a single molecule of chromyl chloride only appears to be involved. An example that is somewhat uncertain, as different workers disagree about the composition of the complex, is triphenylmethane (5, 21). Here there is only one oxidizable C—H, and apparently the three bulky phenyl groups preclude dimerization to form a binuclear chromium(IV) complex. A consequence is the binding, in an

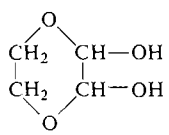
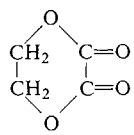
unknown manner, of additional chromyl chloride, so that various workers have reported ratios of chromyl chloride to hydrocarbon ranging from 1.2 to nearly 2.

With the cyclic ethers the organic products can be explained by assuming attack of two molecules of chromyl chloride, on the same carbon of tetrahydrofuran, and on adjacent carbons of dioxan. The tetrahydrofuran product appears to involve an unusual attack on a carbon bearing two oxygens, facilitated by the formation of the binuclear complex. The main oxidized product of hydrolysis should then be γ-butyrolactone, as observed. In the dioxan product, attack on the carbon already bearing two oxygens by the second chromyl chloride molecule is avoided, and the adjacent carbon is attacked instead. We postulate that the primary product of hydrolysis is the cyclic double hemiacetal **1**, and that this is partly hydrolyzed to glyoxal and glycol and partly oxidized to ethylene oxalate, **2**, in a similar manner to the ether complex, discussed below.



1



2

We have not yet been able to detect or isolate **1**, but believe that it may be more resistant to hydrolysis than are ordinary non-cyclic hemiacetals, as we could not detect glyoxal in the reaction mixture from hydrolysis of the complex, but found it in the steam distillate.

Hydrolysis of the complexes of the cyclic ethers in the presence of iodide, and titration of the liberated iodine, gave apparent oxidation numbers lower than 4 for chromium. The assumption that these complexes contain chromium(IV) was based in part on the results of e.s.r. spectrum measurements (22). The samples examined all gave identical spectra consisting of a broad, intense line with g close to 2 and a half-width of the order of 500 G, unaffected by cooling to 77 °K, and apparently identical to that observed by Necsoiu and co-workers (3) with the Etard product obtained from toluene. This is believed to contain chromium(IV) in a similar state of bonding to that in the present complexes. In the discussion of the diethyl ether complex, below, an explanation of the low apparent oxidation numbers found by titration is proposed, which is probably applicable here also.

Class B contains the products of reactions of 1:1 stoichiometry, which show no OH band in the i.r., but do show the bands assigned to Cr=O, and in the u.v. show a single intense absorption maximum at about 230 mμ. We were tempted to conclude that these were Lewis adducts, but the magnetic susceptibility of the triphenylphosphine product was incompatible with chromium(VI). In fact, it is in close agreement with the other measurements on complexes believed to contain chromium(IV) (9). (The value obtained for the magnetic moment of $CrO_2Cl_2.(C_6H_5)_3P$ was 3.00 ± 0.05 B.M.) The arsenic analogue was presumed to be similar. Since each yielded the oxide of the base (or its hydrate) on hydrolysis, it is clear that the interaction with chromyl chloride was through oxygen.

We were puzzled by the persistence in the i.r. of bands similar to the O=Cr=O bands of chromyl chloride, shifted only about 20–30 cm^{-1}. This may be due to interaction in the solid between Cr=O groups in neighboring molecules. Brisdon and Edwards (23) and Bagnall *et al.* (24) came to a similar conclusion with regard to the spectrum of $ReOCl_4$, taken in Nujol mull, which contained a pair of bands at 1033 and 1016 cm^{-1}. If our bands at 955 and 935 cm^{-1} in the triphenylphosphine product and 970 and 950 cm^{-1} in the triphenylarsine product are due to splitting of a single Cr=O band in the solid state, they should reduce to one sharp, strong absorption band in solution. We have not yet found a suitable solvent. There should be a band due to coordinated Cr—O, in the region 450–350 cm^{-1} (25), which may be obscured by the Cr—Cl stretching vibrations. As is well established, the ν(P=O) and ν(As=O) absorptions move to lower frequencies on coordination (26–31). In our complexes the medium broad absorption bands at 1130–1145 and 885 cm^{-1} are assigned to coordinated P=O and As=O respectively. All the Whiffen bands (32) *q*, *r*, and *t* show small shifts in frequency[3]. The frequencies and assignments are listed in Table III.

[3]Modes in which ring vibrations are coupled to C—P or (C—As) motion, and which are sensitive to coordination.

The products that fall neither into class A nor class B are those obtained from dimethylsulfoxide, triphenylamine, acetone, and diethyl ether. The first of these we have been unable to characterize, the complex being excessively unstable. The hydrolyzed products included dimethylsulfone, which suggests that one molecule of dimethylsulfoxide is attacked by chromyl chloride at the sulfur to give a complex of the sulfone which is further complexed by a second dimethylsulfoxide molecule. The last two present some unusual features, but can be considered as variants of class A. Triphenylamine behaved in a distinctly different manner in that oxidative coupling to tetraphenyl benzidene occurred. This is a common product of oxidation of triphenylamine, so we did not investigate it further at this time.

Necsoiu and co-workers (4) report that diethyl ether reacts with only one molecule of chromyl chloride, as we have confirmed. The hemiacetal, which would be the "normal" product of hydrolysis of the complex according to the above proposal for class A, presumably suffers further oxidation and hydrolysis leading to the reported products, ethyl acetate and acetaldehyde. (Ethanol would also be expected, but was not detected.) This complex, when hydrolyzed in water containing potassium iodide, liberated almost no iodine, so the chromium was apparently reduced very rapidly to chromium(III). A possible sequence of reactions on hydrolysis might be

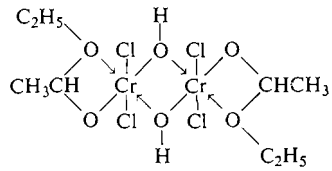
[1] $C_2H_5—O—\underset{\displaystyle CH_3}{\underset{|}{CH}}—O—Cr(OH)Cl_2 + H_2O \rightarrow C_2H_5O—\underset{\displaystyle CH_3}{\underset{|}{CHOH}} + [Cr^{IV}(OH)_2Cl_2]$

[2] $2Cr^{IV} \rightarrow Cr^{V} + Cr^{III}$

[3] $C_2H_5O\underset{\displaystyle CH_3}{\underset{|}{CHOH}} + Cr^{V} \rightarrow C_2H_5O\underset{\displaystyle CH_3}{\underset{|}{C}}=O + Cr^{III}$

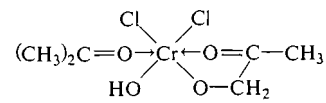
[4] $C_2H_5O\underset{\displaystyle CH_3}{\underset{|}{CHOH}} \rightarrow C_2H_5OH + CH_3CHO$

If this is to be accomplished without oxidation of iodide by the very reactive chromium(IV) and (V) species, steps [1] to [3] must take place within such a closed environment as that afforded by a binuclear complex. We suggest, therefore, that the structure of the ether complex is something resembling **3**, which is in accord with the facts noted above, and is analogous with the structure proposed earlier for the ternary complexes.



3

The product obtained with acetone showed both OH and Cr=O bands in the i.r., and conformed to class B in the u.v., but to neither class in stoichiometry. If the regularly spaced group of u.v. bands is characteristic of the complexes of the cyclic ethers with chromium-(IV), the probability is that the acetone product is in other respects similar to class A. The significance of the 1:2 stoichiometry is not clear but it can be accommodated by the structure **4**, which on hydrolysis should yield equal amounts of acetone and hydroxyacetone or its oxidation products.



4

We have not succeded in identifying the oxidized products.

The X-ray powder diffraction photographs of the complexes $CrO_2Cl_2.2CH_3COCH_3$, $2CrO_2Cl_2.3C_4H_8O$, $2CrO_2Cl_2.3C_4H_8O_2$, $CrO_2Cl_2.(C_2H_5)O$, and $CrO_2Cl_2.P(C_6H_5)_3$ show no lines, and hence the complexes are amorphous. The complexes $CrO_2Cl_2.2DMSO$ and $2CrO_2Cl_2.3(CH_3)C_5H_4N$ show a few lines, but not enough for indexing. These lines are due neither to dimethylsulfone nor to 4-picolinium chloride. The three strongest lines are at approximately 4.1, 3.7, and 6.6 Å in $2CrO_2Cl_2.3(CH_3)C_5H_4N$ and 2.72, 1.93, and 1.58 Å in $CrO_2Cl_2.2DMSO$.

We conclude that, if chromyl chloride is a Lewis acid, it is a very weak one. None of the products examined were pure molecular addition compounds. In all of the cases studied, chromyl chloride is reduced and the ligand is oxidized. The two main different types of compounds

obtained are (*a*) Etard-type products with additional coordinated base and (*b*) the products of reaction of triphenyl-phosphine and -arsine, which we conclude should be considered as complexes of the base oxides with chromium(IV) oxydichloride.

Molecular rotational relaxation time of aniline in deuterated benzene solution at 20 °C

E. BOCK
Parker Chemistry Laboratory, University of Manitoba, Winnipeg, Manitoba

AND

E. TOMCHUK
Department of Physics, University of Winnipeg, Winnipeg, Manitoba

Received October 21, 1968

The molecular rotational relaxation time of the aniline molecule in deuterated benzene solution was determined at 20 °C by pulsed nuclear magnetic resonance (n.m.r.) techniques. It was found that the rotational relaxation time, τ_r, in infinitely dilute deuterated benzene solution was 3.2×10^{-12} s, a value which is in fair agreement with the dielectric molecular relaxation time reported by Grubb and Smyth for aniline in dilute benzene solution.

Canadian Journal of Chemistry, 47, 2301 (1969)

Introduction

The dielectric relaxation of NR_3 type molecules has been the subject of many investigations (1, 2). The reason for the great interest shown in the relaxation behavior of the above type molecules is that these molecules may possess a relaxation mechanism whereby the electric dipole moment may reverse direction by an inversion process in addition to a simple molecular rotation process. To the best of our knowledge there has been only one attempt made to determine the molecular rotational relaxation time of the aniline molecule by other means than by dielectric relaxation techniques, viz. by n.m.r. technique (3). However, the measurements reported in ref. 3 were made on pure aniline and, moreover, the experimental data were interpreted on the assumption that the intermolecular contribution to the spin–lattice relaxation time, T_1, is relatively unimportant and makes only a minor contribution to the measured value of T_1. We thought it, therefore, not inappropriate to redetermine the molecular rotational relaxation time of the aniline molecule using a pulsed n.m.r. method and an experimental technique which permitted the separation of the *inter-* and *intra-*molecular contributions to the overall measured spin–lattice relaxation time T_1.

Experimental

Solvent

The solvent used, benzene-d_6, 99.5 atom % D, was obtained from Merck, Sharp, and Dohme Co. of Canada Ltd., and was used without further purification.

Solute

The aniline, obtained from Eastman Organic Chemicals, was further purified by redistillation from anhydrous KOH.

Apparatus and Procedure

The spin–lattice relaxation time of pure aniline and four different solutions of progressively lower concentration of aniline in heavy benzene was determined at 20 °C on a PS-60A NMR specialties pulsed n.m.r. spectrometer using a 180–90° pulse sequence (4). The experimental solutions were carefully degassed by repeated freeze–pump–thaw cycles to remove dissolved oxygen and were sealed under vacuum. To minimize vaporization from the liquid phase the experimental glass sample tubes, 8 mm diameter, were provided with a restriction leading to the vapor space as suggested by Green and Powles (5).

Results and Discussion

The experimental results are shown graphically in Fig. 1 in a form of a graph of T_1^{-1} vs. the mole fraction of aniline in solution. The rotational relaxation time, τ_r, was calculated using the extrapolated value of T_1^{-1} and the following relationship between the intramolecular relaxation time, i.e. the extrapolated value of T_1, and the rotational relaxation time, τ_r (6).

$$[1] \qquad T_1^{-1}\,(\text{intra}) = A\tau_r$$

$$[2] \qquad A = \frac{\hbar^2\gamma^4}{n}\sum_i\sum_j \beta_{ij} d_{ij}^{-6}$$

Here n is the number of protons in the molecule,

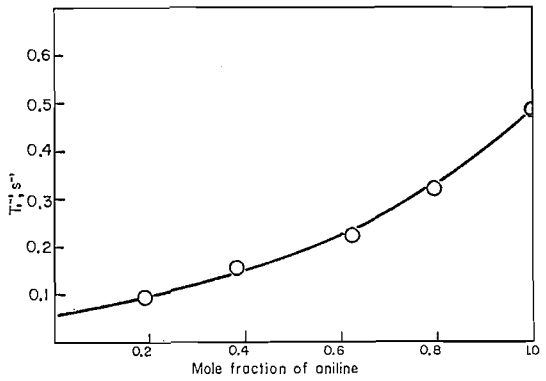

FIG. 1. Plot of T_1^{-1} vs. mole fraction of aniline in C_6D_6.

β_{ij} is a constant factor equal to 3/2 for equivalent protons and 1 for nonequivalent protons, γ is the magnetogyric ratio of the proton, and d_{ij} is the distance between proton i and proton j. The necessary data for the calculation of the constant A in eq. [2] was taken from the microwave data of Lister and Tyler (7). The resulting value for the molecular rotational relaxation time, τ_r, was found to be 3.2×10^{-12} s. This value may be compared with the dielectric molecular, i.e. rotational, relaxation time, τ_D, obtained by Fischer, 6.7×10^{-12} s (8), and by Grubb and Smyth, 8.0×10^{-12} s (1), in dilute benzene solution at 20 °C. In making this comparison it should be remembered that on theoretical grounds it is expected that $\tau_D = 3\tau_r$ (9). Considering that the probable error in τ_r is at least 10%, the agreement between $3\tau_r = 9.6 \times 10^{-12}$ s and τ_D of Grubb and Smyth, viz. 8.0×10^{-12} s, is quite satisfactory. The agreement is not quite as close when the value for τ_D determined by Fischer is used for comparison, but there is reason to believe that Fischer's value is less accurate than the value reported by Grubb and Smyth since the latter workers were able to measure the dielectric loss of their solutions at frequencies nearer to the maximum dielectric absorption than was Fischer. One tentative conclusion which may be drawn from the close agreement between τ_D and $3\tau_r$ is that either the inversion process contributes little to the rotational part of the spin–lattice relaxation time, or that the ring and amide group motions are essentially similar, as suggested by Powles and Neale (3). However, it should be pointed out that in our interpretation of the experimental results we assumed the existence of but one correlation time; also in our experimental measurements we were unable to distinguish between the relaxation times of the ring protons and $-NH_2$ protons.

In our opinion, no meaningful comparison can be made between our results and those obtained by Powles and Neale (3), except to note that our value of T_1 for pure aniline is in fair agreement with that reported by them, viz. ~2 s in both cases. The measurements of Powles and Neale were made on pure aniline only. It was impossible for them on the basis of their measurements to separate the translational and rotational contributions to T_1. In fact, they assumed that the translational or intermolecular contribution to T_1 was negligible. But they did point out that this assumption, viz. neglect of intermolecular contribution to T_1, could be checked by comparing "the pure liquid T_1's with those for dilute solution in the perdeutero compound". In part we have done just that, but only in part. For it may be fairly assumed that perdeutero benzene molecule closely simulates the motional properties of the ring fragment of the aniline molecule, but what is missing is the $-ND_2$, and it may be that the presence of this group severely alters the motional properties of the molecule by the formation of hydrogen bonds with the neighboring molecules. At any rate, our measurements show that T_1 does become significantly longer with increase in dilution, and that in perdeutero benzene solution at least the intermolecular contribution to T_1 is not negligible. However, it may very well be that in perdeutero aniline the intermolecular contribution to T_1 is negligible as assumed by Powles and Neale. The fact that their measured value of $3\tau_r$ does agree with the measured value of τ_D for pure aniline does suggest that their assumption is probably correct.

Acknowledgments

Firstly we would like to thank both referees for pointing out to us a glaring error in our calculation of the constant A of eq. [2]. We thank Dr. T. Schaefer for helpful suggestions. Finally the financial assistance of the National Research Council of Canada is deeply appreciated.

*All determinations were done in duplicate; ΔH values are given with their average deviations.
†ΔH_f^0 values of compounds used in our calculations are from N.B.S. Circular No. 500 (1951). The above ΔH_f^0 values were calculated using Kopp's Rule approximation with $\Delta C_p^0 \approx 0$ in the equation

$$\Delta H_T^0 = \Delta H_{298\,^\circ K}^0 + \int_{298\,^\circ K}^{T} \Delta C_p^0 dT$$

because ΔC_p^0 values for most compounds in the decomposition reactions are unavailable to us. Integral term was negligible for $Zn(OH)_2$ (1).

Our value of ΔH_f^0 for $Cu(OH)_2$ compares very well with the literature value, but the ΔH_f^0 values for $Cu(OH)_3Br$ and $CuF_2\cdot 2H_2O$ from this work and the literature (2, 3) differ considerably. Our ΔH_f^0 values for these latter two compounds are internally consistent with two or more reactions, namely, reactions [7] and [7*a*] for $Cu(OH)_3Br$ and reactions [9], [10], and [11*a*] for $CuF_2\cdot 2H_2O$.

$CuBr_2$ disproportionates concomitantly with dehydroxylation in the $Cu_2(OH)_3Br$ reaction. If one assigns the experimentally observed ΔH of decomposition for the two combined processes to reaction [7*a*], a value of −182.9 kcal/mole is obtained which approaches the literature value of −186.8 kcal/mole. In the case of $CuF_2\cdot 2H_2O$, the literature ΔH_f^0 value (3) was obtained on the basis of simple dehydration

$$[13] \qquad CuF_2\cdot 2H_2O_{(c)} \rightarrow CuF_{2(c)} + 2H_2O_{(v)}$$

The assignment of our observed ΔH of reaction to [13] yields a ΔH_f^0 value of −270.6 kcal/mole, approaching the literature value of −274.5 kcal/mole.

The slight variations in the ΔH values of the four structural forms, α-, β-, γ-, and δ-$Cu_2(OH)_3Cl$ are associated with their lattice arrangements.

The column of values for ΔH per mole of H_2O formed indicates higher values for the copper hydroxychlorides and hydroxyiodide relative to the parent $Cu(OH)_2$; the sole exception to this pattern is the bromide. The decomposition behavior of the basic fluorides involving dehydrofluorination along with dehydroxylation does not permit a similar comparison. The above pattern in basic chlorides and basic iodide of copper parallels the cadmium hydroxyhalide where it was interpreted that the Cd—OH bond increases in strength by substitution of the halogen in the parent hydroxide.

The decomposition temperatures for the derivative compounds are all higher relative to their parent hydroxides. This is attributed primarily to increased separation of neighboring OH groups by interposition of the halogen substituent. The halogen substituent in $Cu_2(OH)_3Br$ effects a higher decomposition temperature but weakens the bonding between the OH group and the copper cation; such effects parallel the halogen substituent in ZnOHCl and ZnOHF.

Background scattering of a supersonic free jet: source temperature dependence[1,2]

RODNEY L. LEROY[3,4], THOMAS R. GOVERS[3], AND JACQUES M. DECKERS
Lash Miller Chemical Laboratories, University of Toronto, Toronto 5, Ontario

Received November 7, 1967

The attenuation of nozzle beams by scattering on background gas in the expansion chamber is examined experimentally. It is found that, due to the velocity dependence of the collision cross section, this attenuation is significantly reduced as the source temperature is increased.

Canadian Journal of Chemistry, 47, 2305 (1969)

The intensities of nozzle beams can be strongly affected by background scattering of the expanding jet in the nozzle exhaust chamber (1–4). The purpose of this note is to illustrate that the importance of this effect is reduced at elevated nozzle stagnation temperatures.

The apparatus has been described elsewhere (4). Center-line beam fluxes (I) were measured as a function of the background pressure in the nozzle exhaust chamber (p_b) for various combinations of the nozzle–skimmer separation s, the source pressure p_0, and the source temperature T_0. Argon was used throughout. Typical primary data are shown in Fig. 1.

Following a procedure similar to that proposed by Fenn and Anderson (2), we correlated the data obtained for different values of s and p_0 by plotting the quantity $-(\mathrm{d} \ln I/\mathrm{d}n_b)/p_0$ vs. s/p_0 (n_b is the number density corresponding to p_b). This is illustrated in Fig. 2. For each of the source temperatures shown, the data at larger values of s/p_0 can be represented by an equation of the form

$$\frac{1}{p_0}\frac{\mathrm{d} \ln I}{\mathrm{d}n_b} = -\frac{Q_{\mathrm{eff}}}{p_0}(s - s_p)$$

where Q_{eff} is the slope of the limiting straight lines in Fig. 2, and s/p_0 is the intercept with the abscissa. Q_{eff} can be regarded as an effective scattering cross section, and s_p as the distance from the source at which the background gas has completely penetrated the jet. The source temperature dependence of the scattering data is further illustrated in Fig. 3. These results were obtained at source pressures low enough ($15 \leqslant p_0 \leqslant 20$ Torr) to ensure effective background penetration of the expansion. For a given value of s/p_0, an increase in T_0 from 290 to 1200 °K reduced the attenuation coefficient $\mathrm{d} \ln I/\mathrm{d}n_b$ by about 40%. Since s_p/p_0 remained nearly constant

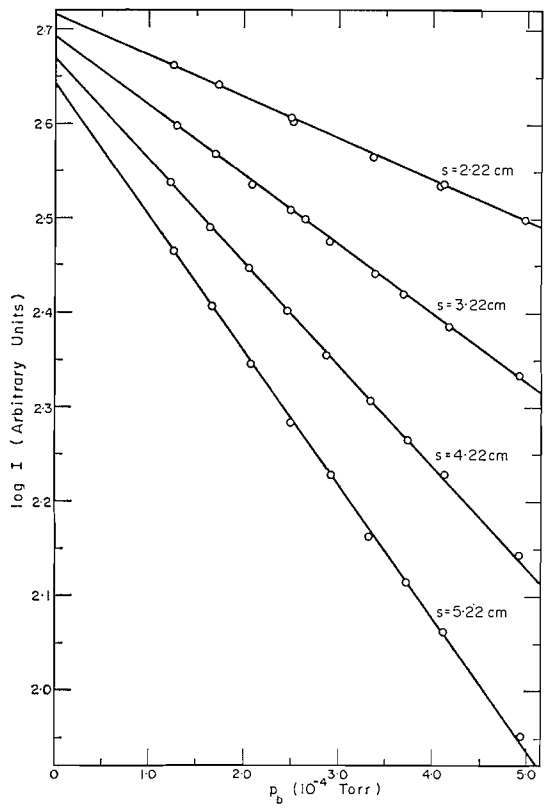

FIG. 1. Typical primary scattering data. The beam flux is plotted logarithmically against the pressure in the nozzle exhaust chamber. Source conditions are $p_0 = 19.6$ Torr and $T_0 = 476$ °K.

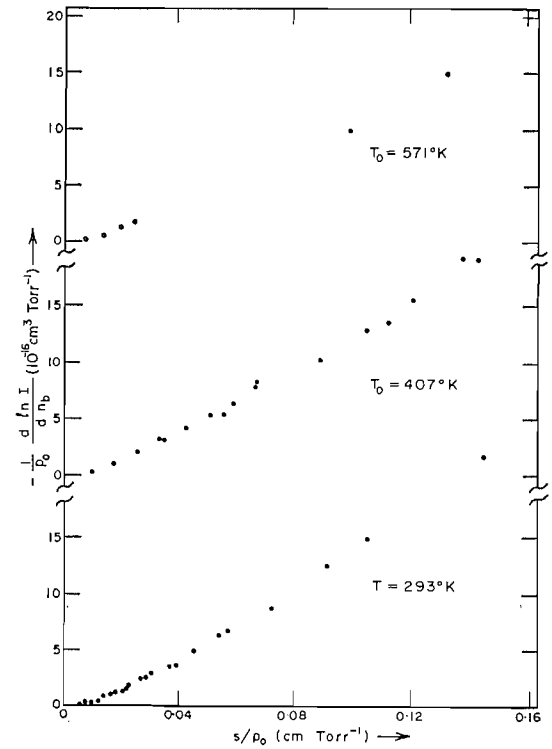

FIG. 2. Correlation of data obtained at different source pressures. Results at $T_0 = 293$ and 407 °K include data taken at $p_0 = 15$, 30, 60, and 120 Torr, while the results at $T_0 = 571$ °K were obtained at two source pressures ($p_0 = 15$ and 60 Torr).

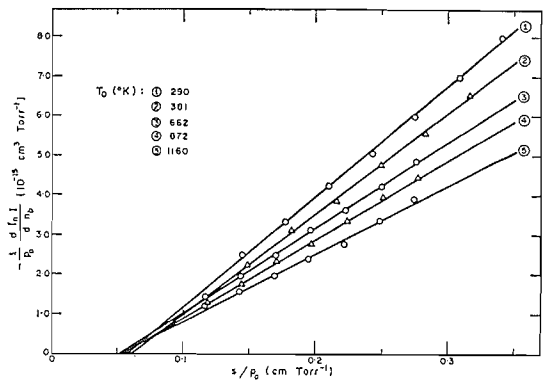

FIG. 3. Plots of $-(\mathrm{d} \ln I/\mathrm{d}n_b)/p_0$ vs. s/p_0 for different source temperatures. The source pressure p_0 was between 15 and 20 Torr for all the data indicated.

(constant "x intercept" in Fig. 3), this reduction can be attributed mainly to the velocity dependence of Q_{eff}. In fact the slopes of the straight lines in Fig. 3 ($=Q_{\mathrm{eff}}$) vary as the $-2/3$ power of the relative velocity of jet and background molecules (5), as expected on the basis of simple classical scattering theory (6).

The observations presented here may be of practical interest when limited pumping speeds in the nozzle exhaust chamber result in significant background scattering of the jet.

attributed by Brauman and Blair to differences in the polarizabilities of alkyl groups and hydrogen atoms (1).

To investigate these effects further, we have performed self-consistent field molecular orbital calculations for the valence electrons of a number of small alkoxide anions RO^-, by the semi-empirical MINDO method (2). The MINDO procedure is a variant of the INDO method described recently by Pople *et al.* (3) and has been found to accurately predict the bonding energies and heats of formation of a wide variety of neutral organic molecules (2) and carbonium ions (4). For the anions considered, the bond lengths and idealized bond angles established for the neutral alcohols ROH (2) have been used. Both experimental (5) and theoretical (6) studies indicate that the O—H bond distance in HO^- is virtually identical to that in HO·. No structural information is as yet available for the other anions considered.

In Table I, the heats for the reactions

$$[1] \qquad ROH + R'O^- \rightarrow RO^- + R'OH$$

calculated from the heats of formation of the alcohols (2) and of the alkoxide anions, are listed for R, R′ = H, CH_3, CH_3CH_2, and $(CH_3)_2CH$. In agreement with the ion cyclotron results, the acidity order isopropanol > ethanol > methanol ≫ water is obtained.

TABLE I

Calculated ΔH for reaction [1] (kcal/mole)

R or R′	H	CH_3	CH_3CH_2	$(CH_3)_2CH$
H	0.0	+23.8	+28.9	+33.3
CH_3	−23.8	0.0	+5.1	+9.5
CH_3CH_2	−28.9	−5.1	0.0	+4.4
$(CH_3)_2CH$	−33.3	−9.5	−4.4	0.0

Following Streitwieser and Hammons (7) the energetics of the reaction

$$[2] \qquad ROH \rightarrow RO^- + H^+$$

can be analyzed as the sum of contributions from the processes: (*i*) bond dissociation to RO· and H·; (*ii*) ionization of H· to H^+; and (*iii*) formation of RO^- from RO·. The electron affinities of the radicals RO· (step *iii*), have been computed from the calculated heats of formation of the ROH and RO^- species, together with the known energy requirements for step *i* (104 kcal/mole for R = alkyl (1) and 119.2 kcal/mole for R = H (8) and for step *ii* (313.5 kcal/mole (2)), and are predicted to increase in the order HO· (+30 kcal/mole), CH_3O· (+38), CH_3CH_2O· (+43), and $(CH_3)_2CHO$· (+48)[1].

Hence alkyl groups are effective in stabilizing the net negative charge associated with the oxygen atom. The stabilization order isopropyl > ethyl > methyl ≫ hydrogen found for these anions is identical to that predicted for carbonium ions (4).

The electron density distributions calculated for the anions support the interpretation of Brauman and Blair (1), that polarization of alkyl groups is responsible for the order of stabilization observed for alkoxide anions. The calculations predict that all the carbon–hydrogen bonds in the hydrocarbon fragments of such species become strongly polarized in the direction $C^{\delta+}H^{\delta-}$. For example, the carbon atom in CH_3O^- carries a net positive charge of +0.77e, and a net charge of −0.29e is associated with each hydrogen atom. Each of these C—H dipoles is of the correct direction and magnitude to stabilize the net charge of ∼ −1e associated with the oxygen atom by a charge–dipole interaction

The calculations also predict that a portion of the total stabilization occurs via hyperconjugative release of electron density from oxygen, since the oxygen atom net charge decreases from −1.08e in HO^- to −0.91e in CH_3O^-, to −0.85e in $CH_3CH_2O^-$, and to −0.81e in $(CH_3)_2CHO^-$.

[1]Recent experimental data for the simplest species of this series, HO·, yield an electron affinity of +42.2 ± 0.9 kcal/mole (5). The present calculation represents an improvement over the Hartree–Fock prediction of −2.3 kcal/mole (6), but is not as accurate as the Hartree–Fock result corrected for correlation energy (6).

Polarizations of atomic and molecular charge distributions

R. F. W. BADER, I. KEAVENY[1], AND G. RUNTZ
Department of Chemistry, McMaster University, Hamilton, Ontario

Received November 25, 1968

It is shown that the dominant polarization of a molecular charge distribution in the region of a nucleus of an atom which employs p orbitals in its bonding (Be → F, Mg → Cl) is quadrupolar in nature, and dipolar for an atom which employs s orbitals (H, He, Li, Na). That these polarizations are of a fundamental nature is demonstrated by showing that they represent the primary response of a charge distribution to an electric field, whether it be internal or external, static or dynamic.

Canadian Journal of Chemistry, 47, 2308 (1969)

The polarization of a molecular charge distribution measured relative to the charge densities of its constituent separated atoms is determined by a density difference distribution $\Delta\rho_{SA}(r)$. Such a distribution is constructed by subtracting from the molecular distribution, one obtained from the overlap of the undistorted atomic densities, the atomic densities being centered at the same nuclear positions as in the molecule. An extensive investigation of such $\Delta\rho_{SA}(r)$ distributions (1–4)[2] for diatomic molecules formed from atoms in the first two rows of the periodic table, has revealed that the component atomic densities exhibit one of two dominant polarizations on the formation of a chemical bond. The polarization of atoms which employ principally s orbitals in their bonding, e.g., H, He, Li, and Na, is *dipolar* in character. The $\Delta\rho_{SA}(r)$ distribution in the vicinity of such a nucleus shows that the change in the atomic charge density corresponds to a simple transfer of charge from one side of the nucleus to the other. This is exemplified by the $\Delta\rho_{SA}(r)$ map in the region of the proton for the OH molecule (Fig. 1(*a*)). The redistribution of charge found in the $\Delta\rho_{SA}(r)$ distributions for Be → F or Mg → Cl atoms is characterized by an increase in charge density along the bond axis on both the bonded *and* nonbonded sides of the nucleus, and in its removal from a torus-like region perpendicular to the bond axis at the position of the nucleus. Such a *quadrupolar* polarization, i.e., charge increase along one axis and its removal from another perpendicular to it, results in a gross accumulation of charge density in the antibinding as well as in the binding region and is illustrated by the charge redistribution in the region of the oxygen nucleus in the $\Delta\rho_{SA}(r)$ map for OH.

In this note we wish to point out that the dipolar, and in particular, the quadrupolar polarizations, are the dominant ones in the formation of polyatomic systems as well, and offer evidence that such polarizations represent the primary response of a charge distribution to an imposed field.

Figure 1(*b*) shows a $\Delta\rho_{SA}(r)$ map for the water molecule in the plane of the nuclei[3]. The pattern of the charge rearrangement in the vicinity of the oxygen nucleus is quadrupolar, and dipolar in the region of each proton. In fact, there is a striking similarity between this $\Delta\rho_{SA}(r)$ map and the map for the OH diatomic molecule. The *principal* increase in charge density again occurs along a single axis, the two-fold symmetry axis, and charge is again concentrated in both the binding and antibinding regions of the oxygen nucleus. As in the OH molecule, the charge decrease occurs in a belt perpendicular to the axis of charge increase at the position of the oxygen nucleus. These same features persist in the plane perpendicular to the nuclear plane.

[1]Present address: Department of Chemistry, University of California, San Diego, La Jolla, California 92037.

[2]In addition, density distributions over 300 diatomic molecular states have been obtained in preparation of a research monograph by Bader and Cade on molecular charge distributions.

[3]The density distribution for the water molecule was determined from a linear combination of atomic orbital molecular orbital wave function. The basis set consisted of the self consistent field atomic functions of Clementi (13), for the ^3P state oxygen and a 1s orbital ($\zeta = 1.32$) on each H atom. The wavefunction was determined by requiring the charge density to balance the forces on the nuclei and give the measured dipole moment. The resulting density gives expectation values for other one-electron properties in excellent agreement with experiment. Further details may be found in ref. 14. The configuration $1s^2 2s^2 2p_x^1 2p_y^1 2p_z^2$ (where the x and y axes lie in the molecular plane) was used in the construction of the $\Delta\rho_{SA}(r)$ map. This gives circular contours for the O atom density in the plane of the nuclei.

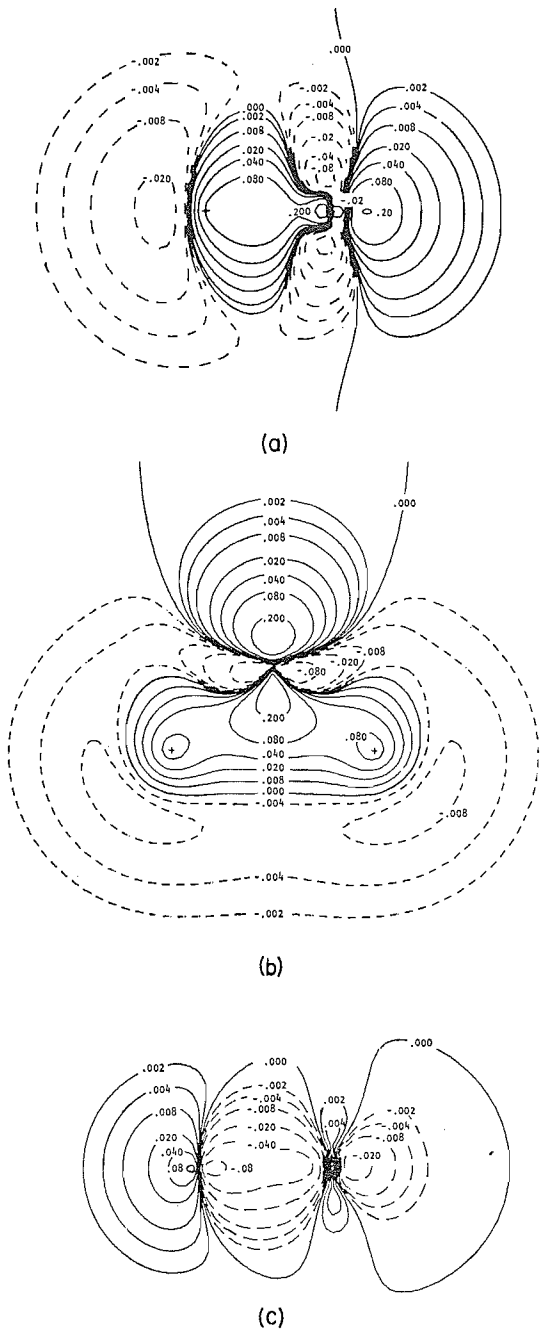

FIG. 1. (*a*) Density difference map $\Delta\rho_{SA}(r)$ for the OH molecule at the equilibrium separation of 1.8342 a.u. (*b*) Density difference map $\Delta\rho_{SA}(r)$ for the water molecule at the equilibrium geometry. Note the similarity in the values of the contours between the OH and H_2O molecules. (*c*) A density difference map showing the change in density for the OH molecule when the bond length is *increased* by 0.166 a.u. The O nucleus is held stationary. For a bond *contraction* the algebraic signs of the contours are reversed.

The polarization in the vicinity of each proton is a simple dipolar one; charge is removed from the antibinding region and concentrated in the binding region. The only major difference between the $\Delta\rho_{SA}(r)$ maps for the H_2O and OH molecules is the spreading of the charge increase in the binding region of the water molecule to encompass the protons which lie off the axis of the principal charge increase. The formation of the ammonia molecule exhibits the same type of reorganization with respect to the separated atoms as noted for the water molecule (or for NH or OH). A $\Delta\rho_{SA}(r)$ map for an approximate density for NH_3 has been previously given (5). The principal charge increase occurs along the three-fold symmetry axis both on the bonded and nonbonded side of the nitrogen nucleus. The charge removal again occurs in a torus-like region around the nitrogen nucleus, perpendicular to the symmetry axis.

In terms of the molecular charge distributions, the principal features of the binding in the diatomic hydrides NH, OH, HF, and the polyatomic hydrides NH_3 and H_2O are the same. The main increase in charge density occurs along one principal axis of polarization and the charge is removed from a region perpendicular to this axis at the heavy nucleus[4]. This preferred quadrupolar polarization in the region of the heavy nucleus overrides the "line of sight" field between the heavy nucleus and each proton, and density is not concentrated directly along each O—H or N—H internuclear axis.

We have previously pointed out that such a disposition of the charge increase on the bonded side of the O and N nuclei in H_2O and NH_3 molecules is the expected one, in terms of regions where charge must be accumulated to achieve electrostatic equilibrium (5). One can determine a spatial region in a polyatomic molecule, the binding region, in which the electron density binds all the nuclei simultaneously. It can also be shown that a $\Delta\rho_{SA}(r)$ map must exhibit a charge increase in the binding region if the system is to achieve electrostatic equilibrium (6). The binding region in the water molecule is triangular in shape, subtending an angle at the oxygen nucleus slightly less than the bond angle. In the ammonia molecule, the binding region is pyramidal in

[4]Such a quadrupole polarization is not possible for the C atom in CH_4 in which case an octupole moment is the lowest moment allowed by the tetrahedral symmetry.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 188.143.235.115 on 09/06/12
For personal use only.

shape, enclosed within the region of all 4 nuclei with its apex at the nitrogen nucleus. The $\Delta\rho_{SA}(r)$ maps for H_2O and NH_3 demonstrate that the charge increase arising from the quadrupolar type polarization on the N and O nuclei effectively concentrates charge density in the central portion of the binding for both molecules.

The polarization of the charge density along a single axis in H_2O is evident in the total molecular charge density in the form of ellipsoidal contours centered on the oxygen nucleus with their major axis coincident with the symmetry axis. The same ellipsoidal polarizations of the total charge density are evident in the regions of the apex nuclei in contour plots of the charge densities for NO_2^- and FO_2 (7). Quadrupole polarizations are also found in the regions of heavy nuclei in linear molecules (8).

When a system is placed in an external electric field, the polarizations of the charge distribution again exhibit the same dipolar and quadrupolar rearrangements. Stevens and Lipscomb (9, 10) have determined the first-order change in the charge distributions of the HF and F_2 molecules when they are perturbed by an external electric field. The density difference maps given by these authors

$$\Delta\rho(r) = \rho(\text{molecule in field}) - \rho(\text{unperturbed molecule})$$

are remarkably similar in appearance to the $\Delta\rho_{SA}(r)$ maps for the same molecules in the regions of the fluorine nuclei. The results of Stevens and Lipscomb for HF (9) show that when the direction of the positive field is from the proton to the fluorine, charge is removed from a torus-like region perpendicular to the axis at the position of the F nucleus, and transferred to both the binding and antibinding regions of the F nucleus along the internuclear axis. Thus the polarizations evident in the $\Delta\rho_{SA}(r)$ maps, which show the response of the atomic charge densities to a field resulting from the close approach of nuclei, are identical in form to the response of a system to an externally applied field.

The manner in which a molecular charge distribution relaxes during a vibrational motion of the nuclei may be illustrated in the form of a density difference map between the extended and equilibrium molecular charge distribution. Such charge relaxation diagrams exhibit a striking correlation with their corresponding $\Delta\rho_{SA}(r)$ maps (11). As an example, Fig. 1(*c*) shows such a relaxation map for an outward displacement of the oxygen nucleus in the OH molecule. Inasmuch as increasing the bond length is the reverse of bond formation, one might expect the relaxation map for bond extension to exhibit a reversal of the polarizations depicted in the $\Delta\rho_{SA}(r)$ map. Figure 1(*c*) shows this to be the case. The charge relaxation in the region of the oxygen nucleus is quadrupolar in character, corresponding to a removal of charge density from along the bond axis and to its accumulation in a belt around the axis at the oxygen nucleus. The relaxation in the neighborhood of the proton is a simple dipolar transfer of charge from the binding to the antibinding region. The vibrational relaxation maps involve the difference between two molecular charge densities and hence show directly the polarizations induced in a molecular charge distribution by a change in the nuclear potential field.

The same polarizations are also evident in the approach of two molecules in a chemical reaction. Using the wavefunctions of McLean and Yoshimine (12) we have investigated the change in the charge distributions of the HF molecule and the F^- ion as they approach one another to form the $(FHF)^-$ ion (8). The results indicate that the field of the fluoride ion causes a removal of charge from the region of the proton, enhancing the positive field directed at the fluorine nucleus in the HF molecule. This increased field, in complete analogy with the results of Stevens and Lipscomb (9), enhances the quadrupole polarization already present in the region of the fluorine nucleus in HF, with the result that still more charge is transferred from the perpendicular belt-like region to the binding and antibinding regions of the fluorine nucleus along the internuclear axis.

Granted the nonclassical concept of a charge distribution, the simple dipolar polarization as exemplified in the $\Delta\rho_{SA}(r)$ maps by the hydrogen atom is the expected one on classical grounds; a build-up of charge in the region of low potential between the nuclei and its depletion from the regions of relatively high potential energy on the nonbonded side of the nucleus. The quadrupolar-type polarization is, however, not anticipated by classical arguments. It is instead a direct conse-

quence of quantum mechanics and its effect of imposing a preferred spatial direction on the motions of electrons which possess angular momentum in the field of a nucleus. When the angular momentum arises from the occupation of p orbitals and the symmetry of the field is less than cubic[5], the result is an increase in the charge density along the principal axis of the field and a decrease in the charge density in a continuous ring about this axis. Within the framework of an orbital description, the quadrupolar polarization is the result of an increase in the population of the $p\sigma$ orbitals at the expense of the s orbitals, and of a polarization of the $p\pi$ orbitals away from the perpendicular plane. The examples given in this note demonstrate that the dipolar or quadrupolar polarizations are the dominant ones regardless of the exact symmetry of the field provided it is less than cubic, and regardless of whether it is static or dynamic, internal or external. The quadrupolar-type polarization in particular must play a dominant role in determining reaction mechanisms and molecular geometry.

[5]In a field of cubic symmetry all three p orbitals are equivalent and the lowest possible polarization is an octupolar one.

Radiation induced bonding of hexamethyldisiloxane to silica

R. S. Chahal and L. E. St. Pierre

Department of Chemistry, McGill University, Montreal, Quebec

Received November 22, 1967[1]

An infrared technique was used to study the interfacial interaction between silica and hexamethyldisiloxane systems in the absence and presence of a radiation field. In the absence of the radiation, physisorbed hexamethyldisiloxane and higher molecular weight silicone compounds could be completely removed from the silica surface. In the irradiated samples, however, relatively large amounts of hexamethyldisiloxane were found to be chemisorbed on the surface. The evidence presented supports a radiation-induced chemical bonding of the products of the radiolysis of hexamethyldisiloxane to a silica surface at coverages of less than a monolayer.

Canadian Journal of Chemistry, 47, 2311 (1969)

The crosslinking of silica-filled polydimethylsiloxane by high-energy radiation has been investigated (1, 2), and a G value of 2.5 ± 0.4, equal to that found for the unfilled system, has been reported (3–9). Similar observations were made by Charlesby *et al.* for the same system (10) and for another involving squalene and silica (11).

[1]Revision received November 29, 1968.

The influence of the silica on the radiation-induced crosslinking efficiency was thus regarded to be negligible, and the possibility of covalent bonding of the irradiation products to the silica was discounted (10). This conclusion has been resisted by some workers (12, 13) who have had to invoke attachment of polymer molecules to filler particles in order to rationalize the results of swelling and modulus experiments. However, they have been reluctant to define their "firm

Radiation induced bonding of hexamethyldisiloxane to silica

R. S. Chahal and L. E. St. Pierre

Department of Chemistry, McGill University, Montreal, Quebec

Received November 22, 1967[1]

An infrared technique was used to study the interfacial interaction between silica and hexamethyldisiloxane systems in the absence and presence of a radiation field. In the absence of the radiation, physisorbed hexamethyldisiloxane and higher molecular weight silicone compounds could be completely removed from the silica surface. In the irradiated samples, however, relatively large amounts of hexamethyldisiloxane were found to be chemisorbed on the surface. The evidence presented supports a radiation-induced chemical bonding of the products of the radiolysis of hexamethyldisiloxane to a silica surface at coverages of less than a monolayer.

Canadian Journal of Chemistry, 47, 2311 (1969)

The crosslinking of silica-filled polydimethylsiloxane by high-energy radiation has been investigated (1, 2), and a G value of 2.5 ± 0.4, equal to that found for the unfilled system, has been reported (3–9). Similar observations were made by Charlesby *et al.* for the same system (10) and for another involving squalene and silica (11). The influence of the silica on the radiation-induced crosslinking efficiency was thus regarded to be negligible, and the possibility of covalent bonding of the irradiation products to the silica was discounted (10). This conclusion has been resisted by some workers (12, 13) who have had to invoke attachment of polymer molecules to filler particles in order to rationalize the results of swelling and modulus experiments. However, they have been reluctant to define their "firm

[1]Revision received November 29, 1968.

attachment" as covalent bonding and instead have proposed it to be strong multipoint physical adsorption.

During the course of investigations into systems similar to those described above, we have utilized infrared (i.r.) spectroscopy as an analytical tool and the results have caused us to come to a conclusion as to the nature of the bonding. Results of experiments involving radiolysis of hexamethyldisiloxane physisorbed on silica surfaces suggest that chemical bonding between one or several of the products of radiolysis and the surface of silica occurs.

Experimental

Samples of thermal silica, Cab-O-Sil M-5, with a surface area of 200 m^2/g (determined by nitrogen adsorption) were placed in a flask to which was attached a side arm. In the side arm were placed known amounts of carefully purified hexamethyldisiloxane, sealed in breakable ampoules, as in Fig. 1. The silica was then dried at 100 °C and 10^{-3} mm Hg pressure for 1 h and the flask sealed. The ampoule containing hexamethyldisiloxane was then broken and the system was allowed to equilibrate overnight at room temperature. By suitable choice of sample sizes of silica and hexamethyldisiloxane, different initial surface coverages could be obtained. Infrared absorption measurements at 2960 cm^{-1} (ν asymmetric CH_3) were performed on discs pressed out of 30 mg samples of silica at a pressure of 5000 p.s.i. Comparisons of absorption intensity were made between samples with physisorbed hexamethyldisiloxane, the same sample washed and devolatilized, and a duplicate sample irradiated and then washed and devolatilized, see Fig. 2.

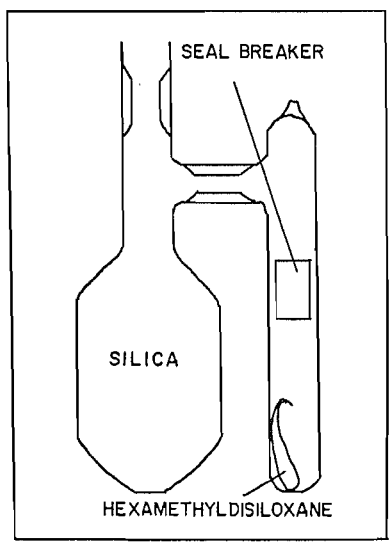

FIG. 1. Apparatus for adsorption of hexamethyldisiloxane on silica.

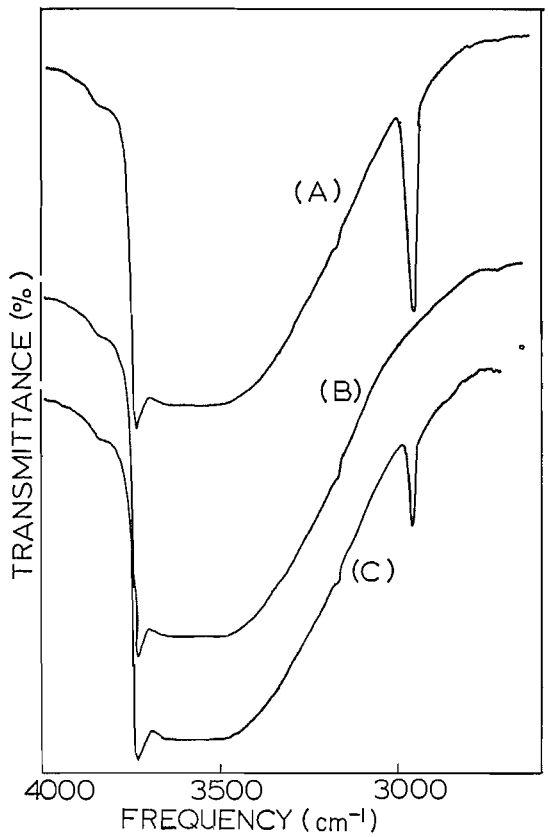

FIG. 2. Infrared absorption: (A) hexamethyldisiloxane adsorbed on silica, (B) after washing and devolatilization of adsorbed hexamethyldisiloxane, (C) after irradiation of adsorbed hexamethyldisiloxane, washing, and devolatilization.

The irradiations were performed in a ^{60}Co source at a dose rate of 2.73×10^4 rads/h.

The pre-irradiation coverage could not be calculated precisely since the adsorption isotherm was not obtained. However, the ratios of materials used were such that if all the hexamethyldisiloxane was adsorbed, coverages of less than 0.6 monolayer would have resulted.

Results and Discussion

In discussing the results, it must be kept in mind that, since the nature of the post-irradiation products is unknown, a quantitative definition of the amount of irradiation-induced chemisorption is impossible. Nevertheless, we can, through comparisons of the i.r. absorption (Fig. 2), establish whether chemisorption of irradiation products does occur, since the absorption at 2960 cm^{-1}, after irradiation and devolatilization, can

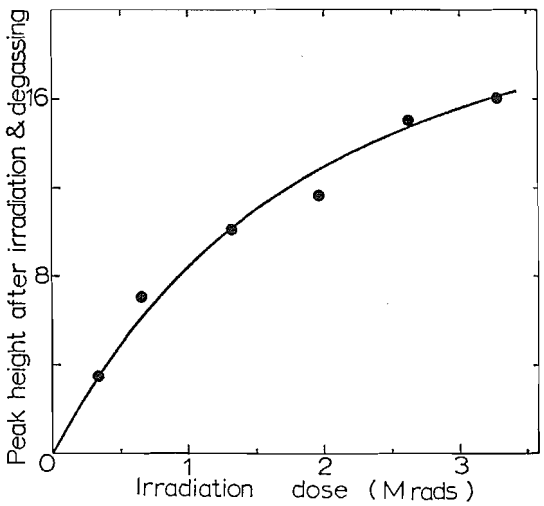

FIG. 3. Radiation products retained on the surface vs. dose at a given concentration of hexamethyldisiloxane (by i.r. absorption at 2960 cm^{-1}).

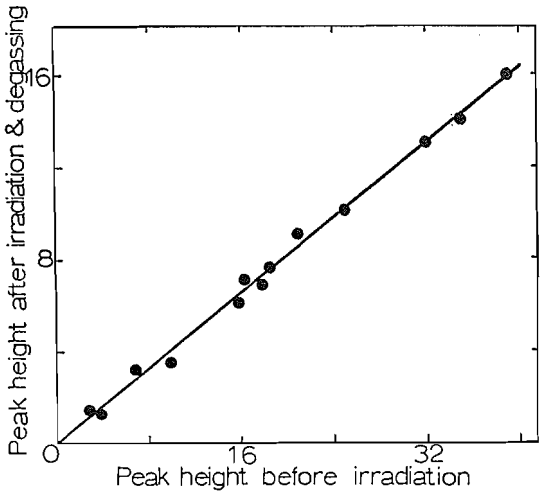

FIG. 4. Radiation products retained on the silica surface relative to initial concentration of hexamethyldisiloxane (by relative i.r. absorption at 2960 cm^{-1}) at constant radiation dose of 3.27 Mrads.

only be due to irradiation fragments from the hexamethyldisiloxane which have become chemically attached to the silica. The possibility that the retained absorption is due to the physisorption of silicone compounds is rejected on the grounds that molecules more than ten times as large as hexamethyldisiloxane are completely removed by the washing and devolatilization techniques used.

The relationship between the irradiation dose and the amount of C—H containing materials (those which absorb at 2960 cm^{-1}) remaining on the surface after washing and devolatilization can be seen from Fig. 3. The initial coverage of hexamethyldisiloxane was the same in all cases, approximately 0.6 monolayer, assuming total adsorption. The data are plotted in terms of relative i.r. absorption at 2960 cm^{-1}.

The non-linearity in the yield with dose is to be expected since the surface concentration of unreacted hexamethyldisiloxane is reduced with increasing dose.

The relationship between the amount of hexamethyldisiloxane on the silica prior to irradiation to the amount of material retained after, at constant dose, is shown in Fig. 4. The relationship is one of strict linearity.

Prior to the identification of the irradiation products, including those which remain chemically attached to the silica, it is not considered to be meaningful to calculate G values for the chemisorption or indeed to speculate too far on the nature of the adsorbed species. However, the results of Dewhurst and St. Pierre (14), who performed irradiation experiments on liquid and solid hexamethyldisiloxane, suggest numerous possibilities for the formation of species which could react with the surface SiOH groups on the silica. While they identified products which indicated that there was cleavage of all types of bonds present in the hexamethyldisiloxane, they found a considerable amount of product resulting from cleavage of the siloxane bond itself. Recombination of these fragments to form Me_3SiOH or Me_3SiH, both reactive with silanol groups, could result in reactions to form chemical bonds to the surface. Indeed, other studies involving heterogeneous systems (15, 16) and work presently under way in these laboratories suggest a considerable enhancement in total irradiation yields of physisorbed species, which would in turn result in increased chemisorption.

Work aimed at a more quantitative definition of the radiation chemistry of the physisorbed species is presently under way. However, the results disclosed in this note are considered proof of irradiation-induced chemical bonding of hexamethyldisiloxane irradiation fragments to silica. With the establishment of the quantitative aspects of this bonding, it will be possible to

expand present theories of network structure in filled polymers to allow a more complete understanding of the structure – physical property relationship.

Excitation and ionization of Hg by metastable states of N_2 and CO[1]

C. H. DUGAN
Department of Physics, York University, Toronto 12, Ontario

Received November 13, 1968

When metastable states of N_2 and CO collide with mercury atoms, the excitation energy can be transferred to the mercury atom, yielding a fluorescence in the spectral lines of mercury. This note describes observations of this process using a thermal beam of metastable molecules excited by electron impact. Metastable CO excites only the 6^3P levels of Hg. Metastable N_2 excites predominantly 6^3P, but some 10% of collisions excite 6^1P, and higher states are also excited. In addition, ionization of Hg by excited N_2 (but not by CO) is reported. Other observations are reported briefly.

Canadian Journal of Chemistry, 47, 2314 (1969)

This note reports an experimental study of processes involving excitation and ionization of Hg using thermal velocity beams of metastable excited electronic states of N_2. The excitation curve for the ionization produced by N_2^* in collision with Hg is presented, and a rudimentary spectral analysis of the emitted light is given. Experiments with other gases are also reported.

Hg is of interest because of the possibility of using it as an "indicator" for the presence of various metastable species: it might be used in an experiment in which both the optical and ionic mass spectra of an afterglow are studied with the goal of investigating the time history of the several excited species of N_2. Čermák (1) has reported recently on Penning ionization by N_2^* of molecules whose ionization potentials are higher than that of Hg (10.38 eV) so that it might be expected that Penning ionization ($N_2^* + Hg \rightarrow N_2 + Hg^+ + e$) will occur.

Experimental Procedure

Several earlier publications have dealt with the instrumentation of the experiments here (2). Briefly, the arrangement is this: an electron beam of variable energy but constant current excites a thermal velocity beam that enters a collision chamber after travelling some 10 cm in a vacuum of 10^{-5} to 10^{-6} Torr. The collision chamber contains a higher pressure of some added gas (earlier: NO at about 1 mTorr, here Hg at some 10^{-4} Torr) with

which collisions occur. We compare different ways of detecting the metastable species. In striking a metal surface they release electrons if they have enough internal energy (Auger effect). We collected these electrons. Second, we detected the emission of light, either from the beam or (with a target gas added) due to collisions and transfer of excitation to the struck molecules. Light from the collision region was detected directly by a quartz envelope photomultiplier attached (inside the vacuum system) to the collision chamber, viewing the interior through a LiF window. To study the spectral distribution of the light, we inserted filters in front of the photomultiplier to isolate broad spectral regions. We used these filters: (*a*) a window of Vycor whose transmission at λ2537 Å is about 70%, which does not transmit λ1849 Å; (*b*) a Pyrex window that blocks both λ1849 and λ2537 Å but transmits light of wavelength $\lambda > 3000$ Å. This allowed us to "resolve" the light into three important spectral regions: $\lambda < 2000$ Å, 2000 Å $< \lambda <$ 3000 Å, and $\lambda > 3000$ Å, in order to detect separately the two resonance emissions and the emission in transitions among higher excited levels.

Finally, we detected positive ions formed by Penning collisions. Ions were observed by collecting the positive ions on a fine wire electrode biased negative with respect to the chamber walls; a detector of small area was used to avoid a signal due to Auger electron emission from the detector caused by elastically scattered metastable particles striking the detector.

The energy resolution possible with this electron gun is poor because the rather long filament was directly heated, giving a 0.5 V potential drop along the filament, approximately.

Summary of Experiments

Several exploratory experiments were conducted using different gases in the source and target. These are listed below, along with those to be described in more detail. Figure 1 is an energy level diagram of several relevant molecules.

(*a*) A beam of N_2 was excited by electron impact and collided with Hg. Both light and ions were detected. This is discussed below.

(*b*) A beam of CO was excited by electron impact and collided with Hg. Light was observed but no ionization was detected. Electrons were not ejected by CO* from the metal target owing to the high work functions of the metal used as a target. The light that was observed is discussed below.

(*c*) A beam of Ar was excited before collisions with Hg. No light was observed. Ar* in collision with CO and O_2 yielded no light emission. Ar* in collision with N_2 yielded a light signal that was strong by the standards of this experiment. These results agree with flow-tube observations of Robertson (3). Electrons ejected by Ar* from metallic targets were readily observed (2). Penning ionization was not studied.

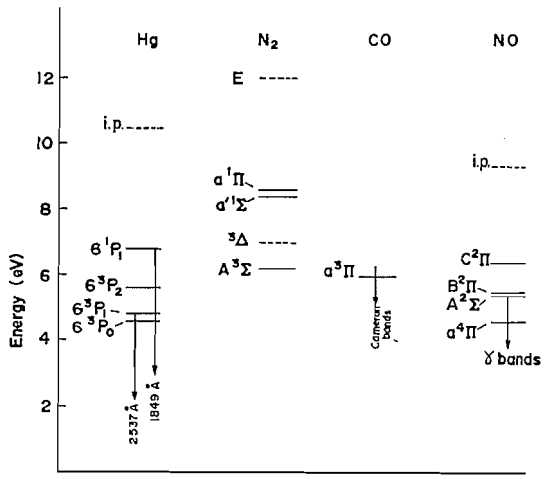

FIG. 1. Energy levels of molecules and atoms considered in the present experiment.

(*d*) A beam of NO was excited by electron impact; in collision with Hg the metastable states (if present) produced no light signal, and no Auger-ejected electrons were found using a NO beam. Vibrational levels $v \geq 2$ in NO ($a^4\Pi$) have sufficient energy to populate Hg (6^3P).

N_2 + Hg*

Brennen and Kistiakowsky (4) observed excitation of λ2537 Å and longer wavelengths in the afterglow of a nitrogen discharge when Hg was added; this was attributed to energy transfer from excited molecules. They reported no observation of λ1849 Å, and they found that radiation from higher excited states accounted for only 2% of their signal. The presence of only a very small emission from any singlet Hg atom was cited as evidence that spin-conservation was effective in the collision. They consider it unlikely that highly excited vibrational states of $N_2(X^1\Sigma)$ caused the emission, but as with the proposed $A^3\Sigma_u^+$ component, their experiment did not observe the active species directly.

The use of a beam that is detected independently offers some simplification in interpretation. Direct excitation of high vibrational levels of $X^1\Sigma$ is unlikely; the vibrationally excited ground-state molecules that are present come mostly from downward transition from excited electronic states. This means that they are not greatly more

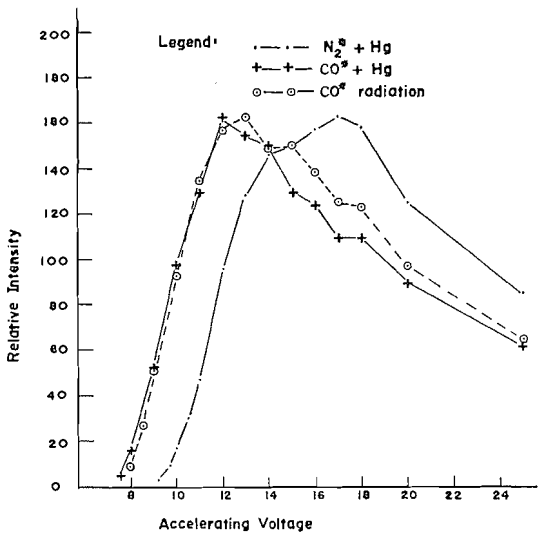

FIG. 2. Excitation function for production of light by collision of metastable molecules with Hg. Also shown is the excitation function of the emission directly from the excited CO beam.

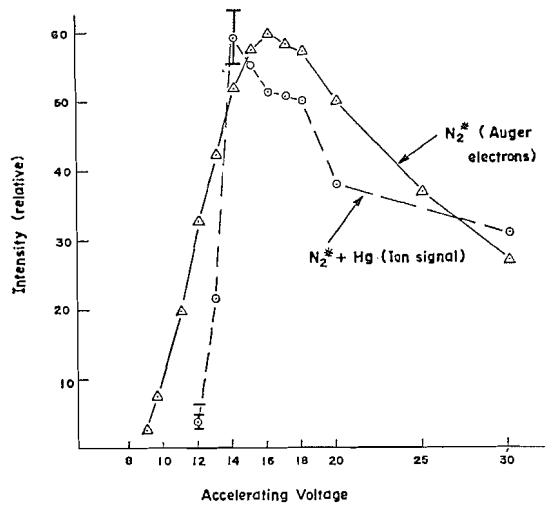

FIG. 3. Penning ionization of Hg by N_2^*. The excitation function for this process is compared with the signal due to electrons emitted from a metallic detector by N_2^*.

numerous than long-lived excited electronic states, as they might be in an afterglow. Earlier (2), we discussed whether atoms can play a part in causing these emissions and explained that it seems most unlikely. The presence of energetic photons in the beam may be expected and this has been studied previously (2). It is not a significant feature in this experiment. We can thus confidently assert that the predominant excited species in the beam is electronically excited molecules.

The distribution of excited states found in the beam will be somewhat different from that found in an afterglow and the excitation produced in Hg may be expected to be different. Based on the signals we detected we assign the light to mercury radiation at appropriate wavelengths. For electrons with an excitation energy of 15 eV, the N_2 beam produces a fluorescence that is 12% at λ1849 Å, 81% at λ2537 Å, and 7% for $\lambda > 3000$ Å. At an excitation energy of 30 eV, the fluorescence is 9% at λ1849 Å, 74% at λ2537 Å, and 17% at $\lambda > 3000$ Å. (Of course, every photon emitted at $\lambda > 3000$ Å gives rise to the emission of a photon at λ1849 or λ2537 Å.) These numbers were obtained in a way that makes the determination of the fraction above the Pyrex cut-off most reliable, although there are uncertainties of a few percent in these values. Less accurate is the determination of the fractions of the light in the two resonance lines, because uncertainty in the $\lambda > 3000$ Å component and in the measurement of window transmission propagates in determinations of the other two fractions. It was not possible to isolate the light signal at λ1849 Å with a narrow-band filter or monochromator, so that we had to rely on transmission of various materials to isolate the spectral region rather than the line. An additional qualification is the fact that this assignment of fractions of the light is simply an assignment of the current to the anode of an uncalibrated photo-multiplier. In assigning the fractions to the light we assumed that the photo-multiplier response is constant; this is not true, but calibrating the multiplier at λ1849 Å was not something we were equipped to do.

The possibility that different Hg states are excited preferentially by any of the possible N_2^* states could in principle be studied with the present experimental technique by recording excitation curves for different Hg emissions. Unfortunately we were unable to accomplish this goal satisfactorily. Figure 2 gives excitation functions for the total light emitted by Hg when excited by N_2^*. In an earlier study (2) of excitation of NO by N_2^* the excitation curve showed two distinct maxima; we see only one peak in this experiment.

The positive ion signal collected in the detection chamber as a function of exciting electron

For personal use only.

energy is shown in Fig. 3, and for comparison purposes we show the Auger electron signal obtained with a Ni target. The threshold is higher for the Penning ion formation than for the appearance of ejected electrons at the metal surface. The decrease in the Penning signal for higher energies appears to be more rapid than for the total metastable signal, although the error flag shown for the Penning signal near the peak of the curve makes it uncertain that we can distinguish between the shapes of the two curves. (Signals near threshold do not have such a large error flag.)

No vibrational state of $N_2(A^3\Sigma)$ is sufficiently energetic to cause ionization in Hg. The state responsible must, therefore, be one of the other metastable states having a higher dissociation limit. Molecules in the state $a^1\Pi_g$ with vibrational quantum number 10 have sufficient energy to ionize Hg. Čermák reported the ionization of C_2H_2 (ionization potential = 11 eV) by N_2* in his experiment[2].

CO + Hg*

CO ($a^3\Pi$) is long-lived and readily excited by electron impact (2, 5), and it has sufficient energy to excite the 6^3P level of Hg. However, we found no evidence to suggest that a state whose energy is above the ionization potential of Hg is excited; we found no Penning ionization of Hg using CO. Based on an observation (6) of CO* using a detector unfavorable for the detection of $a^3\Pi$ it was conjectured earlier that the state $b^3\Sigma^+$ at 10.9 eV was detected. This state should ionize Hg unless selection rules prevent it; if it was present in the beam, it was below the detection threshold of this experiment. As reported earlier (5) the CO beam excited by electron impact yields an observable radiation even in the absence of any target gas; very likely we saw the Cameron bands. Figure 2 shows the total light signal excited by CO* in Hg; it is distinguishable from the corresponding curve for N_2* in its energies at threshold and at the maximum signal. Of this light, less than 1% had $\lambda > 3000$ Å; 6% of the light was at λ1849 Å.

[2]Since the completion of this note, Dr. R. S. Freund has informed me that he has observed the emission spectrum of this state, $N_2(E)$, in a beam experiment. I am grateful to him for sending me a pre-publication copy of his paper.

Characterization and photolysis of octacyanomolybdic(IV) acid: isolation of a red photoproduct

R. P. Mitra, B. K. Sharma, and Hari Mohan

Department of Chemistry, University of Delhi, Delhi -7, India

Received November 13, 1968

pH and conductometric titration of aqueous octacyanomolybdic acid shows that it has 4 strong H^+ ions per Mo(IV). Photolysis of an ice-cold solution of the acid gives a red anion, $[Mo(CN)_7H_2O]^{3-}$, which has been isolated as a silver salt. When the corresponding (red) acid is titrated, 3 strong H^+ ions are first neutralized and then one more equivalent of the base is consumed in a slow substitution reaction to give a yellow anion, $[Mo(CN)_7OH]^{4-}$.

Canadian Journal of Chemistry, 47, 2317 (1969)

Yellow needle-shaped crystals of octacyanomolybdic(IV) acid were obtained by bubbling hydrogen chloride gas into a concentrated cold (0 °C) solution of the acid prepared by the percolation of aqueous potassium octacyanomolybdate(IV) through beds of the cation exchanger, Amberlite I.R. 120 resin (H form). The infrared (i.r.) spectrum of the solid acid showed C≡N

No vibrational state of $N_2(A^3\Sigma)$ is sufficiently energetic to cause ionization in Hg. The state responsible must, therefore, be one of the other metastable states having a higher dissociation limit. Molecules in the state $a^1\Pi_g$ with vibrational quantum number 10 have sufficient energy to ionize Hg. Čermák reported the ionization of C_2H_2 (ionization potential = 11 eV) by N_2* in his experiment[2].

CO + Hg*

CO ($a^3\Pi$) is long-lived and readily excited by electron impact (2, 5), and it has sufficient energy to excite the 6^3P level of Hg. However, we found no evidence to suggest that a state whose energy is above the ionization potential of Hg is excited; we found no Penning ionization of Hg using CO. Based on an observation (6) of CO* using a detector unfavorable for the detection of $a^3\Pi$ it was conjectured earlier that the state $b^3\Sigma^+$ at 10.9 eV was detected. This state should ionize Hg unless selection rules prevent it; if it was present in the beam, it was below the detection threshold of this experiment. As reported earlier (5) the CO beam excited by electron impact yields an observable radiation even in the absence of any target gas; very likely we saw the Cameron bands. Figure 2 shows the total light signal excited by CO* in Hg; it is distinguishable from the corresponding curve for N_2* in its energies at threshold and at the maximum signal. Of this light, less than 1% had $\lambda > 3000$ Å; 6% of the light was at λ1849 Å.

[2]Since the completion of this note, Dr. R. S. Freund has informed me that he has observed the emission spectrum of this state, $N_2(E)$, in a beam experiment. I am grateful to him for sending me a pre-publication copy of his paper.

Characterization and photolysis of octacyanomolybdic(IV) acid: isolation of a red photoproduct

R. P. Mitra, B. K. Sharma, and Hari Mohan

Department of Chemistry, University of Delhi, Delhi -7, India

Received November 13, 1968

pH and conductometric titration of aqueous octacyanomolybdic acid shows that it has 4 strong H^+ ions per Mo(IV). Photolysis of an ice-cold solution of the acid gives a red anion, $[Mo(CN)_7H_2O]^{3-}$, which has been isolated as a silver salt. When the corresponding (red) acid is titrated, 3 strong H^+ ions are first neutralized and then one more equivalent of the base is consumed in a slow substitution reaction to give a yellow anion, $[Mo(CN)_7OH]^{4-}$.

Canadian Journal of Chemistry, 47, 2317 (1969)

Yellow needle-shaped crystals of octacyanomolybdic(IV) acid were obtained by bubbling hydrogen chloride gas into a concentrated cold (0 °C) solution of the acid prepared by the percolation of aqueous potassium octacyanomolybdate(IV) through beds of the cation exchanger, Amberlite I.R. 120 resin (H form). The infrared (i.r.) spectrum of the solid acid showed C≡N

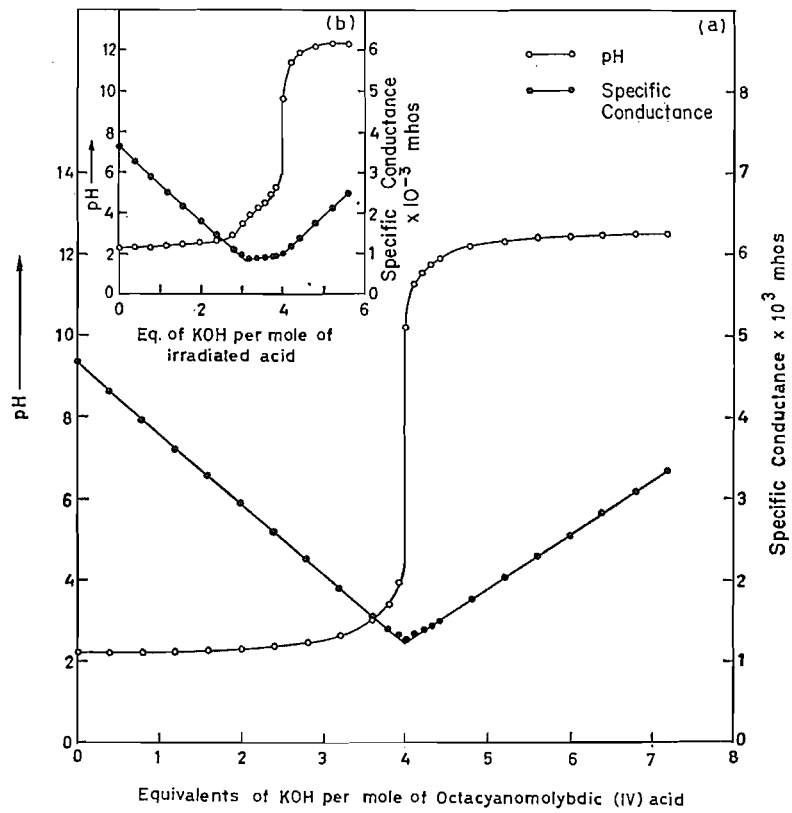

FIG. 1*a*. pH and conductometric titration curves of 5.0×10^{-3} f octacyanomolybdic(IV) acid with KOH.
1*b*. (Inset) pH and conductometric titration curves of photolyzed solution of 5×10^{-3} f octacyanomolybdic(IV) acid corresponding to the stage of maximum optical density at 512 mμ.

stretching frequencies 2160, 2130, and 2090 cm^{-1}. Aqueous solutions of the acid gave absorption peaks at 368 and 240 mμ characteristic of the $Mo(CN)_8^{4-}$ ion (1, 2). The conductometric titration curve of the aqueous acid showed a sharp minimum and its pH titration curve showed a corresponding pronounced inflexion (Fig. 1*a*), at which 4 equivalents of strong H^+ ions were neutralized for each equivalent of Mo(IV), as estimated by redox titration against potassium permanganate.

Anal. Calcd. for $H_4Mo(CN)_86H_2O$: Mo, 23.05; C, 23.08; N, 26.92; H_2O, 25.95. Found: Mo, 22.94; C, 23.07; N, 26.89; H_2O, 26.2.

On irradiation with ultraviolet (u.v.) light from a Philips mercury discharge lamp with a filter which transmitted radiation of wavelengths in the range 340–430 mμ, the yellow solution of octacyanomolybdic acid turned first red and then brown. Adamson and Perumareddi (1) reported a transient red species which was formed by the action of u.v. light on aqueous $K_4Mo(CN)_8$ and showed an absorption peak at 510 mμ. The red species could not be isolated by them. Its production was accompanied by a release of CN^- ions. Hydrolysis of these ions caused the pH to rise to 9.5. Since we used octacyanomolybdic acid which had a pH as low as 2.2, almost all the CN^-, which would be disengaged by the action of the u.v. light, would be present as HCN. When the irradiation of the acid was stopped and the solution kept in the dark, the red color disappeared to give back the original yellow solution. To prevent the back (thermal) reaction, the temperature of the solution was maintained at 0 °C and HCN was removed as fast as it was formed by bubbling N_2 gas through the solution as it was irradiated. During irradiation, the peak at 368 mμ decayed

For personal use only.

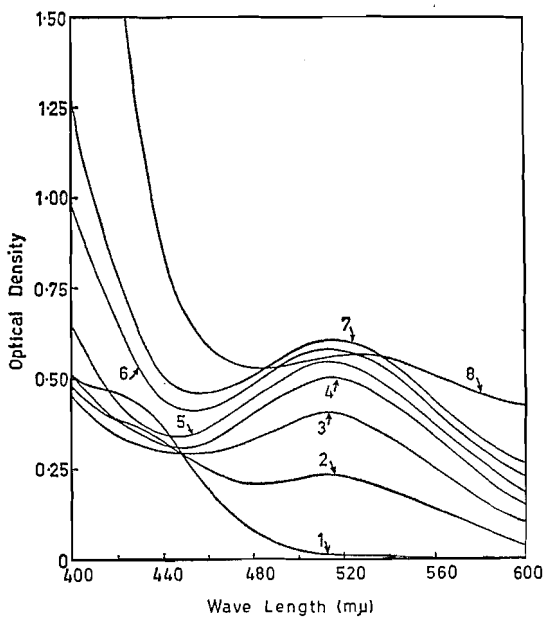

FIG. 2. Spectral variations of a 5×10^{-3} f solution of octacyanomolybdic(IV) acid during irradiation with u.v. light (1 cm light path). Curve numbers 1, 2, 3, 4, 5, 6, 7, and 8 refer to irradiation times of 0, 4, 9, 12, 14, 15, 17.5, and 30 min, respectively.

and a new peak at 512 mμ, synchronizing with the appearance of the red color, was observed. This peak grew in height as the red color deepened (Fig. 2) and, later on, it decayed. A titrimetric and spectral study of aliquots taken out at regular intervals showed that H^+ ions were lost (as HCN) as irradiation proceeded and, further, when the loss was one equivalent, the peak at 512 mμ, characterizing the red species, attained its maximum height (Fig. 2, curve 7).

To isolate the red species, an intense beam of u.v. light was next switched on to a fresh 100 cc of the (5×10^{-3} f) acid which had been cooled to 0 °C and through which N_2 gas was kept bubbling. When one equivalent of H^+ was lost as found by titration, an ice-cold solution of $AgNO_3$ was added. A red silver salt was precipitated.

Anal. Calcd. for $Ag_3Mo(CN)_7H_2O$: Ag, 52.21; C, 13.56; N, 15.81; Mo, 15.47; H_2O, 2.93. Found: Ag, 52.46; C, 13.6; N, 15.97; Mo, 15.73; H_2O, 3.4.

Redox titrations of aliquots of the irradiated solution against $KMnO_4$ indicated that up to the stage where the red species was precipitated as silver salt, the oxidation state of molybdenum did not change; 1.0 equivalent of $KMnO_4$ was taken up per Mo(IV). The standard redox [Mo(IV) $\rightleftharpoons$ Mo(V)] potential also remained constant (0.799 V at 0 °C).

The i.r. spectrum of the red silver salt gave a peak at 898 cm^{-1} consistent with the presence of coordinated water (3). This peak was not found in the spectrum of the solid acid. The formulation of Jakob *et al.* (4–5) of the red species as a super complex, $[Mo(CN)_8 2H_2O]^{4-}$, does not agree with the composition of our red silver salt and it does not fit with our observation that HCN is liberated when the red species is formed. We think that the red anion is $[Mo(CN)_7H_2O]^{3-}$. According to Carassiti and Claudi (6), it could be one of the photoproducts of the $Mo(CN)_8^{4-}$ ion. They, however, neither isolated it nor characterized it by its absorption spectrum. Adamson and Perumareddi (1), like us, thought that the red species would be an aquocomplex. According to them, it would function as a weak acid and would have the composition $[Mo(CN)_7OH]^{4-}$ at pH 9.5. When we titrated the red acid, $H_3[Mo(CN)_7H_2O]$, in the photolyzed solution at the stage where the silver salt was precipitated, we found that, first, three strong H^+ ions were neutralized and, then, a slow reaction set in, in which one equivalent of the base was consumed (Fig. 1*b*). This slow reaction could not be due to proton loss from coordinated water. We believe that it is one of ligand exchange in which the coordinated water in $[Mo(CN)_7H_2O]^{3-}$ is replaced by an OH^- ion. The change from red to yellow by the action of an alkali was not reversible. The solution remained yellow when kept in the dark at room temperature (30 °C). The red color did not return even on acidification.

Studies on the solvent extraction of metal dithiocarbamates[1,2]

VEDULA S. SASTRI, KEIJO I. ASPILA, AND CHUNI L. CHAKRABARTI[3]
Department of Chemistry, Carleton University, Ottawa 1, Canada

Received July 8, 1968

Studies on the solvent extraction of morpholine dithiocarbamic acid complexes of divalent metal ions Mn, Fe, Co, Ni, Cu, Zn, Pb, Cd, Hg, and Sn were carried out, and the extraction constants and the overall stability constants were determined. The stability constants of complexes of Cu(II) formed with various substituted dithiocarbamic acids, showed a variation of the stability constants with the basicity of the nitrogen and sulfur atoms in the reagents.

Canadian Journal of Chemistry, 47, 2320 (1969)

Introduction

Complexation reactions of various substituted dithiocarbamates have been reviewed by Hulanicki (1). Most of the analytical methods for metals which use dithiocarbamic acids, involve extraction with organic solvents like chloroform or carbon tetrachloride, followed by the spectrophotometric determination. Thus, solvent extraction of the metal dithiocarbamate is an important step in analytical procedures. Solvent extraction has been extensively used in the determination of stability constants of metal complexes (2–6) and in the study of the equilibria of complex-ions (7–12). The present investigation was directed at (*i*) determination of the extraction constants for divalent metal ions with morpholine DTC (dithiocarbamate) as the complexing agent, and the overall stability constants of the complexes, and (*ii*) to determine the effect of various substituents at the nitrogen atom in disubstituted dithiocarbamic acids on the magnitude of the stability constants.

Theory

Dithizone Extraction

Studies on solvent extraction of metal dithizonates of copper, lead, cadmium, and nickel in the presence of bis(carboxymethyl)dithiocarbamate as a masking agent, were carried out by Hulanicki and Minczewska (13), and the stability constants of the metal dithiocarbamates were calculated (13).

In the solvent extraction of metal dithizonate (MDZ) in the absence of masking agent, morpholine DTC,

$$M^{2+} + 2(HDZ)_0 \rightleftarrows (MDZ_2)_0 + 2H^+$$

the distribution ratio, D, can be written as

$$[1] \qquad D = K\frac{[HDZ]_0^2}{[H^+]^2}$$

where K represents the extraction constant for the metal dithizonate. At $pH_{\frac{1}{2}}$ the distribution ratio is unity, and thus

$$[2] \qquad 2pH_{\frac{1}{2}} = -\log K - 2\log [HDZ]_0$$

In the case of the masked extraction with morpholine DTC as the masking agent, the contribution of the metal–dithiocarbamate complexes in masking the extraction of the metal–dithizonate complex depends on the values of the stability constants β_i for the various complexes, and also on the concentration of free dithiocarbamic acid, and is given by a complexation function F, defined by

$$[3] \qquad F = \sum_{i=0}^{N} \beta_i[\text{Morpholine DTC}]^i$$

where $\beta_0 = 1$

For the masked extraction the distribution ratio D^* is

$$[4] \qquad D^* = K\frac{[HDZ]_0^{*2}}{[H^+]^{*2}F}$$

where K has the same value as in eq. [1].

Equation [4] can be written in the form

$$[5] \qquad -\log K = 2\log [HDZ]_0^* + 2pH_{\frac{1}{2}}^* - \log F$$

where symbols with an asterisk refer to the masked extraction. From eqs. [2] and [5], one can write

$$[6] \qquad -\log F = 2(pH_{\frac{1}{2}}^* - pH_{\frac{1}{2}}) + 2\log\frac{[HDZ]_0^*}{[HDZ]_0}$$

The stability constants of the complexes formed by divalent metal ions, Sn, Pb, Ni, and Cd, with morpholine DTC, were obtained by the use of eqs. [6] and [3].

At the pH values used for the extraction of the metal dithizonates in the presence of morpholine DTC, both the aqueous and the organic phase were analyzed, and it was found that the amount of metal morpholine DTC complex extracted into the organic phase was negligible.

Extraction of Metal–Morpholine DTC Complexes

Stary and Kratzer (14) have determined the extraction constants and the overall two-phase stability constants of several metal ions with diethyl–dithiocarbamic acid. The theory of the extraction has been outlined by Stary (4), and the basic equations applicable to the extraction of metal–morpholine DTC complexes are given below.

Solvent extraction of metal ions by a chloroform solution of morpholine DTC occurs thus

$$M^{n+} + n(HA)_{org} \rightleftharpoons MA_n + nH^+$$

and the extraction constant for the process is given by

$$[7] \qquad K = \frac{[MA_n]_{org}[H^+]^n}{[M^{n+}][(HA)_{org}]^n}$$

In the cases where the distribution ratio of the metal–dithiocarbamate complex was high, masking agents, e.g., EDTA, oxalate, and iodide, were used to form the non-extractable metal complex, MX_y, where X stands for the anion of the masking agent.

$$[8] \qquad K = q\{1 + \beta_y[X^{n-}]^y\}\frac{[H^+]^n}{[(HA)_{org}]^n}$$

where q is the distribution ratio of the metal in the presence of the masking agent, and where β_y is the stability constant of the metal complex MX_y. The stability constant of the metal–dithiocarbamate complex was calculated by the use of eqs. [9] and [10].

$$[9] \qquad \beta_{n_{org}} = \frac{[MA_n]_{org}}{[M^{n+}][A^-]^n} = K\left(\frac{p_{HA}}{K_{HA}}\right)^n$$

where p_{HA} is the partition coefficient of HA and is defined as

$$p_{HA} = \frac{[HA]_{org}}{[HA]}$$

and K_{HA} is the dissociation constant of HA and is defined as

$$K_{HA} = \frac{[H^+][A^-]}{[HA]}$$

$$[10] \qquad \log \beta_{n_{org}} = \log K + n \log\left(\frac{p_{HA}}{K_{HA}}\right)$$

The use of eqs. [7] or [8] in combination with eq. [9] enabled the determination of the stability constants of complexes of divalent metal ions, Mn, Fe, Co, Zn, Cu, and Hg, formed with morpholine DTC.

In the case of Cu^{2+}, the stability constant of the complex was also determined by the competition method of Janssen (15) using oxine as the competing ligand in 75% alcohol–water medium.

Experimental

Reagents

Analytical-reagent grade chemicals were used. (*a*) Stock solutions of 0.1 *M* of all the metals were prepared from the corresponding metal nitrates. (*b*) Dithizone solution in chloroform was prepared fresh just before use. (*c*) Morpholine DTC solutions were prepared fresh before use. (*d*) Spectral-grade chloroform was used for extraction.

Apparatus

A Bausch and Lomb spectronic 505 spectrophotometer was used for recording absorbance values.

Procedure

(a) Metal Dithizonates (13, 16)

For every metal ion, two series of experiments were done: (*i*) extraction in the absence of morpholine DTC; (*ii*) extraction in the presence of morpholine DTC. Extraction was done using 25 ml of aqueous solution which was 10^{-4}–10^{-5} *M* in metal ion and 10^{-3} *M* in morpholine DTC. This was extracted with 25 ml of dithizone reagent in chloroform. The time of equilibration was 10 min. All experiments were done at a temperature of 25 ± 1 °C.

The following points may also be noted. (*i*) In the pH range of non-masked extraction, Cd^{2+}, Pb^{2+}, Ni^{2+}, and Sn^{2+} do not form any hydroxocomplexes, (*ii*) pH of the solutions were maintained by using buffer solutions, (*iii*) the ionic strength was kept constant at 0.1 by the addition of potassium nitrate, (*iv*) the formation of mixed complexes was checked spectrophotometrically by comparison of the spectra with those of the corresponding complexes obtained in the absence of morpholinodithiocarbamic acid, and it was found that mixed complexes were absent, (*v*) the absorbance of the metal dithizonate in the organic phase was used for obtaining the % extraction as a function of pH, both in the absence and presence of morpholinedithiocarbamic acid from which the $pH_{\frac{1}{2}}$ values were evaluated.

(b) Metal Dithiocarbamates (14)

(*i*) 25 ml of a solution of morpholine DTC in chloroform was equilibrated with an equal volume of aqueous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

solution of the metal salt of appropriate pH for about 10 min, and the equilibrium concentrations of the free ligand and metal ion were determined spectrophotometrically. This was used as the reference solution against which the extent of formation of the metal–morpholine complexes under the conditions given in (*ii*) below, was compared, (*ii*) 25 ml of an aqueous solution containing the metal ion of appropriate pH, and 0.1 *M* of EDTA or oxalate ion, was equilibrated with 25 ml of chloroform solution of morpholine DTC, and the equilibrium concentrations of the metal ion and the ligand were determined spectrophotometrically. Extraction was carried out also in the absence of masking agent. All extractions were carried out at a temperature of 25 ± 1 °C. The time of equilibration for Mn^{2+}, Fe^{2+}, Co^{2+}, Zn^{2+}, Cu^{2+}, and Hg^{2+} was 30 min. The masking agents were as follows

Metals	Masking agents
Mn^{2+}, Fe^{2+}, Co^{2+}, Zn^{2+}	Oxalate
Cu^{2+}	EDTA
Hg^{2+}	Iodide

The concentrations used in (*b*) metal–dithiocarbamates (*i*) and (*ii*) were as follows: metal 10^{-4}–10^{-5} *M*, morpholine DTC 10^{-3}–10^{-4} *M*, and masking agents 10^{-2} *M*.

In both cases of extraction of (*a*) metal dithizonates and (*b*) metal dithiocarbamates, the process was continued for a further period of time up to 2 h in order to test for completion of the equilibration, and it was found that the equilibration was complete in the time mentioned in (*a*) and (*b*) above.

Results and Discussion

In Table I, data for the stability constants of copper dithiocarbamate complexes for various substituted dithiocarbamic acids are presented together with p*K*'s for the nitrogen and sulfur sites of the reagents. In general, the stability constants increase with increasing basicity of the sulfur site of the reagent, with the exception of diphenyldithiocarbamate. A similar correlation of the stability constants is seen with the basicity of nitrogen centers (pK_N) of the reagents, with the exception of morpholine dithiocarbamic acid.

The data on the stability constants and extraction constants of complexes of Mn(II), Fe(II), Co(II), Ni(II), Cu(II), Zn(II), Pb(II), Cd(II), Sn(II), and Hg(II), are given in Table II. In discussing the order of stability constants for complexes of Mn(II), Fe(II), Co(II), Cu(II), and Zn(II) with sulfur, nitrogen, and oxygen substituted iminodiacetic acids, Burger (17) invoked the concept of the π bonding ability of sulfur atoms, and concluded that this was responsible for the deviation in the order of stability constants from the natural order of stability predicted by Irving and Williams (18). However, the experimental evidence shows that the stability constants of complexes of divalent metal ions with sulfur donors, such as S-ethylthioglycolic, 3-(S-ethyl)mercaptopropionic, and *o*-ethylmercaptobenzoic acids (19), and thiodiglycolic acid (20, 21), follow the natural order, i.e.,

$$Cu > Ni > Pb > Co > Zn > Cd$$

In the case of diethyl (14) and morpholine dithiocarbamate complexes, the order of stability constants has been found to be

$$Mn(II) < Fe(II) < Co(II) < Ni(II) < Cu(II) > Zn(II)$$

and

$$Mn(II) < Fe(II) > Co(II) < Ni(II) < Cu(II) > Zn(II)$$

respectively.

Data on the extraction constants of morpholine and diethyl dithiocarbamate complexes show the order of decreasing extraction

$$Hg > Cu > Zn > Fe > Co > Mn$$

which agrees well with the previous findings of Stary and Kratzer (14) and Eckert (22).

Effects of hydrogen bonding and homoconjugation on the titration curves of a synthetic polynuclear phenolic compound in non-aqueous solvents

S. K. CHATTERJEE
Department of Chemistry, Delhi University, Delhi-7, India

Received December 31, 1968

A straight chain polynuclear phenolic compound containing 9 phenolic nuclei has been synthesized and titrated in several non-aqueous solvents. In some of the solvents, a stepwise neutralization of OH groups in the compound has been observed. Some of the OH groups in the compound have a hyper-acid character, and a sharp increase in conductance was observed as these OH groups are neutralized by the base. Some of these features have been discussed in terms of intramolecular hydrogen bonding and homoconjugation between the acid and its anion.

Canadian Journal of Chemistry, **47**, 2323 (1969)

The presence of hydrogen bonds has often been postulated to explain the peculiar behavior of certain phenolic resin intermediates (1, 2). Coggeshall's (3) infrared spectroscopic results on ortho diphenyl methanes have shown the presence of intramolecular hydrogen bonds in these compounds. Sprengling (4) potentiometrically titrated some *o,o'*-dihydroxy diphenyl methane type of compounds in benzene – isopropyl alcohol mixture, and observed that one of the OH groups in the molecule had a strong acid character. He suggested that the cause of the strong acid character was to be found in an intramolecular hydrogen bond formation between neighboring OH groups in the molecule, as shown in **1–3**

Effects of hydrogen bonding and homoconjugation on the titration curves of a synthetic polynuclear phenolic compound in non-aqueous solvents

S. K. CHATTERJEE
Department of Chemistry, Delhi University, Delhi-7, India

Received December 31, 1968

A straight chain polynuclear phenolic compound containing 9 phenolic nuclei has been synthesized and titrated in several non-aqueous solvents. In some of the solvents, a stepwise neutralization of OH groups in the compound has been observed. Some of the OH groups in the compound have a hyper-acid character, and a sharp increase in conductance was observed as these OH groups are neutralized by the base. Some of these features have been discussed in terms of intramolecular hydrogen bonding and homoconjugation between the acid and its anion.

Canadian Journal of Chemistry, **47**, 2323 (1969)

The presence of hydrogen bonds has often been postulated to explain the peculiar behavior of certain phenolic resin intermediates (1, 2). Coggeshall's (3) infrared spectroscopic results on ortho diphenyl methanes have shown the presence of intramolecular hydrogen bonds in these compounds. Sprengling (4) potentiometrically titrated some *o,o'*-dihydroxy diphenyl methane type of compounds in benzene – isopropyl alcohol mixture, and observed that one of the OH groups in the molecule had a strong acid character. He suggested that the cause of the strong acid character was to be found in an intramolecular hydrogen bond formation between neighboring OH groups in the molecule, as shown in **1–3**

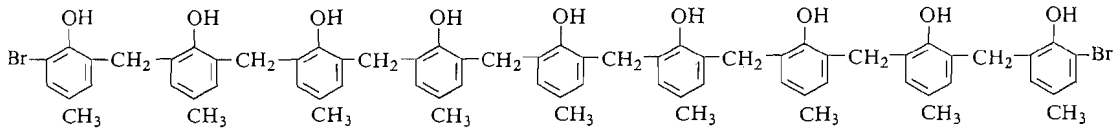
3

However, he failed to observe any stepwise neutralization of phenolic OH groups in these compounds. Mitra and Chatterjee (5–7) titrated a series of low molecular weight synthetic polynuclear phenolic compounds in various non-aqueous solvents, and showed that a stepwise neutralization of phenolic OH groups in these compounds could be obtained if solvents and titrant bases were properly chosen. This note is intended to present certain facts concerning intramolecular hydrogen bonding and homoconjugation, and their influence on the titration curves of a large synthetic polynuclear phenolic compound. The structure and the chain length of the synthetic compound (4) used in this investigation were known from its synthesis.

Experimental

For the preparation of the synthetic polynuclear phenolic compound (4), the methods of Kammerer and Rausch (8) were followed



4

p-Cresol (0.01 mole) was condensed with slightly more than 0.02 mole of 3-bromo, 3′-hydroxy methyl, 2-2′-dihydroxy, 5-5′-dimethyl diphenyl methane (Br–2–CH_2–OH) in the presence of concentrated HCl as a catalyst. The resultant dibromo pentanuclear compound is then dehalogenated with Raney nickel. The dehalogenated pentanuclear compound was (0.01 mole) further condensed with slightly more than 0.02 mole of Br-2-CH_2OH in the presence of concentrated HCl as a catalyst. After the reaction, the fused mass was dissolved in dioxan and precipitated with methanol.

For potentiometric work, glass electrodes (Beckman), saturated calomel electrodes (as reference half cells), and a Beckman *pH* meter (H-2 model) were employed. For conductometric titrations, a Pt–Ir bridge was used in conjuction with a Muirhead audio frequency oscillator as the source of alternating electromotive force. Analytical grade solvents were used without further purification.

Results and Discussions

Figure 1 shows the titration curves of the nonanuclear compound (4) in various non-aqueous solvents. The conductometric titration of the compound in acetone with sodium methoxide as the titrant base is shown in curve 1. It shows 5 breaks in all, and the smallest interval between two successive breaks is found to be 80 meq. of base per 100 g of the compound. This amount of base incidently coincides with the calculated quantity of base required to neutralize one OH group in the compound. Therefore, from the quantities of base required at the various stages of neutralization of the conductometric titration curve, the number of OH groups neutralized at different steps can be ascertained. The corresponding potentiometric curve is shown by curve 2, which indicates only three inflexions. One OH group each is neutralized at the first two inflexions, and the third inflexion accounts for the neutralization of two more OH groups. The final break of the conductometric titration curve accounts for the neutralization of all the 9 OH groups of compound (4). However, the complete neutralization of the compound is not indicated by the potentiometric curve. Curves 3 and 4 in the same figure show the conductometric and potentiometric titration curves, respectively, of compound (4) in acetonitrile with sodium methoxide. The potentiometric curve shows two inflexions, where two OH groups are neutralized at each step. However, the corresponding conductometric curve (cf. curve 3) shows 6 breaks in all, and each of the first 4 breaks coincides with the neutralization of one OH group. On comparing the conductometric curves with the potentiometric curves, it can be seen that OH are neutralized mostly in a stepwise manner in the conductometric curve and more often they are lumped in the potentiometric curve. These extremely interesting observations can be interpreted in terms of homoconjugation as proposed by Kolthoff *et al* (9–11). Kolthoff defined homo-

conjugation as the association of an anion with its conjugate acid:

$$A^- + HA \rightleftarrows AHA^-$$

In solvents that are weak hydrogen bond doners, such as acetonitrile and acetone, homonuclear phenols form very stable homoconjugate complexes AHA^-. It seems likely that some of this tendency will persist with polynuclear phenols. In fact the observed maxima in the conductometric titration curves are exactly what would be expected if homoconjugation occurs. The formation of AHA^- and its effect on the characteristics of conductometric (12–14), and potentiometric (14, 15) titration curves have been considered in some recent publications. The large synthetic polynuclear molecule (**4**) in solution is likely to have intramolecular hydrogen bonds consisting of 2, 3, or 4 OH groups. In fact, the number of hydroxyl groups involved in the hydrogen bond formation should depend on the particular orientation of the molecule in solution. It may thus be considered that the polynuclear molecule (**4**) may dissociate in solution to give rise to a series of anions. The presence of various anions in solution may lead to the formation of a number of acid–anion complexes. Perhaps the difference of degree of dissociation of some of these homoconjugate complexes may be responsible for the stepwise neutralization of phenolic OH groups in the conductometric titration curves.

Van Meurs and Dahmen (16) showed that dielectric constant of the solvent and size of cation of titrant base play an important role in getting a particular shape of the titration curve. Therefore, it was considered of interest to vary the dielectric constant of the solvent by mixing with a solvent of low dielectric constant, such as benzene, and to study its influence on the nature of titration curves. In Fig. 2 are presented the titration curves of the polynuclear phenolic compound (**4**) in some mixed solvents. Curve 1 is the conductometric titration curve of the compound in a 1:1 mixture of dimethyl formamide (DMF) and benzene (B) with sodium methoxide as the titrant base. It shows 7 well defined breaks in all, and one OH group is neutralized at each of the first three

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

steps. The complete neutralization of all the OH groups in compound (**4**) is indicated by the final break of the conductometric titration curve. The neutralization of the first two OH groups of the compound is also indicated by the two inflexions of the potentiometric curve (cf. curve 2).The conductometric titration curve of the compound in a 1:1 mixture of acetonitrile (AN) and benzene (B) shows 6 breaks in all (cf. curve 3). The corresponding potentiometric titration curve indicates only two inflexions, where one OH group is neutralized at the first step and three in the subsequent step. Since the smallest interval between 2 successive breaks or inflexions in the titration curve coincides with the calculated amount of base required to neutralize one OH group of the compound, one can, therefore, make use of this fact to calculate average degree of polymerization (*DP*) of linear polymers having acidic or basic functional groups. The average *DP* would be obtained by dividing the total amount of base (740 meq.), expressed in meq./100 g of compound, added up to the final break in the titration curve, by the amount added during the smallest interval (80 meq.). Thus the average *DP* of the compound (**4**), would be equal to 740/80 = 9(approx.). This number, interestingly enough, coincides with the number of repeat units of the compound (**4**), which is known from its synthesis. It may thus be concluded that conductometric titration in suitable non-aqueous solvents provides an excellent method for quantitative estimation of phenolic OH groups in a polynuclear phenolic compound.

Determination of the activity of water in highly concentrated perchloric acid solutions

Henry Wai[1] and Keith Yates

Department of Chemistry, University of Toronto, Toronto 5, Ontario

Received November 25, 1968

The water activities of concentrated aqueous perchloric acids in the range 40–75% have been determined at 25 °C using a modified isopiestic method.

Canadian Journal of Chemistry, 47, 2326 (1969)

In connection with our studies of equilibria (1) and rates (2) in concentrated mineral acids, we have found that the available data for the activity of water (3, 4) in perchloric acid solutions are rather inadequate for correlation purposes, because such data are only available up to about 60% acid (4). We have estimated the activity of water in perchloric acid ranging from 40–75%

*Water activity values are interpolated graphically from data in ref. 7. Plots of a_w or $-\log a_w$ versus $\%H_2SO_4$ were used for the interpolations in less than and more than 66% (w/w) H_2SO_4 respectively.

acid at 20 °C by the isopiestic method (5) in a modified apparatus (see Experimental section) using sulfuric acid as the reference solution. This extends the useful range of water activity for acidity function work by more than three logarithmic units (on the H_0 scale). The results are listed in Table I, and are plotted as a function of acid concentration in Fig. 1.

The activity of water in perchloric acid up to 12 molal (ca. 55%) has been determined by Pearce and Nelson (3) by the dynamic method. It has also been determined by Robinson and Baker (4) up to 16 molal (ca. 62%) by the isopiestic method, using sodium chloride solution as the reference for perchloric acid below 4.5 molal and sulfuric acid above that[2]. These results agree closely with one another. It can be seen from Fig. 1 that the smoothed data from the literature (3, 4) and the raw data from the present work follow virtually the same curve in the regions where they overlap. This shows that the values in Table I, which are easily obtained by the

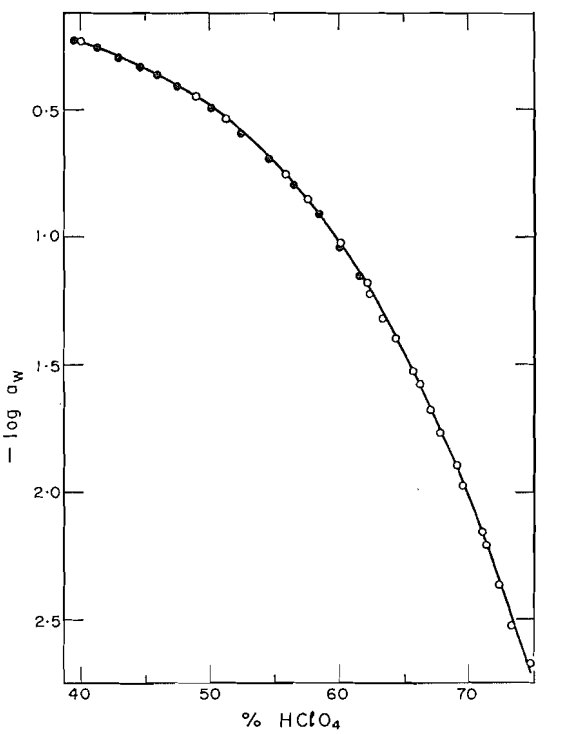

FIG. 1. Variation of water activity ($-\log a_w$) as a function of acid concentration in aqueous perchloric acid at 20 °C; ○, present work; ●, data taken from refs. 3 and 4.

[2]Some limited data at higher concentrations of perchloric acid have been reported by Haldna, Koppel, and Kuura (6). However, these are of questionable value since they were apparently based on isopiestic measurements at 20 °C using sulfuric acid reference data obtained at 25 °C (7).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

present modified apparatus, may be used with confidence and that this simple method could be used to extend the somewhat sparse water activity data available for other concentrated acid systems. It can also been seen from Table I that for a pair of isopiestic solutions, sulfuric acid is generally much more concentrated than perchloric acid in the highly concentrated regions. This suggests that the amount of "free" water available in perchloric acids is much less than that in sulfuric acids of comparable concentration.

Experimental

A "Labconco" fiberglass glove box was converted to a constant temperature controlled box by fitting the built-in circulating duct with a "muffin fan" made by Rotron Manufacturing Co., Glendale, California. A 100-W wire heater was mounted in front of the fan which had a circulating capacity of 100 cu. ft/min. The box was thermostatically controlled at 25 ± 0.1 °C by means of a solid-state relay box connected to the heater.

The modified apparatus for the isopiestic determination of water activity is shown in Fig. 2. By using this all-glass apparatus, not only the necessity of very expensive platinum dishes (5) can be eliminated, but also the possibility of platinum catalyzed decomposition of perchloric acid (8) (especially in the highly concentrated region). Thermal communication between the two solutions in this glass apparatus is not a problem, since the whole apparatus is placed in the constant-temperature air-bath.

Perchloric acid solutions (Baker and Adamson reagent (70% minimum) and G. Frederick Smith Chemical Co. $HClO_4$ monohydrate) and sulfuric acid solutions (CIL C.P. reagent) were put separately into the pairs of flasks. Each flask had an indentation at the bottom to help provide turbulence. The common atmosphere above the acids was evacuated with a rotary vacuum pump to accelerate the attainment of equilibrium. The flasks were allowed to equilibrate (with gentle shaking) in the thermostatically controlled glove box at 25 ± 0.1 °C for 48 to 72 h, depending on the concentrations used. At the end of the equilibration, the concentrations of the acids were determined titrimetrically with standard sodium hydroxide solution, prepared from Fisher certified reagent concentrated solution. The times necessary to achieve isopiestic equilibrium were established by means of repeat determinations on duplicate samples, which had been equilibrated for different lengths of time, until constant titration values were obtained. The activity of water in each pair of the two isopiestic acids was interpolated graphically from data compiled by Robinson and Stokes for sulfuric acid (9).

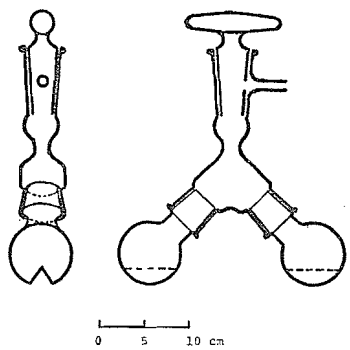

FIG. 2. Diagram of all glass apparatus used for equilibration of isopiestic acid solutions.

That the equilibration did not lead to any molecular transfer of the two mineral acids themselves was demonstrated in the following manner. A saturated barium hydroxide solution when added to the diluted perchloric acid after equilibration failed to detect the presence of any sulfate. To test for the presence of perchloric acid in the sulfuric acid after equilibration, the latter was carefully neutralized with analytical grade sodium hydroxide (British Drug Houses). The solution was evaporated to dryness and the sample was analyzed for chlorine content. In eight different samples analyzed by two independent microanalysis laboratories, chlorine was only found in one sample to the extent of 0.07%, the rest being reported as 0.00%. These results do not support the previously reported (6) suggestion that the isopiestic method is only valid up to about 72% $HClO_4$ because of volatilization of the acid.

Formation of 2,3-epoxyperfluoropropionylfluoride from the mercury photosensitized oxidation of 1,3-perfluorobutadiene

WAYNE STUCKEY, JULIAN HEICKLEN[1], AND VESTER KNIGHT
Aerospace Corporation, El Segundo, California 90045

Received October 30, 1968

The mercury photosensitized oxidation of 1,3-C_4F_6 gives nearly equal amounts of CF_2O and a new compound 2,3-epoxyperfluoropropionylfluoride and smaller amounts of *c*-C_3F_4. The infrared (i.r.) and mass spectra of 2,3-epoxyperfluoropropionylfluoride are presented.

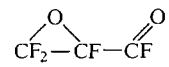
We wish to report the synthesis and identification of 2,3-epoxyperfluoropropionylfluoride (1)

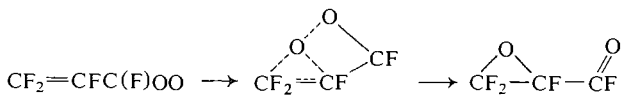


1

This molecule is prepared, along with CF_2O and *c*-C_3F_4, in the mercury-photosensitized oxidation of 1,3-C_4F_6 at room temperature. The experimental procedure was identical to that used in the study in the absence of O_2 (1). CF_2O and $OCF_2CFC(F)O$ were produced in nearly equal amounts under all operating conditions, though their absolute quantum yields varied markedly. Perfluorocyclopropene, which has been described previously (2), is produced in smaller quantities.

A possible reaction sequence[2] leading to products is

$$\begin{aligned}
&Hg + h\nu(2537\ \text{Å}) \rightarrow Hg^*\\
&Hg^* + 1,3\text{-}C_4F_6 \rightarrow 1,3\text{-}C_4F_6^*\\
&Hg^* + O_2 \rightarrow Hg + O_2^*\\
&O_2^* + 1,3\text{-}C_4F_6 \rightarrow O_2 + 1,3\text{-}C_4F_6^*\\
&1,3\text{-}C_4F_6^* + O_2 \rightarrow CF_2O_2 + C_3F_4 \rightarrow c\text{-}C_3F_4\\
&\qquad\qquad \rightarrow CF_2\ (\text{triplet}) + CF_2{=}CFC(F)OO\\
&CF_2\ (\text{triplet}) + O_2 \rightarrow CF_2O_2\\
&\qquad 2\ CF_2O_2 \rightarrow 2\ CF_2O + O_2
\end{aligned}$$



Other reactions which deactivate the excited states must also occur to account for the variation in quantum yields which varied from 0.1 to 0.8 for the major products under our experimental conditions, i.e. $[O_2] = 1.5$–100 Torr, $[1,3\text{-}C_4F_6] =$ 0.9–100 Torr, $I_a = 7.4 \times 10^{12} - 1.5 \times 10^{14}$ quanta/cc s. *It is clear that O_2 does not add across the double bonds in 1,3-C_4F_6*; if it did, no reasonable mechanism exists which leads to the observed products.

The molecular weight of $OCF_2CFC(F)O$ was obtained from vapor density measurements. Two determinations gave 145.7 and 143.0 which compare favorably to the theoretical value of 144. Further confirmation comes from the mass spectrum shown in Fig. 1. The peak of highest *m/e* is at 144 and all the cracking peaks are consistent with $C_3F_4O_2$. In fact no carbon–fluorine–oxygen molecule with a different empirical formula has a molecular weight of 144. The predominant cracking peaks corresponding to CFO^+, CF_2^+, and $C_2F_2O^+$ suggest the presence of these groups in the molecule. The peak corresponding to CF_3^+ must be a mass spectral rearrangement peak, since fluorine migration is not likely under the oxidation conditions employed. The presence of CF_3^+ is often found in mass spectra of compounds with no CF_3 groups (2).

[1]Present Address: Department of Chemistry, The Pennsylvania State University, University Park, Pennsylvania 16802.

[2]A referee has suggested that an alternative to intramolecular rearrangement in the biradical $CF_2{=}CFC(F)OO$ would be the addition of a second O_2, to give $O_2CF_2CF{=}CFO_2$ which could convert to $OCF_2CFC(F)O$ by reaction with other peroxide radicals, or by intramolecular elimination of O_2.

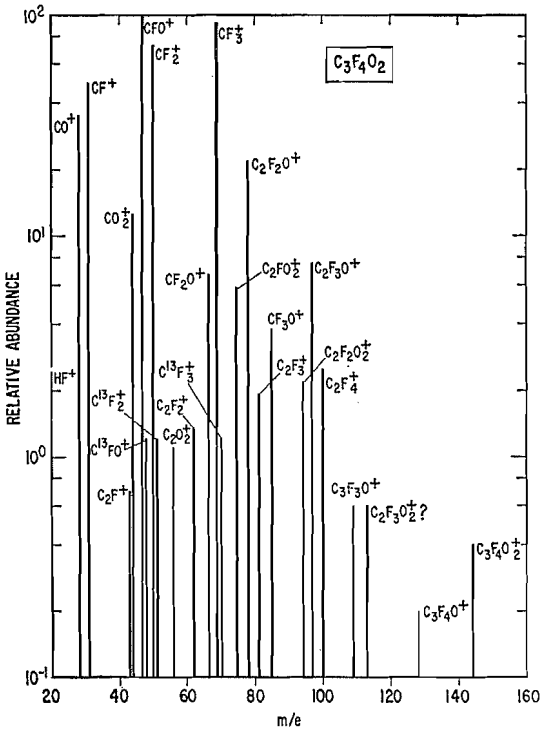


FIG. 1. Mass spectrum of $OCF_2CFC(F)O$ at 70 eV ionizing voltage.

Final confirmation of the structure comes from the i.r. spectrum, shown in Fig. 2. Bands appear at 5.35, 6.61, 7.72, 7.42, 8.65, 9.00, 9.84, 12.30, 13.00, and 13.82 μ. The strong band at 5.35 μ is characteristic of the —C(F)O group and the

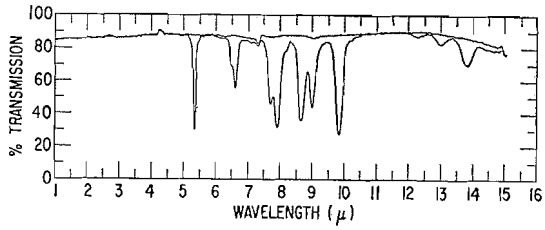

FIG. 2. Infrared spectrum of $OCF_2CFC(F)O$ taken at about 2 Torr pressure on a Beckman IR5A spectrometer.

weaker band at 6.61 μ can be identified with the perfluorinated epoxide group; e.g. the epoxide band in OCF_2CFCF_3 is at 6.45 μ (3).

The heat of vaporization of $OCF_2CFC(F)O$ was measured between −97 and −73 °C and found to be 6.9 kcal/mole with an extrapolated boiling point of 16 °C; the resulting Trouton's constant is 23.0.

Nuclear magnetic resonance investigation of intermediates formed by the action of nucleophiles on substituted stilbenes

C. A. FYFE[1,2]

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received September 18, 1968

A nuclear magnetic resonance investigation of the colored species formed by the action of bases on a series of α-cyano-4-nitro-4′-X-stilbenes characterizes these as the intermediate carbanions formed by the addition of base to the β-carbon atom of the double bond. The nuclear magnetic resonance spectra reveal that, whereas there is free rotation about the β-phenyl—Cβ and Cβ—Cα bonds in these adducts, there is restricted rotation around the α-phenyl—Cα bond due to very substantial delocalization of the negative charge into this ring. It has been verified that the same intermediates are formed by the action of bases on either the *cis* or *trans* isomers of α-cyano-4-nitrostilbene. The relation of these observations to the theory of alkene nucleophilic substitution reactions is discussed.

Canadian Journal of Chemistry, 47, 2331 (1969)

Introduction

Alkenes substituted by one more electronegative groups are susceptible to nucleophilic attack by a variety of bases (1). Almost all proposed mechanisms (1, 2) for alkene nucleophilic substitution reactions have the formation of the carbanion (**1**) as the first step [1], the particular products in a given reaction depending on the subsequent reaction of (**1**).

[1] 
1

The color producing reactions between alkoxide ion and a large number of α-cyano-4,4′-disubstituted stilbenes have recently been investigated by Stewart and Kroeger using ultraviolet (u.v.) spectroscopy (5, 6). From the similarity between the u.v. spectra of the products formed from α-cyano-4-nitro-4′-X-stilbenes and those of the anion of 4-nitrophenylacetonitrile (5), and the general effect of substituents on the equilibrium (6), it was concluded that the colored species formed was the anion (**2**) formed by the addition of the alkoxide ion [2], and not (**3**) which would be formed by proton abstraction by the base [3]. It is known (1) that cleavage of α-cyanostilbenes can occur in basic media in the presence of labile hydrogens. Although the systems used were, as far as possible, anhydrous, in view of the general arguments used concerning the nuclear magnetic resonance (n.m.r.) data, consideration must be given to the possible occurrence of reaction [4] forming the anion of 4-nitrophenylacetonitrile.

Results and Discussion

The present investigation was of the intermediate formed by the attack of various nucleophiles on a series of α-cyano-4′-X-stilbenes. The substitution in the 4-position was purely for simplification of the n.m.r. spectra. For comparison, the anion of 4-nitrophenylacetonitrile was investigated under the same experimental conditions.

The n.m.r. spectra of the products of reactions corresponding to [2]–[4] would be expected to be quite different and diagnostic. Thus one would expect the product (**2**) to have an n.m.r.

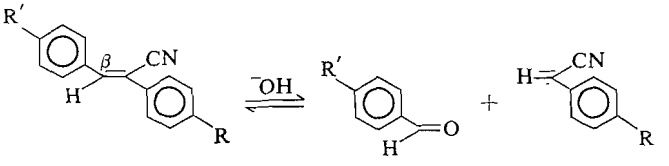
[4]



spectrum consisting of a 'normal' aromatic spectrum for the β-phenyl ring and a spectrum closely corresponding to the spectrum of the anion of 4-nitrophenylacetonitrile for the α-phenyl ring, but showing some variation with both nucleophile and substituents. There should be a large change in the chemical shift of Hβ from an alkene hydrogen at low field to an sp^3 hydrogen at higher field, whose chemical shift would be dependent on the nature of the nucleophile.

The spectra produced by reaction [4] would be similar to those from reaction [2], but in this case the complete spectrum should be *independent* of the nature of the nucleophile. Thus the α-phenyl ring should show exactly the spectrum of the anion of 4-nitrophenylacetonitrile with the methylene hydrogen at high field, and the β-phenyl ring the spectrum of 4-X-benyaldehyde, with the aldehydic proton at low fields and again independent of nucleophile.

The spectrum of compound (**3**) would be quite different, a critical feature being the complete lack of an absorption corresponding to the abstracted alkene proton Hβ.

The experimental results for the different systems are quite diagnostic and are discussed individually.

Section I: The Anion of 4-Nitrophenylacetonitrile

(a) By the Action of Anhydrous Sodium Methoxide in DMSO Solution

The addition of less than one equivalent of anhydrous sodium methoxide to a solution of 4-nitrophenylacetonitrile in DMSO causes the appearance of two new multiplets at higher fields, centered at $\delta = -7.39$ (relative intensity 2) and $\delta = -6.27$ (relative intensity 2), and a sharp singlet at $\delta = -3.95$ (relative intensity 1). These resonances can be assigned to the anion. The spectrum of the unreacted substrate is present simultaneously, indicating that under these conditions there is no significant anion–substrate exchange. However, in contrast to the spectrum of the ion which is quite sharp, that of the substrate is very broad and shows no fine structure whatsoever. This broadening is due to exchange with radicals produced in the system (the solutions show intense electron spin resonance absorptions[3]), but since there is no anion–substrate exchange, they do not affect the spectrum of the anion.

Addition of further quantities of methoxide

[3]The nature and reactions of these, and related radicals are at present under investigation.

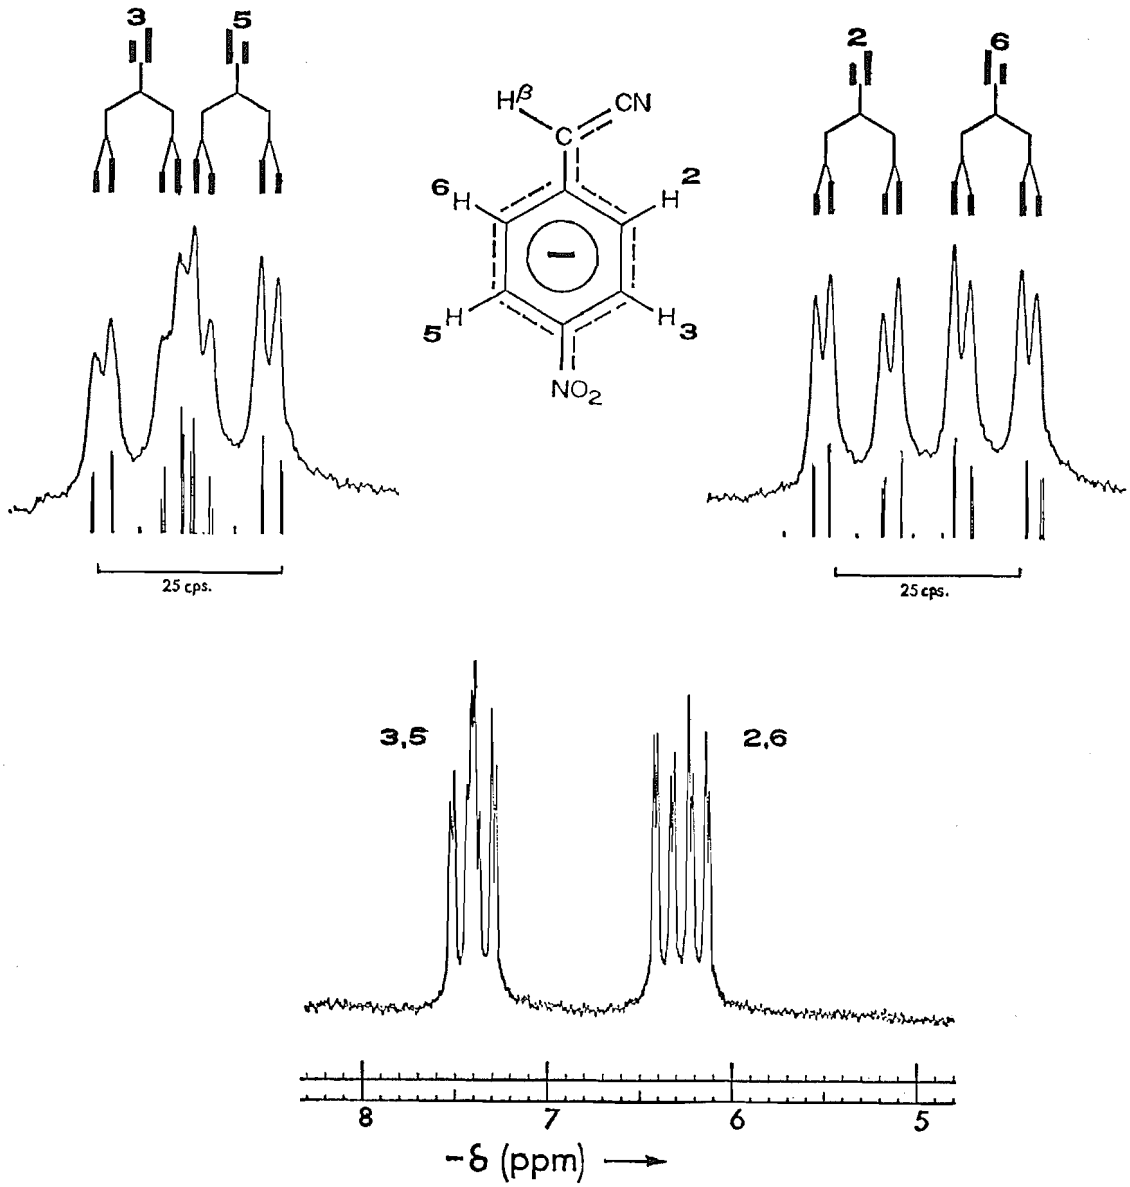

FIG. 1. The 100 MHz nuclear magnetic resonance spectrum of ring hydrogen resonances of 4-nitrophenylacetonitrile anion in DMSO solution with (inset) expended spectra of the multiplets and calculated spectra based on parameters given in the text.

increases the resonances of the ion and decreases those of the substrate until the spectrum shown in Fig. 1 is obtained. The major splittings in this spectrum are similar to those in the 100 MHz spectrum in 70% DMSO/30% MeOH solution recently observed by Crampton (7). The spectrum can be interpreted as an ABXY spectrum with $J_{2,3} = J_{5,6} = 9.0$ Hz, $J_{2,5} = J_{3,6} = 0.0$ Hz, $J_{2,6} = 2.3$ Hz, $J_{3,5} = 2.6$ Hz, $\nu_0\delta$ 3,5 = 13.0 Hz, and $\nu_0\delta$ 2,6 = 19.0 Hz, as shown in Fig. 1. The non-equivalence within the two pairs of ring protons is due (7) to restricted rotation about the (phenyl—carbon) bond. Similar conclusions have been drawn from the spectrum of the

anion of *N*-methylpicramide (8, 9). Although a reasonable assignment can be made on a first-order basis as shown in Fig. 1, the calculated spectrum shows that in fact that situation is more complex. Second-order effects will become more important in cases where the chemical shift differences within the AB and XY multiplets become smaller.

The non-observation by Crampton (7) of the smaller 2,6 and 3,5 couplings may be due to a small amount of anion–substrate exchange under the conditions of his experiment as this system contains 30% MeOH. There is no evidence for any exchange of this type under the conditions of the present experiments. There is, however, exchange between the substrate and anion radicals produced in the system, as evidenced by the extreme broadening of the spectrum of unreacted 4-nitrophenylacetonitrile. In general, this exchange reaction will greatly simplify spectra of ions produced under these conditions by effectively removing the spectrum of any unreacted aromatic material.

The observation of the n.m.r. spectra of ions in general will only be evidence for the absence of radicals where it can also be shown that ion substrate exchange exists.

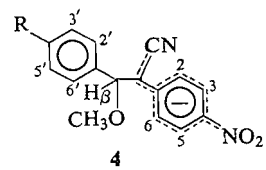
(b) By the Action of Anhydrous Sodium Methoxide in Acetone Solutions

The addition of anhydrous sodium methoxide to an acetone solution of 4-nitrophenylacetonitrile did not give rise to an n.m.r. spectrum corresponding to that observed in the previous section, although some coloration was produced. The anion was, however, produced by the addition of anhydrous sodium methoxide to a solution of 4-nitrophenylacetonitrile in a solvent system of 80% acetone – 20% DMSO. The spectrum was similar to that in Fig. 1, but showed minor changes with the change in solvent. The two multiplets were centered at $\delta = -6.25$ p.p.m. and $\delta = -7.37$ p.p.m. with $J_{2,3} = J_{5,6} = 8.9$ Hz, $J_{2,5} = J_{3,6} = 0.0$ Hz, $J_{2,6} = 2.1$ Hz, $J_{3,5} = 2.5$ Hz, $V_{o\delta}$ 2,6 = 23.5 Hz, $V_{o\delta}$ 3,5 = 13.5 Hz. Again there was pronounced broadening of the spectrum of the substrate, due to the presence of radicals.

Section II: Intermediates Produced by the Action of Bases on α-Cyano-4-nitro-4′-methoxystilbene

(a) By Addition of Methoxide Ion

The addition of anhydrous sodium methoxide to a DMSO solution of the above stilbene gives an intense violet-pink coloration (λ_{max} 550 mμ) and causes the broadening and eventual disappearance of the spectrum of the stilbene and the appearance of a new spectrum at higher fields (Fig. 2). The new spectrum consists of an AA′XX′ pattern centered at $\delta = -6.95$ (relative intensity 4), two multiplets centered at $\delta = -7.34$ (doublet, relative intensity 2), and $\delta = -6.38$ (approximately a triplet with further splitting, relative intensity 2), and a sharp singlet at $\delta = -5.01$ (relative intensity 1). The spectrum is consistent with the formation of the intermediate (**4**), R = OCH_3, as shown in Fig. 2.



4

It is inconsistent with the occurrence of either reactions [3] or [4]. Thus the AA′XX′ pattern can be assigned to the four hydrogens on the β-phenyl ring and the singlet at $\delta = -5.01$ to the Hβ proton. The shifts of other two multiplets correspond very closely to those observed for the ring hydrogens of 4-nitrophenylacetonitrile anion, although the multiplet structures are different, and can be assigned to the four hydrogens of the α-phenyl ring. That these do not form a simple AA′XX′ system suggests that, as in the case of the 4-nitrophenylacetonitrile anion, there is restricted rotation around the α-phenyl—Cα bond, the complexity of the resonance at $\delta = -6.38$ arising because $J_{2,3} = V_{o\delta}$ 2,6. This, and the very large changes in the chemical shifts of the α-phenyl resonances suggest very substantial delocalization of the negative charge into the α-phenyl ring, so that the complex is probably more properly formulated as in (**4**), rather than with the negative charge localized on the α-carbon atom as is usually done. This is thought to be the case for all the compounds studied. Such a delocalization would be favored by a planar rather than a tetrahedral configuration at the α-carbon atom, and it is possible that this is the case for stilbenes with very electronegative groups in the 4-position.

The sharpness of the Hβ resonance would suggest that there is free rotation round the Cα—Cβ bond, as required for such intermediates

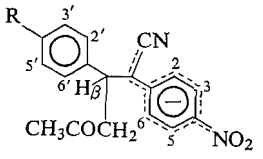
to take part in the *cis–trans* isomerization of alkenes (11).[4]

The solutions are quite stable for several days.

(b) By Addition of Acetone Anion

The addition of anhydrous sodium methoxide to a solution of α-cyano-4-nitro-4′-methoxystilbene in acetone gives rise to an intense coloration (λ_{max} 543 mμ, 576 mμ) and causes the broadening and disappearance of the stilbene spectrum and the appearance of a new spectrum at high fields (Fig. 3). This is similar in general appearance to that in Section II*a*, but different in several significant respects. The spectrum can be rationalized in terms of the intermediate (**5**) R = OCH_3 as shown in Fig. 3. The postulated addition of the acetone anion to the stilbene double bond may not be by direct attack, but by solvolysis of the methoxy adduct (**4**) R = OCH_3. An identical spectrum can be obtained by the addition of acetone to a DMSO solution of (**4**) R = OCH_3.

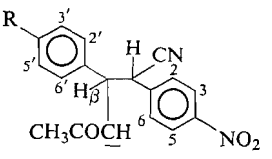


5

The spectrum is again inconsistent with the occurence of reactions [3] or [4]. The AA′XX′ spectrum of the β-phenyl ring is centered at δ = −6.87 and the multiplets corresponding to H_2, H_6 and H_3, H_5 occur at δ = −6.47 "triplet" (relative intensity 2) and δ = −7.35 "doublet" (relative intensity 2). The shift values of the α-phenyl ring hydrogens are very similar to those observed for the anion of 4-nitrophenylacetonitrile although the multiplet structures are again different. The complexity of the multiplets indicate restricted rotation about the α-phenyl—Cα bond, and a structure close to that of the methoxy adduct. That they are not exactly the same as those of the methoxy adduct is evidence against the occurrence of reaction [4].

The absorption at δ = −4.17 assigned to Hβ is now a triplet (relative intensity 1, J = 3.7 Hz), due to coupling with the two methylene hydrogens of the acetone moiety. Generation of the adduct in acetone-d_6 causes this resonance to collapse to a broad singlet (Fig. 3, inset), confirming the assignment of Hβ. In structures of type (**5**), Cβ is an asymmetric carbon atom and, in principle, Hβ could give a more complicated absorption than the simple triplet observed due to the effect of the asymmetric center on the methylene protons. The complete assignment of the spectrum is given in Table II.

The spectrum is unchanged over several days. In particular, there is no change in the triplet splitting of Hβ. It has been suggested (10) that adducts formed by nucleophiles with active methylene groups may undergo an isomerization involving hydrogen transfer, to form a carbanion with the nucleophile to give, in this case, compound (**6**) R = OCH_3. This would be expected to have quite a different n.m.r. spectrum from (**5**) R = OCH_3. The lack of change in the spectrum observed here suggests that there is no fast conversion of (**5**) into (**6**) to any appreciable extent.



6

Section III: Intermediates Produced by the Action of the Bases on α-Cyano-4-nitro-4′-methylstilbene

(a) Addition of Methoxide Ion

Treatment of a DMSO solution of α-cyano-4-nitro-4-methylstilbene with methoxide causes similar changes in the u.v. and n.m.r. spectra to those described in the previous section. The n.m.r. spectrum is in accordance with the formation of (**4**), R = CH_3 as indicated in Fig. 4. Although this spectrum is similar in general appearance to that observed in Section II*a* (Fig. 2), there are significant differences, especially in the resonances ascribed to the α-phenyl ring hydrogens (inset). These differences argue strongly that an intermediate is being formed in each case, and eliminate further the possibility of breaking of the Cα—Cβ bond via reaction [4].

[4]This observation is also consistent with either the Hβ proton resonances having identical chemical shifts in the different conformers or the system being entirely in one fixed conformation, but these are considered less likely as they would have to be the case for all the compounds studied.

*NOTE: The data is presented in this way because it is felt that, in general, in a system of this complexity, no one assignment can be regarded as entirely unambiguous, and in these particular spectra, the ratio of observed peaks to possible transitions is so low that the presentation of absolute chemical shift values from the data would not be meaningful. However, calculated spectra from this data agree reasonably well with those observed experimentally both at 100 MHz (as shown inset in the figures) and also at 60 MHz, (although in these spectra the signal/noise ratio was much worse). None of the multiplets can be interpreted in terms of an AA′ XX′ spectrum. The errors given indicate the approximate variation in the parameters which still gives approximate agreement with the observed spectrum, all the other parameters being kept constant at the values in the Tables I and II.

For personal use only.

(b) Addition of Acetone Anion

Base addition to an acetone solution of the stilbene as in Section II*b* causes intense coloration (λ_{max} 543 mμ, 576 mμ) and the appearance of a new n.m.r. spectrum, ascribed to (**5**), R = CH_3 as shown in Fig. 5. The complete assignment is given in Table II. Again it is thought that the differences in the multiplets assigned to the α-phenyl ring hydrogens in Figs. 3 and 5 are evidence that the spectral changes are not caused by reaction [4].

Section IV: Intermediates formed by the Action of Bases on α-Cyano-4-nitro-4′-nitrostilbene

The addition of anhydrous methoxide to solutions of this stilbene in DMSO or acetone gives rise to spectra which can be assigned to (**4**), R = NO_2 (λ_{max} 555 mμ) and (**5**), R = NO_2 (λ_{max} 550 mμ, 510 mμ) respectively. The complete assignments of the n.m.r. spectra are given in Tables I and II. In the case of this particular stilbene, the assignment of the resonances of the two rings is made unambiguous by the broadening and gradual disappearance of the resonances of the β-phenyl ring while the rest of the spectrum is only slightly broadened.

These changes are probably due to the formation of anion radicals on the β-phenyl ring, which in this particular complex is very electronegative. Electron transfer exchange of this radical with the complex will cause the disappearance of the β-phenyl resonances but would affect the α-phenyl resonances only slightly as an extremely small electron density would be expected in this ring in the radical due to repulsion by the negative charge already localized there.

Section V: Intermediates Produced by the Action of Bases on cis- and trans-α-Cyano-4-nitrostilbene

An important test of the conclusions drawn in the previous sections, and one directly connected to the theory of base-catalyzed *cis–trans* isomerizations (1, 3, 4) is that, if the species observed here do have the proposed structures, then the same species should be formed from both *cis* and *trans* isomers, giving consequently identical n.m.r. spectra.

(a) Addition of Methoxide Ion

Addition of anhydrous sodium methoxide to a solution of either *cis*- or *trans*-α-cyano-4-nitrostilbene in DMSO, produces an intense coloration (λ_{max} 547 mμ) and a new n.m.r. spectrum at higher fields than those of either of the stilbenes. The two spectra are absolutely identical, and can be rationalized in terms of (**4**), R = H as indicated in Fig. 6*a*. The number of peaks resolved in this spectrum makes it unlikely that the correspondence in the two spectra is a fortuitous one, and the spectrum is considered good evidence that the same compound is being formed in both instances. The resonances ascribed to Hβ and the α-phenyl ring hydrogens correlate well with the results of previous sections (Table I).

(b) Addition of Acetone Anion

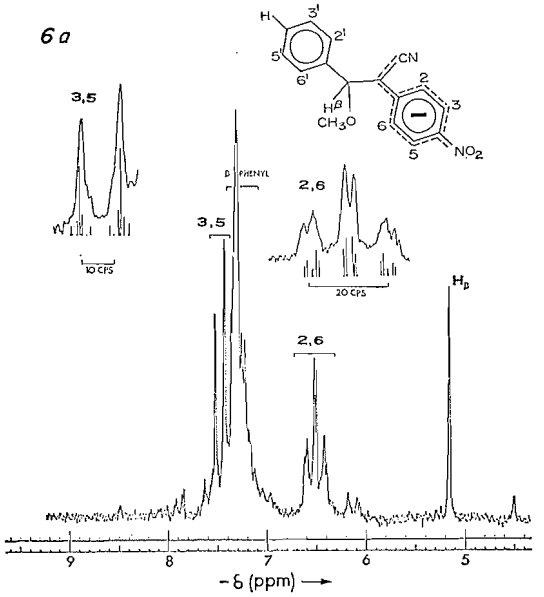
The addition of anhydrous sodium methoxide to a solution of either *cis*- or *trans*-α-cyano-4-nitrostilbene in acetone gives a bright pink-violet coloration (λ_{max} 542 mμ, 578 mμ) and again gives rise to identical spectra from both isomers. This spectrum is in agreement with the formation of (**5**) (R = H), in both cases as indicated in Fig. 6*b*. Again, it is thought that the resolution of the spectrum is sufficient to make a fortuitous agreement extremely unlikely.

In this spectrum, Hβ does not appear as a simple triplet, but shows a splitting of the center peak due to slightly different couplings (J_1 = 3.4 Hz, J_2 = 4.1 Hz) from the methylene hydrogens caused by the asymmetry at Cβ. The multiplet collapses to a broad singlet in acetone-d_6.

Although the observation of identical spectra from both isomers in these two cases does not constitute proof as to the nature of the complexes formed, it is *required* by the suggestion that these have the structures (**4**) and (**5**) and, if this is the case, has direct relevance to the theory of *cis–trans* isomerizations referred to earlier.

In general, the various aspects of the n.m.r. spectra produced by the attack of bases on the substituted stilbenes can all be interpreted in terms of the general structure corresponding to (**1**). If this interpretation is correct, then the results would suggest that the intermediates are quite stable compounds (at least in solution). The n.m.r. spectra reveal restricted rotation around the α-phenyl—Cα bond in all the complexes and delocalization of the negative charge into the α-phenyl ring, suggesting perhaps the favoring of a planar configuration at this carbon atom.

The above effects will, in general, be very



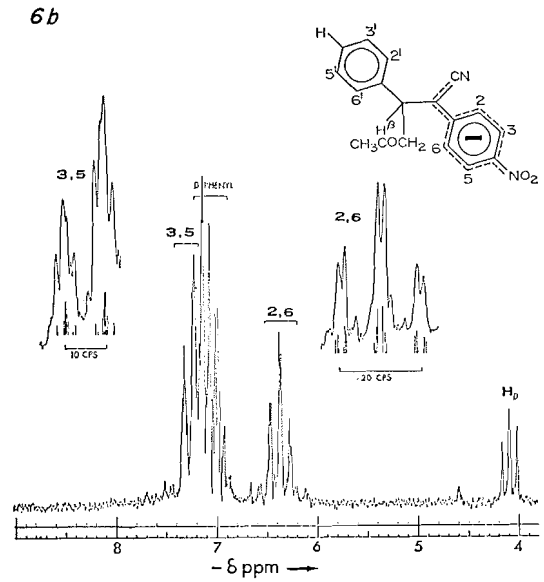


FIG. 6.(*a*) The 100 MHz nuclear magnetic resonance spectrum of a DMSO solution of *trans*-α-cyano-4-nitrostilbene after the addition of anhydrous sodium methoxide (the *cis* isomer gives an identical spectrum).

FIG. 6.(*b*) The 100 MHz nuclear magnetic resonance spectrum of an acetone solution of *cis*-α-cyano-4-nitrostilbene after the addition of anhydrous sodium methoxide (the *trans* isomer gives an identical spectrum).

dependent on the nature and position of substituents in the α-phenyl ring, but it is thought that the results obtained from these more activated substrates may be of general applicability.

Experimental

The n.m.r. spectra were recorded at 60 MHz on a Varian A60 spectrometer and at 100 MHz on a Varian HA100 spectrometer. Theoretical spectra were calculated using a copy of the n.m.r. program "TWOSUM" originally written by Dr. J. Martin which was available in this department. The program was used in its non-itterative mode. The u.v. spectra were measured on a Beckman S.P. 800 spectrophotometer.

The chemicals used were either from commercial sources or prepared by literature methods, and on purification gave melting points in agreement with published values: *p*-nitrophenylacetonitrile was a purified sample supplied by Eastman–Kodak, α-cyano-4-nitro-4′-methoxystilbene and α-cyano-4-nitro-4′-methylstilbene were generous gifts from Dr. R. Stewart (U.B.C.). The other stilbenes were prepared by the methods indicated: α-cyano-4-nitro-4′-nitrostilbene (11), *trans*-α-cyano-4-nitrostilbene (12), *cis*-α-cyano-4-nitrostilbene (13). Anhydrous grade DMSO supplied by Matheson, Coleman and Bell was distilled from calcium hydride and stored over Linde 5A molecular sieve.

Acknowledgments

The author would like to acknowledge the help given by Miss P. A. Watson in the measurement of the 60 MHz n.m.r. spectra; and Drs. R. Foster, L. D. Hall, and R. Stewart for helpful advice and discussion; also the help given by Professor C. A. McDowell during this work; the Department of Chemistry for the provision of facilities; and the University of British Columbia for the award of a Killam Postdoctoral Fellowship.

Synthesis of acetylenic diols

SHOJI WATANABE, KYOICHI SUGA, AND TOSHIMITSU SUZUKI
Department of Applied Chemistry, Faculty of Engineering, Chiba University, Yayoicho, Chiba, Japan

Received February 6, 1969

Lithium naphthalene reacts with acetylenic carbinol, such as 3-methyl-1-butyn-3-ol or propargyl alcohol, to give the corresponding dilithio compounds. The reaction of these dilithio compounds with various ketones gives the corresponding acetylenic diols in good yield. By the new convenient one-step procedure for chain-lengthening, various acetylenic diols can be prepared from two kinds of ketones and acetylene using lithium naphthalene.

Canadian Journal of Chemistry, 47, 2343 (1969)

Synthesis of acetylenic diols is achieved by the interaction of acetylenic Grignard reagents or lithium derivatives of acetylenic compounds with carbonyl compounds: for example, 1-(1′-hydroxylcyclohexan-1′-yl)-3-methyl-1-pentyn-3-ol (**5**) can be prepared by the action of the dimagnesium bromide of ethynylcyclohexanol (**2**) with methyl ethyl ketone (**4**). When cyclohexanone (**1**) is used as the starting material, two reactions, namely the ethynylation of **1** and the Grignard reaction of **2** with **4**, are necessary for the preparation of **5**.

Recently, it was reported by us that lithium naphthalene in tetrahydrofuran solution is an excellent agent for the oligomerization of conjugated dienes (1–2). The previous paper indicated that α,β-unsaturated ketones react with various alkylacetylenes in the presence of lithium naphthalene in a tetrahydrofuran solution (3). This article concerns new convenient procedures for the preparation of acetylenic diols using lithium naphthalene under mild conditions. The authors have now found two such procedures for the preparation of long-chain acetylenic diols.

Thus, one mole of compound **2** was dropped very slowly into a solution of lithium naphthalene (two moles of lithium) and this underwent reaction for several hours to give the dilithio derivatives (**3**) of compound **2**. One mole of **4** was added to this solution and an acetylenic diol (**5**) was obtained in 60% yield. The composition ($C_{12}H_{20}O_2$) was confirmed by an elementary analysis. The infrared (i.r.) absorption spectrum showed characteristic bands of the tertiary alcohol group at 3440 and 1060 cm^{-1}. The absorptions of a terminal ethynyl group at 3320 and 2120 cm^{-1} disappeared. The nuclear magnetic resonance (n.m.r.) spectrum showed the signals of methyl protons ($-CH_2-CH_3$) at 1.02 p.p.m., methyl protons of $-\overset{\displaystyle CH_3}{\underset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}}-$ at 1.45 p.p.m., methylene protons at 1.2–1.9 p.p.m., and hydroxyl protons at 2.18 p.p.m. These results indicated that this diol (**5**) was 1-(1′-hydroxylcyclohexane-1′-yl)-3-methyl-1-pentyn-3-ol. Similarly, various

*Acetylene was passed into a solution of metallating agent (I). The resulting solution of ethynylcyclohexanol was metallated with metallating agent (II).

acetylenic diols were obtained from other acetylenic carbinols and various ketones. The addition products and their properties are given in Table I.

Various organic reactions for carbon chain-lengthening method are known. We have found that a new convenient one-step procedure for chain-lengthening can be carried out by the action of lithium naphthalene in tetrahydrofuran solution. For example, compound **5** can also be synthesized as follows: to lithium acetylide prepared from acetylene and lithium naphthalene (one mole of lithium), one mole of **1** was added to give the mono lithio salt of **2**. Without decomposition of this mixture, one mole of metallic lithium was added continuously, and interestingly, the metallic lithium cuts dissolved easily in this solution to give the dilithio compound (**3**). One mole of methyl ethyl ketone (**4**) was added to the resulting solution and the compound **5** was obtained in 50–60% yield. The identity of **5** was confirmed by comparison of the i.r. and n.m.r. spectra with those of an authentic sample. If the usual synthetic method is employed to prepare a long-chain diol such as **5**, at least two reactions are necessary. By our new one-step synthetic method, the preparation of long-chain diols can be performed easily and in high yield. Similarly, from the other ketones and acetylene, high conversions of acetylenic diols can be achieved by this new method. The addition products and their properties are given in Table II.

In our new one-step synthetic method, the effect of metallating agents has been examined, and typical results are presented in Table III. Sodium naphthalene and alkyl magnesium bromide both resulted in the formation of an acetylenic diol in low yield. Combination of lithium naphthalene and other metallating agents did not give a good result. The use of lithium naphthalene gave the optimum yield.

The foregoing observations indicate that long-chain acetylenic diols can be prepared easily by using lithium naphthalene in tetrahydrofuran solution.

Experimental

Materials

Commercial tetrahydrofuran was purified by drying it with metallic sodium and then distilling it over metallic sodium under nitrogen. Naphthalene and other reagents were purified. Nitrogen and acetylene were dried by passing them through columns of calcium chloride. All the experiments were carried out in a dry apparatus under nitrogen.

Reaction of Ethynylcyclohexanol with Methyl Ethyl Ketone

To a mixture of 5.2 g (0.04 mole) of naphthalene and 150 ml of tetrahydrofuran, 0.6 g (0.08 mole) of metallic lithium was added, and the mixture was agitated at room temperature in an atmosphere of dry nitrogen. After 1 h, a mixture of 5.0 g (0.04 mole) of ethynylcyclohexanol (**2**) and 10 ml of tetrahydrofuran was added very slowly to give the dilithio compound **3**. When the mixture was added rapidly, the lithium naphthalene complex tended to be destroyed. To the tetrahydrofuran solution, 2.9 g (0.04 mole) of methyl ethyl ketone (**4**) were gradually added, and the mixture was stirred for an additional 3 h at room temperature. The reaction mixture was decomposed with saturated ammonium chloride solution, and the organic layer was isolated with isopropyl ether. The isopropyl ether extracts were washed with water and dried over anhydrous sodium sulfate. After low boiling fractions were removed by vacuum distillation, the residue was distilled with a pot type molecular distillation still to give 4.5 g of a pale-yellow viscous oil (**5**). It had the following properties: b.p. 100–120° at 10^{-3} Torr; infrared (i.r.): 3440 and 1060 cm^{-1} (OH); nuclear magnetic

resonance (n.m.r.) (δ, p.p.m.): 1.02 (3 H, triplet, —CH_2—CH_3), 1.45 (3 H, singlet, HO—C(—CH_3)—), 1.9–1.2 (12 H multiplet, —CH_2—), 2.18 (2 H, singlet, —O*H*).

Anal. Calcd. for $C_{12}H_{20}O_2$: C, 73.5; H, 10.2. Found: C, 73.2; H, 10.1.

The identity of **5** was confirmed by comparison of the i.r. and n.m.r. spectra with those of an authentic sample. Authentic **5** was prepared from the dimagnesium bromide of compound **2** with compound **4** in the usual way.

Other acetylenic diols were prepared and identified similarly. Typical results are presented in Table I.

Synthesis of Acetylenic Diols by New One-step Method

Reaction of Acetylene with Cyclohexanone and Methyl Ethyl Ketone

Purified dry acetylene was slowly passed into a tetrahydrofuran solution (150 ml) of 0.1 mole of lithium and 0.1 mole of naphthalene to give lithium acetylide quantitatively. Cyclohexanone (0.1 mole) was gradually added to the tetrahydrofuran solution, and the mixture was stirred for an additional 2 h at room temperature. Without decomposition of this mixture, 0.1 mole of metallic lithium was added continuously. The metallic lithium dissolved slowly in the solution producing green lithium naphthalene. After 1 h, 0.1 mole of methyl ethyl ketone was added, and the tetrahydrofuran solution was stirred for an additional 2 h at room temperature. The reaction mixture was decomposed with saturated ammonium chloride solution, and the organic layer was extracted with isopropyl ether. The isopropyl ether solution was treated as usual. After low boiling fractions were removed by vacuum distillation, the residue (10 g) was distilled with a molecular distillation still to give 7.5 g of a pale-yellow oil (**5**), b.p. 100–120 °C at 10^{-3} Torr. The identity of **5** was confirmed by comparison of spectral data with those of an authentic sample.

Other acetylenic diols were prepared and identified similarly. Typical results are presented in Table II.

Reaction of Acetylene with Cyclohexanone and Methyl Ethyl Ketone Using Other Metallating Agents

Acetylene was passed slowly into a tetrahydrofuran solution of sodium naphthalene, which had been prepared from 0.1 mole of naphthalene and 0.1 mole of sodium cuts. Cyclohexanone (0.1 mole) was added to the solution. After 1 h, 0.1 mole metallic sodium was added as the second metallating agent. After 3 h, 0.1 mole of methyl ethyl ketone was added, and the reaction mixture was treated in the usual way to give compound **5**. As the second metallated agent, metallic lithium, *n*-butylmagnesium bromide or ethylmagnesium bromide were used as mentioned above. The identity of **5** was confirmed by comparison of the i.r. absorption spectra with those of an authentic sample. Typical results are given in Table III.

Infrared Absorption Spectra

Spectra were measured on a Koken IRS spectrophotometer.

Nuclear Magnetic Resonance Spectra

Spectra were determined on a Japan Electron Optics Lab. instrument (60 Mc.p.s.) with carbon tetrachloride solutions and with tetramethylsilane as an internal standard.

Sur les *tert*-butyl-4 triméthyl-1,2,2 cyclohexanols epimères

JEAN-CLAUDE RICHER ET CLAUDE LAMARRE
Département de Chimie, Université de Montréal, Boite Postale 6128, Montréal, Québec

Reçu le 1 octobre 1968

La stéréochimie des alcools tertiaires isomères formés par addition de l'iodure de méthylmagnésium sur la *tert*-butyl-4 diméthyl-2,2 cyclohexanone est déterminée. La transformation des acétates de ces alcools en *tert*-butyl-4 diméthyl-2,2 méthylènecyclohexane et en *tert*-butyl-4 triméthyl-1,6,6 cyclohexène a été effectuée. La stéréochimie de l'époxydation de ces alcènes a aussi été établie.

Canadian Journal of Chemistry, 47, 2349 (1969)

Introduction

Dans le cadre de nos travaux (1–4) sur la stéréochimie des produits dérivés de la *tert*-butyl-4 diméthyl-2,2 cyclohexanone (**1***b*), il nous apparaissait intéressant d'établir la stéréochimie de l'addition de l'iodure de méthylmagnésium sur cette cétone, et d'en comparer les résultats avec ceux obtenus (5–7) dans une réaction semblable sur la *tert*-butyl-4 cyclohexanone non substituée (**1***a*) afin d'évaluer l'influence des groupes méthyles en position-2 sur la stéréochimie de cette addition. Les résultats obtenus au cours de cette étude font l'objet de la présente communication.

Résultats et discussion

L'addition de l'iodure de méthylmagnésium sur la *tert*-butyl-4 diméthyl-2,2 cyclohexanone (**1***b*) effectuée d'après la procédure expérimentale décrite précédemment (5) conduit à un mélange d'alcools tertiaires **2***b* et **3***b* qui a été analysé par chromatographie en phase gazeuse (c.p.g.), et qui serait formé de 40% de *tert*-butyl-4 triméthyl-1,2,2 cyclohexanol *cis*[1] et 60% de l'isomère *trans*. Ce mélange d'alcools tertiaires a pu être transformé en acétates correspondants (**2***c* et **3***c*) selon la technique habituelle (8); l'analyse par c.p.g. effectuée sur ces dérivés confirme le résultat analytique précédent puisque les acétates seraient présents dans le mélange réactionnel dans la proportion de 39% de l'acétate du *tert*-butyl-4 triméthyl-1,2,2 cyclohexanol *cis* (**2***c*) et de 61% de l'isomère *trans* (**3***c*). Alors que la réaction de Grignard décrite dans le présent travail conduit à la formation prépondérante de l'alcool *trans* **3***b*, il est maintenant bien établi (6–9) que la même réaction effectuée sur la *tert*-butyl-4 cyclohexanone (**1***a*) conduit à la formation préférentielle de l'alcool *cis* **2***a*; cette différence serait dûe à l'influence du groupe méthyle axial en position-2 (3) qui provoque une attaque du réactif nucléophile par la face opposée de la molécule.

La stéréochimie de ces alcools qui peut être présumée d'après les quantités relatives formées au cours de cette réaction de Grignard (3) est attribuée en se basant sur les temps relatifs de rétention de ces alcools en c.p.g. (2, 9) et grâce à la position dans la résonance magnétique nucléaire (r.m.n.) des pics dus aux protons des groupes OH par comparaison avec les résultats rapportés récemment par Meakins *et al.* (9). Il est à noter aussi que, conformément aux observations de Laszlo et Welvart,[2] la largeur ($w_{1/2}$) de cette bande est plus grande pour l'isomère *cis* que pour l'isomère *trans*. D'autre part, Corey et Chaykovsky (10) ont démontré que le traitement de la *tert*-butyl-4 cyclohexanone (**1***a*) par l'ylide (**6**) conduit à l'époxyde *cis* (**4***a*); appliquée à la *tert*-butyl-4 diméthyl-2,2 cyclohexanone (**1***b*) cette méthode conduit à un mélange 84/16 d'époxydes (**4***b*/**5***b*) qui par réduction avec $LiAlH_4$ conduit à un mélange 88/12 des alcools tertiaires **2***b* et **3***b*. Par comparaison de ces résultats avec ceux obtenus par Corey et Chaykosvky, il est possible d'attribuer la configuration *cis* à l'époxyde formé d'une façon prépondérante, et cette conclusion basée sur une réaction chimique est en accord avec les configurations assignées précédemment en se basant sur des méthodes physiques.

Pour fins de comparaison, la stéréochimie de

[1]La notation *cis* ou *trans* pour les alcools tertiaires se rapporte à la position relative des groupes *tert*-butyles et hydroxyles.

8 + 	79	55 (13)

introduite en position axiale. Ces résultats sont en accord avec ceux rapportés précédemment (2) pour la réduction de la *tert*-butyl-4 diméthyl-2,2 cyclohexanone (**1***b*) et supportent la théorie complètement stérique proposée (3) pour expliquer la stéréochimie des additions (non réversibles) sur des carbones du type sp^2 contenus dans des cycles.

Au cours du présent travail, il a été observé que la chromatographie sur alumine, en présence de pentane, des acétates **2***c* et **3***c* des *tert*-butyl-4 triméthyl-1,2,2 cyclohexanols provoque une élimination d'acide acétique et la formation soit exclusive du *tert*-butyl-4 triméthyl-1,6,6 cyclohexène (**8***b*) à partir de l'acétate *cis* **2***c* soit d'un mélange 72/28 des alcènes **8***b*/**7***b* en partant de l'acétate **3***c*. Cette réaction inusitée pourrait être attribuée à l'encombrement stérique présent dans les acétates **2***c* et **3***c* qui serait provoqué par la présence de quatre substituants en positions-1 et -2 de ces cyclohexanes. Le fait qu'un des acétates conduise à une seule oléfine alors que l'autre conduit à un mélange suggère que les alcènes ne sont pas équilibrés dans les conditions de la réaction.

Partie expérimentale

Les techniques expérimentales générales ont été décrites dans les publications précédentes (1). Les propriétés physiques des produits obtenus au cours de cette étude sont résumées dans le Tableau II. Les époxydes tant endocycliques (**9***b*) qu'exocycliques (**4***b* et **5***b*) n'ont pu être obtenus stéréochimiquement purs; les propriétés

rapportées doivent donc être jugées pour les compositions mentionnées. Tous les pourcentages relatifs d'épimères qui sont rapportés ont été déterminés en faisant l'hypothèse (15) que dans le cas de composés épimères les surfaces relatives sous les pics peuvent être assimilées aux pourcentages relatifs de produits présents.

Synthèse de la tert-butyl-4 diméthyl-2,2 cyclohexanone (1b)

(Réf. 2)

Synthèse du tert-butyl-4 diméthyl-2,2 méthylène-1 cyclohexane (7b)

A 330 g de bromure de méthyl-triphénylphosphonium dans 1 l d'éther anhydre, on ajoute sous atmosphère d'azote, 64 g de butyl lithium en solution dans l'hexane. Après l'addition, l'agitation est maintenue pendant 2 h. La solution devient jaunâtre. A cette solution de méthylène triphénylphosphine, 55 g de cétone (**1***b*) en solution dans 200 ml d'éther anhydre sont ajoutés goutte à goutte. L'addition se fait sur une période de 2 h et l'agitation est maintenue pendant 1 h supplémentaire à la température de la pièce. La solution est portée à reflux 2 h. L'éther est déplacé par distillation et 1 l de tétrahydrofurane est ajouté pendant cette distillation. Le mélange réactionnel est ensuite porté à reflux 13 h. Après refroidissement et agitation supplémentaire de 3 h, 1 l d'eau y est ajouté. Le méthylène (**7***b*) est extrait par l'éther, la phase organique est lavée à l'eau saturée de chlorure de sodium, séchée sur sulfate de sodium anhydre, et évaporée sous vide. Le résidu est filtré sur alumine (activité I) en employant l'éther de pétrole 30–60 °C comme éluant. Le méthylène est obtenu avec un rendement de 81% (45.0 g).

tert-Butyl-4 triméthyl-1,2,2 cyclohexanols-1 cis et trans (2b et 3b)

Une solution de 25.3 g de cétone (**1***b*) dans 50 ml d'éther anhydre est traitée à 0 °C par de l'iodure de méthyl magnésium (préparé à partir de 5.0 g de magnésium et de 13 ml d'iodure de méthyle dans 160 ml d'éther anhydre), à la façon habituelle. Le mélange d'alcools est obtenu avec un rendement de 87% (24.0 g). Ce mélange d'alcools (9.3 g) est mis en solution dans 100 ml d'hexane et chromatographié sur 500 g d'alumine Merck. Le diamètre de la colonne est de 50 mm. L'élution de la colonne, en augmentant la polarité de l'hexane pur à de l'éther pur (variation de la concentration de 10% tous les 100 ml d'éluant) ne conduit à aucun produit. Avec de l'éther pur il est récupéré : 1°—1.6 g d'alcool *cis* **2***b* contaminé par des traces de cétone **1***b* de départ. 2°—3.2 g d'un mélange d'alcools *cis* et *trans* **2***b* et **3***b*; 3°—4.3 g d'alcool *trans* pur.

Synthèse de l'acétate du tert-butyl-4 triméthyl-1,2,2 cyclohexanol-1 cis (2c)

En suivant le mode opératoire de DePuy et King (8), 512 mg de *tert*-butyl-4 triméthyl-1,2,2 cyclohexanol-1 *cis* (**2***b*) conduisent à 520 mg d'acétate (**2***c*), soit un rendement de 84%.

Synthèse de l'acétate du tert-butyl-4 triméthyl-1,2,2 cyclohexanol-1 trans (3c)

Selon le mode opératoire de DePuy et King (8), 410 mg de *tert*-butyl-4 triméthyl-1,2,2 cyclohexanol-1 *trans* (**3***b*) conduisent à 428 mg d'acétate (**3***c*), soit un rendement de 86%.

p-Nitrobenzoates des tert-butyl-4 triméthyl-1,2,2 cyclohexanol-1 cis et trans (2d et 3d)

Ils sont préparés selon Hennion et Barrett (16); *cis* : p.f 153–154 °C (EtOH). *trans* : p.f. 178–179 °C (EtOH).

Elimination d'acide acétique lors de la chromatographie des acétates cis et trans (2c et 3c) sur alumine

Essai sur l'acétate cis (2c)

Une solution de 155 mg d'acétate *cis* (**2***c*) dans 10 ml pentane est chromatographiée sur une colonne de 12 mm de diamètre contenant 19 g d'alumine Merck. L'élution par 250 ml de pentane donne 102 mg (88%) de *tert*-butyl-4 triméthyl-1,6,6 cyclohexène (**8***b*) identifié par superposition en c.p.g., infrarouge (i.r.), et r.m.n.

Essai sur l'acétate trans (3c)

Dans les conditions identiques décrites précédemment, 154 mg d'acétate *trans* (**3***c*) conduisent à 100 mg (86%) d'un mélange de 72% de *tert*-butyl-4 triméthyl-1,6,6 cyclohexène (**8***b*) et 28% de *tert*-butyl-4 diméthyl-2,2 méthylènecyclohexane (**7***b*). Les deux alcènes (**7***b* et **8***b*) sont identifiés par c.p.g., i.r., et r.m.n.

Essai sur un mélange d'acétates cis et trans (2c, 3c)

Dans les mêmes conditions décrites précédemment, 115 mg d'acétates *cis* et *trans* (**2***c* et **3***c*) donne 75 mg (87%) d'alcènes (**7***b* et **8***b*). L'analyse en c.p.g. montre que l'alcène (**8***b*) est présent à 83%, tandis que l'alcène (**7***b*) est à 17%.

Synthèse du tert-butyl-4 triméthyl-1,6,6 cyclohexène (8b)

Selon le mode opératoire décrit par Hammond et

Navitt (12), 4.58 g d'alcools *cis* et *trans* (**2***b* et **3***b*) chauffés en présence de 60 mg d'iode à 148 °C pendant 1 h et demie, conduisent à 3.28 g d'alcène **8***b* (78%).

Synthèse des époxydes cis et trans (4b et 5b)

Epoxydation de la tert-butyl-4 diméthyl-2,2 cyclohexanone (1b)

A 1.3 g d'hydrure de sodium (suspension 50%), recouvert de 15 ml de diméthyl sulfoxyde anhydre (distillé sur hydrure de calcium), on ajoute d'un coup 5.25 g d'iodure de triméthyl-oxosulfonium et 5 ml de diméthyl sulfoxyde. Après quelques instants, la solution devient grise et très visqueuse, alors 6 ml de diméthyl sulfoxyde y sont ajoutés de façon à avoir une agitation. Après 2 h d'agitation 1.83 g de cétone (**1***b*) en solution dans 5 ml de diméthyl sulfoxyde sont ajoutés goutte à goutte. Le mélange est ensuite agité pendant 22½ h sous une atmosphère d'azote. Le mélange réactionnel est ensuite chauffé à 65 °C pour 3 h, et ensuite l'agitation est maintenue 21 h à la température ambiante. La solution est hydrolysée par 20 ml d'eau et reprise par de l'éther. La phase éthérée est lavée par de l'eau jusqu'à neutralité, séchée sur sulfate de sodium anhydre, et évaporée. On obtient 1.1 g (54%) d'époxydes *cis* et *trans* (**4***b* et **5***b*), dans un rapport 84/16.

Des essais de séparation de ces époxydes par chromatographie en phase gazeuse préparative n'ont conduit qu'a des produits de décomposition et ont du être abandonnés.

Les configurations *cis*/*trans* ont été établies par réduction du mélange des époxydes en *tert*-butyl-4 triméthyl-1, 2,2 cyclohexanol-1 *cis* (**2***b*) et *trans* (**3***b*).

A une suspension agitée de 300 mg d'hydrure de lithium et d'aluminium dans 10 ml de tétrahydrofurane, on ajoute une solution de 200 mg du mélange des époxydes *cis* (**4***b*) et *trans* (**5***b*) dans 7 ml de tétrahydrofurane. Le mélange est chauffé à reflux pendant 20 h, puis le complexe est décomposé par l'addition à 0 °C de 25 ml d'une solution d'acide chlorhydrique à 10%. Le mélange d'alcool (193 mg de **2***b* et **3***b*) est extrait de la façon habituelle. L'analyse du produit brut par c.p.g. a donné 88% de l'alcool *cis* **2***b* et 12% de l'alcool *trans* **3***b*.

Expoxydation du tert-butyl-4 diméthyl-2,2 méthylène-1 cyclohexane (7b)

A 2.0 g de tert-butyl-4 diméthyl-2,2 méthylène-1 cyclohexane, on ajoute 30 ml d'une solution chloroformique (10 ml) et dichlorométhane (20 ml), d'acide para-nitro perbenzoique (préparé selon la réf. 17) contenant 4.0 g de peracide. Le mélange est refluë 1 h sous atmosphère d'azote et ensuite agité 16 h à la température de la pièce, la solution est filtrée, et le précipité est lavé par du dichlorométhane. Le filtrat est lavé par de l'eau et la phase aqueuse est reprise par de l'éther. Les phases chloroformique/dichlorométhane et éthérée sont réunies et lavées successivement par 200 ml d'une solution de sulfite acide de sodium 10%, par 300 ml d'hydroxyde de sodium 5% et par de l'eau jusqu'à neutralité puis séchées et évaporées. On obtient 1.65 g d'époxydes *cis* **4***b* (72%) et *trans* **5***b* (28%) avec une rendement de 76%.

Les configuration *cis–trans* ont été établies par réduction du mélange des époxydes en *tert*-butyl-4 triméthyl-1,2,2 cyclohexanol-1 *cis* (**2***b*) et *trans* (**3***b*).

Selon le mode opératoire décrit précédemment, 200 mg d'époxydes *cis* **4***b* et *trans* **5***b* sont réduits avec un rendement brut de 95% par 300 mg d'hydrure de lithium et d'aluminium. L'analyse par c.p.g. montre que l'alcool *cis* (**2***b*) forme 72% du mélange tandis que l'alcool *trans* (**3***b*) en forme 28%.

Epoxydes cis et trans du tert-butyl-4 triméthyl-1,6,6 cyclohexène (9b)

En suivant fidèlement le mode opératoire décrit précédemment on obtient en partant de 2.0 g de *tert*-butyl-4 triméthyl-1,6,6 cyclohexène (**8***b*), 1.15 g (52%) du mélange d'époxydes *cis* et *trans* (**9***b*). Les deux époxydes sont dans un rapport *cis*/*trans* (79/21). Les configurations *cis–trans* ont été établies par réduction du mélange des époxydes en alcools *cis* (**2***b*) et *trans* (**3***b*)[3]. Selon le mode opératoire décrit précédemment, 200 mg d'époxydes (**9***b*) sont réduits avec un rendement brut de 98% par 300 mg d'hydrure de lithium et d'aluminium. L'analyse par c.p.g. indique que les alcools *cis* (**2***b*) et *trans* (**3***b*) sont dans un rapport 78/22.

[3]Même s'il est possible d'envisager que la réduction par $LiAlH_4$ du mélange d'époxydes *cis* et *trans* (**9***b*) peut conduire à quatre alcools (dont deux secondaires et deux tertiaires), il est supposé (voir réf. 18) que ces réductions étant des processus S_N2 elles ne conduisent qu'aux alcools tertiaires provenant d'une attaque sur le carbone le moins substitué.

Base strengths of substituted 2- and 4-styrylpyridines in the ground and excited states

J. C. DOTY, J. L. R. WILLIAMS, AND P. J. GRISDALE
Research Laboratories, Eastman Kodak Company, Rochester, New York 14650

Received November 18, 1968

The base strengths of various 2- and 4-styrylpyridines in the ground state and first-excited-singlet state have been determined. The base strengths are found to conform to the Hammett equation if the proper σ values are chosen.

Canadian Journal of Chemistry, 47, 2355 (1969)

The base strengths (pK_a) of various 2- and 4-styrylpyridines (1) substituted in the 3′- or 4′-positions have been measured by the procedure described previously (2). The excited-state base strengths (pK_a^*) were calculated from the absorption spectra of the free bases and their conjugate acids (Table I) by the method employed by Jaffe, Jones, and Isaks (3) for the excited-state pK_a^* of azobenzene.

In the cases of mono-substituted azo and azoxybenzenes it was found that the best correlations were obtained when both the σ^+ and σ^- values for mesomerically electron donating and withdrawing groups respectively were used. This was attributed to the high polarity of the compounds. We have applied the same reasoning to the 2- and 4-styrylpyridine series.

In the present work it was impossible to use the measurements of fluorescent emission since the *cis* isomers do not fluoresce. Jaffe and Jones (4) have discussed the requirements and assumptions necessitated by the use of the absorption spectral data rather than fluorescent emission data in the Forster cycle. The results are listed in Tables II–IV.

The pK_a values obtained are in agreement with those found by Katritzky *et al.* (5) and Cauzzo *et al.* (6). A direct comparison cannot be made, however, since different solvent systems were used in each case.

The ground state (pK_a) and first-excited-singlet state (pK_a^*) values were first plotted versus the corresponding Hammett σ constants (7). It was found that the substituents which are able to participate in resonance with the large conjugated system did not fit on the line obtained. The pK_a values were then plotted by using the extreme σ values (Figs. 1–8) for the substituents capable of resonance participation. The substituents that

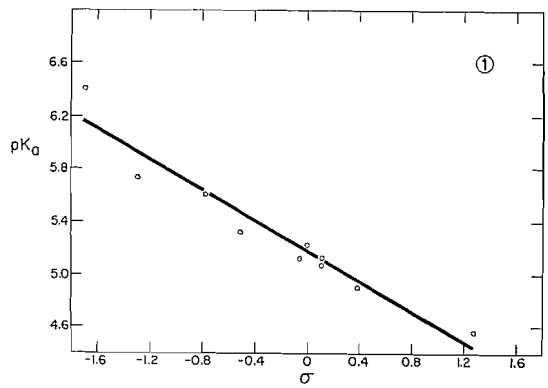

FIG. 1. pK_a Values of substituted *trans*-2-styrylpyridines vs. σ.

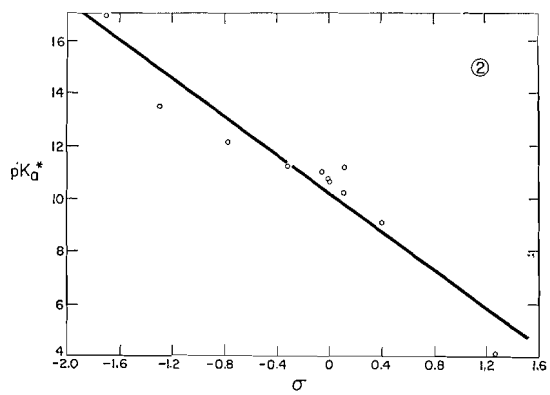

FIG. 2. pK_a^* Values of substituted *trans*-2-styrylpyridines vs. σ.

can donate electrons were represented by σ^+ (8) and those capable of withdrawing electrons were represented by σ^- (9). The equation of the straight line that best fit these points was calculated by the least-squares method. The ρ values

were found to be similar to those found for the azobenzenes (3). The equations and correlation coefficients (r) are listed in Table V.

The correlation coefficients found for these lines indicate that the Hammett equation can predict the effects of the influence of 3′- and 4′-substituents on the base strengths of the styrylpyridines. The correlation coefficient is low for the *cis* form of the 2-styrylpyridine in the ground state. The *cis*-2-styrylpyridine molecule is very similar to *cis*-stilbene and is nonplanar in the ground state (10). The nonplanarity reduces the amount of resonance interaction between the rings.

Since we are trying to correlate the effect of substitution in one ring with the base strength of the nitrogen in the second ring, it is not surprising that the results for *cis*-2-styrylpyridine are not accurately predicted by the Hammett equation.

However, in the excited state, the correlation coefficient for *cis*-2-styrylpyridine is quite good. This would suggest that the planarity of the molecule is much greater in the excited state than in the ground state and that greater interaction between the rings takes place.

The ρ value of the Hammett equation represents a measure of the sensitivity of the molecular system to substitution. The excited-state ρ values of the styrylpyridine systems are 8–10 times greater than those of the ground-state molecules. The greater effect of substituents on the excited-

state pK_a* can be rationalized in terms of the electron distribution in the conjugated system, the electron distribution of which must be very different in the excited state from that in the ground state, since a drastic increase in base strength of unsubstituted compounds occurs in the excited state. In the ground state, the pK_a's of the styrylpyridines are not very different from that of pyridine. This would indicate that the styryl group does not contribute much to the basicity. Since the absorption spectrum of the pyridinium ion is shifted slightly bathochromically compared to the free base, the excited-state pK_a* should be slightly lower. Since the styrylpyridines become much stronger bases in the excited state, a very significant contribution is made by the styryl part of the molecule. Substitutions on the phenyl ring would then also be expected to affect the basicity of the pyridine nitrogen more in the excited state.

The results of the measurement of the base strength of the substituted styrylpyridines in the ground state and the corresponding calculated base strengths of the first-excited-singlet state show that the substituent effects are those predicted by the Hammett equation in both electronic states.

Experimental

The physical constants of various *trans*-3′-substituted styrylpyridines are listed in Table VI. The general synthesis was described previously (1).

The absorption spectra at various values of pH showed very sharp isosbestic points indicative of isomerically pure compounds. All of the compounds investigated were sufficiently soluble in water at all pH values as indicated by the sharp isosbestic points. A typical set of absorption spectra at various pH values is shown in Fig. 9.

2,4,4-Trimethylpentenyl anions

D. H. HUNTER AND R. W. MAIR
Department of Chemistry, University of Western Ontario, London, Ontario
Received March 4, 1969

The allylic anions derived by proton abstraction from 2,4,4-trimethyl-1-pentene **1** and 2,4,4-trimethyl-2-pentene **2** have been studied as short-lived intermediates. The anions were generated in *t*-butyl alcohol-*O*-*d*-potassium *t*-butoxide at 215 °C and relative rates of hydrogen–deuterium exchange and isomerization were compared. The isomerization of the thermodynamically less stable **2** to **1** occurs through the *cis*-allylic anion with a low 10% intramolecular component. The intermediate anion preferentially collapses to give **2** (3 to 1). Treatment of **1** leads more frequently into the less substituted allylic anion.

Introduction

Allylic anions have been implicated as intermediates in most base-catalyzed allylic isomerizations and their detailed behavior has been investigated for a number of systems (1). The features of the isomerizations that have received much attention are the intramolecularity of the 1,3-proton transfer (2), the collapse ratio in carbanion protonation (3), and the stability of the carbanions (4). For the phenyl substituted anions it has been possible to study the effect of medium, base, and substrate structure on all of these features. For the less stable anions derived from simple alkenes, the solvent–base pair widely employed has been dimethyl sulfoxide – potassium *t*-butoxide (5). While the effect of olefin structure in the alkenes has been extensively investigated, this solvent has limited the conclusions that could be drawn about intramolecularity and collapse ratios.

As a result we felt it would be interesting to change the solvent–base system to see what effect this would have, particularly upon the intramolecularity. Desiring a protic solvent and a strong base, we chose *t*-butyl alcohol-*O*-*d*-potassium *t*-butoxide which, however, required a high temperature (~215 °C) to effect reaction. The olefin pair selected for study was 2,4,4-trimethyl-1-pentene (**1**) and 2,4,4-trimethyl-2-pentene (**2**).

These olefins have been studied previously to obtain an estimate of their acidity (4) and to determine the gross amounts of hydrogen exchange (6) but no attempt had been made to discuss the details of their interconversion.

Results and Discussion

Equilibration

The relative stability of 2,4,4-trimethyl-1-pentene (**1**) and 2,4,4-trimethyl-2-pentene (**2**) were established under the present reaction conditions by reacting the olefins individually. The results of treatment of **1** and **2** with potassium *t*-butoxide in *t*-butyl alcohol at 215 °C for about 100 h are reported in Table I. The equilibrium composition corresponds to an equilibrium constant of 2.36 at 215 °C favoring the terminal olefin **1**. The thermodynamic relations between this pair of olefins has received considerable previous attention. Equilibrium has been observed with acid ($K = 5.3$ at 25 °C) (7), base ($K = 5.6$ at 55 °C) (4), and silica gel ($K = 5$ at 25 °C) (8). Heats of combustion, hydrogenation, and free energies have been obtained by several workers (9). These results are in substantial agreement and show that 2,4,4-trimethyl-1-pentene is thermodynamically more stable than 2,4,4-trimethyl-2-pentene under all the conditions employed. This observation has been rationalized in terms of the interactions between the *t*-butyl group and the *cis*-methyl in the **2**-isomer (10).

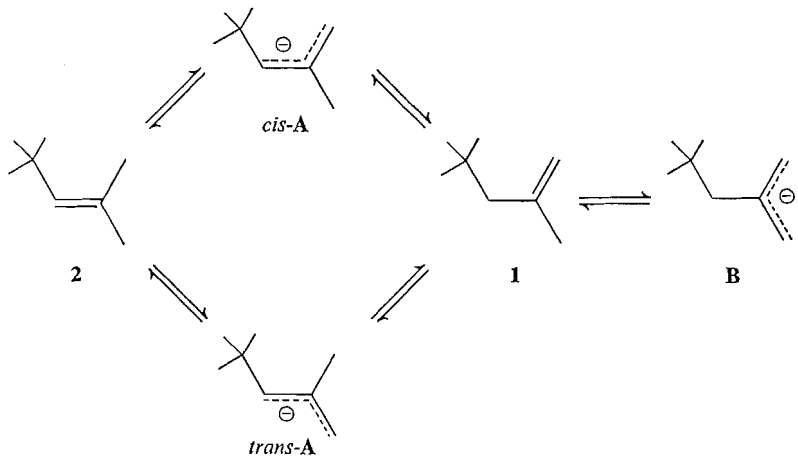
*±0.5%.

Relative Reactivities of the Olefins

Treatment of the 2,4,4-trimethylpentenes with the base was expected to lead into three distinct allylic anion systems. Anions *cis*-**A** and *trans*-**A** would provide routes for isomerization between the olefins **1** and **2** and concurrent exchange



while anion **B** would only provide a mechanism for hydrogen–deuterium exchange of **1**.

Since nuclear magnetic resonance (n.m.r.) was used to determine the hydrogen–deuterium exchange behavior of **1** and **2**, the HA-100 n.m.r. spectra of 2,4,4-trimethyl-1-pentene **1** and 2,4,4-trimethyl-2-pentene **2** (5 wt. % in CCl_4) are shown in Figs. 1 and 2 along with the results of a first-order analysis of the spectrum of **2**.

As will be shown later, the relative ease of formation of *cis*-**A** and *trans*-**A** was determined from deuterium incorporation into the allylic methyls of olefin **2**. Therefore, nuclear Overhauser experiments were run to assign these methyl protons. Frequencies in the region of the allylic methyl groups were systematically irradiated and the peak corresponding to the olefinic proton was integrated. Results were obtained with varying irradiating powers, on two different Varian HA-100 spectrometers and on a Varian HA-60 spectrometer. At 100 MHz experiments were attempted, locking on TMS and on benzene. Irradiation of the upfield methyl group provided an average enhancement in the integral of 17 ± 4% while the downfield methyl showed 6 ± 4%. As a result the downfield peaks (1.68 p.p.m. from TMS) have been assigned to the methyl hydrogens *cis* to the *t*-butyl group as in Fig. 2. The opposite conclusion had been reached on the basis of chemical shifts (11) but our assignment agrees with more recent evidence, for example, ref. 12.

In the hydrogen–deuterium exchange reactions, samples of 2,4,4-trimethyl-1 and 2-pentene were treated separately with 0.16 *M* potassium *t*-butoxide in *t*-butyl alcohol-*O*-*d* in sealed degassed Carius tubes at 215 °C. After gas–liquid phase chromatography (g.l.p.c.) analysis, the mixture of olefins obtained from each reaction was separated by preparative g.l.p.c. and the individual olefins were analyzed for deuterium uptake by n.m.r. spectroscopy. Runs 3 and 4 of Table II contain the results obtained at two times with olefin **1** as the substrate. Runs 5–8 of Table II contain the results at varying times with olefin **2**.

As is evident from runs 7 and 8 the incorporation of deuterium as a function of the percentage of isomerization is quite reproducible. On the other hand for most runs time–isomerization results are reproduced only approximately, presumably due to the relatively large vertical temperature gradient (≃ 15 °C) across the sample tubes. Since conclusions were reached by comparing isomerization and exchange within a run, the time variations should not be very important. In all the exchange runs the percentage of protons in the solvent pool was kept below 5% throughout the run.

The results of Table II (in particular, run 3) can be used to obtain an estimate of the ease of formation of anion **B** relative to *cis*-**A** and *trans*-**A**. From the extensive exchange of the methyl and vinyl protons relative to the methylene protons of the recovered **1**, anion **B** is formed about 10 times more readily than the *cis*-**A** and *trans*-**A** anions. When the temperature effects are included, this difference in rate is approximately that calculated from the results of a study comparing the relative rates of base-catalyzed isomerization of several alkenes (4).

The relative rates of formation of such allylic

carbanions have been rationalized in terms of inductive and steric effects in the transition states for anion formation (4). While these factors are involved it is interesting to compare our extended Hückel calculations on the *cis*- and *trans*-butenyl systems with the isobutenyl system. For the allylic cations *trans*-butenyl is about 9 kcal/mole more stable than *cis*-butenyl or isobutenyl while for the anions, isobutenyl is about 9 kcal/mole more stable than the *cis*- or *trans*-butenyl anions. The π-molecular orbital being filled in passing from cation to anion in the butenyl systems involves considerable mixing of the orbitals on the methyl group. Thus hyperconjugation could be playing an important part in affecting anion stability and consequently a significant role in determining which anion is formed.

Reactivity of Geometric Isomers

Olefin **2** can lead to either of two anions (*cis*-**A** or *trans*-**A**). Collapse of these anions could regenerate **2** or produce **1** (both either exchanged or unexchanged). By comparing the relative amounts of exchange of the allylic methyl hydrogens in **2**, it is possible to determine which anion is preferentially formed. This assumes that *cis*-**A** and *trans*-**A** provide the major pathway for exchange and that exchanged **1** is not significantly involved. This assumption will be justified in a later section.

As the results of Table II show, the methyl *cis* to the *t*-butyl group in **2** exchanges faster than the *trans*-methyl and the relative amounts of exchange yield a factor of at least 11. On this basis the anion *cis*-**A** is the dominant intermediate and presumably the more stable anion. The preferential formation of *cis*-allylic anions appears to be a general phenomenon when stabilizing groups such as phenyl rings are absent (13). A variety of explanations have been offered to interpret these results. Among these are dipole moments of the anions (14), electronic stability of the anions as obtained by extended Hückel calculations (15), steric effects on solvation of the anions (1), ground state conformational preferences (16), and non-bonded interactions in the anions (17).

Intramolecularity

Before further consideration can be given to the exchange results reported in Table II, it is necessary to correct for the fact that 3.2% of **1** was present in **2**. The pertinent corrected results are contained in Table III. With these results and the equilibrium data of Table I, we have obtained information on the intramolecularity of the 1,3-proton shift in the allylic isomerization of **2** to **1** and on the energy profile for the interconversion.

Although we have assumed above that intermediates are involved in these isomerizations based upon analogy with similar systems (1), their involvement can be readily demonstrated with this olefin pair. Ignoring isotope effects, the equilibrium results show that the relative rates for interconversion of the olefins **1** and **2** are in the ratio of 2.4:1.

Assuming the kinetic scheme depicted in the heading of Table IV, the percentages of the two olefins that would have arisen were calculated to simulate the results collected in Table III. It is clear that even at the greatest extent of reaction, very little **2** has been regenerated (symbolized **2′**). If no intermediates were involved then the only source of deuterium in **2** would be from regenerated **2′**. The results of Table III show on the other hand that considerable incorporation of

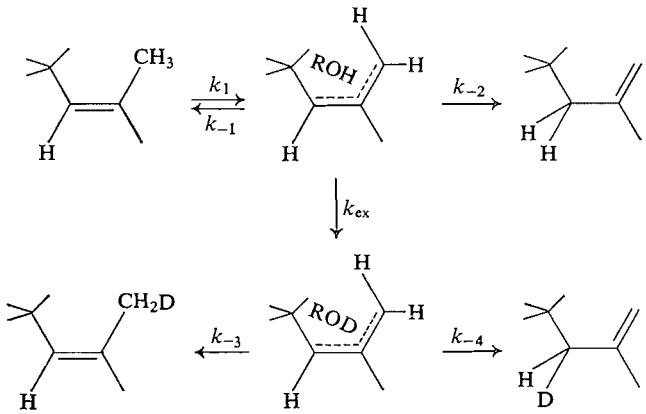
*The headings 2, 3, and 4 represent the ratio of k_a/k_d chosen for the calculation of that column.

deuterium has occurred while little **2′** has been produced and thus an intermediate must be invoked. The results of Table IV are of further significance since they justify ignoring further reactions of **1** for the periods of reaction studied since only 1.3% of **2′** has been formed, although 23% of **2** has reacted. Generation of anion **B** is a probable exception to this rule but it produces only exchange of the methyl and vinyl protons of **1** which need not be considered in the further discussion.

With these results in mind, the data of Table III were considered in terms of the partial mechanistic scheme depicted below. In this working



model the intermediate anions are represented in a grossly oversimplified manner in which the details of solvation and the mechanism for exchange are excluded. This is intentional since our evidence does not bear directly on these points. To facilitate kinetic analysis this mechanism was converted to the scheme shown below.

Rate constants were assigned to the kinetic scheme to obtain a best fit. The general scheme followed in assigning rate constants is as follows: (*1*) a ratio of k_a/k_d was chosen; (*2*) a ratio of k_d/k_c was chosen; (*3*) a kinetic isotope effect was then assumed.

Applying this isotope effect and with statistical weighting, the ratio of k_a/k_b is then fixed. Similarly the ratios $k_c:k_e:k_g$ and $k_d:k_f:k_h$ are fixed.

The calculated deuterium incorporation into the methylene group of olefin **1** depended only upon the ratio assumed for k_d/k_c in the range of k_a/k_d chosen. A good fit was obtained for k_d/k_c = 9. The ratio k_a/k_d determined the extent of deuterium incorporation into the methyl group of olefin **2** at a particular extent of isomerization. The sensitivity of the results to the assumed k_a/k_d ratio can be seen from the calculated results included in Table III. For these calculations the ratio $k_d/k_c = 9$ and the kinetic isotope effect

6	87.2	87.6	12.0	0.33	0.01
7	76.9	75.9	22.7	1.3	0.1

*The symbols **2** and **1** refer to unreacted 2,4,4-trimethyl-2 and 1-pentene respectively while **2′** and **1′** refer to the regenerated olefins.
†The relative rate constants are assigned from the equilibrium constant since $K = k_2/k_1 = 2.37$.

$k_H/k_D = 1$. The best fit is obtained for $k_a/k_d = 3$. This result was insensitive to the magnitude of the kinetic isotope effect presumably because of the small extent of deuterium incorporation. While definite values can be assigned to the ratios, the inaccuracies in the n.m.r. method of deuterium analysis suggest that $k_a/k_d = 3 \pm 0.5$ and $k_d/k_c > 8$.

The calculated ratios can be interpreted in terms of the mechanistic scheme by noting that with a steady state approximation for the anions

$$k_a = k_1k_{ex}k_{-3}/(k_{-1} + k_{-2} + k_{ex})(k_{-3} + k_{-4})$$

$$k_c = k_1k_{-2}/(k_{-1} + k_{-2} + k_{ex})$$

$$k_d = k_1k_{ex}k_{-4}/(k_{-1} + k_{-2} + k_{ex})(k_{-3} + k_{-4}).$$

One of the interesting results of this study was the lack of a significant intramolecular proton transfer component in the isomerization. The isolated olefin **1** contained 0.9 of an atom of deuterium or only 10% of the isomerization had occurred with an intramolecular 1,3-proton transfer. This is in direct contrast to results obtained for perdeuterio-1-pentene in 0.4 *M* *t*-butyl alcohol in dimethyl sulfoxide – potassium *t*-butoxide at 55 °C where isomerization led total exchange by a factor of 16 (18). The ratio of isomerization to total exchange $(k_c + k_d)/(k_a + k_d)$ for 2,4,4-trimethyl-2-pentene in *t*-butyl alcohol potassium *t*-butoxide at 215 °C is about 0.27. This corresponds to a factor of 60 difference in relative rates between the two studies. This 10% intramolecular proton transfer is one of the lowest that has been observed even for more delocalized anionic intermediates (1).

The large difference between the intramolecularity in 0.4 *M* *t*-butyl alcohol dimethyl sulfoxide and *t*-butyl alcohol probably has two major causes; temperature and proton (deuteron) availability. In terms of a mechanism like that shown on p. 2367, it is possible to estimate the change in $k_{ex}/(k_{-1} + k_{-2})$ that has occurred in these two contrasting experiments. Assuming that the intermediate in the perdeuterio-1-pentene isomerization collapses predominantly to 2-pentene, the change is a factor of 145. The *t*-butyl alcohol concentration has changed by a factor of about 25 and should account for a major portion of the rate ratio change.

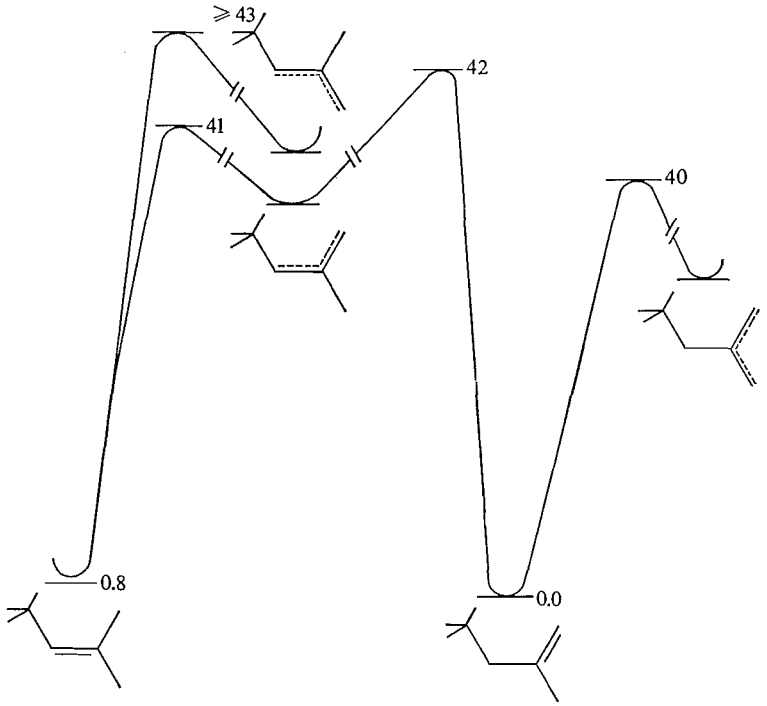
Such a conclusion is supported by a calculation of the difference in $\Delta H^{\ddagger}$ between k_{ex} and $(k_{-1} + k_{-2})$ if the rate ratio changes were ascribed to temperature alone. The $\Delta\Delta H^{\ddagger}$ is calculated to be about 10 kcal/mole which is unreasonably high since both reactions are undoubtedly low energy processes.

On the basis of these arguments it seems sensible to expect that the absence of readily exchangeable hydrogens in the medium is an important factor in the high intramolecularity in dimethyl sulfoxide and that the high temperature is mainly responsible for the low intramolecularity in *t*-butyl alcohol.

Collapse Ratio

From the exchange and isomerization results it is possible to deduce the collapse ratio (k_{-1}/k_{-2} or k_{-3}/k_{-4}) for the proposed anionic intermediates. From the ratio $k_a/k_d = k_{-3}/k_{-4} = 3 \pm 0.5$, it is apparent that deuteron (and proton) capture by the allylic intermediate occurs more readily at the less substituted carbon to give the less stable isomer. This result can be interpreted as a steric interaction outweighing a thermodynamic effect. Extended Hückel results on the analogous *cis*-butenyl anion indicate a higher charge density on the 1-carbon than 3-carbon.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



Although calculated values for absolute charges are not to be trusted (19), the relative charge distribution in the anion itself is consistent with favored attack at the less substituted carbon.

The kinetic results are summarized in the accompanying free energy diagram. Energies are in kcal/mole at 215 °C.

Experimental

Compounds

The 2,4,4-trimethyl-1-pentene and 2,4,4-trimethyl-2-pentene (Phillips Petroleum Co.) were distilled before use. The 2,4,4-trimethyl-1-pentene was judged to be 99.5% pure by gas–liquid partition chromatography analysis. The 2,4,4-trimethyl-2-pentene contained 3.2% of 2,4,4-trimethyl-1-pentene and 0.3% of an unidentified impurity as estimated by g.l.p.c. This impurity persisted through the isomerization and exchange reactions but was separated before deuterium analysis.

The *t*-butyl alcohol-*O-d* (0.98 atoms D/molecule as determined by nuclear magnetic resonance (n.m.r.)) was prepared as previously reported (20). The base solutions were obtained by dissolving freshly cut potassium metal in the alcohol under a nitrogen atmosphere.

Nuclear Magnetic Resonance Spectra

Proton spectra were run on the Varian HA-100 and A-60A spectrometers using a C-1024 time average computer for the more dilute samples. Deuterium analyses were obtained on carbon tetrachloride solutions of olefins obtained directly from preparative g.l.p.c. Integrations are the average of 10 scans with maximum expanded range and are relative to the 9 protons of the *t*-butyl group in each olefin.

Nuclear Overhauser experiments were run on degassed solutions of the olefins in carbon tetrachloride. Ten integrals were run at each irradiating frequency.

Exchange and Isomerization Reactions

Typically the substrate and base solution were sealed under vacuum after degassing in a Carius tube. The tube was then submerged in a thermoregulated Wood's metal bath for the reported time. The vertical temperature gradient in the bath was about 15 °C and the average temperature is reported.

After cooling the tube was opened and the solution was treated with pentane and three water extractions. After drying the excess pentane was carefully removed by distillation and the residual oil analyzed by g.l.p.c. A 1/4 in. × 18 ft column of 10% SE-30 on 40/60 mesh firebrick was employed for the analyses. Area percentages are reported.

Preparative separation of the olefin mixture was obtained with a 3/8 in. × 15 ft glass column of 10% SE-30 on 40/60 mesh firebrick. The eluted olefins were transferred with small amounts of carbon tetrachloride into n.m.r. tubes for deuterium analysis. Typical recoveries are estimated at 30% with the major loss occurring in transferring from the g.l.p.c. collector to the n.m.r. tubes.

Extended Hückel Calculations

Calculations were run on three basic allylic skeletons (isobutenyl, *cis*-butenyl, and *trans*-butenyl) looking at both the cations and the anions. In all these calculations

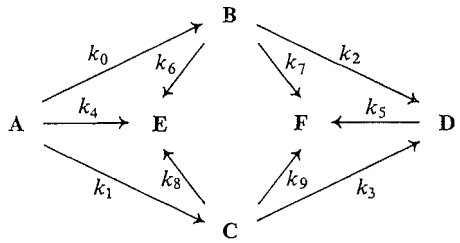
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

idealized bond angles were employed and the bond lengths were chosen on the basis of a preprint kindly supplied to us by one of the authors (21). In all three systems the methyl group was rotated and the lowest energy form chosen.

The program employed involved conventional extended Hückel calculations analogous to the program available from the Quantum Chemistry Program Exchange.

Kinetic Calculations

The mechanistic schemes analyzed in this article were obtained as limiting cases of a more general scheme developed for another study in progress. This general case is shown below



Setting $A + B + C + D + E + F = 1$, $A_o = 1$ and $B_o = C_o = D_o = E_o = F_o = 0$ the solution is

$$A = \exp -k_a t$$

$$B = k_0/(k_b - k_a)[(\exp -k_a t) - (\exp -k_b t)]$$

$$C = k_1/(k_c - k_a)[(\exp -k_a t) - (\exp -k_c t)]$$

$$D = (\alpha + \beta)/(k_5 - k_a)[(\exp - k_a t) - (\exp -k_5 t)] - \alpha/(k_5 - k_b)[(\exp -k_b t) - (\exp -k_5 t)] - \beta/(k_5 - k_c)[(\exp -k_c t) - (\exp -k_5 t)]$$

$$E = \delta/k_b[(\exp -k_b t) - 1] + \gamma/k_c[(\exp -k_c t) - 1] - \varepsilon/k_a[(\exp -k_a t) - 1]$$

$$F = 1 - A - B - C - D - E,$$

where $k_a = k_0 + k_1 + k_4$; $k_b = k_2 + k_6 + k_7$; $k_c = k_3 + k_8 + k_9$; $\alpha = k_0 k_2/(k_b - k_a)$; $\beta = k_1 k_3/(k_c - k_a)$; $\gamma = k_1 k_8/(k_c - k_a)$; $\delta = k_0 k_6/(k_b - k_a)$; and $\varepsilon = k_4 + \delta + \gamma$.

Thermal decomposition of optically active unsymmetrical azoalkanes. (−)-(*S*)-1,1′-Diphenyl-1-methylazomethane[1]

KARL R. KOPECKY AND THOMAS GILLAN[2]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received December 24, 1968

The ratio, $(k_c/k_r)_{cage}$, of the rate of coupling of the 1-phenylethyl radical with the benzyl radical to the rate of its rotation with respect to the benzyl radical in the solvent cage has been determined for several solvents. The optically pure title compound, (−)-(*S*)-**4**, has been prepared and its absolute configuration determined. Thermal decomposition of (−)-(*S*)-**4** yields (−)-(*R*)-1,2-diphenylpropane, (−)-(*R*)-**9**, with partial retention of configuration. The maximum rotation of (−)-(*R*)-**9** has been determined. At 100° in benzene, cyclohexane, chlorobenzene, (all containing ca. 1 *M* butanethiol) and butanethiol, the cage effects for the decomposition of (±)-**4** were found to be 28.3, 31.7, 33.4, and 18.2%, respectively. Under these conditions (−)-(*R*)-**9** was formed from (−)-(*S*)-**4** with 10.3, 10.9, 13.0, and 17.3% net retention of configuration, respectively. A simple expression for $(k_c/k_r)_{cage}$ can be derived:

$$(k_c/k_r)_{cage} = F(1 - f)[(-)\text{-}(R)\text{-}\mathbf{9}/(+)\text{-}(S)\text{-}\mathbf{9} - 1]$$

F is the fraction of radicals consumed within the solvent cage and *f* is the fraction of radicals consumed within the solvent cage that disproportionate. Under the above conditions values for $(k_c/k_r)_{cage}$ were found to be 0.059, 0.069, 0.090, and 0.070, respectively. The values of the cage effect and $(k_c/k_r)_{cage}$ given were calculated assuming $f = 0.1$, but change little if *f* is assumed to be 0. The relevance of these results to the stereochemistry of the Wittig and Meisenheimer rearrangements and of the decomposition of diacyl peroxides is discussed.

Canadian Journal of Chemistry, 47, 2371 (1969)

The stereochemical fate of free radicals generated from optically active precursors has not yet received the systematic study accorded that of carbonium ions and carbanions derived from such sources. This appears to be due to a number of factors including the observations of essentially complete loss of either optical activity (1) or isomeric identity (2) in early systems studied, and ambiguity (3) concerning the mechanisms of decomposition of diacyl peroxides from which optically active products have been obtained (4).

In reactions which almost certainly proceed by radical pathways, stereoselectivity has been observed in the decomposition of substituted pyrazolines (5) and substituted tetrahydropyridazines (6) to substituted cyclopropanes and substituted cyclobutanes, respectively, photochemical decomposition of acyclic azoalkanes in frozen solution at low temperature (7), in a cage disproportionation reaction (8), in perester decompositions under very high pressures of oxygen (9), in addition of hydrogen bromide to olefins at low temperature and at high hydrogen bromide concentration (10), in certain photobromination reactions at low temperature (11), and in the cyclization of a propargylic ester to a γ-lactone (12). In the reactions involving open-chain systems stereoselectivity decreased with both increasing temperature (7, 9–11) and with decreasing concentration of radical trapping species (9–11). In all these cases radicals were generated with either another radical or a very efficient radical trapping species either within or as part of the solvent cage. Only in frozen solution was complete stereospecificity observed (7). It is clear that free radicals formed in the liquid or vapor phase by homolytic fission of a bond at an asymmetric carbon atom cannot maintain asymmetry for longer than ca. 10^{-9} s, if at all. One cannot tell if loss of asymmetry is due to a requirement that the radical assume a planar conformation or is due to rapid interconversion between two pyramidal conformations. Spectral studies of free radicals indicate that the planar conformation is the more stable (13), but radicals can be formed at the bridgehead carbon atom of small, bicyclic ring systems with energy requirements not much greater than in those systems in which radicals can assume a planar conformation (14, 3).

Vinyl radicals also lose geometrical identity quite rapidly (15) and these species can be trapped before isomerization only at low temperatures and with high concentrations of reactive hydrogen atom donors (16).

In order to be able to detect asymmetric products from radical reactions in solution involving asymmetric substrates it is necessary to use a reaction in which radicals are consumed at a rate which can compete with the rates of their diffusion and rotation.

The decomposition of a series of optically active unsymmetrical azoalkanes, eq. [1], appears well suited for a general and systematic investi-

[1] $$R{-}N{=}N{-}R' \rightarrow R{-}R' + R{-}R + R'{-}R' + N_2$$

gation of the stereochemical capabilities of free radicals and of the relative rates of the various processes which radicals formed in pairs in close proximity to each other can undergo. The radical nature of the decomposition of azoalkanes is well known and there is good evidence in both cyclic (*5b*, 17) and acyclic (18) systems that the decomposition is a concerted process which gives directly a molecule of nitrogen and a pair of radicals. These can combine at a rate which competes with the rate of their diffusion apart (19). The study of the decomposition of unsymmetrical azoalkanes offers several advantages over that of symmetrical azoalkanes. Separation of diastereomeric starting materials is unnecessary. Stereoselectivity would only be observed as a result of a cage recombination (19) reaction which can produce only the unsymmetrical coupling product R—R′. This product should be easily separable from the symmetrical products, R—R and R′—R′, which are only formed by combination of radicals which have diffused away from their original partners. The yield of symmetrical coupling products is dependent upon the proportion of radicals which diffuse away from their original partners. This could allow an estimate to be made of the proportion of cage recombination which occurs without recourse to the radical counting techniques usually required, and/or allow an estimate to be made of the relative rates of coupling between various radicals. Finally, the nature of the groups R and R′ can be varied independently and in a way that the stereochemistry of even bulky radicals can be studied. For example, if R is big, R′ can be made small so that a significant amount of cage recombination might still occur. Only a very small amount of cage recombination is observed in decomposition in solution of symmetrical azoalkanes with bulky alkyl groups (7).

The preparation and some studies of the decomposition of racemic and optically active 1,1′-diphenyl-1-methylazomethane are presented in this report. After the experimental work reported in this paper had been completed a report of the stereochemistry of decomposition of (−)-1,1′-diphenylazoethane was presented (20). The results described in that report are in excellent agreement with those of the present study.

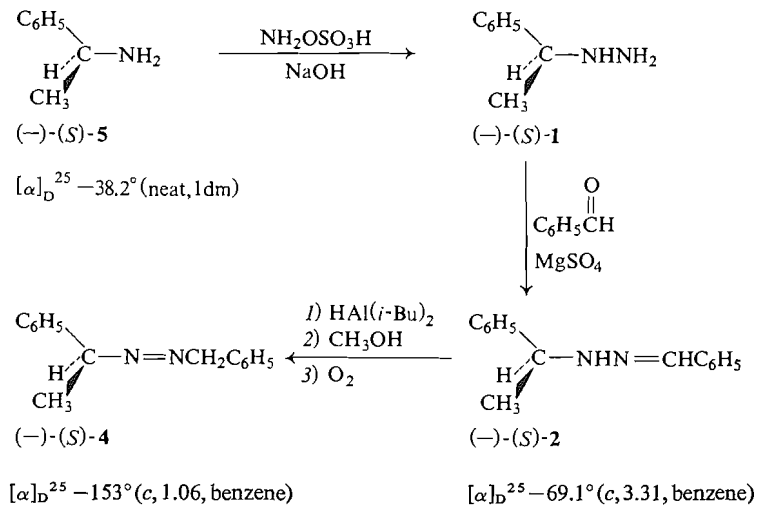
Absolute Configurations of Starting Material and Product

The preparation of (−)-(*S*)-1,1′-diphenyl-1-methylazomethane, (−)-(*S*)-**4**, and its degradation to (−)-(*S*)-1-phenylethylamine, (−)-(*S*)-**5**, are outlined in Chart I.

N-Benzyl-*N*′-(1-phenylethyl)-hydrazine, **3**, was prepared by condensation of 1-phenylethylhydrazine, **1** (18*c*), with benzaldehyde followed by reduction of the benzaldehyde 1-phenylethylhydrazone, **2**, formed. The compound, **3**, was quite sensitive to air oxidation and was readily oxidized to **4** by stirring solutions containing it under an atmosphere of oxygen. The azoalkane, **4**, was very sensitive to acid, base, and light. Rearrangement to the hydrazone, **2**, occurred readily under the influence of any one of these catalysts. This behavior contrasts with that of 1,1′-diphenylazoethane which in our hands is much less sensitive. Distillation of **4** was not attempted. It was purified by concentration of solutions containing it until the refractive index of the residual oil remained constant. When the preparation of **4** was carried out in the dark using carefully neutralized apparatus, the product was analytically pure, contained less than 1–2% hydrazone, **2**, as determined by ultraviolet (u.v.) spectroscopy, and no extraneous peaks could be detected in its nuclear magnetic resonance (n.m.r.) spectrum.

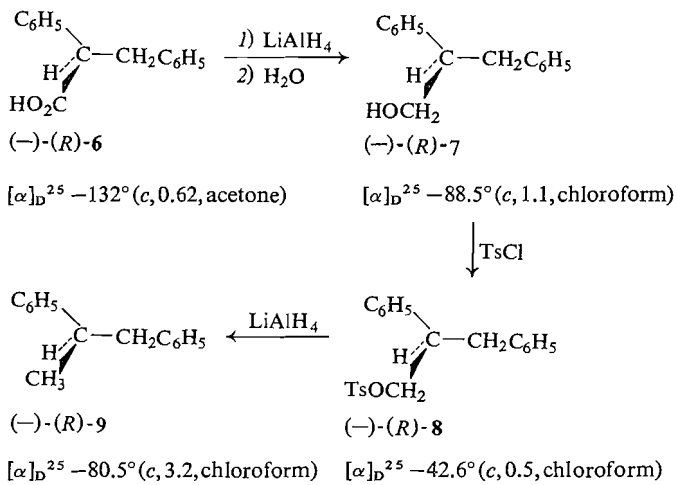
The resolution of **3** was accomplished by fractional crystallization of the *d*-camphorate salt until the rotation of the salt remained constant. Attempts to obtain the rotation of (−)-(*S*)-**3** gave variable results because of its ready oxidation to (−)-(*S*)-**4**. A sample of (−)-(*S*)-**4**, $[\alpha]_D^{25}$ −152° (*c*, 1.06, benzene), was hydrogenolyzed with Raney nickel in methanol at 25° to (−)-(*S*)-1-phenylethylamine, (−)-(*S*)-**5**, $[\alpha]_D^{25}$ −31.4° (*c*, 5.4, dioxane), whose absolute configuration is established (21) and whose maximum rotation (22) under these conditions was determined: $[\alpha]_D^{25}$ −39.6° (*c*, 5.4, dioxane). This result indicates that either this sample of (−)-(*S*)-**4** was 79% optically pure or racemization took place under the conditions of the hydrogenolysis. There was no racemization of (−)-(*S*)-**5** under the reaction conditions. Racemization could occur before hydrogenolysis, either by the process involved in the racemization which accompanies reduction in the catalytic hydrogenation of (−)-(*R*)-3-phenyl-1-butene to (−)-(*R*)-2-phenylbutane (23), or as a result of isomerization, by base adsorbed on the catalyst, of (−)-(*S*)-**4** to the benzylhydrazone of acetophenone, **10**, followed by reduction and hydrogenolysis.

In an alternate attempt to determine the maximum rotation of (−)-(*S*)-**4** a sample (−)-(*S*)-**5**, $[\alpha]_D^{25}$ −36.6° (neat, *l* 1 dm), was converted to



Rotations given are for optically pure compounds

CHART II



Rotations given are for optically pure compounds; Ts = *p*-toluenesulfonyl

CHART III

(−)-(*S*)-**4**, $[\alpha]_D^{25}$ −146° (*c*, 1.36, benzene),[3] by a route which quite certainly does not affect the asymmetric center (Chart II). On the basis that the maximum rotation of (−)-(*S*)-**5** is 38.2° (neat, *l* 1 dm) (22) the maximum rotation of (−)-(*S*)-**4** determined in this manner would then be −153°. This is essentially identical with the value obtained by resolution, and (−)-(*S*)-**4** of $[\alpha]_D^{25}$ −152° must be optically pure or very nearly so.

The absolute configurations of the 1,2-diphenylpropanes, (+)- and (−)-**9**, the unsymmetrical coupling products expected from decomposition of (+)-(*R*)- and (−)-(*S*)-**4**, have been determined (24), but there appeared to be some doubt about the maximum rotation of these compounds. Values of $[\alpha]_D^{19}$ −63.5° (24), $[\alpha]_D^{25}$ +76.7° (25), and $[\alpha]_D^{25}$ −76.3° (25) (all *c*, 2.2–2.3, chloroform) have been reported for these materials prepared by different routes. An independent determination of the maximum rotation of these materials seemed necessary[4] and was carried out by the route shown in Chart III. Optically pure (−)-(*R*)-2,3-diphenylpropanoic acid, (−)-(*R*)-**6** (28), was converted to (−)-(*R*)-**9**, $[\alpha]_D^{25}$ −80.5° (*c*, 3.2, chloroform), by reactions which did not involve the asymmetric center. This sequence establishes chemically the absolute configuration of (−)-(*R*)-**6**[5] as well as the maximum rotations of (−)-(*R*)-**9** and the intermediates shown in Chart III. The enantiomers of **9** prepared previously were clearly not optically pure (25).

Kinetic Studies

The rates of decomposition of **4** in cumene were determined by measuring the rates of nitrogen evolution. An insufficient amount of nitrogen was evolved in each of the kinetic runs and plots of log $(V_\infty - V_0)/(V_\infty - V_t)$ vs. time showed considerable curvature, especially at the lower temperature. The rate constants given in Table I were determined from the initial slopes of the plots using the theoretical values for V_∞. The initial rates are independent of concentration. An n.m.r. spectral analysis of a run at 106° indicated that considerable amounts of hydrazone, **2**, had been formed. There was no evidence for the presence of any of the isomeric hydrazone, acetophenone benzylhydrazone, **10**. It was

[3]After correction for the presence of 8 mole % of (−)-(*S*)-**1**.

[4]Raney nickel reduction of a sample of (−)-(1*S*,2*S*)-1,2-diphenyl-1-propanol (26) afforded the enantiomer with $[\alpha]_D^{25}$ − 76.3°, while the enantiomer with $[\alpha]_D^{25}$ +76.7° had been prepared by a sequence involving Raney nickel hydrogenolysis of a hydroxyl group at the asymmetric center. This hydrogenolysis would have to have proceeded with 100% retention of configuration if the (−)-enantiomer were optically pure and if no optical fractionation occurred during further reactions leading to the (+)-enantiomer. Such a high degree of stereospecificity does not appear to occur in Raney nickel hydrogenolyses of other systems (27).

[5]The absolute configuration of (+)-(*S*)-**6** has been assigned correctly on the basis of empirical methods (29). Also, (+)-methyl-1,2-methyl-1,2-diphenylpropionate, obtained by a degradation process, has been converted to (+)-(*S*)-**9** (25).

shown in separate experiments that **2** did not evolve nitrogen under these reaction conditions.

It can be predicted from the summary (30) of the activation parameters of a series of azoalkanes that ΔH^* for the decomposition of **4** should be about 33.5–34.5 kcal/mole and ΔS^* about 6 e.u. The value of ΔH^* obtained for the decomposition of **4**, Table I, is in good agreement with this prediction but the value for ΔS^* appears to be significantly different.

Products

Decomposition of **4** in benzene solution results in the formation of products according to eqs. [5]–[13]. The decomposition of **4** produces benzyl radicals and 1-phenylethyl radicals in a solvent cage (19). These radicals can react within the solvent cage to form the unsymmetrical coupling product, **9**, and the disproportionation products styrene and toluene, or in a competitive process, diffuse away from each other. The radicals which have diffused away from the solvent cage may now encounter and react with one of their own kind. An encounter between two 1-phenylethyl radicals will result in coupling to form *meso* and *dl*-2,3-diphenylbutane, *meso*- and *dl*-**11**, and in disproportionation to form styrene and ethylbenzene. The only reaction resulting from an encounter between two benzyl radicals will be coupling to form bibenzyl. An encounter between a 1-phenylethyl radical and a benzyl radical will result in the same products as are formed in the original solvent cage. The product distributions over a range of concentrations are given in Table II. No styrene could be found in the run at 0.5 M **4**. It was probably consumed by radical addition reactions. The amounts of the low molecular weight products, styrene, ethylbenzene, and toluene, formed in runs at the lower concentrations in benzene, could not be determined because the benzene peak in the gas–liquid chromatogram (g.l.c.) was so broad.

The ratio of the two kinds of symmetrical coupling products, *meso*- and *dl*-**11** to bibenzyl, decreases as the initial concentration of **4** decreases to a limiting value of about 0.90–0.94. The larger ratio at the higher initial concentrations of **4** reflects the greater reactivity of the benzyl radical as compared to the 1-phenylethyl radical in hydrogen abstraction from **4** and from reaction products, and in addition to any styrene formed. As the initial concentration of **4** is decreased such radical–molecule reactions become less important. The fact that the ratio, *meso*- and *dl*-**11** to bibenzyl, tends to a limit indicates that at an initial concentration of **4** of

†Equal amounts of *meso-* and *dl*-**11** were formed.

ca. 1×10^{-3} M, all radicals produced are consumed by radical–radical reactions. The ratio would be expected to be 1.0 if there were no disproportionation between two 1-phenylethyl radicals, and if the rate constants for the coupling reactions that form bibenzyl, **9** and *meso-* and *dl*-**11** are all equal (see below). The actual ratio indicates that there is ca. 6–10% disproportionation. This appears to be a reasonable value. The amount of disproportionation observed during the decomposition of azocumene is 6% (30). No attempt was made in this study to determine accurately the amount of disproportionation which occurs during the decomposition of **4** and no study seems to have been made of the disproportionation occurring during decomposition of 1,1′-diphenylazoethane, but there is no reason to believe that disproportionation in these systems will be much different from 6–10%.

Cage Effect

If the radicals derived from **4** which have diffused from the original solvent cage couple randomly, an estimate of the cage effect in the decomposition of **4** may be made on the basis of the relative yields of the coupling products in decompositions at low initial concentrations of **4**. In the absence of disproportionation the amounts of bibenzyl, **9** and the sum of *meso-* and *dl*-**11** formed outside the original solvent cage would be in the ratio 1:2:1. The amount of **9** formed in excess of this ratio would represent the amount of **9** formed by cage recombination. In practice there is disproportionation which reduces the relative amounts of **9**, *meso-* and *dl*-**11** which would otherwise be formed. Noting that in the absence of disproportionation the amounts of *meso-* plus *dl*-**11** should equal the amount of bibenzyl formed, and correcting the amount of **9** found by the amount of disproportionation which occurs between benzyl and 1-phenylethyl radicals, the cage effect can be calculated from eq. [13]. The assumption

$$[13] \quad \% \text{ cage recombination} = 100\left(\frac{\mathbf{9} - 2 \times \text{bibenzyl}}{\mathbf{9} + 2 \times \text{bibenzyl}}\right)$$

is also made that the amount of disproportionation is the same within the original solvent cage as it is without.

The cage effect can also be calculated from the product distribution resulting from the decomposition of **4** in the presence of butanethiol. Butanethiol will scavenge all radicals which diffuse away from the original solvent cage, converting them to toluene and ethylbenzene. This assumption is shown to be correct for no trace of the symmetrical coupling products, bibenzyl and *meso-* and *dl*-**11** can be found when **4** is decomposed in the presence of butanethiol. The cage effect can then be calculated from the relative yields of **9** and ethylbenzene or toluene. Such a procedure has previously been used in the study of the decomposition of azocumene (31).

There are two values for the size of the cage effect for each entry in Table III. One value is calculated without correction for disproportionation between the benzyl and the 1-phenylethyl radicals. The other is calculated assuming 10% disproportionation. For the runs in the presence of butanethiol there is a difference of from 1.2 to 3% between these values depending on the magnitude of the cage effect and the method by which it is obtained. It is likely that 10% disproportionation is a maximum value so that the true values of the cage effects probably lie between the "corrected" and "uncorrected" values listed in Table III. The size of the cage

TABLE III

Cage effects in the decomposition of **4**

Solvent	[**4**] (M*)	[C_4H_9SH] (M)*	Temperature (°C)	% Cage reaction†	
				Uncorrected‡	Corrected§
Benzene	0.0013	0	110	30.2, 24, 4	34.4, 28.5
Benzene	0.13	0.97	110	26.3±0.5	28.3±0.5
Cyclohexane	0.09	1.3	115	29.7±0.4	31.7±0.4
Chlorobenzene	0.30	1.1	108	30.4±0.2	33.4±0.2
Butanethiol	0.22	9.3	110	16.9±0.8	18.2±0.8

*Concentrations refer to solutions as made up at 25° and are not corrected for solvent expansion.
†Values from runs in the presence of butanethiol are averages of at least 3 determinations, and are based on relative yields of ethylbenzene and 9 except in chlorobenzene. In chlorobenzene, values are based on relative yields of toluene and 9. Values in first entry are calculated using eq. [13]. Errors are average errors.
‡Calculated from experimentally observed product ratios.
§Calculated from experimentally observed product ratios corrected for an assumed 10% disproportionation between benzyl and 1-phenylethyl radicals.

effect in solvent butanethiol is considerably smaller than it is in the other three solvents. This is probably due to a solvent effect and not due to scavenging of radicals from within the solvent cage or of interception to secondary recombination processes. The rate constant for hydrogen atom abstraction from benzylmercaptan by the benzyl radical is $5.1 \times 10^4\ M^{-1}\ s^{-1}$ at 25° (32). The rate constants for hydrogen atom abstraction from butanethiol by the radicals derived from **4** should have a similar magnitude and are surely much too small for butanethiol to interfere with primary and secondary recombination processes (19) in the present system.

The presence of ca. 1 M butanethiol in the other solvents probably reduces the size of the cage effect by about 2% from what it would be in the pure solvents. The solvent order of increasing size of the cage effect, benzene, cyclohexane, chlorobenzene is also observed in the decomposition of azocumene (31), where the difficulties involved in interpreting such solvent effects have already been discussed. The "corrected" cage effect for the decomposition of **4** in benzene containing butanethiol agrees well with the value of 29% found for the cage effect found in the decomposition of 1,1′-diphenylazoethane at 105° in benzene (18*e*). This is a system for which a cage effect similar to that found in the decomposition of **4** is to be expected (7).

There is considerable error in calculating cage effects from product distributions in the absence of scavenger using eq. [13] in the present system (first entry in Table III). The products upon which this calculation is based are eluted quite closely together under the best g.l.c. conditions we were able to obtain. Small samples had to be injected to prevent overlap so that peak heights probably were not optimum. There is, however, fair agreement between these "corrected" values and the "corrected" value found in benzene in the presence of 0.97 M butanethiol. This indicates that radicals which have escaped from the original solvent cage do in fact react in a random manner. The difference in stability between benzyl and 1-phenylethyl radicals is not reflected in the rates of their various reactions among each other. Lack of sensitivity to radical stability in the rate of radical–radical coupling reactions (33) and the relative rates of coupling and diffusion of radicals formed in a solvent cage (7) have already been noted.

Attempts to determine the cage effect in the photochemical decomposition of **4** were unsuccessful. Photolysis of **4** resulted in the almost exclusive formation of the hydrazones, **2** and **10**. Similar results were obtained in the photolysis of *cis*-3,6-diphenyl-3,4,5,6-tetrahydropyridazine (*6b*), in which mainly the corresponding hydrazone was formed.

Stereochemistry of Cage Recombination

Optically pure (−)-(*S*)-**4** was decomposed thermally in several solvents with and without butanethiol as scavenger. In all cases the unsymmetrical coupling product, (−)-(*R*)-**9**, was formed. It was shown above that (−)-(*S*)-**4** and (−)-(*R*)-**9** have the same configuration so that (−)-(*R*)-**9** is formed with retention of configuration. The results in Table IV show that extensive racemization has occurred even in the presence of butanethiol where the unsymmetrical coupling

product is formed only by recombination within the original solvent cage. It is possible that the low optical yield obtained in the presence of butanethiol is due to racemization of starting material and product as a result of reversible hydrogen atom abstraction from these materials by butanethiyl radicals as shown in Chart IV. Hydrogen atom abstraction from hydrocarbons

$$C_6H_5\dot{C}HCH_3 \text{ or } C_6H_5\dot{C}H_2 + C_4H_9SH \rightarrow C_6H_5CH_2CH_3 \text{ or } C_6H_5CH_3 + C_9H_9S\cdot$$

Chart IV

by thiyl radicals is a well known reaction (34). Qualitative evidence that such a hydrogen atom abstraction occurs in the present system is furnished by the observation that small amounts of a light-yellow, low-melting solid were formed in all reactions carried out in the presence of butanethiol. Larger amounts were formed when butanethiol was used as solvent. This material had a g.l.c. retention time similar to that of (−)-(*R*)-**9**. It was not investigated further but is assumed to be the unsymmetrical azine, acetophenone benzaldehyde azine, **12**, formed by dehydrogenation of (−)-(*S*)-**4**. Such a dehydrogenation reaction is also observed in the decomposition of 1,1′-diphenylazoethane in the presence of octanethiol in which acetophenone azine is formed (35). These dehydrogenations may be initiated by hydrogen abstraction from the azo compounds by thiyl radicals.

12

Two control experiments were carried out in an attempt to determine the amounts of racemization of starting material and product which might occur during decomposition of (−)-(*S*)-**4** in the presence of butanethiol. In the first a solution of optically pure (−)-(*R*)-**9** and 1,1′-diphenylazoethane in butanethiol was heated at 110° for a time equivalent to ∼ 10 half lives of decomposition of the azo compound. Recovered (−)-(*R*)-**9** was 20% racemized. While 1,1′-diphenylazoethane and (−)-(*S*)-**4** decompose at somewhat different rates, the steady state concentration of butanethiyl radicals generated by the decomposing azo compounds should be closely similar in each case. The amount of racemization observed in the control experiment should represent an upper limit for the amount of racemization of (−)-(*R*)-**9** after its formation during the decomposition of (−)-(*S*)-**4** in butanethiol for two reasons. The concentration of (−)-(*R*)-**9** in the control experiment was already at its maximum value at the beginning of the reaction while during the decomposition of (−)-(*S*)-**4** it built up from 0. Since racemization is first order in both (−)-(*R*)-**9** and butanethiyl radicals, it proceeded at a faster rate in the control reaction during most of the run. Also, in butanethiol, (−)-(*S*)-**4** probably isomerizes to hydrazone much faster than does 1,1′-diphenylazoethane. Both azo compounds had probably

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

completely disappeared as a result of decomposition and isomerization well before the reactions were stopped, but (−)-(*S*)-**4** disappeared faster. The result is that radicals were generated for a longer period of time in the control run, again giving more racemization of (−)-(*R*)-**9**.

In the second control run a decomposition of (−)-(*S*)-**4** in butanethiol at 110° was interrupted after a time equivalent to ~ 20% decomposition. The coupling product, (−)-(*R*)-**9**, which was isolated was 17.3% optically pure. This optical yield is identical to that from a run under the conditions which had gone to completion and shows that little, if any, racemization of (−)-(*R*)-**9** occurs after its formation. This also indicates that there is little, if any, racemization of (−)-(*S*)-**4** during its decomposition. The greater amount of racemization which was observed in the control run probably occurs for the reasons cited above.

Recovery of starting material from the interrupted reaction gave a mixture, $[\alpha]_D^{25}$ −101°, consisting of 71.5% (−)-(*S*)-**4** and 28.5% of the hydrazone, (−)-(*S*)-**2**, as determined by n.m.r. spectroscopy. On the assumption that the (−)-(*S*)-**2** present was optically pure the recovered azo compound would have $[\alpha]_D^{25}$ −114°, indicating that it was 25% racemized. This, however, represents an upper limit for the amount of racemization for racemic azo compound may have been introduced during work-up. The unreacted azo compound was reduced with a 13-fold excess of diimide to the hydrazine which was then extracted into aqueous acid to free it from hydrazones, azine, and (−)-(*R*)-**9** which are also present in the reaction mixture. The hydrazine was liberated and oxidized back to the azo compound with oxygen. Diimide was used because it reduces azo compounds rapidly, it reduces polar double bonds such as are present in the hydrazones and azine more slowly (36), and because catalytic hydrogenation was precluded by the presence of sulfur compounds. It is possible that some reduction of acetophenone benzylhydrazone, if present, and azine, **12**, occurred. This would have resulted in the formation of racemic hydrazine, **3**, and, thus, racemic azo compound, **4**. The actual amount of racemization of (−)-(*S*)-**4**, may thus have been quite small, as was concluded above by comparing the optical yields of (−)-(*R*)-**9** isolated from the interrupted and completed runs.

Consideration of the stereochemistry of the decompositions in pure solvents in the absence of butanethiol also leads to the conclusion that there is little racemization of either starting material or product during decompositions in the presence of butanethiol. In chlorobenzene, for example, the cage effect in the decomposition of **4** is 33%. In the absence of hydrogen abstraction from starting material by the radicals which have escaped from the original solvent cage, the amounts of unsymmetrical coupling product formed from (−)-(*S*)-**4** inside and outside the original solvent cage would be equal.[6] That portion formed outside the original solvent cage will surely be racemic so that (−)-(*R*)-**9** formed by recombination within the original solvent cage would have twice the optical purity of the material actually isolated. The (−)-(*R*)-**9** isolated from a decomposition in pure chlorobenzene is 8.2% optically pure. That portion formed in the original solvent cage should then be 16.4% optically pure. This is greater than the 13% observed when the decomposition is carried out in the presence of 1.1 *M* butanethiol where only cage product is formed. It was shown from the dependence of product ratios upon initial concentration of **4** that a significant fraction of the radicals which escape from the original solvent cage do not give coupling products at the concentration used for decomposition of (−)-(*S*)-**4**. Less of the racemic coupling product would then be produced outside the original solvent cage. An accurate correction cannot be made for this effect, but any correction would be in a direction so as to make the stereochemistry of the cage recombination in pure chlorobenzene more similar to that in the presence of butanethiol.

Taken together, all the evidence indicates that any racemization of starting material or product during decomposition of (−)-(*S*)-**4** in the presence of butanethiol cannot be significant. The low optical yield of (−)-(*R*)-**9** from decomposition of (−)-(*S*)-**4** in the presence of butanethiol then must be almost entirely due to a racemization process taking place within the solvent cage after decomposition of (−)-(*S*)-**4** and before coupling of the radicals to (−)-(*R*)-**9**.

[6]Of the ca. 67% of the coupling products which are formed outside the original solvent cage ca. 1/4 is bibenzyl, 1/4 is *meso*- + *dl*-**11**, and 1/2 is **9**.

Although the 1-phenylethyl radical must be either planar or very nearly so and rapidly inverting, it is in an asymmetric environment after it is generated as long as it remains in the original solvent cage (Chart V). Coupling product of inverted configuration can result from cage recombination only if the 1-phenylethyl radical rotates with respect to the benzyl radical before coupling with it. The relative rates of rotation, k_r, of the 1-phenylethyl radical with respect to the benzyl radical and of coupling k_c, of the two radicals within the solvent cage can be calculated with the information at hand. Chart V illustrates all the possible reactions of the caged radical pair. The 1-phenylethyl radical is assumed to be planar and the nitrogen molecule is not shown although it is present in the original solvent cage and must be displaced from between the radicals before they can couple. Equation [14] is derived by using the steady

$$[14]\quad \frac{(-)\text{-}(R)\text{-}\mathbf{9}}{(+)\text{-}(S)\text{-}\mathbf{9}} = 1 + \left(\frac{k_c + k_{disp} + k_{diff}}{k_r}\right)_{cage}$$

state assumption for the concentrations of the enantiomeric radical pairs within the original solvent cage. An expression for $(k_c/k_r)_{cage}$, eq. [15], can now be obtained using the relationships

$$[15]\quad (k_c/k_r)_{cage} = F(1-f)\left(\frac{(-)\text{-}(R)\text{-}\mathbf{9}}{(+)\text{-}(S)\text{-}\mathbf{9}} - 1\right)$$

between k_c, k_{disp}, and k_{diff} which are given in eqs. [16] and [17]. F is the fraction of radicals which

$$[16]\quad \left(\frac{k_c + k_{disp}}{k_c + k_{disp} + k_{diff}}\right)_{cage} = F$$

$$[17]\quad \left(\frac{k_{disp}}{k_c + k_{disp}}\right)_{cage} = f$$

are consumed by coupling and disproportionation before diffusion from the original solvent cage and f is the fraction of radicals consumed in this way which undergo disproportionation. In general it will be assumed that the relative amount of disproportionation will be the same within and without the original solvent cage.

The two sets of values for $(k_c/k_r)_{cage}$ in Table IV, calculated assuming either 0 or 10% disproportionation, are very similar and show that the ratio, $(k_c/k_r)_{cage}$, is not very sensitive to reasonable errors ($\sim 10\%$) in the determination of the cage effect. Even within the original solvent cage the rate of rotation of the 1-phenylethyl radical with respect to the benzyl radical about any axis perpendicular to the line joining the two is much greater than its rate of coupling with the benzyl radical. The rate of such rotation of 1-phenylethyl radicals within the solvent cage is also found to be much greater than their rate of coupling during the decomposition of (−)-1,1′-diphenylazoethane in benzene at 110° (20). There

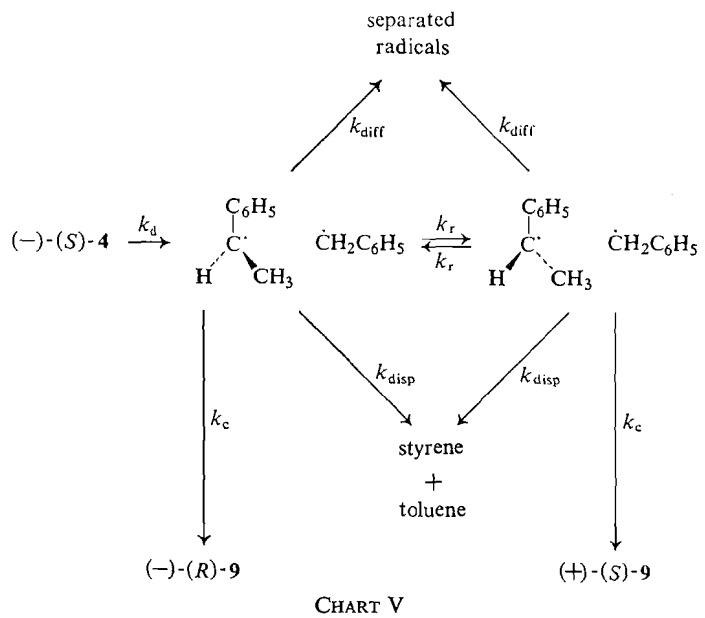

CHART V

For personal use only.

is no significant solvent effect on the ratio, $(k_c/k_r)_{cage}$.

This very small ratio of coupling to rotation contrasts dramatically with ratios of coupling to rotation found in studies of diradicals generated from cyclic precursors (6, 33) in which k_c/k_r can be greater than 50 (6*a*). This must be due to the position of the nitrogen atom in the solvent cage in the acyclic systems. Decomposition of acyclic azo compounds most probably occurs with the groups in the *trans* arrangement about the N=N bond. When formed the two radicals have a nitrogen molecule situated between them on the line joining them, eq. [18]. Numerous collisions may take place before the nitrogen molecule is

[18] 
displaced from this position allowing ample time for rotation to take place. Diradicals generated from the cyclic systems studied do not have any such molecules situated between them even when these are derived from azo compounds, eq. [19], and there is no such hindrance to coupling.

[19] 
Even in acyclic systems there is a very large spread in the values of $(k_c/k_r)_{cage}$ among the only three systems already studied. In frozen solution $(k_c/k_r)_{cage}$ for the 3-methyl-2-phenyl-2-butyl radical pair, generated photochemically from either *meso*- or *dl*-3,3′-dimethyl-2,2′-diphenyl-azo-2-butane, appears to be as large as 50 (7), while for the 1-phenylethyl-benzyl radical pair in liquid solution at 110° it is as small as 0.060. This is a range of $\sim 10^3$ and leaves much room for further investigation.

The optically active esters obtained from decomposition of optically active diacyl peroxides are formed with very high (75–90%) retention of configuration in the alcohol part of the ester (4). On the basis of the results observed in the present study the very high degree of retention observed in the diacyl peroxide decompositions does not seem to be compatible with a process in which the ester is formed by the cage recombination of an acyloxy radical with an alkyl radical. The formation of the alkyl radical would have to be a two-step process proceeding via the acyloxy radical and the present results indicate that the orientation of the two acyloxy radicals with respect to one another must very rapidly become randomized. The original interpretation that ester does not arise by a free radical process (4*a*) thus gains added support, and it is likely that at least the majority of the ester is formed by an alternative route (3) which should give high retention.

Stereoselective cage recombinations of radicals are probably involved in other processes. The Wittig rearrangement of metallated benzyl ethers to benzyl carbinol salts proceeds with partial retention of configuration when optically active substrates are used (37) as does the Meisenheimer rearrangement (38). It now appears that stereoselective free radical cleavage – recombination processes are involved in both the Wittig (39, 40) and Meisenheimer (38, 41) rearrangements. The chromic acid oxidation of tertiary hydrocarbons to tertiary alcohols proceeds with a high degree of retention of configuration and it has been suggested that this reaction also proceeds by a free radical pathway involving stereoselective cage recombination (42). All three of these reactions proceed with a considerably higher degree of retention of configuration (~ 30 to $\sim 100\%$) than is observed in the cage recombination of the radicals derived from (−)-(*S*)-**4**. In each of these reactions there is no hindrance to the recombination of the fragments as is provided by the nitrogen molecule during the decomposition of (−)-(*S*)-**4** so that a higher degree of retention might be expected. The formulation of these reactions as proceeding via radical intermediates is therefore entirely consistent with the results of the studies of decomposition of optically active azo compounds.

Experimental

All melting points and boiling points are uncorrected. Elemental analyses were performed by Mrs. Darlene Mahlow and Mrs. Andrea Dunn. Nuclear magnetic resonance (n.m.r.) spectra were recorded on a Varian A-60 analytical spectrometer using tetramethylsilane as internal standard. Unless otherwise specified spectra were taken of 10–20% w/v solutions in carbon tetrachloride. Infrared (i.r.) spectra were recorded on a Perkin–Elmer recording infrared spectrophotometer, model 421. Ultraviolet

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

spectra were recorded on a Bausch and Lomb Spectronic 600 spectrophotometer. Optical rotations were measured with a Rudolph polarimeter, model 80, or with a Perkin–Elmer 141 polarimeter. Optical rotatory dispersion (o.r.d.) measurements were taken on a model ORD/uv-5 Japan Spectroscopic Company spectrophotometer. Gas–liquid chromatographic (g.l.c.) analyses were done with an Aerograph A90-P3 fractometer using helium as the carrier gas. Unless otherwise indicated a 6 ft × ¼ in. stainless steel column filled with 20% SF-96 on 60/80 Chromosorb P was used.

Solvents

Benzene, cumene, and cyclohexane were shaken with cold sulfuric acid until colorless, several times with water, and once with sodium carbonate solution. After drying over sodium carbonate the solvents were distilled from sodium through a short Vigreaux column and then redistilled through an annular Teflon spinning band distillation column. The middle fraction was taken and stored over sodium. Solvents were redistilled as required just before use. Chlorobenzene was purified in a similar manner except that the preliminary distillation was made over phosphorous pentoxide and it was stored over molecular sieves. Butanethiol was purified by distillation of commercial material, to which some sodium had been added, through a 6 in. Vigreaux column. This was stored for short periods in a brown bottle.

(−)-(S)-1-Phenylethylhydrazine, (−)-(S)-1

A mixture of 80 g (0.66 mole) of (−)-(*S*)-1-phenylethylamine (22) $[\alpha]_D^{25}$ −36.6° (neat, *l* 1 dm), 95% optically pure, and 500 ml water containing 25 g (0.45 mole) potassium hydroxide was stirred vigorously while a solution of 25 g (0.22 mole) freshly prepared (43) hydroxylamine-*O*-sulfonic acid dissolved in the minimum amount of water was added over a 30 min period (44). The temperature rose slowly to 50° during the addition. The reaction mixture was stirred for 2 h longer, cooled, and extracted twice with ether. The combined extracts were dried over sodium carbonate and then concentrated to an oil. The oil was distilled through a 6 in. Vigreaux column until most of the amine had distilled, b.p. 80–90° (25–35 mm), leaving a small amount of higher boiling material. The recovered amine was recycled through the reaction procedure twice more. Twenty-eight grams of starting material were recovered. The high boiling residues were combined and distilled twice through a 6 in. Vigreaux column. The fraction b.p. 70° (1 mm) was collected, 4.5 g (8%), n_D^{25} 1.5436, $[\alpha]_D^{25}$ −29.0° (*c*, 0.784, benzene). Reported (45) for (±)-**1**, b.p. 69° (0.8 mm), n_D^{25} 1.5436. A satisfactory rotation on the pure liquid could not be obtained as bubbles always formed in the polarimeter tube and variable readings were obtained.

Benzaldehyde 1-Phenylethylhydrazone, 2

To a stirred solution of 6.8 g (0.05 mole) 1-phenylethylhydrazine (45) in 80 ml ether were added 6 g anhydrous magnesium sulfate and, 5.5 g (0.052 mole) of freshly distilled benzaldehyde was then added over a period of 30 min. The resulting mixture was stirred overnight and filtered. The solvent was removed under reduced pressure to give a light-yellow oil. Pentane solutions of the oil deposited white crystals, m.p. 50–54°, whose melting point did not change upon recrystallization. Both the oil and the crystals had the same n.m.r. spectrum which showed absorption τ 2.5–3.1 (multiplet, 11.4 H), τ 4.6 (broad singlet, 0.93 H), τ 5.65 (quartet, J = 6.5 c.p.s., 0.93 H), and at τ 8.57 (doublet, J = 6.5 c.p.s., 3.0 H).

(+)-(R)-Benzaldehyde 1-Phenylethylhydrazone, (+)-(R)-2

(+)-(*R*)-1-Phenylethylamine (22), $[\alpha]_D^{25}$ +35.1° (neat, *l* 1 dm), 92% optically pure, was converted to (+)-(*R*)-**1** by the procedure used for the preparation of (−)-(*S*)-**1**. This was converted to (+)-(*R*)-**2**, using the procedure described for the preparation of **2**. After all traces of solvent were removed at reduced pressure (+)-(*R*)-**2** had $[\alpha]_D^{25}$ +63.5° (*c*, 3.31, benzene).

N-Benzyl-N′-(1-phenylethyl)-hydrazine, 3

A solution of hydrazone, **2**, prepared from 42 g of **1** was hydrogenated directly without removing the ether solvent with 5 g of 5% palladium-on-charcoal under an initial pressure of 50 lb hydrogen until uptake of hydrogen ceased. The mixture was filtered under an atmosphere of nitrogen and 39 g of oxalic acid dihydrate dissolved in the minimum amount of hot ethanol was added. An immediate precipitate formed. The mixture was filtered to give 72 g white crystals, m.p. 180–183° after 4 recrystallizations.

Anal. Calcd. for 1:1 base:acid, $C_{17}H_{20}N_2O_4$: C, 64.54; H, 6.40; N, 8.86.

Anal. Calcd. for 2:1 base:acid, $C_{32}H_{38}N_4O_4$: C, 70.82; H, 7.06; N, 10.32. Found: C, 66.30, 66.76; H, 6.58, 6.68; N, 9.63.

The results of the elemental analysis indicate that the salt has the approximate composition $(C_{15}H_{18}N_2)_{1.5}C_2O_4H_2$.

The free hydrazine, **3**, was obtained by addition of 60 g of the recrystallized oxalate salt to an excess of aqueous potassium hydroxide. The aqueous layer was extracted several times with methylene chloride and the combined organic layers were dried over sodium carbonate. After removal of the solvent under reduced pressure the residual oil was distilled to give 41.8 g of a colorless liquid, b.p. 135° (0.5 mm), n_D^{25} 1.5685. All operations were carried out under an atmosphere of nitrogen. The n.m.r. spectrum of **3** showed absorption at τ 2.83 (2 over-lapping singlets, 10 H), τ 6.16 (quartet, J = 7.0 c.p.s.) over-lapping with absorption at τ 6.28 (singlet) due to the hydrogens of the methylene group, (combined area 3.07 H), τ 6.95 (singlet, 2.0 H), and at τ 7.89 (doublet, J = 7.0 c.p.s., 2.94 H).

This material was very sensitive to air oxidation and a satisfactory elemental analysis was not obtained.

1,1′-Diphenyl-1-methylazomethane, 4

Solutions of **3** in ether were allowed to stand under an initial pressure of 10 lb oxygen until oxygen uptake stopped. The ether solution was shaken several times with water and dried over sodium carbonate. The ether was removed under reduced pressure using a rotary evaporator and evaporation continued until there was no further change in refractive index. Yields were quantitative, n_D^{25} 1.5598; λ_{max} (benzene) 358 mμ (ε 51). The n.m.r. spectrum showed absorption at τ 2.80 (multiplet, 10.6 H), τ 5.18 (singlet, ~ 2H) over-lapping with absorption at τ 5.42 (quartet, J = 7.0 c.p.s., ~ 1H) (combined

For personal use only.

area 2.90 H), and at τ 8.50 (doublet, J = 7.0 c.p.s., 3.10 H).

Anal. Calcd. for $C_{15}H_{16}N_2$: C, 80.32; H, 7.19; N, 12.49. Found: C, 80.21; H, 6.99; N, 12.67.

(−)-(S)-1,1'-Diphenyl-1-methylazomethane, (−)-(S)-4

A Via Resolution of 3

A solution of 96 g (0.48 mole) of *d*-camphoric acid in 300 ml ethyl acetate was added to a solution of 108 g (0.51 mole) of **3** dissolved in 325 ml dioxane. The mixture was allowed to stand overnight at 25° and the precipitate which formed was filtered and washed with ether to give 115 g of white crystals, $[\alpha]_D^{25}$ +11.2° (*c*, 3.8, methanol). This material was recrystallized twice: first recrystallization, 55 g, $[\alpha]_D^{25}$ +2.73° (*c*, 3.3, methanol); second recrystallization, 30 g, m.p. 95–105° $[\alpha]_D^{25}$ −2.50° (*c*, 2.5, methanol). Further recrystallization did not alter the rotation or the melting point. The salt could be stored indefinitely at 0° but decomposed slowly at 25°.

The twice crystallized camphorate salt was added to excess aqueous sodium bicarbonate and the resulting oil extracted into ether. The hydrazine was usually not isolated but was converted to the corresponding azo compound by the oxidation procedure described above, $[\alpha]_D^{25}$ −152° (*c*, 1.06, benzene). Material obtained from a second resolution had $[\alpha]_D^{25}$ −150° (*c*, 1.1, benzene). Optical rotatory dispersion (*c*, 0.0179, cyclohexane): $[\Phi]_{600}$ −209°, $[\Phi]_{500}$ −377°, $[\Phi]_{450}$ −628°, $[\Phi]_{400}$ −1676°, $[\Phi]_{380}$ −2528°, $[\Phi]_{354}$ ±0°, $[\Phi]_{350}$ +726°, $[\Phi]_{330}$ +2095°, $[\Phi]_{320}$ +1732°.

Samples of (−)-(*S*)-**3** which were isolated by evaporation of solvent exhibited a negative rotation which varied widely from run to run.

B From (−)-(S)-1

In another experiment a mixture made up from 2.2 g (0.016 mole) of (−)-(*S*)-**1**, prepared from (−)-(*S*)-**5** of $[\alpha]_D^{25}$ −36.6° (neat, *l* 1 dm), 95% optically pure, 1 g magnesium sulfate, and 2.1 g (0.019 mole) benzaldehyde in 10 ml benzene was allowed to stand several hours. The reaction mixture was then filtered and 40 ml of a 25% solution of diisobutylaluminium hydride in benzene were added dropwise to the stirred filtrate under a nitrogen atmosphere. The addition required 30 min. The reaction mixture, which had become warm, was stirred at 25° for 2 days and then cooled in an ice bath. A solution of benzene–methanol (1:1) was added dropwise until there was no vigorous reaction on further addition. This was followed by the addition of 5 ml water, 10 ml 15% potassium hydroxide, and then 5 ml water. The aqueous layer was extracted with ether. The organic fractions were combined, dried over sodium carbonate, and poured into a solution of 2.6 g oxalic acid dihydrate in 10 ml of 98% ethanol. A white precipitate formed immediately. The mixture was allowed to stand at 0° for several hours and then filtered. The crystals, 1.9 g, were recrystallized from ethanol and the resulting solid, 1.5 g, was converted to the free hydrazine, (−)-(*S*)-**3**, as described previously. This material was not isolated but was oxidized directly to the azo compound as described above. The product after removal of the ether using a rotary evaporator contained 7.5% of (−)-(*S*)-**1**, by n.m.r. analysis, and had $[\alpha]_D^{25}$ −140° (*c*, 1.36, benzene). No other absorptions could be found. On the basis that the (−)-(*S*)-**1** present had $[\alpha]_D^{25}$ −28° and has the same density as (−)-(*S*)-**4**, (−)-(*S*)-**4** in the mixture has $[\alpha]_D^{25}$ −146°. Optically pure (−)-(*S*)-**4** would then have $[\alpha]_D^{25}$ −153°.

Hydrogenolysis of (−)-(S)-4

A mixture of 1.7 g (−)-(*S*)-**4**, $[\alpha]_D^{25}$ −152° (*c*, 1.06, benzene), 2 g Raney nickel, and 40 ml methanol was stirred at 25° in a microhydrogenation apparatus at atmospheric pressure. One equivalent of hydrogen was taken up within a few minutes and a second equivalent after two days. Analysis by g.l.c. showed that the main products were benzylamine and (−)-(*S*)-**5** together with small amounts of toluene and ethylbenzene. The mixture was filtered and the filtrate concentrated to a small volume. The residual oil was injected in 100 μl portions into the SF-96 g.l.c. column operating at 160° with a flow rate of 150 ml/min of helium. Partial separation of the amines was achieved in this way.

Material rich in (−)-(*S*)-**5** was collected from the effluent stream. Recycling of this material afforded 55 mg of pure (g.l.c.) (−)-(*S*)-**5**, $[\alpha]_D^{25}$ −31.4° (*c*, 5.4, dioxane). Optically pure (−)-(*S*)-**5** is calculated from literature data (46, 22) to have $[\alpha]_D^{25}$ −39.6° under these conditions.

In a control experiment 2 g of (−)-(*S*)-**5**, $[\alpha]_D^{25}$ −36.6° (neat, *l* 1 dm), in 40 ml methanol was stirred under the above hydrogenolysis conditions with 2 g Raney nickel for three days. The recovered amine had n_D^{25} 1.5245, $[\alpha]_D^{25}$ −36.5° (neat, *l* 1 dm).

2,3-Diphenyl-1-propanol, 7

A solution of 11 g (0.049 mole) of 2,3-diphenylpropionic acid, **6**, in 100 ml ether was added slowly to a slurry of 4.75 g (0.125 mole) of lithium aluminium hydride in 180 ml ether. The reaction mixture was stirred overnight and then hydrolyzed by the addition of water, followed by sulfuric acid. The ether layer was shaken twice with aqueous sodium carbonate, dried over sodium carbonate, and concentrated. Distillation of the residue gave 6.0 g (60%) of a light yellow oil, b.p. 140° (0.4 mm), n_D^{25} 1.5758; reported (47) b.p. 300–302°. The n.m.r. spectrum showed absorption at τ 2.95 (multiplet, 10.0 H), τ 6.3–7.4 (broad multiplet, 5.0 H), and at τ 8.05 (singlet, 1.1 H).

(−)-(R)-2,3-Diphenylpropanol, (−)-(R)-7

Using the above procedure, (−)-(*R*)-**6** (28), $[\alpha]_D^{25}$ −132° (*c*, 0.062, chloroform), 100% optically pure, was converted to (−)-(*R*)-**7**, n_D^{25} 1.5745, $[\alpha]_D^{25}$ −88.5° (*c*, 1.08, chloroform). Reported (25) for (+)-(*S*)-**7**, n_D^{25} 1.5742, $[\alpha]_D^{25}$ +76.3° (*c*, 5.3, chloroform).

2,3-Diphenyl-1-propyl p-Toluenesulfonate, 8

This material was prepared from **7** by the procedure of Schleyer (48), m.p. 79.5–89.5° after recrystallization from ligroin.

Anal. Calcd. for $C_{22}H_{22}O_3S$: C, 72.10; H, 6.05; S, 8.75. Found: C, 72.34; H, 5.88; S, 8.96.

(−)-(R)-2,3-Diphenyl-1-propyl p-Toluenesulfonate, (−)-(R)-8

This material was prepared from (−)-(*R*)-**7**, $[\alpha]_D^{25}$ −88.5°, 100% optically pure, by the above procedure, m.p. 91.0–93.5°, $[\alpha]_D^{25}$ −42.6° (*c*, 0.51, chloroform); reported (25) for (+)-(*S*)-**8**, m.p. 89–90°, $[\alpha]_D^{25}$ +40.2° (*c*, 2.4, acetone).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(−)-(R)-1,2-Diphenylpropane, (−)-(R)-9

A solution of 0.40 g of (−)-(*R*)-**8**, $[\alpha]_D^{25}$ −42.6°, 100% optically pure, in 15 ml ether was added dropwise to a slurry of 1.0 g lithium aluminium hydride in 40 ml ether. The reaction mixture was stirred for two days at 25°. It was hydrolyzed by adding ice water and then 6 *N* hydrochloric acid dropwise. The ether layer was dried over sodium carbonate and then concentrated to an oil. Analysis by g.l.c. showed only one product which was collected from the effluent stream, 0.074 g (30%), m.p. 22.0–23.0°, n_D^{25} 1.5572, $[\alpha]_D^{25}$ −80.5° (*c*, 3.2, chloroform). Optical rotatory dispersion (*c*, 1.54, cyclohexane): $[\Phi]_{600}$ −167°, $[\Phi]_{450}$ −333°, $[\Phi]_{350}$ −833°, $[\Phi]_{300}$ −1666°, $[\Phi]_{280}$ −2666°.

The g.l.c. retention time of this material was identical with a sample of **9** (49) prepared by the hydrogenation of α-methylstilbene; reported (25) for (−)-(*R*)-**9**, n_D^{25} 1.5553, $[\alpha]_D^{25}$ −76.3° (*c*, 2.2, chloroform), for (+)-(*S*)-**9**, n_D^{25} 1.5558, $[\alpha]_D^{25}$ +76.7° (*c*, 2.3, chloroform).

1,1′-Diphenylazoethane

This material was prepared by the published procedure (18*b*) except that the oxidation of the corresponding hydrazone was carried out with oxygen as described for the preparation of **4**, m.p. 68–71°; reported (18*b*), m.p. 72.3–72.9°.

Kinetic Studies

The rates of evolution of nitrogen from solutions of **4** (~ 0.1–0.2 *M*) in cumene were measured using an apparatus and a procedure similar to that described by Peterson(50). Rate constants were determined from the initial slopes of plots of log $(V_\infty - V_0/V_\infty - V_t)$ vs. time using the theoretical value of V_∞. V_0 was determined as described by Petersen *et al.* (50). The results are summarized in Table I.

Product Studies

For quantitative analyses solutions of **4** were placed in Pyrex tubes, degassed by several freeze-thaw cycles, and then heated at the appropriate temperature for at least 6 half-lives after the tubes were sealed. After cooling to −78° the tubes were opened and the solutions analyzed directly by temperature-programmed g.l.c. The temperature of the column was raised from 100 to 200° over a 35 min period beginning immediately after injection. The helium flow rate was 50 ml/min.

Hydrocarbon products were identified by comparison of g.l.c. retention times with those of authentic samples, and in the cases of bibenzyl, **9** and *meso*- and *dl*-**11** also by comparison of the n.m.r. spectra of isolated materials with those of authentic samples. The order of elution of the higher molecular weight products was bibenzyl, **9**, *dl*-**11**, and *meso*-**11**. Authentic samples of *meso*- and *dl*-**11** were prepared by the method of Barber *et al.* (51). Relative thermal response factors for the hydrocarbons were determined to be: toluene, 55; ethylbenzene, 60; bibenzyl, 85; **9**, 100; and *meso*- and *dl*-**11**, 95.

In preparative runs solutions of 1–2 g of (±)-**4** or optically pure (−)-(*S*)-**4** in 20–50 ml of solvent were placed in a 75 ml stainless steel bomb, flushed several minutes with nitrogen, and heated at the appropriate temperature for at least 7 half-lives. Most of the solvent was then removed through the spinning band column. When butanethiol was not present, the products were isolated from the residual oil by temperature-programmed preparative g.l.c. using the above conditions. When butanethiol was present in solution by-products formed which were eluted slowly from the g.l.c. column and repetitive injections of the residual oil could not be made. In these cases the by-products were removed by adsorbing the residual oil on a 5 cm × 40 cm column of activated basic alumina and eluting the hydrocarbon present with 200 ml hexane. After concentration of the hexane eluent through the spinning band column (±)-**9** or (−)-(*R*)-**9** were isolated from the residual oil by preparative g.l.c. using a steady column temperature of 205°. Amounts of (±)-**9** or (−)-(*R*)-**9** obtained, ranged from 10 to 100 mg. The smaller amounts were obtained when the sample had some impurities present after the first g.l.c. pass and had to be recycled.

From decompositions of (−)-(*S*)-**4** carried out in pure butanethiol as solvent, a yellow solid could be isolated which has a g.l.c. retention time very similar to that of (−)-(*R*)-**9**. It was not investigated further but is presumed to be the mixed azine of acetophenone and benzaldehyde. Smaller amounts of this yellow material were formed in decomposition in 1 *M* butanethiol.

Control Experiments

A Racemization of (−)-(R)-9 in Butanethiol

A solution made up of 1.2 g of 1,1′-diphenylazoethane, 36 ml butanethiol, and 80 mg of optically pure (−)-(*R*)-**9**, $[\alpha]_D^{25}$ −80.5° (*c*, 3.2, chloroform), was heated in the bomb at 110° for 12 h (~ 10 half-lives of decomposition of the azo compound); recovered (−)-(*R*)-**9** had $[\alpha]_D^{25}$ −64.1° (*c*, 1.42, chloroform).

B Interrupted Decomposition of (−)-(S)-4

A solution of 2.0 g optically pure (−)-(*S*)-**4** in 30 ml butanethiol was heated in the bomb at 110° for 5 h (~ 20% decomposition). Butanethiol was removed under reduced pressure and the residue was taken up in 50 ml methanol. Twenty grams of potassium azodicarboxylate were added, followed by the dropwise addition of acetic acid until the reaction mixture became colorless. Ether, 100 ml, was added and the resulting mixture was shaken with dilute sulfuric acid. The aqueous layer was shaken several times with ether, made alkaline with dilute potassium hydroxide solution, and shaken twice with ether. The latter ethereal extracts were combined, allowed to stand under an atmosphere of oxygen for several hours, shaken with water, and then dried over sodium carbonate. Removal of the ether gave a small amount of an oil $[\alpha]_D^{25}$ −101° (*c*, 1.3, benzene). The n.m.r. spectrum of this oil showed it to be a mixture of (−)-(*S*)-**4**, 71.5% and of (−)-(*S*)-**2**, 28.5%. No absorptions other than those due to these materials could be detected. On the basis that the (−)-(*S*)-**2** present is optically pure and has $[\alpha]_D^{25}$ −69°, the rotation of the recovered azo compound would be $[\alpha]_D^{25}$ −114°.

The ether layer remaining after the extraction with sulfuric acid was concentrated to an oil. The oil was chromatographed on alumina and the hydrocarbon, (−)-(*R*)-**9**, 0.012 g, isolated from the concentrated eluent by g.l.c. had $[\alpha]_D^{25}$ −13.9° (*c*, 1.2, chloroform).

Stéréochimie de l'addition de réactifs de Grignard sur la *t*-butyl-2 cyclohexanone

JEAN-CLAUDE RICHER ET DENIS EUGÈNE
Département de Chimie, Université de Montréal, Boîte Postale 6128, Montréal, Québec

Reçu le 8 octobre 1968

Les configurations relatives des *t*-butyl-2 éthyl-1 cyclohexanols ont été déterminées. La stéréochimie de l'addition de réactifs de Grignard sur la *t*-butyl-2 cyclohexanone a été étudiée. Les résultats obtenus sont interprétés en fonction d'une théorie complètement stérique.

Canadian Journal of Chemistry, 47, 2387 (1969)

Introduction

La stéréochimie de l'addition de réactifs de Grignard sur la *t*-butyl-4 cyclohexanone (**1**) a été étudiée par plusieurs auteurs (1–4). Toutefois aucune étude parallèle dans le domaine de la *t*-butyl-2 cyclohexanone (**2**) où le carbonyle est soumis à l'encombrement stérique du groupe *t*-butyle de la position-2 n'a été rapportée. Considérant l'importance que pourrait avoir ce substituant volumineux sur la réactivité de la cétone adjacente il apparaissait opportun d'examiner les résultats stéréochimiques de l'addition des réactifs de Grignard sur cette cétone. Les résultats obtenus au cours de cette étude font l'objet de la présente communication.

6

Résultats

Les résultats obtenus lors de l'addition des magnésiens (**3**) d'éthyle, de vinyle et d'éthynyle sur la *t*-butyl-2 cyclohexanone sont rapportés dans le tableau I. Les configurations relatives des alcools tertiaires qui en dérivent ont été établies.

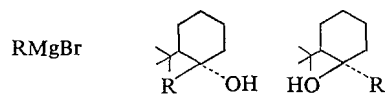
La chromatographie sur alumine du produit obtenu par addition d'un grand excès de bromure d'éthylmagnésium (**3***a*) sur la *t*-butyl-2 cyclohexanone (**2**) permet d'obtenir le *t*-butyl-2 éthyl-1 cyclohexanol *trans*[1] (**5***a*) à l'état pur. Le même alcool est aussi obtenu d'une part par hydrogénation catalytique du *t*-butyl-2 vinyl-1 cyclohexanol *trans* (**5***b*) formé en prépondérance lors de l'addition du bromure de vinylmagnésium (**3***b*) sur la *t*-butyl-2 cyclohexanone (**2**) et d'autre part par hydrogénation catalytique du *t*-butyl-2 éthynyl-1 cyclohexanol *trans* (**5***c*) obtenu par l'action du bromure d'éthynylmagnésium (**3***c*) sur la *t*-butyl-2 cyclohexanone (**2**). Ces résultats indiquent que les alcools obtenus en prépondérance par action des magnésiens sur la *t*-butyl-2 cyclohexanone ont tous la même configuration relative.

TABLEAU I

Stéréochimie des additions des réactifs de Grignard **3** sur la cétone **2**

Grignard **3**	% alcools **5** formés
3*a*	97*
3*b*	95
3*c*	80

*Quantités équimoléculaires de cétone **2** et de magnésien **3***a*.



3 **4** **5**

a) R = $CH_3—CH_2—$
b) R = $CH_2=CH—$
c) R = $H—C\equiv C—$
d) R = H

Les alcools tertiaires de la série *cis* (**4**) ont tous été obtenus à partir du *t*-butyl-2 éthynyl-1 cyclohexanol *cis* (**4***c*) préparé par réaction de la *t*-butyl-2 cyclohexanone (**2**) avec l'acétylure de lithium complexé par l'éthylène diamine (**5**) utilisant le tétrahydrofuranne comme solvant. Il a été bien établi (6) à l'aide de la méthyl-2 cyclohexanone (**6**) que l'addition de sels métalliques d'acétylène conduit à des résultats où le rapport d'alcool tertiaires *cis*/*trans* varie considérablement en fonction des conditions de la réaction.

[1]Les configurations se rapportent à la relation existant entre les groupes alkyles portés par les noyaux cyclohexaniques.

TABLEAU II

Propriétés comparées des alcools **4***a* et **5***a*

Produit	i.r. (cm^{-1})*	r.m.n.† p.p.m.	r.m.n.† $\Delta w_H OH$(c.p.s.)
4*a*	1010–1040	3.45	0.78
5*a*	956	3.32	1.95

*Fréquence de la vibration C—O.
†Spectres déterminés à 84.8 mg/0.5 ml DMSO-d_6.

Les conditions choisies dans la présente étude correspondent à celles qui ont fourni un rapport d'alcool *cis*/*trans* maximum.

La configuration relative des alcools tertiaires obtenus est inférée à partir des résultats de l'analyse chromatographique en phase gazeuse qui indiquent que les alcools formés en prédominance (**5***a*) par l'action des Grignard sur la *t*-butyl-2 cyclohexanone ont les temps de rétention les plus courts; il est maintenant bien établi (4) que ces produits doivent contenir un groupe OH en position axiale. Les fréquences d'absorption dans l'infrarouge ont aussi été fréquemment utilisées (4, 7, 8) afin d'établir des configurations relatives de produits hydroxylés. Le tableau II montre les positions des bandes d'absorption dans la région de 1000 cm^{-1} pour les alcools tertiaires obtenus au cours de ce travail et ces données supportent les configurations proposées précédemment. La résonance magnétique nucléaire (voir tableau II) corrobore ces conclusions tant par la position (déplacement chimique) des protons hydroxyliques (4) que par la largeur de ces bandes (9, 10)[2] grâce à l'observation selon laquelle les largeurs à demi-hauteur des bandes dues à des protons de groupes hydroxyles axiaux sont plus faibles que celles des protons des groupes hydroxyles équatoriaux; cette différence a été attribuée au fait que le couplage à longue distance est plus facile dans un cas que dans l'autre.

L'ensemble des résultats rapportés ici présente une image consistante qui indique que les alcools tertiaires formés en prépondérance lors de l'addition d'un réactif de Grignard sur la *t*-butyl-2 cyclohexanone possèdent la configuration *trans* (**5***b*, et **5***c*). La stéréochimie observée pour ces réactions pourrait à notre avis être attribuée au fait qu'une attaque axiale en position-2 du

groupe *t*-butyle serait empêchée à cause de l'interaction 1,3 diaxale qui se développerait entre le réactif introduit et l'un des groupes méthyles du groupement *t*-butyle présent en position-2; cette proposition est en parfait accord avec les rapports récents soumis pour expliquer les vitesses relatives d'oxydation chromique d'alcools secondaires (11), la stéréochimie d'addition de boranes sur le *t*-butyl-3 cyclohexène (12), ou pour expliquer la stéréochimie des époxidations de cet hydrocarbure (13). L'ensemble de ces observations implique d'une part que la stéréochimie des réactions d'addition de réactifs de Grignard sur des cétones cycliques (14) peut être expliquée grâce à la théori complètement stérique (15) proposée pour expliquer la stéréochimie des additions nucléophiles sur ces cétones et d'autre part qu'un groupement *t*-butyle ne doit pas être considéré comme sphérique mais que les conformations privilégiées de ce groupement doivent toujours être envisagées.

Partie expérimentale

Les techniques expérimentales générales sont décrites dans des publications précédentes (14, 16). Les détails expérimentaux et les spectres de masse sous forme de graphiques sont rapportés dans le mémoire de Maîtrise de M. Denis Eugène dont une copie est déposée à la bibliothèque du Conseil National de Recherches du Canada. Les poids moléculaires sont déterminés au moyen d'un osmomètre à pression de vapeur de la compagnie Hewlett–Packard modèle 301 A. Les chromatographies en phase gazeuse ont été effectuées à l'aide d'un appareil de la compagnie F et M, modèle 810 à ionisation de flamme utilisée avec la colonne A de 8 pd. × 1/4 po. contenant 15% de diglycérol avec 2% d'eau sur du Chromosorb W "non acid wash", maintenue à 110 °C et le débit d'azote au cours de ces études est de 35 ml/min; un appareil Microtek à conductivité thermique a été utilisée avec la colonne B de 10 pd. × 1/4 po. contenant 15% d'hyprose sur du Chromosorb P est maintenue à 170 °C et dans ces conditions le gaz porteur, l'hélium, a un débit de 75 ml/min.

t-Butyl-2 éthynyl-1 cyclohexanols (4c et 5c)

t-Butyl-2 éthynyl-1 cyclohexanol trans (5c)

Par l'intermédiaire d'un tube barboteur, un léger courant d'acétylène purifiée et anhydre est envoyé dans 175 ml de THF anhydre pendant 2 h de façon à saturer le THF en d'acétylène. En maintenant toujours sous un courant acétylène, 60 ml d'une solution tétrahydrofuranique 3.1 *N* de bromure d'éthyl magnésium sont ajoutés goutte à goutte; après cette addition le milieu réactionnel est laissé à la température de la pièce pour 45 min. Le

magnésien formé est insoluble dans le THF à cette concentration. Le courant d'acétylène est arrêté et 24 g de *t*-butyl-2 cyclohexanone (0.156 mole) sont additionnés lentement. La réaction est laissée 48 h à température de la pièce et après hydrolyse avec une solution de NH_4Cl à 10% les produits sont extraits à l'éther à la façon habituelle pour fournir 25 g d'un produit qui par chromatographie en phase gazeuse contiendrait encore 59% de cétone qui n'a pas réagie; l'alcool désiré forme 80% de la fraction alcoolique. Après distillation de la cétone, l'alcool désiré est obtenu par chromatographie sur alumine de la fraction alcoolique en employant un mélange cyclohexane: acétate d'éthyle à 3% comme solvant. L'alcool (**5***c*) pur se présente sous forme d'un liquide incolore; p.e.: 60°/0.25 mm Hg; n_D^{26}: 1.4810; infrarouge (i.r.): bandes à 3520, 3325, 2100 et 968 cm^{-1}; spectre résonance magnétique nucléaire (r.m.n.): le groupe *t*-butyle à 1.04 p.p.m., proton acétylénique à 3.12 p.p.m. et proton hydroxylique à 3.36 p.p.m.; les temps de rétention en chromatographie en phase gazeuse sont sur la colonne A de 22 min et sur la colonne B de 11 min 30. Ce produit peut être caractérisé sous forme d'acétate: p.é.: 54°/0.05 mm Hg; n_D^{26}: 1.4720; poids moléculaire calculé: 222; trouvé: 221: spectre i.r.: bandes à 3300 cm^{-1} et 1730 cm^{-1}; r.m.n.: groupe *t*-butyle à 1.06 p.p.m., proton acétylénique à 2.62 p.p.m., CH_3 de l'acétate à 1.96 p.p.m.

t-Butyl-2 éthynyl-1 cyclohexanol cis (4c)

Une solution de 12.5 g d'acétylure de lithium complexé par l'éthylènediamine dans 110 ml de THF anhydre est maintenue à une température de 45° sous un léger courant d'acétylène purifié et séché sur H_2SO_4. Sous agitation, 15 g de *t*-butyl-2 cyclohexanone sont introduits goutte à goutte et une fois l'addition terminée le chauffage, l'agitation et le courant d'acétylène sont laissés pendant 22 h. Pour effectuer l'hydrolyse 50 ml d'eau sont introduits et un chauffage de 1 h au léger reflux permet de chasser l'excès d'acétylène dissous dans la solution. L'extraction à la manière habituelle conduit à 17.2 g de produit qui par chromatographie en phase gazeuse contiendrait 9% de cétone **2** qui n'a pas réagie: dans ce mélange l'alcool désiré *cis* (**4***c*) forme 88% du total. Cet alcool est un solide qui recristallisé deux fois dans un mélange d'éthanol–eau présente les caractéristiques suivantes: p.f.: 68°; i.r.: bandes à 3630, 3460, 1057 et 3330 cm^{-1}; spectre r.m.n.: groupe *t*-butyle à 1.01 p.p.m., proton acétylénique à 3.16 p.p.m., proton hydroxylique à 3.36 p.p.m.; chromatographie en phase gazeuse: temps de rétention sur la colonne A de 28.3 min et sur la colonne B de 12 min. Cet alcool peut être caractérisé par l'intermédiaire de son acétate: p.é.: 60°/0.08 mm Hg; n_D^{26}: 1.4762 poids moléculaire calculé: 222; trouvé: 220.8; i.r.: bandes à 3300 et 1735 cm^{-1}; r.m.n.: groupe *t*-butyle à 1.09 p.p.m., proton acétylénique 2.68 p.p.m. et CH_3 de l'acétate à 2.00 p.p.m.

t-Butyl-2 vinyl-1 cyclohexanols (4b et 5b)

t-Butyl-2 vinyl-1 cyclohexanol trans (5b)

A une solution de magnésien du bromure de vinyle préparée selon la méthode de Normant (17) à partir de 22.7 g de magnésium et de 100 g de bromure de vinyle, 15 g de cétone **2** sont ajoutés goutte à goutte à la température de la pièce; le mélange est maintenu sous agitation à cette température pendant 36 h. Après extraction à la manière habituelle, 15.6 g de produit sont obtenus; la chromatographie en phase gazeuse indique qu'il reste 44% de cétone **2** qui n'a pas réagie et que l'alcool désiré **5***b* forme 95% de la fraction alcoolique. Le produit ainsi obtenu est traité par 5 g de $LiAlH_4$ dans 200 ml d'éther et extrait à la manière habituelle. La chromatographie de ce mélange d'alcool utilisant 250 g d'alumine permet d'isoler 3.5 g du *t*-butyl-2 vinyl-1 cyclohexanol *trans* (**5***b*) pur: p.é.: 47°/0.07 mm Hg; n_D^{27}: 1.4779; i.r.: bandes à 3630, 3520, 3100, 1638, 1005, 910 cm^{-1}; r.m.n.: groupe *t*-butyle à 0.97 p.p.m., proton hydroxylique à 4.01 p.p.m., protons A, B, et C du groupe vinyle respectivement à 6.1, 4.88 et 5.15 p.p.m. (les constantes de couplages sont J_{AB} 10.25 c.p.s., J_{AC} 17.25 c.p.s. et J_{BC} 1.75 c.p.s.); chromatographie en phase gazeuse: temps de rétention sur la colonne A de 11 min et sur la colonne B de 7.20 min; spectre de masse: pic parent à 182. Cet alcool peut être caractérisé par l'intermédiaire de son acétate: p.é.: 54°/0.07 mm Hg; n_D^{26}: 1.4764; poids moléculaire calculé: 224; trouvé: 222.8; i.r.: bandes à 3080, 1738, 1640 cm^{-1}; r.m.n.: groupe *t*-butyle apparaît à 1.0 p.p.m., CH_3 de l'acétate à 2.05 p.p.m., protons A, B, et C du groupe vinyle respectivement à 6.36, 5.06 et 4.97 p.p.m. (J_{AB} = 12 c.p.s., J_{AC} = 18 c.p.s. et J_{BC} = 1 c.p.s.).

t-Butyl-2 vinyl-1 cyclohexanol cis (4b)

L'hydrogénation de 1.62 g de *t*-butyl-2 éthynyl-1 cyclohexanol *cis* (**4***c*) dissous dans 10 ml de méthanol en présence de 40 mg de palladium sur carbonate de calcium (5%) empoisonné par 40 mg de quinoléine préalablement distillée conduit après distillation à 1.3 g du produit attendu (**4***b*); p.é.: 94°/11 mm Hg; n_D^{26}: 1.4863; i.r.: bandes à 3650, 3490, 3095, 1631, 995, 912 cm^{-1}; r.m.n.: groupe *t*-butyle à 0.96 p.p.m., proton hydroxylique à 4.14, protons A, B et C du groupe vinyle respectivement à 6.42, et 5.04 et 5.32 (J_{AB} = 10.12, J_{AC} = 16.5, et J_{BC} = 2.5 c.p.s.); chromatographie en phase gazeuse: temps de rétention sur la colonne A de 13.3 min et sur la colonne B de 8.3 min; spectre de masse: pic parent à 182. Cet alcool peut être caractérisé par l'intermédiaire de son acétate: p.é.: 55°/0.8 mm Hg; n_D^{26}: 1.4955; poids moléculaire calculé: 224; trouvé: 222.1; i.r.: bandes à 3100, 1730, 1635, 995 et 905 cm^{-1}; r.m.n.: groupe *t*-butyle à 1.0 p.p.m., CH_3 de l'acétate à 1.75 p.p.m., protons A, B et C du groupe vinyle respectivement à 6.25, 4.89 et 4.82 p.p.m. (J_{AB} = 12, J_{AC} = 18 et J_{BC} = 1 c.p.s.).

t-Butyl-2 éthyl-1 cyclohexanol (4a et 5a)

t-Butyl-2 éthyl-1 cyclohexanol trans (5a)

A une solution de 4 moles de magnésien du bromure d'éthyle dans l'éther, 60 g (0.39 mole) de cétone (**2**) sont ajoutés goutte à goutte et une fois l'addition terminée, l'agitation est maintenue pendant 48 h. L'hydrolyse du milieu réactionnel est faite à l'aide d'une solution aqueuse de chlorure d'ammonium dans la glace et l'extraction des produits réactionnels à la manière habituelle conduit à 11 g de produit brut contenant d'après la c.p.g. 23% de cétone qui n'a pas réagi **2**, 22% d'alcools de réduction (**4***d* et **5***d*) et 55% d'alcools d'addition (**4***a* et **5***a*) parmi lesquels le produit désiré *trans*, **5***a* forme 91% du total. Cet alcool est purifié par chromatographie de 11 g de produit brut sur 800 g d'alumine; l'élution à l'éther de pétrole 30–60 permet de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

récupérer la cétone qui n'a pas réagi alors que l'alcool **5***a* est élué grâce à un mélange contenant du benzène et 20% d'éther anhydre. Il se présente sous forme d'une huile incolore. p.é.: 54°/0.18 mm Hg; n_D^{27}: 1.4731; i.r.: bandes à 3630, 3520 et 956 cm^{-1}; r.m.n.: groupe *t*-butyle à 1.03 p.p.m., proton hydroxylique (DMSO-d_6) à 3.32 p.p.m., groupes méthyle et méthylène de l'éthyle à 0.89 et 1.67 p.p.m. respectivement avec $J = 7.5$ c.p.s.; chromatographie en phase gazeuse: temps de rétention sur la colonne A, 13 min, et sur la colonne B, 8 min; spectre de masse: pic parent à 184. Cet alcool peut être caractérisé par l'intermédiaire de son acétate: p.é.: 57°/0.08 mm Hg; n_D^{27}: 1.4672; poids moléculaire calculé: 226; trouvé: 223.9; i.r.: bandes à 1730, 1247, 1265 et 1277 cm^{-1}; r.m.n.: groupe *t*-butyle à 1.05 p.p.m., méthyle de l'acétate à 1.95 p.p.m. et méthyle du groupe éthyle à 0.93 p.p.m.

Cet alcool peut aussi être obtenu par hydrogénation totale en présence d'oxyde de platine dans le méthanol soit des *t*-butyl-2 éthynyl-1 (**5***c*) ou vinyl-1 (**5***b*) cyclohexanols décrits précédemment. La similitude des produits est démontrée grâce à la spectroscopie i.r. et la chromatographie en phase gazeuse.

t-Butyl-2 éthyl-1 cyclohexanol cis (4a)

L'hydrogénation de 3 g de l'alcool **4***b* dissous dans 50 ml de méthanol en présence de 50 mg de PtO_2 conduit après extraction des produits à la manière habituelle à 2.5 g (85% du rendement théorique) de l'alcool désiré (**4***a*): p.é.: 46°/0.07 mm Hg; n_D^{27}: 1.4747; i.r.: bandes à 3640, 3520, 1040 et 1010 cm^{-1}; r.m.n.: groupe *t*-butyle à 1.04 p.p.m., méthyle et méthylène du groupe éthyle respectivement à 0.89 et 1.63 p.p.m. avec $J = 7.5$ c.p.s., proton hydroxylique (DMSO-d_6) à 3.45 p.p.m.; chromatographie en phase gazeuse: temps de rétention sur la colonne A, 15 min et sur la colonne B, 8.6 min; spectre de masse: pic parent à 184. Cet alcool peut être caractérisé par l'intermédiaire de son acétate: p.é.: 58°/0.07 mm Hg; n_D^{27}: 1.4722; poids moléculaire: calculé 226; trouvé 224.2; i.r.: bandes à 1727, 1263, 1250 et 1240 cm^{-1}; r.m.n.: groupe *t*-butyle à 1.05 p.p.m., groupe méthyle de l'acétate à 2.00 p.p.m. et groupe méthyle de l'éthyle à 0.91 p.p.m. Le même alcool peut être obtenu par hydrogénation de l'alcool (**4***c*) en présence de PtO_2 dans le méthanol; l'identité des produits est démontrée grâce à l'i.r. et la chromatographie en phase gazeuse.

Influence of Lewis acids on the Diels–Alder reaction. Part I. An improved synthesis of 7-azanorbornadiene, 3-azaquadricyclane, and azepine derivatives[1]

R. C. BANSAL,[2] A. W. MCCULLOCH, AND A. G. MCINNES
Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received November 28, 1968

Depending on the experimental conditions the $AlCl_3$-promoted reaction of 1-carbomethoxypyrrole and dimethyl acetylenedicarboxylate yields 2,3,7-tricarbomethoxy-7-azanorbornadiene, either in almost quantitative yield or together with dimethyl 1-carbomethoxy-2-pyrrolyl maleate and fumarate. The azanorbornadiene has been quantitatively converted to 1,4,5-tricarbomethoxyazepine via the corresponding 3-azaquadricyclane. The proton magnetic resonance spectra were analyzed with the aid of the Laocoon II program.

Canadian Journal of Chemistry, 47, 2391 (1969)

Prinzbach and co-workers (1, 2) have recently reported the preparation of a number of 7-azanorbornadiene derivatives (**2***a*–**2***e*). These adducts were prepared by heating the appropriate *N*-substituted pyrrole (**1***a*–**1***e*) with a large excess of dimethyl acetylenedicarboxylate (DMAD). Adducts **2***a*–**2***d*, however, were only isolated in yields of 30 to 45% because of the high reaction temperatures (105–142°), the reversible nature of the reactions (see reaction *b*), and in one case a retro Diels–Alder reaction which produced **7***a* and acetylene from **2***a* (see also ref. 16). Adducts **2***e* were prepared at lower temperatures (40–95°) but with one exception (**2***e*, Y = NO_2) their thermal instability limited yields to about 25%.

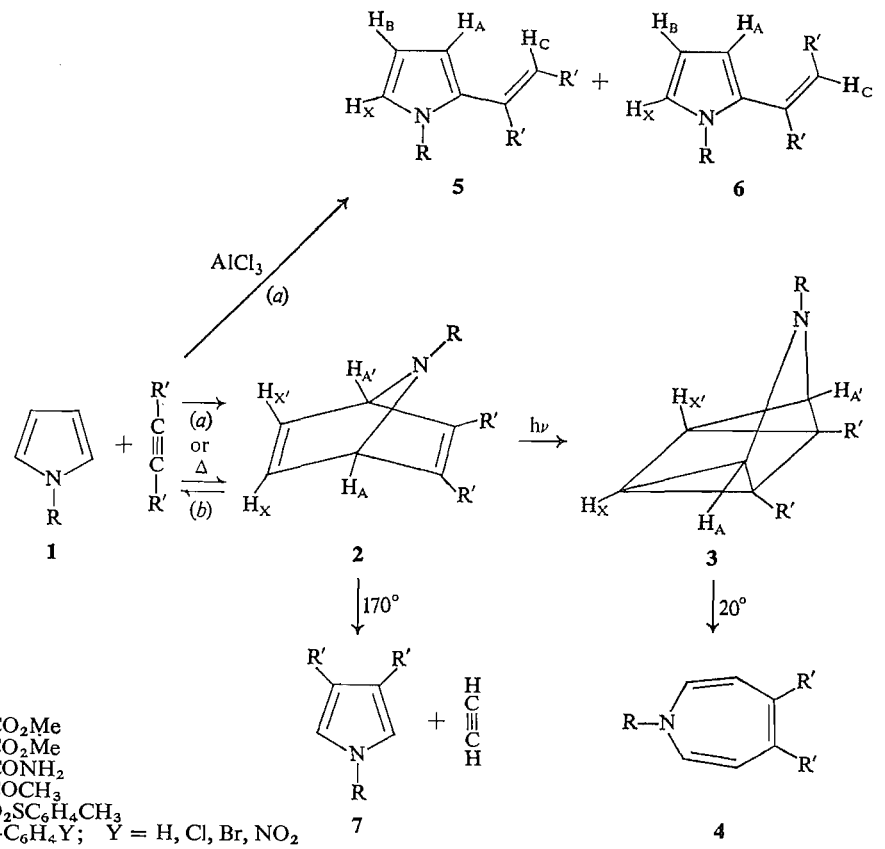
Up until 1968 the only 7-azanorbornadiene derivatives reported were those prepared from *N*-benzyl-, *N*-1-naphthyl-, and *N*-carbomethoxypyrrole with acetylenedicarboxylic acid (3, 4, 16), and recently Prinzbach and co-workers have isolated the corresponding adduct of *N*-methylpyrrole (2). These adducts exist as zwitterions and their isolation has been attributed to their insolubility in the reaction medium (4). Sauer in a recent review article (5) has incorrectly claimed that *N*-benzyl-, *N*-1-naphthyl-, and *N*-triphenylmethylpyrrole react with DMAD to yield adducts. The dienophile used in these reactions, however, was acetylenedicarboxylic acid and the latter diene was unreactive (4). Derivatives **2***a*–**2***e* (1, 2) were the first examples in which an acetylenedicarboxylic ester was used as dienophile. Previous attempts to isolate adducts of such a dienophile with 2-methyl- (6) or *N*-methylpyrrole (7), or with unsubstituted and substituted **1***a* (8), were unsuccessful, although these adducts have been postulated as reaction intermediates (7, 8).

As part of a comprehensive study of the influence of Lewis acids on the Diels–Alder reaction we have recently studied the reaction of substituted furans with acetylenedicarboxylic esters and were able to draw the following conclusions: (*a*) Lewis acids cause an enormous increase in the rate of adduct formation thereby permitting the use of lower temperatures and shorter reaction times (9, 10); (*b*) the addends and adduct all complex with Lewis acids (9); (*c*) conversion of addends to adduct was irreversible in contrast to the thermal reaction due to the formation of a strong adduct – Lewis acid complex.

During the above studies we were able to isolate the previously inaccessible adduct diethyl 1,4-diphenyl-7-oxabicyclo[2·2·1]2,5-heptadiene-2,3-dicarboxylate (9). This suggested that Lewis acids might promote the formation of similar adducts of other heterocyclic dienes. For one such study we chose the reaction of **1***a* with DMAD. When this work was started the adduct **2***a* had not been prepared.[3] Our approach to the synthesis of **2***a* differs significantly from that of Prinzbach (2). We felt that the combination of milder reaction conditions, the irreversible nature of the reaction and the formation of a **2***a* – Lewis acid complex [see (*a*)–(*c*) above] might enable

[1]NRCC No. 10602.
[2]NRCC Postdoctorate Fellow 1967–1968.

[3]This work was reported at the 51st Annual Conference of the Chemical Institute of Canada which was held in Vancouver, British Columbia, on June 3–6, 1968.



this adduct to be prepared in the presence of $AlCl_3$. By analogy with the synthesis of oxepine derivatives (11, 12) **2***a* could then be converted to the azepine **4***a* via the 3-azaquadricyclane derivative **3***a*. Prinzbach and co-workers have used this approach in the synthesis of the azepines **4***c* and **4***d* (1). This communication reports the synthesis of **2***a* in virtually quantitative yield and our independent investigations in developing a facile azepine synthesis. Our mechanistic studies on the formation of adducts like **2***a* in the presence of Lewis acids will be reported elsewhere.

The $AlCl_3$-promoted reaction of **1***a* and DMAD in CH_2Cl_2 yields variable amounts of **2***a*, **5***a*, and **6***a* (see reaction *a*) depending on the reaction conditions. Compounds similar to **5***a* and **6***a* have been obtained previously from thermal reactions of other substituted pyrroles with acetylenedicarboxylic acid or DMAD (3, 6, 16) and are believed to be formed by a Michael type addition (13).

Independent experiments established that **5***a* was isomerized to **6***a* but that neither compound was interconvertible with **2***a* in the presence of $AlCl_3$. Consequently, the formation of **2***a* and **5***a* must have occurred by independent routes with subsequent conversion of the latter to **6***a*. Our results in Table I clearly indicate that low temperatures (≪25°) favor the production of **5***a*

TABLE I

Yields of products obtained from the reaction of **1***a*, DMAD and $AlCl_3$ in CH_2Cl_2*

$AlCl_3$: addend ratio	Temperature	Time (h)	Mole % yield†		
			5*a*	**6***a*	**2***a*
1:1	−75°	2	No reaction		
1:1	−10°	4	36	36	18
1:1	25°	2	34	22	34
1:1	40°	0.5	30	4	54
3:1	40°	1	—	19	76
5:1	40°	1	—	—	93

*Reaction solutions were 0.1 molar in the three reagents, except in the last two experiments in which the $AlCl_3$ concentration was increased by a factor of 3 or 5.

†Reaction composition was determined by proton magnetic resonance.

and **6***a* when the reactants are present in equimolar amounts. Synthesis of **2***a* is favored and side reactions producing **5***a* and **6***a* are minimized at higher reaction temperatures (40°).

Increasing the $AlCl_3$ concentration had a dramatic effect on the product composition (see Table I). A three-fold increase in the $AlCl_3$ concentration at 40° not only raised the yield of **2***a* from 54 to 76% but caused total isomerization of **5***a* to **6***a*. This had important experimental implications since **2***a* could be separated from **6***a* by chromatography on silicic acid impregnated with silver nitrate while its separation from **5***a* was difficult and laborious. The isolable yields of **2***a* were therefore much lower than those estimated by proton magnetic resonance (p.m.r.) when the $AlCl_3$:addend ratio was 1:1 while at higher ratios the estimated and actual yields did not differ significantly. When the $AlCl_3$:addend ratio was increased to 5:1 **2***a* was obtained and could be isolated in almost quantitative yield (≈90%). Since **1***a* and DMAD do not react in CH_2Cl_2 at 40° in the absence of $AlCl_3$ it is clear that the latter must cause an enormous enhancement in the rates of formation of both **2***a* and **5***a*. It should be noted that the preferred formation of **5***a* rather than **6***a* in the initial stages of reaction implies the stereospecific *cis*-addition of the diene to the triple bond of DMAD. The mechanism of this addition is under investigation.

Photochemical conversion of **2***a* to **3***a* was quantitative and the latter rearranged to **4***a* at temperatures $> -20°$.

The molecular formulae of **2***a*, **4***a*, and **6***a* were determined by mass spectral analyses and the structures of these compounds together with those of **3***a* and **5***a* were established by p.m.r. Analyses of the characteristic AXX'A' systems in **2***a* and **3***a*, and the ABX systems in **5***a* and **6***a*, were carried out with the aid of the Laocoon II program (14). Observed and calculated spectra agreed within experimental error. Some spin–spin coupling constants were checked by spin-decoupling. The retro Diels–Alder conversion of **2***a* to **7***a* and acetylene at 170° was additional evidence for its structure. All spectral data are reported in the Experimental. Since Prinzbach and co-workers (2) did not analyze the p.m.r. spectrum of **2***a* the data for this compound have also been included.

The mild reaction conditions and high yields characteristic of the present study suggest that the use of Lewis acids to promote the formation of 7-azanorbornadiene derivatives from pyrroles, containing an electron acceptor substituent on nitrogen, and acetylene derivatives, may have certain advantages over the thermal reaction.

Experimental

The proton magnetic resononce (p.m.r.) spectra were recorded using a Varian HA-100 or A 60-A spectrometer equipped with a variable temperature probe and spin decoupler. Mass spectra were recorded using a Consolidated Electrodynamics Corporation 21-110B mass spectrometer and mass measurements employed electrical detection.

Preparation of 2a, 5a, and 6a

A 10 ml solution of **1***a* (1.26 g; 0.01 *M*) in CH_2Cl_2 was added to a 90 ml solution of DMAD (1.42 g; 0.01 *M*) and $AlCl_3$ (6.70 g; 0.05 *M*) in the same solvent, and the mixture stirred at 40° for 1 h. At the end of this period the dark-red reaction solution was washed with water to remove the Lewis acid and stop the reaction. After drying the organic layer and removing the solvent the dark-red oily residue (2.61 g) containing **2***a* and **6***a* was chromatographed on silicic acid (200 g) using a mixture of petroleum ether (60–80°) and ethyl acetate in the ratio of 7:3 as eluant.

2*a* was isolated in 90% yield as a yellow oil,[4] $n_D^{25} = 1.6560$ which gave a parent molecular ion at *m/e* 267. From its 60 MHz p.m.r. spectrum in $CDCl_3$ signals could be assigned to the bridgehead (2H, multiplet, average $\tau = 4.48$), olefinic (2H, multiplet, average $\tau = 2.83$), *N*-carbomethoxy (3H, singlet, τ 6.35) and carbomethoxy (6H, singlet, τ 6.18) protons. Analysis of the AXX'A' system[5] for the bridgehead and olefinic protons gave: $\Delta\nu_{AX} = 98.7$, $J_{AA'} = 2.2$, $J_{XX} = 5.1$, $J_{AX} = J_{A'X'} = 2.7$ and $J_{AX'} = J_{A'X} = 0.5$ Hz. Identical parameters (except ΔJ_{AX}) were obtained from the 100 MHz spectrum and $J_{XX'} = 5.0$ Hz was determined independently by irradiating the A protons and observing the ^{13}C—H satellite (doublet) of the X-protons.

When the $AlCl_3$:addend ratio was 1:1 **2***a*, **5***a*, and **6***a* were isolated by preparative thin-layer chromatography on silica gel G impregnated with 10% silver nitrate (15) using the solvent mixture described above as eluant. Samples of **5***a* were always contaminated with **2***a* although the amounts of the latter did not prevent the structure of **5***a* being deduced from its p.m.r. spectrum.

5*a* was obtained as a yellow oil and signals in its 60 MHz p.m.r. spectrum in $CDCl_3$ could be assigned to one olefinic proton (singlet, τ 3.64), an *N*-carbomethoxy (3H, singlet, τ 6.24) and two chemically non-equivalent carbomethoxy (6H, 2 singlets, τ 6.10 and 6.22) groups. Analysis of the ABX system for the three pyrrole ring protons (AB multiplet centered at τ 3.67 and X multiplet

[4]Prinzbach and co-workers reported that **2***a* crystallized from petroleum ether, m.p. 56–57° (2). Samples prepared in this laboratory by the thermal or Lewis acid-promoted reaction, although identical (p.m.r., infrared (i.r.)), could not be crystallized.

[5]Refer to figure for the labelling of protons in **2***a*–**6***a*.

at τ 2.62) gave $\Delta\nu_{AB} = 11.3$, $J_{AB} = 3.3$, $J_{AX} = 3.4$, and $J_{BX} = 1.9$ Hz. The chemical shift of the olefinic proton in **5***a* was similar to that for the corresponding protons in dimethyl maleate (τ 3.84).

6*a* was obtained as pale-yellow hexagonal prisms from CH_2Cl_2 – ether, m.p. 61–62° [lit. (16), m.p. 63°]. The 60 MHz p.m.r. spectrum of this compound in $CDCl_3$ gave signals for one olefinic proton (singlet, τ 3.04), one *N*-carbomethoxy (3H, singlet, τ 6.33) and two carbomethoxy (6H, 2 singlets, τ 6.10 and 6.23) groups. Analysis of the ABX system[5] for the three pyrrole ring protons (AB multiplet centered at τ 3.73 and X multiplet at τ 2.64) gave $\Delta\nu_{AB} = 3.2$, $J_{AB} = 3.3$, $J_{AX} = 3.4$ and $J_{BX} = 1.9$ Hz.

Preparation of 3a and 4a from 2a

2*a* (50 mg) was converted quantitatively to **3***a* when a solution in CD_2Cl_2 (2 ml) was irradiated at 3100 Å (Pyrex filter, Rayonet Photochemical Reactor) for 2 h at −25°. The reaction was monitored by p.m.r. and signals in the final 60 MHz spectrum could be assigned to one *N*-carbomethoxy (3H, singlet, τ 6.17) and two chemically equivalent carbomethoxy (6H, singlet, τ 6.32) groups. The remaining four protons formed an AXX′A′ system. The A type (2H, octet, average τ 5.42) and X type (2H, octet, average τ 7.11) protons appeared as deceptively simple doublets with a spacing of 4.8 Hz at a sweep width of 500 Hz. Analysis of this system[5] gave $\Delta\nu_{AX} = 100.0$, $J_{AA'} = 1.8$, $J_{XX'} = 3.1$, $J_{AX} = J_{A'X'} = 4.8$, and $J_{AX'} = J_{A'X} = 0$ Hz. Identical parameters (except $\Delta\nu_{AX}$) were obtained from the 100 MHz spectrum.

3*a* was not isolated because it gradually changes to **4***a* at temperatures above −20°. At room temperature this conversion is complete in 10 min.

4*a* was obtained as a yellow oil, $n_D^{25} = 1.5112$. Molecular ion mass: Anal. Calcd. for $C_{12}H_{13}NO_6$, 267.0743. Found: *m/e* 267.0742. Ultraviolet spectrum (EtOH) $\lambda\lambda_{max}$ 207 (ε 17 300) and 346 mμ (ε 1430). Its 60 MHz p.m.r. spectrum in CD_2Cl_2 contained signals for one *N*-carbomethoxy (3H, singlet, τ 6.21) and two chemically equivalent carbomethoxy (6H, singlet, τ 6.25) groups. The azepine ring protons gave a characteristic AB spectrum (centered at τ 4.16) with $\Delta\nu_{AB} = 27.3$ and $J_{AB} = 8.0$ Hz with an intensity corresponding to 4 protons. The value of J_{AB} was confirmed by decoupling. (It seems reasonable that the protons attached to the carbon atoms bearing nitrogen will appear at lowest field.)

Large amounts of **4***a* were obtained by scaling up the procedure described above.

Acknowledgments

We wish to thank Mr. D. G. Smith and Mr. J. van Ingen for recording the proton magnetic resonance spectra and Mr. D. J. Embree for the mass spectra.

Conformations of some dianhydrohexitols

F. J. HOPTON AND G. H. S. THOMAS
Ontario Research Foundation, Sheridan Park, Ontario

Received October 23, 1968

Proton magnetic resonance spectra of three known diastereoisomers 1,4:3,6-dianhydro-D-glucitol, 1,4:3,6-dianhydro-D-mannitol, 1,4:3,6-dianhydro-L-iditol, and their diacetyl and dimesyl derivatives have been analyzed. The coupling constants obtained have been utilized to determine the conformation of the five-membered rings. Constancy of the couplings between ring protons throughout the series of compounds indicates the existence of one conformation common to all, and this appears to be a composite of the C_s and C_2 forms. It is significant that intramolecular hydrogen bonding, which occurs in two of the three diastereoisomers, has little or no effect on ring conformation.

Canadian Journal of Chemistry, 47, 2395 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

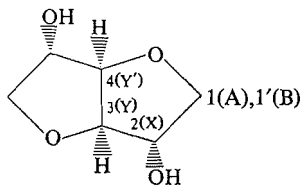
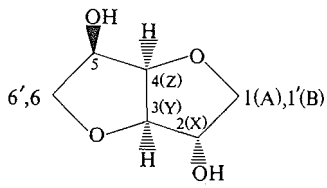
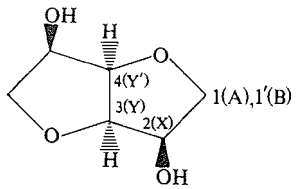
It is well known that the hexitols L-iditol, D-glucitol, and D-mannitol readily form 1,4:3,6-dianhydrides under acidic conditions (1). These 1,4:3,6-dianhydrides each have two free hydroxyl groups located at the C-2 and C-5 positions.



1



2



3

From inspection of molecular models the 1,4:3,6-dianhydrohexitols have two nearly planar *cis*-fused five-membered rings in the form of a "V" with the hydroxyl groups at the C-2 and C-5 positions either inside or outside the "V" shaped wedge. As in other ring systems the configuration of a group inside the wedge is designated as *endo* whereas one outside the wedge is *exo*. In the L-iditol derivative **1** both hydroxyl groups are *exo*, in the D-mannitol derivative **3** both are *endo*, and in the D-glucitol derivative **2** the hydroxyl at C-2 is *exo* and that at C-5 is *endo*.

The stereochemistry of these compounds has been discussed by Mills (2) and the order of stability of the three compounds as deduced from their ease of formation (3, 4), epimerization (5), and general chemical properties (6, 7) indicates that the presence of an *exo* substituent increases the stability of the ring to which it is attached, by virtue of the diminished opportunities for interaction between non-bonded substituents. Furthermore the faces of the rings inside the "V" are less accessible than the faces outside, so *exo* and *endo* isomers exhibit differences in reactivity in the direction determined by the steric requirements of the reaction in question (8, 9). The extent of intramolecular hydrogen bonding, as determined by infrared spectroscopy in this series of compounds (10) illustrates the influence of structure on such bonding. The C-2 and C-3, and C-4 and C-5 oxygen bonds in the iditol derivative are *trans* related as in L-threitan so that intramolecular bonding is precluded. A *cis* relation of the C-4 and C-5 oxygen bonds exists in the D-glucitol analogue permitting a single intramolecular hydrogen bond. In D-mannitol the C-2 and C-3, and C-4 and C-5 oxygen bonds are *cis* related; two intramolecular hydrogen bonds may occur and the absence of detectable absorption for free hydroxyl groups indicates the completeness of the hydrogen bonding.

Correlation of nuclear magnetic resonance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(n.m.r.) coupling constants (J) with dihedral angles (ϕ) is a major step in conformational and configurational analysis. Nuclear magnetic resonance has proved to be an effective means of determining possible conformations of carbohydrate ring systems in solution (11, 12). This paper is concerned with the n.m.r. study of three dianhydrohexitols and their diacetyl and dimesyl derivatives in an attempt to determine their conformations.

Experimental

Spectra (60 Mc.p.s. and 100 Mc.p.s.) were recorded on Varian A60 and HA-100 spectrometers respectively at 33 °C. The spectra were of 1–10 mole % solutions in both acetone-d_6 and deuteriochloroform with tetramethylsilane (TMS) as internal reference. Some spectra of the compounds in pyridine as solvent were also determined. Spin-decoupling and spin-tickling experiments were carried out with the HA-100 spectrometer.

L-Iditol was prepared from L-sorbose by reduction using sodium borohydride. The L-iditol was separated from accompanying D-glucitol by fractional crystallization of the hexaacetyl derivatives (13). The parent hexitol was obtained by deacetylation of the hexaacetyl-L-iditol using sodium methoxide.

The dianhydrohexitols were prepared by the method given by Shen for the preparation of 1,4:3,6-dianhydro-D-glucitol (14). The diacetyl and dimesyl derivatives of the dianhydrohexitols were prepared by standard methods. In all instances the compounds were either recrystallized or distilled until their physical constants corresponded closely with the reported values.

Analysis and Discussion

The ring protons in one ring of any one of the compounds studied constitute either an ABXYY′ or an ABXYZ system. Numbering of these protons is as indicated in formulas [**1**–**3**] and their 100 Mc.p.s. spectra are shown in Figs. 1, 2, and 3. For the symmetric molecules **1**, **3**, and their derivatives, the ring protons are classified as A(H-1, H-6) B(H-1′, H-6′) X(H-2, H-5) Y(H-3) Y′(H-4). In the parent compounds **1** and **3**, H-2 and H-5 are coupled to OH protons. This coupling was removed by addition of a few drops of acid to the sample causing rapid exchange of the OH protons.

The procedure used for simplification of the spectra obtained was to irradiate at the resonance position of H-3 and H-4 with a secondary radio frequency (r.f.) field to clarify the ABX

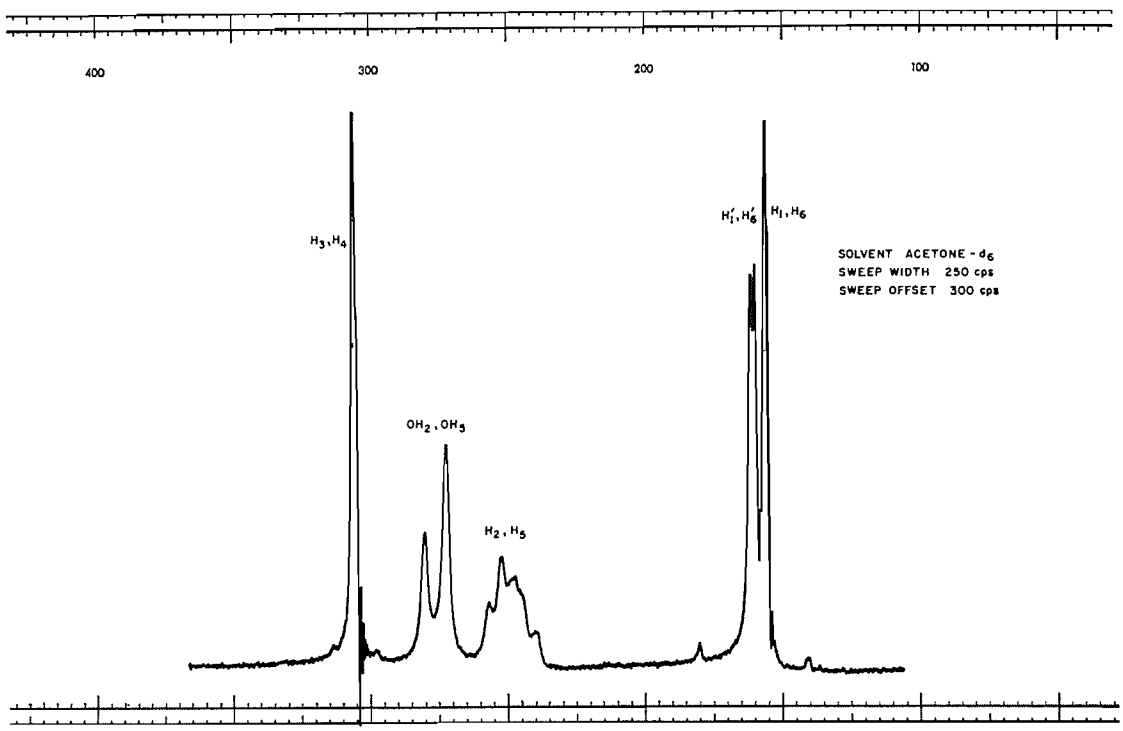


FIG. 1. The 100 Mc.p.s. nuclear magnetic resonance spectrum of 1,4:3,6-dianhydro-L-iditol.

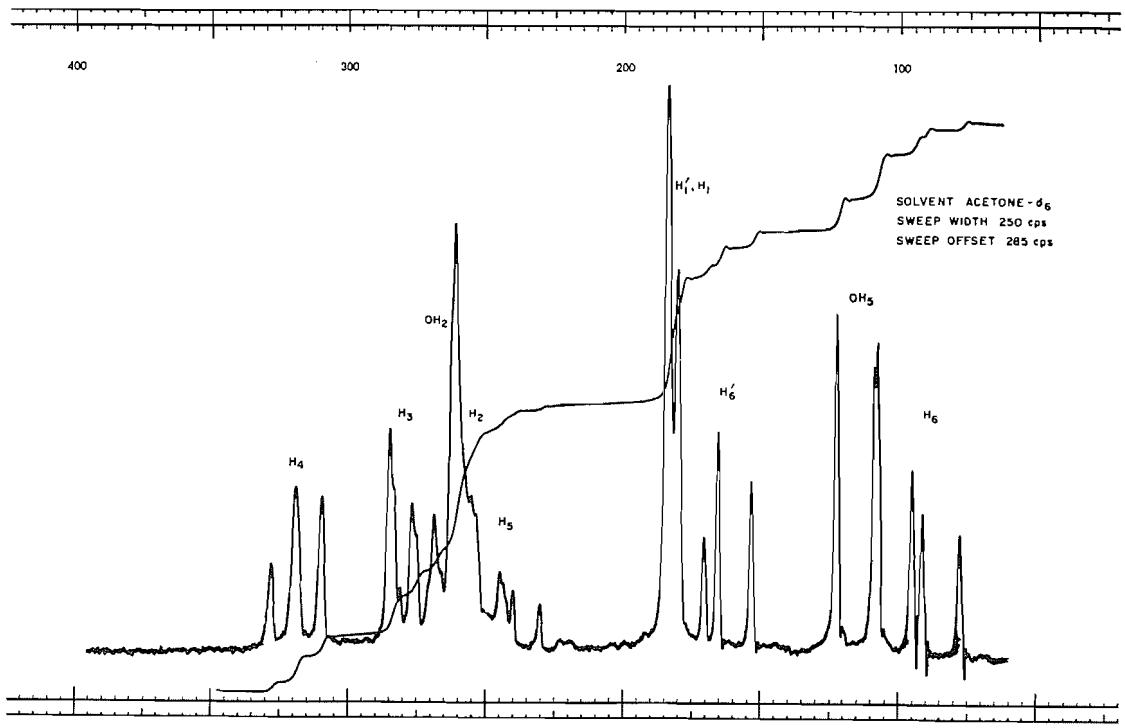

FIG. 2. The 100 Mc.p.s. nuclear magnetic resonance spectrum of 1,4:3,6-dianhydro-D-glucitol.

pattern of H-1, H-1′, and H-2 (H-6, H-6′, and H-5), followed by irradiation at a point midway between the resonance positions of H-1 (H-6) and H-1′ (H-6′) revealing an XX′YY′ pattern, very often approaching MM′YY′ for H-2, H-5, H-3, and H-4. Analysis of the ABX and XX′YY′ patterns was accomplished using established procedures (15). In cases where $\delta_{AB} \ll J_{AB}$ and fewer lines than expected were observed, analysis was made using methods published for other deceptively simple spectra (16). Additional decoupling and tickling experiments were performed to confirm the assignments made and to verify that the geminal coupling constant J_{AB} was of opposite sign to that of the vicinal coupling constants J_{AX} and J_{BX}.

The increased complexity of the spectra of compound **2** and its derivatives arises from a lack of symmetry in these compounds such that H-3 and H-4, H-1 and H-6, H-1′ and H-6′, H-2 and H-5 are no longer chemically equivalent. The procedures for analysis described above were, however, sufficient to evaluate all the chemical shifts and coupling constants from the spectra. Spectra of these compounds in pyridine as solvent were also used to facilitate some of the analyses.

Long range coupling between H-2 and H-4, and H-3 and H-5 is evident for most compounds, though it is extremely small. Irradiation at the H-2 or H-5 resonance with a secondary r.f. field sharpens the lines in the resonance patterns of H-3 and H-4, respectively. A long range coupling of significance is observed in the dimesyl derivative of **2** between H-3 and one of the geminal protons H-1 or H-1′. The spatial arrangement of these protons is most suited to a coupling between H-3 and H-1′ as labelled in **2** where the intervening bonds approach a planar W formation (17). However, this coupling is not observed in the corresponding derivative of **1** where the arrangement of protons must be very similar. The fact that long range coupling between H-3 and H-1′ is to be preferred over a similar coupling between H-3 and H-1 enables identification of the geminal protons to be made, with H-1′ being at lower field than H-1. This is also assumed to be the case in the spectra of the other compounds studied.

Coupling constants and chemical shifts are

given in Tables I and II respectively. It is apparent that substitution has some effect on both vicinal and geminal coupling constants. A decrease in J_{gem} (increased negative value) occurs as the hydroxyl group is replaced by acetoxy and then by mesyloxy. This change in J_{gem} is greater when the substituent is *exo* rather than *endo*, providing further evidence that coupling is dependent both on the electronegativity of a group on an adjacent carbon atom and on the orientation of that group with respect to the geminal protons (18). Vicinal coupling constants vary with orientation of electronegative substituents (19). This stereochemical dependence is readily observed provided other factors, such as bond angles and bond lengths, remain unchanged. No attempt has been made in this study of dianhydrohexitols to correlate changes of particular vicinal coupling constants with electronegativity of substituent groups, because it is thought that the breaking of strong intra- and intermolecular hydrogen bonds, caused by substitution, effect changes in bond angles and possibly bond lengths.

Coupling of the hydroxyl proton to the proton on the same carbon atom when the hydroxyl group is *endo* is almost twice that observed when the hydroxyl group is *exo*. Intramolecular hydrogen bonding fixes the hydroxylic proton for the *endo* hydroxylic group such that the protons concerned are more or less *trans* oriented with respect to the C—O bond giving rise to a coupling of 7.5 c.p.s. When the hydroxylic group is *exo*, the hydroxylic proton has a random orientation with respect to the vicinal C—H proton, even though hydrogen bonding to a solvent may occur, and the coupling observed is much smaller (ca. 4 c.p.s.). It is thought that a conformational dependence exists for J_{HCOH} similar in qualitative form to that observed for J_{HCCH}. A value of 12–13 c.p.s. (20) has been found for J_{HCOH}^{trans} whereas the "free rotation" value of J_{HCOH} is 4 c.p.s.

The Karplus equation (21) and other modified versions (11, 22, 23) have been extensively used to calculate dihedral angles in five- and six-membered ring compounds from observed coupling constants. Variation of vicinal coupling constant J with the dihedral angle ϕ may be expressed by an equation of the following form

$$J = A\cos^2\phi + B$$

where A and B are constants and A is greater for $\phi > 90°$ than for $\phi < 90°$. The value of A in particular is found to vary for different systems in order to give consistent results. However, whatever values the parameters A and B have been given, J always decreases to approximately zero as ϕ increases from 0° to 90°, and increases again as ϕ further increases from 90° to 180°. Thus a small coupling of 1 c.p.s. or less corresponds to an angle of approximately 90°, and any other value of J will give two angles for ϕ, one between 0 and 90° and the other between 90 and 180°. Most of the constants obtained fall in the intermediate range of 3.5–6.0 c.p.s. and, using average values for the parameters A and B taken from the literature, correspond to dihedral angles of 50–30° or 125–145°.

Five-membered rings are generally accepted to be significantly non-planar; the rings may be described in terms of various planes through sets of four or three atoms, or in terms of various dihedral angles. Of the various puckered forms of cyclopentane (24) the so-called C_s or "envelope" form and the C_2 or "twist" (T) form have greater symmetry than all other possibilities, and substituted cyclopentanes exist preferentially with a geometry close to one or other of these forms.

Furthermore, calculations on cyclopentane derivatives containing sp^2 hybridized atoms, e.g. cyclopentanone or hetero-atoms, e.g. tetrahydrofuran, suggest (25) that such molecules exist in the twist form with the maximum puckering occurring at C-3 and C-4, i.e. away from the sp^2 hybridized or hetero-atom. An sp^2 hybridized atom in planar surroundings is not seriously troubled by bond eclipsing (unlike an sp^3 hybridized atom) and it is therefore reasonable that whatever puckering occurs should involve mainly other parts of the molecule. The fact that atoms with free pairs of electrons such as O, S, and N should behave similarly implies that the free pairs give rise to little or no eclipsing of their own. Qualitatively fused ring systems resemble single ring systems of analogous conformation, though a certain rigidity is associated with the bond common to the two fused rings.

For the purposes of comparison of the three diastereoisomers, reference is made to compound **2** in which C-1 – C-4 indicate an iditan-type moiety (*exo*-hydroxyl) and C-3 – C-6 indicate a mannitan-type moiety (*endo*-hydroxyl). The two fused rings in dianhydro-mannitol and dianhydro-iditol are identical in each case and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

hence only the coupling in one ring need be discussed. From the data given in Table I, only two conformations are acceptable for either ring. The first of these is the C_S or envelope conformation in which C-3 is displaced out of the plane formed by atoms C-1, C-2, C-4, and the oxygen in that ring, and C-4 is displaced out of the plane formed by C-3, C-5, C-6, and the oxygen in that ring. This displacement is in such a way as to cause a decrease in angle between the ring planes thus described. The alternative conformation is the C_2 or half chair conformation in which C-2 and C-3 are displaced (symmetrically) below and above (respectively) the plane defined by C-1 and C-4 and the oxygen between them, and C-4 and C-5 are similarly disposed about a plane defined by C-3 and C-6 and the oxygen between them.

It has been shown that the molecular framework of *cis*-fused molecules is fairly rigid and conformational possibilities are restricted (25), and furthermore, that the energy difference between C_2 and C_S conformations for *cis*-fused five-membered rings, such as in the hydrindanes, is small. Unless, therefore, a distinct difference in dihedral angles occurs in the two conformations a preference of one form over the other on the basis of coupling constants is somewhat tenuous. Application of calculated angles obtained for both C_S and C_2 conformations to a mannitan-type ring in the systems under discussion would require the following dihedral angles

C_S conformation	C_2 conformation
$\phi_{45} = \phi_{34} = 46°$ (4.5)	$\phi_{45} = 48°$ (4.3)
$\phi_{56} = 29°$ (6.9)	$\phi_{56} = \phi_{34} = 39°$ (5.4)

The figures shown in parentheses above represent coupling constant values derived from a typically modified Karplus equation previously used for five-membered ring compounds (11).

Average values of the coupling constants J_{34}, J_{45}, and J_{56} taken from Table I for all rings of this type are 4.8, 5.2, and 5.7 c.p.s. respectively. It is readily seen that neither the C_S nor C_2 conformation is preferentially suited to such values. However, since J_{34} is always found to be less than or equal to J_{45}, and J_{56} varies quite considerably with differing substituents on C-5, the C_S conformation appears to be the more favored one. A slight displacement of C-5 from its position in a C_S conformation towards its position in a C_2 conformation would readily account for the coupling constants found. This displacement might well arise from a certain restriction to displacement of C-4 due to its involvement in the bond common to both rings. Similar arguments apply equally well to the iditan-type ring, so that in all the compounds studied, the rings are thought to have the same conformation.

Abraham *et al.* (11) have described in detail the conformation of the rings of 3,6-anhydro-1,2-*O*-isopropylidene-5-*O*-tosyl-α-D-glucofuranose evaluated from coupling constants obtained from a proton resonance study. Both the C_S and C_2 conformations are found to exist in this compound with the anhydro ring in the C_S conformation. These findings are based on an equality of particular coupling constants as a result of symmetric buckling in the ring. However, our results indicate that only a small deformation of either the C_S or C_2 arrangement of atoms can give rise to very similar coupling constant values.

From a paper by Cameron *et al.* (26) on the X-ray crystallographic study of 2-*O*-(*p*-bromobenzenesulfonyl)-1,4:3,6-dianhydro-D-glucitol-5-nitrate, calculations of the atomic positions, using data given in Table II of that publication, indicate the conformations of the two five-membered rings to be very similar. In this compound the most significant non-bonded intramolecular contact is between a nitro group oxygen and the oxygen atoms in the other ring, and the relatively short approach is probably the result of some attractive interaction between the two atoms. This interaction which exists in one ring only has little effect on the ring conformation. In the present study we find that intramolecular hydrogen bonding, which exists in both 1,4:3,6-dianhydro-D-glucitol and 1,4:3,6-dianhydro-D-mannitol, has very little effect on ring conformation.

Sur l'acylation de l'éthyl-1 cyclohexène en présence de chlorure stannique

JEAN ALLARD[1] ET NORMAND DUFORT
Département de Chimie, Université de Montréal, Montréal, Québec

Recu le 18 décembre 1968

L'acylation de l'éthyl-1 cyclohexène par l'anhydride acétique et le chlorure d'acétyle est effectuée en présence de chlorure stannique. Le produit majeur de l'acylation par le chlorure d'acétyle est bicyclique. L'isomérisation et la réduction chimique et catalytique de ce composé bicyclique sont rapportées et les produits formés sont identifiés.

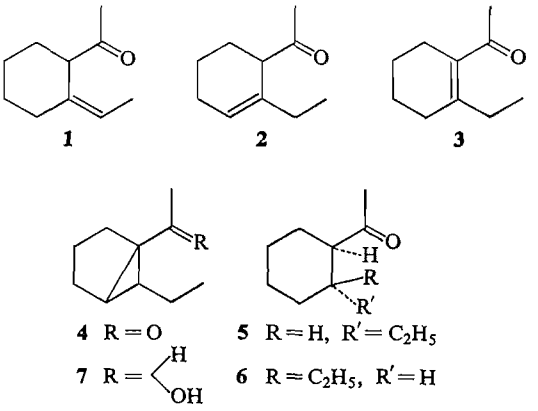
Canadian Journal of Chemistry, 47, 2403 (1969)

A la suite d'un travail publié (1) en particulier sur la condensation de l'éthyl-1 cyclohexène avec l'anhydride acétique en présence de $ZnCl_2$, nous rapportons les résultats de l'acylation de l'éthyl-1 cyclohexène par l'anhydride acétique et le chlorure d'acétyle en présence de $SnCl_4$.

L'acylation de l'éthyl-1 cyclohexène par l'anhydride acétique en présence de $SnCl_4$ indique à l'analyse par chromatographie en phase gazeuse (c.p.g.) la formation de 36% d'acétyl-1 éthylidène-2 cyclohexane (**1**), 43% d'acétyl-1 éthyl-2 cyclohexène-2 (**2**), 12% d'acétyl-1 éthyl-2 cyclohexène-1 (**3**), et deux autres composés formés à 4 et 5% qui n'ont pas été identifiés. L'isomérisation de ces produits en présence d'acide oxalique donne d'après l'analyse par c.p.g. 14% de composé **1**, 22% de composé **2**, et 64% de composé **3**.

L'acylation de l'éthyl-1 cyclohexène par le chlorure d'acétyle en présence de $SnCl_4$ suivie d'une déshydrochloruration par NaOH indique à l'analyse par c.p.g. la présence de 31% d'un mélange formé d'environ 25% de composé **1** et 6% d'un composé non identifié parce qu'il a été impossible de l'isoler à l'état pur (même en variant la longueur de la colonne, l'adsorbant et la température lors de la chromatographie, il fut impossible de bien séparer ces deux composés). Il y a également formation de 18% de composé **2**, 10% de composé **3**, et 41% d'un nouveau composé.

Ce dernier composé pur présente une bande à 1685 cm^{-1} dans l'infrarouge et une absorption maximum à 213 mμ (log ε: 3.65), dans l'ultraviolet indiquant que le groupe carbonyle est



1 **2** **3**

4 R = O

5 R = H, R' = C_2H_5

7 R = H, OH

6 R = C_2H_5, R' = H

conjugué à un cyclopropane (2, 3). Ce composé résiste à l'ozone ce qui confirme la présence d'un cyclopropane dans sa structure. Son spectre de résonance magnétique nucléaire (r.m.n.) présente un multiplet à 1.01 p.p.m. (3H) pour le méthyle de la chaine éthyle et un singulet à 2.01 p.p.m. (3H) pour le méthyle adjacent au carbonyle. Vu qu'il n'y a que trois hydrogènes sous forme de multiplet dans la région de 0–1 p.p.m., la seule structure qui est conforme au spectre r.m.n. et qui a un cyclopropane conjugué avec le carbonyle est l'acétyl-1 éthyl-6 bicyclo[3.1.0]hexane (**4**). En se basant sur un travail fait sur le méthyl-1 cyclohexène (4), ce composé pourrait être l'isomère endo, mais aucune preuve absolue n'a été apportée pour déterminer la configuration de ce composé.

De plus, le composé **4** isomérisé en présence d'acide oxalique donne 14% de composé **1**, 37% de composé **2**, et 49% de composé **3**. La réduction catalytique du composé **4** donne 95% de *trans* acétyl-1 éthyl-2 cyclohexane (**5**) et 5% de *cis* acétyl-1 éthyl-2 cyclohexane (**6**). Ces cétones saturées sont préparées par réduction catalytique d'un mélange des composés **1**, **2**, et **3** et leur

[1]Extrait du mémoire présenté par J. Allard en vue de l'obtention du grade de Maître-ès-Sciences, Faculté des Sciences, Université de Montréal, Montréal, Québec, septembre 1966.

For personal use only.

configuration est déterminée par leur mise en équilibre en présence d'acide oxalique.

La réduction du composé **4** par $LiAlH_4$ indique à l'analyse par c.p.g. la formation d'un seul composé: l'éthyl-6 (hydroxy-1 éthyl)-1 bicyclo[3.1.0]hexane (**7**). Cet alcool oxydé par le complexe anhydride chromique – pyridine (5) redonne la cétone de départ.

Partie expérimentale

Les températures n'ont pas été corrigées. Les analyses par c.p.g. ont été effectuées à l'aide d'un appareil F et M modèle 810 en utilisant une colonne de 2.5 m. contenant 10% d'hyprose supporté sur du chromosorb P. Les spectres de r.m.n. ont été déterminés avec un appareil modèle A60 de la Compagnie Varian pour des solutions dans le CCl_4 et utilisant le tétraméthylsilane comme référence interne.

Condensation de l'éthyl-1 cyclohexène avec l'anhydride acétique

L'éthyl-1 cyclohexène est condensé avec l'anhydride acétique en présence de $SnCl_4$ selon le procédé de Royals et Hendry (6); mais le tout est traité par une solution alcoolique de NaOH 12% pendant 20 h. Il y a formation de 36% de composé **1**, 43% de composé **2**, 12% de composé **3**, et deux autres produits formés à 4 et 5%. Les constantes physiques et spectrales des composés **1** et **2** correspondent à ceux de la littérature (1). Le composé **3** distille à 130°/75 mm; n_D^{25}: 1.4945; i.r.: bande carbonyle à 1675 cm^{-1}; λ_{max} (EtOH): 249 mμ, log ε: 3.75; r.m.n.: triplet à 1.00 p.p.m. (3H, J = 7.5 c.p.s.) et singulet à 2.17 p.p.m. (3H).

Anal. Calc. pour $C_{10}H_{16}O$: C, 78.90; H, 10.59. Trouvé: C, 78.74; H, 10.37.

La semicarbazone (méthanol) fond à 203–204°.

Anal. Calc. pour $C_{11}H_{19}N_3O$: C, 63.12; H, 9.15; N, 20.08. Trouvé: C, 63.19; H, 9.14; N, 19.62.

Condensation de l'éthyl-1 cyclohexène avec le chlorure d'acétyle

A 60 ml de $SnCl_4$ en solution dans 250 ml de CS_2 purifié, sont ajoutés lentement 50 g d'éthyl-1 cyclohexène et 36 g de chlorure d'acétyle à une température inférieure à 0°. Après une agitation de 2 h à la température de la pièce, le tout est refroidi à 0° et 350 g de glace sont ajoutés. Le reste est conforme au procédé de Turner et Voitle (7). L'analyse par c.p.g. indique la présence de 31% d'un mélange formé d'environ 25% de composé **1** et 6% d'un composé non identifié, 18% de composé **2**, 10% de composé **3**, et 41% de composé 4. Ce dernier composé distille à 97°/10 mm; n_D^{25}: 1.4777.

Anal. Calc. pour $C_{10}H_{16}O$: C, 78.90; H, 10.59. Trouvé: C, 78.66; H, 10.41.

La semicarbazone (méthanol) fond à 155.5–156.5°

Réduction catalytique du mélange de cétones insaturées

Dix grammes de cétones venant de l'acylation de l'éthyl-1 cyclohexène par l'anhydride acétique en solution dans 200 ml d'éthanol absolu sont hydrogénés en présence de 6 g de Pd/C 10%. Il se forme 67% de *trans* acétyl-1 éthyl-2 cyclohexane (**5**) et 33% de *cis* acétyl-1 éthyl-2 cyclohexane (**6**) qui sont séparés par c.p.g. préparative. Le composé **6** distille à 98°/25 mm; n_D^{25}: 1.4551; i.r.: bande carbonyle à 1705 cm^{-1}; r.m.n.: multiplet à 0.99 p.p.m. (3H) et singulet à 2.05 p.p.m. (3H).

Anal. Calc. pour $C_{10}H_{18}O$: C, 77.87; H, 11.76. Trouvé: C, 78.13; H, 11.52. Le composé **5** distille à 130°/110 mm; n_D^{25}: 1.4530; i.r.: bande carbonyle à 1705 cm^{-1}; r.m.n.: multiplet à 0.94 p.p.m. (3H) et singulet à 2.04 p.p.m. (3H).

Anal. Calc. pour $C_{10}H_{18}O$: C, 77.87; H, 11.76. Trouvé: C, 78.06; H, 11.55.

Mise en équilibre d'un mélange de trans et cis acétyl-1 éthyl-2 cyclohexane (5) et (6)

Dix grammes d'un mélange formé de 30% de composé **6** et de 70% de composé **5** sont traités par 25 g d'acide oxalique en solution dans 60 ml d'eau à 110° durant 24 h sous atmosphère d'azote. A l'équilibre, il y a formation de 24% de composé **6** et de 76% de composé **5**.

Réduction catalytique de l'acétyl-1 éthyl-6 bicyclo[3.1.0]-hexane (4)

Deux-cent cinquante milligrammes de composé **4** en solution dans 20 ml d'éthanol absolu sont hydrogénés en présence de 100 mg de Pd/C 10%. Il se forme 95% de composé **5** et 5% de composé **6**.

Réduction chimique de l'acétyl-1 éthyl-6 bicyclo[3.1.0]-hexane (4)

Sept grammes de composé **4** sont réduits par $LiAlH_4$ de la manière habituelle mais l'excès d'hydrure est détruit par l'addition de quelques ml d'eau et de 3 ml d'une solution saturée de Na_2SO_4. Après extraction et évaporation de l'éther, l'analyse par c.p.g. du résidu sur une colonne (2.5 m) de glycérol 20% indique la présence d'un seul composé. La distillation du résidu donne 6.1 g d'éthyl-6 (hydroxy-1 éthyl)-1 bicyclo[3.1.0]hexane (**7**): p.e.: 110°/32 mm; i.r.: bande alcool à 3300 cm^{-1}; r.m.n.: multiplet à 1.1 p.p.m. (6H) méthyle de la chaine éthyle et méthyle adjacent à l'hydroxyle, singulet à 2.93 p.p.m. (1H) hydrogène du OH; quadruplet à 3.62 p.p.m. (1H, J = 6.5 c.p.s.) hydrogène carbinolique.

Anal. Calc. pour $C_{10}H_{18}O$: C, 77.92; H, 11.78. Trouvé: C, 77.92; H, 11.94.

Oxydation de l'éthyl-6 (hydroxy-1 éthyl)-1 bicyclo[3.1.0]-hexane (7)

Cinq cent milligrammes de composé **7** sont oxydés par le complexe anhydride chromique – pyridine selon le procédé de Poos *et al.* (5). L'analyse par c.p.g. des produits d'oxydation indique la présence d'un seul composé qui est identifié comme étant la cétone de départ (**4**).

Proton magnetic resonance studies of hydrogen bonding of formamide with bromide ion in solution. The non-equivalence of the amide hydrogens

R. D. GREEN
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received November 18, 1968

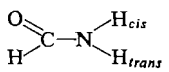
The proton magnetic resonance spectrum of a dilute solution of formamide—^{15}N in CH_3CN at 15 °C undergoes definite changes as bromide ion in the form of $(C_4H_9)_4NBr$ is added. The two amide resonances shift downfield, but at different rates. It is found that each amide hydrogen forms hydrogen bonds with bromide ions, apparently by way of independent equilibrium processes. The hydrogen bond at the *trans* position to the carbonyl oxygen is favored by about 0.7 kcal mole^{-1} over that at the *cis* position. It is postulated that electrostatic repulsion between any base and the carbonyl oxygen of an amide group, tends to favor formation of hydrogen bonds at the more remote, *trans*, hydrogen. This may account for the formation of hydrogen-bonded chains by *N*-monosubstituted amides preferentially with the amide hydrogen *trans* to oxygen.

Canadian Journal of Chemistry, 47, 2407 (1969)

Introduction

In the interactions of unsubstituted and monosubstituted amides with bases, both dipolar and monopolar, there has been some evidence that an amide hydrogen in the position *cis* to the carbonyl oxygen does not behave in exactly the same way as hydrogen in the *trans* position (1–4). For example, *N*-monosubstituted amides tend to have the amide hydrogen *trans* to oxygen, encouraging the formation of long hydrogen-bonded chains of molecules (1).

In the interesting case of the simplest of all amides, formamide, there are several pieces of evidence available which indicate that the *trans*



hydrogen is more electrophilic than the *cis*. Perhaps the most cogent argument is derived from the X-ray-determined crystal structure of formamide (2).

According to the evidence gathered by Pimentel and McClellan (5), there is every reason to believe that hydrogen bond strength correlates with the distances A—H and A—B in the hydrogen bond A—H . . . B; the shorter the bond length, the stronger is the bond. In the formamide crystal, both amide hydrogen atoms are involved in hydrogen bonds to carbonyl oxygens of other formamide molecules. However, the N—H_{cis} . . . O distance is 2.93$_5$ Å, whereas the N—H_{trans} . . . O distance is only 2.880 Å. The shorter hydrogen bond length is presumed to accompany the stronger interaction.

A note of caution should be sounded here. The C—N—O angle from the X-ray crystal data (2), is not the same in each case as is the C—N—H angle, determined by microwave spectroscopy (6), these angles taking the values 109 and 120.6° on the *trans* side, and 118.5 and 117.1° on the *cis* side. Hence, the shorter N—H_{trans} . . . O distance may be due to the fact that the hydrogen atom is not situated on the N—O axis; this would permit a shorter N—O distance without necessarily implying a stronger hydrogen bond. Hence, the crystal data are not conclusive concerning the relative bonding energies.

It has been found (3) that the enthalpy of solvation of ions by formamide is dependent on the orientation of the formamide molecules with respect to the ions. However, it is not possible from solvation enthalpies to establish the geometry of the formamide–anion solvates.

Nevertheless, it was determined (4) that the enthalpies of solvation of a series of salts with a common cation give a linear correlation with the inverse of the anion radius. This is taken as evidence that the anion–formamide interaction is essentially electrostatic in nature.

Results and Discussion

As a part of a continuing study of anion–molecule association in solution, the interaction of formamide—^{15}N with bromide ion in ethanenitrile solvent has been investigated by essentially the same technique as that developed earlier (7). The ^{15}N species was used to make

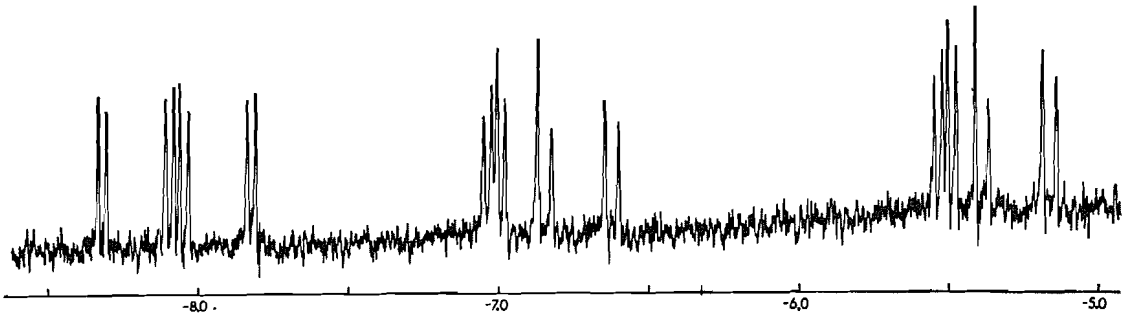


FIG. 1. The 60 MHz nuclear magnetic resonance spectrum of 0.25 *M* formamide—^{15}N in CH_3CN.

observation of the N—H signals a tractable matter. Successive amounts of tetrabutylammonium bromide were added to a 0.1 *M* solution of formamide—^{15}N in CH_3CN. The nuclear magnetic resonance (n.m.r.) signals due to the three protons were monitored as a function of salt concentration; the temperature was maintained at 15 °C, since at higher temperatures, rotation about the C—N bond begins to broaden the signals noticeably. The spectrum of dilute (0.25 *M*) formamide—^{15}N is shown in Fig. 1.

The chemical shift and coupling constant data for the various solutions are presented in Table I. Several trends are evident. First, all three proton signals show a monotonic downfield shift as the salt concentration increases. Second, the formyl proton signal shift is so small as to have no real significance. Third, the two amide proton signals shift significantly downfield, but not by equal amounts. Figure 2 demonstrates that the H_{trans} signal shifts farther than that of H_{cis}, and that its shift-concentration curve is levelling off more quickly.

A Benesi–Hildebrand–Scott analysis of the data (see p. 3660 of ref. 7) yields the complex shifts and equilibrium constants for the association of bromide ion with N—H_{cis} and N—H_{trans}; these are given in Table II. The indicated uncertainties are the standard errors derived as in the Appendix to ref. 7; these make allowance for uncertainties in the experimental measurements, as well as for deviations of the data points from a straight line.

The treatment of the data as representing essentially only hydrogen bonding processes involving bromide ion, appears to be justifiable. Formamide self-association is occurring, but only to a small extent: the shifts of H_{cis} and H_{trans} in neat formamide are −7.2 and −7.4 p.p.m. respectively (8); in a 0.25 *M* solution in CH_3CN, they are −6.0 and −6.3 p.p.m., while in a 0.10 *M* solution, they have changed to only −5.9 and −6.2 p.p.m. In addition, the effect of hydrogen bonding with the solvent is not likely to be very great, since acetonitrile is not a strong base: studies by n.m.r. (7) and infrared (9) spectroscopy confirm that $CHCl_3$ does not hydrogen bond with CH_3CN, although it does complex to an appreciable extent with bromide ions. Hence, the association equilibrium with bromide ion may be expected to predominate.

Equilibrium Constants

The difference in equilibrium constants is sufficiently large to require explanation. It would

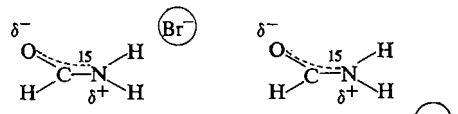
TABLE II

Complex formation data for formamide–bromide ion association in CH_3CN at 15 °C

	Equilibrium constant K, M^{-1}	Complex shift Δ_c, p.p.m.
H_{cis}	1.02±0.10	−1.54±0.13
H_{trans}	3.21±0.23	−2.10±0.08

appear that formamide forms hydrogen-bonded complexes with bromide ion at the two N—H sites, by way of independent equilibrium processes. The complex involving H_{trans} is evidently considerably favored over that at H_{cis}, the $\Delta(\Delta G)$ being ca. 0.7 kcal mole^{-1}. Certainly, the data cannot be explained on the basis of one bromide ion interacting with both hydrogens simultaneously.

The explanation for the discrepancy in free energy of formation of the two complexes probably lies in electrostatic repulsion of the bromide ion by the carbonyl oxygen. When the ion is hydrogen bonded at the *cis* position, this repulsion should be considerably greater than when it is at the *trans* position, resulting in a less stable complex.



more electrostatic repulsion
less stable

The difference in free energy of hydrogen bonding between the two possible sites may account, at least in part, for the observation that polypeptide and protein molecules tend to adopt a *trans* configuration preferentially, although packing and structural factors undoubtedly play a major role also. Nonetheless, in the absence of other restraints, the present results indicate that the *trans* configuration should be favored by a little less than 1 kcal mole^{-1}.

The Complex Shifts

If the assumption is made that a particular molecular species is present in solution in two forms, the "free" molecule and the molecule complexed with a base, then the difference in shifts of any proton in the two forms is given by the Buckingham equation (10)

$$[1] \qquad \Delta_c = AE_z - BE^2$$

which expresses the complex shift as a function of the first and second powers of the electrostatic field of the base (bromide ion). This equation has been found to be applicable to hydrogen-bonded complexes of C—H compounds (7) and O—H compounds (11) with bromide ion. There is no reason to believe that it will not apply to N—H compounds also.

Now, the term in E_z is proportional to cos θ, where θ is the angle between the X—H and H. . . base vectors. Therefore, the magnitude of the shift decreases rapidly as the source of the field moves away from the X—H axis. This fact may be used as a further source of information.

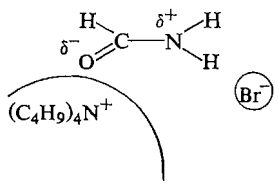
Assuming that the *A* coefficient is characteristic of the N—H bond, and hence is the same for both bonds in the formamide molecule, it is evident that the two N—H...Br^- complexes are not of the same geometry. If the *trans* complex is collinear, then the N—H...Br^- angle in the *cis* complex is about 40°; this non-linearity would presumably be due to the electrostatic repulsion of the bromide ion at the *cis* position by the carbonyl oxygen.

Effect of the Cation

The present results are inconsistent with any considerable interaction between formamide and the tetrabutylammonium ion. Since the salt exists in acetonitrile solution primarily in the form of ion pairs (12), the question of the location of the cation arises.

If the counterion is separated from the molecule by the bromide ion, its effect is predicted by eq. [1] to be no more than about 10–20% of the magnitude of that of the bromide ion, and in the opposite sense. That is, it would have the effect of reducing the proton shift in the complex by 0.2–0.4 p.p.m. This difference would not be detectable in this experiment.

If the counterion were to interact with the formamide molecule, only one possible configuration seems reasonable: *viz.* the ion pair would be coplanar with the molecule. This



configuration would favor complex formation by H_{cis} over H_{trans}, since the complex with H_{cis} permits the cation to interact more strongly with the carbonyl oxygen atom. Since the opposite result is actually obtained, this mode of interaction appears unlikely.

Coupling Constants in Formamide—^{15}N

The variation of each coupling constant with increasing salt concentration (see Table I) is very small, and is not readily assigned any significance. This finding is in sharp contrast to the marked differences found by Sunners *et al.* (8) between formamide—^{15}N solutions in acetone (10 mole %), water (8 mole %), and the neat liquid. In all cases, the present values are within 2% of the ones they found in acetone solution; however, they found changes of up to 50% on going to an aqueous solution, or to the neat liquid, particularly in couplings to the nitrogen nucleus. It may be that there is some fundamental difference in the nature of the hydrogen-bonding interaction of the amide N—H group with a dipolar base. This conclusion would be consistent with an earlier finding (7) that hydrogen bonding of halide ions to C—H appears to differ qualitatively from the interaction of dipolar pyridine with the same molecules.

Experimental

Materials

Formamide—^{15}N (98% isotopic purity) was used as received from Isomet Corporation. The purification of the other materials is described elsewhere (7).

Procedures

All spectra were obtained on a Varian HA-60 spectrometer operating in internal lock mode. Each resonance line (24 per spectrum) was measured by setting the sweep oscillator at the resonance, and measuring the difference between its frequency and that of the lock-in oscillator which was locked onto the tetramethylsilane signal.

Line positions were measured with a precision of approximately ±0.1 Hz. Since the largest ratio of J/Δ encountered was 0.15, all the spectra were analyzed by a first-order analysis; errors caused by this approximation should not exceed 0.1 Hz. Because of the large number of spin–spin couplings in this small molecule, each chemical shift obtained was the average of four measurements, and each coupling constant was the average of four measurements in the case of couplings to ^{15}N, and eight measurements in the case of couplings to other protons. The uncertainties are estimated to be ±0.005 p.p.m. for the shifts, and ±0.1 Hz for the coupling constants.

Acknowledgments

The author is indebted to Dr. John S. Martin for many helpful discussions and for providing the formamide—^{15}N used in this work. The author also wishes to acknowledge gratefully the financial support of the National Research Council of Canada.

Some piperazino analogues of methadone and related ketones: a novel conversion of an *N*-carbethoxy to a triethylmethyl group

J. R. DIMMOCK,[1] N. J. HARPER, R. ISLAM, AND A. F. CASY

School of Pharmacy, Chelsea College of Science and Technology, University of London, London, S.W. 3, England

Received November 21, 1968

A number of derivatives of methadone and related compounds have been prepared, where the dimethylamino group has been replaced by a 4-substituted piperazino function. The preparation of these compounds involved the reaction of *N*-ω-cyanoalkyl-*N'*-carbethoxy piperazines with ethyl magnesium bromide, and various products were obtained. These included replacement of the *N'*-carbethoxy group by a triethylmethyl function and cleavage of the carbethoxy group. In some cases the ω-cyano group reacted to give the corresponding ketone. Reactions of 1-benzyl-4-carbethoxy piperazine with ethyl magnesium bromide and phenyl magnesium bromide gave no evidence for the formation of the triethylmethyl group. However, cleavage of the carbethoxy group occurred and there was evidence for the formation of the corresponding amide.

Canadian Journal of Chemistry, 47, 2413 (1969)

Introduction

Structural modifications of the narcotic analgesic methadone (**1***a*) involving replacement of the terminal dimethylamino group by an alicyclic *t*-basic function have led to several potent compounds, two of which, namely dipipanone (**1***b*) and phenadoxone (**1***c*), have been used clinically (1, 2). The *N'*-methylpiperazino analogue (**1***d*) has also been examined and is significantly active as an analgesic being half as potent as methadone in mice (3). In analgesics based upon 4-phenylpiperidine (e.g. pethidine) and those in which this structural unit forms part of a polycyclic molecule (e.g., dromoran), substitution of *N*-methyl by arylalkyl functions such as 2-phenethyl and 3-phenpropyl generally yields a more potent product (2), while oxygenated functions [e.g. $(CH_2)_4OH$ and $(CH_2)_2OEt$] effectively raise the activity of pethidine (4).

In the light of these findings, it was considered of interest to examine piperazino analogues of methadone and related compounds which carried aryl–alkyl and oxygenated-alkyl *N'*-substituents.

The general route used to prepare the desired methadone analogues is illustrated for one series in Scheme 1. *N'*-Carbethoxy intermediates (**2**) rather than those unsubstituted at this position were chosen on account of the need to avoid active hydrogen sites in certain of the reactions, and also because of the possibility of subsequent replacement of *N'*-CO_2Et in the ketone **3** by a variety of R substituents. It was recognized that the *N'*-CO_2Et group in the cyanide **2** might provide a further point of Grignard attack but this was not considered a disadvantageous complication since it could lead directly to the N'H analogue of **3**. Other piperazino cyanides subjected to the same reaction sequence were the trimethylene analogue **4** and the branched chain derivatives **5***a* and **5***b*. The latter pair both resulted when diphenylacetonitrile was alkylated with *N*-2-chloropropyl-*N'*-carbethoxy piperazine and their structures were established by converting one member to the corresponding *N'*-methyl derivative, previously prepared by an unambiguous route (5).

Reaction of the cyanides **2**, **4**, and **5** with ethyl magnesium bromide (excess of reagent in benzene at the reflux temperature) led in all cases to basic mixtures from which crystalline products could in some instances be isolated as hydrochloride salts. Further evidence of reaction pathways was provided by the nature of products obtained from the uncrystallizable residues after hydrolysis and *N'*-alkylation procedures. With the exception of the highly hindered cyanide **5***b*, all substrates suffered attack at the cyano function and were converted to corresponding ethyl ketones. These were isolated as the *N'*-alkylated products required for pharmacological evaluation. Direct evidence of the removal of the *N'*-CO_2Et group was only obtained in the case of cyanide **4**, through the isolation of the

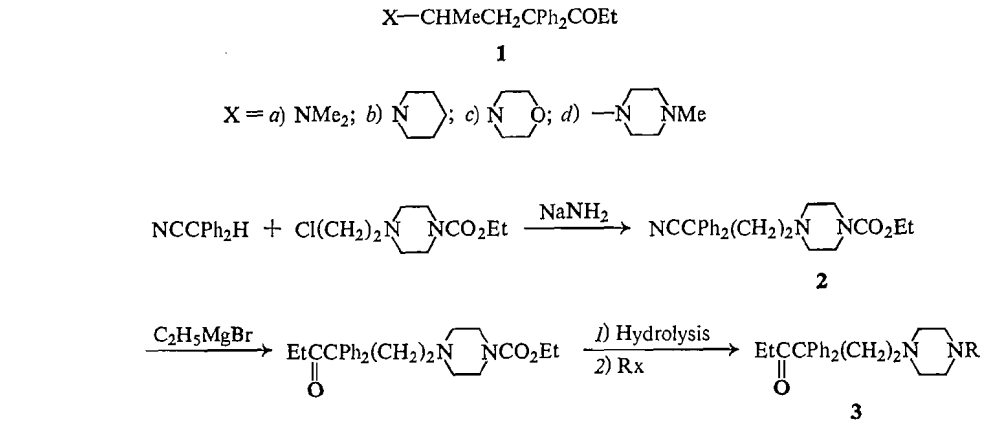
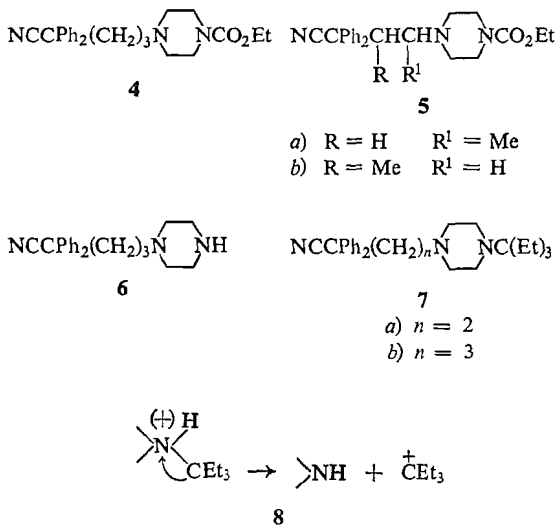


SCHEME 1



sec-amine **6** as a hydrochloride, while an unexpected reaction between the *N*-carbethoxy group and ethyl magnesium bromide, namely its conversion to a triethylmethyl function, was detected in two cases. Structural evidence for the cyanide 2-ethyl Grignard reaction product **7***a* is detailed below:

(*1*) The cyano group of this product is intact because the infrared spectrum of the free base shows a typical $\nu C{\equiv}N$ band at 2280 cm^{-1} (obscured in the salt by the broad $\nu N^{+}H$ band); the N'-CO_2Et group has been modified, however, since the pronounced $\nu C{=}O$ band near 1700 cm^{-1} of the precursor cyanide is absent, as are other bands in the carbonyl stretching region (1800–1620 cm^{-1}).

(*2*) The 60 MHz proton magnetic resonance (p.m.r.) spectrum of the salt demonstrates the presence of three identical *C*-ethyl groups (a 9 proton deformed triplet near 9 τ and a 6 proton multiplet near 8.25 τ). Their identity is supported by the fact that these signals were not further resolved when a spectrum was recorded at 100 MHz (Fig. 1).

(*3*) The mass spectrum of the hydrochloride showed a peak of highest *m/e* ratio at 403, corresponding with the dihydrochloride monohydrate of **7***a*. Prominent peaks consistent with likely fragments were found at 374 (loss of Et), 304 (loss of CEt_3), 192 (due to $NCCPh_2$), and 112 (due to CH_2CH_2N⟨ ⟩N), while a peak at 99 (CEt_3) was also recorded.

(*4*) Elemental analysis of the salt supported the dihydrochloride monohydrate structure **7***a*. Evidence for water of crystallization was provided by a loss on drying determination and infrared characteristics (broad band near 3500 cm^{-1}) of the salt.

A dihydrochloride monohydrate, isolated from the cyanide 4-ethyl Grignard reaction product, was similarly assigned the *N*-triethylmethyl structure **7***b* on the basis of analytical and infrared spectroscopic evidence. Its N'-substituent could be removed under acid conditions (18% HCl—H_2O at the reflux temperature) giving the *sec*-base **6**, and this unusual result (most *N*-alkyl derivatives are stable towards acids) may be attributed to resonance stabilization of the triethyl carbonium ion **8**, a likely reaction intermediate. *N*-Alkyl fission of certain benzhydryl-

amines with water or mineral acid represents an analogous example (6).

Literature data upon the fate of an *N*-carbethoxy group following attack by an organometallic reagent is sparse [chemically *N*-carbethoxy piperazines are substituted urethanes, a class to which no reference is made in standard works on the Grignard reaction (7, 8)], and a tentative reaction mechanism for (*a*) its conversion to a triethylmethyl function and (*b*) its removal is given below (Scheme 2).

Although the amide **10**, proposed as a common intermediate for both pathways, was not detected in reactions involving **3** and **4**, the analogous benzamide was isolated in 28% yield from the analogous reaction between phenyl magnesium bromide and *N*-benzyl-*N'*-carbethoxy piperazine. Treatment of this *N*-benzyl derivative with ethyl magnesium bromide gave *N*-benzyl piperazine (loss of the N'-CO_2Et group) together with the impure *N'*-propionyl amide (infrared evidence). No evidence for pathway (*a*) was obtained in either reaction of the simpler piperazine derivative. Although Scheme 2 depicts N'-CO_2Et loss via the amide **10**, the secondary amine **11***b* might also form upon initial Grignard attack through cleavage of the N—C rather than O—C bond within the complex **9**. However, amides have already been shown to react with Grignard reagents to yield *t*-alkyl amines (9) and secondary amines (10) analogous to **11***a* and **11***b* respectively.

A number of compounds described in this work were evaluated for analgesic activity after subcutaneous injection in mice by a pinch tail method and a modification of the hot plate method described by Janssen and Jageneau (11). Only three compounds showed activity at a dose range of 100 mg/kg, namely **12**, **20**, and **21** (Table I), with approximately 10–15% of the

†Anal. Calcd.: Cl, 14.3. Found: Cl, 14.0.

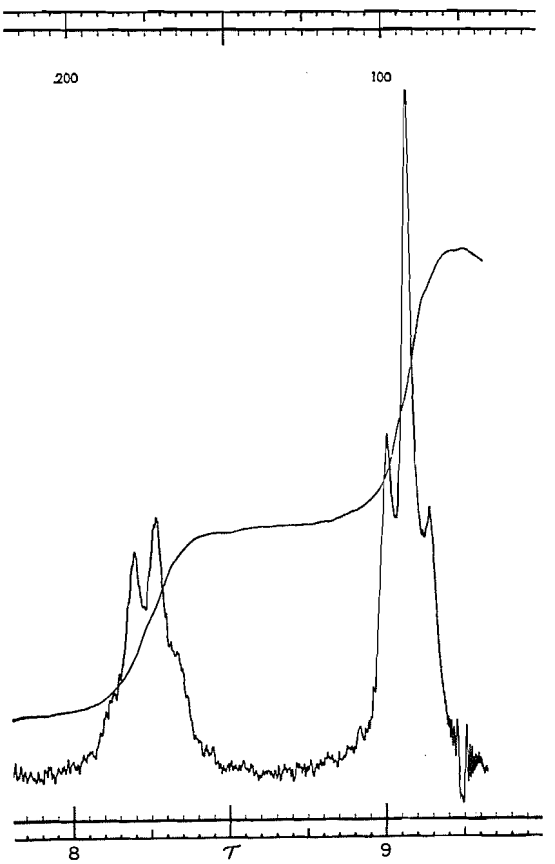

FIG. 1. The 100 MHz proton magnetic resonance spectrum of *7a* in DMSO-d_6.

activity of methadone. None of the cyanides possessed analgesic activity.

Experimental

All melting points and boiling points are uncorrected. The infrared spectra were determined on Unicam SP 100 and Unicam SP 200 spectrophotometers. The proton magnetic resonance (p.m.r.) spectra were recorded on Perkin–Elmer R 10 and Varian HA-100 instruments in dimethyl sulfoxide, operating at 60 and 100 MHz/s respectively with TMS as standard. Equivalent weights of bases and salts were determined by titration with 0.02 *N* perchloric acid in glacial acetic acid with Oracet Blue B as indicator. Microanalyses were performed by Mr. G. S. Crouch, School of Pharmacy, University of London, Dr. G. Weiler and Dr. F. B. Strauss, Microanalytical Laboratory, Oxford, and Mr. M. Ellison, Chesterford Park Research Station, Saffron Waldon, Essex. All organic extracts were washed several times with water and dried over anhydrous sodium sulfate prior to removal of the solvent. Unless otherwise stated, compounds were recrystallized from ethanol or 96% ethanol.

3-(4-Carbethoxypiperazino)-1,1-diphenylpropyl Cyanide (2)

Sodamide (8.6 g) was added to a solution of diphenylacetonitrile (37.6 g) in dry benzene (280 ml) under nitrogen. The mixture was stirred for 1 h and heated under reflux for 4.5 h during which time a further 230 ml of benzene were added. On cooling, a solution of 1-(2-chloroethyl)-4-carbethoxy piperazine (38.5 g) in dry benzene (100 ml) was added and the mixture heated under reflux for 5.5 h. After standing overnight, the excess of sodamide was decomposed with water and the organic extract separated; removal of benzene gave an oil which solidified on trituration with petroleum ether (b.p. 40–60 °C) to give the aminocyanide **2** as yellow crystals (70 g). An analytical sample, melted at 111.5–112.5 °C.

Anal. Calcd. for $C_{23}H_{27}N_3O_2$ (equiv., 377): C, 73.1; H, 7.3. Found (equiv., 372): C, 73.5; H, 7.3.

It gave a hydrochloride m.p. 176.5–178 °C.

Anal. Calcd. for $C_{23}H_{28}ClN_3O_2$ (equiv., 414): C, 66.7; H, 6.8; Cl, 8.6; N, 10.2. Found (equiv., 413): C, 66.6; H, 6.9; Cl, 8.5; N, 10.3.

4-(4-Carbethoxypiperazino)-1,1-diphenylbutyl Cyanide (4)

Reaction between diphenylacetonitrile and 1-(3-chloropropyl)-4-carbethoxy piperazine using the method described in the previous experiment gave the aminocyanide **4**, as pale-yellow crystals, m.p. 139 °C.

Anal. Calcd. for $C_{24}H_{29}N_3O_2$ (equiv., 391): C, 73.6; H, 7.5; N, 10.7. Found (equiv., 390): C, 73.6; H, 7.5; N, 10.9.

Preparation and Proof of Structure of the Isomeric Cyanides 5a and 5b

Diphenylacetonitrile (37.6 g) was condensed with 1-(2-chloropropyl)-4-carbethoxy piperazine (41.3 g) using the method described previously to give an oil (72.0 g), which yielded pale-yellow crystals (40.0 g) from ethanol, m.p. 119–122 °C. Recrystallization gave **5a**, m.p. 122 °C.

Anal. Calcd. for $C_{24}H_{29}N_3O_2$ (equiv., 391): C, 73.7; H, 7.4; N, 10.7. Found (equiv., 392): C, 74.4; H, 7.4; N, 10.8.

The hydrochloride melted at 177–178 °C.

Anal. Calcd. for $C_{24}H_{30}ClN_3O_2$ (equiv., 427.5): C, 67.4; H, 7.0; Cl, 8.3; N, 9.8. Found (equiv., 428): C, 67.1; H, 7.2; Cl, 8.2; N, 9.3.

Evaporation of the combined ethanolic mother liquors gave an oil (28.0 g) which could not be crystallized. A solution of the oil in a mixture of equal parts of benzene and petroleum ether (b.p. 40–60 °C) was chromatographed on alumina, followed by elution with petroleum ether containing increasing concentrations of benzene gave the isomeric cyanide **5b** (23.0 g), m.p. 113–114 °C from ethanol. It gave a hydrochloride, m.p. 124–125.5 °C.

Anal. Calcd. for $C_{24}H_{30}ClN_3O_2$ (equiv., 427.5): C, 67.4; H, 7.0; Cl, 8.3. Found (equiv., 430): C, 66.8; H, 7.1; Cl, 8.3.

5a (15.0 g) was heated under reflux for 6 h with 20% alcoholic potassium hydroxide solution (100 ml). After removal of the alcohol the reaction product was extracted with chloroform to give 3-piperazino-1,1-diphenylbutyl cyanide (11.0 g), the picrate crystallizing from acetone as solvated needles, m.p. 208–210 °C.

Anal. Calcd. for $C_{21}H_{25}N_3 \cdot 2C_6H_3N_3O_7 \cdot C_3H_6O$: C, 51.7; H, 4.5; N, 15.1. Found: C, 52.0; H, 4.6; N, 15.9.

This cyanide (3.2 g), 90% formic acid (1.2 g) and 36% formaldehyde solution (0.5 g), were heated under reflux for 6 h after which time hydrochloric acid was added and the formic acid and formaldehyde removed by distillation. Basification of the reaction mixture and extraction with chloroform gave an oil which solidified on titration with petroleum ether (b.p. 40–60 °C) to give a solid (3.3 g) which on recrystallization from petroleum ether (b.p. 80–100 °C) gave 3-(4-methylpiperazino)-1,1-diphenylbutyl cyanide, m.p. 107 °C, lit. m.p. 108–110 °C (5).

Calcd. for $C_{22}H_{27}N_3$: equiv., 166.5. Found: equiv., 168.

Reaction of Ethyl Magnesium Bromide with 3-(4-Carbethoxypiperazino)-1,1-diphenylpropyl Cyanide (2)

A solution of **2** (12.0 g) in dry benzene (100 ml) was added to a solution of ethyl magnesium bromide (prepared from 13.9 g of ethyl bromide and 3.05 g of magnesium) in ether (90 ml). After removal of the ether the mixture was stirred at room temperature for 4 h and then heated under reflux for 16 h. On cooling the product was decomposed with ice and dilute hydrochloric acid and the benzene layer was separated. Basification of the aqueous phase followed by extraction with ether and subsequent evaporation of the solvent gave an oil (12.2 g) which could not be crystallized. The oil (9.05 g) was dissolved in ethanol and treated with ethanolic hydrochloric acid and stored one month at 1 °C when **7***a* separated as the dihydrochloride monohydrate (2.8 g), m.p. 190 °C from ethanol.

Anal. Calcd. for $C_{27}H_{39}Cl_2N_3 \cdot H_2O$ (equiv., 247): C, 65.6; H, 8.4; Cl, 14.3; N, 8.5. Found (equiv., 245): C, 65.8; H, 8.3; Cl, 14.1; N, 8.7. Loss of H_2O at 120 °C. Anal. Calcd. for 1 H_2O: 3.6. Found: 3.85.

ν(Nujol): 3450 (OH), 670,710 (monosub., aromatic) cm^{-1}; ν(neat, free base), 2280 (CN) cm^{-1}: p.m.r. characteristics in DMSO-d_6: 9.03 (deformed triplet, 9H), 8.23 (multiplet, 6H), 6.90 (triplet, 2H), 2.56 (multiplet, 10H). Prominent *m/e* peaks: 403(**7***a*), 374[loss of C_2H_5], 304 [loss of $C(C_2H_5)_3$], 192[due to NC.C. $(C_6H_5)_2$], 112 [due to CH_2CH_2N⟨⟩N], 99[due to $C(C_2H_5)_3$].

The residue (30 g) from the mother liquors of several batches was heated under reflux with 18% hydrochloric acid (300 ml) for 5.5 h. The free base recovered from the aqueous phase was an oil **A** which could not be crystallized or converted to a solid salt. It was characterized by alkylation as follows.

2-Phenylethyl Bromide

A mixture of the oil **A** (5.3 g), 2-phenylethyl bromide (1.6 g), sodium bicarbonate (2.0 g), and ethanol (25 ml) was heated under reflux for 5.5 h. After removal of the inorganic matter by filtration, the ethanol was removed and the resultant oil basified with ammonia and extracted with ether. Evaporation of the solvent gave an oil which when treated with ethanolic hydrochloric acid gave 3-[4-(2-phenylethylpiperazino)]-1,1-diphenylpropyl cyanide dihydrochloride (2.5 g), m.p. 264–266 °C. An analytical sample melted at 266–267 °C.

Anal. Calcd. for $C_{28}H_{33}Cl_2N_3$ (equiv., 241): C, 69.7; H, 6.9; N, 8.7. Found (equiv., 244): C, 69.0; H, 7.0; N, 9.0.

Further alkylated derivatives together with compounds isolated from the aminocyanides **4**, **5***a*, and **5***b* were prepared by similar procedures. Relevant analytical and physical data are given in Table I.

Reaction of Ethyl Magnesium Bromide with 4-(4-Carbethoxypiperazino)-1,1-diphenylbutyl Cyanide (4)

Ethyl magnesium bromide (prepared from 65.4 g ethyl bromide and 14.6 g magnesium) was reacted with **4** (58.6 g) using the conditions described previously.

The product (55 g) was acidified with ethanolic hydrogen chloride and fractionally crystallized from ethanol to give

(i) 4-piperazino-1,1-diphenylbutyl cyanide dihydrochloride (6) (5.0 g), m.p. 260–261 °C from ethanol.

Anal. Calcd. for $C_{21}H_{27}Cl_2N_3$ (equiv., 196): C, 64.2; H, 6.9; Cl, 18.1; N, 10.7. Found (equiv., 198): C, 64.2; H, 6.8; Cl, 18.4; N, 10.9.

(ii) 4-(4-triethylmethylpiperazino)-1,1-diphenylbutyl cyanide dihydrochoride monohydrate (7b) m.p.. 180–182 °C.

Anal. Calcd. for $C_{28}H_{41}Cl_2N_3 \cdot H_2O$ (equiv., 254): C, 66.1; H, 8.6; N, 8.3. Found (equiv., 256): C, 66.3; H, 8.4; N, 8.5. Its infrared spectrum was similar to that of **7***a*.

A mixture of **7***b* (30.0 g) and 18% hydrochloric acid (300 ml) was heated under reflux for 6 h. The free base, recovered as usual, was acidified with ethanolic hydrochloric acid to give 4-piperazino-1,1-diphenylbutyl cyanide dihydrochloride, m.p. and mixture m.p. 260–261 °C.

Hydrolysis of residues from the mother liquors of the Grignard reaction product, carried out as before, gave an oil from which 7-piperazino-4,4-diphenylheptan-3-one dihydrochloride monohydrate m.p. 105–110 °C was obtained.

Anal. Calcd. for $C_{23}H_{32}Cl_2N_2O \cdot H_2O$ (equiv., 220): C, 62.6; H, 7.8; N, 6.3; Cl, 16.0. Found (equiv., 222): C, 62.5; H, 8.2; N, 6.3; Cl, 15.5.

ν(Nujol): 3350(H_2O), 1700(CO) cm^{-1}.

Reaction of Ethyl Magnesium Bromide with 3-(4-Carbethoxypiperazino)-1,1-diphenylbutyl Cyanide 5a

Reaction between the cyanide **5***a* (39 g) and ethyl magnesium bromide (prepared from 43.1 g of ethyl bromide and 8.8 g magnesium) gave an oil (35.0 g) from which an unidentified solid **A** (11 g) separated as a hydrochloride. This salt was hydrolyzed with 18% hydrochloric acid as usual and the product alkylated with 2-phenylethyl bromide to give 3-[4-(2-phenylethylpiperazino)]-1,1-diphenylbutyl cyanide dihydrobromide m.p. 282 °C, undepressed by an authentic sample of the salt prepared in the following manner. The carbethoxy group of **5***a* (15.0 g) was hydrolyzed with 20% alcoholic potassium hydroxide solution (100 ml) and the product alkylated.

Anal. Calcd. for $C_{29}H_{35}Br_2N_3$ (equiv., 292): C, 59.5; H, 6.0; Br, 27.3; N, 7.2. Found (equiv., 294): C, 59.6; H, 6.1; Br, 27.4; N, 7.1.

Hydrolysis of the residues from the mother liquors remaining after solid **A** had separated (18.0 g) with excess 18% hydrochloric acid gave 6-piperazino-4,4-diphenylheptan-3-one (14.0 g)' identified as the picrate, m.p. 259–260 °C (from acetone).

Anal. Calcd. for $C_{23}H_{30}N_2O \cdot 2C_6H_3N_3O_7$: C, 51.9; H, 4.5; N, 13.8. Found: C, 50.6; H, 4.6; N, 13.5.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Reaction of Ethyl Magnesium Bromide with 3-(4-Carbethoxypiperazino)-1,1-diphenyl-2-methylpropyl Cyanide 5b

Ethyl magnesium bromide (prepared from 4.4 g of ethyl bromide and 1.0 g of magnesium) was reacted with **5b** (3.9 g) using the method described previously to give an oil **B** (3.6 g) which failed to solidify or form a crystalline salt.

Hydrolysis of the Oil B

Hydrolysis of **B** (3.4 g) with 18% hydrochloric acid (30 ml) gave another oil **C** (2.7 g) which similarly failed to solidify or give a crystalline derivative.

Alkylation of the Oil C

Alkylation of **C** (2.0 g) with 2-phenylethyl bromide gave 3-[4-(2-phenylethyl)piperazino]-1,1-diphenyl-2-methylpropyl cyanide dihydrobromide (2.8 g) m.p. 297–299 °C.

Anal. Calcd. for $C_{29}H_{35}Br_2N_3$ (equiv., 293): C, 59.5; H, 6.0; Br, 27.3; N, 7.2. Found (equiv., 294): C, 59.7; H, 6.2; Br, 27.2; N, 7.1.

The compound was also prepared from **5b** by hydrolysis and subsequent alkylation with 2-phenylethyl bromide by the methods described previously.

Reaction of Phenyl Magnesium Bromide with 1-Benzyl-4-carbethoxy Piperazine

1-Benzyl-4-carbethoxy piperazine (12.5 g) and phenyl magnesium bromide (from 17.5 g phenyl bromide and 2.6 g of magnesium) were reacted under conditions described previously, except that the time of heating under reflux was 4 h. Treatment of the crude reaction product with ethanolic hydrobromic acid gave a solid, fractionally crystallizing from ethanol to give

(i) 1-benzyl-4-benzoyl piperazine hydrobromide (1.35 g) m.p. 250 °C. An analytical sample, melted at 257–259 °C, undepressed when mixed with an authentic sample prepared below.

Anal. Calcd. for $C_{18}H_{21}BrN_2O$ (equiv., 361): C, 59.8; H, 5.9; Br, 22.1; N, 7.8. Found (equiv., 370): C, 60.4; H, 6.2; Br, 21.7; N, 8.1. Benzoylation of 1-benzyl piperazine gave 1-benzyl-4-benzoyl piperazine hydrochloride m.p. 247.5–248.5 °C (lit. m.p. 245 °C (12)).

Calcd. for $C_{18}H_{21}ClN_2O$: equiv., 315.5. Found: equiv., 317.

Liberation of the free base followed by treatment with ethanolic hydrobromic acid yielded an authentic sample of 1-benzyl-4-benzoyl piperazine hydrobromide.

(ii) 1-benzyl-4-carbethoxy piperazine hydrobromide (0.94 g) m.p. 215.5–217 °C. Recrystallization raised the m.p. to 219.5–220.5 °C, undepressed when mixed with an authentic sample prepared below.

Calcd. for $C_{14}H_{21}BrN_2O_2$: equiv., 329. Found: equiv., 325.

1-Benzyl-4-carbethoxy piperazine, prepared from an authentic sample of the hydrochloride, on treatment with ethanolic hydrobromic acid gave an authentic sample of the salt, m.p. 227–227.5 °C. Found: equiv., 327.

Evaporation of the ethanolic mother liquors gave an oil (1.62 g) from which no further crystalline material could be isolated.

Reaction between Ethyl Magnesium Bromide and 1-Benzyl-4-carbethoxy Piperazine

1-Benzyl-4-carbethoxy piperazine (9.64 g) was reacted with ethyl magnesium bromide (from 9.36 g ethyl bromide and 2.07 g of magnesium) under the conditions of the previous experiment to give a golden oil (8.01 g). Treatment of the oil with ethanolic hydrochloric acid gave a solid which was fractionally crystallized from ethanol and ether–ethanol to give

(i) 1-benzyl piperazine dihydrochloride (1.79 g), 239 °C decomp.). An analytical sample melted at 256 °C (lit. m.p. 253° C (12)).

Anal. Calcd. for $C_{11}H_{18}Cl_2N_2$: C, 53.0; H, 7.3. Found: C, 53.0; H, 7.3.

(ii) 1-benzyl-4-carbethoxy piperazine hydrochloride (2.15 g) m.p. 210–212 °C. Recrystallization raised the m.p. to 215.5–217.5 °C, undepressed when mixed with an authentic sample.

(iii) a fawn solid (2.40 g). The infrared spectrum (Nujol) indicated the presence of 1-benzyl-4-carbethoxy piperazine hydrochloride (νCO, 1710 cm^{-1}) and a small peak at 1650 cm^{-1} (tertiary amide) indicated the presence of 1-benzyl-4-propionyl piperazine hydrochloride.

Acknowledgments

We should like to thank Mr. R. F. Branch of the School of Pharmacy, Chelsea College of Science and Technology, and Professor J. A. Elvidge of the Department of Chemistry, University of Surrey for profitable discussions. We are grateful to Smith, Kline & French Laboratories who undertook the pharmacological testing and provided samples of the cyanides **2**, **4**, and **5**. Dr. D. H. Williams of the University Chemical Laboratories, Cambridge, kindly determined the 100 MHz proton magnetic resonance spectrum.

Total synthesis of anisomycin

C. M. Wong, J. Buccini, I. Chang, J. Te Raa, and R. Schwenk
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received January 7, 1969

Two synthetic approaches to anisomycin had been studied. One approach used 2R 3R tartaric acid as starting material and was successfully converted to the hydrochlorides of (+)-anisomycin (**22**) in an overall yield of about 5% and (−)-anisomycin (**1**) in about 1% yield. Liberation of the free bases gave (+)-anisomycin and (−)-anisomycin. The other approach started with α-anisyl pyrrole and was converted to (±)-deacetyl anisomycin **2**. The conversion of **2** to anisomycin was done by treating natural deacetyl anisomycin with benzyl bromide to give **9**. Conversion of **8** and **9** to (+)-anisomycin and (−)-anisomycin was done by selective acetylation with acetic anhydride and debenzylation under hydrogenation condition.

Canadian Journal of Chemistry, 47, 2421 (1969)

Introduction

Anisomycin (**1**) (1) was isolated from cultures of various streptomyces species. It was reported to be active against some pathogenic protozoa (2). The correct structure was elucidated by X-ray crystallography (3) which revealed only the relative stereochemistry.

We reported in our previous work the absolute configuration of anisomycin and a simple approach to deacetyl anisomycin (4, 5) and recently Oida (7) reported the total synthesis of (DL)-anisomycin.

Results and Discussion

N-Benzyl tartrimide prepared from 2R 3R tartaric acid reacting with anisylmagnesium chloride in tetrahydrofuran gave the keto-amide **3** (5). Heating **3** in absolute ethanol at 140 °C under nitrogen atmosphere gave the unsaturated lactam (**4**).[1] Hydrogenation of **4** using 5% Pd/C as catalyst in ethanol gave the lactam **5** and a minor compound (**6**). The separation of **5** from **6** was not successful and the presence of the small amount of **6** in the hydrogenation reaction was uncovered only after the lithium aluminium hydride reduction of **5** and **6** to **7** and **9**. Separation of **7** from **9** was easily done by thin-layer chromatography (t.l.c.) on silica. The overall yields of **7** and **9** from *N*-benzyl tartrimide were 37% and 1% respectively. The conversion of **7** to the epoxide (**11**) via the monoacetate (**10**) and the conversion of **10** to (+)-deacetyl anisomycin (**20**) was reported earlier (5).

The (±)-deacetyl anisomycin was also prepared starting with α-anisyl pyrrole (3). Clemmenson reduction of α-anisyl pyrrole gave 2-anisyl 3-pyrroline (**12**). Acetylation of **12** with acetic anhydride followed by peracetic acid oxidation gave the epoxide (**13**) as the major product together with a small amount of epoxide (**14**). Separation of **13** from **14** by t.l.c. or vapor-phase chromatography (v.p.c.) was unsuccessful. However, epoxide **14** gave the monoacetates **15** and **16** by refluxing in glacial acetic acid for 16 h while the epoxide **13** gave the monoacetate **17**. The opening of the epoxide ring of **13** was very slow compared with that of **14**. Thus careful column chromatography on alumina of the reaction mixture gave **13**, **15**, **16**, **17**, and the diol **18** which was formed by prolonged contact of the epoxide **13** with alumina. The acetate **15** was isolated only in negligible quantities and its structure was assigned only by comparing the infrared (i.r.) spectra with that of *N*-acetyl isoanisomycin (6), prepared from natural anisomycin. Acetates **16** and **17** were characterized by elemental analyses, mass spectra, and hydrolysis of both monoacetates to the diol **18**. Only the acetate **17** could be converted to the epoxide **14** by phosphorus pentachloride followed by alcoholic potassium hydroxide solution. The

[1]A by-product possibly (*i*) was isolated in about 1% yield. Hydrogenation of (*i*) and **4** gave the same product.

epoxide **14** was also prepared from anisomycin (6)[2] for comparison. The i.r. spectra were superimposable. Refluxing **14** in glacial acetic acid followed by basic hydrolysis gave a mixture of racemic deacetyl anisomycin (**2**). Treating (−)-deacetyl anisomycin with benzyl bromide gave *N*-benzyl deacetyl anisomycin (**9**).

Conformation controlled selective acetylation[3] of (+)-*N*-benzyl deacetyl anisomycin (**8**) with acetic anhydride gave (+)-*N*-benzyl anisomycin (**21**). Debenzylation of **21** with 5% Pd/C in acidic ethanolic solution under hydrogenation condition gave the hydrochloride salt of (+)-anisomycin. Liberation of the free base by dilute sodium hydroxide solution gave (+)-anisomycin (**22**). The i.r., nuclear magnetic resonance (n.m.r.) spectra of **22** were superimposable to those of natural anisomycin.

[2]The stereochemistry of the epoxide prepared from anisomycin as described in (6) should be shown as (*i*).

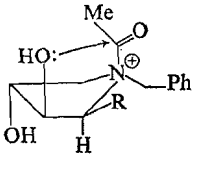
[3]



Experimental

All i.r. spectra were measured on a Perkin–Elmer 137 i.r. spectrophotometer using methylene chloride as solvent or as otherwise specified. Nuclear magnetic resonance (n.m.r.) spectra were measured on a Varian A 56/60 A spectrometer using tetramethylsilane as internal standard, and deuterated chloroform as solvent. Mass spectra were measured on a Hitachi Perkin–Elmer RMU-6D mass spectrometer. Melting points were measured by a Fisher–Johns melting point apparatus and are uncorrected. Microanalyses were performed by Dr. Daesslé of Montreal and optical rotations were measured on a Carl Zeiss polarimeter.

Preparation of the Unsaturated Lactam (4)

The keto-amide (**3**) (5) (6.4 g) and anhydrous magnesium sulfate (6.4 g) in anhydrous alcohol (100 ml) were heated at 135 °C under nitrogen atmosphere of 50 P/in^2 for 7 h in a high pressure hydrogenation apparatus. The magnesium sulfate was filtered off and the alcohol solution was evaporated to dryness under reduced pressure, giving an orange gummy residue. Crystallization of the residue from benzene gave the lactam **4** (3.5 g). The mother liquor was purified by t.l.c. on silica giving an additional amount of the lactam **4** (1.3 g). Yield, 80%; m.p. 148–149 °C; i.r. 3600, 3400, 1720, 1655, 1605 cm^{-1}; n.m.r. (τ) 2.80 (s, 5H's aromatic), 2.77–3.33 (A_2B_2, 4H's aromatic), 4.20 (d, 1H, J = 1.5 c.p.s., vinylic), 4.94 (q, 1H, J = 1.5 and 3.5 c.p.s., C_3—H), 5.27 (s, 2H's, N—CH_2—ph), 5.50 (d, 1H, J = 3.5 c.p.s., C_4—H), 6.30 (s, 3H's, —OCH_3).

Anal. Calcd. for $C_{19}H_{19}O_4N$: C, 70.14; H, 5.89; N, 4.13. Found: C, 70.28; H, 6.06; N, 4.32.

Preparation of the Diol 7 from the Lactam 4

To an alcoholic solution of **4** (50 ml, 2.2 g) was added 5% Pd/C (1.1 g) and the solution was hydrogenated for 18 h at room temperature under 450 P/in^2 of hydrogen. After filtering off the catalyst, the ethanol was removed under reduced pressure. The residue was recrystallized from benzene giving the crystalline lactam **5** (1.8 g). M.p. 111–112 °C; i.r: 3600, 3400, 1695, 1605 cm^{-1}.

Anal. Calcd. for $C_{19}H_{21}O_4N$: C, 69.71; H, 6.46; N, 4.27. Found: C, 69.93; H, 6.26; N, 4.49.

The saturated lactam (**5**) (1.9 g) dissolved in anhydrous tetrahydrofuran (20 ml) was added slowly to a suspension of lithium aluminium hydride (1.06 g) in anhydrous tetrahydrofuran (80 ml), and was refluxed for 7 h. The tetrahydrofuran (60 ml) was removed by distillation and wet ether (100 ml) was added slowly to the residue. Water (50 ml) was then added. The ether layer was separated from the aqueous layer which was extracted exhaustively with ether. The ether solution was evaporated to dryness and the residue was dissolved in benzene (20 ml) which was extracted with 5% hydrochloric acid (30 ml). The acidic solution was then made basic and the basic solution was then extracted with chloroform. Evaporation of the chloroform solution to dryness under reduced pressure gave a light yellow residue (1.85 g). Recrystallization of the residue from benzene heptane (1:1) solution gave the crystalline diol **7** (1.6 g), identical to the sample prepared earlier by another method (5). The mother liquor was purified by t.l.c. on silica to give more diols (**7**) (50 mg) and (**9**) (20 mg).

The Clemmenson reduction of α-Anisyl Pyrrole.

An amalgam was prepared by mixing zinc (100 g) and mercuric chloride (10 g) with hydrochloric acid (0.6 *N*, 130 ml). After stirring for 10 min, the aqueous solution was decanted and the amalgam was placed in a 2 l, 3-necked flask, equipped with an overhead stirrer, a reflux condenser, and a dropping funnel. Sea sand and hydrochloric acid (7 *N*, 175 ml) were added to the amalgam and the mixture was heated to a reflux. A solution of α-anisyl pyrrole (23 g) in ethanol (35 ml) was added very slowly over a period of 3 h. When one-third of the solution had been added, an additional amount of hydrochloric acid (7 *N*, 195 ml) was added to the reaction mixture. When the addition of α-anisyl pyrrole was completed, freshly prepared amalgam and hydrochloric acid were added (25 g amalgam, 40 ml acid) to the reaction mixture. Three further additions of the same amount of amalgam and hydrochloric acid were added at an interval of 1 h. After the last addition of amalgam, the solution was refluxed for 4 h. The reaction mixture was cooled and the residue was removed by filtration. The filtrate was extracted with ethyl acetate (7 × 500 ml) and the aqueous layer was discarded. The ethyl acetate was concentrated and the residue was dissolved in water (150 ml). Sodium hydroxide solution (40%) was added until the zinc hydroxide was redissolved. The strongly basic solution was then exhaustively extracted with ether and the ether solution, dried over magnesium sulfate, was removed under reduced pressure, giving an oily residue (23 g) which was purified by distillation. The fraction distilling out at 109–112 °C/0.5 mm Hg was collected (18.3 g). n_D^{25} = 1.5502; i.r: 3300, 1625, 1575, 1500 cm^{-1}; n.m.r: (τ) 3.17–3.60 (A_2B_2, 4 H's aromatic), 4.52 (m, 2 H's, olefinic), 6.15 (m, 1 H, —N—CH—), 6.50 (s, 3 H's, —OCH_3), 6.55 (t, 2 H's, —N—CH_2—), 7.50 (d, 2 H's, benzylic), 8.38 (s, 1 H, —NH—).

Anal. (as HCl salt) Calcd. for $C_{12}H_{16}ONCl$: C, 63.85; H, 7.14; N, 6.21; Cl, 15.71. Found: C, 64.08; H, 6.90; N, 6.25; Cl, 15.84.

Preparation of the Epoxide (13), Hydroxy Acetates (15), (16), and (17)

2-Anisyl 3-pyrroline (17.7 g) was added dropwise to ice-cooled acetic anhydride (47 g) with stirring. After stirring for 17 h, the acetic anhydride was evaporated under reduced pressure and the oily residue was distilled at 155 °C/0.5 mm Hg giving *N*-acetyl 2-anisyl 3-pyrroline (19.1 g).

A solution of *N*-acetyl 2-anisyl 3-pyrroline (10.7 g), concentrated H_2SO_4 (0.5 g), and glacial acetic acid (65 g) was warmed in an oil bath at 45 °C. To the solution was added H_2O_2 (90%, 7 g) in 3 equal portions at 1 h intervals. After 7 h, sodium bisulfite solution was added to the ice-cooled reaction mixture and the solution was then neutralized by sodium hydroxide solution. Exhaustive extraction of the solution with chloroform and evaporating the chloroform solution to dryness gave an oily residue (12.5 g). The residue was then refluxed in glacial acetic acid (100 ml) for 16 h to convert all epoxide **14** to the hydroxyacetates **15** and **16**. Evaporating the glacial acetic acid solution under reduced pressure gave a gummy residue. Careful chromatography of the residue on alumina gave the starting material *N*-acetyl 2-anisyl 3-pyrroline (1 g), the epoxide **13** (1.8 g), the hydroxyacetate **15** (negligible amount), the hydroxyacetate **16** (1 g), the hydroxyacetate **17** (3.3 g), and the diol **18** (2.3 g) which was shown to form by prolong contact of **13** with grade 1 alumina. The epoxide **13** showed i.r. absorption at 1645, 1620, 1505, 848 cm^{-1}; n.m.r. (τ) at 2.7–3.3 (A_2B_2, 4 H's aromatic), 6.25 (s, 3 H's —OCH_3), 8.06 and 8.13 (d, 3 H's, N—$COCH_3$).[4]

[4]All *N*-acetyl or *O*-acetyl groups in the intermediates showed hindered rotation. Temperature studies showed that the activation energies of free rotation calculated from the coalescence temperatures and the Eyring equation for the *N*-acetyl groups of all the intermediates are 18–22 kcal/mole (8).

The hydroxyacetate **16** m.p. 138–140 °C, showed i.r. absorption at 3580, 1735, 1640, and 1610 cm^{-1}; M^+/e; 307, 186, 144, 126, 121, and 84. The hydroxyacetate **17** m.p. 108–109 °C showed i.r. absorption at 3580, 1750, 1650, and 1615 cm^{-1}; M^+/e 307, 186, 144, 126, 121, and 84.

Anal. Calcd. for $C_{16}H_{21}O_5N$: C, 62.53; H, 6.89; N, 4.56. Found: C, 62.13; H, 6.85; N, 4.72.

The diol **18** m.p. 149–151 °C showed i.r. absorption at 3550, 3300, and 1630 cm^{-1}.

Anal. Calcd. for $C_{14}H_{19}O_4N$: C, 63.38; H, 7.22; N, 5.28. Found: C, 63.56; H, 7.11; N, 5.57.

Conversion of the Hydroxy Acetate (17) to the Epoxide (14)

To an ice-cooled chloroform solution (30 ml) containing the hydroxy acetate **17** (1.52 g) was added in portions (1.04 g) of phosphorus pentachloride. After stirring for 1 h at room temperature, the chloroform solution was evaporated to dryness under reduced pressure leaving an orange foam. Ethanol (8 ml) was added followed by alcoholic potassium hydroxide solution (15 ml, 20%). The solution was stirred for 1 h and then diluted with water (100 ml). The aqueous solution was extracted exhaustively with chloroform. Evaporating the chloroform solution to dryness, followed by purification of the residue by t.l.c. on silica gave the epoxide **14** (640 mg); i.r.: 1610, 1500, and 865 cm^{-1}, superimposable with that of the epoxide derived from natural anisomycin.

Preparation of Racemic Deacetyl Anisomycin (2)

The epoxide **14** (220 mg) was refluxed in glacial acetic acid for 12 h. Evaporating the acetic acid solution to dryness under reduced pressure gave an oily residue which was refluxed overnight under nitrogen in aqueous alcoholic sodium hydroxide solution (20 ml, 5 *N*). The solution was neutralized with hydrochloric acid and extracted continuously by chloroform. Evaporating the chloroform solution to dryness gave a foamy residue (100 mg). Separation of the residue by t.l.c. on silica gave the racemic diols **19** (20 mg) and **2** (25 mg). The diol **19** was identical in every respect with the hydrolysis product of **16**, **17**, and **18**. The racemic deacetyl anisomycin **2**, m.p. 170–172 °C showed a slight difference in the i.r. spectra (Nujol) compared with that of the natural deacetyl anisomycin. The racemic **2** was then converted into the corresponding hydrochloride by adding a few drops of concentrated hydrochloric acid into the methanolic solution containing the racemic base **2**. Evaporating the methanolic solution to dryness gave a solid residue which was recrystallized from methanolic ether solution, m.p. 220–222 °C. The i.r. spectrum was identical with that of deacetyl anisomycin hydrochloride.

Preparation of (+)-Anisomycin (22)

(+)-*N*-Benzyl deacetyl anisomycin was dissolved in acetic anhydride (10 ml) and the solution was stirred for 20 min. The acetic anhydride solution was evaporated to dryness under reduced pressure at 50 °C water bath. The residue was purified by t.l.c. on silica to give (+)-*N*-benzyl anisomycin (280 mg) (**21**)[5] which was then dissolved in ethanol (5 ml) containing concentrated hydrochloric acid (4 drops) and 5% Pd/C (50 mg). The solution was hydrogenated at atmospheric pressure and room temperature for 2 h. After filtering off the catalyst and evaporating the ethanol solution to dryness, the crystalline residue was recrystallized from methanol–ether to give the hydrochloride of (+)-anisomycin (**22**) (140 mg), m.p. 188–189 °C, $[\alpha]_D^{25} = -3.6°$ i.r. spectra (Nujol) was superimposable to that of natural anisomycin hydrochloride. From the mother liquor was isolated (+)-deacetyl anisomycin. Liberation of the free base by dilute sodium hydroxide solution gave (+)-anisomycin (70 mg) plus a small amount of deacetyl anisomycin. They were separated from each other by t.l.c. on silica. The (+)-anisomycin is identical in every respect to the natural anisomycin except an opposite sign of specific rotation and possibly no activity against protozoa (7).

Acknowledgments

The authors wish to express their gratitude to the National Research Council of Canada and Charles Pfizer & Co. Inc., for financial assistance and the supply of natural anisomycin.

Leaf coumarins of *Angelica archangelica*[1]

WARREN STECK AND B. K. BAILEY
Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan
Received February 4, 1969

Coumarin derivatives are abundant in leaves of *Angelica archangelica*, and differ in kind from those of the roots. Angelicin, bergapten, imperatorin, isopimpinellin, xanthotoxin, oxypeucedanin, and five unidentified coumarins were isolated from leaves. A time study of their development was carried out. Methods for the isolation of leaf neutral coumarins are described.

Introduction

Many plants of the family *Umbelliferae* are known to accumulate coumarin derivatives in their roots and seeds (1). The species *Angelica archangelica* L. has been particularly well studied in this respect. Späth and Pesta (2) found the main root coumarin to be osthol (**2** in Fig. 1), accounting for nearly 0.2% of the dry weight. Among the many other coumarins subsequently isolated from this source were osthenol and angelicin (**3**) (2); imperatorin (**8**), bergapten (**5**), umbelliprenin, xanthotoxol, and xanthotoxin (**6**) (3); oxypeucedanin (**9**), oreoselone, and archangelicin (4). The seeds contain a similarly complex array of coumarins (5).

The study of plant leaf coumarins has received less attention, and presents certain difficulties. The main problem is the separation of the ether-soluble neutral coumarins from the chlorophylls, waxes, and other constituents of similar solubility. Occasionally the appreciable solubility of neutral coumarins in hot water has been used to effect the separation directly (6), but more usually an alcohol extract has been made and treated with aqueous alkali for several hours to open the lactone ring and give coumarinate salts, other components then being removed by ether extraction. The coumarin derivatives can themselves be ether-extracted subsequent to their regeneration on acidification of the medium. Washing the final ether extract with carbonate leaves a lactone fraction. In the presence of chlorophyll, which is degraded to dark products by alkali, the isolation of such a lactone fraction is not usually clean-cut and may have to be done twice (7). A more serious objection to the use of alkali is the loss of ester linkages, which are not uncommon in *Angelica* coumarins. For example, ostruthol is transformed to oxypeucedanin.

We report in this paper a general method of leaf treatment which avoids entirely the use of alkali, yet affords a fraction from which neutral coumarins may be conveniently isolated and purified. We have used the technique with several umbellifers, but the case of *A. archangelica*, with its interesting biosynthetic implications, is alone described below.

Methods and Results

Fresh leaves were homogenized in boiling methanol and the hot filtrate adjusted to 60% aqueous methanol, then washed twice with Skelly B (*n*-hexane) to remove chlorophylls and other fatty materials. The Skelly B was back-extracted once with 60% methanol and this was added to the main alcoholic solution. This procedure was shown to retain more than 98% of the xanthotoxin and bergapten in the aqueous part while removing about 70–80% of the total weight of the original methanol extract. Concentration of the alcohol solution resulted in an aqueous suspension; this was extracted overnight with ether to remove the coumarins present.

The ether extract was chromatographed on silicic acid, eluting with 1:1 Skelly B:ether. This solvent mixture is slightly more polar than that used successfully for *Citrus* coumarins by Stanley and Vannier (8), and somewhat less solublizing than the system of Floss and Mothes (9), which was not entirely successful with *Pimpinella* coumarins. The fractions collected were allowed to evaporate overnight to allow deposition of crystalline material.

The first crystalline sample, long needles

[1]NRCC No. 10670.

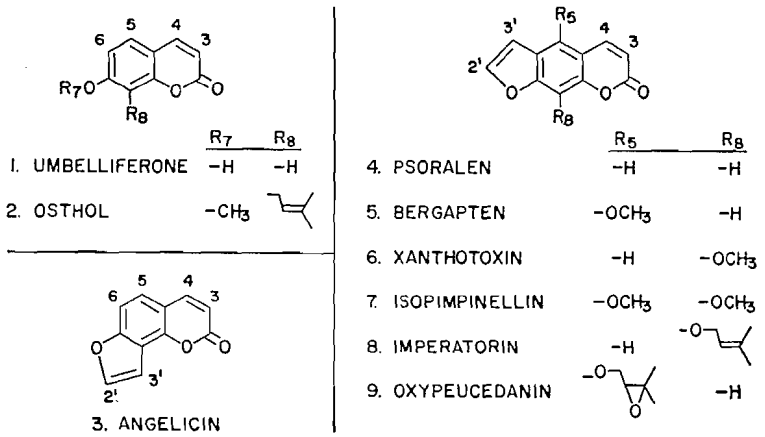

FIG. 1. Some coumarins mentioned in the text.

melting at 97.5–99.5°, was a lactone having an ultraviolet (u.v.) spectrum suggestive of a xanthotoxol derivative. The nuclear magnetic resonance (n.m.r.) spectrum indicated the presence of five aromatic protons: two were typical coumarin pyrone ring doublets ($J = 10$ c.p.s.); two others were typical furan ring doublets ($J = 2 \sim 2.5$ c.p.s.); the fifth was a singlet. All had very nearly the same chemical shifts as those of xanthotoxin. A dimethylallyl group was also evident. The material thus appeared to be imperatorin, lit. m.p. 102° (10). A mixed melting point with an authentic sample (m.p. 96–99°) was undepressed, and the u.v. and n.m.r. spectra of the standard were superimposable upon those of the isolated compounds. Chromatography on paper and examination of fluorescence properties confirmed the identity.

The second group of crystals, m.p. 188–190° with sublimation, also showed lactonic properties. A u.v. maximum near 306 mμ suggested a bergaptol or isobergaptol derivative. The n.m.r. spectrum showed the H_4 signal at $\delta > 8.0$, indicating substitution at the 5-position. The existence of 5 appropriate aromatic protons and a single aromatic methoxyl group suggested bergapten, lit. m.p. 188–189° with sublimation (11), as the identity of the material. A mixed melting point with authentic material was undepressed and direct comparison of u.v., n.m.r., fluorescence, and chromatographic data for isolated and authentic material showed no differences between the two.

The third crystalline deposit, a lactone melting at 144–145°, had the u.v. spectrum of a xanthotoxol derivative. The n.m.r. spectrum, indicating a monomethoxy furocoumarin, was identical with that of xanthotoxin (lit. m.p. 145–146° (12)), and an authentic sample of xanthotoxin had the same chromatographic and fluorescence properties. A mixed melting point was undepressed.

The fourth batch of crystals, melting at 147–149°, gave an absorption maximum at 311 mμ. A furocoumarin with two methoxy groups, one in the 5-position ($\delta > 8.0$ for H_4) was indicated by the n.m.r. spectrum. Since all the pyrone and furan ring protons appeared to be present in the spectrum, the only structures possible, assuming the usual 7-oxy-substitution, were pimpinellin (5,6-dimethoxyangelicin) and isopimpinellin (7), lit. m.p. 148–151° (13). A mixed melting point with an authentic sample of the latter was undepressed, and the u.v. and n.m.r. spectra of the isolated and authentic samples were identical. The fluorescence and chromatographic properties were also those of isopimpinellin. This coumarin, while known in other *Angelica* species, does not seem to have been reported previously in *A. archangelica.*

From the mother liquors of the bergapten fractions, another coumarin was isolated by gas–liquid chromatography (g.l.c.). Collection and recrystallization from alcohol gave crystals melting at 137–138°. Analysis by n.m.r. revealed six protons, all aromatic. The u.v. and n.m.r. spectra of angelicin (lit. m.p. 138–139.5° (2)) were identical with those of the isolated sample, and a mixed melting point showed no depression.

Co-chromatography confirmed the identification.

Leaves of plants from different seed sources gave differing amounts of the above coumarins. The plants examined in the work described here contained relatively large amounts of xanthotoxol derivatives, in contrast to another strain which afforded primarily bergaptol derivatives. Examination of this latter strain showed the presence of all the coumarins described above, and in addition demonstrated the presence of a lactone (m.p. 140–142°) eluting from silicic acid along with isopimpinellin. Its u.v. and n.m.r. spectra strongly suggested it to be racemic oxypeucedanin (lit. m.p. 142–143° (14)). The optically active (+)-isomer, which was available for comparison, gave identical u.v. and n.m.r. spectra.

Study of the non-crystalline fractions from silicic acid was carried out by g.l.c. In this way several other leaf coumarins were detected, but because of their scarcity, none was identified. These included three compounds U_1, U_2, and U_3 eluting with isopimpinellin and having identical xanthotoxol ether u.v. spectra; a compound U_4 eluting with bergapten and having a u.v. spectrum like osthol or herniarin but with chromatographic properties unlike those of any reference compound available; and a compound U_5 eluting just before bergapten in very small quantities, believed (on the basis of its chromatographic behavior) to be psoralen (**4**).

It might be noted here that g.l.c. analyses demonstrated the absence of other simple furocoumarins such as isobergapten (5-methoxyangelicin), sphondin (6-methoxyangelicin), pimpinellin (5,6-dimethoxyangelicin), and phellopterin (5-methoxy-8-dimethylallyloxypsoralen). Neither could osthol be detected, a point to be discussed further below.

Examination of the leaf water-solubles by acid hydrolysis and re-extraction with ether were carried out to test for the presence of furocoumarin glycosides, such as occur in some plants (e.g. ref. 15). No neutral coumarins were liberated by the hydrolysis, but umbelliferone (**1**) was found. It appeared to be present in unhydrolyzed extracts principally as the glucoside, skimmin.

Although osthol could be readily detected in root extracts, we were unable to find it in the leaves. This and the quantitative variation in coumarins from different seed strains prompted us to assay growing *A. archangelica* shoots and roots at various stages of development. This was done by direct g.l.c. of prepared coumarin-rich fractions, with estimation of the detected coumarins by comparison with standard area curves. The results for the seed strain whose component coumarins have just been described are shown in Figs. 2 and 3. The two outstanding features of these results are the selective accumulation of osthol in the roots and the early appearance of leaf coumarins. The data clearly show that the coumarins in the leaves undergo no great qualitative changes during the maturation of the

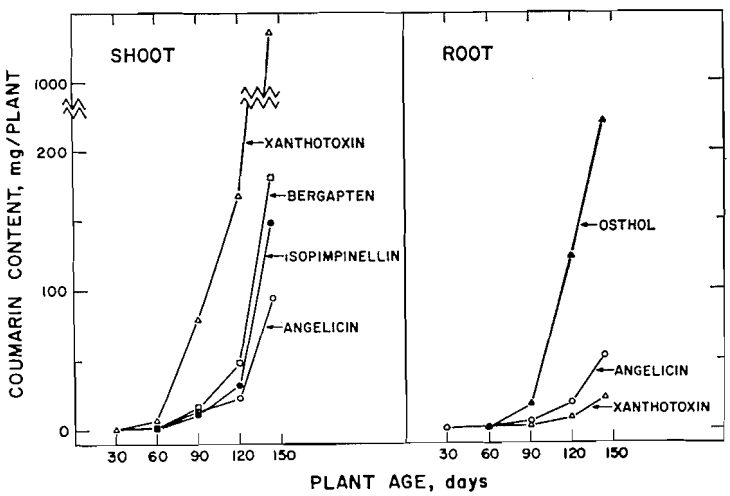

FIG. 2. Development of coumarins in *Angelica archangelica*; total content of some coumarins in shoots and roots.

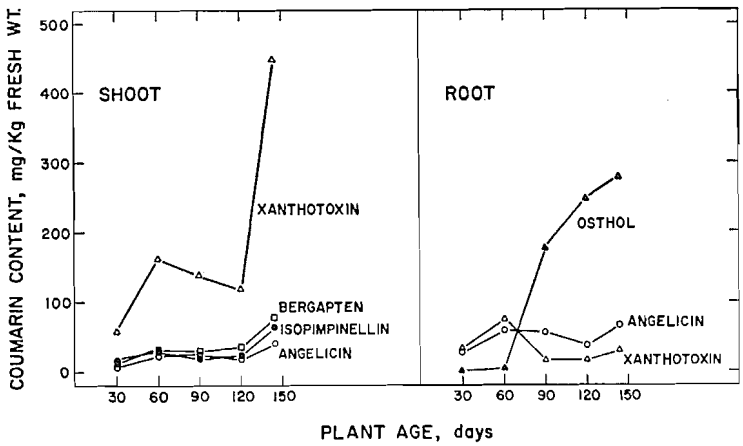

FIG. 3. Development of coumarins in *Angelica archangelica*; concentration of some coumarins in shoots and roots.

plant; they are apparently synthesized simultaneously and in more or less fixed ratios one to another. Moreover, their appearance ahead of, or coincident with the root coumarins suggests the leaves as an independent site of furocoumarin formation.

The situation in the roots is different. Here the main coumarins are angelicin and xanthotoxin in the first two months, but after this time the xanthotoxin concentration falls and osthol begins to accumulate, becoming, as reported in the literature, the main coumarin of the mature roots. How this accumulation comes about is impossible to say at this time, as the biosynthetic pathways leading to osthol and to the furocoumarins are not known with certainty. However, as osthol was not detected in the leaves, it seems probable that it is formed in the roots.

Experimental

A. archangelica was grown from seed in the greenhouse and the plants maintained hydroponically. A constant day length of 14 h was imposed.

Fresh leaves (1720 g, i.e. 300 g dry weight) of three month old plants, trimmed free of petioles and stems, were boiled and homogenized in 3 l methanol. The alcohol solution was adjusted to contain 60% methanol by concentration, then was washed with two 400 ml portions of Skelly B. This petroleum ether was backwashed with 60% methanol and the alcoholic solutions combined; methanol was removed from the orange solution and the aqueous residue continuously extracted overnight with ether. A small amount of white precipitate was filtered off before the extract was concentrated to the point of dryness.

A 4 × 35 cm column of silicic acid (Mallinckrodt, 100 mesh, used as received. Other brands gave less sharp separations.) was prepared by slurrying 200 g powder in about 1 l of 1:1 ether:Skelly B (60–80°), pouring this into the column, and allowing settling until the meniscus approached the top of the silicic acid. The ether extract, dissolved in about 50 ml of the same solvent mixture, was carefully poured upon the top of the column and washed in with a little extra solvent. Two hundred 15 ml fractions were collected and allowed to stand for a day or two to permit the ether to evaporate and thus bring about the slow crystallization of the chief coumarins. These were then filtered off, the appropriate fractions combined, and each crystalline substance recrystallized from ethanol.

Imperatorin

Fractions 41–47 deposited needles of imperatorin, m.p. 97.5–99.5°; λ_{max}(EtOH) 221, 248, 264 (shoulder), and 298 mμ. The n.m.r. spectrum (Varian HA-100, solvent deuterochloroform, internal standard tetramethylsilane) showed signals at δ = 6.32 (H_3) and 7.71 (H_4), both doublets having J = 10 c.p.s.; at 7.31 (H_5), 7.64 ($H_{2'}$), and 6.77 ($H_{3'}$), for a total of 5 aromatic protons. The assignments of aromatic signals here and below follow those of Sheinker *et al.* (16) and Batterham and Lamberton (17). The later work of Reisch *et al.* (18) has also been considered. Other signals, present at 4.97 (CH_2), 5.58 (unsaturated CH), and 1.74 (vinyl methyls), were typical for a 3,3-dimethylallyl substituent. Authentic imperatorin was identical in all respects. The yield was 170 mg; abundance = 0.57 mg/g dry leaves.

Bergapten

Fractions 54–62 gave bergapten, m.p. 188–190° with sublimation; λ_{max}(EtOH) 221, 247, 257, 266, and 306 mμ. The n.m.r. spectrum showed signals at δ = 6.25 (H_3) and 8.14 (H_4) (both doublets, J = 10 c.p.s.); at 7.12 (H_8), 7.59 ($H_{2'}$), and 7.02 ($H_{3'}$). A single aromatic methoxyl group was present at δ = 4.25. Authentic bergapten was identical in all respects. The yield was 46 mg; abundance = 0.15 mg/g.

Angelicin

The bergapten mother liquors were concentrated to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

small volume and a little more bergapten was filtered off. Gas–liquid chromatography of the remaining solution showed several components, the major one emerging, after about 5 min. This was collected and recrystallized to colorless needles, m.p. 137–138°; λ_{max}(EtOH) 218, 242 (shoulder), 248, and 297 mμ. The n.m.r. showed only 6 protons, all in the aromatic region, at δ = 6.36 (H_3), 7.78 (H_4), both J = 10 c.p.s.; 7.40 (H_5), 7.38 (H_6), 7.67 ($H_{2'}$), and 7.12 ($H_{3'}$). Authentic angelicin was identical in all respects. Estimated leaf content = 42 mg; abundance = 0.14 mg/g.

Xanthotoxin

Fractions 67–81 gave crystals of xanthotoxin, m.p. 144–145°; λ_{max}(EtOH) 221, 242 (shoulder), 247, 260 (shoulder), and 297 mμ. The n.m.r. signals were located at δ = 6.32 (H_3) and 7.72 (H_4), both doublets of J = 10 c.p.s.; at 7.31 (H_5), 7.65 ($H_{2'}$), 6.78 ($H_{3'}$), and 3.25 (aromatic OCH_3). Authentic xanthotoxin was identical in all respects. The yield was 260 mg; abundance = 0.87 mg/g.

Isopimpinellin

Fractions 82–88 contained isopimpinellin, deposited as very pale yellow needles, m.p. 147–149°. (In some plants the amount of xanthotoxin present was so large relative to isopimpinellin that the latter was best purified in small quantities by g.l.c.) λ_{max}(EtOH) 221, 240, 247, 266–270 (broad), and 311 mμ. The n.m.r. signals, located at δ = 6.25 (H_3) and 8.08 (H_4), both doublets of J = 10 c.p.s., and at 7.59 ($H_{2'}$) and 6.96 ($H_{3'}$), doublets of J = 2 c.p.s., showed the presence of unsubstituted pyrone and furan rings. Two aromatic methoxyl groups were indicated by a six-proton signal at δ = 4.14. Authentic isopimpinellin was identical in all respects to the isolated material. Estimated leaf content = 34 mg; abundance = 0.11 mg/g.

Oxypeucedanin

Fractions 80–90 from one strain of plants deposited this racemic compound as prisms, m.p. 140–142°. The u.v. spectrum, with λ_{max}(EtOH) 221, 247, 257, 266, and 305 mμ, indicated a bergapten-type nucleus. The n.m.r. signals were seen at δ = 6.24 (H_3) and 8.15 (H_4), doublets of J = 10 c.p.s.; 7.11 (H_8), 7.57 ($H_{2'}$), and 6.92 ($H_{3'}$) for a total of 5 aromatic protons. In addition there were multiplets centered at δ = 4.49 (CH_2) and 3.20 (saturated CH) and sharp three-proton singlets at 1.40 and 1.32 (aliphatic CH_3). Although no authentic racemic sample was available for comparison, (+)-oxypeucedanin gave the same spectra. Abundance in the strain = 0.46 mg/g.

Unidentified Coumarins

U_1, U_2, and U_3 from fractions 82–88 emerged from the gas chromatograph at retention times of 6.2, 6.6, and 8.0 (relative to angelicin = 1.0). All had u.v. maxima at 221, 242 (shoulder), 248, 261 (shoulder), and 298 mμ, suggesting xanthotoxol derivatives.

U_4 from fractions 54–62, relative retention time 3.9, had λ_{max}(EtOH) 218, 247, 256, and 320 mμ, indicating a coumarin without a furan ring. No available coumarin derivative co-chromatographed (e.g. osthol, relative retention time (r.r.t.) 2.6 and herniarin, r.r.t. 1.08).

U_5 from fractions 48–56 was not always present. Its retention times relative to angelicin under several conditions of g.l.c. exactly matched those of psoralen, (r.r.t. = 1.15 under stated g.l.c. conditions).

Development of Coumarins in the Plant

Plants of the same strain were taken 30, 60, 90, 120, and 144 days after germination and separated into weighed root and shoot portions. Both portions were worked-up as above, but the ether-soluble fractions were analyzed directly by g.l.c. The same conditions were used for these analyses as for those above: a 0.25 in. × 10 ft copper column, packed with 5% silicone (SE-30) on acid-washed Chromosorb W-DMCS support (70–80 mesh), was operated at 205°. Injector and detector temperatures were 252 and 264° respectively. A helium flow of 60 ml/min was employed. Imperatorin, most phenolic coumarins, and many complex neutral coumarins do not pass through the g.l.c. column under these conditions, but other simple neutral coumarins could be separated and quantitated in this way. Details of this method and its further applications will appear elsewhere.

Osthol

This coumarin was found at a retention time of 2.6 relative to angelicin in the gas chromatograph. It was collected and crystallized to m.p. 82–84° (lit. m.p. 84° (2)); λ_{max}(EtOH) 219, 247, 256, and 320 mμ indicated the absence of a furan ring. The n.m.r. spectrum showed doublets at δ = 6.19 (H_3), 7.59 (H_4), 7.28 (H_5), and 6.82 (H_6), altogether 4 aromatic protons. Other signals were present at δ = 3.52 (CH_2), 5.23 (unsaturated CH), 3.90 (aromatic OCH_3), 1.83, and 1.67 (vinyl methyls). Authentic osthol gave identical spectra. Finally, a mixed melting point of the sample with authentic osthol showed no depression.

Acknowledgments

The authors wish to thank Dr. B. A. Bohm for his generous gift of authentic isopimpinellin and imperatorin; Dr. G. Caporale for bergapten; Dr. J. M. Baskin for psoralen; and Dr. T. O. Soine for osthol. Thanks are also extended to Mr. M. Mazurek, who recorded the nuclear magnetic resonance spectra.

A synthesis in the series of aconitine and delphinine

K. WIESNER, WEN-LING KAO, AND J. ŠANTROCH
Natural Product Research Center, University of New Brunswick, Fredericton, New Brunswick

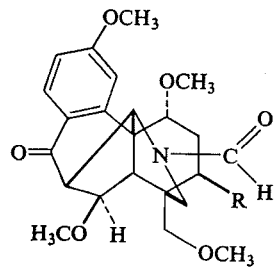
Received December 24, 1968

The synthesis of compound **3** is described. This synthesis represents the solution of most of the problems which will be encountered in the approach to the delphinine and aconitine aromatization products **1** and **2**. The synthetic compound **3** incorporates the complete skeleton and functionality of **1** and **2** except the substitution of ring A.

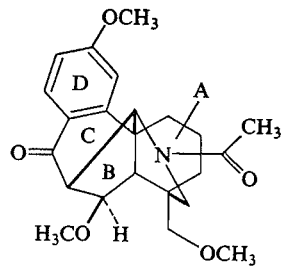
Canadian Journal of Chemistry, 47, 2431 (1969)

In 1959 we deduced the structures of the highly substituted and notorious aconite alkaloids delphinine (1*a*) and aconitine (1*b*).[1] In this structure determination aromatization products of the type **1** and **2** played a considerable role.[2] Our interest in these compounds is two-fold: (*a*) since they may be obtained in relatively good yields and only a few steps from delphinine and aconitine, the products **1** and **2** could serve as a relay in the total synthesis of complex poly-substituted aconite alkaloids; (*b*) the structure of the C/D ring system is one of the several features of aconitine and delphinine which follow with complete rigor from our chemical degradations (1*a*, 1*b*, 2, 3). Since the anisole ring of **1** and **2** has been generated from the C/D ring system of the parent alkaloids, while the remainder of the molecule remained completely intact, it is clear that a total synthesis of the aromatization products would represent a mathematically rigorous and simple structure proof for delphinine and aconitine, based on chemistry alone. This has not been accomplished in the past for too many natural products as complicated as the poly-substituted aconite alkaloids.

In view of our extensive and long standing interest in diterpene alkaloid chemistry we have decided to carry out the synthesis of **1** and **2** and thus to accomplish at least the second of the two objectives. The chief consideration in the total synthesis of the natural alkaloids themselves would then be the cost of such an undertaking. In the present communication we wish to describe the synthesis of compound **3** which represents the solution of most of the problems facing us in the synthesis of **1** and **2**. The synthesis of the fully



1 R = H
2 R = OH



3

SCHEME 1

substituted aromatization products and the correlation of "natural" and synthetic materials will be reported separately.

The synthetic strategy, which we developed in model experiments (4) involved the alkylation of the tetralone **4** with a long-chain iodide destined to form ring A, followed by an alkylation with allyl bromide (see Scheme 2). In the present synthesis it was consequently our first task to prepare the methoxy benzyloxy iodopentane **12** needed for the first alkylation step.

A convenient starting material was the γ-lactone **7** described by Leuchs *et al.* in 1912 (5). This lactone was hydrolyzed by aqueous alkali to the salt of the corresponding hydroxy acid and the hydrolysis mixture was treated with benzyl

[1]The latter was deduced jointly with Professor Büchi's group at the Massachusetts Institute of Technology.

chloride in benzene. The resulting acid **8** was esterified with methanolic hydrochloric acid and the ester **9** obtained in an overall yield of 80% was purified by distillation and characterized by its nuclear magnetic resonance (n.m.r.) spectrum, which showed quantitatively the presence of all three of its functional groups.[3]

The ester **9** was now reduced with lithium aluminium hydride to the alcohol **10**, this material was tosylated to **11**, and finally the iodide **12** was obtained by exchanging the tosyloxy group in **11** for iodine with sodium iodide in acetone. Compound **12** was an oil which was purified by chromatography and characterized by thin-layer chromatography (t.l.c.) and a quantitative evaluation of the n.m.r. spectrum. The overall yield of the conversion **8** → **12** was 72%.

With the side-chain **12** available, it was now possible to proceed with the necessary alkylations of the tetralone **4** (6). After unsuccessful preliminary attempts to introduce the allyl chain first and the methoxy benzyloxy pentyl chain in the second alkylation stage, we have turned our attention to the preparation of the compound **5**. This caused considerable difficulties, since the most obvious method, the Stork reaction, did not yield the desired product. Finally, we have been able to prepare **5** in a 50% yield by treating the tetralone **4** with 2 moles of the iodide **12** and 1 mole of sodium methoxide in methanol.

At this stage it should be pointed out that the seven intermediates of the synthesis between compounds **5** and **18**, inclusive, were mixtures of diastereoisomers resulting from the uncontrolled asymmetric centers marked by the asterisks. They were all purified by careful chromatography until they were apparently homogeneous on a thin-layer plate. Characterization was performed by a quantitative evaluation of the n.m.r. spectrum. This was considered very reliable since n.m.r. spectrography showed clearly the presence of all the functional groups, which were derived from all three components of the molecule (see Experimental). However, in spite of the confidence in this method, we were very relieved when we obtained the highly crystalline intermediates **21** and **22** which allowed not only spectral, but also a full classical characterization.

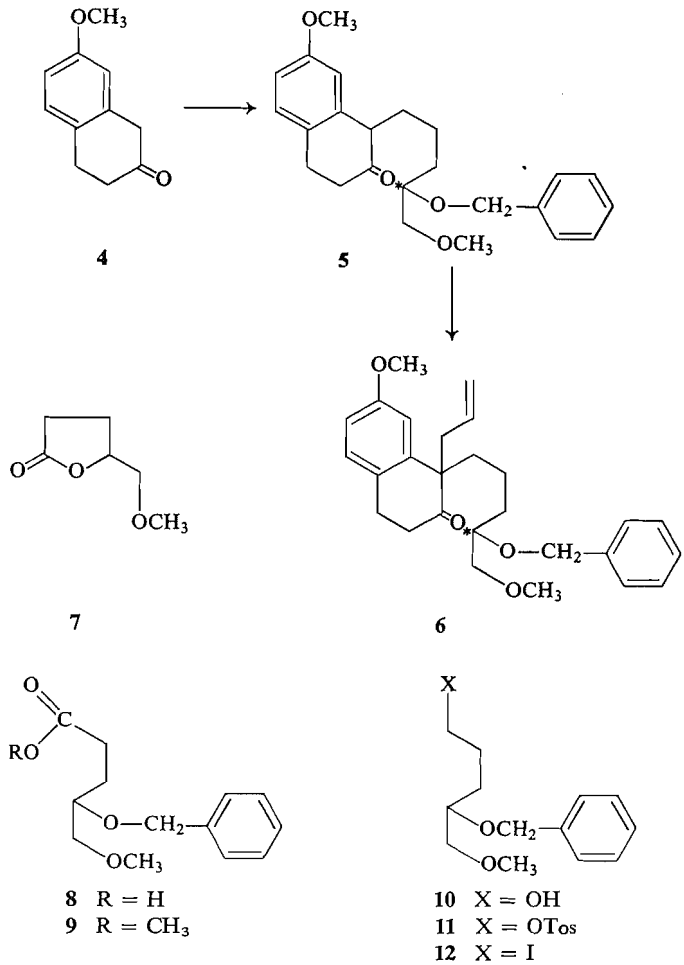
The introduction of the allyl group into the mono-substituted tetralone **5** was performed with allyl bromide and sodium hydride in dry benzene. The yield of the disubstituted tetralone **6** obtained in this manner was 90%. The next two steps, i.e. the hydroxylation of **6** to the diol **13** and the oxidation of this compound to the aldehyde **14** were accomplished in almost quantitative yield, and the products were found (by spectroscopy and t.l.c.) to be pure enough for further work. The hydroxylation was performed with a catalytic amount of osmic acid in the presence of an excess of sodium chlorate in aqueous tetrahydrofuran. The subsequent glycol cleavage was accomplished by metaperiodate in the same solvent.

The ring closure of the keto-aldehyde **14** to the tricyclic bridged hydroxy ketone **15** is a simple aldol condensation and is portrayed by the arrow in formula **14**. The reaction took place readily at 50 °C in aqueous methanolic sodium hydroxide in an 87% yield. The product was purified by chromatography in the form of its tetrahydropyranyl derivative **16**. The infrared (i.r.) spectrum of **16** showed a single sharp carbonyl band at 1755 cm^{-1} for the ketone in the apex of the 1,2,3-bicyclooctane system and no hydroxyl peak.

The next task which had to be accomplished was the conversion of the ketone in **16** to a primary amino group. The required configuration of this group was *anti* to the anisole ring. This was the first asymmetric center which had to be controlled, since all the others would be abolished in the further course of the synthesis. We have established already in our first model study (4) that reductive amination of the ketone with alcoholic ammonia and Raney nickel under high pressure yielded the most favorable proportion of the *anti* and *syn* isomers. In the present case this ratio turned out to be approximately 4:1 in favor of the desired *anti* isomer and the synthesis was thus almost stereospecific. Nevertheless, the two nitrogen epimers were separated only at a later stage, when all the remaining asymmetric centers disappeared.

The mixture of diastereoisomeric amino alcohols **17** which was obtained by the amination of compound **16** (yield 80%) was converted into the acetates **18** and this material was subjected to mild alkaline hydrolysis, hydrogenolysis with palladium on charcoal (to liberate the acetylated and benzylated alcoholic functions), and Jones' oxidation. All these processes gave good yields and the oxidation has reduced the number of

[3]Spectral data are discussed in the Theoretical section only in specially relevant cases. For spectral data of all compounds see the Experimental.



SCHEME 2

diastereoisomers to only two, i.e. the products **19** and **20**. These two epimeric acetylamino diketones were finally separated by careful chromatography on a column of silica gel. The ratio of **19** to **20** obtained in this manner was 4:1 and the required compound **19** crystallized as a waxy low-melting solid, which could not be recrystallized from a solvent.

The i.r. spectrum of **19** showed ketonic maxima at 1750 and 1725 cm^{-1} (five-membered and side-chain ketones), an amide carbonyl group at 1675 cm^{-1}, and the NH of the secondary amide group at 3500 cm^{-1}.

The n.m.r. spectrum of **19** displayed two methoxyl singlets (3H each) at τ = 6.54 and 6.12 p.p.m., the methylenic group unshielded by the primary methoxyl as a singlet (2H) at τ = 5.93 p.p.m., the acetyl methyl group as a singlet (3H) at τ = 7.93 p.p.m., and the hydrogen unshielded by the acetylamino group as a doublet (1H) at τ = 5.28 and 5.43 p.p.m.

The spectral data of compound **20** were similar except that the hydrogen unshielded by the acetylamino group appeared in the n.m.r. spectrum of **20** as a multiplet centered at τ = 5.25 p.p.m.

One can see readily that the n.m.r. peak of the hydrogen unshielded by the acetylamino group is a significant indicator of the configuration at this center. Nevertheless we have not attempted to assign the configurations by a fundamental analysis of the n.m.r. spectra.

Since we have prepared previously configurationally defined model compounds (4) we knew empirically that the doublet displayed by compound **19** corresponded to the desired *anti* configuration of the acetylamino group. A rigorous

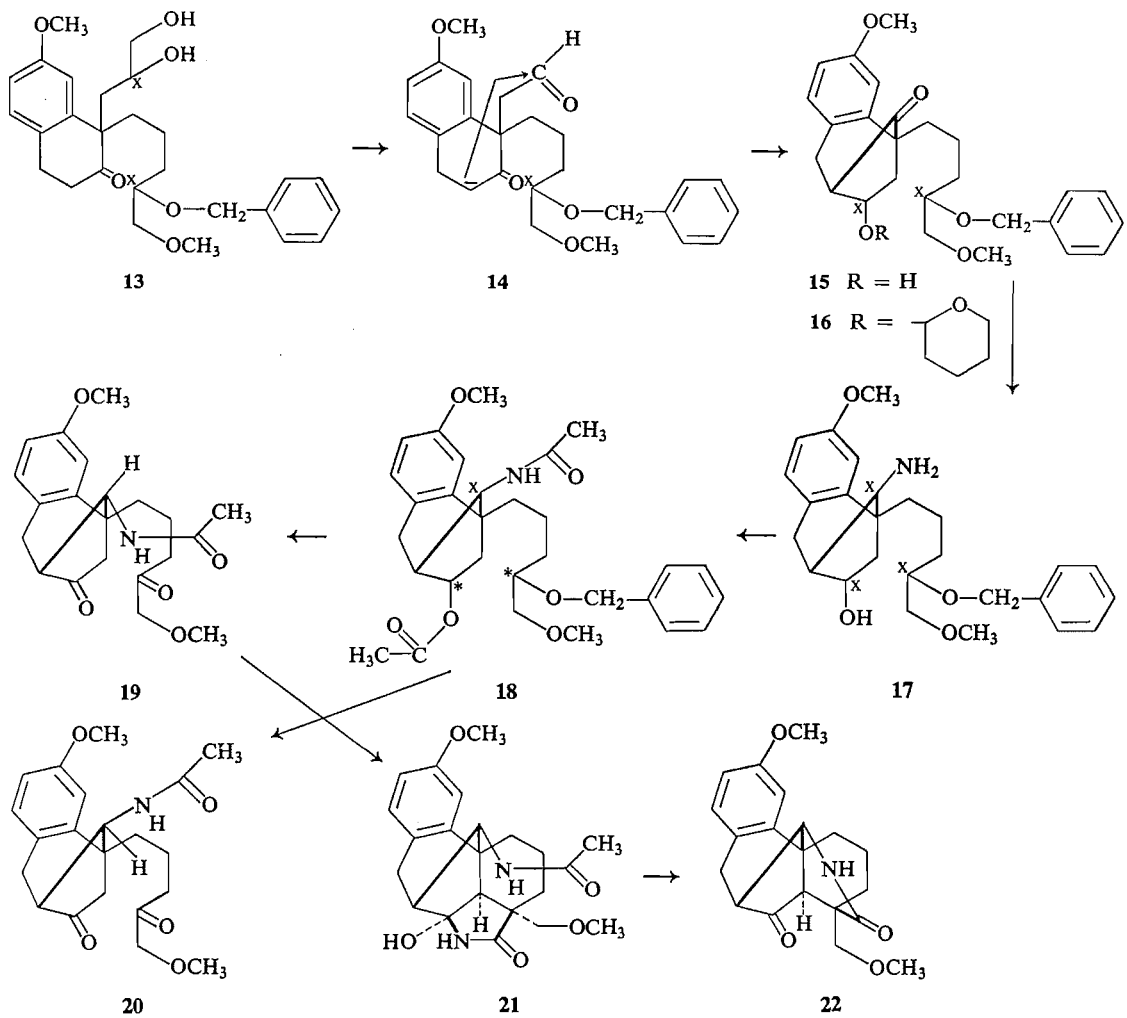

SCHEME 3

chemical corroboration of this preliminary configurational assignment followed subsequently from the conversion of compound **19** to the pentacyclic lactam **22**.

With the configurationally pure acetylamino diketone **19** in hand, the stage was set for the construction of ring A and the nitrogen ring. It was our intention to close ring A by an aldol condensation of diketone **19** and to complete the assembly of the entire carbon system by adding hydrogen cyanide across the double bond of the resulting α,β-unsaturated ketone.

We were not certain that this hydrocyanation reaction would yield a product possessing the required configuration with the nitrile and acetylamino groups *syn*. However, it would probably be simple to settle this point experimentally by ring formation between these two functional groups. As it turned out, the best method to perform the aldol condensation and hydrocyanation reactions was to combine them into one step. Prolonged reflux of the diketone **19** with a moderate excess of alcoholic potassium cyanide gave the highly crystalline sharply-melting lactamol **21** in an 80% yield. Clearly a hydrolysis of the nitrile group to a primary amide and interaction of this function with the five-membered ring B ketone followed the hydrocyanation. The analytical and spectral investigation of compound **21** (see Experimental) supported unambiguously

For personal use only.

the structure assigned to it. On the other hand, the configuration of the lactamol which is portrayed in the formula **21** followed only from the success of the subsequent step, i.e. **21** → **22**.

This crucial process, which gave us the final proof for the configurations of the intermediates **19** and **21** and at the same time completed the construction of the desired skeleton, was brought about in a yield of 80% by refluxing the lactamol **21** with a mixture of methanol and concentrated hydrochloric acid.

The keto lactam **22** was a beautifully crystalline substance, which gave a correct elemental analysis and a strong molecular ion in mass spectroscopy. Its i.r. and n.m.r. spectra left no doubt about the correctness of the structural assignment. The i.r. spectrum in chloroform showed the five-membered ketonic carbonyl at 1750 cm^{-1}, the lactam carbonyl at 1665 cm^{-1}, and the lactam NH at 3400 cm^{-1}. The n.m.r. spectrum displayed two methoxyls as singlets (3H each) at τ = 6.67 and 6.22 p.p.m., the methylenic group unshielded by the primary methoxyl as a singlet (2H) at τ = 6.55 p.p.m. and aromatic hydrogen (3H) at τ = 3.08–3.21 p.p.m.

The synthesis of compound **22** was reported in a preliminary communication (7) by two of the present authors (K.W. and J.Š.). It was subsequently repeated on a larger scale (by W.K.) and the individual steps were not only corroborated, but the overall yield was increased by a factor of 3.

The stage was consequently set for the final adjustment of the functional groups. To this end it was necessary to change the ketone of compound **22** into an *exo*-methoxyl and to introduce a new keto group into conjugation with the anisole ring.

The reduction of the keto group in compound **22** caused considerable difficulties and about 500 mg of substance were consumed in attempts to find a stereospecific method. Finally the keto lactam **22** was reduced with lithium aluminium hydride, the product was acetylated, and the *O*-acetyl group saponified by mild reflux with methanolic alkali. All three steps proceeded in good yields (about 90%) and gave a mixture of the *N*-acetyl alcohols **23** and **24** (ratio about 5:4). These two epimers were readily separated by chromatography and subjected (separately) to methylation with dimethyl sulfate and sodium hydride in dry dioxane. The desired *exo*-methoxy compound **25** obtained by methylation of **23** crystallized nicely from ether and showed,

besides a correct molecular ion in mass spectroscopy, i.r. and n.m.r. spectral properties in agreement with expectations; n.m.r.: singlet (3H) τ = 6.27 p.p.m. (aromatic —OCH_3), singlet (6H) τ = 6.75 p.p.m. (two aliphatic —OCH_3), singlet (3H) τ = 7.98 p.p.m. (acetyl —CH_3), multiplet (3H) centered at τ = 3.20 p.p.m. (aromatic hydrogen); i.r.: no —OH or NH band, amide carbonyl at 1651 cm^{-1}.

The *endo*-methoxy compound **26** remained amorphous even when it was completely pure (t.l.c.). Its mass spectrum was identical with the mass spectrum of **25**, which is good evidence for the epimeric relationship of the two products. The i.r. spectra of **25** and **26** showed small but distinct differences only in the finger-print region. However, the n.m.r. spectrum of **26** displayed a major difference with respect to the spectrum of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

25 and this enabled us to assign to the two products the configurations portrayed in the formulae. The secondary methoxyl singlet which in the n.m.r. spectrum of **25** coincides with the primary methoxyl at $\tau = 6.75$ p.p.m. is shifted in the n.m.r. spectrum of **26** strongly up-field to $\tau = 6.93$ p.p.m. The aromatic and primary methoxyl signals of **25** and **26** are at almost identical τ values and also the remaining peaks in both spectra are very similar. On inspection of the models of compounds **25** and **26** the reason for this n.m.r. behavior becomes clear. The secondary methoxyl of **26** is located in the shielding region of the anisole ring and thus its n.m.r. peak is shifted up-field.[4]

The last operation which faced us in the synthesis was the introduction of a new carbonyl group into conjugation with the anisole ring. No difficulties were encountered in this task, which was accomplished in a yield of 77% by Jones' oxidation. In this way the two compounds **25** and **26** were converted to the final products **3** and **27**, respectively.

This time the *endo*-methoxy product **27** was crystalline and the desired *exo*-methoxy derivative **3** remained amorphous, although it was completely homogeneous on t.l.c. in several systems. Both products gave not only correct molecular ion peaks in mass spectroscopy, but the entire mass spectra were practically identical. The i.r. spectrum of **3** showed no peak in the OH—NH region and three peaks in the carbonyl region at 1680, 1642, and 1600 cm^{-1}. The i.r. spectrum of **27** was practically the same and showed only small differences in the finger-print region. The ultraviolet (u.v.) spectra of **3** and **27** were identical and superimposable on the spectrum of the "natural" aromatization products **1** and **2** [$\lambda_{max} = 278$ mμ ($\log \varepsilon = 4.12$), $\lambda_{max} = 230$ mμ ($\log \varepsilon = 4.09$)].

Our final compound **3** contains the complete functionality of the aromatization products **1** and **2** except the substitution of ring A. In order to synthesize by the same method the "natural" compound **1** itself, it is clearly necessary to prepare an analogue of the intermediate **19** with an additional methoxyl suitably placed in the side-chain. This task is very laborious, but it has now been accomplished on a small scale by two routes.[5] It will be reported in due course.

[4]In this connection it might be mentioned that the "natural" aromatization products of aconitine (2) display methoxyl signals exactly like the epimer **25** and unlike **26**. However, we do not wish to use this as a corroboration of our assignment, which is quite unambiguous in its own right, since one of the purposes of the present work is a rigorous synthetic structure proof for aconitine.

Addendum

While this paper was being refereed and a high resolution mass spectrum of the final product obtained at the suggestion of the referee, we finally succeeded in securing a sufficient supply of pure aconitine to prepare the aromatization product **2** and convert it into the optically active forms of **25** and **3**. These "natural" compounds were shown to be identical with the corresponding synthetic racemates by t.l.c. (in six different systems using two adsorbents), i.r., n.m.r., and mass spectroscopy. This work completes a rigorous purely chemical structure proof for aconitine and delphinine, and also proves the configuration of the ring B methoxyl in these alkaloids. The entire structural argument will be reviewed in a future publication.

Experimental

Preparation of the Methoxy Benzyloxy Methyl Ester **9**

The lactone **7** (5) (13 g) was added to a mixture of dioxane (35 ml) and sodium hydroxide (20 g). The resulting suspension was stirred for 1 h at 80°. After this time the suspension was diluted with dry benzene (100 ml) and benzyl chloride (40 ml) was added dropwise over a period of 10 h. In the course of this addition the temperature was maintained at 80° and rapid stirring was continued. The acid **8** was isolated from the reaction mixture in the usual manner. The yield was 21 g (88%) and it was converted to the ester **9** without further purification. The acid **8** (23.8 g) was dissolved in absolute methanol (100 ml) and the solution was cooled to −15°. Gaseous hydrogen chloride was introduced for 30 min and the solution was allowed to stand overnight at room temperature. The solution was then neutralized with sodium bicarbonate, the methanol evaporated *in vacuo*, and the residue dissolved in ether. The ether solution was washed with water, dried, and the ether distilled off. The residue was fractionated *in vacuo*. The fraction boiling at 115–120° (0.2 mm Hg) was the pure ester **9** homogeneous in t.l.c. and g.l.c. The yield was 22.8 g (90%). Infrared spectrum: no OH band; 1740 cm^{-1} (ester carbonyl). Nuclear magnetic resonance spectrum: singlet (5H) $\tau = 2.75$ p.p.m. (aromatic hydrogen); singlet (2H) $\tau = 5.40$ p.p.m. (benzylic hydrogen); two singlets (3H each) $\tau = 6.35$ and 6.60 p.p.m. (2 —OCH_3). Mass spectrum: strong peaks at *m/e* 207 ($CH_3O_2C(CH_2)_2CHOCH_2C_6H_5$); 45 ($CH_2$-

OCH_3); 59 (CO_2CH_3); 91 ($CH_2C_6H_5$); 115 (CH_3CO_2-$(CH_2)_2CO$).

Preparation of the Methoxy Benzyloxy Iodopentane **12**

The ester **9** (25.2 g) was heated under reflux in dry ether (250 ml) with lithium aluminium hydride (3.7 g). Work-up in the usual manner gave the alcohol **10** (22.5 g) as a colorless oil in a quantitative yield. It was pure in t.l.c. and was immediately used for further work. Infrared spectrum: 3480 cm^{-1} (hydroxyl); no carbonyl peak. Nuclear magnetic resonance spectrum: singlet (5H) τ = 2.67 p.p.m. (aromatic hydrogen); singlet (2H) τ = 5.46 p.p.m. (benzylic hydrogen); singlet (3H) τ = 6.60 p.p.m. (—OCH_3).

The alcohol **10** (22.4 g) was dissolved in dry pyridine (40 ml) and cooled to −15°. Tosyl chloride (20 g) was gradually added under vigorous stirring and cooling. After the addition was completed the stirring was continued at 0° for 1 h. After this period, water (250 ml) and crushed ice were added and the oily suspension was extracted with ether. The ether solution was washed with dilute hydrochloric acid, aqueous bicarbonate and water, dried, and evaporated to dryness. The yield was 34 g (90%) of the crude tosylate **11**. This material (37.9 g) was dissolved in dry acetone, the solution was cooled to 0° and sodium iodide (75 g) was added to it. The mixture was stirred for 12 h after which time the acetone was distilled off *in vacuo* and water (300 ml) and crushed ice were added. The aqueous mixture was extracted with ether and the combined ether extracts were washed with a 10% thiosulfate solution and with water. After drying and evaporation to dryness the crude oily product was chromatographed on silica gel. Ether in benzene (5%) eluted the iodo compound **12**. It was homogeneous in t.l.c. and was obtained in a yield of 80% (26.8 g).

Mol. Wt. Calcd. for $C_{13}H_{19}O_2I$: 334. Found (mass spectrometry): 334.

Infrared spectrum: no OH and carbonyl band. Nuclear magnetic resonance spectrum: singlet (5H) τ = 2.61 p.p.m. (aromatic hydrogen); singlet (2H) τ = 5.37 p.p.m. (benzylic hydrogen); singlet (3H) τ = 6.52 p.p.m. (—OCH_3); multiplet (4H) centered at τ = 8.34 p.p.m. (C—CH_2—CH_2—C).

Preparation of the Monoalkylated Tetralone **5**

The methoxy tetralone **4** (6) (35.2 g) was added to a solution of sodium (4.6 g) in absolute methanol (1000 ml) under nitrogen. The solution was stirred for 1 h after which time the iodide **12** (120 g) was added and the stirring was continued at 25° for 48 h. The methanol was evaporated and water (500 ml) was added to the residue. The aqueous phase was extracted with ether (5 × 200 ml) and 2% aqueous sodium hydroxide (50 ml) was added to the combined ether extracts. Air was vigorously bubbled through both phases for a short time, after which the aqueous alkaline phase was separated and discarded. This operation destroyed the remaining starting material **4** while leaving the product **5** unaffected. The ether layer was now dried, evaporated to dryness, and the residue chromatographed on silica gel (3.2 kg). The product **5** was eluted with benzene–ether (10:1) as a colorless oil. The yield was 39 g (51%) and the product was apparently homogeneous in t.l.c. Infrared spectrum: no OH band; 1710 cm^{-1} (ketone). Nuclear magnetic resonance spectrum: singlet (5H) τ = 2.72 p.p.m. (aromatic hydrogen of the benzyl group); multiplet (3H) τ = 2.97–3.38 p.p.m. (aromatic hydrogen of the anisole ring); singlet (2H) τ = 5.48 p.p.m. (benzylic hydrogen); singlets (3H each) τ = 6.25 and 6.66 p.p.m. (2 —OCH_3).

Preparation of the Dialkylated Tetralone **6**

Compound **5** (38.2 g) was added to dry benzene (250 ml) containing a 50% emulsion (3.1 g) of sodium hydride in mineral oil. The mixture was stirred at room temperature for 1 h, after which time it was cooled in an ice bath and allyl bromide (24.2 g) was added over a period of 30 min. The temperature was then gradually raised to 45° and the stirring was continued for 24 h. After cooling, the reaction mixture was washed with water, dried, evaporated to dryness, and the residue was chromatographed on silica gel (2 kg). The product **6** was eluted with benzene–ether (20:1). It was a colorless oil homogeneous in t.l.c. and was obtained in a yield of 90%. Infrared spectrum: no OH band; 1720 cm^{-1} (ketone); 928 cm^{-1} (C=CH_2). Nuclear magnetic resonance spectrum: singlet (5H) τ = 2.77 p.p.m. (aromatic hydrogen of the benzyl group); multiplet (3H) τ = 3.02–3.22 p.p.m. (aromatic hydrogen of the anisole ring); multiplet (3H) centered around τ = 5.06 p.p.m. (vinylic hydrogen); singlet (2H) τ = 5.53 p.p.m. (benzylic hydrogen); two singlets (3H each) τ = 6.23 and 6.68 p.p.m. (2 —OCH_3).

Preparation of the Aldehyde **14**

The disubstituted tetralone **6** (21 g) was dissolved in tetrahydrofuran (100 ml) and a solution of osmium tetroxide (0.06 g) in tetrahydrofuran (6 ml) was added. The mixture was stirred for 10 min at room temperature, after which time sodium chlorate (6 g) in water (25 ml) was added. The stirring was continued at room temperature for 48 h. After this period most of the tetrahydrofuran was distilled off *in vacuo*, water was added, and the aqueous layer was exhaustively extracted with ether. After drying and evaporation to dryness the ether extract gave a quantitative yield (22.8 g) of a compound which was apparently homogeneous in t.l.c. and showed a strong hydroxyl band in the i.r. spectrum. It was converted to the aldehyde **14** without purification. To this end the above material (22.8 g) was dissolved in aqueous tetrahydrofuran (1:1, 400 ml) and sodium metaperiodate (81.1 g) was added to the solution. The mixture was vigorously stirred under nitrogen for 5 h at room temperature. During this time a heavy precipitate was formed. It was filtered off and washed thoroughly with ether. The ether was in turn washed with water, dried, and evaporated to dryness. The residue was the practically pure (t.l.c.) aldehyde **14** (21.2 g) obtained in quantitative yield. It was purified by chromatography on silica gel and stored under nitrogen. Infrared spectrum: no OH band, 2710 cm^{-1} (aldehyde); 1730 and 1725 cm^{-1} (aldehyde and ketone carbonyls); no vinyl group around 900 cm^{-1}. Nuclear magnetic resonance spectrum: narrow multiplet (1H) τ = 0.61 p.p.m. (aldehyde hydrogen); singlet (5H) τ = 2.73 p.p.m. (aromatic hydrogen of the benzyl group); multiplet (3H) τ = 3.26–3.38 p.p.m. (aromatic hydrogen of the anisole ring); singlet (2H) τ = 5.50 p.p.m. (benzylic hydrogen); two singlets (3H each) τ = 6.24 and 6.70 p.p.m. (2 —OCH_3).

Preparation of the Tetrahydropyranyl Ketone **16**

The keto aldehyde **14** (21.2 g) was dissolved in methanol (700 ml) and sodium hydroxide (2 g) in water (30 ml) was added under vigorous stirring. The stirring was continued under nitrogen at 50–55° for 24 h. After this time the methanol was partly evaporated *in vacuo*, ice water (150 ml) was added, and the solution was extracted with ether. After washing and drying the ether extract was evaporated to dryness. The yield was 18.15 g (86.5%) of the crude hydroxy ketone **15**. For purification it was converted into the tetrahydropyranyl derivative **16**. Infrared spectrum of crude **15**: 3500 cm^{-1} (OH); 1755 cm^{-1} (five-membered ketone). The crude hydroxy ketone **15** (21.2 g) was dissolved in dry chloroform (250 ml) and dihydropyran (22 g) was added to the solution. After the addition of two drops of concentrated hydrochloric acid the solution was allowed to stand for 24 h at room temperature. The chloroform was then washed with a dilute sodium bicarbonate solution and water, dried, and evaporated to dryness. The residue was chromatographed on neutral alumina (1.1 kg). Petroleum ether – dry chloroform (1:1) eluted 18.2 g (72%) of the t.l.c. homogeneous compound **16**. Infrared spectrum: no OH band; 1755 cm^{-1} (five-membered ketone). Nuclear magnetic resonance spectrum: singlet (5H) τ = 2.70 p.p.m. (aromatic hydrogen of the benzyl group); multiplet (3H) τ = 3.26–3.38 p.p.m. (aromatic hydrogen of the anisole ring); singlet (2H) τ = 5.34 p.p.m. (benzylic hydrogen); multiplet (13H) between singlets at τ = 6.24 and 6.58 p.p.m. (hydrogens unshielded by oxygen plus the two methoxyls).

Preparation of the N,O-Diacetyl Derivative **18**

The tetrahydropyranyl ketone **16** (18 g) was dissolved in methanol (60 ml) and the solution was saturated with ammonia. The solution was then hydrogenated at 2500 p.s.i. for 8 h in the presence of Raney nickel (4 g) at 165°. The catalyst was filtered off and the filtrate was evaporated to dryness. The basic fraction was separated in the usual manner and yielded 12 g of crude compound **17**. This material was dissolved in methylene dichloride (100 ml) and triethylamine (25 g) was added to the solution. The solution was then cooled in an ice bath and acetyl chloride (12.5 g) was added dropwise with vigorous stirring. The stirring was continued at room temperature for 24 h. After this time the mixture was diluted with chloroform, washed with dilute hydrochloric acid, aqueous sodium bicarbonate and water, dried, and evaporated to dryness. The residue was chromatographed on silica gel (600 g). The diacetyl compound **18** was eluted with ether–methanol (10:1) as an oil (11 g), apparently homogeneous in t.l.c. Infrared spectrum: 3450 cm^{-1} (NH); 1730 cm^{-1} (O—CO—CH_3); 1670 cm^{-1} (N—CO—CH_3). Nuclear magnetic resonance spectrum: singlet (5H) τ = 2.78 p.p.m. (aromatic hydrogen of the benzyl group); multiplet (3H) τ = 3.10–3.36 p.p.m. (aromatic hydrogen of the anisole ring); singlet (2H) τ = 5.48 p.p.m. (benzylic hydrogen); two singlets (3H each) τ = 6.30 and 6.66 p.p.m. (2 —OCH_3); two singlets (3H each) τ = 7.97 and 8.15 p.p.m. (2 —C(=O)—CH_3).

Preparation of the Acetylamino Diketone **19**

Compound **18** (10 g) was dissolved in methanol (200 ml) and 10% aqueous sodium hydroxide (40 ml) was added. The solution was refluxed for 1 h after which time the methanol was evaporated *in vacuo*, water (200 ml) was added, and the product extracted with chloroform. The chloroform extracts were washed with dilute hydrochloric acid, aqueous bicarbonate and water, dried, and evaporated to dryness. The residue (6.5 g) was practically homogeneous in t.l.c. and showed no acetoxy band in the i.r. spectrum. It was dissolved in ethanol (200 ml) and acetic acid (2 ml) was added. The solution was hydrogenated for 24 h at atmospheric pressure with 10% palladium on charcoal (2 g). The hydrogenation mixture was worked up as usual and gave after chromatography on silica gel (200 g, eluant chloroform–methanol 10:1) an oily product (4 g) which showed the absence of both the acetoxy and the benzyl group in the i.r. and the n.m.r. spectrum. This material was dissolved in acetone (250 ml) and the solution was cooled in an ice-bath to 5°. Jones' reagent was then added dropwise with stirring until the solution became orange. Stirring was continued for 20 min after which period the reaction mixture was neutralized with a saturated solution of sodium bicarbonate in water. The precipitate which had formed was filtered off and the filtrate was evaporated to dryness. The residue was suspended in water (50 ml) and extracted with chloroform (6 × 50 ml). The chloroform extract was dried, evaporated to dryness, and the residue was chromatographed on silica gel (400 g). Chloroform–methanol (25:1) eluted the pure epimer **19** as an oil which gradually crystallized to a low melting solid and was homogeneous in several t.l.c. systems. The yield was 2 g (50%).

Mol. Wt. Calcd. for $C_{21}H_{27}NO_5$: 373. Found (mass spectrometry): 373.

For the i.r. and n.m.r. spectra, see the Theoretical section.

Preparation of the Lactamol **21**

The diketone **19** (1.015 g) was dissolved in ethanol (50 ml) and a solution of potassium cyanide (0.54 g) in water (4 ml) was added. The mixture was heated under reflux for 18 h. The solvent was evaporated *in vacuo*, the residue was taken up in water (40 ml), and extracted with chloroform (6 × 50 ml). The chloroform extract was washed with dilute hydrochloric acid and water, dried, and evaporated to dryness. The crude product was chromatographed on silica gel (40 g). Chloroform–methanol (100:3) eluted the pure crystalline lactamol **21**. It was recrystallized from methanol to a melting point of 236–238°. The yield was 0.86 g (80%).

Anal. Calcd. for $C_{22}H_{28}N_2O_5$: C, 66.00; H, 7.00; N, 7.00. Found: C, 65.89; H, 6.69; N, 6.96.

Infrared spectrum (KBr pellet): 1670 and 1715 cm^{-1} (*N*-acetyl and five-membered lactam). Nuclear magnetic resonance spectrum: singlets (3H each) τ = 6.20 and 6.70 p.p.m. (2 —OCH_3); singlet (2H) τ = 6.54 p.p.m. (CH_2 unshielded by primary methoxyl); singlet (3H) τ = 8.10 p.p.m. (—C(=O)—CH_3). Mass spectrum: strong peak at *m/e* 382 (M—H_2O).

Preparation of the Keto Lactam **22**

The crystalline lactamol **21** (1.2 g) was heated under reflux with a mixture of methanol (30 ml) and concen-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

trated hydrochloric acid (70 ml) for 24 h. After this time the solution was evaporated to dryness *in vacuo*. The residue was dissolved in chloroform and filtered through a column of neutral alumina (50 g). Evaporation of the filtrate yielded the pure crystalline keto lactam **22**. It was recrystallized from methanol and melted at 185–186°. The yield was 820 mg (80%).

Anal. Calcd. for $C_{20}H_{23}NO_4$ (mol. wt. 341): C, 70.50; H, 6.75; N, 4.12. Found (mol. wt. by mass spectrometry, 341): C, 70.49; H, 6.74; N, 4.36.

For i.r. and n.m.r. spectra, see the Theoretical section.

*Preparation of the Epimers **25** and **26***

The keto lactam **22** (400 mg) was dissolved in dry dioxane (20 ml) and heated under reflux for 24 h with an excess of lithium aluminium hydride (800 mg). After work-up in the usual manner 314 mg (85%) of reduced material were obtained. It was dissolved in dry pyridine (6 ml), acetic anhydride (5 ml) was added, and the mixture was allowed to stand overnight at room temperature. Work-up in the usual manner yielded 373 mg (92%) of the *N,O*-diacetate. This material was dissolved in methanol (6 ml) and a 10% aqueous potassium hydroxide solution (5 ml) was added to it. The reaction mixture was stirred overnight at room temperature. After this time the methanol was evaporated *in vacuo*, water (25 ml) was added, and the mixture was extracted with chloroform (7 × 50 ml). The chloroform solution was washed, dried, and evaporated to dryness. It yielded 311 mg of a colorless oil which showed two spots corresponding to the two epimeric alcohols **23** and **24** in a thin-layer chromatogram. The two epimers were separated by chromatography on silica gel (34 g). The epimer **23** (122 mg) was eluted with methanol–ether (3:100) and the epimer **24** (110 mg) with methanol–ether (5:100). Both compounds were oils homogeneous in t.l.c.

Compound **23** has an i.r. spectrum: 3395 cm^{-1} (—OH); 1621 cm^{-1} (N—C—CH_3; $\underset{\underset{O}{\|}}{}$); and an n.m.r. spectrum: multiplet (3H) τ = 2.99–3.15 p.p.m. (aromatic hydrogen); singlets (3H each) τ = 6.22, 6.69, and 7.88 p.p.m. (2 —OCH_3, N—C—CH_3; $\underset{\underset{O}{\|}}{}$).

Compound **24** has an i.r. spectrum: 3395 and 3595 cm^{-1} (—OH); 1625 cm^{-1} (N—C—CH_3; $\underset{\underset{O}{\|}}{}$); and an n.m.r. spectrum: multiplet (3H) τ = 2.95–3.15 p.p.m. (aromatic hydrogen); singlets (3H each) τ = 6.22, 6.71, and 7.93 p.p.m. (2 —OCH_3, N—C—CH_3; $\underset{\underset{O}{\|}}{}$).

The acetylamino alcohol **23** (130 mg) was dissolved in dry dioxane (7 ml) and a suspension of sodium hydride in mineral oil (30 mg) was added. The mixture was stirred overnight at room temperature. After this time dimethyl sulfate (0.25 ml) was added and the solution was heated under reflux for 12 h. The reaction mixture was cooled, water (20 ml) was added, and the solution was extracted with chloroform (7 × 50 ml). The chloroform extract was washed, dried, and evaporated to dryness. The crude product was chromatographed on silica gel (8.5 g). The compound **25** was eluted with benzene–chloroform (1:1) and recrystallized from ether to a constant melting point of 128–130°. The yield was 79 mg.

Mol. Wt. Calcd. for $C_{23}H_{31}NO_4$: 385. Found (mass spectrometry): 385.

For the i.r. and n.m.r. spectra, see the Theoretical section.

The methylation of the acetylamino alcohol **24** to compound **26** was performed in exactly the same manner. From 134 mg of **24** 87 mg of pure compound **26** were obtained. This material remained oily, but was completely homogeneous in t.l.c. and gave a mass spectrum identical with the mass spectrum of the crystalline epimer **25**.

Mol. Wt. Calcd. for $C_{23}H_{31}NO_4$: 385. Found (mass spectrometry): 385.

Infrared spectrum: no OH band; 1655 cm^{-1} (N—C—CH_3; $\underset{\underset{O}{\|}}{}$). Nuclear magnetic resonance spectrum: multiplet (3H) around τ = 3.20 p.p.m. (aromatic hydrogen), singlets (3H each) τ = 6.30, 6.73, 6.93, and 7.99 p.p.m. (3 —OCH_3, N—C—CH_3; $\underset{\underset{O}{\|}}{}$).

*Preparation of the Compounds **3** and **27***

The compound **25** (50 mg) was dissolved in pure acetone (20 ml) and the solution was cooled to 5°. Jones' reagent was added dropwise with stirring until the color of the reaction mixture changed from green to orange. Stirring was continued for 3 h 30 min after which time methanol (5 ml) was added and the mixture was neutralized with sodium bicarbonate. The precipitate was filtered off, the filtrate evaporated to dryness, dissolved in water (10 ml), and extracted with chloroform (6 × 25 ml). After washing and drying, the chloroform extract was evaporated to dryness and the residue was chromatographed on silica gel (15 g). Methanol–ether (8:92) eluted the pure compound **3**. It was an oil homogeneous in t.l.c. Its mass spectrum was identical with the mass spectrum of the crystalline epimer **27**. The yield was 40 mg.

Mol. Wt. Calcd. for $C_{23}H_{29}NO_5$: 399.2046. Found (mass spectrometry): 399.2042.

For the i.r. and u.v. spectra, see the Theoretical section.

The oxidation of compound **26** was performed in exactly the same manner. From 40 mg of **26** 30 mg of compound **27** were obtained. The material was purified by preparative t.l.c. on silica gel and crystallization from ether. It melted at 197–199°.

Mol. Wt. Calcd. for $C_{23}H_{29}NO_5$: 399. Found (mass spectrometry): 399.

Infrared spectrum (KBr pellet): 1678, 1645 and 1600 cm^{-1}. For the u.v. spectrum, see the Theoretical section.

Photochemistry of nitroso compounds in solution.[1] X. The reaction pattern of photo-excited nitrosamides

Y. L. CHOW, N. S. TAM, AND A. C. H. LEE
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received October 10, 1968

The initial step in photolysis of alkyl *N*-nitrosamides **1** and **2** has been shown to be homolysis of the N—N bond, giving amidyl radicals and nitric oxide. Under the reaction conditions nitric oxide disproportionated, in part, to NO_2 and NO_3 radicals. The amidyl radicals abstracted hydrogen atoms intermolecularly from the solvent as well as intramolecularly from the δ-carbon of the alkyl chain, but not from that of the acyl chain. The combined pathways lead to the observed products as shown in Schemes 1 and 2. By this photolysis, the functionalization at the unactivated δ-carbon site of the alkyl chain could be achieved in 55% yield.

Canadian Journal of Chemistry, **47**, 2441 (1969)

Recent studies (1–6) have established that amidyl radicals can abstract a hydrogen atom from a saturated carbon center. We, as well as other groups,[2] have been studying the photolysis of nitrosamides aiming to unravel the reactions of transient amidyl radicals. We now amplify the preliminary report (7) to describe the detailed reaction pattern of nitrosamide photolysis. In particular we were concerned with intramolecular reaction of acyclic amidyl radicals. Since photolysis of nitrosamides in protic solvent gave complicated mixtures (8), the present work concentrated on reactions in hydrocarbon solvents.

Results

Owing to thermal lability of nitrosamides (9), all the preparations and photolyses of these compounds were carried out at a temperature near or below ambient. The crude nitrosamides **1** and **2** were not purified further and exhibited the expected physical properties as summarized in Table I. The apparatus and procedure of the irradiation were described in detail in Experimental. The photodecompositions of the nitrosamides were shown to follow zero-order kinetics up to 75% completion.

The photolysis of *N*-nitroso-*N*-(4-phenylbutyl)-acetamide (**1***a*) in petroleum ether gave *anti*-*N*-(4-phenyl-4-oximinobutyl)acetamide (**3***a*) and *N*-(4-phenylbutyl)acetamide. The structure of the former was determined by the conversion of the oxime to *N*-(4-phenyl-4-oxobutyl)acetamide (**4**) and further to 2-phenylpyrrolidine *p*-toluenesulfonamide (**5**) by standard methods. The *anti*-configuration of the oxime was decided by the nuclear magnetic resonance (n.m.r.) triplet signal τ 7.1 (N=C—CH_2—) by analogy with the chemical shift (τ 7.22) of the α-protons of β-methylbutyrophenone oxime (10). Careful chromatography revealed no other type of oxime (or corresponding *C*-nitroso compound) in the product.

The photolysis of *N*-nitroso-*N*-hexylacetamide (**1***c*) in benzene yielded the *trans*-dimer of *N*-(4-nitrosohexyl)acetamide (**6**) and the parent amide (**7**) in nearly equal amount. The structure of **6** was proven by conversion to *N*-(4-oxohexyl)-acetamide (**8**) through a depolymerization, tautomerization, and deoximation sequence. Decoupling experiments of **8** at 100 Mc.p.s. demonstrated the presence of the CH_3CH_2CO moiety with the chemical shifts at τ 8.99 (t) and 7.56 (q, J = 7 c.p.s.). The *trans* configuration of the dimer **6** was indicated by the strong infrared (i.r.) absorption at 1205 cm^{-1} (11, 12).[3] Careful chromatography did not reveal any γ- or ε-nitroso[4] derivatives isomeric to **6**, but instead afforded *N*-nitro-*N*-hexylacetamide (**9**) and a nitrato derivative of *N*-hexylacetamide. In agreement with an authentic sample prepared according to the known procedure (13), **9** exhibits the typical i.r. absorption at 1720, 1630, and 1570

[1]Part IX of this series; Y. L. Chow and C. J. Colon. Can. J. Chem. **45**, 2559 (1968).

[2]The authors are grateful to Dr. O. E. Edwards of the National Research Council of Canada, and Dr. L. P. Kuhn of Aberdeen Proving Ground, Maryland, who have informed us of their independent studies.

[3]The *trans*-dimers have been shown to isomerize upon low temperature irradiation (320–360 mμ region) to the *cis*-dimers which revert to the *trans*-dimers again on warming to −70° (see ref. 19).

[4]The Greek alphabets γ, δ, and ε refer to the positions of carbon chain with respect to the amide nitrogen atom, throughout this report.

TABLE I

Physical properties of nitrosamides

Nitrosamide	Infrared (cm^{-1})	Nuclear magnetic resonance (τ value)	Ultraviolet (mμ)
$C_6H_5(CH_2)_4$—N(NO)—C(=O)—CH_3	1730 1510	7.2 (s, 3H) 6.3 (m, 2H)	382, 397 415, 435
C_6H_{13}—N(NO)—C(=O)—H	1730 1520	6.3 (t, 2H) 0.63 (s, 1H)	388, 408 426
C_6H_{13}—N(NO)—C(=O)—CH_3	1725 1503	7.28 (s, 3H) 6.29 (t, 2H)	395, 406 425
C_5H_{11}—C(=O)—N(NO)—CH_3	1725 1500	9.09 (t, 3H) 7.00 (s, 3H) 6.92 (t, 2H)	376, 390 408, 427

4 **5**

cm^{-1} and the methyl singlet (for the CH_3CO group) at very low field[5] of τ 6.43. The nitrato compound did not have the ester group on C-5 since the methyl signal in the n.m.r. spectrum was triplet. Since selective δ-hydrogen abstraction is the rule in the photolysis (2), it is almost certainly *N*-(4-nitratohexyl)acetamide (**10**).

The optimum condition for the formation of the *C*-nitroso dimer (**6**) was found to be the exposure of an *n*-pentane solution of **1***c* in sunlight for several days, from which **6** deposited in 40–45% yield. A similar irradiation of *N*-nitroso-*N*-hexylformamide (**1***b*) with sunlight, however, afforded *N*-(4-oximinohexyl)formamide (**3***b*) in 28% yield, in addition to the parent amide. That **3***b* was a mixture of *anti* and *syn* isomers was shown by the superimposed triplets at τ 7.3–7.9. The low yield was probably due to the thermal instability of **1***b* by which it decomposed to *n*-hexylformate (9).

The formation of **9** and **10** from **1***c* was reminiscent of the nitric oxide disproportionation reaction (14–16) and led us to examine similar

[5]The drastic shift to a downfield of this methyl proton must be due to the anisotropic effect of the nitro group.

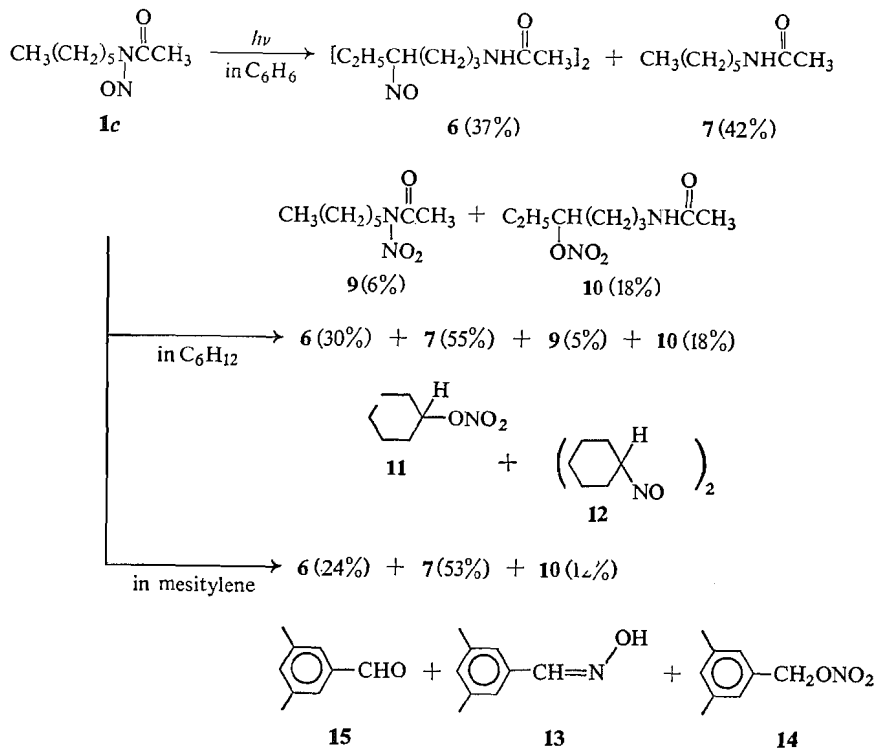

SCHEME I

photolysis in hydrogen donating solvents. The results are summarized in Scheme 1. While the yields of the parent amide **7** increased considerably at the cost of the intramolecular hydrogen exchange products (**6** and **10**), small amounts of the products derived from an intermolecular hydrogen exchange reaction were also obtained. When the photolysis was run in cyclohexane, the products were the *trans*-dimer of nitrosocyclohexane (**12**)[6] (17) and cyclohexylnitrate (**11**); when run in mesitylene, they were 3,5-dimethylbenzaldehyde (**15**) and its oxime (**13**), and 3,5-dimethylbenzylnitrate (**14**). The identity of these compounds was confirmed from their expected spectroscopic data (see Experimental).

The photolysis of *N*-nitroso-*N*-methylhexanamide (**2**, see Scheme 2) in benzene was shown to afford the parent amide (**16**), *N*-nitro-*N*-methylhexanamide (**17**) and the trimer of *N*-formylidenehexanamide (**18**). No intramolecular nitroso–hydrogen exchange product similar to **6** and **10** was obtained. The i.r. spectrum of **18** was consistent with *N*,*N*′,*N*″-trihexanoylhexahydro-*s*-triazine which gave *m*/*e* 281 as the highest mass peak equivalent to M^+-($C_5H_{11}COH$). The N—CH_2—N ring protons show an irregular multiplet due to restricted rotation about N—CO bonds (18, 19). When moisture was not rigorously excluded, hexanamide was isolated instead of **18**. The structure of the nitramide **17** was determined by spectroscopy, analogous to that used for the nitramide **9**. In cyclohexane, the photolysis yielded hexanoic acid, in addition to the nitrate **11** and the *C*-nitroso dimer **12**. Predictably, in a mesitylene solution the photolysis gave, in addition to **16**, good yields of **13**, **14**, and **15**. Variations of the photolysis conditions did not prove to be effective in producing the intramolecular nitroso–hydrogen exchange reaction. It should be added that dimeric compounds derived from solvents (such as dicyclohexyl and 1,2-diphenylethane) were not detected although the photolyzates were extensively analyzed by vapor-phase chromatography.

[6]It is interesting to point out that the *C*-nitroso dimer corresponding to crossed dimerization of nitrosocyclohexane and *N*-(4-nitrosohexyl)acetamide was not isolated from the photolyzate.

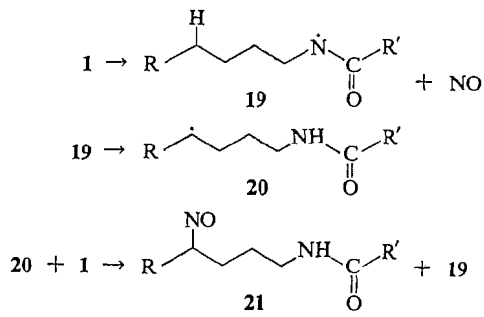
In order to prove the free radical chain process, the quantum yield of the disappearance of the nitrosamides was determined using potassium ferric oxalate actinometry (20). In benzene solutions, the nitrosamide **1***c* gave $\Phi = 2.5 - 3$ while **2** gave $\Phi = 2 - 2.5$.

Discussion

To facilitate the clarity of the discussion, hydrogen abstractions and the formation of *C*-nitroso compounds (and the derivatives thereof) will be described first, followed by the disproportionation of nitric oxide and the by-products therefrom.

Formation of C-Nitroso Compounds

The amidyl free radicals derived from the photolysis of nitrosamides **1** apparently undergo, in part, an intramolecular hydrogen abstraction from the δ-position via a favored transition state (**1** → **19** → **20**) in analogy with the abstraction mechanism proposed by Barton *et al.* (1) and Akhtar (2) and Walling and Padwa (21). The δ-nitroso amides (**21**) are then formed by a reaction of **20** with either another molecule of **1** (chain propagation) or nitric oxide in the bulk (chain termination).



20 + NO → **21**

19 (or20) + SH → S· + **7**

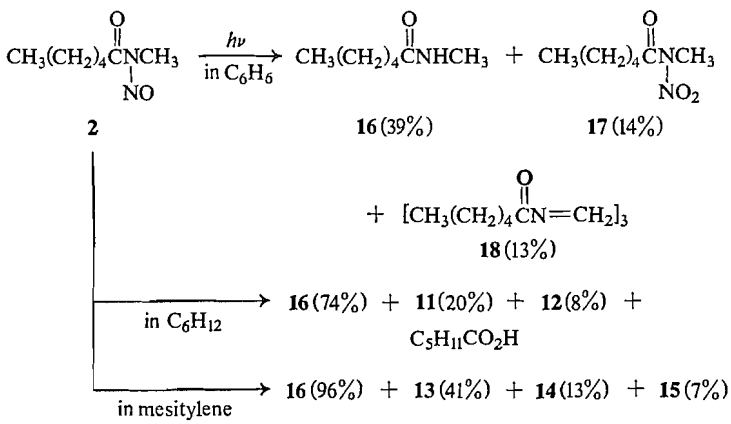
Concurrently an intermolecular hydrogen abstraction by **19** or **20** from the solvent (SH) is expected to compete with the intramolecular hydrogen abstraction process, though not favorably in view of lack of hydrogen abstraction exhibited by amidyl radicals (22–25) and a low entropy factor involved in an intramolecular reaction. The formation of *C*-nitroso compounds (S—NO) derived from the solvent is thus analogous to the intramolecular hydrogen–nitroso group exchange mechanism; the increased yield of the parent amide **7** in cyclohexane and mesitylene is thus to be expected. A possibility of hydrogen abstraction by nitric oxide is considered to be unimportant in view of the reported inertness of this radical (26–28).

Spontaneous formation of *trans*-dimers from *C*-nitroso compounds (**21** and S—NO) leads to **6** and **12** (11). We have demonstrated as other groups have also done (12) that a *C*-nitroso dimer[7] upon irradiation in a Pyrex vessel dissociates to a *C*-nitroso monomer, which slowly tautomerizes to the corresponding oxime. The oxime **3***b* is formed from over-irradiation while **3***a* is favored over the corresponding *C*-nitroso dimer from a facile tautomerization (29). The complete absence of the γ-nitroso (or corresponding γ-oximino) derivative in the photolysis of **1** indicates such intramolecular hydrogen transfer must be highly selective.

It is surprising that the product due to intramolecular hydrogen–nitroso exchange does not form at all when the nitrosamide **2** is photolyzed under various conditions. This implies that intramolecular hydrogen abstraction similar to the process **19** → **20** does not take place with the *N*-methylhexanamidyl radical, which is certainly formed as indicated by the presence of the intermolecular hydrogen–nitroso group exchange products **12** and **13**. That an amidyl free radical does not intramolecularly abstract a δ-hydrogen atom of the acyl chain was also confirmed by other groups (5, 6). Interestingly, in the photolysis of *N*-haloamides (1, 3, 4), varied extents of δ-hydrogen abstraction from the acyl side chain took place depending on the type of halogen substitution and the type of *N*-alkyl group. Two plausible explanations, based on the stereochemistry of the transition state, have been postulated, one by us in our brief communication (7) and the other by Kuhn *et al.* (6). Since no new evidence is available for a refinement, no further comment is necessary at this stage.

In a benzene solution (Scheme 2) since both hydrogen abstraction pathways are blocked, the hexanamidyl radical undergoes a disproportionation reaction involving a β-scission of the C—H bond to give *N*-formylidenehexanamide which is isolated as the trimer **18** or as hexanamide

[7]A *C*-nitroso dimer usually has a strong ultraviolet absorption in the 280 mμ region which tails strongly above 300 mμ.



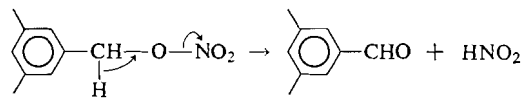
SCHEME 2

(see Experimental). The β-scission of the C—H bond in an alkoxy radical (30) is highly endothermic (31) and, therefore, a scarcely known process except as a part of a disproportionation reaction. Energetically the β-scission process of an amidyl radical is expected to be even more endothermic[8] than that of an alkoxyl radical (31). The overall results, therefore, demonstrate that the intramolecular hydrogen abstraction from the acyl chain is an extremely unfavorable process requiring even higher energy than the β-scission process.

Formation of By-products

The present nitrosamide photolysis differs from the nitrite photolysis (2) in that *N*-nitramides (**9** and **17**) and nitrates (**10**, **11**, and **14**) are formed as the by-products. These products are obviously derived from a combination of the hydrogen transfer reactions and a disproportionation of nitric oxide. Although by itself nitric oxide is unreactive (14), in the presence of a catalytic amount of nitrogen dioxide (and therefore of air), it displays a complex pattern of ill-defined redox reactions (14–16). Whatever the processes are, nitric oxide appears to be disproportionated to N_2, $\cdot NO_2$, and $\cdot NO_3$ (and probably N_2O also) (32) in the process of interacting with a free radical. Reaction of the respective carbon radicals (**20** and S·) with $\cdot NO_3$ would give **10**, **11**, and **14** and that of nitrogen radicals (**19**) with $\cdot NO_2$, **9**, and **17**. These reactions also serve as the chain termination steps. The observed by-products could not be due to an oxidation by traces of oxygen impurity in the nitrogen since the % yields were not significantly changed under various rates of nitrogen purging (down to nil). To form (6 + 18%) of **9** and **10** would have required 52 ml of oxygen if it was the source of these products. This seems impossible in view of the purity of the nitrogen.

3,5-Dimethylbenzaldehyde is probably not derived from the hydrolysis of **13** which is shown to be stable under these conditions. It can be visualized as formed by the elimination of nitrous acid from **14**, which was indeed found to decompose similarly during the working up.



14 **15**

Other oxidation processes are also possible, particularly if the disproportionation of ·NO generates a singlet state O_2 (32), and cannot be excluded at this stage. The formation of hexanoic acid from the photolysis of **2** in cyclohexane was quite unexpected since the thermal decomposition was shown to be absent in the control. Any speculation on the pathway leading to hexanoic acid seems futile unless a far reaching assumption can be made. In any case, the original aim of functionalization at the δ-carbon atom could be achieved readily with a reasonably good yield (up to 55%) which compares favorably with nitrite photolyses.

[8]The heat of formation of an amidyl free radical is expected to be lower than that of an alkoxy free radical since the former is resonance stabilized.

Lastly, the evidence outlined above proves that photolyses of nitrosamides operate exclusively through cleavage of the N—NO bond in sharp contrast to the exclusive N—CO cleavage in the thermolysis of nitrosamides (9). It is indeed very extraordinary that such a clear-cut difference in the bond-breaking process is operating in nitrosamides. We have suggested previously that this difference may be ascribed to the different excited states (vibrational or electronic) from which the bond-breaking processes take place (8).

Experimental

Unless specified otherwise, the i.r. spectra were taken in liquid phase with a Unicam SP 200 spectrophotometer, the n.m.r. spectra in carbon tetrachloride solution with a Varian A56/60 instrument (using TMS as an internal standard), the u.v. spectra were obtained in cyclohexane solution with a Cary 14 spectrophotometer, and the mass spectra were taken at 80 eV with a heated inlet using a Hitachi–Perkin–Elmer RMU-6E instrument. The melting points were taken in a Fisher–Johns hot stage and were uncorrected. The actinometry followed the procedure of Hatchard and Parkers (20). The silicic acid chromatography was carried out with silicic acid by Mallinckrodt, (100 mesh) and chloroform (Shawinigan Chemicals). The pure grade nitrogen (99.995%) was scrubbed with Fieser's solution and dried with sulfuric acid before being introduced to the reaction vessel. The coupling pattern of the n.m.r. spectra was denoted by t (triplet), d (doublet), q (quartet), and m (multiplet), and the number of protons was expressed by *H*. The microanalyses were performed by Dr. A. Bernhardt, West Germany.

Preparation of N-Nitrosamides

The nitrosamides were prepared by nitrosation of the respective amides with excess sodium nitrite in a mixture of acetic acid and acetic anhydride as described in the previous paper (8). Their physical properties are summarized in Table I.

General Procedure of Photolysis

The photolysis was generally carried out in a flat Pyrex flask in order to spread the solution wide and thin and, thus, to increase the irradiation area. Into this flask, a solution (100 ml) about 0.1 *M* in nitrosamide was introduced. The solution was kept under a nitrogen atmosphere. The flask was submerged in a cooling water-bath. In all cases, the temperature of the photolysis was controlled by the running cold water (ca. 10–15°). The solution was irradiated with a G.E. Par 38 (black light) spot lamp unless specified otherwise. The photolysis was continued until the typical u.v. absorption of the nitrosamides (420–430 mμ region) disappeared completely. At intervals aliquots were withdrawn and were diluted (1/10) to record the u.v. absorbance. A plot of the optical density against time gave a straight line up to 75% completion. The plot curved upward slightly from this point. A small portion of the photolysis solution was placed in a flask covered with aluminium foil. This flask was placed in the same water bath as the photolysis apparatus. The u.v. absorption spectrum of this solution remained unchanged over the entire period of photolysis showing that no thermal reaction took place.

*Photolysis of N-Nitroso-N-(4-phenylbutyl)acetamide (**1a**)*

The nitrosamide **1***a* (5.03 g) in petroleum ether (100 ml) was irradiated for 31 h to give a supernatant solution and an oily precipitate. The solution was evaporated to give a liquid which was shown to be mainly 4-phenylbutylacetate by the i.r. (1705, 1630, 1604, and 1262 cm^{-1}) and the n.m.r. (τ 6.34, t, J = 7.5 c.p.s.) spectra.

A liquid (3.98 g) was obtained after the solvent was removed from the oil. The liquid (1 g) was chromatographed on a neutral alumina column. Elution with chloroform–benzene (1:9) gave 4-phenylbutylacetamide (317 mg), the i.r. and n.m.r. spectra of which were shown to be identical with those of an authentic sample. Elution with 2% ethanol in chloroform gave crystals (335 mg) which were recrystallized from ethanol–petroleum ether to yield **3***a*, m.p. 112–113°. **3***a* gave i.r. absorptions at 3360, 1618, 1572, 940, 758, and 690 cm^{-1}; n.m.r. signals at τ 8.25 (q, J = 6.5 c.p.s., 2H), 8.04 (s, 3H), 7.1 (t, J = 7 c.p.s., 2H), and 6.72 (q, J = 6.5 c.p.s., 2H) and λ_{EtOH} 243 mμ.

Anal. Calcd. for $C_{12}H_{16}N_2O_2$: C, 65.42; H, 7.32; N, 12.72. Found: C, 65.45; H, 7.36; N, 12.92.

The liquid (1.2 g) was hydrolyzed with 1 *N* methanolic hydrochloric acid (250 ml). The total extract (408 mg) from the hydrolysis was reduced with lithium aluminium hydride (5.2 g) by refluxing in tetrahydrofuran (80 ml). The basic extract of this reduction was treated with *p*-toluenesulfonyl chloride in 10% sodium hydroxide solution. The precipitate was chromatographed on a silicic acid column to yield pale-yellow crystals which were recrystallized from methanol–petroleum ether to yield **5**, m.p. 103–105 °C. **5** gave i.r. absorptions at 1600 (w), 1343(s), and 1154(s) cm^{-1}; n.m.r. signals at τ 5.2 (t, J = 5 c.p.s., 1H) 6.9 (m, 2H), 7.6 (s, 3H); mass peaks at 301 (9.6%), 224 (30.2%), 155 (19.8%), 146 (100%), and 91 (67%).

When the total extract of the acid hydrolyzate was chromatographed on a neutral alumina column, a white solid was obtained on elution with chloroform. The solid was recrystallized to afford 4-phenyl-4-ketobutylacetamide (**4**), m.p. 93–94.5°; n.m.r. signals at τ 8.02 (s, 3H), 6.92 (t, 2H), 6.64 (t, 2H), 2.5 (m, 3H), and 2.05 (m, 2H); i.r. peaks at 3350, 1680, 1630, and 1560 cm^{-1}.

*Photolysis of N-Nitroso-N-hexylformamide (**1b**)*

The nitrosamide **1***b*, (5.99 g) in *n*-pentane (100 ml) was photolyzed for 10 days in sunlight to give an oily precipitate and a supernatant solution. The solution gave, after removal of the solvent, a liquid (1.12 g) which possessed a strong i.r. peak at 1775 cm^{-1} (hexyl formate). The oil was stripped off the *n*-pentane to give a liquid (4.6 g). A part of the liquid (1.99 g) was chromatographed on an alumina column. Elution with chloroform–benzene (1:1) gave *N*-hexylformamide (405 mg) as was shown by the superimposable i.r. spectrum with that of an authentic sample. Elution with 5% ethanol in chloroform gave an oil (727 mg) which was distilled to afford a *syn* and *anti* mixture of *N*-4-oximinohexylformamide (**3***b*). **3***b* gave n.m.r. signals at τ 8.9 (t, J = 7.5 c.p.s., 3H), 7.3–7.9 (m, 4H), 6.7 (q, J = 6.2 c.p.s.), 1.85 (s, 1H); i.r. absorptions at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

3400, 1670, 1550, and 940 cm^{-1}; mass peaks at *m/e* 158 (0.3%), 156 (2.0%), 141 (5.0%), 130 (1.8%), and 58 (100%).

Anal. Calcd. for $C_7H_{14}N_2O_2$: C, 53.15; H, 8.92. Found: C, 53.37; H, 8.82.

Photolysis of N-Nitroso-N-hexylacetamide (1c)

(*a*) The nitrosamide **1***c* (2.16 g) was photolyzed in benzene (100 ml) for 2 h. An oil (2.29 g) was obtained after evaporation of the solvent. The crude oil (1.67 g) was chromatographed on a silicic acid column to give the following compounds. The first fraction (109 mg) eluted with chloroform was distilled twice to give *N*-nitro-*N*-hexylacetamide (**9**). Infrared absorptions at 1720, 1630, 1570, 1300, 1220, and 1115 cm^{-1}; n.m.r. signals at τ 5.95 (t, J = 7 c.p.s., 2H), 6.43 (s, 3H), 9.1 (t, 3H); mass peak at *m/e* 141 ($M^+ - HNO_2$). The i.r. and n.m.r. spectra were superimposable with those of an authentic sample prepared according to the known method (13). The second fraction (550 mg) eluted with pure chloroform was *N*-hexylacetamide (**7**). The following fraction (350 mg) was vacuum distilled twice to give *N*-(4-nitratohexyl)acetamide (**10**); i.r. absorptions at 1630, 1550, 1275, 865, 755, and 700 cm^{-1}; n.m.r. signals at τ 9.1 (t, 3H), 8.20 (s, 3H), 6.78 (q, 2H), 5.0 (m, 1H); mass peaks at *m/e* 141 (14%), 100 (20%), 86 (30%), 82 (20%), 73 (70%), 72 (75%), 60 (50%), and 43 (68%). Under high vacuum distillation conditions (0.01 mm/80°), **10** decomposes slightly giving no satisfactory sample for analysis.

Elution with 2% methanol in chloroform gave a crystalline fraction (593 mg) which was recrystallized from acetone–pentane mixture to give *C*-nitroso dimer **6**, m.p. 125–127°. **6** has i.r. bands at 3280, 1646, 1555, 1205, and 1170 cm^{-1}; n.m.r. signals at τ 9.1 (t, J = 7 c.p.s., 3H), 8.0 (s, 3H), 6.75 (q, J = 6 c.p.s., 2H), and 4.60 (quintet, J = ca. 5 c.p.s., 2H). The cryoscopic molecular weight determination in water gave 336.

Anal. Calcd., for $C_{16}H_{32}N_4O_4$: C, 55.82; H, 9.36; N, 16.27. Found: C, 56.07; H, 9.35; N, 16.51.

These crystals **6** were warmed in levulinic acid over a water-bath for 2 h. After the usual working up, an oil was obtained which was distilled. The oil had i.r. bands at 3300, 1708, 1650, and 1555 cm^{-1}; n.m.r. signals at τ 8.99 (t, J = 7.2 c.p.s., 3H), 8.04 (s, 3H), 7.56 (q, J = 7.2, 2H), and 6.78 (q, J = 6.5 c.p.s., 2H). When the triplet at τ 8.99 was irradiated in a Varian HA-100 machine, the quartet at 7.56 collapsed to a singlet and vice versa.

The % yields[9,10] of the products are **6** (37%), **7** (42%), **9** (6%), and **10** (18%). The 2,4-dinitrophenylhydrazone of this oil was recrystallized from ethanol–water to give yellow needles, m.p. 119–121°.

Anal. Calcd. for $C_{14}H_{19}N_5O_5$: C, 49.82; H, 5.69; N, 20.76. Found: C, 49.89; H, 5.85; N, 20.81.

(*b*) The nitrosamide **1***c* (2.19 g) was similarly photolyzed in mesitylene (100 ml) for 1.5 h. Mesitylene was distilled off to give an oily residue (4.87 g). A similar chromatography gave, in order of elution, a hydrocarbon fraction (2.43 g), **14** (42 mg), **15** (42 mg), **13** (80 mg), **7** (960 mg), **10** (310 mg), and **6** (520 mg). The vapor-phase chromatographic analyses of the hydrocarbon fraction on an 8 ft SE-30 column at various temperatures showed only one corresponding peak to mesitylene. The % yields of the products were **6** (24%), **7** (53%), and **10** (12%).

(*c*) The nitrosamide **1***c* (1.01 g) in cyclohexane (100 ml) was irradiated for 2 h. Cyclohexane was evaporated to leave a yellow oil (1.11 g). The silicic acid chromatography of this oil (1.10 g) gave three fractions with chloroform. The first fraction (72 mg) was further distilled to an oily **11** which has i.r. absorptions at 1630, 1280, and 870 cm^{-1}; n.m.r. signals at τ 4.9 (broad, 1H) and 8.2 (10 H); mass peaks at *m/e* 145 and 98.

The second fraction (55 mg) was solid and was recrystallized from petroleum ether to give **12**, m.p. 112° (lit. (17) m.p. 116°); i.r. bands at 1390, 1260, and 1200 cm^{-1}; n.m.r. signals at τ 5.1 (broad, 1H) and 8.15 (broad, 10 H); mass peaks at *m/e* 113, 83, 55, and 41. The third fraction (58 mg) was distilled to give **9**. These fractions were followed by, in order of elution, **7** (453 mg), **10** (213 mg), and **6** (300 mg). The % yields of the products were **6** (30%), **7** (55%), **9** (5%), and **10** (18%).

(*d*) The nitrosamide **1***c* (3.12 g) in *n*-pentane (50 ml) was photolyzed in sunlight to give a crystalline deposit which could be recrystallized to give **6**. The oil obtained from pentane solution and the mother liquor were chromatographed on a silicic acid column to give **10** (795 mg) and more **6**. Total yield of **6** was 1.45 g.

Photolysis of N-Nitroso-N-methylhexanamide (2)

(*a*) The nitrosamide **2** (1.87 g) was photolyzed in benzene (100 ml) for 8 h. Benzene was removed by vacuum evaporation to leave an oil (1.78 g). The silicic acid chromatography of this oil (1.29 g) gave, with chloroform, an oil (212 mg) which was distilled twice to afford *N*-nitro-*N*-methylhexanamide (**27**); i.r. absorptions at 1720, 1620, 1570, 1300, and 1220 cm^{-1}; n.m.r. signals at τ 6.43 (s, 3H) and 7.10 (t, 2H). This was followed by **16** (435 mg) and then a solid fraction (136 mg) which was recrystallized from petroleum ether–benzene (1:1) mixture to give **18**, m.p. 172–176°; i.r. peak at 1655 cm^{-1}; n.m.r. signals at τ 5.32 (m, 2H), 7.8 (t, J = 6 c.p.s., 2H), and 9.1 (t, J = 6 c.p.s., 3H). The mass spectrum of **18** showed 281, 167, 127, and 71 peaks. Two more unidentified fractions were obtained. The % yields of the products were **16** (39%), **17** (14%), and **18** (13%).

(*b*) The nitrosamide **2** (1.78 g) was photolyzed in mesitylene (100 ml) for 3 h to afford a residue (4.39 g) after removal of the solvents. This oil was chromatographed on a silicic acid column to afford the following compounds in the order of elution. (*i*) 3,5-Dimethylbenzylnitrate (**14**, 262 mg); i.r. absorptions at 1630, 1270, 860, and 770 cm^{-1}; n.m.r. signals at τ 7.82 (s, 6H), 4.80 (s, 2H), 3.2 (m, 3H); mass peaks at *m/e* 181, 134, 133, 120, 105, and 91. (*ii*) 3,5-Dimethylbenzaldehyde (**15**, 115 mg), i.r. absorptions at 2870, 2730, 1700, 1650, 1570, and 860 cm^{-1}; n.m.r. signals at τ 7.6 (s, 6H), 2.6 (m, 3H), and 0.15 (s, 1H); M^+ of 134. (*iii*) 3,5-Dimethylbenzaldehyde oxime (**13**, 705 mg) which was recrystallized from petroleum ether, m.p. 125–127°; i.r. absorption at 1600, 1470, 1380, 995–960, and 860 cm^{-1}; n.m.r. signals at

[9]The % yields in this report were calculated based on one mole of the product being formed from one mole of the starting nitrosamide.

[10]The percentages were calculated from the results of a small scale column chromatography, a minor weighing error of which caused the total percentage to exceed 100. The percentages, however, accurately represent the ratio of the products.

τ 7.80 (s, 6H), 3.0 (m, 3H), and 2.08 (s, 1H); M^+ at 149. (*iv*) N-Methylhexanamide (**16**, 1.4 g). The % yields of the products were **16** (96%), **13** (41%), **14** (13%), and **15** (7%).

(*c*) A solution of the nitrosamide **2** (1.79 g) in cyclohexane (100 ml) was photolyzed for 3 h. Cyclohexane was evaporated to leave an oil (2.09 g). The oil (1.18 g) was chromatographed on a silicic acid column to give **11** (187 mg), **12** (59 mg), hexanoic acid (122 mg), and **14** (609 mg). Hexanoic acid was identified by comparing the i.r. spectrum with that of an authentic sample. The % yields of the products were **16** (74%), **11** (20%), and **12** (8%).

(*d*) The nitrosamide **2** (5.38 g) in petroleum ether (90 ml) was photolyzed in sunlight for 4 weeks. A brown liquid (5.65 g) was obtained when the solvent was removed. This oil (1.47 g) was chromatographed on a neutral alumina column. Elution with chloroform–benzene (1:9) gave **16** (224 mg). Elution with chloroform–benzene (1:1) gave a solid fraction (100 mg) which was sublimed to give white needles, m.p. 91–94° and mixture m.p. with an authentic hexanamide (m.p. 96–97°) 95–96°. The i.r. and the n.m.r. spectra of the needles were superimposable with those of hexanamide.

Alkaloids of *Lycopodium alopecuroides*. Part 2. Alopecurine, a new type of Lycopodium alkaloid

W. A. AYER, B. ALTENKIRK, N. MASAKI, AND S. VALVERDE-LOPEZ
Department of Chemistry, University of Alberta, Edmonton, Alberta

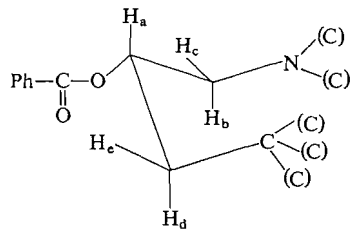
Received February 17, 1969

Alopecurine, a pentacyclic Lycopodium alkaloid, has been shown to possess structure **1**. The structure, including the absolute stereochemistry, was established by X-ray analysis of debenzoylalopecurine hydrobromide, and further confirmed by X-ray analysis of alopecurine methobromide. Some chemical and spectroscopic properties of alopecurine are described. The isolation of four alkaloids in addition to those already reported from *L. alopecuroides* is described. These alkaloids include the known compound fawcettidine and three new bases, acetyldebenzoylalopecurine, alolycopine, and lycopecurine.

Canadian Journal of Chemistry, 47, 2449 (1969)

In Part 1 of this series (1) we reported on the isolation and characterization of alopecurine, $C_{23}H_{29}O_3N$, an alkaloid of *Lycopodium alopecuroides* L. It was shown that alopecurine contains a benzoyloxy group, a hydroxyl group, and a tertiary nitrogen and that the alkaloid is probably pentacyclic. We now wish to report that alopecurine possesses structure **1**, a new type of ring system for this group of alkaloids.

A study of the nuclear magnetic resonance (n.m.r.) spectrum of alopecurine (Fig. 1) indicates that the benzoyloxy group is located in the environment shown in part structure **2**. The signal for the proton geminal to the benzoyloxy group (H_a) appears as a complex multiplet ($w_{1/2} \simeq 15$ c.p.s., axial proton (2)) centered at τ 4.65. By spin decoupling of H_a it is possible to locate the signals due to the protons labelled



2

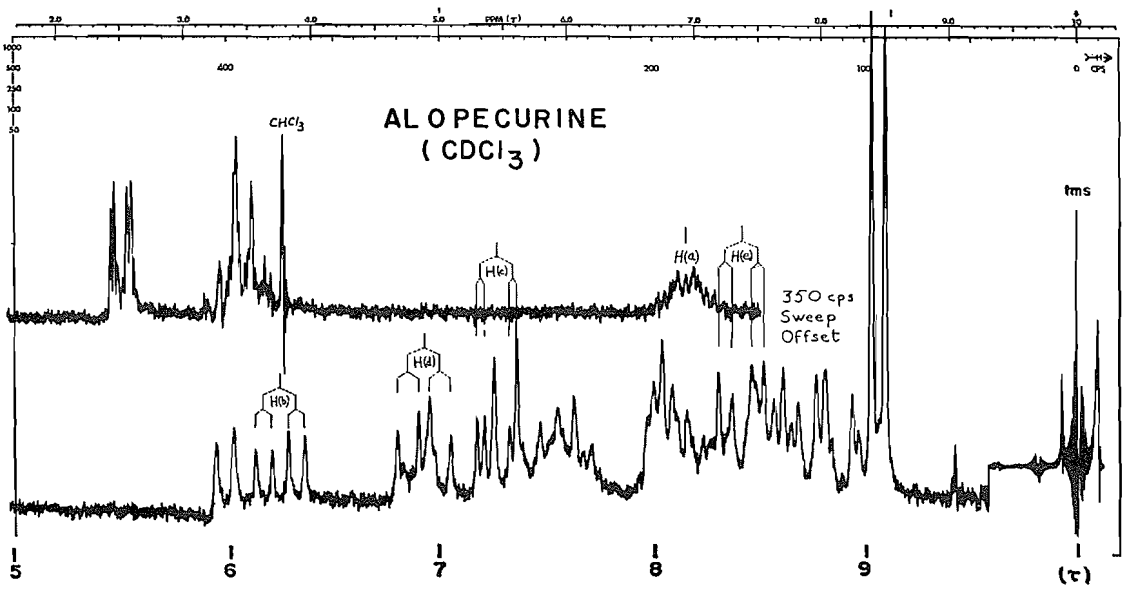


FIG. 1. Nuclear magnetic resonance spectrum (100 Mc.p.s.) of alopecurine in $CDCl_3$.

H_b, H_c, H_d, and H_e in **2**. Simultaneous irradiation of H_a causes the quartet (J = 7.5 and 15.5 c.p.s.) centered at τ 6.25 to collapse to a doublet (splitting 15.5 c.p.s.). Irradiation at τ 6.25 not only simplifies the multiplet at τ 4.65 but also causes the partially obscured quartet (J = 5 and 15.5 c.p.s.) centered at τ 7.28 to collapse to a doublet (splitting 5 c.p.s.). Triple irradiation (τ 4.65 and τ 7.28) causes the quartet at τ 6.25 to collapse to a singlet. In a similar manner the other two protons vicinal to H_a were located. The chemical shifts and coupling constants for these protons are given in Table I.

Of the four methylene protons, the one at lowest field (τ 6.25) was assumed to be on a carbon α to nitrogen to account for its chemical shift and was assigned the axial conformation because of its relatively large vicinal coupling. The signal at τ 6.93 is assigned to the axial proton (H_d), again on the basis of its vicinal coupling constant (10 c.p.s.). It is assumed that the 15 and 15.5 c.p.s. couplings are geminal couplings (3). Since neither H_d nor H_e is further coupled, it appeared that this methylene group is linked to a quaternary carbon.

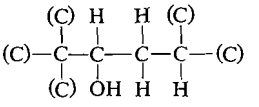
The doublet (J = 8 c.p.s.) at τ 5.98 in the n.m.r. spectrum of alopecurine is due to the proton geminal to the hydroxyl group, since this signal is shifted to τ 4.80 in *O*-acetylalopecurine and is not present in the spectrum of dehydroalopecurine, prepared by Jones' oxidation of alopecurine. Dehydroalopecurine shows carbonyl absorption at 1715 and 1690 cm^{-1}, the former attributed to the benzoyloxy carbonyl and the latter to the newly formed keto group. Sodium borohydride reduction of dehydroalopecurine gave alopecurine. Hydrolysis of dehydroalopecurine gave debenzoyldehydroalopecurine which absorbs at 1690 cm^{-1} in the infrared (i.r.). Both of these compounds show an absorption band at 1410 cm^{-1}, not present in alopecurine itself, suggesting that the keto group is flanked, at least on one side, by a methylene group. Oxidation of either debenzoylalopecurine or debenzoyldehydroalopecurine gave the corresponding diketone which displays carbonyl absorption at 1720 and 1690 cm^{-1}.

TABLE I

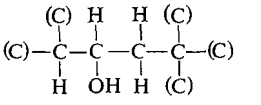
Nuclear magnetic resonance data for ring C protons in alopecurine

Proton	Chemical shift (τ)	Coupling constants (c.p.s.)
H_a	4.65	J_{ab}7.5, J_{ac}5, J_{ad}10, J_{ae}6
H_b	6.25	J_{ab}7.5, J_{bc}15.5
H_c	7.28	J_{ac}5, J_{bc}15.5
H_d	6.93	J_{ad}10, J_{de}15
H_e	8.43	J_{ae}6, J_{de}15

Dehydration of alopecurine with thionyl chloride in benzene gave anhydroalopecurine which shows two olefinic protons in its n.m.r. spectrum, one appearing as a doublet (J = 9 c.p.s.) at τ 4.50 and the other as a quartet (J = 9 and 2 c.p.s.) at τ 4.65.



3a



3b

The datum above indicates that the environment of the hydroxyl group is as shown in *3a* or *3b*, with *3a* preferred since the proton geminal to the hydroxyl group appears as a doublet in the n.m.r. spectrum (i.e., *3a* requires that only one coupling constant be zero).

Since at this stage it appeared that an unambiguous chemical solution to the structural problem was not close at hand, an X-ray crystallographic study was undertaken. Four heavy atom derivatives of alopecurine were prepared. Both the hydrobromide and the hydrochloride formed tetragonal crystals of large unit cell volume and were rejected. Alopecurine methobromide formed monoclinic crystals, space group $P2_1$, containing two molecules per unit cell of dimensions a = 10.96, b = 10.42, and c = 9.48 Å, β = 90.0°. Debenzoylalopecurine hydrobromide crystallized from methanol–acetone in the orthorhombic system space group $P2_12_12_1$, with four molecules in the unit cell of dimensions a = 7.52, b = 28.05, c = 7.05 Å. Since the $P2_12_12_1$ system is more suitable for application of the heavy atom method, debenzoylalopecurine hydrobromide was selected for the analysis. The X-ray reflections were recorded on equi-inclination Weissenberg photographs taken along the a and c axes with CuK_α radiation. The structure was solved by the heavy-atom method and refined by full-matrix least squares methods to an R-factor of 11.1%.[1] The molecular

[1]Full details of the X-ray analysis will be published separately.

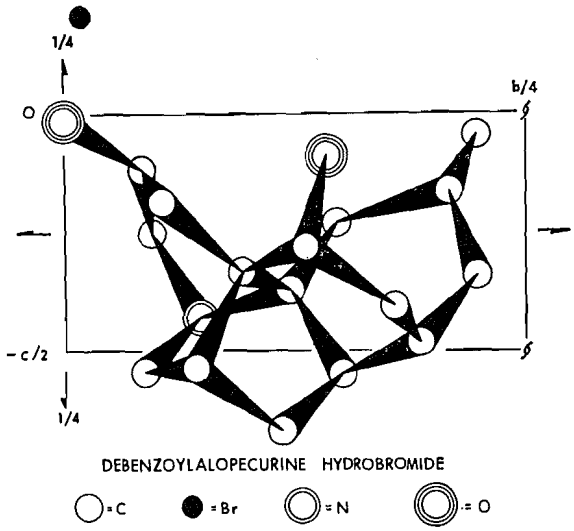


FIG. 2. Perspective drawing of a molecule of debenzoylalopecurine hydrobromide.

structure so derived is shown in Fig. 2, which also depicts the correct absolute configuration as determined by anomalous dispersion calculations. Structure **4** (**4***a* and **4***b* are other representations of the same molecule) thus represents debenzoylalopecurine. Since the n.m.r. evidence clearly indicates that the carbon bearing the benzoyloxy group is flanked on both sides by methylene groups, alopecurine itself is **1** (= **1***a* = **1***b*). As may be seen in **1** and as is emphasized by **1***a*, alopecurine contains the lycopodine-type skeleton with an extra bond connecting C-4 and C-10. As in most Lycopodium alkaloids, C-5 is oxygenated. However, this is the first example of an alkaloid of this group oxygenated at C-2, as well as being the first reported benzoylated Lycopodium alkaloid.

Another interesting feature revealed by the X-ray analysis is that ring C adopts a twist conformation in the crystal. The n.m.r. data quoted previously (Table I) indicates that this is also the preferred conformation of the free base in solution. The value J_{ad} = 10 c.p.s. is consistent only with a dihedral angle approaching 180°. The rather large values for J_{ae} and J_{ae} (5 and 6 c.p.s., respectively) and the relatively small value for J_{ab} (7.5 c.p.s.) may reflect some distortion in this ring, although our lack of knowledge of the effect of the nitrogen (4) on the couplings of H_b and H_c seems to make further speculation on the n.m.r. data unwarranted. In the crystal, the internuclear distance between C-2 and C-14 is 3.10 Å while in Dreiding models of the "undistorted" molecule, measurements indicate an internuclear distance of about 2.5 Å. Apparently the severe nonbonded interaction between the hydroxyl substituent at C-2 and the *exo*-hydrogen at C-9 (see **5**) makes the chair form **5** less stable than the twist form **4**.

The X-ray analysis also reveals a distortion of rings B and D. The internuclear distance between the C-5 oxygen and C-15 is 3.09 Å. In Dreiding models of the "undistorted" molecule, this distance is about 2.0 Å. As mentioned previously, the proton at C-5 gives rise to a doublet, $J \simeq 8$ c.p.s., in the n.m.r. spectrum. This can be accounted for if ring B is distorted toward the half-chair to such an extent that the dihedral angle between the hydrogen at C-5 and the axial hydrogen at C-6 approaches 0°. In this case the dihedral angle which the C-5 hydrogen makes with the equatorial hydrogen at C-6 is close to 90°, and explains the negligible coupling between these two protons. Dehydration of alopecurine, as mentioned, proceeds readily to give anhydro-

9

alopecurine (**6**), which from its spectroscopic properties appears to be unrearranged.

Because of the unusual nature of the ring system the X-ray analysis of alopecurine methobromide has also been completed[1] and the result (Fig. 3) fully confirms structure **1**, with ring C in a twist conformation.

Since our initial report on the isolation of the alkaloids of *L. alopecuroides* (1) we have succeeded in isolating 4 more alkaloids from this plant. One of these is fawcettidine (**7**) (5). The others are new alkaloids: (*i*) a compound $C_{18}H_{27}O_3N$, m.p. 238–240°. It was apparent from the i.r., n.m.r. (Fig. 4), and mass spectra of this alkaloid that it is acetyldebenzoylalopecurine (**8**), in which the benzoyl group of alopecurine is replaced by an acetyl group. Alkaline hydrolysis of **8** gave debenzoylalopecurine (**4**). Oxidation gave the corresponding ketone; (*ii*) a compound $C_{16}H_{21}O_2N$, m.p. 53–56°, which we have named alolycopine, and which has been shown to possess structure **9** (6); (*iii*) a compound $C_{16}H_{25}ON$, m.p. 239–241°, which we have called lycopecurine. The oxygen is present as a hydroxyl group and since there is no evidence for the presence of unsaturation, lycopecurine also appears to be pentacyclic.

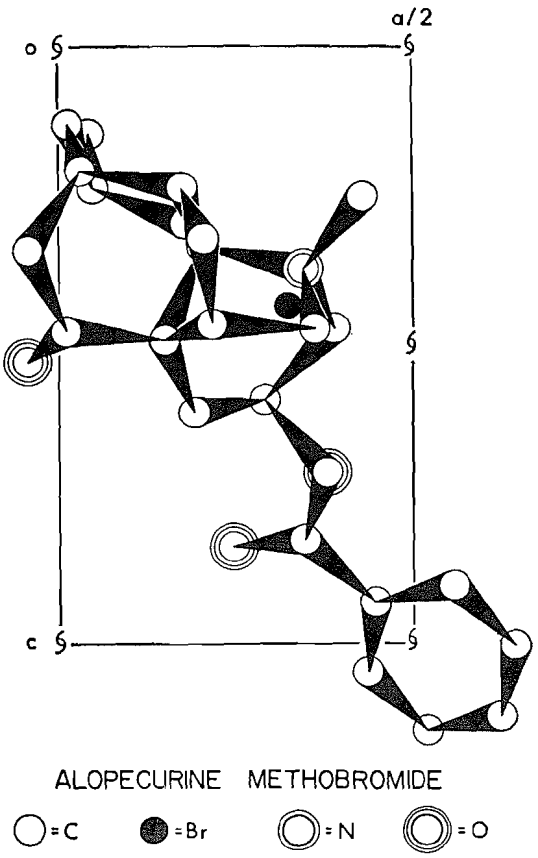

FIG. 3. Perspective drawing of a molecule of alopecurine methobromide.

Experimental

General

Infrared (i.r.) spectra were measured on a Perkin–Elmer model 441 or model 337 spectrophotometer, nuclear magnetic resonance spectra were measured on a Varian Associates model HA-100 spectrometer, and mass spectra were determined on an AEI MS-9 mass spectrometer. Alumina, unless otherwise specified refers to basic alumina of activity II–III (Brockmann scale). Thin-layer chromatograms (t.l.c.) were carried out on Alumina G (American Optical Corporation, Richmond, California) and developed with iodine and/or Dargendorff's reagent. Microanalyses were performed by A. B. Gygli, Toronto. Crystal densities were determined by the neutral buoyancy method using chlorobenzene and carbon tetrachloride.

Alopecurine

Alopecurine, m.p. 244–245°, $[\alpha]_D -105°$, $[\alpha]_{300} -420°$, (*c*, 0.5 MeOH) was isolated as previously described (1). The n.m.r. spectrum is shown in Fig. 1. Mass spectrum: *m/e* 367 (M^+, 26), 352(22), 262(55), 246(30), 245(59), 230(21), 219(38), 204(25), 178(26), 151(19), 122(19), 105(100), 77(50). The i.r. and ultraviolet spectra have been reported (1).

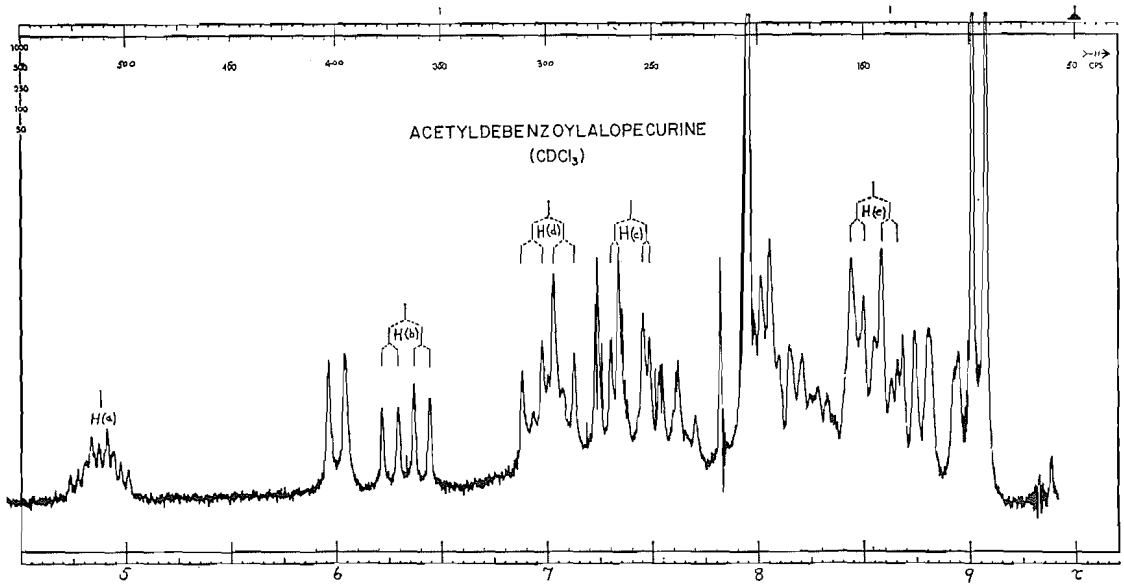

FIG. 4. Nuclear magnetic resonance spectrum (100 Mc.p.s.) of acetyldebenzoylalopecurine.

The *hydrobromide* was prepared in the usual fashion and recrystallized from methanol–acetone to give tetragonal crystals, m.p. > 300° (decomp.), $d^{25°} = 1.35$ g/cm³.

The *hydrochloride* was prepared in methanol and recrystallized from acetone, m.p. 290–300° (decomp.), $d^{25°} = 1.257$ g/cm³.

The *methobromide* was prepared as follows. Alopecurine (10 mg) was dissolved in acetone (6 ml) and a few drops of methyl iodide were added. The solution was heated on the steam bath for 2 h, then the solvents were evaporated, and the glassy residue was crystallized from acetone–ether. The methiodide, m.p. 250°, was dissolved in water and passed through a column of bromide loaded Dowex 2-X8 anion exchange resin (1 g). Evaporation of the water yielded alopecurine methobromide (11 mg), which after recrystallization from methanol–acetone melted at 247–249°, $d^{25°} = 1.397$ g/cm³. Infrared spectrum (Nujol mull): 3300, 1725, 1595, 1580, 1260 cm^{-1}.

Anal. Calcd. for $C_{24}H_{32}O_3NBr$: C, 62.33; H, 6.97. Found: C, 62.26, 62.44; H, 7.12, 7.04.

Debenzoylalopecurine Hydrobromide

The hydrobromide was prepared in the usual way and recrystallized from acetone–methanol, m.p. 249–251°, $d^{25°} = 1.481$ g/cm³.

Anal. Calcd. for $C_{16}H_{26}O_2NBr$: C, 55.81; H, 7.61. Found: C, 55.97, 56.02; H, 7.43, 7.53.

Dehydroalopecurine

Jones' reagent (8 drops) was added to a solution of alopecurine (46 mg) in acetone. After 5 min methanol (10 drops) was added and the solution concentrated almost to dryness. The residue was dissolved in chloroform and washed with dilute sodium bicarbonate. Evaporation left an oil which was homogeneous as determined by t.l.c. but which could not be induced to crystallize. The oil was purified by evaporative distillation (150°/0.1 mm); calculated mol. wt. for $C_{23}H_{27}O_3N$: 365. Found: 365 (mass spectrometry). Infrared spectrum ($CHCl_3$): 1715, 1690, 1410 cm^{-1}. Nuclear magnetic resonance spectrum ($CDCl_3$): τ 2.0–2.5 (5 H, aromatic protons), 4.75 (1 H, multiplet, $w_{1/2} \simeq 15$ c.p.s.), 6.25 (1 H, quartet, $J = 16$ and 7.5 c.p.s.), 7.1 (1 H, quartet, $J = 16$ and 8 c.p.s.), 7.2 (1 H, quartet, $J = 16$ and 2 c.p.s.), 8.1 (1 H, quartet, $J = 16$ and 2 c.p.s.) (the last 4 protons are all coupled to the τ 4.75 proton as shown by spin-decoupling), 9.03 (3 H, doublet, splitting 6 c.p.s.).

Debenzoyldehydroalopecurine

Dehydroalopecurine (36 mg) was dissolved in dioxane (2 ml) and 5% aqueous potassium hydroxide (0.3 ml) was added. After 12 h at room temperature, most of the solvent was evaporated, the residue taken up in water, and extracted with chloroform. Evaporation gave a solid (21 mg) which after recrystallization from acetone melted at 160–162°. Infrared spectrum (Nujol mull): 3100, 1690, 1412 cm^{-1}. Calculated mol. wt. for $C_{16}H_{23}O_2N$: 261.1728. Found: 261.1729 (high resolution mass spectrometry (h.r.m.s.)).

Oxidation of Debenzoylalopecurine

Debenzoylalopecurine (6 mg) was dissolved in acetone (2 ml) and Jones' reagent (2 drops) was added. Methanol (2 drops) was then added and the solution evaporated to dryness. The residue was dissolved in chloroform and washed with dilute sodium bicarbonate. Evaporation of the chloroform gave an oil which was purified by evaporative distillation (130°/0.1 mm). Infrared spectrum ($CHCl_3$): 1720, 1690, 1430, 1410 cm^{-1}. Calculated mol. wt. for $C_{16}H_{21}O_2N$: 259.1572. Found (h.r.m.s.): 259.1574.

The *hydrobromide* was prepared in the normal way and melted at 248–250° (decomp.).

Oxidation of Debenzoyldehydroalopecurine

The oxidation was carried out as described for debenzoylalopecurine and the product obtained was identical with the diketone described above.

Anhydroalopecurine

Alopecurine (25 mg) was dissolved in benzene (10 ml) and thionyl chloride (0.5 ml) was added. The solution was heated under reflux overnight, then water was added, followed by aqueous ammonia. The benzene layer was separated and the aqueous layer extracted twice more with benzene. Evaporation of the benzene left an oil (20 mg) which was chromatographed over alumina (Woelm neutral, activity II, 1 g). Elution with ether gave *anhydroalopecurine* (15 mg) which crystallized from ether, m.p. 105–107°. Infrared spectrum ($CHCl_3$): 1720, 1610, 1590, 1280 cm^{-1}. Nuclear magnetic resonance spectrum ($CDCl_3$): τ 2–2.5 (5 H, aromatic protons), 4.50 and 4.65 (2 H, AB portion of ABX system, J_{AB} = 9 c.p.s., J_{AX} = 0 c.p.s., J_{BX} = 2 c.p.s.), 4.70 (1 H, multiplet), 6.25 (1 H, quartet, J = 16 and 6.5 c.p.s.), 7.00 (1 H, quartet, J = 16 and 1 c.p.s.), 7.55 (1 H, quartet, J = 17 and 8.5 c.p.s.), 8.00 (1 H, quartet, J = 17 and 2.5 c.p.s.), 9.01 (3 H, doublet, splitting 6 c.p.s.). Calculated mol. wt. for $C_{23}H_{27}O_2N$: 349.2042. Found (h.r.m.s.): 349.2045.

Isolation of Fawcettidine

Fraction 3 from the initial chromatographic separation of the crude alkaloids (see ref. 1) was subjected to gas–liquid chromatography (190°, 5 ft × ¼ in. column, 10% QF-1 on Chromosorb W, flow rate (He) 60 ml/min, Aerograph A-90-P3). The middle fraction (of 3, retention time 5 min) was collected and treated with an ethereal solution of picric acid. The picrate thus obtained, m.p. 220–222°, was identical (m.p., m.m.p., i.r. spectrum) with fawcettidine picrate.

Isolation of Acetyldebenzoylalopecurine

Fraction 7 (1) and the mother liquors from fraction 8 were chromatographed over alumina. Elution with ether gave first alopecurine and then a fraction which on crystallization from acetone afforded *acetyldebenzoylalopecurine*, m.p. 238–240°. Infrared spectrum ($CHCl_3$): 3610, 1725, 1240 cm^{-1}. Nuclear magnetic resonance spectrum: see Fig. 4. Mass spectrum: *m/e* 305 (M^+, 41), 290(58), 262(50), 246(60), 245(100), 219(51), 204(46), 178(40). Calculated mol. wt. for $C_{18}H_{27}O_3N$: 305.1991. Found (h.r.m.s.): 305.1990.

Hydrolysis of Acetyldebenzoylalopecurine

Acetyldebenzoylalopecurine (19 mg) in methanol (5 ml) and 5% aqueous KOH (2 ml) were kept at room temperature for 24 h. Work-up in the usual manner gave debenzoylalopecurine (13 mg), m.p. 229–231°, identical with an authentic sample.

Oxidation of Acetyldebenzoylalopecurine

The oxidation of acetyldebenzoylalopecurine (10 mg) with Jones' reagent (10 drops) was carried out in the usual manner. The product (9 mg) was a solid, m.p. 241–243° after recrystallization from acetone. Infrared spectrum (Nujol mull): 1750, 1695, 1230 cm^{-1}. Calculated mol. wt. for $C_{18}H_{25}O_3N$: 303.1834. Found (h.r.m.s.): 303.1834.

Isolation of Alolycopine

The mother liquors from fraction 9 (1) and from several fractions from the chromatogram above showed a strong band at 1640 cm^{-1} in the i.r. These fractions (0.28 g) were combined and subjected to "dry-column" chromatography (7) over neutral alumina (125 g). The column was developed with chloroform–methanol (49:1, 100 ml). From this chromatography an apparently homogeneous (determined by t.l.c.) oil (0.12 g, $R_f \simeq 0.6$) was obtained which, however, could not be induced to crystallize. This oil, which showed hydroxyl absorption in the i.r., was treated at room temperature for 12 h with acetic anhydride – pyridine (4 ml of 1:1). Evaporation left an oil which was dissolved in ether and filtered through basic alumina. Crystallization of the residue from a small volume of ether provided *O*-acetylalolycopine (0.1 g), m.p. 180–182°. Calculated mol. wt. for $C_{18}H_{23}O_3N$: 301.1678. Found (h.r.m.s.): 301.1678.

Hydrolysis of *O*-acetylalolycopine at room temperature in aqueous methanolic potassium hydroxide gave crystalline alolycopine, which after recrystallization from ether melted at 53–56°. The i.r. spectrum of this material was virtually identical with that of the oil obtained from the "dry-column" chromatography. Calculated mol. wt. for $C_{16}H_{21}O_2N$: 259.1572. Found: 259.1571.

A full description of the properties of alolycopine is provided in the following paper (6).

Isolation of Lycopecurine

After standing for several months, the acetone mother liquors remaining from the isolation of alopecuridine (1) deposited crystals (24 mg) of a compound melting at 239–241°, which does not appear to have been described previously. The i.r. spectrum ($CHCl_3$) showed hydroxyl absorption at 3620 cm^{-1} but no absorption in the 1500–1800 cm^{-1} region. High resolution mass spectrometry suggests the molecular formula $C_{16}H_{25}ON$ (calculated mol. wt. 247.1936. Found: 247.1932). The base peak in the mass spectrum occurs at *m/e* 232. The n.m.r. spectrum determined on a small amount of the compound was poorly defined but did reveal the presence of a secondary *C*-methyl group (doublet at τ 9.08) and a lack of olefinic protons. An X-ray crystallographic analysis of the hydrobromide of lycopecurine is in progress.

Acknowledgments

We wish to thank the Smith, Kline, and French Laboratories, Philadelphia and especially Dr. J. A. Weisbach for the supply of crude alkaloids, and the National Research Council of Canada for financial support. We also wish to thank Mrs. Judith Westwood, Dr. A. N. Hogg, and Messrs. R. N. Swindlehurst and G. Bigam for their help in various phases of this work, and Professor David Hall for his help with the X-ray analysis.

Alkaloids of *Lycopodium alopecuroides*. Part 3. Structure of alolycopine

W. A. AYER AND B. ALTENKIRK

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received February 17, 1969

The alkaloid alolycopine is shown to have structure **4***a*. The structural assignment is based on the interpretation of the infrared, ultraviolet, and nuclear magnetic resonance spectra of alolycopine and *O*-acetylalolycopine, and on a correlation of the latter with acetylanhydroaposerratinine (**6**).

Canadian Journal of Chemistry, 47, 2457 (1969)

In Part 2 (1) we reported the isolation of an alkaloid $C_{16}H_{21}O_2N$, m.p. 53–56°, from *Lycopodium alopecuroides* L. This paper describes the elucidation of the structure of this minor alkaloid, which has been named alolycopine.

An examination of the infrared (i.r.), ultraviolet (u.v.), and nuclear magnetic resonance (n.m.r.) spectra of alolycopine and *O*-acetylalolycopine suggested that part structures **1** and **2** are present in the alkaloid.

Part Structure 1

The presence of the hydroxyl group was indicated by i.r. absorption at 3625 cm^{-1}. Its secondary nature was suggested by the signal at τ 5.46 (quartet, J = 12 and 5 c.p.s.) in the n.m.r. spectrum (Fig. 1) of *O*-acetylalolycopine. Since the i.r. spectrum of *O*-acetylalolycopine shows no NH absorption, the nitrogen is tertiary. The presence of the vinyl amine grouping was suggested by the relatively intense carbon–carbon double bond absorption at 1665 cm^{-1} (Fig. 2), similar to that in fawcettidine (**3**) (2, 3), and by the fact that the n.m.r. signal (τ 4.54, Fig. 1) attributed to the proton on this double bond is shifted downfield by about 0.8 p.p.m. when trifluoroacetic acid is added to the solution, again similar to the case of fawcettidine (3). The fact that this proton, subsequently shown to be β to the nitrogen, gives rise to a signal at τ 4.54 rather than at the normal enamine position ($\simeq$ 5.5 (4)), indicates that there is no overlap possible between the nitrogen lone pair orbital and the π orbital of the double bond (i.e., the nitrogen is at a bridgehead). The signal for this olefinic proton, a doublet (J = 6 c.p.s.), was spin-decoupled by double irradiation at τ 7.3. Double irradiation at τ 7.3 also spin-decoupled the methyl doublet at τ 9.03 and removed the 5 c.p.s. coupling from the signal for the proton geminal to the acetoxyl group, *indicating that the carbon bearing the methyl group is situated between the carbon carrying the enamine proton and the carbon carrying the acetoxyl group*. Since the signal for the proton geminal to the acetoxyl is further split, part structure **1** is defined.

Part Structure 2

Both alolycopine and *O*-acetylalolycopine show intense absorption at 1715 and 1640 cm^{-1} in the i.r. (Fig. 2) and at 237 mμ in the u.v., consistent with the presence of an α,β-unsaturated cyclopentanone system. Both the position of the u.v. maximum (5) and the intensity of the carbon–carbon double bond absorption in the i.r. (6) indicate that the α,β-unsaturation is

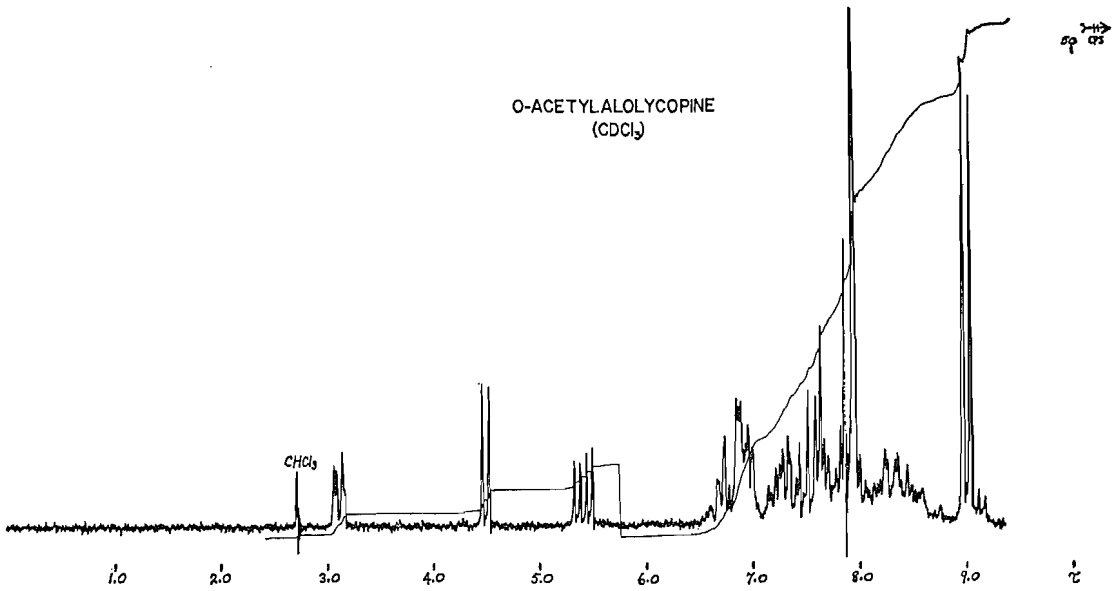

FIG. 1. Nuclear magnetic resonance spectrum (100 Mc.p.s.) of *O*-acetylalolycopine in $CDCl_3$.

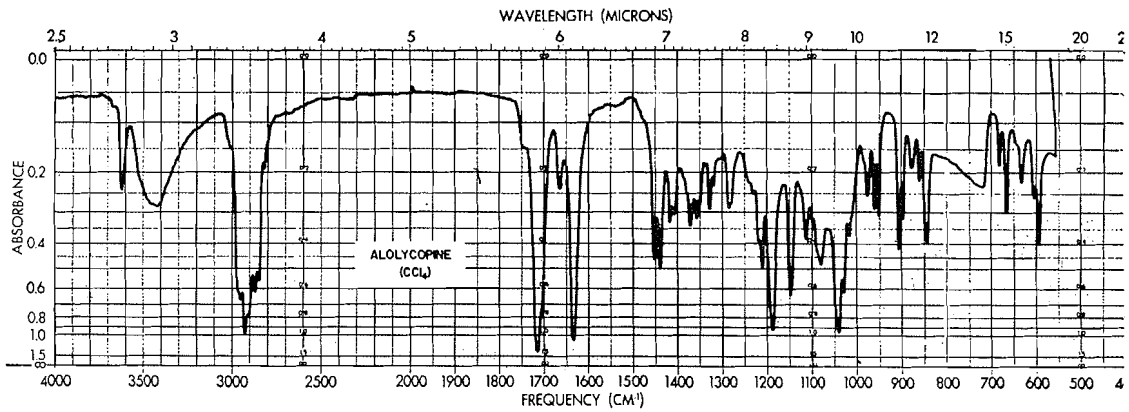

FIG. 2. Infrared spectrum (CCl_4) of alolycopine.

exocyclic to the cyclopentanone ring, and the appearance of a signal at τ 3.18 (quartet, $J = 6$ and 1.5 c.p.s.) in the n.m.r. shows the presence of a β-proton (7). The multiplicity of this signal suggests that the proton is coupled to two vicinal protons, although the possibility of a long range coupling cannot be excluded. The presence of an absorption band at 1410 cm^{-1} in the i.r. spectra of both alolycopine and its acetyl derivative indicates that the carbonyl group is flanked on one side by a methylene group (8).

The part structures **1** and **2** are readily accommodated by a fawcettidine (**3**)-type skeleton, **4**. During the study of the alkaloids serratinine and serratinidine (**5**) Inubushi and co-workers (9) prepared and established the structure of acetylanhydroaposerratinine (**6**). Catalytic hydrogenation of *O*-acetylalolycopine (**4***b*) at atmospheric pressure over palladium–charcoal in methanol gave acetylanhydroaposerratinine (**6**), establishing the structure and stereochemistry of alolycopine as that shown in **4***a*.

Experimental[1]

Alolycopine

Alolycopine, m.p. 53–56°, was isolated as previously described (1). Infrared spectrum: see Fig. 2. Ultraviolet spectrum: λ_{max}(MeOH) 237 mμ (ε 5000). Mass spectrum: *m/e* 259(M^+, 76), 244(15), 242(9), 216(11), 202(9), 188(12), 177(16), 176(100), 175(18), 174(16), 160(22).

O-Acetylalolycopine

O-Acetylalolycopine, m.p. 180–182°, was prepared as described previously (1). Infrared spectrum (Nujol mull): 1740, 1715, 1665, 1640, 1410, 1235 cm^{-1}. Ultraviolet spectrum: λ_{max}(MeOH) 237 mμ (ε 6000). Nuclear magnetic resonance spectrum: see Fig. 1. Mass spectrum: *m/e* 301(M^+, 100), 259(39), 258(26), 242(46), 218(59), 198(24), 176(43), 160(28).

Hydrogenation of O-Acetylalolycopine

O-Acetylalolycopine (25 mg) in methanol (30 ml) was stirred under hydrogen at atmospheric pressure in the presence of 5% palladium-on-charcoal (25 mg) for 2 h. The catalyst was removed by filtration and the solvent evaporated to leave a solid residue which on thin-layer chromatographic (t.l.c.) analysis showed one major component and three minor components. The solid was adsorbed on alumina (1 g) and eluted with ether 10 ml fractions). Fractions 2, 3, and 4 were combined (nd recrystallized from ether to give acetylanhydroaposerratinine (12 mg), m.p. 144–146°, identical (i.r. spectrum, t.l.c. behavior, mixture melting point undepressed) with an authentic sample (9) kindly provided by Professor Y. Inubushi.

[1]The general experimental details are the same as those given in Part 2 of this series (1).

Acknowledgments

We wish to thank Professor Y. Inubushi, Kyoto University, for the sample of acetylanhydroaposerratinine. We are grateful to the National Research Council of Canada and the University of Alberta for financial support of this work.

Tertiary phosphite – alkyl halide reactions in acetonitrile

LANE J. GOODELL AND JOHN T. YOKE
Department of Chemistry, Oregon State University, Corvallis, Oregon 97331

Received February 28, 1969

Olefin elimination does not occur during the interaction of ca. 0.2 *M* triisopropyl phosphite and isopropyl iodide (and of other simple tertiary phosphite – alkyl halide mixtures) in acetonitrile, contrary to a previous report. At and below 50°, the Arbuzov reaction does occur very slowly in these systems. The reaction of trimethyl phosphite and *n*-butyl iodide in acetonitrile gives a larger yield of dimethyl methylphosphonate than of dimethyl *n*-butylphosphonate.

Canadian Journal of Chemistry, 47, 2461 (1969)

There have been several recent kinetic investigations of the Arbuzov reaction

$$(RO)_3P: + R'X \rightarrow R'(RO)_3PX \rightarrow R'P(O)(OR)_2 + RX$$

using dilute solutions in acetonitrile (1, 2). In an infrared (i.r.) spectral study of the triisopropyl phosphite reaction with isopropyl iodide, Aksnes and Aksnes (3) observed that diisopropyl hydrogen phosphonate was formed instead of the Arbuzov product. Propene elimination was postulated to account for this. Olefin elimination from tri-*t*-butyl phosphite to give isobutylene and di-*t*-butyl hydrogen phosphonate has been reported (4) to occur readily either on warming the neat reagent, or (as the major reaction path) in its low temperature Arbuzov reaction with methyl iodide *in the absence of solvent*.

In the present work, several reactions in acetonitrile of tertiary phosphites with alkyl iodides were reinvestigated, with emphasis placed on isolation of products, and especially the detection of any olefins formed. Another aspect of the work dealt with the question of possible competition of the alkyl halide produced in the Arbuzov reaction with a different alkyl halide starting material; the system trimethyl phosphite – *n*-butyl iodide in acetonitrile was chosen for this study.

Experimental

Materials and Equipment

Transfers of reagents to reaction vessels and spectral cells were conducted in a nitrogen-filled dry box. Additions to and separations from reaction mixtures of solvent and volatile reagents, the final purification stages of such reagents, and the reactions themselves were conducted in an all glass high vacuum line in which the residual gas pressure had been reduced to $< 10^{-5}$ Torr.

Acetonitrile was repeatedly shaken with phosphorus(V) oxide, distilled from fresh phosphorus(V) oxide onto calcium hydride, and then redistilled from calcium hydride into the vacuum line. The alkyl iodides were doubly distilled. Trimethyl phosphite (Hooker Chemical Co. and Monsanto Chemical Co. samples) was redistilled in dry nitrogen; nuclear magnetic resonance (n.m.r.) (neat): δ 3.15 (d, J_{POCH} = 11 Hz, OCH_3). Triisopropyl phosphite (Mobil Chemical Co.) was purified as follows. Sodium wire was added to react with any dialkyl hydrogen phosphonate present. After evolution of hydrogen had ceased, the liquid phase was decanted and distilled under reduced pressure in nitrogen using a Nester–Faust Teflon spinning band column. A middle fraction was taken, and then similarly redistilled; n.m.r. (neat): δ 0.98 (d, J = 6 Hz, $CH(CH_3)_2$), 4.05 (m, $CH(CH_3)_2$). Tri-*n*-butyl phosphite (Eastman Kodak) was purified in an identical fashion; n.m.r. (neat): δ 3.59 (m, CH_2O—).

Authentic samples of dialkyl hydrogen phosphonates and dialkyl alkylphosphonates were needed for analytical standards. Commercial samples of the following were redistilled under reduced pressure, with a middle fraction taken: dimethyl hydrogen phosphonate (Mobil Chemical Co. and Monsanto Chemical Co.); n.m.r. (neat): δ 3.55 (J_{POCH} = 12 Hz, OHC_3), 6.55 (d, J_{PH} = 694 Hz, PH); di-*n*-butyl hydrogen phosphonate (Mobil); n.m.r. (neat): δ 3.85 (m, OCH_2), 12.30 (one component of PH doublet, other component obscured by CH_3); dimethyl methylphosphonate (Aldrich); n.m.r. (neat): δ 3.54 (d, J_{POCH} = 12 Hz, OCH_3), 1.32 (d, J_{PCH} = 18 Hz, PCH_3). Diisopropyl hydrogen phosphonate was prepared (3) by boiling triisopropyl phosphite with water in acetonitrile under nitrogen. The solvent and water were stripped off and the product (60%) distilled: b.p. 73–74° (9 mm); n.m.r. (neat): δ 1.07 (d, J = 7 Hz, $CH(CH_3)_2$), 4.50 (m, $CH(CH_3)_2$), 6.78 (d, J_{PH} = 704 Hz, PH). The previously unreported dimethyl *n*-butylphosphonate was prepared by the Arbuzov reaction from neat trimethyl phosphite and *n*-butyl bromide at ca. 110°, with methyl bromide evolved. The product (25%) was distilled: b.p. 76–78° (19 mm); n.m.r. (neat): δ 3.55 (d, J_{POCH} = 11 Hz, OCH_3). Di-*n*-butyl ethylphosphonate was synthesized by treating di-*n*-butyl hydrogen phosphonate in hexane first with sodium and then with ethyl bromide. The reaction mixture was washed with water to remove sodium bromide, the solvent was stripped off, and the product (60%) was distilled under reduced pressure using a spinning band column; n_D^{25} 1.4258 [lit. (5), n_D^{25} 1.4258]; n.m.r. (neat): δ 3.86 (m, OCH_2). An attempted synthesis of diisopropyl isopropylphosphonate by the Arbuzov reaction using neat triisopropyl phosphite and isopropyl bromide was unsuccessful. However, a sample was obtained in very low yield after heating a mixture of 50 ml of triisopropyl phosphite, 25 ml of isopropyl bromide,

and a trace of iodine in 200 ml of purified anhydrous acetonitrile at 78° for 10 days. The solvent and unreacted isopropyl bromide were stripped off and the residue was distilled. Most of the starting phosphite was recovered: b.p. 64–69° (11.5 mm), and then a small fraction (6%) of the desired product was collected: b.p. 92° (11.5 mm); infrared (i.r.): (CCl_4) 1202 and 1242 cm^{-1} (P=O); n.m.r. (neat): δ 4.46 (m, $\text{C}H(\text{CH}_3)_2$), 1.14 (d, J = 5 Hz, $\text{OCH}(\text{C}H_3)_2$), 0.82 (d, J = 6 Hz, $\text{PCH}(\text{C}H_3)_2$). The ratio of the (planimeter) integrated intensities of the latter two doublets was 1.8 ± 0.2, theory 2.0.

An F and M model 700 chromatograph was used for gas–liquid chromatography (g.l.c.) analyses, with dual 6 ft stainless steel columns and helium as the carrier gas. Two sets of columns were used: (*A*) 1/8 in., 10% silicone oil W98 on 80–100 mesh Chromosorb W; (*B*) 1/4 in., 20% Reoplex 400 on 30–60 mesh Chromosorb W. Spectra were obtained with a Varian A-60 proton n.m.r. spectrometer and a Beckman Microspec double beam recording i.r. spectrophotometer.

Reaction Studies

For each tertiary phosphite – alkyl iodide combination studied, the reaction flask was connected through the vacuum system to a manometer and gas storage bulb. The reaction conditions, degrees of conversion, and analytical observations are indicated in Table I. For each system, the vapor pressure of the reaction mixture remained constant during the entire period, and the equilibrium pressure dropped to < 1 mm when the reaction was terminated by quenching to −63.5°. The i.r. and g.l.c. analyses involved comparison of the acetonitrile reaction solutions with acetonitrile solutions of the reference standards. Where quantitative i.r. spectrophotometric analysis is indicated, the validity of Beer's Law and the lack of interference by other components had been established. Nuclear magnetic resonance spectra were obtained on the neat residues remaining after distillation of the volatile solvent and alkyl halides in the vacuum line.

Results and Discussion

The Arbuzov reactions of aliphatic tertiary phosphites and iodides in dilute solution in acetonitrile at and below 50° are very slow. In each of the systems studied, the major portions of the starting materials were recovered unchanged after a week or more. A previous report (1) of more rapid reaction in such systems has been attributed (2) to possible contamination of the solvent by traces of water. The present experimental results definitely prove that no olefin was formed in any of the systems studied, including the triisopropyl phosphite – isopropyl iodide system in which propene elimination had been postulated (3). The report of the formation of diisopropyl hydrogen phosphonate in that study (3) presumably may also be attributed to impurities in the solvent.[1]

That polar solvents may be of practical synthetic value as Arbuzov reaction media is suggested by the present work. Under typical synthetic conditions (neat reagents at reflux), triisopropyl phosphite and isopropyl bromide gave no reaction. When the reaction was conducted in acetonitrile at reflux, diisopropyl isopropylphosphonate slowly formed. The use of a higher boiling solvent should provide a more practical synthetic method for sterically hindered phosphonates. Alternatively, photolysis has been

[1]G. Aksnes. Personal communication.

For personal use only.

used (6) to generate diisopropyl isopropylphosphonate from the tertiary phosphite.

An explanation for this effect of a polar solvent may be suggested. Aksnes and Aksnes have reported (2) that the first step of the reaction is rate-determining in acetonitrile. That the second step is normally rate-determining is indicated by the isolation of the intermediate in aliphatic (7) as well as aromatic systems. The presence of a polar solvent would markedly increase (7) the ionic dissociation of a phosphorane or ion-paired phosphonium halide intermediate. The change in kinetics and the reduction in steric hindrance may both be attributed to this change in the structure of the intermediate.

Additional evidence is the formation of five times as much dimethyl methylphosphonate as dimethyl *n*-butylphosphonate, in the reaction of trimethyl phosphite with *n*-butyl iodide in acetonitrile. In the absence of a solvent, such competition of an alkyl halide product with a different alkyl halide starting material is not a practical problem. To the extent that formation of the intermediate is the fast step (and irreversible), the tertiary phosphite would no longer be available. Even in acetonitrile, the effect is not seen unless the alkyl halide formed is significantly more reactive; thus no mixed products were observed in the tri-*n*-butyl phosphite–ethyl iodide system.

Optical rotatory dispersion studies of 2*H*-naphtho(1,8-*bc*)- and naphtho(2,3-*b*)furan derivatives

P. Joseph-Nathan and Ma. P. González[1]

Departamento de Química del Centro de Investigación y de Estudios Avanzados, Instituto Politécnico Nacional, P.O. Box 14-740, Mexico City, Mexico

Received December 20, 1968

The study of the optical rotatory dispersion (o.r.d.) curves of some derivatives of the title systems, possessing various degrees of oxidation which contain asymmetrical centers near the chromophores, permits correlations between Cotton effects and stereochemistry. The configurations of those asymmetrical centers not known earlier, have been determined with the aid of the o.r.d. curves.

Canadian Journal of Chemistry, **47**, 2465 (1969)

The appearance of papers dealing with the use of optical rotatory dispersion (o.r.d.) and circular dichroism (c.d.) for studying the behavior of aromatic compounds with asymmetrical centers in the vicinity of their chromophores, has increased in the last years due to the advent of instruments capable of measuring optical activity to below 200 mμ (for a recent survey see ref. 2). However, the Cotton effects exhibited by many optically active aromatic substances, have not as yet been studied adequately (3–8). Therefore, we describe the o.r.d. spectra of some derivatives of the 2*H*-naphtho(1,8-*bc*)- and the naphtho(2,3-*b*)-furan systems, which were obtained during the elucidation of structures and chemical behavior of some Mexican natural products. Some of the substances studied here, should later be useful as o.r.d. models for other compounds, since they have small conformational flexibilities, and with few exceptions, their stereochemistry is known through independent chemical work.

According to the definitions of aromatic structures given by Crabbé and Klyne (2), the derivatives of the naphthofuran systems possess arylic heteroatoms and benzylic asymmetrical centers. Simultaneously such compounds as cacalone (**2***a*) and perezinone dibenzoate (**4**) can be classified as containing inherently dissymmetric chromophores. Some of the compounds contain quinonoid type rings which have not been considered adequately (2). We propose that the definitions of structures given recently (2) should be extended to quinones, which can be considered as aromatic compounds, since there is a measurable degree of cyclic delocalization of π-electrons (9).

[1]Taken in part from ref. 1.

Another important analogy between the compounds is that they possess a methyl group inserted in an asymmetrical center located α to the chromophore. Its configuration has been established in all compounds by degradative oxidation and chemical correlation (10–15). Application of the Sequence Rule (16) shows that in all cases, the methyl group is located in an asymmetrical center with absolute configuration (*R*). In addition, compounds **7** to **9** possess a second center of asymmetry, whose configuration was determined from the o.r.d. data.

It is well known that aromatic compounds show three major transitions in the ultraviolet (u.v.) region, two of which are strong absorptions near 180 and 200 mμ, and the third a weak one, generally with considerable fine structure, at about 260 mμ. We shall refer to the last one, known as the ^1L_b band in the Platt notation (17), since in dissymmetric aromatic compounds this π–π* transition is optically active.

Cacalol (**1***a*), cacalol acetate (**1***b*), and methyl cacalol (**1***c*) show very similar isotropic absorption spectra and similar o.r.d. curves (Fig. 1). They contain asymmetrical chromophores (the benzofuran system) which are dissymmetrically perturbed by the methyl group. The π–π* transition of their hexasubstituted benzene ring (near 260 mμ) is associated with strong positive Cotton effects with some fine structure, whose amplitude ranges between 169 in cacalol acetate (**1***b*) and 207 in methyl cacalol (**1***c*). The nearest analogy to this behavior appears to be shown by some 1-substituted indanes (18) with an absolute configuration (*R*), which give rise to weak positive Cotton effects with similar fine structures as compounds **1***a*, **1***b*, and **1***c* in the 260–270 mμ region. However, no Cotton effect was observed in the

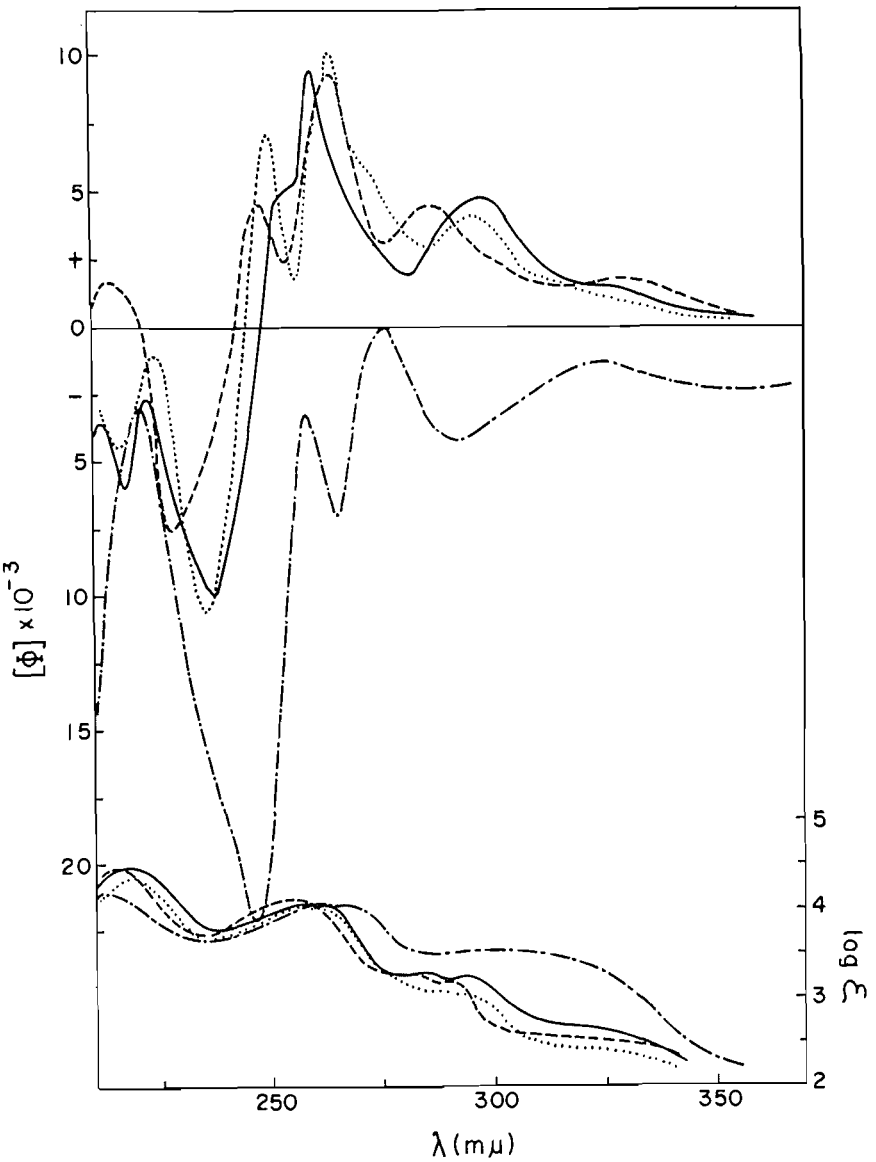

FIG. 1. The optical rotatory dispersion (in MeOH) and ultraviolet (in EtOH) curves of cacalol (**1***a*,———), cacalol acetate (**1***b*, - - - - -), methyl cacalol (**1***c*, ...), and the norquinone **3** (—.—.—.—.). (Ultraviolet spectra determined in MeOH are similar to those depicted. See Experimental.)

o.r.d. curve of (*R*)-1-methyl-indane (18). This fact, as well as the differences in the intensities of the Cotton effects, can be justified since cacalol (**1***a*) and its derivatives (**1***b* and **1***c*) possess two heterosubstituents on the aromatic ring itself, which appear to be necessary to provide an optically active transition of high intensity (19).

The o.r.d. curve (Fig. 1) of the norquinone (**3**) obtained by oxidation of cacalol (**1***a*) (10, 11) showed a negative Cotton effect in the 300 mμ region. The absolute configuration of its asymmetrical center must be the same (*R*) as that of its precursor (**1***a*), since this center is not affected during oxidation. This is demonstrated by the

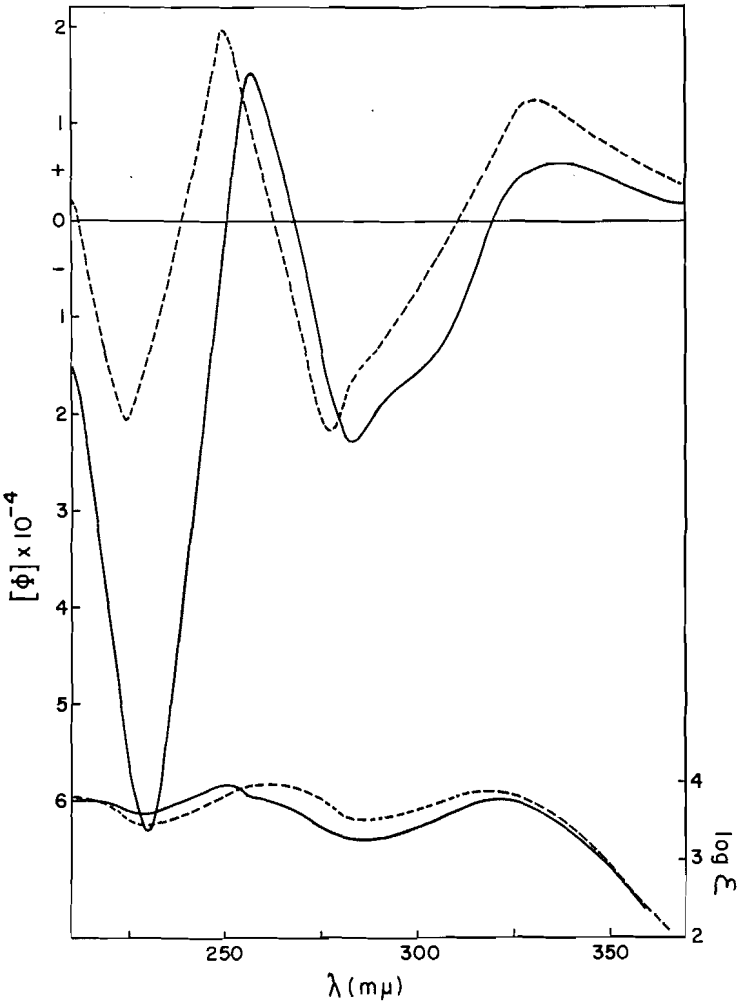

FIG. 2. The optical rotatory dispersion (in MeOH) and ultraviolet (in EtOH) curves of cacalone (**2***a*, ———) and cacalone acetate (**2***b*, - - - - -). (Ultraviolet spectra determined in MeOH are similar to those depicted. See Experimental.)

fact that some *p*-quinones possessing a center of asymmetry with absolute configuration (*R*) in the vicinity of their chromophores, give rise to negative Cotton effects in the 300 mμ region (20, 21), and the o.r.d. curve of the norquinone (**3**) resembles to some extent that of a *p*-quinone obtained by oxidation of latifolin (22).

Cacalone (**2***a*) and its acetate (**2***b*) belong to the class of compounds possessing inherently dissymmetric chromophores (2), since a carbonyl group is conjugated with the benzofuran system. They contain two optically active transitions in the u.v. region, each with positive Cotton effects, the first (near 320 mμ) being due to the carbonyl group (Fig. 2) and the second to the ^1L_b band of the aromatic moiety. Although some o.r.d. studies of substituted 1-tetralones have been described (23, 24), since their true aromatic Cotton effects have not been reached due to equipment limitations, and since they possess (23, 24) more than one asymmetric center near the chromophore, they are not suitable models for the natural product (**2***a*) and its acetate (**2***b*), which have only one center of asymmetry.

However, as in the case of compounds **1***a*, **1***b*, and **1***c*, the ^1L_b transition of cacalone (**2***a*) and its acetate (**2***b*) displayed positive Cotton effects.

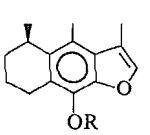
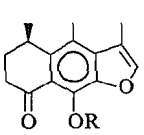
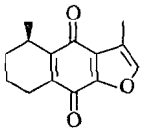
NOTE ADDED IN PROOF: Very recent evidence (28)[2] implies that the structure of compounds **1** to **3** are as shown:



1



2

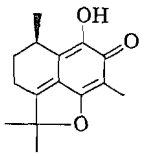


3

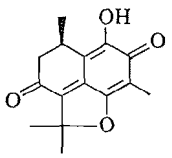
The change in position of the methyl group does not affect either the assignments or conclusions of the present work.

Another type of inherently dissymmetric chromophore having only one asymmetrical center is represented by perezinone dibenzoate (**4**). Its u.v. spectrum showed (12) three major transitions ca. 235, 270, and 325 mμ; the first and second bands contain isotropic absorption contributions from the benzoate aromatic rings (25) whereas the second and third bands are optically active. The positive Cotton effect associated with the 270 mμ band can be rationalized in terms of the ^1L_b band of the aromatic ring, since this transition is perturbed by the (*R*)-methyl group in a similar way as in the naphtho(2,3-*b*)furan derivatives **1***a*, **1***b*, and **1***c*.

Valuable information could be obtained from the o.r.d. curves of the hydroxyquinonemethide perezinone (**5**) and of the hydroxydihydro-*amphi*-quinone oxoperezinone (**6**). Their isotropic absorption and o.r.d. spectra are shown in Fig. 3. The o.r.d. curves reveal that their transitions are optically active, having negative Cotton effects with fine structure. This fact is in excellent accord with the o.r.d. curve of the norquinone (**3**) which also gave a negative Cotton effect (*vide supra*), since the three quinones (**3**, **5**, and **6**) possess a methyl group with absolute configuration (*R*) located *alpha* to the chromophore.



5



6

Hydrogenation of perezinone (**5**) (13) and oxoperezinone (**6**) (12) in the presence of Ac_2O afforded the diacetates **7** and **8** respectively, whereas *m*-chloroperbenzoic acid treatment of perezinone dibenzoate (**4**) gave compound **9** (12). The three reaction products contain in addition to the (*R*)-methyl group a second center of asymmetry which is also located *alpha* to the aromatic ring. Its configuration is deduced from the o.r.d. data as follows: the ^1L_b band of leuco-dihydroperezinone diacetate (**7**) shows a negative Cotton effect (26) in contrast to the positive ones displayed by the furotetralin derivatives **1***a*, **1***b*, and **1***c* which contain only the methyl group located at a center of asymmetry. After considering that in compound **7** the carbon having the *gem*-dimethyl group contributes more to the Cotton effect due to its size than the C-5 methyl group, the only way to explain the ^1L_b negative transition is to assume that the second asymmetrical center possesses an absolute configuration (*S*). During the transformation of **5** into **7**, hydrogen would be expected to attack the under, less hindered side of the molecule since the methyl group on the upper side hinders its approach. This was indeed observed, in good agreement with the Cotton effects. On the other hand, since compounds **7** and **8** were obtained from **5** and **6** under identical reaction conditions, and had similar geometry, the new asymmetric center in the products should have the same configuration. This can be proved easily by applying the octant rule (3, 6) to the keto group of leuco-dihydro-

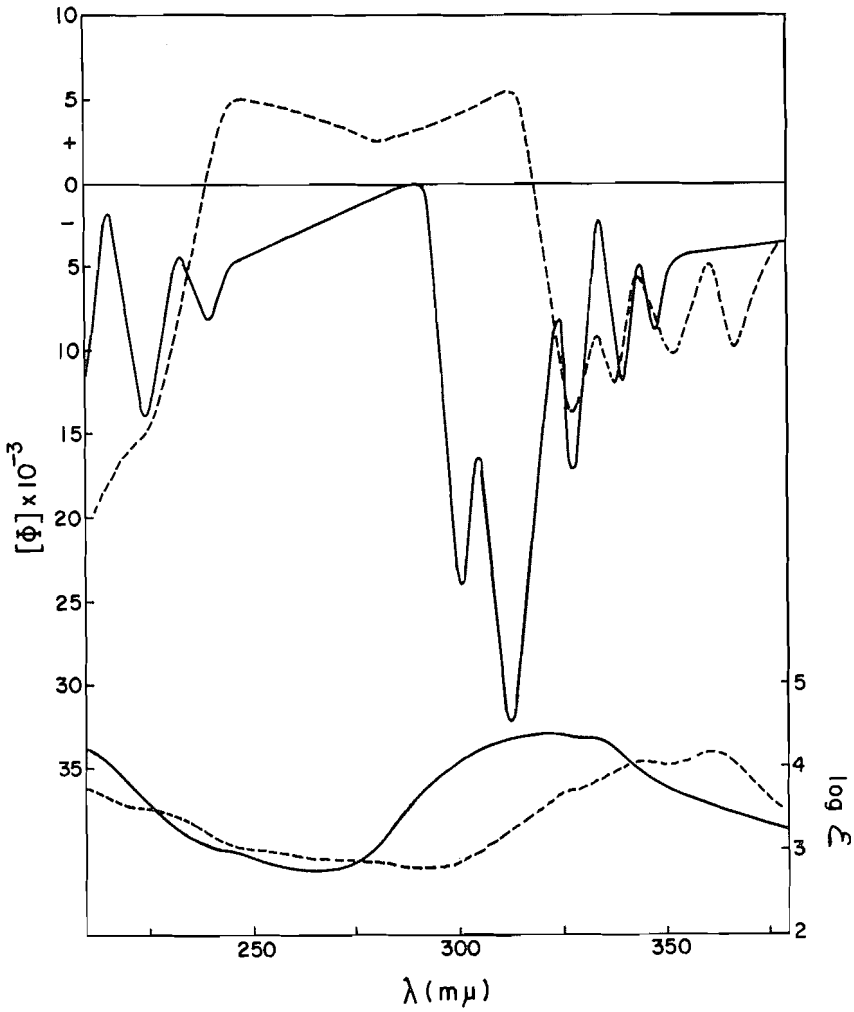

FIG. 3. The optical rotatory dispersion (in MeOH) and ultraviolet (in EtOH) curves of perezinone (**5**, ———) and oxoperezinone (**6**, ----). (Ultraviolet spectra determined in MeOH are similar to those depicted. See Experimental.)

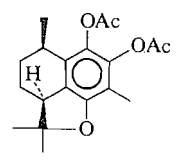
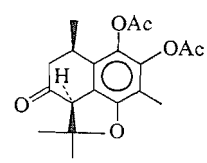
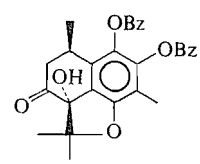
öxoperezinone diacetate (**8**). Construction of Dreiding models reveals that when the hydrogen atom at the new asymmetric center is *beta* (absolute configuration (*R*)) the transition of the carbonyl group should give a negative Cotton effect, whereas an absolute configuration (*S*) would give a positive one. The o.r.d. curve of **8** displayed a weak positive Cotton effect with fine structure in the 320 mμ region. Furthermore the ^1L_b transition of the aromatic ring again showed a negative Cotton effect as in the case of the diacetate (**7**). It is also very reasonable that the Cotton effect in the 320 mμ region **8** is a weak one, since necessarily an equatorial or *quasi*-equatorial



7



8



9

bond of the tetrahydrobenzene ring must be used for the junction to the furan ring.

The fact that compound **9** showed a strong positive Cotton effect with similar fine structure as **8** in the 320 mμ region is also congruent with the above observations. This can only be explained adequately in terms of formula **9** after proper application of the octant rule, since the reverse stereochemistry at the carbon having the hydroxyl group, leads to a negative Cotton effect. The higher intensity of the Cotton effect associated with the 320 mμ band of **9** compared to **8**, is due to the presence of the axial hydroxyl group since it is well known (3, 6) that axial substituents *alpha* to carbonyl contribute much more to Cotton effects than equatorial ones, and **9** has both axial and equatorial substituents, whereas **8** possesses only an equatorial one. In addition the ^1L_b band of compounds **8** and **9**, as expected from the observations described herein, give negative Cotton effects.

We can tentatively conclude that asymmetric centers located on the aliphatic ring *alpha* to the aromatic ring in tetralins, will show positive Cotton effects associated to the aromatic ^1L_b transitions, when the absolute configuration is (*R*); whereas if the absolute configuration is (*S*), these tetralins will show negative Cotton effects. It is also apparent that when the aromatic ring of a tetralin has quinonoid character, an asymmetric center located in the aliphatic ring *alpha* to the oxidized ring, gives rise to negative Cotton effects in the 300–320 mμ region when its absolute configuration is (*R*). However, these conclusions must be applied with care until more data are available. It would be helpful to study this type of compounds by c.d., but unfortunately we do not have access to such equipment.

The conformation of the aliphatic ring of all compounds, has recently been determined by 100 MHz double nuclear magnetic resonance spectroscopy (27).

Experimental

Materials

All derivatives of the naphtho(2,3-*b*)furan system were isolated or prepared as described (10, 11) for the structural elucidation of cacalol (**1***a*) and cacalone (**2***a*) and the 2*H*-naphtho(1,8-*bc*)furan derivatives were obtained as published recently (12, 13).

Measurements

The ultraviolet (u.v.) spectra of perezinone (**5**) and its derivatives were taken from the recent published data (12), whereas those of the naphtho(2,3-*b*)furan were repeated on Unicam SP800 in ethanolic solutions. They are plotted in Figs. 1 and 2 and are in good agreement with earlier reported values (10, 11).

For elegance in comparison between u.v. and optical rotatory dispersion (o.r.d.) spectra, the former were also determined in methanolic solutions and the pertinent data are given in this section.

A detailed comparison of the u.v. curves determined in MeOH, with those obtained in EtOH, reveals that solvent effects are negligible.

The o.r.d. curves were obtained with a JASCO ORD/UV-5 spectropolarimeter using JASCO 10 mm path dismountable Teflon cell in methanolic solutions between 22 and 26°.

Nuclear magnetic resonance studies of hydrogen bonding in acetylenes containing oxygen functions[1]

W. E. BENTZ[2] AND L. D. COLEBROOK
Department of Chemistry, University of Rochester, Rochester, New York 14627

Received August 16, 1968

Dilution shifts in carbon tetrachloride and cyclohexane solution have been obtained for the terminal acetylenic proton signals in the nuclear magnetic resonance (n.m.r.) spectra of some acetylenes. The presence of an oxygen atom results in a significant increase in the magnitude of the dilution shift, suggesting that oxygen is an important proton acceptor site in these compounds. Steric influences on the dilution shift and differences between the infinite dilution chemical shifts in the two solvents used, have been observed.

Canadian Journal of Chemistry, 47, 2473 (1969)

It has been known for some time that compounds with terminal acetylene groups are capable of forming hydrogen bonds between the slightly acidic acetylenic hydrogen atom and electron donor groups. Weak hydrogen bonds of this type are amenable to study by nuclear magnetic resonance (n.m.r.) methods and several reports of work in this area have appeared (1).

Hatton and Richards (2) have examined the n.m.r. spectra of propargyl chloride, phenylacetylene (3), and benzoylacetylene in various solvents. They found that dilution with a poor electron donor solvent, such as cyclohexane, resulted in a small upfield shift of the acetylenic proton line position. It was assumed that, at infinite dilution in cyclohexane, acetylene–acetylene interactions were at a minimum. The lower field position of the acetylene proton resonance in the neat liquid was taken as evidence for deshielding produced by weak intermolecular hydrogen bonding between the acetylenic protons and the π-electron system. Whipple and co-workers (3) obtained comparable results when studying the spectrum of propargyl bromide in similar solvents.

Elsakov and Petrov (4, 5) have studied the dilution shifts in carbon tetrachloride of a number of acetylenes, including one containing an ether oxygen atom. Their results suggested that hydrogen bonding may be more extensive in acetylenes containing oxygen than in the corresponding hydrocarbons.

In order to obtain more information on the chemical shifts of acetylenic protons than has been available in the literature, we have undertaken a study to ascertain the extent to which the presence of an oxygen atom influences the magnitude of the dilution shift. Carbon tetrachloride was selected as the main solvent since it is a poor proton acceptor and it is a commonly used solvent for n.m.r. studies. However, in a study of the O—H stretching frequencies of a number of alcohols in several solvents, Allerhand and Schleyer (6) have found that $\Delta\nu = \nu_{\text{"free"}} - \nu_{H\text{-bonded}}$ is larger in carbon tetrachloride than in cyclohexane. Since $\nu_{\text{"free"}}$ and $\nu_{H\text{-bonded}}$ were found to be shifted to different extents in going from cyclohexane to carbon tetrachloride, these authors concluded that the latter solvent must interact in some specific way with solute molecules, and thus is not a totally "inert" solvent. Schaefer *et al.* (7) have also reported results which they interpret as evidence for a solvent effect on proton chemical shifts by carbon tetrachloride as compared to cyclohexane. For these reasons we have also determined the dilution shifts of some of the acetylenes in the apparently "more inert" solvent cyclohexane. The chemical shifts of the acetylenic protons of a number of compounds, some with oxygen atoms and some without, were measured as a function of concentration in carbon tetrachloride and cyclohexane. Concentrations in both solvents ranged from almost neat liquids to the lowest mole fraction which yielded spectra that could be measured with tolerable accuracy. The dilution curves obtained in this way were extrapolated to mole fractions of 1.00 and 0.00 (see Fig. 1 for carbon tetrachloride dilution curves). Extrapolation error was small because in no case was

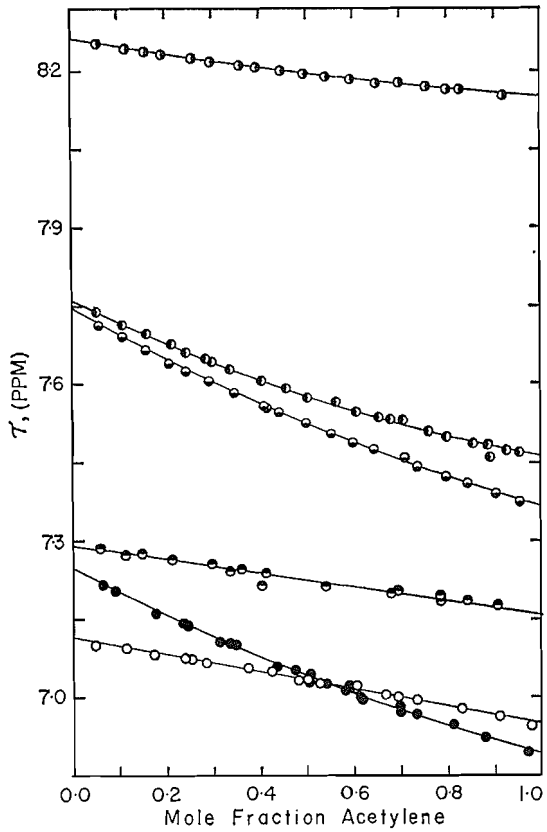

FIG. 1. Chemical shift vs. concentration in carbon tetrachloride solution of acetylenic protons: ◑, compound **1**; ◓, compound **2**; ○, compound **3**; ●, compound **4**; ◐, compound **5**; ◒, compound **6**. See Table I.

the curvature of the plot very great. The chemical shifts of the neat liquids and of the infinitely dilute solutions in carbon tetrachloride and cyclohexane are shown in Table I. Some data from ref. 2 are included for comparison purposes. Internal references were used in all cases.

Measurement of Spectra

All samples were prepared by weighing an appropriate amount of the acetylene directly into the sample tube. Carbon tetrachloride samples were prepared by weighing a solution of 5 or 15% of tetramethylsilane in the solvent into the tube. Cyclohexane solutions of **6** (see Table I) were prepared similarly, while samples of **2** and **3** were prepared without the addition of tetramethylsilane. The weight of tetramethylsilane was taken into account in calculating the mole fractions, which were accurate to ±0.003 or better. Analytical grade carbon tetrachloride and cyclohexane were dried by standing over Fisher type 4A molecular sieve before use.

The spectra of compounds **1**, **5**, and **6** in carbon tetrachloride and **2**, **3**, and **6** in cyclohexane were determined using a JEOLCO 4H-100 spectrometer operating at 100 MHz. Line positions, accurate to ±0.1 Hz, were measured directly from the recorded peak maxima using the internal frequency counter. The spectra of compound **2** in carbon tetrachloride were determined with a Varian HR-60 spectrometer and the spectra of compounds **3** and **4** in carbon tetrachloride with an A-60 spectrometer, both instruments operating at 60 MHz. Line positions were measured by the sideband method, using a Hewlett Packard 200 CD audio oscillator and a CMC 201 B frequency counter, to an accuracy of ±0.2 Hz.

Results and Discussion

Weak hydrogen bonds of the type studied in this project must be considered as transient on the n.m.r. time scale. At a given instant some molecules will be bonded and some will be "free". When several electron donor sites exist (as many as three in the current series), acetylenic protons will be present in a number of hydrogen-bonded complexes as well as in the "free" or unassociated state. The observed time-averaged chemical shift must be dependent on the chemical shift of protons in each of the environments, and on the relative numbers of protons in each state. If the chemical shift at infinite dilution is the true "free" chemical shift then the observed dilution shift (the difference between the chemical shift of the neat liquid and that of the infinitely dilute solution) will be a measure of the net effect of the factors which displace the chemical shift from its "free" value. If the solvent is not completely "inert", as may be the case with carbon tetrachloride, the chemical shift of acetylene molecules bonded to solvent molecules will also influence the resultant chemical shift. A change in molecular structure which alters the chemical shift of protons bound at a particular site, or which affects the relative numbers of molecules bound at that and other sites, may be expected to influence the resultant chemical shift.

Compounds **1**–**6** may be grouped into two distinct classes on the basis of their dilution

TABLE I

Acetylene proton dilution shifts

No.	Compound	Solvent	Infinite dilution (τ)	Neat liquid (τ)	Dilution shift (Δτ, p.p.m.)
1	$CH_3(CH_2)_5C{\equiv}CH$	CCl_4	8.262	8.150	0.112
2	$CH_2{=}C(CH_3)C{\equiv}CH$	CCl_4	7.290	7.162	0.128
		C_6H_{12}	7.388	7.150	0.238
3	$C_6H_5C{\equiv}CH$	CCl_4	7.115	6.950	0.165
		C_6H_{12}	7.203	6.935	0.268
		C_6H_{12}	7.26*	6.91*	0.35*
4	*cis*-$CH_3OCH{=}CHC{\equiv}CH$	CCl_4	7.247	6.894	0.353
5	$CH_3OC(CH_3)_2C{\equiv}CH$	CCl_4	7.764	7.458	0.306
6	$CH_3OCH_2C{\equiv}CH$	CCl_4	7.750	7.388	0.362

*See ref. 2.

shifts in carbon tetrachloride solution. The hydrocarbons show dilution shifts of less than 0.2 p.p.m. whereas the compounds containing oxygen show dilution shifts greater than 0.3 p.p.m. (Table I). The magnitude of the dilution shift is an unreliable indication of the strength of the hydrogen bonds since the chemical shift of a bonded hydrogen atom is determined by magnetic anisotropy as well as by the electron polarization produced by bond formation. However, the greater dilution shift (by a factor of 2 to 3 or more) when an oxygen atom is present in the molecule suggests that this atom can be an important proton acceptor site in these compounds. The presence of an oxygen atom may also influence the extent of hydrogen bonding at other electron donor sites.

Compounds **2**, **3**, and **6** were also examined in cyclohexane solution (Table I). Compounds **2** and **6** were selected for this study to determine whether or not the large difference in dilution shift between compounds with and without oxygen functions is also observable in this solvent. A logical choice for a non-oxygen containing acetylene would have been **1**, but the acetylenic proton of this compound absorbs too close to the cyclohexane solvent line position for accurate analysis. Compound **3** was reinvestigated in this solvent because its dilution shift in cyclohexane reported by Hatton and Richards (2) was more than double that found in this laboratory for carbon tetrachloride solutions.

The dilution shifts of both **2** and **6** were found to be increased by approximately 0.12 p.p.m. in cyclohexane as compared to carbon tetrachloride. Compound **6** still shows a shift larger by a factor of 2 than that of **2**, which supports the inference that the oxygen atom is a major electron donor in hydrogen bond formation in these compounds. In this respect, the results are the same in the two solvents. The dilution shift of **3** is also increased in cyclohexane compared to that in carbon tetrachloride. However, the shift was not found to be as large as that reported previously by Hatton and Richards.

In all cases the differences between the dilution shifts in the two solvents result from the infinite dilution chemical shifts in cyclohexane being at higher field than those seen in carbon tetrachloride. The small differences in the chemical shifts reported for the neat solutions in Table I reflect extrapolation errors. These results imply that carbon tetrachloride undergoes some type of specific association with the acetylene molecules, which causes a small downfield shift in the acetylenic proton signals.

Steric factors which hinder the approach of an acetylenic hydrogen atom to a donor site may be expected to reduce the magnitude of the dilution shift. This steric effect is likely to be particularly marked if a major bonding site which makes an important contribution to the total chemical shift is affected. This situation is well illustrated by a comparison of the dilution shifts in carbon tetrachloride of 3-methoxy-1-propyne (**6**), and 3-methyl-3-methoxy-1-butyne (**5**). These two compounds have the same carbon skeleton but differ in that **5** has two methyl substituents on C-3. Since the infinite dilution chemical shifts of these compounds are very similar, it is clear that the structural differences have little

direct effect on the shielding of the acetylenic proton. The two methyl groups on the carbon bearing the oxygen atom in **5** should be expected to hinder the approach of another molecule of the acetylene, particularly to the bonding site on oxygen. It is found that the dilution shift of the more hindered compound, **5**, is about 15% smaller than that of the less hindered compound **6**, in accord with this prediction. The dilution shift of **5** is also substantially smaller than that of compound **4**, which is relatively unhindered.

Introduction of a double bond has little effect on the dilution shift in carbon tetrachloride. Elsakov and Petrov have noted (4) that conjugation of a double bond with the acetylenic triple bond has only a small effect on the magnitude of the shift. The presence of the phenyl group conjugated with the triple bond in **3** results in a more marked increase in the magnitude of the dilution shift. Interpretation of the shift in this case is complicated by the effect of the anisotropy of the aromatic ring.

Elsakov and Petrov (4, 5) have reported dilution shifts in carbon tetrachloride for compound **2** ($\Delta\tau = 0.16$ p.p.m.) and compound **4** ($\Delta\tau = 0.28$ p.p.m.), plus the additional compounds vinylacetylene ($\Delta\tau = 0.09$ p.p.m.) and 3-methyl-1-butyne ($\Delta\tau = 0.07$ p.p.m.). The last compound would be expected to show a dilution shift similar to that observed for 1-octyne, (**1**), in this laboratory. The agreement is reasonable, but not excellent. While the reported dilution shifts for compounds **2** and **4** are in general agreement with our results, they differ somewhat in magnitude. Experimental data obtained at the lower concentrations contain the main source of the discrepancies. The dilution shift reported for compound **4** is smaller than we obtained and tends to de-emphasize the role of oxygen as a proton acceptor site. Data reported by these authors were obtained from a much smaller number of measurements than were made in the present study.

Jouve (8) has determined the chemical shifts at infinite dilution in carbon tetrachloride of a number of terminal acetylenes and has presented an explanation of these shifts in terms of the molecular environment of the acetylenic protons. The reported infinite dilution chemical shifts of several straight chain terminal acetylenes (C-3 to C-7) show close agreement with the value obtained in this laboratory for 1-octyne. From the information now available it may be concluded that the chemical shift at infinite dilution in carbon tetrachloride of the acetylenic proton in compounds of this type is likely to fall in the range τ 8.24–8.27. Jouve has also reported infinite dilution chemical shifts for compounds **2**, **3**, and **6** in carbon tetrachloride differing by no more than 0.04 p.p.m. from the values obtained in this laboratory. The experimental data now available are adequate to indicate the approximate range within which the acetylenic protons of a variety of compounds may be expected to absorb in carbon tetrachloride solution. By combining the infinite dilution chemical shifts given in ref. 8 with the dilution shifts of representative compounds given in Table I and in refs. 4 and 5, it should be possible to make a reasonably satisfactory prediction of the chemical shifts of the acetylenic protons of many compounds at typical concentrations in carbon tetrachloride solution.

Hatton and Richards (2) have observed that the methylene protons of propargyl chloride were shifted by 0.26 p.p.m. when this compound was diluted with cyclohexane. We have observed a similar effect when compound **4** is diluted with carbon tetrachloride, the lines arising from the protons on the double bond undergoing an upfield shift (Table II). The chemical shift of the protons of the methyl group in this compound is essentially independent of concentration.

Experimental

Boiling points are uncorrected.

1-Octyne (1)

1-Octyne was obtained from Chemical Procurement Laboratories. Before use it was distilled twice, yielding a colorless liquid, b.p. 125–127°, n_D^{26} 1.4165. Samples with mole fractions of 0.056–0.920 were prepared in carbon tetrachloride and the chemical shift of the acetylenic proton from an internal TMS lock was measured. The position of the center peak of the triplet arising from the acetylene proton was taken as the chemical shift.

TABLE II

Vinyl proton chemical shifts of *cis*-methoxy-1-butene-3-yne (**4**) (carbon tetrachloride solutions)

Proton	Infinite dilution (τ)	Neat liquid (τ)	Dilution shift ($\Delta\tau$, p.p.m.)
C_2-H	5.647	5.558	0.089
C_1-H	3.824	3.616	0.208

2-Methyl-1-butene-3-yne (2)

Compound **2**, obtained from the Aldrich Chemical Company, was distilled before use. The colorless distillate, b.p. 33–34°, n_D^{25} 1.4123, was used to prepare samples with mole fractions of 0.060–0.908 in carbon tetrachloride. The chemical shift from TMS of the broad acetylenic singlet was measured. Samples of mole fraction 0.084–0.897 were prepared using cyclohexane as solvent. The position of the broad acetylenic singlet relative to cyclohexane was determined. This shift was then added to the slightly concentration dependent cyclohexane–TMS separation for the concentration in question in order to obtain the chemical shift relative to TMS.

Phenylacetylene (3)

This compound was obtained from Eastman Organic Chemicals Company and was distilled before use, yielding a colorless distillate, b.p. 138.5–139.5°, n_D^{26} 1.5461. Samples with mole fractions of 0.048–0.980 were prepared with carbon tetrachloride as solvent. The position of the acetylenic proton singlet relative to TMS was measured. Samples with mole fractions of 0.086–0.964 were prepared in cyclohexane. In this case the acetylene–cyclohexane separation was measured. This was then added to the concentration dependent cyclohexane–TMS separation to obtain the acetylene–TMS separation.

cis-1-Methoxy-1-butene-3-yne (4)

This compound was obtained from the Aldrich Chemical Company as an 80% solution in methanol. Fractional distillation in small quantities immediately before use yielded a colorless liquid, b.p. 59–61° (60 mm), n_D^{24} 1.4789. Samples with mole fractions of 0.066–0.975 in carbon tetrachloride solution were analyzed. The position of the highest field member of each acetylenic and olefinic proton quartet was measured with respect to TMS. Chemical shifts for each proton were taken to be the centers of the respective quartets.

3-Methoxy-3-methyl-1-butyne (5)

This compound was prepared in a manner similar to that of Kreevoy *et al.* (9). The entire reaction was carried out at 0 °C. 48 ml (0.15 mole) of dimethyl sulfate (Eastman Organic Chemicals practical grade) were added with stirring to a mixture of 42 g (0.50 mole) of 2-methyl-3-butyne-2-ol (Eastman Organic Chemicals practical grade), 53 ml of water, and 5 g of 50% sodium hydroxide solution. To this an additional 50 g of 50% sodium hydroxide solution (a total of 0.69 mole) were added slowly over a period of several hours. The upper layer of the resulting two phase system was extracted with cold water and dried over $MgSO_4$. The dried material was fractionally distilled, the fraction boiling at 70–87° being collected. This fraction was then redistilled using an 18 in. spinning band column. The desired material (8.6 g, 8.8%) was collected at 77–78.5°, n_D^{22} 1.3988. Samples with mole fractions of 0.054–0.956 in carbon tetrachloride were prepared and the position of the acetylenic proton singlet measured. The singlet at 1.385 p.p.m. from TMS arising from the geminal dimethyls was used as the lock signal. It was found that the position of this signal was independent of concentration.

3-Methoxy-1-propyne (6)

This compound was prepared from 3-hydroxy-1-propyne, obtained from Eastman Organic Chemicals Company, by the method of Reppe (10) yielding 41% of the desired product, b.p. 57–61°, n_D^{25} 1.3931. Samples with mole fractions of 0.057–0.993 were prepared in carbon tetrachloride, while cyclohexane was used to prepare samples of mole fractions 0.115–0.993. In both solvents the slightly concentration dependent methoxyl singlet at approximately 3.3 p.p.m. from TMS was used as the lock signal. The methoxyl–acetylene and methoxyl–TMS separations were measured for each sample. Subtraction of the former from the latter yielded the acetylene–TMS separation.

Acknowledgments

We are indebted to Mr. David M. Morse for some of the preliminary measurements and to one of the referees for helpful suggestions.

NOTES

Contribution à l'étude du mécanisme d'oxydation chromique de cycloalcanols secondaires

JEAN-CLAUDE RICHER ET NGUYEN THI THANH HOA[1]
Département de Chimie, Université de Montréal, Boîte Postale 6128, Montréal, Québec
Reçu le 9 mai 1968

Les vitesses d'oxydation chromique d'alcools secondaires cycliques ont été étudiées en fonction de la grandeur des cycles, ceux-ci ayant un nombre de carbones de 4 à 13 et 15. Les vitesses d'oxydation mesurées à quatre températures différentes ont permis de calculer les entropies, enthalpies et énergies libres d'activation. Les résultats sont discutés en fonction de la grandeur des cycles. L'effect isotopique cinétique a été déterminé pour les oxydations chromiques de certains cyclanols.

Canadian Journal of Chemistry, 47, 2479 (1969)

Introduction

Au cours d'un travail précédent (1) il a été suggéré, à la suite de Rocek (2) et de Venkatasubramian (3) que les états de transition dans des oxydations chromiques d'alcools épimères se rapprochent de beaucoup du produit final, à savoir de la cétone. Cette hypothèse a toutefois été prise à partie par Kwart (4, 5) en se basant entre autres sur le fait que les vitesses d'oxydation du cyclopentanol et du cyclohexanol ne diffèrent que très peu l'une de l'autre alors que les vitesses de solvolyse des tosylates correspondants sont très différentes. Les résultats rapportés dans la présente communication ont été obtenus au cours d'un travail entrepris afin d'établir des résultats expérimentaux pour les vitesses d'oxydation chromique de cyclanols couvrant la gamme des cycles classiques, moyens et des grands cycles; il était envisagé que les résultats obtenus pourraient être discutés en fonction des notions de la théorie des tensions internes développées par Brown (6–8).

Partie expérimentale

Les alcools examinés au cours du présent travail ont été obtenus de sources commerciales ou par réduction de la cétone correspondante avec de l'hydrure double de lithium et d'aluminium ou par le deutérure double de lithium et d'aluminium. L'homogénéité (pureté plus grande que 99%) des alcools étudiés a été établie grâce à la chromatographie en phase gazeuse; leurs propriétés physiques sont résumées dans le tableau I.

Les constantes de vitesses d'oxydation chromique ont été mesurées dans l'acide acétique aqueux à l'aide d'un spectrophotomètre Perkin–Elmer modèle 4000 A, d'après le protocole expérimental décrit précédemment (1). Les calculs de ces constantes et des facteurs d'activation qui en découlent ont été faits à l'aide de l'ordinateur électronique 3400 de la compagnie CDC au Centre de Calcul de l'Université de Montréal utilisant la méthode des moindres carrés et le programme "Fast Regress". Une description détaillée de la procédure expérimentale et des méthodes de calcul utilisées est présentée dans la thèse de doctorat de Mlle Nguyen dont copie est déposée à la Bibliothèque du Conseil National de Recherches du Canada.

Résultats et discussion

En se basant sur le fait qu'un effet isotopique primaire de 5.9 est observé au cours de l'oxydation chromique du cyclohexanol-d_1, il a été conclu (4) que l'étape déterminante de cette réaction implique la rupture du lien carbone–hydrogène carbinolique. Afin de s'assurer que dans le cas des composés à cycle moyen l'étape déterminante de la réaction d'oxydation chromique est toujours l'enlèvement de l'atome d'hydrogène carbinolique, l'effet isotopique primaire de cette réaction a été établi pour un nombre représentatif de ces cyclanols. Les résultats obtenus sont rapportés dans le tableau II; les effets isotopiques primaires observés permettent de conclure que dans les oxydations chromiques d'alcools secondaires de cycles moyens comme dans le cas général observé par Westheimer et

[1]Les résultats rapportés dans le présent travail sont tirés en partie de la thèse de doctorat soumise par Mlle Nguyen Thi Thanh Hoa en vue de l'obtention du grade de Doctorat es Sciences, Faculté des Sciences, Université de Montréal, août 1967.

(20); utilisant la notation de Brown (8), les valeurs de log K_n/K_6 (constante de vitesse d'un produit cyclanique correspondant contenant n chainons/ la vitesse correspondante en série cyclohexanique) sont aussi rapportées. Si une comparaison des résultats log K_{nox}/K_6 est faite avec les valeurs log $K_{nsolv.}/K_6$ et les fréquences de vibration du groupement carbonyle de la cétone correspondante (en excluant comme l'a fait Foote (20) les résultats obtenus en séries cyclobutaniques et cyclopentaniques où des effets supplémentaires sont en causes) un parallélisme étroit entre toutes ces données est alors observé; il peut alors en être conclu que les vitesses d'oxydation chromique d'alcools secondaires, comme les vitesses de solvolyse des tosylates correspondants sont directement reliées à la stabilité de la cétone qui se forme. Cette conclusion implique, comme il a été proposé précédemment (1–3), que l'état de transition des réactions d'oxydation chromique d'alcools secondaires ressemble au produit final et comporte un caractère cétonique bien développé.

Thermal decomposition of alkyl *N*-(*o*-nitrophenyl)carbamates: A novel synthesis of benzofurazan

J. M. PROKIPCAK, P. A. FORTE, AND D. D. LENNOX
Department of Chemistry, University of Guelph, Guelph, Ontario

Received January 30, 1969

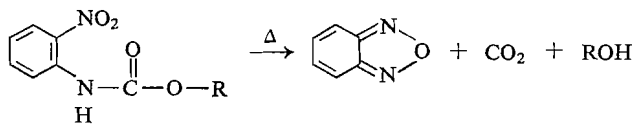
Several alkyl *N*-(*o*-nitrophenyl)carbamates have been shown to undergo thermal breakdown to give benzofurazan with the methyl derivative giving the optimum results.

Canadian Journal of Chemistry, 47, 2482 (1969)

During an investigation into the mechanism of the breakdown of nitrourethanes, it was found that alkyl *N*-(*o*-nitrophenyl)carbamates could be converted into benzo-2,1,3-oxadiazole (benzofurazan) by heating the carbamates to 250–270°.

Gaughran *et al.* (1) have prepared benzofurazan by the reduction of benzofurazan *N*-oxide with alkaline hydroxylamine. The benzofurazan *N*-oxide can be obtained by the oxidation of *o*-nitroaniline (1, 2) or by the pyrolysis of *o*-nitrophenyl azide (3). The method used in our laboratory involved the pyrolysis of alkyl *N*-(*o*-nitrophenyl)carbamates and afforded a ready source of pure benzofurazan in yields up to 53% in the case of the methyl carbamate.

The alkyl *N*-(*o*-nitrophenyl)carbamates were made using the method outlined by Synerholm *et al.* (4). Table I indicates the carbamates synthesized and used in the preparation of benzofurazan.



National de Recherches du Canada et le Bureau de l'Aide Extérieure du Canada (Plan Colombo) pour l'aide financière apportée sous forme d'octrois et de bourse de recherches.

†Reported m.p. 53 °C (5).
‡Reported m.p. 57 °C (5).
§Reported m.p. 61–62 °C (6).

Undoubtedly an intermediate reaction that had to be considered was the formation of isocyanate (7, 8). The carbamates could be decomposing into the *o*-nitrophenyl isocyanate which then could lead to the formation of benzofurazan. However, when the *o*-nitrophenyl isocyanate was subjected to the same conditions as the carbamates, only a very small amount of benzofurazan (5%) was obtained, the major portion being a black tar. Thus the benzofurazan formation from the carbamate does not seem to include preliminary isocyanate formation.

The rate at which decomposition temperature was reached played an important part in the yield of benzofurazan. When the flask contents were brought to decomposition temperature slowly, the yield of benzofurazan was quite low (10%). However, if the flask contents were brought to the decomposition temperature rapidly, the yield of benzofurazan was greatly increased. This could be due to a decrease in the competing isocyanate reaction.

Thus thermal decomposition of methyl *N*-(*o*-nitrophenyl)carbamate has been shown to afford a quick method of preparing pure benzofurazan in good yields. Further investigation on this reaction is in progress.

Experimental

All melting points were determined on the Fisher–Johns melting point apparatus and are uncorrected. Analyses were performed by Organic Microanalyses, 5757 Decelles Avenue, Montreal, Quebec.

The preparation of the carbamates and their decomposition can be outlined by describing the general procedure used for the methyl *N*-(*o*-nitrophenyl)carbamate.

Preparation of Methyl N-(o-nitrophenyl)carbamate

o-Nitrophenyl isocyanate (16.4 g, 0.10 mole) was added over a period of 10 min to a solution of 3.5 g (0.11 mole) methanol in 150 ml of dry benzene. The reaction mixture was refluxed for a period of 2 h. The benzene was removed *in vacuo* and the resultant oil was taken up in hot hexane. After filtration, the solution was cooled and the resultant crystals were recovered by filtration, m.p. 51–52°. The yields for the different carbamates varied from 60–90%.

Thermal Decomposition of Methyl N-(o-nitrophenyl)-carbamate

Using a simple distillation set-up, 30 g (0.15 mole) of the carbamate were placed in a 50 ml distilling flask. The flask contents were heated quickly to 250–270 °C by means of a heating mantle. The gas evolved was allowed to escape into the atmosphere and the alcohol which distilled off was collected. The benzofurazan then began to distil over (distilling head temperature 190°) and solidified in the condenser. The crude product (11.40 g) was collected and purified by sublimation to give 9.70 g of pure benzofurazan, m.p. 51.5–53.0° in a 53% yield.

By comparison of physical properties and infrared spectra this compound was shown to be identical with

benzofurazan prepared by the method of Gaughran *et al.* (1). In all cases, the remainder of the flask contents was unidentified.

Anodic addition of hydroxy and benzoyloxy groups to stilbenes[1]

Kikuhiko Koyama, Tatsuyoshi Ebara, Tadahiko Tani, and Shigeru Tsutsumi
Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamadakami, Suita, Japan

Received May 28, 1968

The anodic reaction of benzoic acid in acetonitrile has been carried out in the presence of *trans*- and *cis*-stilbenes using platinum electrodes. The reaction with added *trans*-stilbene gave meso-hydrobenzoin dibenzoate together with *threo*-2-benzoyloxy-1,2-diphenylethanol. Under similar conditions, *cis*-stilbene also gave these products. No evidence for the isomerization of *cis*-stilbene to the *trans*-isomer during the electrolysis was found. Stereoisomeric *dl*-hydrobenzoin dibenzoate and erythro-2-benzoyloxy-1,2-diphenylethanol were not obtained from either stilbene. For comparison, the "wet" Prévost reaction of *cis*-stilbene with silver acetate and iodine was studied. These results are discussed on the basis of a stepwise oxidation mechanism which involves a cyclic 1,2-benzoxonium ion intermediate.

Canadian Journal of Chemistry, 47, 2484 (1969)

Over the last decade, considerable attention has been devoted to electrochemical addition reactions. An example of such reactions is the polymerization of vinyl monomers during the Kolbe electrolysis (1, 2). The free radicals produced by the Kolbe electrolysis are capable of attacking 1,3-dienes present, giving rise to the additive dimers (3–5). Smith *et al.* (6) have investigated the stereochemistry of the addition of free radicals to dienes in the anodic oxidation of carboxylic anions.

A previous communication (7) from this laboratory indicated that the electrolysis of sodium methoxide in methanol in the presence of *trans*- and *cis*-stilbenes afforded a mixture of meso- and *dl*-hydrobenzoin dimethyl ethers. More *cis*-adduct than *trans*-adduct was formed in each case. These results seem to be consistent with simultaneous addition of two methoxy radicals to a carbon–carbon double bond of an adsorbed stilbene from one side of the double bond, analogous to the catalytic hydrogenation of unsaturated compounds. An alternative mechanism involves a benzylic cation intermediate formed from stilbene during a stepwise two-electron transfer to the anode (8).

Recently, Mango and Bonner (9) found that electrolysis of sodium acetate in acetic acid in the presence of *trans*-stilbene yielded mainly meso-hydrobenzoin diacetate under anhydrous conditions, and *threo*-2-acetoxy-1,2-diphenylethanol together with a mixture of epimers of 1,2-diphenyl-1-propyl acetate under moist conditions. The stereoisomeric *erythro*-hydroxyacetate was not obtained from either experiment with added *trans*-stilbene. They concluded that the mechanism involved a cyclic acetoxonium ion intermediate **1** which was formed stereoselectively on the surface of an anode. Although the details of the formation of the cyclic intermediate ion, **1**, in this mechanism were not completely clear from their work, they suggested two possibilities; one-step and two-step oxidation mechanisms, as illustrated in Schemes 1 and 2, respectively.

The present study deals with the mechanism of

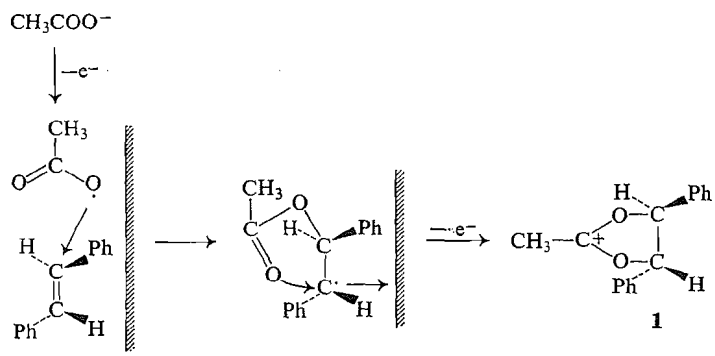
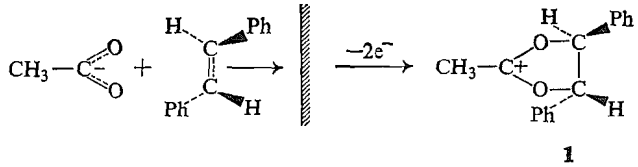


SCHEME 1



SCHEME 2

anodic addition of hydroxy and benzoyloxy groups to the stilbenes.

Results and Discussion

The electrolysis of benzoic acid in acetonitrile containing a small amount of triethylamine was conducted in the presence of *trans*-stilbene. After the usual work-up, the products which could be isolated were characterized by comparison with authentic samples, and found to consist of meso-hydrobenzoin dibenzoate **2** and *threo*-2-benzoyloxy-1,2-diphenylethanol, **3**. When benzoic acid was electrolyzed in the presence of *cis*-stilbene, it was also converted into a mixture of **2** and **3** in a fairly good yield. Each electrolysis was repeated several times, but no other compounds could be identified. In some cases, however, a small amount of a thick yellow oil, which gave an infrared (i.r.) spectrum displaying major absorption bands at 710, 760, 1110, 1270, 1670, and 1710 cm^{-1}, was produced. None of the stereoisomeric *erythro*-monobenzoate and *dl*-dibenzoate was obtained in either case. The relative yield of the diester, **2**, to the monoester, **3**, appeared to be affected by water present in the solvent; the ratio increased markedly when the solvent freshly distilled from phosphorus pentoxide, while it decreased when the solvent had been stored without any protection from moisture.

There was no evidence of isomerization of *cis*- to *trans*-stilbene under the electrolytic conditions employed; ultraviolet (u.v.) spectra of crude *cis*-stilbene recovered from the electrolyzed mixture showed no absorbance at 295 and 310 mμ characteristic for the *trans*-isomer.

As has been established in the stereochemistry of the "dry" and "wet" Prévost reactions, the stereoselective addition of hydroxy and benzoyloxy groups to the stilbenes, i.e., *cis*-hydroxylation and *trans*-benzoyloxylation, strongly suggests the formation of a common cyclic benzoxonium ion intermediate, **4**, from both stilbenes.

The inversion of configuration during anodic addition to *cis*-stilbene also suggests that the formation of **4** proceeds through a stepwise transfer of two electrons to the anode. If a cyclic ion intermediate were formed from an adsorbed *cis*-stilbene on the anode surface in one step as illustrated in Scheme 2, the *cis*-stilbene would be converted with retention of configuration into *dl*-hydrobenzoin dibenzoate and *erythro*-monobenzoate.

The u.v. analyses rule out the possibility of *cis–trans* inversion before the attack of a benzoate anion or radical on an anodically adsorbed stilbene.

The Prévost reaction on *cis*-stilbene, which so far as we know has not been reported, was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

examined using silver acetate in wet acetic acid. It also afforded *threo*-2-acetoxy-1,2-diphenylethanol as the sole product, but the epimeric *erythro*-monoacetate was not produced.

Winstein and Seymour (10) have suggested that the diastereomeric stilbene dichlorides are first converted mainly into *erythro*-acetoxychloride when the dichlorides are treated with silver acetate in dry or moist acetic acid. The present investigation, however, affords evidence for the possible inversion of configuration during the formation of the cyclic ion intermediate **4**.

Our conclusion, based on the evidence above, is that the anodic addition of hydroxy and benzoyloxy groups to stilbenes proceeds via the formation of the cyclic benzoxonium ion intermediate **4** with the more stereochemically favorable configuration. It seems probable that two electrons are transferred stepwise from stilbene or from benzoate anion and stilbene to the anode.

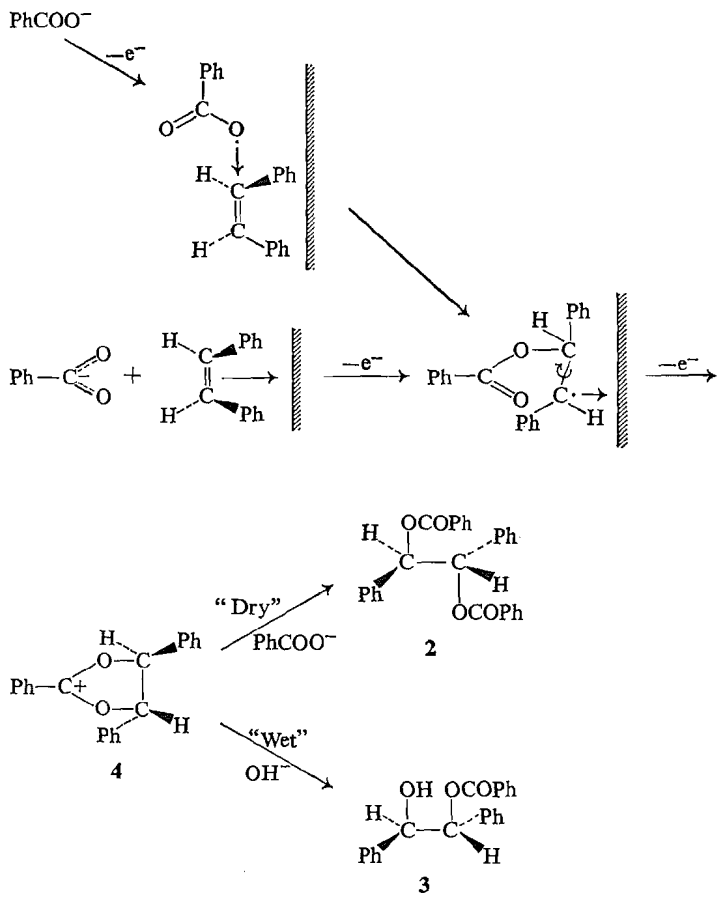
Experimental

All melting points and boiling points are uncorrected. The i.r. spectra were obtained with a Shimadzu IR spectrophotometer IR-27C. The electrolyses were carried out in a cylindrical glass cell equipped with a reflux condenser, thermometer, and electrode unit. The electrode unit consisted of two platinum foil electrodes having an area of ca. 3 cm^2 each, spaced 1 cm apart. The cell was immersed in a water-bath, and the contents were stirred magnetically.

Electrolysis of Benzoic Acid in the Presence of trans-Stilbene

A solution of benzoic acid (6.1 g, 0.05 mole) and *trans*-stilbene (4.5 g, 0.025 mole) in acetonitrile (90 ml) containing triethylamine (2 g) was electrolyzed at 20–25 °C for 14 h (electric current; 0.1 A, applied potential; 31–35 V).

The bulk of the solvent was removed by evaporation at reduced pressure, and the residue was dissolved in chloroform. The chloroform solution was extracted twice with 5% aqueous sodium bicarbonate solution, then washed with water, dried over anhydrous magnesium sulfate, filtered, and evaporated to give a thick brown oil (7 g). A portion (3 g) of the crude product was chromatographed on silica gel (50 g), and eluted with chloroform–methanol mixtures. After removal of the solvent, the



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

collected fractions were combined on the basis of the i.r. and thin-layer chromatography (t.l.c.) analyses.

The first combined residue (0.8 g) was shown by its i.r. spectrum to be unchanged stilbene. Recrystallization from *n*-hexane – benzene yielded white crystals, m.p. 122–124 °C, which showed no melting point depression when mixed with authentic *trans*-stilbene.

The second combined fraction (1.2 g) was recrystallized from *n*-hexane – benzene yielding 0.8 g of white crystals, m.p. 243–245 °C, which was identified as meso-hydrobenzoin dibenzoate, **2**, (m.p. 244–245 °C (11)). The product and an authentic sample of **2** had identical i.r. spectra and, on admixture, showed no melting point depression.

Anal. Calcd. for $C_{28}H_{22}O_4$: C, 79.60; H, 5.25. Found: C, 79.83; H, 5.61.

The third fraction, a yellow oil, gave an i.r. spectrum with major absorption bands at 710, 760, 1110, 1270, 1670, and 1710 cm^{-1}, and was examined by t.l.c. It consisted of several compounds, which were not further investigated.

The electrolysis was repeated in slightly wetted solvent. After working up the electrolyzed mixture in a manner similar to the experiment described above, the crude product (11.6 g) was subjected to chromatographic separation, and gave 4 combined fractions. The first combined fraction (0.2 g) consisted mainly of unchanged *trans*-stilbene, m.p. and mixed m.p. 121–123 °C. The second combined fraction (1.5 g) was filtered to separate a thick solid (0.03 g), m.p. 183–228 °C. The solid was washed with a *n*-hexane – benzene mixture, and recrystallized from boiling toluene to yield white crystals, m.p. 237–240 °C, which were identified as **2** (mixed m.p. 240–242 °C).

The third combined residue (3.9 g) was dissolved in benzene and, after addition of *n*-hexane to the solution, yielded a white solid (3.1 g), m.p. 149–152 °C. It was identified after recrystallization from benzene – *n*-hexane mixture as *threo*-2-benzoyloxy-1,2-diphenylethanol, **3**, m.p. 152.5–154.5 °C, undepressed on admixture with an authentic sample. The i.r. spectra of the product and authentic **3** were identical.

Anal. Calcd. for $C_{21}H_{18}O_3$: C, 79.22; H, 5.70. Found: C, 79.12; H, 5.74.

A dark-brownish residue (0.5 g) was not investigated.

Electrolysis of Benzoic Acid in the Presence of cis-Stilbene

A solution of benzoic acid (6.1 g, 0.05 mole) and *cis*-stilbene (4.5 g, 0.025 mole) in acetonitrile (90 ml) containing triethylamine (2 g) was electrolyzed in the manner described above for experiments with *trans*-stilbene. After the electrolysis, a portion (3.2 g) of the crude product (9.6 g) was subjected to chromatographic separation.

The first combined residue (0.61 g) was shown to be unchanged *cis*-stilbene by its i.r. spectra. The u.v. spectrum of this residue in ethanol solution showed the absorption band at 280 mμ, but no absorptions at 295 and 310 mμ which are characteristic for *trans*-stilbene.

The second combined residue (0.2 g), a white solid, was identified after recrystallization from toluene as **2**, m.p. 244–245 °C, not depressed by mixture with an authentic sample. The i.r. spectra of these two samples were identical.

Anal. Calcd. for $C_{28}H_{22}O_4$: C, 79.60; H, 5.25. Found: C, 80.56; H, 5.37.

The third combined residue (0.6 g) gave, after recrystallization from *n*-hexane – benzene, white crystals, m.p. 150–152 °C, not depressed by mixture with an authentic **3**.

Anal. Calcd. for $C_{21}H_{18}O_3$: C, 79.22; H, 5.70. Found: C, 79.83; H, 5.94.

A portion (0.1 g) of the third fraction was heated under reflux with 20% potassium hydroxide in aqueous ethanol for 2.5 h, and the solvent was then removed under reduced pressure. The residue was extracted three times with ether, and the combined ethereal solutions were washed twice with sodium bicarbonate solution, then with water, and were then dried over anhydrous magnesium sulfate. The evaporation of ether left a small amount of a white solid, which was characterized after two recrystallizations from *n*-hexane – benzene mixtures as *dl*-hydrobenzoin, m.p. 119–120 °C, undepressed on admixture with an authentic sample.

The last combined residue (0.34 g) was a dark-brownish semisolid, which was not characterized.

Authentic **2** (m.p. 244–245 °C, 78% yield) was prepared from meso-hydrobenzoin. Authentic **3** (m.p. 154.5 °C, 76.5% yield) was prepared from *erythro*-1-benzoyloxy-2-bromo-1,2-diphenylethane by a method similar to that described by Wiberg and Saegebarth (11), and was hydrolyzed to give authentic *dl*-hydrobenzoin, m.p. 118 °C.

The "Wet" Prévost Reaction on cis-Stilbene

The method used here was virtually identical with that of Mango and Bonner (9). To a solution of *cis*-stilbene (4.5 g, 0.025 mole) and silver acetate (10.5 g, 0.06 mole) in glacial acetic acid (75 ml) containing water (1 ml) was added powdered iodine (6.4 g, 0.05 mole) in small portions with vigorous stirring over a period of 1 h at room temperature. After all of the iodine was added to the solution, the mixture was heated at 90–95 °C for 3 h with vigorous stirring. The usual work-up of the reaction mixture gave a thick oil (5.3 g), which crystallized on standing. Recrystallization from a benzene – *n*-hexane mixture gave white crystals, m.p. 87–89 °C, undepressed on admixture with authentic *threo*-2-acetoxy-1,2-diphenylethanol.

Réactions de Ritter sur les *tert*-butyl-4 méthyl-1 cyclohexanols *cis* et *trans*

JEAN-CLAUDE RICHER ET ROBERT BISSON
Département de Chimie, Faculté des Sciences, Université de Montréal, Montréal, Québec

Reçu le 6 novembre 1968

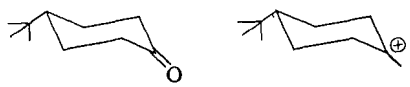
La réaction de Ritter a été effectuée sur les *tert*-butyl-4 méthyl-1 cyclohexanols, et la stéréochimie de ces réactions a été déterminée. Les amines qui peuvent en découler ont été isolées et caractérisées.

Canadian Journal of Chemistry, 47, 2488 (1969)

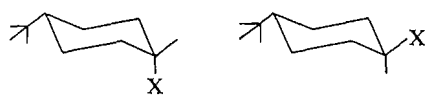
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Introduction

Il semble maintenant bien établi (1) que la réaction de Ritter procède par l'intermédiaire d'un carbocation. Formellement la réaction de l'acide cyanhydrique (ou d'un cyanure) sur ce carbocation serait une réaction d'addition nucléophile qui pourrait être rapprochée des additions nucléophiles sur le carbone des groupements carbonyles. Il s'avérait donc intéressant d'examiner la stéréochimie des produits issus de la réaction de Ritter sur les *tert*-butyl-4 méthyl-1 cyclohexanols (**1***a* et **2***a*) et de comparer les quantités relatives de produits formés à celles obtenues lors d'additions nucléophiles sur la *tert*-butyl-4 cyclohexanone (**A**) qui est formellement l'analogue carbonylé du carbocation **B** considéré comme intermédiaire dans la réaction de Ritter sur les alcools **1** et **2**.



A **B**



1 **2**

a) X = OH
b) X = NH_2
c) X = NH_3+
d) X = $NHSO_2C_6H_4CH_3$—*p*
e) X = $N(CH_3)_2$
f) X = N—C—H (‖ O)

Résultats et discussion

Les alcools tertiaires désirés **1***a* et **2***a* ont été préparés d'après la méthode décrite par Gravel (2). La réaction de Ritter a été effectuée sur chacun de ces alcools et sur un mélange approximativement 50/50 de chacun. Les produits obtenus ont été hydrolysés en milieu acide et les amines libres isolées ont été chromatographiées en phase gazeuse. Les pourcentages de *tert*-butyl-4 méthyl-1 cyclohexylamine *cis*[1] (**1***b*) obtenus dans chacune des réactions sont rapportés dans le tableau I.

TABLEAU I

Pourcentages* d'amine *cis* (**1***b*) formé au cours des réactions de Ritter

Alcool utilisé	1° essai	2° essai	Moyenne
1*a*	94	93	93,5
2*a*	88	90	89
45% **1***a*/55% **2***a*	91	94	92,5
			91,6

*Valeurs déterminées par chromatographie en phase gazeuse à 140 °C, utilisant une colonne de 10 pds. × 1/4 po. contenant du Chromosorb W 30–60 imprégné de 5% de KOH, 4% d'hyprose et 15% de Carbowax 20 M. Avec un débit d'hélium de 75 ml/min les temps de rétention sont de 19 min pour **1***b* et 25 min pour **2***b*.

Chacune des amines obtenue a été caractérisée et leur configuration relative a été attribuée en se basant d'une part sur leur temps de rétention relatif en chromatographie en phase gazeuse et grâce à leur pK_a, et d'autre part en notant comme l'ont fait Alleon-Aimi *et al.* (3) dans le cas des amines **1***e* et **2***e* que la transformation des amines **1***b* et **2***b* en leur chlorhydrate provoque dans les spectres de résonance magnétique nucleaire (r.m.n.) de **1***c* un déplacement chimique du groupe *tert*-butyle vers les champs faibles tandis qu'il n'y a aucun déplacement lorsqu'on passe de **2***b* à **2***c*. Les résultats stéréochimiques obtenus indiquent que l'addition du groupe NC sur le carbocation **B** s'effectue à 90% par le côté axial de la molécule. Ce résultat est en parfait accord avec ceux obtenus lors des additions nucléophiles par des

[1]La stéréochimie reflète la position relative des groupes fonctionnels et du groupe tertiobutyle.

For personal use only.

petits réactifs sur la *tert*-butyl-4 cyclohexanone (4); ces résultats ont été expliqués grâce à une interprétation toute stérique qui serait aussi valable pour expliquer la stéréochimie des réactions de Ritter. La proposition récente de Cherest et Felkin (5) qui attribue ces résultats à des intéractions de torsion (plutôt qu'à des intéractions stériques) entre les réactifs et les substituants axiaux en position-2 et -6 permettrait aussi de rendre compte des résultats expérimentaux obtenus.

Partie expérimentale

Les spectres de résonance magnétique nucléaire ont été pris sur un spectromètre A-60 de la compagnie Varian; le $CDCl_3$ est utilisé comme solvant et les déplacements chimiques (δ), exprimés en p.p.m., se réfèrent au tétraméthylsilane utilisé comme standard interne. Les spectres infrarouges des produits ont été pris entre deux plaques de chlorure de sodium à l'état pur lorsque liquides et en suspension dans du Nujol lorsque solides; l'appareil utilisé est un spectromètre IR-8 à double faisceau de la compagnie "Beckman". Les analyses par chromatographie en phase gazeuse ont été effectuées sur un chromatographe F et M, modèle 810. Les indices de réfraction ont été mesurés à l'aide d'un réfractomètre, modèle 44 061 de la compagnie Zeiss. Les points de fusion ont été mesurés sur un appareil "Hot Stage" de la compagnie "Reichert".

tert-Butyl-4 méthyl-1 cyclohexanols **1***a et* **2***a*

Ils sont préparés selon les indications de Gravel (2). L'alcool **1***a* fond à 71–71.5° (litt. (2) 71°) alors que le p.f. de l'alcool **2***a* est de 99–99.5° (litt. (2) 98–99°).

tert-Butyl-4 méthyl-1 cyclohexylamines **1***b et* **2***b*

D'une manière générale, une solution contenant 0.1 mole d'alcool tertiaire (**1***a*, **2***a* ou mélange contenant 45% **1***a* et 55% **2***a*) dans 65 ml d'éther butylique anhydre et contenant 0.25 mole de cyanure de sodium finement pulvérisé est traitée, goutte à goutte tout en maintenant sous bonne agitation et à une température n'excédant pas 40–45 °C par 30 ml d'acide sulfurique concentrée. Lorsque l'addition est terminée l'agitation est maintenue durant 1 h, le mélange réactionnel ramené à la température de la pièce puis versé sur 300 ml d'eau glacée. L'extraction des produits réactionnels est effectuée à la manière habituelle par de l'éther après avoir alcalinisé le milieu par addition de soude 20%. Les dérivés formylés (**1***f* et **2***f*) ainsi obtenus sont hydrolysés par ébullition durant 5 h avec deux fois leur volume d'acide chlorhydrique concentré. L'extraction des amines libres (**1***b* et **2***b*) se fait par de l'éther à la manière habituelle; le rendement global est d'environ 80%.

Le mélange d'amine obtenu précédemment est mis en solution dans 150 ml d'éther anhydre; on y fait barboter du HCl gazeux jusqu'à ce que la précipitation soit complète. Les chlorhydrates d'amines **1***c* et **2***c* sont recueillis par filtration et se présentent sous forme de cristaux différents qui peuvent être séparés manuellement.

tert-Butyl-4 méthyl-1 cyclohexylamine cis **1***b*

Le chlorhydrate recueilli d'une façon prépondérante (**1***c*) a un p.f. de 256° (tube capillaire) et se sublime. Son spectre r.m.n. montre la présence de singulets à 0.88 p.p.m. (*tert*-butyle) et 1.43 p.p.m. (méthyle en position-1— voir. réf. 3). L'amine libre **1***b* régénérée serait pure par c.p.g. et se présente sous forme de liquide incolore, p.e.: 84°/11 mm Hg; n_D^{20}: 1.4562 montrant une bande de vibration N—H à 1610 cm^{-1} dans son spectre infrarouge, un pic *m/e* à 169 dans son spectre de masse et des singulets à 0.85 p.p.m. (*tert*-butyle) et 1.05 p.p.m. (méthyle) dans son spectre r.m.n. Cette amine peut être caractérisée sous forme de *p*-toluènesulfonamide **1***d* de p.f. 173° montrant dans son spectre r.m.n. des pics à 0.76 p.p.m. (*tert*-butyle) et 1.16 p.p.m. (méthyle). Le pK_a de cette amine déterminé[2] dans le méthylcellosolve est de 9.54.

tert-Butyl-4 méthyl-1 cyclohexylamine trans **2***b*

Le chlorhydrate recueilli d'une façon mineure (**2***c*) peut être recristallisé dans un mélange éther–éthanol. Son point de fusion est de 310–320 °C (déc.) et son spectre r.m.n. montre des singulets à 0.84 p.p.m. (*tert*-butyle) et 1.41 p.p.m. (méthyle). L'amine libre **2***b* régénérée est chromatographiquement pure; elle présente les caractéristiques suivantes: p.f. 41.5–43.5°; pK_a (méthylcellosolve)[2]:8.97; i.r.: bande à 1580 cm^{-1} (N—H); spectre de masse: pic parent à *m/e* de 169; r.m.n. singulets à 0.84 p.p.m. (*tert*-butyle) et 1.04 p.p.m. (méthyle). Cette amine donne une *p*-toluènesulfonamide de p.f. 129–130° qui montre dans son spectre r.m.n. des pics à 0.80 p.p.m. (*tert*-butyle) et 1.21 p.p.m. (méthyle).

Epoxides of 1,1-dichloro-2,2-difluoroethylene and chlorotrifluoroethylene

D. CHOW, M. H. JONES, M. P. THORNE, AND E. C. WONG
Department of Physical Chemistry, Ontario Research Foundation, Sheridan Park, Ontario

Received February 6, 1969

The major products from the photochemically initiated oxidation of 1,1-dichloro-2,2-difluoroethylene and chlorotrifluoroethylene in the liquid phase are the corresponding epoxides and acyl halides. The epoxides have been isolated in pure form and characterized.

Canadian Journal of Chemistry, 47, 2491 (1969)

Halogenated derivatives of ethylene are susceptible to direct oxidation by molecular oxygen because of the electronegativity of the substituents and this represents a potential method for preparation of the corresponding epoxides. However, a variety of oxidation products may be obtained depending on the structure of the olefin and the reaction conditions. For example, dibromofluoroethylene reacts readily with oxygen to give the acyl bromide (1). Similarly, the major product in the photochemically initiated oxidation of chlorotrifluoroethylene is reported (2) to be the acyl fluoride, although the epoxide (3) has been isolated in substantial yield from direct oxidation of the olefin at its boiling point. More recently, it has been shown (4–6) that the photochemical and γ-ray initiated oxidation of tetrafluoroethylene yields primarily the epoxide and carbonyl fluoride.

The oxidation of 1,1-dichloro-2,2-difluoroethylene and chlorotrifluoroethylene by molecular oxygen at temperatures of −60 to +20 °C is slow, but the reaction can be accelerated appreciably by ultraviolet (u.v.) irradiation, particularly in the shorter wavelength region of 2000–3000 Å where significant absorption by the olefin occurs (7). The most convenient preparative method for the epoxides has been found to be irradiation of the olefin under reflux at atmospheric pressure, while bubbling dry oxygen through the liquid. The progress of the reaction may be followed by means of the infrared (i.r.) absorption bands of the mono and dichloro olefins at 1792 and 1740 cm^{-1} respectively.

With both olefins, at least 90% of the oxidation products are volatile and consist of the epoxide and acyl halides. Liquid peroxides occur in both cases but represent less than 5% of the total products. With chlorotrifluoroethylene, a small quantity of solid precipitates during the reaction and was shown to be polychlorotrifluoroethylene by i.r. analysis. In a typical photo-oxidation of 1,1-dichloro-2,2-difluoroethylene, approximately 40% of the volatile product is the epoxide, 50% is chlorodifluoroacetyl chloride, and 10% is dichlorofluoroacetyl fluoride. In the case of chlorotrifluoroethylene, the epoxide constitutes approximately 60% of the volatile product, the remainder being chlorodifluoroacetyl fluoride.

Isolation of the epoxides from the acyl halides proved to be difficult. Fractional distillation, gas–liquid chromatographic and adsorption methods were unsuccessful, resulting in either little or no separation of the components, or decomposition of the epoxides. Two procedures were employed. For the 1,1-dichloro-2,2-difluoroethylene oxide, the acyl halides were removed by successive extraction of a heptane solution with ice water and the epoxide recovered by nitrogen stripping of the heptane at ambient temperature. With the chlorotrifluoroethylene oxide, the acyl fluoride was separated by gas scrubbing with water and a dilute sodium hydroxide solution at 0 °C, using nitrogen as a carrier gas. In both cases the purity of the epoxide was at least 98% in terms of residual acyl halide and olefin as determined by i.r. analysis. However, aqueous treatments resulted in considerable decomposition of the epoxides, the yields of purified material being 10–30%.

As 1,1-dichloro-2,2-difluoroethylene oxide has not been described previously and information on chlorotrifluoroethylene oxide is limited, the epoxides were characterized and their physical properties determined. The data are given in Table I and the i.r. spectra of the two derivatives are shown in Fig. 1. The mass spectra did not show parent ions but the fragmentation patterns were consistent with the epoxide structures.

Both epoxides have limited thermal and hydrolytic stability. For example, a small sample of 1,1-dichloro-2,2-difluoroethylene oxide isom-

erized almost entirely to dichlorofluoroacetyl fluoride on standing at 10 °C for 3 days. This rearrangement reaction, involving fluorine migration, is probably catalyzed by traces of moisture or acid and a similar process occurs with chlorotrifluoroethylene oxide. With the latter it has been shown, also, that contact with an excess of water results in complete hydrolysis to oxalic acid and hydrogen halides as indicated by Meyer (8).

Experimental

Materials

The 1,1-dichloro-2,2-difluoroethylene (99% pure) was obtained from Peninsula Chemresearch Inc., and chlorotrifluoroethylene (99% pure) was obtained from Matheson Company. In both cases, the materials were given a bulb to bulb distillation or distilled into the reaction flask to eliminate the inhibitor. Dry oxygen (99.65% purity) was obtained from Linde Company.

Photo-oxidation Reaction

A 3-necked quartz flask (250 ml) was equipped with a dry-ice reflux condenser and gas inlet and outlet tubes. Exit locations were protected from moisture ingress by tubes containing Drierite. Approximately 100 g of the required olefin were condensed in the flask and allowed to reflux. Oxygen, dried by passing through a bed of Linde 13X molecular sieve, was bubbled through the liquid olefin at a rate of 6–9 l/h. A Westinghouse H44-4AB medium pressure mercury lamp (100 W) was used as the ultraviolet (u.v). source and a roughly collimated beam covering the flask area was obtained with a quartz lens. Progress of the reaction was followed by vaporizing small samples of the liquid reaction mixture into an evacuated 10 cm gas cell with KBr windows and measuring the optical density of the olefin absorption band ($Cl_2C=CF_2$, 1740 cm^{-1}; $ClFC=CF_2$, 1792 cm^{-1}). On complete consumption of the olefin, the volatile products, consisting of the epoxide and acyl halide, were vacuum distilled into a second container. The peroxide content of the liquid residue could be determined by iodine titration.

Isolation of Epoxide

For 1,1-dichloro-2,2-difluoroethylene oxide, the volatile reaction product was dissolved in a 10–20 fold excess of cold heptane, extracted 4 times with ice water and once with dilute sodium hydroxide solution (0.1 *N*) at 0 °C. The heptane solution was dried over anhydrous magnesium sulfate and the epoxide recovered by stripping with dry nitrogen at room temperature. The product was given a final bulb-to-bulb distillation at low temperature to remove traces of heptane.

For chlorotrifluoroethylene oxide, a flask containing the volatile reaction product was connected to a gas scrubbing system consisting of two aqueous washes and a sodium hydroxide wash (0.1 *N*), the scrubbers being maintained at 0 °C. The reaction product was maintained 5–10° below its boiling point and the vapor carried through the train by a stream of nitrogen. It was found necessary to use small quantities of the reaction mixture (10–15 ml) to limit acid build-up in the scrubbers which accelerates decomposition of the epoxide. The vapor stream was dried with a bed of Drierite and the product condensed in a dry-ice – acetone trap, protected by a liquid nitrogen trap. This technique can also be applied to separation of the epoxide from the reaction product of 1,1-dichloro-2,2-difluoroethylene. The purified epoxides were stored at −80 °C.

Synthesis of some methylated tetroses and pentoses

G. G. S. Dutton, K. B. Gibney, and P. E. Reid[1]

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received March 27, 1968

Oxidation of 2,3-di-*O*-methyl-D-glucitol (≡ 4,5-di-*O*-methyl-L-gulitol) and 2,3-di-*O*-methyl-D-mannitol (≡ 4,5-di-*O*-methyl-D-mannitol) with an excess of periodate gave 2,3-di-*O*-methyl-L-threose and 2,3-di-*O*-methyl-D-erythrose, each characterized as the 2,4-dinitrophenylhydrazone. Borohydride reduction of the sugars gave 2,3-di-*O*-methyl-L-threitol and 2,3-di-*O*-methylerythritol characterized as their di-*p*-nitrobenzoates. Oxidation of the hexitols with 1 mole of periodate gave 3,4-di-*O*-methyl-L-xylose characterized as methyl 3,4-di-*O*-methyl-α-L-xylopyranoside and 3,4-di-*O*-methyl-D-arabinose identified as 3,4-di-*O*-methyl-D-arabonamide. 2-*O*-Methyl-D-erythritol (≡ 3-*O*-methyl-L-erythritol) and 1-*O*-methyl-D-threitol (≡ 4-*O*-methyl-D-threitol) were also prepared and characterized as the tri-*p*-nitrobenzoates.

Canadian Journal of Chemistry, 47, 2494 (1969)

Complex polysaccharides on methylation and hydrolysis may give isomeric methylated sugars, the separation and identification of which can be difficult. Sequential periodate oxidation and borohydride reduction of such mixtures may facilitate the process (1–3), particularly when partially methylated pentoses and tetroses are available as reference compounds. A previous paper (4) has described the 2,4-di-*O*-methyl-D- (and L-) tetroses and the present paper reports some mono- and di-*O*-methyltetroses and two di-*O*-methylpentoses (Table I).

Oxidation of 2,3-di-*O*-methyl-D-glucitol and 2,3-di-*O*-methyl-D-mannitol with an excess of periodate yielded respectively 2,3-di-*O*-methyl-L-threose and 2,3-di-*O*-methyl-D-erythrose, characterized as their 2,4-dinitrophenylhydrazones. Each tetrose was reduced to the glycitol and characterized as the *p*-nitrobenzoate. Oxidation of the two hexitols with one mole of periodate (5–8) gave high yields of 3,4-di-*O*-methyl-D-arabinose and 3,4-di-*O*-methyl-L-xylose, indicating a preferential attack of the C-5, C-6 bond.

4-*O*-Methyl-D-threose (9) was prepared by periodate oxidation of methyl 6-*O*-methyl-αβ-D-galactofuranosides. These furanosides form very readily and pure samples of the α-D- and β-D-furanosides were separated by cellulose-column chromatography and characterized. The periodate oxidation required about 50 h for completion in agreement with the findings of Jackson and Hudson (10) but longer than the time reported by Richards (9). The dialdehyde obtained was subjected to methanolysis in an attempt to reduce the extensive decomposition which has been reported on hydrolysis (9). In spite of some decomposition, the 4-*O*-methyl-D-threose was isolated as the dimethylacetal but could only be characterized through the threitol.

Similar difficulties were encountered in the attempted preparation of 2-*O*-methyl-D-erythrose from methyl 4-*O*-methyl-α-D-mannoside. The dialdehyde was resistant to hydrolysis or methanolysis and it was eventually reduced with borohydride before hydrolysis to give directly 2-*O*-methyl-D-erythritol.

The difficulty of isolating 2-*O*-methyl-D-erythrose as such, poses an interesting point in the general use of this degradative method for identifying higher sugars. Whereas 2- and 3-*O*-methyl-D-erythrose are structural isomers with distinct physical properties, the corresponding glycitols, 2-*O*-methyl-D-erythritol and 3-*O*-methyl-D-erythritol or 2-*O*-methyl-L-erythritol are enantiomorphs. These could be distinguished by reduction with sodium borodeuteride and mass spectrometry. A similar technique has recently been used with great success by Lindberg *et al.* (11) for labelling the terminal position in partially methylated alditols.

As it is most likely that the tetroses and tetritols described here will be encountered in various chromatographic procedures their mobilities are recorded in two common solvents (Table I). Only the essential points are given in the Experimental as further details may be found elsewhere (12).

Experimental

Evaporations were carried out *in vacuo* at a bath temperature of 35–45°. Borate was removed by distillation with 1% methanolic hydrogen chloride. Optical rotations were measured at 21 ± 2°. Gas–liquid chromatographic (g.l.c.) separations were made on an F and M model 720 instrument using an 8 ft × 0.5 in. column packed with 20% SF 96 on 80–100 mesh Diatoport S (F and M Division, Hewlett Packard, Avondale, Pennsylvania). Butanone–water azeotrope was used for all chromatographic separations unless otherwise specified and silica gel was used for thin-layer chromatography (t.l.c.). 2,4-Dinitrophenylhydrazones were prepared as previously described (4), purified by t.l.c. using ether–toluene (2:1), and recrystallized from aqueous ethanol. *p*-Nitrobenzoates were similarly purified. Melting points are uncorrected.

2,3-Di-O-methyl-L-threose

Methyl 2,3-di-*O*-methyl-α-D-glucopyranoside was synthesized by the method of Irvine and Scott (13) and hydrolyzed to the free glycose. 2,3-Di-*O*-methyl-D-glucose (3.0 g) was reduced with sodium borohydride (0.6 g) for 36 h and gave 2,3-di-*O*-methyl-D-glucitol (3.1 g), as a syrup $[\alpha]_D$ 15° (*c*, 3 in H_2O); lit. (14) $[\alpha]_D$ 13° (*c*, 2.54 in H_2O). 2,3-Di-*O*-methyl-1,4,5,6-tetra-*O*-*p*-nitrobenzoyl-D-glucitol crystallized from acetone–methanol had m.p. 88–91°.

Anal. Calcd. for $C_{36}H_{30}O_{18}N_4$: C, 52.0; H, 3.6. Found: C, 52.3; H, 3.8.

2,3-Di-*O*-methyl-D-glucitol (2.02 g) was dissolved in water (1 l) and oxidized with sodium metaperiodate (6.12 g, 3 moles) for 4 h. The product (1.35 g) was shown to contain two components (R_f 0.67 and 0.59) by t.l.c. and evaporation of an aqueous solution containing pyridine gave pure 2,3-di-*O*-methyl-L-threose $[\alpha]_D$ 12° (*c*, 1.6 in MeOH).

Anal. Calcd. for $C_6H_{12}O_4$: C, 48.6; H, 8.2. Found: C, 48.4; H, 8.3. The 2,4-dinitrophenylhydrazone had m.p. 125–126°.

Anal. Calcd. for $C_{12}H_{16}O_7N_4$: C, 43.9; H, 4.9; N, 17.1. Found: C, 44.0; H, 5.1; N, 16.9.

2,3-Di-*O*-methyl-L-threose (100 mg) was reacted for 16 h with sodium borohydride (200 mg) to give 2,3-di-*O*-methyl-L-threitol (65 mg) as a syrup, $[\alpha]_D$ 76° (*c*, 1.4 in MeOH).

Anal. Calcd. for $C_6H_{14}O_4$: C, 48.0; H, 9.3. Found: C, 48.2; H, 9.5.

The derivative 2,3-di-*O*-methyl-1,4-di-*O*-*p*-nitrobenzoyl-L-threitol had m.p. 143–144°.

Anal. Calcd. for $C_{20}H_{20}O_{10}N_2$: C, 53.6; H, 4.5; N, 6.3. Found: C, 53.3; H, 4.6; N, 6.2.

2,3-Di-O-methyl-D-erythrose

Methyl-α-D-mannopyranoside (15) was converted to methyl-4,6-*O*-benzylidene-α-D-mannoside (16) which was methylated to give methyl-4,6-*O*-benzylidene-2,3-di-*O*-methyl-α-D-mannoside as a syrup, $[\alpha]_D$ 60.7° (*c*, 2.4 in $CHCl_3$); lit. (17) $[\alpha]_D$ 62.7° (*c*, 1.18 in $CHCl_3$). Acid hydrolysis of this syrup (3.0 g) followed by borohydride reduction gave 2,3-di-*O*-methyl-D-mannitol (1.8 g) which was recrystallized from ethyl acetate, m.p. 101–102°; lit. (18), m.p. 101–103°.

Anal. Calcd. for $C_8H_{18}O_6$: C, 45.7; H, 8.6. Found: C, 45.6; H, 8.5.

2,3-Di-*O*-methyl-D-mannitol (1.0 g) was dissolved in water (500 ml) and oxidized for 4 h with sodium metaperiodate (3.06 g, 3 moles). The product (885 mg) contained two components on t.l.c. Pure 2,3-di-*O*-methyl-D-erythose was separated on a cellulose–hydrocellulose column (19) and had $[\alpha]_D$ −55.3° (*c*, 1.13 in MeOH).

Anal. Calcd. for $C_6H_{12}O_4$: C, 48.6; H, 8.2. Found: C, 48.4; H, 8.3.

2,4-Dinitrophenylhydrazone had m.p. 100–101°.

Anal. Calcd. for $C_{12}H_{16}O_7N_4$: C, 43.9; H, 4.9; N, 17.1. Found: C, 44.1; H, 5.1; N, 17.0.

Borohydride reduction of the glycose (50 mg) gave 2,3-di-*O*-methylerythritol (35 mg).

Anal. Calcd. for $C_6H_{14}O_4$: C, 48.0; H, 9.4. Found: C, 48.3; H, 9.3.

The derivative 2,3-di-*O*-methyl-1,4-di-*O*-*p*-nitrobenzoylerythritol had m.p. 178°.

Anal. Calcd. for $C_{20}H_{20}O_{10}N_2$: C, 53.5; H, 4.5; N, 6.3. Found: C, 53.5; H, 4.4; N, 6.4.

2-O-Methyl-D-erythritol

Methyl-α-D-mannopyranoside (25 g) was dissolved in 98–100% formic acid (100 ml) and acetone (750 ml) was added. Drierite (30 g) was added on the fourth day and the reaction was allowed to proceed for a total of 14 days. The Drierite was removed by filtration and the filtrate poured into a slight excess of 15% sodium hydroxide. The acetone was evaporated and the residue extracted with chloroform (3 × 500 ml) and with ether (3 × 500 ml). The extracts were combined, concentrated, and the residue was dissolved in water. This solution was extracted with 30–60° petroleum ether (3 × 300 ml) to remove all the methyl-2,3;4,6-di-*O*-isopropylidene-α-D-mannoside. The aqueous solution was concentrated to a syrup which was dissolved in hot ethyl acetate to yield

methyl-2,3-*O*-isopropylidene-α-D-mannopyranoside (10.9 g), m.p. 107–108°; lit. (20), m.p. 105°.

Methyl-4-*O*-methyl-α-D-mannoside was prepared according to Smith (21) and a pure sample isolated from a cellulose–hydrocellulose column slowly crystallized from butanone, m.p. 101–102°; lit. (22), m.p. 101–103°. This glycoside (0.8 g) was oxidized with sodium metaperiodate (1.2 g, 1.5 moles) in water (200 ml) for 24 h. Treatment with barium acetate and reduction with sodium borohydride for 24 h followed by dilute acid hydrolysis gave 2-*O*-methyl-D-erythritol (0.39 g) $[\alpha]_D$ 12° (*c*, 0.8 in H_2O).

Anal. Calcd. for $C_5H_{12}O_4$: C, 44.1; H, 8.9. Found: C, 44.2; H, 8.8.

The derived 2-*O*-methyl-1,3,4-tri-*O*-*p*-nitrobenzoyl-D-erythritol had m.p. 151–152° after purification by t.l.c.

Anal. Calcd. for $C_{26}H_{21}O_{13}N_3$: C, 53.7; H, 3.7; N, 7.2. Found: C, 53.6; H, 3.5; N, 7.2.

Samples obtained by recrystallization only had melting points varying from 140 to 220°. This value of 151–152° corrects that previously reported (23).

4-O-Methyl-D-threose

6-*O*-Methyl-D-galactose was prepared from 1,2;3,4-di-*O*-isopropylidene-D-galactose and after recrystallization from ethanol had m.p. 128°, $[\alpha]_D$ 115° (*c*, 2.1 in H_2O); lit. (24), m.p. 128°, $[\alpha]_D$ 114° (*c*, 2.1 in H_2O).

A 2% methanolic solution of 6-*O*-methyl-D-galactose (5 g) containing 0.012% hydrogen chloride (25) was refluxed for 18 h by which time the solution was only faintly reducing (Fehling test). The syrup obtained on neutralization and concentration was separated into 3 fractions on a cellulose–hydrocellulose column. The flow rate was 30 ml/h and tubes were collected at 30 min intervals.

Fraction 1, tubes 23–38: 2.48 g, methyl 6-*O*-methyl-β-D-galactofuranoside $[\alpha]_D$ −117° (*c*, 4.7 in MeOH); methyl 6-*O*-methyl-2,3,5-tri-*O*-*p*-nitrobenzoyl-β-D-galactofuranoside, m.p. 82–85°.

Anal. Calcd. for $C_{29}H_{25}O_{15}N_3$: C, 53.2; H, 3.85. Found: C, 53.0; H, 3.75.

Fraction 2, tubes 42–60: 0.74 g, methyl 6-*O*-methyl-α-D-galactofuranoside $[\alpha]_D$ 95° (*c*, 1.96 in MeOH); methyl 2,3,5-tri-*O*-*p*-nitrobenzoyl-α-D-galactofuranoside, m.p. 107–110°. Found: C, 53.1; H, 3.80.

Fraction 3, tubes 100–160: 0.15 g, methyl 6-*O*-methyl-α-D-galactopyranoside, m.p. 132–134°.

The observed anomeric proton coupling constant for fraction 1 was 1.6 c.p.s. in agreement with the value of 2 c.p.s. or less for 1,2-*trans*-furanosides (26). The value for fraction 2 was 4.4 c.p.s. corresponding closely to the value for methyl α-D-galactofuranoside (26).

Methyl 6-*O*-methyl-αβ-D-galactofuranoside (3.0 g) was oxidized with sodium metaperiodate (1.5 moles) in water (1.2 l) for 3 days to give 2.87 g of product which was refluxed with 3% methanolic hydrogen chloride for 24 h. Column chromatography of the resulting syrup (1.67 g) gave a fraction (0.63 g) with properties consistent with the dimethylacetal of 4-*O*-methyl-D-threose having 3 methoxyl and 2 hydroxyl groups in its proton magnetic resonance (p.m.r.) spectrum and $[\alpha]_D$ 5° (*c*, 0.8 in MeOH). Hydrolysis with sulfuric acid (0.5 *N*) gave 4-*O*-methyl-D-threose $[\alpha]_D$ 5° (*c*, 1.3 in H_2O); lit. (9), $[\alpha]_D$ 3° (*c*, 2 in H_2O).

Sodium borohydride reduction of a portion of periodate oxidized furanosides (1.0 g), followed by hydrolysis gave 1-*O*-methyl-D-threitol $[\alpha]_D$ 4.7° (*c*, 1.2 in H_2O).

Anal. Calcd. for $C_5H_{12}O_4$: C, 44.1; H, 8.9. Found: C, 44.1; H, 8.7.

The derivative 1-*O*-methyl-2,3,4-tri-*O*-*p*-nitrobenzoyl-D-threitol had m.p. 129°.

Anal. Calcd. for $C_{26}H_{21}O_{13}N_3$: C, 53.5; H, 3.6; N, 7.2. Found: C, 53.3; H, 3.6; N, 7.2.

3,4-Di-O-methyl-L-xylose

Oxidation of 2,3-di-*O*-methyl-D-glucitol (1.11 g) with sodium metaperiodate (1.12 g, 1 mole) in water (175 ml) for 24 h showed 1 major and 3 minor products by t.l.c. The major component was isolated by column chromatography to give 3,4-di-*O*-methyl-L-xylose (0.74 g), $[\alpha]_D$ −14.6° (*c*, 2.1 in MeOH); lit. (27) for the D-isomer $[\alpha]_D$ 13° (*c*, 1.6 in MeOH). Methanolysis and separation by g.l.c. gave a pure sample of methyl-3,4-di-*O*-methyl-α-L-xyloside, m.p. 87–89°; lit. (28) for the D-isomer, m.p. 89–90°.

Anal. Calcd. for $C_8H_{16}O_5$: OMe, 48.3. Found: OMe, 48.2.

3,4-Di-O-methyl-D-arabinose

Similarly the oxidation of 2,3-di-*O*-methyl-D-mannitol (1.15 g) with 1 mole of periodate gave 1 major and 3 minor products. Column chromatography gave as the major product 3,4-di-*O*-methyl-D-arabinose (0.83 g) having $[\alpha]_D$ −118° (*c*, 1.3 in H_2O); lit. (27) for the L-isomer $[\alpha]_D$ 125° (*c*, 2.4 in H_2O). Oxidation with bromine water and conversion of the lactone to the amide gave 3,4-di-*O*-methyl-D-arabonamide which, crystallized from acetone, had m.p. 132–133°; lit. (27) for the L-isomer, m.p. 133°.

Anal. Calcd. for $C_7H_{15}NO_5$: C, 43.5; H, 7.8. Found: C, 43.5; H, 7.9.

Synthesis of 3-hexuloses

K. G. A. JACKSON AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received February 17, 1969

A general procedure for the syntheses of derivatives of 3-hexuloses from L-*threo*-hexeno-furano lactone is described[1].

Une méthode générale de synthèse de 3-hexuloses avec du L-*threo*-hexeno-furano lactone est décrite.

Canadian Journal of Chemistry, 47, 2498 (1969)

The recent isolation from an antibiotic, and identification of coriose (1), as D-*altro*-3-heptulose, previously isolated by Begbie and Richtmyer (2) prompts us to give details of a general synthesis of 3-hexuloses. In an earlier publication (3) the synthesis of 2-*O*-methyl-3-hexuloses and 2-*O*-methyl-3-heptuloses was described and a modification of this synthesis was later (4) suggested which might lead to the 3-hexuloses. It is now shown that this suggested procedure does in fact lead to the synthesis of sugars named in the title of this paper.

L-Ascorbic acid (**1**, $R^2 = R^3 = H$) is readily acetonated to yield 5,6-*O*-isopropylidene-L-ascorbic acid (**2**, $R^2 = R^3 = H$) (5). Treatment of this substance with one equivalent of diazomethane produces mainly the 3-*O*-methyl ether (**2**, $R^2 = H$; $R^3 = CH_3$) (4). The sodium salt of this compound reacts with benzyl chloride to give crystalline **2** ($R^2 = CH_2Ph$; $R^3 = CH_3$). Elimination of acetone by acid hydrolysis yields 2-*O*-benzyl-3-*O*-methyl-L-ascorbic acid (**1**, $R^2 = CH_2Ph$; $R^3 = CH_3$). 2,3-Di-*O*-substituted derivatives of L-ascorbic acid rearrange in the presence of base (6), to yield furanoside derivatives by addition at the vinylic carbon, in this case to yield **3** ($R^2 = CH_2Ph$; $R^3 = CH_3$) which reduces 0.97 equivalent of periodate. Reduction of the lactone by lithium aluminium hydride then results in the formation of a methyl glycoside of a 3-hexulose derivative. If now the benzyl residue is removed by hydrogenation and the resultant glycoside **4** ($R^2 = H$; $R^3 = CH_3$) treated with acid a 3-hexulose **4** ($R^2 = R^3 = H$) results, which consumes 1.7 equivalent of periodate and yields 0.81 equivalent of formaldehyde. However in the rearrangement described above two new asymmetric centers are produced at C-2 and C-3, but only two products are detected. Models indicate that the addition at C-3 yields the less strained component which contains two *cis*-fused five-membered rings. The two isomers produced are separable by thin-layer and gas–liquid chromatography (t.l.c. and g.l.c.). The absolute configuration of the

For personal use only.

L-*xylo*-isomer was determined by reducing the 3-hexulose to a mixture of glucitol and galactitol, the acetates of which were identified by g.l.c. (7). A syrupy dinitrophenylhydrazone **5** of **4** ($R^2 = R^3 = H$) was prepared. Its oxidation produced formaldehyde (1.5 moles) and formic acid (0.78) with a consumption of 2.8 moles of periodate per mole. These figures obtained from a product isolated by chromatography, are in reasonable agreement with the theoretical values which are 2.0, 1.0, and 3.0 respectively (see below). The subsequent isolation of 2,4-dinitrophenylazomalondialdehyde is in agreement with the structure postulated, **5** (8).

Experimental

For details of separations of sugar derivatives by paper chromatography and t.l.c. see Jackson and Jones (4).

5,6-O-Isopropylidene-L-ascorbic acid (2, $R^2 = R^3 = H$)

A mixture of L-ascorbic acid (10 g) in acetone (40 ml) containing acetyl chloride (1.0 ml) was shaken mechanically. Crystalline 5,6-*O*-isopropylidene-L-ascorbic acid separated from the solution soon after the L-ascorbic acid had dissolved. After storage at 0° there was obtained on filtration, 10.1 g of needle-shaped crystals of m.p. 217–223° (5). This material was used in the next step without further purification.

2-O-Benzyl-5,6-O-isopropylidene-3-O-methyl-L-ascorbic acid (2, $R^2 = CH_2Ph$; $R^3 = CH_3$)

A methanolic solution of 5,6-*O*-isopropylidene-L-ascorbic acid (35 g) was treated at 0° with an ethereal solution of diazomethane to a yellow end point which persisted for about 1 min. Evaporation of the solvent yielded a mobile syrup which was dissolved in methanol and converted to the sodium salt by the addition of methanolic sodium methoxide (6.0 *N*, 21.0 ml).

After evaporation of the methanol the residual brown gum was dispersed in benzyl chloride (70 ml) and the mixture was heated at 80° (2.5 h) and then poured into water. After evaporation of excess benzyl chloride, the product crystallized and was recrystallized from methanol to yield the product (16.0 g) of m.p. 85–87°, identical with that described earlier (4) but in higher yield.

For personal use only.

2-O-Benzyl-3-O-methyl-L-ascorbic acid (1, $R^2 = CH_2Ph$; $R^3 = CH_3$)

A solution of the above isopropylidene derivative (3.0 g) above in acetic acid (50%, 50 ml) was heated at 90–100° for 4 h. Water (200 ml) was then added and the solution was extracted with chloroform (2 × 200 ml). The chloroform extracts were dried ($MgSO_4$), filtered, and the filtrate was evaporated. The crystalline residue (1.3 g) was recrystallized from chloroform. The product had m.p. 124° and $[\alpha]_D = +48° \pm 1°$ (*c*, 1.0 in methanol).

Anal. Calcd. for $C_{14}H_{15}O_6$: C, 60.0; H, 5.7. Found: C, 59.6; H, 5.5.

The infrared (i.r.) spectrum (KBr disk) revealed strong absorptions at 1660, 1745, and 3300 cm^{-1}. The nuclear magnetic resonance (n.m.r.) spectrum (DMSO-d_6) revealed peaks at τ 2.61 (singlet, 5 aromatic protons), and 6.09 (singlet, 3 methyl protons) as well as other peaks.

Methyl 2-O-Benzyl-L-(lyxo + xylo)-3-hexulofuranosidonolactones (3, $R^2 = CH_2Ph$; $R^3 = CH_3$)

An aqueous solution of **1** ($R^2 = CH_2Ph$; $R^3 = CH_3$) (8.3 g) was saponified at 60° with sodium hydroxide (1.96 *N*, 11.2 ml). The solution was then passed down a column of ion exchange resin (H^+) and the acidic effluent collected. The column was washed with warm water until the effluent gave a negative Molisch test and the aqueous solutions were concentrated and extracted with chloroform (2 × 10 ml). The extracts were dried ($MgSO_4$), filtered, and the filtrate was evaporated to a syrup (6.6 g) which had $[\alpha]_D = -10° \pm 1°$ (*c*, 1.0 in methanol). Two components were detected by paper chromatograms (solvent *a*) and were visualized in iodine vapor. The i.r. absorption ($CHCl_3$) revealed absorptions at 1800 cm^{-1} (strong) and 3450 cm^{-1} (medium).

Methyl 2-O-Benzyl-L-(lyxo + xylo)-3-hexulosides (4, $R^2 = CH_2Ph$; $R^3 = CH_3$)

The syrupy product above (14.3 g from two preparations) was dissolved in ether (100 ml) and the solution added dropwise to a solution of $LiAlH_4$ (14.0 g) in ether (200 ml). An immediate precipitate resulted. Ten minutes after completion of the addition, excess of $LiAlH_4$ was destroyed with ethyl acetate (300 ml) followed by the cautious addition of water (200 ml). The ethyl acetate layer was separated and the residue was extracted with a further quantity of ethyl acetate (100 ml). The combined extracts were washed with water (100 ml), dried ($MgSO_4$), filtered, and the filtrate was evaporated to a pale yellow syrup (10.5 g) of $[\alpha]_D = -6° \pm 1°$ (*c*, 1.0 in methanol). Analysis by t.l.c. indicated the presence of two components of R_f 0.6 and 0.7 in the approximate ratio 2:3. The i.r. absorption of the mixture in chloroform indicated a peak at 3500 cm^{-1} (medium) but none at 1605–2000 cm^{-1}.

Periodate Oxidation of the Syrupy Mixture of Glycosides

Periodate uptake and formic acid yield on 116 mg of the mixture, dissolved in water (100 ml) were carried out in the usual way (4) using screened (methylene-blue)-methyl red indicator.

Found: Moles periodate consumed per mole of compound at the times indicated: 0.31, (0.5 h); 0.38 (1 h); 0.51 (2 h); 0.72 (4.5 h); 0.91 (20 h); 0.97 (94 h). The yield of formic acid rose from 0.02 to 0.08 in the same period.

Methyl L-(lyxo + xylo)-3-hexulosides (4, $R^2 = H$; $R^3 = CH_3$)

The syrupy mixture of glycosides (9.0 g) (above) was dissolved in ethanol (100 ml) and reduced with Raney nickel catalyst and hydrogen at 2 atmospheres pressure during 4 days. At the end of this time reaction was complete as judged by t.l.c. The solution was filtered and the filtrate evaporated to a syrup which was dissolved in water and extracted with chloroform (100 ml) to remove the last traces of toluene. Evaporation of the aqueous layer afforded a syrup (5.6 g) of $[\alpha]_D = +35° \pm 1°$ (*c*, 1.0 in methanol). Paper chromatography (solvent *a*) revealed one component with $R_f = 0.48$ and $R_{rhamnose} = 1.45$.

Periodate Oxidation of Methyl L-(lyxo + xylo)-3-hexulosides

Periodate uptake, formic acid production, and formaldehyde release were determined in the usual manner on 110 mg syrup in water (100 ml).

Found: Uptake of periodate at the times indicated: 0.91 (0.25 h); 1.05 (1 h); 1.26 (3.5 h); 1.45 (10 h); 1.64 (23 h); 1.70 (30 h). Formaldehyde yield: 0.02 (0.4 h); 0.81 (21 h). The formic acid yield changed from 0.01 (0.25 h) to 0.04 (23 h). All results are given in mole/mole of glycoside.

Methyl 1,2,4,5-Tetra-O-acetyl-L-(lyxo + xylo)-3-hexulosides

The mixed glycosides (1.0 g) were acetylated with pyridine (30 ml) and acetic anhydride (5 ml) at 0° for 12 h. The acetylated products were isolated in the usual manner as a clear colorless syrup. Thin-layer chromatography revealed components at $R_f = 0.60$ (medium) and 0.75 (major). Analysis by gas–liquid chromatography (g.l.c.) using 5% LAC-4-R-886 (Chromatographic Specialities, Brockville, Ontario) at 200° and at a flow rate of 100 cc/min (Pye Argon g.l.c.) showed two components, the L-*xylo* and L-*lyxo* derivatives respectively, 3.5 min and 5.8 min, in the ratio 55:45.

Separation of the Glycosides

A portion of the mixture was separated by preparative t.l.c. on plates 8 in. × 8 in. coated with silica gel G using chloroform, methanol (9:1 v/v) as eluant. The bands of material could be located visually or better with the aid of an ultraviolet lamp. The faster moving component (540 mg) isolated after extraction of the appropriate region of the silica gel G with acetone had a retention time of 3.5 min (see above) and had $[\alpha]_D = +14° \pm 1°$ (*c*, 1.0 in methanol) and was identified as methyl 1,2,4,5-tetra-*O*-acetyl-L-*xylo*-3-hexuloside (see below).

Anal. Calcd. for $C_{15}H_{22}O_{10}$: C, 49.7; H, 6.1. Found: C, 50.0; H, 6.4.

The slower moving component (200 mg) was therefore methyl 1,2,4,5-tetra-*O*-acetyl-L-*lyxo*-3-hexuloside with $[\alpha]_D = +5° \pm 1°$ (*c*, 1.0 in methanol). It was not further examined. The i.r. spectra of these two substances ($CHCl_3$) were indistinguishable and revealed absorption bands at 1730 cm^{-1} (strong) and at 1375 cm^{-1} (medium).

Purification of Methyl L-xylo-3-hexuloside

Methyl 1,2,4,5-tetra-*O*-acetyl-L-*xylo*-3-hexuloside (540 mg) was deacetylated by the method of Zemplén. After

12 h the product was isolated as a clear colorless syrup (250 mg) with $[\alpha]_D = -29° \pm 1°$ (*c*, 1.0 in methanol). On periodate oxidation of a sample (5.5 mg) formaldehyde (0.31 mole/mole, 21 h) was produced.

L-xylo-3-Hexulose (4, $R^2 = R^3 = H$)

The glycoside (100 mg) was dissolved in water (20 ml) and hydrolyzed at 80° with acid ion exchange resin (Amberlite IR-120) during 0.33 h. At the end of this time hydrolysis was complete as indicated by paper chromatography. The product in solvent *a* had $R_{rhamnose} = 0.69$; $R_{tagatose} = 1.25$ and $R_{sorbose} = 1.45$ and gave a bright-yellow color with the *p*-anisidine hydrochloride spray. The reducing sugar was isolated as a syrup after removal of the ion exchange resin and evaporation of the solution. It had $[\alpha]_D = +10° \pm 1°$ (*c*, 0.5 in water).

Sodium Borohydride Reduction of L-xylo-3-Hexulose (4, $R^3 = R^4 = H$) and Identification of the Resultant Hexitols

The ketose **4** ($R^3 = R^4 = H$) (20 mg) was reduced in water (50 ml) by addition of sodium borohydride (30 mg). When reduction was complete, as indicated by paper chromatography, the solution was passed through a column of ion exchange resin (Amberlite i.r. 120 H) and the effluent evaporated to dryness. Boric acid was removed as methyl borate by co-distillation with methanol and the residue acetylated (pyridine and acetic anhydride) in the usual way. The mixture of acetates was then examined by g.l.c. and was resolvable into two components which were indistinguishable, on an F and M model 500 g.l.c. machine, from sorbitol and dulcitol hexa-acetates under standardized conditions.

L-xylo-3-Hexulose 2,4-Dinitrophenylhydrazone (5)

The L-*xylo*-methyl glycoside (**4**, $R^2 = H$; $R^3 = CH_3$) (0.175 g) was dissolved in dimethyl sulfoxide (2 ml) containing 1 drop of conc. hydrochloric acid and 2,4-dinitrophenylhydrazine (0.165 g). After 2 h, paper chromatography (solvent *a*) indicated the presence of a yellow major component with $R_f = 0.66$, $R_{rhamnose} = 1.78$. This substance was isolated as a yellow gum after preparative chromatography on six 8 in. × 8 in. glass plates coated with silica gel G. The product (93 mg) had $[\alpha]_D = 20° \pm 4°$ (*c*, 0.9 in methanol) and was homogeneous by paper chromatography.

Periodate Oxidation of L-xylo-3-Hexulose 2,4-Dinitrophenylhydrazone

The hydrazone derivative (37.5 mg) was oxidized in duplicate in the usual manner.

Found: Mole of formic acid produced by moles of periodate consumed per mole of compound at the times indicated: 0.78, 2.8 (0.17 h); 0.7, 2.8 (0.67 h). Formaldehyde produced mole/mole 1.50 (0.5 h).

During the oxidation a yellow precipitate separated from solution. It had m.p. 160° and its i.r. spectrum (KBr disk) showed strong peaks at 1590, 1655, and 1685 cm^{-1} with no absorption in the region 1700–2300 cm^{-1}. The ultraviolet absorption was strong at $\varepsilon_{max} = 395$ mμ with $\varepsilon = 2.5 \times 10^4$. 2,4-Dinitrophenylazomalondialdehyde has m.p. 160–161°, $\varepsilon_{max} = 395$ mμ with $\varepsilon = 2.45 \times 10^4$ (8).

Total synthesis of (±)ochotensine

R. B. Kelly and B. A. Beckett
Department of Chemistry, University of New Brunswick, Saint John, New Brunswick

Received February 20, 1969

A total synthesis of (±)ochotensine is described.

Canadian Journal of Chemistry, 47, 2501 (1969)

A very recently published total synthesis of (±)ochotensine (**1**) (1) by Irie *et al.* (2) has just come to our attention, prompting us to report an independent, but similar, synthesis of this alkaloid. An account (3) of our total synthesis of analogues **5** and **6** of ochotensine and ochotensimine respectively, appeared some months ago. We anticipated (3) that the synthesis of

For personal use only.

these analogues would serve as a model for us for a total synthesis of ochotensine (**1**). Both the synthesis of Irie *et al.* (2) and that reported here parallel exactly our model synthesis (3) of **5** and **6**. However, they differ considerably in execution. We therefore feel that the experimental details of our synthesis would be of value, especially in view of the intense interest shown recently in the synthesis of ochotensine (**1**) and ochotensimine (**2**) (2, 3, 4). A total synthesis of the latter by McLean *et al.* (4) has appeared within the past year.

8 X = NOH

2,3-Dihydroxybenzoic acid, prepared from *o*-vanillin by a published route (5) was used as starting material for the synthesis of the indanedione **7**. Methyleneation of the ethyl ester of this acid by the method of Dallacker and Korb (6) gave 2,3-methylenedioxybenzoic acid (cf. ref. 7). The ethyl ester of the latter benzoic acid was reduced with lithium aluminium hydride and the resulting benzyl alcohol was oxidized to 2,3-methylenedioxybenzaldehyde with manganese dioxide under mild conditions. The aldehyde was converted to the known (7) 2,3-methylenedioxycinnamic acid by a Knoevenagel reaction and the cinnamic acid was reduced catalytically under mild conditions to 2,3-methylenedioxyhydrocinnamic acid. The acid chloride of the hydrocinnamic acid was cyclized, in 28% yield, in benzene with aluminium chloride as catalyst to 4,5-methylenedioxyindane-1-one which was converted via the oximinoketone (**8**) to the indanedione (**7**). Unless otherwise indicated, the yields of the individual steps of the above sequence were 80–90%.

A Pictet–Spengler condensation between the indanedione **7** and 3-hydroxy-4-methoxyphenethylamine (8) in ethanolic hydrochloric acid afforded the condensation product (**3**) in 46% yield. The condensation product was converted to the *N*-methylamine (**4**) by heating with an aqueous mixture of formic acid and formaldehyde. A Wittig reaction carried out on the tetrahydropyranyl derivative of **4**, chromatography of the crude product on silica gel and acid hydrolysis gave, in 35% yield, (±)ochotensine.

The ultraviolet (u.v.) and infrared (i.r.) spectra and the fragmentation pattern of the mass spectrum of the synthetic ochotensine were superimposable on the corresponding spectra of the natural alkaloid. Furthermore, the synthetic alkaloid exhibited the same behavior on thin-layer chromatography as the natural alkaloid.

Experimental

Ethyl 2,3-Dihydroxybenzoate

2,3-Dihydroxybenzoic acid (10.0 g) (5) was esterified in absolute ethanol saturated with dry hydrochloric acid gas in the usual manner. Crystallization of the product from ethanol–water afforded 10.1 g (86%) of the ester, m.p. 69°; ν_{max} (Nujol) 1705 cm^{-1} (ester).

Anal. Calcd. for $C_9H_{10}O_4$: C, 59.34; H, 5.53. Found: C, 59.16; H, 5.44.

2,3-Methylenedioxybenzoic Acid

A solution of 45.5 g of ester in 125 ml of ethylene glycol was saturated with hydrogen gas and the reaction was then carried out in a hydrogen atmosphere as follows. To the glycol solution were added 70 g of anhydrous potassium carbonate and 50 g of bromochloromethane. The temperature of the reaction mixture was gradually raised to 120° over a period of 4 h and thereafter maintained at 100–120° for 18 h. Solvent (65 ml) was removed by distillation *in vacuo* and water (1 l) was added to the concentrate. The resulting solution was cooled and acidified (Congo paper) with 6 *N* hydrochloric acid whereupon the desired product, 2,3-methylenedioxybenzoic acid crystallized. The crystalline acid (36.0 g, 87%) melted at 225° (lit. (7) m.p. 227°).

The *ethyl ester*, prepared by treatment of the acid with ethanol saturated with dry hydrogen chloride and distillation of the product, melted at 35° (lit. (7) m.p. 35.5°); ν_{max} (Nujol) 1710 (ester) and 915 cm^{-1} (—O—CH_2—O—).

Anal. Calcd. for $C_{10}H_{10}O_4$: C, 61.85; H, 5.19. Found: C, 62.01; H, 5.11.

2,3-Methylenedioxybenzaldehyde

Lithium aluminium hydride (6.2 g) was added from a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Soxhlet apparatus over a period of 1.5 h to a refluxing solution of 52.0 g of ethyl 2,3-methylenedioxybenzoate in 500 ml of ether. After stirring at room temperature for 1 h, 15 ml of concentrated brine were added to the reaction mixture and stirring was continued for 1 h. Anhydrous sodium sulfate was added, the mixture was filtered, and the solid material was washed well with ether. The combined filtrate and washings, on evaporation *in vacuo*, afforded 40.5 g of oil which was dissolved in 250 ml of chloroform and treated with 120 g of activated manganese dioxide (9). The mixture was stirred at room temperature for 5 h then filtered. The solid material was washed well with chloroform. The combined filtrate and washings were evaporated *in vacuo* and the residue was crystallized from petroleum ether (b.p. 40–60°) whereby 37.9 g (94%) of the desired product was obtained, m.p. 35° (lit. (7) m.p. 34°); ν_{max} (neat) 1685 (—CHO) and 925 cm^{-1} (—O—CH_2—O—).

Anal. Calcd. for $C_8H_6O_3$: C, 64.00; H, 4.03. Found: C, 63.84; H, 4.03.

2,3-Methylenedioxyhydrocinnamic Acid

2,3-Methylenedioxycinnamic acid prepared from 2,3-methylenedioxybenzaldehyde by the method of Perkin and Trikojus (7) was reduced catalytically as follows. A solution of 2.00 g of the acid in 250 ml of absolute alcohol was hydrogenated over 200 mg of Pd/C (10%) catalyst at 2 atm and room temperature for 2 h. Removal of the catalyst by filtration and evaporation of the filtrate gave 1.80 g (89%) of crystalline product, m.p. 72–75°. Recrystallization from ether – petroleum ether (b.p. 40–60°) afforded a sample melting at 76–78° (lit. (2) m.p. 78–79°); ν_{max} (Nujol) 1710 (COOH) and 925 cm^{-1} (—O—CH_2—O—).

Anal. Calcd. for $C_{10}H_{10}O_4$: C, 61.85; H, 5.19. Found: C, 61.73; H, 5.47.

4,5-Methylenedioxyindane-1-one

A solution of 10.0 g of 2,3-methylenedioxyhydrocinnamic acid in 125 ml of dry benzene was cooled on an ice bath and treated with 9.25 ml of freshly distilled oxalyl chloride. After stirring on an ice bath for 1 h, the solution was left at room temperature for 5 h. The solvent was removed by evaporation *in vacuo*. A solution of the acid chloride in 230 ml of dry benzene was cooled to −10° and treated, over a period of 5 min, with 13.3 g of freshly sublimed aluminium chloride. The mixture was then stirred on an ice bath for 30 min and finally at room temperature for 15 min. The reaction mixture was decanted onto ice and the resulting mixture was extracted with chloroform. The chloroform extracts were washed with 1 *N* sodium carbonate, brine, and finally water, dried over anhydrous sodium sulfate, and evaporated *in vacuo*. The residue, on crystallization from methylene chloride – ether yielded 1.98 g (28%) of desired product, m.p. 167–168° (lit. (2) m.p. 164–167°; (4) m.p. 165–168°); λ_{max}(EtOH) 285 mμ (ε 8950), 300 mμ (sh) (ε 7300); ν_{max} (Nujol) 1700 (ketone) and 925 cm^{-1} (—O—CH_2—O—).

Anal. Calcd. for $C_{10}H_8O_3$: C, 68.18; H, 4.58. Found: C, 68.29; H, 4.37.

4,5-Methylenedioxyindane-1,2-dione (7)

A stirred mixture of 500 mg of 4,5-methylenedioxyindane-1-one and 10 ml of methanol was cooled on an ice bath and treated with 0.75 ml of isoamyl nitrite and 0.25 ml of concentrated hydrochloric acid. After stirring at 50° for 15 min, the mixture was cooled to 0° and the product collected and washed with ethanol. Recrystallization from a large volume of ethanol gave 476 mg of the hydroxyimino derivative (**8**), m.p. 237–240° (decomposed) (lit. (2) m.p. 245–250°). This derivative (470 mg) was mixed with 5.5 ml of a solution of formaldehyde and concentrated hydrochloric acid (8:2). The resulting mixture was placed in a water bath at 50° and the temperature was raised, with vigorous stirring to 90° over a period of 10 min. After cooling, a yellow precipitate was collected and crystallized from benzene whereby 350 mg (64%) of **7** were obtained, m.p. 170–178° (lit. (4) m.p. 158–168°; (2) m.p. 171–178°); λ_{max}(EtOH) 293 mμ (ε 8500), 310 mμ (sh) (ε 7800); ν_{max}($CHCl_3$) 1715 and 1765 cm^{-1} (ketone).

Anal. Calcd. for $C_{10}H_6O_4$: C, 63.16; H, 3.18. Found: C, 63.35; H, 3.21.

Pictet–Spengler Condensation Product (3)

A mixture of 915 mg of the indanedione (**7**), 934 mg of 3-hydroxy-4-methoxyphenethylamine (**8**), 5 ml of concentrated hydrochloric acid and 95 ml of absolute ethanol were stirred at 55° for 60 h. The solvent was evaporated *in vacuo* and the residue was dissolved in the minimum volume of chloroform and ether was added until precipitation of solid material ceased. The precipitate was dissolved in 75 ml of 1 *N* ammonium hydroxide and the aqueous solution was extracted with chloroform. The chloroform extracts were washed with brine then with water and dried over anhydrous sodium sulfate. Crystallization of the residue obtained by evaporation of the chloroform extracts *in vacuo* from ethanol afforded 746 mg (46%) of **3**, m.p. 100–104° (lit. (2) m.p. 194–195°; (4) m.p. 104–107°);[1] λ_{max}(EtOH) 236 mμ (ε 28 500), 290 mμ (ε 12 100), 315 mμ (sh) (ε 7000); ν_{max}($CHCl_3$) 3525 (phenol) and 1710 cm^{-1} (ketone).

Anal. Calcd. for $C_{19}H_{17}NO_5$: C, 67.24; H, 5.05; N, 4.13. Found: C, 67.18; H, 5.25; N, 3.86.

N-Methylamine (4)

A solution of 750 mg of **3** in 4 ml each of 88% formic acid and 37% formaldehyde was stirred at 95° for 4 h. The cooled reaction solution was diluted with 20 ml of water, adjusted to pH 7 with concentrated ammonium hydroxide and extracted with chloroform. The chloroform extracts were washed with brine then with water, dried over anhydrous sodium sulfate, and evaporated *in vacuo*. The residue on crystallization from benzene, gave 578 mg (74%) of **4**, m.p. 100–103° (lit. (2) m.p. 101–103°); u.v. spectrum, similar to **3**, ν_{max}($CHCl_3$) 3525 (phenol) and 1708 cm^{-1} (ketone).

The *picrate*, crystallized from ethanol, melted at 213–217° (lit. (2) m.p. 213–217°).

Anal. Calcd. for $C_{26}H_{22}N_4O_{12}$: C, 53.61; H, 3.81; N, 9.62. Found: C, 53.37; H, 3.96; N, 9.78.

---

[1]It is suspected that the discrepancies between the reported melting points of this compound are due to dimorphism. Similar behavior has been observed, but not reported, by the authors in related compounds (3).

(±)Ochotensine (1)

A solution of 293 mg of **4** in 4.2 ml of dimethyl sulfoxide was treated, while cooled on an ice bath, with 4.2 ml of dihydropyran and 0.83 ml of trifluoroacetic acid. The resulting solution was left at room temperature for 4 h, cooled on an ice bath, and treated with 30 ml of 1 *N* sodium hydroxide. The alkaline solution was extracted with chloroform and the extracts were washed successively with 1 *N* sodium hydroxide and water, then dried over anhydrous sodium sulfate. The Wittig reaction was carried out on the oily tetrahydropyranyl derivative (362 mg), obtained by evaporation of the chloroform extracts, in an atmosphere of dry, oxygen-free nitrogen. Thus, a stirred mixture of 886 mg of methyltriphenylphosphonium bromide in 9 ml of ether was treated with 1.20 ml of a 2.3 *M* ethereal solution of *n*-butyllithium and the mixture was stirred for 2 h at room temperature. The resulting orange solution was treated with a solution of 362 mg of the tetrahydropyranyl derivative in 9 ml of tetrahydrofuran. After stirring at room temperature for 1 h, the ether was removed by distillation and replaced by 5 ml of tetrahydrofuran. The reaction solution was then heated under reflux for 3 h, cooled, treated with 1 ml of water, and the solvent was evaporated *in vacuo*. The residue was dissolved in chloroform and washed with water. The chloroform solution, after drying over potassium carbonate, was evaporated *in vacuo*. The residue was chromatographed on a column (diameter 2.5 cm) of 20 g of silica gel. The column was developed with 50% petroleum ether (b.p. 30–60°) in ether and the tetrahydropyranyl derivative was eluted with 25% petroleum ether in ether. Combination of the appropriate column fractions and evaporation of the solvent gave 126 mg of residue. This was stirred with 1.2 ml each of absolute ethanol and 4 *N* hydrochloric acid at room temperature for 5 h. Evaporation of the solvent and crystallization of the residue from ethanol afforded (113 mg, 35%) of the crystalline (±)ochotensine hydrochloride, m.p. 205–212°. The free alkaloid was obtained quantitatively from the hydrochloride by dissolving the salt in 0.1 *N* NaOH, adjusting the alkaline solution to pH 8.0, collecting the precipitate and crystallizing it from ethylene dichloride. The synthetic (±)ochotensine melted at 238–239° (lit. (2) m.p. 241–243.5°); λ_{max}(EtOH) 226 mμ (ε 25 800), 287 mμ (ε 15 800); ν_{max}(KBr) 1645 and 1605 cm^{-1} (C=C).

The u.v., i.r., and mass spectra of the synthetic ochotensine were superimposable on the corresponding spectra of the natural alkaloid. The synthetic alkaloid was not separated from the natural alkaloid on thin-layer chromatograms developed in benzene – methanol (95:5) and in ethylene dichloride – methanol (95:5).

Calcd. for $C_{21}H_{21}NO_4$: molecular weight 351. Found: molecular weight 351 (mass spectrum).

2-Amino-4-methyl-5-hexenoic acid, a naturally occurring antimetabolite antibiotic

R. B. KELLY,[1] D. G. MARTIN, AND L. J. HANKA

Research Laboratories, The Upjohn Company, Kalamazoo, Michigan, 49001

Received March 17, 1969

A new antimetabolite antibiotic has been isolated from a *Streptomyces* culture. The antibiotic has been shown to be 2-amino-4-methyl-5-hexenoic acid, a hitherto unknown compound.

Canadian Journal of Chemistry, 47, 2504 (1969)

Previously we reported (1) the isolation and structure elucidation of an antimetabolite antibiotic, the antimicrobial activity of which was reversed by biotin. This was shown to be a new compound, α-dehydrobiotin (double bond in conjugation with the carboxyl group). We now wish to describe the isolation and structure

For personal use only.

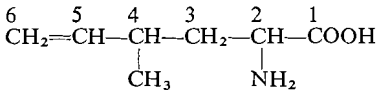
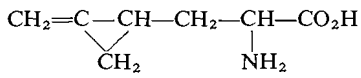
determination of another member of this class of antibiotics. The new antibiotic is produced by a *Streptomyces* (Sp. UC5159), is active against a variety of gram-positive organisms[2] and its antimicrobial activity is reversed by the presence of leucine. Valine or isoleucine were less effective reversing agents.

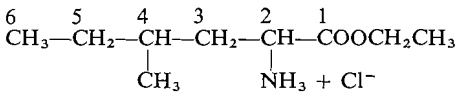
Details of fermentation and isolation procedures are given in the Experimental section. Elemental analyses (C, H, and N) of the crystalline antibiotic were in excellent agreement with the formula $C_7H_{13}NO_2$. A violet color developed on heating the antibiotic with ninhydrin reagent and the infrared (i.r.) spectrum displayed bands attributable to an α-amino acid. Bands at 1645, 995, and 920 cm^{-1}, consistent with the structural feature $CH_2 = CHR$, were also prominent in the i.r. spectrum. The nuclear magnetic resonance (n.m.r.) spectrum (Table I) in conjunction with the above data uniquely defined the structure of the antibiotic as 2-amino-4-methyl-5-hexenoic acid (**1**), a hitherto unknown compound. The structural relationship to the novel amino acid, hypoglycin A (**2**), (2), isolated from the fruits of *Blighia sapida* ("Ackee"), is noteworthy. A double bond isomer of **1**, 2-amino-4-methyl-4-hexenoic acid, has been synthesized and found to be a competitive antagonist of both phenylalanine and leucine (3).



1



2



3

An optical rotatory dispersion (o.r.d.) curve with positive Cotton effect (peak 215 mμ) indicates that the antibiotic has the same configuration at C-2 as the naturally occurring α-amino acids (4).

The antibiotic was further characterized by catalytic reduction to the corresponding substituted hexanoic acid and conversion of the latter to the crystalline ethyl ester hydrochloride (**3**). In the n.m.r. spectrum of **3** taken in deuteriochloroform,[3] 14 protons were detected in the region δ 0.70–2.30 due to 3 methyl groups, 2 methylenes (at C-3 and C-5), and the methine at C-4. This region contained a triplet at δ 1.32 (J = 7 Hz) due to the methyl group in the ester; the overlapping signals of the other two methyl groups were at ca. δ 0.97. The methylene in the ester group appeared as a quartet at δ 4.28 (J = 7 Hz) superimposed on the signal for the methine at C-2. A broad singlet due to NH_{3+} was centered at δ 8.58 (3H, exchangable with D_2O). A prominent peak in the mass spectrum at *m/e* 173 established the molecular weight of the free ester of **3** as 173 ($C_9H_{19}NO_2$) and consequently that of the antibiotic **1** as 143 ($C_7H_{13}NO_2$). Elemental analyses of the ester hydrochloride (**3**) are in agreement with the formula $C_9H_{19}NO_2 \cdot HCl$.

The above data support the structure of the derived ester hydrochloride as **3** thus corroborating structure **1** for the antibiotic.

Experimental

Fermentation and Isolation

Fermentations were carried out at 32 °C in media consisting of 1% each of mannitol, starch, and Phytone,[4] 5% of calcium carbonate, and 0.2% of sodium chloride. Peak titres were reached after 4 or 5 days of incubation. The antimicrobial activity of fermentation liquors was determined by assay against *Escherichia coli* grown in a synthetic medium. This assay also served as a guide during isolation.

Two l of filtered fermentation liquor was percolated through a column of 400 ml of carbon. After washing the column with 2 l of water and 800 ml of 2% acetone in water, an active fraction was eluted with 4 l of 5% acetone in water. Evaporation of the active eluate *in vacuo* left 7.00 g of residue which was applied in 200 ml of water to a column of 400 ml of Dowex 50 (H+) resin. After washing the column with 2 l of water, an active fraction was eluted with 2.8 l of 1 *N* ammonium hydroxide. Evaporation of the active eluate left 1.26 g of crystalline residue. Five recrystallizations of this material from 95% ethanol afforded 191 mg of antibiotic having m.p. 260° (decomposing). The following data pertain to the o.r.d. curve in water (*c*, 0.993; 0.1 dm cell): $[\theta]_{300}$,

[2]For example, *Staphylococcus aureus*, *Sarcina lutea*, and *Bacillus subtilis*.

Conversion of the Antibiotic to 3

The antibiotic (120 mg) was hydrogenated at room temperature and atmospheric pressure over 100 mg of palladium–charcoal (10%) catalyst in 95% ethanol. The theoretical quantity of hydrogen was absorbed within 30 min. The catalyst was removed by filtration and the residue obtained by evaporation of the filtrate *in vacuo* was treated with 30 ml of absolute ethanol saturated with dry HCl gas. The resulting solution was left for 2 h at room temperature then evaporated *in vacuo* to dryness. The residue was treated twice with ethanolic hydrochloric acid as above. Crystallization of the resulting solid from ethyl acetate afforded the ethyl ester hydrochloride **3** melting at 118–122 °C. The infrared (i.r.) spectrum (Nujol) had a series of bands between 3000 and 2500 cm^{-1} attributable to the ammonium ion. There was also a band at 1745 cm^{-1} due to the ester.

Carbon-13 kinetic isotope effects. V.[1] Substituent effects on k_{12}/k_{13} for alcoholysis of 1-phenyl-1-bromoethane

JAN BRON AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario, London, Ontario

Received November 25, 1968

As a test of our earlier interpretations of the ^{13}C kinetic isotope effects found for alcoholysis of 1-phenyl-1-bromoethane, we have examined the effect of the *p*-methyl and *p*-bromo substituents on the ^{13}C fractionations in ethanol and methanol. Isotopic fractionation at the α-carbon is found to be substituent dependent, and the observed trend is consistent with the proposal that stabilization of the cationic center by the phenyl ring is a major factor governing the isotope effect in these systems. The first example of an inverse primary kinetic isotope effect for carbon ($k_{12}/k_{13} < 1$) is described.

Canadian Journal of Chemistry, 47, 2506 (1969)

Earlier it was found that k_{12}/k_{13} is 1.0065 for the methanolysis of 1-phenyl-1-bromoethane (**1**) at 25 °C (1). This relatively small isotope effect was attributed to resonance stabilization of the carbonium ion intermediate by the phenyl group, as well as to hyperconjugative interaction with the α-methyl group. The latter point has recently received support from measurements of the

Conversion of the Antibiotic to 3

The antibiotic (120 mg) was hydrogenated at room temperature and atmospheric pressure over 100 mg of palladium–charcoal (10%) catalyst in 95% ethanol. The theoretical quantity of hydrogen was absorbed within 30 min. The catalyst was removed by filtration and the residue obtained by evaporation of the filtrate *in vacuo* was treated with 30 ml of absolute ethanol saturated with dry HCl gas. The resulting solution was left for 2 h at room temperature then evaporated *in vacuo* to dryness. The residue was treated twice with ethanolic hydrochloric acid as above. Crystallization of the resulting solid from ethyl acetate afforded the ethyl ester hydrochloride **3** melting at 118–122 °C. The infrared (i.r.) spectrum (Nujol) had a series of bands between 3000 and 2500 cm^{-1} attributable to the ammonium ion. There was also a band at 1745 cm^{-1} due to the ester.

Carbon-13 kinetic isotope effects. V.[1] Substituent effects on k_{12}/k_{13} for alcoholysis of 1-phenyl-1-bromoethane

JAN BRON AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario, London, Ontario

Received November 25, 1968

As a test of our earlier interpretations of the ^{13}C kinetic isotope effects found for alcoholysis of 1-phenyl-1-bromoethane, we have examined the effect of the *p*-methyl and *p*-bromo substituents on the ^{13}C fractionations in ethanol and methanol. Isotopic fractionation at the α-carbon is found to be substituent dependent, and the observed trend is consistent with the proposal that stabilization of the cationic center by the phenyl ring is a major factor governing the isotope effect in these systems. The first example of an inverse primary kinetic isotope effect for carbon ($k_{12}/k_{13} < 1$) is described.

Canadian Journal of Chemistry, 47, 2506 (1969)

Earlier it was found that k_{12}/k_{13} is 1.0065 for the methanolysis of 1-phenyl-1-bromoethane (**1**) at 25 °C (1). This relatively small isotope effect was attributed to resonance stabilization of the carbonium ion intermediate by the phenyl group, as well as to hyperconjugative interaction with the α-methyl group. The latter point has recently received support from measurements of the

β-deuterium isotope effects in solvolyses of **1**, the corresponding chloride, and several substituted derivatives (2). Indirect support for the proposal of an appreciable influence of the phenyl ring on k_{12}/k_{13} has been presented by Kresge, Lichtin, Rao, and Weston (3) from their study of the dissociation of trityl chloride in liquid SO_2. In addition, crude calculations show (4) that the loss of the C—Br stretching mode in the initial state can be offset, in the transition state, by a reasonable degree of Ar—C^+ bond strengthening by π-overlap via resonance. Intuitively, stabilization by the phenyl ring should be governed by the polarity of ring substituents, and the present study was undertaken to examine the effect of *p*-methyl and *p*-bromo groups on k_{12}/k_{13} for alcoholysis to test our original proposal (1).

The ^{13}C isotope effects for 1-(4′-methylphenyl)-1-bromoethane in methanol and ethanol at 0° and for 1-(4-bromophenyl)-1-bromoethane in methanol at 0 and 25 °C were determined. The results are listed in Table I together with some data obtained previously (5).

As noted previously (1), there is evidence that the major path for alcoholysis of 1-phenyl-1-bromoethane itself is through an intimate ion-pair, i.e. the process is a limiting S_N1 reaction proceeding via a carbonium ion intermediate. A plot of the present kinetic data (see Experimental) for methanolysis at 0° *vs.* the σ^+ parameter yields a ρ value of −5.4 which is consistent with the foregoing. Thus, it is to be expected that generation of positive charge at the benzylic carbon will be assisted by resonance interaction with the phenyl ring, the extent of which may be governed by *p*-substituents. The methyl group should increase the interaction while a *p*-bromo atom should reduce electron supply from the aryl ring, both relative to **1**. If the fractionation at the benzylic carbon is sensitive to conjugative interaction with the aryl ring, as we have proposed (1), the k_{12}/k_{13} values should reflect this.

Of the reaction conditions examined, one is common to the three reactants, methanolysis at 0°, and it is clear that the isotope effect is largest for the electron-withdrawing *p*-Br group and smallest for the electron-releasing methyl substituent. In fact the latter value represents an inverse effect, i.e. the ^{13}C isotope reacts faster, and we believe this to be the first example of a primary inverse *kinetic* effect for carbon isotopy, although inverse equilibrium isotope effects for carbon have been reported (3). The precision of the present measurements is sufficient to establish that the trend from *p*-Me → *p*-Br is real. Further evidence is given by the 25° results for **1** and its *p*-bromo derivative.

As noted above, semi-quantitative estimations of the ^{13}C isotope effect for **1** in solvolysis have shown that the α-phenylethyl carbonium ion model for the transition state can accommodate the observed results, on the basis of the Bigeleisen formulation (6), and that a strengthening of the Ar—C^+ bond in the transition state can offset the loss of the C—Br stretching mode in the initial state (5). Arguments to support the view that the carbonium ion is an appropriate model have been presented (1). Kresge *et al.* (3) have shown, for the closely related dissociation of trityl chloride in sulfur dioxide, that the carbon–phenyl bonds in the triphenyl-carbonium ions must be much stronger than those in trityl chloride. These authors have discussed an extension of their reasoning to provide an explanation for the relatively small kinetic isotope effects found for S_N1 processes. As discussed in an earlier part of this series (5), it is difficult to make quantitative estimates of the magnitudes of the vibrational frequency differences for the

change, initial state → transition state. It is gratifying, however, to find that the experimental results agree qualitatively with the predictions based on the model which is intuitively reasonable.

Although the correspondence between the experimental results for the substituent effect and the predicted trend appears to be intuitively satisfactory, there is another explanation of the fact that the carbon isotope effect is larger for the *p*-bromo derivative. If the reaction of 1-(4′-bromophenyl)-1-bromoethane with methanol does not proceed exclusively through a limiting carbonium ion mechanism, but rather involves the incursion of some nucleophilic character, the isotopic fractionation at the α-carbon would be expected to be greater than that found for a pure S_N1 process, on the basis of the available isotope effect data for processes believed to be "pure" S_N2 reactions (4, 7). For example, the S_N2 reaction of 1-phenyl-1-bromoethane with a ethoxide ion exhibits a carbon isotope effect of 3.2–3.6% over the temperature range 0–25 °C (4). Clearly, the 1.1–1.3% effect found for the *p*-bromo derivative over the same range is much smaller and somewhat less sensitive to a change in temperature. For the bimolecular displacements, k_{12}/k_{13} decreases with increasing temperature while the opposite trend is found for alcoholyses of 1-phenyl-1-bromoethane itself (5). Because the reactivity of the *p*-methyl derivative in alcohol limits the conveniently accessible temperatures at which determinations may be done, its isotope effect was measured only at a single temperature, 0 °C, in both ethanol and methanol. Of the three compounds, however, the *p*-methyl derivative is the most likely to exhibit truly limiting behavior.

In any event, on the available evidence it is not possible to decide whether the influence of these substituents on the carbon isotope effect is signalling a mechanistic shift from the limiting case for the *p*-methyl derivative to one in which there is some nucleophilic character for the *p*-bromo compound, or whether the substituents govern the degree of resonance stabilization in the carbonium ion. It can be noted that the α- and β-deuterium secondary isotope effects for a series of substituted α-phenylethyl chlorides and bromides undergoing solvolysis in aqueous solution, suggest that the reaction is partly nucleophilic for those reactants having electron-withdrawing substituents (2). It is reasonable to assume that the secondary deuterium effects for alcoholysis would exhibit similar behavior and it would be interesting to measure these effects.

Experimental

The methods employed in this study were somewhat modified from those described previously (1, 4, and 5). After quenching a given isotope effect run, the remaining bromide was hydrolyzed completely to α-phenylethyl alcohol by heating, with vigorous stirring, at 50–60° for 12 h with aqueous sodium carbonate before isolation of the ether by fractional distillation.[2] Gas–liquid chromatography and refractive index determinations were used to assess the purity of the isolated product. To compare the results obtained by this modification with our previous data, the isotope effect for methanolysis of 1-bromo-1-phenyl-ethane was redetermined at 0 °C and found to agree precisely with our earlier data.

The oxidative degradations to the benzoic acids were also modified in this work. For the *p*-methyl derivatives, oxidation to *p*-toluic acid was accomplished in the following way. The methyl ether (1 g) was added to an ice-cold solution of potassium dichromate (9 g) in 300 ml of 45% (w/w) sulfuric acid. The mixture was shaken for 30 min while warming to room temperature. After extraction with low-boiling petroleum ether (3 times), the combined extracts were washed with saturated sodium bicarbonate solution and dried. To the residue, after removal of the solvent in vacuum, was added a solution containing sodium hydroxide (5 g), sodium hypochlorite solution (100 ml of Javex), and water (200 ml). The mixture was shaken for 1 h at room temperature before the addition of sodium metabisulfite (15 g). After the addition of ice, concentrated hydrochloric acid (40 ml) was added and the *p*-toluic acid extracted with ether. Removal of the solvent afforded *p*-toluic acid in 92% yield, m.p. 177–179°, completely free of terephthalic acid.

The *p*-bromo derivatives were oxidized in a manner similar to that described previously (1) except that the manganese dioxide was not removed by filtration after completion of the oxidation. Instead the MnO_2 was destroyed, after the addition of 30% sulfuric acid, by the addition of sodium metabisulfite. The *p*-bromobenzoic acid precipitated from solution and was isolated by filtration in 95% yield, m.p. 253–254°.

As in the earlier work (1, 4, and 5), the kinetics were measured by acid–base titration, at least in duplicate, and the data are:

1-(4′-bromophenyl)-1-bromoethane. Methanolysis; $k_1 = 4.17 \times 10^{-7}$ s^{-1} (0°), 1.27×10^{-5} s^{-1} (25°).

1-(*p*-tolyl)-1-bromoethane. Ethanolysis; $k_1 = 7.81 \times 10^{-6}$ s^{-1} (0°); methanolysis, $k_1 = 1.07 \times 10^{-4}$ s^{-1} (0°).

[2]Within the limits of the methods employed, there is no evidence of styrene formation under these reaction conditions. Thus we conclude that the amount formed is much less than 1%.

Acknowledgments

Synthesis of buf-20(21)-enolides and bufa-20,22-dienolides[1]

GEORGE R. PETTIT, DYRAL C. FESSLER, KENNETH D. PAULL,
PETER HOFER, AND JOHN C. KNIGHT
Department of Chemistry, Arizona State University, Tempe, Arizona 85281

Received February 7, 1969

A practical three-step procedure for converting an aldehyde to a 5-substituted dihydro-2-pyrone or by an additional step to the corresponding 2-pyrone has been summarized. Synthesis of 2-pyrone **5**, buf-20(21)-enolide **9** (and Δ^5-derivative) and bufadienolide **10** were used for illustration.

Canadian Journal of Chemistry, 47, 2511 (1969)

The intriguing biological properties[2] of bufalin (1) and related naturally occurring bufadienolides led us to investigate synthetic routes to 5-substituted 2-pyrones.[3] From a variety of approaches to 5-substituted 2-pyrones evaluated, we wish to report the following new route and application to synthesis of buf-20(21)-enolides and corresponding bufa-20,22-dienolides.

Heptaldehyde provides an illustration. Piperidine enamine **2** derived (7) from *n*-heptaldehyde was condensed in acetonitrile solution with methyl acrylate. Following mild (acetic acid – water) hydrolytic cleavage of the resulting enamine, aldehyde **3**, b.p. 114°[4] (4 mm) was isolated in 45% yield. The aldehyde proton appeared as a doublet (J = 4 c.p.s.) at 9.54 δ. Gentle saponification (sodium carbonate in water – methanol – tetrahydrofuran), acidification, and subsequent treatment (12 h) with *p*-toluenesulfonic acid in refluxing benzene provided (50%) enol lactone **4**: b.p. 102–103° (1.5 mm); vinyl proton as a broad signal centered at 6.4 δ. Dehydrogenating (8) enol lactone **4** (0.3 g) with 10% palladium on carbon (0.15 g) in refluxing *p*-cymene (50 ml, with nitrogen passing through the solution) afforded 2-pyrone **5** (0.14 g), boiling at 101–102° (0.8 mm) and exhibiting vinyl proton signals at 6.15 (H_a, doublet, J = 11 c.p.s.), 7.20 (H_b, set of doublets, J = 11 c.p.s. and J = 3 c.p.s.), 7.23 (H_c, doublet, J = 3 c.p.s.): M^+ 166.105060.

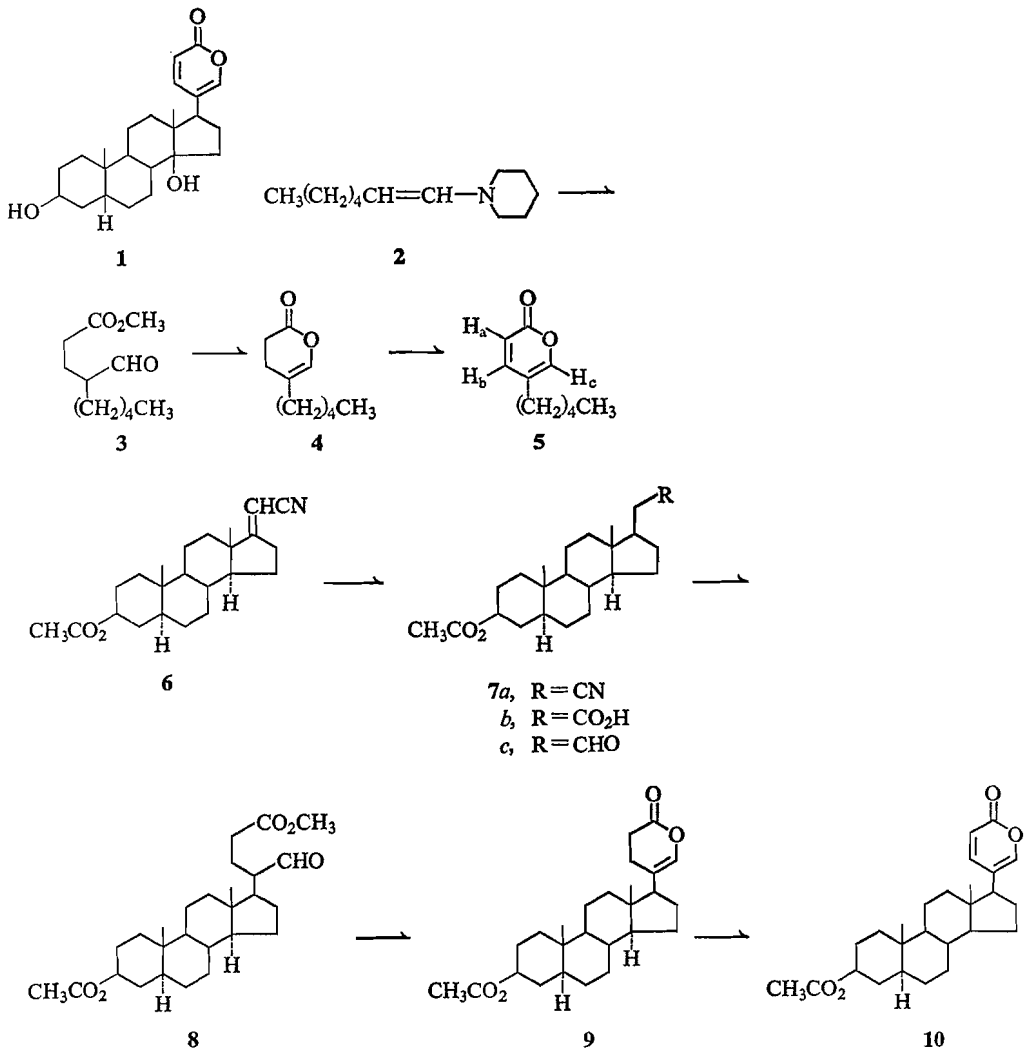
Application of the preceding four-step synthesis of 5-substituted 2-pyrones to obtaining representatives of the hitherto unknown bufa-20(21)-enolides proved satisfactory. First, nitrile **6** (m.p. 199–200°) was prepared in one step by condensing 3β-acetoxy-17-oxo-5α-androstane with the phosphorane (9) prepared from diethyl cyanomethylphosphonate and sodium hydride in tetrahydrofuran. Hydrogenation of olefin **6** with 5% palladium-on-calcium carbonate suspended in tetrahydrofuran yielded (100%) nitrile **7a**, m.p. 200–202°. Hydrolysis (potassium hydroxide in ethylene glycol) of the nitrile followed by acetylation (acetic acid – acetic anhydride) gave carboxylic acid **7b**, m.p. 190–195°. Rosenmund reduction (10% palladium on barium sulfate, refluxing toluene, 2 h) of the corresponding acid chloride (oxalyl chloride – benzene, 1.5 h at room temperature) provided (86–96%) aldehyde **7c** melting at 109–110.5°. Reacting aldehyde **7** (2.7 g) with piperidine in toluene solution and treating the resulting enamine as summarized above for enamine **2** gave aldehyde **8** (1.5 g, with 0.45 g of aldehyde **7c** recovered). The methyl ester protons appeared as a singlet at 3.65 δ and the aldehyde proton as a doublet with J = 4 c.p.s. at 9.5 δ. The remaining step to

[1]Steroids and Related Natural Products. LIX. For part LVIII, refer to (1).

[2]For example, local anesthetic (2), cardiac (2, 3), vasopressor (2*a*, 4), respiratory (2*a*, 4), and possibly of most potential importance, antitumor activity (5).

[3]When the present general study was initiated no bufadienolide (**1**) had been obtained by total synthesis and, in fact, no method (6*a*) was available which could be extended to this problem. Meanwhile, preliminary summaries of syntheses leading to two steroidal α-pyrones of the bufadienolide-type have been reported (6*b* and 6*c*).

[4]Each new substance gave satisfactory elemental analytical data and proton magnetic resonance spectra were obtained with a Varian A-60 spectrometer (deuteriochloroform as solvent with tetramethylsilane as internal standard).



bufa-20(21)-enolide **9** (40% yield, m.p. 177–179°, 21-vinyl proton at 6.36 δ) was performed as noted above for enol lactone **4**. By an analogous series of reactions 3β-acetoxy-bufa-5,20(21)-dienolide (m.p. 184–186°) was also prepared.

The preceding approach to bufa-20(21)-enolides appears generally useful and is presently being utilized in one synthetic approach to bufa-20,22-dienolides. For example, heating (221–227°, 30 min) a mixture of sulfur (0.2 g) and buf-20(21)-enolide **9** (0.1 g) readily afforded (0.06 g, m.p. 194–195°) bufa-20,22-dienolide **10**. The sulfur reaction represents a new approach to 2-pyrones. A variety of more obvious dehydrogenation methods including those that performed well with enol lactone **4** were quite unsuccessful when applied to the superficially easy buf-20(21)-enolide → bufa-20,22-dienolide transformation.

Raman and far infrared spectra of *s*-trinitrobenzene and *s*-trinitrobenzene-d_3

H. F. SHURVELL AND A. R. NORRIS
Department of Chemistry, Queen's University, Kingston, Ontario

AND

D. E. IRISH
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received January 30, 1969

Raman spectra have been recorded of *s*-trinitrobenzene and *s*-trinitrobenzene-d_3 both in solution and in the solid phase. Eighteen of the 22 Raman active fundamentals in D_{3h} have been observed for both molecules.

Two fundamentals have been observed in the far infrared spectrum of each molecule.

Nous avons enregistré les spectres Raman du *s*-trinitrobenzène et *s*-trinitrobenzène-d_3 en solution et aussi l'état solide. Dix-huit des 22 vibrations fondamentales ont été observées pour les deux molécules.

Deux vibrations fondamentales ont été observées dans les spectres infrarouge lointain pour chaque molécule.

Canadian Journal of Chemistry, 47, 2515 (1969)

Introduction

The infrared (i.r.) spectra of *s*-trinitrobenzene and *s*-trinitrobenzene-d_3 have been discussed previously (1). Although assignments were compatible with a molecule of D_{3h} symmetry, Raman spectra were desired to substantiate that conclusion and give a more complete vibrational assignment. The far i.r. spectrum was also needed, since two of the i.r. active fundamentals were not observed in the previous work (1).

Experimental

Materials were prepared in the same way as for the i.r. work (1). Raman spectra were recorded from chloroform and acetone solutions and from the polycrystalline solid. Raman spectra of solid *s*-trinitrobenzene and *s*-trinitrobenzene-d_3 are shown in Figs. 1 and 2.

Spectra were recorded on three different spectrometers; one a Cary model 81 instrument with mercury arc excitation, and two different experimental assemblies employing argon ion laser excitation and Spex 1400 double monochromators with photoelectric detection systems. One of these experimental assemblies is in the laboratory of Dr. H. J. Bernstein at the National Research Council of Canada, Ottawa; the other is in the Department of Physics at the University of Waterloo. In recording spectra of solid *s*-trinitrobenzene and *s*-trinitrobenzene-d_3, both the 4880 and the 5145 Å argon ion laser lines

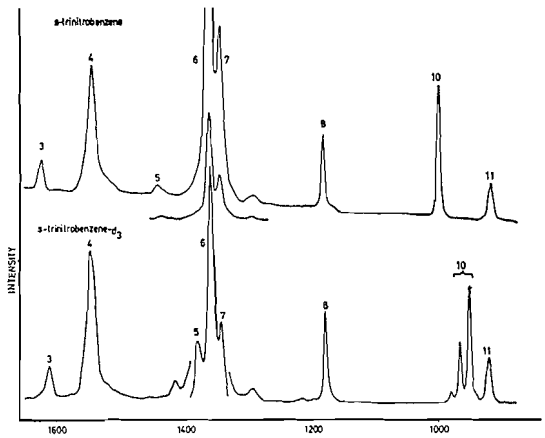

FIG. 1. Raman spectra of solid *s*-trinitrobenzene and *s*-trinitrobenzene-d_3 in the region 800–1600 cm^{-1}, excited by the 5145 Å line of an argon ion laser.

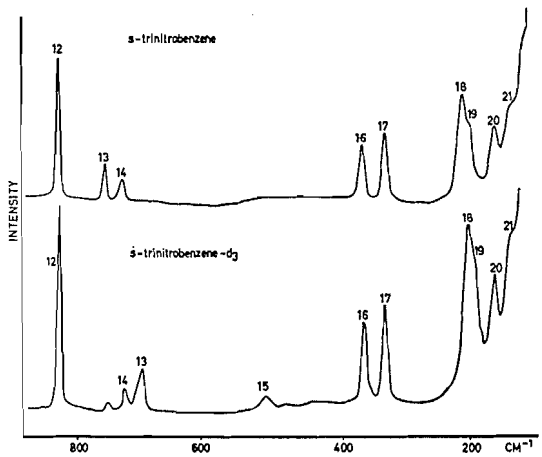

FIG. 2. Raman spectra of solid *s*-trinitrobenzene and *s*-trinitrobenzene-d_3 in the region 100–800 cm^{-1}, excited by the 4880 Å line of an argon ion laser.

were used to excite the Raman spectra. Most of the frequencies listed in Table I are the averages of several runs on solution and solid phase samples. The frequencies are believed to be correct to within ± 2 cm^{-1} in most cases. However, for the CH and CD stretching frequencies and for frequencies below 400 cm^{-1}, the errors are somewhat larger. The last 4 frequencies for each molecule in Table I were taken from spectra of the solids excited by the 4880 Å argon ion line.

The polarization data were obtained from acetone solutions, using the Cary 81 spectrometer.

Far i.r. spectra of Nujol mulls of *s*-trinitrobenzene and *s*-trinitrobenzene-d_3 supported between polyethylene discs were recorded on a Perkin–Elmer model 301 spectrophotometer in the laboratory of Dr. E. Whalley at the National Research Council of Canada, Ottawa, and are shown in Fig. 3.

Results and Discussion

Spectra obtained from chloroform and acetone solutions were essentially the same as the solid state spectra shown in Figs. 1 and 2. Some relative intensity differences were noted, but no evidence of splittings attributable to crystal effects was observed.

The normal vibrations of the *s*-trinitrobenzene molecule span the irreducible representations of the point group D_{3h} as follows

$$6\,A_1' + 5\,A_2' + 11\,E' + 1\,A_1'' + 4\,A_2'' + 5\,E''$$

Of these, only those vibrations belonging to the

species E' and A_2'' are i.r. active, while those belonging to the species A_1', E', and E'' are Raman active. Thus the Raman spectrum should contain 22 fundamentals of which 6 of species A_1' will be polarized, 11 will coincide with i.r. active fundamentals of species E', and the remaining 5 will be the E'' modes.

Discussion of the assignments will be facilitated by using descriptions of normal vibrations based on symmetry coordinates. In certain cases it is probable that the symmetry coordinate will provide a good description of the normal mode; for example the symmetrical CH stretching mode of species A_1'. In other cases, particularly for the modes of low frequency, considerable mixing may occur and the description will be at best approximate. By using the coordinates of the various groups of atoms as bases for reducible representations of the point group D_{3h} (2), we may predict qualitatively the numbers and types of group vibrations to be expected in the Raman spectrum.

Following this procedure, the Raman active vibrations may be described as follows. There are 6 vibrations involving the carbon atoms of the benzene ring, 4 CH vibrations, 4 CN vibrations, and 8 NO_2 group vibrations. This qualitative approach, coupled with previous evidence from various nitrobenzenes (3–7) and *s*-trichlorobenzene (8), has lead to the assignments given in Table I. The assignments to the various symmetry species are based on polarization studies and on coincidences with i.r. absorption frequencies. The notation used to describe the various vibrations of the substituted benzene ring is due to Whiffen (9).

A_1' Vibrations

There are 6 Raman active, totally symmetric fundamentals of the *s*-trinitrobenzene molecule, which should give rise to polarized lines in the spectra. One of the modes of species A_1' involves the hydrogen atoms. This can only be a symmetric stretching vibration and should be found near 3100 cm^{-1} in *s*-trinitrobenzene and 2300 cm^{-1} in the deuterated molecule. In the spectrum of the normal molecule, we have observed a weak line at about 3100 cm^{-1}, and a very weak line near 2310 cm^{-1} for the deuterated sample. These frequencies were only observed for solid samples, and no polarization data are available. There is therefore no way of distinguishing the symmetry species and we have assigned these frequencies to both A_1' and E' species of the CH and CD stretching modes.

The NO_2 symmetric stretching mode is assigned to a very strong polarized line at 1365 cm^{-1}, which is virtually unshifted on deuteration. This frequency is well within the usual range observed for symmetric NO_2 stretching vibrations in various nitrobenzenes (3–7). The frequency is 20 cm^{-1} higher than that of the doubly degenerate NO_2 stretching mode of species E' in the same molecule. A strong, polarized line at 1184 cm^{-1} is assigned to the symmetric CN stretching mode. The frequency of this mode is also unaffected by deuteration of *s*-trinitrobenzene. The frequencies of the corresponding mode in *s*-trichlorobenzene, (normal and deuterated) are 1149 and 1146 cm^{-1}, respectively (8).

A strong, polarized line at 1002 cm^{-1} in the spectrum of *s*-trinitrobenzene is assigned to the ring "breathing" mode. This vibration usually gives rise to frequencies near 1000 cm^{-1} in monosubstituted benzenes (9), and Scherer *et al.* have reported a frequency of 995 cm^{-1} in the Raman spectrum of *s*-trichlorobenzene (8). In the spectrum of deuterated *s*-trinitrobenzene, a doublet is observed at 976, 960 cm^{-1}. Both components are polarized and must therefore be assigned to vibrations of A_1' symmetry. Since only one fundamental is expected in this region, these two lines probably arise as a result of Fermi

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

resonance between the ring breathing fundamental of species A_1', and an overtone or combination line belonging to the same irreducible representation. None of the i.r. or Raman active fundamentals would have an overtone in the region of 970 cm^{-1}, and no combination of these fundamentals belonging to species A_1' lies in this region. The second component of the Fermi doublet must be either an overtone of an inactive fundamental or involve an inactive fundamental. The observed frequency of the ring breathing mode in *s*-trichlorobenzene-d_3 was 956 cm^{-1} (8).

A polarized line at 825 cm^{-1} is assigned to the NO_2 symmetric deformation mode. In the i.r. spectrum of nitrobenzene, Stephenson *et al.* (5) have assigned a peak at 850 cm^{-1} to this vibration. We have previously assigned i.r. bands near 725 cm^{-1} in the spectra of normal and deuterated *s*-trinitrobenzene to a symmetric NO_2 deformation mode of species E' (1). At that time we stated that this provided support for the assignment made by Green *et al.* (4) of a peak at 677 cm^{-1} in the i.r. spectrum of *s*-trinitrobenzene to the NO_2 symmetric deformation mode. In view of the present Raman spectra, it would appear that the assignment of Stephenson *et al.* (5) is the better one, and this conclusion is in agreement with the work of Pinchas *et al.* (6) on ^{18}O labelled nitrobenzene.

The last polarized line at 355 cm^{-1} is attributed to a symmetric ring deformation. In *s*-trichlorobenzene the corresponding mode gives rise to a Raman line at 379 cm^{-1}. This vibration involves motion of the carbon atoms to which the NO_2 groups are attached (or Cl atoms in the case of *s*-trichlorobenzene). Scherer (10) has given diagrams of the planar vibrations of *s*-trichlorobenzene and *s*-trichlorobenzene-d_3, and it is likely that the corresponding A_1' modes in *s*-trinitrobenzene have similar forms, with the chlorine atoms replaced by nitro groups.

E' Vibrations

The 11 E' type vibrations are active in both the i.r. and Raman spectra. However, definite coincidences have been observed in only 7 cases. The agreement between i.r. and Raman frequencies is good in these cases. The doubly degenerate CH and CD stretching modes should give rise to Raman lines near 3100 cm^{-1} for *s*-trinitrobenzene and 2300 cm^{-1} for the deuterated molecule. Only one line has been observed in each region. These lines have been assigned to the CH and CD stretching modes of species A_1', but it is possible that the E' modes could have similar frequencies. We have therefore attributed the observed lines to both A_1' and E' type fundamentals.

One of the far i.r. frequencies should be due to an E' type fundamental and a coincident Raman line is expected. We have assigned the line at 160 cm^{-1} in the spectrum of *s*-trinitrobenzene to the lowest frequency E' fundamental, an in-plane CN deformation mode (βCN). A line at the same frequency was observed for the deuterated molecule. The corresponding frequencies in the far i.r. region were 156 and 155 cm^{-1} for the normal and deuterated molecules respectively. The differences between i.r. and Raman frequencies are 5 cm^{-1}, which is probably within experimental error.

A second far i.r. band was observed at 130 cm^{-1} for *s*-trinitrobenzene, and at 129 cm^{-1} for the deuterated molecule. These appear to coincide with Raman features observed as shoulders on the exciting line at 133 and 132 cm^{-1} for the normal and deuterated molecules respectively, and offer an alternative assignment for the lowest frequency E' mode. However, we have assigned the i.r. bands to the A_2'' mode of lowest frequency, and the Raman lines to an E'' mode in each molecule.

The i.r. frequencies assigned to E' type modes but not observed in the present Raman spectra were at 1075 and 620 cm^{-1} for *s*-trinitrobenzene and 806 and 518 cm^{-1} for the deuterated molecule (1). These were assigned respectively to the in-plane CH deformation (βCH) and ring deformation (αCCC) vibrations. A very weak Raman line observed at 520 cm^{-1} in the spectrum of solid *s*-trinitrobenzene-d_3, probably corresponds to the 518 cm^{-1} i.r. absorption.

The assignments of the other E' type vibrations are the same as for the previous i.r. work (1).

E'' Vibrations

There should be 5 depolarized lines in the Raman spectra of both *s*-trinitrobenzene and *s*-trinitrobenzene-d_3, having no counterparts in the i.r. spectra. These are the out-of-plane E'' vibrations. Two lines and two shoulders have been located in the spectrum of each molecule. A weak line at 754 cm^{-1} that is displaced to 704 cm^{-1} on deuteration is attributed to the out-of-plane CH bending mode (γCH). The corresponding pair of lines in the Raman spectra of normal and deuterated *s*-trichlorobenzene were located

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

at 869 and 712 cm^{-1}. The smaller shift in the trinitro compounds is difficult to explain.

A fairly strong line at 212 cm^{-1} in the spectrum of *s*-trinitrobenzene shifts to 204 cm^{-1} in the spectrum of the deuterated molecule. These frequencies are assigned to an out-of-plane ring deformation (ϕCC). Coupling with other E'' type vibrations could account for the low frequency of this mode in *s*-trinitrobenzene as compared with other substituted benzenes (11). The other normal modes of species E'' are two out-of-plane NO_2 deformations and an out-of-plane CN bending mode (γCN). We have arbitrarily assigned the two shoulders to NO_2 deformations. The missing line may either be too weak to be observed in the Raman spectrum, or is obscured by another fundamental.

Far Infrared Spectra

The far i.r. spectra of *s*-trinitrobenzene and *s*-trinitrobenzene-d_3 are shown in Fig. 3. The observed frequencies were 156 and 130 cm^{-1} for the normal molecule and 155 and 129 cm^{-1} for the deuterated compound. The absorption at higher frequency coincides with a Raman line for both molecules, and this is assigned to the in-plane CN deformation mode of species E'. The lower frequency absorption is then assigned to the out-of-plane CN deformation of species A_2''.

Overtones and Combinations

Two very weak lines in the Raman spectrum of *s*-trinitrobenzene at 1520 and 1296 cm^{-1} have been assigned to overtone or combination frequencies. In the spectrum of *s*-trinitrobenzene-d_3, 4 very weak lines at 1420, 1298, 989, and 754 cm^{-1}, in addition to one component of the Fermi doublet at 976, 960 cm^{-1} have been assigned to combinations or overtones.

Conclusions

We have observed 18 of the 22 Raman active fundamentals in D_{3h} of *s*-trinitrobenzene and *s*-trinitrobenzene-d_3 in the present work and have made qualitative assignments to these frequencies in terms of symmetry coordinates based on group vibrations. Three of the remaining Raman active fundamentals belonging to the E' species have been observed in previous i.r. spectra. The two fundamentals observed in the far i.r. spectra complete the total of 15 i.r. active modes. There remain, however, 6 fundamentals inactive in both spectra, and the frequencies of these modes can only be estimated from normal coordinate calculations. We hope to make these calculations in the near future.

Acknowledgments

We are very grateful to Dr. H. J. Bernstein and Dr. E. Whalley of the National Research Council of Canada, Ottawa, and Dr. A. Anderson of the Department of Physics, University of Waterloo, for placing the facilities of their laboratories at our disposal. We thank Mr. E. A. Symons for help with the preparation and analysis of *s*-trinitrobenzene-d_3, and Mrs. J. Weerheim for technical assistance. The financial support of the National Research Council of Canada is gratefully acknowledged.

Three forms of aluminium in aqueous systems determined by 8-quinolinolate extraction methods[1]

R. C. TURNER
Soil Research Institute, Canada Department of Agriculture, Ottawa, Canada

Received December 5, 1968

8-Quinolinolate extraction methods for the determination of Al^{3+} plus mononuclear hydroxyaluminium ions, polynuclear hydroxyaluminium ions, and the initial solid phase formed when a base is added to $AlCl_3$ solutions, are presented. The methods are based on the rates of reactions of 8-quinolinol with the 3 forms of aluminium substances. Results under a variety of experimental conditions are reported.

Canadian Journal of Chemistry, 47, 2521 (1969)

Introduction

Okura *et al.* (1) proposed an 8-quinolinolate method of analysis of Al in solution which is supposed to measure only the Al^{3+} and mononuclear (with respect to Al) hydroxyaluminium ions. The principle involved is that 8-quinolinol reacts instantaneously with the mononuclear ions but more slowly with polynuclear hydroxyaluminium substances. Consequently, their method requires that the length of time of contact between the test solution and the 8-quinolinol should be kept at a minimum. The method proposed by them is as follows. Pour 10 ml of H_2O and 2 ml portions of 8-quinolinol (dissolve 2.0 g of 8-quinolinol in 5 ml of glacial acetic acid and dilute to 200 ml with H_2O) and sodium acetate (1 *M*) into a separatory funnel. Add exactly 10 ml of chloroform. Add an appropriate volume of the test sample and shake immediately for 10 s. Allow the mixture to separate into two layers and draw off the chloroform layer. Determine the Al extracted in the chloroform colorimetrically.

This method was further investigated using dilute $AlCl_3$ solutions which had been neutralized or partially neutralized with NaOH, with the object of developing methods for differentiating between Al^{3+} plus mononuclear hydroxyaluminium ions, polynuclear hydroxyaluminium ions, and the initial solid phase formed when a base is added to an $AlCl_3$ solution.

Experimental

Mononuclear Ions

Preliminary experiments showed that, with dilute $AlCl_3$ solutions (10^{-3} to 2×10^{-1} *M*) which had been partially neutralized with NaOH, shaking the solutions in the separatory funnels for lengths of time greater than the 10 s prescribed by Okura *et al.* (1) increased the amount of Al in the chloroform extract. It was found, however, that if the 8-quinolinol plus test solution was shaken for a given length of time before adding the chloroform, followed by 10 s shaking with chloroform, the amount of Al in the chloroform was much greater than if the chloroform was present during the entire shaking period. Since the length of time that the test solution was in contact with the 8-quinolinol before shaking with chloroform commenced was very critical, the procedure outlined by Okura *et al.* (1) was modified to reduce this to a minimum. The modification was to mix the 8-quinolinol and sodium acetate solutions and H_2O together so that all the reagents could be added in one operation. In this way, the length of time between the first contact of the 8-quinolinol with the test solution and the beginning of shaking was reduced to a few seconds, regardless of how much of the test solution was required. Even with this modification, reproducible results could not always be obtained with the partially neutralized $AlCl_3$. This was apparently caused by the fact that there was some foreign substance in the solutions that slowed down the separation of the chloroform and aqueous phases, which defeated the effect of the short time of shaking. Centrifuging the test solution at 18 000 r.p.m. for 20 min did not eliminate the problem. Filtering through a 10 mμ pore size "Millipore" filter, however, removed a considerable portion of the total Al in the systems, and the separation of the 2 phases in the separatory funnels was normal when the filtrates were analyzed. (It should be pointed out that Goto and Yotsuyanagi (2) eliminated this problem of slow separation of the two phases by adding the surfactant sodium dodecyl sulfate after shaking.)

The procedure for determining the concentration of mononuclear ions in solution that resulted from these experiments is as follows. Filter an appropriate aliquot of the test solution through a 10 mμ pore size "Millipore" filter under suction. Discard the first aliquot that passes the filter, pass a second aliquot through the filter, and use the second filtrate for analysis. The loss in weight due to evaporation under suction must be determined by the difference between the weight of the aliquot poured on the filter and that of the resulting filtrate. Transfer an appropriate aliquot of the filtrate to a separatory funnel which

[1]Contribution No. 293.

For personal use only.

contains 5 ml of H_2O and add exactly 10 ml of chloroform. Introduce 14 ml of the composite 8-quinolinol reagent by means of a plunger-type repipet and shake immediately for 10 s. Allow the chloroform phase to separate and drain it off. Place cotton wool in the end of the drainage tube of the funnel to remove moisture from the chloroform as it drains from the funnel. Determine the concentration of Al in the chloroform extract with a spectrophotometer at a wavelength of 395 mμ. Correct the result for the loss in weight during filtration. The composite 8-quinolinol reagent consists of 10 ml H_2O to 2 ml of the 8-quinolinol solution to 2 ml of molar sodium acetate.

Polynuclear Ions

The method for determining the concentration of Al in the form of polynuclear hydroxyaluminium ions was developed on the basis of the rate of reaction of these ions with 8-quinolinol. Both the polynuclear ions and the initial solid phase reacted with 8-quinolinol in the absence of chloroform, but more slowly than did the mononuclear ions. When the polynuclear ions and solid phase were present, the rate of the reaction or reactions did not seem to follow any particular order of reaction based on the Al present. The concentration of 8-quinolinol was suffciently large relative to that of the Al present that changes in its concentration from the reactions could be ignored and the reaction was irreversible. When the filtrates which passed through a 10 mμ pore size "Millipore" filter were used in the rate studies, the reactions followed a first order process with respect to the Al present. The specific rate constant was 0.18 per min at 26 °C, providing the partially neutralized systems were allowed to react for one day or more before filtering. When the reaction was studied immediately after adding the base to the $AlCl_3$ solution, the reaction started at a relatively fast rate and slowed down to a first order process after the first few minutes. In all cases, however, the reaction was essentially complete after 30 min. The procedure for determining the polynuclear ions which developed from these experiments is as follows. Transfer an appropriate aliquot of a filtrate obtained as described in the method for mononuclear ions, to a separatory funnel containing 5 ml of H_2O. Add 14 ml of composite 8-quinolinol reagent with a plunger-type repipet and shake for 30 min at room temperature (the temperature should be 25 °C or above). Add exactly 10 ml of chloroform and shake for 10 s. Drain off the chloroform and proceed as described in the method for mononuclear ions. The difference between the Al found after 30 min shaking and after zero time shaking (mononuclear ions) is the amount in the polynuclear form. The determination must be done immediately after filtering.

Initial Solid Phase

When the $AlCl_3$ solutions were 100% neutralized with NaOH, the rate of the reactions between 8-quinolinol and the Al material in the systems immediately after adding the base followed a two-third order reaction to a fairly good approximation. The length of time required for complete reaction was less than 3 h at 25 °C. The procedure for determining the Al in the initial solid phase is as follows. Transfer an appropriate aliquot of the unfiltered test suspension to a separatory funnel containing 5 ml of H_2O. Add 14 ml of the composite 8-quinolinol reagent by means of a plunger-type repipet and shake immediately for 3 h at room temperature (the temperature of the reaction mixture should not be less than 25 °C). Add exactly 10 ml of chloroform and shake 10 s. Drain off the chloroform and determine the Al in this chloroform extract. The Al thus determined, less that determined as mono plus polynuclear ions, is the Al in the initial solid phase.

Experimental Results

Method for Mononuclear Ions

The method for mononuclear ions was tested by comparing the results obtained with concentrations estimated from neutralization curves. When partially neutralized $AlCl_3$ solutions are titrated with a base, after various lengths of time of reaction, there are two buffer zones in the neutralization curves (3). The first occurs in the same pH range as for fast titrations of $AlCl_3$ solutions to which no base had been added prior to titration (3, 4), and the second in a pH range considerably above this.

Figure 1 shows neutralization curves for 5.8×10^{-2} *M* solutions of $AlCl_3$ which had been partially neutralized and then aged for various lengths of time. At the same time as the titrations were done, the Al concentration in the mononuclear form was determined by the 8-quinolinolate extraction method described above. The lower section of Fig. 1 shows the similarity between the first buffer zone of the neutralization curve of 5.8×10^{-2} *M* solution which had been 50% neutralized and aged for 1 day (curve *a*), and the neutralization curve of a 2.2×10^{-2} *M* solution to which no base had been added prior to titration (curve *b*). The volume of solutions titrated and the concentration of NaOH used were the same for the two titrations. Although it is impossible to determine the exact end point for the titration of the material that caused the first buffer zone with the partially neutralized sample, it is obvious that the amount was only slightly greater than that in the 2.2×10^{-2} *M* $AlCl_3$ solution, which is in excellent agreement with 2.3×10^{-2} *M* found by the 8-quinolinolate extraction method. The upper section of Fig. 1 shows the neutralization curves for a 5.8×10^{-2} *M* solution which had been 80% neutralized and aged for two different lengths of time before titration with NaOH. When the solution had been aged for only 1 h, there was not a clear distinction between the two buffer zones (curve *e*) so that it was impossible to make a very good estimate of the concentration of Al represented by the first buffer zone. Comparison with the

For personal use only.

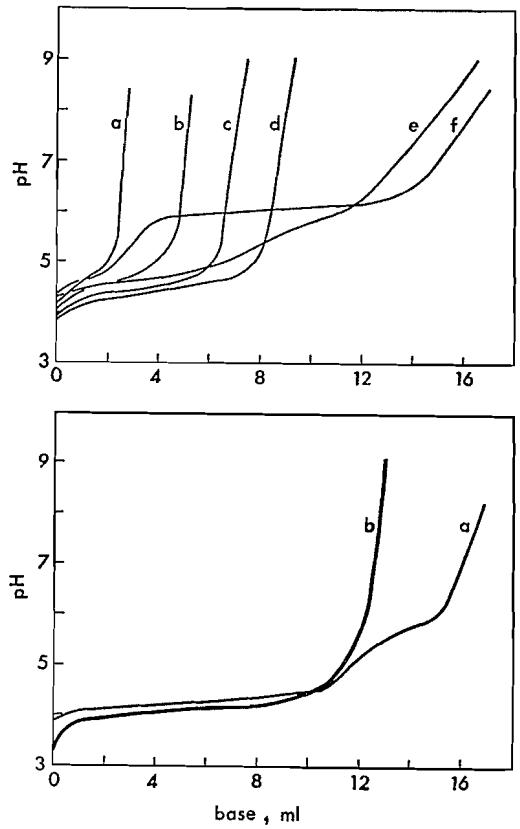

FIG. 1. Neutralization curves of $AlCl_3$ and partially neutralized $AlCl_3$ solutions. *Upper section*, 50 ml of solution titrated with 0.10 *N* NaOH. Curves *a*, 1.8×10^{-3}; *b*, 3.5×10^{-3}; *c*, 4.7×10^{-3}; *d*, 6.0×10^{-3} *M* $AlCl_3$ solutions. Curves *e*, 80% neutralized 5.8×10^{-2} *M* $AlCl_3$ aged 1 h; *f*, 80% neutralized $AlCl_3$ aged 23 days. *Lower section*, 20 ml of solution titrated with 0.10 *N* NaOH. Curve *a*, 60% neutralized 5.8×10^{-2} *M* $AlCl_3$ aged 1 day; Curve *b*, 2.2×10^{-2} *M* $AlCl_3$ solution.

neutralization curves for 4.7×10^{-3} and 6.0×10^{-3} *M* $AlCl_3$ solutions (curves *c* and *d*), however, shows that the concentration was between these two, and the mononuclear concentration determined by the 8-quinolinolate extraction method was 5.9×10^{-3} *M*. When the 80% neutralized solution was aged for 23 days, there was a distinct break between the two buffer zones (curve *f*) and there is no doubt that the Al concentration represented by the first buffer zone was considerably less than 3.5×10^{-3} *M* (curve *b*) and only somewhat greater than 1.8×10^{-3} *M* (curve *a*), which agrees with 2.0×10^{-3} *M* found by the 8-quinolinolate extraction method.

The results in Fig. 1 present rather convincing evidence that the method proposed measures only the mononuclear Al ions. Since the partially neutralized systems had pH values near 4 in all cases, however, Al^{3+} must have been essentially the only mononuclear ions present so that one can not conclude from these results that the method measures mononuclear hydroxyaluminium ions. The fact that $AlOH^{2+}$ is measured along with Al^{3+} was demonstrated with a 10^{-4} *M* solution of $AlCl_3$. This solution had a pH of 4.64 which means that $AlOH^{2+}$ represented roughly 30% of the total Al (Al^{3+} + $AlOH^{2+}$) present (5) and all the Al present was measured by the method. Furthermore, it was found that when a 10^{-3} *M* $AlCl_3$ solution was 100% neutralized the method showed essentially no mononuclear Al present, but when the base added exceeded the equivalent amount by 20%, the method showed a concentration of 2.3×10^{-4} *M* for mononuclear Al expressed as Al^{3+}. This shows that the method also measured the mononuclear hydroxyaluminium ions $Al(OH)_4^-$.

Methods for Polynuclear Ions and the Initial Solid Phase

The experimental evidence supporting the validity of these methods is based on the rate and nature of the reactions between polynuclear ions, initial solid phase, and 8-quinolinol, by which the hydroxyaluminium materials are destroyed. The test solutions or suspensions were shaken at constant temperature, for various lengths of time with the 8-quinolinol reagent as described in the previous section. Chloroform was then added and the mixture again shaken for 10 s after which the Al in the chloroform extract was determined colorimetrically. Since, as mentioned above, there was a great excess of 8-quinolinol in the reaction mixtures, any change in its concentration could be ignored and the reaction was irreversible. The rates of the reactions were thus dependent on the concentration of hydroxyaluminium material present. It was assumed that the reactions destroyed the hydroxyaluminium material and that Al^{3+} was the product so that the results could be expressed in moles per liter of Al.

The polynuclear ions, i.e., the material that passed through 10 mμ pore size "Millipore" filters but was not measured as mononuclears, reacted with 8-quinolinol much more slowly than did the mononuclear ions. When the filtrates from partially neutralized $AlCl_3$ solutions which had been aged for 1 day or more were used, the reaction followed a first order process with a rate

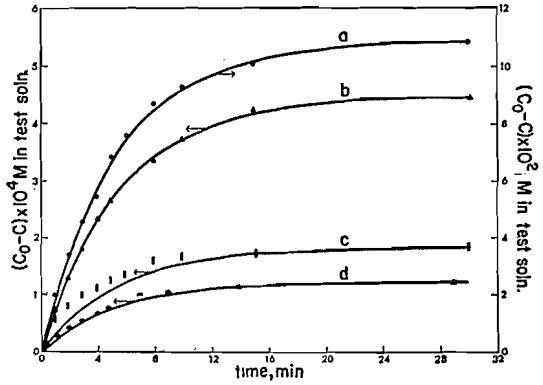

FIG. 2. Rate curves for the reaction with polynuclear ions at 26 °C. The smooth curves are first order curves with rate constants of 0.18 per min. The experimental points are for 80% neutralized 1.95×10^{-1} *M* $AlCl_3$ solutions aged 93 days (curve *a*); 80% neutralized 1.0×10^{-3} *M* $AlCl_3$ solutions aged 1 day (curve *b*); 80% neutralized 1.0×10^{-3} *M* $AlCl_3$ solutions not aged (curve *c*); 80% neutralized 1.0×10^{-3} *M* $AlCl_3$ solution not aged, with 1 min made zero time (curve *d*).

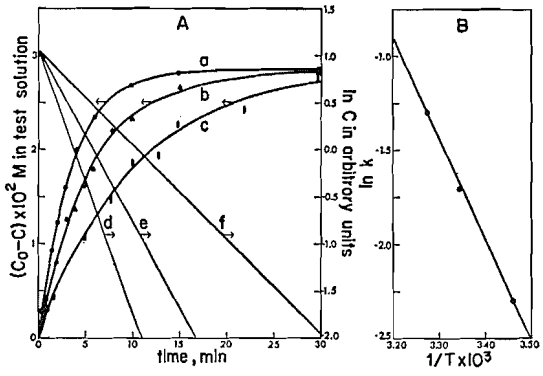

FIG. 3. Effect of temperature on the rate of the reaction with polynuclear ions. *Left section*, the smooth curves are first order curves with rate constants 0.28 at 34 °C (curve *a*); 0.18 at 26 °C (curve *b*); 0.10 at 16 °C (curve *c*) per min. Curves *d*, *e*, and *f* are the ln *C* vs. *t* plots from the smooth curves *a*, *b*, and *c*, respectively. The experimental points are for a 50% neutralized 5.8×10^{-2} *M* $AlCl_3$ solutions. *Right section*, the Arrhenius plots from which an activation energy of 11 kcal/mole was calculated.

constant of 0.18 per min at 26 °C (Fig. 2, curves *a* and *b*) regardless of the initial concentration of $AlCl_3$. When the filtrates were from unaged partially neutralized systems, the rate of reaction was much faster during the first few minutes than was predicted by a rate constant of 0.18 per min (Fig. 2, curve *c*) but if the reaction during the first minute was ignored, i.e., 1 min was made zero time, the reaction followed the first order process with the correct rate constant (Fig. 2, curve *d*). These results (curves *c* and *d*) probably mean that polynuclear material started as very low molecular weight ions and increased in size to a maximum. In any event the reaction with 8-quinolinol was complete in 30 min (curves *a*, *b*, *c*, and *d*). The effect of temperature on the rate of reaction with the polynuclear ions is shown in Fig. 3. The smooth curves *a*, *b*, and *c* in the left section of Fig. 3 were constructed with rate constants of 0.28, 0.18, and 0.10 for 34, 26, and 16 °C, respectively. Curves *d*, *e*, and *f* are the ln *C* vs. *t* plots from the smooth curves *a*, *b*, and *c*, respectively. The right section of Fig. 3 shows the Arrhenius plot from which an activation energy of the reaction of 11 kcal/mole was calculated.

The reaction with the initial solid phase was studied by using aliquots of the unfiltered suspensions immediately after adding the base to the $AlCl_3$ solutions. When the solutions of $AlCl_3$ were 100% neutralized no correction for polynuclear ions was necessary because they did not exist in the systems. It was necessary, however, to make corrections for the polynuclear ions when partially neutralized systems were used, and this was done by making parallel rate experiments on the filtrates from systems prepared in exactly the same way.

In all cases the reaction with the initial solid phase was a two-thirds order process. The simple model used as a guide for interpreting the experimental results was the one in which all the solid phase particles are identical and symmetrical in shape, e.g. spheres or cubes. It was assumed that the rate of the reaction was proportional to the surface area of the particles exposed to the 8-quinolinol reagent, that the 8-quinolinol was in sufficient excess that its concentration remained constant throughout the reaction, and that the reactions were irreversible. If there are *n* particles in a given volume, the rate of the reaction can be expressed by the equation

$$[1] \qquad (nM_0)^{1/3} - (nM)^{1/3} = n^{1/3} k't$$

where M_0 is the mass of a single particle at zero time, M is its mass at time t, and k' is a combination of constants including the specific rate constant. Furthermore, nM_0 and nM are proportional to C_0 and C, respectively, where C_0 and C are the number of moles of Al per liter which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

exists in the solid phase at zero time and at time t, respectively. Therefore

$$[2] \qquad C_0^{1/3} - C^{1/3} = n^{1/3}kt = k_c t$$

where k is a constant and k_c is a constant at any given concentration. It follows that the time for a complete reaction is independent of the concentration of the solid phase and the slope of the $C^{1/3}$ vs. t plot, k_c, is proportional to $n^{1/3}$ and, therefore, to $C_0^{1/3}$.

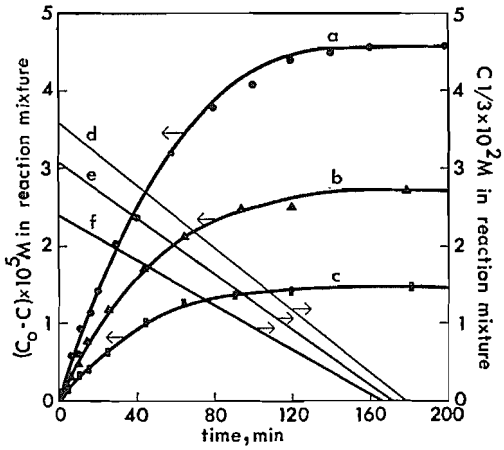

FIG. 4. Rate curves for the reaction with the initial solid phase at 25 °C. The experimental points are for 1.0×10^{-3} M solutions of $AlCl_3$ with 3 different degrees of neutralization. The smooth curves are two-thirds order rate curves with $k_c = 2.0 \times 10^{-4}$ for 100% neutralization (curve *a*); $k_c = 1.8 \times 10^{-4}$ for 80% neutralization (curve *b*); $k_c = 1.5 \times 10^{-4}$ $C^{1/3}$/min for 60% neutralization (curve *c*). Curves *d*, *e*, and *f* are the $C^{1/3}$ vs. t plot from the smooth curves *a*, *b*, and *c*, respectively.

Figure 4 shows the results obtained at 25 °C from a solution of 1.0×10^{-3} M $AlCl_3$ which had been 100, 80, and 60% neutralized. The smooth curves *a*, *b*, and *c* were constructed with k_c equal to 2.0×10^{-4}, 1.8×10^{-4}, and 1.5×10^{-4}, respectively, assuming a two-thirds order process. Equation [2] predicts that the k_c's should have been in the ratio 2.0:1.7:1.4 which shows that the experimental systems did not behave exactly according to the theoretical model to which the equation applies. This is shown in another way by the fact that curves *d*, *e*, and *f*, which are the $C^{1/3}$ vs. t plots for the smooth curves *a*, *b*, and *c*, respectively, did not intersect at zero concentration. The differences between experimental results and those predicted by the model are small, however, and it can be concluded that the experimental systems behaved like the model to a good approximation. From a practical point of view, curves *d*, *e*, and *f* show that the time required for complete reaction is very little affected by the concentration of solid phase present or the degree of neutralization. Since both the concentration of solid phase and the degree of neutralization varied in these experiments, other experiments were made in which only 100% neutralized systems were used.

The results obtained with 100% neutralized $AlCl_3$ solutions where the concentration in the reaction mixture was varied by using different amounts of the test suspension, are shown in Fig. 5. The ratio of the volumes used were 1:2.5:7.5 and the reactions were studied at 34 °C. The smooth curves *a*, *b*, and *c* in Fig. 5 were constructed with k_c equal to 8.2×10^{-4} for the highest, 5.8×10^{-4} for the intermediate, and 4.8×10^{-4} for the lowest Al concentration, respectively. The values of k_c according to eq. [2] should have been in the ratio of 8.2:5.3:4.1 and

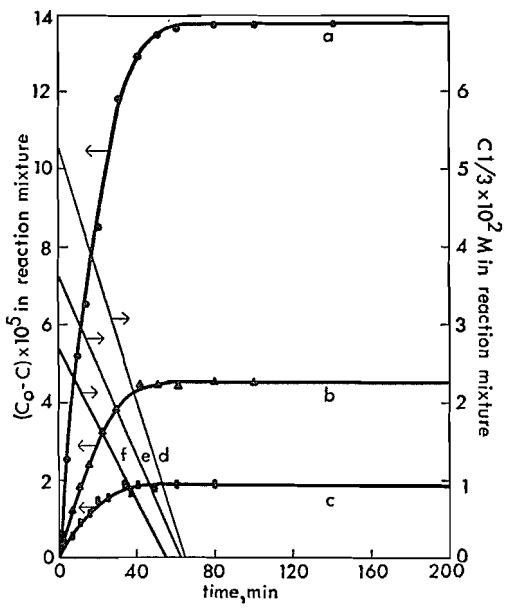

FIG. 5. Rate curves for the reaction with the initial solid phase at 34 °C. The experimental points are for a 100% neutralized 1.0×10^{-3} M $AlCl_3$ solution with 3 different concentrations of solid phase in the reaction mixture. The smooth curves are two-thirds order rate curves with $k_c = 8.2 \times 10^{-4}$ with 3 ml of test solution (curve *a*); $k_c = 5.8 \times 10^{-4}$ with 1 ml of test solution (curve *b*); $k_c = 4.8 \times 10^{-4}$ $C^{1/3}$ per min with 0.4 ml of test solution (curve *c*). Curves *d*, *e*, and *f* are the $C^{1/3}$ vs. t plots from the smooth curves *a*, *b*, and *c*.

the $C^{1/3}$ vs. t plots (curves d, e, and f) should have intersected at zero concentration, showing that even when all the initial solid phase was prepared under the same conditions, the experimental results did not agree exactly with eq. [2]. As with the systems in which the concentration of the solid phase was varied by changing the degree of neutralization (Fig. 4), however, the experimental systems behaved like the assumed model to a fairly good approximation.

The effect of temperature on the rate of the reaction with the initial solid phase is shown in Fig. 6. The smooth curves a, b, and c in the lower section were constructed with k_c equal to 5.8×10^{-4} at 34 °C, 2.0×10^{-4} at 25 °C, and 0.67×10^{-4} at 16 °C, respectively. The upper section of the Fig. 6 shows the Arrhenius plot from which an activation energy of 20 kcal/mole was calculated.

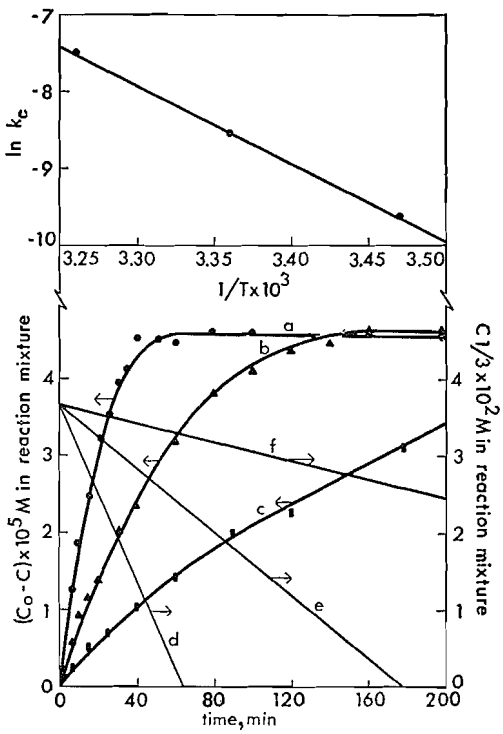

FIG. 6. Effect of temperature on the rate of reaction with the initial solid phase. *Lower section*, the smooth curves are two-thirds order rate curves with $k_c = 5.8 \times 10^{-4}$ at 34 °C (curve *a*); $k_c = 2.0 \times 10^{-4}$ at 25 °C (curve *b*); $k_c = 0.67 \times 10^{-4}$ $C^{1/3}$ per min at 16 °C (curve *c*). Curves *d*, *e*, and *f* are the $C^{1/3}$ vs. t plots from the smooth curves *a*, *b*, and *c*, respectively. Discussion

The object of the experiments discussed above was to show that the proposed methods measure quantitatively 3 distinct forms of Al, i.e., mononuclear ions, polynuclear ions, and the initial solid phase formed when a base is added to an $AlCl_3$ solution. The evidence that there are in fact these 3 distinct forms is very convincing: (*a*) the mononuclear ions react, for all practical purposes, instantaneously with 8-quinolinol whereas the other 2 forms react much more slowly; (*b*) the polynuclear ions are not separated from the liquid phase by filtration through a 10 mμ pore "Millipore" filter whereas the initial solid phase is; (*c*) the reaction between the polynuclear ions and an excess of 8-quinolinol is a first order process whereas the corresponding reaction with the initial solid phase is a two-thirds order process, and the activation energy of the reaction with the solid phase was almost double that for the reaction with the polynuclear ions. The evidence that the material, designated as polynuclear ions, is cations in moderately acid solutions and a component of the liquid phase is very strong: (*a*) they show exchange properties with clays (6) and exchange resins (7) as do simple cations such as Ca^{2+} and Na^+; (*b*) they are not separated from solution by filtration; (*c*) the reaction between them and an excess of the other reactant in solution is a first order process. (This conclusion should be compared with the results obtained by Goto and Yotsuyanagi (2) who found that the initial reaction without removing the solid phase was a first order process.) The evidence that the initial solid phase is a solid phase in fact as well as in name is also very strong: (*a*) it can be separated from solution by filtration; (*b*) the reaction between it and an excess of 8-quinolinol is a two-thirds order process which, to a good approximation, behaves as if it consisted of uniform solid particles with the rate of the reaction proportional to the surface exposed to the other reactant; (*c*) it is removed from the liquid phase by clays but not in an exchangeable form (6). Finally, there is the quantitative aspect of the analytic methods. The results in Fig. 1 show that if the partially neutralized systems are allowed to react for some time, the method for mononuclear ions does not measure anything but mononuclear ions. Furthermore, the experiment with 10^{-4} M $AlCl_3$ shows that the method

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

measures $AlOH^{2+}$ as well as Al^{3+}, and the experiment in which the neutralization was carried beyond 100% showed that it also measures $Al(OH)_4^-$. There is, however, a problem concerning the unaged partially neutralized systems. In this case, the rate of the reaction of the polynuclear ions with 8-quinolinol starts at a faster rate than usual and slows down after the first minute or so to the usual 1st order process (Fig. 2, curves *c* and *d*). Analogous to this behavior is the fact that the neutralization curves for the unaged partially neutralized systems did not show a distinct break between the two buffer zones (Fig. 1, curve *f*). It is probable as mentioned above, that some very low molecular weight polynuclear ions are present immediately after adding the base and gradually disappear with the formation of higher molecular weight ions. There is no convincing experimental evidence that these low molecular weight ions are excluded entirely from the mononuclear ions by the method proposed. Okura *et al.* (1), however, claimed that their experiments showed that ions with more than 2 Al atoms were excluded and there is no experimental evidence that those with 2 Al atoms are included with the mononuclear ions. Consequently, it must be kept in mind that there may be a small error in assuming that the method measures only mononuclear ions, but if the error does exist it must be very small. With respect to the methods for the polynuclear ions and the initial solid phase, the rates of their reactions with 8-quinolinol have been studied under such a variety of conditions. For example, Figs. 2–6 show that there is no doubt that the methods as outlined measure these 2 forms. It should be pointed out, however, that the initial solid phase changes fairly rapidly with length of time of aging and it is only the initial solid phase that is measured. After 24 h, for instance, only a fraction of the solid phase present is measured by the method. This will be the subject of a later communication.

Photo-initiated reactions of thiols and olefins. III. Addition of methanethiol to acetylene and butadiene-1,3

D. M. GRAHAM AND J. F. SOLTYS
Department of Chemistry, University of Western Ontario, London, Ontario

Received November 27, 1968

The kinetics of addition of methanethiol to acetylene and butadiene-1,3 have been investigated. The butadiene reaction exhibits no chain character due to the low reactivity of the adduct radical formed, and no rate constants could be determined. Thiyl radical addition to acetylene was found to be reversible at 25 °C, and the results obtained are consistent with the mechanism previously postulated for olefins, except that in this case, the rate of dehydrogenation of thiol by the adduct radical is comparable to the rate of radical decomposition. This competition permitted determination of the ratio of rate constants for these two reactions, and the rate constant for thiyl radical attack on acetylene.

Canadian Journal of Chemistry, 47, 2529 (1969)

Introduction

In Part II (2) it was shown that the photo-initiated addition of methanethiol to an olefin (A) could be described by the following mechanism over the concentration range available to gas phase measurements.

$$CH_3SH + h\nu \rightarrow CH_3S + H \qquad (\text{rate} = r_i)$$

[1] $$CH_3S + A \rightarrow X$$

[2] $$X + CH_3SH \rightarrow XH + CH_3S$$

[3] $$X \rightarrow A + CH_3S$$

[4] $$2CH_3S \rightarrow CH_3SSCH_3$$

Because of the reversibility of the attack step [1], only the rate constant ratio k_1k_2/k_3 is obtainable from addition rate measurements. This results from the fact that, over all experimentally feasible ranges of concentration and temperature, the rate of reaction [3] is much greater than reaction [2]. The rate constant for reaction [1] may be obtained directly only if *cis* and *trans* forms of the olefin exist (or may be synthesized by deuteration); this seriously limits any investigation of double bond reactivity where reversible attack occurs. In order to gain further insight into this problem, a kinetic study has been made of the addition of methanethiol to two different molecules, acetylene and butadiene-1,3, for which the rates of reactions [2] and [3] might differ appreciably from those for the simple olefins.

Experimental

The techniques used were as previously outlined (1, 2), except for the following differences. In order to decrease the size of the correction for non-uniform absorption of light, a shorter cell, 2 cm in length and 5 cm in diameter, was used. Addition rates were measured using a more sensitive differential pressure transducer. This gauge consists of 2 stainless-steel bellows (one for temperature compensation) connected to a linear variable differential transformer, the output of which is rectified and applied to a recorder. The gauge was found to be completely linear over a range of about 50 Torr, and its maximum sensitivity was limited by temperature control of the reaction cell thermostat. A sensitivity of 3 Torr per mV was found to be sufficient for measurement of reaction rates at conversions of less than 1%. The internal volume of the gauge and connecting tubing was less than 1% of that of the reaction flask, and no correction was made for this volume. In all cases, the relation between concentration change and pressure change was checked, over the entire concentration range of the experiments, by gas chromatography and, in some cases, by running the reaction to completion.

Mean square-root initiation rates, $\overline{r_i^{\frac{1}{2}}}$, were obtained from rates of thiyl catalyzed isomerization of *cis*-butene-2, and are ultimately related to rates of hydrogen production of pure thiol, corrected for non-uniform light absorption (1). The rate constants given here therefore are essentially relative rate constants.

Acetylene (Matheson 99.6% min.) and butadiene-1,3 (Matheson 99.5% min.) were purified by trap-to-trap distillations using the appropriate slush baths. Rates measured using samples purified by gas chromatography were identical with those obtained from the distilled compounds.

Results

Acetylene

The addition of methanethiol and ethanethiol to monosubstituted acetylenes in solution has been shown to proceed through the mono- to the di-adduct in an anti-Markownikoff manner (3–5). Although no attempt at product analysis was made in this investigation, an addition rate study carried out to completion indicated that 2 moles of thiol add to 1 mole of acetylene, and that addition to the mono-adduct is a little faster than to acetylene itself.

TABLE I

Addition to acetylene*

Methanethiol (moles l^{-1}) × 10^3	$r_i^{\pm}$ (moles l^{-1} s^{-1})$^{\pm}$ × 10^4	R_a (moles l^{-1} s^{-1}) × 10^7			
		25 °C	40 °C	55 °C	70 °C
2.15	3.36	3.24	2.32	1.72	1.37
2.69	4.00	4.40	3.28	2.36	1.85
3.76	5.00	6.62	5.58	3.58	2.78

9.14	8.90	15.3	14.6	10.9	9.78

*[Acetylene] = 2.15 × 10^{-3} moles l^{-1}.

The effect of temperature on the initial rate of addition (R_a) is shown in Table I. It is apparent from these results that the attack step [1] must be reversible since the rates decrease with increasing temperature. The overall activation energy varies from −2.1 to −4.0 kcal at 9.14 × 10^{-3} and 2.15 × 10^{-3} moles l^{-1} methanethiol, respectively.

For reversible addition the rate is given by (2)

$$[5]\quad R_a = -\frac{d[A]}{dt} = \frac{r_i^{\pm}}{(2k_4)^{\pm}} \frac{k_1[A]k_2[RSH]}{k_3 + k_2[RSH]}$$

Using calibrated screens, it was demonstrated that R_a was proportional to the half power of the incident light intensity, and hence to $r_i^{\pm}$, over the full concentration range of the results presented here. The first order dependence on acetylene is illustrated in Fig. 1. If eq. [5] holds for this reaction, a plot of $r_i^{\pm}/R_a$ against the inverse of the thiol concentration should be linear, and since k_4 is known (2), k_1 may be obtained from the intercept, and k_2/k_3 from the intercept/slope ratio. Two sets of results obtained at different acetylene concentrations are shown in Fig. 2. These give k_1 = 8.00 × 10^4 and 7.86 × 10^4 l $mole^{-1}$ s^{-1}, and k_2/k_3 = 297 and 270 l $mole^{-1}$. Inverse plots at different temperatures using the data of Table I are shown in Fig. 3. Least-square fits to this data yield scattered intercepts, and a value for E_1

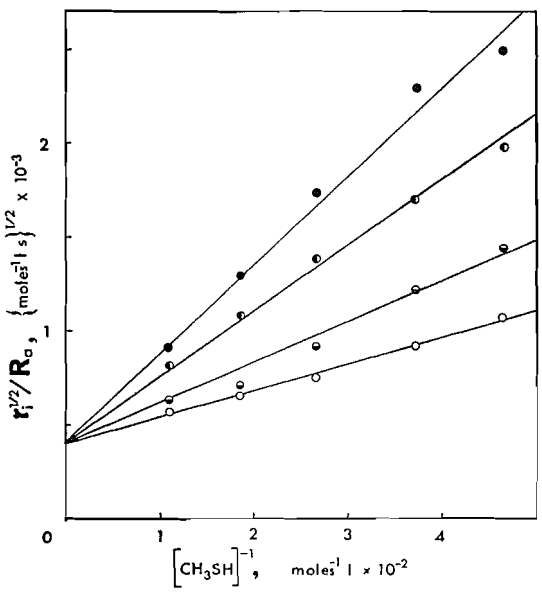

FIG. 3. Dependence of the rate of addition to acetylene on temperature; acetylene = 2.15×10^{-3} moles l^{-1}; ○, 25 °C; ◒, 40 °C; ◐, 55 °C; ●, 70 °C.

of -1.6 ± 1.3 kcal which is obviously meaningless. In order to obtain a better estimate for $E_2 - E_3$, therefore, it was assumed that $E_1 \simeq 0$, and that all intercepts were identical with that calculated using the average value of k_1 obtained at 25 °C from Fig. 2. The Arrhenius plot of the k_2/k_3 values obtained from these lines (shown in Fig. 3) is given in Fig. 4 which gives $E_2 - E_3 = -5.6$ kcal.

Butadiene-1,3

Free radical addition of simple aliphatic thiols to butadiene in solution has been found to yield predominantly the 1,4-mono-adduct with up to about 5% of the 1,2-addition product (6, 7). Gas chromatographic analysis, on a 300 ft Apiezon capillary column, of the products at low conversion of the gas phase reaction showed one broad peak and a smaller peak representing 94% and 5% of the total area, respectively. These peaks had retention times that would be expected for the adduct species. The mass spectrum of the reaction products is also consistent with the 1,4-mono-adduct being the primary product. The highest mass peaks observed were 102 and 101; the strongest peak occurred at 55, which

For personal use only.

could arise from allyl scission of the 1,4-adduct. In addition, fairly strong peaks due to 2,3-dithiabutane were seen.

The addition rate measurements are given in Table II. It is apparent that the reaction is zero order with respect to reactants, and approximately first order on the rate of thiol photolysis. This suggested the possibility that the reaction may have been occurring on the walls of the reaction vessel. In fact, during reaction, on the illuminated face of the cell, a mist was observed which disappeared immediately the light was blocked off. Heterogeneous effects probably may be eliminated however, since cleaning the cell with hydrofluoric acid, coating it with a baked film of dimethyldichlorosilane, or increasing the surface 13 times with glass-wool had no effect on the reaction rate.

The apparent chain lengths shown in the 5th column indicate that the reaction cannot properly be treated as a chain reaction. The chain length seems to increase with increasing thiol concentration and temperature, although these trends may only be apparent. Because of non-uniform initiation along the length of the cell, $(\overline{r_i^{\frac{1}{2}}})^2 \leq \overline{r_i}$, and the chain lengths may be overestimated at large thiol concentrations. Also, thermally induced reactions of butadiene may complicate the picture at the higher temperatures.

Discussion

Because of the very short chain lengths observed for butadiene, it is necessary to modify the kinetic treatment given previously to include a more detailed description of the primary initiation step. The rates of the following reactions must therefore be considered

$$CH_3SH + h\nu \rightarrow CH_3S + H \quad (\text{rate} = r_i/2)$$

[a] $$H + CH_3SH \rightarrow CH_3S + H_2$$

[b] $$H + A \rightarrow R$$

[c] $$R + CH_3SH \rightarrow RH + CH_3S$$

Addition of radicals other than thiyl to butadiene can probably be neglected since this is unlikely to be competitive with the attack on thiol. In solution, for example, the ratio of the rate constant for propagation of butadiene polymerization to that for dehydrogenation of straight chain thiols is 0.06 at 50 °C (8).

Assuming thiyl radical combination is the most important termination reaction, steady state analysis now gives the rate of addition as

$$[6] \quad R_a = \frac{(r_i/2)k_b[A]}{k_b[A] + k_a[RSH]} + \left(\frac{r_i}{2k_4}\right)^{\frac{1}{2}} \frac{k_1[A]k_2[RSH]}{k_3 + k_2[RSH]}$$

Thus, inclusion of these additional reactions introduces an extra term which is first order on light intensity. Since addition to butadiene produces an allyl-type radical, the activation energy for the reverse reaction should be about 20 kcal. The results indicate a small positive overall activation energy, and reaction [3] can probably be neglected. Hence, in the presence of butadiene, the thiyl radical population will be appreciably smaller than that for the adduct radical, X, and the main mode of termination should involve this latter species. The presence of appreciable disulfide in the reaction products, and the lower limit of 0.5 for the apparent chain length, suggest that the termination reaction should be $CH_3S + X$. Neglecting the chain propagation step [2] for the moment, and assuming the allyl radicals R and X to be kinetically indistinguishable, a steady state analysis with this termination yields $R_a = r_i/2$ which is consistent with the observed zero order kinetics. The detected addition products would appear to arise from radical combination reactions rather than from reaction [2].

As the thiol concentration or the temperature is increased, reaction [2] must become competitive with termination. This would produce an additional term in R_a proportional to $r_i^{\frac{1}{2}}$. The increase in chain length could also be due to a change in termination mechanism (X + X, for example, would yield $R_a = r_i$). However, since the increase occurs simultaneously with a decrease in the order dependence on light intensity, onset of chain propagation appears a more likely explanation.

In the case of acetylene also, low chain lengths were observed, particularly at lower thiol concentrations and higher temperatures. A more correct expression for the rate therefore would be eq. [6]. Since half-order dependence on light intensity was observed even at chain lengths less than unity, the first term of the equation must be negligible. The only way that this could occur,

For personal use only.

which would be consistent with the kinetic measurements, would be for $k_a[\mathrm{RSH}] \gg k_b[\mathrm{A}]$. It may be crudely estimated that, over the concentration ranges used, as long as $k_a \gtrsim 3k_b$, contributions from the first term would be negligible within experimental error. The effect of the first term would be greater at higher temperatures, and could possibly produce the apparent deviation from linearity of the 70 °C results, in which case, $E_2 - E_3$ has been overestimated.

Thus butadiene and ethylene appear to be at opposite extremes. Addition to ethylene produces a very unstable radical which decomposes much more rapidly than it dehydrogenates thiol, and kinetic measurements can yield only the ratio k_1k_2/k_3, whereas addition to butadiene produces a very stable radical which reacts only very slowly with thiol, and no rate constants may be determined from rate studies. Acetylene represents an intermediate case, because the very reactive vinyl adduct radical attacks thiol at about the same rate that it decomposes. This competition allows k_1 and k_2/k_3 to be separately determined.

TABLE III

Kinetic data for reaction with methanethiol*

Reactant	$k_1k_2/k_3 \times 10^{-5}$	$k_1 \times 10^{-5}$	$E_1 + E_2 - E_3$
Acetylene	230	0.79	−5.6
Ethylene	20	4.8	−5.1
Propylene	51	—	−5.4
Butene-2	15	16†	−6.4

*Rate constants are in units of moles, l, and s; activation energies in kcal; temperature equals 25 °C.
†*cis–trans* equilibrium weighted rate constant (eq. [5], ref. 2).

For comparison, the kinetic data obtained so far are shown in Table III. In calculating the results given in Parts I and II (1, 2), a factor involving the length of the cell was inadvertently omitted in correcting for non-uniform light absorption. The corrected rate constant for thiyl radical recombination is now $2k_4 = 5.0 \times 10^9$ l mole^{-1} s^{-1} and the new values of the other rate constants are listed in Table III. In addition, the activation energy given in Part II (2) for butene-2 is in error (probably as a result of a leaky pressure gauge). The activation energies have all been redetermined using the more sensitive transducer gauge and are given in the table as well.

The lower reactivity of acetylene and the relatively small trend in k_1 values may be rationalized by postulating π-complex formation in the initial stages of attack. The zero activation energy observed for this step also is consistent with this idea. However, it is probably presumptuous to attempt to generalize at this time on the basis of only three results.

Kinetic study of the reduction of cobalt(II) by carbon monoxide in an aqueous system

H. N. HALVORSON
Technical Research Centre, Cominco Ltd., Trail, British Columbia

AND

E. PETERS
Department of Metallurgy, University of British Columbia, Vancouver, British Columbia

Received December 27, 1968

A study of the catalyzed reduction of cobalt(II) to metal by carbon monoxide from aqueous, ammoniacal solutions between 180 and 230 °C and from 0 to 50 atm CO is reported.

The reaction proceeds through the intermediate formation of a cobalt carbonyl anion. Under the conditions of this study this intermediate is produced homogeneously and also heterogeneously in the presence of cobalt sulfide. Metal formation occurs only in the presence of cobalt sulfide.

The stoichiometry of the production of cobalt carbonyl anion is consistent with the equation

$$2Co(NH_3)_n^{2+} + 11CO + (12 - 2n)NH_3 + 6H_2O \rightarrow 2Co(CO)_4^- + 3CO_3^{2-} + 12NH_4^+$$

Metal formation follows the stoichiometry of the equation

$$9Co(NH_3)_n^{2+} + 2Co(CO)_4^- + (32 - 9n)NH_3 + 16H_2O \xrightarrow[CoS_x]{} 11Co^0 + 8CO_3^{2-} + 32NH_4^+$$

A mechanism that is consistent with the kinetic observations is presented.

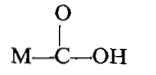
Canadian Journal of Chemistry, 47, 2535 (1969)

Introduction

Recovery of metals from aqueous leach solutions has been achieved traditionally by cementation, by electrowinning, and more recently, by displacement with reducing gases. Hydrogen has been the most commonly used gas but there has been a growing interest in the use of carbon monoxide for this application.

To assess the potential of carbon monoxide for use as a reductant in hydrometallurgy and also to gain fundamental knowledge of the mechanisms involved in such reactions, various metal ion – carbon monoxide systems have been studied. Most of this work has been done at the Department of Metallurgy at the University of British Columbia over the period 1956 to 1965.

Detailed kinetic studies of the reaction of carbon monoxide with Cu(II), Ni(II), Ag(I), Hg(II), MnO_4^-, $Cr_2O_7^{2-}$, and OH^- are reported (1–7). Briefly, these studies demonstrated that in most cases the formation of a carbon monoxide insertion complex of the type



was suggested as an intermediate in the reactions. In addition, it was shown that only the most noble metals were finally obtained as metals. With nickel, only the carbonyl $Ni(CO)_4$ was obtained.

Cobalt, from thermodynamic considerations, is probably the least noble metal that can be reduced by carbon monoxide. No literature references were found for the reduction of Co(II) by carbon monoxide in aqueous systems. There are, however, many references to the formation of cobalt carbonyls in organic systems. These references demonstrate the ease of formation and the marked stability of these compounds. Therefore, if a reaction between Co(II) and carbon monoxide in aqueous medium were found to occur, it may be expected that (*1*) a cobalt carbonyl, rather than metallic cobalt might be the end product of the reaction, and (*2*) that a cobalt – carbon monoxide insertion complex might be a reaction intermediate from similarity with other CO reductions.

It was the purpose of this work to investigate the Co(II)–CO–H_2O system to determine if a reaction occurred and, if so, to establish its mechanism.

Experimental

(*a*) *Apparatus*

A 2 l Parr pressure reaction autoclave, series 4500, was used. It was of 316 stainless steel construction with a

titanium liner. Stirrer shafts were belt driven at speeds between 800 and 1000 r.p.m. Heating was provided by a ring-type burner acting as a pilot light with a bunsen burner controlled by a solenoid valve activated by a Thermistemp temperature controller, model 71. Using a thermister probe and this heating system, temperature control was maintained to within ± 0.3 °C. Reactor pressures were measured with a 1500 p.s.i. helicoid gauge.

(b) Procedure

The experimental procedure involved preparing the charge under an argon atmosphere to minimize Co(III) formation, transferring the charge to the autoclave while flushing with argon, and heating to the required temperature. Carbon monoxide partial pressure was applied and the reaction followed by taking slurry and gas samples. The total pressure in the vessel was maintained constant by admitting more carbon monoxide. At the end of the run the entire reaction vessel was quenched in cold water.

The kinetics of the reaction were determined primarily by analyzing the Co(II) content in solution of the periodic slurry samples using EDTA with murexide as indicator. Carbon monoxide, carbon dioxide, and hydrogen were determined in the gas samples using standard gas–liquid chromatography (g.l.c.) techniques. Other standard assays employed were the acid titration method for CO_3^{2-} and the acidification and distillation method for $HCOO^-$. A special technique reported by Hieber (8, 10) for $Co(CO)_4^-$ determination involving its gravimetric determination as $[Ni(1,10\text{-phenantholine})_3][Co(CO)_4]_2$ was used.

Results

1. Stoichiometry

Preliminary experiments established that Co(II) and CO did react under reasonably attainable laboratory conditions. Typical conditions established for convenient rate measurements were: 1 liter of solution (3 *M* Co(II), 1 *M* $(NH_4)_2SO_4$, and 3–5 *M* NH_3), 25 atm CO, 215 °C, and 0.06 *M* S^{2-}. Under these conditions, the reaction times were about 15 min. It was shown, however, that cobalt metal did not result from this reaction unless a catalyst was present. In the absence of this catalyst the cobalt reaction product was a cobalt carbonyl.

The catalyst found active in promoting metal formation was a cobalt sulfide formed by adding $(NH_4)_2S$ to the system. X-ray and electron diffraction patterns indicated the sulfide to be either γ-Co_6S_5 or Co_9S_8. Chemical analysis indicated that γ-Co_6S_5 was the more likely form. CoS_x and CuS were the only materials found active as catalysts for Co metal production in this system. The known homogeneous catalysts for CO – metal ion reactions, (Cu(II), Ag(I), Hg(II), and Hg_2(II)), were inactive as were Hg, Ag, Ti, Ni, and Cu metals, CdS, and the ions Fe(II), Cd(II), Ni(II), and Zn(II). Two materials, cyanide and tartrate ions, were found to catalyze the production of the cobalt carbonyl but their effect, if any, on metal formation was not established.

The presence of a cobalt carbonyl compound was established during the reaction of CO and Co(II). In the absence of CoS_x, it was the only cobalt end product of the reaction. In the presence of CoS_x, it was often observed along with cobalt metal. It was present as sparingly-soluble, white crystalline flakes, floating on the aqueous solution. If air were excluded from such mixtures, this compound was stable at room temperature and atmospheric pressure for several months. Chemical assay and infrared spectrophotometry suggested the material to be a Co(II) salt of cobalt hydrocarbonyl, i.e. $Co(NH_3)_6[Co(CO)_4]_2$. Hieber (10) describes such a compound and elsewhere (8) reports an analytical method specific for $Co(CO)_4^-$. This test confirmed that the unknown was the cobalt salt of $Co(CO)_4^-$.

To determine the role of $Co(CO)_4^-$ in the mechanism, the following two part experiment was done under conditions with which experience had shown both cobalt metal and substantial amounts of carbonyl were formed. At the end of the run the autoclave was quenched, CO gas released, and all residual CO was flushed from the vessel with N_2. The bomb was opened, fresh $CoSO_4 \cdot 7H_2O$ was added to replenish the initial $Co(NH_3)_n^{2+}$ concentration, the bomb was closed, and the charge taken to temperature where it was held without CO addition. Liquid samples were taken to see if reduction of Co(II) occurred. The result is shown in Fig. 1.

It is evident that Co(II) is reduced by $Co(CO)_4^-$. However, this experiment did not establish the role of CoS_x in this reduction. To answer this point, two additional experiments were conducted. The first of these (experiment 151) was identical to the one above except that no S^{2-} was added to either part A or B; the second (experiment 155) had CoS_x present only in part B. The rate of reduction of Co(II) is shown in Fig. 2.

Without the addition of S^{2-} to part A, only $Co(CO)_4^-$ is produced. Only when S^{2-} is added to part B does the reduction of Co(II) by $Co(CO)_4^-$ occur.

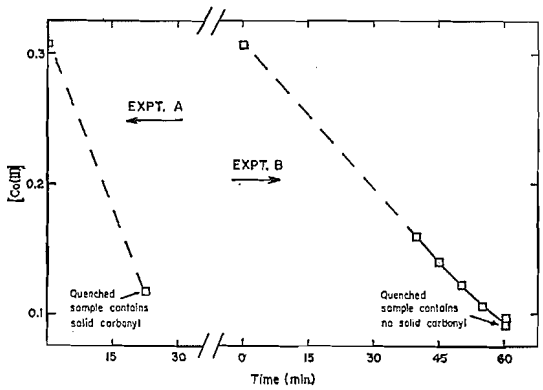

FIG. 1. Reduction of Co(II) by $Co(CO)_4^-$. *Experiment A*, production of $Co(CO)_4^-$ by reaction of CO and Co(II) in the presence of CoS_x; initial conditions: 0.046 M S^{2-}, 4.9 M NH_3, 1.1 M $(NH_4)_2SO_4$, 27.2 atm CO. *Experiment B*, reduction of Co(II) by the end products of experiment A in the absence of CO; initial conditions: 0.046 M S^{2-}, 4 M NH_3, 1.6 M $(NH_4)_2SO_4$, all reduction products from experiment A.

A and B of run 155 indicated the following stoichiometry

A. Reaction of CO with Co(II)

[1] $Co(NH_3)_n^{2+} + 5.5CO + 6NH_3 + 3H_2O \rightarrow Co(CO)_4^- + 1.5CO_3^{2-} + 6NH_4^+ + nNH_3$

B. Reaction of $Co(CO)_4^-$ with Co(II)

[2] $4.5Co(NH_3)_n^{2+} + Co(CO)_4^- + 16NH_3 + 8H_2O \xrightarrow{CoS_x} 5.5Co^0 + 4CO_3^{2-} + 16NH_4^+ + 4.5nNH_3$

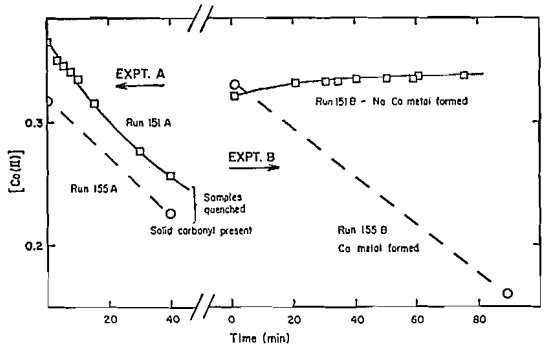

FIG. 2. Role of CoS_x in the reduction of Co(II) by $Co(CO)_4^-$. *Experiment A*, production of $Co(CO)_4$ in the absence of CoS_x; initial conditions: 1.1 M $(NH_4)_2SO_4$, 26 atm CO, 5 M NH_3, 190 °C. *Experiment B*, reactions of Co(II) with $Co(CO)_4^-$ produced in A in the absence of CoS_x (run 151 B) and in the presence of CoS_x (run 155 B); initial conditions: run 151 B: > 1.1 M $(NH_4)_2SO_4$, > 5 M NH_3, all products of experiment A, 190 °C, no S^{2-}; run 115 B: > 1.1 M $(NH_4)_2SO_4$, > 5M NH_3, all products of experiment A, 190 °C, 0.05 M S^{2-}.

The summation of eqs. [1] and [2] indicates that the overall reduction of Co(II) to metal by CO in the presence of the catalyst CoS_x should follow the stoichiometry

[3] $Co(NH_3)_n^{2+} + CO + 4NH_3 + 2H_2O \xrightarrow{CoS_x} Co^0 + CO_3^{2-} + 4NH_4^+ + nNH_3$

The comparison of the calculated stoichiometry of an overall reaction using eq. [3] and the experimental stoichiometry obtained with a typical run showed discrepancies of 9, 14, and 10% for the amount of CO consumed, NH_3 neutralized, and CO_3^{2-} produced. The agreement is sufficiently close to support the above hypothesis.

2. Kinetics

Stoichiometric studies indicated two major steps in the mechanism. Kinetic studies were used to elucidate more details of the reaction mechanism.

The rate of reduction of Co(II) was followed by determining the Co(II) content of periodically taken samples. Typical rate curves are shown in Fig. 3. Data so obtained fit no simple zero, first, or second order rate laws. It was observed, however, that maximum rates taken from zero order rate curves gave reproducible rates (maximum variation of $\pm 10\%$) and these rates were used throughout the study for evaluation of the kinetics. Using this technique, the effect on the rate of the experimental parameters was established.

Figure 4 shows the effect of the initial concentration of NH_3, $[NH_3]_i$, on the rate at three catalyst addition levels. The rate appears to be first order in initial NH_3 concentration up to about 3 M (or more correctly, for $[NH_3]_i/[Co(II)]_i < 10$) after which the reaction is independent of NH_3. By consideration of the simultaneous effect of the initial $(NH_4)_2SO_4$ and NH_3 concentration on the rate, it was established that the effect of NH_3 on the rate was due to changing the OH^- concentration and not to NH_3 complexing of Co(II). The rate determining step was, therefore, concluded to be first order in initial OH^- concentration below $[NH_3]_i/[Co(II)]_i = 10$ and to approach zero order in OH^- above this ratio.

The effect of the amount of CoS_x catalyst present was investigated at two levels of initial NH_3 concentration to determine the effect in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

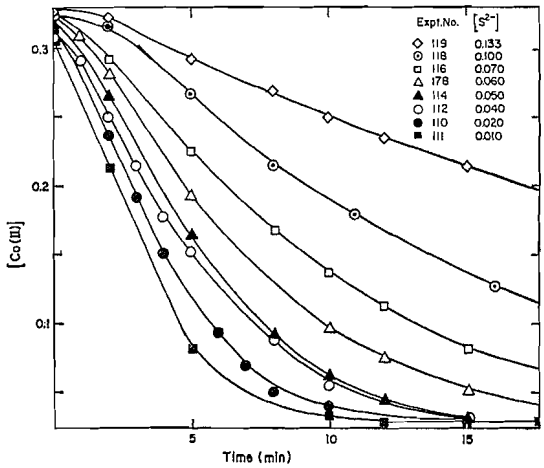

FIG. 3. Typical rate curves. Initial conditions: > 3.3 *M* NH_3, 1.1 *M* $(NH_4)_2SO_4$, 26 atm CO, 215 °C.

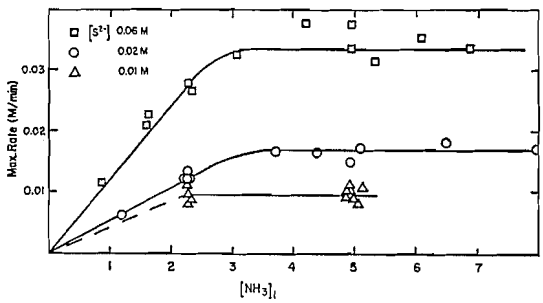

FIG. 4. Effect of initial NH_3 concentration on reduction rate at 215 °C. Initial conditions: 1.2 *M* $(NH_4)_2SO_4$, 0.31 *M* Co(II), and 26 atm CO.

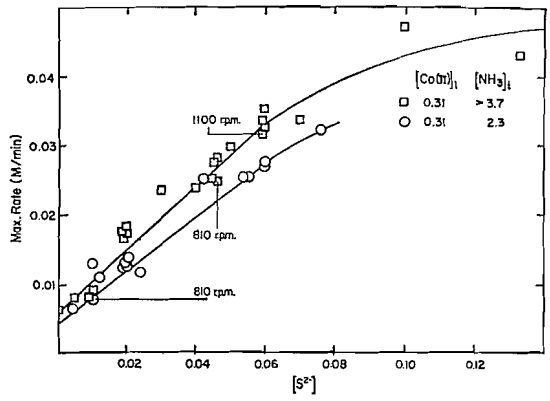

FIG. 5. Effect of S^{2-} addition on rate. Initial conditions: 1.1 *M* $(NH_4)_2SO_4$, 26 atm CO, 1005 r.p.m. stirring speed, 215 °C.

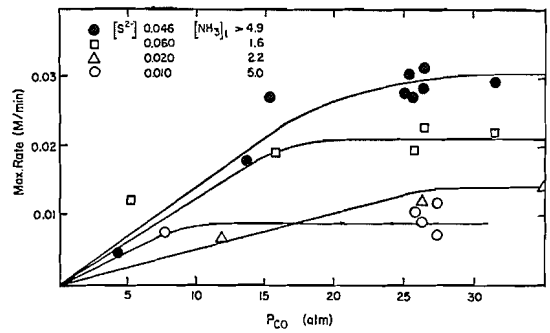

FIG. 6. Effect of initial CO pressure on rate. Initial conditions: 0.31 *M* Co(II), 1.2 *M* $(NH_4)_2SO_4$, 215 °C.

regions of zero and first order dependency on initial NH_3 concentration. The results are shown in Fig. 5. In both cases there is a measurable rate of Co(II) removal from solution in the absence of CoS_x. This is due to $Co(CO)_4^-$ formation and is sufficiently small, compared to total rates when CoS_x is present, to be ignored. With the addition of increasing amounts of S^{2-} the rate increases. A plot of log rate vs. log $[S^{2-}]$ indicated the order in S^{2-} addition to be about 0.6 to 0.7. This dependency is consistent with a linear dependency in surface area if the CoS_x particle numbers and shapes are unchanged with increasing S^{2-} concentration, but the sizes of the precipitate particles are larger.

The effect of CO pressure is shown in Fig. 6. Four series at various S^{2-} and initial NH_3 concentrations were done to check for possible interdependence of the variables. Initially the rate is apparently first order in P_{CO} but this dependency becomes zero order at high P_{CO}. The level at which the rate is independent of P_{CO} varies according to the NH_3 and S^{2-} concentrations but at the P_{CO} usually used in the study (26 atm), the rate is independent of P_{CO}.

Figure 7 demonstrates the effect of the initial Co(II) concentration. The rate determining step appears first order in initial Co(II) concentration at low levels decreasing to an apparent zero order at high levels.

The temperature dependence of the reaction was determined over the range 180–230 °C at high S^{2-} additions and at 3 different initial NH_3 levels. The corresponding Arrhenius plots are shown in Fig. 8. The calculated activation energies are within experimental error of the same value and indicate that the same mechanism is rate-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

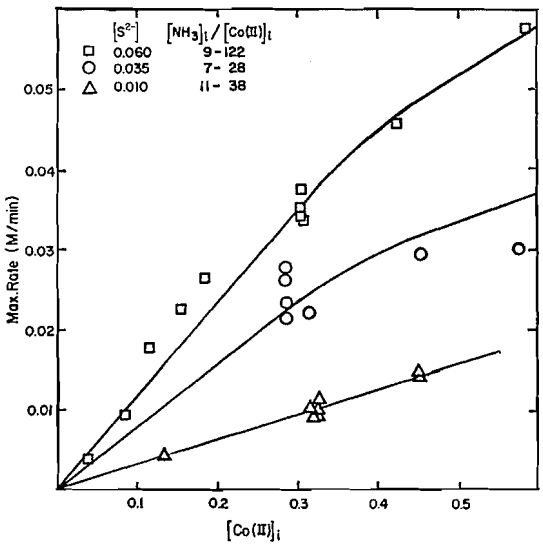

FIG. 7. Effect of initial Co(II) concentration on rate. Initial conditions: 1.1 M $(NH_4)_2SO_4$, 26 atm CO, 215 °C.

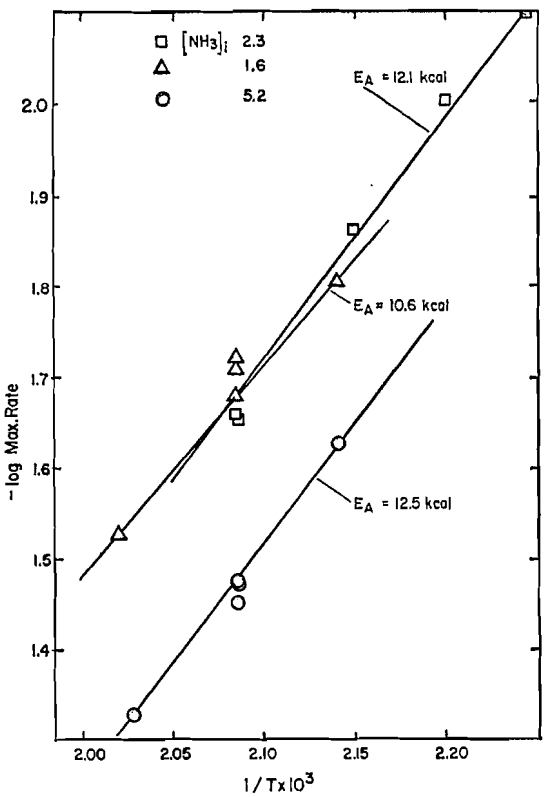

FIG. 8. Arrhenius plot. Initial conditions: 0.31 M Co(II), 0.06 M S^{2-}, 26 atm CO, 1.2 M $(NH_4)_2SO_4$.

controlling over the range of conditions used in this work, with an apparent activation energy of 11 ± 1 kcal/mole. This value is too high for diffusional mass transfer in aqueous solutions.

No dependency on the rate of stirring, or on Co(III) and CO_3^{2-} concentrations was observed. Adding Mg(II) and K(I) had no effect on the rates.

By-product formation of H_2 and $HCOO^-$ was observed in this study. Separate tests showed that $HCOO^-$ does not reduce Co(II) at an appreciable rate under the test conditions used in this study. H_2 reduction of Co(II) occurs under the conditions of this study but at a much lower rate, calculated to be equivalent to about 2% of the CO reduction rates at the H_2 pressures generated during these experiments.

To establish the effect on the rate of the presence of the Co metal produced, one recycling test was done. The procedure consisted of using the reduced solution and solids from a first run as partial feed to a second (in addition, $CoSO_4 \cdot 6H_2O$, NH_3, and H_2O were added to regain the original concentrations). The second run was, therefore, identical to the first except that CoS_x was not fresh and that Co metal was present from the start. The results of this recycling are shown in Fig. 9. The two runs have rates identical within experimental error, indicating the rate is independent of the amount of Co metal present and that

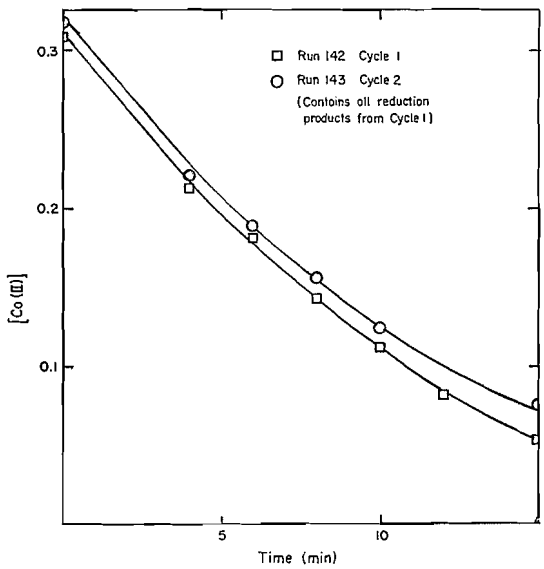

FIG. 9. Effect of recycling on rate. Initial conditions: 0.046 M S^{2-}, > 5 M NH_3, > 1.2 M $(NH_4)_2SO_4$, 26.5 atm CO, 215 °C.

the active sites on CoS_x are not destroyed by coating with Co metal. Electron microscopy partially confirmed this conclusion by indicating that the CoS_x was present as spherical particles while Co metal was present as platelets. A cobalt particle completely free of CoS_x was found.

3. Experimental Rate Law

The kinetic data produced the following experimental rate laws

Condition A

$$[4]\quad \frac{-d[Co(II)]}{dt} = k_1[OH^-][S^{2-}]^{0.6}[Co(II)]P_{CO}$$

valid for

$$0 < [NH_3]_i/[Co(II)]_i < 10$$
$$0 < [S^{2-}]$$
$$0 < P_{CO} < 26 \text{ atm}$$
$$0 < [Co(II)]_i < 0.6$$

Condition B

$$[5]\quad \frac{-d[Co(II)]}{dt} = k_2[S^{2-}]^{0.6}$$

valid for

$$[NH_3]_i/[Co(II)] > 10$$
$$0 < [S^{2-}]$$
$$P_{CO} > 26 \text{ atm}$$
$$[Co(II)]_i > 0.6$$

Conditions intermediate between *A* and *B* have not received enough experimental attention for complete resolution of a rate law.

In these rate law expressions the contribution of the homogeneous formation of $Co(CO_4)^-$ to the overall rate is omitted because it is small in comparison to the heterogeneous contribution at a finite S^{2-} addition.

Discussion

The mechanism has been shown to consist of two distinguishable stages: the formation of $Co(CO)_4^-$ and the formation of Co metal. Based on the literature, the kinetics in this present study would be expected to involve a rate-determining step consisting of the formation of a CO insertion complex. In the case of Cu(II), Ag(I), and Hg(II) similar insertion complexes react with another metallic ion resulting in reduced net valence states for the metals. In the case of Ni(II) the insertion complex reacts with further CO to form stable $Ni(CO)_4$ and no metal results. This present work indicates that Co(II) behavior is more comparable to the Ni(II) reaction than with those of the others, since a stable carbonyl also forms. This is the product of the reaction, unless a catalyst is present which permits this carbonyl to react with additional Co(II) ions forming metal, not unlike the reaction of the insertion complexes of Ag(I), Hg(II), and Cu(II). The formation of $Co(CO)_4^-$ is more complicated than that of $Ni(CO)_4$ in that the cobalt product has an awkward electronic change not obtainable through simple capture of CO molecules and normal decomposition of the Co(II) insertion complex. Rather, the cobalt – CO insertion complex must be further reduced. CoS_x is a likely vehicle for the reduction by reason of its content of metal in a variable valence.

The following assumed mechanism is consistent with both the experimental kinetics obtained and steps that would be expected in the literature

$$[6]\quad Co(NH_3)_n^{2+} + CO + NH_3 + H_2O \overset{K_1}{\rightleftharpoons} [(NH_3)_nCo{-}\overset{\overset{O}{\|}}{C}{-}OH]^+ + NH_4^+$$

$$[7]^1\quad [(NH_3)_nCo{-}\overset{\overset{O}{\|}}{C}{-}OH]^+ + C_S \xrightarrow{k_r} [(NH_3)_nCo{-}\overset{\overset{O}{\|}}{C}{-}OH]^+_{ads}$$

$$[8]^1\quad [(NH_3)_nCo{-}\overset{\overset{O}{\|}}{C}{-}OH]^+_{ads} + CoS_x \xrightarrow[\text{fast}]{} [(NH_3)_nCo{-}\overset{\overset{O}{\|}}{C}{-}OH]^0_{ads} + CoS_x^+$$

cathodic reaction

[1]Reactions [8] and [10] are coupled; i.e., as they occur stoichiometric with respect to each other, there is no net change in the electronic charge of CoS_x. Similarly eqs. [7] and [9] are coupled to maintain a constant concentration of vacant adsorption sites C_2 on the surface of CoS_x particles.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$[9] \quad [(NH_3)_nCo{-}\overset{\overset{O}{\|}}{C}{-}OH]^0_{ads} \xrightarrow{k_{r_1}} [(NH_3)_nCo{-}\overset{\overset{O}{\|}}{C}{-}OH]^0 + C_S$$

$$[10]^1 \quad CoS_x^+ + \tfrac{1}{2}CO + 2NH_3 + H_2O \xrightarrow[\text{fast}]{} CoS_x + \tfrac{1}{2}CO_3^{2-} + 2NH_4^+$$

anodic reaction

$$[11] \quad [(NH_3)_nCo{-}\overset{\overset{O}{\|}}{C}{-}OH]^0 + 4CO + (3-n)NH_3 + H_2O \xrightarrow[\text{fast}]{} Co(CO)_4^- + CO_3^{2-} + 3NH_4^+$$

$$[12] \quad Co(CO)_4^- + 4.5Co(NH_3)_n^{2+} + (16 - 4.5n)NH_3 + 8H_2O \xrightarrow[\text{fast}]{CoS_x} 5.5Co^0 + 4CO_3^{2-} + 16NH_4^+$$

where CoS_x^+ denotes the removal of an electron from a CoS_x crystal. Adjustments in the charged double layer on the CoS_x crystal can neutralize the change in charge with a negligible change in potential for each electron.

Experimentally, the CoS_x surface can be considered as playing two independent roles. The first is to act as an electron source for adjusting the valence of Co during conversion from the insertion complex

$$[(NH_3)_n\,Co{-}\overset{\overset{O}{\|}}{C}{-}OH]^+$$

to the carbonyl anion $Co(CO)_4^-$. CoS_x is not necessary for this to occur but the rate is much faster in its presence. The second is to provide a path for metal crystal formation from $Co(CO)_4^-$ ions and unreduced Co(II) species.

Equation [12] is the overall stoichiometric statement for metal formation. It can be subdivided in several alternate ways, depending on whether the catalyst CoS_x can only exchange electrons or can also add or release cobalt atoms. Eventually, metal nucleation and growth is probably the result of homogeneous decomposition of the species $Co_4(CO)_{12}$, viz.

$$2Co_4(CO)_{12} \rightarrow 2Co^0 + 3Co_2(CO)_8$$

This would mean the above equation would generate $Co_4(CO)_{12}$ on the CoS_x surface utilizing a combination of $Co(CO)_4^-$ (ads), $Co_2(CO)_8$, and $Co(NH_3)_4^{2+}$ for this purpose.

Alternative metal deposition equations require the loss of carbon monoxide in homogeneous reaction. It has already been shown that all carbon monoxide initially in the form of $Co(CO)_4^-$ is oxidized. This could not happen if it was not returned to the surface as some cobalt carbonyl species such as $Co_2(CO)_8$.

The absence of cobalt metal on the catalyst surface precludes a mechanism as simple as eq. [12] seems to suggest, i.e. not involving additional carbonyl compounds of cobalt not shown in the stoichiometry.

In the mechanism as shown, if the assumption is made that $k_r > k_{r_1}$ for high values of P_{CO_i}, $[NH_3]_i/[Co(II)]_i$, and $[Co(II)]_i$ and $k_r < k_{r_1}$ for low values of P_{CO_i}, $[NH_3]_i/[Co(II)]_i$, and $[Co(II)]_i$, then adsorption of the cobalt insertion complex on the CoS_x surface (eq. [7]) becomes rate determining at low reactant concentrations, while the desorption of the reduced insertion complex (eq. [9]) is rate determining at high reactant concentrations.

If the reaction shown in eq. [7] is rate determining, the rate of reduction is given by

$$[13] \quad \frac{-d[Co(II)]}{dt} = \theta k_r \frac{K_1}{K_2}[Co(II)]P_{CO}[OH^-][S^{2-}]^{0.6}$$

where θ is the proportionality constant relating the amount of CoS_x present and the number of active adsorption sites and

$$K_2 = \frac{[NH_4^+][OH^-]}{NH_3}$$

Equation [13] is identical to eq. [4], the experimental rate law for low reactant concentrations, if

$$k_1 = \frac{\theta k_r K_1}{K_2}$$

If the rate determining step is that given by

eq. [9], then the rate of reduction is given simply by

$$[14] \qquad \frac{-d[Co(II)]}{dt} = \theta_1 k_{r_1}[S^{2-}]^{0.6}$$

where θ_1 is the proportionality constant relating the amount of CoS_x present with the number of sites available for adsorption. Equation [14] is identical to eq. [5], the experimental rate law at high reactant concentrations, if $k_2 = \theta k_{r_1}$.

From the experimental data, the values of k_1 and k_2 were determined. The value of k_1 was found to be about 3.3×10^4 l^2 mole^{-2} and k_2 to be about 0.39/min. From the literature K_2 is reported to be 2×10^{-6} moles/l at 215 °C. Using these values and the integrated forms of eqs. [13] and [14], it is possible to calculate reduction rate curves. Such calculated curves are compared with experimental rate curves in Figs. 10 and 11. The agreement between calculated and experimental curves is considered sufficiently good in both cases to support the mechanism.

Conclusions

In ammoniacal solutions in the temperature range 180 to 230 °C and CO pressures from 0 to 50 atm, the reduction of Co(II) to metal by CO in aqueous solution is found to proceed through the formation of $Co(CO)_4^-$ as an intermediate step. The production of metal results from the reduction of $Co(NH_3)_n^{2+}$ by $Co(CO)_4^-$. CoS_x catalyzes both steps of the overall reaction. $Co(CO)_4^-$ can be produced by a homogeneous step but at a much slower rate than when CoS_x is present. The rate determining step at low reactant concentrations is postulated to be the adsorption of a CO insertion complex of $Co(NH_3)_n^{2+}$ on a CoS_x surface. At high reactant concentrations the rate determining step is postulated to be the desorption of the reduced insertion complex. A mechanism consistent with the experimental rate measurements can be postulated involving these steps. A contribution to the overall rate by a homogeneous step for the production of $Co(CO)_4^-$ is neglected. The role of the cobalt sulfide catalyst is supposed to be electrochemical in that it acts as a source and sink for electrons so that otherwise awkward

charge changes in reacting species are accommodated.

CO reacts with OH^- to form $HCOO^-$ which in the presence of CoS_x reacts to form H_2. Under the conditions used in this work CO is a more effective reductant for Co(II) than is H_2.

Infrared study of the interactions of acetone and siliceous surfaces

J. C. McManus, Yoshio Harano, and M. J. D. Low
Department of Chemistry, New York University, New York 10453

Received November 13, 1968

Adsorbed acetone is held to silica surfaces by hydrogen bonds between surface silanols and the acetone carbonyl groups. Acetone is adsorbed by this mechanism on porous glass surfaces but there is also some decomposition, as shown by the increase in surface B—OH groups and by formation of new C—H absorptions at 2984 and 2940 cm^{-1}. Experiments with boron-impregnated silica indicated that the presence of boron in the porous glass can account for this decomposition process. Bands at 1660–1670 and 1650 cm^{-1}, observed when acetone and acetone-d_6, respectively, were adsorbed on either porous glass or boron-impregnated silica, are attributed to ν(C=O) of the carbonyl group coordinated with a surface boron atom. The surface hydroxyls of both silica and porous glass could exchange with the deuterium of acetone-d_6 via a mechanism involving an enol intermediate.

Canadian Journal of Chemistry, 47, 2545 (1969)

Introduction

Recent work has shown that many of the differences in the surface properties of porous glass and pure silica can be attributed to the minority constituents on the glass (1, 2). Pure silica is relatively inert, but can be made "active," so that it resembles porous glass in behavior, by impregnating the silica with oxides such as alumina or boria. As much of the recent infrared (i.r.) work had been carried out with water (3) and nitrogenous compounds (4–6), it was thought desirable to extend the studies to oxygen-containing adsorbates such as methanol (7) and acetone, so that information would be available on the reactions of adsorbates having different "functional groups".

The present paper describes our attempts to characterize the interactions of acetone with porous glass and some silicas by i.r. techniques. The acetone – porous glass system has been examined previously (8, 9), but the studies were brief. Also, i.r. studies involving adsorbates such as acetone are fraught with difficulty because there is always the possibility that grease may be transported from joints onto the adsorbent surface. In the present experiments we approached this problem by using acetone and acetone-d_6 which were purified and stored in a grease-free system. Work with isotopic acetone not only gave more reliability to the results but also enabled the interactions to be more fully characterized.

Experimental

Acetone ("Baker Analysed"), acetone-d_6 (Stohler Isotope Chemicals, 99% D), and 1,1,3-trifluorotrichloroacetone (Aldrich Chemical Co.) were stored and purified in a section of the apparatus made entirely from glass and Teflon stopcocks. These adsorbates were dried *in vacuo* over either anhydrous copper or calcium sulfates and degassed by freeze–pump–thaw cycles until no pressure burst was evident on the Pirani gauge. Infrared spectra of acetone and acetone-d_6 in both the gas and liquid phase showed excellent agreement with the data of Dellepiane and Overend (10). Corning Grade 7930 porous glass was used in the form of 1 mm-thick plates. Thinner, ground samples (approx. 0.2 mm) were used in some experiments. Other samples were self-supporting discs of Cab-O-Sil (Cab-O-Sil M5 Silica, supplied by G. Cabot, Boston, Mass.), and of Cab-O-Sil impregnated with either 1% of boron or 1% of aluminium by the incipient-wetness method. All samples were outgassed *in vacuo* at 600° for 3 h, heated in 50 Torr oxygen for 6 h at 600°, and then degassed for 12 h at 800°.

Spectra were recorded with a Perkin–Elmer Model 621 spectrophotometer, using ordinate and abscissa scale expansion as required. A reference cell was always used to compensate for the absorptions of the atmosphere and the gaseous adsorbate.

Results and Discussion

A large number of experiments were carried out with various adsorbents. Each of these had its complexities and a number of reactions were observed. Thus, for the sake of simplicity, a summary of the bands of adsorbed acetone and their assignments is given in Table I, and each of the adsorbents is considered in turn.

Cab-O-Sil Silica

The reaction of acetone and also of acetone-d_6 with pressed Cab-O-Sil pellets was studied to evaluate the contribution of silica to the activity of porous glass. Figure 1 shows the results of the interaction of acetone with deuteroxylated Cab-O-Sil. Our results for acetone adsorption on

hydroxylated and deuteroxylated Cab-O-Sil surfaces showed that, in the main, acetone was held to the surface by a hydrogen-bonding mechanism involving surface silanol groups and the carbonyl grouping of acetone. This is in agreement with the work of Young and Sheppard (11). In addition to the bands due to "perturbed" hydroxyls at 3400 cm^{-1} and adsorbed acetone at 3003, 2960, 2926, and 1711 cm^{-1} observed by those workers, we obtained absorption bands at 1415 and 1360 cm^{-1}. These latter bands were in a similar position to those respectively observed for the asymmetric and symmetric CH_3 deformation vibrations of acetone (10) and, since they were not observed when acetone-d_6 was adsorbed, we believe that these vibrations are the cause of the absorptions. The position of ν(C=O) was insensitive to surface coverage and remained constant to ± 1 cm^{-1} over the absorbance range 0.1–0.9 during adsorption and desorption. The other bands of adsorbed acetone showed similar behavior. Like Young and Sheppard, we were unable to detect the splitting of ν(C=O) reported by Bertoluzza *et al.* (12).

After 30 min evacuation at room temperature, no bands due to adsorbed acetone could be observed and the concentration and type of silanol groups appeared to be unchanged from the initial state. This was found for samples outgassed in the range 450–800°. However, in many experiments, a small band (approx. 1% absorption) was detected at 3003 cm^{-1} when no absorption due to ν(C=O) could be observed. This band was not observed when the sample was treated with acetone-d_6 but no band was observed in the ν(C—D) region either. However, extinction coefficients of C—D absorptions are smaller

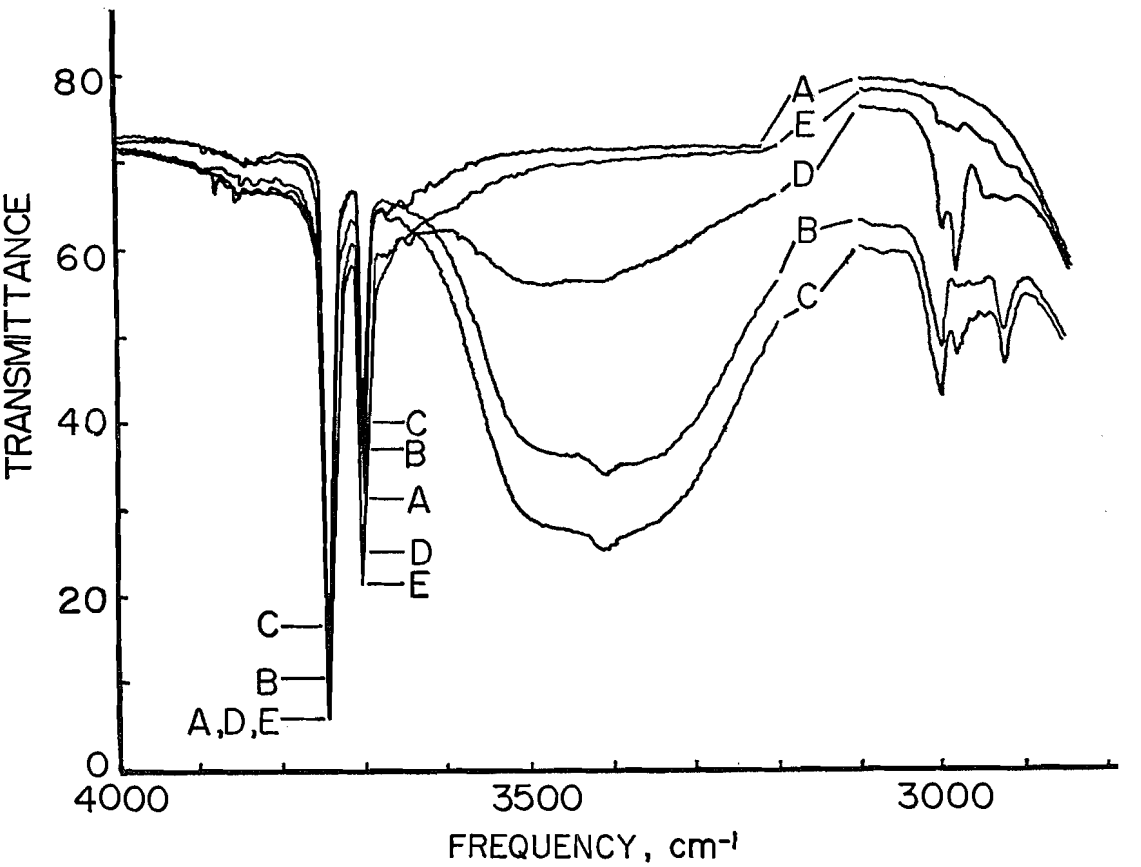

FIG. 2. Acetone sorption on porous glass. A: after outgassing at 840°; B: after exposure to 17 Torr acetone; C: after exposure for 1 h to 17 Torr acetone; D: after 14 h degassing at 25°; E: after 30 min degassing at 170°. The ordinates of spectra A, E, and D were displaced in the 3100–2800 cm^{-1} region to prevent overlapping.

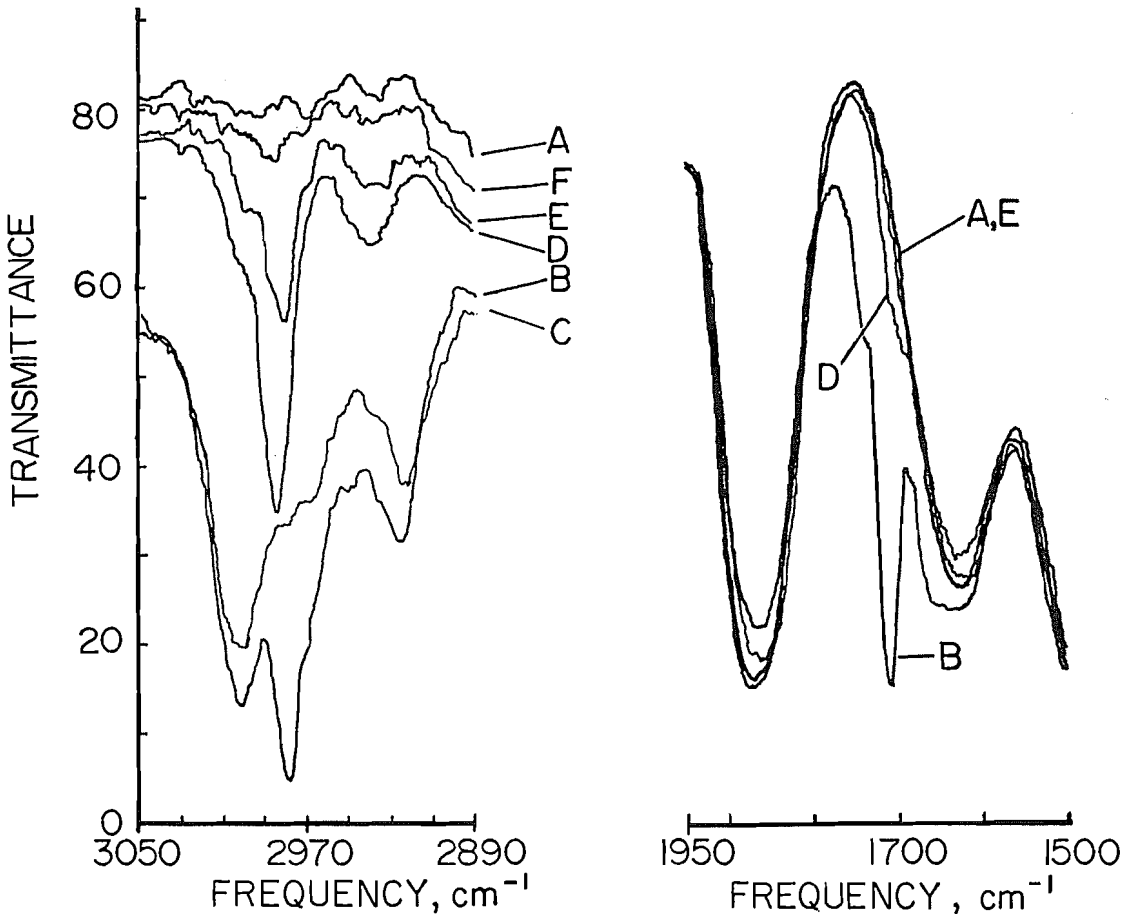

FIG. 3. Acetone sorption on thin porous glass. A: after outgassing at 800°; B: after exposure to 25 Torr acetone; C: 13 h after the addition of acetone; D: after 4 h degassing at 25°; E: after 30 min degassing at 70°; F: after 30 min degassing at 165°. For the 3050–2890 cm^{-1} region, 2.5-fold abscissa and 5-fold ordinate scale expansions were used. For the 1950–1500 cm^{-1} region, screen compensation with the 2× slit program (256 μ at 1800 cm^{-1}) was used.

than those of the corresponding C—H absorptions. The presence of this C—H band was briefly mentioned by Young and Sheppard. It seems unlikely that the 3003 cm^{-1} band was due to residual acetone because of the failure to observe ν(C═O). The species responsible for the absorption did not desorb until degassing temperatures of 90° were used and its exact nature remains uncertain. Figure 1 clearly shows that exchange between surface deuteroxyl groups and hydrogen in the acetone occurred, but discussion of this is left until later.

Porous Glass

As can be seen from Fig. 2, the main interaction of acetone with porous glass surfaces involved hydrogen-bonding between surface hydroxyls and the acetone carbonyl groups. The interaction was very similar in magnitude to that observed with Cab-O-Sil. The bands at 3745 and 3703 cm^{-1} are due to "free" Si—OH and B—OH groups (1, 2) respectively. When thick samples of high surface area were used, a band at 3410 cm^{-1}, superimposed on the broad absorption, was observed. The 3410 cm^{-1} band is attributed to the first overtone of ν(C═O). Both Figs. 2 and 3 show that, when porous glass was initially exposed to acetone, bands could be observed at 3003 and 2927 cm^{-1}. However, when the acetone remained in contact with the surface, a new band formed at 2984 cm^{-1}. Evacuation at room temperature for 30 min removed much of the hydro-

gen-bonded acetone, but the band at 2984 cm^{-1} was little affected. This treatment revealed a new band at 2940 cm^{-1} (which was probably obscured at higher coverage by the acetone C—H bands), and the intensity of the 3703 cm^{-1} B—OH band increased. These facts suggest that, apart from reversible adsorption, some chemisorption had also taken place. We were unable to observe a band at 2960 cm^{-1} to correspond with that observed when acetone was adsorbed on Cab-O-Sil. Figure 1 shows that that band was weak, and we therefore believe that it was probably obscured by other C—H absorptions (including possible small contributions at 2984 and 2940 cm^{-1}).

The spectra below 2000 cm^{-1} in Fig. 3 were obtained with a 0.2 mm-thick sample using a slit program wider (256 μ at 1800 cm^{-1}) than normally required, together with a scanning speed of 20 cm^{-1} per min and 2.5-fold abscissa expansion; the reference beam was attenuated with a wire screen. The absorption due to ν(C═O) is clearly revealed at 1710 cm^{-1}. However, making allowance for the background, a plot of absorbance vs. wavenumber for trace B in Fig. 3 indicates the presence of a band at 1665–1670 cm^{-1}. The experimental difficulties were quite large, but further evidence tends to substantiate this observation. Figure 3 shows that, in contrast to Cab-O-Sil, the ν(C═O) band did not entirely disappear until the sample had been degassed at 70°. Even so, it is evident that the absorptions at 2984 and 2940 cm^{-1} and at least some of the absorption at 3003 cm^{-1} were not related to ν(C═O), but show the presence of a new product or products. Degassing temperatures of 150° were required to remove these bands. Also, results for acetone-d_6 adsorption on porous glass could be satisfactorily compared with the acetone – porous glass system. Figure 4 shows that, initially, hydrogen-bonded acetone-d_6 was present on the surface, the C—D bands at 2260 and 2220 cm^{-1} being similar in position to those of liquid acetone-d_6, while the first overtone of ν(C═O) was shifted to 3390 cm^{-1}. However, some decomposition process is indicated; 18 h after the addition of the acetone-d_6 the lower-frequency C—D band shifted to 2230 cm^{-1} and, while degassing at 50° removed most of the hydrogen-bonded material, a pronounced band remained at 2236 cm^{-1}. We think that this band is due to a product similar in nature to that responsible for the absorption at 2984 cm^{-1} observed with the acetone – porous glass system. At no time were bands observed in the ν(C—H) region. Figure 4 also shows that exchange had occurred between the surface OH groups on porous glass surfaces and the deuterium in acetone-d_6, but discussion of this is deferred. Experiments with thin porous glass samples (Fig. 5) showed that ν (C═O) had its maximum absorption at 1700 cm^{-1}. The lowering in wavenumber (also observed for the acetone-d_6 – Cab-O-Sil system) of the band-head position compared to acetone may be caused by the heavier reduced mass of the acetone-d_6 molecule. Plots of absorbance vs. wavenumber again revealed the presence of a second, weaker band at 1650 cm^{-1}, which is 15 cm^{-1} lower than that found for acetone.

Impregnated Silicas

The effects of surface boron on adsorption properties were studied using a self-supporting disc of Cab-O-Sil containing 1% boron. The results given in Fig. 6 show that boron-impregnated silica behaved very much like porous glass. There was evidence for much acetone held by hydrogen-bonding forces to surface hydroxyls, but decomposition products which absorbed at 3001, 2982, and 2940 cm^{-1} were observed as with porous glass, and the concentration of B—OH groups increased. Similarly, as with the acetone-d_6 – porous glass system, a decomposition product which absorbed at 2236 cm^{-1} was observed. In addition to these findings, strong absorptions were observed at 1661 and 1650 cm^{-1} when pressures greater than 10 Torr acetone and acetone-d_6 respectively were in contact with boron-impregnated silica. Thus it seems that the presence of boron can account for all the observable differences between porous glass and silica. To see if aluminium acted in a similar way, some experiments were carried out with a Cab-O-Sil pellet containing 1% aluminium. These showed that some acetone was adsorbed by a hydrogen-bonding mechanism, but much of the acetone decomposed, as would be expected from the results of Hair and Chapman (13). The decomposition product gave a strong absorption at 2960 cm^{-1}. A similar product was not observed on porous glass, indicating that while a similar reaction involving aluminium is not ruled out, aluminium can play only a minor role compared to boron.

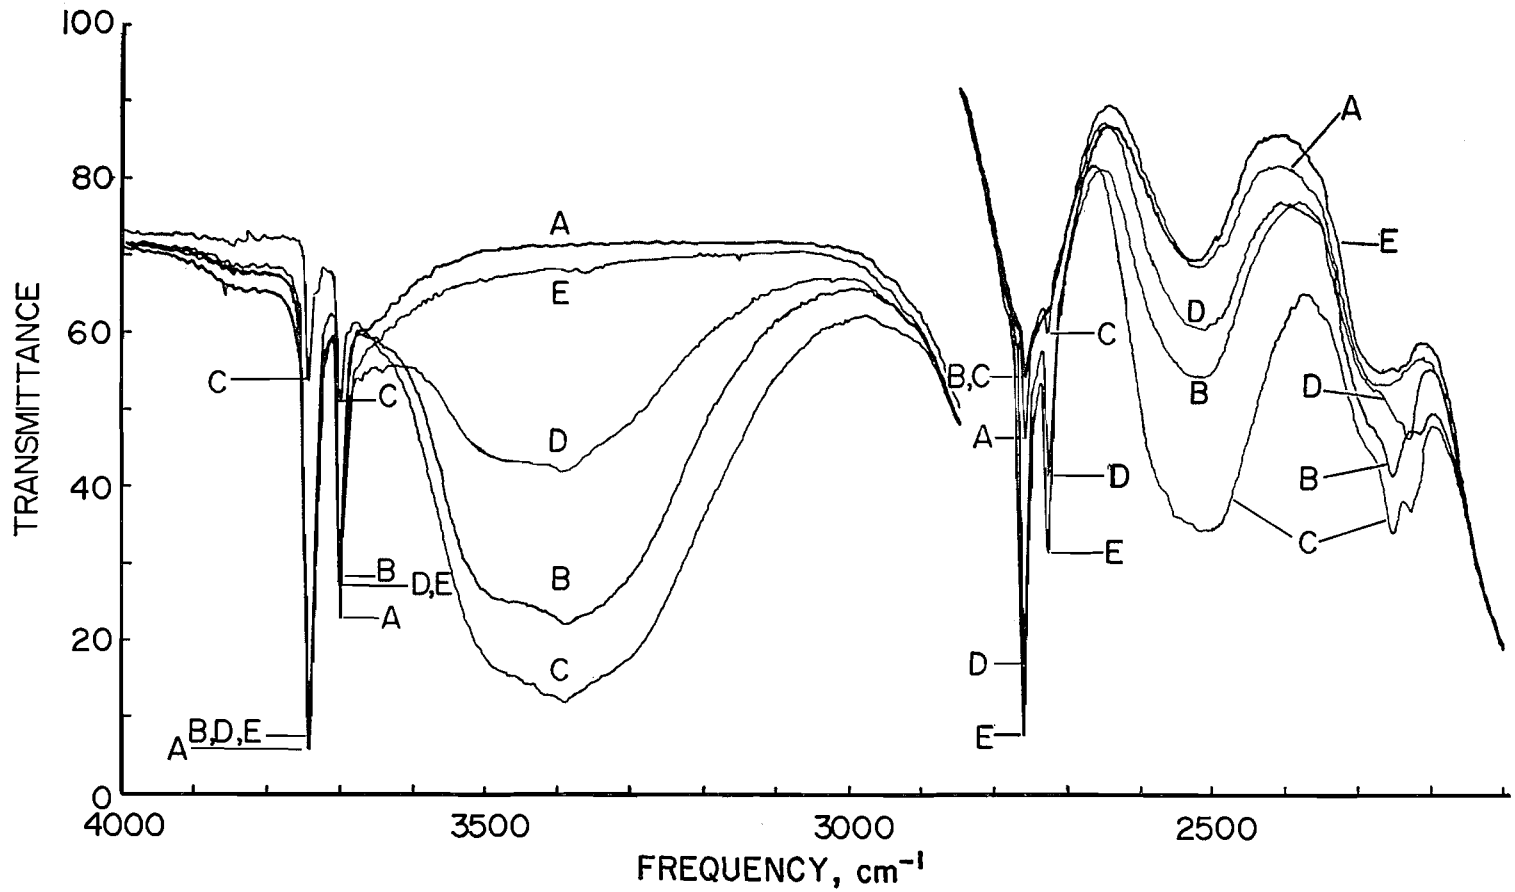

FIG. 4. Acetone-d_6 sorption on porous glass. A: after degassing at 800°; B: after exposure to 21 Torr acetone-d_6; C: 19 h after the acetone-d_6 addition; D: after 2 h degassing at 60°; E: after 70 min degassing at 110°. All spectra were screen-expanded below 2850 cm^{-1}.

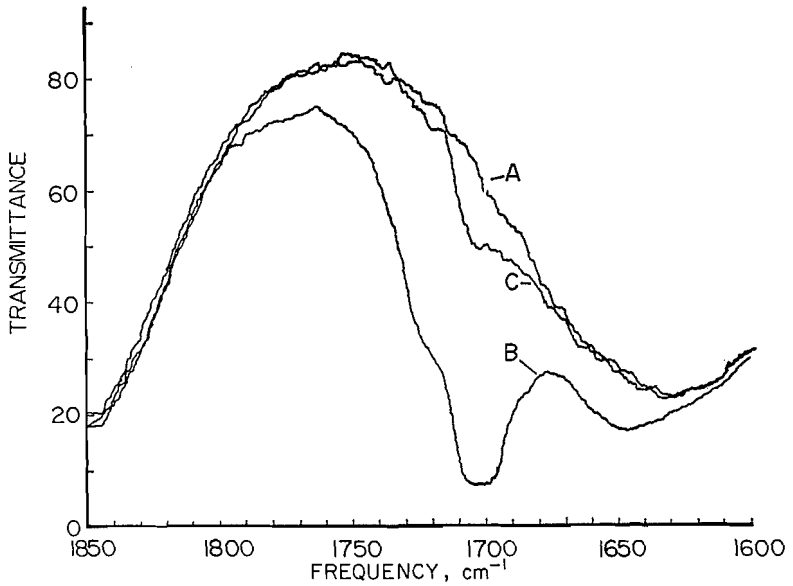

FIG. 5. Acetone-d_6 sorption on thin porous glass. A: after degassing at 800°; B: after exposure to 26 Torr acetone-d_6; C: after 30 min degassing at 25°. Ordinate expansion using screens, 5-fold abscissa scale expansion, and the 2× slit program (256 μ at 1800 cm^{-1}) were used.

The Absorptions at 1650–1660 cm^{-1}

It is likely that the bands in the region of 1650–1660 cm^{-1} were observed with greater ease on the boron-impregnated Cab-O-Sil samples because the surface area and radiation-transmitting properties of this material were greater than those of porous glass. There are two possible interpretations of the bands. (*a*) The bands at 1661 and 1650 cm^{-1} may be due to acetone and acetone-d_6 respectively coordinated to surface boron. Complexes of BF_3 and acetone have been prepared (14), and it was shown that the carbonyl absorption band frequency was lowered by 72 cm^{-1} whereas the C—H band positions were not affected. (*b*) The bands may be due to ν(C=C) of an enolic structure.

Attempts were made to differentiate between these two possibilities by observing the spectrum of adsorbed 1,1,3-trifluorotrichloroacetone. The 1,1,3-trifluorotrichloroacetone pressure was in the range 25–30 Torr. A single band at 1784 cm^{-1} was detected on Cab-O-Sil, but this band was accompanied by a second small band at 1747 cm^{-1} on boron-impregnated Cab-O-Sil. Porous glass spectra clearly showed the 1784 cm^{-1} band, but only a slight asymmetry could be observed on its low wavenumber side. In view of the similarities mentioned previously, the failure to observe a definite band in the 1740–1750 cm^{-1} region with porous glass was probably due to the lower surface area of this sample compared to that of boron-impregnated silica. We feel that a good interpretation of this lower-frequency band is that it was caused by the carbonyl grouping coordinated to a surface boron atom. This must be an uncertain assignment, but it has been shown that a ketone which could not enolize gave two bands in the carbonyl region when adsorbed on boron-containing silica surfaces. Moreover, there were no olefinic C—H or C—D bands which could be related to those at 1661 or 1650 cm^{-1}. These facts do not support assignment (*b*) but tend to give more credence to the assignment that the bands at 1661 and 1650 cm^{-1} were due to carbonyl bonds coordinated with surface boron atoms.

The Decomposition Reaction

The nature of the decomposition process is obscure because it is not possible to identify the products merely from their C—H stretching vibrations. However, the fact that new B—OH groups were formed suggests that surface B—O—B bridges were able to abstract hydrogen from adsorbed acetone. It is possible that part of this process resulted in the formation of a species

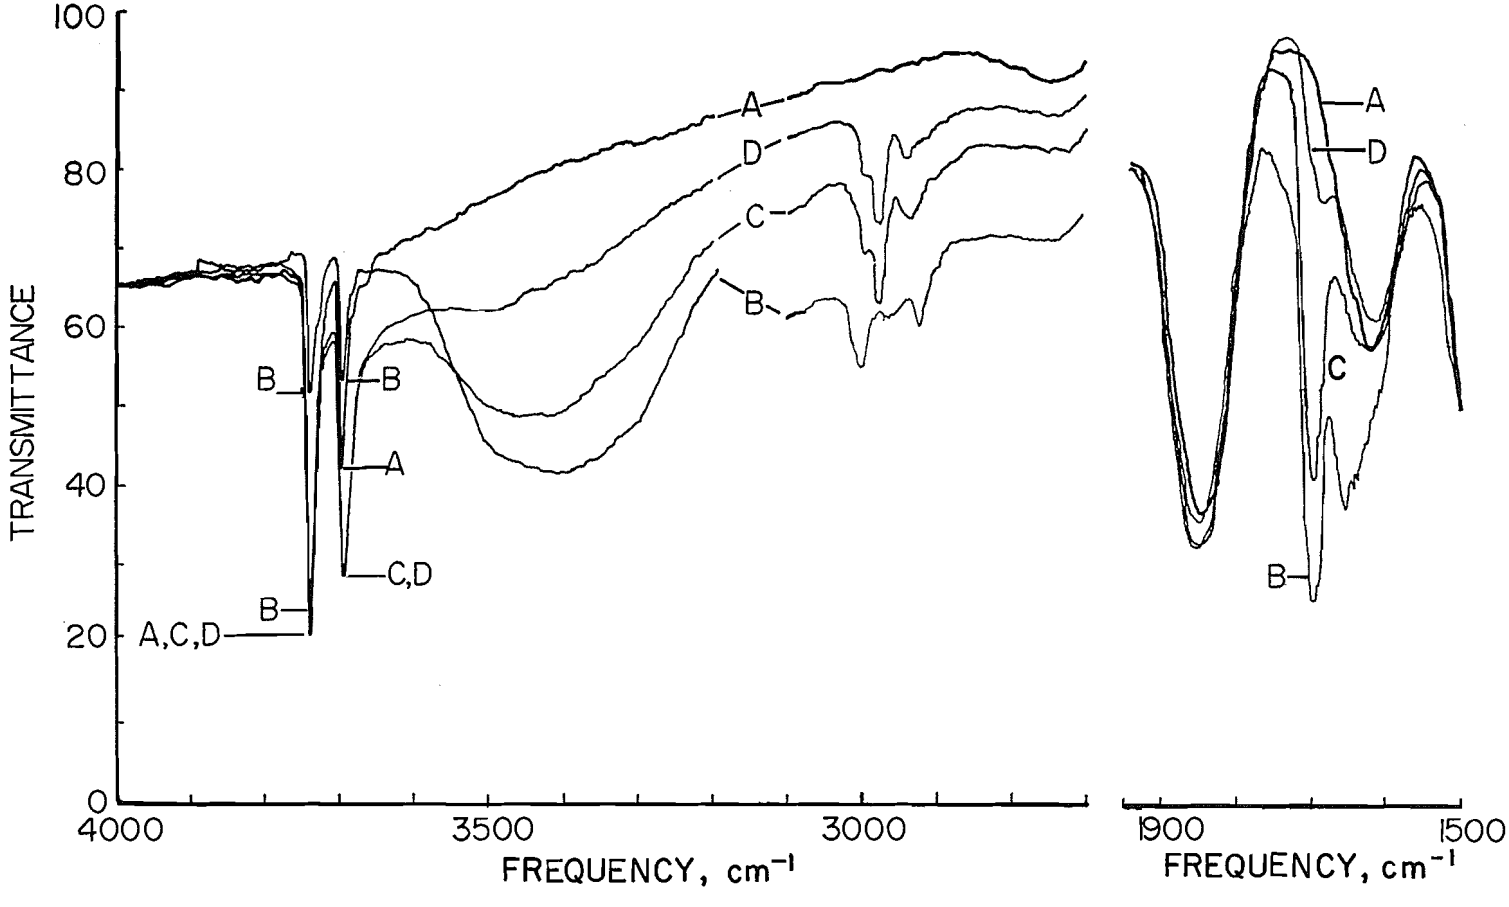

FIG. 6. Acetone sorption on boria-silica. A: after outgassing at 800°; B: after exposure to 20 Torr acetone; C: the cell was isolated for 17 h and then evacuated for 15 s at 25°; D: after 4.5 h degassing at 25°. The ordinates of spectra B and C were displaced in the 3100–1700 cm^{-1} region to avoid overlapping.

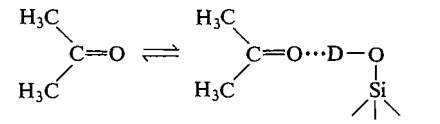
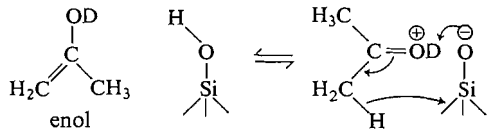
of the type $\equiv B—CH_2—CO—CH_3$. Such species would explain the added stability of ν(C═O) on porous glass and on boron-impregnated silica surfaces compared to Cab-O-Sil, because ν(C═O) and ν(C—H) should be very similar to those found in acetone. However, there must have been further reaction to give the species having absorption bands at 2984, 2940, and 3003 cm^{-1}. No mechanism is given because of the difficulty of identifying the species.

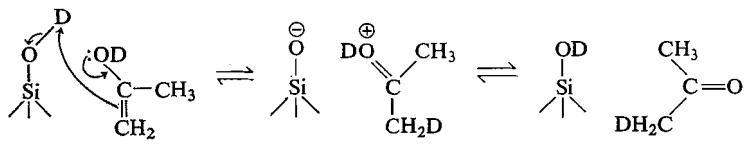
The Exchange Reaction

Figure 1 shows that, after exposing a silica surface containing mainly OD groups to 20 Torr acetone, there was, in addition to bands of acetone hydrogen-bonded to deuteroxyl groups, a broad absorption, centering at 3400 cm^{-1}, attributed to perturbed hydroxyl groups. After 15 h of isolation the concentration of adsorbed acetone increased to a slight extent but the concentration of perturbed OH groups increased quite markedly, while OD concentration decreased. Thus, some time-dependent exchange process occurred between surface OD groups and the hydrogen of the acetone. Qualitative experiments showed that the amount of exchange was also related to the gas phase pressure (and, thus, to surface concentration) of acetone. We tentatively propose the following mechanism for the exchange process





Enol must migrate and react with another OD group if the scheme is to account for exchange after acetone has been removed from the surface. Thus



Justification for this mechanism comes mainly from the fact that exchange reactions involving ketones in solution are thought to involve an enol intermediate (15); a different intermediate is difficult to visualize. Absorbance vs. wavenumber plots in the region 1850–1550 cm^{-1} derived from data carefully obtained using scanning speeds of 30 cm^{-1}/min and 2.5-fold abscissa expansion revealed only a slight asymmetry on the low-frequency side of the 1711 cm^{-1} carbonyl band. This may contain a contribution from ν(C═C) of an enolic structure, but there is no definite proof of this (16). Figure 4 shows that exchange occurred on porous glass and that B—OH groups were active in the process, but there is nothing to suggest that they were much more active than Si—OH groups. Experiments with a thin, hydroxylated porous glass sample showed that when the sample was exposed to 3 Torr acetone-d_6, exchange took place and "free" OD groups formed. This indicates that there was no close interaction of the exchange products. As suggested by the mechanism, these are probably free to migrate on or desorb from the surface. This also seems to explain convincingly the failure to observe bands due to C—H absorption when acetone-d_6 interacted with hydroxylated porous glass.

The germanium–selenium phase diagram[1]

L. Ross and M. Bourgon
Department of Chemistry, University of Montreal, Montreal, Quebec

Received January 31, 1969

The Ge–Se phase diagram was determined in the composition range 0–66.67 at. % Se by the method of differential thermal analysis. The diagram differs totally from the one reported by Liu *et al.* (1) but is in good agreement with the diagram recently reported by Karbanov *et al.* (13). In its broad features the Ge–Se phase diagram is quite similar to the diagrams of the Ge–S, Sn–S, and Sn–Se systems.

Canadian Journal of Chemistry, 47, 2555 (1969)

Introduction

Liu *et al.* (1) investigated the germanium–selenium system over the whole composition range. The main features of the reported phase diagram are

(*a*) The existence of two selenides of germanium, GeSe and $GeSe_2$; the diselenide melts congruently at 740 °C while the monoselenide melts incongruently at 670 °C according to the reaction

[1] $$GeSe(s) \rightarrow GeSe_2(s) + \text{liquid}$$

(*b*) The existence of a Ge–GeSe eutectic at 650 °C (40 at. % Se).

(*c*) The existence of a polymorphic transformation at 620 °C in GeSe. The thermal arrest corresponding to this transition was detectable readily on the cooling curves of the GeSe–Ge alloys. Resolution of this effect was considerably worse on the heating curves. In the GeSe–$GeSe_2$ region, the transformation of the monoselenide was recorded only on cooling curves, for compositions close to GeSe.

The three IV–VI compounds GeS, SnS, and SnSe are isostructural with GeSe (black-phosphorus-type structure) (2). Furthermore, the Ge–S (3, 4), Sn–S (5), and Sn–Se (6) phase diagrams show strong similarities; they are characterized by the presence of a monotectic reaction on the metal-rich side, by the presence of a eutectic in the MX–MX_2 region (X = chalcogen), and a degenerate eutectic in the MX_2–X region.

The Ge–Se phase diagram, as reported by the above investigators, is quite different from the phase diagrams of the Ge–S, Sn–S, and Sn–Se systems. Because of this discrepancy and because of the fact, also, that results obtained during the course of electrical conductivity measurements on liquid GeSe could not be reconciled entirely with the reported Ge–Se diagram, the latter was re-examined to the composition of $GeSe_2$ (66.67 at. % Se); the method of differential thermal analysis (d.t.a.) was used in the study of this diagram.

Experimental

Preparation of the Ge–Se Alloys

Alloys corresponding to the different compositions were prepared in 2 g quantities by fusing together weighed amounts of the elements in evacuated and sealed quartz vials. The germanium used (Sylvania Corporation) was of electronic grade with a minimum resistivity, at 27 °C, of 40 Ω cm. High purity selenium shot containing at least 99.99% selenium was obtained from Canadian Copper Refiners. To prevent the loss of selenium during sealing of the vials and to ensure a minimum vapor space, the following procedure was used.

Quartz tubes (12 cm long, 0.5 cm internal diameter) were constricted at two different levels. Germanium and selenium, ground to pass a 10 mesh sieve, were weighed directly in the tubes; the rough grinding prevented sticking of germanium or selenium powder to the tubes during weighing. The tubes were then evacuated (10^{-3} mm Hg) and sealed at the upper constriction. The samples were contracted to a point below the lower constriction by heating just above the melting point of selenium (220 °C); during this operation, a small quantity of selenium sublimed to the top of the tube. The sublimed selenium was returned below the constriction by placing the upper part of the tube in a small furnace heated at approximately 700 °C while the lower part of the tube was surrounded by a water-cooled brass block. After all the selenium had returned to the bottom of the tube, the latter was sealed at the lower constriction. It is believed that the percentage compositions were known to better than 0.03%. Each vial was then enclosed in a second quartz tube also sealed under vacuum; this last precaution was taken to avoid oxidation of the samples in case of inner vial breakage during cooling.

The germanium-rich samples (Ge > 50 at. %) were homogenized in the liquid state at a temperature of 960 °C i.e. just above the melting point of germanium; the selenium-rich samples were homogenized in the

[1]This paper was presented at the 36th Annual Conference of the Association Canadienne-Française pour l'Avancement des Sciences (ACFAS), Ottawa, November 1968.

For personal use only.

liquid state at a temperature of 850 °C for a period of 1 h. All samples were baked at 765 °C for 2 days and at 690 °C for 5 h; they were then annealed at 650 °C for 17 h, at 600 °C for 8 h, and at 550 °C for 24 h, in a controlled furnace with a 13 cm constant temperature zone. Since preliminary work had indicated the possible existence of a monotectic reaction on the germanium-rich side, all samples containing between 2–50 at. % Se were mixed thoroughly, by rocking the furnace vigorously during the entire period that they were in the liquid state; this precaution was taken in order to prevent separation of two liquid phases which would increase the necessary equilibration time at the lower temperatures. After annealing, all the samples were cooled to room temperature, in the furnace, at the rate of approximately 10 °C/min. The samples were then ground to a fine powder as a preparation for d.t.a.

Some samples corresponding to the overall compositions GeSe and $GeSe_2$ were prepared as described above. The selenides were also obtained by subliming stoichiometric alloys; the GeSe was sublimed at 425 °C under vacuum while the $GeSe_2$ was sublimed at 550 °C under an atmospheric pressure of helium. Germanium diselenide disproportionates to some extent during sublimation. This is evidenced by the presence of three rather sharply defined sections in the sublimate which correspond to Se, GeSe, and $GeSe_2$. The monoselenide has a bright metallic appearance while the diselenide is orange-yellow.

Differential Thermal Analysis

The d.t.a. instrument and the technique used for preparing the samples have been described in a previous publication (4). All the thermograms were obtained from undiluted samples (2–3 mg), sealed in quartz under vacuum, at a heating rate of 4–5 °C/min and at a cooling rate of 4–6 °C/min. Platinel thermocouples were used. The calibration curves of the thermocouples provided by the manufacturer of the d.t.a. instrument were used as such. It is believed that the temperatures reported are precise to ±2 °C. The temperatures given are those of the maximum of the peaks since they proved to be the most reproducible. An empty quartz capsule was used as reference material. The measured melting points of pure germanium and pure selenium were 950 and 220 °C, respectively.

X-Ray Diagrams

The X-ray diagrams were taken with a Philips instrument (Cu Kα radiation, Ni filter) using a Guinier camera; exposure time varied between 4–14 h depending on the particular information required. Diffractograms also were obtained by means of a Norelco diffractometer.

Results

The germanium–selenium phase diagram as determined in this investigation is shown in Fig. 1. The diagram was traced from the data obtained during heating cycles; small Ge–Se samples are subject to severe supercooling and for this reason, not much information on equilibrium freezing temperatures can be obtained from cooling curves. The points obtained during cooling are shown on the diagram. All transformations observed during heating cycles were endothermic, and during cooling cycles all were exothermic. It should perhaps be emphasized that the pressure over the samples was not 1 atm but rather the equilibrium vapor pressure at a particular temperature–composition.

The Ge–GeSe Region

The addition of selenium depresses the melting point of germanium to a minimum of 900 °C, the temperature of the monotectic reaction; the thermal effect corresponding to this reaction was large and easily detectable during both heating and cooling cycles. Further evidence for this monotectic reaction was obtained by visual examination of samples held vertically in the furnace, at 960 °C, for a period of 2 h and quenched to room temperature. Two layers could be distinguished: one layer was hard and had the physical aspect of germanium; the d.t.a. trace of this layer showed two small peaks at 660 and 666 °C and a rather large one at 900 °C. The other layer was flakier and resembled GeSe; the thermogram showed two large peaks at 660 and 666 °C and a small one at 900 °C. The approximate compositions of the two liquid phases in equilibrium at the monotectic temperature are respectively 11–12 at. % Se on the germanium-rich side and 40–42 at. % Se on the selenium-rich side.

The temperature limits of immiscibility in the two-liquid region could not be determined by d.t.a. because of small heat effects. Between 900 and 666 °C the liquidus is quite steep. By successive heating and cooling of samples, approximate points on the liquidus curve could be obtained for some compositions. The point at 710 °C which corresponds to the GeSe composition was obtained during the course of electrical conductivity measurements on liquid GeSe (7); this point was obtained under equilibrium conditions and can be regarded with some degree of confidence.

The two thermal effects at 661 and 666 °C were detectable easily on heating curves of all samples of composition between 2–50 at. % Se; these arrests were also very sharp on cooling curves but they occurred at lower temperatures. No evidence was found that would indicate the existence of a Ge–GeSe eutectic.

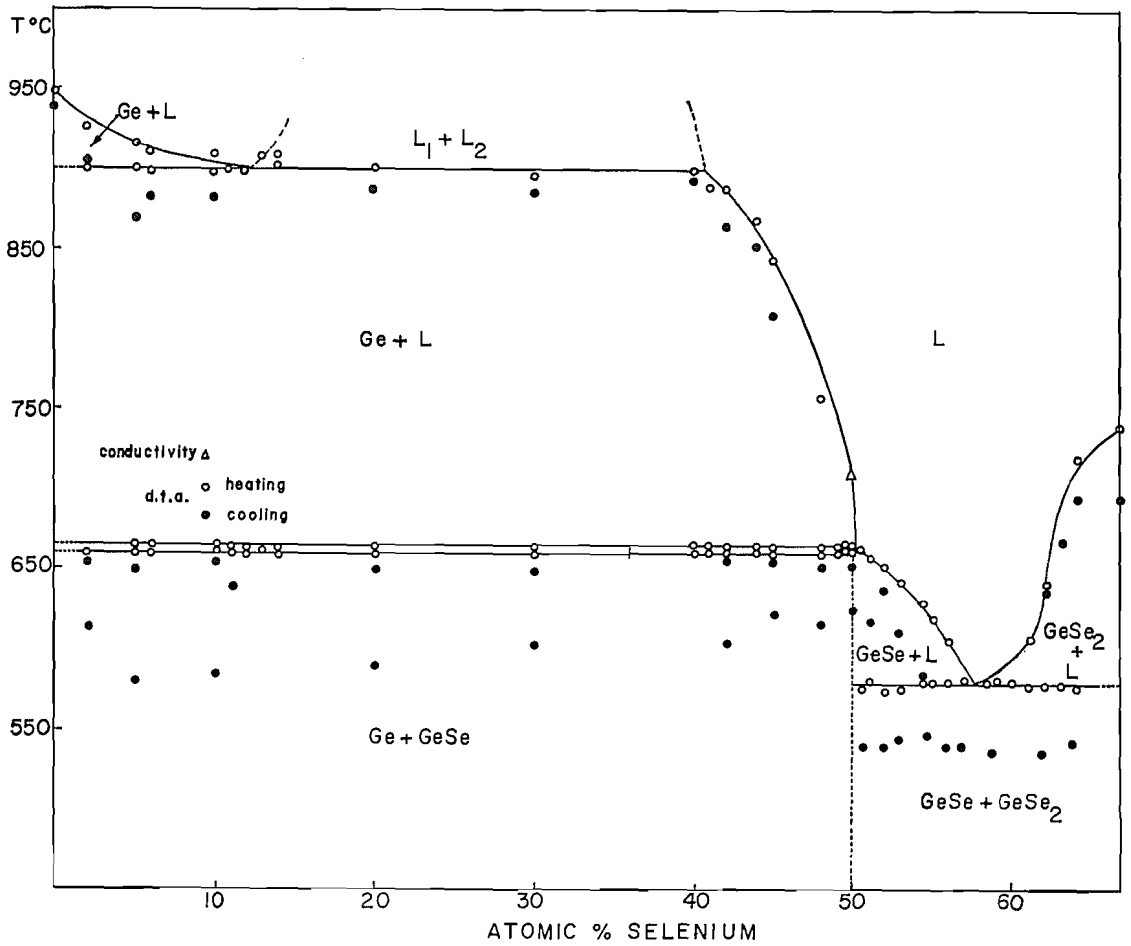

FIG. 1. The germanium–selenium phase diagram.

The Compounds $GeSe_2$ and GeSe

Congruent melting of $GeSe_2$ at 740 °C is confirmed in the present investigation; the same melting point was obtained from annealed samples prepared by weighing and from sublimed samples. X-Ray diagrams were obtained from sublimed $GeSe_2$ samples; the calculated spacings of the lattice planes were identical with those reported by Pashinkin *et al.* (8). According to these investigators, the structure of germanium diselenide is apparently a highly deformed version of an eight-layered cadmium iodide type.

All GeSe samples, sublimed or annealed and quenched, gave identical X-ray diagrams. The diagrams of the quenched samples showed a regular increase in the unit cell parameters as a function of temperature of annealing due, presumably, to dilation of the lattice or to the changing stoichiometry of GeSe on heating. The symmetry of the lattice and the parameters of the unit cell were determined from the X-ray diagrams of samples annealed at 350 °C and quenched; all the lines could be accounted for on the basis of a unit cell of orthorhombic symmetry, space group *Pcmn*, of parameters: $a = 4.38$ Å, $b = 3.83$ Å, $c = 10.78$ Å. These results are in substantial agreement with those of the literature (2, 9, 10).

The peak at 661 °C which appears on the thermograms of all samples on the germanium-rich side of the diagram is due presumably to a solid-state transition which occurs in GeSe; this transition could not be detected on the selenium-rich side of the diagram. The importance of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

peak is more indicative of a first-order transition. Transformations of the second order are known to exist in the compounds SnS (11) and SnSe (12) which are isostructural with GeSe: in both these cases, however, the thermal effects are very small and barely detectable on a d.t.a. trace. Attempts were made to fix the high temperature crystalline form of GeSe by quenching; this proved to be impossible.

No extensive study of the homogeneity region of GeSe was made; preliminary results seem to indicate, however, that this region is very narrow.

All the evidence accumulated during the course of this investigation leads to the conclusion that germanium monoselenide melts incongruently because of the peritectic disproportionation

$$[2] \qquad GeSe(s) \rightarrow Ge_{(1-x)}Se(l) + xGe(s)$$

where the phase $Ge_{(1-x)}Se$ can be considered as a solution of $GeSe_2$ in GeSe. Germanium lines could not be detected on the X-ray diagrams of GeSe samples annealed at 690 °C and quenched; this is an indication that the peritectic point lies quite close to the composition GeSe.

The GeSe–$GeSe_2$ Region

The GeSe–$GeSe_2$ region of the phase diagram is of the simple eutectic type; the eutectic has the composition 57–58 at. % Se and melts at 578 °C. The thermal effect corresponding to melting of the eutectic was detectable readily at all compositions between GeSe and $GeSe_2$. The liquidus temperatures were determined without difficulty at compositions lying to the left of the eutectic point; the phase reactions which correspond to crossing of the liquidus at compositions to the right of the eutectic point were, however, very sluggish and the temperatures were determined with more difficulty. It should be mentioned that samples prepared by different methods gave essentially the same results. Some alloys were prepared as described above, others were prepared by weighing the necessary quantities of sublimed GeSe and $GeSe_2$ with or without annealing.

X-Ray diffractograms obtained from samples in the selenium-rich region consistently showed the presence of both the $GeSe_2$ and the GeSe peaks; the $GeSe_2$ peaks were more intense to the right of the eutectic point while the GeSe peaks were more intense to the left of the eutectic point.

Discussion

The phase diagram as determined in this work is quite different from the one obtained by Liu *et al.* (1). These investigators did not detect the monotectic reaction on the germanium-rich side of the diagram. Furthermore, the thermal arrests which they observed on the thermograms of germanium-rich samples occurred at lower temperatures than the ones that were observed in this work; a possible explanation is that they determined these points from cooling curves. Their results on the selenium-rich side of the diagram are in direct contradiction with our results; no explanation for this discrepancy can be suggested; no single piece of evidence was found that would agree with reaction [1].

The very recent work of Karbanov *et al.* (13) on the Ge–Se phase diagram is in close agreement with the present work although the two diagrams differ in some details. Their diagram was plotted from d.t.a. data, using 2 g samples. The liquidus line was plotted from heating data (3 °C/min) and only the region between the GeSe–$GeSe_2$ eutectic and $GeSe_2$ was plotted from cooling data (3 °C/min). Karbanov *et al.* made the following observations.

(*a*) The melting points of Ge and Se were found to be 941 and 218 °C respectively. GeSe melts incongruently at 675 °C according to reaction [2]; the peritectic point was found to lie at 50.5 at. % Se. $GeSe_2$ melts congruently at 740 °C.

(*b*) A region of immiscibility was found to exist in the liquid at 17–40 at. % Se; the monotectic reaction occurs at 905 °C.

(*c*) Heating and cooling curves indicated an endothermic effect, corresponding to a polymorphic transformation of GeSe, at 664 °C. Effects, related to changes in the crystal structure of GeSe, were observed on cooling curves at 645 °C, in the region of 20–50 at. % Se. (In the present work, the transition was observed at 661 °C on heating curves only. The first arrest, on cooling curves, occurred in the vicinity of 650 °C while a second arrest was observed at temperatures between 580 and 620 °C, depending on composition.)

(*d*) In the GeSe–$GeSe_2$ region, the GeSe transformation was detected on heating and cooling curves at 579 °C while a eutectic, of composition 56.5 at. % Se, was found to melt at 587 °C. (In the present work, one peak only was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

found on heating curves at 578 °C; during cooling this peak occurred in the vicinity of 540–550 °C and it was observed that this temperature decreased if the rate of cooling was increased.)

The Ge–Se phase diagram as determined in this work and in the work of Karbanov *et al.* is more consistent with the phase diagrams of the Ge–S (3, 4) and the Ge–Te (14) systems. Regular trends can be observed in these diagrams.

(*a*) The width of the two-liquid region decreases on going from the Ge–S system to the Ge–Te system; in fact, this two-liquid region has disappeared in the Ge–Te system; this is consistent with the increasing metallic character of the melt on going from the Ge–S to the Ge–Te system.

(*b*) The melting point of the dichalcogenide decreases from GeS_2 to $GeSe_2$ and in the Ge–Te system the ditelluride does not exist.

(*c*) A solid-state transition exists in GeTe at 430 °C; at this temperature the rhombohedral structure changes to the NaCl structure. As discussed above, a solid-state transition seems to exist in the Ge–Se system, but at a higher temperature. There is no evidence for the existence of a polymorphic transformation in GeS (4).

(*d*) The peritectic point approaches the composition 50 at. % chalcogen on going from GeS to GeTe; in fact, it is not definitely known whether melting of GeTe is congruent or incongruent. Also, the melting point of the monochalcogenide increases on passing from GeS to GeTe.

N-Chlorination of secondary amides. I. Kinetics of N-chlorination of N-methyl acetamide

M. WAYMAN AND E. W. C. W. THOMM

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto 5, Ontario

Received November 1, 1968

The rate of N-chlorination of N-methyl acetamide has been studied in acetate buffered hypochlorous acid solutions. The reaction rate is dependent upon pH, chloride ion concentration, and acetic acid concentration. The results fit the following rate expression

$$d[CH_3CO.NCl.CH_3]/dt = k_{obs}[CH_3CO.NH.CH_3][HOCl]$$

The observed rate constant, k_{obs}, has three components

$$k_{obs} = k_1 + k_2[H^+][Cl^-] + k_3[CH_3COOH]$$

The results suggest that the active chlorinating species in the pH range 3.0–6.0 are HOCl, Cl_2, and CH_3COOCl, in order of increasing reactivity. The values of the corresponding rate constants at 25 °C are $k_1 \simeq 0.1$, $k_{Cl} \simeq 5.0 \times 10^3$, and $k_{AcOCl} \simeq 5.8 \times 10^5$ l mole^{-1} min^{-1}, the last two rate constants being related to k_2 and k_3 through the respective equilibrium constants.

At temperatures near room temperature, the N-chlorination reaction has an apparent activation energy of 14 kcal/mole when Cl_2 is the active species, and 5 kcal/mole when CH_3COOCl is the chlorinating agent.

Canadian Journal of Chemistry, 47, 2561 (1969)

Introduction

The kinetics of N-chlorination of N-methyl acetamide in hypochlorous acid solutions has been previously studied over a narrow range of conditions. Soper and co-workers (1, 2) investigated the N-chlorination of the amide by hypochlorous acid in aqueous solutions, buffered with acetate solutions containing acetic acid up to 0.12 *M* at 25 °C, pH 5 and 6. Mauger and Soper (1) proposed that the active chlorinating agents under their conditions were hypochlorite ion and acetyl hypochlorite. The specific rate constant for acetyl hypochlorite, however, was not obtained. The role of chlorine in the chlorination of N-methyl acetamide was not determined.

Recently, Wayman *et al.* (3) have reported the development of chlorine exchange resins which contain amide functional groups, of which the nitrogen atoms take up positive chlorine reversibly. In order to shed more light on this N-chlorination process, it was decided to re-investigate the N-chlorination of N-methyl acetamide in the pH range 3–5, in which the resins are most useful. Accordingly, the results extended those of Soper and co-workers. N-Methyl acetamide was chlorinated in hypochlorous acid solutions buffered with acetic acid – sodium acetate solutions. The effects of pH, chloride ion concentration, acetic acid concentration, and temperature were investigated.

Experimental

(a) Reagents

N-Methyl acetamide was purchased from Eastman Kodak Co. It was distilled under reduced pressure in a nitrogen atmosphere before use. The undistilled amide showed no significant difference from the distilled product in the kinetic runs, and later experiments were carried out using the amide as purchased.

Sodium hypochlorite was purchased from Fisher Scientific Co., as a 5% solution. The chloride and hydroxide contents of the solutions made up from this concentrated solution were determined before use. Hypochlorous acid was prepared by acidifying the hypochlorite solutions.

Other reagents were British Drug Houses "AnalaR" grade chemicals.

(b) Experimental Procedure

Kinetic runs were carried out according to Mauger and Soper (1). A brief outline is presented below.

Hypochlorous acid and N-methyl acetamide solutions of twice the required concentration were prepared in acetic acid – sodium acetate buffers, to which sodium chloride had been added. The acetic acid concentration was corrected for the hydroxide content of the sodium hypochlorite stock solution. The chloride concentration was determined by a Mohr titration. When both solutions had attained the temperature of the thermostat, which was held to ±0.02 °C, 100 ml of the hypochlorous acid solution was added to an equal volume of the amide solution. The pH of the reacting solution was frequently measured during the course of the reaction.

The N-chloro-N-methyl acetamide content of the reaction mixture was determined at suitable intervals by pipetting 5 ml portions into 5 ml of saturated, freshly prepared phenol solutions and stirring for 30 s. This was followed by the addition of 5 ml of 3 *N* acetic acid, and then 1 g of potassium iodide. The liberated iodine was

titrated with standardized sodium thiosulfate solutions.

The combined hypochlorous acid plus chloroamide content was determined by the same procedure but omitting the addition of the phenol solution.

It was verified by determination that the chloroamide did not react with phenol to any noticeable extent in the duration of the analysis. The decomposition of the hypochlorous acid was found to be negligible during the time of the reaction.

Results of a typical run

Time (min)	Titre of N—Cl (ml)	Total titre (ml)	pH
0		13.89	5.01
5	3.50		
10	5.77	13.89	
15	7.47		5.01
20	8.65	13.87

NOTE: Reaction conditions: 25 °C, $[CH_3COOH] = 0.25\ M$, $[Cl^-] = 0.032\ M$, $[CH_3CO.NH.CH_3]_0 = 0.0060\ M$, $[Na_2S_2O_3] = 0.00206\ N$.

(c) Treatment of Data

All results fit the following rate expression

$$\frac{d[CH_3CO.NCl.CH_3]}{dt} = k_{obs}[CH_3CO.NH.CH_3][HOCl]$$

Thus, k_{obs} was calculated from the best straight line of the plot of log $[CH_3CO.NH.CH_3]/[HOCl]$ vs. time.

Results and Discussions

The observed rate constants, k_{obs}, at different pH, acetic acid concentration, and temperature, are presented in Figs. 1 – 5 as a function of chloride concentration. It was found that k_{obs} is a linear function of $[Cl^-]$. Furthermore by comparing the slopes $\Delta k_{obs}/\Delta[Cl^-]$ in Figs. 1, 2, and 3, it can be readily seen that k_{obs} is also a linear function of the hydrogen ion concentration, as shown in Table I.

By extrapolating the lines in Figs. 1–5 to zero chloride concentration, rate constants, k_0, are

obtained, and have been presented in Fig. 6 as a function of the acetic acid concentration of the buffer. As can be seen, k_0 is a linear function of the acetic acid concentration, and is independent of hydrogen ion concentration. The extrapolated k_0 values at pH 3, 4, and 5 agree very well with the observations at pH 5 and 6 reported by Mauger and Soper (1).

The rate constant k_0 is primarily the contribution to the total rate constant, k_{obs}, by the active species formed by reaction between hypochlorous acid and acetic acid, and is independent of $[Cl^-]$ and pH, plus a small residual value k_1. As can be seen in Fig. 6, the k_0 vs. $[CH_3COOH]$ lines do not go through the origin, but result in this residual value. The agreement between the k_0 values at 25° and the data of Mauger and Soper obtained in the absence of chloride lends support to the validity of the extrapolation.

The total rate constant k_{obs} can be broken up into three components: (*i*) the residual part that is independent of hydrogen ion and chloride ion

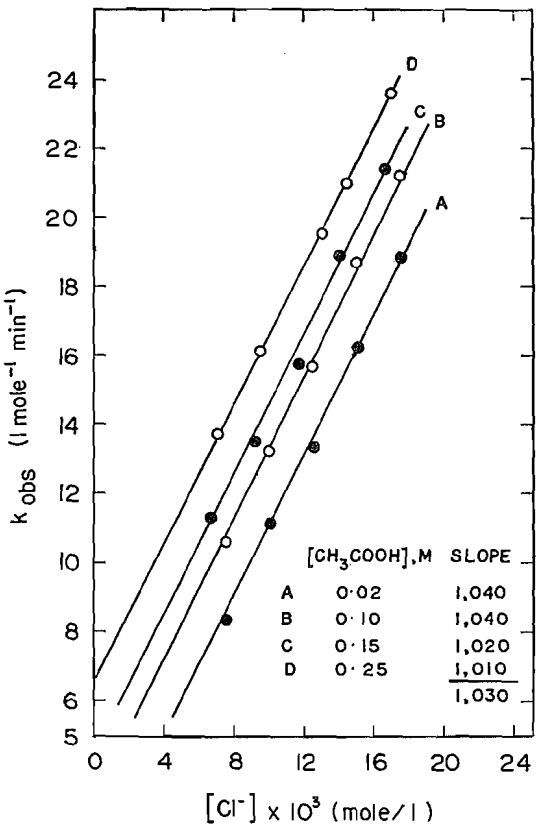

FIG. 2. k_{obs} at pH 4.00, 298 °K.

concentrations; (*ii*) the contribution from the involvement of hydrogen ions and chloride ions in the reaction; and (*iii*) the contribution due to acetic acid.
Thus

$$k_{obs} = k_1 + k_2[H^+][Cl^-] + k_3[CH_3COOH]$$

and

$$k_0 = k_1 + k_3[CH_3COOH]$$

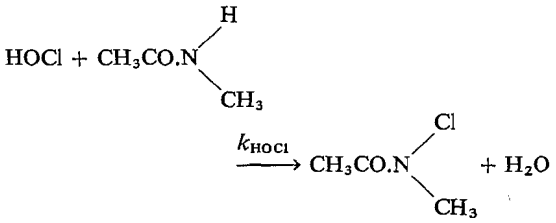
In the absence of Cl^- and CH_3COOH, the rate of N-chlorination of the amide is slight. The chlorinating species may be hypochlorous acid itself or its dissociation products. At these pH values, the proportion of OCl^- is very small. It was proposed by de la Mare *et al.* (4) that the positive chloride ion, Cl^+, is a possible chlorinating species.

$$ClOH + H^+ \rightleftharpoons ClOH_2^+ \rightleftharpoons Cl^+ + H_2O$$

However, this is inconsistent with the present findings. If positive chloride ions were so formed, then k_1 would be a function of the hydrogen ion concentration. This has not been found over a 1000-fold variation of $[H^+]$ (pH 3–6). Similar argument can be presented against the following equilibrium

$$HOCl \rightleftharpoons Cl^+ + OH^-$$

Thus, under these conditions, we believe that molecular hypochlorous acid is the most likely chlorinating agent



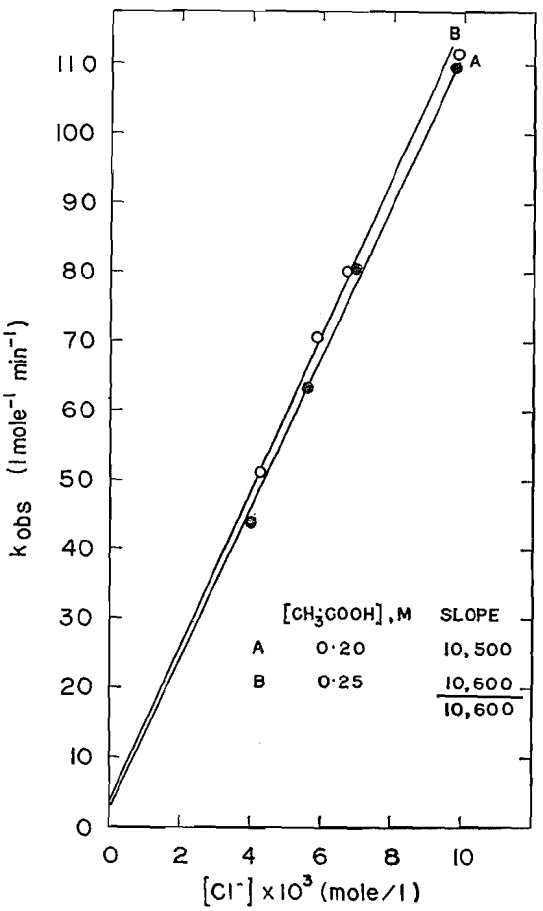


FIG. 3. k_{obs} at pH 3.00, 298 °K.

with the rate law expression

$$\frac{d[CH_3CO.NCl.CH_3]}{dt} = k_{HOCl}[HOCl][CH_3CO.NH.CH_3]$$

where $k_{HOCl} = k_1$.

The second term in the k_{obs} expression suggests that, in the presence of hydrogen and chloride ions, molecular chlorine is formed, and that it is a much more powerful N-chlorinating agent than HOCl. In a number of chlorination studies of aromatics, molecular chlorine has been found to be an effective chlorinating agent (5–10).

The chlorination reaction proposed is as follows

$$Cl_2 + CH_3CO.NH.CH_3 \xrightarrow{k_{Cl_2}} CH_3CO.N(Cl)(CH_3) + HCl$$

and the rate law expression is

$$\frac{d[CH_3CO.NCl.CH_3]}{dt} = k_{Cl_2}[Cl_2][CH_3CO.NH.CH_3]$$

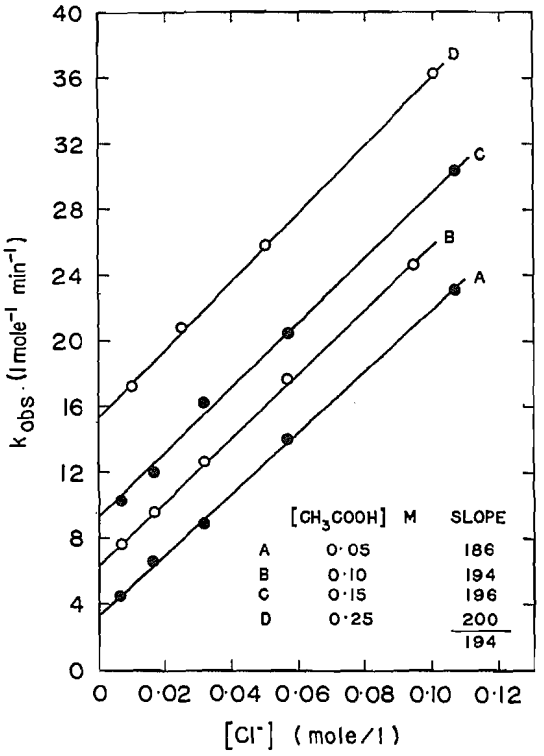

FIG. 4. k_{obs} at pH 5.00, 313 °K.

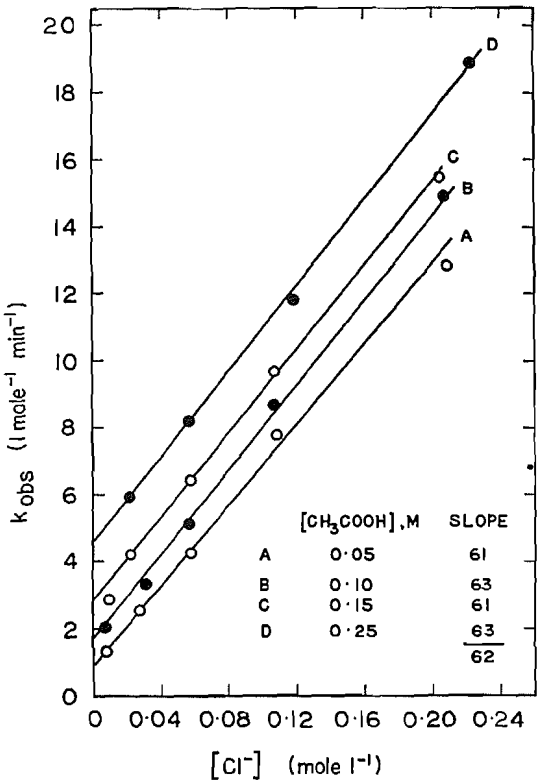

FIG. 5. k_{obs} at pH 5.00, 288 °K.

The chlorine concentration in the reacting mixture is such that it obeys the following equilibrium, which is quickly established

$$H^+ + Cl^- + HOCl \rightleftharpoons Cl_2 + H_2O$$

with the equilibrium constant

$$K_{Cl_2} = \frac{[Cl_2]}{[H^+][Cl^-][HOCl]}$$

By substitution, the above rate law expression becomes

$$\frac{d[CH_3CO.NCl.CH_3]}{dt} = k_{Cl_2}K_{Cl_2}[H^+][Cl^-] \times [HOCl][CH_3CO.NH.CH_3]$$

where

$$k_{Cl_2}K_{Cl_2} = k_2$$

The formation of chlorine has been suggested by de la Mare, Ketley, and Vernon (6) via the following scheme

$$H^+ + HOCl \rightleftharpoons ClOH_2^+$$

$$ClOH_2^+ + Cl^- \rightleftharpoons Cl_2 + H_2O$$

*Data from ref. 11.
†$k_{Cl_2} = k_{obs}/[H^+][Cl^-]\,K_{Cl_2}$.

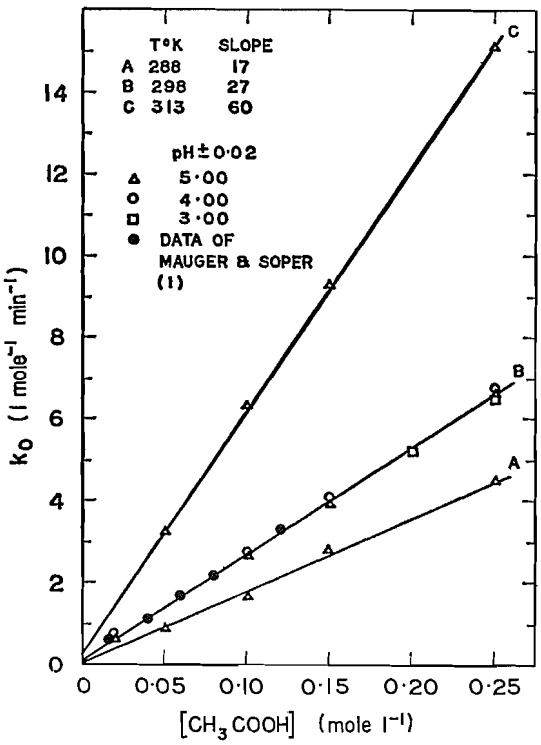

FIG. 6. k_0 vs. [CH_3COOH].

In our work we have no evidence bearing on the species $ClOH_2^+$.

A mass balance on the Cl_2-chlorination process indicates that there is no net change in hydrogen ion concentration. This was found to be so, as the pH of the reacting mixtures remained constant through the course of the reaction, even when the buffer concentration was very low.

The slopes $\Delta k_{obs}/\Delta[Cl^-]$ of the lines in Figs. 1–5 are equal to $k_2[H^+]$. Thus k_{Cl_2} can be calculated by

$$k_{Cl_2} = \frac{k_2}{K_{Cl_2}} = \frac{\dfrac{\Delta k_{obs}}{\Delta[Cl^-]} \Big/ [H^+]}{K_{Cl_2}}$$

The calculated results are presented in Table II.

In Fig. 7, k_{Cl_2} is also plotted against the inverse of temperature. From the slope of the line, the activation energy of the N-chlorination process by molecular chlorine was calculated to be 14.1 kcal/mole.

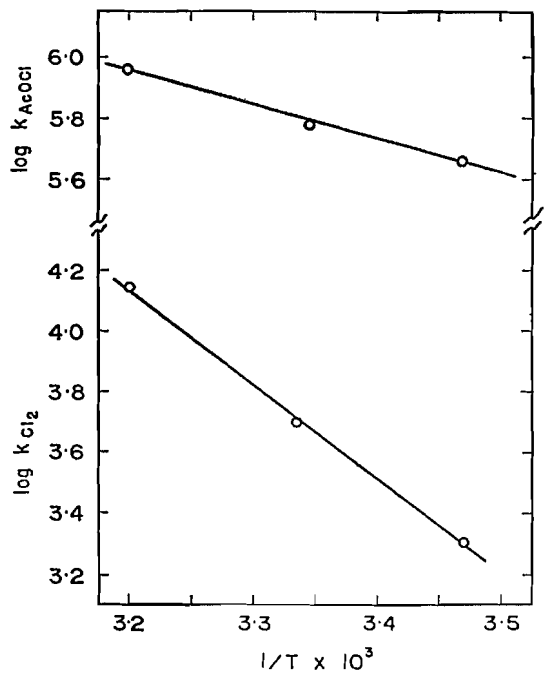

FIG. 7. log k_{Cl_2} and log k_{AcOCl} vs. $1/T$.

313	60	55.5	3.4×10^{-3}‡	9.9×10^{5}

*Reference 9.
†$k_{AcOCl}=\Delta k_0/\Delta[AcOH][H_2O]\ K_{AcOCl}$.
‡Extrapolated.

In a mixture of HOCl and acetic acid, an intermediate is formed which serves to be an effective chlorinating agent. Various authors (1, 2, 7, 9, 10) have proposed acetyl hypochlorite (chlorine acetate) formation

$$CH_3COOH + HOCl \rightleftharpoons CH_3CO.OCl + H_2O$$

$$K_{AcOCl} = \frac{[CH_3CO.OCl][H_2O]}{[CH_3COOH][HOCl]}$$

Stanley and Shorter (7) reported that there is considerable combination of HOCl and acetic acid in 75% aqueous acetic acid solutions even though de la Mare and co-workers reported a small K_{AcOCl} value of 0.0025 at 25 °C (9). The present investigation lends support to the chlorination process by chlorine acetate

$$CH_3COOCl + CH_3CO.N(H)(CH_3) \xrightarrow{k_{AcOCl}} CH_3CO.N(Cl)(CH_3) + CH_3COOH$$

with the corresponding rate law expression

$$\frac{d[CH_3CO.NCl.CH_3]}{dt} = k_{AcOCl} \times [CH_3COOCl][CH_3CO.NH.CH_3]$$

By substitution, the preceding rate law expression becomes

$$\frac{d[CH_3CO.NCl.CH_3]}{dt} = k_{AcOCl}K_{AcOCl} \times \frac{[CH_3COOH]}{[H_2O]}[HOCl][CH_3CO.NH.CH_3]$$

where

$$k_{AcOCl}\frac{K_{AcOCl}}{[H_2O]} = k_3$$

It can be seen also that k_3 is equal to the slope $\Delta k_0/\Delta[CH_3COOH]$ of the k_0 vs. $[CH_3COOH]$ lines in Fig. 6, and k_{AcOCl} can be calculated as

$$k_{AcOCl} = \frac{k_3[H_2O]}{K_{AcOCl}} = \frac{\Delta k_0}{\Delta[CH_3COOH]}[H_2O]\Big/K_{AcOCl}$$

At 15 °C, K_{AcOCl} was determined to be 0.0021 in acetic acid medium by employing the methods of de la Mare *et al.* (9). If we can assume that the equilibrium values are independent of acetic acid concentration, then these values can be applied to an aqueous medium. Table III summarizes the values of K_{AcOCl} as well as those of k_{AcOCl}.

The k_{AcOCl} values are also plotted against $1/T$ in Fig. 7. From this curve, it can be seen that the N-chlorination of the amide by chlorine acetate requires a relatively small activation energy of about 5 kcal/mole. While the principal assumption made, namely that the value of K_{AcOCl} determined in concentrated acetic acid is valid in dilute acetic acid, is reasonable, it has not been proved and this calculated activation energy should be regarded with caution.

Thus, the N-chlorination at near room temperatures of the amide in aqueous acetic acid solution by chlorine acetate has a lower apparent activation energy than that by molecular chlorine, and has a rate constant about 100 times as great. Hypochlorous acid is rather unreactive by comparison. Similar conclusions have been reported by de la Mare *et al.* (10) in a study of the chlorination of toluene.

Complexes du germanium(IV) et du bore(III) avec des *o*-diphénols substitués

R. MEILLEUR ET R. L. BENOIT
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 5 février 1969

La formation de complexes entre le germanium(IV) et le bore(III) et une série d'*o*-diphénols substitués H_2L a été étudiée par potentiométrie et spectrophotométrie. On a établi des relations linéaires entre les constantes de stabilité des complexes GeL_3^{2-} et $BL(OH)_2^-$ et les constantes d'acidité des diphénols.

Complex formation between germanium(IV) and boron(III) and some substituted *o*-diphenols H_2L has been studied by potentiometric and spectrophotometric methods. Correlations are established between the stability constants of GeL_3^{2-} and $BL(OH)_2^-$ complexes and the acidity constants of the diphenols.

Canadian Journal of Chemistry, 47, 2569 (1969)

Introduction

Les réactions entre le germanium(IV) et quatre *o*-diphénols substitués (H_2L) ont été récemment examinées (1). Dans le but d'élargir le domaine de validité de la relation linéaire obtenue entre les constantes d'acidité des ligands et les constantes de stabilité des complexes GeL_3^{2-}, on a étudié les complexes avec 2 autres catéchols substitués, le chloroacétyl-4 catéchol et le tétrachlorocatéchol (TCC).

On a ensuite examiné le comportement d'un élément voisin, le bore(III), avec 5 des ligands précédents. L'acide borique forme, en effet, des complexes stables avec de nombreux diols, diphénols ou polyols présentant des groupes OH en ortho et en *cis*. Les résultats des recherches antérieures (2–9) indiquent que l'acide borique forme des complexes de stoéchiométrie 1:1 et 1:2 avec les catéchols selon les réactions suivantes

$$[1]\quad B(OH)_3 + H_2L \rightleftarrows BL(OH)_2^- + H^+ + H_2O,\ (\beta_1^0)$$

$$[2]\quad B(OH)_3 + 2H_2L \rightleftarrows BL_2^- + H^+ + 3H_2O,\ (\beta_2^0)$$

On a montré, dans ce travail, que l'équilibre [1] prédomine et déterminé les constantes β_1^0 afin de relier la stabilité des complexes $BL(OH)_2^-$ aux propriétés acides–bases des ligands et à la stabilité des complexes GeL_3^{2-} correspondants.

Partie Expérimentale

A. Réactifs

Les solutions aqueuses de germanium(IV) environ 4×10^{-2} *M* ont été préparées par dissolution du bioxyde (GeO_2 5 *N*, Koch-Light Laboratories) et dosées par titrage potentiométrique avec de la soude non carbonatée en présence de mannitol.

L'acide borique (J. T. Baker Chemical), dosé potentiométriquement avec de la soude non carbonatée en présence de mannitol, donne une pureté de 99.7%.

Le chloroacétyl-4 catéchol (Aldrich Chemical Co.) a été recristallisé dans un mélange eau–éthanol jusqu'à l'obtention d'un produit blanc fondant à 170 °C. Un titrage potentiométrique avec de la soude non carbonatée indique une pureté > 99.5%.

Le TCC (Aldrich Chemical Co.) a été purifié par 2 recristallisations dans un mélange eau–alcool et fond à 189–190 °C (litt. (10) 185–190 °C). Le dosage potentiométrique par de la soude non carbonatée du produit dissous dans un mélange acétone–eau donne une pureté de 98.5%. Les solutions environ 1.5×10^{-4} *M* de ce ligand ont été préparées dans l'eau distillée, bouillie et saturée d'azote. Des solutions fraîchement préparées ont été toujours utilisées.

La purification des autres ligands a été décrite antérieurement (1). Les autres réactifs sont de pureté analytique.

B. Technique expérimentale

Les mesures de densité optique ont été effectuées au moyen des spectrophotomètres Zeiss PMQ II et Bausch and Lomb, munis de cuvettes de quartz dont l'épaisseur varie de 0.20 à 10.0 mm. La concentration des ions H^+ est mesurée avec un appareil Radiometer 22, avec des électrodes de verre et de calomel–KCl saturé.

La linéarité de l'électrode a été vérifiée dans l'intervalle $1.00 < -\log(H^+) < 3.30$ et $3.60 < pH < 12.5$. Le facteur de correction expérimental est négligeable, même pour les valeurs élevées de *pH*, la standardisation étant effectuée avec des tampons recommandés par le N.B.S. Des solutions de concentration (H^+) connue et de force ionique 0.1 (HCl–KCl) ont aussi servi à la standardisation. Toutes les expériences ont été faites à 25.0 ± 0.1 °C, en milieu KCl 0.10 *M* et sous atmosphère d'azote.

C. Méthodes

a. Constantes d'acidité

Les constantes d'acidité K_1 et K_2 du chloroacétyl-4 catéchol et du TCC ont été déterminées par une méthode spectrophotométrique (1) et une méthode potentiométrique reposant sur l'interprétation mathématique de

TABLEAU I

Constantes d'acidité des ligands et constantes de stabilité des complexes

Ligand	pK_1	pK_2	log β_3^0 (GeL_3^{2-})	log β_1^0 ($BL(OH)_2^-$)	log β_1/K_B
Catéchol	9.3	13.1*	−1.45*	−5.13	17.3±0.2
Chloro-4	8.60	12.55*	0.65*	−4.87	16.3±0.1
Chloroacétyl-4	7.45	11.54	2.20	−4.35	14.6±0.2
Nitro-4	6.78*	10.90*	3.90*	−3.91	13.8±0.1
TCC	5.80	10.10	6.67	−3.10	12.8±0.2

*Référence (1).

la courbe de neutralisation de l'acide par de la soude. Cette dernière méthode a aussi permis la détermination de la constante d'acidité de l'acide borique ($pK_B = 9.05 \pm 0.03$ où $K_B = (B(OH)_4^-)(H^+)/(B(OH)_3)$).

b. Constantes de stabilité

Les constantes β_3^0 des complexes du Ge(IV) ont été déterminées par les méthodes spectrophotométriques décrites précédemment (1).

Les constantes de stabilité des complexes du bore(III) ont été déterminées par l'analyse des courbes de dosage potentiométrique de solutions contenant, pour un système donné, une concentration fixe de ligand et des concentrations variables d'acide borique. Pour tous les systèmes, dans le domaine de concentration étudié, ($C_L \simeq 5 \times 10^{-3}$ M et C_M variant entre 5×10^{-2} et 2×10^{-3} M) toutes les courbes sont expliquées par la présence en solution du seul complexe $BL(OH)_2^-$. Les bilans

$$C_L = (H_2L) + (HL^-) + (BL(OH)_2^-)$$
$$C_B = (HL^-) + (BL(OH)_2^-) - (H^+)$$
$$C_M = (B(OH)_3) + (BL(OH)_2^-)$$

(où C_L, C_B et C_M représentent les concentrations molaires totales du ligand, de la base et du métal respectivement) permettent le calcul de β_1^0. Pour toutes les courbes d'un système donné, on obtient la même constante aux limites d'erreurs près. Ces calculs n'ont pas été effectués à pH élevé ($pH > 7.5$) et sur les courbes à forte concentration en acide borique afin de ne pas avoir à tenir compte de l'acidité de l'acide borique et de la stabilité des espèces polyborates.

La constante β_1^0 trouvée par calcul est ensuite affinée par le programme SCOGS (11) et le programme ACEMCA (12) est utilisé pour générer, après l'affinement, une courbe calculée $pH_{cal.} = f(v_{exp.})$. Dans les deux cas, on donne, à l'entrée du programme, les conditions de départ (volume total, concentrations), les coordonnées de chaque point expérimental ($v_{exp.}$, $pH_{exp.}$), ainsi que les constantes des équilibres impliqués dans le système (les constantes d'acidité du ligand et de l'acide borique, la constante de stabilité β_1^0 du complexe, le produit ionique de l'eau ($pK_w = 14.0$) et les constantes d'équilibre des espèces polyborates données par Ingri (13)).

Pour toutes les courbes de dosage, le programme ACEMCA conduit à des résidus $|pH_{cal.} - pH_{exp.}|$ qui n'excèdent pas 0.03, même à pH élevé et dans les cas où la concentration d'acide borique est grande. L'accord entre les courbes expérimentales et les courbes calculées confirme donc le schéma réactionnel [1] et les valeurs des constantes de stabilité. Dans le cas du système acide borique – catéchol, les calculs habituels, effectués sur les courbes de dosage potentiométrique de solutions ayant une concentration élevée de catéchol ($C_L > 0.25$ M), ne donnent pas une valeur constante pour β_1^0. On suppose alors l'existence en solution d'un second complexe BL_2^-. Un bilan d'électroneutralité, des bilans relatifs au ligand et au métal, ainsi que la connaissance de β_1^0 permettent le calcul de β_2^0(log $\beta_2^0 = -4.68$). Le programme ACEMCA a justifié ensuite cette interprétation.

Résultats et Discussion

Les valeurs des constantes obtenues sont résumées au Tableau I, les résultats expérimentaux détaillés étant exposés par ailleurs (14). L'étude des systèmes Ge(IV) – TCC et Ge(IV) – chloroacétyl-4 catéchol permet d'étendre le domaine de validité des relations linéaires entre pK_1 et pK_2 d'une part, et entre les constantes de stabilité des complexes GeL_3^{2-} et les constantes d'acidité des ligands d'autre part (1).

On a aussi relié les constantes de stabilité des complexes du bore(III) aux propriétés acides–bases des ligands. De fait, une relation linéaire satisfaisante est obtenue entre log β_1^0 et la somme des constantes d'acidité ($pK_1 + pK_2$). La pente de la droite est −0.3. Comme dans le cas du germanium(IV) (1), pour que la réaction [1] soit strictement comparable à celle d'un ion métallique M^+, soit $M^+ + L^- \rightleftarrows ML$, on écrit la réaction de formation de $BL(OH)_2^-$

$$B(OH)_2^+ + L^{2-} \rightleftarrows BL(OH)_2^-, (\beta_1)$$

où le cation hypothétique $B(OH)_2^+$ est relié à l'acide borique par l'équilibre

$$B(OH)_2^+ + H_2O \rightleftarrows B(OH)_3 + H^+$$

avec

$$K_B = (B(OH)_3)(H^+)/(B(OH)_2^+)$$

la constante hypothétique K_B inconnue étant extrêmement élevée. La constante de stabilité

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$\beta_1{}^0$ trouvée expérimentalement est reliée à la constante de stabilité β_1 par l'équation

$$\beta_1 = \beta_1{}^0 K_B/K_1K_2$$

Les valeurs de $\log \beta_1/K_B$ données dans la dernière colonne du Tableau I sont portées en fonction de $(pK_1 + pK_2)$ sur la Fig. 1. Une droite de pente positive $0.70 = (1.0 - 0.3)$ est obtenue comme dans le cas des cations M^+ (15).

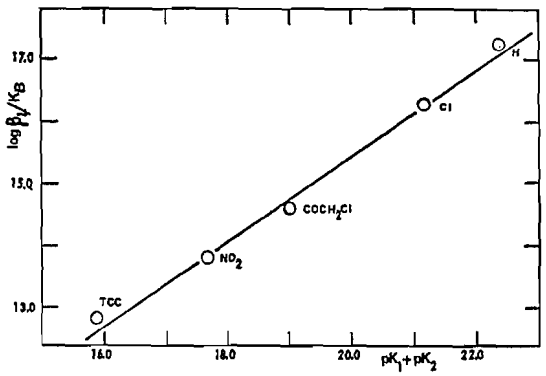

FIG. 1. Les valeurs de $\log \beta_1/K_B$ en fonction de $(pK_1 + pK_2)$ pour les complexes du B(III) avec les dérivés du catéchol: H, catéchol; Cl, chloro-4; NO_2, nitro-4; $COCH_2Cl$, chloroacétyl-4; TCC, tétrachloro-catéchol.

Une comparaison intéressante est aussi faite entre le comportement du germanium(IV) et du bore(III). Les stabilités des complexes $GeL_3{}^{2-}$ et $BL(OH)_2{}^-$ dépendant linéairement des constantes d'acidité des ligands, les valeurs de $\log \beta_3{}^0$ varient aussi linéairement en fonction des valeurs de $\log \beta_1{}^0$ (Fig. 2). Les points sont alignés sur une droite dont la pente est 3.80, ce qui montre la grande similitude de comportement de $Ge(OH)_4$ et $B(OH)_3$. Une étude précédente (1) ayant montré que la stabilité des complexes du Ge(IV) dépendait linéairement de la stabilité des complexes du Si(IV), il en ira donc de même pour les complexes du B(III). L'influence des ligands sur la stabilité des complexes du B(III), du Ge(IV), du Si(IV) étend donc la validité des relations générales entre la stabilité des complexes et la basicité des ligands aux complexes des éléments présents sous forme d'oxydes hydratés en solution aqueuse.

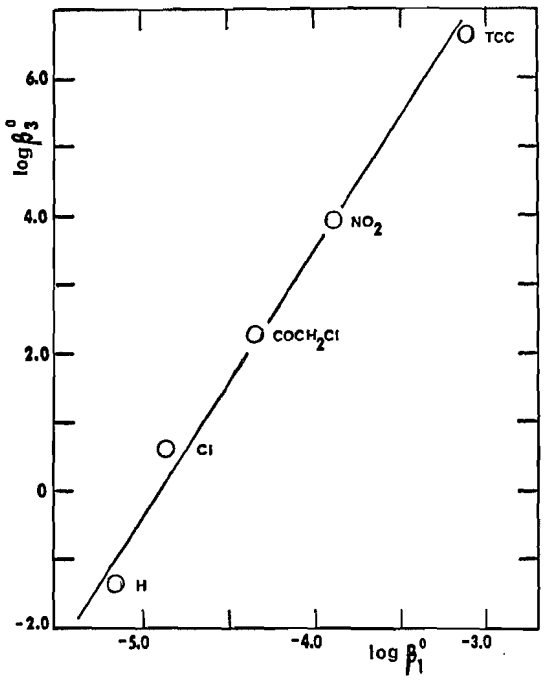

FIG. 2. Les valeurs de $\log \beta_3{}^0$ pour les complexes 1:3 du Ge(IV) en fonction des valeurs de $\log \beta_1{}^0$ pour les complexes 1:1 du B(III) avec les dérivés du catéchol.

Remerciements

Nous remercions le Conseil National de Recherches du Canada pour une subvention et une bourse (R.M.). Nous sommes reconnaissants au Professeur A. L. Beauchamp pour la mise au point des programmes et au Centre de Calcul de l'Université de Montréal pour l'utilisation de l'ordinateur électronique CDC 3400.

Coordination complexes of acetylene diphosphines. II. Diphosphine bridged palladium(II) and platinum(II) derivatives

A. J. Carty and A. Efraty
Chemistry Department, University of Waterloo, Waterloo, Ontario

Received January 28, 1969

Complexes of the type $(MX_2)_2(DPPA)_2$ (M = Pd, Pt; X = Cl, Br, I, SCN; DPPA = bis(diphenylphosphino)acetylene) have been prepared and characterized. Raman, infrared, and molecular weight data have been used to show that the structures are binuclear with bridging bis(diphenylphosphino)-acetylene groups. The infrared spectra of the compounds $[M(SCN)_2]_2(DPPA)_2$ are suggestive of the presence of both N and S bonded thiocyanate within the same molecule.

Les complexes de formule $(MX_2)_2(DPPA)_2$ (M = Pd, Pt; X = Cl, Br, I, SCN; DPPA = bis(diphenylphosphino)acétylène) ont été préparés et caractérisés. Les spectres Raman, infrarouge et les poids moléculaires ont servi à etablir que les groupements bis(diphenylphosphino)acétylène forment des ponts entre les atomes des metaux. Les spectres infrarouges des composés $[M(SCN)_2]_2(DPPA)_2$ semblent indiquer la présence des liaisons M—NCS et M—SCN dans la molécule.

Canadian Journal of Chemistry, 47, 2573 (1969)

Introduction

In several recent publications (1–4) we have described the preparation and characterization of a series of metal halide and carbonyl complexes of the ligand bis(diphenylphosphino)-acetylene, **1** (DPPA). The typical behavior of this disubstituted acetylene is to form bridged binuclear or polymeric complexes in which only the phosphorus atoms of the ligand are coordinated. It was of interest therefore, to investigate the reactions of **1** with platinum(II) and palladium(II) halides since it is well known that these metals form stable acetylene complexes (5) as well as a great many square planar phosphine compounds (6). We describe herein the first binuclear diphosphine bridged palladium(II) and platinum(II) compounds of the type $M_2X_4L_2$ (M = Pd, Pt; X = Cl, Br, I, SCN; L = bis-(diphenylphosphino)acetylene).

Experimental

The ligand **1** was prepared as previously described (see Part I, ref. 1).

Tetrachloro[di-μ-bis(diphenylphosphino)acetylene]diplatinum(II), $(PtCl_2)_2(DPPA)_2$

A solution of K_2PtCl_4 (1.0 g, 2.4 mmoles) in water (10 ml) was added dropwise to a solution of **1** (1.0 g, 2.5 mmoles) in ethanol (120 ml). The reaction mixture

$$Ph_2PC{\equiv}CPPh_2$$

1

was stirred for 35 h at room temperature and the white precipitate filtered off, washed with ethanol, and extracted with dichloromethane. Slow evaporation of solvent on a rotory evaporator gave the crystalline product; yield 1.4 g (96% based on the amount of metal salt used), m.p. 309–315° (decomp.).

Anal. Calcd. for $Pt_2Cl_4(DPPA)_2$ (mol. wt., 1321): C, 47.31; H, 3.05; Cl, 10.74; P, 9.38. Found (mol. wt., osmometric in CH_2Br_2, 1260): C, 47.29; H, 2.91; Cl, 11.01; P, 9.27.

Tetrabromo[di-μ-bis(diphenylphosphino)acetylene]diplatinum(II), $(PtBr_2)_2(DPPA)_2$

A solution of K_2PtCl_4 (1.0 g, 2.5 mmoles) in water (40 ml) was saturated with potassium bromide and an additional amount (2.0 g) of solid potassium bromide added. The mixture was diluted to 400 ml with ethanol and stirred for 3 h. A solution of **1** (1.0 g, 2.5 mmoles) in ethanol was then added dropwise. After stirring for 8 h the pale yellow precipitate was filtered off, stirred thoroughly in water to remove excess potassium bromide, and finally boiled in cyclohexane. Recrystallization from ethanol/dichloromethane afforded pale yellow crystals; yield 1.5 g (84.1%), m.p. 297–300° (decomp.).

Anal. Calcd. for $Pt_2Br_4(DPPA)_2$ (mol. wt., 1499): C, 41.65; H, 2.69; Br, 21.31. Found (mol. wt., CH_2Br_2, 1469): C, 41.90; H, 2.72; Br, 21.60.

Tetraiodo[di-μ-bis(diphenylphosphino)acetylene]diplatinum(II), $(PtI_2)_2(DPPA)_2$

This was prepared from K_2PtCl_4 and **1** in similar fashion to the bromide but with potassium iodide replacing potassium bromide. The m.p. was 275–279° (decomp.).

Anal. Calcd. for $Pt_2I_4(DPPA)_2$: C, 37.02; H, 2.39; I, 30.09. Found: C, 37.38; H, 2.27; I, 29.81.

Tetrathiocyanato[di-μ-bis(diphenylphosphino)acetylene]diplatinum(II), $[Pt(SCN)_2]_2(DPPA)_2$

This was prepared in similar fashion to the bromide using potassium thiocyanate, m.p. 262–268° (decomp.).

Anal. Calcd. for $Pt_2(SCN)_4(DPPA)_2$ (mol. wt., 1411):

Tetrachloro[di-μ-bis(diphenylphosphino)acetylene]dipalladium(II), $(PdCl_2)_2(DPPA)_2$

Reaction of **1** (0.7 g, 1.8 mmoles) in ethanol (75 ml) with a slight excess of Na_2PdCl_4 (0.7 g, 2.4 mmoles) in the same solvent (75 ml) gave the crystalline complex which was washed with boiling cyclohexane and recrystallized from ethanol/dichloromethane; yield 0.75 g (55%), m.p. 263–266° (decomp.).

Anal. Calcd. for $Pd_2Cl_4(DPPA)_2$ (mol. wt., 1143): C, 54.64; H, 3.53; Cl, 12.40; Pd, 18.62. Found (mol. wt., CH_2Br_2, 1159): C, 54.01; H, 3.31; Cl, 12.61; Pd, 19.00.

Tetrabromo[di-μ-bis(diphenylphosphino)acetylene]dipalladium(II), $(PdBr_2)_2(DPPA)_2$

$PdCl_2$ (1.0 g, 5.7 mmoles) and potassium bromide (4.0 g) were boiled together in water for 30 min then stirred for 3 h. Reaction of this solution with **1** (1.3 g, 3.3 mmoles) in ethanol gave, after recrystallization from ethanol/dichloromethane, brown-yellow crystals of the pure product; yield 1.96 g (53%).

Anal. Calcd. for $Pd_2Br_4(DPPA)_2$ (mol. wt., 1321): C, 47.28; H, 3.04; Br, 24.24; Pd, 16.10. Found (mol. wt., CH_2Br_2, 1343): C, 46.50; H, 3.08; Br, 25.10; Pd, 16.40.

Tetraiodo[di-μ-bis(diphenylphosphino)acetylene]dipalladium(II), $(PdI_2)_2(DPPA)_2$

This complex was prepared from either $(PdCl_2)_2(DPPA)_2$ or $(PdBr_2)_2(DPPA)_2$ by metathesis with potassium iodide in ethanol/dichloromethane; m.p. 286–289° (decomp.).

Anal. Calcd. for $Pd_2I_4(DPPA)_2$: C, 41.30; H, 2.68; I, 33.30; Pd, 14.00. Found: C, 41.17; H, 2.63; I, 33.21; Pd, 14.40.

Tetrathiocyanato[di-μ-bis(diphenylphosphino)acetylene]dipalladium(II), $[Pd(SCN)_2]_2(DPPA)_2$

Metathesis of $(PdCl_2)_2(DPPA)_2$ with potassium thiocyanate in acetone followed by normal work-up gave the product as orange crystals, m.p. > 300 °C.

Anal. Calcd. for $Pd_2(SCN)_4(DPPA)_2$ (mol. wt., 1234): C, 54.50; H, 3.02; N, 4.61; Pd, 17.30. Found (mol. wt., CH_2Br_2, 1639): C, 54.19; H, 3.19; N, 4.70; Pd, 17.25.

Physical Measurements

Infrared spectra in the range 4000–600 cm^{-1} were recorded on a Beckmann IR-9 spectrophotometer as Nujol or hexachlorobutadiene mulls between sodium chloride windows. Spectra were calibrated with polystyrene and frequencies are accurate to $\pm 2\ cm^{-1}$. In the region 400–200 cm^{-1} a Beckmann IR-12 spectrophotometer was used. Samples were examined as Nujol mulls between polyethylene plates.

Raman spectra of the solid complexes were measured on a helium/neon gas laser Raman spectrophotometer using the 6328 Å exciting line. In some cases spectra were unobtainable due to the strong fluorescence of the sample. Calibrations were made using the 6518 Å line of carbon tetrachloride and frequencies are accurate to $\pm 2\ cm^{-1}$.

Microanalyses were carried out by A. B. Gygli, Toronto and by Alfred Bernhardt, Mulheim, Germany. Palladium was estimated gravimetrically by direct ignition. Molecular weights were measured osmometrically in dichloromethane and dibromomethane using Mechrolab and Hitachi Perkin–Elmer vapor pressure osmometers.

Results

The ligand **1** reacts readily with sodium tetrachloropalladate(II) and potassium tetrachloroplatinate(II) to give crystalline, air stable, diamagnetic[1] complexes of empirical formula $MCl_2(DPPA)$. The corresponding bromides, iodides, and thiocyanates can be obtained either by metathesis or by preliminary conversion of the tetrachloro salt into the tetrabromo, tetraiodo, or tetrathiocyanato derivative. The compounds are soluble in dichloromethane (iodides sparingly) but virtually insoluble in the polar solvents nitromethane, acetonitrile, and ethanol, almost certainly ruling out an ionic formulation.

Infrared Spectra

The infrared (i.r.) spectra (2200–650 cm^{-1}) of the ligand and complexes are shown in Table I. Spectra of the complexes are very similar to the free ligand spectrum, the most notable changes being an increase in intensity and frequency of the 1090 cm^{-1} ligand band, a resolution of bands in the 690–850 cm^{-1} region in some complexes, and the appearance of an extra weak absorption in the 1550–1600 cm^{-1} region. The 1090 cm^{-1} absorption is characteristic of the grouping P–phenyl and increases in frequency and intensity for this band are a good diagnostic test for coordination of phenyl phosphines (7 and references therein). For the compounds $[M(SCN)_2]_2(DPPA)_2$ two bands due to $\nu(C{\equiv}N)$ of coordinated thiocyanate appear in each spectrum. The higher of these is strong and sharp whereas the lower is broad. Possible reasons for the appearance of two widely separated $\nu(C{\equiv}N)$ frequencies are discussed later.

The far-infrared spectra (450–200 cm^{-1}) of **1** and the complexes are shown in Table II. The ligand is relatively free from strong absorptions in this region and comparison of analogous complexes allowed ready identification of bands due to $\nu(M{-}X)$. Two platinum–chlorine stretching vibrations were found for $(PtCl_2)_2(DPPA)_2$ at 328 and 302 cm^{-1} in the normal range for $\nu(Pt{-}Cl)$ in square planar complexes (8, 9).

$\nu(Pd{-}Cl)$ modes were similarly identified at 320 and 298 cm^{-1}. Only one $\nu(M{-}Br)$ mode was found at 218 cm^{-1} for M = Pt and at 244 cm^{-1} for M = Pd, the other expected vibration being presumably below the range of the instrument. The compounds $[M(SCN)_2]_2(DPPA)_2$ each exhibit a broad band envelope between 260–310 cm^{-1} consisting of at least 3 strong peaks. This is the region in which $\nu(M{-}S)$ and $\nu(M{-}N)$ occur for complexes containing S-bonded or N-bonded thiocyanate (10, 11).

Raman Spectra

Previous workers on acetylene complexes have used i.r. data almost conclusively to deduce whether the C≡C bond is coordinated (5, 12). Raman data are more useful, however, since $\nu(C{\equiv}C)$ gives rise to a very intense absorption in the Raman effect whereas $\nu(C{\equiv}C)$ for a coordinated triple bond may only appear weakly in the i.r. Using helium/neon excitation, $\nu(C{\equiv}C)$ was readily identified for **1** and the solid complexes which were not highly colored (Table III).

[1]Good quality nuclear magnetic resonance spectra were obtained in deuterochloroform solutions.

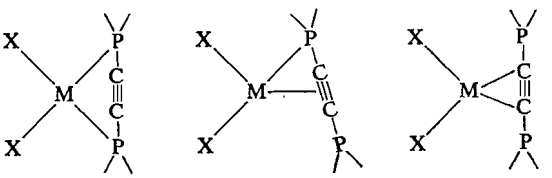
Discussion

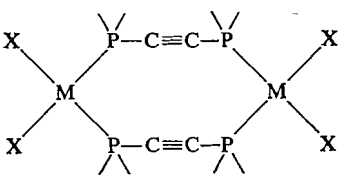
Several possible structures (**2**–**7**) can be envisaged for compounds of empirical formula MX_2(DPPA). Although many square planar mononuclear diphosphine complexes of type **2**



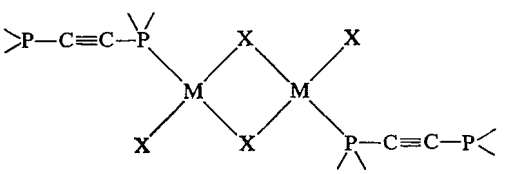
2

3

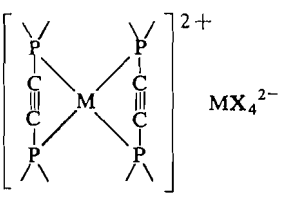
4



5



6



7

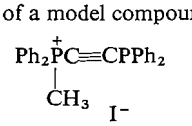
are known (6, 13), the molecular weight data in dibromomethane indicate that the compounds MX_2(DPPA) (M = Pd, Pt; X = Cl, Br, I, NCS) are binuclear. Moreover, the linear P—C—C—P skeleton of **1** and the long P—P distance of 4.7 Å (1) prevent chelation. Structures **2** and **7** can therefore be eliminated.

The presence of electronegative substituents on acetylenes markedly increases the ability of the triple bond to coordinate to transition metals (5, 14). Recent calculations (15) have shown that the diphenylphosphino group is strongly electron withdrawing. On this basis the triple bond of **1** might coordinate as in **3** where one phosphorus atom is attached to the metal, or as in **4** by analogy with the known compounds $(Ph_3P)_2Pt$(Ac) (Ac = acetylene) (16). ν(C≡C) is i.r. inactive in symmetrically disubstituted acetylenes but on coordination of the triple bond, a lowering of symmetry occurs and ν(C≡C) appears in the i.r. at a frequency 200–400 cm^{-1} lower than in the free acetylene (12, 16). From Table I, the absence of any band in the region 2200–1600 cm^{-1} assignable to ν(C≡C) of a coordinated triple bond argues convincingly against a formulation as acetylene complexes. Moreover, this is confirmed by the Raman data (Table III) where an increase of 39–50 cm^{-1} for ν(C≡C) occurs on coordination of the ligand.

Spectroscopic evidence also infers that a structure **6** (or similar *cis* isomers) based on bridging halide and monodentate **1** is unlikely. Coordination of only one phosphorus atom of the ligand would certainly cause ν(C≡C) to appear strongly in the i.r.[2] A bridged halide complex of the type shown, exhibits two distinct regions of absorption due to ν(M—X) in the far-infrared. For a chloride complex with a *trans* C_{2h} skeleton one terminal ν(M—Cl) (B_u) mode about 320 cm^{-1} and two bridging ν(M—Cl) (B_u) modes, one above 290 cm^{-1} and the other between 250–290 cm^{-1} are expected (17). The presence of only two ν(M—Cl) modes for the chloride and the absence of a band below 290 cm^{-1} rule out the bridging halide structure.

The only structure consistent with molecular weights, i.r., and Raman data is **5** in which two

[2]An i.r. spectrum of a model compound



analogous to the case of a monodentate **1** shows ν(C≡C) as an intense absorption in the i.r. at 2108 cm^{-1}.

diphosphine molecules symmetrically bridge two MX_2 units. For the D_{2h} planar skeleton two metal–halogen stretching modes (B_{2u} + B_{3u}) are expected in the i.r. in agreement with the two observed ν(M—Cl) bands for $(MCl_2)_2$-$(DPPA)_2$. To confirm this result a Raman spectrum of $(PtBr_2)_2(DPPA)$ was run in the region 400–100 cm^{-1}. Comparison with the Raman spectrum of **1** in the same region shows that ν(Pt—Br) modes appear as one intense and one medium strong band at 232 and 177 cm^{-1}. For D_{2h} symmetry two modes (A_g + B_{1g}) are expected in the Raman and these should be non-coincident with the i.r. modes. Without polarization data a definite assignment is impossible but on the basis of relative intensity the highest band may arise from the symmetric A_g mode. Both i.r. and Raman spectra are therefore nicely interpreted in terms of structure **5**.

Although a number of palladium(II) and platinum(II) diphosphine complexes of the type MX_2 (diphos.) have been prepared (6, 13, 26), these are either monomeric with chelating diphosphine molecules or ionic dimers $[M(diphos)_2][MX_4]$ (6, 26). However, the phosphido bridged dimeric species $M_2X_2(PR_2)_2(PR_3)_2$ (M = Pd, Pt; X = Cl, Br, I; R = CH_3, C_6H_5) are well known (24) and recent work has shown that ethylenediamine bridged platinum(II) complexes exist (25). The preparation of the diphosphine bridged species described herein nevertheless illustrates the importance of ligand geometry in determining the structures of coordination complexes.

The shifts of ν(C≡C) to higher frequency on complexing are worthy of comment. We have recently pointed out (18) that the low ν(C≡C) frequency for **1** is a consequence of pπ–dπ C→P interaction in the linear P—C—C—P skeleton of **1**. On coordination to a transition metal, back donation Mdπ–Pdπ lessens the π electron drift from bonding carbon pπ orbitals to phosphorus dπ orbitals and causes ν(C≡C) to move higher. Comparison of data for copper(I), gold(I), mercury(II), palladium(II), and platinum(II) (18) shows that whereas mercury(II) produces the smallest shift (ca. 20 cm^{-1}), platinum(II) and palladium(II) (Table III) produce a Δν of the order of 40–50 cm^{-1}, indicating extensive π bonding between phosphorus and these metals.

The nature of the bonding of thiocyanate in the complexes $[M(SCN)_2]_2(DPPA)_2$ is of interest, particularly in view of recent X-ray results for compounds thought to contain both N *and* S bonded thiocyanate (19). Infrared correlations have frequently been used with success to predict the occurrence of metal–NCS or metal–SCN bonding in thiocyanate complexes (11, 20, 27). Various authors have used the C—N stretching, C—S stretching, NCS bending, and M—N or M—S stretching regions of the spectra for analytical purposes (20) as well as measurements of the integrated intensity of the ν(C≡N) absorption (21). Two ν(C≡N) absorptions are

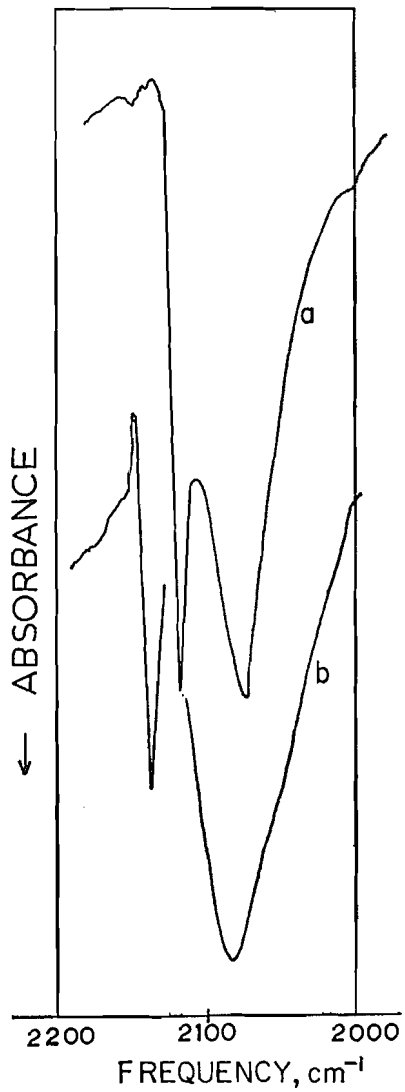

FIG. 1. Infrared spectra in the ν(C—N) region for (*a*) $[Pd(SCN)_2]_2(DPPA)_2$ and (*b*) $[Pt(SCN)_2]_2(DPPA)_2$.

expected for metal–thiocyanate–phosphine complexes of the type *cis* ML_2X_2. However, these are usually separated by $< 20\ cm^{-1}$ and occur above $2100\ cm^{-1}$ for S bonded thiocyanate and below $2100\ cm^{-1}$ for the N bonded isomer (22). Moreover, for M—NCS, $\nu(C{\equiv}N)$ is broad whereas for M—SCN, it is sharp. In $[M(SCN)_2](DPPA)_2$ (M = Pd, Pt), two bands are observed in each case; one is broad and below $2100\ cm^{-1}$ while the other is sharp, and well above $2100\ cm^{-1}$ (Fig. 1). The situation is further complicated by the fact that in phosphine complexes of palladium and platinum thiocyanates, thiocyanate is usually N bonded (22).

Two possible reasons for this behavior can be suggested. Either these compounds belong to a small group having both N and S bonded thiocyanate within the same molecules (23), or two linkage isomers exist for each compound and are difficult to separate by crystallization. Examination of the i.r. spectra in the C—S stretching or N—C—S bending regions provides no further information since the ligand absorbs strongly in these regions and although ν(Pd—N) and ν(Pd—S) are said to absorb in different ranges (11), the absorption for $[Pd(SCN)_2]_2(DPPA)_2$ near $300\ cm^{-1}$ is sufficiently broad and complex that no definite assignments can be made. We are currently attempting to resolve this question by an X-ray crystallographic study of $[Pd(SCN)_2]_2(DPPA)_2$.

Crystal structures of potassium, ammonium, rubidium, and cesium tetrafluoborates

M. J. R. Clark and H. Lynton
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received January 9, 1969

The crystal structures of potassium, ammonium, and rubidium tetrafluoborates have been redetermined. The structure of cesium tetrafluoborate has also been established. These 4 compounds are isomorphous and show orthorhombic symmetry, space group *Pbnm*. Atomic parameters have been obtained from a block diagonal least squares refinement using anisotropic temperature parameters. The final agreement residuals for observed reflections were KBF_4, $R = 0.072$; NH_4BF_4, $R = 0.075$; $RbBF_4$, $R = 0.064$; and $CsBF_4$, $R = 0.051$.

There are significant differences between some of the B—F bond distances in the $[BF_4]^-$ ions. The shortest N---(H)F distance in NH_4BF_4 is 2.914 Å (estimated standard deviation 0.005 Å) which is long for a hydrogen bond. The positions of the hydrogen atoms in the NH_4^+ ion could not be established.

Introduction

Fluoboric acid and its salts were first characterized by Gay-Lussac and Thénard (1) and by Berzelius (2). Sodium and potassium tetrafluoborates have since been found to occur naturally in volcanic deposits (3, 4).

Interestingly, the alkali metal and ammonium tetrafluoborates have been found to exist in an orthorhombic phase at room temperature (5–15), and in a cubic phase at high temperatures (16–18). In addition, a modification of the orthorhombic phase of NH_4BF_4 has been observed at low temperatures (17, 19).

Crystal structures for the orthorhombic phase have been determined for the sodium (4, 15, 42, 43), potassium (7), rubidium (9), and ammonium (9) salts. The structure determinations of KBF_4, NH_4BF_4, and $RbBF_4$ are inaccurate by present standards. The structure of $CsBF_4$ has not previously been determined.

Crystals of NH_4BF_4, KBF_4, and $RbBF_4$ were obtained by slow evaporation of an aqueous solution formed by the reaction of fluoboric acid on the carbonate, the fluoboric acid being in slight excess. Crystals of $CsBF_4$ were obtained in the same way using the chloride. Crystals of KBF_4 were also prepared by mixing ice-cold concentrated aqueous solutions of boric acid and potassium fluoride, and allowing the resultant solution to stand for several days in an ice bath.

All 4 compounds were analyzed using Dowex 50-X and Dowex 2-X ion exchange resins (20). The boron content was obtained using a Zeiss flame spectrophotometer, the emission line at 521 mμ being examined. The results of these analyses are given in Table I.

Crystallographic Data

The crystal data are given in Table II. All 4 compounds are isomorphous and show orthorhombic symmetry. The systematic absences are compatible with the space groups $Pbn2_1$, and *Pbnm*. The results of the structure analyses confirm the assignment of the space group as *Pbnm*.

Precise cell dimensions were determined using Weissenberg photographs calibrated with aluminium powder. These cell dimensions and those

*Cell dimensions converted from kX units to Å by the conversion factor 1.00202.

previously reported in the literature are given in Table III.

The discrepancy that exists between the presently reported cell dimensions for KBF_4, confirmed by the U.S. Bureau of Mines (8), and those published by Pesce (5) and Sharp and Thorley (6), is due to their incorrect interpretation of the X-ray powder pattern for this compound. We are unable to explain the cell dimensions reported by Bellanca and Sgarlata (7), but we note that there are several other errors in their paper. Wyckoff (21) quotes Pesce's cell dimensions but with a list of atomic parameters which are those of Bellanca and Sgarlata with a change of origin.

Intensity Data

The crystals chosen for data collection, with the exception of the KBF_4 a axis crystal, were roughly cube shaped. The average thickness for each crystal is given in Table IV. Absorption corrections were made to these data assuming spherical shape. The KBF_4 a axis crystal was a needle of length 0.35 mm and average cross section of 0.11 mm; absorption corrections for this crystal were made assuming cylindrical shape.

Using the multiple filmpack technique, equi-inclination Weissenberg photographs were taken of all layers accessible on the a and c axes. In addition, the $h0l$ layer for each compound was also obtained.

		c	0.37	*hk*0–*hk*4		
$RbBF_4$	0.10	*a*	0.10	0*kl*–6*kl*		
		b	0.09	*h*0*l*	443	341
		c	0.10	*hk*0–*hk*4		
$CsBF_4$	0.03	*a*	0.08	0*kl*–6*kl*		
		b	0.10	*h*0*l*	520	407
		c	0.12	*hk*0–*hk*5		

The number of permitted independent reflections within the range of photographs taken with Cu Kα radiation is given in Table IV. The number of reflections with intensities above the minimum required for observation is also given in the same table. The intensities of all reflections were estimated by visual comparison with calibration strips prepared using a suitable reflection from each intensity crystal. Lorentz-polarization factors were applied to all intensity data.

Structure Refinement

The structure refinement for all 4 compounds was by successive cycles of block diagonal least squares[1], employing only the observed reflections. The quantity minimized was $\sum w(F_o - F_c)^2$. The matrices used were 3 × 3 for the positional parameters and 6 × 6 for the anistropic thermal parameters of each atom. The weighting scheme $w = 1/a + |F_o| + c|F_o|^2$ was employed with the following values for a and c: KBF_4 a = 5.06, c = 0.028; NH_4BF_4 a = 2.50, c = 0.043; $RbBF_4$ a = 11.04, c = 0.018; and $CsBF_4$ a = 12.50, c = 0.011.

Scattering factor curves used were those given in International Tables (23) for B, N, K^+, and Rb^+. The fluorine scattering curve was for $F^{-1/4}$ obtained by interpolation between F and F^-. Cs^+ was obtained from Cromer and Waber (24).

No correction was made for extinction, and in the last cycle for each compound no parameter shift exceeded 0.3 estimated standard deviations (e.s.d.).

In the case of NH_4BF_4, a difference Fourier evaluated at the end of the last cycle showed no residual electron density near the nitrogen atom that could be associated with the 4 hydrogens.

The final agreement residual, $R = \sum| |F_o| - |F_c| |/\sum|F_o|$, for observed reflections was KBF_4, $R = 0.072$; NH_4BF_4, $R = 0.075$; $RbBF_4$, $R = 0.064$; and $CsBF_4$, $R = 0.051$.

Results

There are 4 molecules in the unit cell. For each molecule, the cation, boron and two fluorine atoms F(1) and F(2) lie in one of the two mirror planes at $Z = 1/4$ and $Z = 3/4$, special positions (4*c*). The two remaining fluorine atoms of the tetrafluoborate ion, F(3) and F(3′), occupy general positions (8*d*) above and below the mirror planes.

The final atomic coordinates are listed in Table V, together with their estimated standard deviations. The temperature parameters are given in Table VI. A detailed analysis of the agreement of individual reflections is summarized in Table VII. The overall agreement residual used in this table included the unobserved reflections.

Tables VIII and IX give the distances and angles in the $[BF_4]^-$ ion together with their e.s.d. A table is also provided listing all the shortest distances between other atoms, Table X. A final set of structure factors for each compound has

[1]All computations were carried out on an IBM 360/50 computer using the programs of Ahmed *et al.* (22).

been placed in the Depository of Unpublished Data[2].

Discussion

An examination of the interatomic distances in the $[BF_4]^-$ ions, Table VIII, shows that there are significant differences between some of the B—F bonds. These results may be compared with some values from the literature, Table XI.

None of the F—B—F bond angles differ greatly from tetrahedral, the largest distortion occuring in $CsBF_4$ where the smallest angle is 105.59° (e.s.d. 0.99°) and the largest 114.74° (e.s.d. 1.17°).

All the distances given in Table X show a change in length with change in cation, in the order

$$K^+ < NH_4^+, Rb^+ < Cs^+$$

The shortest F---F and M^+---F distances are given in Table XII, together with some values from the literature. It can be seen that the cation effect is paralleled in other complex fluorides.

An examination of all the shortest N---(H)F distances in NH_4BF_4 shows that they are long for hydrogen bonds. The shortest distance 2.914 Å (e.s.d. 0.005 Å) compares with 3.02 and 3.04 Å found in $H_3N \cdot BF_3$ (30) and $(CH_3)H_2N \cdot BF_3$ (36) where only very weak hydrogen bonding is suggested. In NH_4F and $N_2H_6F_2$ where strong hydrogen bonding is thought to exist, both nuclear magnetic resonance (n.m.r.) and X-ray studies give internuclear N---(H)F distances in the range 2.6–2.7 Å, see Table XII. In a n.m.r. examination of NH_4BF_4, Pendred and Richards (41) concluded that only very weak hydrogen bonds are present and that the NH_4^+ ion is in motion even at 20 °K. This would account for the absence of localized hydrogen atom positions in our difference synthesis.

Infrared spectra of adducts of tetrasulfur tetranitride with metal halides

P. J. ASHLEY[1] AND E. G. TORRIBLE[1]
Department of Chemistry, Queen's University, Kingston, Ontario

Received February 3, 1969

New complexes of S_4N_4 with $TiBr_4$, $ZrCl_4$, $NbCl_5$, and $TaCl_5$ have been prepared. The infrared spectra of these complexes together with the spectra of previously reported complexes have been determined. Possible structures for the complexes are discussed.

Canadian Journal of Chemistry, 47, 2587 (1969)

Introduction

The complexes of tetrasulfur tetranitride (S_4N_4) with transition metal halides have not been extensively studied. Adducts of the form $MX_n.S_4N_4$ ($n = 4, 5$) have been formed with $TiCl_4$, VCl_4, WCl_4, $SbCl_5$, $MoCl_5$, and adducts of the form $MX_4.2S_4N_4$ have been formed with $SnCl_4$ (1). Recently Wynne and Jolley reported the preparation of 1:1 adducts with the boron trihalides (2), and Becke-Goehring and Magin have reported the preparation of $2TiCl_4.S_4N_4$ (3). The structures of $SbCl_5.S_4N_4$ (4) and $BF_3.S_4N_4$ (5) have been determined by X-ray crystallographic studies. In this paper we report the preparation and infrared (i.r.) spectra of some new complexes of tetrasulfur tetranitride with transition metal halides, together with the i.r. spectra of the previously known complexes. Possible structures for the complexes are suggested based on the i.r. spectra and on the X-ray data for the antimony pentachloride and boron trifluoride complexes.

Experimental

Special precautions were taken to exclude water from the apparatus and reactants, and all reactions between metal halide and ligand were carried out in a dry nitrogen atmosphere. Solvents were dried by refluxing over sodium or phosphorous pentoxide and then fractionally distilled. Carbon tetrachloride, prepared as solvent for reactions involving niobium and tantalum pentachlorides, was further distilled from those halides and saturated with dry nitrogen. The metal halides were either distilled or sublimed directly into the reaction apparatus immediately prior to use.

Tetrasulfur tetranitride was prepared from ammonia and sulfumonochloride using the conditions described by Villena-Blanco (6), extracted with dioxane from the crude reaction products, and fractionally recrystallized from benzene. The orange crystals melted at 182 °C; lit. 178 °C (7), 184 °C (6).

The complexes were all prepared using the same general method. Either the pure liquid halide or a solution or slurry of solid halide in carbon tetrachloride was added to a refluxing solution of S_4N_4 in carbon tetrachloride. The resulting mixture was refluxed and stirred until reaction was complete; the products, which were all insoluble in carbon tetrachloride, were filtered, washed with hot carbon tetrachloride, and dried in vacuo. All complexes reacted vigorously with water and were hydrolyzed in air. The complexes were non-volatile and appeared insoluble in solvents with which no solvolysis occurred.

Metal, halogen, and nitrogen contents were determined by standard methods. The i.r. spectra were determined as Nujol mulls between KRS-5 plates on a Beckman IR-10 grating instrument.

Results and Discussion

Complexes of S_4N_4 with $TiCl_4$, VCl_4, and $SnCl_4$ were prepared as previously described (1). New complexes with $TiBr_4$, $ZrCl_4$, $NbCl_5$, and $TaCl_5$ were also prepared. Analytical data for these complexes are found in Table I. The i.r. spectra of these complexes and of $2TiCl_4.S_4N_4$, together with the reported spectra (2) of the antimony and boron halide complexes are listed in Table II.

The structural determinations for the BF_3 (5) and $SbCl_5$ (4) complexes gave evidence for S_4N_4 coordinated to the metal atom through one nitrogen atom, as shown in Fig. 1, where MX_n represents the coordinated metal halide. Free

*Decomposed.

S_4N_4 has a cage-like structure with the 4 nitrogen atoms coplanar and with 2 sulfur atoms above the plane and 2 below. Weak S—S bonding has been postulated (10). As a result of coordination, the configuration of the S_4N_4 molecule changes from the cage-like structure to that of a more open ring type structure in which the sulfur atoms are coplanar (4). Considering the symmetry of the ligand itself, this change in structure would not be expected to alter the number of i.r. active modes of the ligand. However, in the complex, the overall symmetry will govern the number of i.r. active vibrations, and for this reason it was expected that there would be an increase in the number of absorption bands associated with the coordinated ligand over that for the free ligand. Our spectrum for the free ligand shows closer agreement with that of Chapman and Massey (8) than with that of Lippincott and Tobin (9). However, our spectrum does show a weak shoulder at 1040 cm^{-1} in agreement with the weak band at 1040 cm^{-1} reported by Lippincott and Tobin.

From Table II it can be seen that the spectra of the complexes were very similar to those reported for the BF_3 and $SbCl_5$ complexes. The VCl_4 complex spectrum also showed some similarity to the spectrum of $2TiCl_4.S_4N_4$. The spectra were characterized by strong bands at about 1040, 960, 790, 505, and 350 cm^{-1}, respectively. The strong bands at 1040 and 790 cm^{-1} do not appear in the spectrum of S_4N_4 and appear characteristic of the monodentate S_4N_4 ligand.

Only one attempt to assign the frequencies for tetrasulfur tetranitride has so far been reported (9). The model on which the assignments were based has since been shown to be incorrect (10). However, the symmetry of that model has the same D_{2d} symmetry as the presently accepted structure; thus although the assignments made by Lippincott and Tobin are probably incorrect, their symmetry analysis of the i.r. and Raman active modes will apply to the correct structure. On this basis we have tentatively assigned the 920 cm^{-1} band in free S_4N_4 to an S—N stretch of B_2 symmetry. Lippincott and Tobin had previously assigned this band to an N—N stretch. Our assignment of the 920 cm^{-1} to an S—N stretching mode is supported by the results of Banister *et al.* (12) who examined the relationship between S—N stretching frequencies and S—N bond lengths. The S—N bond length of free S_4N_4 has been found to be 1.616 Å (11); Banister's results predict a corresponding stretching frequency of about 940 cm^{-1}. The X-ray studies on the $SbCl_5$ complex (4) indicate that the bond lengths of S_4N_4 are changed on coordination. The S—N distance for the coordinated nitrogen is about 1.75 Å and corresponds to the S—N stretching frequency at 785 cm^{-1} in the $SbCl_5$ complex. Thus the strong band at about 790 cm^{-1} in the complexes can be assigned to the S—N stretching frequency associated with the coordinated nitrogen. Similarly the strong band at around 1020–1040 cm^{-1} can be assigned to S—N stretching of the shortened bonds (13), e.g. 1.55 Å in the $SbCl_5$ complex. The frequency at 960 cm^{-1} in the complexes corresponds to the band at 920 cm^{-1} in free S_4N_4 and can be assigned to the S—N stretch of the bonds unchanged in length from free S_4N_4. The multiple structure of these bands can be attributed to the asymetric nature of the coordinated S_4N_4 ligand (4, 5).

The spectra of both niobium and tantalum pentachloride complexes were very similar to that of the $SbCl_5 . S_4N_4$ complex, indicating that the structures of these complexes were similar to that of the $SbCl_5$ complex. The bands at 330 and 315 cm^{-1} in the niobium and tantalum complexes respectively are assigned as metal–halide bands, and the values are characteristic of the 6 coordinate metals (14).

The spectra of the titanium and zirconium tetrahalide complexes were also similar to that of the $SbCl_5$ complex. The ligand frequencies indicated a monodentate S_4N_4 ligand which would require a 5 coordinate metal. However, the metal halide bands at 365, 375, and 330 cm^{-1} assigned to the Ti—Cl and Zr—Cl stretching modes, respectively, indicated 6 coordinate metal (14). In such situations it is possible that a 5 coordinate complex forms initially and then achieves 6 coordination by halide bridging, as suggested by Rivest (15). Such a structure has been determined for the $TiCl_4 . POCl_3$ complex (16).

The absence of a terminal and bridging metal–halogen frequency in the spectrum of the $TiCl_4 . S_4N_4$ complex requires explanation. The terminal frequency was assigned as the band at 365–375 cm^{-1}. According to Adams and Chandler (17), bridging frequencies are found about 40 cm^{-1} lower than the terminal frequency, and hence would be expected at 325–335 cm^{-1}. At this frequency the metal–halide bridge absorption will be masked by a strong ligand absorption.

The spectrum of the $SnCl_4$ complex again showed ligand bands indicative of a monodentate ligand. $SnCl_4 . 2L$ complexes have been found to be *cis*-coordinated for small ligands, and *trans*-coordinated for bulky ligands (18). Identification of these two species was based on the number of observed metal–halide absorption bands. For the *cis*-configuration 3 peaks between 360 and 290 cm^{-1} were expected, but only one at about 330 cm^{-1} for the *trans*-configuration. On this basis the single peak at 304 cm^{-1} supported the *trans*-configuration proposed by Weiss (19).

The spectrum of the VCl_4 complex shows some similarity to those of the other tetrahalide complexes but also shows some striking differences. The band at 1010 cm^{-1} in the VCl_4 complex was a singlet, whereas in a complex with monodentate S_4N_4 the band was multiple. Also a strong band system appeared at 840–850 cm^{-1}, about 50 cm^{-1} higher than the corresponding band in complexes containing the monodentate ligand. The band at 670 cm^{-1} was strong whereas for the others it was weak. The i.r. spectrum of a sample of the compound $2TiCl_4 . S_4N_4$ showed a singlet absorption at 1020 cm^{-1}, a strong band system at 820–840 cm^{-1}, but no absorption in the 670 cm^{-1} region. However, a strong band at 472 cm^{-1} in the $2TiCl_4 . S_4N_4$ complex was observed as a doublet in the VCl_4 complex. Becke-Goehring has suggested that in $2TiCl_4 . S_4N_4$, the ligand is bidentate and acts as a bridge between the two $TiCl_4$ molecules which are also halide bridged (3). We suggest that in $VCl_4 . S_4N_4$, the ligand is also bidentate and bridges 2 vanadium atoms. This would give the complex a *trans*-polymeric structure and vanadium a coordination number of 6 (Fig. 2). This is supported by the observed absorption at 385 cm^{-1}, which is reported as characteristic of a V—Cl stretching mode in six-coordinated vanadium complexes (14).

Calculated R.R.K.M. unimolecular dissociation rate constants for hydrazine[1]

D. W. SETSER[2] AND W. C. RICHARDSON
Department of Chemistry, Kansas State University, Manhattan, Kansas 66502

Received November 26, 1968

Unimolecular rate constants for hydrazine dissociation by thermal and chemical activation have been calculated according to the R.R.K.M. theory. The two activated complex models used in the calculations represent plausible upper and lower bounds to the rate constants. The calculations are mainly directed toward establishing expected decomposition to stablilization ratios of N_2H_4 produced by combination of NH_2 radicals; however, a general comparison to available experimental data for hydrazine dissociation is made.

Canadian Journal of Chemistry, 47, 2593 (1969)

Introduction

During the course of an experimental investigation (1) of NH and NH_2 radical reactions in our laboratory, the stabilization (S) to decomposition (D) ratio at various pressures and temperatures of hydrazine formed by reaction [1] was needed.

$$[1] \qquad NH_2 + NH_2 \rightleftarrows N_2H_4^* \xrightarrow{\omega} N_2H_4(S)$$
$$\xrightarrow{k_a} 2\ NH_2(D)$$

Since experimental information was not available, a Rice Ramsperger Kassel Marcus (R.R.K.M.) (2) theoretical estimate of the S/D ratio (3) was made. The NH_2 radical combination reaction has been suggested to be of importance in many photolysis and pyrolysis systems involving nitrogen–hydrogen compounds, and our calculated results are summarized and compared to the existing experimental data. The calculations suggest that most experiments were done at much too low a pressure to obtain the true rate constant for NH_2 combination due to the occurrence of reverse dissociation. For the models chosen for the activated complex, the calculated results also indicate that the shock tube investigations of N_2H_4 dissociation have been conducted in the fall-off region rather than in the high pressure region.

Reliable experimental information, e.g., entropy of activation, is not available for the formulation of a good model for the activated complex for hydrazine dissociation. Therefore, N_2H_4 decomposition was assumed to belong to the class of dissociation reactions having loose transition states and positive entropies of activation, such as the dissociation of ethane (4). Or in terms of the reverse reaction, NH_2 combination, the assumption is that the combination rate constant is typical for radical combination. R.R.K.M. (2) calculations were performed for two models which are believed to give upper and lower bounds to the rate constants. Only a very general outline of the equations (3, 5) and procedures (1) used in the calculations are presented because they are relatively standard.

We also have done R.R.K.M. calculations for the dissociation of methylamine. The rate constants have values similar to those for acetaldehyde (5). Since CH_3NH_2 is of less general interest than hydrazine, these rate constants are not included here, but they are available upon request (1).

Calculated Results

In order to obtain R.R.K.M. values of the specific rate constants, k_ε, for hydrazine, a model of the molecule, models of the activated complex for reaction [1], and the critical energy for rupture of the $H_2N—NH_2$ bond are needed. The thermochemistry (8), vibrational frequencies (9*a*), and moments of inertia of N_2H_4 (9*b*) are relatively well known. However, despite several shock tube investigations (6, 7) of N_2H_4 dissociation, a reliable value for the high pressure pre-exponential factor is not available and other information was used to obtain an estimate of this pre-exponential factor. We combined calculated values of the equilibrium constant (NH_2, N_2H_4) with values of the NH_2 bimolecular combination rate constant to obtain the pre-exponential factors for the

			1499(2)		1.21	134.0

[a]The measured torsional frequency of 377 cm^{-1} was used for computation of density of states for N_2H_4 molecule. For the complex the torsional motion was treated as a free internal rotor with a symmetry number of 2.
[b]For both molecule and complex the three overall rotations were treated as adiabatic. The moments of inertia of the complex were obtained by extending the r(N—N) of hydrazine from 1.47 to 3.0 Å and assuming the complex to be planar.
[c]The N_2H_4 frequencies are from ref. 9.
[d]The three high sets of frequencies for the complexes are the same as for NH_2 (12). The two low sets were assigned to obtain the steric factors specified in the text.

unimolecular rate constant which served to define the model of the activated complex.

The thermochemistry of reaction [1] seems well established, and if a 1 kcal $mole^{-1}$ barrier is taken as the activation energy for association of NH_2 radicals, the critical energy for N_2H_4 decomposition becomes 56.8 kcal $mole^{-1}$. The overall rotational degrees of freedom of N_2H_4 were considered to be adiabatic, and all internal degrees of freedom were taken to be active. The torsional motion was treated as a vibration for the computation of the density of states for N_2H_4, although the barrier to internal rotation is only 2.5 kcal $mole^{-1}$ (9*b*). Representing the torsion as a vibration gives a lower limit to the density while using an internal rotor gives an upper limit. The latter would have increased the density of states by about a factor of 3; and hence, the rate constants would be lowered by this amount. For our purpose of estimating a range of rate constants, there is no point in considering anharmonicity (10) or centrifugal stretching (11) effects. The model for N_2H_4 is summarized in Table I.

The N_2H_4, NH_2 equilibrium constant was calculated from the model of N_2H_4, $D(H_2N—NH_2)$ and the molecular parameters of NH_2 (12). The combination reaction of NH_2 radicals has not been thoroughly studied but the available data (13, 14) indicate that it is a "typical" radical combination reaction with a rate constant between 0.1 and 0.01 of the collision number. The pre-exponential factors from these two assumed steric factors correspond to the models of activated complex which are listed in Table I. In terms of partition function ratios and critical energies, the unimolecular high pressure thermal activation rate constants are $k_\infty = 3.35 \times 10^{16} \exp(-56.8 \text{ kcal mole}^{-1}/RT)$ and $2.52 \times 10^{15} \exp(-56.8 \text{ kcal mole}^{-1}/RT)$ at 720 °K. The torsional degree of freedom of the complex was treated as a free rotation; the three overall rotations were taken to be adiabatic as in the molecule. The vibrational frequencies of the activated complex are those of 2 NH_2 radicals (12) with 4 additional low bending frequencies. The latter were arbitrarily adjusted to obtain the two pre-exponential factors defined by the values of the NH_2 combination rate constants. It could be argued that one of the overall rotational degrees of freedom should be active for both the complex and the molecule; this would merely lower the specific rate constants by about a factor of 2 (5).

The specific rate constants and distribution functions, $f(\varepsilon)$, of activated N_2H_4 molecules formed by NH_2 association were computed from standard equations (5) and are shown in Figs. 1 and 2. These rate constants must be matched against a collisional deactivation model and then averaged over the distribution function to obtain quantities (S/D, k_a) which can be compared to

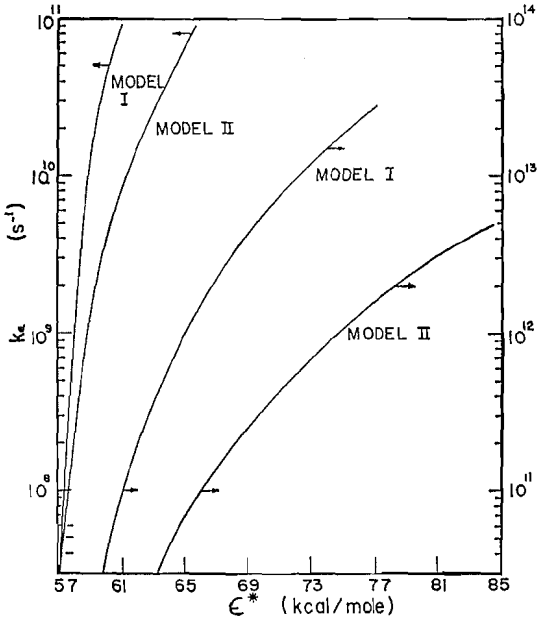

FIG. 1. Hydrazine R.R.K.M. specific rate constants for models I and II as a function of the energy in the molecule; $\varepsilon_0 = 56.8$ kcal mole^{-1}.

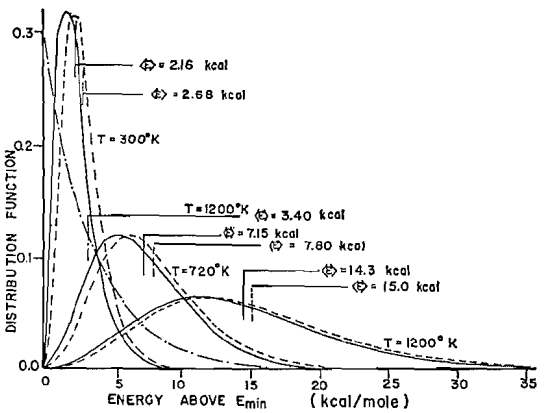

FIG. 2. Distribution functions of activated N_2H_4 molecules in chemical (reaction[1]) and thermal activation. The average energies are specified for each distribution function. –·–, thermal activation at 1200 °K; – – –, chemical activation model I (300, 720, 1200 °K); ——, chemical activation model II (300, 720, 1200 °K).

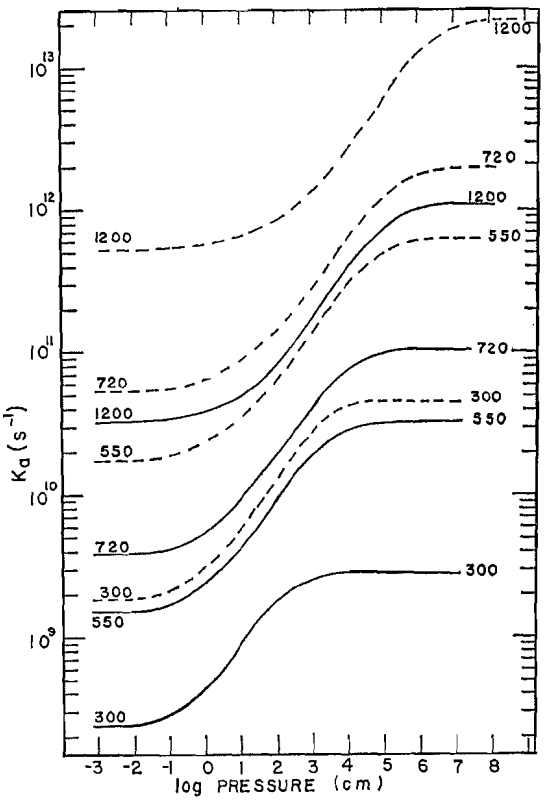

FIG. 3. Values of the chemical activation rate constants at various temperatures (°K) for model I (dotted lines) and model II (solid lines). The k_a values match the S/D values at the indicated pressures of Table II.

experiment. We have used a strong collision formulation with the appropriate equations (3, 5); the S/D results are listed in Table II, and the $k_a = \omega(D/S)$ values are plotted in Fig. 3. The k/k_∞ curves often used in thermal activation studies may be constructed (3) from the S/D values of Table II, i.e., $k/k_\infty = S/(S + D)$. Since some shock tube investigations employ a Kassel s parameter, these values were also extracted from the calculations. Kassel s values were obtained from the average energy of the reacting molecules at high pressure in thermal activation ($s' = \langle\varepsilon\rangle_r\dagger/RT$), which were $s' = 5.4$ and 5.0 at 720 °K and $s' = 6.3$ and 6.0 at 1200 °K for models I and II, respectively. These Kassel parameters were compared to those obtained by matching the shape of the Kassel and R.R.K.M. fall-off curves, and the values were quite similar, as would be expected (15).

Since the distribution functions of N_2H_4 in chemical activation depend upon the model of the association complex (3), the $f(\varepsilon)$ of Fig. 2 are slightly different for models I and II. The exact shape of chemical activation distribution functions is usually not very important. However, it is of interest for hydrazine because the average

		II	24.7	22.2	18.7	16.1	14.8	14.4	14.3

[a]A temperature independent collision cross section of 3.5 Å was used for the calculation of the collision frequency.
[b]$\langle\varepsilon\rangle_r$† is the average internal energy of the reacting molecules above ε_0 (56.8 kcal mole^{-1}).
[c]The average energy of the formed molecules for complex models (I) and (II) is 2.68 and 2.16 kcal mole^{-1} at 300 °K, 5.61 and 5.02 kcal mole^{-1} at 550 °K, 7.80 and 7.15 kcal mole^{-1} at 720 °K, and 15.0 and 14.3 kcal mole^{-1} at 1200 °K.

TABLE III

Reported and calculated Arrhenius rate constants for hydrazine dissociation

Reference	Arrhenius rate constant (s^{-1})	Conditions
(7)	$10^{13.0}$ exp (-54 kcal mole$^{-1}/RT$)	(970–1100 °K, 2.6–8 atm)[a]
(6*a*)	$10^{14.0}$ exp (-60 kcal mole$^{-1}/RT$)	(1100–1500 °K, 2.6–8 atm)[b]
(6*b*)	$10^{12.0}$ exp (-48 kcal mole$^{-1}/RT$)	(1370–1600 °K, 2.3–3.3 atm)[c]
(6*b*)	$10^{12.8}$ exp (-52 kcal mole$^{-1}/RT$)	(1270–1580 °K, 6.8–9.8 atm)[c]
Model I	6.72×10^{17} exp (-61.2 kcal mole$^{-1}/RT$)	1200 °K, ∞ pressure
Model II	3.23×10^{16} exp (-60.5 kcal mole$^{-1}/RT$)	1200 °K, ∞ pressure

[a]The rate under these conditions depended upon $[N_2H_4]$ and the [pressure]$^{1/2}$. The results were "corrected" to the high pressure limit and combined with data from ref. 6*a* to obtain the Arrhenius parameters.
[b]These results were not sufficiently complete for experimental determinations of Arrhenius parameters so the authors used 60 kcal as the activation energy in order to assign a pre-exponential factor.
[c]The experiments were done at constant density which corresponds to the two pressure ranges quoted. The Arrhenius parameters were obtained under conditions where chain reactions were believed to be negligible.

energies of formed molecules differ by about 0.5 kcal mole^{-1} which enhances the difference in k_ε since the broader $f(\varepsilon)$ goes with the higher k_ε values for the calculation of S/D ratios. The distribution functions also give the average energies of reacting molecules at the low and high pressure limits. The distribution function of reacting N_2H_4 molecules at the high pressure limit in the thermal activation system is the same as the distribution function of formed chemically activated molecules, reaction [1], at the same temperature. The difference in average energies of reacting molecules at the low and high pressure limits in thermal activation is 11.6 and 10.9 kcal mole^{-1} for models I and II, respectively. This energy difference at 1200 °K for the chemical activation is similar, 11.3 and 11.1 kcal mole^{-1}. These large values arise from the steep energy dependence of the rate constants and the broad 1200 °K distributions. These are the same factors which cause the large change in the values of the chemical activation rate constants with pressure shown in Fig. 3. Since the difference between the average energies for the two limiting pressures, $\langle\varepsilon\rangle_r^\infty - \langle\varepsilon\rangle_r^0$, decline with decreasing temperature (4.7 and 2.3 kcal mole^{-1} at 550 and 300° for model I), the ratio of k_a^∞ to k_a^0 also diminishes with temperature. However, even at room temperature the ratio is quite large, more than a factor of 10, due to the very steep dependence of k_ε upon energy in the energy range just above ε_0.

Comparison of Calculated Results to Experimental Data

The point of view adopted for these calculations was that our knowledge of radical combination rate constants was more reliable than the existing unimolecular decomposition data for N_2H_4. It is now interesting to compare the results from shock tube studies (6, 7) with the calculated predictions. Table III gives the Arrhenius parameters and shows serious disagreement between the calculated and experimental Arrhenius A factor. Diesen (14) seems to have directly shown that the primary process is reaction [1] and not the less endothermic formation of NH and NH_3, and even at the lower temperatures (1400 °K) the reaction was essentially second order at 0.15 atm pressure. The rate constant at 1400 °K and 0.15 atm was reported (14) as 3×10^3 s^{-1} but the accuracy of these values has been questioned (7). McHale studied the reaction at low temperatures and found that at 2.6–8 atm the rate depended upon the square root of the total pressure (mostly argon). A correction factor was applied to the measured rate constants to give rate constants at $P = \infty$, and these rate constants were combined with other high temperature data (6*a*) to obtain the first set of Arrhenius parameters listed in Table III. The recently reported rate constants of Michel and Wagner (6*b*) show a slight dependence upon gas density but the data are not of great accuracy. The Arrhenius parameters from their first study (6*a*) were merely assigned (see Table III) and are probably not reliable. It should be noted that the experimental rate constants of Table III are numerically about the same at 1200 °K but differ in their temperature coefficients.

The measured pressure dependence of the reaction and the low activation energies from most shock tube investigations point to the hydrazine decomposition reaction being in the

fall-off region even at 2–8 atmospheres of pressure. The calculated $k/k_\infty = S(S + D)$ values are in agreement with this. At 1200 °K and for 5 atm pressure of a *unit efficiency* gas, k/k_∞ is 0.018 and 0.12 for models I and II. Since argon was the actual experimental gas which has a collisional efficiency of ~0.1 (16), the experimental rates should be only 10^{-3} and 10^{-2} of the high pressure values of model I and II, respectively. Thus if the degree of fall-off is as great as outlined above, this explains the apparent discrepancy in the pre-exponential factors of Table III. It is worth noting that the calculated limiting low pressure activation energy at 1200 °K would be about 49 kcal/mole. The arguments of this paragraph indicate that the shock tube data do not provide compelling reasons for considering the N_2H_4 dissociation to be different from C_2H_6 (3) or C_2F_6 (16) dissociation[3] reactions. If future data are obtained which show that activated complex models with a tighter structure (smaller pre-exponential factor and smaller steric factor) are appropriate, then those models would not require the experimental data of Table III to be as far into the fall-off region as they presently appear.

Calculated R.R.K.M. unimolecular rate constants have been shown to satisfactorily describe a large variety of unimolecular reaction rate data (18, and recent papers by Rabinovitch) if proper models for the reaction are chosen. The arguments already presented indicate that our calculations for N_2H_4 should encompass the correct description of its unimolecular dissociation. Therefore, it should be possible to use the calculated results with some confidence. The calculations show (for either model) that at temperatures of 300 °K or more, pressures of 100 cm are needed to stabilize a large fraction of N_2H_4* formed by radical association. Most experiments have been done at considerably lower pressures, and reverse dissociation of N_2H_4* should have been important. From a practical point of view, stabilization of N_2H_4* produced by higher energy chemical activation reactions, such as $H + N_2H_3$, would be a slow and strictly pressure dependent reaction (19).

The combination reaction of NH_2 has been suggested in a variety (20) of photolysis and photosensitization studies of NH_3 and N_2H_4 but only a few attempts have been made to extract rate constants. In one such effort Hanes and Bair (13*a*) used a pulsed radio frequency discharge in ammonia and followed the NH_2 concentration by ultraviolet absorption spectroscopy. The data were originally discussed in terms of a simple bimolecular association process. The error of ignoring the NH_2 disproportionation reaction in this treatment was pointed out by Diesen (14)

$$[2] \qquad NH_2 + NH_2 \xrightarrow{k_d} NH_3 + NH \qquad \Delta H_R^\circ = -10 \text{ kcal/mole}$$

In Diesen's (14) shock tube study the rate constant for disproportionation was given as 2.5×10^{13} cc mole^{-1} s^{-1} (2000 °K) and k_d/k_c was estimated as 0.4. A reinvestigation by Salzman and Bair (13*b*) using room temperature NH_3 flash photolysis revealed that the rate of NH_2 disappearance was dependent on total pressure in the pressure range of 5–10 Torr. Extrapolation to low pressure gave the disproportionation rate constant as 0.46×10^{12} cc mole^{-1} s^{-1}, and extrapolation to high pressure gave 2.5×10^{12} cc mole^{-1} s^{-1} as the combination rate constant (k_c). These data give $k_d/k_c = 0.18$, which is a reasonable value by comparison with ethyl radical kinetics. However, some caution should be maintained because the high pressure extrapolation was made from data in the 1–10 Torr region which, according to Table II, are 2 orders of magnitude away from the high pressure limit. A recent investigation (21) of NH_2 kinetics used an ammonia glow discharge flow system as the NH_2 source. The reported k_d/k_c ratio was 1.0, but the absolute values of the rate constants seem impossibly low.

The pressure dependence of the rate of NH_2 combination found by Bair is in qualitative agreement with the calculated results. Further data are required before any discrimination can be made in favor of model I or II.

The decomposition of N_2H_4 was assumed to be a reaction similar to the decomposition of C_2H_6 or CH_3CHO for which R.R.K.M. calcula-

[3] C_2F_6 dissociation (17) has recently been treated by using a Gorin model for the activated complex to obtain a frequency factor of $\sim 5 \times 10^{17}$. The C—C distance was extended by nearly a factor of 4 relative to C_2F_6 which introduced a large centrifugal correction factor. Such a correction is not necessary, if the C—C distance is not extended so much and the high frequency factor is obtained from the large entropy contributions of low frequency bending vibrations, as was done in the N_2H_4* models of Table I.

tions have been done. It is instructive to compare the results from chemically activated C_2H_6 and CH_3CHO to those of Table II. Similar models should be used for the comparison, and we will compare models that most nearly resemble model I for N_2H_4. The easiest comparison is the half quenching pressures ($S/D = 1$) which are 1, 7, and 1400 Torr, at 300 °K for C_2H_6*, CH_3CHO* and N_2H_4*, respectively. In this series the critical energies are 85.3, 79.0, and 56.8 kcal, and the number of active degrees of freedom successively decline by 3 for each member. Detailed examinations of the relative values of sums and densities of states for these three reactions show that the increase in rate constant for N_2H_4 relative to CH_3CHO is due to both the lower critical energy (about a factor of 15) and to the smaller number of vibrational degrees of freedom. The vibrational frequencies for N_2H_4 are higher than those for CH_3CHO which also enhances the difference in rate constants for N_2H_4 relative to CH_3CHO. Although the models for C_2H_6, CH_3CHO, and N_2H_4 dissociation reactions are not strictly comparable, it is worth noting that CH_3CHO is the anomalous member of the series due to the fact that replacing 2 hydrogen atoms by 1 oxygen atom introduces sufficiently low frequencies in the CH_3CHO molecule, so that the density of states for CH_3CHO is nearly the same as for C_2H_6.

Electron spin resonance study of γ-irradiated ethyleneimine in the solid state[1]

D. CORDISCHI AND R. DI BLASI
Laboratorio di Chimica delle Radiazioni e Chimica Nucleare del C.N.E.N.
Istituto di Chimica Generale ed Inorganica, Università di Roma, Rome, Italy

Received October 18, 1968

The electron spin resonance (e.s.r.) study of the ethyleneimine in polycrystalline and glassy state shows that the radical  is formed by γ-irradiation at 77 °K. The features of the e.s.r. spectrum of this radical are discussed in terms of the isotropic and anisotropic hyperfine coupling constants of the hydrogen and nitrogen nuclei. The effects of bleaching the γ-irradiated sample with visible and ultraviolet light are also reported.

Various aliphatic amines have been studied by e.s.r. in an attempt to identify the paramagnetic species produced by γ- and ultraviolet (u.v.) irradiation in the solid state (1–4). The low melting points of these compounds make single crystal studies difficult. The published spectra have been obtained from irradiated polycrystalline samples. The anisotropic effects give rise to poorly resolved spectra which are generally difficult to interpret unambiguously. Only in a few cases are fairly clear spectra obtained.

In the present investigation the example of ethyleneimine, which gives a well resolved spectrum, is reported.

Experimental

Ethyleneimine (Fluka reagent) was purified by distillation and dried with a sodium mirror. Ethyleneimine-d_1 was prepared by exchange of ethyleneimine with D_2O. Its isotopic purity, checked by nuclear magnetic resonance, was better than 95%.

Spectrosil quartz tubes filled with about 0.1 g of the substance, were sealed under vacuum at 10^{-4} Torr. Samples were irradiated by γ-rays from a Co^{60} source at −196 °C with a dose rate of 0.23 Mrad/h. A high pressure mercury lamp was used for u.v. irradiation of the samples frozen in liquid nitrogen.

The e.s.r. spectra were recorded at 9.2 GHz using a Hilger and Watts Microspin spectrometer with a TE_{011} cylindrical cavity.

The measurements were performed at —196 °C by keeping the sample tubes in a quartz Dewar filled with liquid nitrogen, or at higher temperatures by using a variable nitrogen flow system.

Small samples of diphenyl picryl hydrazyl (DPPH) were used as g markers. The g value of DPPH was taken as 2.0036.

The field sweep calibration was carried out by a Mn^{2+} doped sample of MgO (5).

Results

Anhydrous ethyleneimine frozen at −196 °C gives an opaque crystalline matrix which after γ-irradiation shows a weak blue color. The product containing about 20% of water gives a transparent glass with an intense blue color after γ-irradiation. The e.s.r. spectrum, recorded at −196 °C, is practically the same in both cases and does not change from −196 to about −90 °C. The only difference is a narrowing of the line-width, from 8 G (peak to peak) at −196 °C to 5.8 G at about −100 °C.

The apparent intensity of the spectrum is of the same order of magnitude in the amorphous and crystalline samples and diminishes continuously with increasing temperature up to about −85 °C, where it disappears. A typical spectrum is reported in Fig. 1*a*. It consists of 5 lines with 30.0 G splitting and of 2 outer weak satellites; the measured g value is 2.0044 ± 0.0004. The spectrum of the deuterated compound (Fig. 1*b*) is practically identical, although slightly better resolved (line width of 5.2 G at −100 °C).

After bleaching the samples with visible or u.v. light the blue color disappears and the e.s.r. spectrum changes, as shown in Figs. 3*a* and 3*b*. The u.v. irradiation of ethyleneimine does not produce any e.s.r. signal without previous γ-irradiation.

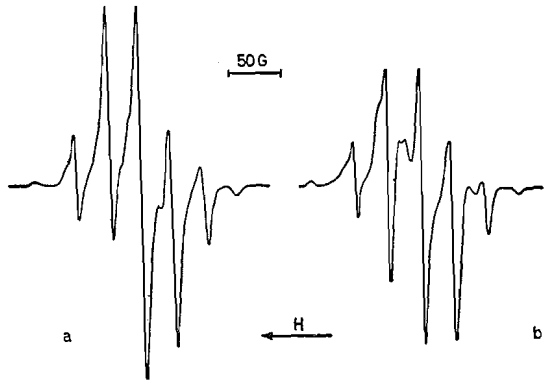

FIG. 1. Electron spin resonance spectra of ethyleneimine γ-irradiated at −196 °C; dose 1.5 Mrads; (*a*) undeuterated sample observed at −140 °C, (*b*) deuterated sample observed at −160 °C.

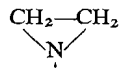
Discussion

The spectrum of Fig. 1*a* may be assigned to the



radical. The identical spectrum (Fig. 1*b*) obtained from the N-deuterated compound confirms this assignment. The relative intensities of the 5 lines are near to the theoretical pattern for 4 equivalent protons. The absence of α-protons and the spatial equivalence of the β-protons accounts for the good resolution.

An anisotropic nitrogen hyperfine interaction is expected for this kind of radical. However, at first order, the central line ($M_I = 0$) of the nitrogen hyperfine triplet is isotropic. The other two lines ($M_I = \pm 1$) have an angular dependence and are therefore broadened in a powder sample. Each of these lines is split into 5 components by the hyperfine interaction with the 4 equivalent protons, but only the central quintet is well resolved. An indication of the presence of the 2 unresolved external quintets is provided by the 2 satellite lines.

The anisotropy of the g factor is small, as shown from the linewidth of the quintet. This anisotropy accounts for the different distances of satellites from the central line and for their different broadening (6).

In order to support this interpretation, the theoretical spectrum for a radical where an anisotropic, axially symmetrical interaction with a nitrogen nucleus and an isotropic interaction with 4 equivalent protons are present, was calculated by an I.B.M. 7040 computer.

The method of calculation indicated by Vänngård and Aasa was followed (7). The values of hyperfine parameters for nitrogen were deduced from the data reported in literature, concerning similar radicals in monocrystals (8), while for proton splitting the experimental value was used. An axial g tensor with $\Delta g = 0.002$ and a Lorentzian line shape were also assumed.

Generally, radicals with the unpaired electron on nitrogen exhibit an almost axial hyperfine nitrogen tensor but a completely asymmetrical g tensor; therefore, our assumption about the latter parameter is only a rough approximation. However, on account of the small g anisotropy, the rather simple calculation relative to the axial case has been carried out.

The splitting between satellite lines is given by $2\,A_{\parallel}^{N} + 4\,a^{H}$, where $A_{\parallel}^{N}$ is the principal value of nitrogen coupling tensor parallel to the unpaired electron orbital, and a^{H} is the isotropic coupling constant with protons.

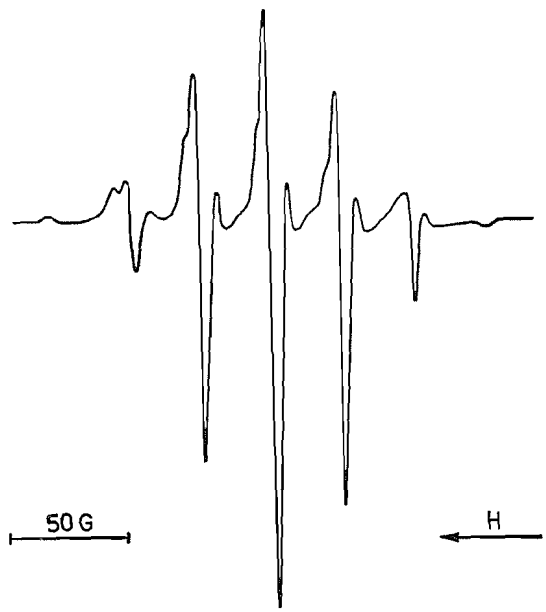


FIG. 2. Calculated spectrum of  radical in polycrystalline matrix. Values of spin Hamiltonian parameters used for calculation: $g_{\parallel} = 2.003$, $g_{\perp} = 2.005$, $A_{\parallel}^{N} = 33$ G, $A_{\perp}^{N} = 5$ G, $a^{H} = 30$ G, $(\Delta H)_{m.s.} = 2$ G. $g_{\parallel}$ and $g_{\perp}$, $A_{\parallel}^{N}$ and $A_{\perp}^{N}$ are the principal values of g and hyperfine coupling tensor; a^{H} is the isotropic coupling constant with protons. $(\Delta H)_{m.s.}$ is the linewidth at maximum slope.

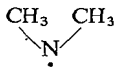
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

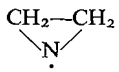
As can be seen, the calculated spectrum, shown in Fig. 2, approximates to the experimental ones satisfactorily.

A similar pattern may be observed in the e.s.r. spectrum of the



radical. The spectrum of this radical, shows a main septet with a splitting of 28.0 G and an external satellite line (1, 2). This spectrum has been interpreted in terms of equal, isotropic, proton and nitrogen splitting constants (1). However, the asymmetry of the spectrum and the variation of the line shape indicate an anisotropic nitrogen interaction.

The u.v. irradiation of ethyleneimine does not produce any e.s.r. signal without previous γ-irradiation; this suggests that the radical formed by bleaching comes from the



radical. The spectra of Fig. 3*a* and 3*b* are too complex for a straightforward interpretation. The spectrum of the undeuterated sample (Fig. 3*a*) is less resolved but shows the same components as the other spectrum. Their pattern does not change with temperature until they disappear.

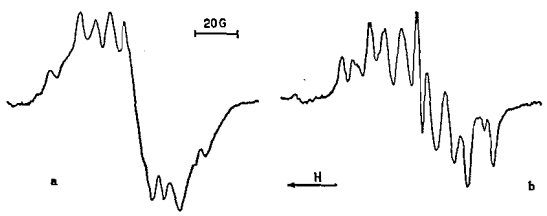


FIG. 3. Electron spin resonance spectra of ethyleneimine γ-irradiated at −196 °C; dose 1.5 Mrads, after 10 min u.v. irradiation; (*a*) undeuterated sample observed at −160 °C, (*b*) deuterated sample observed at −120 °C.

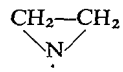
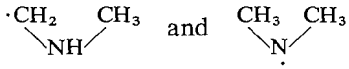
Tentatively these spectra may be assigned to the $CH_2—CH—NH$ or $CH_2—N—CH_2$ radicals. On account of delocalization of the unpaired electron, these allyl-like radicals may have proton and nitrogen splittings lower than that of the



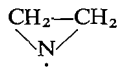
radical.

Unlike ethyleneimine, the dimethylamine gives, by γ-irradiation at −196 °C, two types of radicals (2)



It has also been found that on standing at −196 °C the latter radical converts, by an intramolecular migration of a hydrogen atom, to the former, and by u.v. irradiation the opposite conversion occurs.

In some experiments with the dimethylamine we confirmed these results and we found that these conversions can be done several times with only a small decrease in intensity. The intramolecular migration of hydrogen atom, which probably also takes place in the photolysis of



would provoke the ring opening. This fact would explain the lack of reversibility encountered in this case.

The blue color of the irradiated samples is not apparently related to the observed paramagnetic species; no signal from the trapped electron is displayed. The effect of γ-irradiation on ethyleneimine in the solid state is to cleave the N—H bond, in agreement with the reaction of this compound with radicals in the gaseous phase (9, 10).

Molecular complexes: effects of multiple equilibria on calculated absorptivities and association constants

C. C. THOMPSON, JR.

Department of Chemistry, Memphis State University, Memphis, Tennessee 38111

Received December 23, 1968

Simulated absorbance data have been used to demonstrate the effects of 2:1 molecular complexes on formation constants and absorptivities calculated for 1:1 donor–acceptor interactions. By systematic variation of associated spectral, thermodynamic, and concentration parameters for these systems, it is found that previous attempts to describe effects produced by the presence of more than one stoichiometric complex species are inadequate. Formation constants and absorptivities calculated with the assumption of a simple 1:1 interaction may be increased or decreased by the occurrence of higher order complexes. These variations depend largely on the ratios of complex absorptivities, relative formation constants, and the range of donor concentrations. Equations incorporating 5 of the experimental variables permit the prediction of formation constants and absorptivities to a high degree of accuracy.

Introduction

In recent years considerable attention has been given to spectroscopic studies of organic molecular complexes involving interactions between electron donor and acceptor molecules (1–3). By means of a variety of mathematical treatments (1, 4), equilibrium constants and absorptivities for these complexes have been calculated from spectral data collected at one or more wavelengths. Among the possible interactions between donor (D) and acceptor (A) molecules we may consider

[1] $$A + D \overset{K_1}{\rightleftharpoons} C_1$$

[2] $$A + 2D \overset{K_2}{\rightleftharpoons} C_2$$

and

[3] $$D + C_1 \overset{K_3}{\rightleftharpoons} C_2$$

where C_1 and C_2 are 1:1 and 2:1 complexes respectively. The corresponding equilibrium constants are given as

[4] $$K_1 = \frac{[C]_1}{([A]_0 - [C]_1 - [C]_2)([D]_0 - [C]_1 - 2[C]_2)}$$

and

[5] $$K_2 = \frac{[C]_2}{([A]_0 - [C]_1 - [C]_2)([D]_0 - [C]_1 - 2[C]_2)^2}$$

Here $[A]_0$ and $[D]_0$ refer to the initial concentrations of acceptor and donor, respectively. Equilibrium constants for the simultaneous (eq. [2]) and consecutive (eq. [3]) mechanisms are very simply related by the expression

$$K_3 = K_2/K_1$$

Although the possible occurrence of higher order complexes has been suggested by several authors (5–8), attempts at complete quantitative treatments of systems containing complexes of more than one stoichiometry have met with only limited success. If, as is usually the case, the presence of a possible 2:1 complex is ignored and computations are carried out for the 1:1 species only, the calculated equilibrium constant, hereafter referred to as K^*, and absorptivity, a_C^*, will differ from the "true" values of K_1 and a_{C_1}. Linear plots obtained from the Benesi–Hildebrand (9) and related procedures generally have been accepted as evidence that higher order complexes are not present. Recently, this conclusion has been shown to be incorrect (8). In addition, equilibrium constants which show a considerable wavelength dependence have been reported (9–13). Variations of K with wavelength cannot be explained by the presence of isomeric 1:1 complexes or by "contact" charge-transfer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

absorptions. It has been pointed out that the presence of 2:1 or other higher order complexes could lead to wavelength variations in equilibrium constants calculated for a 1:1 interaction (8, 14, 15). However, the magnitude of this expected wavelength dependence and the experimental conditions that favor its occurrence have not been fully investigated. Hayman (14) has derived an expression to relate K^* to the true equilibrium constants and absorptivities for 1:1 and 2:1 complexes. Using the terminology of eqs. [1]–[3], Hayman's equation becomes

$$[6] \qquad K^* = K_1 - K_2 a_{C_2}/K_1 a_{C_1}$$

An independent treatment by Jurinski (14) yields a different relationship

$$[7] \qquad K^* = K_1 + K_2[D]_0$$

Since all variables in eqs. [6] and [7] are positive quantities, the two expressions predict reverse trends in K^*. The variations of K^* predicted by these equations have not been verified.

The purpose of this paper is to study systematically the behavior of systems containing both 1:1 and 2:1 complexes by means of computer-generated absorbance data. The principal objectives are threefold: to determine which factors produce significant effects on the calculated absorptivities and equilibrium constants of molecular-complex systems, to evaluate the direction and magnitude of these effects, and to be able to predict K^* and $a_C{}^*$ if the necessary empirical information is available. Two distinct advantages make it highly desirable to use simulated rather than actual experimental data. First, the parameters which define the system under consideration are known exactly and may be varied at will. Secondly, the simulated data are essentially free from experimental errors, unavoidable in real systems, but which frequently make precise analyses impossible.

Methods of Computation

If it is assumed that variables such as temperature, solvent, and path length are suitably controlled, 8 additional factors may be listed which could influence calculated equilibrium constants and absorptivities. These parameters include K_1, K_2, a_{C_1}, a_{C_2}, absorptivities of free donor and acceptor (a_D and a_A), and initial concentrations of D and A ($[D]_0$ and $[A]_0$). The simulated data presented in this paper were calculated by a computer program employing the method outlined below. Computations were carried out on an IBM 1620 computer.

The first phase of the method involved generation of absorbance data using specific values of the above parameters as input information.

Step 1

Assuming initially that $K_2 = 0$, the concentration $[C]_1$ is calculated from eq. [4] which may be rearranged to give

$$[8] \quad [C]_1 = [K_1([A]_0 + [D]_0) + 1 - (K_1{}^2([A]_0 - [D]_0)^2 + 2K_1([A]_0 + [D]_0) + 1)^{\frac{1}{2}}]/2K_1$$

Step 2

First approximations for the equilibrium concentrations of A and D are computed from the relations, $[A] = [A]_0 - [C]_1$ and $[D] = [D]_0 - [C]_1$.

Step 3

Introducing the selected value of K_2, $[C]_2$ is calculated from the relation

$$[9] \qquad [C]_2 = K_2[D][C]_1/K_1$$

Step 4

$[C]_1$ is recalculated by replacing $[A]_0$ and $[D]_0$ of eq. [8] with $[A]'$ and $[D]'$, defined as $[A]' = [A]_0 - [C]_2$ and $[D]' = [D]_0 - 2[C]_2$.

Step 5

Equilibrium concentrations of A and D are computed from the correct expressions

$$[A] = [A]_0 - [C]_1 - [C]_2$$

and

$$[D] = [D]_0 - [C]_1 - 2[C]_2$$

Step 6

A new value of $[C]_2$ is calculated from eq. [9] and steps 3–5 are repeated until $[C]_1$ and $[C]_2$ are unchanged for successive iterations.

Step 7

The simulated absorbance, A_m, is computed from eq. [10] using a convenient path length, b, and selected absorptivities for the various species.

$$[10] \quad A_m = b(a_{C_1}[C]_1 + a_{C_2}[C]_2 + a_A[A] + a_D[D])$$

In phase two, the generated absorbance values and the initial concentrations of A and D are used

to calculate 1:1 equilibrium constants (K^*) and absorptivities (a_C^*) by a modification of the Benesi–Hildebrand treatment (9) which is outlined below. Specific details of this method have been described previously (10).

Results and Discussion

Approximately 300 different combinations of the 8 input parameters were processed. These combinations were selected systematically in order to determine the combined as well as the separate effect of the various parameters. The total ranges over which the input parameters were varied are listed in Table I. These limits are representative of the usual values encountered in experimental donor–acceptor systems.

TABLE I

Range of input parameters

Parameter	Range	Parameter	Range
K_1	0.2– 50.0	a_A	0.0 –200.0
K_2	0.0– 100.0	a_D	0.0 – 10.0
a_{C_1}	200.0–3600.0	$[A]_0$	0.001– 0.1*
a_{C_2}	0.0–5000.0	$[D]_0$	0.01 – 0.6*

*Concentrations are expressed in moles l^{-1}.

Numerous checks of the results from the absorbance generator program demonstrate conclusively that the method converges to correct values for $[C]_1$ and $[C]_2$. For K_1 and K_2 of the same order of magnitude, convergence to within 0.01% of the absolute concentrations generally requires from 3 to 6 iterations. If K_2 exceeds K_1 by a factor of 10 or more, oscillation may sometimes occur. In this event the calculation is terminated and the offending set of parameters is discarded.

Characteristics of Systems Containing 1:1 and 2:1 Complexes

Results of typical calculations from simulated absorbance data are given in Table II. Columns 2–9 contain "true" equilibrium constants, absorptivities, and concentrations which were used as input parameters. Values of K^* and a_C^* obtained from the method outlined above by treating the absorbance data as though only the 1:1 equilibrium existed, are tabulated in columns 10 and 11.

With reference to specific items in Table II the following generalizations regarding the effects of 2:1 complexes may be inferred[1].

(*a*) When only a 1:1 complex is present, the computational method converges to correct values for K_1 and a_{C_1}. These results are unaffected by absorbance due to free donor and acceptor or by changes in the initial concentrations, $[A]_0$ and $[D]_0$ (lines 1–3).

(*b*) For fixed values of K_1 and K_2 the calculated K^* and relative deviations in absorptivity are dependent only on the *ratio* a_{C_2}/a_{C_1} and not on the absolute magnitudes of these parameters (lines 4 and 5). If absorption bands of the 2 complexes maintain a constant ratio throughout a given wavelength range, the calculated K^* will be numerically incorrect, but will show no wavelength dependence in this region.

(*c*) K^* is greater than K_1 for low a_{C_2}/a_{C_1} ratios, but decreases to considerably smaller values as the absorptivity ratio increases. The behavior of a_C^* follows a reverse pattern (lines 6–10).

(*d*) For a given K_1 and absorptivity ratio, K^* decreases as K_2 increases (lines 11–14).

(*e*) The relative importance of a 2:1 complex is diminished sharply as the absolute value of K_1 increases (lines 15–17). Thus, other factors being equal, the effects of 2:1 species will be minimal in systems containing very strong 1:1 interactions.

(*f*) A 100-fold increase in $[A]_0$ has little effect on K^* and a_C^* (lines 12 and 18).

(*g*) An increase in donor concentration results in a pronounced increase in K^* and an associated decrease in a_C^* (lines 19–21).

(*h*) For non-zero absorptivities of free donor and acceptor, K^* and a_C^* differ only slightly from the case in which $a_A = a_D = 0$ (lines 22 and 23).

It is interesting to note that even a relatively small amount of a 2:1 complex can cause large variations in K^* and a_C^*. This effect can be seen readily by considering the ratio of concentrations of 2:1 to 1:1 complexes for a given set of parameters. From eq. [9], $[C]_2/[C]_1 = K_2[D]/K_1$. Using the parameters of line 10 of Table II, the $[C]_2/[C]_1$ ratio varies from 0.0095 to 0.199 as the total donor concentration is increased from 0.01 to 0.20 mole l^{-1}. Even with these small ratios,

[1]The values reported in Table II were selected from the approximately 300 separate computations in order to illustrate the conclusions noted here. Therefore, each item in this discussion has been fully substantiated through numerous additional calculations.

there is a 68% decrease in K^* and a 315% increase in $a_C{}^*$ compared to the values of K_1 and a_{C_1}.

As noted previously, eq. [6] predicts that K^* will always decrease with the occurrence of 2:1 complexes, whereas eq. [7] permits only an increase. However, the results of the present work show that K^* and $a_C{}^*$ may be either *greater than or less than* the true K_1 and a_{C_1} depending upon the specific combination of parameters at each wavelength. Of the 8 parameters studied, 5 are seen to produce significant changes in K^* and $a_C{}^*$. These 5 include the equilibrium constants, K_1 and K_2, absorptivities of the complexes, a_{C_1} and a_{C_2}, and concentrations of the donor. Since for most real systems it is unlikely that a_{C_2}/a_{C_1} will be constant over a wide spectral range, a wavelength dependence of K^* would be expected.

Prediction of Absorptivities and Equilibrium Constants

Applying the conditions, $a_A = a_D = 0$ and $[D]_0 \gg [A]_0$, to eqs. [1] and [2] and choosing a path length of 1 cm, the absorbance is given by

$$A_m = a_{C_1}[C]_1 + a_{C_2}[C]_2$$

and upon substituting for $[C]_2$

$$[11] \quad A_m = [C]_1 a_{C_1}\left(1 + \frac{[D]_0 K_2 a_{C_2}}{K_1 a_{C_1}}\right)$$

Also, since $[D]_0 \simeq [D]$ and $[A]_0 = [A] + [C]_1 + [C]_2$

$$[12] \quad [A]_0[D]_0 = [D]_0([A] + [C]_1 + [C]_2)$$
$$= [C]_1\left(\frac{1}{K_1} + [D]_0 + \frac{K_2[D]_0{}^2}{K_1}\right)$$

Using the present symbols, the Scott (16) form of the Benesi–Hildebrand treatment for a simple 1:1 interaction is

$$[13] \quad \frac{[A]_0[D]_0}{A_m} = \frac{1}{K_1 a_{C_1}} + \frac{[D]_0}{a_{C_1}}$$

For the simultaneous occurrence of both 1:1 and 2:1 complexes eq. [12] can be divided by eq. [11] to yield

$$[14] \quad \frac{[A]_0[D]_0}{A_m} = \frac{\frac{1}{a_{C_1}}\left(\frac{1}{K_1} + [D]_0 + \frac{K_2[D]_0{}^2}{K_1}\right)}{1 + \theta}$$

where θ equals $[D]_0 K_2 a_{C_2}/K_1 a_{C_1}$. If θ is less than unity, the expression can be approximated as

$$[15] \quad \frac{[A]_0[D]_0}{A_m} = \frac{1}{a_{C_1}}\left[\left(\frac{1}{K_1} + [D]_0 + \frac{K_2[D]_0{}^2}{K_1}\right)\sum_{r=0}^{n}(-\theta)^r\right]$$

which can be rearranged to give

$$[16] \quad \frac{[A]_0[D]_0}{A_m} = \frac{1}{K_1 a_{C_1}} + \frac{[D]_0}{a_{C_1}}\left[1 + \frac{K_2[D]_0}{K_1} + \left(1 + \frac{1}{K_1[D]_0} + \frac{K_2[D]_0}{K_1}\right)\sum_{r=1}^{n}(-\theta)^r\right]$$

Designating the term in brackets as σ, eq. [17] is obtained.

$$[17] \quad \frac{[A]_0[D]_0}{A_m} = \frac{1}{K_1 a_{C_1}} + \frac{[D]_0\sigma}{a_{C_1}}$$

Thus, the Scott equation, eq. [13], is a special case of eq. [17] in which $\sigma = 1$ for a simple 1:1 interaction. It is important to note that σ is a function of the 5 parameters which were found to have the greatest effect on K^* and $a_C{}^*$.

In the standard experimental procedure for studying donor–acceptor interactions, spectral measurements are carried out for several solutions of varying donor concentration. Since σ is a function of $[D]_0$, it will vary throughout the series of solutions in which different donor concentrations are used. If we select one of the initial donor concentrations, say $[D]_{0_i}$, then for this solution eq. [17] becomes

$$[18] \quad \frac{[A]_0[D]_{0_i}}{A_{m_i}} = \frac{1}{K_1 a_{C_1}} + \frac{[D]_{0_i}\sigma_i}{a_{C_1}}$$

Equation [18] can be rearranged to give

$$[19] \quad a_{C_1} = \frac{A_{m_i}}{[A]_0}\left(\frac{1}{[D]_{0_i}K_1} + \sigma_i\right)$$

For a different donor concentration within the series, say $[D]_{0_j}$, and with a fixed acceptor concentration, $[A]_0$, another equation of exactly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the same form as eq. [18] can be written. Rearranging this second equation to give

$$K_1\left(a_{C_i} - \frac{A_{m_j}\sigma_j}{[A]_0}\right) = \frac{A_{m_j}}{[A]_0[D]_{0_j}}$$

and substituting for a_{C_i} from eq. [19], we have

$$[20] \quad K_1 = \frac{[D]_{0_i}A_{m_j} - [D]_{0_j}A_{m_i}}{[D]_{0_i}[D]_{0_j}(A_{m_i}\sigma_i - A_{m_j}\sigma_j)}$$

For calculations in which the 2:1 complex is ignored, it is implicitly assumed that $\sigma_i = \sigma_j = 1$. In that case, eq. [20] will not give K_1, but will yield the value of K^* instead.

$$[21] \quad K^* = \frac{[D]_{0_i}A_{m_j} - [D]_{0_j}A_{m_i}}{[D]_{0_i}[D]_{0_j}(A_{m_i} - A_{m_j})}$$

Upon dividing eq. [21] by eq. [20], we obtain

$$[22] \quad \frac{K^*}{K_1} = \frac{A_{m_i}\sigma_i - A_{m_j}\sigma_j}{A_{m_i} - A_{m_j}}$$

By dividing the numerator and denominator of the right hand side of eq. [22] by A_{m_i} and letting $\xi_{ij} = A_{m_j}/A_{m_i}$, the expression may be solved for K^* to give

$$[23] \quad K^* = K_1\left(\frac{\sigma_i - \xi_{ij}\sigma_j}{1 - \xi_{ij}}\right) = K_1\beta_{ij}$$

where

$$\beta_{ij} = (\sigma_i - \xi_{ij}\,\sigma_j)/(1 - \xi_{ij})$$

A similar procedure can be followed to obtain a relationship for predicting $a_C{}^*$. Again, if the 2:1 complex is ignored, $\sigma_i = 1$ and eq. [19] will become

$$[24] \quad a_C{}^* = \frac{A_{m_i}}{[A]_0}\left(\frac{1}{[D]_{0_i}K^*} + 1\right) = \frac{A_{m_i}}{[A]_0}\left(\frac{1}{[D]_{0_i}K_1\beta_{ij}} + 1\right)$$

Upon dividing eq. [24] by eq. [19] and rearranging, one gets

$$[25] \quad a_C{}^* = \frac{a_{C_i}(1 + K_1\beta_{ij}[D]_{0_i})}{\beta_{ij}(1 + K_1\sigma_i[D]_{0_i})}$$

Thus, K^* and $a_C{}^*$ can be predicted from eqs. [23] and [25], respectively, using values of σ_i, σ_j, and β_{ij} computed from specific combinations of input parameters.

An immediate problem in the evaluation of σ involves the number of terms which must be included in the summation of $(-\theta)^r$ in eq. [16]. Equation [6] was obtained by terminating the series at $n = 1$ and disregarding all but first-power terms of $[D]_0$. However, as mentioned earlier, eq. [6] predicts only negative deviations from K_1. By extending the series to $n \geq 2$ both positive and negative deviations of K^* and $a_C{}^*$ are permitted. Moreover, in the derivation of eq. [16] it has been assumed that θ is less than unity. A comparison of the exact reciprocal of eq. [11] with the approximate summation in eq. [16] shows that termination of the series at $n = 1$ introduces large errors if θ is greater than 0.2. By expanding the summation to $n = 5$, the approximation will be reasonably good up to a value of $\theta = 0.5$; if θ exceeds 1, the entire approximation breaks down.

Columns 11–15 of Table II give K^* predicted by eqs. [6] and [7] as well as K^* and $a_C{}^*$ predicted by eqs. [23] and [25] from values of σ computed with $n = 5$. The close correlation between calculated equilibrium constants and absorptivities, and those predicted by eqs. [23] and [25] illustrates the importance of the 5 parameters included in the evaluation of σ. The absence of a wavelength dependent term in eq. [7] precludes its use for predicting wavelength variations of K^*.

In summary, the presence of even small amounts of 2:1 complexes can have substantial effects on equilibrium constants and absorptivities computed for 1:1 interactions. The ratio of absorptivities for the 2 complex species, their respective association constants, and the range of donor concentrations are the determining factors for the observed variations. These factors are closely interrelated so that a full assessment of their combined effect requires a more elaborate mathematical analysis than has been attempted heretofore.

Studies of the phosphorodiamidates of alkali metals

Y. N. SADANA
Department of Chemistry, Laurentian University, Sudbury, Ontario

Received November 8, 1968

Phosphorodiamidates of lithium, rubidium, and cesium have been prepared and characterized. The infrared spectra and the X-ray powder diffraction patterns of these and the previously known sodium and potassium salts have been recorded and discussed.

Canadian Journal of Chemistry, 47, 2613 (1969)

Introduction

Even though phosphorodiamidic acid, $HPO_2(NH_2)_2$ has been known since 1894 (1), work on its salts has been rather scanty and only a few phosphorodiamidates have been reported. The earlier work on phosphorodiamidates has been recently reviewed (2, 3). We have now repeated the preparation of the already known sodium (4) and potassium (5) salts and have characterized also the phosphorodiamidates of lithium, rubidium, and cesium. The infrared (i.r.) spectra and the powder diffraction patterns of the new and the previously known alkali metal phosphorodiamidates have been recorded.

Experimental

General

Chemicals used were of C.P. Grade. $POCl_3$ was freshly distilled before use. Liquid ammonia was used directly from a cylinder (Matheson) without further purification. Lithium, rubidium, and cesium hydroxides were purchased from Alfa Inorganics.

Infrared spectra were taken on a Beckman IR-10 spectrophotometer. The spectra were run in Nujol or hexachlorobutadiene mulls or in KBr discs. KRS-5 plates were used for aqueous solutions. Ultraviolet (u.v.) spectra were taken on a Bausch and Lomb SP600 spectrophotometer and X-ray powder diffraction patterns using a Phillips X-ray unit. The samples were charged in Lindemann glass capillary tubes (0.3 and 0.5 mm diameter).

The phosphorodiamidates were prepared by reacting $OP(NH_2)_3$ with an alkali metal hydroxide. $OP(NH_2)_3$ was prepared from freshly distilled $POCl_3$ and liquid ammonia (6), and purified by the method of Klement and Koch (4). $OP(NH_2)_3$ was characterized from its i.r. spectrum and X-ray powder diffraction pattern and by chemical analysis.

Anal. Calcd. for $OP(NH_2)_3$: N, 44.2; P, 32.95. Found: N, 43.8; P, 33.5.

As an example, the preparation of the lithium salt is described in detail.

$OP(NH_2)_3$ (0.237 g) was dissolved in water (20 ml) in 150 ml beaker. To this a solution of LiOH (0.060 g) in water (20 ml) was added. The solution was heated on a water bath (60–65 °C) until the evolution of ammonia had ceased (about 4 h). The solution was then filtered into a 600 ml beaker. Alcohol was added to precipitate the salt, which separated as an oily liquid. The oily liquid changed into a crystalline mass when left aside in a refrigerator.

Chemical Analysis

Nitrogen was determined by the Micro-Kjeldahl method (7). Phosphorus was determined either as phosphomolybdate (8) or by the pH titration method (9). Analyses of the compounds prepared are shown in Table I.

Results and Discussion

The chemical reaction of $OP(NH_2)_3$ with alkali metal hydroxides can be represented by

$$OP(NH_2)_3 + M^+ + OH^- \xrightarrow{H_2O} M^+ + PO_2(NH_2)_2^- + NH_3\uparrow$$

where M = Li, K, Rb, and Cs in the present work, and M = Na in ref. 4.

The mechanism of the reaction is not immediately obvious but it seems reasonable to assume that $OP(NH_2)_3$ first adds on a molecule of water to form ammonium phosphorodiamidate, which is then decomposed

$$OP(NH_2)_3 + H_2O \rightleftharpoons NH_4^+ + PO_2(NH_2)_2^-$$

$$NH_4^+ + M^+OH^- \rightleftharpoons M^+ + H_2O + NH_3\uparrow$$

The compounds are white crystalline solids, highly soluble in water. The aqueous solutions show a strong absorption band at 215 mμ. The X-ray powder diffraction patterns of the phosphorodiamidates are complex, indicating crystal structures of low symmetry. The three strongest lines of each salt and their corresponding visual intensities are given in Table II.

A literature search showed that the i.r. spectra of only zinc (10), barium (11), and silver phosphorodiamidates (12) had been reported by previous workers. In the present study, the i.r. spectra (400–4000 cm^{-1}) of the hydrated phosphorodiamidates of alkali metals and of anhydrous sodium phosphorodiamidate were examined and are recorded in Table III. The assignments of the principal bands in the table are based on the assignments made for silver phosphorodiamidate by Steger and Frei (12). The anion $PO_2(NH_2)_2^-$ has C_{2v} symmetry and possesses 9 fundamentals, out of which 8 are i.r. active (13).

The vibrations involving the PO_2 group are stretching vibrations (ν_{as} and ν_s), a bending vibration (δPO_2), and wagging (ρ_w), twisting (ρ_t) and rocking (ρ_r) vibrations. The last two, viz. ρ_t and ρ_r, would most probably occur below 400 cm^{-1}, the region not covered in the present study. The absorption band at 1680 cm^{-1} is assigned to the bending mode of H_2O and is absent from the spectrum of anhydrous sodium phosphorodiamidate. The asymmetric PO stretch, ν_{as}, assigned to the strong absorption band at 1200 cm^{-1} shifts to a lower frequency (1170 cm^{-1}) in aqueous solution. Similar shifts for the asymmetric PO stretch have been noticed in the i.r. spectra of $H_2PO_2^-$ and $(CH_3O)_2PO_2^-$ ions (14) and ascribed to hydrogen bonding. PN stretching vibrations were, for some unknown reason, not observed in the spectrum of anhydrous sodium phosphorodiamidate.

In a recent paper, the relation of phosphorus–oxygen stretching vibrations to the bond length, bond order, and the force constant of the PO bond has been discussed and important correlations developed (15). PO stretching vibrations in amidophosphates occur at higher wavenumbers than in orthophosphates and this is indeed as expected, because the PO bond order would be expected to increase in the series PO_4^{3-}, PO_3X^{2-}, $PO_2X_2^-$, and POX_3, (15). A comparison of the phosphorus–oxygen stretching vibrations in the fluoro-, chloro-, and amido-derivatives of phosphates is shown in Table IV. It is seen that in fluoro- and chlorophosphates, the successive replacement of oxygen by halogen atoms increases the PO vibration steadily to a maximum value in POX_3 (X = F, Cl) i.e. the PO stretch in POX_3 occurs at a higher wavenumber than the PO stretches in $PO_2X_2^-$ and PO_3X^{2-} (X = F, Cl). In amido-derivatives, on the other hand, the replacement of the first two oxygens by NH_2 groups increases the PO vibrations, but the replacement of the third oxygen does not affect the PO vibration or, if at all, lowers it slightly.

The bonding in phosphates is interesting because of the possibility of phosphorus 3d orbital participation. Commonly used simple valence bond structures for PO_4^{3-}, PO_3X^{2-}, $PO_2X_2^-$, and POX_3 give values of 1.25, 1.33, 1.5, and 2 respectively for the PO bond orders; however, Cruickshank (16) has suggested that in orthophosphates and in substituted phosphates in which phosphorus is tetrahedrally coordinated, the $3d_{x^2-y^2}$ and $3d_{z^2}$ orbitals of phosphorus may take part in d_π–p_π bonding.

On this basis, an average PO bond order of 1.5 is obtained for the orthophosphate ion. In substituted phosphates the prediction of bond order would depend on the nature of the substituent ligand and the extent to which, if any, it takes part in π-bonding with the phosphorus

atom. If the substituent atom does not take part in π-bonding, the d_π–p_π bonding would then involve phosphorus and oxygen atoms only, giving bond orders of 1.67 for PO_3X^{2-}, 2.00 for $PO_2X_2^-$, and 3.00 for POX_3. If, however, the substituent ligand is a good Lewis base, it may take an active part in π-bonding with phosphorus reducing the PO π-bond order and hence the effective PO bond order. In amido-phosphates, the substituent NH_2 group has a lone pair on nitrogen, which is also a good Lewis base, and therefore the PO bond orders would be expected to be less than those mentioned above for the substituted phosphates, in which the substituent was assumed not to take part in π-bonding.

Robinson (15) has shown that for a number of oxygen compounds of phosphorus, the force constant of the PO bond can be estimated from stretching vibrations, by using the Lehmann average rule (17) and the appropriate formula. He has also established an empirical equation relating bond order (n) to force constant. Following his procedure, PO bond order values of 1.80, 1.69, and 1.61 are obtained for $PO(NH_2)_3$, $PO_2(NH_2)_2^-$, and $PO_3(NH_2)^{2-}$ respectively. Assuming, as suggested by Cruickshank (16), that a total of only two π-bonds can be formed by phosphorus, the PN bond orders (n) then are: $PO(NH_2)_3$, $n = 1.40$; $PO_2(NH_2)_2^-$, $n = 1.31$; $PO_3(NH_2)^{2-}$, $n = 1.17$. Thus the averaged PN vibrational frequency and the PN bond force constant would be expected to decrease in the series $PO(NH_2)_3$, $PO_2(NH_2)_2^-$, and $PO_3(NH_2)^{2-}$. In $PO(NH_2)_3$ and $PO(NH_2)_2^-$ the averaged PN stretches, calculated by using Lehmann's rule (17), are respectively 804 and 750 cm^{-1} and the corresponding force constants (dyn/cm) are 3.671×10^5 and 3.194×10^5, which are in the expected order. In $PO_3(NH_2)^{2-}$ the PN stretch has been assigned by Steger (18) to a medium intensity band at 810 cm^{-1} which is higher than that expected from bond order considerations. However, in the spectrum reported by Steger, there is an unassigned band at 700 cm^{-1}, and if this band were to be assigned to the PN stretch, a force constant of 2.783×10^5 dyn/cm would be obtained for the PN bond in $PO_3(NH_2)^{2-}$. By making this assignment, the PN stretches and the PN bond force constants in amidophosphates would follow the pattern expected from the estimated bond orders. The band at 810 cm^{-1} in the published spectrum could possibly be reassigned as ρ_ω NH_2 vibration.

Hydration of the potassium ion in the gas phase: enthalpies and entropies of hydration reactions $K^+(H_2O)_{n-1} + H_2O = K^+(H_2O)_n$ for $n = 1$ to $n = 6$

S. K. Searles and P. Kebarle
Chemistry Department, University of Alberta, Edmonton, Alberta

Received January 31, 1969

The thermodynamic constants $\Delta H^0_{n-1,n}$, $\Delta G^0_{n-1,n}$, and $\Delta S^0_{n-1,n}$ for the reaction $[n-1, n]$: $K^+(H_2O)_{n-1} + H_2O = K^+(H_2O)_n$ proceeding in the gas phase were measured for $n = 1$ to $n = 6$. The equilibria were studied in a reaction chamber containing water vapor at pressures from 0.3 to 6 Torr and at temperatures from −11 to 390 °C. The potassium ions were produced by thermionic emission in a filament chamber and then were equilibrated with the water vapor in the reaction chamber. The relative ionic concentrations were detected with a mass spectrometer. The experimental $\Delta H^0_{n-1,n}$ values are compared with potential energy differences for the reactions $[n-1, n]$ based on simple electrostatic model calculations. The electrostatic calculations produce values in fair agreement with the experimental results. The $\Delta S^0_{0,1}$ calculated on basis of statistical mechanics and energies obtained with the electrostatic model is in very good agreement with the experimental result.

Canadian Journal of Chemistry, **47**, 2619 (1969)

Introduction

In a series of papers published over the past few years (1–5), we have tried to show that important information on the solvation of ions can be obtained by measurement of reaction equilibria involving gaseous ions and molecules of a given "solvent" vapor. An example of such an equilibrium is the gas phase reaction $[n-1, n]$ involving the clustering of water molecules around the potassium ion.

$$K^+(H_2O)_{n-1} + H_2O = K^+(H_2O)_n \qquad [n-1, n]$$

If the equilibrium concentrations of the clustered ions can be measured, and the pressure of the solvent vapor is known, then one can evaluate the equilibrium constant $K_{n-1,n}$. Such equilibrium constants, determined at different temperatures can then be used in Van't Hoff plots for the evaluation of $\Delta H_{n-1,n}$ and thus also $\Delta S^0_{n-1,n}$. The method relies on mass spectrometric determination of the relative ionic concentrations. The primary ions are created by various methods, generally ionizing radiation in a reaction chamber (the ion source) containing the vapor of the solvent. The reaction chamber has a small leak through which the gases and ions bleed out into a high vacuum system where the ions are captured by electric fields and subjected to mass analysis and detection. Conditions in the ion source are so selected that sufficient time is allowed for the establishment of the clustering equilibrium. The measured, mass separated ion currents are assumed proportional to the concentration in the ion sources. Results of the comprehensive investigations of the systems $H^+(H_2O)_n$ (1) and $NH_4^+(NH_3)_n$ (2) have been published, as well as some experiments describing competitive solvation of the proton by methanol and water (3) and of the NH_4^+ ion by water and ammonia (4). The hydration of halide negative ions (F^-, Cl^-, Br^-, and I^-) has also been studied (5). For some time we had wanted to investigate the hydration of the alkali ions. The reasons for this are quite obvious. Since the alkali ions are spherical, one might expect that their hydration energies should be most amenable to classical calculations based on ion dipole interactions. Thus comparisons of experiment with simple theory would be meaningful. The alkali ions have also played an important role in the study of ionic hydration. For example, attempts to evaluate single ion hydration energies, like those of Latimer, Pitzer, and Slanski (6) have been based on the hydration energies of the alkali halide salts. Having succeeded in measuring some hydration energies of the halide ions we became particularly interested in the alkali ions, since interesting comparisons of the hydration of positive and negative ions should be possible when data on both systems become available.

In order to measure hydration equilibria involving the alkali ions one must first find a way of creating these ions in the gas phase under conditions where thermal and clustering equilibrium could be achieved. Ionization by fast

electrons, protons, or α particles, which we had used before, could not be applied, since no compounds containing the alkali atoms and having sufficient vapor pressure could be found. Therefore, a method depending on thermionic emission of positive ions from a filament painted with an alkali salt was developed. The arrangements used are described in the experimental part.

Experimental

Creation of Potassium Ions under Clustering Equilibrium Conditions

The mass spectrometer used for the detection of the potassium hydrates was the instrument formerly connected to a proton generator. This "proton beam" mass spectrometer has been described elsewhere (1) so that no discussion of the gas handling and mass analysis part of the apparatus will be given here. Instead of the proton source, a thermionic source was installed. This new source, and the tests which were made to establish whether clustering equilibrium was established, will be described below.

It is well known that an abundant supply of alkali ions can be obtained by thermionic emission from a heated filament coated with a suitable salt containing the desired ion. Thermionic production is a standard method used in mass spectrometric isotopic determinations of a number of elements. However, for the measurement of hydration equilibria one must meet some special conditions. The ions must be ultimately brought in the presence of water vapor of pressures in the Torr range. Furthermore the ions must be in thermal equilibrium with the surrounding water vapor. Since thermionic emission can be obtained only at elevated temperatures, one must separate the thermionic source from the reaction chamber whose temperature is to be controlled independently. The arrangement used in the present work is shown in Fig. 1. The platinum filament (*5*) coated with the alkali salt preparation is contained in the filament housing (*5a*). The filament housing is attached to the top of the reaction chamber (*1*) and communicates with it by means of an orifice in a polished nichrome disc (*5d*). The disc is in electrical contact with the reaction chamber. A ceramic insulator (*5b*) provided electrical and thermal insulation between the filament housing and the reaction chamber. A positive potential (relative to the reaction chamber) is applied to the filament, filament housing (*5a*), and repeller (*5c*). This field causes the positive ions to drift through the water vapor (which is present in both reaction chamber and filament housing) to the entrance orifice (*5d*) of the reaction chamber. The ions passing through the orifice and into the field free reaction chamber gradually lose their excess energy and become thermalized. Ions diffusing to the exit slit and escaping into the vacuum region are captured by electric fields, accelerated, and then magnetically mass analyzed.

The reaction chamber could be heated by means of electrical heaters placed in heater wells milled out in the chamber block. In the low temperature runs the ion source was cooled by circulating a refrigerated mixture of water and ethylene glycol through channels drilled in the reaction chamber block.

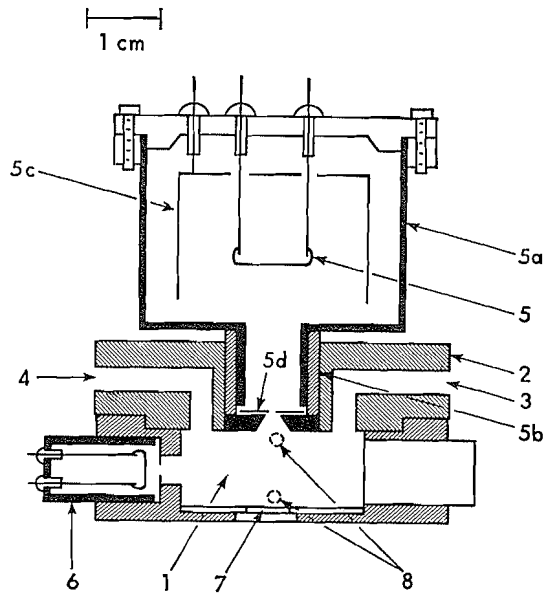

FIG. 1. Reaction chamber for hydration reactions of potassium ions. (*1*) Reaction chamber milled out of solid stainless block; (*2*) chamber lid carrying channels for (*3*) vapor supply and (*4*) pressure measurement; (*5*) potassium ion source consisting of platinum ribbon filament coated by suitable potassium salt (axial filament); (*5a*) filament housing; (*5b*) ceramic insulator between filament housing and reaction chamber; (*5c*) repeller; (*5d*) radiation shield and orifice to reaction chamber backed by copper plate for heat dissipation, diameter of orifice 1.5 mm; (*6*) alternative potassium ion source (right angle filament); (*7*) ion exit slit leading to ion accelerating electrodes and mass analysis; (*8*) thermocouple wells. The reaction chamber also incorporates heaters placed in heater wells which are not shown in the figure.

The coating of the platinum filaments used for the thermionic emission of the potassium ion was a fused mixture of salts which was prepared according to the procedure described by Kunsman (see ref. 7).

To prove that the relative ionic concentrations were not affected by the presence of the filament, whose temperature was about 600 °C and thus some 200–600° higher than the temperature of the reaction chamber, 3 different filament arrangements were used. In the first arrangement the axial filament (*5*) was mounted at only 3 mm distance from the orifice (*5d*). The orifice was also large (5 mm diameter). In later experiments the orifice was closed down to 1.5 mm diameter. A third set of experiments was done with the alternative potassium source (*6*) which was mounted to the side of the reaction chamber such that the ions entering and leaving the reaction chamber were at right angles. A comparison of the results is shown in Fig. 4 which gives the Van't Hoff plots of the equilibrium constants. It can be seen that the equilibrium constants agree for all arrangements so long as the reaction chamber temperature is high. The equilibrium constants (see $K_{2,3}$ Fig. 4) obtained with the larger orifice and the axial filament mounted close are lower than the results obtained with the small orifice

and with the right angle filament. This indicates that with the large orifice the effective temperature was higher than the chamber wall temperature measured by the thermocouples. The agreement between the results with the smaller orifice and the right angle filament indicates that with these arrangements the results are not affected by thermal gradients. All further work was done with the axial filament and the small orifice since that geometry gave better sensitivity than the right angle filament. Moving the axial filament further away to the position shown in Fig. 1 produced no change in the observed equilibrium constants (see Fig. 4). As a final test the temperature of the filament was changed by varying the electric power supplying the filament. A change from 22 to 14 W left the equilibrium constants unchanged even when the reaction chamber was in the low temperature range, where the effect of thermal gradients would be most noticeable.

Since an electric field is applied which causes the potassium ions to drift from the filament to the entrance orifice of the reaction chamber, one must show that the ions do have time to reach thermal equilibrium in the field free reaction chamber. To examine this point, the potential between the filament and the reaction chamber was changed. Variation of the electric field strength[1] from 10 to 400 V/cm left the equilibrium constants unchanged even at the lowest reaction chamber pressures (0.4 Torr) used for the equilibria determinations. (These experiments were done at 58 °C.) The usual electric field strength employed was 100 V/cm. The agreement between the determinations with the axial and right angle filaments also suggests that the ions are thermalized. Qualitative calculations (8) based on Wannier's equation also indicate that the excess translational energy of the ions entering the reaction chamber is low and that it is rapidly dissipated through collisions in the reaction chamber.

Results

In Figs. 2 and 3 some representative plots of $K_{0,1}$ and $K_{5,6}$ vs. water pressure are shown. The equilibrium constants $K_{n-1,n}$ were evaluated from the equation

$$K_{n-1,n} = \frac{I_n}{I_{n-1}p}$$

where I_n and I_{n-1} are the measured ion intensities of the ions $K^+(H_2O)_n$ and $K^+(H_2O)_{n-1}$, and p is the directly measured water pressure in Torr. The assumption is made that the measured ion intensities are proportional to the equilibrium ion concentrations in the reaction chamber and that the proportionality constants are identical. The plots in Figs. 2 and 3 illustrate the temperature range (385 to −11 °C) and the pressure range covered in the experiments.

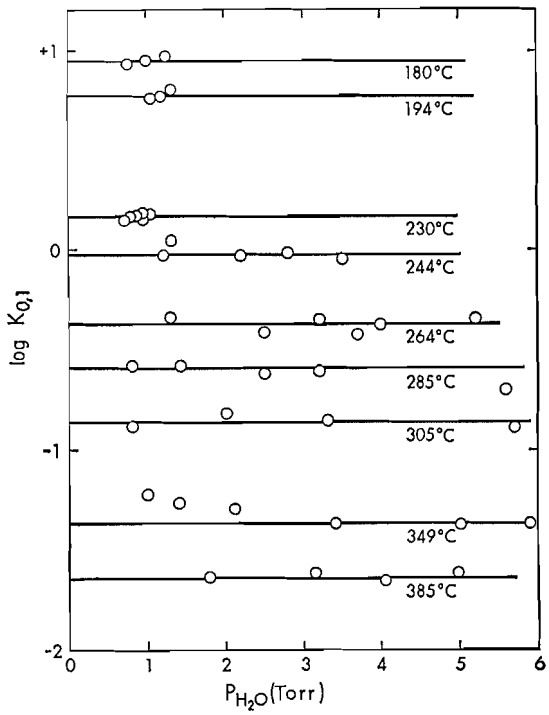

FIG. 2. Plots of $K_{0,1}$ as a function of pressure and temperature of the reaction chamber. Plots illustrate observed constancy of K with water pressure and temperature range covered in experiments. (Standard state for K as given in these plots is 1 Torr.)

Van't Hoff plots of the data are shown in Fig. 4 and the $\Delta H_{n-1,n}$ values obtained from least square fits are given in Table I, together with the values for $\Delta G^0_{n-1,n}$ and $\Delta S^0_{n-1,n}$.

TABLE I

Experimental thermodynamic values for the gas phase reactions: $K^+(H_2O)_{n-1} + H_2O \rightleftarrows K^+(H_2O)_n$ $[n-1, n]$

*At standard state 1 atm. The ΔS values are for temperatures in the temperature range in which each reaction was studied (see Fig. 4). They also are approximately true for 300 °K. The ΔG values are for 298°.

†Constants for the equation $\log (K_{n-1,n}) = (A/T \times 10^3) - B$, data for water pressure in Torr.

[1]The electric field strength quoted above was obtained by dividing the voltage by the distance between the filament and the orifice. Since the electrode geometry is not that of 2 parallel planes, the actual field strength is variable and, for the axial filament in Fig. 1, decreases as the orifice is approached.

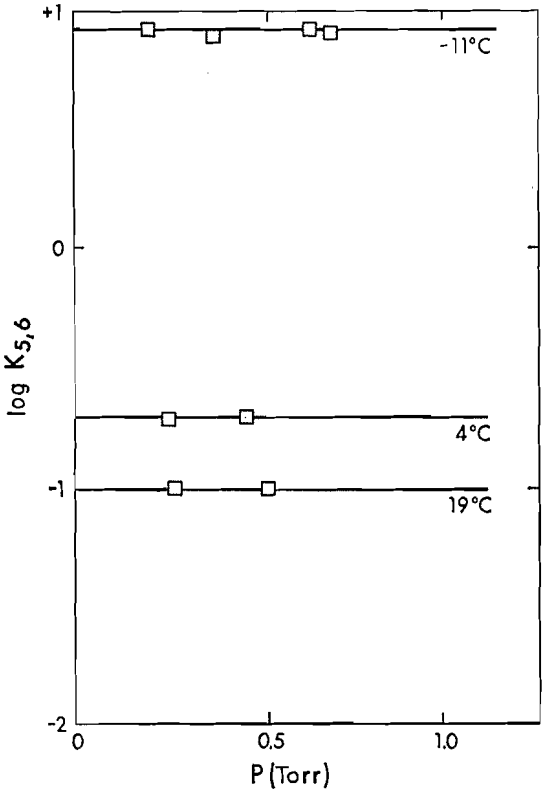

FIG. 3. Plots of $K_{5,6}$ as a function of pressure and temperature of the reaction chamber. Plots illustrate observed constancy of K with water pressure and temperature range covered in experiments. (Standard state for K as given in these plots is 1 Torr.)

The data given in Table I allow the evaluation of the approximate relative equilibrium cluster concentrations over a range widely exceeding the experimental conditions. The relative concentrations given in Fig. 5 illustrate one such calculation made for a temperature of 300 °K. A logarithmic scale was used for the pressure in order to accommodate a wider pressure range. It is interesting to note that the potassium ion is still monohydrated at water pressures as low as 10^{-6} Torr. The simple method by which the calculations of the relative concentrations are made is described in a previous publication (1).

The equilibrium constant $K_{0,1}$ has been obtained in earlier work by Chupka (9). The possibility for determining this equilibrium constant occurred to Chupka while he was measuring the dissociation energies of complex gaseous halide ions. To produce the ions K^+ and $K^+(H_2O)$ he passed water vapor at a pressure of 2×10^{-3} Torr through an oven which was coated with KCl and heated to 570 °C. The resulting ions were detected mass spectrometrically. The value obtained in this manner was $K_{0,1} = 1.2$. The present measurements extend only to 385 °K. However, a reasonably accurate extrapolation can be obtained by means of the Van't Hoff plot constants A and B given in Table I. The extrapolated value obtained in this manner is $K_{0,1} = 0.93$ (both constants are for standard state 1 atm). The very close agreement between Chupka's and the present $K_{0,1}$ is probably fortuitous, considering the widely different experimental conditions. Also Chupka's constant was obtained at a single water pressure which was not directly measured but estimated.

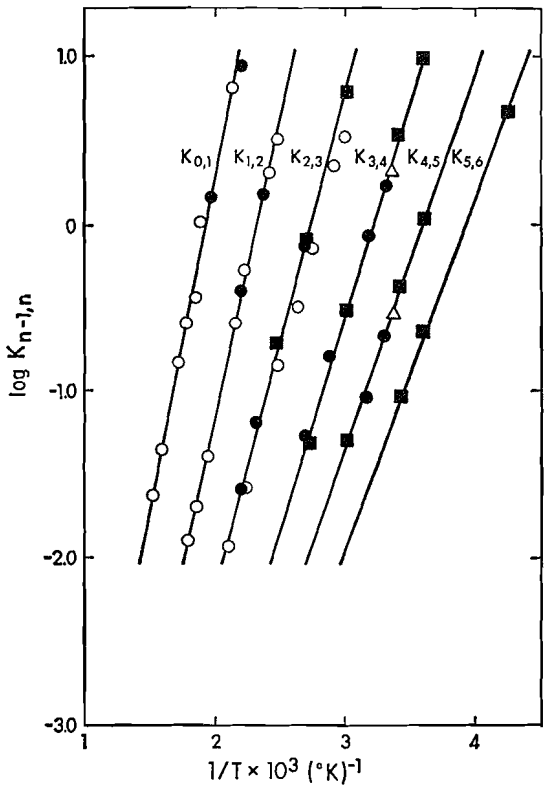

FIG. 4. Van't Hoff plots of equilibrium constants $K_{n-1,n}$. Data illustrate also variation of $K_{n-1,n}$ with different spatial arrangement of filament described in experimental part. ○, axial filament close to reaction chamber and large (5 mm) entrance to reaction chamber; ■, axial filament close to reaction chamber and small (1.5 mm) entrance to reaction chamber; △, axial filament with increased distance from reaction chamber and small (1.5 mm) entrance; ●, right angle filament.

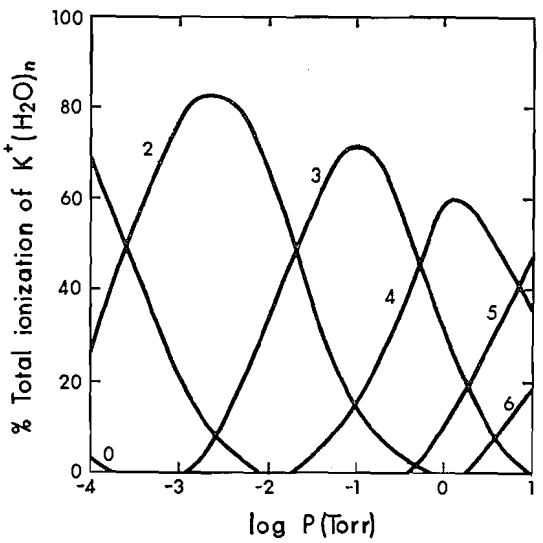

FIG. 5. Equilibrium abundances of $K^+(H_2O)_n$ clusters at different water pressures and 300 °K. Abundances calculated on basis of experimental data by using straight line extrapolation of the Van't Hoff plots in the regions not directly covered by experiment.

Calculations and Comparisons with Experimental Results

Electrostatic Calculations of the Potential Energies of the Complexes $K^+(H_2O)_n$ and Comparison with the Experimental Enthalpy Changes[2]

Many electrostatic calculations of the potential energy changes for attachment of water molecules to ions have been made in the past. In particular, the potential energy of $K^+(H_2O)_6$ (relative to ion and water molecules at infinity) has been calculated by Garrick (10) and that for $K^+(H_2O)_4{}^+$ has been calculated by Muirhead-Gould and Laidler (11). Unfortunately the energies for the other potassium clusters are not available. In order to compare the experimental $\Delta H_{n-1,n}$ with predictions made on the basis of electrostatic attractions we calculated the potential energies of the clusters $K^+(H_2O)_n$ for $n = 1$ to $n = 6$ on the basis of the following models and equations. The total potential energy E_n for a cluster consisting of the potassium ion and n water molecules was expressed by the equation

$$E_n = E_{DIP} + E_{POL} + R_{DIP} + R_{EL}$$

where E_{DIP} is the energy due to ion – permanent dipole attractions, E_{POL} the energy of ion – induced dipole attraction, R_{DIP} is the repulsion of the permanent dipoles, and R_{EL} is the repulsion of the electronic charge clouds of the potassium and oxygen atoms. A point charge model was used for the permanent dipole of the water molecule. The hydrogen atoms were assumed to carry each +0.33 electronic charges (located at the position of the H nuclei) while the oxygen atom carried −0.66 charges located at the O nucleus. The HOH angle in water was taken as 105° and the OH distance as 0.97 Å. The point charge model and other features of the calculation are similar to those used by Doyne and Caldwell (12). The ion – induced dipole attraction energies E_{POL} were calculated on basis of the atomic polarizabilities 0.6 $Å^3$ for oxygen and 0.44 $Å^3$ for hydrogen (13) assumed to be located in the center of the respective atoms. For clusters with $n > 2$ a number of structures are possible. We assumed in all cases structures in which the distances of all oxygen atoms to the potassium ion were equal. The structure for $n = 3$ was of trigonal and planar symmetry. The structure selected for $n = 4$ was tetrahedral, the structure for $n = 5$ was a trigonal bipyramid, and the structure for $n = 6$ was an octahedron. The potassium ion was located in the center, while the water molecules were at the corners of the polyhedra mentioned above. The water molecules were so oriented that the potassium ion was lying on the extension of the bisector of the HOH angle.

The potential energy terms E_{DIP}, E_{POL}, and R_{DIP} for the complex $K^+(H_2O)$ were evaluated for a range of K^+—OH_2 distances by substitution of the above mentioned values in the appropriate equations (8). The numerical computations were performed with an IBM 360 computer. These results are summarized in Fig. 6. The dipole repulsion terms R_{DIP} for $n = 1$ to $n = 6$ and a range of distances were also evaluated with the computer. These results are shown in Fig. 7. The last term R_{EL} in the equation for the total energy E_n accounts for the electronic repulsion between the ion and the water molecules. For this term one uses generally a potential dependence of the form A/R^a where A is a constant, R is the distance, and the power a has a value somewhere between 6 and 12. Neither A nor a is known for the potassium–water pair;

[2]The computer calculations are due to only one of the authors (S.K.S.). These calculations are described in greater detail in ref. 8.

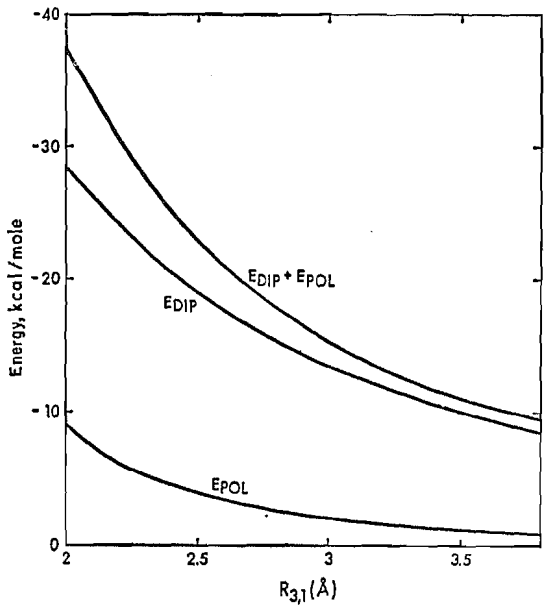

FIG. 6. Plot of calculated electrostatic potential energies for singly charged positive ion – water molecule complex in function of $R_{3,1}$, the distance from the oxygen nucleus to the center of the positive ion. E_{DIP} = ion–dipole attraction; E_{POL} = ion–induced dipole attraction.

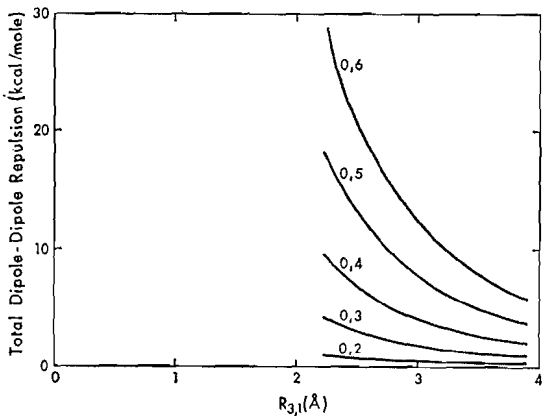

FIG. 7. Plot of dipole–dipole repulsion energies for water molecules around positive ion as functions of $R_{3,1}$, the distance from the oxygen nucleus to the center of the positive ion, 0,n refers to the repulsion of n water molecules around the ion. Geometries of complexes given in text.

however, approximate values could have been selected on the basis of experimentally determined repulsion potentials for the pair Ar—Ne. Since we were more interested in the change of E_n with n rather than in the absolute values, we chose to determine A by setting the (minimized) value for E_1 (K^+—OH_2) equal to the experimental value $\Delta H_{0,1}$. The value of $a = 12$ was used in this calculation. The value for A determined in this way was $A = 3.3 \times 10^5$ kcal/mole^{-1} Å^{12}. R refers to the distance between the potassium and oxygen atom nuclei. The total energies E_n were then evaluated as functions of the distance R. Plots of E_1 and E_6 are shown in Fig. 8. The energy minima E_n^0 in these plots correspond to the total potential energy of the clusters.

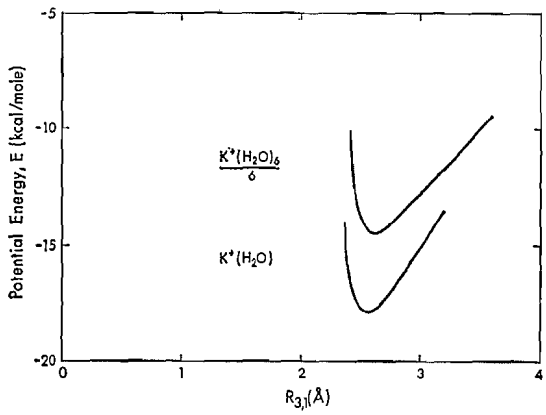

FIG. 8. Plot of calculated potential energy of clusters $K^+(H_2O)$ and $K^+(H_2O)_6$ relative to potassium and water molecules at infinity. The potential energy of $K^+(H_2O)_6$ has been divided by 6 in order to fit on the same scale.

Some calculations were made in which the H_2O molecules in the clusters were rotated around the bisector of the HOH angle. The positions of maximum and minimum energy were found to differ by only a fraction of a kcal. The effect of this rotation was therefore not considered further.

The calculated $E^0_{n-1,n} = E_n^0 - E_{n-1}$ are compared with the experimental $\Delta H_{n-1,n}$ values in Fig. 9. Before considering the meaning of Fig. 9 it is of some interest to compare the results of the present calculations with the quoted calculations of Garrick (10) and Muirhead-Gould and Laidler (11).

Garrick used a point dipole model for the water molecule. Otherwise his approach was very similar except for the ion – oxygen atom electron charge repulsion term for which Garrick used a dependence to the ninth power of the

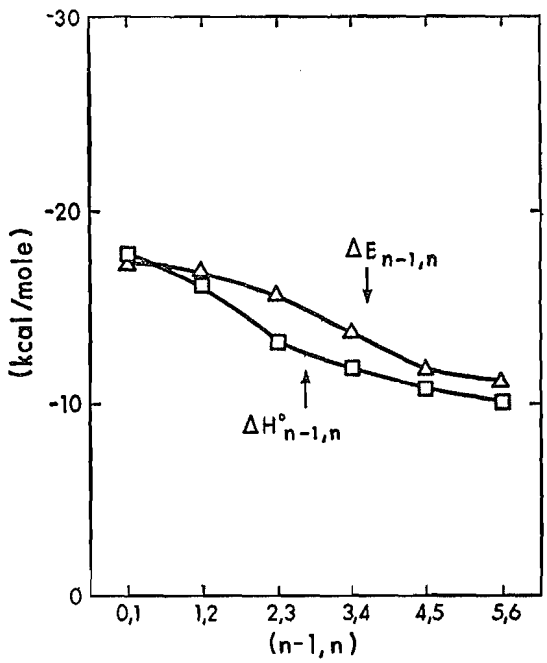

FIG. 9. Comparison of calculated potential energy differences $\Delta E_{n-1,n}$ for reactions $(n-1, n)$ and experimentally determined enthalpy changes, $\Delta H_{n-1,n}$.

radius i.e. AR^{-9}. Garrick used a value for A which was obtained from Lennard–Jones calculations for inert gas repulsions, and a minimization of the total energy. Garrick also included in his calculation a term for the electronic repulsion between water molecules. For the hexahydrate ($n = 6$) Garrick's results gave R_{EL} as +18 kcal/mole and $E_{DIP} + E_{POL} + R_{DIP} = -102$ kcal/mole and the total potential energy $E_6 = -84$ kcal/mole. In comparison the values from this work are +19 kcal/mole for the R_{EL} energy and −86 kcal/mole for the total E_6.

The calculations of Muirhead-Gould and Laidler (11) also involved a point dipole model. These authors did calculations on the $K^+(H_2O)_4$ ion, but unfortunately their results for this ion were presented as a total of a cycle dealing with the heat of hydration of the potassium ion. However, the individual energy contributions to the cycle were given for the ion $Rb^+(H_2O)_4$. Since the ionic radius of Rb is only 0.16 Å larger than the radius of K^+, one would expect the electrostatic energy of formation of $Rb^+(H_2O)_4$ to be slightly smaller than the energy of formation of $K^+(H_2O)_4$. The total potential energy for $Rb^+(H_2O)_4$ by Laidler's calculations is −61 kcal/mole while the corresponding energy for $K^+(H_2O)_4$ by the present calculations is −66 kcal/mole.

On the whole we may conclude that the present calculations give results which are similar to previous calculations based on the electrostatic model and should thus be fairly representative of the predictions of the simple electrostatic theory. The plot in Fig. 9 compared the calculated values $\Delta E^0_{n-1,n}$ with the experimentally determined enthalpy differences. It can be seen that the calculation gives values which qualitatively agree with the experimental results. In comparing the results more closely it is apparent that the $-\Delta H^0_{n-1,n}$ values decrease initially ($n-1,n$ = 1,2; 2,3; and 3,4) considerably more rapidly than the $\Delta E^0_{n-1,n}$ values. The decrease in the electrostatic values is due to dipole–dipole repulsion. Thus dipole–dipole repulsions alone do not seem adequate to explain the initial decrease of the binding energies. Since in initial interactions the primary solvation shell is very uncrowded, the repulsions of the induced dipoles and the electronic repulsions between the water molecules (which were neglected in the electrostatic calculation) are also not likely to provide an explanation for the discrepancy. Thus more recent calculations (14) including these repulsion terms also fail to reproduce the rapid initial drop off in the $\Delta H_{n-1,n}$ terms. A reasonable explanation for the rapid initial drop off would be to invoke a screening effect of the cationic charge by the lone pair oxygen electrons as suggested by Magnusson (15). The presence of the lone pair oxygen electrons in the vicinity of the potassium atom should be due to a certain small amount of covalent (dative bonding) between the oxygen lone pair electrons and empty orbitals of the potassium ion. This covalent effect should be stronger in sodium and lithium. Experimental results for these ions, to be published in the near future (14), confirm this expectation.

The Entropy Changes: $\Delta S^0_{n-1,n}$

The electrostatic calculations described in the previous section are also of help in the comparison of the measured entropy changes $\Delta S^0_{n-1,n}$ (Table I) with theoretical predictions. Thus the entropy change $\Delta S^0_{0,1}$ for the attachment of one water molecule to the potassium ion can be evaluated with fairly good accuracy by standard

equations from statistical mechanics. The total entropy change is

$$\Delta S_{0,1} = \Delta S_{tr} + \Delta S_{rot} + \Delta S_{vib}$$

The translational entropy change which is by far the most important term is readily evaluated by means of the Sackur Tetrode equation

$$\Delta S_{tr} = \frac{3}{2} R \ln \frac{M_1}{M_2 \cdot M_3} \frac{3}{2} R \ln T + 2.311$$

where M_1, M_2, and M_3 are the molecular weights of $K^+(H_2O)$, H_2O, and K^+ respectively. Substituting for $T = 570$ °K one obtains $\Delta S^0_{tr} = -36.8$ e.u. The temperature 570 °K corresponds to the average in the temperature range of the Van't Hoff plot from which $\Delta H_{0,1}$ and thus also $\Delta S_{0,1}$ was obtained (see Fig. 4).

To evaluate the rotational entropy change one needs the moments of inertia of the water molecule and the $K^+(H_2O)$ complex. The moments of inertia of water $I_x = 1.91$, $I_y = 1.02$, and $I_z = 2.94 \times 10^{-40}$ g cm^2 are well known. The moments of inertia for the complex were evaluated on the basis of the $K^+—OH_2$ distance of 2.6 Å obtained from the electrostatic calculations in the previous section, and the distances and bond angle of the water molecule. The moments of inertia were found to be equal to: $I_x = 1.91$, $I_y = 1.47$, and $I_z = 1.49 \times 10^{-40}$ g cm^2. Substitution of these values in the equation

$$\Delta S_{rot} = \tfrac{1}{2} R \ln \{(I_x I_y I_z)_2 / (I_x I_y I_z)_1\}$$

leads to $\Delta S_{rot} = 9$ e.u.

To calculate the vibrational entropy change we assume that the vibrations of the water molecule are the same before and after the formation of the complex. In this case the vibrational entropy change is due to 3 new vibrations in the complex. The first of these is a stretching vibration in which the potassium and water molecules are treated as two mass points. The frequency of this vibration was evaluated as $\nu_1 = 8.47 \times 10^{12}$ s^{-1} from the electrostatic potential energy calculation of the $K^+(H_2O)$ complex of the preceding section (see Fig. 8) and the standard equations relating the potential energy to the force constant and thus to the frequency.

The two other assumed vibrations were due to torsional oscillations of the water molecule as a whole around its center of mass. In one oscillation the K, O, and H atoms remain in the same plane, in the other, the O atom moves in the plane perpendicular to the plane.

The potential energy for these motions was evaluated from the electrostatic model and led to the frequencies $\nu_2 = 1.6 \times 10^{13}$ and $\nu_3 = 1.03 \times 10^{13}$ s^{-1}. The corresponding entropies were then obtained from the standard equation for vibrational entropy. The total vibrational entropy change evaluated in this manner was $\Delta S_{vib} = 6.5$ e.u. Combining ΔS_{tr}, ΔS_{rot}, and ΔS_{vib} one obtains $\Delta S^0 = -21.3$ e.u. which is in very good agreement with the experimental value of -21.6 e.u. given in Table I.

A growing number of assumptions would be required for the evaluation of the entropy changes of the reactions leading to the larger potassium–water complexes. Therefore, such calculations were not done. The experimental data in Table I show a gradual increase of $(-\Delta S_{n-1,n})$ with growth of the clusters. This probably reflects the gradual restriction of motion with increased crowding of the water molecules in the first hydration shell. Unfortunately experimental $\Delta S_{n-1,n}$ values could not be obtained for n larger than 6 since at the experimental conditions required to measure these equilibria, condensation of water occurred in the ion source.

Measurements of the hydration of Li^+, Na^+, Cs^+, and Rb^+ by the method described in this paper could be made and will be described in a future publication (14) where a comparison of all the alkali ions will be given also. Measurements of the enthalpies and entropies observed in the hydration of the negative halogen ions are also almost completed. Some interesting differences in the hydration of positive and negative ions will be given in the publication of this work (16).

The $\Delta H_{0,1}$ combined with available thermochemical data permit the evaluation of the proton affinity of KOH. The proton affinities of the alkali hydroxides evaluated from such data are to be found in ref. 17.

Structural studies on the glycolato, lactato, and mandelato solid complexes of some bivalent iron series metals

ANDREW FISCHINGER, ALLEN SARAPU[1], AND AUDREY COMPANION
Department of Chemistry, Illinois Institute of Technology, Chicago, Illinois 60616

Received July 18, 1968

Electronic absorption spectra, infrared vibrational spectra, and X-ray powder patterns have been measured for anhydrous bis(glycolato), bis(lactato), and bis(mandelato) complexes of bivalent Mn, Co, Ni, Cu, and Zn. Despite indications of considerable differences in crystal structure, the visible spectra of all complexes are quite similar to those of analogous hexaaquo complexes. A ligand field analysis yields as new data a spectrochemical series for the ligands

$$Dq(\text{lactato}) > Dq(\text{glycolato}) > Dq(\text{mandelato})$$

in agreement with the order of proposed metal–oxygen stretch frequencies and previously measured acid pK's of the ligands.

An interesting red to blue color change, observed in all cobalt complexes on heating, is shown to be reversible in the glycolate. A tentative model proposed for the complex appears to be consistent with all the experimental data including the color change phenomena.

Canadian Journal of Chemistry, 47, 2629 (1969)

Introduction

Although considerable effort has been directed toward the study and interpretation of the infrared spectra of the bis(glycolato) (1–4) and bis(lactato) (5) complexes of divalent iron series metal ions, relatively little is known of their structure or of the nature of the reversible color change occurring in the Co(II) complex on gentle heating. In this paper we present the results of investigations of the infrared and visible–near ultraviolet spectra of the anhydrous solid bis(glycolato) metal complexes of composition $M(II)(CH_2OHCOO)_2$ and of similar complexes with lactate ($CH_3CHOHCOO^-$) and mandelate ($C_6H_5CHOHCOO^-$) anions as ligands. Some rough conclusions on comparative crystal structure and the far infrared spectra of lactate and mandelate complexes are presented. For brevity, the glycolate, lactate, and mandelate ions will henceforth be abbreviated G^-, L^-, and M^-, respectively.

Experimental Details

The glycolate and lactate complexes were prepared according to the procedure given by Nast and Ruckemann (2), recrystallized, and heated in vacuo at 50 °C. Mandelate complexes were simply precipitated from aqueous solutions of metal ions of the haloaquo salts by addition of slightly alkaline aqueous mandelic acid. These latter were extremely insoluble in water and common organic solvents and consequently were just washed repeatedly before drying. Results of analysis are shown in Table I.

Samples of the above crystalline solids were ground to a fine powder either by hand or with a Wig-L-Bug mechanical grinder prior to measurement of spectra. When ground mechanically, all three Mn(II) complexes partially decomposed and consequently were powdered carefully by hand. All three Co(II) complexes underwent a gradual color change from red to lavender in the Wig-L-Bug agate capsule and also on gentle heating (up to a temperature of 200 °C) in a vacuum oven. Further heating at 210 °C produced a dramatic color change from lavender to a deep blue first in CoL_2 and much later in CoM_2, but not in CoG_2 which remained lavender. The deep blue color of CoL_2 and CoM_2 as well as the lavender color of CoG_2 persisted from 210 °C to the decomposition temperature, about 240 °C. The color change proved to be rapidly reversible for the lavender form of CoG_2 which totally reverted to the red form in about 30 min as verified by transmission spectra of the two forms and by X-ray powder patterns of the red form before and after reversion. No such definite blue to red reversible change has been observed in the lavender or deep blue forms of CoL_2 and CoM_2.

X-Ray powder patterns were obtained for all samples with a GE XRD-1 diffractometer. Although a thorough crystal structure analysis was not feasible, inspection of the films permitted the following conclusions: (*a*) All compounds were crystalline, with the possible exception of the lavender or blue forms of CoL_2 and CoM_2, which gave no observable lines during the exposure time required by our present equipment (6–8 h). (*b*) Because of the rapidity of the color change in CoG_2 (30 min) relative to exposure time required, no definite evidence could be obtained establishing a structural change with change of color. (*c*) All glycolates with the exception of those of Ni and Zn have distinctly different X-ray patterns. NiG_2 and ZnG_2 appear to be similar in crystal structure but not isomorphous. (*d*) Lactates of Co, Ni, Zn, and Mn appear to be similar in crystal structure, the first three of

[1]Present address: Department of Chemistry, University of Wisconsin, Madison, Wisconsin.

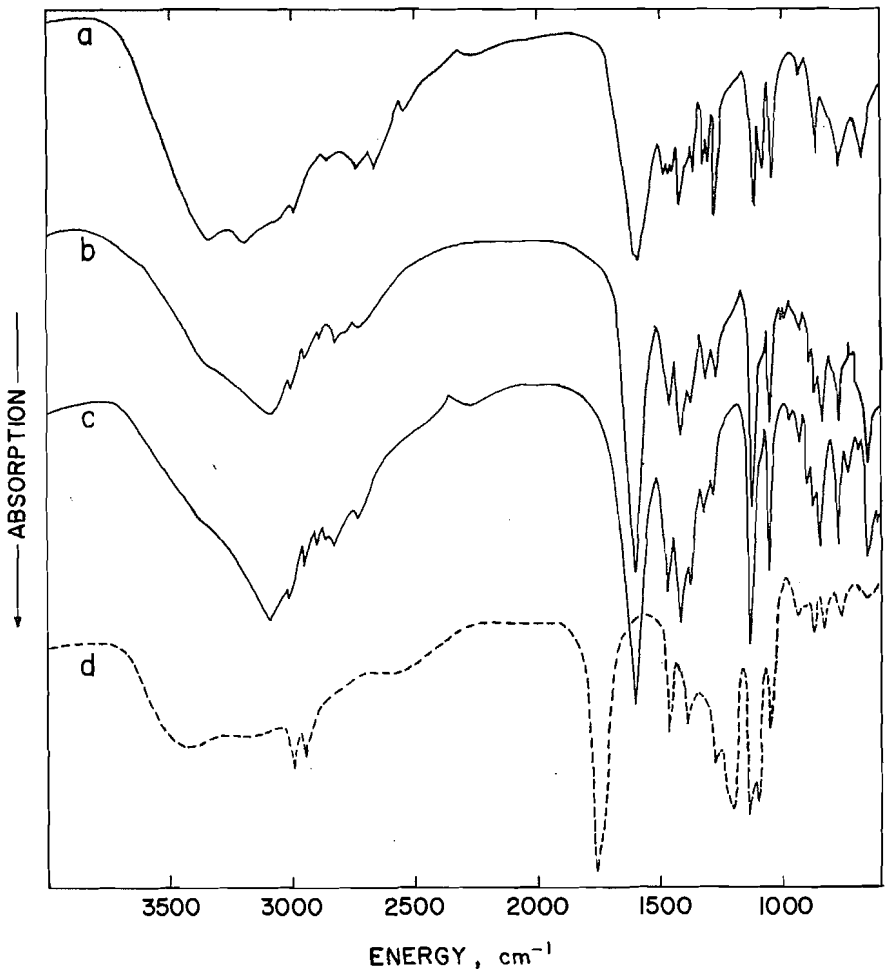

FIG. 1. Infrared spectra of cobalt lactates (4000–600 cm^{-1}): *a*, CoL_2, red form; *b*, CoL_2, lavender form (heated at 168 °C in vacuum oven for 1 day); *c*, CoL_2, deep blue form (heated at 210 °C in vacuum oven for 1 day); *d*, DL-lactic acid, (98% water free but identical to aqueous lactic acid spectrum except for the absence of strong water bands).

these being possibly isomorphous. CuL_2 yields a distinctly different pattern. (*e*) Mandelates of Co, Ni, Zn, and Cu have similar crystal structures, the first three of these being possibly isomorphous. MnM_2 has a distinctly different pattern.

Infrared spectra of the complexes were measured with a Beckman IR 12 spectrophotometer over the region 4000 to 200 cm^{-1}. Figure 1 illustrates tracings obtained for red, lavender, and blue forms of CoL_2 and lactic acid in the region 4000 to 600 cm^{-1}, where evidence supporting coordination is normally found. Table II summarizes for all complexes our proposed energies of the antisymmetric (as) and symmetric (s) stretching modes of the carboxyl group, the alcohol O—H and C—O stretching modes, along with available similar data of other investigators. Figures 2 and 3 reproduce tracings observed for the lactates and mandelates of Cu, Ni, Co (red), Zn, and Mn in the region 600 to 200 cm^{-1}, where metal–oxygen stretching frequencies should be observed. In this region the spectra of blue forms of the cobalt complexes show essentially no shift in peak positions from those of the red forms. The energies of proposed metal–oxygen bands for all complexes are listed in Table III.

The visible, near infrared, and near ultraviolet spectra of the powdered solid complexes were obtained on the Cary Model 14 PMR spectrophotometer with both diffuse reflectance and Nujol mull techniques (7). In general the reflectance spectra agreed quite well with transmission spectra when particles were ground to a sufficiently small size (less than 1 μ in diameter) that contributions from specular reflections were minimal. This small particle size proved to be of critical importance in the case of NiG_2 and NiM_2, both of which exhibited in the hand ground sample a 27 kK peak, which, however, disappeared on prolonged mechanical grinding. X-Ray diffraction studies established that the peak disappearance

[a]Numbers in parentheses represent shoulders.
[b]There is some doubt as to the validity of these shoulder peak assignments since the calculated energies for these transitions are considerably higher, being in the range between 18.1 to 18.8 kK.

was not associated with a structural change in the complex. Since, except for strong charge transfer bands in the near ultraviolet, all spectra closely resembled the known spectra of hexaaquo ions, we have simply listed in Table IV the predominant observed peak positions. The spectra for the red and lavender forms of CoG_2 are illustrated in Fig. 4, and for the red, lavender, and deep blue forms of CoL_2 and CoM_2 in Figs. 5 and 6, respectively. All data are reported in terms of kilokaysers (1 kK = 1000 cm^{-1}). The maximum estimated experimental error in these reported peaks is believed to be ± 0.08 kK.

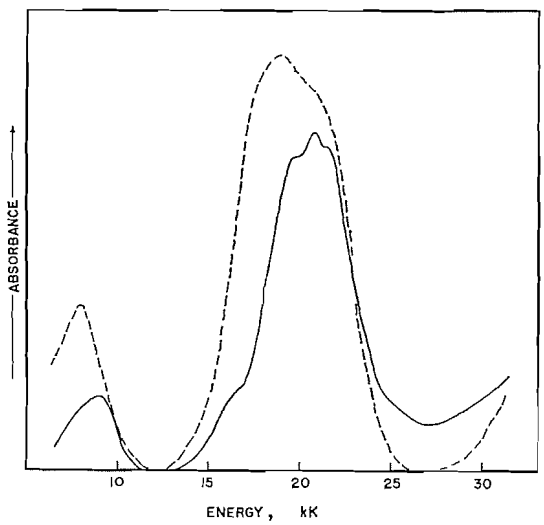

FIG. 4. Visible and near infrared absorption spectra of CoG_2 mulls. The solid curve pertains to the red form while the dashed upper curve describes the lavender form. Relative intensities of absorption are not drawn to scale.

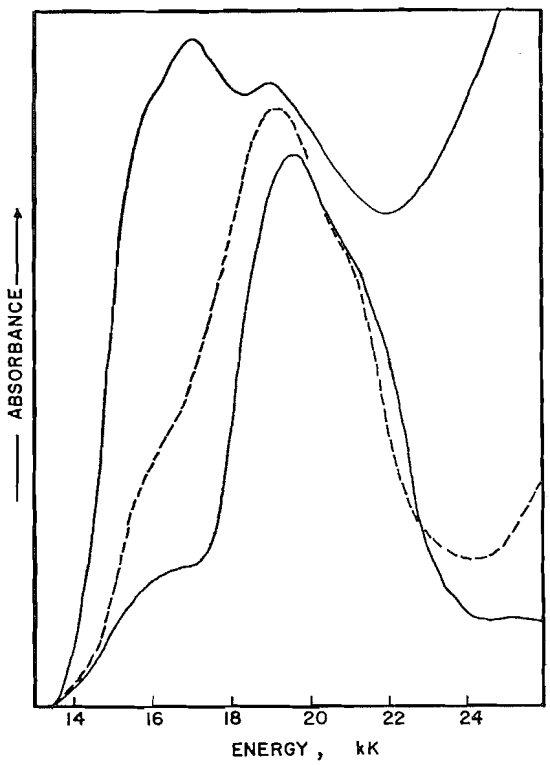

FIG. 5. Visible absorption spectra of CoL_2 mulls. The lower curve refers to the red form, the dashed to the lavender form, and the upper to the deep blue form. Relative intensities are not drawn to scale.

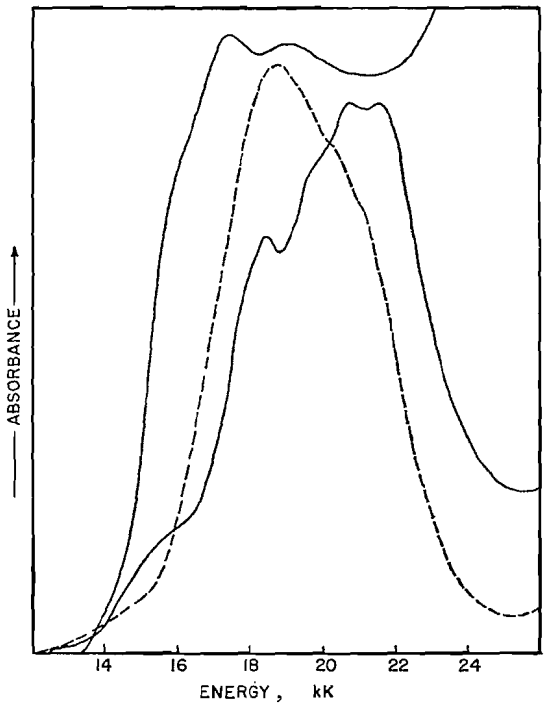

FIG. 6. Visible absorption spectra of CoM_2 mulls. The lower curve refers to the red form, the dashed to the lavender form, and the upper to the deep blue form. Relative intensities are not drawn to scale.

Discussion

Examination of Table II shows that in all complexes studied ν(COO^-, as), ν(O—H), and ν(C—OH) are shifted toward energies lower than those observed in the free acids. Such shifts are generally indicative of coordination of the hydroxyl and carboxyl groups. In some of the lactates, ν(O—H) (which is obscured in the free acid by strong hydrogen bonds) and ν(C—OH) bands are split, yet nevertheless show a definite center-of-gravity shift to lower energy. Similar splitting and shifts are observed in the ν(O—H) and ν(COO^-, as) bands of MnM_2. These splittings may be due to strong hydrogen-bonding between hydroxyl groups with uncoordinated carboxyl groups and other hydroxyl groups, to the presence of both chelate and bridge ligand groups or, particularly in the case of MnM_2, to the presence of some uncoordinated or loosely coordinated ligand groups in the complex. In the red to blue conversion in CoG_2 and CoM_2 no shifts at all occur in the four frequencies listed in Table II. For CoL_2 (Fig. 1), on heating, the separation between the symmetric and antisymmetric COO^- peak positions increases slightly, indicating a possible small increase in the strength of the metal–oxygen bond. Similarly, ν(O—H) shifts strongly toward lower energy as the blue conversion occurs, a shift associable with increased metal–oxygen bond strength or increased hydrogen-bonding in the blue form. The variations shown in Fig. 1 and the lack of variations in the spectra of red and blue CoG_2 and CoM_2 appear consistent with the idea that no chelate bonds are broken in the color conversion process.

Indirect evidence that the ligands are more likely chelates than bridges may be deduced from recent X-ray studies. The structure of anhydrous bis(glycolato)copper(II) has been described (8, 9) as that of a sheet coordination polymer, in which each copper atom is joined in *trans* conformation to two glycolate ligands, forming coplanar rings. The coordination octahedron is completed by carboxy-oxygens of complexes in adjacent layers. No further complete structures have been reported for anhydrous glycolate or lactate compounds. However, structures of related hydrated complexes are known. Aquobis(DL-lactato)copper(II) hemihydrate crystals contain copper atoms *trans* chelated to two lactate ligands in a bow-shaped, almost planar configuration, with the coordination octahedra completed by a water molecule and a weakly interacting neighboring carboxy-oxygen (9). Hydrogen bonds join double ribbons of complexes in sheets, with isolated water molecules in channels between ribbons. It seems reasonable to assume that during loss of water to form the anhydrous lactate the bis-chelate conformation and also the layered structure would be retained.

No X-ray studies have been reported for either anhydrous or hydrated mandelates. However, in diaquobis(phenoxyacetato)copper(II) (9) (in which the ligand differs from mandelate by displacement of the phenyl group from the carbon to the coordinating oxygen), the two *trans* chelate rings and their phenyl groups are almost coplanar, with the complexes hydrogen-bonded to form sheets. Again it seems reasonable that the complex could lose the two water molecules completing the coordination sphere with retention of its bis-chelate and sheet characteristics.

A recent structure determination of isomor-

phous $ZnG_2 \cdot 2H_2O$, $CoG_2 \cdot 2H_2O$, and $MnG_2 \cdot 2H_2O$ (10) indicates that both glycolate ligands are chelated in a non-coplanar twisted *cis* configuration with the two water molecules occupying near neighbor positions of the coordination octahedron. The complexes form puckered sheets with pairs of water molecules of neighboring complexes in a channel between the sheets. Since these crystals easily dehydrate in a vacuum at 60–70 °C, one may deduce that if the chelate bonds are not ruptured on dehydration, the molecules will retain the *cis* conformation, with coordination octahedra completed by loosely attracted carboxy-oxygens in adjacent layers. This postulate is in agreement with results of a normal coordinate analysis of the infrared spectrum of anhydrous CoG_2 carried out by Nakamoto, McCarthy, and Miniatas (1), who suggested that the environment around Co(II) should be at most C_{2v}, consistent with a *cis* square-planar configuration.

Although none of the infrared or X-ray evidence definitely precludes the existence of more complicated bridged oligomeric or polymeric structures for the complexes studied, we have assumed as a working model that the compounds contain *cis* or *trans* square-planar 1:2 chelates in layered structures with coordination octahedra completed by oxygen atoms of chelates in neighboring layers, the chelate molecules and layers held together by a network of hydrogen bonds. Such octahedral coordination is consistent with the colors and visible spectra of all freshly prepared complexes.

In line with this model, the visible spectra were analyzed with weak crystal field octahedral matrices of the Orgel type (11), including configuration interaction. Excitation energies for the necessary isolated atom states were calculated by the barricentric method described by Jorgensen (ref. 12, p. 78). The Dq and β values derived are listed in Table V. For all Ni(II) and Mn(II) complexes and the red Co(II) complexes, almost quantitative agreement was obtained between experimental and calculated transition energies.

Despite the observed differences in crystal structures of the complexes, the derived crystal field parameters do exhibit some order. In all complexes the Dq values show that the spectrochemical series of central ions is obeyed for each ligand, i.e.

$$Dq(\text{Cu}) > Dq(\text{Co}) > Dq(\text{Ni}) > Dq(\text{Mn})$$

TABLE V

Octahedral crystal field parameters for complexes

Complex	Dq (cm^{-1})	β
MnG_2	740	0.92
MnL_2	760	0.92
MnM_2	710	0.91
CoG_2(red)	1000	0.89
CoL_2(red)	958	0.84
CoM_2(red)	1000	0.93
NiG_2	860	0.86
NiL_2	875	0.87
NiM_2	845	0.88
CuG_2	1380	—
CuL_2	1360	—
CuM_2	1350	—

Examination of all Mn(II) and Ni(II) complexes indicates the following spectrochemical series for the ligands

$$Dq(\text{L}^-) > Dq(\text{G}^-) > Dq(\text{M}^-)$$

The nephelauxetic series for these ligands cannot be readily established, since the observed β values are essentially invariant in Mn(II) and Ni(II) complexes. For each given ligand, β for the Mn(II) complex is consistently larger than that of the corresponding Ni(II) complex, in agreement with the nephelauxetic series of central ions as advocated by Jorgensen (ref. 12, p. 138).

Except for their position in the spectrochemical series of central ions, the parameters of the red Co(II) complexes appear to be quite erratic in behavior. This may be due to the well-known ambiguities in properly estimating the $^4T_{1g}(P)$ band position in Co(II) complexes, to possible radical deviations from octahedral symmetry (static Jahn–Teller distortions are expected for Co(II) complexes), or to possible presence even in the freshly prepared solid of a small amount of blue form. That the Dq values for the Cu(II) complexes do not obey the expected spectrochemical series of ligands may also be due to Jahn–Teller distortion. It is probable that these Cu(II) complexes are tetragonally distorted (with CuG_2 being least distorted) as some preliminary investigations (13) of electron paramagnetic resonance spectra indicate. Furthermore, the useful "σ ratio" method of Jorgensen (ref. 12, p. 124) yields a value of 1.6 for these compounds, again indicating a strongly tetragonal symmetry.

The lavender or intermediate blue forms of CoG_2, CoL_2, and CoM_2 all have very similar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

spectra with intense peaks near 8.1 and 18.8 kK. The $^4T_{2g}$(F) and $^4T_{1g}$(P) peaks in the corresponding red complexes all undergo a distinct red shift and substantial increase in intensity as the conversion occurs, while the weak $^4A_{2g}$(F) shoulder in the red complexes disappears or is obscured by stronger bands (Figs. 4, 5, 6). As the CoL_2 and CoM_2 samples become increasingly blue, prominent peaks appear near 7.5 and 17.1 kK. These latter correlate well with those observed for known implanted tetrahedral Co(II) species, for example, Co(II) in ZnO (14), for which two main bands are observed at 6.1, 7.0, 7.5 kK and 15.3, 16.4, 17.6 kK. The lavender complexes, however, lie between the theoretical octahedral and tetrahedral peak positions expected for Co(II) coordinated to oxygen atoms. This implies that only a partial conversion to a tetrahedral species has occurred. Since electronic transitions in a tetrahedral molecule are not Laporte forbidden and hence are associated with higher intensities, a relatively small concentration of tetrahedral species may be sufficient to cause the observed color change.

If the postulated structure of these complexes is correct (square-planar species coordinated axially through adjacent layers), on heating, the bonds between layers are most likely weakened or broken, yielding square-planar Co(II) species. For Co(II), weak field square-planar coordination is uncommon (15) and probably less stable than the usual four-coordinated symmetry, tetrahedral. In our series of complexes tetrahedral symmetry may be attained by a 90° twist of one chelate ring with respect to the other. The absence of X-ray diffraction patterns for the lavender to blue forms of CoL_2 and CoM_2 indicates, however, that the postulated twisting must be quite random. In CoG_2 the twisting motion may be relatively unhindered, so that interconversion of red and blue forms occurs readily. In CoL_2, where a methyl group has been introduced on each chelate ring, reversion to tetragonal coordination may be appreciably hindered. Thus a large number of tetrahedral species may accumulate, culminating in the deep blue color never achieved by the glycolate complex. Similar arguments may obtain for CoM_2. Furthermore, the greater steric hindrance caused by the phenyl group possibly makes it more difficult for the twisting to occur in CoM_2, thus explaining why CoM_2 requires a much longer time than CoL_2 to be converted to the deep blue form at 210 °C.

The lower energy (600–200 cm^{-1}) infrared spectra of these complexes appear to substantiate this "twisting" model. The spectra of blue forms of the cobalt complexes show no shift in peak positions from those in the red form in this critical region where metal–oxygen stretching frequencies are to be found. The invariance of all peak positions indicates also that no drastic change in metal–oxygen bond strength occurs on color change; hence the large ν(O—H) shift observed in blue CoL_2 must reflect a change in hydrogen-bonding. Table III lists proposed higher energy metal–oxygen stretching bands for our complexes, deduced by comparison of the spectra with those of the metal glycolates as analyzed by Nakamoto, McCarthy, and Miniatas (1). The positions of these bands are also indicated with dots in Figs. 2 and 3. The magnitude of these frequencies for each given ligand indicates that as the metal ion is varied, the strength of the metal–oxygen bonds decrease in the order

$$Cu(II) > Ni(II) > Co(II) \approx Zn(II) > Mn(II),$$

correlating perfectly with the Irving–Williams stability constant series for metal ions (16). In addition, for each metal ion, these frequencies decrease with change in ligand as

$$\nu(L^-) > \nu(G^-) > \nu(M^-)$$

paralleling exactly the order of oxygen – acidic hydrogen bond strengths in the acids as indicated by their observed pK's (17), HL, 3.86; HG, 3.84; HM, 3.39. Note also that this frequency order is that of the spectrochemical series of these ligands as determined from our Mn(II) and Ni(II) spectra, further evidence of a relation between thermodynamic stability of a complex as reflected in bond strengths and crystal field stabilization.

Further studies on these and related compounds, in search of additional information on their structure, are in progress.

Diagramme de phase du système $Rb–Rb_2O$: le sous-oxyde de rubidium Rb_3O

PH. TOUZAIN
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 21 janvier

Le diagramme de fusion du système $Rb–Rb_2O$ est obtenu par la méthode de l'analyse thermique différentielle. Les échantillons de diverses compositions sont élaborés par combinaison directe de rubidium bidistillé et d'oxygène gazeux. Ce système présente un eutectique fondant vers -10 °C de couleur jaune mordorée pour une composition voisine de $RbO_{0.2}$, et un composé à fusion incongruente (à 48 °C). Ce dernier pouvant être séparé par centrifugation du mélange liquide en cristaux rouges cuivrés est un sous-oxyde de formule Rb_3O. On observe la dismutation de Rb_2O en Rb_2O_2 et Rb à la température de 410 °C.

The $Rb–Rb_2O$ diagram system has been obtained by the technique of differential thermal analysis. The samples of different compositions were prepared by direct synthesis from doubly distilled rubidium and gaseous oxygen. This system shows a golden eutectic which melts at -10 °C for a composition close to $RbO_{0.2}$, and a compound which exhibits incongruent melting (at 48 °C). The latter can be isolated as copper colored crystals by centrifugation of the liquid mixture; it is a sub-oxide with the formula Rb_3O. Dismutation of Rb_2O in Rb_2O_2 and Rb is observed at 410 °C.

L'étude des sous-oxydes des métaux alcalins commencée par Rengade (1) vers 1909 présente un grand intérêt du point de vue de leurs valences et de leurs structures chimiques.

En traçant le diagramme de phase du système $Cs–Cs_2O$ par analyse thermique, Rengade (2) mis en évidence 4 composés définis du césium: Cs_7O, Cs_4O, Cs_7O_2 et Cs_3O. Brauer (3) détailla une partie de ce diagramme (Cs à Cs_4O) par mesure des coefficients de résistivité des mélanges césium-oxydes en fonction de la température. Les sous-oxydes Cs_7O (3), Cs_4O (3) et Cs_3O (4) examinés aux rayons X présentent en fait des structures cristallines partiellement métalliques. D'ailleurs ces composés conduisent le courant électrique à peu près de la même façon que le césium pur.

Dans le cas des autres métaux alcalins, De Forcrand (5) signale en 1898, le sous-oxyde Na_3O se formant en "arborescences volumineuses grises" au dessus du sodium métallique, mais aucune autre expérience n'a encore confirmé ce résultat.

Rengade (6) observa durant l'oxydation de rubidium par de l'oxygène, la formation d'un liquide jaune roux à éclat métallique et l'apparition au refroidissement de "gros cristaux mordorés". Plus récemment, Herald et Weatherford (7) remarquèrent que l'addition de seulement 1000 p.p.m. d'oxygène au rubidium abaisse son point de fusion de 1 °C. Une mesure très précise de cette température de fusion serait même un critère de pureté du rubidium. Cette dernière méthode, préconisée par Tepper (8), permet de déterminer la concentration en oxygène dans le rubidium avec une précision de 2 p.p.m. tant que cette concentration reste inférieure à 500 p.p.m.

Ayant observé la dissolution des oxydes de rubidium dans le rubidium métallique à des températures même inférieures à 0 °C (9), nous avons pensé étudier le diagramme de phase du systéme $Rb–Rb_2O$, ce qui nous permettrait, en même temps, de prouver l'existence ou l'absence de sous-oxydes de rubidium. Nous avons utilisé pour déterminer les températures de ce diagramme la technique de l'analyse thermique différentielle sur des échantillons de $Rb–Rb_2O$ de l'ordre de 10 mg.

Techniques Expérimentales

Préparation du mélange rubidium–oxygène

Les mélanges $Rb–Rb_2O$ de diverses compositions sont préparés par synthèse directe à partir de rubidium métallique et d'oxygène gazeux.

Le rubidium obtenu par la méthode Hackspill (10) est bidistillé sous vide (10^{-4} mm Hg) suivant une technique déjà décrite (9). Environ 1 g de ce métal est utilisé à chaque expérience.

Un volume précis d'oxygène est alors mis en communication avec le métal. L'absorption de la totalité de l'oxygène par le rubidium est rapide à la température de 70–90 °C tant que la surface en contact entre le gaz et le métal est suffisament grande.

Le poids de métal est déterminé exactement après échantillonnage, par un dosage acidimétrique de la solution aqueuse de rubidine, solution obtenue par attaque ménagée du mélange rubidium–oxyde par l'eau.

Un calcul simple nous permet de trouver le rapport oxygène/métal du mélange ainsi préparé.

Analyse thermique différentielle (a.t.d.)

(a) Appareillage

La tête semi-micro de l'appareil a.t.d. utilisé dans cette étude et mis au point par Mazières (11), comporte un ensemble de 3 coupelles cylindriques en platine (pour échantillon et références) constituant elles-mêmes la soudure des thermocouples. Ce dernier fait augmente la sensibilité et le pouvoir de résolution de l'appareil. Le volume utilisable des coupelles est de 25 µl.

Un enregistreur à 2 voies galvanométriques est couplé à l'analyseur thermique différentiel. Le signal de température différentielle est enregistré sur une voie particulièrement sensible (62.5 µV échelle).

(b) Préparation des échantillons

Etant très hygroscopiques, les métaux alcalins ou leurs oxydes doivent être introduits à l'abri de l'air, sous vide, à l'intérieur d'un petit tube de verre. Celui-ci sera placé dans la coupelle en platine de l'a.t.d. prévue pour l'échantillon au moment de l'analyse thermique.

La Fig. 1 indique les techniques employées pour introduire du mélange alcalin (environ 10 mg) dans une petite ampoule de verre. Cette ampoule est obtenue par soufflage d'un tube capillaire en verre Pyrex à forte épaisseur et préalablement étiré.

Deux cas se présentent suivant que le point de fusion du mélange est situé en dessous ou au dessus de 50 °C.

Dans le premier cas, le mélange est maintenu à l'état liquide dans un bain thermostaté à 50 °C. Il est homogénéisé par agitation puis on en remplit les ampoules échantillons par gravité. Les ampoules sont alors scellées à l'aide d'une micro-torche, ainsi prêtes pour l'analyse thermique.

Dans le deuxième cas, la température du mélange est d'abord maintenue vers 90 °C pendant plusieurs heures[1]. Refroidi rapidement à la température ordinaire, le mélange y subit sa recuisson qui permet la cristallisation du ou des composés. Ensuite il est réduit en poudre à l'aide d'une masselotte en acier que l'on avait pris soin de placer à l'intérieur du tube laboratoire. Cette opération est conduite à la température de −80 °C pour rendre le mélange alcalin plus brisant. Un peu de cette poudre est introduite dans les ampoules qui sont alors scellées comme dans le premier cas.

L'échantillon de référence pour l'a.t.d. est une petite ampoule de verre identique à celles utilisées pour les échantillons alcalins mais vide de toute substance.

[1]On s'apercevra quand on examinera le diagramme de phase du systéme Rb–Rb_2O sur la Fig. 2 qu'en maintenant la température d'un échantillon au dessus de 50 °C par exemple à 90 °C, au moins une partie du mélange se trouve à l'état liquide. Cette phase liquide réduit en les mouillant les peroxyde ou superoxyde solides qui éventuellement auraient pu se former pendant la période d'oxydation du métal. En fait, maintenir l'échantillon à une température supérieure à celle du liquidus nous conduirait à n'obtenir qu'une seule phase liquide et ainsi une homogénéisation parfaite. Cependant du fait de la température élevée de ce liquidus pour les % d'oxygène proches de celui de Rb_2O, cette méthode occasionnerait à la longue l'attaque du verre Pyrex par le rubidium ou même la dismutation de Rb_2O à partir de 400 °C.

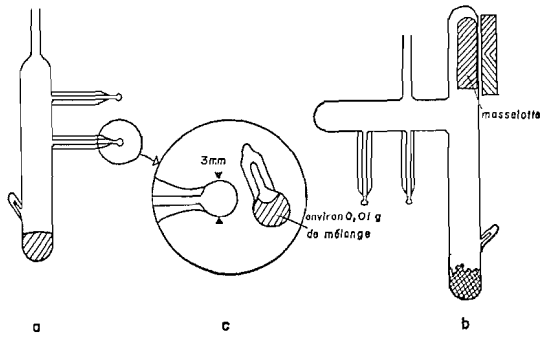

FIG. 1. Préparation des échantillons de Rb–Rb_2O pour l'analyse thermique différentielle. (*a*) Échantillonnage d'un mélange liquide à une température inférieure à 50 °C, (*b*) échantillonnage d'un mélange solide ou en partie solide à 50 °C, (*c*) ampoules-échantillons pour l'a.t.d.

(c) Analyse thermique

Les échantillons alcalins ont tendance à rester en surfusion pendant parfois quelques dizaines de degrés en dessous de leurs points de congélation théorique. Ce phénomène exclut toute précision des mesures que l'on pourrait faire par refroidissement. C'est pourquoi nos courbes d'analyses thermiques $\Delta T = f(T)$ ont été obtenues par chauffage et non par refroidissement du mélange alcalin.

Pour effectuer une analyse thermique, on commence donc par refroidir la tête de l'analyseur aux alentours de −40 °C jusqu'à équilibre thermique puis on procède à l'élévation de température à une vitesse de 3–4 °C par minute.

Les pics des courbes thermiques $\Delta T = f(T)$ ont une hauteur comprise en général entre 1 et 10 µV. Ce sont leurs sommets qui ont permis la détermination la plus reproductible des températures de fusion des échantillons. La calibration des thermocouples (platinel) effectuée par le fabriquant de l'a.t.d. a été utilisée telle quelle. La précision des mesures peut-être fixée à ±2 °C.

Résultats

Le diagramme de phase du système Rb–Rb_2O, obtenu par analyse thermique différentielle, est porté sur la Fig. 2. Ce diagramme présente les points particuliers suivants.

(*a*) Formation d'un eutectique se solidifiant à −10 °C. Le minimum du liquidus correspond au % atomique d'oxygène d'environ 16% (à peu près $RbO_{0.2}$). La couleur jaune dorée du mélange va en s'approfondissant au fur et à mesure que la proportion d'oxygène augmente, allant du blanc argent pour le métal pur au brun doré pour les mélanges de % atomique d'oxygène supérieur à 20.

(*b*) Existence d'un sous-oxyde à fusion incon-

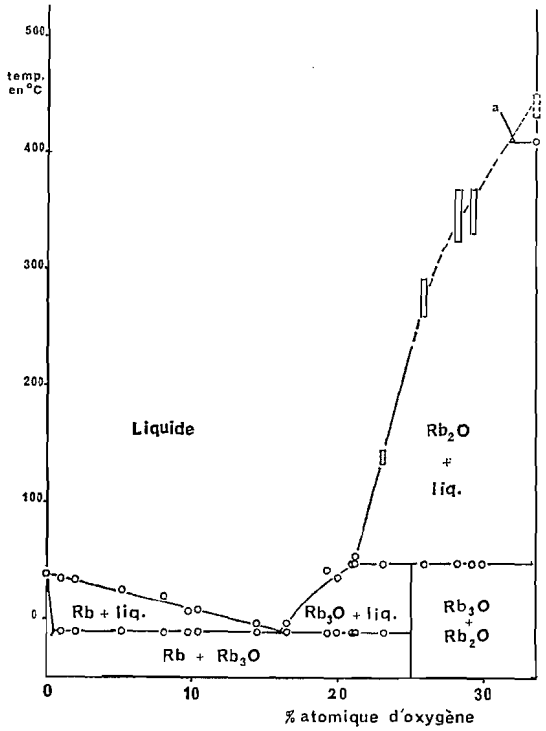

FIG. 2. Diagramme de phase du système Rb–Rb_2O. (*a*) Dismutation de Rb_2O en Rb_2O_2 et Rb.

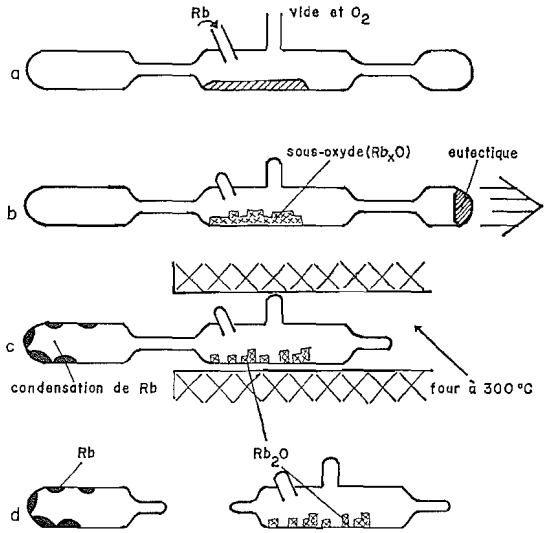

FIG. 3. Préparation et analyse du sous-oxyde de rubidium. (*a*) Introduction de rubidium par distillation et oxydation ménagée de celui-ci par O_2, (*b*) séparation par centrifugation du liquide de la phase solide (le sous-oxyde), (*c*) décomposition thermique à 300 °C du solide Rb_xO (avec $x > 3$) en oxyde Rb_2O et métal qui se condense sur la paroi froide du tube, (*d*) séparation de Rb et Rb_2O. L'analyse se continue par la dissolution dans l'eau de Rb et Rb_2O puis par une acidimétrie de ces deux solutions.

gruente (péritectie à 48 °C) répondant à la formule Rb_3O.

Pour confirmer la formule de ce sous-oxyde, nous l'avons isolé et analysé de la même manière qu'il avait été fait pour un des sous-oxydes de césium (2).

On distille dans un tube en verre de forme particulière (Fig. 3*a*) une certaine quantité de rubidium auquel on ajoute de l'oxygène jusqu'à obtention d'un mélange fondu qui commence à se solidifier vers 45 °C (environ 20% atomique d'oxygène). Ce mélange comporte alors une phase cristallisée (le sous-oxyde) et une phase liquide (l'eutectique). La partie liquide est éliminée grâce à une centrifugation rapide (Fig. 3*b*). Le sous-oxyde reste sous la forme de cristaux rouges à aspect cuivré. Ce composé se dismute à 48 °C selon la réaction :

$$Rb_3O \rightarrow Rb_2O + Rb$$

A 300–320 °C, le rubidium est libéré et se condense sur la partie froide de l'appareil (Fig. 3*c*). Après séparation du tube contenant l'oxyde du tube contenant le métal (Fig. 3*d*), on effectue une mise en solution aqueuse de Rb_2O et de Rb et enfin une analyse acidimétrique de chacune de ces solutions. Le rapport en volume d'acide neutralisant est pour l'oxyde Rb_3O pur :

$$\frac{\text{Rb distillé}}{Rb_2O} = 0.50$$

Expérimentalement, le rapport est trouvé égal à 0.58 ce qui correspond à la formule $Rb_{3.16}O$. La petite quantité de rubidium en excés (5%) s'explique par la couche liquide qui est restée adhérée à la surface des cristaux malgré la centrifugation.

Par analyse thermique différentielle ou par voie chimique, on a donc bien mis en évidence l'existence du sous-oxyde Rb_3O (monooxyde de trirubidium).

(*c*) D'autre part, nous avons essayé de déterminer le point de fusion de Rb_2O qui n'était pas connu avec exactitude. Le monooxyde de dirubidium est préparé par distillation prolongée sous vide, à 300 °C, de rubidium traité par une quantité insuffisante d'oxygène.

L'analyse thermique ainsi que l'observation

visuelle du phénoméne dans un tube en verre Pyrex scellé, nous permet seulement de situer la fusion de Rb_2O aux alentours de 430–450 °C. Le verre Pyrex est attaqué à partir de 500 °C.

En fait, il ne semble pas que l'oxyde Rb_2O posséde un point de fusion net car il se décompose d'aprés Rengade (12), déjà vers 400 °C. Nous avons déterminé cette température de dismutation avec plus de précision grâce à une analyse thermogravimétrique sous vide. L'échantillon de Rb_2O d'une vingtaine de mg est placé dans un petit creuset en alumine suspendu au fléau de la thermobalance (électrobalance Cahn). L'élévation de température de l'èchantillon est réglée à 4 °C par minute. On observe une très importante perte de poids due à la volatilisation du rubidium métallique à partir de 405–415 °C. De plus, l'analyse thermique différentielle faite sur un échantillon plus important de Rb_2O nous donne un pic endothermique vers 410 °C également.

Le monooxyde Rb_2O fond donc incongruement à 410 °C selon la réaction :

$$2Rb_2O \rightarrow Rb_2O_2 + 2Rb$$

La précision des températures du liquidus pour les % atomiques d'oxygène supérieurs à 25 est faible car la pente du liquidus est importante. C'est pourquoi, nous avons tracé cette partie du liquidus en pointillés sur le diagramme de la Fig. 2.

Discussion

Le diagramme de phase du système Rb–Rb_2O est comparable par de nombreux points à celui du système Cs–Cs_2O. En effet, il existe, dans les 2 cas, un eutectique respectivement à -10 et à -8 °C pour le même % d'oxygène (16% atomique) bien que ces 2 eutectiques correspondent à 2 réactions différentes (Rb métal + Rb_3O dans un cas et Cs_7O + Cs_4O dans l'autre), un sous-oxyde de formule identique Rb_3O et Cs_3O et enfin un liquidus dont la température s'éléve rapidement quand on s'approche du monooxyde Rb_2O ou Cs_2O. Ces 2 derniers oxydes sont d'ailleurs instables dans les 2 cas avant leurs températures de fusion.

D'autre part, la pente du liquidus du rubidium métallique pour un petit % atomique d'oxygène n_0 permet de calculer l'entropie de fusion du rubidium. La pente linéaire de ce liquidus est

$$\frac{\Delta T}{n_{O(n_0 \rightarrow 0)}} = \frac{\Delta T}{n_0(\text{eut})} = \frac{(39.0 - (-10.0))}{16.0}$$
$$= 3.07\ ^\circ\text{C par \% atomique d'oxygène}$$

et l'entropie est

$$\Delta S_f = \frac{R T_f}{100 \Delta T / n_0} = \frac{2(273 + 39)}{307}$$
$$= 2.03\ \text{cal}\ ^\circ\text{C}^{-1}\ \text{g-atom}^{-1}$$

Les travaux de Tepper (8) permettent également ce calcul d'autant plus qu'ils se rapportent aux très faibles concentrations d'oxygène. L'abaissement cryoscopique est selon lui

$$\Delta T / n_0 = 0.0017\ ^\circ\text{C par p.p.m. d'oxygène}$$

soit 3.18 °C par % atomique d'oxygène et l'entropie de fusion

$$\Delta S_f = \frac{2(273 + 39)}{318} = 1.96\ \text{cal}\ ^\circ\text{C}^{-1}\ \text{g-atom}^{-1}$$

Selon Perel'man (13), la valeur de l'entropie de fusion du rubidium est

$$\frac{\Delta H_f}{T_f} = \frac{540}{(273 + 39)} = 1.73\ \text{cal}\ ^\circ\text{C}^{-1}\ \text{g-atom}^{-1}$$

Notre valeur expérimentale de cette entropie serait donc 17% trop importante et celle de Tepper plus exacte mais encore 13% supérieure.

Avec la vraie valeur de ΔS_f (1.73), on peut calculer le % théorique d'oxygène n_0 pour la composition de l'eutectique à -10 °C

$$100 \times n_0(\text{eut}) = \frac{100 \times \Delta S_f \times \Delta T}{R \times T_f}$$
$$= \frac{100 \times 1.73 \times 49}{2 \times 312}$$
$$= 13.6\%\ \text{atomique d'oxygène}$$

Avec la valeur de ΔS_f de 1.96 de Tepper, le % d'oxygène à la composition de l'eutectique à -10 °C serait

$$100 \times n_0'(\text{eut}) = \frac{100 \times 1.96 \times 49}{2 \times 312}$$
$$= 15.4\%\ \text{atomique d'oxygène}$$

soit 1.8% supérieur à la valeur théorique.

La seule explication de cette différence serait d'admettre une solubilité de 1.8% d'oxygène ou d'oxyde Rb_3O dans le rubidium métallique solide à -10 °C. Cependant, une analyse thermique différentielle faite sur un échantillon de rubidium contenant 1% atomique d'oxygène seulement et recuit pendant 70 h à -10 °C, indique toujours très nettement le pic de fusion

de l'eutectique à −10 °C. Il faudrait donc admettre une légére erreur soit dans les mesures de l'abaissement cryoscopique soit dans la détermination de l'enthalpie de fusion du rubidium. Néanmoins, comme nous l'avons indiqué sur la Fig. 2, il est fort probable qu'il existe une petite zone de solubilité de l'oxygène dans le rubidium solide.

En conclusion, l'étude du diagramme de phase du système Rb–Rb_2O nous a permis de mettre en évidence un sous-oxyde de rubidium (Rb_3O) dont l'existence était insoupçonnée jusqu'à présent. Il sera intéressant d'en examiner la structure cristalline ainsi que les propriétés physiques et chimiques afin de pouvoir le comparer avec les sous-oxydes alcalins déjà connus.

Remerciements

Nous remercions le Conseil National des Recherches du Canada pour l'aide financière apportée à ce travail. Nos remerciements vont également au Professeur Marcel Bourgon de l'Université de Montréal qui a permis la réalisation de ces recherches dans son laboratoire et au Docteur M. A. Bredig (Oak Ridge National Laboratory) pour sa contribution dans la discussion de ce rapport.

Structure of the second coordination sphere of transition metal complexes. I. Co(II) complexes with aniline and pyridine

D. R. EATON
Department of Chemistry, McMaster University, Hamilton, Ontario

Received February 11, 1969

Geometric and thermodynamic parameters relating to the structure of labile second sphere coordination complexes formed between Co(II) chelates and aniline and pyridine molecules in carbon tetrachloride solution have been obtained. The effect of dipolar interactions, resulting from the magnetic anisotropy of the cobalt chelate, on the nuclear magnetic resonance spectra of the complexing molecules has been utilized for this purpose. Both aniline and pyridine show a preferred direction of approach perpendicular to the three fold symmetry axis of the cobalt compound used. In both cases the preferred intermolecular separation corresponds closely to that expected for a second coordination sphere ligand. The preferred orientation of the aniline molecule places the amino group adjacent to the cobalt complex and the pyridine is oriented with the γ hydrogen closest to the chelate. Enthalpy changes of -2.4 ± 0.2 kcal and -2.9 ± 0.3 kcal have been obtained for the formation of the aniline and pyridine complexes, respectively. The effect of averaging tumbling and translational motions on the dipolar shifts has been considered. The meaning of the parameters derived is discussed in the light of the very labile nature of the second coordination sphere complexes. The relevance of these results to the mechanisms of ligand substitution processes and homogeneous catalysis is emphasized.

Canadian Journal of Chemistry, 47, 2645 (1969)

Introduction

The concept of a second coordination sphere of metal complexes has a venerable history dating back to the work of Werner (1, 2). Bjerrum (3*a*) and Beck (3*b*) have recently reviewed this area. For the case of charged metal complexes, outer sphere coordination is synonymous with ion-pairing. A variety of physical techniques has been used to investigate the structure of such ion pairs. Thus Linhard (4) first inferred ion-pairing from studies of charge transfer bands in the ultraviolet and other workers have employed dialysis (5), polarography (6), ion exchange resins (7), and optical rotation techniques (8) to obtain information on this subject. None of these methods have given completely unambiguous answers to such questions as to whether the outer sphere ligands occupy spatially well defined positions and whether forces other than purely electrostatic attraction are involved. Non-ionic outer sphere complexes have received little or no attention.

The idea that the structure of the second coordination sphere is relevant to studies of the mechanisms of reactions involving metal complexes has also been extensively discussed (9, 10). Outer sphere mechanisms for electron transfer reactions have been particularly emphasized. However, the concept has also been invoked to account for ligand substitution processes. Thus Tobe (11), for example, in a discussion of the mechanism of substitution of octahedral cobalt-ammine complexes suggests "that these reactions can be regarded as rearrangement processes of the aggregate whereby an inner sphere ligand changes places with an outer sphere ligand". He points out, though, that such a mechanism is not necessarily general for Co(III) complexes but that the existence of a relatively stable second coordination sphere may depend on hydrogen bonding involving the NH groups of ammine complexes. Our interest in this area derives from speculation regarding the mechanism of homogeneous catalysis involving rhodium complexes (12). It was suggested that a combination of relatively strong binding in the second coordination sphere and relatively weak binding in the first coordination sphere might be particularly favorable for catalytic activity. These complexes are neutral, as are most homogeneous catalysts, so that there is no question of ion pairing. There is at present no firm information bearing on the questions of whether there is a discrete second coordination sphere for neutral molecules, whether molecules in such a sphere have a preferred orientation, what is the nature of the binding forces in the second coordination sphere, and whether it is at all plausible that these binding energies should approach those of first coordination sphere ligands. The present experiments were therefore designed to provide some data pertinent to these questions.

The nuclear magnetic resonance (n.m.r.) technique is particularly suitable for the study

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of solvation effects (13–16) since it provides a sensitive probe for small changes in nuclear environments. In some cases specific interactions such as hydrogen bonding can be identified and some indirect but elegant inferences regarding hydrogen bonding between Co(III) complexes of ethylenediamine and solvent molecules have been reported by Fung (17). The present studies are concerned with interactions in a more general sense and have utilized the enhanced chemical shift effects associated with paramagnetic complexes. It is common to distinguish two such effects (18), namely contact shifts and pseudo-contact shifts. The former demands a finite probability of finding the unpaired electron at the nucleus in question and will probably be negligible in the cases of ion pairing and solvation which do not involve covalent metal–ligand bonds. The latter is a dipolar effect and depends purely on the geometry of the complex. It is, therefore, equally effective for ligands held in the second coordination sphere by electrostatic or other interactions which do not involve admixture of ligand and metal orbitals, as it is for the covalently bonded ligands in the first coordination sphere. It is this effect which we wish to utilize. Pseudo-contact shifts are given by an expression of the form (19)

$$[1] \quad \Delta\nu = -D\frac{(3\cos^2\theta - 1)}{r^3}(g_{\parallel} - g_{\perp})$$

where r is the distance between the metal atom and the nuclear dipole under consideration and θ is the angle between the principal axis of the molecule and the vector joining the metal to the ligand nucleus. D is a constant which depends on the relative values of the electron spin relaxation time, the Zeeman anisotropy energy, and the correlation time for molecular tumbling as has been recently discussed by Jesson (20). It will be noted that the pseudo-contact shift vanishes unless $g_{\parallel} - g_{\perp} \neq 0$, i.e., there must be magnetic anisotropy.

LaMar and others (21–23) have previously utilized pseudo-contact effects to study the geometry of ion pairs in solution. Although the qualitative effect has been clearly demonstrated there has remained some ambiguity in the detailed interpretation of the results. There were two main reasons for this. Firstly, the values of $g_{\parallel}$ and $g_{\perp}$ for the complexes studied were not known so that there is an initial problem in disentangling the geometric factor in eq. [1] from the anisotropy factor. Secondly, counter ions such as $(C_4H_9)_4N^+$ which possess considerable flexibility were utilized so that there is a further problem in averaging over the different conformations resulting from the internal motions of the ion. In the present work these problems have been largely avoided by using rigid ligand molecules and complexes with known g values. A very convenient complex for this purpose is Co(II) trispyrazoyl borate (24) which has the structure shown in Fig. 1. This complex has a very large g value anisotropy ($g_{\parallel} = 8.46$, $g_{\perp} = 0.98$) and the magnetic properties are known in considerable detail from the low temperature electron spin resonance work of Jesson (25). The latter author has also analyzed the isotropic n.m.r. shifts of the pyrazoyl protons (26) and derived an experimental value of D appropriate for use in eq. [1]. On the other hand, the other physical properties (27) of this complex show that it is a typical, almost octahedral, non-labile, Co(II) complex so that the structure of its second coordination sphere should not be greatly dissimilar from that of other stable complexes of Co(II) and neighboring transition metal ions. The magnetic anisotropy merely serves as a convenient probe to locate surrounding molecules. It was initially guessed that polar molecules would participate in the second coordination sphere in preference to non-polar molecules. It is also desirable to have several different sets of protons in the complexing molecule. These considerations lead

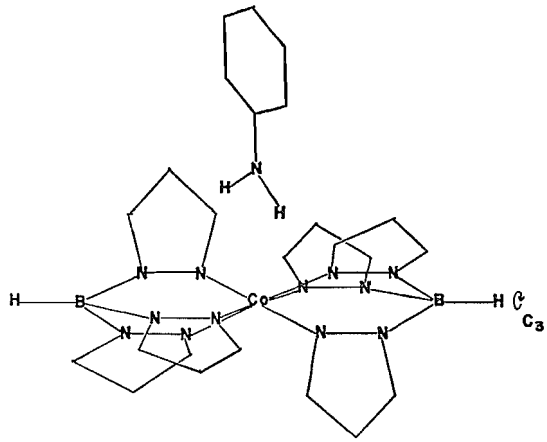

FIG. 1. Structure of Co(II) trispyrazoylborate and preferred direction of approach of aniline molecule.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

to the choice of carbon tetrachloride as a hopefully "inert" solvent and pyridine and aniline as complexing agents. Both of these molecules are rigid (except for rotation of the NH_2 of aniline) and possess comparable dipole moments (aniline = 1.53 D, pyridine = 2.23 D) (28). They differ in that in one case the functional group is the positive end of the dipole (aniline) (29) and in the other case it is the negative end (pyridine).

Results

Figure 2 shows a series of traces of the ^1H spectrum of aniline in the presence of increasing concentrations of Co(II) trispyrazoyl borate (abbreviated $Co[HBpz_3]_2$). Figure 3 shows a similar series for pyridine. Sizable shifts are apparent with those for aniline being greater than those for pyridine. There is broadening of the resonances at higher concentrations of $Co[HBpz_3]_2$, as is expected in a paramagnetic system, but the assignments of individual protons are unambiguous from the spin–spin splittings and intensities. It might next be asked to what extent these shifts are attributable to pseudo-contact interactions. Information on this point can be obtained by carrying out similar experiments with $Zn[HBpz_3]_2$. The Zn and Co complexes are structurally very similar, differing significantly only in the paramagnetism of the latter. From the data in Table I it is apparent that the Zn shifts are very small. Paramagnetic interactions are therefore dominant.

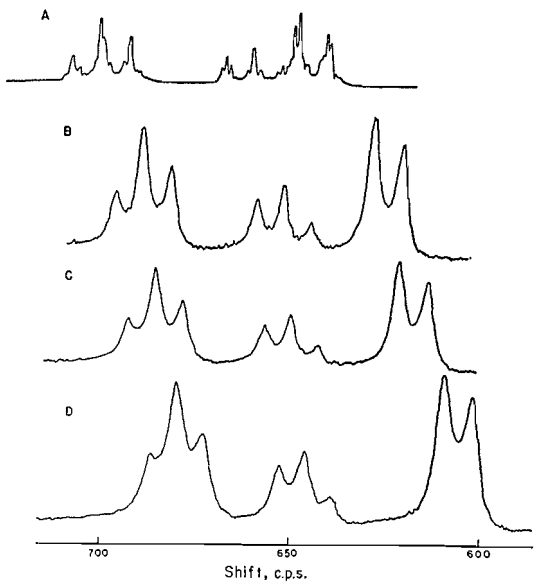

FIG. 2. The n.m.r. spectra of aniline 100 Mc.p.s., CCl_4 solution. A, pure aniline; B, C, D, increasing amounts of $Co[HBpz_3]_2$. Shifts are in c.p.s. to low field of TMS. The lines are assigned as meta, para, and ortho from left to right.

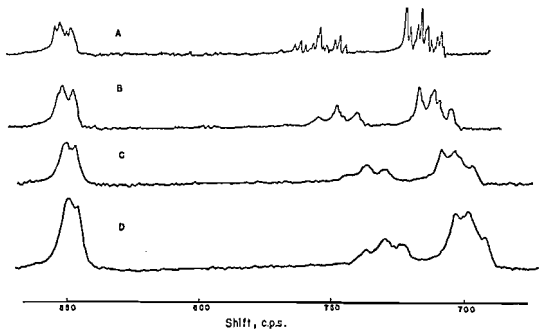

FIG. 3. The n.m.r. spectra of pyridine 100 Mc.p.s., CCl_4 solution. A, pure pyridine; B C, D, increasing amounts of $Co[HBpz_3]_2$. Shifts in c.p.s. to low field of TMS. The lines are assigned as α, γ, and β from left to right.

0.078	646	700	658.5	336

*Shifts in c.p.s. at 100 Mc.p.s. from TMS, CCl_4 solutions.

A number of qualitative inferences can be drawn immediately. Both aniline and pyridine enter the second coordination shell in preference to carbon tetrachloride, the common solvent. The shifts are uniformly to high field. Since D and $g_{\parallel} - g_{\perp}$ are both positive quantities, eq. [1] determines that $(3\cos^2\theta - 1)$ must be negative and hence that the preferred position of solvation is in a quadrant perpendicular to the symmetry axis of the molecule. This is indicated diagrammatically in Fig. 1. For aniline the shifts decrease in the order NH_2 > ortho > meta > para. The $1/r^3$ dependence of eq. [1] strongly suggests that aniline is oriented with the NH_2 closest to the complex. For pyridine the shifts decrease in the order $\gamma > \beta > \alpha$. Approach of the γ proton to the complex is

indicated. In both cases the orientation of the dipole is with the positive end towards the metal. This is of course the opposite to the situation in the first coordination sphere. Such a double layer structure has obvious mechanistic implications.

Further analysis requires a model for the system. It will be assumed initially that there is rapid exchange (on the n.m.r. time scale) between ligand (L = aniline or pyridine) in solution and in the second coordination sphere of the complex X and that

$$X + L \rightleftharpoons XL$$

with equilibrium constant K. With this assumption it may be easily shown that

$$[2] \qquad \Delta\nu_{obs} = \frac{K[X]\Delta\nu_0}{1 + K[X]}$$

where $\Delta\nu_{obs}$ is the observed shift from the ligand frequency and $\Delta\nu_0$ is the chemical shift of XL relative to the ligand. Hence on this model the shifts are independent of [L]. A number of experiments were carried out to check this point. In these experiments relative concentrations were found by integration of the n.m.r. spectra. Thus in one run in the range of [L]/[X] 0.81–8.31 there was a 2.5 c.p.s. variation in the ortho chemical shift, a 2.0 c.p.s. variation in the meta chemical shift, and a 0.5 c.p.s. variation in the para chemical shift of aniline. The lines were relatively broad and these shifts were only just significant. It was concluded from these experiments that formation of XL_2 or higher complexes is not important at ratios of [L]/[X] of < 5. Subsequent experiments were carried out in this concentration range. From eq. [2] it is also apparent that if $K[X] \ll 1$ a plot of $\Delta\nu_{obs}$ against [X] should be a straight line passing through the origin. Such plots are shown in Figs. 4 and 5 for the ortho and meta protons of aniline and for the β and γ protons of pyridine respectively. The slopes of these lines give values for $K\Delta\nu_0$. Plots for other protons are similar and values of the relative slopes are included in Tables II and III. It might be noted that at room temperature 0.1 M $Co[HBpz_3]_2$ solutions (which are close to the maximum solubility in CCl_4) give shifts of about 50 c.p.s. for the ortho proton of aniline and 30 c.p.s. for the γ proton of pyridine both at 100 Mc.p.s. At room temperature the maximum observed shift for the NH_2 protons is about 55 c.p.s. and at the low concentrations of aniline used, no anomalies in the concentration

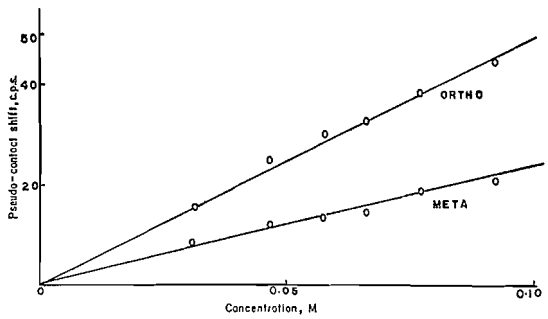

FIG. 4. Plot of the pseudo-contact shifts of the ortho and meta protons of aniline vs. concentration of Co-$[HBpz_3]_2$.

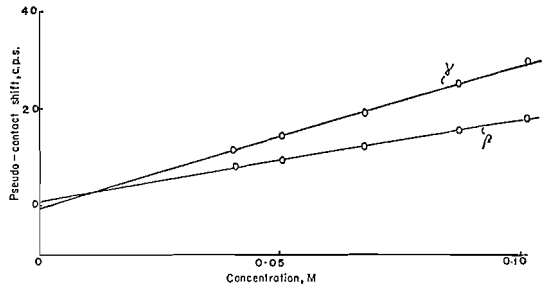

FIG. 5. Plot of the pseudo-contact shifts of the β and γ protons of pyridine vs. concentration of $Co[HBpz_3]_2$.

TABLE II

Calculated relative shifts of aniline protons

Model	r (Å)	Ortho	Meta	Para

dependence attributable to association were found. Using the relationship

$$-RT \ln K = \Delta H - T\Delta S$$

and assuming as above that $K[X] \ll 1$ it follows that

$$[3] \quad \ln \Delta\nu_{obs} = \frac{-\Delta H}{RT} + \frac{\Delta S}{R} + \ln [X] + \ln \Delta\nu_0$$

However, the pseudo-contact shift $\Delta\nu_0$ will have a temperature dependence of approximately $1/T$ (Curie law) (18) and correction for this effect is necessary before utilizing eq. [3] to obtain ΔH. This correction was applied in the following manner. The shifts of the pyrazoyl protons of $Co[HBpz_3)_2$ relative to $Zn[HBpz_3]_2$ were measured in CCl_4 over the temperature range +60 to −20 °C. These shifts show the expected Curie law dependence. $\Delta\nu_0$ must have exactly this temperature dependence. The aniline shift relative to the zinc complex at temperature T was therefore multiplied by the ratio of the pyrazoyl shift at temperature T to that at 25 °C to give a corrected shift $\Delta\nu_{corr}$. The slope of plots of $\ln \Delta\nu_{corr}$ against $1/T$ then gives ΔH. Such a plot for the meta H of aniline is shown in Fig. 6. In this way values of $\Delta H = -2.4 \pm 0.2$ kcal were obtained for aniline and $\Delta H = -2.9 \pm 0.3$ kcal for pyridine. Values obtained from the temperature dependences of the different protons were in good agreement. It might be noted that in the temperature range +60 to −20 °C there is approximately a 25% increase in the pyrazoyl proton shifts whereas the aniline shifts increase by a factor of 4 and the pyridine shifts by a factor of 5. The temperature dependence of the solvation equilibrium constant is clearly the major factor in determining the variation of the shifts with temperature.

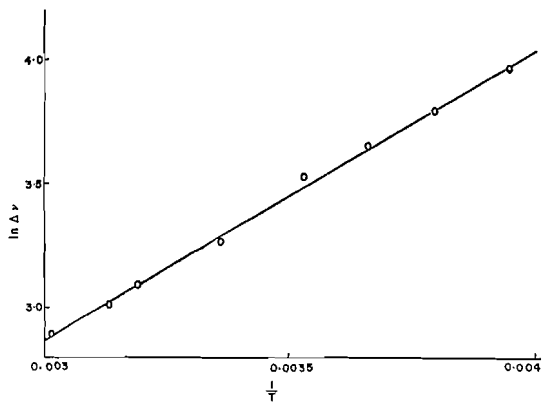

FIG. 6. Plot of $\ln \Delta\nu_{corr}$ vs. $1/T$ for the meta protons of aniline.

In the above manner it is clearly possible to obtain the enthalpy change ΔH for outer sphere coordination without postulating a specific model for the complex. The entropy change ΔS, though, requires a knowledge of $\Delta\nu_0$ and a more detailed discussion of the geometric arrangement of the outer sphere ligands is necesssary.

Discussion

The qualitative considerations of the preceding section have demonstrated that second sphere coodination complexes can be regarded as discrete entities with some degree of geometric structure and with bonding energies of the order of 2 or 3 kcal. However, such complexes are certainly very labile since only the average n.m.r. frequencies for complexed and free ligands are observed. Using the experimental value of D given by Jesson (26), calculation shows that the pseudo contact shift for the ortho proton of an aniline molecule placed on an axis perpendicular to the symmetry axis of $Co[HBpz_3]_2$ with the N atom 7 Å from the Co (a reasonable distance) is +736 c.p.s. at 100 Mc.p.s. Hence the lifetime of the second sphere complex is less than $1/2\pi\Delta\nu \sim 10^{-3}$–$10^{-4}$ s.

It would not be expected that such a loosely bound and transient complex would have a rigid geometry with the well defined bond distances and angles of a conventional chemical compound. The approach adopted in the present discussion will, therefore, be to determine an approximate position for the ligand molecule relative to the complex and then to investigate the effects of various kinds of motion on the pseudo-contact shifts. Three such types of motion may be distinguished: tumbling of the metal complex, tumbling of the ligand, and variation of the intermolecular distance. The absolute pseudo-contact shifts are not available from the experimental data since the entropy changes are unknown. However, the ratios of the shifts for different ligand protons are readily obtained from the slopes of plots such as those of Figs. 4 and 5. These ratios provide the key information needed to determine the geometry. Knowing the geometry, in principle

$\Delta\nu_0$ can be calculated and the entropy changes obtained.

Consider first the case of aniline. As an initial model the aniline molecule was placed perpendicular to the symmetry axis of the $Co[HBpz_3]_2$ with the amino group directed towards the cobalt complex as suggested by the preliminary interpretation of the pseudo contact shifts. Molecular models suggest that the Van der Waals radius of the chelate is ~5 Å, with the molecule being almost spherical. Values of the geometric factors $(3\cos^2\theta_i - 1)/r_i^3$ were therefore calculated for each type of proton (i) for separations (R) between the Co and the N of the aniline of from 4–12 Å. The ratios of these geometric factors give the relative pseudo-contact shifts for the different protons. These ratios are plotted as a function of R in Fig. 7. Note the different scale for the NH_2 protons. At $R = 7$ Å (approximately the correct distance for close contact of the two molecules) the calculated ratios of NH_2:ortho:meta:para are 3.52:1.00:0.55:0.45 compared with the experimental ratios of 1.07:1.00:0.47:0.32. Values at other distances can be inferred for Fig. 7. Free rotation of the NH_2 group is assumed. At no value of R is the overall agreement of the ratios much better than that quoted above. It is apparent that although this model is qualitatively satisfactory, it by no means reproduces the data to within the experimental accuracy. The largest discrepancy is for the NH_2 protons. Before proceeding further, two possible mechanisms other than the pseudo-contact effect for the NH_2 shifts should be considered. First of all, there could be a deshielding of the amino protons due to hydrogen bonding with the complex resulting in a smaller high field shift. Such bonding has been observed by Fung (17) for ethylenediamine complexes. However, such an effect should be equally effective with the zinc complex and, since this gives shifts of only 2 or 3 c.p.s. from aniline, it seems that hydrogen bonding is unlikely to account for the discrepancies of up to 100 c.p.s. observed. Secondly, it is conceivable that the amino protons could experience a contact shift if the cobalt d orbitals containing the unpaired electrons have a significant density at the proton position. This again would be a downfield shift reducing the observed pseudo-contact shift. A rough calculation using the analytical orbitals of Clementi (30) for Co^{2+} gave a shift 8 orders of magnitude too small for a proton 6 Å from the cobalt.

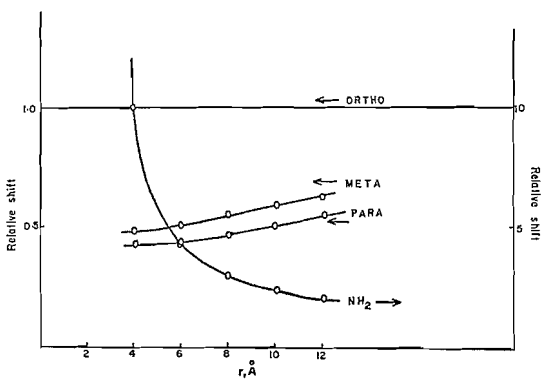

FIG. 7. Calculated pseudo-contact shifts from aniline protons for the model of Fig. 1, r = separation of Co and amino N.

There remains the possibility of a contact shift originating from the spin density on the nitrogen. Such spin density will be much smaller than that on the cobalt but a closer interaction with the amino hydrogens is possible. However, no contact shifts have previously been observed due to spin density transition through even relatively strong hydrogen bonds and Potenza and Poindexter (31) report in a recent paper that they were unable to detect scalar (contact) interactions for solvent protons even by Overhauser effect measurements. It appears, therefore, that the explanation must be sought in terms of the pseudo-contact effect (32)[1].

Before considering motional effects the question might first be asked as to whether a better fit can be obtained with a static model in which the direction of approach is not along the axis perpendicular to the symmetry axis of the molecule. Briefly, the answer to this question is no. The observation of high field shifts restricts the possible directions of approach to a cone of half angle 35° 16′ surrounding the perpendicular to

[1]These authors have attributed proton shifts of chloroform in the presence of ionic Co(II) and Ni(II) phosphine complexes to contact interactions arising from hydrogen bonding. The negative charge on the metal complex makes this perhaps the most favorable situation for observing such an effect. However, their conclusions are not entirely unambiguous since both the detailed geometry of the complex and the g value anisotropies are unknown. In the present case we prefer not to invoke hydrogen bonded contact interactions but would point out that in any event a modest contact contribution to the NH_2 shift would not affect the qualitative conclusions of this paper.

the symmetry axis. If the approach is not perpendicular all shifts are reduced with para being reduced less than meta < ortho < NH_2. The two ortho protons, for example, become nonequivalent and average values of $(3\cos^2\theta - 1)$ were taken. The effect is rather small, is in the wrong direction to improve the experimental ortho:para ratio, and, although in the right direction to improve the ortho:NH_2 ratio, is not large enough to produce any close agreement. In addition molecular models suggest no reason why there should be any favored angle different from $\theta = \pi/2$.

Consider now a model in which the aniline molecule is fixed in space and the cobalt complex is allowed to tumble. It should first be noted that if the tumbling is entirely free, the angular term in the expression for the average dipolar shift is given by

$$\frac{\int_0^{\pi/2} (3\cos^2\theta - 1)\sin\theta\, d\theta}{\int_0^{\pi/2} d\theta} = 0$$

i.e. the pseudo-contact shifts are averaged to zero. This is clearly not the case. Consider next the situation in which there is a preferred orientation and a distribution of geometries with a maximum probability at $\theta = \pi/2$. For simplicity assume that the distribution function is proportional to $\sin\theta$. The averaged pseudo-contact shift is proportional to

$$\frac{\int_0^{\pi/2} (3\cos^2\theta - 1)\sin^2\theta\, d\theta}{\int_0^{\pi/2} d\theta} = -\frac{1}{4}$$

If the distribution function had been a δ function centered at $\theta = \pi/2$ (i.e. the static model) the angular part of the expression would have had the value -1. Thus the effect of allowing restricted tumbling of the complex is to uniformly reduce the dipolar shifts by a factor equal to 1/4 for a sinusoidal distribution. For other possible forms of the angular dependence this factor will take on values between 0 and 1. In any event such a uniform reduction will merely contribute to the entropy term.

As the opposite extreme to the static model one could consider a very weakly bound pair of molecules with a binding energy ε at a distance of closest approach of a given proton r_0 and with $\varepsilon \ll kT$. There would then be a distribution of molecules with separations varying from $r = r_0$ to $r = \infty$ with the potential energy $u = f(r)$. The average pseudo-contact shift would obviously be less than that of the static model with $r = r_0$ and the variation of this average shift can be investigated as a function of r_0. Thus if the distance of the center of mass of the complexing molecule from the metal atom is x, then the number of molecules at distance x is proportional to $xe^{-u/kT}$. Considering only the radial dependence of the pseudo-contact shift.

$$\Delta\nu \propto \frac{1}{r^3} xe^{-u/kT}$$

For proton a, let $r = x + a$, and for proton b, let $r = x + b$, then

$$\frac{\langle\Delta\nu_a\rangle}{\langle\Delta\nu_b\rangle} = \frac{\int \frac{xe^{-u/kT}}{(x+a)^3}\, dx}{\int \frac{xe^{-u/kT}}{(x+b)^3}\, dx}$$

In general the relative shifts will be a function of u. Taking the particularly simple case for which $u = 0$ if $x > x_0$ and $u = \infty$ if $x < x_0$ i.e. $\varepsilon \ll kT$ and a hard sphere approximation, it is easily shown that

$$\frac{\langle\Delta\nu_a\rangle}{\langle\Delta\nu_b\rangle} = \left(\frac{r_{0b}}{r_{0a}}\right)^4 \left(\frac{r_{0a} + 3x_0}{r_{0b} + 3x_0}\right)$$

where $r_{0a} = x_0 + a$ and $r_{0b} = x_0 + b$. For the case where a and b are small relative to x_0 it is apparent that the shifts are proportional to the inverse fourth power of r_0 rather than the inverse cube. Thus in general a rather faster fall off of shift with distance is expected for a labile complex than for the static model. In Table II are shown the calculated ratios of the ortho, meta, and para shifts for separations of the metal atom and amino nitrogen of 6 and 8 Å and for $1/r^3$, $1/r^4$, and $1/r^5$ dependence of the shifts. The experimental ratios are also given for comparison. It is apparent that the experimental data agrees best with a $1/r^4$ dependence indicating substantial lability.

The final type of motion to be considered is tumbling of the aniline molecule. Averaging of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

this type of motion has been considered by LaMar (21) for the case of freely tumbling tetraalkyl ammonium ions placed on the symmetry axis of the complex. A slight modification of his result gives

$$\left\langle \frac{(3\cos^2\theta - 1)}{R^3} \right\rangle = -\frac{[A^2 - 1.25Q_i^2]}{A^3(A^2 - Q_i^2)}$$

where A is the distance of the center of gravity of the tumbling molecule from the metal ion and Q_i is the radius of rotation of the ith proton, for the case in which the tumbling molecule is situated perpendicular to the axis of symmetry of the complex. Qualitatively the effect of this motion is that when $A \gg Q$ the shifts of all protons in the molecule become equal but when $A \sim Q$ the average shift of protons close to the center of gravity is greater than that of protons further from the center of the molecule. For this reason LaMar observed the shifts of the tetraalkyl ammonium ion protons to diminish in the order $\alpha > \beta > \gamma > \delta$. His analysis led to an interionic distance of 3.8 Å. In the present case the intermolecular distance A is much larger ($\sim$ 10 Å) for a reasonable model and we are much closer to the limit $A \gg Q$. Thus for amino nitrogen – metal distances of 6 and 8 Å we obtain NH_2:ortho:meta:para ratios of 0.987:1.0:0.983:0.975 and 0.992:1.0:0.990:0.985, respectively. Clearly these ratios do not closely resemble those obtained experimentally and a model involving free tumbling of the aniline is inadmissible. It is, however, of interest to compare these results with those from the static molecule. At $r = 8$ Å, the relative shift of the NH_2 protons has been reduced from 2.962 to 0.992 whereas the experimental value is 1.07. A model involving restricted tumbling of the aniline, i.e. where there is a preferred orientation of the aniline molecule with respect to the cobalt complex but other orientations also contribute, could certainly help to account for the observed NH_2 shift.

The qualitative conclusions regarding the effects of non-rigidity of the second sphere complex on the observed pseudo-contact shifts can therefore be summarized as follows. Free tumbling of the transition metal complex averages the shifts to zero. Restricted tumbling with a preferred orientation reduces all the shifts uniformly and does not affect the ratios of NH_2:ortho:meta:para shifts. Free tumbling of the aniline placed in a specified position with respect to the complex tends to equalize the different shifts. Restricted tumbling will tend to make the ratios more nearly equal. A distribution of different intermolecular separations over the range r_0 (the distance of closest approach) to infinity diminishes all the shifts relative to a static model with separation r_0 and accentuates the difference in relative shifts between the closer and farther protons. It is apparent that a combination of these effects will suffice to account for the experimental results. Detailed calculations with a computer would be feasible but it seems doubtful whether they would identify a unique model or whether if such a model was identified it would add significantly to the understanding of second coordination sphere structure.

The considerations for the pyridine case are essentially similar. In Table III calculated ratios for the α, β, and γ pseudo-contact shifts for a static model with the pyridine placed on an axis perpendicular to the symmetry axis of the complex and with different values of the γH to metal distance are shown. For closest approach this distance is expected to be 6–7 Å. The observed ratios are 1.0:0.57:0.05. All the observed shifts are smaller than those for aniline and the α shifts in particular are very small ($\sim$ 2 c.p.s.) so that the last ratio is not very meaningful since it could be affected substantially by effects other than pseudo contact. Qualitatively, however, it is apparent that the pattern is quite similar to that for aniline, in particular in that the relative shift of the closest proton (in this case γH) is somewhat smaller than expected for reasonable values of r, which is taken as evidence for restricted tumbling of the pyridine.

The Structure of the Second Coordination Sphere

It is apparent from the above results that a discussion of the structure of second coordination sphere complexes should not be phrased in the terms usually associated with molecular structure, i.e. well defined bond lengths, bond angles, and bond energies. In terms of the current conventional subdivisions of chemistry, structural and dynamic effects are not separable on the time scale of these experiments. It could be argued that on a sufficiently short time scale the effects would be separable, but since the real

interest of the chemist is in chemical reactions the lifetime of a structure relative to the half life of the chemical rate process of interest is a relevant factor. Thus in the present case we may define an experimentally determined enthalpy change in terms of an equilibrium of the form

$$X + L \rightleftharpoons XL$$

providing it is understood that XL represents the time average of a large number of different geometric structures each appropriately weighted according to its statistical probability of occurrence. ΔH is therefore a rather imprecisely defined quantity in comparison to the changes in enthalpy resulting from well defined chemical reactions but nevertheless it is the correct quantity to use in a discussion of the significance of second coordination sphere complexes in transition metal reactions. The energy of a transient complex is not too useful for this purpose unless it is combined with some measure of the probability of a particular complex ligand arrangement. The point is perhaps illustrated even better by the entropy changes ΔS. Such entropy changes can only be found if a definite model is assumed. Thus the experimental results indicate

(*1*) There is a definite preferred distance of separation of X and L. This distance corresponds rather nicely to a second coordination sphere; the results are not compatible, for example, either with a model in which the aniline molecule is always separated from the complex by a layer of solvent molecules or with one in which the aniline can occupy a position comparable in distance to a first coordination sphere ligand.

(*2*) There is a definite preferred orientation of the complex; the symmetry axis of $Co[HBpz_3]_2$ is perpendicular to the Co–aniline vector.

(*3*) There is a definite preferred orientation of the aniline, with the amino group directed towards the $Co[HBpz_3]_2$ molecule. Using a static model based on these preferences, $\Delta\nu_0$ can be calculated and ΔS found from the slopes of $\Delta\nu_{obs}$ vs. [X] plots since these slopes equal $K\Delta\nu_0$. Results from such a calculation are shown in Table IV. The values obtained for different protons on the same molecule are not the same, i.e. these values of ΔS are not the true entropy changes for a reaction

$$X + L \rightleftharpoons XL$$

but also contain various quantities associated with the internal motions of XL some of which are different for different protons as demonstrated in the discussion. Since such motions contribute to the disorder of the system the "true" entropy change, if measured on a very small time scale, would be more negative than any of the derived values. Consider, however, the virtues of a second coordination sphere complex as an intermediate in a ligand substitution process. If it is to provide a favorable pathway there must be a smaller free energy of activation for the overall process. It could be visualized that this end would be accomplished if the pre-formation of a second sphere complex placed the incoming ligand in the right position for further reaction and hence reduced the entropy requirements of the actual substitution process. If the lifetime of a given second sphere configuration is short compared with the rate of the subsequent substitution step, then a time averaged entropy change for the formation of the outer sphere complex is relevant. Thus it is significant that the values in Table IV are sufficiently large (10–15 e.u.) to make a meaningful impact on a free energy of activation and that they are significantly different for aniline and pyridine. Moreover the ordering of the ligand molecules in the outer sphere is not necessarily entirely helpful from the substitution point of view. Thus the preferred orientation of the pyridine molecule would appear to be unfavorable for further reaction and the advantage of an outer sphere mechanism to be therefore doubtful. It is apparent that the possibilities can be quite subtle and may well help to rationalize some of the rather devious reaction pathways which occur in homogeneous catalysis.

The purpose of the present paper is to demonstrate the utility of this n.m.r. method for studying weak interactions between metal complexes and potential ligands. It is not appropriate to

TABLE IV

Entropy changes for static models

Aniline*	ΔS (e.u.)	Pyridine†	ΔS (e.u.)

draw too many far-reaching conclusions from the two examples studied. Molecular models suggest that the preferred geometry of the complex can be best rationalized in terms of the closest allowed approach of the aniline or pyridine molecule to the negatively charged nitrogen atoms surrounding the cobalt. The ΔH values obtained of course represent a difference between the solvation energies of an aniline or pyridine molecule associated with the cobalt complex or with carbon tetrachloride. The higher ΔH with pyridine may well indicate stronger solvation of aniline by carbon tetrachloride rather than stronger solvation of the cobalt complex by pyridine. The ΔH and ΔS parameters may be strongly influenced by steric as well as electronic factors. These factors will be investigated by using substituted anilines and pyridines as well as a variety of other ligands in experiments of this kind. It is also apparent that in the present case the binding energies for second sphere coordination are considerably less than those for first sphere coordination. This will not necessarily be the case for coordinately non-saturated complexes, e.g. $Rh(P\phi_3)_3Cl$. Investigations aimed at elucidating this situation are also planned and will be reported in subsequent papers in this series.

Experimental

The n.m.r. spectra were obtained on a Varian HA 100 spectrometer. The proton shifts were measured relative to tetramethylsilane used as an internal calibrant. Carbon tetrachloride, aniline, and pyridine were obtained commercially and used without further purification. Cobalt and zinc trispyrazoyl borates were prepared by Dr. S. Trofimenko in a manner described previously (24).

Acknowledgments

The author is indebted to Dr. S. Trofimenko of the Central Research Department, E. I. DuPont Co., Wilmington, Delaware, for gifts of cobalt and zinc trispyrazoyl borates and to the National Research Council of Canada for financial support of this research.

γ-Radiolysis of cyclohexane with electron scavengers. VII. Perfluorocyclohexane and perfluorobenzene as electron scavengers[1,2]

N. H. SAGERT, J. A. REID[3], AND R. W. ROBINSON
Research Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

Received March 7, 1969

The room temperature, liquid phase radiolysis of cyclohexane has been investigated using perfluorocyclohexane (C_6F_{12}) and perfluorobenzene (C_6F_6) as electron scavengers. Yields of the respective monohydrofluorocarbons were investigated over several orders of magnitude scavenger concentration. The $C_6F_{11}H$ yield from the C_6F_{12}–cyclohexane system has previously been shown to result from electron capture by C_6F_{12}. The data over the extended concentration range were used to calculate a total ion yield of 4.3 ± 0.2 *G* units and a free ion yield of 0.14 ± 0.02 *G* units. With C_6F_6 as an electron scavenger, hydrogen, cyclohexene, and dicyclohexyl yields were all reduced. However, C_6F_5H yields were much lower than the $C_6F_{11}H$ yields from C_6F_{12}. On changing the neutralization step by adding the proton scavenger ethanol, C_6F_5H yields were obtained equal to the $C_6F_{11}H$ yields from C_6F_{12}. Thus C_6F_6 is as efficient an electron scavenger as C_6F_{12}. Since a change in the neutralization process produces a large change in yield, it is likely that C_6F_5H (or C_6F_5) is produced in the neutralization process.

Canadian Journal of Chemistry, 47, 2655 (1969)

Introduction

In recent years, it has been realized that the geminate recombination of ions plays an important part in the radiolysis of non-polar liquids (1). Since they lose energy rapidly, only a small number of electrons escape completely from the fields of their parent ions and become uniformly distributed in the liquid. Typically, the total ion yield for aliphatic hydrocarbons is 4.3 ion pairs for each 100 eV absorbed (4.3 *G* units) (2, 3) and the free ion yield is about 0.1 *G* units (4). One method of studying this phenomenon is to add solutes which react with or scavenge electrons before they can be captured by a positive ion. Theoretical treatments of this electron scavenging have been proposed (5, 6) but one of the most useful treatments is the empirical one of Warman, Asmus, and Schuler (1). This treatment is supported by the theoretical work of Hummel (6), which in turn is largely based on an earlier theoretical paper by Monchick (7).

Rajbenbach (8, 9) has shown that perfluorocyclohexane (C_6F_{12}) and perfluorobenzene (C_6F_6) both reduce hydrogen yields from the radiolysis of liquid hydrocarbons and has argued that they do this by capturing electrons. We have previously used perfluorocycloalkanes as electron scavengers (10), equating the yield of the monohydrofluorocarbon with the electron yield. In the work reported here, we have extended the results for C_6F_{12} to concentrations less than 10^{-5} *M* to allow a comparison with theory. We also wanted to see if C_6F_{12} could effectively scavenge fully thermalized electrons, in order to eliminate the possibility that the production of $C_6F_{11}H$ requires epithermal electrons.

Perfluorobenzene was investigated as an electron scavenger to see if significant C—F bond breaking occurs with aromatic fluorocarbons. As the amount of C—F bond breaking was smaller than with C_6F_{12}, the effect of changing the neutralization process was investigated by adding a proton scavenger such as ethanol (11).

Experimental

Fisher Spectrograde cyclohexane was used as received for experiments at scavenger concentrations greater than 10^{-2} *M*. Phillips Research Grade cyclohexane was also used after treatment overnight with sulfuric acid to remove cyclohexene. For experiments at lower scavenger concentrations, the Fisher cyclohexane was passed through a silica gel column. It was transferred to a vacuum line and pumped on at room temperature until ⅓ of its volume was removed, distilled onto a sodium mirror, and kept in contact with this mirror for several days. It was then distilled into a measuring volume, and pumped on at room temperature until ⅓ of its volume was removed. This procedure was necessary to remove CO_2. A final degassing was done by the freeze – pump – thaw technique. The C_6F_{12} and C_6F_6 (Aldrich) were also pumped on at room temperature for experiments at low scavenger concentrations. The C_6F_{12} had no detectable $C_6F_{11}H$ or C_6F_{10} impurities. The C_6F_6 had a measurable

amount of C_6F_5H which was allowed for when calculating yields. Absolute ethanol was passed through a silica gel column to remove any traces of benzene.

Solutions of high scavenger concentrations were made up volumetrically or by weighing, as appropriate. Solutions of low scavenger concentrations were made up by measuring out, from a calibrated volume, aliquots of vapor in equilibrium with the thermostated solid or liquid. Vapor pressures as a function of temperature were taken from Reed (12) for C_6F_{12} and from Patrick and Prosser (13) for C_6F_6. Solutions were irradiated in Pyrex cells of 2 ml volume fitted with a breaking device. All sample preparations were carried out on a mercury-free grease-free vacuum line.

Samples were irradiated at 25 °C in a ^{60}Co γ-source at a mean dose rate (in cyclohexane) of 9.7×10^{15} eV/g s as determined by ferrous sulfate dosimetry taking $G(Fe^{3+}) = 15.6$. Appropriate corrections were made to the absorbed dose for the varying electron densities of the solutions.

After irradiation, gases not condensable at 77 °K were measured volumetrically and analyzed mass spectrometrically. Liquid products were determined by gas chromatography (14). The $C_6F_{11}H$ was determined on an XE-60 column at 40 °C and C_6F_5H on a squalane column at 60 °C. For C_6F_6 solutions, cyclohexene was determined on a β,β-oxydipropionitrile – silver nitrate column, as its retention time on the normally more satisfactory 1,2,3-tris(2-cyanoethoxy)propane column was close to that of C_6F_6. Products were identified by retention time and by mass spectrometry (10, 15).

Results

(i) Perfluorocyclohexane in Liquid Cyclohexane

The major features of the γ-radiolysis of liquid cyclohexane in the presence of up to 0.3 M C_6F_{12} have been described (10). Large yields of $C_6F_{11}H$ were noted and were ascribed to the effects of electron capture by C_6F_{12}. In this work, the range of solute concentrations has been extended to below 10^{-5} M C_6F_{12}. The results are shown in Fig. 1. Yields at lower concentrations were quite dose dependent and G values were determined from the initial slopes of plots of the concentration of $C_6F_{11}H$ against the absorbed dose. At the lowest scavenger concentrations, these plots were linear only at doses below 3×10^{17} eV/g, where about 10% of the C_6F_{12} was decomposed. At the highest concentrations the plots were linear to 10^{19} eV/g. At low scavenger concentrations yields of $C_6F_{11}H$ were eliminated by less than 0.1 M of N_2O, SF_6, or CO_2, indicating that electrons are precursors of this yield. Previously, N_2O was shown to compete with C_6F_{12} for electrons in the high scavenger concentration range (10).

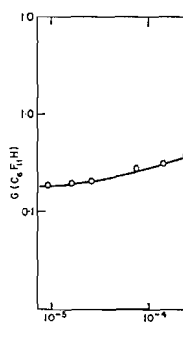

FIG. 1. Yields of $C_6F_{11}H$ as a function of C_6F_{12} concentration on a double logarithmic scale.

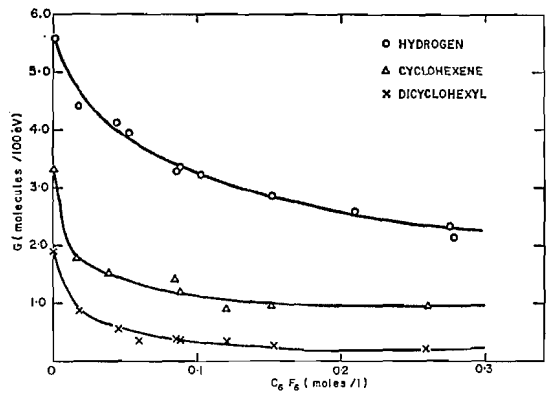

FIG. 2. Hydrogen, cyclohexene, and dicyclohexyl yields from the radiolysis of the C_6F_6 –cyclohexane system. Dose = 1.42×10^{19} eV/g.

(ii) Perfluorobenzene in Liquid Cyclohexane

Perfluorobenzene, (C_6F_6), reduces hydrogen yields from the γ-radiolysis of cyclohexane as has been noted by Rajbenbach (8, 9). The data in Fig. 2 show that dicyclohexyl and cyclohexene yields are reduced as well. In fact, they are reduced well below the limiting yields obtained with relatively uncomplicated electron scavengers such as SF_6 (2) and CO_2 (16). There were a number of unidentified products of both higher and lower molecular weight than dicyclohexyl observed on the XE-60 column at 170 °C, and it is possible that polymers of even higher molecular weight were formed. Polymer formation would account for lower cyclohexene and dicyclohexyl yields. Yields of C_6F_5H are shown in Fig. 3 for a wide range of C_6F_6 concentrations. These yields are all calculated from the initial linear portions of plots of molecules produced against absorbed dose. At the lowest C_6F_6 concentrations these

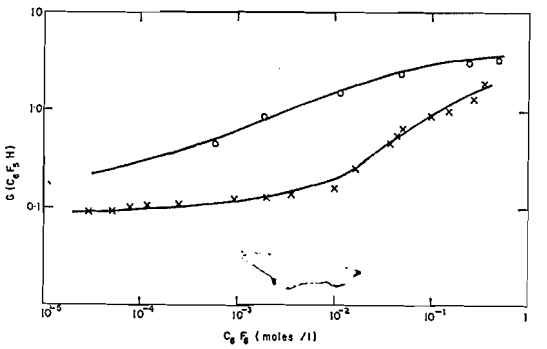

FIG. 3. Yields of C_6F_5H as a function of C_6F_6 concentration on a double logarithmic scale. The crosses (×) represent the C_6F_6 – cyclohexane system. The circles (○) represent yields of the same system with 0.14 *M* ethanol. The upper curve is from Fig. 1.

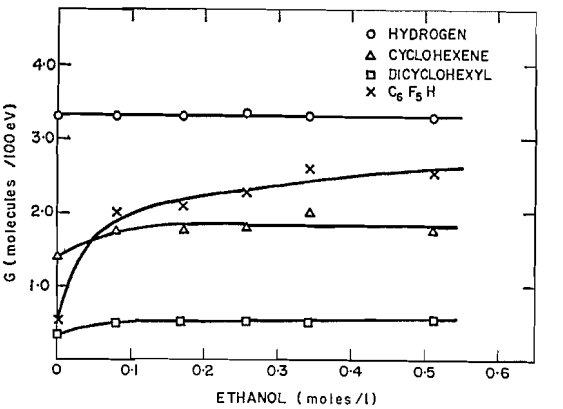

FIG. 4. Hydrogen, cyclohexene, dicyclohexyl, and C_6F_5H yields from the radiolysis of the C_6F_6 – ethanol – cyclohexane system. $C_6F_6 = 0.085_8$ *M*. Dose = $2.1_2 \times 10^{19}$ eV/g.

curves were only linear well below 10^{18} eV/g. Yields of C_6F_5H are much lower than the corresponding yields of $C_6F_{11}H$ from C_6F_{12} shown in Fig. 1. For comparison, the curve from Fig. 1 is shown as the upper curve in Fig. 3. It should be emphasized that the cyclohexane was given the same purification treatment as was given that used for radiolyses with C_6F_{12}. Both N_2O and SF_6 drastically reduced the yield of C_6F_5H, showing that electrons were precursors of this product.

In order to change the neutralization process, ethanol and ammonia, which are known to be efficient proton scavengers (11, 17), were added to the C_6F_6– cyclohexane system. Figure 4 gives yields of the major products of cyclohexane radiolysis with varying amounts of ethanol at a fixed concentration (0.086 *M*) of C_6F_6.

Within experimental error, no significant effect of total dose was noted from $1.0_3 \times 10^{19}$ eV/g to 6.4×10^{19} eV/g. No effect was noted on the hydrogen yield and only small, but significant, increases were noted in the dicyclohexyl and cyclohexene yields. Neither 1-cyclohexyl ethanol nor 2-cyclohexyl ethanol were found in measurable amounts. A large increase was noted in the C_6F_5H yield to a value close to that measured for $C_6F_{11}H$ from C_6F_{12} in cyclohexane at a comparable scavenger concentration.

Yields of C_6F_5H at varying C_6F_6 concentrations in the presence of 0.14 *M* ethanol are given in Fig. 3. These points were obtained at much lower doses, taking care to be always in the linear portion of a plot of C_6F_5H produced against dose. The upper line in Fig. 3 is not drawn through these points, but is the line drawn through the $C_6F_{11}H$ yields in Fig. 1. Except at the highest concentrations, the yield of C_6F_5H from C_6F_6 with ethanol present is equal to the yield of $C_6F_{11}H$ from C_6F_{12}. Unfortunately experimental difficulties prevented us from going to lower C_6F_6 concentrations.

Some work was done with ammonia as a proton scavenger, and increased yields of C_6F_5H were noted in its presence. However, no quantitative results are included since solutions of NH_3 and C_6F_6 in cyclohexane became yellow before irradiation, perhaps due to formation of $C_6F_5NH_2$ and related polymers (18).

Discussion

Rajbenbach (8) was the first to propose that perfluorocycloalkanes affect the radiolysis of liquid hydrocarbons by capturing electrons. Recent work by one of us (10) and by Mittal and Libby (19) support this view. Our work showed that electron capture by C_6F_{12} in cyclohexane (reaction [1])

$$[1] \qquad C_6F_{12} + e^- \rightarrow C_6F_{12}^-$$

leads to an anion which does not produce hydrogen on neutralization and, before or during neutralization, does produce two cyclohexyl radicals, a C_6F_{11} radical, and, as shown by Rajbenbach (9), a molecule of HF. These products could conceivably be produced by dissociation of the $C_6F_{12}^-$ anion (reaction [2])

$$[2] \qquad C_6F_{12}^- \rightarrow C_6F_{11} + F^-$$

even though reaction [2] is 1.8 eV endothermic (20) in the gas phase, because of solvation effects. However, we have shown (15) that $C_6F_{11}H$ is produced in the gas phase radiolysis of the cyclohexane – C_6F_{12} system where reaction [2] cannot occur. Hence it now appears that these products are produced mainly in the neutralization step (reaction [3])

$$[3a]\quad C_6F_{12}^- + C_6H_{12}^+ \rightarrow C_6F_{11} + C_6H_{11} + HF$$

$$[3b]\quad \rightarrow C_6F_{11}H + C_6H_{11} + F$$

Although reaction [3*b*] is slightly less favorable thermodynamically, it may occur by proton transfer to $C_6F_{12}^-$ followed by dissociation of the complex (9). Either F or C_6F_{11} would rapidly abstract a hydrogen from cyclohexane.

The results shown in Fig. 1 were fitted to the empirical expression used by Warman, Asmus, and Schuler (1) for electron scavenging

$$[4]\quad G(C_6F_{11}H) = G_{fi} + \frac{G_{gi}\{\alpha_{C_6F_{12}}[C_6F_{12}]\}^{\frac{1}{2}}}{1 + \{\alpha_{C_6F_{12}}[C_6F_{12}]\}^{\frac{1}{2}}}$$

where G_{fi} is the yield of free ions, i.e. the yield of ions which escape the field of their parent ion, and G_{gi} is the geminate ion yield, i.e. the yield of ions which recombine with their parent ion. The $\alpha_{C_6F_{12}}$ is a constant characterizing the reactivity of C_6F_{12} to electrons. This expression was used by its originators to correlate a large number of results with electron scavengers. At low scavenger concentration it reduces to

$$[5]\quad G(C_6F_{11}H) = G_{fi} + G_{gi}\{\alpha_{C_6F_{12}}[C_6F_{12}]\}^{\frac{1}{2}}$$

This same square root dependence is predicted directly by Hummel (6). At scavenger concentrations below 10^{-3} *M*, a plot of $G(C_6F_{11}H)$ against the square root of the scavenger concentration should give a straight line with intercept equal to G_{fi}. Rzad and Warman (21) have applied this method to the determination of the free ion yield from hydrocarbons using $^{14}CH_3Br$ as a scavenger and obtained free ion yields in good agreement with those obtained by other methods. Figure 5 shows our results plotted in this fashion. A free ion yield of 0.14 ± 0.02 *G* units is obtained. This is in good agreement with the 0.12 *G* units obtained by Rzad and Warman using the $^{14}CH_3Br$ scavenging method (21), the 0.14 *G* units obtained by Schmidt and Allen using the clearing field method (4), and the 0.11 *G* units obtained by Tewari and Freeman using the steady state conductivity method (22).

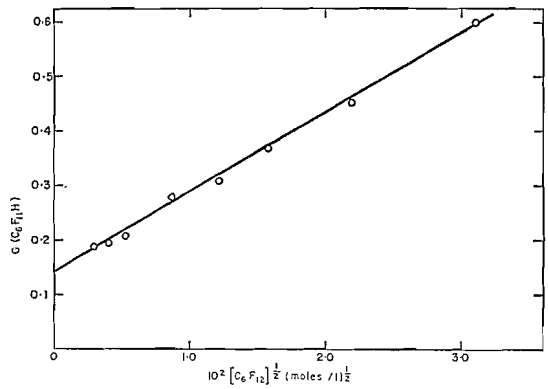

FIG. 5. Determination of free ion yield from the data in Fig. 1.

Over the entire concentration range a plot of $[G(C_6F_{11}H) - G_{fi}]^{-1}$ against $[C_6F_{12}]^{-\frac{1}{2}}$ should be linear. Our results at high concentrations are shown in Fig. 6. This analysis gives a geminate ion yield of 4.2 ± 0.2 *G* units and an $\alpha_{C_6F_{12}}$ of 30 ± 1. Thus the total electron yield is about 4.3 *G* units, close to that predicted from the gas phase *W* values (4, 23), and C_6F_{12} is shown to be a very efficient electron scavenger with one of the highest α's known (1). Furthermore, since C_6F_{12} reacts efficiently with well thermalized electrons to give $C_6F_{11}H$, there is no possibility that excess electron energy is necessary to produce this product, in agreement with conclusions reached previously (10).

Perfluorobenzene is known to attach electrons very rapidly in the gas phase, as the response of an

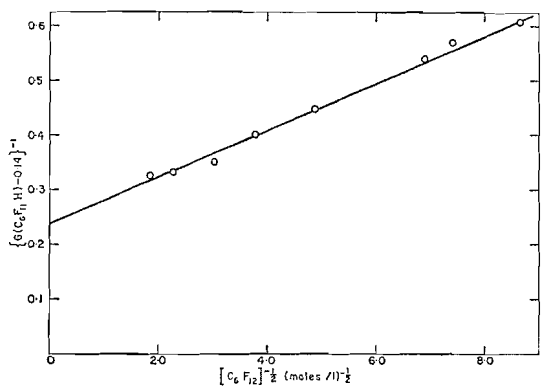

FIG. 6. Determination of the total ion yield and $\alpha_{C_6F_{12}}$ from the data in Fig. 1.

electron capture detector is very high towards it (24). It captures electrons in liquid hydrocarbons as well, since Rajbenbach (8, 9) has shown that it can reduce nitrogen yields from the radiolysis of N_2O–hydrocarbon systems. The results in Fig. 2 show that the hydrogen yield is reduced as efficiently as with C_6F_{12} (10). In contrast to results with C_6F_{12} (10), cyclohexene, and dicyclohexyl are reduced proportionately more than the hydrogen yield, so that there is a hydrogen surplus of about 1.9 *G* units at 0.05 *M* C_6F_6 and 1 *G* unit at 0.3 *M* C_6F_6. This behavior is similar to that observed with the cyclohexane–benzene system (25), where polymer formation had to be considered to account for a hydrogen surplus of 1 *G* unit at 0.2 *M* C_6H_6.

Some C_6F_5H is formed (Fig. 3) and therefore

[6*a*] $C_6F_6^- + C_6H_{12}^+ \rightarrow C_6F_5 + C_6H_{11} + HF$

[6*b*] $\rightarrow C_6F_5H + C_6H_{11} + F$

reaction [6] occurs to some extent, but the C_6F_5H yields do not fit eq. [4]. One possible complication is the transfer of excitation energy to C_6F_6. Another is the transfer of positive charge to C_6F_6. The gas phase ionization potential of C_6H_{12} is 9.88 eV (26) and that of C_6F_6 is 9.88 (27) to 9.97 eV (28). However, as discussed by Bralsford, Harris, and Price (28), the ionization potential of an aromatic fluorocarbon is a delicate balance between an inductive effect which raises it in saturated fluorocarbons (to 13.2 eV for C_6F_{12} (29)) and resonance effects which lower it by stabilizing the molecular ion. Hence the effects on the ionization potential of the cyclohexane solvent may not be at all equal for cyclohexane and for C_6F_6, and there may be significant charge transfer by reaction [7]

[7] $C_6F_6 + C_6H_{12}^+ \rightarrow C_6F_6^+ + C_6H_{12}$

Neutralization would then be between $C_6F_6^-$ and $C_6F_6^+$, leading to no hydrocarbon products.

In the presence of ethanol, proton transfer to ethanol has been shown to proceed efficiently (11, 30).

[8] $C_6H_{12}^+ + C_2H_5OH \rightarrow C_6H_{11} + C_2H_5OH_2^+$

Neutralization of $C_2H_5OH_2^+$ by an unscavenged electron leads to H_2 formation (reaction [9])

[9] $C_2H_5OH_2^+ + e^- \rightarrow C_2H_5OH + H$

with about the same efficiency as the neutralization of $C_6H_{12}^+$ with e^-, since no large effects of adding ethanol are noted on the hydrogen yield (11).

With C_6F_6 and ethanol both present, neutralization of $C_2H_5OH_2^+$ by $C_6F_6^-$ leads to the efficient formation of C_6F_5H

[10*a*] $C_2H_5OH_2^+ + C_6F_6^- \rightarrow C_6F_5$ + products (C_2H_5OH + HF)

[10*b*] $\rightarrow C_6F_5H$ + products (C_2H_5OH + F)

As the hydrogen yield is not increased, the "products" in reaction [10] do not include H_2 precursors. The actual products of these reactions are not known. The suggestions made in reaction [10] are given to show stoichiometry. Reaction [10*b*] may take place by proton transfer to form a C_6F_6H complex which then eliminates an F atom. A somewhat analogous reaction between protonated methyltetrahydrofuran and the anion of α-methylstyrene has been noted recently (31). Competition between reactions [7] and [8] may account for the fact that C_6F_5H yields are slightly lower than $C_6F_{11}H$ yields from C_6F_{12} at the highest C_6F_6 concentrations. The C_6F_5H yields in Fig. 4 show that a high ratio of ethanol to C_6F_6 is necessary to give the maximum C_6F_5H yield.

The cyclohexyl radicals, produced in reaction [8] and from products formed in reaction [10], are reflected in the small increases in dicyclohexyl and cyclohexene yields, but the hydrogen balance is very poor, so nothing quantitative can be said.

The C_6F_5H yields, in the presence of 0.14 *M* ethanol are very close to those of $C_6F_{11}H$ from the C_6F_{12}–cyclohexane system. Thus, like C_6F_{12}, C_6F_6 is an extremely efficient scavenger for electrons. The large increases on the addition of ethanol imply that C_6F_5H is produced in the neutralization step and not by a unimolecular dissociation of $C_6F_6^-$. In the latter case a change in the neutralization step would not have such a large effect.

Acknowledgment

It is a pleasure to acknowledge useful aid and advice from colleagues Drs. D. A. Armstrong, A. W. Boyd, and C. Willis. We are especially indebted to Dr. J. M. Warman who discussed his results and methods of purifying cyclohexane with us prior to their publication.

Organic compounds of gallium. III. Reactions of gallium alkoxides with acetylacetone, ethyl acetoacetate, methyl acetoacetate, and methyl salicylate

R. C. MEHROTRA AND S. R. BINDAL
Chemical Laboratories, University of Rajasthan, Jaipur, India

Received November 5, 1968

Derivatives of gallium of the type: $Ga(i\text{-}C_3H_7O)_{3-x}lig_x$ (x = 1, 2, or 3; and H lig = acetylacetone, methyl and ethyl acetoacetate, or methyl salicylate) have been synthesized by reacting gallium alkoxides with ligands in various molar ratios. The compounds are soluble in organic solvents and could be volatilized under reduced pressure. Their molecular weights have been determined ebullioscopically. The infrared spectra of some of the compounds have been studied.

Canadian Journal of Chemistry, 47, 2661 (1969)

Introduction

The reactions of alkoxides of aluminium, lanthanum, neodymium, preseodymium, titanium, niobium, and tantalum (1–7) with bidentate monofunctional ligands like β-diketones and β-ketoesters have recently been studied in these laboratories with interesting results regarding the volatility and coordination number of the products. In the cases of the first 4 elements, all the 3 isopropoxy groups could be replaced by the chelating ligands, but in the cases of the last 3, only partial replacement was possible; e.g. the final end products were $Ti(OR)_2lig_2$ and $Nb(OR)_2lig_3$.

In view of the above studies, it was considered of interest to carry out similar reactions with gallium alkoxides. The synthesis of gallium tris-acetylacetonate was reported as early as 1921 by Morgan and Drew (14). In the present investigation, the acetylacetone and β-ketoester derivatives of gallium have been prepared by the following reactions in benzene solution

$$(i\text{-}C_3H_7O)_3Ga + x\ H\ lig = Ga(i\text{-}C_3H_7O)_{3-x}\ lig + x\ i\text{-}C_3H_7OH$$

where x = 1, 2, or 3; and H lig = acetylacetone, methyl acetoacetate, ethyl acetate, or methyl salicylate.

Isopropanol liberated was fractionated azeotropically and estimated. The products obtained by the above general reactions are soluble in benzene and except those of methyl salicylate can be distilled or sublimed under reduced pressure. All the products obtained in a molar ratio of 1:1 showed dimeric association and the 1:3 derivatives are monomers. However, the compounds obtained in a molar ratio of 1:2 varied in molecular complexity as the ligands were changed; the methyl acetoacetate, the ethyl acetoacetate, and the acetylacetonate derivative showed molecular complexities of 2, 1.3, and 1, respectively.

The derivatives could be distilled at higher temperatures compared to gallium isopropoxide indicating that chelation has the expected effect of lowering the volatility.

A mixed ligand product $Ga(acac)(meacac)_2$ was also obtained by reacting $Ga(i\text{-}C_3H_7O)(meacac)_2$ and acetylacetone in excess (acac = acetylacetone, meacac = methyl acetoacetate). The compound is monomeric in benzene.

Infrared spectra of some of the derivatives have been recorded in the range 4000–670 cm^{-1} (2.5–15 μ). The data and the modes assigned on the basis of previous measurements (8–13) are given in Table I. The bands at about 3400–3500 cm^{-1} may be due to slight hydrolysis of isopropoxy derivatives during handling and recording of the spectra.

Experimental

An all-glass apparatus fitted with interchangeable joints was used, special precautions being taken to exclude moisture. All reactions were carried out in a flask under a column packed with Rasching rings and fitted to a total condensation variable take-off stillhead.

Molecular weights were determined ebullioscopically in boiling benzene by means of a semimicro (Gallenkamp) ebulliometer using thermistor sensing. Infrared spectra were recorded on a Perkin–Elmer spectrophotometer model 137B.

Gallium isopropoxide was prepared as previously described (8) and benzene was dried similarly. Methyl acetoacetate, ethyl acetoacetate, and methyl salicylate were distilled over aluminium isopropoxide. Acetylacetone was fractionated over aluminium isopropoxide.

Gallium and isopropanol were estimated as described earlier (8). Isopropoxy in mixed β-diketonate compounds was estimated by liberating the isopropanol with excess of the ligand.

The same synthetic procedure was used in all the cases. Details are, therefore, given for the typical derivatives only; the other reactions are summarized in Table II.

Synthetic Reactions

Reaction of Gallium Isopropoxide and Acetylacetone in Molar Ratio 1:2

Gallium isopropoxide (2.00 g) and acetylacetone (1.62 g) were refluxed in benzene (60 ml) followed by slow distillation of isopropanol azeotropically between 72–80 °C. The remaining solvent was removed under reduced pressure and the product dried at room temperature (35 °C) at 0.5 mm pressure for 2 h. A yellow solid (2.56 g) was obtained.

The analysis of isopropanol in azeotrope required for 2 moles of isopropanol, 0.97 g. Found: 0.97 g.

Anal. Calcd. for $C_{13}H_{21}O_5Ga$: Ga, 21.32; isopropoxy, 18.48. Found: Ga, 21.22; isopropoxy, 18.68.

This compound (2.0 g) was distilled under reduced pressure at 171 °C/0.5 mm as a brown liquid (0.85 g); it solidified after a few minutes on cooling, m.p. 148–149 °C, and this solid was found to be 21.42% Ga.

Reaction of Gallium Ethoxide and Acetylacetone in Molar Ratio 1:2

Gallium ethoxide (1.62 g) and acetylacetone (1.58 g) were refluxed in benzene (55 ml) and ethanol was removed azeotropically between 68–80 °C followed by excess of benzene. On leaving the clear solution overnight, cream colored crystals appeared. The mother liquor was decanted off and the crystals were dried at room temperature (35 °C) at 0.4 mm pressure yielding a crystalline solid (1.58 g). The analysis of ethanol in the azeotrope required for 2 moles of ethanol, 0.73 g. Found: 0.72 g.

The solid was recrystallized from benzene giving crystals (m.p. 175–176 °C) having the same appearance and analysis.

Chemistry of metal hydrides[1]. VI. Cationic platinum(II) carbonyls stabilized with tertiary arsines and stibines

W. J. CHERWINSKI AND H. C. CLARK
Department of Chemistry, University of Western Ontario, London, Ontario

Received February 24, 1969

The synthesis of $[Pt_2Cl_2(R_3M)_4][BF_4]_2$, and its cleavage with carbon monoxide to form the cationic carbonyl species $[PtCl(CO)(R_3M)_2]^+$ is described for R = ethyl or phenyl, and M = As or Sb. A comparison of the physical properties and spectroscopic data of these compounds, and the analogues for M = P is made with related complexes of other transition metals.

Only *trans*-$[PtCl(CO)(Et_3As)_2][BF_4]$ reacts with water to give *trans*-$[PtHCl(Et_3As)_2]$ and carbon dioxide. *trans*-$[PtCl(CO)(Ph_3As)_2][BF_4]$ reacts readily with methanol or ethanol to give an alkoxy carbonyl $[PtCl(COOR)(Ph_3As)_2]$, where R = CH_3 or C_2H_5. Unlike their phosphine analogues, these species and the stibine-stabilized cationic carbonyls do not produce the corresponding hydrides on reaction with water in the presence of a salt catalyst. These differences in chemical reactivity are related to the basicity of the ligands.

Canadian Journal of Chemistry, 47, 2665 (1969)

Introduction

An examination of the $[PtCl(CO)(R_3P)_2]^+$ cation (2) has been prompted by the well-known catalytic activity of the isoelectronic species $[RhCl(Ph_3P)_3]$ and *trans*-$[IrCl(CO)(Ph_3P)_2]$ in the homogeneous hydrogenation of olefins (3). Phosphine-stabilized platinum(II) compounds including the dihalo-bridged cationic dimers $[Pt_2X_2(R_3P)_4][BF_4]_2$, the carbonyl cations *trans*-$[PtX(CO)(R_3P)_2][BF_4]$, and the alkoxy carbonyls $[PtX(COOR)(Ph_3P)_2]$ have recently been studied (1, 2). Analogous arsine and stibine complexes have now been prepared, and compared to the former both in physical properties and chemical reactivity. Significant differences have been found, particularly in the ease of formation of the hydrido platinum(II) compounds from the platinum(II) carbonyl cations by the direct reaction with water, and indirectly via alkoxy carbonyl compounds.

Results and Discussion

The synthesis of dihalo-bridged diplatinum cations by reaction of the appropriate dihalo-bisarsine (or stibine) complex with boron trifluoride as previously reported (2), was successful for $[Pt_2Cl_2(R_3M)_4][BF_4]_2$ where M = As or Sb, and R = ethyl. For R = phenyl, a sequence involving silver tetrafluoroborate at room temperature was employed (4).

[1] $2cis\text{-}[PtCl_2(Ph_3M)_2] + 2AgBF_4 \rightarrow [Pt_2Cl_2(Ph_3M)_4][BF_4]_2 + 2AgCl$

[1]For Part V, see ref. (1).

For the resulting two series of compounds, where R = ethyl or phenyl, a marked decrease in melting point and a color change from white to yellow occurs as the ligand donor atom changes down the series P, As, Sb (Table I). A decrease in stability is also apparent since in the series with R = ethyl, both the phosphine- and arsine-stabilized compounds are air-stable, while the stibine analogue decomposes slowly in air; also for R = phenyl and M = Sb, reaction [1] affords a product unstable in solution.

These new dimeric cations, like their phosphine analogues, react in minutes in a chloroform suspension with carbon monoxide at 1 atm pressure, to yield a series of well defined carbonyl platinum(II) salts in the *trans* configuration (2).

[2] $[Pt_2X_2(R_3M)_4][BF_4]_2 + 2CO \rightarrow 2[PtX(CO)(R_3M)_2][BF_4]$

The one step syntheses of $[PtCl(CO)(R_3M)_2]^+$, where M = As or Sb, by (*a*) displacement of chloride ion with carbon monoxide from the complexes $[PtX_2(R_3M)_2]$ in the presence of sodium tetraphenylborate or sodium tetrafluoroborate (5) or, (*b*) reaction of hydrido platinum(II) compounds with aqueous tetrafluoroboric acid and carbon monoxide (2), have also been successful.

For R = ethyl, the carbonyl cations range from the white, crystalline phosphine- and arsine-stabilized complexes to the pale yellow, oily stibine analogue. Similarly, for R = phenyl, the high-melting, lightly-colored compounds for

*Previously reported.
†Isolated as impure solid.

M = P or As are in marked contrast to the low-melting, yellow-orange stibine salt (Table I).

Like their phosphine analogues (1), arsine-stabilized carbonyl cations react with pure methanol or ethanol. The reaction of *trans*-$[PtCl(CO)(R_3As)_2][BF_4]$ for R = ethyl gives an unstable, oily alkoxy carbonyl, while for R = phenyl, the products are crystalline, off-white solids.

[3] R^1OH + *trans*-$[PtCl(CO)(R_3As)_2][BF_4]$ $\rightarrow [PtCl(COOR^1)(R_3As)_2] + [HBF_4]$

where R^1 = methyl or ethyl.

Unlike substituted rhodium and iridium carbonyl complexes (6) under basic conditions, the stibine platinum compounds undergo no such reaction.

For the platinum(II) carbonyl cation where M = As or P, and R = ethyl, reaction with water, or aqueous methanol or ethanol takes place quantitatively.

[4] $[PtCl(CO)(R_3M)_2][BF_4] + H_2O$ $\rightarrow$ *trans*-$[PtHCl(R_3M)_2] + CO_2 + [HBF_4]$

This reactivity decreases but is still observed, for M = P and R = phenyl. However, for M = As and R = phenyl, the hydrido platinum(II) complex is not formed, either in this direct fashion, or via the alkoxy carbonyl intermediate species as reported for the triphenylphosphine complex (1). The compounds *trans*-$[PtHCl(R_3Sb)_2]$ where R = ethyl or phenyl are unknown.

The above trends in physical properties of the dihalo-bridged diplatinum cations and of the platinum(II) carbonyl cations are parallel to others reported. For the series of neutral dimeric salts (7) of platinum and palladium, $L_2M_2Cl_4$, stabilities decreased and colors became more intense on changing the donor atom from P to As to Sb. Here also, the stibine-stabilized complex was air-sensitive. Similar gradations of properties have been found for carbonyl complexes of vanadium (8), nickel (9), and rhodium (10). Indeed, it is well-known (11) that, although the differences in electronegativity are not great, the order of co-ordinating affinities of Group V atoms in donor ligands is P > As > Sb > Bi. It has been found more difficult to relate this order to changes in the C—O infrared stretching frequencies of carbonyl complexes, although for nickel carbonyl complexes, small changes in these frequencies have been attributed (12) to differences in the σ-donor and π-acceptor properties between phosphine and arsine ligands. Similarly for these new platinum(II) cationic carbonyl complexes, the changes in $\nu_{C=O}$ are very small; indeed, for R = ethyl, in descending the series P, As, Sb, the frequency changes are negligible, and for R = phenyl, both the arsine and stibine complex show the same carbonyl frequency, only slightly greater than that of the phosphine derivative. The higher frequencies of the carbonyl cations where R = phenyl, compared with those containing R = ethyl are consistent with the less basic character of the former type of ligands.

In interpreting the lesser reactivity of *trans*-$[PtCl(CO)(Ph_3P)_2]$ compared to its triethylphosphine analogue in sequence [4], both the lower stability of the carbonyl, and the greater electron withdrawing ability of the triphenylphosphine ligands lowering the reactivity at carbonyl carbon, have been considered important. When M = As, a similar difference in reactivity occurs for R = ethyl and R = phenyl. Moreover, the chemical reactivity of the carbonyl cations decreases with the order of basicity down the series P > As > Sb. For R = ethyl, only the ligands with M = P and As remain sufficiently basic to support reaction of the carbonyl cation with water to give the corresponding hydride. Sequence [4] is also successful for R = phenyl and M = P, while the more acidic ligands with M = As support conversion only to the intermediate alkoxy carbonyl species. No reaction occurs when M = Sb. Related trends in reactivity have been observed (13) for the series of rhodium compounds, $[RhCl(MPh_3)_3]$ where M = P, As, Sb, although in many of their reactions the tendency is for the arsine and stibine complexes to give more stable derivatives than the phosphine analogue, rather than show a reduced reactivity (14).

Differences in ligand basicity also appear to influence the proton magnetic resonance (p.m.r.) spectra of $[PtCl(COOR)(Ph_3M)_2]$. For R = methyl and M = P, the methyl proton absorption appears as a triplet at 7.6 τ with J_{Pt-H} = 15 c.p.s., while for M = As, this absorption is reduced to a singlet at 7.5 τ, with $J_{Pt-H} < 2$ c.p.s. Similarly for R = ethyl, the methylene proton multiplet at 7.5 τ for M = P appears as a quartet at 7.1 τ for M = As with a corresponding reduction in the platinum–hydrogen coupling constant from 15 to < 2 c.p.s. (Table

			7.1 (q)‡	< 2	15

*(t) = triplet, (s) = singlet, (m) = multiplet, (q) = quartet.
†The methyl protons are split by ^{195}Pt (34% abundance) with $I = \frac{1}{2}$ into a 1:4:1 triplet.
‡The multiplet results from splitting by CH_3 protons and ^{195}Pt.

II). These small decreases in chemical shift and remarkable reductions of J_{Pt-H} may well arise from a depletion of electron density on platinum by the more acidic arsine ligands.

Experimental

Previously described techniques and instrumentation (2) were used. The tertiary arsine and stibine Pt(II) dihalide complexes employed as starting materials were prepared according to established procedures (15). Physical properties and analytical data for prepared derivatives are summarized in Tables I and II.

1. Preparation of $[Pt_2X_2(Et_3M)_4][BF_4]_2$

The reported procedure (2) for the preparation of $[Pt_2X_2(R_3P)_4][BF_4]_2$ proved effective only for the synthesis of the dichloro-bridged species where R = ethyl, and M = As or Sb. Although a range of temperature conditions was employed, compounds with R = phenyl, and M = As or Sb were isolated in poor yield and in an impure condition by this method.

(*a*) *cis*-$[PtCl_2(Et_3As)_2]$ (0.25 g) and boron trifluoride (0.3 g), maintained at 23 °C in a silica Carius tube for 12 h in dried chloroform (5 ml), yielded pale yellow needles of $[Pt_2Cl_2(Et_3As)_4][BF_4]_2$ (0.14 g), which were recrystallized from a methylene chloride – diethyl ether – light petroleum ether mixture. Solubility properties were similar to those of the phosphine analogue (1); prolonged exposure to the atmosphere gave no indication of decomposition.

(*b*) *cis*-$[PtCl_2(Et_3Sb)_2]$ (0.15 g) and BF_3 (0.3 g), after 12 h at 23 °C in dry chloroform (5 ml) yielded yellow crystals of $[Pt_2Cl_2(Et_3Sb)_4][BF_4]_2$ (0.11 g) upon recrystallization as in (*a*). Discoloration was apparent after air-exposure over a period of days.

2. Preparation of $[Pt_2X_2(Ph_3M)_4][BF_4]_2$

(*a*) An acetone solution of silver tetrafluoroborate (0.045 g) was added dropwise with stirring to *cis*-$[PtCl_2(Ph_3As)_2]$ (0.20 g) in a small volume of methylene chloride, and the mixture was maintained at 23 °C for 1 h. When the silver chloride precipitate had been filtered off, crystallization in the clear yellow filtrate was induced by addition of diethyl ether. The off-white solid product was filtered off, washed several times with water, and recrystallized as in (*1*(*a*)), affording pure $[Pt_2Cl_2(Ph_3As)_4][BF_4]_2$ (0.17 g). Characteristic BF_4^- absorptions were prominent in the infrared (i.r.) spectrum, while sensitivity to atmospheric exposure was not observed.

(*b*) The same procedure was employed using *cis*-$[PtCl_2(Ph_3Sb)_2]$; however, the initial filtration yielded a yellow-orange solution which darkened with time. The most successful recrystallization attempts afforded a brown precipitate whose i.r. spectrum was in accord with that anticipated for a charged dimeric species. Its instability in solution prohibited further investigation.

3. Reaction of $[Pt_2Cl_2(R_3M)_4][BF_4]_2$ with Carbon Monoxide

(*a*) The compound $[Pt_2Cl_2(Et_3M)_4][BF_4]_2$ (0.20 g) where M = As or Sb, was stirred for 1 h at 23 °C in degassed chloroform solution (10 ml) under 1 atm of carbon monoxide. The solution was then filtered and the solvent evaporated off. For M = As, white crystalline *trans*-$[PtCl(CO)(Et_3As)_2][BF_4]$ (0.10 g) was recovered by recrystallization from ethyl acetate. For M = Sb, *trans*-$[PtCl(CO)(Et_3Sb)_2][BF_4]$ (0.09 g) was isolated under a carbon monoxide atmosphere from CO-saturated solvents as a pale-yellow oil. Although both compounds slowly discolored on exposure to air, this effect was far more pronounced in the latter case.

(*b*) The procedure above was repeated for $[Pt_2Cl_2(Ph_3M)_4][BF_4]_2$ (0.20 g) where M = As or Sb. After filtration, pale yellow *trans*-$[PtCl(CO)(Ph_3As)_2][BF_4]$ (0.10 g) was isolated by recrystallization from a methylene chloride – diethyl ether – light petroleum ether mixture. Orange *trans*-$[PtCl(CO)(Ph_3Sb)_2][BF_4]$ (0.06 g) was recovered in a similar fashion from reaction of the impure dimeric analogue (see *2*(*b*)).

4. Alternative Preparations of trans-$[PtCl(CO)(R_3M)_2]^+$

(*a*) *trans*-$[PtHCl(Et_3As)_2]$ (0.10 g) in 10 ml benzene was heated with 7 drops aqueous 48% fluoroboric acid in a stainless steel autoclave under a pressure of 5 atm of carbon monoxide at 120° for 48 h. After separation by procedures similar to those previously reported (2), white, solid *trans*-$[PtCl(CO)(Et_3As)_2][BF_4]$ (0.06 g) was obtained and recrystallized from ethyl acetate.

(*b*) *cis*-$[PtCl_2(Et_3M)_2]$ (0.10 g) for M = As, was stirred with sodium tetraphenylborate (0.06 g) in freshly distilled tetrahydrofuran (5 ml) under carbon monoxide (1 atm). The solution became cloudy almost immediately but stirring was continued for 1 h at 23 °C before

removal of solvent under vacuum. Extraction of the residues with methylene chloride gave white, solid *trans*-$[PtCl(CO)(Et_3As)_2][BPh_4]$ (0.10 g), while extraction with water, followed by acidification and addition of silver nitrate, yielded silver chloride (0.02 g). A similar reaction sequence for M = Sb, yielded the cationic carbonyl salt as a yellow oil, while products spectroscopically identical to those of preparation *3*(*a*) for M = As and Sb were obtained from reactions using sodium tetrafluoroborate in acetone (Table I).

(*c*) *cis*-$[PtCl_2(Ph_3M)_2]$ (0.10 g) for M = As was similarly treated with $NaBPh_4$ (0.40 g) in dry methylene chloride – acetone solution. Following filtration, work-up was effected in a carbon monoxide atmosphere by addition of the methylene chloride solution to a carbon monoxide saturated diethyl ether – petroleum ether mixture. The resulting yellow solid, *trans*-$[PtCl(CO)(Ph_3As)_2][BPh_4]$ which could not be recrystallized from other solvents without decomposition, showed a prominent carbonyl absorption in the i.r. spectrum. For M = Sb, evaporation of the filtrate afforded a viscous yellow oil whose i.r. spectrum was consistent with expected carbonyl; however, similar work-up procedures yielded an uncharacterized yellow solid lacking the carbonyl i.r. absorption. In both cases, solubility difficulties prohibited the reaction sequence involving $NaBF_4$.

5. Preparation of trans-[PtCl(COOR)(Ph$_3$As)$_2$]

(*a*) For R = methyl, $[PtCl(CO)(Ph_3As)_2][BF_4]$ was stirred in methanol at 23 °C for 1 h. The fine yellow precipitate was filtered, washed with water and methanol, then dried under vacuum.

The reaction was identical where ethanol replaced methanol, (R = ethyl), and both sequences afforded essentially quantitative conversion to the alkoxy species. Solubility properties were identical to those of the Ph_3P analogues, while i.r. assignments, and p.m.r. absorptions were qualitatively similar (Table II).

(*b*) Similar conditions applied to $[PtCl(CO)(Ph_3Sb)_2][BF_4]$ at 23 and at 60 °C yielded only unreacted starting material.

6. Reaction of trans-[PtCl(CO)(Et$_3$M)$_2$][BF$_4$] with Dry Methanol

(*a*) For M = As, *trans*-$[PtCl(CO)(Et_3As)_2][BF_4]$ (0.30 g) in dry methanol (5 ml) was maintained at 90 °C for 12 h in a dried, evacuated Pyrex Carius tube. Volatiles were removed under vacuum leaving a pale yellow oil in quantitative yield, which was then purified by Florisil chromatography with elution with methylene chloride. Proton magnetic resonance absorptions were obscured by arsine peaks in the same region (~2.5 p.p.m.), although for R = ethyl, $—CH_3$ protons were detected at 0.55 p.p.m. The carbonyl cation with M = Sb failed to react under similar conditions. Infrared spectroscopy ($\nu_{C=O}$ at 1601 cm^{-1}) indicated a compound analogous to the reported $[PtCl(COOR)(Et_3P)_2]$ (1), where R = methyl.

7. Reaction of trans-[PtCl(CO)(Et$_3$As)$_2$][BF$_4$] with Water

trans-$[PtCl(CO)(Et_3As)_2][BF_4]$ (0.20 g) was heated at 90 °C for 12 h in degassed methanol (5 ml) with several drops of water in an evacuated Pyrex tube. The volatile products were fractionated under vacuum through −78, −120, and −196 °C traps, and carbon dioxide was collected and identified by i.r. spectroscopy. Extraction of the residue with water afforded a white solid with i.r. absorption characteristic of SiF_6^{2-} and BF_4^- anions. A light petroleum ether extract yielded white, crystalline *trans*-$[PtHCl(Et_3As)_2]$ (0.075 g) characterized by its melting point (89–91 °C), p.m.r. spectroscopy, i.r. spectroscopy, and elemental analysis. Water–methanol mixtures containing greater amounts of water resulted in pronounced decomposition. Similar reactions for M = Sb were unsuccessful.

8. Reactions of trans-[PtCl(COOCH$_3$)(Ph$_3$As)$_2$] with Water

(*a*) *trans*-$[PtCl(COOCH_3)(Ph_3As)_2]$ (0.20 g) was heated with saturated aqueous potassium chloride solution (5 ml) at 110 °C for 12 h in an evacuated Pyrex tube. Extensive decomposition was observed. Carbon dioxide and methanol could not be identified in the volatile products. Extraction of the residue with methylene chloride afforded an uncharacterized oil. No evidence for hydride formation was found.

(*b*) Identical reactions conducted at 80 and 100 °C proceeded with less decomposition, although starting material was the only solid recovered, and carbon dioxide could not be detected in the volatile components.

Acknowledgments

We are grateful to the National Research Council of Canada for financial assistance, and for the award of a 1967 Science Scholarship (to W.J.C.). The loan of platinum compounds from Johnson, Matthey and Company is also gratefully acknowledged.

Activities from vapor pressure measurements of lithium and of sodium chlorates in water and water–dioxane solvents

A. N. CAMPBELL AND B. G. OLIVER[1]

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received January 8, 1969

The vapor pressures of solutions of sodium chlorate and of lithium chlorate in water and in solvents consisting of 44.5% dioxane – 55.5% water and of 64.5% dioxane – 35.5% water, at 25 °C, were determined using a differential manometer. The vapor compositions of the dioxane–water solutions were found by the air-saturation method.

The mean molal activity coefficients were calculated from the vapor pressures and compositions. The activity coefficients of the solute were fitted to the theoretical equations of Stokes and Robinson and of Glueckauf, yielding hydration numbers for the cations of the salts.

The minimum dioxanation numbers of sodium and of lithium chlorates in the dioxane–water mixtures were calculated from the experimental activity coefficients by the method of Grunwald. The results show that lithium chlorate is more highly solvated than sodium chlorate and that dioxane plays a major role in the solvation of both electrolytes in the dioxane–water mixtures.

Canadian Journal of Chemistry, 47, 2671 (1969)

Introduction

We had previously determined the conductances of sodium and of lithium chlorates in water and water–dioxane mixtures (1), and it seemed to us appropriate to follow this with an investigation of the activities of the same salts in the same media. The technique chosen was that of vapor pressure and vapor composition. From these data, the partial pressures of the components of the mixed solvents and, by way of the Gibbs–Duhem theorem, the activities of the salts could be obtained.

Experimental

Materials

Salts

Fisher certified sodium chlorate (major impurity 0.01% bromate) was dried at 120° for 48 h or longer, before use. Lithium chlorate was prepared by the method of Campbell and Griffiths (2). The melting point was found to be 127.9°, in agreement with the value of Campbell and Williams (3).

Solvents

Water, of specific conductance 2–5 $\times$ 10^{-7} mhos/cm, was obtained by passing ordinary distilled water through a mixed-resin demineralizing column. Dioxane of spectro quality was further purified by refluxing with sodium, according to the method of Hess and Frahm (4). After purification, the dioxane had a refractive index of $n_D^{25} = 1.4202$ and a density of 1.0278 g/cc at 25°. This is in close agreement with the refractive index of 1.42025 found by Frey and Gilbert (5) and the density of 1.02804 found by Schott (6).

Apparatus

A 3 ft high cylinder was used as one of three thermostats, for work with the differential manometer. Vigorous stirring with a 1/4 hp motor gave a temperature control of $\pm 0.005°$, despite the height of the mass of liquid. The other two thermostats were of conventional type. Temperature was measured with Beckmann thermometers which were calibrated, and frequently re-calibrated, against a platinum resistance thermometer and Mueller bridge. Temperature fluctuations never exceeded $\pm 0.005°$.

Vapor Pressure Measurements

Following Gilson and Adams (7) and Shankman and Gordon (8), a differential manometer was used for the determination of total vapor pressure. A modification of Gilson and Adams' apparatus, introducing glass spirals between the manometer and the three-way cocks to the vacuum line, saved us many breakages. As manometer liquid, we used vacuum pump oil for water solutions, as recommended by Shankman and Gordon (8), but we found it necessary to change the oil after about 5 runs, because of contamination of the oil–glass interface with water. From the densities of oil and mercury and the accuracy of the cathetometer, it would seem that vapor pressures could be measured with an accuracy of ± 0.005 mm of mercury but, as pointed out by McAllan (9), difficulties such as slow drainage time and dissolved gases lead to higher errors than this. We estimate the error of our measurements to be ± 0.01 mm of mercury.

When investigating solutions in water–dioxane mixtures, we found that pump oil, diethyl phthalate, dibutyl phthalate, and other manometric liquids, all dissolve dioxane, and we were therefore forced to use mercury as manometer liquid. The limbs of the manometer were widened to 22 mm so that the capillary depression became negligible. Using mercury, the accuracy of measurement was reduced to ± 0.05 mm. All measurements were reduced to 0° in the usual way.

The solvent was degassed by freezing in dry ice–acetone mixture, pumping down to 1.0 μ, melting, and

---

[1]Present address: Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York.

repeating the whole process five times. The solvent was then vacuum distilled on to the salt which had previously been placed in one of the manometer flasks. After the determination of vapor pressure, the concentration of the solution was determined by evaporation of a weighed portion to dryness. Separate experiments showed that the composition of the mixed solvent did not change during the manometric experiment.

Vapor Composition

The compositions of the vapors in equilibrium with liquid mixtures of given composition were determined by the air saturation method, using what was essentially the apparatus of Bichowsky and Storch (10). Vapor compositions by this method were reproducible to within 0.1%. The condensed vapor was analyzed refractometrically.

Treatment of Results

As the mathematical treatment is involved, we confine ourselves, for the most part, to referring to published papers, in which this treatment is described.

The activity of the water in the aqueous solutions was calculated from the relation

$$a_1 = p_1/p_1^0$$

where p_1 is the vapor pressure of the water in solution and p_1^0 the vapor pressure of pure water. In what follows subscripts 2 and 3 refer throughout to dioxane and electrolyte, respectively. The activity of the solute was then calculated from the activity of the solvent by using the Gibbs–Duhem equation

$$S\mathrm{d}T - V\mathrm{d}P + \sum N_i \mathrm{d}\bar{G}_i = 0$$

which for constant temperature and pressure, simplifies to

$$\mathrm{d} \ln a_3 = -(N_1/N_3)\mathrm{d} \ln a_1$$

The details of the method are given by Randall and White (11). Because the data were not sufficiently accurate below 0.1 molal, we took the value of $\log \gamma$ at 1 molal as known and integrated to the observed concentration. For sodium chlorate in water at a concentration of 1 molal, we used the figure of Jones (12) for the activity coefficient, viz. 0.589. For lithium chlorate, at 1 molal concentration, we used the value $\gamma = 0.809$ from the freezing point data of Scatchard and Prentiss (13). Scatchard's figure refers necessarily to the freezing point of the solution and, in using the same figure at 25°, we make an assumption that may not be justified. Such an assumption may lead to an error as great as 3% but, when accurate data become available for the dilute region at 25°, our results can be corrected by multiplying by the appropriate factor.

The above simple treatment cannot be used when the solvent is a mixture of water and dioxane. It is now necessary to know both the vapor pressure and the vapor composition in order to calculate the activities of the two components of the solvent. Assuming the applicability of Dalton's law

$$p_i = N_i P$$

and knowing N_i, the mole fraction of the ith component in the vapor, the partial pressure is obtained and the activity of component i in solution results as

$$a_i = p_i/p_i^0$$

The addition of solute to a two-component solvent at constant N_1 can be represented by the equation

$$N_1 \mathrm{d} \ln a_1 + N_2 \mathrm{d} \ln a_2 = -m_3 M_{12} \mathrm{d} \ln a_3/1000$$

where $M_{12} = N_1 M_1 + N_2 M_2$, is the mean molecular weight of the binary solvent. If the solution is not ideal, the equation shows that a_1 and a_2 may alter by different factors. Indeed, where there is strong preferential solvation of the solute by component 1, it is possible for the decrease in a_1 to be so pronounced that a_2 actually increases.

We used the treatment of Grunwald and Baccarella (14). In this treatment, attention is focussed on $\mathrm{d} \ln a_1/a_2$ or, what amounts to the same thing, on the experimental quantity, $\mathrm{d} \ln \alpha_1/\alpha_2$, where $\alpha_1 = p_1/p_1^*$ and $\alpha_2 = p_2/p_2^*$: p_1 and p_2 are the partial pressures of water and of dioxane over the solution containing solute, and p_1^* and p_2^* are the partial pressures of water and of dioxane over the solvent of composition N_1, in the absence of solute.

It is unnecessary to repeat the treatment of Grunwald and Baccarella here. Suffice it that the following equation results for 1–1 electrolytes

$$[1] \quad (1000/M_{12})(N_1 \mathrm{d} \ln \alpha_1 + N_2 \mathrm{d} \ln \alpha_2) = -2\,\mathrm{d}m - 2m\mathrm{d} \ln \gamma_{\pm}$$

Here m is expressed in formula weights of electrolyte per kg of binary solvent. Following

Scatchard and Prentiss (13) $\ln \gamma_\pm$ can be expanded in a power series in $m^{1/2}$

$$[2] \quad \ln \gamma_\pm = -Sm^{1/2} + Bm + Cm^{3/2} + Dm^2 + Em^{5/2} + \cdots$$

In eq. [2], S is the Debye-Hückel limiting slope and $B, C, D, E, \cdots$ are adjustable constants. The latter are evaluated from the experimental data as follows. Substitution of [2] in [1] and integration leads to

$$[3] \quad (-1000/M_{12})(N_1 \ln \alpha_1 + N_2 \ln \alpha_2) = 2m - 2/3 Sm^{3/2} + Bm^2 + 6/5 Cm^{5/2} + 4/3\, Dm^3 + 10/7\, Em^{7/2} + \cdots$$

In eq. [3], the terms on the left and the first two terms on the right involve only experimental data and known solvent properties. The adjustable constants in the remainder are evaluated by standard least squares methods, using a computer. Once the constants are obtained, it is a simple matter to insert them in eq. [2] in order to calculate the activity coefficients. In no case were terms higher than Dm^2 found to be necessary.

Results and Discussion

(a) Results in Pure Water (Table I)

At comparable concentrations, the activity coefficients of lithium chlorate in water are considerably larger than those of sodium chlorate. This is consistent with the idea that the smaller lithium ion ($r = 0.68$ Å) is more extensively hydrated in aqueous solutions than the larger sodium ion ($r = 0.97$ Å). The extremely high value attained by the activity coefficient of the lithium salt, ($\gamma = 16.25$ at 43.7577 m) is probably due to the extensive hydration of the lithium ion.

We attempted to treat our results with the theoretical equation of Stokes and Robinson (15) viz.

$$[4] \quad \log \gamma_\pm = \frac{-A|Z_1 Z_2| I^{1/2}}{1 + BaI^{1/2}} - \frac{h}{\nu} \log a_A - \log [1 + 0.001 W_A(\nu - h)m]$$

This eq. contains two adjustable parameters, h, the hydration number, and a, the distance of closest approach. The first term is the well known Debye–Hückel equation. In a more recent paper (16) Stokes and Robinson have developed an equation for the evaluation of a. Assuming that only the cation is hydrated, the parameter a is

$$[5] \quad a = [(\bar{V}_+^{\,0} + 18h)/4.35 \times 10^{24}]^{1/3} + [\bar{V}_-^{\,0}/4.35 \times 10^{24}]^{1/3}$$

The partial molal volumes of the sodium and lithium ions which we introduced into the above eq. were obtained from the data of Mukerjee (17), and that of the chlorate ion from Couture and Laidler (18). These values are $\bar{V}_{Na^+}^{\,0} = -5.7$ cc/mole, $\bar{V}_{Li^+}^{\,0} = -5.2$ cc/mole, and $\bar{V}_{ClO_3^-} = +40.9$ cc/mole. The values of the hydration number h, the 'a' values calculated by the above method, and the calculated activity coefficients are presented in Table I.

Table I shows good agreement between the experimental activity coefficients of sodium chlorate and the theory over the entire concentration range, viz. 4.0–9.4 molal. The results of Jones (12) for the more dilute region when treated in the same way run smoothly into ours. This is to be expected, since sodium chlorate is only slightly hydrated ($h = 1.05$) and there are plenty of free water molecules even at saturation. On the other hand, the theory begins to break down above 2 molal, for lithium chlorate. This also is not surprising, since lithium chlorate is highly hydrated ($h = 6.7$) and there are only a limited number of water molecules available. In fact, Stokes and Robinson (15) have stated that in the majority of cases, the equation breaks down when the product of the hydration number, h, and the molality, m, exceeds 10 or 15. To proceed to higher concentrations it would be necessary to use a hydration number which was a suitably decreasing function of concentration.

We then fitted the experimental activity coefficients to an equation developed by Glueckauf (19).

$$[6] \quad \ln \gamma_\pm = \frac{-A|Z_1 Z_2| I^{\frac{1}{2}}}{1 + BaI^{\frac{1}{2}}} + 0.018mr(r + h - \nu) + \frac{h - \nu}{\nu} \ln (1 + 0.018mr) - \frac{h}{\nu} \ln (1 - 0.018mh)$$

This equation has two adjustable parameters, h and a. The number of adjustable parameters was

reduced to one by substitution of eq. [5] for a. The values of the hydration number, h, the a values calculated by eq. [5] and the calculated activity coefficients are shown in Table I.

Glueckauf's eq. represents the data as well as that of Stokes and Robinson. In fact, it seems to be valid over the entire concentration range for sodium chlorate, and up to 2.5 molal for lithium chlorate. The hydration numbers found by this method are lower than those obtained by the Stokes and Robinson equation and this agrees with Glueckauf's own findings. Both equations give values for h and a (the distance of closest approach) of the right order of magnitude.

Although Glueckauf's derivation takes into account the size differences between the hydrated ions and the water molecules, both Glueckauf (19) and Stokes and Robinson (15) assume that

all the differences between the experimental and the calculated activity coefficients can be ascribed to hydration. It is true that the resulting equations are remarkably useful in describing observed results but this should not obscure the fact that, while hydration is a very important factor, it is not the only one which determines the complicated equilibria in an electrolyte solution. To put it briefly, the secondary hydration has been stretched to cover a number of effects, the quantitative nature of which requires a great deal of investigation.

We attempted to get some information about the behavior of the concentrated lithium chlorate solutions, on the basis of the concept of Stokes and Robinson (15) that the ions adsorb layers of water molecules in accordance with the Brunauer, Emmett, and Teller (B.E.T.) equation (20). Modifying the notation of those authors to suit the present case, their equation is

$$[7] \qquad \frac{ma_w}{55.51(1 - a_w)} = \frac{1}{bg} + \frac{(b - 1)}{bg} a_w$$

where a_w is the water activity of the solution; m is the molality, g is the number of molecules of water in the unimolecular hydration layer when it is complete, and b is a constant related to the heat of adsorption E of the molecules in the layer and is given by the approximate relation $b = \exp (E - E_L)/RT$, E_L being the heat of liquefaction of pure water. Equation [7] may be tested by plotting the left hand side (determined from experimental m and a_w) against a_w. When we did this, we obtained a straight line for lithium chlorate in water at 25° when the water activity of the solution is less than 0.420, i.e. above 12 molal. The best values of b and g were obtained from the slope and intercept of the line, by the method of least squares.

The accuracy of the fit is fairly good over the range 12–44 molal, (a mean deviation in a_w of 0.0032). The value of g, 3.11, is between 3 and 4 in accordance with the values found by Stokes and Robinson (15) for other 1–1 electrolytes. The value of b, 8.75, is also reasonable and corresponds to $E - E_L = 1.29$ kcal/mole of water adsorbed. An unsatisfactory feature of eq. [7] is that it demands a non-integral g value. This can scarcely correspond to any physical reality, and has probably arisen as a result of approximations in the Brunauer, Emmett, and Teller theory and its application to this case. The most drastic of these approximations is that of treating all water molecules beyond the first layer as being held by ordinary liquid forces, with a heat of liquefaction of E_L.

Anderson (21) has introduced a modification of the B.E.T. equation, in which the subsequent layers have a heat of adsorption less than that of water by d. This has the effect of multiplying a_w, wherever it occurs in eq. [7] by a factor $K = e^{-d/RT}$ and leads to the equation

$$[8] \qquad \frac{ma_w}{55.51(1 - Ka_w)} = \frac{1}{bKg} + \frac{(b - 1)}{bg} a_w$$

To test the appropriateness of this equation, the value of g is set at 4. Then eq. [8] is written in the form

$$[9] \qquad b = \left(\frac{1}{K} - a_w\right) \Big/ \left(\frac{gma_w}{55.51(1 - Ka_w)} - a_w\right)$$

and by trial and error, the value of K which leads to a reasonably constant b over the widest possible range of molality is found: this value of K is 0.785.

The average deviation of eq. [8] is the same as that of eq. [7] but the range fitted is slightly smaller (12–37 molal). The value of the parameter b, 6.9, is plausible and corresponds to $E - E_L = 1.14$ kcal/mole of water in the second and subsequent layers. This relatively small energy might easily correspond to a weak ordering effect on the water molecules concerned. The parameter b has a value of 4. This means that lithium chlorate has 4 sites available for occupation by water molecules in the inner layer, each being held with an energy some 1.14 kcal/mole greater than the latent heat of evaporation of water (10.48 kcal/mole at 25°).

The Stokes–Robinson approach used for lower concentrations and the B.E.T. approach used for higher concentrations are not mutually contradictory. As the concentration increases, the hydration number h diminishes and the ions tend to a quasi-crystalline structure with some of the water molecules imbedded in the remnants of crystal lattice (adsorbed water) and some present as "free" solvent. These are the two extremes of a more general theory, which should cover the entire concentration range.

(b) Results in Mixed Water–Dioxane Solvents (Table II)

The properties of solutions in the mixed

solvents will be largely determined by certain physical properties of the mixed solvents, notably the dielectric constant and the viscosity. These, at 25°, are as follows for the three solvents

Solvent	Dielectric constant	Viscosity (cP)
Water	78.3	0.890
44.5% dioxane – 55.5% water	40.6	1.784
64.5% dioxane – 35.5% water	23.4	1.923

Figure 1 gives the change of the water and dioxane activities with addition of sodium chlorate to a solvent consisting of 44.5% dioxane, 55.5% water. It is seen that the water activity decreases upon addition of salt whereas the activity of dioxane increases. These results can be explained on the assumption that sodium chlorate is strongly preferentially solvated by water. As salt is added to the solution, more water than dioxane is bound by the salt, in forming a solvation sheath. Thus the remaining solvent becomes richer in dioxane and the partial pressure and activity of dioxane in the system rises. Similar changes in the water and dioxane activities are observed when sodium chlorate is added to a solvent consisting of 64.5% dioxane – 35.5% water and a similar explanation applies.

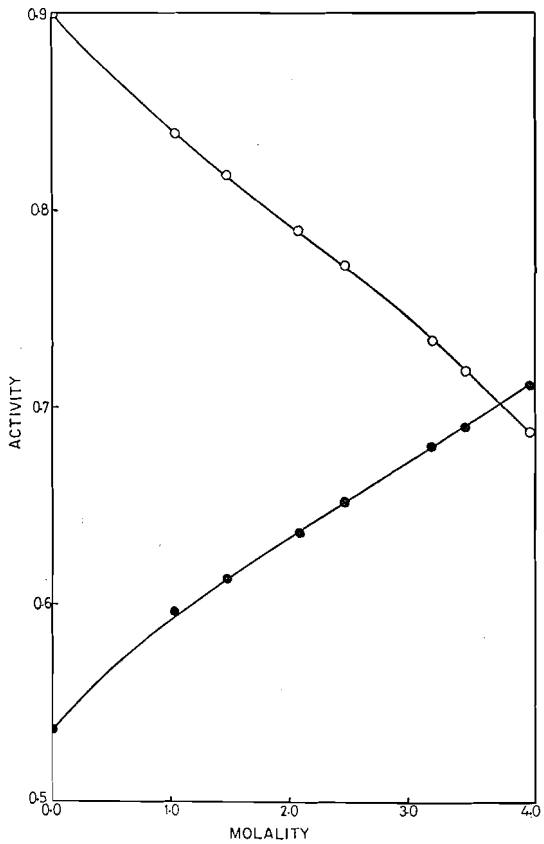

FIG. 1. Water and dioxane activity vs. molality for the system: sodium chlorate – 44.5% dioxane – 55.5% water, at 25°, as determined from vapor pressure and vapor composition; ○, water activity; ●, dioxane activity.

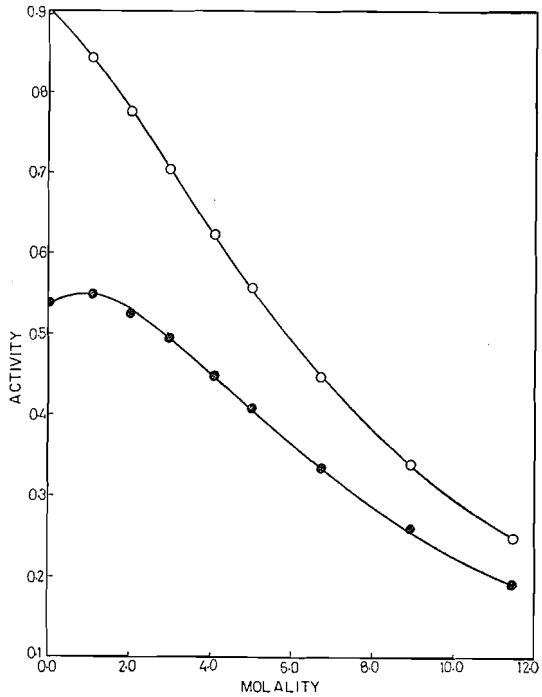

FIG. 2. Water and dioxane activity vs. molality for the system: lithium chlorate – 44.5% dioxane – 55.5% water, at 25°, as determined from vapor pressure and vapor composition; ○, water activity; ●, dioxane activity.

The changes in water and dioxane activity for lithium chlorate in 44.5% dioxane (Fig. 2) and in 64.5% dioxane are quite different from those of sodium chlorate. The water activity in the presence of lithium chlorate decreases to a greater extent than with sodium chlorate, while the dioxane activity at first shows a slight increase and then decreases. The larger decrease in water activity with lithium chlorate is to be expected because of the higher hydration of the lithium ion.

The activity coefficients of sodium and of lithium chlorate in these dioxane–water mixtures were calculated by the method of Grunwald and Bacarella (14) as modified by Scatchard and Prentiss (13) (see "Treatment of Results"). The

*Total vapor pressures, vapor compositions, and partial vapor pressures of solutions of sodium chlorate and of lithium chlorate in 44.5% dioxane and in 64.5% dioxane at 25°, together with activity coefficients according to Grunwald and Bacarella (14).

†α_1 is defined as (partial pressure of water over mixed solvent containing salt)/(partial pressure of water over the mixed solvent).

‡α_2 is defined as (partial pressure of dioxane over mixed solvent containing salt)/(partial pressure of dioxane over the mixed solvent).

values of the constants, of eq. [2] calculated by the method of least squares on a computer, are given in Table III. These constants represent the experimental quantity ($N_1 \ln \alpha_1 + N_2 \ln \alpha_2$) of eq. [3] for all systems in mixed solvent, over the entire concentration range, with a maximum deviation of 2%. This means that the activity coefficients are accurate to about the same extent.

Graphs of the activity coefficients of sodium and lithium chlorate in 44.5% dioxane and in 64.5% dioxane are shown as Figs. 3 and 4. The curve for lithium chlorate lies much above that of sodium chlorate, over the entire concentration range. This behavior is similar to that in aqueous solution and can again be explained as due to a higher degree of solvation of the lithium ion. When the activity coefficients of each salt in each solvent (including water) are plotted against salt concentration, it is seen that the activity coefficients of both sodium chlorate and lithium chlorate are greatly reduced on changing the solvent from water to 44.5% dioxane to 64.5% dioxane. Much of the decrease can be ascribed to the large change in dielectric constant, with consequent increased tendency to ion pair formation.

Many inconsistencies appear in the literature as to the nature of solvation in dioxane–water mixtures. Grunwald (22), in a study of a variety of electrolytes in 50% dioxane–water mixtures by

a vapor pressure technique, observed partial solvation of the electrolytes by dioxane. Fratiello and Douglass (23) used nuclear magnetic resonance (n.m.r.) to show that the chlorides of Li, Na, K, Mg, Ca, Zn, and Cd, along with the sodium salts of I, NO_3, ClO_4, and SO_4 are preferentially solvated by water in 50% dioxane – water mixtures: they found no evidence of solvation by dioxane. Other n.m.r. evidence by Hinton *et al.* (24) indicates solvation of aluminium perchlorate by dioxane. Analysis of conductance data by Hyne (25) also indicated interaction between dioxane and electrolyte in similar mixtures.

We attempted to determine the nature of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

solvation in the mixed solvents by the method of Grunwald (14, 22, 26). His final equation is

$$[10]\quad \frac{1000}{M_{12}}\ln\frac{\alpha_1}{\alpha_2} = \frac{2}{RT}\left(\frac{dG_\pm{}^0}{dN_1}\right)m - m^{3/2}\left(\frac{4}{3}\frac{dS}{dN_1} - \frac{2}{3}Sr\right) + m^2\left(\frac{dB}{dN_1} - Br\right) + m^3\left(\frac{2}{3}\frac{dD}{dN_1} - \frac{4}{3}Dr\right)$$

Here $G_\pm{}^0$ is the mean value of G^0 for cation and anion. The coefficient of the $m^{3/2}$ term was calculated from the Debye–Hückel limiting slope S, along with the slope of the curve of S plotted against N_1. The values of the other coefficients on the right in eq. [10] were obtained by fitting the data by the method of least squares on a computer. The constants that reproduced the experimental quantity $\ln \alpha_1/\alpha_2$ over the entire concentration range, with a maximum deviation of 2%, are presented in Table IV, together with other useful quantities. The values of $dG_\pm{}^0$ were calculated from the values of $2/RT \cdot dG_\pm{}^0/dN_1$ of Table IV. The values of the quantities $d \ln \varepsilon/dN_1$, $d \ln a_1/dN_1$ and $d \ln a_2/dN_1$ were calculated by plotting $\ln \varepsilon$, $\ln a_1$, and $\ln a_2$ against N_1. The required data for the dielectric constants (ε) of various dioxane–water mixtures were obtained from Critchfield *et al.* (27), while the data required for the activities of water and dioxane in water–dioxane mixtures were obtained from Bacarella *et al.* (28).

If it is assumed that the solute is present at extreme dilution and that it exists as an equilibrium mixture of molecular complexes of the type $S \cdot iH_2O \cdot j$dioxane, it is possible to obtain the average solvation numbers h^0 and d^0. The treatment is complex and it is unnecessary to go into it here but suffice it that the following equations are obtained

$$[11]\quad \frac{-Ne^2}{b_\pm \varepsilon}\left(\frac{d \ln \varepsilon}{dN_1}\right) = \frac{dG_\pm{}^0}{dN_1} + h^0RT\frac{d \ln a_1}{dN_1} + d^0RT\frac{d \ln a_2}{dN_1}$$

where $b\pm$ is a harmonic average, defined by the eq.

$$[12]\quad \frac{1}{b_\pm} = \frac{1}{2}\left(\sum_i \sum_{j \text{ cations}} \frac{\phi_{ij}{}^0}{b_{ij}} \cdot \sum_i \sum_{j \text{ anions}} \frac{\phi_{ij}{}^0}{b_{ij}}\right)$$

where $\phi_{ij}{}^0$ is the fraction of total formula weight which exists in the form $S \cdot iH_2O \cdot j$dioxane.

In order to apply eqs. [11] and [12] to our data, it is convenient to represent $b_\pm$ as a function of $r_\pm$, h^0, and d^0. It is assumed that the harmonic average of the b_{ij} values may be approximated by the radius calculated for a hypothetical "average solvate", defined as ion with unsolvated radius $r_\pm$ complexed with $h^0/2$ water molecules and $d^0/2$ dioxane molecules. Assuming spherical molecules and closest packing of spheres, the following eq. results

$$[13]\quad (b_\pm)^3 = 1.351\left[r_\pm{}^3 + \left(\frac{h^0}{2}\right)r_1{}^3 + \left(\frac{d^0}{2}\right)r_2{}^3\right]$$

where r_1 and r_2 were taken as 1.6 and 2.7 Å, respectively. (These radii are computed from the molar volumes of the pure liquids, assuming random packing of spheres, i.e. the actual volume occupied by the molecules is 58% of the total volume.) Using the values quoted in Table IV, eqs. [11] and [13] can be simplified to the form

$$[14]\quad \frac{dG_\pm{}^0}{dN_1} = \frac{-36.7}{b_\pm} - 0.437h^0 + 2.605d^0$$

$$[15]\quad b_\pm = 1.106(r_\pm{}^3 + 2.05h^0 + 9.84d^0)^{1/3}$$

for 44.5% dioxane, while for 64.5% dioxane the following simplified equation can be written

$$[16]\quad \frac{dG_\pm{}^0}{dN_1} = \frac{-59.0}{b_\pm} - 0.264h^0 + 0.613d^0$$

Equations [14], [15], and [16] can now be used to estimate solvation numbers. The first step is to show that d^0 is greater than zero. When $dG_\pm{}^0/dN_1$ for sodium chlorate in 44.5% dioxane is plotted against h^0, the calculated value of $dG_\pm{}^0/dN_1$ is always more negative than the experimental value. Similar behavior is observed with sodium chlorate in 64.5% dioxane and with lithium chlorate in the same solvents. Agreement between the experimental and calculated values is possible only if d^0 is greater than zero. This means that there are two unknown parameters, h^0 and d^0, but since there is only one experimental quantity, $dG_\pm{}^0/dN_1$, it is evidently not

possible to obtain a unique solution. It is possible, however, by substituting all the values of h^0 and d^0 that are consistent with the experimental results, to find the smallest value of d^0 which gives the experimental value for $dG_{\pm}{}^0/dN_1$. Minimum dioxanation numbers, calculated in this way, along with the corresponding values of h^0, are given in Table V.

TABLE V

Minimum values of the average dioxanation number at 25°

Solution	d^0_{min}	h^0
$NaClO_3$ in 44.5% dioxane	2.14	0.0
$LiClO_3$ in 44.5% dioxane	2.08	0.0
$NaClO_3$ in 64.5% dioxane	7.25	0.0
$LiClO_3$ in 64.5% dioxane	5.53	0.0

Thus dioxane plays a major role in the solvation of electrolytes in dioxane–water mixtures. This at first sight may appear unlikely since pure dioxane has such a low dielectric constant (2.21 at 25°) and, therefore, a low dipole moment. Hyne (25), however, has shown that addition of electrolyte to dioxane–water mixtures greatly increases the microdielectric constant above the bulk value. Such an increase is in keeping with the displacement of the boat–chair equilibrium for dioxane in favor of the boat form, under the influence of the Coulombic field of the ionic species. Due to the opposition of the bond moments in the chair form, the preponderance of this form in pure dioxane results in a low dielectric constant, but the preponderance of the boat form, with its bond moments acting together, when electrolyte is added to the system, may explain the strong interaction between dioxane and electrolytes.

Diffusion coefficients of sodium and lithium chlorates in water, at 25°

A. N. CAMPBELL AND B. G. OLIVER[1]
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received January 14, 1969

The diffusion coefficients of sodium chlorate and lithium chlorate in water have been determined, using the Stokes' diaphragm technique. The diffusion coefficients of the solutions have been treated by the extended Hartley–Crank analysis to obtain hydration numbers for the electrolytes.

Canadian Journal of Chemistry, 47, 2681 (1969)

Since we had already studied the conductances of sodium and lithium chlorates in water (1) and the activity coefficients from vapor pressure measurements (2), we thought that a study of diffusion coefficients might add to our knowledge of the structure of these solutions. Janz and Mayer (3) have given a comprehensive treatment of the Stokes' diaphragm technique for diffusion, along with a complete literature survey of the work that has been done on diffusion in electrolyte solutions.

Experimental

The methods of preparation and purification have been given previously (2).

The diffusion coefficients were measured using a magnetically stirred diaphragm cell, as recommended by Stokes (4). One slight modification of the cell was introduced: instead of rubber stoppers, the necks of the cell were closed at the bottom with a capillary bore stopcock and at the top with a fine capillary plug. Both stoppers were lubricated with Dow Corning high vacuum silicone grease; no evaporation of solvent was observed.

The diaphragm cell was calibrated with potassium chloride solutions which were approximately 0.5 M in the lower compartment; pure water was used in the upper compartment. The diffusion coefficients of potassium chloride have been tabulated by Stokes (5). Diaphragm wear by the action of the stirrers and enlargement of the pores from the flow of the solutions causes the cell constant to change with time. Because of this, the cell was calibrated after every 5 runs and the cell constant interpolated for each experimental run. When these precautions are taken and the error of analysis estimated as not more than 0.1%, an accuracy of about $\pm 0.2\%$ in the final measurement can be expected, provided the concentrations of the solutions be kept above 0.05 M; below this concentration, surface transport in the cell leads to significant errors.

Since we had previously determined the conductance of sodium chlorate in water at 25° very accurately (1), we used this method to determine the concentrations of sodium chlorate solutions. It was necessary, however, to dilute some of the more concentrated solutions because the specific conductance passes through a broad maximum beyond 2.5 M. Analyses by this method were accurate to about $\pm 0.1\%$. A volumetric method of analysis, taken from Vogel (6) and Talbot (7) was used for the determination of lithium chlorate because, at the time, sufficiently accurate conductance data were not available.

Our method of determining conductance has been previously described (1). Viscosity was determined with a Cannon and Fenske type viscometer, for which the drainage and kinetic energy corrections are negligible.

Results

Treatment of Results

The theory for calculating the diffusion coefficient for concentration-dependent systems was outlined by Gordon (8) and extended by Stokes (9). It is therefore unnecessary to repeat the treatment here. Computer calculations were used extensively.

The experimental results are given in Tables I and II. The symbols D, $\bar{D}$, and $\bar{D}^0$ mean, respectively, the differential diffusion coefficient, the diaphragm cell integral diffusion coefficient, and the integral diffusion coefficient for a run of vanishingly small duration.

Discussion

The graphs of the differential diffusion coefficients of sodium and lithium chlorates in water vs. the square root of the concentration (in moles/l) are shown in Fig. 1. There is a marked difference between the shapes of the two curves. The differential diffusion coefficient of lithium chlorate is greater than that of sodium chlorate, above 1.23 M. A possible explanation of this is the greater thermodynamic non-ideality of lithium chlorate. Division of the observed D values by the corresponding activity factor, $\mathrm{d} \ln f_{\pm}/\mathrm{d} \ln m$, gives a quantity proportional to the actual mobility of the diffusing solute,

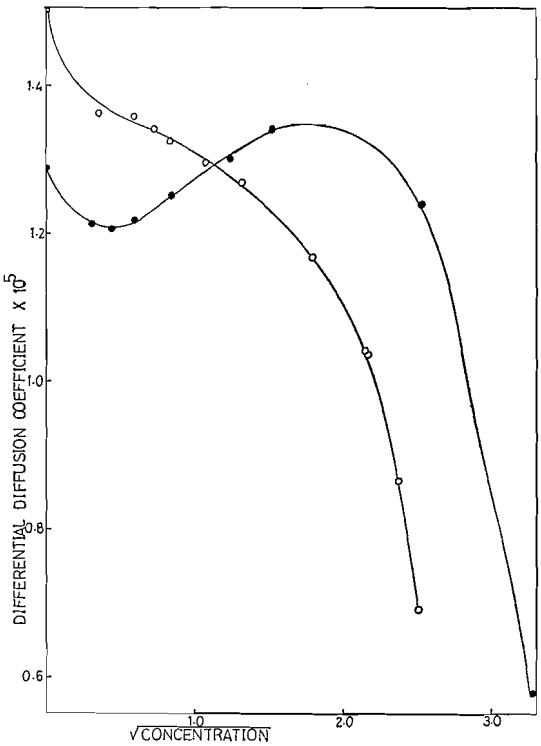

FIG. 1. Differential diffusion coefficients vs. square root of concentration (moles/l) for sodium chlorate (○) and for lithium chlorate (●), in water at 25°.

D_{corr}. The D_{corr} values for lithium chlorate are below the corresponding values for sodium chlorate, over the entire concentration range, indicating that much of the observed change is due to activity coefficient differences.

We attempted to fit the experimental diffusion coefficients to the theoretical equation of Hartley and Crank (10), as extended to electrolytes by Wishaw and Stokes (11). Their two equations are

$$[1] \quad \frac{\eta}{\eta_0} f(D) = 1 + 0.036m[(D^*_{H_2O}/\bar{D}^0) - h]$$

and

$$[2] \quad f(D) = 1 + 0.036[(D^*_{H_2O}/\bar{D}^0) - h']$$

where

$$[3] \quad f(D) = D_{obs}/[(\bar{D}^0 + \Delta_1 + \Delta_2) \times (1 + m \cdot \mathrm{d} \ln \gamma/\mathrm{d}m)]$$

All the quantities, except the hydration numbers, are calculable from experimental limiting mobilities and thermodynamic data; the terms Δ_1 and Δ_2 involve the assumption of some value for the ion size parameter, a, but since this appears only in small correction terms, the exact value chosen is not highly critical (12). The values of the quantities in eqs. [1] and [3] used to fit the experimental data are shown in Tables III and IV.

An examination of eq. [1] shows that the plot of $\eta/\eta_0 f(D)$ vs. m should be a straight line of slope $0.036(D^*_{H_2O}/\bar{D}^0 - h)$. Similarly, from eq. [3], the plot of $f(D)$ vs. m should be a straight line of slope $0.036(D^*_{H_2O}/\bar{D}^0 - h')$. When our figures are plotted, straight lines are obtained below a concentration of 2 molal (Figs. 2 and 3). The values of h and h' are obtained from the slope of these plots by the method of least squares, taking the value of $D^*_{H_2O}$ (the self-diffusion coefficient of water) to be 2.44×10^{-5} cm^2 s^{-1} (13). The hydration numbers calculated in this way, along with the corresponding calculated values of the differential diffusion coefficient are shown in Tables III and IV. It can be seen from

the tables that the equations represent the experimental data fairly well, with a maximum deviation of 2%, up to a concentration of 2 *M*.

The values of the hydration numbers obtained by this treatment are reasonable. Lithium chlorate appears more highly hydrated than sodium chlorate, but the viscosity corrected eq. [1] gives very different hydration numbers from those of the uncorrected eq. [2]. A comparison of these hydration numbers with those obtained from activity (2) indicates that the viscosity corrected equation gives values which are too low, while the uncorrected equation gives values which are too high. The determination of hydration by diffusion will be weighted in favor of the firmly bound water molecules, since the ion carries the hydrating water molecules with it through the diaphragm. Thus, diffusion will give a good approximation to the lower limit of the hydration number, i.e. it measures the primary hydration. The determination of hydration from activity, on the other hand (cf. our previous paper (2)) will include secondary hydration, since any interaction between solvent and ions will affect the activity coefficient. Therefore, the viscosity corrected

eq. [1] should give the minimum hydration number, while the Stokes–Robinson equation (cf. our previous paper (2)) should give the maximum hydration number.

Although the theories we have used in this and our preceding paper (2) are useful in predicting the behavior of the activity and the diffusion coefficients and in giving an approximation to the degree of hydration, the results show that the numerical values of the hydration number depend on the equation used to calculate them. This is not surprising because each theory ascribes different importance to solvation and, in some cases, many important factors, such as dielectric constant, viscosity, etc., have been completely omitted. Until a theory has been developed which can predict the effect of dielectric constant, viscosity, ion–ion interaction, ion–solvent interaction, etc., on activity and diffusion, the concept of solvation number will remain vague.

The mechanism of formation of pre-passive films on nickel: a chronoellipsometric study[1]

A. K. N. REDDY[2] AND B. RAO[3]

Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pa. 19104

Received February 11, 1969

The authors have previously shown that the anodic passivation of nickel in acid solutions is a two-stage process; the first stage of which involves the formation of a pre-passive film. In this study, the mechanism of formation of the precursor film on nickel in a 0.5 *M* K_2SO_4 (pH = 3.1) solution has been investigated by means of the technique of chronoellipsometry which consists of the ellipsometric *in situ* monitoring of the anode surface during a galvanostatic experiment. The main finding is that, before the pre-passive film forms, there must elapse an induction time which is affected by the current density and mass-transport factors. The nature of the dependence of the induction time upon current density indicates that the pre-passive film is formed by a dissolution–precipitation mechanism. It is proposed that the pre-passive film consists of precipitated $Ni(OH)_2$.

Canadian Journal of Chemistry, 47, 2687 (1969)

Introduction

A steady-state ellipsometric study (1–3) of the mechanism of the anodic passivation of nickel in acid solutions has demonstrated that the process occurs in two stages. The first stage consists of the formation of a precursor or pre-passive film which is transformed in the second stage into a material that is probably a semiconductor. It is the latter material that confers the property of passivity upon the electrode surface.

The object of this paper is to report on a chronoellipsometric study of the mechanism of formation of the pre-passive film. Chronoellipsometry (4–6) permits the continuous *in situ* optical monitoring of the surface of a mirror-like anode, and the registering of the time interval between the imposition of a constant anodic current and the formation of a surface film.

Experimental

(a) Ellipsometer and Cell

A schematic representation of the ellipsometer and cell is shown in Fig. 1. The ellipsometer was a commercial unit (O. Rudolph and Sons) modified to permit adjustment of the polarizer and analyzer azimuths with the quarter-wave plate being fixed with its axes at 45° to the plane of incidence. The cell (4.5 × 2.19 × 4.65 cm^3) was made by the Ultracell Co. of transparent Corning synthetic fused quartz (refractive index $n = 1.458$ at 5461 Å). The cell cover was fabricated out of Teflon, and permitted the introduction of a platinized-platinum counter-electrode, a saturated calomel electrode[4], and an inlet for the bubbling of pre-purified nitrogen.

(b) Electrolyte

In view of the detailed work of Sato and Okamoto (7, 8) on the anodic passivation of nickel, the present experiments were carried out under similar conditions, i.e., at room temperature (~20 °C) in solutions of 0.01 *N* H_2SO_4 plus 0.5 *M* K_2SO_4 (pH = 3.15). Prior to, but not during a chronoellipsometric experiment, pre-purified nitrogen was bubbled through the electrolyte. The polarographer's thumb-rule was followed, i.e., about 1 min of bubbling per ml of electrolyte.

(c) Electrodes

Nickel tape (0.0375 cm thick) of 99.5% purity, obtained from the American Silver Refining Co. was found to have sufficient mirror finish to be used as the reflecting electrode. After degreasing in hot absolute alcohol, the nickel tape was washed in conductivity water, and then for 2 min in a 50–50 mixture of nitric and sulfuric acids to dissolve away air-formed oxides. After another rinse in conductivity water, the nickel was maintained at a potential of −0.15 V (vs. normal hydrogen electrode (n.h.e.)) by means of a Wenking 61-R potentiostat. Under these conditions of potentiostatic control, the nickel could be expected to be thermodynamically immune to surface film formation (cf. the potential–pH diagram for nickel (9)). This expectation was not derived by the ellipsometrically determined optical constants of the nickel (potentiostated at −0.15 V) which were found to be fairly consistent with those given in the literature for a film-free nickel surface.

[4]The standard calomel electrode (s.c.e.) used in the present study was a Beckman fibrejunction type with a negligible volume flow rate of electrolyte solution, (less than 0.1 ml per 24 h). The fact that passive films were formed (1–3) despite the use of s.c.e. was taken to mean that the efflux of Cl^- ions from the reference electrode, though finite, was too negligible to prevent passivation and obstruct its mechanism.

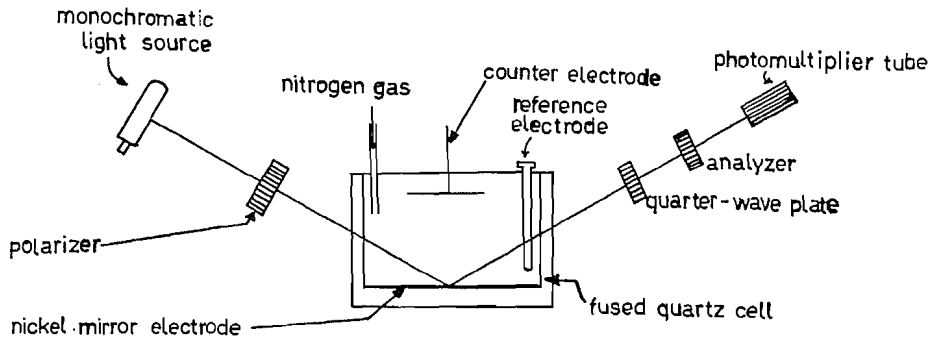

FIG. 1. Schematic representation of ellipsometer cell.

(d) Chronoellipsometric Procedure

While potentiostatically maintaining the nickel mirror electrode under film-free conditions, the azimuths of the polarizer and analyzer (P and A, respectively) were adjusted. The intensity, I_0, of light transmitted by the analyzer can easily be shown, for example by a Poincare sphere derivation (6), to be given by

$$[1] \quad I_0 = \sin^2 \psi_0 + A) - \sin 2\psi_0 \sin 2A \sin^2 \left(\frac{\Delta_0 + P - 90^\circ}{2}\right)$$

where Δ_0 and ψ_0 are the relative phase retardation and amplitude diminution introduced by the film-free metal. If $A = \psi_0$ and $P = 270^\circ - \Delta_0$, then the polarizer and analyzer are in their extinction positions, and $I_0 = 0$.

The initial intensity, I_0, corresponding to film-free conditions was fed via a photomultiplier tube and a preamplifier to one input of a Tektronix RM-35 oscilloscope with a Type CA plug-in. (The other input of the oscilloscope was used to monitor the potential of the nickel electrode relative to the s.c.e.)

The chronoellipsometric experiment consisted of using a fast switch incorporating a Western Electric 275B Relay to switch off the potentiostat used to maintain film-free conditions, and simultaneously (within $< 10\,\mu s$) to impose a constant current across the mirror electrode – solution interface. During such a galvanostatic transient, a simultaneous oscilloscopic record of the electrode potential and ellipsometer intensity were made as a function of time.

The basis of the chronoellipsometric technique is that the formation and growth of a surface film produces a change of the relative phase retardation and amplitude diminution from the "clean surface" values, Δ_0 and ψ_0 to new values, Δ and ψ. The latter change as the film thickens and/or undergoes transformations in composition. Since, during the experiment, the polarizer and analyzer are kept at the initial azimuths P and A respectively, the intensity transmitted by the analyzer during film growth is given by

$$[2] \quad I = \sin^2(\psi + A) - \sin 2\psi \sin 2A \sin^2 \left(\frac{\Delta + P - 90^\circ}{2}\right)$$

From eqs. [1] and [2], it is clear that since $\psi \neq \psi_0$ and $\Delta \neq \Delta_0$ correspond to a film-covered surface, and Δ_0 and ψ_0 to a film-free surface, $I \neq I_0$. In other words, film formation is manifested as a deviation of the intensity from the initial value, I_0. Thus, the onset of film formation can be detected in the transient of ellipsometer intensity vs. time.

An analysis of eqs. [1] and [2] shows that $(I - I_0)$, the change of intensity associated with film formation, depends upon the analyzer azimuth, and is least when $A = \psi_0$, i.e., when $I_0 = 0$. Hence, as stressed in earlier papers on the chronoellipsometric technique (4, 5), film formation can be detected with greater sensitivity and made to reveal itself more distinctly if the polarizer and analyzer are set at off-extinction azimuths when the mirror is in its initial film-free reference state. This means that the initial intensity, I_0, will not be zero. Since, however, the values of P and A are not used in chronoellipsometry to calculate the thickness and optical constants of the film, the actual value of I_0 only serves as an arbitrary "zero."

Results

A typical curve for the variation of ellipsometer intensity with time after imposition of the constant current is shown in Fig. 2. It is obvious from the figure that a time, τ_i, elapses before the ellipsometer intensity, I, changes from the initial value, I_0, corresponding to a film-free nickel anode surface.

The galvanostatic potential–time transient (which is included in Fig. 2) is similar to that obtained by Sato and Okamoto (7, 8). It shows that a plateau potential of +0.04 V vs. n.h.e. is attained by a charging process involving a time X. Thereafter, the potential remains steady until the completion of the induction time, τ_i, at Y. Further, the time taken for the electrode to attain the plateau potential is markedly less than the induction time required for the ellipsometer intensity to deviate from the initial value, I_0. Thus, Fig. 2 shows that the nickel electrode

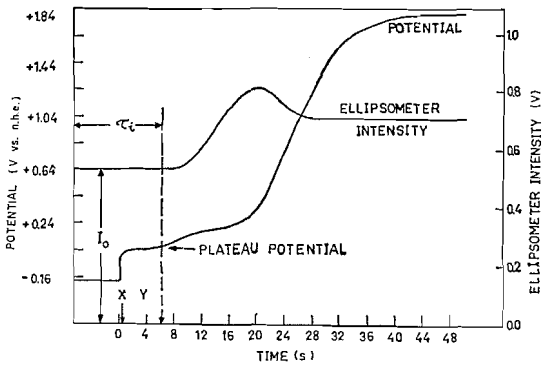

FIG. 2. Potential–time and ellipsometer intensity–time transients obtained with a galvanostatic current density of 1.5 mA cm^{-2}.

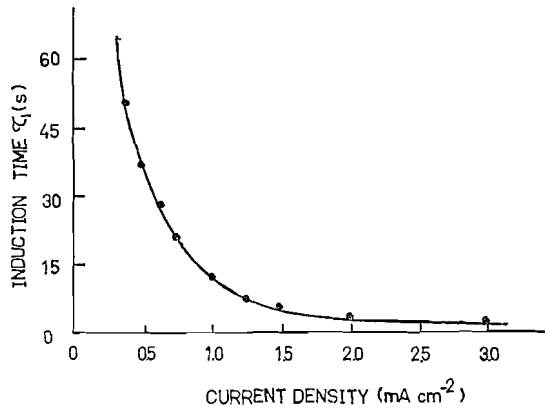

FIG. 3. Induction times observed at various current densities.

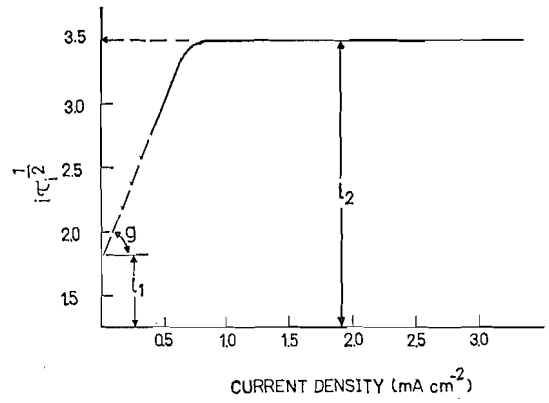

FIG. 4. The function $i\sqrt{\tau_i}$ plotted against current density (the induction times have been taken from the smooth curve of Fig. 3).

potential goes from −0.15 to +0.04 V within 1 s after switching-on the constant current, whereas an induction time of 8 s elapses before the intensity increases.

As observed in the study on calomel (5), the induction time was found to depend upon the magnitude of the constant current density used. A plot of the induction time, τ_i, vs. the galvanostatic current density, i, is given in Fig. 3. From a $i\sqrt{\tau_i}$ vs. i plot (Fig. 4), it is seen that $i\sqrt{\tau_i}$ is independent of i except in the range of low current densities where it increases linearly with i.

An important, though qualitative, result is the fact that the induction time was observed to increase when the electrolyte was stirred (by nitrogen bubbling) during the passage of the galvanostatic stimulus.

Discussion

A possible interpretation of the form of ellipsometer intensity vs. time curve is that the intensity rise (after the induction time) is due to changes in the anolyte refractive index resulting from nickel dissolution. This interpretation, however, is difficult to sustain in view of the fact that between $t = 0$ and $t = \tau_i$ there is a virtually constant intensity despite the occurrence of nickel dissolution. Hence, changes in the refractive index of the solution are obviously inadequate, at least in the case of nickel dissolution, to account for the intensity increase after the induction time. A similar argument can be used to discount the view that the roughening of the nickel surface due to anodic dissolution is responsible for the intensity increase after τ_i. Further confirmation that neither changes of electrolyte refractive index nor changes of surface topography produce the intensity change after τ_i comes from the steady-state work (1–3). There, it was observed that, in the range of potentiostatically-controlled potentials from −0.250 to −0.025 V, the Δ and ψ are constant despite anodic dissolution and its inevitable results, viz., changes of solution refractive index and topography[5].

[5]The above arguments are solely with reference to the present chronoellipsometric experiments on nickel in acid solutions. In the case of other media and/or metals, it may well turn out that solution and/or topographical changes may have to be invoked to interpret small changes in intensity preceding the significant intensity jump associated with the induction time.

In view of the discussion just presented, the intensity rise in the ellipsometer intensity–time curve can be interpreted as being due to film formation after an induction time τ_i. Thus, the basic experimental results that need explanation are: (*a*) the existence of an induction time for film formation; (*b*) the attainment of a steady potential in a time significantly less than the induction time (Fig. 2); (*c*) the type of dependence of induction time upon current density revealed in the $i\sqrt{\tau_i}$ vs. i plot (Fig. 4); (*d*) the sensitivity of the induction time to factors (e.g., stirring) that affect mass transfer in the electrolyte.

It has been shown in earlier papers (4–6) that such results are precisely what one would expect if film formation occurs by a dissolution–precipitation mechanism. The essence of such a mechanism is that the anodic dissolution of the metal results in the generation of a soluble species which accumulates in the vicinity of the anode. The accumulation proceeds until the soluble species attains a critical concentration at which stage an insoluble substance precipitates on to the electrode as a film. In unstirred solutions in which natural convection is minimized by appropriate electrode configuration, the accumulation of the species is determined by a diffusion-dependent process. Further, the critical concentration of the soluble species is, to a first approximation[6] decided by the solubility product of the precipitating film-forming substance.

The dependence of the induction time upon the current density has been worked out for the following reaction model

$$[3] \qquad R \xrightarrow{-ne} O$$

$$[4] \qquad O \underset{k^+}{\overset{k^-}{\rightleftharpoons}} Y$$

$$[5] \qquad O + X^- \rightarrow OX\downarrow$$

The general expression for $i\sqrt{\tau_i}$ derived in an earlier paper (4) yields two special cases. At low current densities, i.e., large τ_i

$$[6] \quad i\sqrt{\tau_i} = \frac{\sqrt{(D\pi)nF}}{2}(1 + K_1)C^* + \frac{K_1\sqrt{\pi}}{2\sqrt{Z}}i = l_1 + gi$$

and, at high current densities, i.e., small τ_i

$$[7] \quad i\sqrt{\tau_i} = \frac{\sqrt{(D\pi)nF}}{2}\left(\frac{1 + K_1}{1 - K_1}\right)C^* = l_2$$

where D, Z, n, and F have their usual connotation, $K_1 = k^-/k^+$, $C^* = K_{sp}/C_X^-$ (K_{sp} is the solubility product corresponding to reaction [5]), l_2 is the extrapolated intercept of the i-independent portion of the $i\sqrt{\tau_i}$ vs. i plot, and l_1 and g are the intercept and slope, respectively, of the $i\sqrt{\tau_i}$ vs. i straight line expected at low current densities.

The above precipitations regarding the form of the $i\sqrt{\tau_i}$ vs. i plot expected on the basis of a dissolution–prediction model for film formation are seen to be in excellent agreement with the results of chronoellipsometric experiments on the anodic behavior of nickel in acid solutions. It may be concluded, therefore, that the pre-passive or precursor film in the anodic passivation of nickel in acid solutions is formed by a dissolution–precipitation mechanism.

The next step in the discussion concerns the identity of the species involved in the dissolution–precipitation model (cf. eqs. [1], [2], and reaction [3]). The detailed steady-state, galvanostatic and potentiostatic work of Sato and Okamoto (7, 8) has shown that the initial product of the anodic dissolution of nickel is the species, $NiOH^+$. By analogy with the study of Bockris and co-workers (10) on the dissolution and deposition of iron, in which the species $FeOH^+$ was considered, one can postulate the following reaction sequence

$$[8] \qquad Ni + OH^-_{bulk} \rightarrow Ni + OH^-_{ads}$$

$$[9] \qquad Ni + OH^-_{ads} \rightarrow NiOH_{ads} + e$$

$$[10] \qquad NiOH_{ads} \rightarrow NiOH^+ + e$$

to yield the overall nickel dissolution reaction (cf. eq. [3])

$$[11] \qquad Ni + OH^- \rightarrow NiOH^+ + 2e$$

Thus, the soluble intermediate in the dissolution–precipitation mechanism is suggested to be $NiOH^+$.

The homogeneous chemical equilibrium (cf. reaction [4]) responsible for the two-section $i\sqrt{\tau_i}$ vs. i plot is most probably the breakdown of $NiOH^+$ into the simple aquo-ion and the

[6]In the first approximation version of the theory (4–6), no account has been taken of the kinetics of precipitation of the insoluble substance, in particular of the need for supersaturation.

corresponding reverse reaction

$$[12] \qquad NiOH^+ \underset{k^+}{\overset{k^-}{\rightleftharpoons}} Ni^{2+} + OH^-$$

As to the identity of the precipitate resulting from the accumulation of $NiOH^+$, there are two possibilities: NiO and $Ni(OH)_2$.

Thus, the induction-time analysis must be applied to the following model for the formation of the precursor film in the anodic passivation of nickel

$$[13] \qquad Ni + OH^- \xrightarrow{-2e} NiOH^+ \qquad k^- \Updownarrow k^+ \qquad Ni^{2+} + OH^-$$

followed by either

$$[14] \qquad NiOH^+ \xrightarrow{-H^+} NiO$$

or

$$[15] \qquad NiOH^+ + OH^- \rightarrow Ni(OH)_2$$

Reaction [14] is the one proposed by Sato and Okamoto (7, 8) on the basis of their electrochemical study. Reaction [15] is proposed here as an alternative for the precipitation reaction; it corresponds to the formation of $Ni(OH)_2$ by the two-step addition of OH^- ligands to nickel.

One approach to deciding between the two precipitation reactions [14] and [15] is by calculating the solubility products of NiO and $Ni(OH)_2$ from the induction-time data, and comparing these calculated values with the experimental values published in the literature. The calculation involves the computation of $K_1 = [Ni^{2+}][OH^-]/[NiOH^+]$ by the elimination of C^* from eqs. [6] and [7].

Using the value of Sato and Okamoto (7, 8) of $K_2 = [NiOH^+]/[NiO][H^+] = 10^{2.78}$, the calculated solubility product of NiO, i.e., $K_{sp} = K_1K_2 = [Ni^{2+}][OH^-]/[NiO][H^+]$, turns out to be $10^{2.46}$. To compare this value obtained from the present experiments with the work of previous authors, it is necessary to use a published value of K_1. Unfortunately, the comprehensive compilation (11) contains a spread of values for K_1; the lowest being $10^{-3.1}$ and the average being $10^{-4.9}$. Using the lowest and most favorable value, the solubility product of NiO is $10^{-0.32}$ in contrast to $10^{-2.12}$ based on the average value of K_1. Hence, the chronoellipsometric support for a NiO film is not strong.

In the case of $Ni(OH)_2$, the scatter in the published values for $K'_2 = [NiOH^+][OH^-]/[Ni(OH)_2]$ ranges from the highest value of $10^{-14.98}$ to one of $10^{-11.28}$ calculated from the paper of Pourbaix *et al.* (9). These yield chronoellipsometric values of the solubility product of $Ni(OH)_2$, i.e., $K'_{sp} = [Ni^{2+}][OH^-]^2/[Ni(OH)_2]$, of $10^{-15.1}$ (corresponding to $K'_2 = 10^{-14.98}$) to $10^{-11.60}$ (corresponding to $K'_2 = 10^{-11.28}$), in comparison with the figure of Pourbaix *et al.* (9) of $10^{-15.87}$ and the average value of Sillen (11) of $10^{-14.4}$. Thus, the chronoellipsometric support for a $Ni(OH)_2$ can only be termed fair.

It is seen, therefore, that on the basis of chronoellipsometry and the widely-varying literature values for K_2, K'_2, and K'_{sp}, it is difficult to decide in favor of either NiO or $Ni(OH)_2$ with any degree of certainty. If one chooses favorable values of K_2, K'_2, and K'_{sp}, then the scales appear to be tilted very slightly in favor of reaction [15], viz., the precipitation of $Ni(OH)_2$. In the case of NiO, even favorable values of K_1 do not help to match theory and experiment.

Though the chronoellipsometric evidence is not unambiguously in favor of $Ni(OH)_2$ constituting the precipitated pre-passive film, the formation of $Ni(OH)_2$ rather than NiO is suggested here in view of the following supplementary arguments:

(*a*) All the electrochemical data quoted by Sato and Okamoto (7, 8) as the basis for suggesting NiO can be used to argue equally strongly in favor of $Ni(OH)_2$. This assertion follows naturally from the very small difference (0.310 kcal $mole^{-1}$) in the free energy change associated with the reactions [14] and [15].

(*b*) $Ni(OH)_2$ is thermodynamically more stable than NiO, according to Pourbaix *et al.* (9) the free energy of formation of $Ni(OH)_2$ is -108.300 kcal $mole^{-1}$ in contrast to -107.990 kcal $mole^{-1}$ for NiO + H_2O (see, however, the contrary view of Milner and Thomas (12)). On this basis, $Ni(OH)_2$, which has a lower solubility product than NiO, would be expected to precipitate before NiO. Indeed, Pourbaix *et al.* do not include NiO in the potential–pH diagram for nickel.

(*c*) When the experimental values of the refractive index of the *pre-passive* film are determined by steady-state ellipsometry (1, 2) and then compared with theoretical values calculated for $Ni(OH)_2$, NiO, etc., the comparison favors a pre-passive film of $Ni(OH)_2$. However, these calculations need confirmation because

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

they are based on (*a*) the existence of crystalline substances and (*b*) the use of the Lorenz–Lorentz equation for the evaluation of index of refraction, which is not free of shortcomings.

(*d*) The potential–pH diagram for nickel indicates that anodic film formation is impossible at a pH of 3.1. Hence, the observed formation of a pre-passive film shows that the pH in the immediate vicinity of the anode is much higher than in the bulk. In view of this, one would expect the electrochemistry of the nickel oxide electrode in nickel–cadmium and Edison cells to have some bearing on that of anodic passivation. The considerable work (12–14) on the nickel oxide electrode has demonstrated that $Ni(OH)_2$ and not NiO is the starting material for the oxidation to NiOOH. The substance NiO, not only has a face centered cubic lattice dissimilar to the layer lattice of NiOOH, but is electrochemically inert except for the surface layers. $Ni(OH)_2$, on the other hand, has a layer lattice like NiOOH and can be converted into it more easily. The upshot of this comparison with the nickel oxide electrode is the suggestion that, even in the case of the anodic passivation of nickel, the pre-passive film is probably $Ni(OH)_2$.

In conclusion, the present chronoellipsometric experiments and the various auxiliary arguments lend some weight to the suggestion that the precipitation reaction is [15] and leads to the formation of $Ni(OH)_2$. There is no gainsaying the fact, however, that more convincing discriminatory work is required before one can assert that $Ni(OH)_2$, rather than NiO, is formed in the dissolution–precipitation mechanism for the formation of the precursor film in the anodic passivation of nickel in acid solutions.

Acknowledgments

The authors take this opportunity to thank Professor J. O'M. Bockris for the continued interest and encouragement which sustained this work. The final form of this paper was influenced by the thought-provoking critique of Miss Vlasta Brusic (of the Electrochemistry Laboratory, University of Pennsylvania) to whom we express our appreciation. The mechanism of passivation of nickel as determined by an automatic recording ellipsometer[1]

A. K. N. REDDY[2] AND B. RAO[3]

Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pa. 19104

Received February 11, 1969

The process of anodic passivation of nickel in acid solutions has been investigated by means of an automatic recording ellipsometer in which the light emerging from a rotating analyzer has been electronically processed to yield a continuous read-out of the changes of polarization state of light reflected from a nickel anode during a galvanostatic transient. Digital computer analysis of the ellipsometric data has revealed: (*a*) the existence of an induction time for film formation; (*b*) a linear growth law for the film during a time interval commencing with the induction time and ending before the passivation time; (*c*) the occurrence of passivation when the absorption coefficient of the film jumps from a near-zero value to a fractional value; and (*d*) continuous changes of the refractive index of the film during the period of film growth. These phenomena are consistent with a model in which (*a*) a pre-passive film forms and thickens by a dissolution–precipitation mechanism, (*b*) the growth of the film is accompanied by its electrochemical oxidation, (*c*) the film growth – oxidation process continues until the pre-passive film is transformed into an electronically-conducting material, and (*d*) the conversion of the pre-passive film into an electronic conductor constitutes the essence of the so-called active–passive transition.

Canadian Journal of Chemistry, 47, 2693 (1969)

Introduction

The techniques (2) of steady-state ellipsometry and chronoellipsometry, developed in the Electrochemistry Laboratory of the University of Pennsylvania, have been used successfully (1–5) to throw light on the mechanism of anodic passivation of nickel in acid solutions.

Steady-state ellipsometry (1, 3, 4) has demonstrated that passivation is a two-stage process. The first stage involves the formation of a non-passivating precursor film, and the second stage involves the transformation of this pre-passive film into a substance, the absorption coefficient of which corresponds to that of an electronic-conductor.

Chronoellipsometry (5) has established that the pre-passive film which has been suggested to be $Ni(OH)_2$, forms by a dissolution–precipitation mechanism.

It must be stressed, however, that both steady-state ellipsometry and chronoellipsometry only reveal partial aspects of the passivation process. The former technique assumes that the steady-state films observed at various steady-state potentials represent the sequence of changes on the anode surface during a non-steady-state dynamic growth process. Chronoellipsometry, by not furnishing quantitative information on film thickness, refractive index, and absorption coefficient, focusses attention on what happens up to the instant of film formation and thus ignores the subsequent events which involve film growth and/or film transformation.

What is needed is a technique which permits *in situ* monitoring and reporting of the changing characteristics of the nickel surface during, for instance, an anodic galvanostatic transient. A technique which fulfills these requirements has been made possible by the development of an automatic recording ellipsometer (1, 6). The object of the present paper is to describe (*a*) the results of a study on the anodic passivation of nickel using an automatic recording ellipsometer and (*b*) the light thrown by these results on the process of formation and growth of pre-passive films and on the conversion of pre-passive to passive films.

Experimental Procedure[4]

The experiments were carried out in a transparent Corning synthetic fused quartz rectangular cell (4.50 × 2.19 × 4.65 cm^3) mounted on the specimen carrier of the

[1]This work was in partial fulfillment of the requirements of the Ph.D. degree awarded to B. Rao in 1966.

For personal use only.

ellipsometer. The Teflon cell cover was designed to permit (*a*) bubbling of pre-purified nitrogen through the 0.5 *M* K_2SO_4 (pH = 3.1) electrolyte, and (*b*) the introduction of a platinized platinum counter-electrode and a saturated calomel electrode[4]. Commercial nickel tape of adequate reflectivity was held at the bottom of the cell so as to function as an anode and as a mirror.

After pre-treatment[4] of the nickel anode, it was potentiostatically maintained at a cathodic potential of −0.15 V (vs. normal hydrogen electrode (n.h.e.)). Under these film-free conditions, the polarizer and analyzer azimuths, *P* and *A*, respectively, of the conventional ellipsometer (with fixed quarter-wave plate) were adjusted for extinction. Using the relations, $\Delta_0 = 2P - 90°$ and $\psi_0 = A$, the relative phase retardation (Δ_0) and amplitude diminution (ψ_0) introduced by the clean metal surface were calculated.

The ellipsometer was then automated as follows (1, 6). Instead of the quarter-wave plate and analyzer (both of which were removed) a rotating analyzer was mounted as described elsewhere. The modulated light emerging from the rotating analyzer was sensed by a photomultiplier, and the output of this tube was electronically processed for a recorder read-out of the two parameters, azimuth (λ) and ellipticity (ω), characterizing the polarization state of the reflected light[5]. The response time of the instrument was 0.05 (see Appendix I).

After the completion of the steps required for the automation of the ellipsometer, the anodic passivation of the nickel was initiated by means of a constant current. The magnitude of the galvanostatic current was chosen small enough to permit the passivation to proceed far more slowly than the response time of the instrument. The passivation transient was "triggered" by a standard switching circuit which terminated the potentiostatic control of the nickel electrode potential and simultaneously imposed the galvanostatic current across the nickel–solution interface.

The basis of automatic recording ellipsometry is that if any changes on the mirror surface are produced by the constant anodic current, then these changes result in the azimuth (λ) and ellipticity (ω) of the reflected light deviating from the initial pre-transient values characteristic of a film-free nickel anode. Thus, the automated ellipsometer was used to record the changing values of $\lambda(t)$ and $\omega(t)$ during the passivation transient. With the aid of standard transformation formulae (1), these values were converted to give the time-variation of relative phase retardation (Δ) and amplitude diminution (ψ) during the course of the transient. The values of $\Delta(t)$ and $\psi(t)$ were then subjected to digital computer analysis (1, 4) for the elucidation of the thickness, $L_F(t)$, refractive index, $n(t)$, and absorption coefficient, $\kappa(t)$, for times greater than $t = 0$ which marks the switching-on of the constant current.

[5]The actual read-out of the automatic recording ellipsometer was in voltage units. To convert these voltage values into λ and ω in degrees, the instrument was calibrated with Si and Au mirrors as follows: Firstly, the λ–ω values of light reflected from these calibration substrates were determined by the ellipsometer in its conventional form; secondly the ellipsometer was automated; and finally, the calibration values of λ–ω were associated with voltage read-outs resulting from the monitoring of the Si and Au standards by the automatic recording ellipsometer. Within the λ_{Si}–λ_{Au} and ω_{Si}–ω_{Au} range, linearity was assumed.

Results

The galvanostatic anodic passivation of nickel was carried out at three current densities: 1, 0.8, and 0.1 mA cm^{-2}. A typical result showing the

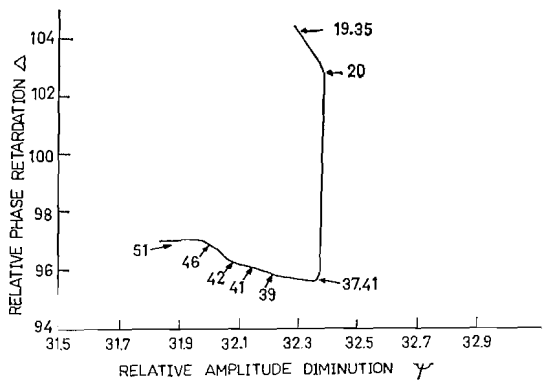

FIG. 2. Ellipsometric Δ–ψ plot corresponding to Fig. 1. The numbers next to the curve represent the time in seconds which has elapsed since $t = 0$, the commencement of the transient.

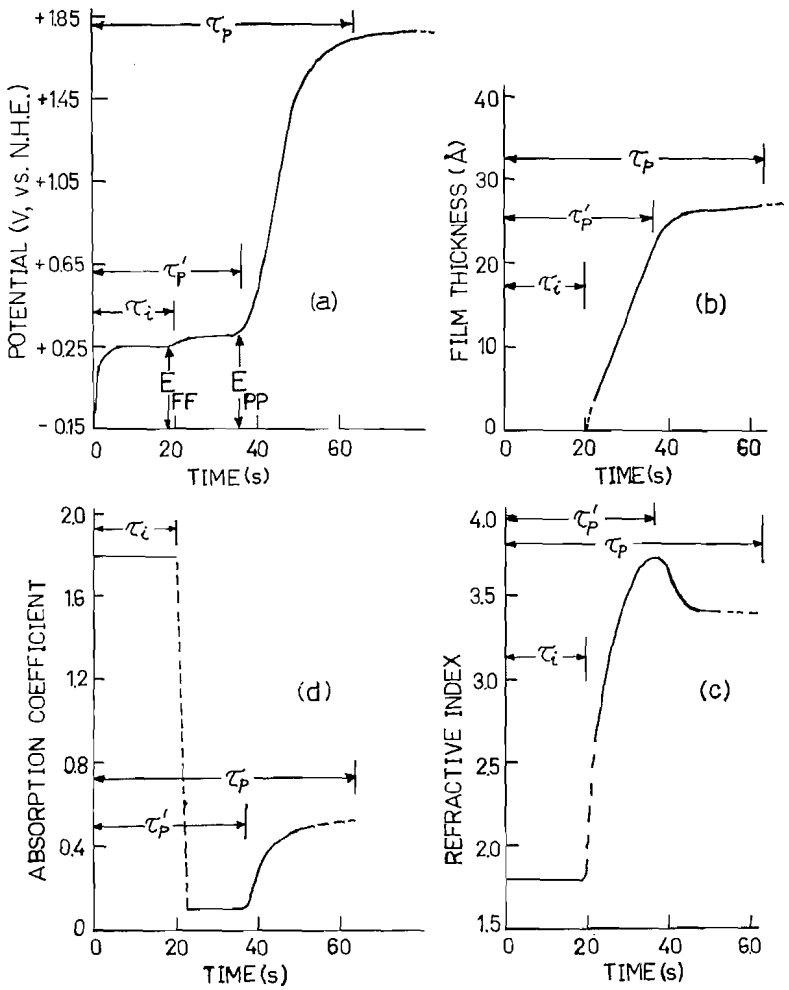

FIG. 3. The time-variation of *a*, nickel electrode potential; *b*, film thickness; *c*, refractive index; and *d*, absorption coefficient in the anodic passivation of nickel at a constant current density of 1 mA cm^{-2}.

variation of Δ and ψ as a function of time is given in Fig. 1. The resulting Δ–ψ plot (Fig. 2) was subject to computer analysis to reveal the time-variation of film thickness (L_F), refractive index (n), and absorption coefficient (κ) during the course of the passivation transient (Fig. 3*b*, *c*, and *d*). Shown for comparison (Fig. 3*a*) is the potential–time transient which was recorded simultaneously with the azimuth–time and ellipticity–time transients.

Several interesting features of the results will now be highlighted.

(*a*) Despite the imposition of a galvanostatic anodic current, the initially film-free nickel surface continues to remain uncovered with an anodic film (cf. Fig. 3*b*) for a time, t, in the range $0 < t < \tau_i$. The time interval after which an anodic film covers the electrode will be referred to as the induction time, τ_i.

(*b*) The lapse of the induction time in the ellipsometrically determined thickness–time plot is reflected in the electrochemically-determined potential–time transient by the occurrence of an inflection at E_{FF} (cf. Fig. 3, *a* and *b*). Thus, the inflection E_{FF} in the potential–time plot denotes film formation.

(*c*) As has been observed in the chronoellipsometric work of the authors, the induction time depends upon the current density used for the transient. The induction times of 16, 20, and 45 s corresponding to current densities of 1, 0.8, and 0.1 mA cm^{-2}, respectively, fit in reasonably

well with the τ_i vs. i curve determined by chronoellipsometry.

(*d*) After the lapse of the induction time, the film thickness increases linearly with time for a certain time interval τ'_P subsequent to which the film thickness tapers off to a value which remains virtually constant after the time τ_P.

(*e*) The lapse of time interval τ'_P registered in the thickness–time curve (Fig. 3*b*) is reflected in the potential–time curve (Fig. 3*a*) by the occurrence of an inflection E_{PP} after which the electrode potential climbs rapidly to the oxygen evolution potential.

(*f*) The absorption coefficient, κ, has a value characteristic of clean nickel until the lapse of the induction time, τ_i, after which it falls to a value of almost zero. It remains at that almost zero value until the time τ'_P, then climbs to a value of about 0.4. The time interval (see Fig. 3*c*) after which there is a virtual stabilization of the κ value at about 0.4 is equal to τ_P, i.e., the time interval after which there is cessation of film growth (Fig. 3*b*) and the jump to the oxygen evolution potential (Fig. 3*a*).

(*g*) The refractive index of the film changes continuously during the time interval defined by $\tau_i < t < \tau_P$ with the maximum at τ'_P.

Discussion

In contrast to chronoellipsometry (5) which has yielded inferential and indirect, though powerful, evidence for the existence of an induction time for film formation, the automated ellipsometry results quoted above have directly and unambiguously demonstrated that despite the passage of an anodic current there is no anodic film between $t = 0$ and $t = \tau_i$. Thus, the approximately 20 mC cm^{-2} passed between $t = 0$ and $t = \tau_i$ in the 1 mA cm^{-2} galvanostatic transient are utilized for an anodic process which does *not* involve build-up of material on the nickel surface. Hence, theories requiring or implying the formation of a film (whether crystalline or not) as an immediate and direct consequence of the passage of an anodic current, do not have a *prima facie* case for validity. To claim consideration, a theory must allocate the 20 mC cm^{-2} towards an anodic process in which the product is injected into the electrolyte and not on the surface. By insisting that the immediate product of anodic dissolution is a soluble ionic species, the dissolution–precipitation model, not only allows for the existence of an induction time, but considers its lapse to be a necessary precondition for film formation.

Elsewhere, the authors have stressed that the dissolution–precipitation model predicts certain characteristics of induction times. For example, τ_i should depend upon factors affecting mass transport of the soluble product of anodic dissolution. It should also depend upon the current density in the following way. Provided there is a homogeneous reaction involving the soluble intermediate, $i\sqrt{\tau_i}$ should increase linearly with i at low i's and be independent of i at high i's. These predictions which have been confirmed by the chronoellipsometric experiments (5) are in accord with the present experiments in so far as the values of τ_i determined by automated ellipsometry fit into the τ_i vs. i chronoellipsometric plot.

In addition, however, the present experiments have led to a finding which is of considerable importance to the mechanism of film formation and growth. Reference is made here to the linear increase of thickness with time. Such a linear growth law emerges simply in the following fashion from the dissolution–precipitation model.

From $t = 0$ to $t = \tau_i$, the current is used for the anodic generation of a soluble intermediate. This ionic species which has been argued to be $NiOH^+$ diffuses away from the interface. Thus its accumulation near the anode becomes a diffusion-controlled process. When the concentration of $NiOH^+$ reaches a value corresponding to the solubility product of an insoluble substance which has been suggested to be $Ni(OH)_2$, the precipitation of this material on the anode occurs. It is reasonable to assume that, after the induction time, the region next to the electrode is saturated with $NiOH^+$, so that any further dissolution current, i_d, leads to the generation of fresh $NiOH^+$. Barring a certain fraction, α, of this $NiOH^+$ which diffuses away into the solution, the remainder immediately precipitates on the anode surface by the reaction

$$NiOH^+ + OH^- \rightarrow Ni(OH)_2\downarrow$$

Thus, after the lapse of the induction time, $(\alpha i_d A t)$ coulombs of electricity produce[6] $\alpha i_d A t M/\rho n F = (\rho A L_F)$ grams of $Ni(OH)_2$. The growth

[6]Where ρ is the density and M the molecular weight of the film forming compound.

law for the precipitating film, therefore, turns out to be

$$[1] \qquad L_F = \left(\frac{\alpha i_d M}{\rho n F}\right) t = \text{constant} \times t$$

Hence, according to the dissolution–precipitation model, the film thickness should be zero between $t = 0$ and $t = \tau_i$, and then there should be a linear increase of film thickness with time. Both these predictions are in agreement with the observations. It should perhaps be emphasized here that a unified explanation of the existence of an induction time for film formation followed by a linear growth law does not seem possible on the basis of theories involving discharge followed by simultaneous film build-up.

The increase of film thickness is not the only process occurring between τ_i and τ_P. The ellipsometric results clearly demonstrate that during the period of linear film growth, the refractive index of the film is continuously changing (cf. Fig. 3 *b* and *c*). Thus a chemical transformation of the precipitated film is occurring along with further growth of the film. This variation of refractive index has been observed in steady state experiments too (1, 3, 4), and since it occurs with an increase of the potential in the anodic direction, it has been interpreted as arising from an electrochemical oxidation of the film, in which nickel is oxidized from a Ni^{2+} state in $Ni(OH)_2$, to a higher oxidation state. Whatever the actual identities of the species, it follows that a part of the galvanostatic current is utilized for the electrochemical oxidation of the film, the remainder being utilized for anodic dissolution.

Further work is required before a definitive answer is given to the question of how anodic oxidation of the precipitated film occurs along with metal dissolution and film growth. If, as seems to be the case, the film forms by a dissolution–precipitation mechanism, it is highly likely to be patchy and/or porous, in which case metal dissolution can occur in bare areas and/or through pores. A technique such as electron microscopy ought to throw light on this problem.

That the film formed by the dissolution–precipitation mechanism is not the passive film is clearly proved by the following experimental observations. (*a*) If the jump to the oxygen evolution potential in the potential–time curve is taken to be the electrochemical criterion of passivation, then it is clear that this jump does not occur along with film formation. (*b*) The film growth process which has been explained fairly convincingly on the basis of a dissolution–precipitation model implies that the metal is still corroding and that the surface has not yet been passivated. It must be concluded, therefore, that the surface film formed in the galvanostatic experiment after the induction time and undergoing growth with simultaneous oxidation between τ_i and τ_P, is only a *pre-passive* film which lacks the essential characteristic of the final passivating film. (It must be emphasized here that steady-state ellipsometry too has demonstrated (1, 3, 4) the formation of a pre-passive film as a preliminary step to passivation.)

The nature of the essential characteristic of the final passive film emerges from a consideration of the ellipsometrically revealed plot of absorption coefficient versus time. It is seen that the pre-passive film has an absorption coefficient of almost zero. However, when the absorption coefficient starts rising, the rate of film growth, i.e., dL_F/dt, starts decreasing and in addition the potential starts climbing towards the oxygen evolution potential; and when the absorption coefficient stabilizes at a value of about 0.4, the nickel surface becomes passive as shown not only by the film growth process coming to a virtual stop but by the electrode potential attaining the oxygen evolution value. If, therefore, it is meaningful and legitimate to single out of the complex process of anodic passivation a so-called act of passivation, then one may characterize the active–passive transition by the jump in the absorption coefficient of the film from a near-zero value. On this point too, the present experiments support the conclusions reached by steady-state ellipsometry (1, 3, 4). Thus, by using the latter technique it was shown that the corrosion current starts falling precisely at the potential at which the absorption coefficient starts rising, and that the metal becomes passive when the absorption coefficient stabilizes at a fractional value.

The jump in the film absorption coefficient has been singled out as the essence of passivation because, as stressed earlier, the absorption coefficient is a measure of the electrical conductivity of the film at optical frequencies, and it is invariably, though not always, true that increases in the optical conductivity are paralleled by increases in d.c. electronic conductivity. On this

basis, the following model of the active–passive transition is suggested. The pre-passive film is patchy and/or porous because it is formed by precipitation. Even if it were coherent, it is an electronic insulator and ionic conductor ($\kappa_F \approx 0$); hence, it permits ion transport through the film. In other words, corrosion can occur despite the existence of the pre-passive film. When the film becomes electronically conducting (cf. the jump in κ_F), ionic conduction through the film becomes inhibited, film growth by nickel dissolution through the film becomes negligible, and corrosion is drastically reduced, i.e., the surface has become passivated.

Though the automated ellipsometric experiments have demonstrated that passivation is associated with the jump in absorption coefficient, an understanding of why there is a jump in κ_F has not emerged with any degree of certainty. It is clear, however, that this understanding will be based on the electrochemical transformations underlying the changes in refractive index. Some idea of the dimensions of the problem can be gained by realizing that the precipitated and intermediate films are probably porous and hydrated, that the final film is probably a non-stoichiometric oxide semiconductor with electronic conductivity, and that the solid state electrochemistry concerns a very thin film (< 50 Å thick). The problem would have been more straightforward if the refractive indices of thin films of the various oxides, hydrated oxides and hydroxides of nickel were available in the literature. In the absence of such experimental data and pending definitive identification of the chemical compounds involved in the intermediate stages of passivation, the best that can be done is to fall back (*a*) on comparison of the observed refractive index values with those calculated by the Lorenz–Lorentz equation which is not without limitations, and (*b*) on an analogy with the nickel oxide electrode. This is the standpoint from which it is tentatively suggested that the real passivation process consists of the electrochemical oxidation of the pre-passive film, $Ni(OH)_2$, via NiOOH to a non-stoichiometric semiconductor $NiO_{1.7}$.

Acknowledgments

The development and application of the automated ellipsometer was very largely due to the tremendous encouragement from Professor J. O'M. Bockris whom we thank warmly. Financial support from the Aeronautical Systems Command, U.S. Air Force under Contract No. AF 33(616)-8150 and from the National Aeronautical and Space Administration under Contract No. NsG-325 is gratefully acknowledged. One of us (A.K.N.R.) thanks the Council of Scientific and Industrial Research, India, for the grant of leave of absence. We also thank Dr. Mel Benjamin and the staff of Bionic Instruments for their help with the electronics.

Appendix

A brief note on the automated ellipsometer

The fabrication of the automatic recording ellipsometer was based on a rotating analyzer (2) which consisted of a rigid polaroid sheet driven by a well-balanced synchronous motor (600 r.p.m.). The rotating analyzer was placed in the paths of the reflected beam and of the reference beam of linearly polarized light. The two chopped signals at a frequency of 20 c.p.s. were sensed by two separate photomultiplier tubes and the resultant outputs were fed to a phase detector after suitable amplification. The output of this phase detector, which corresponds to the azimuth of the reflected polarized light, was recorded on one channel of a fast strip-chart recorder. A portion of the output from the amplifier handling the chopped reflected beam was fed to electronic circuitry which provided the ratio of the maximum to the minimum of the signal. This ratio which corresponds to the ellipticity of the reflected light under study was recorded on the second channel of the recorder. With the present unit, an accuracy of 0.02° in both azimuth and ellipticity was attained. Further technical details about the design and operation of the automated units are described elsewhere (1).

Complexes of palladium(II) with *cis*- and *trans*-1,2-bis(dimethylarsino)ethylene

G. J. ERSKINE[1]

Chemistry Department, Queen's University, Kingston, Ontario

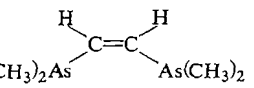
Received March 10, 1969

Palladium(II) complexes of *cis*- and *trans*-1,2-bis(dimethylarsino)ethylene, **1** and **2**, respectively, in the metal: ligand ratios 1:1 and 1:2 are described. Their structures are discussed in terms of nuclear magnetic resonance, infrared, conductivity, and analytical data, and by comparison with the corresponding platinum(II) complexes (1). The *cis*-isomer, *cis*-ED, is a strong chelating ligand and forms the complexes Pd(*cis*-ED)X_2, **9** (X = Cl^-, Br^-), and Pd(*cis*-ED)$_2X_2 \cdot 3H_2O$, **8** (X = Cl^-, Br^-, ClO_4^-, PF_6^-). The *trans*-isomer, *trans*-ED is a bridging ligand and forms the dimeric complexes, [Pd(*trans*-ED)X_2]$_2$, **10** (X = Cl^-, Br^-), and Pd$_2$(*trans*-ED)$_4X_4 \cdot 3H_2O$, **7** (X = Cl^-, Br^-, ClO_4^-, PF_6^-). All these complexes contain 4-coordinate, square planar palladium(II). The anhydrous form of **7** (X = Cl^-) shows evidence for a Pd—Cl bond, suggesting 5-coordination in the solid state. Room temperature irradiation (with ultraviolet light) of **7** (X = Cl^-), in non-aqueous solvents, causes isomerization of the ligand and the formation of complex **8** (X = Cl^-). No change occurs under these conditions in aqueous solutions. Contrary to the original suggestion for the corresponding platinum(II) derivative, **10** (M = Pt(II), ref. 1) far infrared evidence supports a *cis*-configuration about the metal ion rather than the *trans*-configuration, **6**.

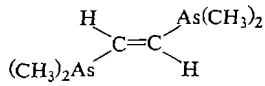
Canadian Journal of Chemistry, 47, 2699 (1969)

Introduction

In a recent publication (1), we reported on the complexes formed between *cis*- and *trans*-1,2-bis(dimethylarsino)ethylene (*cis*-ED, **1**, and *trans*-ED, **2**, respectively) and the salts of platinum(II).

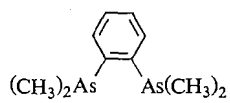


1

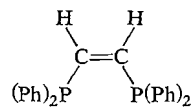


2

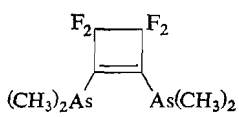
These ligands are of interest, first of all, with respect to their coordinating ability relative to similar systems such as *o*-phenylenebisdimethylarsine **3** (2), *cis*-1,2-bis(diphenylphosphino)ethylene **4** (3), 1,2-bis(dimethylarsino)tetrafluorocyclobutene (and its diphenylphosphino analogue) **5** (4).



3



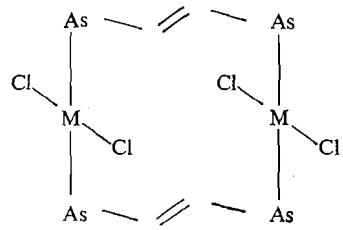
4



5

The ligand, *cis*-ED, has the advantage of low steric factors compared to the latter ligands and might be expected to show a special coordinating ability where steric considerations are important. *trans*-ED, on the other hand, can act only as a bridging ligand. Second, complexes of *cis*- and *trans*-ED would hold olefinic double bonds in rigid positions relative to the metal ion, and it is of interest to know how the reactivity of these double bonds is affected by this positioning.

In ref. 1 it was shown that the complexes of platinum(II) were of three types, **6**, **7**, and **8**. It



6

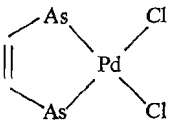
8



9

(X = Cl^-, ClO_4^-, PF_6^-)

was reported that, at room temperature, conversion of **7** to **8** could be effected in solution with ultraviolet irradiation. In order to make a comparative study of the olefin systems involved here, both from the point of view of this conversion reaction, as well as other reactions of olefins stereochemically fixed relative to metal ions, we have extended the range of complexes to other metals. We now report on the complexes of *cis*- and *trans*-ED with the salts of palladium(II).

Experimental

Cis- and trans-1,2-bis(dimethylarsino)ethylene

These were prepared as described in a previous paper (1). The product is a mixture of isomers (approximately 90% *trans*); attempts to effect a separation of isomers by fractional distillation and gas–liquid chromatography failed. The columns used were Carbowax and SE30 at temperatures of 127 and 167 °C.

Tetrachloro-di-μ-(trans-1,2-bis(dimethylarsino)ethylene)-dipalladium(II)

To the ligand (2.16 g, 1 mole) in ethanol (10 ml) was added concentrated hydrochloric acid (2 ml), and the solution warmed to 60 °C. Potassium tetrachloropalladate(II) (3.00 g, 1 mole) in water (15 ml), was added dropwise. A wine-red solution formed first, followed by the precipitation of a pale orange powder. The mixture was cooled to room temperature, and the orange precipitate was filtered and washed with ethanol and diethyl ether to give a quantitative yield of product. Melting point determination showed that it blackened at 260 °C, and decomposed above 300 °C.

Anal. Calcd. for $C_{12}H_{28}As_4Pd_2Cl_4$: C, 17.4; H, 3.4; Cl, 17.2; Pd, 25.8. Found: C, 17.1; H, 3.3; Cl, 17.6; Pd, 25.7.

Corresponding Tetrabromide Derivative

To a solution of potassium tetrabromopalladate(II) (1 mole) in water, containing excess bromide ion, was added an aqueous solution of Pd_2(*trans*-ED)$_4Cl_4$ (1 mole) (see below). The near quantitative precipitate of red-orange powder was filtered and washed with ethanol and ether.

Anal. Calcd. for $C_{12}H_{28}As_4Pd_2Br_4$: C, 14.4; H, 2.8. Found: C, 14.7; H, 3.3.

Tetra-μ-(trans-1,2-bis(dimethylarsino)ethylene)dipalladium(II) Tetrachloride Trihydrate

Using exactly the conditions described for the 1:1 compound, the ligand (2 moles) was treated with potassium tetrachloropalladate(II) (1 mole). An initial orange precipitate immediately re-dissolved and the product formed as a deep, wine-red solution. Because of oxidation and impurities in the ligand, a slight excess of ligand was used to dissolve the orange precipitate that formed again towards the end of the addition. The solution was cooled to room temperature and left over-night. Filtration and drying under a nitrogen atmosphere yielded red crystals (2.28 g, 73.5%), which melted with decomposition above 260 °C.

Anal. Calcd. for $C_{24}H_{56}As_8Pd_2Cl_4 \cdot 3H_2O$: C, 21.3; H, 4.6; Cl, 10.5; Pd, 15.7. Found: C, 21.0; H, 4.7; Cl, 10.1; Pd, 15.6.

Corresponding Tetrabromide Derivative

To a solution of the chloride complex (0.200 g, 10 ml H_2O) was added excess sodium bromide (3 ml of saturated aqueous solution). An orange powder precipitated from the deep red solution (0.142 g, 63%).

Anal. Calcd. for $C_{24}H_{56}As_8Pd_2Br_4 \cdot 3H_2O$: C, 18.8; H, 4.0. Found: C, 18.6; H, 4.3.

Tetra(hexafluorophosphate) Derivative

To an aqueous solution of the chloride complex was added an excess aqueous ethanol solution of potassium hexafluorophosphate. The yellow-orange powder was filtered and dried.

Anal. Calcd. for $C_{24}H_{56}As_8Pd_2P_4F_{24}$: C, 16.6; H, 3.2; Pd, 12.1. Found: C, 17.0; H, 3.5; Pd, 12.3.

Tetra(perchlorate) Derivative

To an aqueous solution of the chloride complex was added excess 30% perchloric acid. The yellow precipitate was filtered and dried.

Anal. Calcd. for $C_{24}H_{56}As_8Pd_2Cl_4O_{16}$: C, 18.5; H, 3.6. Found: C, 18.3; H, 3.8.

Dichloro(cis-1,2-bis(dimethylarsino)ethylene)palladium(II)

To the filtrate of the reaction yielding Pd_2(*trans*-ED)$_4 \cdot 3H_2O$ (see above), was added potassium tetrachloropalladate(II) (0.4 g), ethanol (30 ml) and concentrated hydrochloric acid (4 ml). The mixture was warmed and held at reflux for 1 h. After filtration of the insoluble dimer, [Pd(*trans*-ED)Cl_2]$_2$, the filtrate was evaporated to dryness on a steam bath and extracted with ethanol. Cooling gave pale yellow crystals (0.47 g, corresponding to approximately 10% *cis*-ED in the original ligand). Melting point determination indicated that it blackened above 260 °C, and left a dry black powder above 300 °C.

Anal. Calcd. for $C_6H_{14}AsPdCl_2$: C, 17.4; H, 3.4; Cl, 17.2; Pd, 25.8. Found: C, 16.9; H, 3.1; Cl, 17.2; Pd, 25.7.

Corresponding Bromide Derivative

To a solution of the chloride complex (0.100 g) in acetonitrile (20 ml) was added excess sodium bromide in acetonitrile solution. The color of the solution darkened immediately and removal of the solvent by a rotary evaporator yielded yellow crystals (0.05 g, 41%).

Anal. Calcd. for $C_6H_{14}AsPdBr_2$: C, 14.4; H, 2.8. Found: C, 14.8; H, 3.1.

Di-(cis-1,2-bis(dimethylarsino)ethylene)palladium(II) Dichloride Trihydrate

The insoluble orange dimer, [Pd(*trans*-ED)Cl_2]$_2$ (0.40 g), suspended in acetonitrile (10 ml) was treated with

excess *trans*-ED (containing ca. 10% *cis*-ED). First a red solution was formed, then yellow crystals were deposited and the solution became light yellow. The crude yield was 0.69 g, but included an unknown impurity containing acetonitrile. Washing with dichloromethane removed this impurity. The yield was 0.50 g (76%) and it decomposed above 230 °C.

Anal. Calcd. for $C_{12}H_{28}As_4PdCl_2·3H_2O$: C, 20.5; H, 4.8; Cl, 10.1; Pd, 15.1. Found: C, 21.0; H, 4.8; Cl, 10.3; Pd, 14.8.

Corresponding Bromide Derivative

To the chloride complex (0.100 g) in hot acetonitrile (20 ml) was added excess potassium bromide (in hot acetonitrile). The solution was filtered and the solvent removed at the pump to give yellow crystals. The crystals were filtered and washed several times with acetone to remove any excess potassium bromide (0.050 g, 44%).

Anal. Calcd. for $C_{12}H_{28}As_2PdBr_2$: C, 19.5; H, 3.8. Found: C, 19.4; H, 4.0.

Di(hexafluorophosphate) Derivative

This was prepared as for the corresponding derivative of Pd_2-(*trans*-ED)$_4Cl_4·3H_2O$ and was a pale yellow powder.

Anal. Calcd. for $C_{12}H_{28}As_4PdP_2F_{12}$: C, 16.6; H, 3.2. Found: C, 16.7; H, 3.1.

Diperchlorate Derivative

This was prepared as for the corresponding derivative of Pd_2-(*trans*-ED)$_4Cl_4·3H_2O$ and was a pale orange powder.

Anal. Calcd. for $C_{12}H_{28}As_4PdCl_2O_8$: C, 18.5; H, 3.6. Found: C, 18.4; H, 3.2.

Analyses for metal were carried out by the author. Other analyses were done by the Alfred Bernhardt Analytical Laboratory of West Germany. Precise determination of waters of hydration were not carried out. Where the infrared spectra indicated the presence of water, the number of water molecules was adjusted to give the best fit with the other analyses. It is felt that this is justified where four elements have been determined, but there must remain some uncertainty for the water-containing perchlorate and hexafluorophosphate derivatives. Infrared spectra were recorded on a Beckman IR-10 instrument as Nujol or hexachlorobutadiene mulls. KBr salt plates were employed throughout. Far infrared mull spectra were recorded on a Perkin–Elmer 621 instrument and on a Beckman IR-20 instrument using KRS-5 plates. Conductivity measurements were done using a Phillips Direct Reading conductivity bridge, model PR 9501. Nuclear magnetic resonance (n.m.r.) spectra were recorded on a Varian A60 instrument. Ultraviolet (u.v.) irradiation experiments employed a high pressure mercury lamp, model SOL-608-A-36 from Hanovia Lamp Division of Engelhard Hanovia Inc.

Results and Discussion

The complexes formed between *cis*- and *trans*-ED and palladium(II) salts are structurally similar to those of platinum(II) (1). Thus, the reaction between *trans*-ED and potassium tetrachloropalladate(II), in 1:1 molar ratio, yields an orange powder, insoluble in all common solvents. Its infrared spectrum (Table I) is identical to that of the corresponding platinum(II) complex, **6**, and shows that the ligand retains the *trans*-configuration about the double bond. There is a strong absorption at 968 cm^{-1} due to the out-of-plane (=CH) deformation mode, and no absorption at ca. 1550 cm^{-1}, attributable to the (C=C) stretching vibration. These features are characteristic of symmetrical *trans*-disubstituted ethylenes (5) and agree with the infrared spectrum of the free ligand, *trans*-ED. Far infrared spectra (to be discussed below), however, indicate that the Cl^- ions are *cis* to one another and it is suggested that complex **6** should be given the structure **10**. Molecular models show that structure **10** results in much less ring strain. Whereas in **6** the planes of the metal and ligand donor atoms are parallel, in the *cis*-structure, **10**, these planes spread away from each other at the edges occupied by Cl^- ions.

Mixing *trans*-ED and potassium tetrachloropalladate(II) in a 2:1 molar ratio yields deep orange-red crystals (**7**, M = Pd) whose infrared

spectrum is identical to the platinum(II) complex (7, M = Pt). X-Ray powder photographs of both complexes indicate that they are isomorphous. These complexes are essentially monodentate tertiary arsine complexes of the type, $[M(L)_4]^{2+}$, and as such are extraordinarily stable. In an early paper by Nyholm (6), the addition of excess diphenylmethylarsine to the complex, $PdBr_2(AsMePh_2)_2$, yielded only the complex $[PdBr(AsMePh_2)_3]Br$, which dissociated readily into free arsine and starting material in organic solvents at room temperature. It is clear that stabilization by means of multidentate ligands is not restricted to simple chelation effects. Conductivity measurements (Table II), interpreted by the method of Feltham and Hayter (7), indicate that the palladium complex is a 4:1 electrolyte in aqueous solution. At concentrations above ca. 3×10^{-3} M, significant association occurs, as indicated by non-linear Λ_e vs. $\sqrt{c}$ graphs. Both tetra(perchlorate) and tetra(hexafluorophosphate) derivatives have been prepared, but their low solubilities in nitromethane and acetonitrile have made conductivity measurements impossible. A direct comparison of the conductivity of the palladium and platinum complexes could not be made because the former is very unstable in non-aqueous solutions. The platinum(II) complex, on the other hand, dissolves in water only with some concomitant decomposition, making conductivity measurements meaningless.

The presence of water molecules is very important in these "cage" complexes. Under vacuum, both the palladium and platinum complexes change color, the palladium complex changing from orange to deep scarlet. Upon exposure to the atmosphere, the original color returns, and it has been clearly established that it is water that is being removed and replaced each time. Exposure of the dehydrated complex to an atmosphere of D_2O also produces this reversible color change and the infrared spectrum of the hydrate shows the presence of D_2O. If the hydrate is now re-exposed to the atmosphere (even in the Nujol mull) for only a few seconds, the absorptions due to D_2O disappear and the infrared spectrum is that of the original complex. In the case of the platinum(II) analogue, the water molecules are more firmly held and removal of only a portion of the water is possible. This leads to a change in color of the complex, but the infrared spectrum is unchanged. With the palladium complex almost all the water can be removed and there is a significant change in the infrared spectrum, the (=CH) deformation mode shifting to 970 cm^{-1} (from 1013 cm^{-1}) and the spectrum generally approaching that of the dimer **10**, (M = Pd).

The stability of complex **7**, (M = Pd) depends

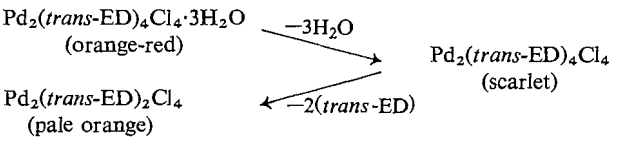
on its water content. In aqueous solution, or under moist air, the complex appears to be stable indefinitely, but under prolonged vacuum, or under conditions of low humidity at atmospheric pressure, the complex gradually loses two molecules of *trans*-ED and the color fades to light orange. The residue is the complex **6**, (M = Pd).

[1]



Presumably, oxidation of the escaping *trans*-ED drives the reaction to completion.

Thermogravimetric measurements at atmospheric pressure confirm these observations, showing a smooth elimination of a weight corresponding to two molecules of *trans*-ED at 120–130 °C, followed by a gradual elimination of a further two molecules of *trans*-ED up to 300 °C. The water molecules present are eliminated gradually and do not show a noticeable elimination region. The corresponding platinum(II) derivative shows a similar behavior in the 120–130 °C region, but a more complex behavior at higher temperatures. The significance of the water molecules is discussed below.

Complexes of cis-ED

The ligand, *trans*-ED, as prepared, always contains ca. 10% of the *cis*-isomer, and by-products of the reactions forming the complexes of *trans*-ED are the complexes of *cis*-ED. Because of its favorable stereochemistry, *cis*-ED behaves as a strong bidentate ligand that readily displaces *trans*-ED from its complexes. Thus, by treating either *trans*-ED complex **10** or **7** with excess ligand in acetonitrile solution, pale yellow crystals of a substance analyzing as $Pd(ED)_2Cl_2 \cdot 3H_2O$ are produced. The infrared spectrum of the complex shows strong absorptions at ca. 1640 and 3400 cm^{-1} (H_2O), a sharp strong absorption at 1575 (ν(C=C)), and an intense, rather broader absorption at 725 cm^{-1} (δ(=CH)). The latter two absorptions are characteristic of symmetrical, *cis*-disubstituted ethylenes (5). The band at 970 cm^{-1}, characteristic of the *trans*-ED spectrum, is absent. Conductivity measurements, interpreted by the method of Feltham and Hayter (7), show that in water the complex is a 2:1 electrolyte, but that in nitromethane solution considerable association occurs giving essentially a 1:1 electrolyte. This result is similar to that found for $Pt(cis\text{-}ED)_2Cl_2 \cdot 1.5H_2O$ (1). The perchlorate and hexafluorophosphate derivatives have the formulae, $Pd(cis\text{-}ED)_2X_2$ (X = ClO_4^-, PF_6^-), and conductivity measurements show them to be 2:1 electrolytes in nitromethane solution. These complexes are therefore given the structure **8** (X = Cl^-, PF_6^-, ClO_4^-). (It is interesting to note here the advantage of using the Feltham–Hayter method over that of simply comparing the conductivity of 10^{-3} *M* solutions to determine electrolyte type. For the two complexes, $Pd_2(trans\text{-}ED)_4Cl_4 \cdot 3H_2O$, and $Pd(cis\text{-}ED)_2Cl_2 \cdot 3H_2O$, the molar conductivities of 10^{-3} *M* solutions are 214 and 236 mho cm^2 $mole^{-1}$, respectively, both being in the range quoted for 2:1 electrolytes in aqueous solution (8). The slopes of the Feltham–Hayter plots, however, are 246 and 456, clearly distinguishing the two complexes.)

By treating complex **8** (X = Cl^-) with an equivalent amount of potassium tetrachloropalladate(II), yellow crystals of formula Pd(ED)Cl_2 are obtained. This complex is nonconducting in nitromethane solution, and its infrared spectrum shows bands characteristic of the ligand *cis*-ED. The structure of the complex is therefore assumed to be the neutral species **9**. The corresponding platinum(II) derivative could not be prepared under similar conditions (1). These results are analogous with the behavior of the ligand *o*-phenylenebisdimethylarsine, **3**, which readily gives a complex similar to **9** with palladium(II) (2*a*), but only under special conditions could the corresponding platinum(II) derivative be prepared (9).

Nuclear Magnetic Resonance Spectra

The n.m.r. spectra of the ligands and complexes are summarized in Table III. In each case, the spectrum consists simply of two

TABLE III

Nuclear magnetic resonance spectral data*

Complex	Vinyl protons (τ)	Methyl protons (τ)
trans-ED	3.23	9.01
cis-ED	3.06	9.02†
Pd(*cis*-ED)Cl_2	2.59	8.23
Pd(*cis*-ED)$_2Cl_2$	2.36	8.10
[Pd(*trans*-ED)Cl_2]$_2$	Insoluble	
Pd_2(*trans*-ED)$_4Cl_4$	2.45	8.05‡

*Data shown are for d_6-dimethylsulfoxide solutions except where indicated. Resonance absorptions are quoted in p.p.m. downfield from TMS = 10.
†Private communication from M. A. Bennett.
‡In D_2O solution. The n.m.r. spectra do not appear to be very solvent dependent and a similar set of data is obtained in d_3-acetonitrile.

resonances (with additional absorptions for attached solvent molecules where relevant) in the ratio 1:6, corresponding to vinyl and methyl protons, respectively. Coordination of the ligands to the metal ion causes a downfield shift of ca. 0.4–1.0 p.p.m. in the proton absorptions relative to those of the free ligands. In the case of the ligand, *cis*-1,2-bis(diphenylphosphino)ethylene, **4**, coordination with the Group VI hexacarbonyl complexes caused a downfield shift in olefinic proton resonances of about 1.3 p.p.m., relative to the free ligand (3). The authors suggested that this shift might reflect a significant amount of ring current in the ring formed between the metal ion and the ligand atoms. Such a delocalization would involve the non-bonding t_{2g} electrons of the metal atom and would help to relieve the build-up of electron density on the metal because of the carbon monoxide groups. This type of "back bonding" is probably not as strong in the d^8 palladium(II) case and might account for the significantly smaller shift in these complexes. It is hoped to explore the question of this ring current in future work by examination of the reactivity of the double bond

Far Infrared Spectra

The absorptions of the complexes in the far infrared region are listed in Table I *trans*-ED has a strong absorption at ca. 315 cm^{-1} which appears in this position in all of its complexes. The *cis*-ED has recently been obtained in a pure state (10), but the far infrared spectrum was not given. However, a sample of *trans*-ED, rich in *cis*-ED, shows a sharp band at 1550 cm^{-1} ($\nu_{C=C}$) and a characteristic strong, sharp absorption at ca. 450 cm^{-1}, both of which appear in all the complexes of *cis*-ED. The δ(=CH) deformation band appears at 650 cm^{-1} in the free ligand and at ca. 700 cm^{-1} in the complexes of *cis*-ED.

The complex, [Pd(*trans*-ED)Cl_2]$_2$, has two absorptions in the far infrared region, at 284 and 258 cm^{-1}, which disappear upon substitution of Cl^- by Br^-. These absorptions are assumed to be associated with metal–halogen stretching frequencies (the infrared spectra are otherwise unaltered by the substitution).

Complexes of the type, *cis*- and *trans*-Pd(AsR_3)$_2X_2$, have been studied in this region (11). *cis*-Isomers show two bands associated with metal–chloride stretching vibrations, at ca. 310–315 cm^{-1} and 280–300 cm^{-1}, while *trans*-isomers show a single absorption at ca. 350 cm^{-1}. For a molecule as complicated as [Pd(*trans*-ED)Cl_2]$_2$ it is difficult to assign structures on the basis of the *number* of metal–halogen vibrations, but both the number and position of the bands are more consistent with a *cis* arrangement of halogens rather than a *trans* arrangement as originally suggested (1). Models confirm that such a structure exhibits less ring strain, and the proposed structure is shown as structure **10**.
