A detailed study has been made of both the ^1H and ^{19}F nuclear magnetic resonance (n.m.r.) spectra of a series of hexopyranosyl fluoride derivatives. Some of the ^1H spectra were measured at 220 MHz. The ^1H spectral parameters define both the configuration and the conformation of each of these derivatives. Study of the ^{19}F n.m.r. parameters revealed several stereospecific dependencies. The ^{19}F chemical shifts depend upon, (*a*) the orientation of the fluorine substituent with respect to the pyranose ring and, (*b*) the relative orientation of other substituents attached to the ring; for acetoxy substituents, these configurational dependencies appear to be additive. The *vicinal* ^{19}F–^1H coupling constants exhibit a marked angular dependence for which J_{trans} = ca. 24 Hz whilst J_{gauche} = 1.0 to 1.5 Hz for J_{F_a,H_e} and 7.5 to 12.6 Hz for J_{F_e,H_a}. The *geminal* ^{19}F–^1H couplings depend on the orientation of the substituent at C-2; when this substituent is equatorial $J_{F,H}$ is ca. 53.5 Hz and when it is axial the value is ca. 49 Hz.

Canadian Journal of Chemistry, 47, 1 (1969)

Introduction

During the past several years it has become apparent that the determination of the precise conformations of carbohydrate derivatives in solution, by proton magnetic resonance (p.m.r.) spectroscopy, is considerably more complex than was at first appreciated (1). Unfortunately, the confidence limit which can be placed on such determinations has been severely compromised by the lack of any independent, and generally applicable, check upon the accuracy of the p.m.r. method. A further shortcoming of this technique arises from the comparatively low sensitivity of most p.m.r. parameters with respect to changes in steric environment, which precludes the *facile* study of carbohydrate systems which are conformationally mobile.

In principle, these inherent disadvantages of the p.m.r. method could be eliminated if a second "magnetic" nuclear species, were to be included in the molecule under study. Investigation of the nuclear magnetic resonance (n.m.r.) parameters of this second nuclear species could, in principle, afford an independent check on the geometry of the compound under investigation. This second nuclear species could thus be effectively utilized as a "stereospecific probe" and, in the event that its parameters were more sensitive to changes in steric environment than are p.m.r. parameters, it could, in effect, be used as an "amplifier" for studying conformational distortions and mobilities which might otherwise be overlooked in a p.m.r. study.

For a variety of reasons, fluorine is an obvious choice for this second nuclear species. Thus, the natural abundance of the magnetic ^{19}F isotope

(spin $\frac{1}{2}$) is 100% and its n.m.r. signals can be readily determined by essentially the same high-resolution techniques as are conventionally used for protons,[4] and with approximately the same sensitivity.

More important from the conformational viewpoint, is the fact that certain ^{19}F nuclear magnetic resonance (^{19}F n.m.r.) parameters are known to be extremely sensitive to the precise steric environment of the fluorine substituent under investigation. Illustration of this point with respect to the chemical shifts of fluorine attached to a six-membered ring system, follows from a comparison of the chemical shift separation (at low temperatures) between the axial and the equatorial proton resonances (δ_{ae}) of cyclohexane (0.47 p.p.m.) (2, 3), with the separation of the corresponding fluorine resonances of perfluorocyclohexane (18.2 p.p.m.) (4); thus for these two derivatives the ^{19}F shifts are ca. 40 times more sensitive than the proton shifts. Similarly, for cyclohexyl fluoride, Bovey *et al.* (5) showed that the δ_{ae} value for the H-1 resonances is only 0.46 p.p.m. whereas the δ_{ae} value for the F_1 resonances is 20.5 p.p.m. Thus, the fluorine chemical shift is ca. 45 times more sensitive to steric environment than is the shift of the proton attached to the *same* carbon. For many systems, the measurement of ^{19}F shifts at 94 MHz is equivalent, in terms of the "steric-sensitivity" to the measurement of ^{1}H shifts with a spectrometer operating at ca. 4000 MHz. Roberts and coworkers (6) have recently used this high steric sensitivity of ^{19}F n.m.r. shifts to facilitate the study of conformationally mobile 1,1-difluorocycloalkanes.

Although fluorine was an obvious choice for this "stereospecific probe" for studying the conformations of carbohydrate derivatives, its selection at the time we initiated these studies[5] created several attendant problems. The first of these was that only two classes of specifically fluorinated sugars were known at that time; these contained either a fluorine substituent at the terminal carbon atom, the so-called "primary" fluorides (8, 9) or a fluorine substituent attached to the anomeric carbon, the glycopyranosyl fluorides (10, 11). The second problem was that very little was known at that time of the precise angular and other dependencies of ^{19}F n.m.r. parameters.

The aim of the present study was an investigation of the stereospecific dependencies of ^{19}F n.m.r. parameters, with particular emphasis on the behavior of fluorine attached to six-membered ring systems. The glycopyranosyl fluorides were, for several reasons, chosen as model systems for these studies. Firstly, because a large variety of derivatives were readily available through either of two stereoselective routes, which had originally been studied by Brauns (10) and reviewed recently by Micheel and Klemer (11), and secondly because the configurations of these derivatives were predictable within certain limits and could be readily checked by the p.m.r. method. Finally, these derivatives each contain only one fluorine substituent and, therefore, simple ^{19}F n.m.r. spectra could be anticipated.

Results and Discussion

The glycopyranosyl fluoride derivatives were prepared by standard literature procedures, or were kindly donated to us by Dr. Christian Pedersen (12, and references listed in the Experimental). Originally, the anomeric configurations of these derivatives had been assigned on the basis of the method used for their synthesis, and by comparisons of optical rotations. The first stage of the present investigation involved a detailed study of the p.m.r. spectra of these derivatives which confirmed, in every case, the previously assigned anomeric configuration; this also established that the anhydrous HF, which had been used in several of the syntheses, had caused no configurational changes elsewhere in the molecule. Furthermore, the p.m.r. parameters showed that, to a first approximation, these derivatives all existed in the anticipated conformations. Details of the method used to assign these spectra are given in the Experimental section.

The fluorides ((**1**) and (**3**)) obtained from D-glucopyranose pentaacetate can be used to illustrate this aspect of the study. The observation of a 2.7 Hz coupling between H-1 and H-2 in the spectrum (See Figs. 1*a*, 2*a*) of the product obtained by reaction of the above pentaacetate with

[4]For a static magnetic field of 23,500 G, ^{1}H resonates at 100.000 MHz and ^{19}F at 94.071 MHz.

[5]These studies were started in 1964. Preliminary accounts were presented at the 3rd International Fluorine Symposium, Munich, Germany, August 30 to September 2, 1965 and at the 153rd meeting of the American Chemical Society, Miami Beach, Florida, April 9–14, 1967 (see also ref. (7)).

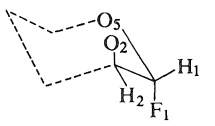
HF, immediately confirms that these protons have a *gauche* relationship. This, together with the additional observation of large (ca. 9.5 Hz) ^1H–^1H couplings between each of the remaining pairs of *vicinal* protons shows unequivocally that this compound has the α-D-*gluco*-configuration; it also shows that the compound has a shape approximating the $^4C_1$ (D) conformation.[6] A similar interpretation of the spectrum of the fluoride obtained from α-D-glucopyranosyl bromide tetraacetate by AgF exchange, which shows large couplings between each of the pairs of *vicinal* ring protons, confirms that this derivative has the β-D-*gluco*- configuration (Figs. 1*b*, 2*b*, 1*c*, 2*c*). The conformation of this derivative will be discussed subsequently; for the present we shall assume that it also has the $^4C_1$ (D) conformation. The first-order parameters obtained for these and the other derivatives studied in this paper are listed in Tables I and II.

For compounds having an equatorially oriented hydrogen atom at C-2, it was not possible to assign the anomeric configuration solely on the basis of the H_1–H_2 coupling, since this proton would be *gauche* to both the fluorine and proton at C-1. However, the shift of the H-5, and in some instances the H-3 resonance could be related to an α- rather than a β-configuration. Furthermore, it was subsequently found that whilst the ^{19}F shifts of the α-anomers (**1**, **15**) were essentially temperature invariant, those of the β-anomers (**3**, **8**, **14**) were subject to large (4 to 8 p.p.m.) shifts for a temperature change from 190 °K to 330 °K (*vide infra*). On the basis of the data listed in the Tables it was felt that the structures and approximate conformations of the derivatives under investigation were known with some certainty, and at this point the ^{19}F n.m.r. parameters were considered.

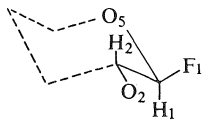
Measurement of the ^{19}F n.m.r. spectra (for example, see Fig. 3) gave directly the ^{19}F–^1H couplings and also the ^{19}F chemical shifts, from which stereospecific dependencies of ^{19}F n.m.r. parameters were to be derived. In most instances there was no discrepancy between the magnitudes of the ^{19}F–^1H couplings derived from the ^1H and the ^{19}F spectra. For those compounds (**1**, **2**, **5**, **7**, **9**, **11**, **13**, **19**) which possess a *trans-diaxial* arrangement of fluorine at C-1 and hydrogen at C-2, a ^{19}F–^1H coupling of ca. 24 Hz is observed. This coupling was found to be essentially unaltered when the C-2 substituent was either OAc, OBz, OMe, or OH and is approximately 4 times larger than those *trans-diaxial* ^1H–^1H couplings observed as $J_{1,2}$ of the β-D-hexopyranosyl fluoride derivatives.

The magnitudes of *vicinal* ^{19}F–^1H couplings corresponding to a *gauche* relationship were found to fall in two distinct ranges which appear to reflect a "configurational" electronegativity dependence for such couplings, thus: (*a*) for compounds with an axial fluorine at C-1 and an equatorial proton at C-2 (compounds **15**, **16**, **17**, **18**) the coupling is 1.0–1.5 Hz. (*b*) for compounds with an equatorial fluorine at C-1, and an axial proton at C-2 (compounds **3**, **4**, **6**, **8**, **10**, **12**, **14**, **20**) the coupling is 7.5–12.6 Hz.

A similar configurational dependence has also been observed previously for ^1H–^1H couplings of pyranose carbohydrates (14, 27), steroidal alcohols (15) and claimed for other cyclic systems (16) and is also observed for the ^1H–^1H couplings of the derivatives under consideration. Thus, for derivatives (**15**, **17**, **18**) in which both H-1 and H-2 are equatorially oriented, the coupling is ca. 1.5 Hz, whereas, for derivatives (**1**, **5**, **7**, **9**, **11**, **13**, **19**) in which H-2 is axial, the coupling is ca. 2.7 Hz. On the basis of Booth's electronegativity hypothesis (16) the smaller magnitude of the couplings of the compounds in group (*a*) above compared with those in group (*b*), would be rationalized in terms of the anti-planar relationships (shown in **A**) of the O_2—C_2, C_1—F_1 and O_5—C_1, C_2—H_2 bonds; these anti-planar interactions are not present for the compounds in group (*b*) (shown in **B**).



A



B

In spite of the rather wide range of *vicinal* ^{19}F–^1H couplings observed for the *gauche*

[6]The convention adopted for identification of the two possible chair conformations, is based on the suggestion of Hall (13); any four atoms of a pyranose ring system are used to define a reference plane and then the remaining atoms are indicated as superscript if they are "above" that plane or as a subscript if they are "below". Thus the "normal" chair conformation (C1-D) is referred to as $^4C_1$ indicating that C-4 is above and C-1 below the plane defined by C-2, C-3, C-5, and O-5. On this basis the (1C-D) conformation is $^1C_4$(D).

NOTE: The compounds listed above were each measured in chloroform-*d* (*c*), acetone-d_6 (*a*), and benzene-d_6 (*b*) solution. The benzoate ester protons resonated at ., τ 2 and ca. τ 2.5. The methine proton of the benzylidene substituent was observed at ca τ 4.5, whilst the aromatic protons were observed at ca. τ 2.5. The methyl her protons resonated at ca. 6.5, (*d*) measured at 220 MHz in chloroform-*d* solution; (*e*) measured at 220 MHz in acetone-d_6 solution. R_1 = H, R_2 = F for anomers and R_1 = F, R_2 = H for β-anomers. [f]This compound was the L-enantiomer. [g]Overlapping resonances.

relationships, it is noteworthy that those ^{19}F–^{1}H couplings corresponding to a *nominal* dihedral angle of ca. 180° are larger than those which correspond to a dihedral angle of ca. 60°. This angular dependence appears to be similar to that described by Karplus (17) for *vicinal* ^{1}H–^{1}H couplings. Furthermore, the ^{19}F–^{1}H couplings are several times greater in magnitude than the corresponding ^{1}H–^{1}H couplings, and are thus apt to be more sensitive, (absolutely) to changes in dihedral angle. This may prove to be one of the advantages of using ^{19}F n.m.r. spectroscopy for studying conformational distortions of cyclic systems. Other results from this (18) and other laboratories (19–22) further support the suggestion that *vicinal* ^{19}F–^{1}H and ^{1}H–^{1}H couplings exhibit a fundamentally similar angular dependence.

All of the derivatives showed a *geminal* coupling of ca. 50 Hz; however, there are clearly two distinct ranges for these couplings. For those molecules with an equatorial substituent at C-2, the *geminal* coupling is ca. 53.5 Hz, whereas, when the C-2 substituent is axially oriented, this coupling has a value of ca. 49 Hz. Again these couplings are *nominally* ca. 4 times those found for ^{1}H–^{1}H *geminal* couplings (23) in similar environments. A detailed discussion of these coupling constant dependencies will be reserved for a subsequent paper in this series.

Inspection of the ^{19}F chemical shifts obtained from the ^{19}F n.m.r. spectra (Table I) revealed several marked stereospecific dependencies and it is convenient to consider initially only those derivatives having equatorially oriented substituents (D-*gluco*-series). For such derivatives, a fluorine substituent having an equatorial orientation (**3**, **6**, **8**, **10**, **12**, **14**, **20**) has a shift within the range[7] ϕ_c +131.8 to ϕ_c +137.8, whilst for a corresponding axially oriented fluorine, the shift is ϕ_c +147.8 to ϕ_c +149.9 p.p.m. On this basis there is an average ^{19}F chemical shift difference of ca. 14 p.p.m. between the resonances of an axial and an equatorial fluorine substituent and in every case the equatorial fluorine gives a resonance to low field of its axial counterpart. This dependence thus parallels that already recognized for the p.m.r. shifts of anomeric (25, 26) and other ring proton (26) and indeed, for the anomeric proton shifts of the derivatives under discussion. The ^{19}F n.m.r. shifts of compounds in this class show a slight dependence upon the nature of the various *O*-substituents attached to the pyranose ring, at least when these are acetate, benzoate or methyl. Compare for example, the shifts of **1** and **3** which have acetoxy substituents at C-2 with the shifts of **9** and **10** which have a benzoyloxy substituent and **7** and **8** which have a methoxy substituent. When the non-acylated glucopyranosyl fluorides were measured in aqueous solutions with external Freon-11 as reference, the shift of the α-anomer (**2**) was found to be essentially unaltered from that of the fully acetylated derivative **1**, whereas, the shift of β-D-glucopyranosyl fluoride (**4**) came at significantly higher field (+8.1 p.p.m.) than that of derivative **3**. Thus, for all compounds having only equatorial oriented substituents, the ^{19}F chemical shift provides a convenient and unequivocal means for identifying the orientation of the fluorine substituent with respect to the pyranose ring.

A striking dependence of ^{19}F chemical shift on changes in the configuration of remote centers is noted when one considers that chemical shift of those *derivatives* possessing an axial *O*-substituent at C-2 (**15**, **17**, **18**) i.e. having typically the D-*manno* configuration. The shift of these derivatives, which also possess an axial fluorine at C-1, fall[8] within the range ϕ_c +137.6 to +138.8 which coincides with the range previously observed for the β-D-glucopyranosyl fluorides (**3**, **6**, **8**, **10**, **12**). There are two possible rationales for this observation; either, that all of the compounds in this group do not possess the α-D-configuration, or, that *fluorine chemical shifts are extremely sensi-*

[7]The ranges quoted are for chloroform solutions with ca. 20% $CFCl_3$ as internal reference (24) and are referred to as "ϕ_c" values. The ^{19}F chemical shifts are somewhat concentration dependent and also vary with solvent to a small extent, thus they are only quoted to four significant figures although they were measured to at least five significant figures. The concentration shift was greatest for the fully *O*-acetylated glucose derivatives (**1**) and (**3**). The shift of the α-anomer (**1**) varied by only 0.2 p.p.m. over a concentration range of 1.0–0.0 molal, whereas, that of the β-anomer (**3**) varied by 0.9 p.p.m. over the same concentration range.

[8]The shift of α-D-mannopyranosyl fluoride (**16**), measured in aqueous solution with external Freon-11 as reference, was found to be essentially the same as that of the tetraacetate. This result parallels that already found for the α-D-gluco derivatives (**1**, **2**). If this invariance of chemical shift is general for all *axially* oriented fluorine substituents, it may serve as a convenient method for establishing anomeric configurations of hexopyranosyl fluorides.

tive to the relative orientation of the substituent attached to the adjacent center. The latter explanation seemed the more appropriate; however, at the time of this study it had no precedent in the field of ^{19}F n.m.r. spectroscopy, although it had a counterpart in the carbohydrate p.m.r. field (25, 26) where it has been shown that changes in the orientation of a C—O bond can influence the shifts of protons at "remote" centers.

Further unpublished ^{19}F n.m.r. studies in this laboratory on sugars fluorinated at C-2 (18*b*) and C-3 (18*c*), together with specifically fluorinated cyclohexanes (18*d*) and published data from other fluorinated systems (22) have all confirmed the generality of the particular stereospecific shift outlined above.

The two D-galactopyranosyl fluorides (**8** and **14**) also exhibit the same general dependence as the D-*gluco* derivatives; however, the inherent axial:equatorial shift difference for these derivatives is only 8.7 p.p.m. Comparison of the chemical shift of **13** and **14** with those of the corresponding D-*gluco* derivatives (**1** and **3**) shows that inversion of an acetoxy group at C-4 of a pyranose carbohydrate induces an upfield shift on a fluorine atom at the anomeric center.

Measurement of the ^{19}F chemical shift of α-D-allopyranosyl fluoride tetraacetate (**19**) showed that the fluorine of this derivative now resonated to lower field of **1** by 3.9 p.p.m. Since the p.m.r. spectra showed this molecule to have the α-D-configuration, and to possess the $^4C_1$ (D) conformation, the shift to low-field was attributed solely to a deshielding effect of an axial acetoxy substituent on a *cis-axial* fluorine atom. A similar effect is well characterized in the field of p.m.r. spectroscopy (26, 27) and has also been observed for the p.m.r. parameters of the derivatives under consideration. When the ^{19}F chemical shift of the β-anomer (**20**) was measured, it was found to resonate to *higher* field than its axial counterpart by 0.6 p.p.m. Again, the difference between the behavior of these two derivatives and their D-*gluco* counterparts was attributable to a specific chemical shift contribution from the acetoxy substituents. The individual ^{19}F chemical shift changes induced by inversion of an acetoxy substituent from an equatorial to an axial orientation are summarized in Table III.

In order to test the possibility that these configurationally induced chemical shift changes might be strictly additive, an attempt to synthesize α-D-altropyranosyl fluoride tetraacetate and measure its ^{19}F n.m.r. spectrum was undertaken. Unfortunately the reaction resulted in a mixture of the two anomeric fluorides, which could not be separated.[9] Nevertheless the chemical shift of the α-anomer, which was identified by its ^{19}F–^1H coupling $J_{F,H} = 48.3$ Hz, $J_{F,H_2} = 2.7$ Hz was precisely that predicted on the assumption that these induced shift changes are truly additive.

TABLE III

Induced shifts for an axially oriented fluorine substituent, following inversion of a "remote" acetoxy substituent

Compound	Orientation of acetate at C-2	C-3	C-4	ϕ_c	Induced shift p.p.m.
D-*gluco* (**1**)	eq	eq	eq	+149.9	0.0
D-*manno* (**15**)	*ax*	eq	eq	+138.8	−11.1
D-*allo* (**19**)	eq	*ax*	eq	+146.0	−3.9
D-*galacto* (**13**)	eq	eq	*ax*	+151.1	+1.2

Calculated shift (ϕ_c − value) = Shift of α-D-*gluco* (**1**) − Δ(C_2-inversion) − Δ(C_3-inversion)

$$= +149.9 - 11.1 - 3.9 = +134.9$$

Observed Shift $= +134.9$

Deviation 0.0 p.p.m.

On the basis of the empirical "rules", summarized in Table III, for calculating the chemical shift of an axially oriented fluorine atom attached to the anomeric carbon of a pyranose carbohydrate, it is possible to predict the ^{19}F chemical shifts (ϕ_c-values) for the remaining pyranosyl fluorides of rare hexoses; assuming that these all exist exclusively in the $^4C_1$ (D) conformation the calculated values are:

α-D-idopyranosyl fluoride tetraacetate: $\phi_c = +149.9 - 11.1 - 3.9 + 1.2 = +136.1$

α-D-talopyranosyl fluoride tetraacetate: $\phi_c = +149.9 - 11.1 + 1.2 = +140.0$

α-D-gulopyranosyl fluoride tetraacetate: $\phi_c = +149.9 - 3.9 + 1.2 = +147.2$

It is not appropriate at this time to make similar predictions for equatorially oriented fluorine substituents since too small a selection of these

[9]Dr. C. Pedersen (private communication) has also synthesized these derivatives; his samples have also failed to crystallize so far.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

derivatives is at present available and, furthermore, there is the possibility of conformational distortion for these anomers. We are currently investigating the synthesis of the above derivatives.

Whilst the above discussion has been primarily concerned with information associated with the ^{19}F parameters it is convenient to mention at this point, several further aspects which involve some of the ^{1}H parameters.

The *vicinal* ^{1}H–^{1}H couplings of the α-D-*gluco* derivative (**1**) appear to support quite successfully the original assumption that this derivative exists exclusively in the $^{4}C_1$ (D) conformation. Thus $J_{2,3}$ = 10.0 Hz, $J_{3,4}$ = 9.5 Hz, and $J_{4,5}$ = 9.7 Hz which indicates (17) that each of these pairs of protons have a *trans-diaxial* relationship. However, the *vicinal* ^{1}H–^{1}H couplings for the β-D-anomer (**3**) are generally smaller than their counterparts in the α-D-anomer (**1**). A similar behavior is observed for the couplings of each of the other anomeric pairs of D-glucopyranosyl fluorides. If it is accepted that the smaller couplings for the β-anomers are due either to time averaging between the two chair forms ($^{4}C_1 \leftrightarrows {}^{1}C_4$) or to some local or static distortions from the $^{4}C_1$ (D) chair conformation, it is unexpected that D-*gluco* derivatives would show this behavior. All arguments based on "repulsive" non-bonded interactions, would lead one to expect these derivatives, more than any other hexopyranoses, to exist in the "ideal" $^{4}C_1$ (D) chair conformation since this would have all the substituent groups equatorial. It is of further interest to note that those D-*gluco* derivatives (**6**, **10**) with a benzoyloxy substituent at C-2 exhibit the smallest *vicinal* couplings (i.e. the maximum deviation from "normality").

The driving force for either of the above conformational distortions could be the powerful "anomeric effect" (28–30) of the (nominally) equatorially oriented fluorine substituent, which would tend to force this substituent to adopt an *axial* orientation. There would be no necessity for such a distortion for an α-anomer where the fluorine substituent is already axially oriented in the $^{4}C_1$ (D) conformation. Further indication that the β-anomer (**3**) is apparently subject to a conformational mobility, not shown by the α-anomer (**1**) followed the measurement of the ^{19}F shift at different temperatures. In acetone solution, over the range 190 °K to 330 °K, the ^{19}F shift of the α-anomer was essentially invariant, whilst that of the β-anomer changed −8 p.p.m. (+143 to +135 p.p.m.). Over the same temperature range, the ^{1}H spectra of the α-anomer showed *only* minor chemical shift changes, whilst for the β-anomer, the *vicinal* couplings *increased* by ca. 10%. Although this evidence would appear to indicate the occurrence of a $^{4}C_1 \leftrightarrows {}^{1}C_4$ inversion process for the β-anomer, it was not possible to lower the temperature sufficiently to stop this inversion. This was unexpected, and bothersome, since the energy barrier for the above chair–chair interconversion was expected to be of the order of 10 Kcal/mole (2–6, 31).

The 4,6-*O*-benzylidene derivatives (**11**) and (**12**) were examined; they each have two *trans*-fused six-membered rings and should, by analogy with the *trans*-decalin system (6, 32), be incapable of undergoing a gross, chair–chair conformational inversion. In particular the pyranose ring of these derivatives should be locked in the $^{4}C_1$ (D) conformation. It was evident even before the low temperature spectra were run, that this anticipation was not entirely correct since the *vicinal* ^{1}H–^{1}H couplings of the β-anomer (**12**) were again significantly smaller than those of the α-anomer (**11**). The low temperature spectra indicated that these benzylidene derivatives had nearly the same characteristics as the parent glucosyl fluorides. However, the temperature-induced shift change of the β-anomer was smaller ($\Delta\ ^{19}F$ = 3.5 p.p.m.) than that of **3** ($\Delta\ ^{19}F$ = 8 p.p.m.).

It is known (33) that some ^{19}F shifts are *per se* temperature dependent. However, it seems highly improbable that the shift of an equatorially oriented fluorine substituent should be so markedly temperature dependent, whilst a chemically similar, but axially oriented fluorine should be essentially independent of temperature.

Two possible rationales for the source of this observation remain. The first is that the observed chemical shift dependencies reflect changes in the rotamer populations of the various ester substituents attached to the ring. However, it is difficult to see why such changes should be reflected in the shift of an equatorial, but not of an axial, fluorine substituent; in particular the C_2-acetoxy substituent which is *gauche* with respect to the fluorine substituent for both the α- and the β-series, would seem to be implicitly excluded from such an argument.

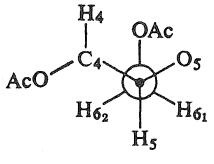
If we discount the above rationale, the final

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

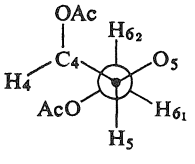
alternative is that the β-D-anomers suffer a distortion about the O-5,C-1,C-2 region of the pyranose ring, into a conformational symmetry which is capable of undergoing conformational inversion process(es) with a very small activation energy barrier. This would appear to be consistent with all the observations we have made thus far; however, it should be emphasized that no unequivocal evidence to support this suggestion is available at this time. The search for such evidence is to be continued in this laboratory, (*a*) by measuring spectra at ultra-low temperatures (ca. 110 °K) in the hope of "freezing" out any low-barrier inversion processes and (*b*) by examining the n.m.r. behavior of other glycosyl fluoride derivatives. It is felt that unequivocal evidence for the existence of a conformational inversion process can only be obtained by actually "freezing out" the process and observing the separate resonances of the participating conformers. The only serious disadvantage of this conformational indeterminacy at this time, is that it detracts somewhat from the confidence which can be placed in the *vicinal* ^{19}F–^{1}H couplings found for the β-D-glucosyl fluorides. However, it seems highly improbable that a conformational distortion alone could account for the six-fold, or greater, difference between these *gauche* couplings and those of the α-D-mannosyl fluorides.

A detailed examination of the *vicinal* ^{1}H–^{1}H couplings arising from the C-5 and C-6 protons has revealed an interesting dependency. The *preferred* rotamer about the C_5—C_6 bond is different for those compounds having an equatorially oriented substituent at C-4 (typically, D-*gluco* derivatives) than for those having an axially oriented substituent (D-*galacto* derivatives). For simplicity, the effects of rotamer time-averaging will not be considered.

For compounds having the D-*gluco* configuration, it is observed that $J_{5,6_1} \simeq 4.5$ Hz and $J_{5,6_2} \simeq 2.5$ Hz. These values are consistent with a *preference* for the rotamer shown in **C** below,



C

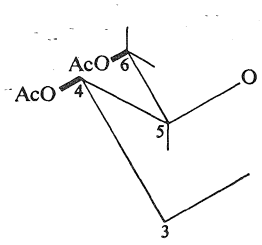


D

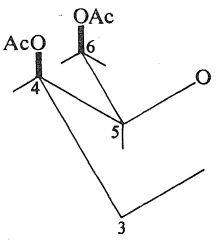
in which H-5 is *gauche* with respect to both $H\text{-}6_1$, and $H\text{-}6_2$. The difference in magnitude between these two couplings, both of which have the same nominal dihedral angle (60°) with H-5, is anticipated on the basis of the configurational dependence (14–16, 27) of *vicinal* couplings. It has been shown that any proton which is *antiparallel* to an electronegative substituent will give smaller (less positive) couplings than a proton which is *gauche* with respect to the same electronegative substituent. Thus $H\text{-}6_2$, which is anti-planar with respect to O-5 should give a smaller coupling than $H\text{-}6_1$.

The couplings observed for derivatives having the D-*galacto* configuration are $J_{5,6_2} = 7$ Hz and $J_{5,6_1} = 5.5$ Hz. These values are consistent with a preference for the rotamer shown in **D**, where $H\text{-}6_2$ is antiparallel ($\phi = 180°$) with respect to H-5, and $H\text{-}6_1$ is *gauche*. It is important to note that $H\text{-}6_1$ is not antiparallel with respect to any electronegative substituent, and hence would be expected to exhibit a fairly large coupling with H-5.

A simple rationale for the above conformational preferences can be offered as follows. Assume that steric or dipolar (or both) interactions between the C_4—OAc and C_6—OAc groups are of sufficient magnitude to eliminate any significant population of a rotamer having these substituents oriented as in (**E**) or (**F**); these involve the equivalent of a 1,3-*diaxial* interaction



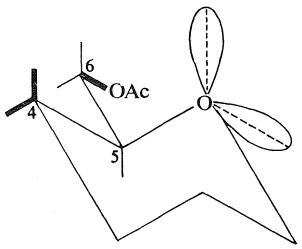
E



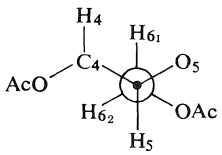
F

on a cyclohexane ring system. Although it is more difficult to effectively eliminate one remaining conformer for each of the two series, it is noteworthy that our interpretation implies that the conformer represented in **G** is particularly unfavored for both configurations at C-4. Possibly this is due to dipolar interactions with the ring oxygen substituent.

A parallel study (34), in this laboratory, of the above problem involved the measurement of the *vicinal* H_5–F_6 couplings of a series of 6-deoxy-6-fluoro carbohydrates. The observation of a ca. 30 Hz coupling for derivatives having the D-*gluco*



G



H

configuration implies a marked preference for the rotamer equivalent to **C** in which H-5 and F-6 are antiparallel. In like fashion the ca. 15 Hz coupling found for the D-*galacto* series is consistent with rotamer **D**.

The interpretation outlined above is at variance with that previously preferred by Lemieux and Stevens (26), who suggested that the rotamer depicted in **H** was preferred. The strongest argument in favor of their assignment is that it does not have OAc_6 *gauche* with respect to both C-4 and O-5, which is an apparent disadvantage of rotamer **C**. Nevertheless the further understanding of the dependencies of *vicinal* ^1H–^1H couplings, which has been gained since Lemieux and Stevens published their study, would appear to effectively eliminate their suggested rotamer. In particular, it would not seem reasonable to assign a coupling of ca. 4.5 Hz to an antiparallel relationship between two *vicinal* protons. Our conclusions are also at variance with those recently reported by Horton and co-workers (35). Unfortunately there seems little opportunity of resolving unequivocally these discrepancies at this time. However, two further points appear to be relevant. Firstly, the *geminal* H_{6_1}–H_{6_2} coupling constants of these derivatives are consistent with our interpretation. Thus, rotamer **C** requires (14, 23) the C_5—O_5 bond to be *external* to the H_{6_1}—C_6—H_{6_2} angle which would require a coupling of ca. 13 Hz, the observed value is ca. 12.8 Hz. In like fashion rotamer **D** which has the C_5—O_5 bond bisecting the H_{6_1}—C_6—H_{6_2} angle requires a coupling of ca. 11 Hz; the experimental value is ca. 10.8 Hz. Secondly, it has been found (18*c*) that for methyl 2-*O*-acetyl-4,6-*O*-benzylidene-3-deoxy-3-fluoro-β-D-glucopyranose $J_{5,6} = 4.8$ Hz. The 4,6-*O*-benzylidene substituent effectively requires one particular C_5—C_6 rotamer **C** and it would seem to be more than coincidence that the magnitude of this *gauche* coupling agrees so closely with that independently assigned to a pair of protons having the identical stereo-relationship ($J_{5,6_1}$ in rotamer **C**). Indeed, it is remarkable that a discussion which ignores the effects of rotamer time-averaging should be as adequate as appears to be the case.

In conclusion, our studies indicate that a combination of ^1H and ^{19}F n.m.r. studies provide a direct, and generally applicable, method for elucidating the structures of unknown fluorinated carbohydrates. It would also seem that the general characteristics of the stereospecific dependencies of ^{19}F n.m.r. parameters resemble those of the corresponding ^1H parameters, although their sensitivity towards changes in steric environment is much greater. As far as glycopyranosyl fluoride derivatives are concerned, our studies indicate that the "anomeric" effect of a fluorine substituent is appreciable, and the next paper in this series will be primarily concerned with an elaboration of this statement.

Experimental and Spectral Assignments

General Methods

All evaporations were carried out under reduced pressure. All optical rotations were measured for chloroform (ethanol-free) solutions, using a Bendix ETL-NPL Automatic Polarimeter (Type 143A) with either a 4 cm, or a 0.5 cm, cell. Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Microanalyses were determined by Mr. P. Borda of this Department.

All acetylations were performed at ca. 0° using excess acetic anhydride – pyridine (1:1). Excess reagent was decomposed by adding aqueous sodium bicarbonate. Evaporation of the dried (Na_2SO_4) chloroform solution generally afforded a syrup contaminated with pyridine, which was effectively removed by repeated evaporation with toluene. The pyridine-free syrup generally could be induced to crystallize from aqueous ethanol.

Fully acylated glycopyranosyl bromides were prepared by dissolving the fully esterified aldose in excess hydrogen bromide – acetic acid (35%, w/w). After the starting material had all dissolved, the solution was left at room temperature for ca. 2 h. This reaction mixture was then diluted with dichloromethane, washed with water, dried (Na_2SO_4), and evaporated. The syrupy glycopyranosyl bromide was either reacted directly or crystallized from diethyl ether at ca. −5°.

Synthesis of Glycopyranosyl Fluoride Derivatives

Since the preparation of these derivatives followed one or other of the two standard literature procedures (reviewed by Micheel and Klemer (11)), only one detailed example of each procedure will be given. All syntheses started from the fully *O*-acylated sugar.

α-D-Glucopyranosyl Fluoride Tetraacetate (1)

D-Glucose pentaacetate (5 g) was dissolved in anhydrous liquid HF (20 ml) which had been cooled in a polyethylene

For personal use only.

vessel to −78° (solid CO_2/acetone). The resulting solution was left to warm to room temperature (ca. 20 min) and was then poured directly into a mixture of ether and aqueous sodium bicarbonate solution. The ether layer was washed with water and dried (Na_2SO_4). Evaporation of this solution produced a clear syrup which crystallized as needles from ethanol solution (3.3 g, 74%), m.p. 107–111°. Recrystallization from aqueous ethanol afforded pure (**1**), m.p. 110–112°, $[\alpha]_D^{23}$ +91.0° (*c*, 2.93) (lit. (10) m.p. 108°, $[\alpha]_D^{20}$ +90.1°).

A sample (3.3 g) of **1** was dissolved in absolute methanol (12 ml) and sodium methoxide (2.4 ml, 1%) was added. After 20 min the basic solution was neutralized with ion exchange resin (Amberlite 1R-120-H), filtered, and evaporated to give α-D-glucopyranosyl fluoride (**2**). It had a fluorine chemical shift (aqueous solution; external Freon-11) of +149.7 p.p.m. and $J_{1,F}$ 53.0 Hz; $J_{2,F}$ 26.8 Hz.

β-D-Glucopyranosyl Fluoride Tetraacetate (3)

α-D-Glucopyranosyl bromide (40) tetraacetate (5 g), prepared in the usual manner from D-glucose pentaacetate, was dissolved in acetonitrile (25 ml) containing powdered silver monofluoride (5 g). Light was excluded and the mixture was shaken overnight. The resulting solution was filtered and aqueous sodium chloride was added to precipitate any silver ions from solution. This mixture was filtered and concentrated to a mobile syrup which was dissolved in chloroform, extracted with water, dried (Na_2SO_4), evaporated, and dissolved in boiling diethyl ether. Crystallization was completed by the addition of light petroleum (b.p. 65–110°) to give (3.5 g, 80%) of **3** as sturdy prisms, m.p. 86–89°; recrystallization from diethyl ether afforded pure **3**, m.p. 89° (lit. (36) m.p. 88°, $[\alpha]_D$ +20°; (42) m.p. 98°, $[\alpha]_D$ +21.9°).

A sample of **3** was de-*O*-acetylated to give β-D-glucopyranosyl fluoride (**4**). The ^{19}F chemical shift (aqueous solution external Freon-11) was +142.9 p.p.m. and $J_{1,F}$ 52 Hz; $J_{2,F}$ 12.5 Hz.

α-D-Mannopyranosyl Fluoride Tetraacetate (15)

Synthesis by the method used for the preparation of either **1** or **3** afforded the same syrupy product (by nuclear magnetic resonance (n.m.r.)). This crystallized after seeding with a sample provided by C. Pedersen. The product (**15**) had m.p. and mixture m.p. 69–71° (lit. (37) m.p. 68–69°).

A sample of **5** was de-*O*-acetylated to give α-D-mannopyranosyl fluoride (**16**). The ^{19}F chemical shift (aqueous solution; external Freon-11) was +138.8 p.p.m. and $J_{1,F}$ 50.0 Hz, $J_{2,F}$ ca. 1.5 Hz.

α-D-Galactopyranosyl Fluoride Tetraacetate (13)

Preparation of this derivative followed the method described for **1**. However, the reaction yielded a syrup which failed to crystallize. The syrupy product was chromatographed on a column of silica gel, using 1% methanol in dichloromethane as eluant. The fastest moving component was shown to be pure (**13**), by inspection of both its ^1H and ^{19}F n.m.r. spectra $[\alpha]_D^{25}$ +106.6° (*c*, 0.84).

Anal. Calcd. for $C_{14}H_{19}O_9F$: C, 48.0; H, 5.45; F, 5.45. Found: C, 48.2; H, 5.6; F, 5.7.

Pedersen[10] has also mentioned that the above compound is non-crystalline.

[10]Dr. C. Pedersen. Private communication.

β-D-Galactopyranosyl Fluoride Tetraacetate (14)

The preparation of this derivative followed the conversion of D-galactose pentaacetate (5 g) to syrupy α-D-galactopyranosyl bromide tetraacetate (38) which was allowed to react, without purification, with silver monofluoride in acetonitrile. Inspection (^{19}F n.m.r.) of the crude, syrupy fluoride showed the presence of ca. 5% of the α-anomer, which was not isolated in the work-up. The crude product was crystallized from diethyl ether to yield 1.7 g (40% from the pentaacetate), of **14** m.p. 103–104° (lit. (39) m.p. 98–99°; $[\alpha]_D^{18}$ +22°).

α-D-Allopyranosyl Fluoride Tetraacetate (19) and β-D-Allopyranosyl Fluoride Tetraacetate (20)

When D-allose pentaacetate (0.75 g) was subjected to the conditions discussed above, for the formation of **1**, an almost equimolar mixture of **19** and **20** was obtained, (0.63 g, 91%). The β-fluoride (**20**) was also produced from the syrupy α-bromide and crystallized from diethyl ether. Recrystallization from aqueous ethanol afforded **20** as fine needles (m.p. 149–151°, $[\alpha]_D$ −1.3° (*c*, 1.55).

Anal. Calcd. for $C_{14}H_{19}O_9F$: C, 48.0; H, 5.45; F, 5.45. Found: C, 47.8; H, 5.4; F, 5.2.

Successive crystallization of the β-anomer from the mixture obtained from the HF reaction left mainly the α-anomer which was chromatographed (silica gel, 1% MeOH in CH_2Cl_2) to give impure **19**. It contained ca. 25% impurities by p.m.r.; thin-layer chromatography showed only one spot.

α-D-Altropyranosyl Fluoride Tetraacetate and β-D-Altropyranosyl Fluoride Tetraacetate

Reaction of methyl α-D-altropyranoside tetraacetate with anhydrous liquid HF yielded a mixture of the α- and β-fluorides, which has so far failed to crystallize. These fluorides have been characterized on the basis of their ^{19}F n.m.r. parameters which are given below. α-Anomer ϕ_c +134.9; $J_{1,F}$ 48.3 Hz; $J_{2,F}$ 2.7 Hz; β-anomer ϕ_c +138.5; $J_{1,F}$ 54 Hz; $J_{2,F}$ 20 Hz. Pedersen[10] has also mentioned that the benzoate analogues of these derivatives are non-crystalline.

2,3-Di-O-acetyl-4,6-O-benzylidene-α-D-glucopyranosyl Fluoride (11) and 2,3-Di-O-acetyl-4,6-O-benzylidene-β-D-glucopyranosyl Fluoride (12)

These two compounds were obtained by acetylation of the corresponding (40) 4,6-*O*-benzylidene compounds. These compounds were not, however, obtained in sufficient quantity or purity for detailed physical characterization. **11** had m.p. 137–143° after two recrystallizations from aqueous ethanol. **12** had m.p. 142–148°, also after recrystallization from aqueous ethanol. Nuclear magnetic resonance showed them to be at least 95% pure since no impurity peaks were discernable.

The following derivatives were kindly donated to us by Dr. Christian Pedersen and were used as received. Their ^1H and ^{19}F spectra provided confirmation of their structures and of their purity: *α-D-Mannopyranosyl Fluoride Tetrabenzoate (17) (37); α-L-Rhamnopyranosyl Fluoride Tribenzoate (18) (12); α-D-Glucopyranosyl Fluoride Tetrabenzoate (5) (41); β-D-Glucopyranosyl Fluoride Tetrabenzoate (6) (12); 2-O-Methyl-α-D-glucopyranosyl Fluoride Tribenzoate (7) (42); 2-O-Methyl-β-D-glucopyranosyl Fluoride Tribenzoate (8) (42); 3-O-Methyl-α-*

D-glucopyranosyl Fluoride Tribenzoate (9) (43); 3-O-Methyl-β-D-glucopyranosyl Fluoride Tribenzoate (10) (43).

Nuclear Magnetic Resonance Spectra

Most p.m.r. spectra were measured with a Varian HA-100 spectrometer operating in the "frequency-sweep" mode using tetramethylsilane as internal reference for the lock signal. Appropriate sweep-widths and sweep-times were used for optimal resolution and non-linearities of the sweep-widths were monitored by using the "difference 1" setting of the instrument. All ^1H–$\{^1H\}$ decoupling experiments were performed in the frequency-sweep mode, using a Hewlett Packard 200 CD, or a Hewlett Packard 204B, or a modified (14) Hewlett Packard 200 AB audio-oscillator.

All ^{19}F n.m.r. spectra were measured on the same spectrometer, which was tuned to 94.071 MHz for this purpose. The spectrometer was used either in the "unlocked" HR-mode, or in the "locked" field-sweep mode using the "infinite offset" modification of Douglas[11] (which was further modified by Mr. R. Burton of this Department). For either mode of operation, Freon-11 (trichlorofluoromethane) was used as internal reference (24); "ϕ_c" values are in p.p.m. and refer to a chloroform solution of the derivative, containing ca. 20% Freon-11.[12]

Some of the p.m.r. spectra were measured by Dr. N. S. Bhacca at the Varian Research Laboratories, Palo Alto, California, using a spectrometer operating at 220 MHz.

Spectral Assignments

Generally the spectral assignments were quite straightforward and followed the usual procedure of matching the splittings observed in the individual multiplets. The spectra were measured in three different solvents, (chloroform-*d*, acetone-d_6, benzene-d_6) to facilitate assignments and where appropriate, frequency-sweep spin decoupling experiments were also employed. To illustrate this general method of assignment, the spectra of the α- (1) and β- (3) anomers of D-glucopyranosyl fluoride tetraacetate are described in some detail below. The 100 MHz spectrum of the α-anomer (1) in $CDCl_3$ solution (Fig. 1*a*) shows, as the lowest field resonance, a doublet (2.7 Hz) which has an integrated intensity equivalent to 0.5 proton. This doublet can be assigned to the H-1 resonance if it is assumed that the other "half" of this resonance lies at ca. τ 4.6; the separation between the two "halves" corresponds to a *geminal* H_1–F_1 coupling of 52.8 Hz. The quartet centered at ca. τ 5.3 also integrates for 0.5 proton and since it exhibits a splitting equal to that observed in the resonance assigned H-1, it can tentatively be assigned to H-2. The remaining "half" of the H-2 resonance must then be partially concealed by the rather broad triplet at τ 4.86. It now remains to assign either this triplet, or the one centered at τ 4.52, to the H-3 resonance. It is not possible to make an assignment solely on the basis of spectral splittings since both of these triplets contain the splitting of ca. 9 Hz observed in the H-2 resonance. However, if the triplet at τ 4.86 had been due to H-3, the transitions assigned to H-1 and the triplet at τ 4.52 would then have been broadened by virtual coupling (44); in fact H-1 and the triplet at τ 4.52 are quite sharp. Thus, the triplet at τ 4.52 is assigned to H-3 and the triplet at τ 4.86 to H-4. This latter triplet is notably broadened as a result of virtual coupling resulting from the H-5 and the two H-6 resonances which are themselves observed as a complex multiplet centered at τ 5.6. The above assignment of the H-3 and H-4 resonances is also consistent with the α-anomeric configuration, insofar that one would expect an axial fluorine substituent at C-1 to deshield preferentially H-3 with respect to H-4. If this overall assignment is correct then, $J_{F,1}$ = 52.8 Hz and $J_{F,2}$ = 23.8 Hz, and this is confirmed by direct measurement of the ^{19}F n.m.r. spectrum (shown in Fig. 3*a*).

In $CDCl_3$ solution at 100 MHz, the β-anomer (3) gives a poorly resolved spectrum (Fig. 1*b*) which does, however, have some features consistent with the β-anomeric configuration. Most noteworthy is the observation of the H-5 resonance to higher field (ca. τ 6.1) than the H-5 resonance of the α-anomer (ca. 5.8); again, one would expect an axial fluorine substituent to have resulted in the preferential deshielding of H-5. The poorly resolved multiplet at ca. τ 4.4, intensity 0.5 proton, is assignable to part of the anomeric resonance. It is quite evident that the poor resolution of this resonance is due to virtual coupling between other ring protons, since the spectrum of the same sample measured in acetone solution (Fig. 1*c*) now exhibits one half of the H-1 resonance as a fairly sharply resolved doublet ($J_{1,2}$ 6.6 Hz) at ca. τ 4.3. At the time the H-2 and H-3 resonances are now seen to be chemically shifted from one another. The remaining assignment of this spectrum was straightforward. Confirmation of these assignments again followed from measurement of the ^{19}F n.m.r. spectra. For chloroform solution, the ^{19}F n.m.r. spectrum was obviously virtually coupled (see Fig. 3*b*) in the same fashion as the proton spectrum. However, in acetone solution (Fig. 3*c*) a sharp quartet was observed which confirmed that the magnitudes of $J_{F,1}$ and $J_{F,2}$ were respectively 52.6 and 12.0 Hz.

Although confident with the above assignments, it was a pleasure to accept the opportunity to confirm them by measurement of the spectra at 220 MHz. These p.m.r. spectra, shown in Fig. 2 were obtained by N. S. Bhacca using a 220 MHz spectrometer. The increase in dispersion as compared with the spectra measured at 100 MHz is quite revealing and fully confirms the former assignments. Noteworthy for the α-anomer, is the clear resolution of all four of the H-1 transitions and all eight of the H-2 transitions, besides the considerable simplification of the H-5 and the two H-6 resonances. It is apparent, however, that the triplet assigned to H-4 is still less well resolved than the H-3 triplet, which is a result of the H-5 and the two H-6 resonances still being fairly strongly coupled (44). In fact, the first-order assignments made for these resonances are not *strictly* justifiable. However, this in no way invalidates

[11]A. W. Douglas. Private communication.

[12]The preliminary communications of this work referred the ^{19}F shifts to neat trifluoroacetic acid, which was used in a capillary tube. All shifts quoted in this paper have been *remeasured* as outlined above. Some difficulties were experienced initially due to paramagnetic impurities in the Freon 11, which resulted in detectable line broadening; these impurities were removed by bulb-to-bulb distillation. Blank experiments indicated that the amount of Freon 11 added to the chloroform solution could be varied over wide limits without appreciably altering the ^{19}F shift.

the other assignments and is not required for the determination of the conformational symmetry of the molecule as a whole. In Fig. 2*b*, some of the spectral features are more clearly resolved, and in particular the virtual coupling of the H-1 resonance has been considerably diminished. Note, however, that even with this increased dispersion, the spectrum is less clearly resolved than that of the 100 MHz spectrum for acetone-d_6 solution. In Fig. 2*c*, the various ring proton resonances are now mutually shifted so that the assignment can be seen more clearly and this substantiates the assignment made at 100 MHz. Once again the assignment of the C-5 and C-6 proton resonances is beyond the limits of a first-order analysis; the H-5,H-6 resonances are usually best resolved in benzene solutions.

Although 220 MHz spectra were only measured for the above mentioned glucosyl fluorides, all of the other hexopyranosyl fluorides were subjected to a rigorous spectral assignment at 100 MHz in the solvents mentioned.

Acknowledgments

It is a pleasure to acknowledge the generous gifts of samples from Dr. Christian Pedersen, of the Technical University, Lyngby, Denmark, which helped us so much during the initial stages of this work. Financial assistance from the National Research Council of Canada and the National Cancer Institute of Canada is also gratefully acknowledged. This paper was written during the tenure (by L. D. H.) of a Royal Society and Nuffield Foundation Commonwealth Bursary at the University of New South Wales, Australia; it is a pleasure to acknowledge the hospitality of Professor S. J. Angyal during this period.

Studies of specifically fluorinated carbohydrates. Part II. Nuclear magnetic resonance studies of pentopyranosyl fluoride derivatives

L. D. HALL[1] AND J. F. MANVILLE[2]
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia
Received May 14, 1968

Detailed studies, by ^{1}H and ^{19}F nuclear magnetic resonance spectroscopy, of a series of fully esterified pentopyranosyl fluorides, show that all such derivatives favor that conformer in which the fluorine substituent is axially oriented. This conclusion is supported by separate considerations of the *vicinal* and *geminal* ^{19}F–^{1}H and ^{1}H–^{1}H coupling constants, of the *long-range* (^{4}J) ^{1}H–^{1}H and ^{19}F–^{1}H coupling constants and of the ^{19}F chemical shifts. The limitations of the above conformational model are discussed.

Introduction

In the previous paper of this series (1) we described the use of hexopyranosyl fluoride derivatives as models for an investigation of the stereospecific dependences of ^{19}F nuclear magnetic resonance (^{19}F n.m.r.) parameters. In the present paper we describe an essentially parallel investigation of a series of pentopyranosyl fluoride derivatives which, besides confirming some aspects of the previous ^{19}F n.m.r. study, indicates that an anomeric fluorine substituent can have a profound influence on the preferred conformation of a pyranose derivative.[3]

Results and Discussion

Our original intention in studying the proton and fluorine nuclear magnetic resonance (n.m.r.) spectra of a series of pentopyranosyl fluorides was to extend directly the studies which we had made of hexopyranosyl fluorides. However, it became apparent early in this study that the derivatives in this series all showed a most marked preference for that conformation in which the fluorine substituent had an axial orientation. In order to present most clearly the evidence which led to this conclusion, and supported it, the data obtained for the α- and β-D-xylopyranosyl fluoride systems, which are the limiting cases, will be discussed first in some detail; the remaining derivatives will then be discussed by analogy.

It is relevant to note that from both a conformational and an n.m.r. viewpoint, the D-xylopyranose and the D-glucopyranose systems are closely related, the sole difference being at C-5 where the D-glucose system has an equatorially oriented hydroxymethyl (or acetoxymethyl, benzoyloxymethyl, etc.) substituent in place of H-5e of the D-xylose system in the $^{4}C_{1}$(D) conformation. On this basis one would anticipate fundamentally similar n.m.r. spectra for the two systems.

Consider the partial 100 MHz spectrum for α-D-xylopyranosyl fluoride triacetate (**1**) shown in Fig. 1*a*. The resemblance between this spectrum and the one previously presented (1) for α-D-glucopyranosyl fluoride tetraacetate (**15**) is quite evident; noteworthy is the similarity between the H-1, H-2, and H-3 resonances. The transitions in the complex region at τ 5.0, which had not already been assigned to H-2, were assigned to H-4 since they had the same splitting (9.7 Hz) as that found in the H-3 resonance. The remaining resonances centered at τ 6.15 were assigned to the C-5 protons, the triplet at higher field (τ 6.29) being attributed to H-5a since it displayed a large splitting (10.8 Hz), characteristic of a *trans-diaxial, vicinal* coupling. This left the remaining transitions centered at τ 6.02 assignable to H-5e, which displayed the same *geminal* ^{1}H–^{1}H coupling (10.8 Hz) as H-5a and a smaller *vicinal* coupling (5.7 Hz) indicative of a *gauche* relationship with H-4. Measurement of the ^{19}F spectrum supported this overall assignment since the *geminal* (53.3 Hz) and

[3]Preliminary accounts of these conclusions were presented at the 3rd International Fluorine Symposium Munich, Germany, August 30 to September 2, 1965 and at the 153rd meeting of the American Chemical Society, Miami Beach, Florida, April 9–14, 1967. See also references (2) and (3).

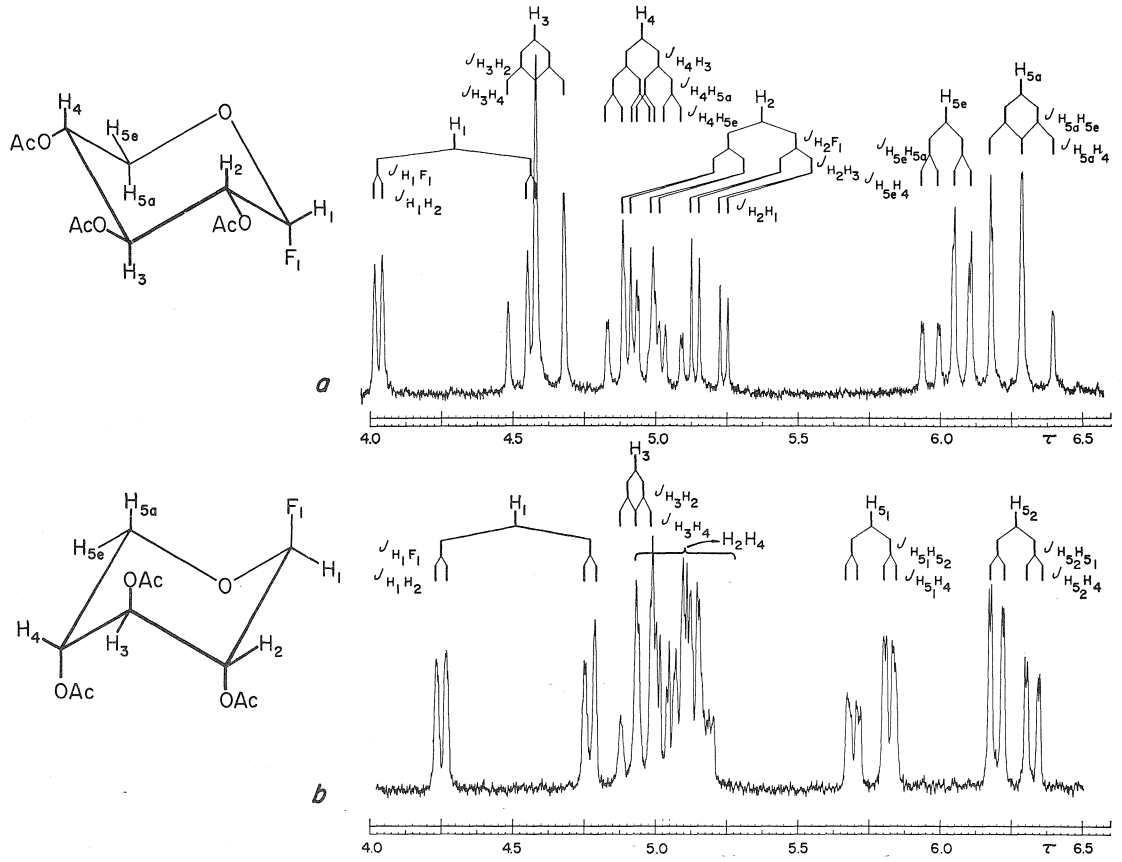

FIG. 1. Partial 100 MHz proton magnetic resonance spectra of: (*a*), α-D-xylopyranosyl fluoride triacetate (**1**) and (*b*), β-D-xylopyranosyl fluoride triacetate (**3**) in acetone-d_6 solutions.

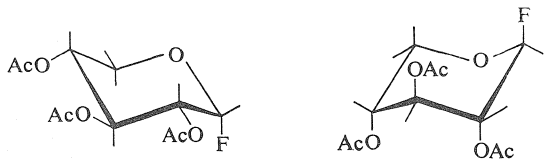
vicinal (24.1 Hz) ^{19}F–^{1}H couplings are indicative of a *trans-diaxial* relation between H-2 and F-1. Hence, the conformation of (**1**) must approximate to the $^{4}C_{1}$(D) symmetry (**1***a*).



1*a*

3*a*

Consider now the spectrum (Fig. 1*b*) of β-D-xylopyranosyl fluoride triacetate (**3**), which was anticipated to resemble that of the corresponding β-D-glucosyl fluoride tetraacetate (**16**) (1) and to a certain extent that of the α-D-xylopyranosyl triacetate fluoride (**1**) (1). It is immediately apparent that this expectation is not fulfilled. The H-1 and H-5 resonances are particularly noteworthy in this respect. The *vicinal* H_1–H_2 coupling is only 3.5 Hz which is half the value found for the corresponding coupling of the β-D-*gluco* derivative (**16**). Furthermore, neither of the H-5 resonances exhibit the large (ca. 10Hz) splitting anticipated for the *trans-diaxial* coupling with H-4a. Since there seemed to be little chance that the halogen exchange reaction, used in the synthesis of this derivative from the known α-D-xylosyl bromide triacetate, could have effected simultaneously inversion at both C-4 and C-2, the only reasonable rationale for the proton n.m.r. data was based on a gross conformational inversion of the pyranose ring. Previous experience had already indicated (1, 5) the "anomeric effect" of a fluorine substituent to be significant, and it seemed possible that in this case it had caused the

β-D-xylosyl fluoride (**3**) to adopt a conformation approximating to the $^1C_4$(D) conformation (*3a*); this would allow the fluorine substituent to adopt an axial orientation but would also require the acetoxy substituents at C-2, C-3, and C-4 to be axially oriented. This inversion would account for the small magnitudes of the H_1–H_2 and H_4–H_5 couplings[4] together with the rather small *vicinal* ^{19}F–^1H coupling (ca. 7Hz) and the multitude of *long-range* ^1H–^1H couplings in the various resonances.

If it is accepted for the present that the β-D-*xylo* derivative (**3**), and its benzoate analogue (**4**) do exist in the $^1C_4$ conformation, then it is highly probable that *all of the other pentopyranosyl fluorides described in this paper adopt that chair conformation having the fluorine substituent axially oriented.* Inspection of the *vicinal* coupling constants listed in Table II indicates that, to a first approximation, this is correct.

Further evidence supporting the above view, which is *completely independent of any arguments based on the angular dependence of vicinal coupling constants*, follows a consideration of the ^{19}F chemical shifts (ϕ_c-values) of the fully acetylated derivatives. Using the empirical rules derived previously (1) for predicting the chemical shifts (ϕ_c-values) of an axial fluorine substituent attached to the anomeric carbon atom of a pyranose carbohydrate, it is possible to calculate the ϕ_c-values for all of the pentopyranosyl fluoride triacetates. Table III lists the experimental ϕ_c-values for these derivatives, together with the values calculated on the assumption that all derivatives exist exclusively in that conformation having the fluorine substituent axially oriented; the calculated values have been normalized with respect to the shift of the α-D-xylopyranosyl fluoride triacetate. It can be seen that the mean deviation between the experimental and calculated values is essentially the same for the α-($\pm$0.6 p.p.m.) and β-($\pm$0.8 p.p.m.) series of compounds.

Before the above evidence is acceptable it is necessary to show that calculations based on those conformations having an equatorially oriented fluorine substituent are less satisfactory than those listed in Table III. Although this is not possible in every instance due to the lack of suitable model compounds in the hexopyranose series, in the two cases where it is possible, the alternate conformations lead to ϕ_c-values seriously at variance with the experimental values. The inherent axial:equatorial ^{19}F shift difference ($\delta_{a,e}$) is known (1) to be 12.1 p.p.m. for the D-glucosyl fluoride tetraacetates (**15** and **16**) and −0.6 p.p.m. for the D-allosyl derivatives (**19** and **20**); these values can be used to calculate the shifts expected for the β-D-*xylo* (**3**) and β-D-*ribo* (**7**) derivatives if they were to adopt the $^4C_1$(D) conformation. For example, using the shift of α-D-xylopyranosyl fluoride triacetate (**1**) as reference, together with the $\delta_{a,e}$ value for the D-glucosyl fluorides (**15**) and (**16**), the β-D-xylopyranosyl fluoride triacetate (**3**) in the $^4C_1$(D) conformation should have a shift of 140.0 p.p.m.; this is +3 p.p.m. from the experimental value, whereas, the error in the value calculated for the $^1C_4$(D) conformation is −1.3 p.p.m. In like fashion, the calculated value for β-D-ribopyranosyl fluoride triacetate (**7**) in the $^4C_1$(D) conformation is 148.8 p.p.m., which is +7.4 p.p.m. from the observed value; in this case the error for the $^1C_4$(D) value is only −0.8 p.p.m.

A further set of ^{19}F shift comparisons can be formulated, in which each of the pentose derivatives is compared with the configurationally related hexose counterpart. This is shown in Table IV; from these comparisons it is clear that an equatorially oriented acetoxymethyl substituent at C-5 *deshields* an axially oriented fluorine substituent at C-1 by ca. 2.5 p.p.m. Clearly, it would be of some interest to obtain the glycosyl fluorides of the "rare" hexoses in order to complete this set of comparisons. Nevertheless, the comparisons which can be made at this time are consistent with the conformations postulated for the pentopyranosyl fluorides.

Several series of comparisons can be made between the ^1H chemical shifts of some of these derivatives in $CDCl_3$ solutions; these also support the anticipated conformational symmetries and, at the same time, help to confirm the assignments of the H-5e and H-5a resonances for those compounds (**3**, **4**, **7**, **8**, **9**) where the C_4—H_4 bond is *gauche* with respect to both of the C_5—H_5 bonds. Consider first those derivatives for which an unequivocal assignment of the

[4]The C-5 protons were assigned on the basis of the empirical rules advanced by Lemieux and Stevens (4) from consideration of shielding parameters of acetoxy substituents on remote protons. See also (5).

β-D-arabino	(11)	$^1C_4$(D)	eq	eq	ax	153.3	153.7	+0.4

H-5 resonances can be based on the *vicinal* couplings between H-4a and H-5a. Comparison of the H-5a shifts of **2** and **6**, shows that inversion of a benzoyloxy substituent at C-3 from an equatorial to an axial orientation shifts H-5a by −0.34 p.p.m.; however, a similar comparison for **14** and **10** gives a shift of −0.52 p.p.m. Only one comparison can be made for inversion of an acetoxy function, namely that of **13** with **9**, which gives a shift parameter of −0.38 p.p.m. Turning now to those derivatives having H-4 equatorially oriented, it can be seen that according to the assignments chosen for Table I, inversion of a C_3-benzoyloxy substituent (**8** and **4**) deshields H-5a by −0.37 p.p.m. whilst the shift for the corresponding acetates (**13** and **9**) is −0.38 p.p.m.; both of these shifts are in reasonable agreement with those listed earlier. For a similar inversion of acetoxy functions in the hexopyranose pentaacetate system, Lemieux and Stevens (4) report −0.25 p.p.m.

The remaining ^1H n.m.r. parameters of most of these pentopyranosyl fluoride derivatives appear to be reasonably consistent with the hypothesis that they all adopt either the $^1C_4$(D) or the $^4C_1$(D) conformational symmetry. Thus the *vicinal* couplings, $J_{a,a}$, fall within the range 9.5 to 10.8 Hz, in agreement with values observed for the hexose derivatives. The values for *vicinal* $J_{e,a}$ couplings fall in two distinct ranges, namely 2.0–3.5 Hz for couplings between H-1, H-2, H-3, and H-4, and 5.0–6.2 Hz for those couplings between H-4a and H-5e that have no associated *anti-planar* electronegative groups (derivatives in $^4C_1$(D) conformation). The observation of such large *vicinal* couplings (ca. 6 Hz) between two protons that are separated by a dihedral angle of 60° is at variance with that value anticipated from consideration of the known configurational dependencies (6, 7) in conjunction with the Karplus relationship (8). These large couplings occurred in spectra of the α-D-xylosyl fluorides (**1**, **2**), both of which appear to exist in the $^1C_4$(D) conformation as evidenced by the remaining couplings. This *vicinal* coupling is even larger than the one observed (9) in 2-deoxy-α-D-*arabino*-hexopyranosyl fluoride triacetate for which H-2e, H-3a is 5.2 Hz. It is therefore

TABLE IV

apparent that *vicinal* couplings associated with a $—CH_2—$ function, can vary over a considerable range.

Measurement of ^{19}F spectra showed that the *vicinal* $^{19}F–^{1}H$ couplings of these derivatives were also consistent with the anticipated symmetries. For a *trans-diaxial* relationship between F-1 and H-2, the coupling is 22.2 to 26.3 Hz, whilst for a *gauche* relationship between these substituents, a coupling of 2 to 5 Hz is observed. These values are similar to those reported previously (1) for the hexopyranosyl fluorides.

A further set of interesting comparisons concerns the *geminal* couplings, $F_1–H_1$ and $H_{5e}–H_{5a}$. For those derivatives that possess an axial substituent at C-2, the *geminal* $F_1–H_1$ coupling is 48.6–49.5 Hz, whilst those compounds having the C-2 substituent equatorial give couplings of 53.1 to 53.5 Hz. This same dependence was noted (1) in the $F_1–H_1$ couplings of the hexopyranosyl fluorides. However, it is in contrast with the dependence observed for the *geminal* $H_{5e}–H_{5a}$ couplings; compounds (**7**, **8**, **11**), which possess an *axial* acetoxy substituent at C-4, display a *larger* coupling (ca. 13Hz) than do those derivatives (**1**, **2**, **5**, **6**, **13**, **14**) having an equatorially oriented substituent, when the coupling is ca. 10.8 Hz. Previous studies in this laboratory have established that whilst the *absolute* sign of a *geminal* $^{19}F–^{1}H$ coupling is positive (10), that of a *geminal* $^{1}H–^{1}H$ coupling is negative (11). With this fact in mind it can be seen that the two sets of *geminal* couplings listed above do in fact demonstrate the same phenomenon; in each case, an axially oriented acetoxy group (and, possibly, other electronegative substituents) attached to a *vicinal* position results in a *geminal* coupling which is *absolutely more negative* than when that substituent is equatorially oriented. From a conformational viewpoint it is important to note that in all but two cases (*vide infra*) the magnitudes of the various *geminal* couplings are again in accord with that undistorted chair conformation having the anomeric fluorine substituent axially oriented.

These pentosyl fluoride derivatives also exhibit a wide selection of *long-range* $^{1}H–^{1}H$ coupling constants across four bonds (^{4}J), and in every case their occurrence was in accord (11, 12) with the anticipated conformational symmetry. In view of our recent finding (13) that *long-range* (^{4}J) couplings of ca. 4 Hz occur between a fluorine and a proton substituent having a 1,3-diequatorial orientation, it is particularly noteworthy that none of the derivatives included in this study show any couplings of this magnitude; this further supports our contention that these derivatives have the fluorine substituent axially oriented.

We shall now discuss in greater detail the two derivatives whose predicted ^{19}F chemical shifts showed the greatest deviation from the experimental values, namely β-D-xylopyranosyl fluoride triacetate (**3**) and α-D-arabinopyranosyl fluoride triacetate (**9**). It could be argued that since the calculated shifts for these two derivatives involve the summation of, respectively, three and two inversion contributions, these maximal deviations merely reflect the accumulation of the errors involved in these empirical shift parameters; certainly the minimal errors are observed for those two derivatives (**11**, **13**) for which the predicted shifts are obtained by considering a single inversion only. However, we consider that the deviations observed for **3** and **9**, do in fact reflect a genuine breakdown of the idealized conformational models considered thus far.

We shall now justify this statement. For α-D-mannopyranosyl fluoride tetraacetate (**17**), $J_{F_{1a}H_{1e}}$, = ca. 48.5 Hz, $J_{F_{1a}H_{2e}}$, = ca. 1.0 Hz and $J_{H_{1e}H_{2e}}$, = ca. 1.5 Hz. The corresponding couplings for derivatives **13** and **14**, which have nominally the same configurations at C-1 and C-2 are in good agreement with these values. However, the agreement is less good for those derivatives having *two* axially oriented acetoxy substituents and is poorest for β-D-*xylo* derivatives (**3**, **4**) and the α-D-*arabino* derivatives (**9**, **10**). The *geminal* H-5e, H-5a couplings of these derivatives also seem to be somewhat anomalous. The couplings for **3**, **4** are slightly less than that of **11**, ca. 13 Hz, which has only a single axial acetoxy function, and which we assume is close to the $^{1}C_4$(D) symmetry; in like fashion the couplings for **9**, **10** are somewhat larger than those of their counterparts (**1**, **2**) for which $J_{5e,5a}$ = ca. 10.8 Hz. Clearly some of the above "deviations" are somewhat small, but it does seem more than fortuitous that they all happen to be maximal for the same derivatives which are, furthermore, just those systems

For personal use only.

having the maximal number of "axially" oriented acetoxy substituents. On this basis we suggest that whilst the powerful "anomeric-effect" (14, 15) of a fluorine substituent is sufficiently predominant to exert overall control of the conformational preference of these derivatives, classical, non-bonded interactions are capable of distorting the conformational symmetry of the system. This is the converse of the situation which we have previously (1) envisaged for the D-hexopyranosyl fluoride systems.

It would seem that for the pentopyranosyl fluorides *three* sets of repulsive non-bonded interactions are required to cause a detectable distortion from an "ideal" chair conformation; in this regard we consider only the following 1,3-interactions, OAc_a; H_a, OAc_a; F_a and OAc_a; OAc_a. Again it is necessary to consider whether the conformational deviations implied by the room-temperature n.m.r. data reflect a true distortion of a ground-state conformational symmetry, or whether they reflect some conformational time-averaging process(es). As found previously for the hexopyranosyl fluoride system, variable temperature studies with the equipment available at this time do not enable us to make an unequivocal distinction between these two possibilities. The ^{19}F shift of the β-D-xylo-derivative (**3**) changed by ca. 2 p.p.m. between 190 °K and 330 °K. We plan to reinvestigate this point at a future date.

It is of some interest to compare the parameters of the two triacetate derivatives (**3**, **9**) with those of the corresponding tribenzoates (**4**, **10**, respectively). In each case the parameters of the tribenzoate are closer to the values anticipated for undistorted chair conformations than are those of the triacetate. This observation could imply that the anomeric effect of a fluorine substituent is greater for the tribenzoates than for the triacetates. Alternatively, the *gauche* interaction between a pair of *vicinal* benzoyloxy substituents may be greater than that between a corresponding pair of acetoxy substituents. Although these isolated examples do not merit further discussion at this time it is interesting to note that the results previously quoted for hexopyranosyl fluoride derivatives appear to reflect a remarkable similarity to those outlined above.

Whilst the studies described in this paper were in progress two other groups of workers have reported results concerning the conformations of pentopyranose derivatives which are in accord with many of our observations. Coxon (5) studied a series of D-ribopyranose derivatives and concluded that ". . . . the operation, or non-operation of the anomeric effect appears to be the principal factor determining which particular chair conformation predominates." In a somewhat broader study, Horton and Turner (16*a*) investigated the "thermodynamically-favored" pentopyranosyl halides and also concluded that the anomeric effect of a halogen substituent is of predominant importance in controlling the conformations of pentopyranose derivatives. Of particular relevance to the present study was the observation (16*b*) that β-D-xylopyranosyl chloride triacetate favors the $^1C_4$(D) conformational symmetry. Unfortunately, it is not possible to make a detailed comparison of this derivative with the corresponding fluoride because insufficient coupling constants are available for the β-chloride.

It will be noted in the above discussions we have considered only "repulsive" non-bonded interactions and have ignored the possible existence of attractive forces between substituent groups (17). We do not feel that we have yet sufficient data to comment meaningfully on such forces; however, the possibility of an attraction between a pair of 1,3-diaxially related substituents would clearly stabilize further several of the conformations suggested in this paper. At this time it would seem reasonable to ascribe the conformational preferences of these pentopyranosyl fluoride derivatives to the various properties associated with the highly polar C_1–F bond and which would familiarly be termed the "anomeric-effect" of the fluorine substituent. However, it remains to be seen whether this phenomenon results solely from dipolar interactions between the polar bond at C-1 and the ring oxygen.

Experimental

The basic procedures used in this study were identical to those outlined previously for the hexopyranosyl fluoride derivatives (1).

α-D-Xylopyranosyl Fluoride Triacetate (1)

A sample of this derivative was synthesized by the method of Brauns (18). The crude reaction product contained ca. 5% of the corresponding β-isomer (**3**) as shown by ^{19}F n.m.r., which was not isolated in the work-up; **1** had m.p. 86–88°; (lit. (18), m.p. 87°).

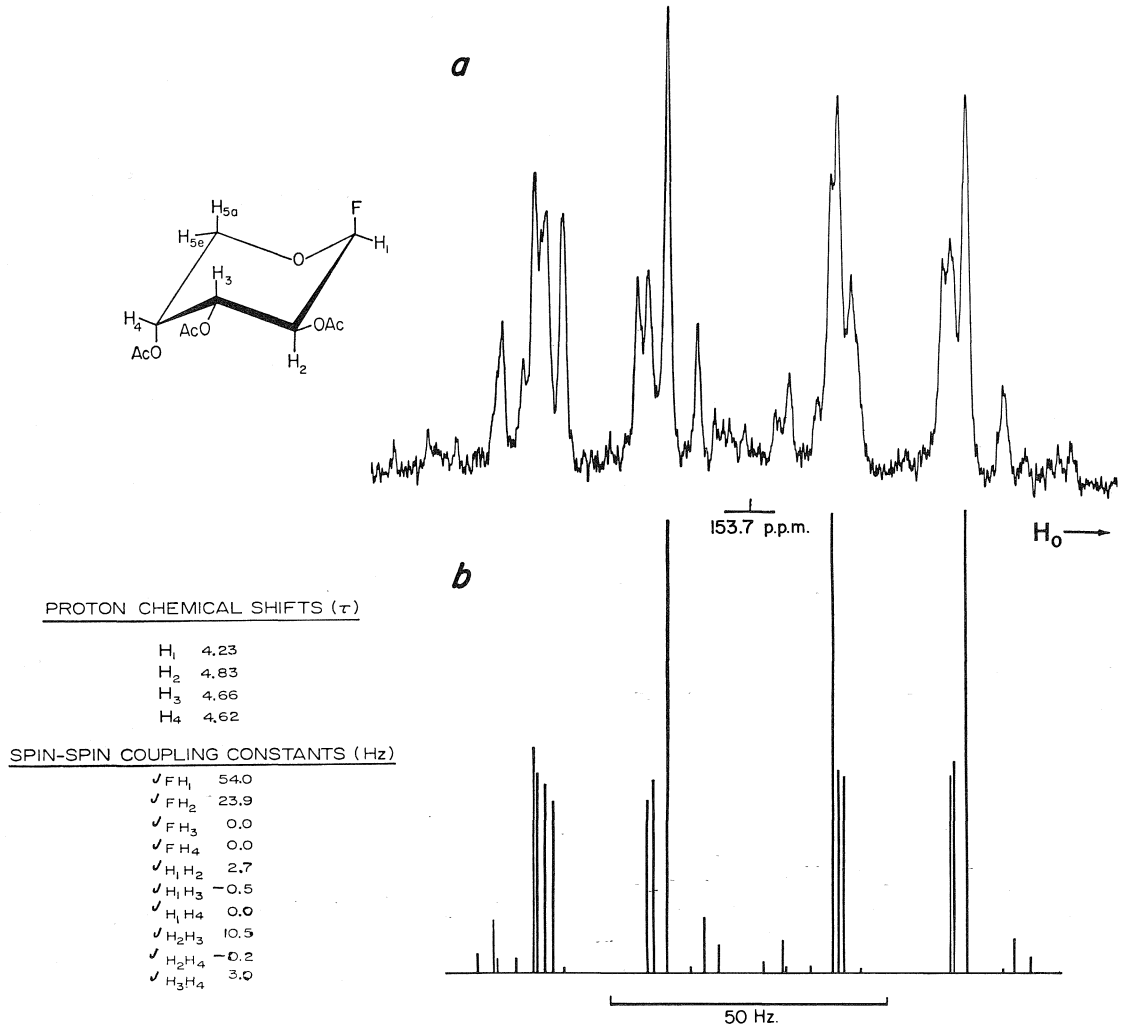

FIG. 2. (*a*) The ^{19}F nuclear magnetic resonance spectrum of β-D-arabinopyranosyl fluoride triacetate (**11**) in acetone-d_6 solution, and (*b*), the spectrum calculated from the estimated first-order parameters. The correlation between the two spectra is not perfect (*vide infra*).

β-D-*Xylopyranosyl Fluoride Triacetate (3)*

The preparation of this derivative followed the method of Lundt and Pedersen (19), except that crystalline α-D-xylopyranosyl bromide triacetate (20) was used. **3** had m.p. 52–55°; (lit. (19), m.p. 56–57°, $[\alpha]_D^{23}$ −56.4°).

β-D-*Ribopyranosyl Fluoride Triacetate (7)*

The preparation of this derivative also followed the method of Lundt and Pedersen (19). Examination by ^{19}F n.m.r. of the crude reaction product showed the presence of a second component which we assigned to the α-D-ribopyranosyl fluoride triacetate (**5**) on the basis of its chemical shift and first-order coupling constants. This compound was not isolated; however, its ^{19}F n.m.r. parameters were measured and found to be: ϕ_c + 147.7, $J_{1,F}$ 52.1 Hz, $J_{2,F}$ 26.3 Hz; (**7**) had m.p. 94–96°; (lit. (19), m.p. 93–95°).

α-D-*Ribopyranosyl Fluoride Tribenzoate (6) and* β-D-*Ribopyranosyl Fluoride Tribenzoate (8)*

These derivatives were prepared by the method of Pedersen and Fletcher (21), **6** had m.p. 202–204°; (lit. (21), m.p. 205–206°). **8** had m.p. 135–137°; (lit. (21), m.p. 139–140°).

α-D-*Lyxopyranosyl Fluoride Triacetate (13)*

This compound was synthesized in the manner of Lundt and Pedersen (19), (**13**) had m.p. 85–87°; (lit. (19), m.p. 87–89°).

The following derivatives were generously donated by Dr. Christian Pedersen of the Technical University, Lyngby, Denmark. These samples were used as received and inspection of their ^1H and ^{19}F n.m.r. spectra effectively constitutes further evidence for their purity and structure: α-D-*Xylopyranosyl fluoride tribenzoate* (**2**) (22);

β-D-*Xylopyranosyl fluoride tribenzoate* (**4**) (22); α-D-*Arabinopyranosyl fluoride triacetate* (**9**) (19); α-D-*Arabinopyranosyl fluoride tribenzoate* (**10**) (19); β-D-*Arabinopyranosyl fluoride triacetate* (**11**) (18, 19); α-D-*Lyxopyranosyl fluoride tribenzoate* (**14**) (23).

Generally the pentopyranosyl fluorides gave clearly resolved spectra, in at least one solvent, and the couplings were then easily extracted by a first-order analysis. However, for the β-D-*arabino* derivative (**9**) the spectrum was never first-order (see Fig. 2*a*) and consequently it was felt that some check was required to evaluate the accuracy of the estimated couplings that were extracted from the spectral splittings. These were tested by computing[5] the theoretical spectrum based on these estimated parameters. This result, for the ^{19}F spectrum, is given below the actual spectrum in Fig. 2*b*. It should be noted that the calculated spectrum is not in perfect agreement with the experimental spectrum. However, the agreement is sufficiently close to demonstrate that, even in a highly coupled spectrum ($J_{i,j}/\delta_{i,j} \rightarrow 1$), fairly accurate values for the couplings and chemical shifts can be obtained by first-order analysis.

Acknowledgments

This work was supported by grants from the National Research Council of Canada and the National Cancer Institute of Canada. It is a pleasure to acknowledge gifts of samples from Dr. Christian Pedersen. This paper was written during the tenure (by L. D. H.) of a Royal Society and Nuffield Foundation Commonwealth Bursary at the University of New South Wales, Australia; it is a pleasure to thank Professor S. J. Angyal for his hospitality during this period.

Synthesis of 2,6-Di-*O*-methyl-D-mannose[1]

M. B. Perry and Ann C. Webb
Division of Biochemistry and Molecular Biology, National Research Council of Canada, Ottawa, Canada
Received August 22, 1968

2,6-Di-*O*-methyl-D-mannose was synthesized using the following sequence of reactions: 1,3,4,6-tetra-*O*-acetyl-2-*O*-methyl-β-D-mannopyranose → methyl 2-*O*-methyl-α-D-mannopyranoside → methyl 2-*O*-methyl-6-*O*-trityl-α-D-mannopyranoside → methyl 3,4-di-*O*-acetyl-2-*O*-methyl-6-*O*-trityl-α-D-mannopyranoside → methyl 3,4-di-*O*-acetyl-2-*O*-methyl-α-D-mannopyranoside → methyl 3,4-di-*O*-acetyl-2,6-di-*O*-methyl-α-D-mannopyranoside → 2,6-di-*O*-methyl-D-mannose. The preparation and properties of derivatives of the 2,6-di-*O*-methyl-D-mannose are recorded.

Canadian Journal of Chemistry, 47, 31 (1969)

For personal use only.

2,6-Di-*O*-methyl-D-mannose has been tentatively identified as a fission product of several methylated glycans (1–3) suggesting the presence of either D-mannopyranosyl units substituted at positions-3 and -4 or D-mannofuranosyl units substituted at positions-3 and -5 in the original polymers. This note records the synthesis of 2,6-di-*O*-methyl-D-mannose which was required for the identification of a product obtained from methylated glycans produced by *Cryptococcus* and *Tremella* species.

1,3,4,6-Tetra-*O*-acetyl-2-*O*-methyl-β-D-mannopyranose (4) with hot methanolic hydrogen chloride afforded methyl 2-*O*-methyl-α-D-mannopyranoside which on treatment with one mole of triphenylchloromethane was converted to methyl 2-*O*-methyl-6-*O*-trityl-α-D-mannopyranoside. Subsequent acetylation of this compound gave methyl 3,4-di-*O*-acetyl-2-*O*-methyl-6-*O*-trityl-α-D-mannopyranoside which on treatment with hydrogen bromide – acetic acid mixture underwent detritylation to yield methyl 3,4-di-*O*-acetyl-2-*O*-methyl-α-D-mannopyranoside. The methyl 3,4-di-*O*-acetyl-2-*O*-methyl-α-D-mannopyranoside could be reconverted to methyl 3,4-di-*O*-acetyl-2-*O*-methyl-6-*O*-trityl-α-D-mannopyranoside indicating that no acetyl group migration had occurred during the detritylation process. The methyl 3,4-di-*O*-acetyl-2-*O*-methyl-α-D-mannopyranoside was methylated with diazomethane using boron trifluoride etherate catalyst (4) and the resulting methyl 3,4-di-*O*-acetyl-2,6-di-*O*-methyl-α-D-mannopyranoside on hydrolysis gave 2,6-di-*O*-methyl-D-mannose.

All the intermediates were pure by thin-layer chromatography and their nuclear magnetic resonance (n.m.r.) spectra and elemental analyses were consistent with the proposed structures.

The 2,6-di-*O*-methyl-D-mannose gave a single spot on paper chromatogaphy and had no mobility on electrophoresis in borate buffer. On methanolysis it gave a glycoside which gave a single peak on gas–liquid chromatography. On oxidation with bromine, the glycose was converted to 2,6-di-*O*-methyl-D-mannono-1,4-lactone which gave a single peak on gas–liquid chromatography and its infrared spectrum showed a single carbonyl absorption peak at 1780 cm^{-1} characteristic of hexono-1,4-lactones (5); the lactone was converted to crystalline 2,6-di-*O*-methyl-D-mannonic acid phenylhydrazide.

The 2,6-di-*O*-methyl-D-mannose on reduction with sodium borohydride gave 2,6-di-*O*-methyl-D-mannitol which on periodate oxidation released no formaldehyde but consumed approximately two moles of periodate and released one mole of formic acid per mole hexitol, a result consistent with the proposed structure.

Experimental

Paper chromatography was performed by the descending method (6) on Whatman No. 1 filter paper using pyridine – ethyl acetate – water (2:5:5 v/v, top layer) as the mobile phase. Glycoses were detected with *p*-anisidine hydrochloride (7) and their rates of movement are quoted relative to 2,3,4,6-tetra-*O*-methyl-D-glucose (R_G). Gas–liquid chromatography was carried out at 200 °C using a Hewlett–Packard model 402 gas chromatograph with a hydrogen flame detector and fitted with glass U tubes (4ft × 6mm × 3mm internal diameter) packed with 10% neopentylglycol sebacate polyester on 80–100 mesh acid-washed Chromosorb W. Retention times are quoted relative to methyl 2,3,4,6-tetra-*O*-methyl-α-D-glucoside (T_G). The purity of all intermediates was determined by thin-layer chromatography on silica gel G using acetone–benzene (1:4 v/v) mixture as the mobile

[1]Issued as NRCC No. 10418.

For personal use only.

phase and detection was made by spraying the developed plates with sulfuric acid – ethanol (1:1 v/v) mixture and heating them for 10 min at 120 °C.

Nuclear magnetic resonance (n.m.r.) spectra were recorded at 60 MHz with a Varian A-60A spectrometer with tetramethylsilane (τ 10.00) as an internal standard for spectra measured in chloroform-*d*, and sodium 4,4-dimethy-4-silapentane-1-sulfonate (τ 10.00) as the internal standard for spectra measured in deuterium oxide.

Melting points were determined on a Fisher–Johns apparatus and are corrected. Solutions were concentrated under reduced pressure, below 40 °C. Optical rotations were determined at 20 °C using a Perkin–Elmer 141 polarimeter.

Methyl 2-O-Methyl-6-O-trityl-α-D-mannopyranoside

1,3,4,6-Tetra-*O*-acetyl-2-*O*-methyl-β-D-mannose (4) (20 g) in 2.5% methanolic hydrogen chloride solution (400 ml) was boiled under reflux for 4 h and the neutralized (Ag_2CO_3) solution was concentrated to yield methyl 2-*O*-methyl-α-D-mannopyranoside (11 g) as a syrup which had $[\alpha]_D$ +56° (*c*, 1.7 in methanol) (Calcd. OMe, 29.8. Found: OMe, 29.6.). The n.m.r. spectrum of the product in deuterium oxide showed two equal (3 protons each) signals for methoxyl groups at τ 6.53 and 6.57 and exhibited an H-1 doublet at τ 5.07 with a spacing of 1.7 c.p.s. No formaldehyde was produced on periodate oxidation of the compound indicating the absence of any furanoside derivatives.

Methyl 2-*O*-methyl-α-D-mannopyranoside (10 g) was dissolved in dry pyridine (70 ml) and after the addition of triphenylchloromethane (18.6 g) the mixture was heated at 90 °C for 1 h. The cooled mixture was added dropwise to a vigorously stirred ice-water mixture (1.5 l) and the collected precipitated product was washed with water and then dried under vacuum. The crystalline methyl 2-*O*-methyl-6-*O*-trityl-α-D-mannopyranoside (17.1 g) obtained from ethanol solution had m.p. 143–144 °C and $[\alpha]_D$ +2° (*c*, 1 in chloroform) and $[\alpha]_D$ +25° (*c*, 3 in methanol).

Anal. Calcd. for $C_{27}H_{30}O_6$: C, 71.98; H, 6.71; OMe, 13.77. Found: C, 71.5; H, 6.8; OMe, 14.0.

The n.m.r. spectrum of the product in $CDCl_3$ showed a complex multiplet for the triphenylmethyl group centered at τ 2.70, two equal methoxyl signals at τ 6.56 and 6.59 and an H-1 doublet at τ 5.23 with a spacing of 1.3 c.p.s.

Methyl 3,4-Di-O-acetyl-2-O-methyl-6-O-trityl-α-D-mannopyranoside

Methyl 2-*O*-methyl-6-*O*-triytyl-α-D-mannopyranoside (15 g) dissolved in dry pyridine (45 ml) was treated with acetic anhydride (45 ml) and the mixture was kept at 22 °C for 48 h. The reaction mixture was added dropwise to a vigorously stirred ice-water mixture (2 l) and the precipitated product was collected, washed with water, and dried to yield methyl 3,4-di-*O*-acetyl-2-*O*-methyl-6-*O*-trityl-α-D-mannopyranoside (15.2 g) (m.p. 59–61 °C) which after recrystallization from ethanol had m.p. 60–61 °C and $[\alpha]_D$ +44° (*c*, 2 in chloroform).

Anal. Calcd. for $C_{31}H_{34}O_8$: C, 69.63; H, 6.41; OMe, 11.6. Found: C, 69.9; H, 6.6; OMe, 11.4.

The n.m.r. spectrum of the product in $CDCl_3$ showed a complex multiplet for the triphenylmethyl group centered at τ 2.70, two equal methoxyl signals at τ 6.51 and 6.53, two equal acetoxyl signals at τ 7.96 and 8.26 and an H-1 doublet at τ 5.19 with a spacing of 2.1 c.p.s.

Methyl 3,4-Di-O-acetyl-2-O-methyl-α-D-mannopyranoside

Methyl 3,4-di-*O*-acetyl-2-*O*-methyl-6-*O*-trityl-α-D-mannopyranoside (14 g) dissolved in acetic acid (100 ml) was treated with a saturated solution of hydrogen bromide in acetic acid (15 ml) and after 20 min at 22 °C the reaction mixture was added dropwise with stirring to an ice-water mixture (2 l). The precipitated triphenylcarbinol was removed by filtration and the filtrate, kept at 0 °C, was neutralized with sodium bicarbonate. The solution was extracted with chloroform (3 × 400 ml) and the dried (anhydrous Na_2SO_4) extract was concentrated to a syrup (6.9 g) which slowly crystallized. Pure methyl 3,4-di-*O*-acetyl-2-*O*-methyl-α-D-mannopyranoside (6 g) obtained by recrystallization from ether had m.p. 91 °C and $[\alpha]_D$ +73° (*c*, 1 in chloroform).

Anal. Calcd. for $C_{12}H_{20}O_8$: C, 49.31; H, 6.90; OMe, 21.2. Found: C, 49.2; H, 7.0; OMe, 21.1.

The n.m.r. spectrum of the product in $CDCl_3$ showed two equal methoxyl signals at τ 6.51 and 6.57, two equal acetoxyl signals at τ 7.91 and 7.94, and an H-1 doublet at τ 5.20 with a spacing of 1.8 c.p.s.

A portion of the methyl 3,4-di-*O*-acetyl-2-*O*-methyl-α-D-mannopyranoside (0.1 g) in pyridine (1.5 ml) containing triphenylchloromethane (0.12 g) was kept at 80 °C for 1 h and the product isolated in the normal way was fractionated by preparative thin-layer chromatography to yield methyl 3,4-di-*O*-acetyl-2-*O*-methyl-6-*O*-trityl-α-D-mannopyranoside (0.12 g) which had m.p. and mixture m.p. 90 °C, $[\alpha]_D$ +72° (*c*, 1 in chloroform) and gave an n.m.r. spectrum identical with the authentic material.

Methyl 3,4-Di-O-acetyl-2,6-di-O-methyl-α-D-mannopyranoside

Methyl 3,4-di-*O*-acetyl-2-*O*-methyl-α-D-mannopyranoside (5.5 g) in dry dichloromethane (60 ml) containing boron trifluoride etherate (0.1 ml) kept at 0 °C was treated with diazomethane in dichloromethane until a faint yellow color persisted and after 30 min the white solid (polymethylene) was removed on a coarse sintered glass filter and the filtrate was concentrated to a syrup (5.2 g). The syrup was dissolved in an ether – light petroleum (b.p. 60–80 °C) mixture and on cooling to 10 °C crystalline methyl 3,4-di-*O*-acetyl-2,6-di-*O*-methyl-α-D-mannopyranoside (5 g) was obtained which had m.p. 61 °C and $[\alpha]_D$ +65.2° (*c*, 1.5 in chloroform).

Anal. Calcd. for $C_{13}H_{22}O_8$: C, 50.98; H, 7.24; OMe, 30.37. Found: C, 51.1; H, 7.3; OMe, 30.3.

The n.m.r. spectrum of the product in $CDCl_3$ showed three equal methoxyl signals at τ 6.57, 6.60, and 6.65, two equal acetoxyl signals at τ 7.96 and 8.00 and an H-1 doublet at τ 5.25 with a spacing of 1.8 c.p.s.

2,6-Di-O-methyl-D-mannose

Methyl 3,4-di-*O*-acetyl-2,6-di-*O*-methyl-α-D-mannopyranoside (5 g) in ethanol (5 ml) was treated with 2 *N* sulfuric acid (70 ml) and the mixture was heated on a boiling water bath for 5 h. The cooled reaction mixture after neutralization ($BaCO_3$) was passed down a column of mixed Rexyn 101(H^+) and Duolite A4(OH^-) ion-exchange resins (25 ml) and the eluate and washings were

concentrated to a syrup (3.1 g). Paper chromatographic analysis of the product showed a major component giving a red color with the *p*-anisidine hydrochloride spray reagent (R_G 0.72) together with a very faint spot corresponding in position with a mono-*O*-methylhexose. The syrup was fractionated on a cellulose column (5 × 40 cm) using butan-1-ol half saturated with water as the mobile phase and the fraction corresponding to 2,6-di-*O*-methyl-D-mannose was collected and concentrated to a syrup (2.8 g). The 2,6-di-*O*-methyl-D-mannose gave a single spot on paper chromatography (R_G 0.72) and had $[\alpha]_D$ +22.4° (*c*, 3.5 in water).

Anal. Calcd. for $C_8H_{16}O_6$: C, 46.15; H, 7.75; OMe, 29.8. Found: C, 46.1; H, 7.7; OMe, 30.0.

The n.m.r. spectrum of 2,6-di-*O*-methyl-D-mannose in deuterium oxide showed three methoxyl signals (total six protons) having τ 6.53, 6.58, and 6.61 and two doublets at τ 4.70 (spacing 1.5 c.p.s.) and τ 5.11 (spacing 2 c.p.s.) in the ratio 1:1.4 which are assigned to the respective α and β anomers of the glycose present in equilibrium.

Gas–liquid chromatographic analysis of the trimethylsilylated 2,6-di-*O*-methyl-D-mannose gave two peaks having T_G 0.77 (63%) and 0.96 (37%). The glycose had zero mobility on paper electrophoresis in 0.05 *M* sodium tetraborate.

2,6-Di-*O*-methyl-D-mannose (15 mg) was heated in a sealed tube at 90 °C for 5 h with 2% methanolic hydrogen chloride (2 ml) to yield the glycoside which on gas–liquid chromatography gave a single peak having T_G 3.24.

2,6-Di-O-methyl-D-mannonic Acid Phenylhydrazide

2,6-Di-*O*-methyl-D-mannose (0.1 g) was oxidized with bromine water at room temperature (48 h) and the 2,6-di-*O*-methyl-D-mannono-1,4-lactone (92 mg), isolated in the usual way, was a syrup which had $[\alpha]_D$ +58° (*c*, 5 in water) and on gas chromatography gave a single peak having T_G 3.68. Its infrared spectrum (smear on KBr disk) showed a carbonyl absorption at 1780 cm^{-1}. The lactone (80 mg) gave a phenylhydrazide derivative which after recrystallization from ethanol gave pure 2,6-di-*O*-methyl-D-mannonic acid phenylhydrazide (40 mg) which had m.p. 130 °C and $[\alpha]_D$ −40° (*c*, 0.5 in water).

Anal. Calcd. for $C_{14}H_{22}N_2O_6$: C, 53.49; H, 7.05; N, 8.91. Found: C, 53.5; H, 7.0; N, 9.0.

2,6-Di-O-methyl-D-mannitol (1,5-di-O-methyl-L-mannitol)

2,6-Di-*O*-methyl-D-mannose (0.1 g) in water (5 ml) was reduced by the addition of sodium borohydride (50 mg) and after 6 h the mixture was acidified with acetic acid and was passed down a column of Rexyn 101(H^+) ion-exchange resin (15 ml). The eluate and washings were concentrated to dryness and the residue was reconcentrated from methanol solution (5 × 25 ml) to remove boric acid to yield 2,6-di-*O*-methyl-D-mannitol (82 mg) as a syrup which had $[\alpha]_D$ +18.5° (*c*, 0.5 in water).

2,6-Di-*O*-methyl-D-mannitol (45 mg) was oxidized with 0.15 *M* sodium metaperiodate (5 ml) in a solution made up to 25 ml with distilled water. Samples were withdrawn at intervals for analysis; 1.88 moles of periodate were consumed and 0.85 mole of formic acid was released per mole of di-*O*-methylhexitol (constant value after 2 h oxidation at 22 °C). No formaldehyde was produced during the oxidation.

Peak doubling in the nuclear magnetic resonance spectra of certain phosphorus esters

R. V. JARDINE, A. H. GRAY, AND J. B. REESOR
Chemistry Section, Defence Research Establishment Suffield, Ralston, Alberta

Received May 28, 1968

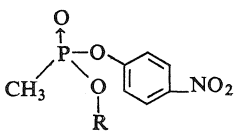
Doubling of nuclear magnetic resonances of certain mixed phosphorus esters has been observed and has been attributed to the presence of rotational conformers occupying "up" and "down" orientations of the ester moieties. Treatment of these esters with uranyl nitrate results in the expected resonances, although chemically shifted.

This is believed to be due to the "freezing" of rotational conformers by complex formation. Dependence of the observed resonances upon temperature supports this hypothesis. There appears to be some steric control over the relative population of the contributing conformers.

Canadian Journal of Chemistry, 47, 35 (1969)

Introduction

The literature contains several references to the doubling of absorptions in nuclear magnetic resonance (n.m.r.) spectra obtained on a variety of compounds. A number of explanations for this phenomena have been advanced, including partial bond hybridization (1), stereochemical nonequivalence of geminal protons (2), and hindered rotation (3, 4). Pertinent to this investigation is the work of Siddall and Prohaska (5) who reported doubling of resonances in a number of arylphosphinic and arylphosphonic esters and offered several alternative explanations. For example they attributed their findings to a different magnetic environment experienced by the phosphoryl alkoxy groups due to rotation about the P — O — C linkage, the observed resonances due then to contributions from one alkoxyl group "up", the other "down" with respect to the phosphoryl function. They also suggested, for the case of the isopropyl derivatives, a magnetic nonequivalence of the β methyl protons due to a "near to" and "far from" orientation with respect to the benzene ring, and they did not rule out the possibility of selective separation of diastereomers during preparation of the compound. It was concluded by these authors that a phenyl ring was a necessary structural feature.

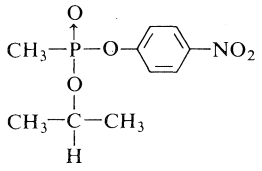


1

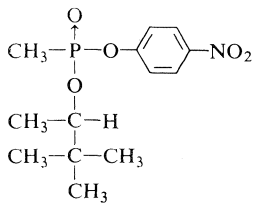
We have investigated mixed phosphorus esters of the general formula, **1**, and have observed doubling of resonances in a number of cases. Our choice of mixed esters, which include variation in asymmetry and in steric properties, has allowed a clear separation of the O—R moieties in the n.m.r. spectrum. With these compounds it has been possible to demonstrate that the O-alkyl function is occupying "up" and "down" conformations, a conclusion supported by temperature studies which show that peak doubling is not maintained at higher temperatures, i.e. 150 °C. We have further demonstrated that the conformation may be "frozen" probably in the "down" position by complex formation, utilizing uranyl nitrate. The alternative argument of "near to" and "far from" β methyl protons cannot be applied consistently to our compounds.

Results and Discussion

The spectra of isopropyl *p*-nitrophenyl methylphosphonate, (**2**), pinacolyl *p*-nitrophenyl methylphosphonate, (**3**), and pinacolyl *o*-chloro-*p*-nitrophenyl methylphosphonate, (**4**,) exhibited peak doubling.



2



3

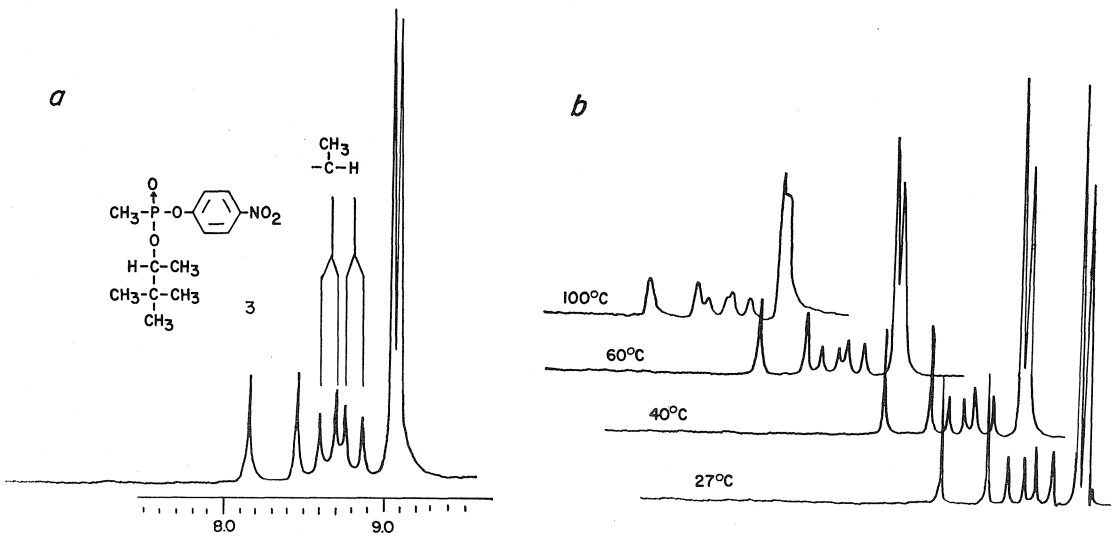


FIG. 1*a*. Partial nuclear magnetic resonance spectrum of pinacolyl *p*-nitrophenyl methylphosphonate, **3**, obtained in carbon tetrachloride using TMS as internal standard; *b*. Partial nuclear magnetic resonance spectra of pinacolyl *p*-nitrophenyl methylphosphonate, **3**, obtained in tetrachloroethylene at various temperatures.

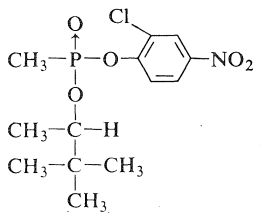

4

In isopropyl *p*-nitrophenyl methylphosphonate, (**2**), the β methyl protons appear as two doublets in solution. The β methyl protons of **3**, and **4**, appear as two doublets at $\tau = 8.83$ ($|J_{H-H}| = 6.5$ Hz); $\tau = 8.66$ ($|J_{H-H}| = 6.5$ Hz), (**3**): and $\tau = 8.65$ ($|J_{H-H}| = 6.5$ Hz); $\tau = 8.80$ ($|J_{H-H}| = 6.5$ Hz), (**4**): instead of the expected doublet (s) (see Table I). The tertiary butyl protons of the pinacolyl groups, normally singlets, as in pinacolyl methylphosphonochloridate, also appear as *two* singlets (see Fig. 1*a*).

The methine protons[1] of isopropyl *p*-nitrophenyl methylphosphonate, (**2**), and pinacolyl *p*-nitrophenyl methylphosphonate, (**3**,) revealed apparent 16 and 13 line spectra respectively (Figs. 4*a*, 4*b*). These resonances result from two sets of signals chemically shifted from each other by 1.9 Hz (**2**) and 2.05 Hz (**3**), which are split by phosphorus ($|J_{P-H}| = 8.0$ Hz) and resplit by the β methyl protons ($|J_{H-H}| = 6.4$ Hz), (**2**); ($|J_{H-H}| = 6.5$ Hz), (**3**).[2]

A computer programed for an A_6B system produced essentially the same pattern for the B region of **2** when four spectra were superposed 1.9, 8.0 and 9.9 Hz apart. Two superposed A_3BX spectra separated by 2.05 Hz produced the B portion of **3** (see Figs. 4*a*, 4*b*).

In all cases only one set of resonances due to the aromatic ring are present. We believe that this results from the fact that the aromatic protons lie well under the π electron cloud of the benzene ring, preventing operation of a through space mechanism (8). The *p*-nitrophenyl derivatives exhibit resplitting ($J = 1.0$ Hz) of the high field aromatic protons. This is probably due to

[1]The authors gratefully acknowledge Dr. T. H. Siddall III, Savannah River Laboratory, E. I. Dupont de Nemours & Co., Aiken, South Carolina, U.S.A., for drawing to our attention the significance of fully interpreting the methine proton signals.

[2]These spin systems may be regarded as superposed A_6BX, $A_6'B'X$ and A_3BX, $A_3'B'X$ respectively. As an approximation, the B portion of an A_6BX system has been calculated by superposing two parts of A_6B systems (6) in each of which there are 16 non zero lines. The system A_6B and A_6BX has been fully treated by Ranft (7). A note on the computer technique is to be published by A. Delaney.

the proximity of the phosphorus atom. Long-range phosphorus coupling has recently been described in substituted benzyltriphenylphosphonium bromides. The magnitude of the coupling constant was found to be $p\text{-}CH_3 > o\text{-}CH_3 > m\text{-}CH_3$ (9).

Spectra of pinacolyl methylphosphonochloridate (neat and in CCl_4) also exhibited small doubling of the β methyl resonances ($\simeq 1$ Hz), which illustrates that a phenyl ring is not an essential structural feature. However, no similar doubling was noted in the spectrum of isopropyl methylphosphonochloridate or pinacolyl methylphosphonofluoridate (Soman, **5**). The complete spectrum of the latter, is presented in Fig. 2*a* for reference.

The dependence of the resonances of **2**, **3**, and **4** upon temperature was determined in tetrachloroethylene. Spectra of pinacolyl *p*-nitrophenyl methylphosphonate, (**3**), are presented in Fig. 1*b* and show that the peak separation for the β methyl and tertiary butyl groups are temperature dependent. As the temperature is increased, the peaks tend to coalesce.[3] The boiling point of the solvent did not allow higher temperature runs, however, in diphenyl ether complete coalescence of the peaks was observed at 150 °C, although the peaks were considerably broadened. Thus isopropyl *p*-nitrophenyl methylphosphonate, (**2**), pinacolyl *p*-nitrophenyl methylphosphonate, (**3**), and pinacolyl *o*-chloro-*p*-nitrophenyl methylphosphonate, (**4**), must exist in two rotameric conformations.

Moreover, compound **4** assumes "preferred" conformations in a ratio of about 2:3 (Fig. 2*b*). This is probably due to steric factors associated with the chlorine atom in close juxtaposition to the phosphorus. The n.m.r. spectra of compounds **2** and **3** did not reveal a similar preference (Fig. 1*a*).

Finally, isopropyl *p*-nitrophenyl methylphosphonate, **2**, pinacolyl *p*-nitrophenyl methylphosphonate, **3** and pinacolyl *o*-chloro-*p*-nitrophenyl methylphosphonate, **4**, were complexed with uranyl nitrate in pyridine. Burdett and Burger (10) have shown this to be a particularly useful technique for separating overlapping absorptions in n.m.r. spectra. They showed that the presence

[3]The same effect has been demonstrated in dimethyl formamide (3). At room temperature two absorptions are observed for the methyl protons, these coalesce at about 150 °C into a singlet.

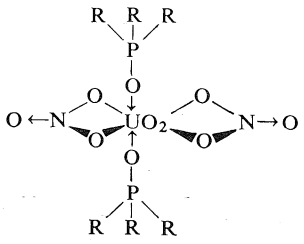
of uranyl nitrate produced a significant downfield chemical shift[4] of the resonances of protons located on atoms as far as three bonds removed from phosphorus. All three compounds, **2**, **3**, and **4**, when complexed with uranyl nitrate[5] revealed this characteristic downfield shift. More significant, however, was the disappearance of peak doubling of the β methyl and tertiary butyl groups of the pinacolyl functions of **3** and **4** (Fig. 3*a*, 3*b*) and Table I. This is undoubtedly due to the fixation of the molecules into one conformation. The experimental technique does not permit a selective separation of diastereoisomers in the case of compounds **3** and **4**. The methine protons of **2** and **3** were simplified by complex formation. In pyridine **2** and **3** revealed broadened 8 and 5 line spectra respectively. Splitting of high-field aromatic protons is maintained after complex formation, confirming the integrity of the P—O—phenyl bond (acetone solution).

Our conclusion that certain organophosphorus esters exist in two forms, viz., "up" and "down" rotational conformers is well substantiated by our experimental results. It is consistent with the observations of doubling of spectra and changes which occur at high temperature. The use of mixed esters of vastly differing chemical shift has been used advantageously to observe the resonances of individual O—R moieties both in complexed and non-complexed forms.



6

Experimental

Nuclear magnetic resonance (n.m.r.) spectra were determined on a Varian Associates A-60 instrument equipped with a V-6057 variable temperature system. Spectra were obtained as 20% w/v solutions in pyridine unless otherwise noted. Temperature experiments were cycled and spectra (n.m.r. and infrared (i.r.)) were obtained before and after, precluding decomposition during the experiment. On pertinent spectra the field was swept in both directions. Computed spectra were obtained on an IBM 1130 computer.

Thin-layer chromatography (t.l.c.) was carried out on Eastman Chromagram Sheet, type K 301 R (silica gel)

[4]While a downfield shift is normally observed, J. R. Ferraro (11) reports some cases of more highly shielded protons, as a result of complex formation with uranyl nitrate.

[5]X-ray crystallographic studies (12) have shown uranyl nitrate complexes of phosphoryl compounds to have the structure **6**.

with reagent chloroform as eluting solvent. Spots were visually located with iodine vapor. Elemental and n.m.r. analyses were in agreement with the proposed structures.

Column chromatography was carried out on Mallinckrodt silicic acid (chromatographic grade) eluting with benzene.

Isopropyl p-Nitrophenyl Methylphosphonate (2)[6]

Essentially the Fukuto (13) procedure was followed using 32.2 g (0.2 mole) of anhydrous sodium *p*-nitrophenoxide and 31.2 g (0.2 mole) of isopropyl methylphosphonochloridate in 250 ml of dry toluene. The yellow sodium salt had been previously dehydrated by azeotropic distillation of a toluene suspension to yield the red, anhydrous salt. After allowing the reagents to react for 15–20 min at room temperature the red color of the solution was discharged and a white precipitate (NaCl) formed. After refluxing 2 h the mixture was washed with 6 × 150 ml of distilled water and dried over anhydrous sodium sulfate. Distillation afforded the pure ester, b.p. 109°/0.005 mm; yield 31 g (61%); lit. (14) 130°/0.25 mm. Thin-layer chromatography of the material showed two spots of R_f 0.51 and 0.25. It was shown that with this and with a different solvent system, 5% MeOH/$CHCl_3$, the lower spot had an R_f value, identical with an authentic sample of *p*-nitrophenol. The n.m.r. spectra, however, showed no free phenol.

Pinacolyl p-Nitrophenyl Methylphosphonate (3)

Method a

A procedure similar to that used to prepare **2** was carried out on 32.2 g (0.2 mole) sodium *p*-nitrophenoxide and 39.7 g (0.2 mole) of pinacolyl methylphosphonochloridate in 250 ml toluene. The red color of the anhydrous salt disappeared after about 15–20 min. After further refluxing for 2 h the product was washed several times with water, dried over Na_2SO_4, and distilled to yield 33 g (55%) of yellow oil of b.p. 130–135°/0.03 mm, n_D^{25} 1.5092. Thin-layer chromatography showed two spots, an upper one of R_f 0.56 and a lower one of 0.25 corresponding to *p*-nitrophenol.

Anal. Calcd. for $C_{13}H_{20}NO_5P$: C, 51.82; H, 6.69; N, 4.65; P, 10.28. Found: C, 51.50; H, 6.67; N, 5.15; P, 10.10.

Method b

A run similar to Method *a* was carried out on 20 g (0.1 mole) of the chloridate and 16.1 g (0.1 mole) sodium *p*-nitrophenoxide. The red color of the salt disappeared after 10–15 min. Thin-layer chromatography of an aliquot taken after 1 h of refluxing showed the same two spot pattern as the distilled material from run *a*. The solution was refluxed 4 h more and let stand overnight. Thin-layer chromatography of an aliquot showed no further change had taken place. The toluene solution was then filtered through Celite and the solvent distilled. A fraction of this yellow residue (10.5 g) was chromatographed on 200 g of silicic acid eluting with benzene. The early fractions contained *p*-nitrophenol (note reverse order—the phenol is the lower spot on t.l.c.). After several hundred ml of eluent were collected, the desired material began to come off as shown by t.l.c. and inhibited cholinesterase preparation. In this way about 5 g of material were collected. The n.m.r. and t.l.c. results were identical to those obtained with the distilled material from Method *a*.

Pinacolyl o-Chloro-p-nitrophenyl Methylphosphonate (4)

Anhydrous sodium *o*-chloro-*p*-nitrophenoxide 12.65 g (0.073 mole) in 100 ml dry toluene was treated with 14.5 g (0.073 mole) pinacolyl methylphosphonochloridate in 50 ml dry toluene in a dropwise manner. An exothermic reaction ensued (28–42°). On completion of addition the products were refluxed 3 h, cooled and a quantity of Celite added. The products were then filtered through a Celite filter pad, followed by toluene. The resulting solution was then distilled yielding a viscous yellow oil (5 g, 21.8%) of b.p. 135–138°/0.01 mm.

[6]CAUTIONARY NOTE: The compounds described in this paper are toxic anticholinesterases and must be handled with requisite care.

Uranyl Nitrate Complexes General

One molar equivalent of uranyl nitrate hexahydrate in sufficient pyridine to maintain solubility was treated with two equivalents of the phosphorus ester. The resulting solution was stirred 8 h and the n.m.r. spectrum obtained directly from an aliquot of the resulting yellow solution. When it was of interest to examine the aromatic region, the complexes were prepared in acetone.

Acknowledgments

The authors wish to thank Mr. A. S. Hansen, Miss L. E. Nelson, and Mr. L. R. Provost for assistance in the synthesis of the compounds described and for the n.m.r. spectra. Thanks are also extended to Mr. R. Hicken for the elemental analyses and to Mr. A. Delaney for programming computed spectra.

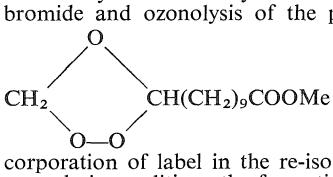
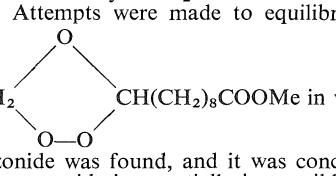
Reactions of ozonides. VIII. An examination of the possibility of reversible ozonide formation using ^{14}C labelling

DUNDAPPA R. KERUR AND DENNIS G. M. DIAPER
Department of Chemistry and Chemical Engineering, Royal Military College of Canada, Kingston, Ontario
Received May 15, 1968

Carboxyl-^{14}C-10-formyldecanoic acid was made by $^{14}CO_2$ carbonation of 10-undecenylmagnesium bromide and ozonolysis of the product. Attempts were made to equilibrate its methyl ester with



and

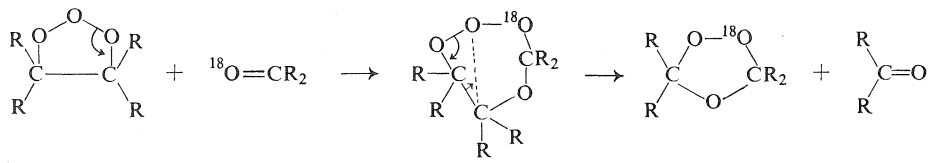


in various solvents. Little incorporation of label in the re-isolated ozonide was found, and it was concluded that under normal ozonolysis conditions the formation of ring ozonide is essentially irreversible. Slight incorporation in chloroform is explicable either by reversal of the Criegee mechanism of ozonide formation or by reversal of the recently suggested regenerative carbonyl – primary ozonide reactions.

Canadian Journal of Chemistry, 47, 43 (1969)

A recent interest in the mechanism of formation of ozonides from olefins has been sparked by a close examination of the stereochemistry of the reaction. The Criegee mechanism (1) accommodates stereospecificity by invoking a solvent cage which must be penetrated in cross-ozonide formation (2). To explain different *cis–trans* ozonide ratios in cross ozonides from *cis* and *trans* olefins, a mechanism has been proposed involving a carbonyl – primary ozonide interaction step (3). Recently, refinements have been added to the Criegee mechanism by advocating the formation of *syn* and *anti* zwitterions which combine stereospecifically with aldehydes or ketones to yield ozonides (4).

Two schools have studied ozonide ring formation using isotopic oxygen (3*b*, 5, 6). Incorporation of the label in both the ether and peroxidic oxygens of aliphatic ozonides was interpreted to mean simultaneous operation of the Criegee mechanism and a regenerative carbonyl – primary ozonide interaction as shown:



In the aromatic ^{18}O study, peroxide incorporation was very nearly negligible and the label appeared in the ether oxygen. This supports the Criegee mechanism, but does not exclude interactions of the type shown above, because it was pointed out that the same seven-membered intermediate can give ether-labelled ozonide by a C—O fission of the primary ozonide as shown below rather than O—O fission as shown above:

‡Counting errors were determined as standard deviations (7).

These results have prompted us to reexamine the reversibility of ozonide formation. Each of the mechanisms considered calls for nonreversible ozonide formation but the nonuniform ^{18}O incorporation in peroxide and ether oxygens could also be explained by reversal of the carbonyl–ozonide step. Early work was based on ozonolyses in the presence of foreign carbonyl compounds and indicated nonreversibility. We have used a ^{14}C tracer technique which is more sensitive and permits the "foreign" aldehyde to be chemically identical with that from the substrate.

For our studies we chose the ozonide of methyl 10-undecenoate. This ozonide is readily purified from peroxidic reaction products, is relatively stable and is easy to handle. The nonperoxidic decomposition product of interest obtained from this ozonide is the methyl ester of sebacic semialdehyde. In earlier experiments we prepared this compound labelled with ^{14}C on the ester methyl carbon by reacting ^{14}C-diazomethane with sebacic semialdehyde. However, it soon became evident that use of this compound in equilibration studies with the ozonide was obscured by considerable ester interchange.

We then decided to use the next higher homologue, the methyl ester of carboxyl-^{14}C-10-formyldecanoic acid. This was readily prepared from 11-bromo-1-undecene by the sequence of steps shown in the Experimental section.

Equilibration of methyl 10-undecenoate ozonide with the ^{14}C-labelled aldehyde ester was attempted at room temperature for 18–48 h in solvents which varied over a wide range of polarity. Solvents used were chloroform, methanol, ether, acetone, and dimethyl sulfoxide. Ozonide could be recovered in good yield from each of these solvents except the last.

Separation of the ozonide and the aldehyde ester was effected on a silica gel column. Advantage was taken of the fact that on elution with 5% ether in petroleum ether (30–60°), the ozonide moved considerably faster than the aldehyde ester. Once the ozonide fraction had been completely removed, recovery of the aldehyde ester fraction was expedited by washing the column with ether.

Under the experimental conditions used, the ozonide did not show any appreciable decomposition except in dimethyl sulfoxide. The latter proved to be unsuitable for our purposes and no ozonide was recovered after attempted equilibration. The effects of this solvent on ozonides will be the subject of a later communication.

Examination of Table I reveals that, in none of the solvents used except chloroform did we observe any significant amounts of radioactivity in the recovered ozonide fraction. Almost all of the activity could be accounted for in the non-ozonide fraction. In chloroform some equilibration does occur, negligible under normal ozonation conditions.

The chloroform experiment was repeated using the methyl ester of carboxyl-^{14}C-10-formyldecanoic acid and methyl 11-dodecenoate ozonide. After contact, specific activity of the recovered ozonide was 6.06 ± 0.13 *c*/min/mg and that of the recovered aldehyde ester was 147.8 ± 0.43 *c*/min/mg. The ozonide fraction was rechromatographed and found to have a specific activity of 7.09 ± 0.22 *c*/min/mg. The fact that purification did not decrease the specific activity but rather slightly increased it, shows that the radioactivity was not attributable to impurity. While negligible under ordinary

preparative conditions, this must mean that during prolonged contact, some formation of ozonide from the carbonyl moiety can occur.

A time study of aldehyde–ozonide reaction in chloroform showed that equilibrium was approximately half way attained in 0.5–4 h. There was no attempt to control catalyst traces (such as HCl from chloroform photooxidation in moist air) and no quantitative conclusions were drawn about reaction rate, but in this solvent, under ordinary ozonolysis conditions, exchange amounting to a few per cent may be possible.

If this reaction takes place by the reopening of the ozonide ring to form carbonyl and zwitterion fragments, this implies a finite lifetime for the zwitterion in chloroform during which a nonradioactive carbonyl fragment is replaced by a labelled carbonyl fragment which has diffused to the reaction site. Reaction of the zwitterion with itself or with solvents such as methanol or acetone, would prohibit labelled ozonide formation.

If the carbonyl – initial ozonide regenerative mechanism for ozonide formation can be reversed, the nature of the solvent should also affect the rate and extent of the reverse mechanism. Acetone would compete with the labelled carbonyl compound and lead to low incorporation. Polar solvents by encouraging charge separation would assist forward and reverse reactions. Incorporation of the label would therefore depend on reactions competing with the forward reaction. It was noticed that a purified ozonide during prolonged storage gives polymeric peroxidic products as well as the aldehyde and acid expected as decomposition products. The observed small incorporation of label when ozonide and aldehyde are contacted for prolonged periods in chloroform is therefore explicable by both types of ozonide formation mechanisms. Caution must be used in detailed quantitative interpretation of labelling mechanism studies if conditions permit reverse reaction.

Any quantitative study of ozonide formation, such as the recent ^{18}O work (5, 6) should be interpreted with the possibility of equilibration in mind. Aromatic compounds show less incorporation of ^{18}O in the peroxide oxygen of the ozonide ring than do the aliphatic compounds reported. It is not likely that the difference can be explained by equilibration, which our study shows to be near negligible under ordinary ozonolysis conditions, rather it is explicable by reactivity differences between the various intermediates involved. An aromatic zwitterion for example would be expected to be different from an aliphatic zwitterion because of resonance stabilization.

In view of these observations, it seems safe to conclude that there is no equilibrium established between the ozonide on the one hand and the zwitterion and the carbonyl moiety on the other, under customary ozonide preparation conditions when carbonyl concentration is low, temperature is low and contact time short. Moreover, significant fission of the ozonide ring to reform the zwitterion is also unlikely. Fliszar (8, 9) has shown that the zwitterion can change into carbonyl compound by bimolecular elimination of oxygen. Ozonide ring closure is thus essentially nonreversible in ozonide formation from this terminal olefin.

Experimental

Barium carbonate-^{14}C was from New England Nuclear Corp., Boston, Massachusetts. It had a specific activity of 5.0 millicuries/mmole.

"Baker Analyzed" reagent grade silica gel powder was used for column chromatography.

Thin-layer chromatography was performed on Eastman Chromagram sheets without fluorescent indicator.

3% Potassium iodide in 5% aqueous acetic acid was used for spraying.

Melting point was determined on a Fisher–Johns melting point apparatus and is uncorrected.

Counting of radioactive samples was done on a Nuclear-Chicago counter. Nuclear magnetic resonance (n.m.r.) spectrum was recorded on a Varian A-60A model spectrometer using tetramethylsilane as internal reference.

Microanalyses were carried out by Microanalyses Laboratory, Toronto.

10-Undecenoic acid, m.p. 21–23°, was from Brickman and Company, Montreal. Its methyl ester, b.p. 244–248°, n_D^{24} 1.4388, was prepared by refluxing with methanol in the presence of concentrated sulfuric acid.

The ozonide of methyl 10-undecenoate was prepared by passing a stream of ozone-oxygen mixture through a solution of the ester in carbon tetrachloride. After removing the solvent on a rotary evaporator, the residue was chromatographed on a silica gel column. A solution of 5% ether in petroleum ether (30–60°) was used for elution. Fractions were examined by thin-layer chromatography and those that reacted readily with the spray reagent to give single spots were pooled. Removal of the solvent gave the ozonide as a white powdery material. It was stored under nitrogen at −10° and was used as soon as feasible. Methyl 11-dodecenoate ozonide was similarly prepared and isolated using the corresponding olefinic ester as starting material. Its n.m.r. spectrum in $CDCl_3$

showed the expected $COOCH_3$ signal at $\delta = 3.63$ p.p.m. and the chain CH_2 protons as a broad peak at $\delta = 1.32$. The α-CH_2 triplet (position-2) was centered at $\delta = 2.28$. The characteristic terminal alkene ozonide signal was two singlets of the non-equivalent methylene located at $\delta = 4.98$ and 5.12 superimposed on the CH triplet centered at $\delta = 5.09$ with a coupling constant of 4.5 c.p.s.

^{14}C-Labelled aldehyde ester was prepared by the following sequence of reactions.

$$CH_2{=}CH(CH_2)_8CH_2Br \xrightarrow[2)\ {}^{14}CO_2\ 3)\ H^+\ 4)\ CH_2N_2]{1)\ Mg} CH_2{=}CH(CH_2)_8CH_2{}^{14}CO_2CH_3$$

$$CH_2{=}CH(CH_2)_8CH_2{}^{14}CO_2CH_3 \xrightarrow[2)\ Zn/CH_3CO_2H]{1)\ O_3} CHO(CH_2)_8CH_2{}^{14}CO_2CH_3$$

The n.m.r. spectrum of an undiluted sample of the aldehyde ester showed a singlet at $\delta = 3.63$ ascribed to $-COOCH_3$, two α-CH_2 triplets centered at $\delta = 2.05$ and $\delta = 2.29$. The chain $-CH_2$ protons gave a peak at $\delta = 1.30$ and the —CHO proton was observed at $\delta = 9.70$. The characteristic terminal ozonide signal at $\delta = 5$ p.p.m. was absent. Peaks due to ozonide were absent from the infrared spectrum. A nonradioactive sample of the aldehyde–ester and the radioactive sample had identical infrared spectra. The semicarbazone of the aldehyde ester melted at 112–114° (lit. (10) 114–115°).

Anal. Calcd. for $C_{13}H_{25}O_3N_3$: N, 15.49. Found: N, 15.04, 14.99.

The radioactive aldehyde–ester was dissolved in ether and aliquots were withdrawn for equilibration experiments. The ether solution registered about 20 000 *c*/min/ml.

The ozonide and the radioactive aldehyde ester were mixed in 1–5 ml each of methanol, chloroform, acetone, and dimethyl sulfoxide at room temperature for about 18–48 h. After standing, solvent was removed if necessary and the residue chromatographed on a silica gel column. Appropriate fractions corresponding to the ozonide and the aldehyde ester were pooled and evaporated. Residues were usually taken up in 10 ml of ether. One ml of this solution was evaporated on a planchet and counted. In order to clarify the slight incorporation observed when chloroform was used as a solvent a further experiment was conducted as follows: Methyl 11-dodecenoate ozonide and the methyl ester of carboxyl-^{14}C-10-formyldecanoic acid were mixed in 5 ml of chloroform and allowed to stand at room temperature for 24 h. The ozonide and aldehyde–ester fractions were separated using a silica gel column as described above and their specific activities determined. The recovered ozonide was repurified using a silica gel column and its specific activity was redetermined.

In another experiment 250 mg of methyl 11-dodecenoate ozonide and approximately 250 mg of the methyl ester of carboxyl-^{14}C-10-formyldecanoic acid (128.2 $\pm$ 0.71 *c*/min/mg) were mixed in 5 ml of chloroform at 28°. Separation was performed by silica gel chromatography as previously described after 30 min of contact. The specific activity of recovered ozonide was 4.79 $\pm$ 0.10 *c*/min/mg raised to 4.85 $\pm$ 0.09 *c*/min/mg on repurification. In a similar experiment with similar quantities but a contact time of 1 h, recovered ozonide had 3.42 $\pm$ 0.22 *c*/min/mg. After 8 h of further contact with an additional 250 mg of radioactive aldehyde–ester in 5 ml of chloroform, this sample was re-isolated and now had 8.32 $\pm$ 0.10 *c*/min/mg. In a similar experiment with 4 h of contact time, recovered ozonide had 3.44 $\pm$ 0.20 *c*/min/mg and after a further 14 h of contact with a fresh 250 mg sample of radioactive aldehyde–ester this was raised to 7.90 $\pm$ 0.19 *c*/min/mg.

Corrections were made for background counts (81–108 *c*/min.)

Synthesis of 3-(1,1-ethylenedioxyoctyl)-cyclopentanone

D. E. Orr and F. B. Johnson
Department of Chemistry, Lakehead University, Port Arthur, Ontario
Received August 12, 1968

1,4-Cyclohexanedione has been converted into compounds **8** and **9**. Treatment of **8** and **9** with base produces compound **10**, which has been converted into 3-(1,1-ethylenedioxyoctyl)-cyclopentanone.

Canadian Journal of Chemistry, 47, 47 (1969)

A number of publications have recently appeared (1–6) describing the syntheses of various naturally occurring prostaglandins and related compounds. With the exception of the elegant method of Corey *et al.* (1) all the syntheses described so far rely on the modification of a five-membered ring compound to produce the prostaglandin skeleton.

We have approached the problem by using a readily available six-membered carbocyclic ring compound as the starting material. A seven carbon atom side chain is added in the first step. At a later stage in the reaction sequence, the length of the seven carbon atom chain is increased by one carbon atom by the contraction of the six-membered ring to produce a suitably substituted five-membered ring. The ring contraction not only gives a side chain of the correct length but also generates a ketone function in the eight carbon side chain, in a position suitable for later introduction of the allyl alcohol function.

When a half-molar equivalent of *n*-heptyl magnesium bromide was added to 1,4-cyclohexanedione it was possible to separate 4-heptyl-4-hydroxycyclohexanone **1** as the mono-adduct from the reaction mixture.

The keto-alcohol **1** was quantitatively reduced to 1-heptyl-1,4-cyclohexanediol **2**. The nuclear magnetic resonance (n.m.r.) spectrum has broad multiplets at τ 6.15 and 6.5 of roughly equal area corresponding to epimeric alcohols. Thin-layer chromatography (t.l.c.) confirmed that two closely related compounds were present.

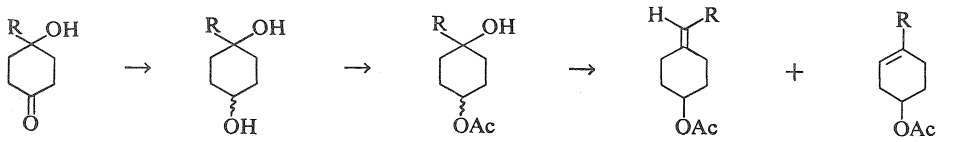
Acetylation of the epimeric mixture of diols with acetic anhydride – pyridine gave the monoacetate **3**. The acetate **3** was dehydrated by heating under reflux in acetic anhydride to give a product composed of two compounds (by t.l.c.). The n.m.r. spectrum has peaks due to a hydrogen atom on a double bond and a hydrogen atom attached to the same carbon atom as the acetoxy group. Also included in the spectrum are two sharp peaks at τ 8.06 and 8.02, due to two very similar acetate methyl groups. The chromatographic and n.m.r. evidence is compatible with the product being composed of exocyclic and endocyclic double bond isomers **4** and **5**, respectively.

Acid-catalyzed equilibration of this olefinic mixture converted it into the more stable endocyclic olefin **5** (7). The reaction could be followed conveniently by the disappearance of one of the spots on the t.l.c. plate. Further reactions in the synthetic sequence, and the broad peak in the n.m.r. spectrum at τ 4.7 indicate that the product is correctly represented by structure **5**.

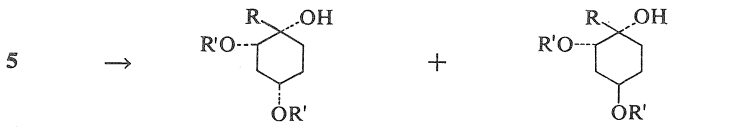
cis-Hydroxylation of 1-heptyl-4-acetoxy-1-cyclohexene **5** was effected by treating it with OsO_4–pyridine in ether (8). The intermediate complex was decomposed on treatment with mannitol. The decomposition of the complex also resulted in partial hydrolysis of the acetoxy group. Complete hydrolysis occurred on treatment of the product with KOH in aqueous alcohol, to give the two possible epimeric triols **6** and **7**.

The triol epimers were converted into the corresponding secondary ditosylates by treating with tosyl chloride and pyridine. Two crystalline ditosylates **8** and **9** (R = Ts) could be isolated from the reaction product. Elemental analyses and almost identical infrared (i.r.) spectra were consistent with the fact that these two compounds were indeed epimeric at the secondary tosyl group in the 4-position.

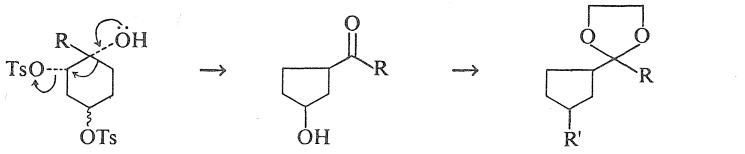
Treatment of the mixture of crystalline tosylates with $CaCO_3$ in dimethyl formamide under reflux brought about the desired ring contraction, as was shown by the appearance of a peak at 1700 cm^{-1} in the i.r. spectrum of the product **10** (9). The secondary tosyl group was also lost in the work-up as was shown by the absence of characteristic peaks in the i.r. and n.m.r. spectra, and by



1 R = *n*-heptyl **2** R = *n*-heptyl **3** R = *n*-heptyl **4** R = *n*-hexyl **5** R = *n*-heptyl



6 R = *n*-heptyl R′ = H
8 R = *n*-heptyl R′ = Ts
7 R = *n*-heptyl R′ = H
9 R = *n*-heptyl R′ = Ts



8 or **9** R = *n*-heptyl **10** R = *n*-heptyl **11** R = *n*-heptyl R′ = OH
12 R = *n*-heptyl R′ = =O

the presence of a peak at 3400 cm^{-1} in the i.r. spectrum of the product, due to the hydroxyl group.

The rearrangement product **10**, which was homogeneous on t.l.c., was converted into the ethylene ketal **11** by heating under reflux in benzene with ethylene glycol and a catalytic amount of *p*-toluenesulfonic acid.

The ketal was oxidized with chromium trioxide in pyridine to give the keto-ketal **12**. The product was homogeneous by t.l.c. analysis and had a peak in the i.r. spectrum at 1740 cm^{-1}, showing the presence of a five-membered ring ketone.

Elemental analyses and the n.m.r. spectrum were also in agreement with structure **12**. A sharp peak at τ 6.1 is indicative of the ethylene ketal protons and a broad multiplet centered at τ 7.8 is due to the hydrogen atoms α to the ketone. The remainder of the n.m.r. spectrum is in agreement with the presence of a large hydrocarbon side chain.

These results show that this approach to the prostaglandin skeleton is feasible and we are now in the process of incorporating the seven carbon atom side chain by direct alkylation or by rearranging the appropriately substituted cyclohexane ring.

Experimental

Infrared (i.r.) spectra were of chloroform or carbon tetrachloride solutions. Nuclear magnetic resonance (n.m.r.) spectra were of deuteriochloroform or carbon tetrachloride solutions with tetramethylsilane as internal standard.

4-Heptyl-4-hydroxycyclohexanone **1**

A solution of *n*-heptyl bromide (17.5 g; 0.1 mole) in anhydrous ether (150 ml) was added dropwise over a period of 2 h to a stirred mixture of magnesium (2.43 g; 0.1 mole) and ether (50 ml). During the addition, reflux was maintained by occasional warming of the reaction flask. After addition was complete, reflux was continued for 1 h. The Grignard reagent solution was cooled and transferred to a dry 250 ml dropping funnel while maintaining a nitrogen atmosphere. The Grignard reagent was then added dropwise to a stirred solution of 1,4-cyclohexanedione (10 g; 0.1 mole), in anhydrous ether (200 ml). Addition was completed in 2 h after which the reaction was heated under reflux for 1 h.

The reaction mixture was allowed to cool and then diluted to 600 ml with ether. The resulting organic layer was washed with a saturated solution of ammonium chloride until the aqueous washings were acidic. The organic layer was then washed with water, and after drying, the ether was removed by flash evaporation. The crude product was obtained as a clear, viscous, yellow oil (5.96 g). Thin-layer chromatography (silica–ether eluent) revealed the presence of four products, in an overall yield of 37%.

Vacuum distillation of the crude product gave 4-heptyl-4-hydroxycyclohexanone **1**; b.p. 0.9 mm 128°, in a 24% yield (3.84 g) as a clear, viscous, yellow oil; n_D^{25} 1.4741.

Thin-layer chromatography (silica–ether eluent) of the product showed the presence of one compound.

Infrared spectrum: 3600 cm^{-1}, 3400 cm^{-1}. Nuclear magnetic resonance spectrum: τ 6.4 (hydroxyl hydrogen, disappears when treated with D_2O), τ 8.1 (4 hydrogens α to the ketone) τ 8.6–9.1 (remaining methyl and methylene hydrogens).

1-Heptyl-1,4-cyclohexanediol **2**

1-Heptyl-4-hydroxycyclohexanone (1.80 g) was dissolved in methanol (50 ml). Sodium borohydride (1.50 g) was added in one portion to the solution. After 1 h, water (10 ml) was added to destroy the excess of sodium borohydride. The reaction mixture was diluted to 100 ml with ether and the organic layer was washed with 2% HCl solution followed by washing with water. The organic layer was dried over anhydrous magnesium sulfate, filtered, and the ether removed by flash evaporation to give 1.67 g of product (92% yield). Thin-layer chromatography (silica–ether eluent) indicated two products with no indication of starting material.

Infrared spectrum: 3600 cm^{-1}, 3400 cm^{-1}. Nuclear magnetic resonance spectrum: τ 6.15 and 6.5 (hydrogens on the same carbon atoms as the hydroxyls), τ 7.6 (hydroxyl hydrogen), τ 8.4–9.1 (methyl and methylene hydrogens).

A sample of the cyclohexanediol was recrystallized, to analytical purity (m.p. 74–77°) from petroleum ether (b.p. 30–60°) – ether. Thin-layer chromatography showed one spot.

Anal. Calcd. for $C_{13}H_{26}O_2$: C, 72.84; H, 12.23; O, 14.93. Found: C, 72.99; H, 12.24; O, 14.91.

1-Heptyl-4-acetoxy-1-cyclohexene **5**

1-Heptyl-1,4-cyclohexanediol (2.21 g) was dissolved in anhydrous pyridine (50 ml) to which acetic anhydride (30 ml) was added. The reaction was allowed to stand at room temperature for 24 h. The excess acetic anhydride and pyridine were removed by flash evaporator and the reaction residue was diluted to 150 ml with ether. The organic layer was washed with 2% HCl solution, sodium bicarbonate solution, followed by water. Removal of the dried ether gave 2.08 g of a clear, viscous, yellow oil in 80% yield. Thin-layer chromatography (silica–ether eluent) indicated that there were two new products.

The product mixture (2.08 g) was not further purified (i.r. and n.m.r. indicated mono-acetate), but was heated under reflux for 24 h in acetic anhydride (100 ml). The reaction was cooled and approximately one-half of the acetic anhydride was removed by flash evaporator. The residue was diluted to 250 ml with ether, then washed with a 1% sodium hydroxide solution until the aqueous extracts were basic then with water until neutral. Removal of the dried ether gave 1.85 g of a yellow, viscous oil, corresponding to a yield of 89%. Thin-layer chromatography (silica–benzene eluent) indicated the presence of two products.

The n.m.r. spectrum showed narrowly spaced singlets (τ 8.04, 8.06) probably due to the exocyclic and endocyclic forms of the alkene acetate **4** and **5** respectively.

The mixture of **4** and **5** (1.85 g) and *p*-toluenesulfonic acid (1.9 g) were dissolved in benzene (50 ml) heated under reflux for 2 h. The reaction was cooled and diluted to 150 ml with benzene. The benzene layer was washed with a 2% sodium bicarbonate solution followed by water. Removal of the dried benzene gave 1.85 g of 1-heptyl-4-acetoxy-1-cyclohexene as a viscous, yellow oil; n_D^{25} 1.4547. The yield was quantitative. Thin-layer chromatography (silica–benzene eluent) indicated one product.

Infrared spectrum: 1740 cm^{-1}, 1600 cm^{-1}. Nuclear magnetic resonance spectrum: τ 4.7 (hydrogen on double bond), τ 5.15 (hydrogen attached to the same carbon atom as the acetoxy group), τ 8.05 (singlet, acetoxy methyl hydrogens), τ 8.7–9.1 (remaining methyl and methylene hydrogens).

Anal. Calcd. for $C_{15}H_{26}O_2$: C, 75.58; H, 10.99; O, 13.42. Found: C, 75.88; H, 11.05; O, 13.15.

1-Heptyl-1,2,4-cyclohexanetriol **6** *and* **7**

Osmium tetroxide (7.0 g) was added to a cold solution of 1-heptyl-4-acetoxy-1-cyclohexene (6.97 g) in dry ether (150 ml) and dry pyridine (4.5 ml). The reaction was left for 6 days at room temperature. The dark colored reaction mixture was filtered to give 6.96 g of a brown complex.

The complex was decomposed by stirring overnight with a solution composed of mannitol (2 g) and KOH (10 g) in water (100 ml). Ether extraction gave 2.44 g of product which was a mixture of the desired triol and monoacetylated triol. Hydrolysis of this mixture with 5% KOH EtOH–H_2O solution (60 ml) converted it into 2.38 g of crude triol.

The above filtrate was similarly treated with mannitol–KOH solution to give a further 2.33 g of product identical with that obtained from the complex. Total product: 4.77 g–72% yield. Infrared spectrum had absorption peaks at 3600 cm^{-1} and 3400 cm^{-1} due to non-bonded and bonded —OH. The n.m.r. spectrum had peaks at τ 5.9 (1 H broad multiplet), τ 6.2 (1 H poorly resolved triplet), τ 7.4 broad peak due to hydroxyl hydrogens, τ 8.0–9.1 envelope due to remaining methylene and methyl hydrogens.

Anal. Calcd. for $C_{13}H_{26}O_3$: C, 67.79; H, 11.38; O, 20.84. Found: C, 67.67; H, 11.63; O, 20.92.

Tosylation of 1-Heptyl-1,2,4-cyclohexanetriol **6** *and* **7**

p-Toluenesulfonic acid chloride (4.6 g) and 2.0 g of a mixture of **6** and **7** were dissolved in dry pyridine (90 ml). The resulting solution was left at room temperature for 20 h.

The majority of the pyridine was removed under reduced pressure, and the residue was dissolved in benzene. The benzene solution was washed with 5% aqueous $NaHCO_3$, and after drying the benzene was removed under reduced pressure to give 4.3 g of crude product.

Crystallization of the residue from a mixture of ether – petroleum ether (b.p. 30–60°) yielded 500 mg of a compound, which after repeated crystallizations melted at 107°.

Infrared spectrum: 3500 cm^{-1}, 1600 cm^{-1}, 1180 cm^{-1}. Nuclear magnetic resonance spectrum: τ 2.15–2.7 (AB quartet, aromatic hydrogens), τ 5.6 (broad multiplet due to hydrogens on same carbon atoms as O-tosyl), τ 7.5 (singlet, aromatic methyl hydrogens), τ 8.0–9.1 (remaining methyl and methylene hydrogens).

Anal. Calcd. for $C_{27}H_{38}S_2O_7$: C, 60.19; H, 7.10; O, 20.79; S, 11.90. Found: C, 60.37; H, 7.32; O, 20.06; S, 11.98.

Crystallization of the material from the above mother liquors from ether – petroleum ether (b.p. 30–60°) yielded 400 mg of a second compound which after repeated crystallizations melted at 62°.

Infrared spectrum: 3500 cm^{-1}, 1600 cm^{-1}, 1180 cm^{-1}. Nuclear magnetic resonance spectrum: τ 2.15–2.7 (AB quartet, aromatic hydrogens), τ 5.4 (broad multiplet due to hydrogens on same carbon atoms as O-tosyl), τ 7.55 (singlet, aromatic methyl hydrogen), τ 8.1–9.1 (remaining methyl and methylene hydrogens).

Anal. Calcd. for $C_{27}H_{38}S_2O_7$: C, 60.19; H, 7.10; O, 20.79; S, 11.90. Found: C, 60.19; H, 7.14; O, 20.97; S, 11.99.

The two crystalline compounds had distinctly different R_f values -0.31 for the isomer melting at 107° and 0.59 for the isomer melting at 62°—on t.l.c. (silica – petroleum ether (b.p. 30–60°) eluent). The i.r. spectra were almost identical (small differences in 900–950 cm^{-1} range).

Rearrangement of 1-Heptyl-1,2,4-cyclohexanetriol-2,4-ditosylate ***8*** *and* ***9***

Crystalline ditosylate (500 mg) was dissolved in freshly distilled dimethyl formamide (30 ml) and dry $CaCO_3$ (500 mg) was added. The resulting suspension was heated under reflux with stirring for $2\frac{1}{2}$ h.

The reaction mixture was added to benzene (100 ml) and washed several times with water. Removal of the benzene gave 175 mg of an oily product **10**—88% yield. Thin-layer chromatography showed one spot. The i.r. spectrum showed absorption bands at 3600 cm^{-1}, 3400 cm^{-1}, and 1700 cm^{-1}. The n.m.r. spectrum showed peaks at τ 5.7 (broad multiplet, hydrogen on some carbon atom as the hydroxyl), τ 7.6 (broad multiplet, methine hydrogen α to ketone), τ 8.1 (poorly resolved triplet, methylene hydrogens α to ketone), τ 8.7–9.1 (broad envelope, due to remaining methylene and methyl hydrogens).

Preparation of Ethylene Ketal ***11***

The hydroxy ketone **10** (163 mg) and a catalytic amount of *p*-toluenesulfonic acid were dissolved in benzene (50 ml) in the presence of ethyleneglycol (1 ml). The resulting mixture was heated under reflux for 3 h. All traces of water were removed by means of a water separator.

After cooling, the benzene solution was washed with 5% $NaHCO_3$ and water. Removal of the benzene yielded 148 mg of ketal. The product gave one spot on t.l.c. examination, showed no ketone in the i.r. spectrum, and had a sharp peak at τ 6.15 in the n.m.r. spectrum due to the ethylene ketal hydrogens.

Preparation of Ketal–Ketone ***12***

The hydroxy ketal **11** (133 mg) dissolved in dry pyridine (2 ml) was added to a slurry of CrO_3 (500 mg) in dry pyridine (15 ml). The resulting mixture was stirred at room temperature for 24 h.

Ether extraction of the product yielded 98 mg of ketone found to be homogeneous by t.l.c. The i.r. spectrum had a band at 1740 cm^{-1}. The n.m.r. spectrum had a sharp peak at τ 6.1 (hydrogens of ethylene ketal), τ 7.8 (broad multiplet, hydrogens α to ketone), τ 8.7–9.1 (broad envelope, due to methylene, methine, and methyl hydrogens).

Anal. Calcd. for $C_{15}H_{26}O_3$: C, 70.82; H, 10.30; O, 18.87. Found: C, 71.28; H, 10.07; O, 17.97.

Acknowledgments

The photochemical Beckmann rearrangement[1]

H. IZAWA,[2] P. DE MAYO, AND T. TABATA
Department of Chemistry, University of Western Ontario, London, Ontario

Received August 26, 1968

The direct irradiation of aryl aldoximes gives the amide (the photochemical Beckmann rearrangement) by intramolecular oxygen migration. This has been shown by the rearrangement of ^{18}O-labelled benzaldoxime in the presence of *p*-tolualdoxime: no exchange of label was observed.

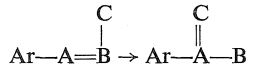
The rearrangement usually gives the amide, but in the case of the anisyl derivative the anilide was also obtained. The highest quantum yield for benzamide formation noted (in acetic acid) was 0.034, but the figure is dependent on irradiation time. The results of low-temperature irradiation suggest that an oxazirane is an intermediate. Phenyl-*N*-methyl oxazirane is converted into the amide on irradiation (though not thermally) and it seems likely that the reaction is induced, under the conditions of the reaction, by benzylic hydrogen abstraction by thermally produced small amounts of benzaldehyde; a fact which may explain the variation in quantum yield of amide formation with extent of irradiation. An additional route from oxazirane to amide may also be available.

The activation of the oxime by high energy sensitizers under the most favorable conditions gives $\Phi_{amide} = 0.002$, and so a singlet pathway for oxazirane formation is preferred. The main route for energy degradation appears to be by *syn–anti* isomerism. This can be induced by a variety of sensitizers and so can be a triplet process. The direct irradiation of benzaldoxime leads to isomerism with $\Phi_{\alpha\beta} = 0.40$ and $\Phi_{\beta\alpha} = 0.38$. From these figures, together with the composition of the stationary state found, the composition of the sensitized stationary state can be calculated in fair agreement with the experimentally found value. This suggests that the isomerization following direct irradiation is also a triplet process.

In a single example of an aralkyl ketoxime (*p*-anisylmethyl ketoxime) irradiation products of both aryl and alkyl migration, were found.

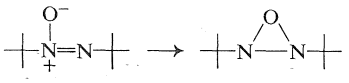
Canadian Journal of Chemistry, 47, 51 (1969)

Many systems of the type (**1**) and its vinylogues have been found to undergo, on irradiation, an overall migration of C, a heteroatom, from B to A.

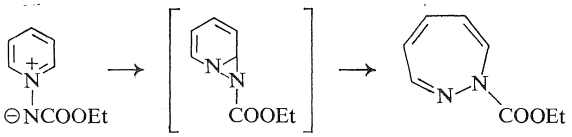


1

Included in this classification[3] are the following: the conversion of azoxybenzenes (A = N; B = $\overset{+}{N}$; C = O^-) to hydroxyazobenzenes (1, 2) and the recent transformation of **2** to **3** (3); the conversion of oxythiobenzoyl chloride (A = C; B = $\overset{+}{S}$; C = O^-) to benzoyl chloride (4) and of 2-methoxynaphthalene thiocarbaldehyde-5-oxide to the aromatic aldehyde (5); the conversion of *N*-oxides and nitrones (A = C; B = $\overset{+}{N}$; C = O^-) to amides (the largest group, of which refs. 6–15 are illustrative); the transformation of methyl isamate to a quinazoline derivative (16, 17) (A = C; B = $\overset{+}{N}$; C = N^-) and, essentially, **4** into **5** (18).[4]



2 **3**



4 **5**

The most studied of these reactions, the nitrone rearrangement, was first reported by Alessandri (19) who noted the isolation of benzanilide from the products of irradiation of *N*-α-diphenylnitrone. An oxazirane intermediate was suspected (20) and later demonstrated (7) in certain cases. Instances have been recorded (22) where the oxazirane does not undergo further transformation to the amide, whilst in others (for example, see refs. 21, 23) the second step is so fast as to preclude the detection of an

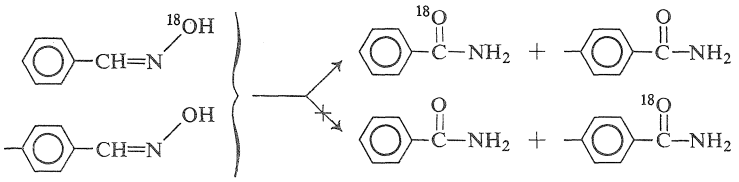
[3]In view of the large literature which has accumulated in recent years on reactions of this type, only a few leading references can be given.

[4]For an analogous carbon transfer see Streith *et al.* (53).



SCHEME I

intermediate whose participation must therefore be conjectural. Occasionally, as in the conversion of **4** to **5**, the intermediate in the heteroatom transfer finds an alternative breakdown pathway (see also ref. 24, and other papers in this series).

In all the instances cited the atom, C, has been such that the bond with A could be formed to give, in principle, a stable product as regards bonding, without necessitating the rupture of a further bond. This transformation appears to be rather general, and further examples of what may be termed a heteroatom transfer may be expected.

Some years ago we reported (25) that aromatic aldoximes gave, on irradiation, the Beckmann products, *viz*, the amides. Briefly, the results then available can be summarized as follows.

Benzamide was obtained from benzaldoxime by irradiation in several solvents. The highest yield (41%) was obtained in acetic acid, but fair yields, comparatively, (20–30%) were obtained in cyclohexane containing 0.5–2.0 equivalents of acetic or trifluoroacetic acids. Lower yields were obtained in dioxan, methanol, or cyclohexane. The reaction was shown to have some generality since rearrangement products were obtained with *p*-methyl-, *p*-chloro-, and *p*-methoxybenzaldoxime, and with α-naphthaldoxime. No amide was obtained with the oximes from *m*- and *p*-nitrobenzaldehyde, *p*-fluorobenzaldehyde, isonicotinic aldehyde, and *p*-cyanobenzaldehyde. The interconversion of the *syn* and *anti* oximes, amongst the earliest of reported photochemical reactions (26) was also observed. Subsequently the obtention of an amide by the irradiation of an alicyclic oxime was reported by Just and his collaborators (27).

This reaction bore at least a superficial resemblance to the nitrone–amide interconversion just discussed. There was, however, a difference of significance. In contrast to the generality of heteroatom transfer reactions an additional nuclear transfer—that of the proton attached to the oxygen—was necessary before an uncharged intermediate could be arrived at. Two other general observations suggested caution in drawing too close a parallel with the nitrone rearrangement. First, the quantum yield, though not known at that stage, was suspected of being very low because of the prolonged times of irradiation needed. Nitrones, on the other hand, rearrange, at least to the oxaziranes, with fair efficiency (28). Secondly, the rearrangement appeared to be best carried out in solvents containing acetic acid, an observation for which there was no analogy in the nitrone series. An analogy with the normal Beckmann itself could be conceived if the relevant excited state of the oxime were sufficiently basic to accept a proton from acids normally too weak to induce the Beckmann rearrangement. In this case reaction would have to follow very rapidly on protonation since collapse to the ground state would be expected to be followed very rapidly by ionization of the proton.

A distinction between the two main pathways available could be clearly made: a heteroatom transfer process would be intramolecular whilst the normal Beckmann is intermolecular (29). To decide, experimentally, between these alternatives, benzaldoxime labelled with ^{18}O was prepared from labelled hydroxylamine. This material was then irradiated in acetic acid in the presence of an equimolecular amount of *p*-tolualdoxime. The amide products were isolated, separated by vapor-phase chromatography, and the ^{18}O content of the individual amides determined. The results clearly indicated that, within the experimental error, all the ^{18}O was retained in the benzamide (1.54 atom % excess) and none found (0.034 atom % excess) in the *p*-toluamide (Scheme I). An intramolecular oxygen transfer, or at least one involving caged radicals or ions was indicated. The photochemical Beckmann, therefore, resembles the normal Beckmann only in so far as the products are concerned.[5]

[5]This was not unexpected since it was known (25) that the oxime acetate did not rearrange. See also ref. 30.

*1:3.
†3% Et_2O.

In a migration of the oxygen atom from nitrogen to carbon, this atom must at some period be bonded to both origin and terminus. This could be, of course, in a transition state, in a reactive intermediate, such as an ion or radical, or as an, in principle, isolable intermediate. In the case of benzaldoxime this would be the presently unknown phenyloxazirane.[6] Despite the fact that simple oxaziranes of this kind were known not to rearrange, at least thermally, to amides, (22) a photochemical route through such species was not excluded (see ref. 32) and seemed attractive. A search for such an intermediate was, therefore, made. Phenyloxazirane[7] has absorption in an inconvenient part of the spectrum since there is much overlap with the starting material and product. The anisyl derivative, on the other hand, is more suitable since any oxazirane formed would be expected to absorb in the window between the main absorption bands of the oxime and of the amide (Fig. 1).

α-*p*-Anisaldoxime was irradiated in *n*-hexane solution at −88°, with light near 290 nm, (see Experimental) in an apparatus in which it was possible, simultaneously, to observe the changes induced in the absorption spectrum. On cooling the solution there was observed a shift in the absorption spectrum (Curve 2, Fig. 2). After irradiation for 50 min, a considerable decrease in absorption was noted in the 270 nm region indicating a decrease in oxime concentration in the beam path. At the same time a peak appeared near 235 nm, the region expected for the oxazirane absorption.[8] On allowing the mixture to warm to room temperature this peak disappeared and the absorption at 270 nm increased though it did not reach its original value. Part of the change must be attributed to slow diffusion in the viscous solution at low temperature and equilibration on warming up.

These results are consistent with the suggestion that, under the conditions of the experiment, an oxazirane was formed. They do not require that the oxazirane necessarily be an intermediate in amide formation.

Further evidence that an oxazirane was formed was obtained from the iodometric test used (22, 31) for quantitative oxazirane estimation. Iodine was liberated from iodide ion at low temperatures, indicating the presence of an oxidizing agent. Addition of iodide ion to the solution after it had warmed to room temperature did not result in iodine liberation. Further, although the amide was a product of this sequence of operations the yield of amide decreased by about 50% if the cold irradiated solution was treated with iodide ion. This suggested a relationship between the oxidizing agent and benzamide formation.

For the oxazirane to be a genuine intermediate in the conversion of the oxime to amide (and not a divergent pathway leading to other products) there must be a thermal or photochemical pathway from it to the amide. This possibility was next examined.

Solutions of phenyloxazirane were found to be very difficult to purify. They contained, as impurities, benzaldehyde and benzaldoxime as well as smaller amounts of unidentified substances. In a solvent mixture of cyclohexane – acetic acid (one of the irradiation media used) the substance was moderately stable, as compared with solutions in pure ether, and the decomposition could be followed. After 24 h (see Table I) little oxazirane, as estimated iodometrically, remained, but the yield of benzamide was about 2%. A similar solution irradiated with an

[6]Recent work by Schmitz (31) has indicated that solutions of this substance may be made, and that derivatives may be prepared, but that the substance itself is unstable. We have confirmed this.

[7]Assuming that this substance absorbs in the same region as the more stable *N*-methyl compound.

§The error in this value may be 100%.

unfiltered medium pressure mercury arc was decomposed rapidly and a yield of 71% amide obtained.

Clearly, then, a route from the oxazirane to the amide was available under the appropriate conditions, but, equally clearly, the problem was not resolved since it was required to be demonstrated that any oxazirane intermediate formed could indeed absorb the incident radiation. For meaningful results, therefore, it was necessary to put the irradiation data on a quantitative basis. Benzaldoxime was irradiated at 2537 Å and near 2900 Å and the quantum yields determined for acetic acid (the best solvent found), cyclohexane and for a mixture of the two. Near 2900 Å the quantum yield was about 3.4% (Table II) and a value of about half that found at 2537 Å. In cyclohexane (2537 Å) a quantum yield of near one-tenth % was obtained. The reaction is therefore very inefficient although the preparative yield is fair. The degradation of the energy was shown to take place mainly through *syn–anti* isomerism (see below)[9] and it thus appeared that if amide formation were a two or multistep process, all (including the rearrangement of the oxazirane) but the first must be quite efficient, at least in acetic acid solution.

That the situation was not simple was revealed when the quantum yield of benzamide was determined after the absorption of varying amounts of energy (Fig. 3).[10] It was found that in the early stages the quantum yield is even lower than found in the earlier determination (Table II) but rises to this value as the reaction proceeds. A tentative conclusion which may be drawn from these results would be that some step in the overall transformation is accelerated (or even induced) by the product itself (the amide) or by a by-product. Specifically, the oxazirane intermediate postulated might be so transformed; and indeed some such explanation is essential if the oxazirane be an intermediate. This is because although irradiation of the oxazirane with unfiltered light does induce the desired transformation, at 290 nm the amount of light absorbed by the oxazirane, especially in the presence of the oxime, is negligible. As has been seen, thermal and acid-catalyzed decay does not lead to the amide. Thus, if the results of the low-temperature experiments be accepted as implying that an oxazirane intermediate be involved in amide formation, then two routes from the oxazirane to the amide must be available. Evidence for a second route was now sought.

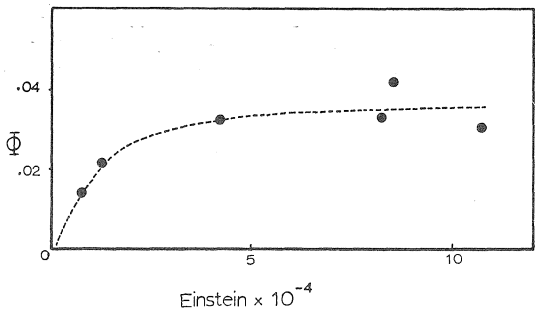

FIG. 3. Variation of quantum yield of benzamide formation in acetic acid solution (0.139 *M* in benzaldoxime) with quanta absorbed near 290 nm.

Of the substances present in the irradiated mixture the most likely candidate for the role of 'catalyst' in the oxazirane–amide conversion was benzaldehyde. The aldehydes are very frequently major products in the thermal breakdown of oxaziranes and their presence in these reactions seems unavoidable. In the present instance the selection of a thermal breakdown product of the oxazirane as the

[9]No emission could be detected at 77 °K.
[10]It was established that the destruction of the amide under these conditions was negligible.

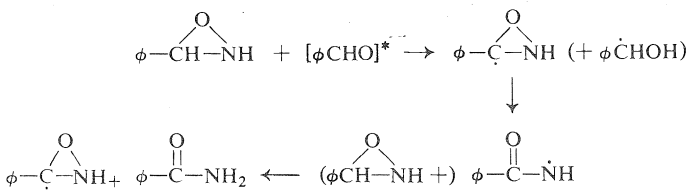
*Irradiation at 334 nm.

conjectural active agent had a further motivation. The accumulation of the oxazirane in detectable amounts in the low-temperature irradiation could be then explained by the absence of this supposed agent following the increased thermal stability of the oxazirane at low temperatures.

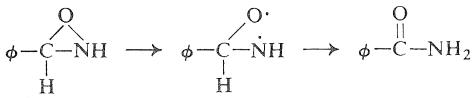
To perform even an approximately quantitative experiment to determine whether benzaldehyde could induce isomerization it was necessary to have a pure oxazirane. We were unable to prepare aldehyde-free solutions of phenyloxazirane itself, but in the hope that the *N*-methyl derivative was a suitable model this substance was prepared and purified such that the residual extinction at 290 nm was ~4.5 (corresponding to a maximum benzaldehyde content of about 0.34%). The absorption gradually increased on standing, decomposition being about 3% in 24 h in acetic acid solution. Irradiation of this solution at 290 nm gave a quantum yield of *N*-methylbenzamide greater than unity (Table III) suggesting a radical chain process. Addition of a small amount of benzaldehyde, such that the aldehyde absorbed 99% of the light, further increased the quantum yield. On the other hand the addition of benzaldoxime reduced the quantum yield dramatically (and led to the formation of some benzamide). Attempted sensitization with triphenylene was largely ineffective.[11]

The evidence available certainly does not lead compellingly to an unequivocal interpretation. One plausible pathway, however, in accord with the available facts, for the conversion of the phenyloxazirane to the amide is that indicated below.



SCHEME II

An alternative pathway from the oxazirane has been suggested (33) as follows:



but whilst this may have relevance to the mechanism for a direct conversion of oxazirane to amide it is not that involved, it would seem, under circumstances when the oxazirane itself does not absorb the light.

The hydrogen-abstracting role of the benzaldehyde in Scheme II is unexceptional, as is the particular abstraction of the benzylic hydrogen atom. The overall scheme therefore favored at

[11]The triplet energy of the phenyloxazirane is not known, but might be expected to be close to that of toluene. Under those circumstances neither benzaldehyde nor triphenylene should be able to sensitize by triplet energy transfer. It does not seem likely that the phenyloxazirane triplet level could be lower than 72 kcal/mole, that of benzaldehyde, yet higher than 67 kcal/mole (triphenylene). Singlet sensitization, previously observed with triphenylene (40), seems the most likely explanation.

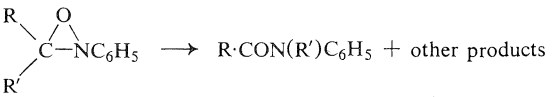
this time is the photochemical conversion of the oxime to the oxazirane, followed by the sequence in Scheme II. Although in the preparative runs unfiltered light was used it is computed that little light could be absorbed by the oxaziranes themselves, until towards the end of the irradiations. At that stage another mechanism may be operative, but we do not consider that, in the cases we have studied, that a direct pathway is unquestionably required. However, in view of our results with a ketoxime (see below) it seems probable. One rationalization would be that the "direct" route merely provided an alternative hydrogen-abstracting radical in a mechanism resembling that in Scheme II. Splitter and Calvin (42) have recently shown that the irradiation of **6** leads both to fragmentation and to rearrangement to the anilide **7**. They have shown that oxygen leads to some quenching of the fragmentation, but not of the anilide formation. In addition, acetone appeared to sensitize the fragmentation, but not the anilide formation,[12] and it is concluded that the anilide formation proceeds through a singlet.



6 **7**

a) R = $(CH_3)_2N{\cdot}C_6H_4$—, R′ = H *b*) R = R′ = C_6H_5—

With a self-consistent and plausible chemical scheme for amide formation available, attention can be turned to the photochemistry of oxime excitation.

The ultraviolet absorption spectra of both the α- and β-oximes of benzaldehyde greatly resemble that of styrene. The O—O band, for instance, of the α-isomer appears to be at 2905 Å (98.0 kcal/mole) whilst that of styrene is, in cyclohexane, at 2915 Å. The origin of this absorption appears to be at about 3100 Å (92 kcal/mole). This absorption is attributed to a $\pi \rightarrow \pi^*$ transition (34, 35), and no absorption corresponding to a lower energy $n \rightarrow \pi^*$ transition has been observed.[13] Further support for the $\pi \rightarrow \pi^*$ assignment was found in the small bathochromic shift observed in polar solvents. The vibronic structure was not blurred. These effects contrast with the large hypsochromic shift expected of $n \rightarrow \pi^*$ absorption bands in general (36).

In styrene, Evans (37) has located the triplet O—O band at 61.7 kcal/mole whilst Hammond and his collaborators give β-methylstyrene as 59.8 kcal/mole (38). This large singlet–triplet splitting (~40 kcal/mole), common to $\pi \rightarrow \pi^*$ systems, if found in the oximes would place the benzaldoxime triplet in the 60 kcal/mole region. We have obtained evidence that it is most probably lower than that. In a rigid matrix at 77 °K the phosphorescence of benzophenone (0.035 *M*) and triphenylene (0.0074 *M*) were both quenched by benzaldoxime (0.17 and 0.018 *M* respectively). In fluid solution, in the presence of biacetyl (55–57 kcal/mole) when the concentration of benzaldoxime (0.099 *M*) exceeded that of biacetyl by 50%, total quenching was observed. The fluorescence of biacetyl was unaffected. Since the *n*, π* singlet–triplet splitting would be expected to be small it

[12]But benzene increases the yield of **7***a* from 10% (in diethylamine) to 24%, and **7***b* from nil to 5%. The fragmentation is also sensitized by *p*-dimethylaminobenzaldehyde which should have a triplet energy far below that of the isolated phenyl or aniline chromophores. The situation is not, therefore, entirely clear-cut.

[13]The $n \rightarrow \pi^*$ of imines appears near 245 nm (39), but is shifted to shorter wavelength in oximes. The C=N absorption in aliphatic oximes is in the 200 nm region, whatever its nature may be.

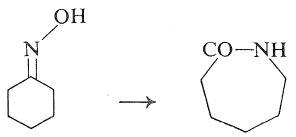
TABLE V

Photostationary states in *syn–anti* isomerism of the benzaldoxime

Irradiation (Å)	$\left[\frac{\beta}{\alpha}\right]$	Sensitizer	E_T (Kcal/mole)
Direct 2537	1.3±0.06	—	—
Sens. >3400	1.7±0.04	*p*-Hydroxyacetophenone	71.3
Sens. >3340	1.6±0.04	Triphenylene	67.2
Sens. >3400	1.8±0.14	Michlers Ketone	62.0

follows that the lowest triplet is π, π*. Hence the states which were most likely candidates for the photochemical Beckmann were the π, π* singlet and π, π* triplet.[14]

Since the phosphorescence quenching showed that triplet energy could be conveyed from triphenylene to benzaldoxime the means were available for testing whether T_1 was the excited species responsible for amide formation. In dioxan solution sensitization with triphenylene or phenanthrene did not lead to the formation of detectable amounts of amide, nor did the use of acetone as solvent (Table IV). The quantum yield on direct irradiation is low under these conditions, however, and sensitization was also attempted in the presence of acetic acid.[15] Under these circumstances a very small quantum yield (0.2%) of amide was detected, but this yield was about 8% of that obtained by direct irradiation at 290 nm under the same solvent conditions. Since, in view of the biacetyl experiment, energy transfer should have been diffusion controlled we are inclined to the view that the π, π* singlet is the photochemically active species leading to oxazirane formation and, hence, to amide. Similar conclusions have been reached by Tanaka and his colleagues with regards oxazirane formation from nitrones (28, 41). An explanation for the very small sensitized quantum yield can be conceived. If the triplet were sufficiently long-lived ($>10^{-3}$ s) the possibility of triplet–triplet annihilation, with concommitant singlet formation, could be considered. But the triplet is not quenched by oxygen (see below), nor does it phosphoresce, so this extended lifetime is improbable. Mixed sensitizer–oxime triplet quenching is also improbable in view of the large excess of acceptor. Just and collaborators (27) have suggested that the rearrangement of **8** to **9** may proceed through a triplet since this reaction is quenched by oxygen. However, as in the present instance, this



8 **9**

may merely mean that some radical intermediate is being trapped. As previously noted for the oxazirane[11] singlet sensitization seems, therefore, the most probable rationalization of this observation.

Geometrical isomerism in the oximes is induced by triplet excitation. Photostationary states in dioxan solution were reached with a number of sensitizers. These states were not identical (Table V) but $\left[\frac{\beta}{\alpha}\right]$ lay between 1.6 and 1.8. The photostationary state ratio obtained by direct irradiation in dioxan solution at 2537 Å was 1.3. The quantum yield for $\beta \rightarrow \alpha$ isomerization, near 2900 Å, was 0.40 ± .013 (dioxan) in the 6–7% reaction range. That for the $\alpha \rightarrow \beta$ was 0.38, and necessitated a small correction for the trace of β isomer contained therein. The photostationary state obtained by direct irradiation should be given by the following expression if the quantum yield of isomerization be independent of wavelength between 2537 and ca. 2900 Å.

$$\left[\frac{\beta}{\alpha}\right] = \left[\frac{\epsilon\alpha}{\epsilon\beta}\right]\left[\frac{\Phi\alpha\beta}{\Phi\beta\alpha}\right]$$

With the available data the right-hand side is estimated as 1.3, in good agreement with the

[14]Very recently (see, for instance, ref. 40) it has been shown that higher states may react chemically. It is not, therefore, excluded that a T_2, formed by intersystem-crossing from S_1, might be the excited state responsible for oxazirane formation.

[15]It was established that the presence of acetic acid did not interfere with energy transfer as indicated by the phosphorescence quenching.

experimentally found value of 1.3. Hammond's simple formula (38) for predicting the photostationary state, *viz.*

$$\left[\frac{\beta}{\alpha}\right] = \left[\frac{\beta}{\alpha}\right]_{sens}\left[\frac{\epsilon\alpha}{\epsilon\beta}\right]$$

does not hold in this instance. It requires that

$$\left[\frac{\beta}{\alpha}\right]_{sens} = \left[\frac{\Phi\alpha\beta}{\Phi\beta\alpha}\right]$$

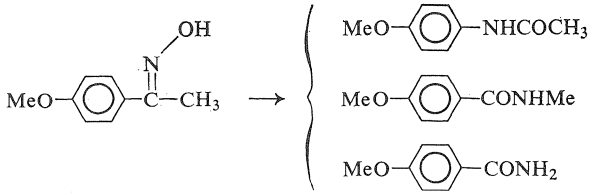
and the former was found, in fact, to be greater than the latter by a factor of 1.6. One of the requirements for the applicability of this formula must, therefore, not hold—perhaps the identity of the intersystem crossing terms. Similar observations have been made with regards to azobenzene isomerization (43, see however 50). It would be reasonable to assume, in view of the closeness of the values, that the isomerization induced by direct irradiation is also passing through the triplet.[16] Such seems to be the case in the stilbenes (44, see however 45), whereas in the azobenzene isomerization the situation is more complex since a ratio of 15–30 was found (43).

Oxygen has no effect on $\Phi_{\alpha\beta}$ despite the fact that sufficient was available to destroy much of the oxime. This would suggest that the triplet has a short lifetime. This isomerization of azobenzene has also been reported to be unaffected by oxygen in solution (46).

In the course of these investigations some further observations were made requiring some modification of the results previously reported (25). *p*-Fluorobenzamide has now been shown to be formed by the irradiation of the oxime in cyclohexane – acetic acid solution through Corex. The yield was about 25%. Irradiation through quartz, as was previously reported, did not give isolable amounts of amide, and it seems probable that the amide produced was destroyed by the shorter wavelength radiation.

The irradiation of *p*-anisaldoxime through Corex gave, in addition to the previously reported anisamide, *p*-methoxyformanilide. Both amides were destroyed by further irradiation. A careful check of the oxime rearrangements previously reported confirmed that the anilides, the products of the alternative migration were absent.

We have investigated a single instance of a ketoxime irradiation. *p*-Methoxyacetophenone oxime in cyclohexane – acetic acid was irradiated through Corex. *N*-*p*-anisylacetamide, *N*-methylanisamide, and *p*-anisamide were obtained in the approximate ratio of 6:6:1.



This reaction involves, together with a minor amount of bond cleavage, both aryl and alkyl migration. The ratio observed seems compatible neither with an ionic nor radical process, but at least one instance of abnormal migration has been observed in a radical process (47).

Experimental

Benzaldoxime-^{18}O

Isotopically enriched potassium nitrite was prepared by equilibration of potassium nitrite (8.5 g) and enriched water (12.5 ml, 1.82 atom % excess ^{18}O) adjusted to pH 4 with concentrated nitric acid. After four days the water was removed, the salt taken up in water and evaporated to dryness under reduced pressure. The residue was redissolved in the same medium at pH 4, left overnight and then diluted with 62 ml enriched water. Sulfur dioxide was passed in (temperature below 0°) and the precipitated potassium hydroxylamine disulfonate collected, washed and dried (19.6 g). The salt (13.44 g) was hydrolyzed with 0.5 *N* hydrochloric acid (62 ml: 100° for 2 h), cooled and barium chloride (60 g) added. After evaporation to dryness the residue was extracted with absolute ethanol to give 3.86 g hydroxylamine hydrochloride.

This product in ethanol (40 ml) containing pyridine (14 ml) and benzaldehyde (5.93 g) was allowed to stand overnight. The solvents were removed and the product isolated with ether.

The ether was removed and the oxime distilled. A small amount of a carbonyl compound was present which was removed by filtering an ethereal solution of the distillate through a thin layer of alumina. The benzaldoxime obtained was checked by comparison of its infrared spectrum with an authentic sample. It contained 1.54 atom % excess ^{18}O.[17]

Irradiation of Benzaldoxime-^{18}O and p-Tolualdoxime

Equimolar amounts (0.00414 *M*) of labelled benzaldoxime and normal *p*-tolualdoxime in acetic acid

[16]Though, indeed, as pointed out by a Referee, there is no *a priori* reason for requiring 'S and 'T states to partition differently.

(200 ml) were irradiated in a quartz well (85 W mercury arc) under nitrogen for 8 h. The acetic acid was removed (< 35°) the residue dissolved in chloroform and the amides separated on a 5 ft × ¼ in. column (3% Craig and 1% Carbowax 20 M on Chromosorb W) at 190°; helium: 170 ml/min. The benzamide (21 min) and *p*-toluamide (35 min) were crystallized from benzene. The benzamide had 1.54 atom % excess ^{18}O and the *p*-toluamide 0.034 atom % excess.[17]

Benzamide Quantum Yields

The solution of β-benzaldoxime in the specified solvent was degassed by the freeze–thaw cycle (to a residual pressure of $< 10^{-4}$ mm). The absorption of light was checked before and after irradiation. After irradiation (using a beam-splitter with a transmittance–reflectance ratio in the region of 10:1) the solvent was removed at low pressure, the residue dissolved in chloroform and the concentration of amide determined by infrared spectroscopy (1676 cm^{-1} band). The conversion (0.5–3.5%) was determined by comparison with a calibration curve. The appropriate controls were carried out. The irradiation took about 24 h. The results are given in Table II.

The variation in quantum yield with total quanta absorbed is shown in Fig. 1.

All actinometry in this and following experiments was by the ferrioxalate method of Hatchard and Parker (48).

Low-Temperature Irradiation of α-p-Anisaldoxime

A cell as described by Hirshberg and Fischer (49) was used. An attachment was made such that degassing could be accomplished outside the rectangular cell. The temperature was measured with an Iron–Constantan thermocouple connected directly to a recorder. The cell was cooled by the passage of nitrogen (dried) precooled by passage through a copper coil immersed in liquid nitrogen. An Osram HBO-200 lamp was used as source and the ~290 nm light isolated by a Baird Atomic interference filter (No. A-21). Irradiations were carried out at right angles to the measuring beam.

Preparation and Irradiation of Phenyloxazirane Solution

To a mixture of 2.12 g benzaldehyde (0.02 *M*), 10 ml of sodium hydroxide (2 *N*), and 16 ml ether, was added a cold solution of 2.26 g (0.02 *M*) hydroxylamine-*o*-sulfonic acid in 20 ml water and 10 ml sodium hydroxide (2*N*) and the stirred solution maintained at 0° for 8 min. The yellow ethereal solution was separated and stirred at 0° for 20 min with a solution of hydroxylamine-*o*-sulfonic acid. The ethereal solution was again separated, washed with water, and dried (Na_2SO_4). The ether was removed with bubbling nitrogen and replaced in portions with cyclohexane. The cyclohexane was then diluted to one-third with acetic acid.

The oxazirane in this solution was estimated by iodide titration (22). After 30 min the original solution (1.3 mg/ml) had decreased to ~85%. After 2 h about half had decomposed and after 24 h about 15% remained. Both the original cyclohexane solution and the cyclohexane – acetic acid solution were examined for benzamide content. The solvents were removed at low temperature. The benzamide was separated by thin-layer chromatography (t.l.c.), extracted with cyclohexane-1-propanol (4:1), centrifuged, and the benzamide estimated spectrophotometrically. The appropriate controls were run. From a set of four experiments the amount of benzamide formed was 2 ± 1%.

The phenyloxazirane solution (63 ml; 5.2 mg/ml in cyclohexane) was diluted to 250 ml with acetic acid. The mixture was degassed with nitrogen and irradiated in an immersion vessel with an 85 W medium pressure mercury arc. After 15 min the irradiation was terminated. No phenyloxazirane remained in the solution. In the control 17% of the phenyloxazirane had been decomposed. Benzamide was estimated as described above. A yield of 71% was found in the irradiated solution and 2% in the non-irradiated control.

Preparation and Irradiation of N-Methyl-3-phenyloxazirane

The oxazirane was prepared by the method of Pews (51) from *N*-methylbenzylidene amine. The product in ethereal solution was washed with hydroxylamine-*o*-sulfonic acid solution to remove benzaldehyde and the solvent evaporated. The resultant material was 85% pure estimated iodometrically. Before use it was distilled four times through a short path distillation column (bath temperature 24°/0.005 mm) ϵ_{289} 4.5; ϵ_{297} 2.5; ϵ_{303} 1.0; ϵ_{313} 0.3, corresponding to a maximum benzaldehyde content of 0.34%.

The oxazirane was irradiated at 290 nm (interference filter) in acetic acid solution, in the presence and absence of added benzaldehyde and benzaldoxime. The results are given in Table III. The amide yields were estimated by thin-layer chromatography (eluent: cyclohexane–acetone 2:1), extraction with cyclohexane–propanol-2 (1:1), centrifugation and estimation by ultraviolet spectrometry. Controls were run. The separation of *N*-methylbenzamide from benzamide was adequate for the estimation of one in the presence of the other.

The Rearrangement of p-Methoxyacetophenone Oxime

The oxime (3.95 g) and acetic acid (24 ml) were dissolved in cyclohexane (200 ml) and the mixture irradiated under nitrogen through a Corex filter in an immersion apparatus (450 W) for 71 h. After removal of the solvent the amides were separated from polymer by preparative thin-layer chromatography (eluent: ethyl ether, light petroleum [35–60°] 1:5), sublimed and the individual amides isolated by thin-layer chromatography in the same solvent system. There was obtained *N*-*p*-anisylacetamide (R_f 0.27) (103 mg), *N*-methyl anisamide (R_f 0.19) (50 mg) and *p*-anisamide (10 mg) (R_f 0.12). All were identified by comparison (including mixture melting points) with authentic specimens.

Irradiation of p-Fluorobenzaldoxime

The oxime (204 mg), acetic acid (8.4 ml), and cyclohexane (200 ml) were irradiated through Corex in an immersion apparatus (450 W). After removal of the solvent the residue was chromatographed. Elution with ethyl ether – light petroleum (5:1) gave the amide, crystallized from ethanol (50 mg).

Irradiation of p-Anisaldoxime

80 ml of a solution of cyclohexane containing 94 mg α-*p*-anisaldoxime and 81 ml acetic acid were irradiated on an optical bench at 290 nm for 16 h. After evaporation of the solvent at low temperature, followed by t.l.c.

separation, *p*-anisamide (44 mg) was obtained together with (3 mg) *p*-methoxyformanilide.

Sensitized Benzaldoxime Equilibration

The relative amounts of α- and β- oximes were determined by taking aliquots periodically during the irradiation. The oximes were separated by t.l.c. (eluent: light petroleum [60–80°] – diethyl ether 4:1). The areas containing the oximes (detectable under ultraviolet light) were extracted with cyclohexane–*n*-propanol (4:1). Control experiments showed that this mixture extracted 99% of the oximes. Further, the silicic acid sedimented rapidly and permitted the obtention of reproducible results when this solvent mixture was used. With other solvents, such as methanol, large blanks were obtained and were variable.

The oximes were shown to be stable to this treatment, and the concentrations were computed from the separately determined molar extinction coefficients in the same solvent system.

The results are given in Table IV.

Structure of "phytic acids"

L. F. JOHNSON
Spectroscopy Applications Laboratory, Varian Associates, Palo Alto, California

AND

M. E. TATE[1]
Department of Agricultural Biochemistry, Waite Agricultural Research Institute, University of Adelaide, South Australia, Australia

Received June 24, 1968

Evidence is presented to show that cereal grain phytic acid has the myoinositol hexaorthophosphate structure suggested by Anderson and not the hydrated myoinositol tripyrophosphate structure proposed by Neuberg. DL-Myoinositol 1,6:2,3:4,5-tripyrophosphate which is structurally related to the Neuberg formulation has been prepared. The "phytic acid" fraction from chicken blood has been shown to be predominantly 1,3,4,5,6-myoinositol pentaphosphate. The structures assigned to these compounds have been confirmed by ^{31}P nuclear magnetic resonance.

Introduction

Myoinositol hexaphosphate or phytic acid as it is frequently called, has been the subject of several reviews (1–4). The name "phytic acid" has been used interchangeably in the literature with the term "phytin" which more correctly refers to the mixed calcium and magnesium salt of the acid (2).

The term "la phytine" was first employed by S. Posternak (5) to describe the major organic phosphate component of seeds, and at that time, he considered it to be an intermediate in the fixation of carbon dioxide by chlorophyll. Although this concept was later abandoned, the name was retained and subsequently applied to similar materials from soil (6) and the blood of birds and turtles (7).

By the application of ion exchange procedures, the heterogeneity of "phytic acid" from soil was revealed (8) and Cosgrove (1) has shown it to be a complex mixture of polyphosphates, which includes esters of inositols other than myoinositol.

The availability of an improved electrophoretic procedure (9) for establishing homogeneity and ^{31}P nuclear magnetic resonance (n.m.r.) for structure determination, has enabled us to reinvestigate the nature of the inositol polyphosphate fractions from cereal grains and chicken blood, with occasionally surprising results. In this paper, the term phytic acid (without quotation marks) will be restricted to signify the myoinositol hexaphosphate from cereal grains.

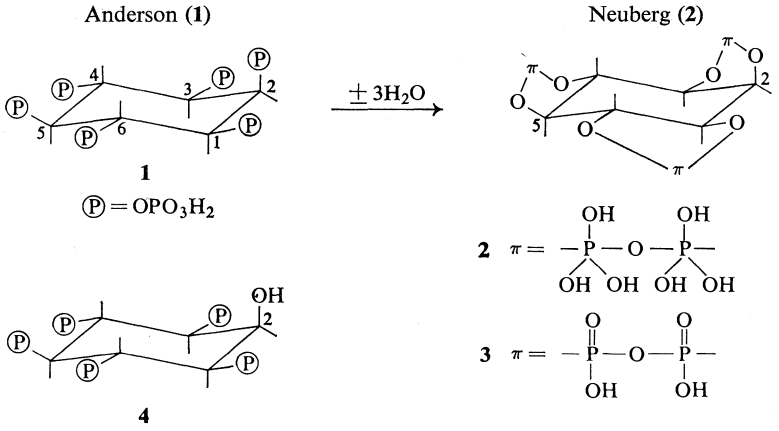
Results and Discussion

(a) Cereal Grain Phytic Acid

If the conformational aspects are neglected, the problem posed by the structure of cereal grain phytic acid simplifies to a consideration of the symmetrical hexaorthophosphate structure **1** proposed by Anderson (10) and the asymmetrical hydrated tripyrophosphate structure **2** proposed by Neuberg (11), to account for the apparently stable trihydrate of phytic acid.

There can be little doubt that many of the earlier studies were hampered by the paucity of criteria for establishing the purity of phytic acid. Several authors (12–14) have commented adversely on the quality of commercial phytate preparations and Fig. 1, lane 3 shows the complexity of one batch of "biochemical grade" sodium phytate. Considerable variation in composition was found among samples from different suppliers and even between batches from a single source. They ranged in purity from the example in Fig. 1 to almost homogeneous sodium phytate. The last traces of lower phosphates were removed from a commercial sample of calcium phytate (ex maize) by conversion to the sodium salt (1, 15) with repeated crystallization from aqueous methanol (16) until the material was chromatographically and electrophoretically homogeneous (Fig. 1, lane 2). At least two crystalline modifications were observed with 31 and 35



molecules of water of crystallization. They differ from the hydrates with 38 and 44 molecules of water described by Posternak (15) and do not melt, instead they display characteristic differential thermal analysis patterns. The stable crystalline sodium phytate with 31 molecules of water was used as the reference standard in this work.

Cogent arguments (2, 4) in favor of the Neuberg formulation **2**, rest mainly on studies indicating that salts of phytic acid form trihydrates, which it was thought (15) were not capable of further dehydration without decomposition, and secondly upon experiments (17) performed with material which analyzed for an octadecasodium salt of phytic acid.

In our work both crystalline hydrates of sodium phytate were found to have a sodium: phosphorus ratio of 2.0:1 in agreement with the observations of Posternak (15) and Hoff-Jorgensen (18). However, by subjecting the crystalline reference material to a precipitation with ethanol from strongly alkaline solution, according to the procedure of Brown, Heit, and Ryan (17), an amorphous product was obtained. It exhibited a high sodium:phosphorus ratio (2.2:1) and was found to be a mixture of sodium phytate and sodium carbonate. Brown, Heit, and Ryan have utilized the high sodium:phosphorus ratio (3:1) obtained for their material, as evidence for the existence of an octadecasodium salt of phytic acid, but as neither a carbon analysis nor an inositol estimation were given to corroborate this assumption, it and the subsequent potentiometric titration data must be considered of doubtful validity. The careful potentiometric titration results by Hoff-Jorgensen (18) on crystalline sodium phytate clearly show the presence of six strongly dissociated protons (pK's < 3.5) and six weakly dissociated protons (pK's 4.6–10) and are in accord with the Anderson structure **1**.

Both of the crystalline hydrates of sodium phytate were found to dehydrate readily at 100° to a product which analyzed for a trihydrate in agreement with previous work (15, 18). However, by prolonged heating *in vacuo* at 145° the trihydrate was found to dehydrate to at least a monohydrate, without detectable decomposition. At higher temperatures (150–210°) the decomposition mentioned by Posternak (15) was observed.

The dehydration of sodium phytate to a monohydrate, obviated the original necessity (11) to postulate the hydrated tripyrophosphate structure **2** for this material. It should not be construed that further dehydration is impossible. However, with standard analytical procedures it is technically very difficult to analyze such hygroscopic material.

It would seem that although the water molecules are strongly held to the phosphate anions, they are held by hydrogen bonds and are not covalently bound by the hydration of P=O groups. It should be noted that the known compounds (19, 20) with the sp^3d orbital arrangement for phosphorus, are unstable in hydroxylic solvents and revert to the the sp^3 arrangement. In the case of structure **2**, this would lead to the formation of the inositol tripyrophosphate structure **3**.

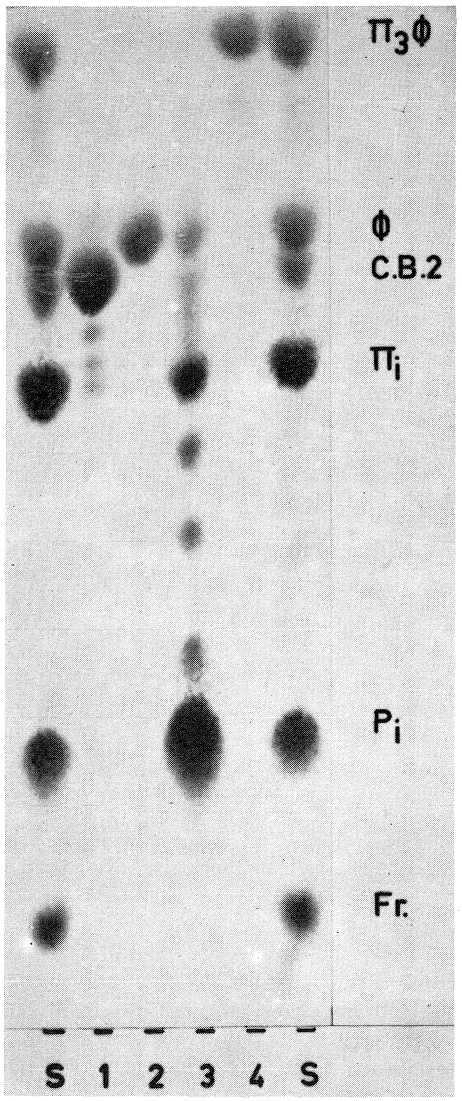

FIG. 1. Electrophoretogram (0.1 *M* oxalate, pH 1.5, 1 h, 1500 V, CCl_4 coolant, phosphomolybdate dip reagent). Components of Lane S in decreasing order of mobility are: myoinositol 1,6:2,3:4,5-tripyrophosphate ($\pi_3\phi$), cereal grain phytic acid (ϕ), major inositol polyphosphate from chicken blood (C.B.2), inorganic pyrophosphate (π_i), inorganic orthophosphate (P_i), uncharged marker (fructose, Fr.). Lane 1, crude inositol polyphosphates from chicken blood. Lane, 2, crystalline cereal grain sodium phytate. Lane 3, commercial sodium phytate. Lane 4, myoinositol 1,6:2,3:4,5-tripyrophosphate.

with dicyclohexylcarbodiimide gave products with electrophoretic mobilities greater than phytic acid. With increased reaction time at 60°, the fastest moving component ($\pi_3\phi$) predominated and is shown in Fig. 1, lane 4. It was rapidly hydrolyzed back to phytic acid under acid conditions and, unlike sodium phytate, the sodium salt showed a strong POO^- antisymmetric absorption at 1255 cm^{-1} (21) in the infrared spectrum. The analysis, chemical behavior, and spectroscopic properties of this product are consistent with the inositol tripyrophosphate structure **3**.

To examine the suggestion (17) that the hexaorthophosphate structure may be a degradation product of the Neuberg formulation, phytic acid was extracted from wheat under conditions which did not degrade the model inositol tripyrophosphate. The sodium salt of the major polyphosphate isolated under these conditions was found to be indistinguishable from the crystalline reference sample of sodium phytate. It appears that, in wheat, phytic acid is stored as the hexaorthophosphate *in situ* and is not an artifact of the usual acidic isolation procedures. In the course of the extraction, ferric ions were observed in those fractions associated with phytic acid and it seems likely that phytic acid is associated with these ions as well as with potassium, calcium, and magnesium in the wheat grain. The view that phytic acid is mainly localized in the aleurone grains, has recently been confirmed directly by Sobolev (22) in the case of the castor oil plant (*Ricinus communis*).

The asymmetry of the Neuberg structure **2** suggests that as phytic acid is a natural product, it would exhibit optical activity. However, no detectable rotation was observed with our material and the error in the molar rotation ($\pm 0.6°$) is well below the smallest molar rotation ($+15°$) which can be calculated for any recorded asymmetric inositol phosphate (23).

(b) Chicken Blood "Phytic Acid"

The occurrence of an unusually high concentration of an inositol polyphosphate in the acid-soluble phosphorus fraction of chicken blood was first observed by Rapoport (7). The term "phytic acid" was applied to this material on the basis of a similarity in properties to cereal grain phytic acid and the results of phosphorus and sodium analyses. This assignment was reexamined in 1964 by Oshima, Taylor, and Williams (24) who supported the hexaphosphate structure with evidence for a phosphorus to inositol ratio of 6:1 using a biological assay for the estimation of inositol.

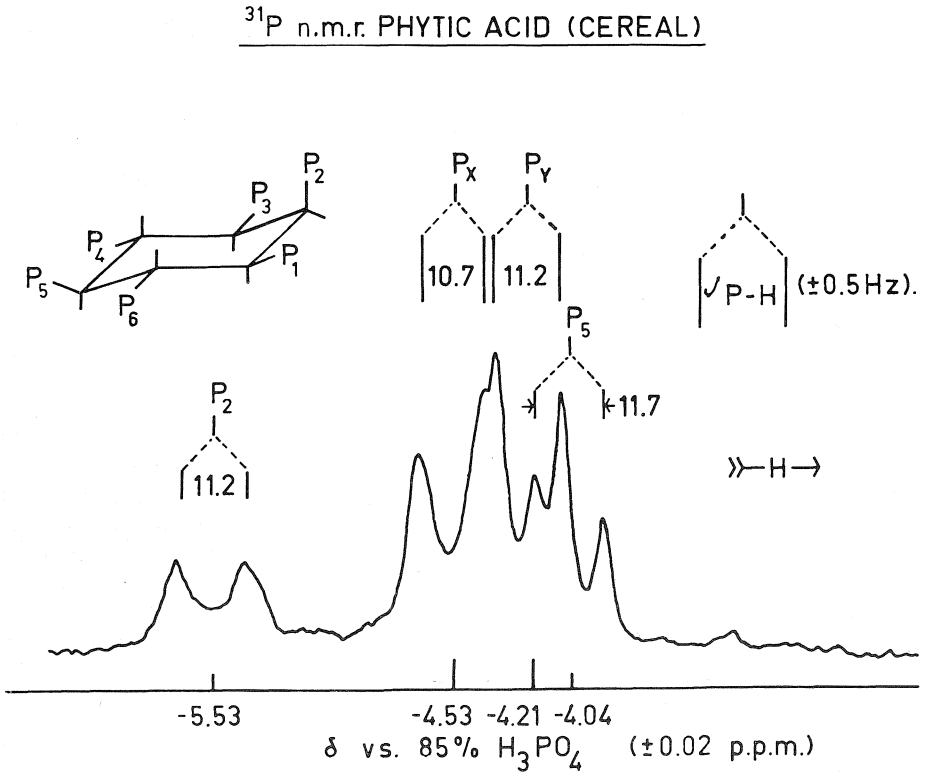

FIG. 2. Phosphorus magnetic resonance spectrum (40.5 MHz) of a saturated solution of crystalline cereal grain sodium phytate in D_2O. The signal to noise ratio has been enhanced by nine scans with a Varian C1024 time averaging computer. P_4O_6 in a sealed capillary was used as the external standard and δ-values have been calculated relative to 85% phosphoric acid.

Figure 1, lane 1, clearly shows that the "phytic acid" fraction of chicken blood is electrophoretically heterogeneous and that the major component is dissimilar to cereal grain phytic acid (lane 2). By ion-exchange chromatography a series of myoinositol polyphosphates was obtained. The sodium salt of the major component (C.B.2), which comprises 93% of the total phosphorus was found to be optically inactive, its analysis, electrophoretic, and ion-exchange behavior corresponded to an inositol pentaphosphate rather than the hexaphosphate structure. Ammonolysis gave myoinositol (1-, 4-, and 5-monophosphates) only. The absence of the axial 2-monophosphate led to the assignment of the symmetrical myoinositol 1,3,4,5,6-pentaphosphate structure **4**.

Of the minor inositol polyphosphates in the chicken blood extract, the fastest moving component (C.B.1) was found to be electrophoretically indistinguishable from cereal grain phytic acid and C.B.3 is probably an enantiomorph or racemate of myoinositol 1,4,5,6-tetraphosphate. The significance of these additional polyphosphates is not clear, they may be metabolically related to the major component (C.B.2) or alternatively it is possible that all the phosphates may arise as degradation products of some larger molecule containing acid labile linkages which are ruptured in the course of isolation.

Although Rapoport and Guest (25) have reported "phytic acid" in the blood of the snapping turtle (*Chelydra serpentina*) and a wide variety of birds, we have been unable to detect inositol penta- or hexaphosphates in the Murray River short-necked tortoise (*Emydura macquarii*).

The prior assignments (7, 24) of the hexaphosphate structure to chicken blood phytate exemplify the difficulty in distinguishing between inositol hexaphosphates and pentaphosphates

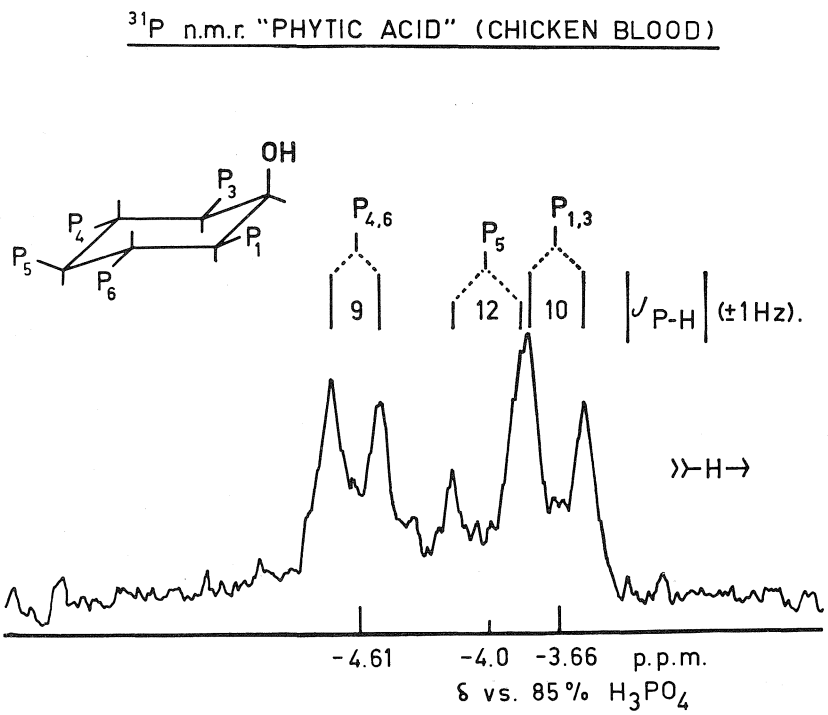

FIG. 3. Phosphorus magnetic resonance spectrum (40.5 MHz) of a saturated solution of the major component (C.B.2) of chicken blood "phytate" in D_2O.

on the basis of analytical values alone. The uncertainty in some methods of myoinositol estimation has led to a preference in this work for the elemental analysis of the sodium salts, whose homogeneity has been previously confirmed by both electrophoresis and paper chromatography.

(c) ^{31}P Nuclear Magnetic Resonance

Although the foregoing results were only compatible with the Anderson hexaorthophosphate structure **1** for cereal grain phytic acid and the myoinositol 1,3,4,5,6-pentaphosphate structure **4**, for chicken blood "phytic acid", there was no satisfactory confirmatory evidence for the structure of the myoinositol tripyrophosphate. The most convincing structural evidence for all these compounds has come from a study of their phosphorus magnetic resonance spectra.

Synthetic myoinositol 2-phosphate (26) was studied as a model compound of known structure. It was examined as the free acid and also as its disodium salt in D_2O at 40.5 MHz. The chemical shift (δ) for the free acid is essentially the same as the primary reference standard of 85% phosphoric acid and the characteristic (27, 28) downfield displacement of 5 p.p.m. for the complete transition from mono-anion to di-anion was observed. The signal is a doublet (J_{P-H} 7.5 Hz), and the splitting appears to be almost independent of the degree of ionization. The similar splitting (J_{H-P} 7.5 Hz) of the equatorial proton to a pair of triplets in the 100 MHz proton magnetic resonance spectrum, confirmed that the doublet formation observed in the phosphorus spectra was due to the ^{31}P nucleus of the axial phosphate group, coupling to the ^{1}H nucleus of the equatorial hydrogen.

An examination of the ^{31}P n.m.r. spectrum of the crystalline dodecasodium salt of cereal grain phytic acid gave the spectrum shown in Fig. 2. The single axial phosphate P_2 (δ −5.53 p.p.m.) appears as a well resolved doublet (J_{P-H} 11.2 Hz) at low field. The remaining five equatorial phosphorus nuclei appear as a sextet at higher field, a situation which is analogous to the methyl groups in the corresponding proton magnetic resonance spectrum of myoinositol hexaacetate (29). The sextet comprises two tall

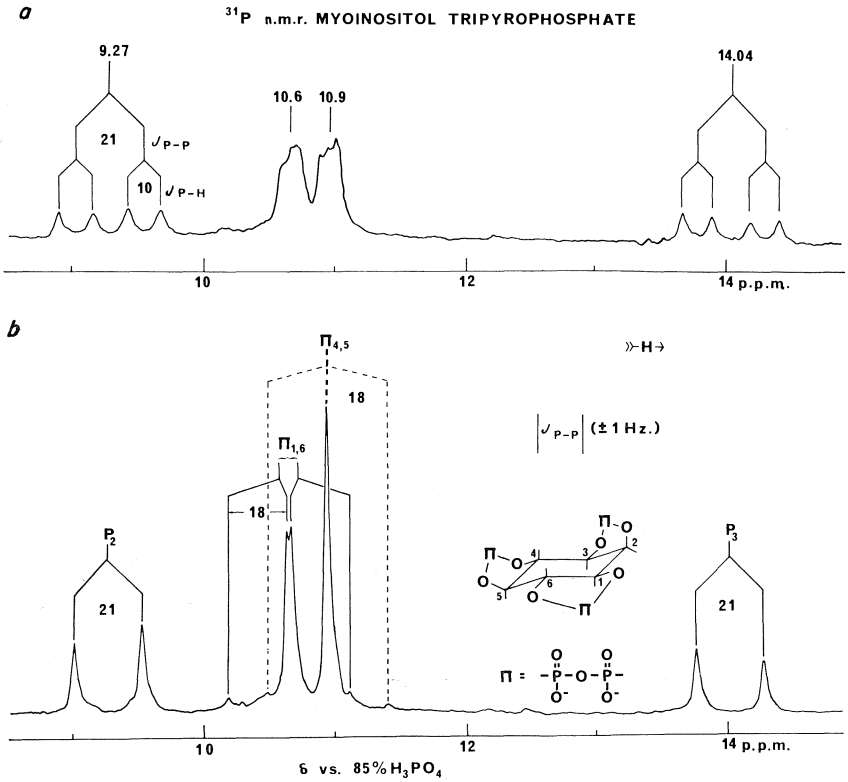

FIG. 4. (*a*) Phosphorus magnetic resonance spectrum (40.5 MHz) of a saturated solution of the hexasodium salt of myoinositol 1,6:2,3:4,5-tripyrophosphate in D_2O.
(*b*) ^{31}P Spectrum of the same sample after all phosphorus–proton couplings have been removed by the proton noise decoupling procedure of Ernst (30) using a Varian V-3512-1 heteronuclear noise decoupler. The signal has been enhanced in both cases by 19 scans with the Varian C1024 time averaging computer.

doublets P_x and P_y together with a smaller doublet (δ −4.04 p.p.m.) which may be assigned to the second meso position (P_5). These three doublets must arise from the phosphorus – axial proton coupling of the three remaining types of phosphorus nuclei. The correct assignment of each of the doublets P_x and P_y to the appropriate pair (P_1, P_3) or (P_4, P_6) of magnetically equivalent nuclei was not possible at this stage. The observed increase in doublet width from the monophosphate ($J_{P-H} \sim 8$ Hz) to the hexaphosphate ($J_{P-H} \sim 11$ Hz) was unexpected, but larger variations have been observed (20) between isomeric orthophosphates.

Confirmation of the 1,3,4,5,6-myoinositol pentaphosphate structure **4** for chicken blood "phytate" (C.B.2) is shown in Fig. 3. Comparison with Fig. 2 shows the absence of the axial phosphate signal at δ −5.53 p.p.m. and a marked upfield shift of the tall doublet (P_y, Fig. 2) from δ −4.21 p.p.m. to δ −3.66 p.p.m. in Fig. 3. The doublets P_x and P_5 in Fig. 2 are recognizable in Fig. 3 as signals located at δ −4.61 and δ −4.0 p.p.m. respectively. As the P_1 and P_3 nuclei have had their electronic environment drastically altered by the removal of the axial phosphate group from position-2, it is reasonable to assign P_y to this pair, whereas the P_x signal which is but little altered in chemical shift in both spectra, can now be assigned to the P_4, P_6 pair.

The ^{31}P n.m.r. spectrum for the racemic inositol tripyrophosphate obtained by the action of dicyclohexylcarbodiimide on cereal grain phytic acid is shown in Fig. 4*a*. The quartets (δ +9.27 p.p.m. and δ +14.04 p.p.m.) correspond to two phosphorus nuclei in unique environments and exhibit both P—P and P—H

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

For personal use only.

coupling (J_{P-P} 21 Hz, J_{P-H} 10 Hz). Confirmation that the two nuclei concerned are coupled by a pyrophosphate bond, was obtained by phosphorus – phosphorus double resonance of the signal at δ +9.27 p.p.m., which gave the expected perturbation of the signal at δ +14.04 p.p.m.

The complexity of the remaining signals located between the two quartets and corresponding to four phosphorus nuclei was initially the subject of considerable conjecture. The problem was eventually solved by the noise decoupling technique of Ernst (30). Figure 4*b* displays the proton noise decoupled ^{31}P n.m.r. spectra with all the splittings due to proton–phosphorus couplings removed. The decoupled spectrum shows a near classical example of three pairs of AB spectra, ranging from the almost AX situation of the signals at δ 9.27 and 14.04 p.p.m. (J_{P-P} 21 Hz), through the intermediate AB case centered at δ 10.6 p.p.m. (J_{P-P} 18 Hz) to the almost A_2 situation centered at δ 10.9 p.p.m. (J_{P-P} 18 Hz).

By simultaneous P—P coherent and P—H noise irradiation of the small peak at δ 11.09 p.p.m. in Fig. 4*b*, the tall signal at δ 10.6 p.p.m. is split to a doublet (δ 10.55 and 10.71 p.p.m.) thus verifying the assignment of the AB pattern.

A completely unequivocal assignment of each AB pair to each corresponding pyrophosphate linkage is still not possible, although it seems reasonable to suggest that the low field signal at δ 9.27 p.p.m. derives from the axial P_2 nucleus and the second signal at δ 14.04 p.p.m. is consequently the P_3 nucleus of the myoinositol tripyrophosphate enantiomorph depicted in Fig. 4*b*. The two remaining AB systems have been tentatively assigned (Fig. 4*b*) on the grounds that the P nuclei of the pyrophosphate ($\pi_{4,5}$) with two *trans*-neighbors will be more equivalent than those of the pyrophosphate ($\pi_{1,6}$) with one *cis*- and one *trans*-neighbor. However, it is clear that the ^{31}P n.m.r. spectra, are compatible with the racemic myoinositol 1,6:2,3:4,5-tripyrophosphate structure **3**.

Conclusions

We have been unable to find any evidence, either physical or chemical, from crystalline samples of the dodecasodium salt of cereal grain phytic acid to support the Neuberg formulation **2** for this compound. The Anderson hexaorthophosphate structure **1** has been independently confirmed by Angyal and Russel[2] in a study of the crystalline dodecamethyl ester of cereal grain phytic acid. Cereal grain phytic acid appears to be present as the hexaorthophosphate **1**, *in situ* and is probably associated with ferric ions (31) as well as calcium, magnesium, and potassium cations.

The elucidation of the ^{31}P n.m.r. spectrum of DL-myoinositol 1,6:2,3:4,5-tripyrophosphate **3**, provided a good example of the simplification which can be achieved with the noise decoupling technique.

Although traces of material corresponding to cereal grain phytic acid were found in the acid-soluble phosphate fraction of chicken blood, the bulk of the phosphorus is undoubtedly present as myoinositol 1,3,4,5,6-pentaphosphate **4**, and not the hexaorthophosphate **1**.

From these studies and those on soil inositol polyphosphates (1) it is clear that in the past, the expression "phytic acid" has been employed to cover a whole range of different polyphosphates, which were indistinguishable from one another at that time. Now that the techniques for separating and identifying these compounds are available, it would seem desirable to restrict its usage to describe the myoinositol hexaorthophosphate **1**.

Experimental

Microanalyses for C, H, and P were made by the Australian Microanalytical Service. Sodium analyses were obtained with an Eel flame photometer. Water of crystallization was measured by dehydration *in vacuo* (140°/0.05 mm Hg/17 h). X-ray fluorescence analyses were obtained by courtesy of Mr. J. Hutton, C.S.I.R.O. Soils Division, Adelaide.

Differential thermal analysis (d.t.a.) patterns were obtained with an instrument supplied by A. R. Bolton and Co., Edinburgh, Scotland and fitted with matched chromel P alumel thermocouples. Samples (100 mg) were tightly packed around the thermocouple and covered with ignited alumina and were compared with ignited alumina in the reference well. The temperature gradient to 400° was at 10°/min.

Electrophoretograms were run by either the routine or moving paper electrophoresis (m.p.e.) techniques (9) in the 0.1 *M* oxalate buffer (pH 1.5) of Seiffert and Agranoff (32). Before electrophoresis or chromatography, samples of insoluble phosphate salts were converted to the free acids by addition of Dowex 50 H^+ (−400 mesh) to a

[2]S. J. Angyal and A. F. Russel. Personal communication.

For personal use only.

suspension of the salt (10 mg) in water (0.5 ml). Phosphates were detected with the Harrap phosphomolybdate dip procedure (33). The papers were heated for 15 min at 65° before irradiation with ultraviolet light. The blue background fades as the paper regains its moisture content and the α-benzoinoxime treatment was only necessary in the case of chromatograms.

Reproducible results for inositol polyphosphates on paper chromatograms were only obtained with papers (Whatman 3 MM and No. 1) which had been chromatographically washed for 17 h with 0.1 *M* oxalic acid and then with 1.5 *M* ammonium hydroxide. The descending technique was used at 30° with the following solvent systems: (*a*) Isopropanol (80 ml), 15 *M* ammonia (20 ml), ethylenediamine – tetraacetic acid (EDTA) (100 mg). (*b*) Isopropanol (60 ml), 15 *M* ammonia (10 ml), water (30 ml), EDTA (100 mg). (*c*) Phenol (80 g), water (20 ml) (34).

Inositols were detected by the method of Anet and Reynolds (35).

Phosphorus magnetic resonance spectra were obtained with a Varian HA 100 instrument operated at 40.5 MHz. Samples whose homogeneity had been confirmed by electrophoresis and paper chromatography (solvent *b*) were prepared as saturated solutions of the sodium salts or the free acid in D_2O. A sealed capillary of phosphorus oxide P_4O_6 was used as the reference standard (36) and lock signal. Chemical shifts have been calculated using the observed separation for 85% phosphoric acid (4556.0 ± 0.2 Hz upfield from P_4O_6) at 40.48 MHz. The sample temperature was 35°. Where necessary the sample was also examined by proton magnetic resonance at 100 MHz. For clarity the signal to noise ratio was enhanced by processing multiple scans with a Varian C1024 time averaging computer. The proton noise decoupled spectra were obtained with the V-3512-1 heteronuclear noise decoupler. Infrared spectra were obtained with a Perkin–Elmer model 237 grating spectrophotometer, on solid samples at a concentration of 0.5% in potassium chloride disks.

Crystallization and Properties of Cereal Grain Sodium Phytate

It should be noted that crystallization of the sodium salt could only be achieved with samples containing only small amounts of both cationic and anionic impurities. Each sample should be examined by electrophoresis and where substantial impurities exist, they should be removed by ion exchange chromatography (12). Factors involved in the purification of calcium phytate and its conversion to sodium phytate have been discussed by Cosgrove (1).

Amorphous sodium phytate (10 g; P, 12%) was dissolved in distilled water (225 ml, 65°) and methanol (75 ml) was added. The hot solution was centrifuged and after decantation the clear supernatant was allowed to cool to 40°. Crystallization was initiated by scratching or seeding and the flask was set aside at ambient temperature (20–25°) for 72 h. A mixture of rhombohedra and clusters of needles were deposited, the crystals were filtered, washed with aqueous methanol (225:75), and air dried (6.4 g, 64%). The product was electrophoretically and chromatographically (solvent *b*) homogeneous and the two crystal types were hand separated. The large rhombohedra were efflorescent and analyzed for the dodecasodium salt with 35 molecules of water.

Anal. Calcd. for $C_6H_6O_{24}Na_{12}\cdot 35\ H_2O$: C, 4.65; H, 4.9; P, 12.0; Na, 17.8; H_2O, 40.6. Found: C, 4.95; H, 5.2; P, 12.2; Na, 18.0; H_2O, 40.3.

The rhombohedra do not melt, but show a loss of birefringence under plane polarized light at 50–57° on the Kofler melting point apparatus. The differential thermal analysis pattern showed endotherms at 63° m, 80° m, 133° s, and an exotherm at 325° w. The infrared spectrum showed the following absorption maxima; 740 w, 775 w, 835 s, 910 w, 940 sh, 975 s, 1010 sh, 1115 s, 1280 w, 1335 w, 1380 w, 1445 w, 1645 s, 2000–2400 w, 2550–3700 s, cm^{-1}. The needles analyzed for the dodecasodium salt with 31 molecules of water.

Anal. Calcd. for $C_6H_6O_{24}P_6Na_{12}\cdot 31\ H_2O$: C, 4.9; H, 4.6; P, 12.5; Na, 18.6; H_2O, 37.7. Found: C, 5.0; H, 4.9; P, 12.7; Na, 18.5; H_2O, 37.5.

The needles do not melt, but show a loss of birefringence at 50–57°. The differential thermal analysis pattern shows endotherms at 80° s, 123° s, and an exotherm at 327° w. An apparently homogeneous crop of needles was obtained by crystallization from the same solvent mixture at constant temperature (30°). The specific rotation for both forms was zero $[\alpha]_D^{20} = 0.00 \pm 0.04$ (*c*, 7; *l*, 4 in water).

Dehydration of either form (110°/0.1 mm Hg/10 h) gave an amorphous white solid corresponding to the trihydrate described by Hoff-Jorgensen (18).

Anal. Calcd. for $C_6H_6O_{24}P_6Na_{12}\cdot 3\ H_2O$: C, 7.4; H, 1.3; P, 19.0. Found: C, 7.6; H, 1.8; P, 19.1.

Further dehydration (145°/10^{-4} mm Hg/30 h) gave a hygroscopic white solid which was electrophoretically and chromatographically homogeneous and analyzed for the monohydrate of sodium phytate.

Anal. Calcd. for $C_6H_6O_{24}Na_{12}\cdot 1\ H_2O$: C, 7.7; H, 0.9; P, 19.7; Na, 29.3. Found: C, 7.7; H, 1.2; P, 19.8; Na, 29.0.

A sample of crystalline sodium phytate (1 g) was dissolved in 5 *M* sodium hydroxide (15 ml) and was precipitated once with ethanol (300 ml) according to the method outlined by Brown, Heit, and Ryan (17). The dried amorphous product (0.6 g) differed from the crystalline starting material in its infrared absorption maxima with peaks (1445 m, and 880 w, cm^{-1}) corresponding to the carbonate anion (37). The product analyzed for C, 8.7; P, 19.6; Na, 32.4% corresponding to Na:P:C ratio of 2.2:1:1.1 and appears to be a mixture of sodium phytate and sodium carbonate.

Using the above analytical figures a mixture of crystalline sodium phytate ($C_6H_6O_{24}P_6Na_{12}\cdot 31\ H_2O$, 135 mg) and anhydrous sodium carbonate (8 mg) was dried, and homogenized in an agate ball mill. The infrared spectrum (KCl disk) of this mixture was virtually superimposable with the amorphous product from the precipitation procedure.

Hexasodium Salt of Myoinositol 1,6:2,3:4,5-Tripyrophosphate

Crystalline sodium phytate (3 g) in water (30 ml) was converted to the free acid by passage through a column of Dowex 50 H^+. The column eluate was adjusted to pH 8 with pyridine and evaporated to dryness, the residue

*These compounds were not isolated and have not been examined for myoinositol content.

was dissolved in water (21 ml) and pyridine (84 ml) containing *N,N*-dicyclohexylcarbodiimide (5.25 g) was added. The reaction mixture was heated 6 h at 50° and evaporated to dryness. The residue was extracted with water (4 × 5 ml) filtered and the filtrate adjusted to pH 10 with 5 *M* sodium hydroxide. The sodium salt was precipitated by the addition of methanol (60 ml) and separated by centrifugation. The solid was redissolved in water (10 ml) and again precipitated, washed with 75% methanol (2 × 15 ml), methanol, and dried *in vacuo* (140°/0.1 mm Hg/8 h) to give the amorphous hexasodium salt of an inositol tripyrophosphate.

Anal. Calcd. for $C_6H_6O_{21}P_6Na_6$: C, 9.8; P, 25.2; Na, 18.7. Found: C, 9.8; P, 25.0; Na, 19.0.

Electrophoresis indicated the product contained a trace amount of an impurity M_π 1.49 which could not be removed by precipitation. The infrared spectrum showed the following absorption maxima: 685 w, 715 w, 742 w, 765 m, 810 m, 843 sh, 862 w, 892 w, 920 m, 955 m, 980 m, 995 sh, 1070 s, 1090 s, 1120 s, 1255 s, 1380 w, 1530 w, 1640 s, 2850 w, 2900 w, sh, 2925 w, 3580 sh, 2800–3800 s, br, cm^{-1}. Hydrolysis in 1 *M* hydrochloric acid (100°/15 min) gave the hexaorthophosphate with some lower phosphates and inorganic phosphate. Electrophoretic and chromatographic mobilities are listed in Table I.

Phytate Extraction from Wheat Bran

Wheat bran (50 g) in water (500 ml) was boiled for 10 min and filtered through muslin, the residue was washed with boiling water (6 × 250 ml). The residue was suspended in a solution of tetrasodium ethylenediaminetetraacetate (EDTA, 5 g) in water (500 ml) and stirred for 2 h. The mixture was filtered through muslin and the residue washed with water (5 × 100 ml). Aliquots of both the water and EDTA extracts were examined by electrophoresis, the bulk of the phytic acid was found in the EDTA extract. Neither extract showed evidence for phosphate compounds with mobilities greater than the crystalline sodium phytate reference marker. Crude barium phytate was recovered from the EDTA extract by the addition of excess 10% w/v barium acetate (100 ml). The flocculant precipitate was centrifuged, washed with water (4 × 100 ml) and dried (2.6 g; P, 8%). The crude barium salt was converted to the crystalline sodium salt (needles) and found to be chromatographically (solvent *b*) and electrophoretically indistinguishable from the crystalline dodecasodium salt ($31 \cdot H_2O$ obtained from commercial sodium phytate (ex maize). The infrared spectrum and d.t.a. patterns were superimposable.

Ultraviolet prints of electrophoretograms of the EDTA extract showed the presence of an ultraviolet absorbing spot M_π 1.73. This material was extracted and gave a positive spot test for ferric ions. The ultraviolet absorption spectra and electrophoresis mobility coincided with that for a dilute solution of ferric chloride in the oxalate buffer. The spot contained no phosphorus and is an anionic ferric oxalate complex. The original bran (oven dried) gave the following analysis, calculated from results obtained by X-ray fluorescence on the ashed sample: P, 1.19; S, 0.05; Si, 0.015; K, 1.6; Mg, 0.57; Ca, 0.10; Fe, 0.015; Mn, 0.014; Al, 0.002.

Isolation of Chicken Blood Inositol Polyphosphates

Crude inositol polyphosphate fractions were isolated by the procedures of Rapoport (7) and Oshima, Taylor, and Williams (24) and were similar to material isolated by the perchloric precipitation, which was simpler on a large scale separation.

Fresh chicken blood (10 l) was collected over a period of 15 min in a stainless steel vessel containing disodium citrate (100 g). Distilled water (2.5 l) and 60% w/v perchloric acid (1.25 l) were added and the mixture was stirred for 1 h. The thick suspension was filtered through a Buchner funnel and the residue was rinsed with a small volume of water. The combined filtrate and washings (8.1 l) contained total phosphorus (38) (153 μg P/ml) and free inorganic phosphorus (39) (34 μg P/ml).

To a portion of the filtrate (1 l), a solution of ferric chloride hexahydrate (2.7 g) and sodium chloride (200 g)

in water (1 l) was added, the mixture was boiled for 10 min and the flocculant white precipitate was allowed to settle overnight. The bulk of the clear yellow supernatant liquor was discarded. The residue was centrifuged and the crude ferric salt was washed with 0.5 *M* hydrochloric acid (2 × 30 ml) and finally with water (2 × 30 ml). The crude ferric salt was suspended in water (20 ml) and 5 *M* sodium hydroxide (1.5 ml) added. The suspension was boiled to coagulate the ferric hydroxide and centrifuged, the clear supernatant was then decanted and evaporated to dryness *in vacuo*. The crude sodium salt was dissolved in water (4 ml) and reprecipitated as an oil by the addition of methanol (8 ml). The two phases were separated by centrifugation and the oily lower solidified on trituration with methanol (13 ml). The hygroscopic solid was separated by centrifugation and dried *in vacuo* (2 h/0.1 mm Hg/100°/P_2O_5) to give the partially purified sodium salt (148 mg; P, 17.9%). The product was electrophoretically heterogeneous (see Fig. 1, lane 1) and showed five phosphate components (C.B. 1–5). The electrophoretic and chromatographic mobilities are listed in Table I.

The crude sodium salt (304 mg) in water (5 ml) was converted to the free acid by passage through a short column of Dowex 50 H^+. The eluate was applied to a second column of Dowex 1 × 2 (42 × 0.8 cm) packed in 0.1 *M* hydrochloric acid. The column was eluted with a gradient from a mixing vessel (11.7 cm I.D.) containing 0.1 *M* hydrochloric acid (1300 ml) connected by a siphon to a donor vessel (9.8 cm I.D.) containing 1.6 *M* hydrochloric acid (900 ml). The column eluate was collected in 20 ml fractions, aliquots (5 μl) were removed from each fraction with a wire loop and spotted onto a grid (10 × 10 cm) ruled on Whatman No. 1 filter paper. Phosphate compounds were detected on the grid by the phosphomolybdate test, and the relevant fractions were examined by electrophoresis.

Electrophoretically homogeneous fractions were combined, adjusted to pH 10 with ammonia, and precipitated by the addition of excess 10% w/v barium acetate solution (5–10 ml). The suspension was diluted with an equal volume of ethanol and allowed to stand overnight. The bulk of the clear supernatant was decanted and the residue was centrifuged, washed with 50% ethanol (2 × 30 ml) and dried *in vacuo*. The fractions, their electrophoretic designation and the weights of the barium salts obtained were as follows: 66–69, C.B.1 (18 mg); 52–59, C.B.2 (369 mg); 43–45, C.B.3 (12 mg). The components C.B.4 and C.B.5 were not detected by the grid procedure and were not isolated. The infrared spectra of all three barium salts (C.B.1–3) were similar and showed absorption maxima at 685 w, 825 w, sh, 853 s, 972 s, 1115 s, br, 1450 s, br, 1635 m, br, 2000–2500 w, 2500–3700 s cm^{-1}. The peaks at 685, 853, and 1453 were correlated with the presence of barium carbonate (37) which precluded the determination of the degree of phosphorylation from the C:P ratio. Hydrolysis (6 *M* hydrochloric acid/125°/40 h) of samples of each barium salt, followed by deionization of the hydrolyzate through a short column of a mixed bed resin (Amberlite M.B.1) with subsequent paper chromatography (solvents *a* and *c*) on the concentrated eluate, showed myoinositol to be the only detectable polyol in C.B.1, 2, and 3.

Table I shows that C.B.1 was indistinguishable from cereal grain phytic acid and that the major component (95% on a total P basis), C.B.2 was indistinguishable from the α component of Cosgrove's pentaphosphate fraction IB (9, 12). Table I also shows that C.B.3 is not electrophoretically (m.p.e.) identical with any of the known pentaphosphates and upon isomerization (1 *M* hydrochloric acid/110°/1 h 20 min), phosphates with the same or lower electrophoretic mobilities (M_π 1.08, 1.02, 0.97, 0.85 w, 0.31) were formed.

The phosphorus-inositol ratio for the crude barium salts of C.B.1 and C.B.3 (5.8:1 and 4.2:1 respectively) were determined by total P analyses (38) and gas chromatography of the acetylated hydrolysis products (40). Periodate oxidation (0.1 *M* periodic acid, pH 2, 25°, 24 h) of the free acid of fraction C.B.3 (10 mg) proceeded smoothly to give a product (M_π 1.04) which was reduced with excess sodium borohydride (pH 8, 24 h) to give an acyclic polyol polyphosphate. The phosphate groups were hydrolyzed (pH 5.0, 110°, 48 h) and the product was passed through a short column of Dowex 50 H^+ and evaporated to dryness with methanol (3 × 50 ml). A final deionization through a mixed bed resin gave material which was chromatographically indistinguishable (solvents *a* and *c*) from L-iditol. Acetylation (pyridine – acetic anhydride) of this product gave material which was indistinguishable by gas chromatography (40) from L-iditol acetate. Although insufficient material was available for the determination of optical activity, the available evidence suggests that C.B.3 is one of the enantiomorphs or alternatively the racemate of myoinositol 1,4,5,6-tetraphosphate. The other minor components C.B.4 and 5 were not detected by the grid procedure and were not isolated.

Identification of the Major Component C.B.2

The carbonate was removed from the major component C.B.2, by conversion to the sodium salt. The barium salt (347 mg) in water (35 ml) was stirred (2 h) with Dowex 50 H^+ (−400 mesh, 750 mg). The mixture was filtered and the residue washed with water (4 × 10 ml), the combined filtrates were passed through a column of Dowex 50 H^+ and the eluate was adjusted to pH 12 with 5 *M* sodium hydroxide. The solution was evaporated to dryness and the residue dissolved in water (2 ml) and the sodium salt was precipitated as an oil by the addition of methanol (3 ml), the phases were separated by centrifugation. The precipitation procedure was repeated until the lower layer was colorless and finally the oil was solidified by trituration with methanol and dried (140°/0.05 mm Hg/P_2O_5/17 h) to give an amorphous, hygroscopic decasodium salt of an inositol pentaphosphate (186 mg), $[\alpha]_D^{20} = 0.0 \pm 1°$ (*c* 3, *l* 0.5 in water). Infrared absorption maxima, 690 w, 780 w, 830 m, 865 sh, 975 s, 1008 w, sh, 1110 s, 1340 w, 1375 w, 1640 s, 2000–2400 w, 2500–3700 s, cm^{-1}.

Anal. Calcd. for $C_6H_7O_{21}P_5Na_{10}$: C, 9.0; P, 19.4; Na, 28.7. Found: C, 9.2; P, 19.6; Na, 28.5.

A solution of the purified sodium salt (20 mg) in 7.5 *M* ammonium hydroxide (1.0 ml) was heated in a sealed tube at 105° for 1 week. The reaction mixture was separated by electrophoresis and after developing guide strips with the phosphomolybdate reagent, the band

corresponding to inositol monophosphates was cut out and eluted with water. The eluates were concentrated and examined by prolonged paper chromatography (14 days) (41) on oxalate washed paper in solvent *a*, myo-inositol 1-, 4-, and 5-monophosphates were detected. The major product was the 4-phosphate but the axial 2-phosphate was not detectable. Thus C.B.2 is the deca-sodium salt of myoinositol 1,3,4,5,6-pentaphosphate.

Two attempts to isolate inositol penta- or hexaphosphates by a similar procedure from the blood of a female Murray River short-necked tortoise (*Emydura macquarii*) were unsuccessful.

Acknowledgments

Financial support of this work by the Commonwealth Wheat Industry Council and the Australian Research Grants Committee is gratefully acknowledged. Thanks are also due to Dr. D. J. Cosgrove of C.S.I.R.O. Division of Plant Industry, Canberra, for a gift of the inositol pentaphosphate fractions I*b* and I*c*. It is a pleasure to acknowledge the technical assistance of Mrs. June Oliphant in this work.

Syntheses related to the carbohydrate moiety in lincomycin

G. B. HOWARTH, D. G. LANCE, W. A. SZAREK, AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received August 15, 1968

Addition of nitroethane to 1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-hexodialdo-1,5-pyranose (**3**) gave a mixture of β-nitro alcohols (**4**), which was acetylated to afford a mixture of β-nitro acetates (**5**). Dehydroacetylation of the latter gave *cis*- and *trans*-6,7,8-trideoxy-1,2:3,4-di-*O*-isopropylidene-7-*C*-nitro-α-D-*galacto*-oct-6-enose (**6** and **7**) in a ratio of about 6:1, respectively. Addition of ammonia to the *cis*-nitroolefin (**6**) gave rapidly a mixture of two stereoisomeric *vic*-nitroamines (**8**), which was acetylated to furnish a mixture of two 6-acetamido-6,7-dideoxy-7-*C*-nitro derivatives (**9**). The same products (**9**) were obtained by the action of ammonia in aqueous tetrahydrofuran upon the preponderant β-nitro acetate, followed by acetylation. Vinylation of the aldehyde **3** gave a mixture of allylic alcohols (**10**); the preponderant epimer was obtained pure in crystalline form. The various 8-carbon sugar derivatives are of interest as potential intermediates in the synthesis of the carbohydrate moiety in lincomycin.

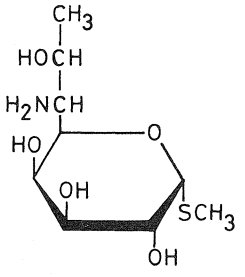
Introduction

The carbohydrate obtained by cleavage of lincomycin, an important new antibiotic with activity against gram-positive organisms, has been shown (1) to be methyl 6-amino-6,8-dideoxy-1-thio-D-*erythro*-α-D-*galacto*-octopyranoside (**1**). The trivial name methyl thiolincosaminide (MTL) has been given to this compound. In the present paper we report the results of some experiments directed towards the synthesis of **1**. The addition of nitroethane to 1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-hexodialdo-1,5-pyranose (**3**) and conversion of the resulting β-nitro alcohols (**4**) to a mixture of two 6-acetamido-6,7-dideoxy-7-*C*-nitro derivatives (**9**) are described. The addition of vinylmagnesium bromide to compound **3** has been achieved also.



1

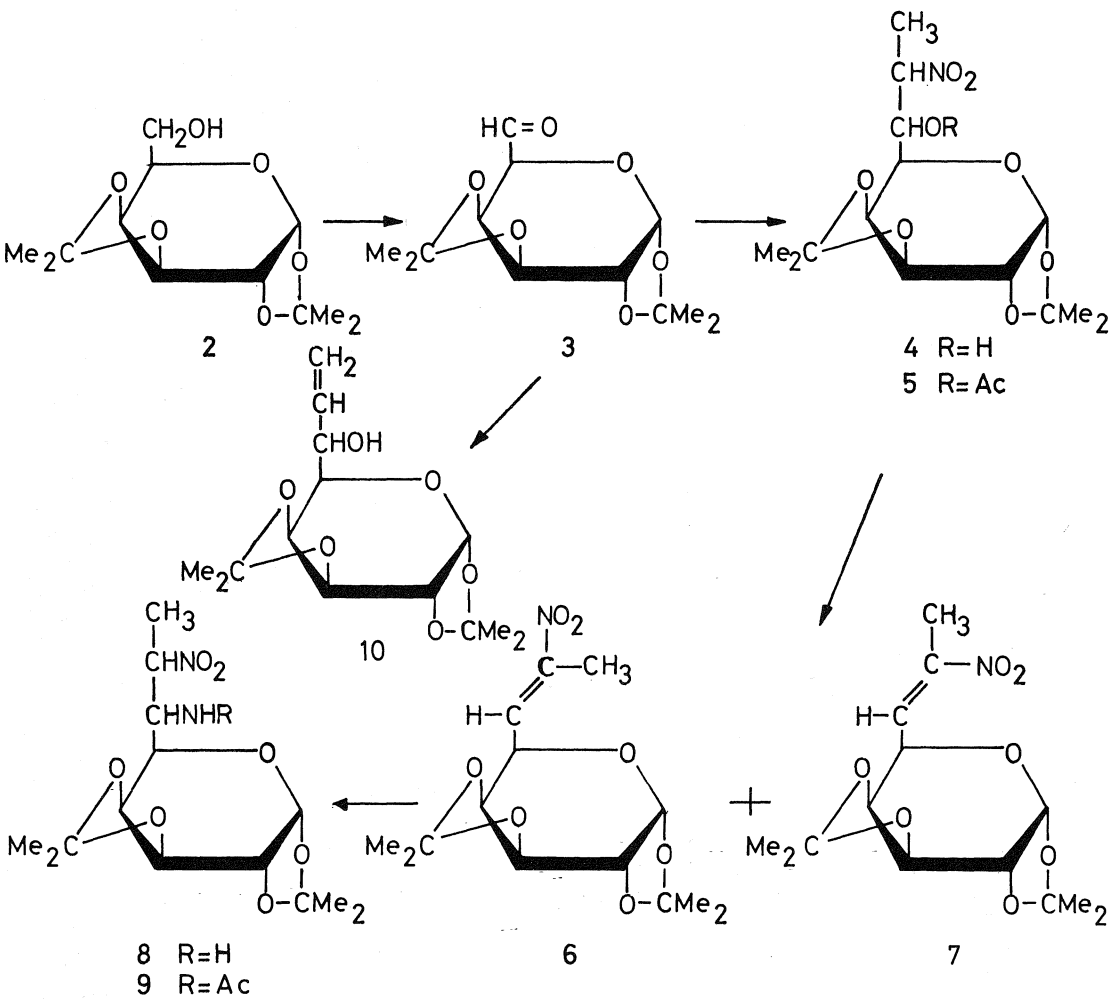
Results and Discussion

Oxidation of 1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-pyranose (**2**) (2) with the Pfitzner–Moffatt reagent (3) (methyl sulfoxide-*N*,*N*′-dicyclohexylcarbodiimide, with pyridine hydrochloride as the proton source) gave the aldehyde **3** (4) in a chromatographically homogeneous state in 83% yield. Our oxidation procedure is a significant improvement over that published earlier (5), by which compound **3** was obtained pure from **2** in 46% yield only after careful fractional distillation of a crude product. Addition of nitroethane to compound **3** in the presence of sodium methoxide gave a mixture of β-nitro alcohols (**4**), which was acetylated with acetic anhydride/sulfuric acid to afford a mixture of β-nitro acetates (**5**). Three stereoisomers were obtained analytically pure by fractional crystallization. Treatment of the nitro alcohols (**4**) with acetic anhydride/pyridine gave a dark solution; the infrared spectrum of the crude product showed strong absorption attributable to α-nitroolefins.

Attempts to dehydroacetylate the β-nitro acetates by sodium hydrogen carbonate in boiling benzene (Schmidt–Rutz reaction) (6) were unsatisfactory. Even after 48 h, very little elimination had occurred. Treatment of the nitro acetates with triethylamine in boiling benzene, however, rapidly gave *cis*-6,7,8-trideoxy-1,2:3,4-di-*O*-isopropylidene-7-*C*-nitro-α-D-*galacto*-oct-6-enose (**6**) and its *trans* isomer (**7**) in a ratio of approximately 6:1, respectively. Some dehydroacetylation occurred also during an attempted separation of the nitro acetates by preparative gas–liquid chromatography at 180°.

Configurational assignments of the *cis* and *trans* unsaturated nitro compounds are made on the basis of their ultraviolet (u.v.) and nuclear

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



magnetic resonance (n.m.r.) spectra. Molecular models show that there is greater steric hindrance to the attainment of coplanarity of the conjugated system for the *trans* isomer (**7**). The u.v. absorption band for this isomer would be expected to occur at shorter wavelength. Thus, to the compound with λ_{max} (ethanol) 232 mμ (ε 4.7 × 10^3) the *trans* stereochemistry shown in **7** is assigned, and that with λ_{max} (ethanol) 245 mμ (ε 1.2 × 10^4) is the *cis* isomer (**6**). In the n.m.r. spectra of the two isomers the signal for the vinyl proton in the *cis* isomer is at lower field than in the *trans* isomer (see Experimental section). When either of the isomers is dissolved in ether containing a trace of triethylamine, isomerization occurs to give again a 6:1 mixture of *cis* and *trans* isomers, respectively. A photochemical *cis–trans* isomerization of **6** and **7** has been demonstrated also in this laboratory (7).

Treatment of the *cis*-nitroolefin (**6**) with saturated methanolic ammonia rapidly gave a mixture of two stereoisomeric *vic*-nitroamines (**8**). The same two nitroamines were formed by the action of ammonia in aqueous tetrahydrofuran upon the preponderant β-nitro acetate itself. These reactions have been previously applied in carbohydrate chemistry for similar syntheses of vicinal nitroamino sugars (8). *N*-Acetylation of the nitroamines (**8**) gave a crystalline, sharp-melting approximately 1:1 mixture of two 6-acetamido-6,7-dideoxy-7-*C*-nitro derivatives (**9**). Attempts to resolve this mixture by fractional crystalliza-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tion, thin-layer, and column chromatography have been unsuccessful.

A useful method for extension of sugar chains is the addition of acetylenic or vinylic Grignard reagents to *aldehydo* sugars (9). Vinylation of the aldehyde **3** with vinylmagnesium bromide (10) in tetrahydrofuran gave a mixture of allylic alcohols (**10**). The preponderant epimer was obtained pure in crystalline form. The stereochemistry at C-6 has not been established. The same compound has been prepared previously by Horton *et al.* (11) by ethynylation of **3** with ethynylmagnesium bromide in tetrahydrofuran, followed by hemihydrogenation of the preponderant acetylenic derivative over Lindlar catalyst.

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141 automatic polarimeter at $21 \pm 2°$ in chloroform containing 0.75% ethanol, unless otherwise stated. Infrared spectra were measured on a Beckman-IR5A spectrophotometer. Nuclear magnetic resonance (n.m.r.) spectra were measured on a Varian A-60A spectrometer in chloroform-*d* and tetramethylsilane as internal standard. Ultraviolet spectra were measured with a Unicam SP.800B spectrophotometer. Thin-layer chromatography (t.l.c.) was performed with Silica Gel G as the absorbent, and 2:3 ethyl acetate – petroleum ether as the developing solvent. The term "petroleum ether" refers to the fraction of b.p. 60–80°. Gas–liquid chromatography (g.l.c.) (F and M chromatograph, model 402) was carried out at a carrier gas flow rate of ca. 100 ml/min on a column of 1% (w/w) Apiezon L supported on 50–60 mesh acid washed DMCS treated Chromosorb W (115 × 0.4 cm) at 180°, unless otherwise stated. Retention times, *T*, are quoted relative to 1,3,5-trinitrobenzene (=1.00). The chromatograph was adapted for preparative separations as described previously (12).

1,2:3,4-Di-O-isopropylidene-α-D-galacto-hexodialdo-1,5-pyranose (3)

To a solution of 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose (2) (25 g) in dry (molecular sieves) methyl sulfoxide (450 ml) were added pyridine hydrochloride (prepared by saturation of a solution of pyridine (5 ml) in ether (100 ml) with dry hydrogen chloride and concentration to dryness) and *N,N'*-dicyclohexylcarbodiimide (61 g). The mixture was stirred for 24 h at room temperature; a solution of oxalic acid (25 g) in methanol (50 ml) was then added, the stirring was continued to decompose the excess of *N,N'*-dicyclohexylcarbodiimide, and the mixture was poured into an aqueous saturated sodium chloride solution (1 l). *N,N'*-Dicyclohexylurea was removed by filtration, and the filtrate was extracted with chloroform (5 × 250 ml). The extracts were washed with aqueous sodium hydrogen carbonate (250 ml) and then with water (6 × 250 ml). The aqueous washings were extracted with chloroform, and the organic phases were combined, dried (magnesium sulfate), and concentrated to dryness. The syrupy residue was dissolved in warm acetone (250 ml), and a small amount of *N,N'*-dicyclohexylurea was removed by filtration. The filtrate was concentrated to give a colorless, chromatographically homogeneous (t.l.c. and g.l.c.) syrup (20.8 g, 83%), b.p. 96–100°/0.1 mm Hg, $[\alpha]_D$ −113° (*c*, 3.4); R_f 0.40 (t.l.c.), *T* 0.27 (g.l.c.). The product had the same infrared and n.m.r. spectral features as those previously reported (5) for compound **3**. For a fraction with b.p. 104–105°/0.5 mm Hg, $[\alpha]_D^{20}$ −131° (*c*, 0.9 in chloroform) has been reported (5).

Anal. Calcd. for $C_{12}H_{18}O_6$: C, 55.8; H, 7.03. Found: C, 55.4; H, 7.11.

An oxime of the syrupy aldehyde **3** was prepared essentially by the method of Horton *et al.* (5), which involves treatment with hydroxylamine hydrochloride in aqueous methanol containing pyridine as the acid acceptor, except that the solution was heated at reflux temperature for 5 h. The product was recrystallized from petroleum ether, and had m.p. 114–115°, $[\alpha]_D$ −132° (*c*, 2.3). For an oxime derivative of **3**, m.p. 107–108° and $[\alpha]_D^{20}$ −116° (*c*, 0.35 in chloroform) have been reported (5).

Anal. Calcd. for $C_{12}H_{19}NO_6$: C, 52.7; H, 7.01; N, 5.13. Found: C, 52.4; H, 7.10; N, 5.47.

Preparation of β-Nitro Acetates (5)

To a slurry of nitroethane (100 ml) in dry methanol (180 ml) containing sodium (2.7 g) was added aldehyde **3** (18.4 g) in methanol (30 ml) dropwise with stirring, and the mixture was allowed to stand at room temperature overnight. The solution was passed then through Rexyn-101 (H form) exchange resin, and the eluate and washings were concentrated to dryness under reduced pressure to give a viscous syrup (20 g) whose infrared spectrum (film) showed strong absorption at 6.4–6.5 μm attributable to C—NO_2, but no carbonyl absorption.

The syrupy product was dissolved in acetic anhydride (200 ml) containing sulfuric acid (2 ml). After 15 min at room temperature methanol (200 ml) was added with cooling, and the solution was poured into an excess of sodium hydrogen carbonate solution. Extraction with chloroform and concentration of the dried (magnesium sulfate) extracts gave a syrup which yielded from ethanol–water a crystalline product (10 g), m.p. 118–124°. Recrystallization of this first crop of crystals from chloroform – petroleum ether afforded large white prisms (6.4 g, 25%), m.p. 127–129°, $[\alpha]_D$ −73° (*c*, 2.4 in ethanol); *T* 2.27 (g.l.c.); λ_{max} (KBr) 5.70 (OAc), 6.45 (C—NO_2), 7.2, 7.25 μm (CMe_2); n.m.r. data: τ 4.49 (1-proton doublet, $J_{1,2}$ 5 Hz, H-1), τ 7.93 (3-proton singlet, OAc), τ 8.44 (3-proton doublet, *J* 7 Hz, C-7 Me), τ 8.46, 8.56, 8.68 (3-, 3-, and 6-proton singlets, CMe_2).

Anal. Calcd. for $C_{16}H_{25}NO_9$: C, 51.2; H, 6.7; N, 3.8. Found: C, 51.4; H, 6.9; N, 3.7.

A second crop of crystals (1.8 g), m.p. 104–110°, was obtained by the addition of more water to the ethanol–water mother liquors above and cooling to 5°. Recrystallization from chloroform – petroleum ether and then ether – petroleum ether gave crystals (1.2 g, 5%), m.p. 116–118°, $[\alpha]_D$ −72° (*c*, 2.6 in ethanol); *T* 1.98 (g.l.c.); λ_{max} (KBr) 5.68 (OAc), 6.43 (C—NO_2), 7.2–7.3 μm

(CMe_2); n.m.r. data: τ 4.50 (1-proton doublet, $J_{1,2}$ 5 Hz, H-1), τ 7.90 (3-proton singlet, OAc), τ 8.40, 8.57, 8.66, 8.90 (3-proton singlets, CMe_2), τ 8.43 (3-proton doublet, *J* 7 Hz, C-7 Me).

Anal. Calcd. for $C_{16}H_{25}NO_9$: C, 51.2; H, 6.7; N, 3.8. Found: C, 51.5; H, 7.0; N, 3.6.

A further crop was obtained from the chloroform – petroleum ether mother liquors remaining after recrystallization of the first crop of crystals, and was shown by g.l.c. to be a 3:2 mixture of the first component (*T* 2.27) and a new third component (*T* 1.64). Preparative g.l.c. of a small amount of this mixture gave a fraction which was mainly this third component. The fraction was recrystallized twice from chloroform – petroleum ether, and then used to nucleate a solution of the mixture in this solvent to yield finally a third crystalline β-nitro acetate (150 mg), m.p. 190–191°, $[\alpha]_D$ −69° (*c*, 3.0 in ethanol); λ_{max} (KBr) 5.7 (OAc), 6.45 (C—NO_2), 7.2, 7.25 μm (CMe_2); n.m.r. data: τ 7.94 (3-proton singlet, OAc), τ 8.40 (3-proton doublet, *J* 7 Hz, C-7 Me), τ 8.50, 8.54, 8.68 (3-, 3-, and 6-proton singlets, CMe_2).

Anal. Calcd. for $C_{16}H_{25}NO_9$: C, 51.2; H, 6.7; N, 3.8. Found: C, 51.3; H, 6.9; N, 3.5.

*cis- and trans-6,7,8-Trideoxy-1,2:3,4-di-O-isopropylidene-7-C-nitro-α-*D*-galacto-oct-6-enose (**6** and **7**)*

A solution of the preponderant β-nitro acetate (*T* 2.27) (2 g) in benzene (50 ml) containing triethylamine (5 ml) was heated at reflux temperature for 2 h. Concentration of the solution after it had been washed successively with sulfuric acid (2 *N*), sodium hydrogen carbonate solution, and water yielded a solid, which was recrystallized from petroleum ether to afford the *cis* isomer (**6**) as white prisms (1.25 g, 75%), m.p. 137–139°, $[\alpha]_D$ −109° (*c*, 2.6 in ethyl acetate); *T* 2.27 (g.l.c.); λ_{max} (KBr) 3.25 (vinylic C—H), 5.93 (C=C), 6.55 (olefinic NO_2), 7.2, 7.3 μm (CMe_2); λ_{max} (Ethanol) 245 mμ (ε 1.2×10^4); n.m.r. data: τ 2.63 (1-proton quartet, $J_{6,5}$ 8 Hz, $J_{6,8}$ 1.2 Hz, H-6), τ 4.27 (1-proton doublet, $J_{1,2}$ 5 Hz, H-1), τ 5.20 (1-proton quartet, $J_{3,2}$ 2.5 Hz, $J_{3,4}$ 8 Hz, H-3), τ 5.50 (1-proton quartet, $J_{2,1}$ 2.5 Hz, $J_{2,3}$ 2.5 Hz, H-2), τ 5.65 (1-proton quartet, $J_{4,3}$ 8 Hz, $J_{4,5}$ 2 Hz, H-4), τ 5.30 (1-proton quartet, $J_{5,4}$ 2 Hz, $J_{5,6}$ 8 Hz, H-5), τ 7.67 (3-proton singlet, C-7 Me), τ 8.40, 8.50, 8.60 (3-, 3-, and 6-proton singlets, CMe_2).

Anal. Calcd. for $C_{14}H_{21}NO_7$: C, 53.4; H, 6.7; N, 4.4. Found: C, 53.4; H, 6.9; N, 4.3.

Gas–liquid chromatographic examination of the petroleum ether mother liquors above showed the presence of a 2:3 mixture of the *cis* isomer (*T* 2.27) and a second component (*T* 1.00). A small amount of the second component was obtained pure by preparative g.l.c., and was used to nucleate a solution of the mixture in ethanol. The *trans* isomer (**7**) crystallized as prisms (40 mg), m.p. 99–100°, $[\alpha]_D$ −90° (*c*, 1.1 in ethyl acetate); λ_{max} (KBr) 3.25 (vinylic C—H), 6.02 (C=C), 6.50 (olefinic NO_2), 7.2, 7.25 μm (CMe_2); λ_{max} (Ethanol) 232 mμ (ε 4.7×10^3); n.m.r. data: τ 4.05 (1-proton broad doublet, $J_{6,5}$ 7.5 Hz, $J_{6,8}$ <1 Hz, H-6), τ 4.5 (1-proton doublet, $J_{1,2}$ 5 Hz, H-1), τ 4.95 (1-proton broad doublet, $J_{5,6}$ 7.5 Hz, H-5), τ 5.35 (1-proton quartet, $J_{3,4}$ 8 Hz, $J_{3,2}$ 2 Hz, H-3), τ 5.57 (1-proton quartet, $J_{4,3}$ 8 Hz, $J_{4,5}$ 2 Hz, H-4), τ 5.68 (1-proton quartet, $J_{2,1}$ 5 Hz, $J_{2,3}$ 2 Hz, H-2), τ 7.76 (3-proton singlet, C-7 Me), τ 8.50, 8.53, 8.68 (3-, 3-, and 6-proton singlets, CMe_2).

Anal. Calcd. for $C_{14}H_{21}NO_7$: C, 53.4; H, 6.7; N, 4.4. Found: C, 53.7; H, 6.9; N, 4.3.

*Preparation of 6-Acetamido-6,7-dideoxy-7-C-nitro Derivatives (**9**)*

*(a) By Addition of Ammonia to cis-Nitroolefin **6***

A solution of *cis*-nitroolefin **6** (0.5 g) in saturated methanolic ammonia (10 ml) was allowed to stand for 2 h at room temperature. Thin-layer chromatography showed the absence of starting material (R_f 0.58) and the presence of two new components (R_f 0.26 and 0.14). The solution was concentrated to a syrup, which was dissolved in a mixture of acetic anhydride (2 ml) and pyridine (3 ml). After standing for 5 h at room temperature, the mixture was poured into water, and a syrup was isolated in the usual manner. The product was crystallized from chloroform – petroleum ether as fine white needles (140 mg), m.p. 220–222°, $[\alpha]_D$ −41.3° (*c*, 0.9); λ_{max} (KBr) 3.1 (amide NH), 6.05 (amide I), 6.45 (C—NO_2) 7.2–7.3 μm (CMe_2); n.m.r. data: τ 4.52 (doublet, $J_{1,2}$ 5 Hz, H-1), τ 7.94, 8.00 (singlets, NAc). Gas–liquid chromatography at 215° showed the presence of two components (two stereoisomers **9**) in an approximately 1:1 ratio (*T* 2.80 and 3.85).

Anal. Calcd. for $C_{16}H_{26}N_2O_8$: C, 51.4; H, 6.95; N, 7.5. Found: C, 51.2; H, 7.08; N, 7.40.

*(b) By Reaction of Ammonia with Preponderant β-Nitro Acetate **5***

To a solution of the preponderant β-nitro acetate **5** (*T* 2.27) (100 mg) in tetrahydrofuran (1 ml) was added concentrated aqueous ammonia (0.5 ml). The mixture was stirred vigorously for two days; t.l.c. showed the presence of the same two *vic*-nitroamines as obtained in (*a*) (R_f 0.26 and 0.14). Acetylation as in (*a*) gave a mixture (40 mg) of the same two *N*-acetyl derivatives (**9**).

*7,8-Dideoxy-1,2:3,4-di-O-isopropylidene-*D*-glycero (and L-glycero)-α-*D*-galacto-oct-7-enopyranose (**10**)*

To a solution of vinylmagnesium bromide (**10**), prepared from magnesium (3 g) and vinyl bromide (12 ml) in tetrahydrofuran (100 ml), was added a solution of aldehyde **3** (3.6 g) in tetrahydrofuran (20 ml), and the mixture was heated at reflux temperature. After 3 h, g.l.c. (on a column of 10% (w/w) LAC-4R-886 wax on 100–120 mesh Chromosorb W at 200°) showed the presence of two components in a ratio of about 1:2. Ether (200 ml) was added and then water. The mixture was filtered, and the filtrate was concentrated to leave a syrup which was distilled under high vacuum. After several days the syrupy distillate crystallized. Two recrystallizations from ether – petroleum ether gave the preponderant epimer as white plates (1.24 g, 31%), m.p. 108–109°, $[\alpha]_D$ −53.5° (*c*, 1.7); λ_{max} (KBr) 2.85 (OH), 7.2, 7.3 μm (CMe_2); n.m.r. data: τ 4.45 (1-proton doublet, $J_{1,2}$ 5 Hz, H-1), τ 8.50, 8.65, 8.68 (6-, 3-, and 3-proton singlets, CMe_2).

Anal. Calcd. for $C_{14}H_{22}O_6$: C, 58.8; H, 7.7. Found: C, 59.0; H, 7.8.

Photolysis of a carbohydrate nitroolefin[1]

G. B. HOWARTH, D. G. LANCE, W. A. SZAREK,[2] AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received August 15, 1968

Irradiation of an acetone solution of *cis*-6,7,8-trideoxy-1,2:3,4-di-*O*-isopropylidene-7-*C*-nitro-α-D-*galacto*-oct-6-enose (**4**) with ultraviolet light gives a complex mixture from which the three major products have been isolated: the *trans* isomer of the nitroolefin **4**, *cis*-6,8-dideoxy-1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-oct-5-enos-7-ulose (**5**), and the *trans* isomer of **5**. The structures of the compounds were established by spectroscopic methods. Signal assignments in the nuclear magnetic resonance spectra have been made by spin decoupling.

Canadian Journal of Chemistry, 47, 81 (1969)

The photochemistry of nitro compounds is of interest because of the similarity of their absorption characteristics to those of carbonyl compounds. Some studies of the action of ultraviolet light on unsaturated nitro compounds have been described (2, 3). Thus, irradiation of β-methyl-β-nitrostyrene (**1**) has been reported (2) to give 1-phenyl-1-oximinopropan-2-one (**2**). A rationalization for this novel photoisomerization has been suggested according to which the initial rearrangement is R—NO_2 to R—O—NO. Cleavage of the nitrite followed by readdition of nitrogen (II) oxide at the α-carbon would give a nitrosoketone which could isomerize to the oximinoketone (**2**).

During the course of our work (4) directed towards the synthesis of the carbohydrate moiety in lincomycin (5), methyl 6-amino-6,8-dideoxy-1-thio-D-*erythro*-α-D-*galacto*-octopyranoside (**3**), we prepared *cis*-6,7,8-trideoxy-1,2:3,4-di-*O*-isopropylidene-7-*C*-nitro-α-D-*galacto*-oct-6-enose (**4**) and its *trans* isomer. Compound **4** was irradiated in acetone with 2537 Å light in an attempt to achieve a photoisomerization of the type described above. The anticipated oximinoketone would be a valuable intermediate in the synthesis of **3**. In the present paper we report the results of the photochemical studies.

Irradiation of **4** gave a complex mixture from which the three major products were isolated. These are the *trans* isomer of the nitroolefin **4**, *cis*-6,8-dideoxy-1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-oct-5-enos-7-ulose (**5**), and the *trans* isomer of **5**. The isolation of the compounds was very difficult because of the similarity of their chromatographic mobilities (gas–liquid and thin-layer chromatography), and was complicated further by the facile isomerization of the *trans* αβ-unsaturated ketone to the *cis* isomer **5** in chloroform. A separation was eventually achieved by a combination of column and preparative gas–liquid chromatography (g.l.c.). The relative amounts of the compounds at the end of the irradiation, as determined by g.l.c., are shown in Table I.

TABLE I
Gas–liquid chromatographic data*

Compound	Relative retention time	Final relative peak area
4	1.00 = 3.4 min	3.3
trans Isomer of **4**	0.54	4.7
5	0.40	1.3
trans Isomer of **5**	0.26	1.0

*See Experimental section for details.

Configurational assignments of the *cis* and *trans* unsaturated nitro compounds have been made (4) on the basis of their ultraviolet (u.v.) and nuclear magnetic resonance (n.m.r.) spectra. Molecular models show that there is greater steric hindrance to the attainment of coplanarity of the conjugated system for the *trans* isomer. The u.v. absorption band for this isomer would be expected to occur at shorter wavelength. The *cis* and *trans* isomers have λ_{max} (Ethanol) 245 mμ (ε 1.2 × 10^4) and λ_{max} (Ethanol) 232 mμ (ε 4.7 × 10^3), respectively (4). In the n.m.r. spectra of the two isomers the signal for the vinyl proton in the *cis* isomer is at lower field than in the *trans* isomer (see Table II).

The signal assignments in the n.m.r. spectra of the *cis*- and *trans*- nitroolefins (Figs. 1 and 2,

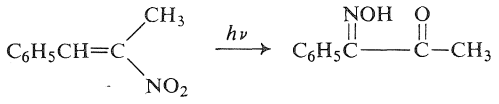
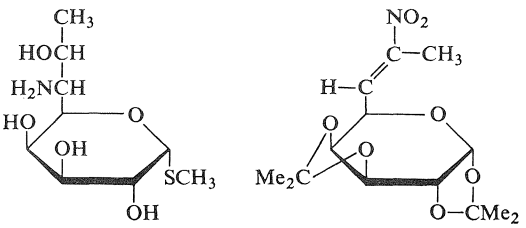
respectively) were made by spin decoupling. For the *cis* isomer **4**, irradiation at τ 4.27 (H-1) caused the quartet centered at τ 5.50 to collapse to a doublet with a splitting of 2.5 Hz. The quartet was assigned, therefore, to H-2, and the coupling constant $J_{2,3}$ = 2.5 Hz. Similarly, irradiation of H-1 in the *trans* isomer (τ 4.50) caused collapse of the quartet centered at τ 5.68 to a doublet, a result which shows that this signal is that of H-2, and $J_{2,3}$ = 2 Hz. Decoupling of H-2 from H-3, H-3 from H-4, and H-4 from H-5 in the *cis* isomer (**4**) was not possible because of the similarity of their chemical shifts. The assignment of the H-3 signal was made on the basis of $J_{2,3}$ = 2.5 Hz, which showed that the signal is the quartet at τ 5.20. The quartet at τ 2.63 was assigned to H-6 because of the small splitting (ca. 1 Hz) owing to long range coupling with the terminal methyl group. Irradiation of H-6 caused the quartet centered at τ 5.30 to collapse to a doublet with a splitting of 2 Hz. This signal is, therefore, that of H-5 with $J_{5,4}$ = 2 Hz. Finally, the quartet at τ 5.65 is assigned to H-4 with $J_{4,5}$ = 2 Hz.



1 **2**

For the *trans*-nitroolefin, irradiation of H-2 caused the quartet centered at τ 5.35 to collapse to a doublet with a splitting of 8 Hz. This signal is, therefore, that of H-3 with $J_{3,4}$ = 8 Hz. The broad doublet at τ 4.05 was assigned to the vinyl proton H-6, since the signal simplified to a sharp doublet on irradiation of the terminal methyl group. Irradiation of H-6 caused the broad doublet at τ 4.95 to collapse to a broad band. The signal has been assigned to H-5. The coupling constant $J_{4,5}$ = 2 Hz was determined from the H-4 signal, which was identified as the quartet at τ 5.57, since it collapsed to a doublet on irradiation of H-5. The splitting of the doublet was 8 Hz, the same value as had been obtained earlier for $J_{3,4}$.

The structures of the two αβ-unsaturated ketones were established by spectroscopic methods. Elemental analysis of the two compounds corresponded in each case to a loss of one atom of nitrogen, oxygen, and hydrogen from the starting *cis*-nitroolefin (**4**). The infrared and u.v. spectra of both compounds showed absorptions attributable to an αβ-unsaturated ketone. The evidence for the configurational assignments of the isomers was their u.v. spectra. In this case molecular models show that there is greater steric hindrance to the attainment of coplanarity of the conjugated system for the *cis* isomer (**5**). Thus, the compound with λ_{max} (ethanol) 248 mμ (ε 1.6 × 10^4) is the *cis* isomer, and that with λ_{max} (ethanol) 256 mμ (ε 1.1 × 10^4) is the *trans* isomer. The n.m.r. spectra of the two isomers showed in each case a 3-proton singlet attributable to the terminal methyl group, a 1-proton singlet attributable to the vinyl proton, and signals assigned to the methyl groups of the isopropylidene rings (see Table II). The remainder of the proton assignments were made by spin decoupling experiments (Figs. 3 and 4). When the H-1 nuclei were irradiated (τ 4.18 for **5** and τ 4.31 for the *trans* isomer), the respective quartets at τ 5.68 and τ 5.78 collapsed in each case to a doublet with a splitting of 3 Hz. The quartets were assigned, therefore, to the H-2 protons with $J_{2,3}$ = 3 Hz. Irradiation of the H-2 protons in **5** and the *trans* isomer caused the respective quartets at τ 5.36 and τ 5.47 to collapse to doublets with splittings of 7 Hz and 6 Hz, respectively. These quartets are, therefore, those of the H-3 protons, and the splittings are the $J_{3,4}$ coupling constants. Irradiation of H-3 in the *trans* isomer caused the doublet at τ 4.15 to collapse to a singlet, indicating that this signal is that of H-4. Decoupling of H-3 from



3 **4**

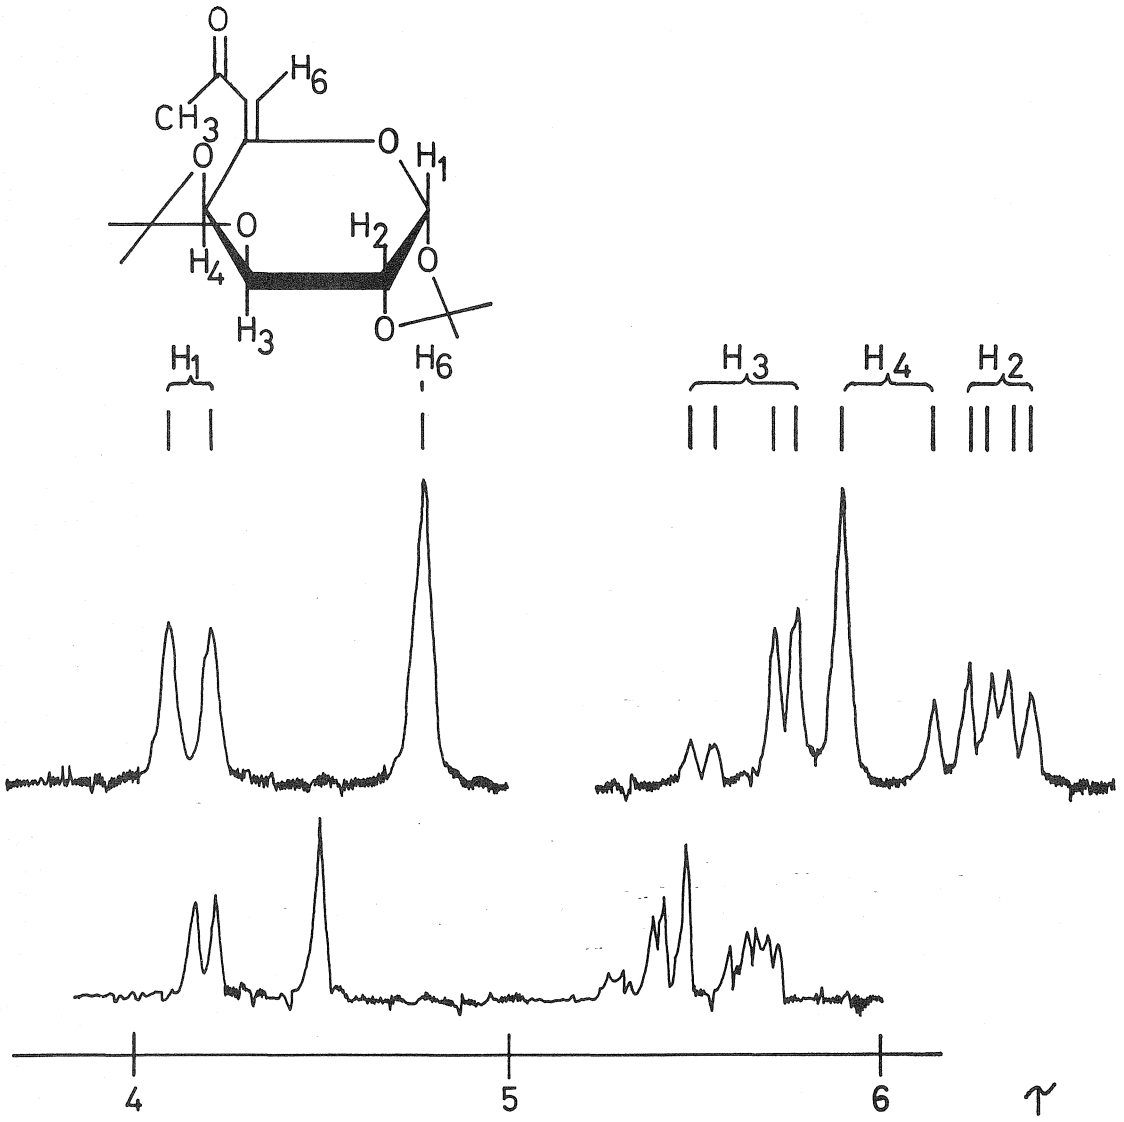

FIG. 3. The low-field portion of the 60 MHz nuclear magnetic resonance spectrum of the *cis* αβ-unsaturated ketone (**5**) in chloroform-*d*.

H-4 in the *cis* isomer (**5**) was not possible because of the similarity of their chemical shifts. In this case, however, the H-4 doublet was clearly seen at τ 5.53 with a splitting of 7 Hz ($J_{4,3}$). It is interesting to note the significantly greater deshielding of the H-4 proton in the *trans* isomer.

The formation of the αβ-unsaturated ketones is of particular interest to carbohydrate chemists, because of the resemblance to the Nef reaction, a procedure widely used in monosaccharide synthesis (6). Such a photochemical reaction has been reported previously (2, 3); irradiation of 6-nitro-Δ^5-cholesteryl 3β-acetate in hexane, aqueous dioxane, or acetone gives in low yield, in addition to other products, 6-oxo-Δ^4-cholesteryl 3β-acetate.

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141

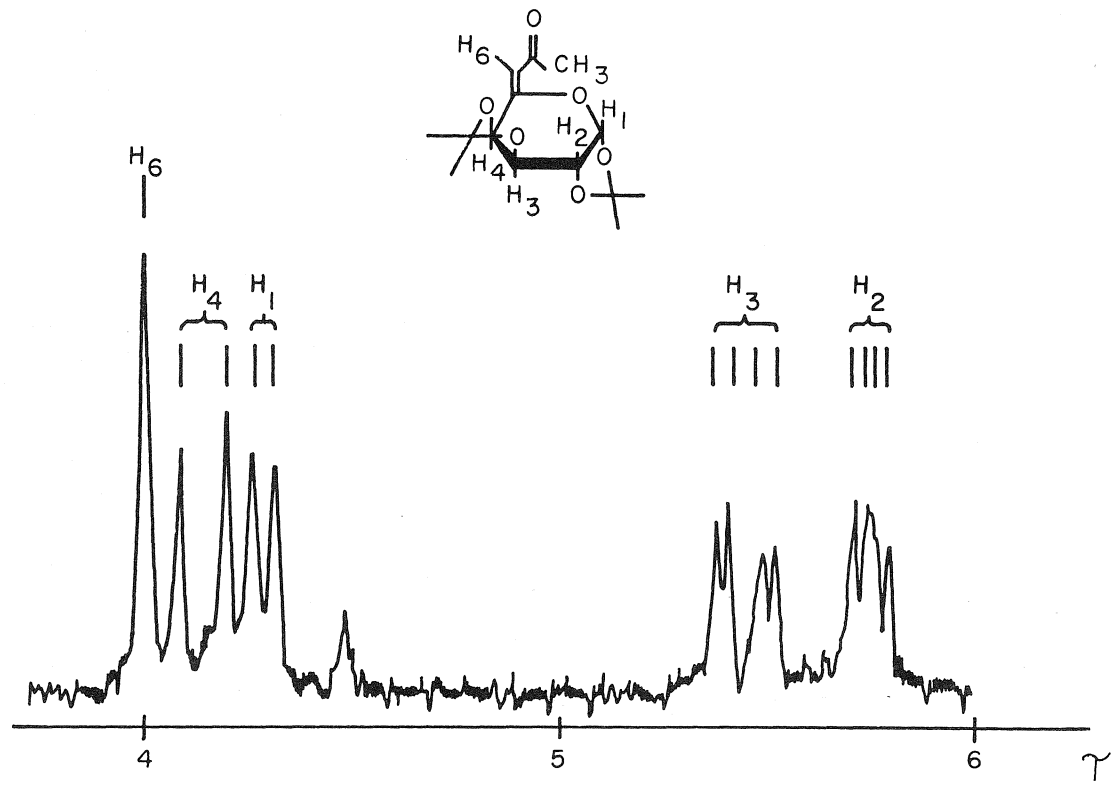

FIG. 4. The low-field portion of the 60 MHz nuclear magnetic resonance spectrum of the *trans* αβ-unsaturated ketone in chloroform-*d*.

automatic polarimeter at 21 ± 2°. Infrared spectra were measured on a Beckman-IR5A spectrophotometer. Ultraviolet spectra were measured with a Unicam SP. 800B spectrophotometer. Nuclear magnetic resonance (n.m.r.) spectra were measured on a Varian A-60A spectrometer in chloroform-*d* and tetramethylsilane as internal standard; a Varian homonuclear spin decoupler was used. Gas–liquid chromatography (g.l.c.) (F and M chromatograph, model 402) was carried out on a column of 1% (w/w) Apiezon L supported on 50–60 mesh acid washed DMCS treated Chromosorb W (115 × 0.4 cm) at 170° with a flow-rate setting of 3.4 at 46 p.s.i. of helium (ca. 100 ml/min). The chromatograph was adapted for preparative separations as described previously (7). Irradiations were performed in quartz tubes with a Rayonet Photochemical Chamber Reactor using a complete set (sixteen) of 2537 Å lamps. The term "petroleum ether" refers to the fraction of b.p. 60–80°.

Photolysis of cis-6,7,8-Trideoxy-1,2:3,4-di-O-isopropylidene-7-C-nitro-α-D-galacto-oct-6-enose (4)

A solution of *cis*-6,7,8-trideoxy-1,2:3,4-di-*O*-isopropylidene-7-*C*-nitro-α-D-*galacto*-oct-6-enose (**4**) (430 mg) in acetone (30 ml) was irradiated as described above. The progress of the reaction was followed by g.l.c.; four major components (see Table I) and a few minor ones were shown to be present. After 4 h the solution was concentrated to give a syrup, which was chromatographed on silica gel, with 2:3 ethyl acetate – petroleum ether as eluent. The fraction rich in the component with relative retention time 0.54 was chromatographed again to yield a syrup, which finally crystallized after a further purification by preparative g.l.c. (115 mg, 27%). Recrystallization from cold ethanol afforded, analytically pure, the *trans* isomer of the nitroolefin **4** (4).

A second column chromatographic separation of the fraction rich in the component with relative retention time 0.40 gave a crystalline product. Recrystallization from chloroform – petroleum ether at −10° afforded pure *cis*-6,8-dideoxy-1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-oct-5-enos-7-ulose (**5**) (31 mg, 8%), m.p. 142–143°, $[\alpha]_D$ −276° (*c*, 0.3 in ethyl acetate); λ_{max} (KBr) 6.03 (conjugated C=O), 6.08 (conjugated C=C), 7.20, 7.25 μm (CMe_2); λ_{max} (ethanol) 248 mμ (ε 1.6 × 10^4); n.m.r. data: (see Table II).

Anal. Calcd. for $C_{14}H_{20}O_6$: C, 59.2; H, 7.0. Found: C, 58.9; H, 7.0.

The fraction rich in the component with relative retention time 0.26 was purified by a second chromatographic separation using the original conditions, and then chromatography on neutral alumina with 1:4 ethyl acetate – petroleum ether as eluent. *trans*-6,8-Dideoxy-1,2:3,4-di-*O*-isopropylidene-α-D-*galacto*-oct-5-enos-7-ulose was obtained as a colorless syrup (23 mg, 6%);

Synthesis of 3-acetamido-2,3,6-trideoxy-D-*lyxo*-hexose (*N*-acetyl-D-daunosamine) and its D-*arabino* isomer

HANS H. BAER, KAREL ČAPEK,[1] AND MARTIN C. COOK
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received July 15, 1968

Two syntheses of 3-acetamido-2,3,6-trideoxy-D-*lyxo*-hexose (*N*-acetyl-D-daunosamine, **14**) are described. The first one starts from methyl 3-acetamido-2,3-dideoxy-β-D-*arabino*-hexopyranoside (**1**) which is converted via its 6-*O*-tosylate (**2**) and 4-*O*-acetyl 6-*O*-tosylate (**3**) into methyl 3-acetamido-4-*O*-acetyl-2,3,6-trideoxy-6-iodo-β-D-*arabino*-hexopyranoside (**5**). Under certain conditions the last step involves a partial anomerization giving the α-anomer (**6**) as an additional product. Both **5** and **6** may be reductively dehalogenated to the corresponding 4-*O*-acetates having a 6-deoxy function (**7** and **8**). Preferably, **5** is reduced and simultaneously de-*O*-acetylated to methyl 3-acetamido-2,3,6-trideoxy-β-D-*arabino*-hexopyranoside (**9**). This glycoside is converted into its β-D-*lyxo* isomer (**13**) by solvolysis of the 4-*O*-mesylate (**12**). Hydrolyses of **9** give 3-acetamido-2,3,6-trideoxy-D-*arabino*-hexose (**10**) and the corresponding amino sugar hydrochloride (**11**), while hydrolyses of **13** give *N*-acetyl-D-daunosamine (**14**) and a syrupy amino sugar hydrochloride. The second synthesis of **14** departs from the D-*lyxo* isomer (**15**) of **1** and proceeds in a similar sequence via the 4-*O*-acetylated derivatives with 6-*O*-tosyl (**16**), 6-deoxy-6-iodo (**17**), and 6-deoxy (**18**) functions, the two last-mentioned compounds being α-glycosides due to anomerization in the step **16** → **17**.

Previous work in this laboratory on the utility of nitro sugars for amino sugar syntheses has furnished methyl 3-amino-2,3-dideoxy-β-D-*arabino*-hexopyranoside (**1**) (1) and its β-D-*lyxo* isomer (**15**) (2). The present article describes the conversion of these two glycosides into derivatives of D-daunosamine, the optical antipode of an antibiotics constituent. The natural product (L-daunosamine) has been obtained by Arcamone and co-workers as a fragment of daunomycin, a *Streptomyces* metabolite showing antitumor activity, and has been demonstrated to be 3-amino-2,3,6-trideoxy-L-*lyxo*-hexose (3). A chemical synthesis of L-daunosamine hydrochloride has recently been accomplished (4), as has a synthesis of the *N*-benzoyl derivative of the D-enantiomer (5). In both instances the introduction of nitrogen at C-3 of the sugars was based on the action of sodium azide upon suitable hexose derivatives which were prepared departing from L-rhamnal and methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside, respectively. As our starting compounds **1** and **15** originate from deoxynitro glycosides that are available via the nitromethane method commencing with methyl β-D-glucopyranoside, the present work offers an alternative entry into the D-daunosamine series. In addition it has afforded the isomer with D-*arabino* configuration.[2]

Compound **1** was treated with 1 mole of *p*-toluenesulfonyl chloride in pyridine and underwent monotosylation in position-6 in high yield. This result accords with findings of Richardson (5) who has reported and discussed a highly selective monotosylation of the α-anomer of **1**. The crystalline 6-*O*-tosylate (**2**) was then acetylated to give the 4-*O*-acetyl 6-*O*-tosyl derivative (**3**). Alternatively, **1** was tosylated and subsequently acetylated without isolation of **2**. For successful monotosylation it proved essential that rigorously dried pyridine be employed. In an experiment neglecting this precaution a sulfur-free mono-*O*-acetate arose; the *O*-acetyl group was presumed to be located in position-6 (**4**) and to have entered there as a consequence of abortive tosylation.

Next, displacement in **3** of the tosyl group by iodine was effected with sodium iodide in refluxing butanone. This reaction was investigated rather thoroughly because it was discovered in initial experiments that the displacement at C-6

[1]On leave of absence from the Laboratory of Monosaccharides, Institute of Chemical Technology, Prague, Czechoslovakia.

[2]In principle, the reaction sequences to be reported could also be carried out in the L-series. The requisite L-enantiomers of **1** and **15**, which have not yet been described, would have to be prepared according to the directions given for the D-compounds (1, 2), from the known nitro precursors with β-L-configuration that have been synthesized starting from methyl β-L-arabinofuranoside (2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was unexpectedly accompanied by partial anomerization at C-1. The presence of two anomeric iodo compounds in the crude reaction mixture was revealed by a nuclear magnetic resonance (n.m.r.) spectrum to be discussed in a later paragraph. Careful fractional crystallization of such a mixture ($[\alpha]_D$ +33°) yielded the pure β-anomer **5** (m.p. 196–198°, $[\alpha]_D$ +5°) and the pure α-anomer **6** (m.p. 175–177°, $[\alpha]_D$ +111°). From the rotation data was calculated a β:α ratio of 2.8:1 for that particular run, which does not necessarily represent an anomeric equilibrium.

It was considered that partial anomerization was caused by traces of acid liberated in a side reaction during the displacement. This conclusion, which appeared reasonable in view of the high reactivity at the anomeric center generally observed in deoxy sugar derivatives (6–9), received support from two facts. First, crystalline **5** was not anomerized but recovered unchanged when it was refluxed with sodium iodide in butanone under the conditions of the displacement. Secondly, the optical rotation of a solution of **5** in butanone slowly increased, signifying progressive anomerization, when the solution was refluxed together with a trace of *p*-toluenesulfonic acid. Consequently, in order to prevent anomerization, the iodide exchange in **3** was performed in the presence of sodium bicarbonate. This became the preferred modification as it proceeded with complete retention of the β-configuration, pure **5** being isolable in yields up to 93% on a preparative scale.

The conversion of the 6-iodo function into a 6-deoxy function, which was required next, was possible with Raney nickel (or platinum) and hydrogen in the presence of diethylamine. The methyl 3-acetamido-4-*O*-acetyl-2,3,6-trideoxy-β- and -α-D-*arabino*-hexopyranosides (**7** and **8**) were in this manner obtained from the iodides **5** and **6**, respectively. However, the reductions were accompanied to a considerable extent by de-*O*-acetylation.

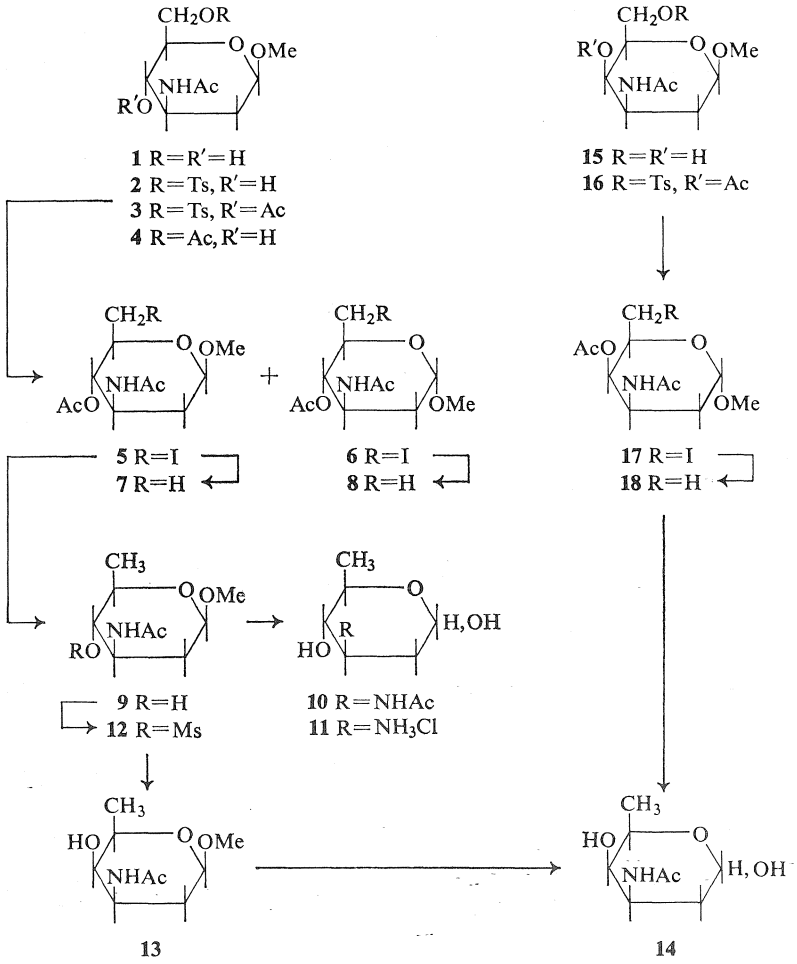
Experiments designed to carry on the plan of synthesis in the α-series were discontinued when it was learned that Richardson (5) had successfully pursued the same course. Efforts were therefore concentrated on the β-series, which happened to be more convenient too, when the β-derivative **5** had become readily accessible in pure form as outlined above.

As it appeared difficult to avoid partial loss of the 4-*O*-acetyl group during the reductive dehalogenation of **5**, and as this group was to be removed later on anyway, compound **5** was hydrogenated with platinum in the presence of sodium methoxide which effected complete de-*O*-acetylation. Methyl 3-acetamido-2,3,6-trideoxy-β-D-*arabino*-hexopyranoside (**9**) was thereby obtained in 80–90% yields. This glycoside was hydrolyzed, with 25% acetic acid to give 3-acetamido-2,3,6-trideoxy-D-*arabino*-hexose (**10**), and with hydrochloric acid to give 3-amino-2,3,6-trideoxy-D-*arabino*-hexose hydrochloride (**11**), a hitherto unknown stereoisomer of daunosamine.

Mesylation of the glycoside **9** afforded the 4-*O*-mesyl derivative **12**, which was isolated in crystalline form in 70% yield and then subjected to solvolysis with sodium acetate in water-containing 2-methoxyethanol, in order to effect inversion of configuration at C-4 by neighboring group participation (10). Methyl 3-acetamido-2,3,6-trideoxy-β-D-*lyxo*-hexopyranoside (**13**) was produced, again in a yield of 70%.[3] Hydrolysis of **13** by dilute acetic acid led to crystalline 3-acetamido-2,3,6-trideoxy-D-*lyxo*-hexose (**14**, *N*-acetyl-D-daunosamine), whereas D-daunosamine hydrochloride, expected to arise by hydrolysis with hydrochloric acid, was obtained as an impure syrup only.

The second synthesis commenced with methyl 3-acetamido-2,3-dideoxy-β-D-*lyxo*-hexopyranoside (**15**) which, with *p*-toluenesulfonyl chloride and acetic anhydride, was in part converted into the 4-*O*-acetyl-6-*O*-tosyl derivative (**16**). Displacement of the tosyl group by sodium iodide produced the calculated amount of sodium *p*-toluenesulfonate. However, only half the expected weight of a syrup containing iodo sugar could be extracted. The syrup apparently contained both anomers of methyl 3-acetamido-4-*O*-acetyl-2,3,6-trideoxy-6-iodo-α-D-*lyxo*-hexopyranoside, and preparative thin-layer chromatography furnished the preponderant product in crystalline form (yield, 20% based on **16**). This product (**17**) was assigned the α-configuration on the basis of its high dextrorotation, $[\alpha]_D$ +155°, which contrasted with the lower rotation, $[\alpha]_D$ +64°, of a second material that was obtained, though as a

[3]Richardson (5) similarly mesylated the α-anomer of **9** but encountered difficulties in attempting to isolate the ester (α-anomer of **12**). However, he found isolation unnecessary and proceeded directly with a solvolysis leading in 42% overall yield to the α-anomer of **13**.



syrup only, and that was probably an α,β-mixture. Further points in support of this assignment will be discussed in a later paragraph. Raney nickel reduction of **17** afforded methyl 3-acetamido-4-*O*-acetyl-2,3,6-trideoxy-α-D-*lyxo*-hexopyranoside (**18**), and this glycoside was converted by alkaline de-*O*-acetylation followed by hydrolysis with an acidic resin into *N*-acetyl-D-daunosamine, identical with **14** obtained in the previous synthesis.

The synthesis of *N*-acetyl-D-daunosamine was thus accomplished in two independent ways involving stereochemically unambiguous reactions and employing starting compounds whose configurations had been rigorously established (1, 2). This fact makes it unnecessary to adduce further configurational proof for the new compounds described, except that the assignment of anomeric configuration to the products arisen in the iodide exchange processes requires justification.

The n.m.r. spectrum of the crude product obtained from **3** by sodium iodide treatment in the absence of bicarbonate displayed two singlets attributable to methoxy groups (τ 6.44 and 6.58). After the material was separated into isomers by fractional crystallization, the τ 6.44 signal was seen to be associated with the anomer (**5**) of low dextrorotation, and the τ 6.58 signal, with the anomer (**6**) of high dextrorotation. Assignment of the β-configuration to the former, and of the α-configuration to the latter, primarily based on the rotations, is in accord with these chemical shifts as, in comparable compounds, protons in equatorial anomeric methoxyls usually resonate at lower field than those in axial

ones. Pertinent examples in the literature (11–13) are supplemented by data given in Table I, special note being taken of the values for the anomeric pair **7** and **8** and of the value for **17** together with that listed in parentheses. Finally, the specific rotations of the α-compounds **6** and **8** were very close in magnitude to those reported (5) for the corresponding derivatives lacking the 4-*O*-acetyl group.

In the D-*lyxo* series the crystalline iodo derivative (**17**), which was assigned α-configuration, exhibited its methoxyl resonance at τ 6.58, and a weak signal suggesting contamination by about 5% of the β-anomer occurred at τ 6.45. The 6-deoxy derivative (**18**) had its methoxyl resonance at τ 6.67, and its melting point and specific rotation were in satisfactory agreement with data reported for the same compound (5) and its enantiomorph (4).

The chemical shifts of the acetoxy and acetamido methyl protons in the compounds of Table I were all in the expected regions (14–16). It is noteworthy that the acetoxy signals of **3** and **16** occurred at higher than usual field, which is attributable (15) to a shielding effect of the aromatic substituent.

Experimental

Melting points were taken in capillaries in an electric aluminium block apparatus equipped with a calibrated thermometer. All evaporations were performed *in vacuo* at a bath temperature of 35–40°. Petroleum ether refers to the fraction of boiling range 30–60°. Thin-layer chromatography (t.l.c.) was done on silica gel G (E. Merck A. G., Darmstadt) with the solvent systems benzene–acetone (2:3, v/v), (solvent *a*) and benzene–acetone (3:7, v/v) (solvent *b*), and spots were made visible with ceric sulfate – sulfuric acid spray. Column chromatography was carried out on silicic acid, 100 mesh (Mallinckrodt Analytical Reagent). Nuclear magnetic resonance (n.m.r.) spectra were obtained from deuteriochloroform solutions on a Varian HA-60 instrument and were calibrated with tetramethylsilane as internal standard. Optical rotations were measured at about 23° in 1-dm tubes, most readings being taken on a Perkin–Elmer 141 automatic polarimeter. Infrared spectra were taken by the Nujol mull technique on a Beckman IR-8 instrument unless otherwise indicated, and the most characteristic frequencies of new compounds are listed in Table II at the end of this section.

*Methyl 3-Acetamido-2,3-dideoxy-6-O-p-tolylsulfonyl-*β*-*D*-arabino-hexopyranoside (2)*

A sample (510 mg) of methyl 3-acetamido-2,3-dideoxy-β-D-*arabino*-hexopyranoside (**1**) (1) in pyridine (10 ml; distilled from sodium hydride) was chilled in a dry ice – acetone bath, and *p*-toluenesulfonyl chloride (530 mg; 1.2 *M* equivalents) was added. The reaction mixture was then stored at 0° for 48 h and at room temperature for 6 h. Water (0.5 ml) was introduced, and after 1 h the solution was concentrated *in vacuo* with several additions of 1% sodium bicarbonate solution, in order to remove most of the pyridine. Finally, the largely aqueous concentrate (ca. 10 ml) was extracted with several portions of chloroform, and the combined extracts were washed once with a small amount of water and dried over sodium sulfate. Inspection by t.l.c. (solvent *a*) of the chloroform phase revealed a strong spot (**2**) accompanied by a much weaker, faster moving spot which presumably represented the 4,6-ditosylate of **1**; the aqueous phase was seen to contain unreacted **1**. The chloroform solution was evaporated to give a crystalline residue (752 mg). Recrystallization from ethyl acetate – petroleum ether afforded **2** (586 mg; m.p. 143–148°). A second recrystallization gave **2** (542 mg) of m.p. 145–148° which could not be raised

further. Work-up of the mother liquors yielded another 62 mg of chromatographically pure **2**, the total thus being 604 mg (70%). The remaining syrup contained the fast-moving by-product. Compound **2** showed $[\alpha]_D$ +25.5 (*c*, 1, chloroform).

Anal. Calcd. for $C_{16}H_{23}NO_7S$ (mol. wt., 373.4): C, 51.47; H, 6.21; S, 8.59. Found: C, 51.50; H, 6.13; S, 8.57.

It was possible and worthwhile to recover unreacted **1** by pooling the extracted, aqueous bicarbonate solutions from several runs, evaporating them to dryness, and eluting **1** with ethyl acetate.

Methyl 3-Acetamido-4-O-acetyl-2,3-dideoxy-6-O-p-tolylsulfonyl-β-D-arabino-hexopyranoside (3)

(a) From 2

A solution of **2** (542 mg) and acetic anhydride (0.5 ml) in pyridine (10 ml) was allowed to stand at 23° for 12 h, after which time t.l.c. (solvent *a*) indicated complete acetylation. Excess water was added, and the reaction mixture was evaporated with several further additions of water. When most of the pyridine and acetic acid was removed, **3** began to crystallize as a hydrate from the remaining aqueous solution and was collected (559 mg) after a few hours of storage at 4°. Upon concentration to about 3 ml and chloroform extraction the mother liquor gave another 25 mg of **3**; total yield, 93%. The hydrate melted at 77–80° (crude) and at 80–82° (recrystallized from ethanol–water). It exhibited infrared absorption at 3600 cm^{-1} (OH) and, in $CDCl_3$ solution, displayed an n.m.r. signal near τ 7.8, with concentration-dependent chemical shift (water). *Anhydrous* **3**, in which these spectral features were absent, crystallized readily from ethyl acetate – petroleum ether, especially when seeded with crystals obtained by repeated evaporation of the hydrate with benzene; m.p. 121–123°, $[\alpha]_D$ +10.5° (*c*, 1, chloroform). Yields of chromatographically pure anhydrous **3** averaging 86% could be obtained when mother liquors of crystallization were worked up.

Anal. Calcd. for $C_{18}H_{25}NO_8S$ (mol. wt., 415.5): C, 52.03; H, 6.07. Found: C, 51.80; H, 6.03.

Anal. Calcd. (for monohydrate): S, 7.38. Found: S, 7.43.

(b) From 1

Compound **1** (600 mg) was tosylated as described for the preparation of **2**, except that 1.1 mole of *p*-toluenesulfonyl chloride and a reaction time of 6 h at 0° followed by 15 h at 4° and 7 h at 23° were employed. Acetic anhydride (1 ml) was then added and the mixture was kept at 23° for 16 h. Addition of water (0.5 ml) was followed after 15 min by dilution with chloroform (50 ml) and consecutive washing with 5% sulfuric acid, water, 1% sodium bicarbonate solution, and water. The organic solution was dried over sodium sulfate and evaporated to leave a residue (824 mg) which was dissolved in ethyl acetate, treated with activated charcoal and recovered by evaporation of the solvent. The hydrate of **3**, m.p. 79–81°, then crystallized from ethanol–water and was converted into the anhydrous form by recrystallization from ethyl acetate – petroleum ether. The product (712 mg; 62%) melted at 121–123°, undepressed on admixture of **3** from (*a*).

Methyl 3-Acetamido-6(?)-O-acetyl-2,3-dideoxy-β-D-arabino-hexopyranoside (4)

In an early attempt at preparing compound **3** an experiment was performed similar to that described in the preceding section (*b*). The reactants were compound **1** (214 mg), *p*-toluenesulfonyl chloride (204 mg), and acetic anhydride (0.2 ml). However, the solvent, reagent grade pyridine, had not been specially dried with sodium hydride. No **3** was produced. Instead, the chloroform phase obtained after washing yielded crystals (60 mg) which melted at 152–154°, showed $[\alpha]_D$ +8.3° (*c*, 0.8, ethanol), and displayed an infrared band at 1733 cm^{-1} (ester carbonyl) but no bands attributable to hydroxyl or tosyl groups. This material was identical with the previously described (1) 4,6-di-*O*-acetate of **1**, m.p. 157.5–158°, $[\alpha]_D$ +9.9° (*c*, 0.6 in ethanol). The aqueous washing liquids were combined, neutralized with sodium bicarbonate, and evaporated to dryness. The solid residue was extracted with ethyl acetate and the extract, upon removal of the solvent, was chromatographed on a column of silica gel (17 g). Benzene–ethanol (20:1) eluted an additional crop (40 mg) of the 4,6-di-*O*-acetate. Subsequent elution with benzene–ethanol (10:1) gave monoacetate **4** (88 mg) which after recrystallization from ethyl acetate – petroleum ether had m.p. 185–187°, $[\alpha]_D$ −19.8° (*c*, 0.4, ethanol).

Anal. Calcd. for $C_{11}H_{19}NO_6$ (mol. wt., 261.3): C, 50.56; H, 7.33; N, 5.36. Found: C, 50.53; H, 7.12; N, 5.46.

Methyl 3-Acetamido-2,3,6-trideoxy-6-iodo-β-D-arabino-hexopyranoside (5) and Methyl 3-Acetamido-2,3,6-trideoxy-6-iodo-α-D-arabino-hexopyranoside (6)

(a) Displacement in the Absence of Sodium Bicarbonate

For purification, commercial butanone (60 ml) was refluxed 1 h with sodium iodide (3 g) and distilled in the presence of anhydrous magnesium sulfate. The distillate dissolved sodium iodide without producing a yellow color.

Compound **3** (200 mg) and sodium iodide (150 mg) were refluxed for 20 h in purified butanone (10 ml). The mixture was then chilled, and sodium *p*-toluenesulfonate (91 mg; 97.5%) was filtered off and washed with chloroform. The filtrate was evaporated to give a pale-yellow residue to which was added chloroform (25 ml), water (5 ml), and 2 drops of 0.1 *N* sodium thiosulfate solution. After thorough shaking the chloroform layer was allowed to separate and, upon drying with sodium sulfate and evaporation, it gave a colorless crystalline material (174 mg; $[\alpha]_D$ +33.4°, *c*, 1.7, chloroform) which was a mixture of **5** and **6**.

This mixture was fractionated in a process involving 20 recrystallizations, with the progress of separation being monitored polarimetrically and fractions of similar rotations being combined. Ether was used to recrystallize fractions of relatively low dextrorotation (rich in **5**), and ethyl acetate – petroleum ether was employed for fractions of relatively high dextrorotation (rich in **6**). The operation afforded 82 mg of pure **5**, m.p. 196–198° decomp., $[\alpha]_D$ +5.0°, (*c*, 1.5, chloroform), and 17 mg of pure **6**, m.p. 175–177° decomp., $[\alpha]_D$ +111°, (*c*, 1, chloroform), $[\alpha]_D$ +96° (*c*, 0.6, dimethyl sulfoxide[4]). In addition there remained mixed fractions totalling 65 mg. Nuclear magnetic resonance spectra of **5** and **6** (Table I)

[4]The rotation in this solvent was measured for comparison with the value, $[\alpha]_D$ +93° in DMSO, recorded (5) for the non-acetylated derivative of **6**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

indicated anomeric purity, whereas a spectrum of the combined mixed fractions showed a β:α ratio of roughly 2:1. Infrared spectra of **5** and **6** were extremely similar although there were minor differences in band positions and relative intensities (Table II).

(b) Displacement in the Presence of Sodium Bicarbonate

Compound **3** (484 mg), sodium iodide (370 mg) and sodium bicarbonate (100 mg) were refluxed with magnetic stirring in purified butanone (22 ml) for 17 h. After cooling, the insoluble matter (330 mg, sodium tosylate and bicarbonate) was filtered off and washed with chloroform, and work-up was proceeded with as described under (*a*). The crude crystalline product (456 mg) showed $[\alpha]_D$ +5.2° (*c*, 4.5, chloroform), i.e. virtually the value of pure **5**. Recrystallization from water (which proved superior to ether) gave **5** (310 mg) as long needles having m.p. 195–197° decomp. and $[\alpha]_D$ +4.9° (*c*, 1.5, chloroform). The yields in five experiments were 70–74%. Column chromatography on silicic acid, with benzene–ethanol (50:1) as eluent, of the material that had remained in the mother liquor of recrystallization furnished additional **5** (90 mg; $[\alpha]_D$ +5.9° in chloroform), thus increasing the yield to 93%.

Anal. Calcd. for $C_{11}H_{18}INO_5$ (mol. wt., 371.2): C, 35.59; H, 4.89; I, 34.19. Found: C, 35.81; H, 5.06; I, 34.00.

Methyl 3-Acetamido-4-O-acetyl-2,3,6-trideoxy-β-D-arabino-hexopyranoside (7)

A solution of **5** (500 mg) and diethylamine (0.14 ml) in methanol (30 ml) was shaken with Raney nickel-T4 (0.1 g) (17) in an atmosphere of hydrogen at room temperature for 5 h. The filtered solution was concentrated to a syrup which was dissolved in chloroform. The chloroform solution was washed successively with cold solutions of sodium thiosulfate, 0.5 *N* hydrochloric acid, sodium bicarbonate, and finally with water. It was then dried with magnesium sulfate and concentrated to a syrup that crystallized from ethyl acetate – petroleum ether. There was obtained 175 mg (53%) of **7**, m.p. 180°, $[\alpha]_D$ +23.4° (*c*, 1, chloroform). This preparation, made from a sample of **5** which was not entirely pure anomerically, contained as a consequence a small admixture of the α-anomer (**8**) accounting for too high a rotation. The n.m.r. spectrum showed a weak signal at τ 6.67 (α-OCH_3) beside the main OCH_3 signal at τ 6.54.

Anal. Calcd. for $C_{11}H_{19}NO_5$ (mol. wt., 245.3): C, 53.86; H, 7.81; N, 5.71. Found: C, 53.75; H, 7.67; N, 5.78.

A similar reduction was performed using *pure* **5** (116 mg), diethylamine (0.1 ml), and *platinum oxide* (50 mg) as catalyst; the solvent was methanol (10 ml). Hydrogen consumption (18 ml at room temperature) was rapid. After 2 h the filtered solution was shown by t.l.c. (solvent *a*) to contain 2 carbohydrate substances, namely fast-moving **7** and its slow-moving product of de-*O*-acetylation (**9**). In addition, diethylammonium iodide was present. The reaction solution was evaporated to give a residue which was treated with chloroform and water, the former dissolving most of **7** and the latter dissolving **9** and the ammonium salt. The chloroform solution was evaporated to yield crystalline **7** (48 mg; 62%), m.p. 177–180° after one and 185–186° after a second recrystallization from ethyl acetate – petroleum ether; $[\alpha]_D$ +7.4° (*c*, 0.4, chloroform). An n.m.r. spectrum showed no evidence for contamination by α-anomer.

The aqueous solution containing **9** was made alkaline by adding 0.35 ml of 1 *N* potassium hydroxide solution and was then evaporated to remove diethylamine. The dry residue (**9** plus potassium iodide) was extracted with ethyl acetate, which yielded 26 mg (40%) of **9**, m.p. 237–239°, identical in its infrared spectrum with **9** described in a subsequent section.

Methyl 3-Acetamido-4-O-acetyl-2,3,6-trideoxy-α-D-arabino-hexopyranoside (8)

A solution of **6** (190 mg) and diethylamine (0.075 ml) in methanol (15 ml) was shaken with Raney nickel-T4 (17) (40 mg) and hydrogen for 4.5 h at room temperature. The solution was evaporated, the residue taken up in chloroform and applied to 2 large t.l.c. plates which were irrigated with solvent *a*. The faster-moving band was scraped off and, upon elution with ethyl acetate, afforded the product **8** (61 mg), m.p. 162–163°, $[\alpha]_D$ +142° (*c*, 1, chloroform). In the n.m.r. spectrum a strong signal at τ 6.67 (α-OCH_3) was accompanied by a much weaker signal at τ 6.53 indicating a slight contamination by the β-anomer. The derivative of **8** lacking the 4-*O*-acetyl group has been reported (5) to show $[\alpha]_D$ +137° (methanol). Extraction of the slower-moving band from the t.l.c. plates afforded some of this derivative as a solid which was used without further purification for obtaining the n.m.r. spectrum ($\mathbf{8}_{4\text{-OH}}$ in Table I).

Methyl 3-Acetamido-2,3,6-trideoxy-β-D-arabino-hexopyranoside (9)

A solution of **5** (276 mg; 0.75 mmole) in methanol (11 ml) containing 1.1 mmole of sodium methoxide was shaken with hydrogen in the presence of platinum catalyst (70 mg of PtO_2). Hydrogen uptake (22 ml) was rapid, about 20 ml being consumed within the first 5 min. After 3.5 h the solution was filtered and its pH was adjusted to about 9 by careful titration with 0.1 *N* sulfuric acid (2.8 ml) against phenolphthalein. The solution, which must stay weakly alkaline at all times, was then evaporated to give a solid. Two ways of further work-up were employed from hereon. In some experiments the solid was dissolved in water and **9** was isolated by exhaustive extraction with chloroform although the distribution coefficient is not very favorable. The method might be convenient for larger scale runs when a liquid–liquid extractor can be used. The dried extract was evaporated and the residue crystallized from ethanol – petroleum ether to give **9** (e.g., 114 mg, 75%). Recrystallized from the same solvents, an analytical sample had m.p. 224–226° and $[\alpha]_D$ −57.6° (*c*, 0.95, water).

Anal. Calcd. for $C_9H_{17}NO_4$ (mol. wt., 203.2): C, 53.19; H, 8.43; N, 6.89. Found: C, 53.28; H, 8.61; N, 7.03.

In runs of the small scale described we preferred chromatographic isolation of **9**. To this end the crude solid was placed on a short column of silicic acid (8 g) and **9** was eluted with benzene–ethanol (20:1) after minor impurities had been eluted with benzene. The yields in **9** were good, e.g. 123 mg (81.5%) in a 0.75 mmole run. The crystals showed m.p. 200–210°, raised to 223–225° by one recrystallization from ethanol – petroleum ether; $[\alpha]_D$ −57.9° (*c*, 1.1, water).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Compound **9** appears to be capable of existing in two crystal modifications. While the melting points just recorded were found in several experiments and could not be raised by further recrystallization of the samples, in two cases a m.p. 237–239° was observed. Such a sample showed the same rotation ($[\alpha]_D$ −57.5°, *c*, 1.2, water) and gave an infrared spectrum identical to that of the lower-melting material. Moreover, both modifications yielded identical reaction products with methanesulfonyl chloride (see a later paragraph).

*3-Acetamido-2,3,6-trideoxy-*D*-arabino-hexose (**10**)*

A solution of **9** (63 mg) in water (3 ml) and acetic acid (1 ml) was boiled under reflux for 25 min. The hydrolysis was monitored by t.l.c. (solvent *b*), which revealed the disappearance of **9** and concomitant formation of more slowly-moving **10**. The hydrolyzate was evaporated and the residue crystallized from 2-propanol – ether. The product (42 mg; 71.5%) had m.p. 196–200°, raised to 199–201° (decomp., sealed capillary) by one recrystallization. The mother liquor gave crystals of m.p. 198–201° decomp. Compound **10** exhibited downward mutarotation: $[\alpha]_D$ +30.4° (4 min) → +18.3° (6 h, constant) (*c*, 0.8, water).

Anal. Calcd. for $C_8H_{15}NO_4$ (mol. wt., 189.2): C, 50.79; H, 7.99; N, 7.40. Found: C, 50.68; H, 7.80; N, 7.25.

*3-Amino-2,3,6-trideoxy-*D*-arabino-hexose Hydrochloride (**11**)*

A solution of **9** (50 mg) in 1 *N* hydrochloric acid (2 ml) was boiled under reflux for 65 min, during which period gradual disappearance of **9** and formation of **11** with intermediary occurrence of **10** was observed by t.l.c. (solvent *b*). The hydrolyzate was evaporated to a syrup which was dried *in vacuo* and then crystallized from 2-propanol – ether giving **11** (43 mg), m.p. 160–170° decomp. One recrystallization from the same solvents gave **11** (31 mg), m.p. 168–170° decomp., unchanged by a further recrystallization. No mutarotation was observed: $[\alpha]_D$ +81.7° (*c*, 0.7, water). A sample reduced hot Fehling solution strongly.

Elemental analysis of a sample dried *in vacuo* at 56° gave a high carbon value which suggested retention of solvent of crystallization. The data did not correspond perfectly to 1 mole of 2-propanol, but its presence was strongly supported by mass spectrometry. A sample heated up to 100° in the high vacuum of the spectrometer released volatile matter that gave a weak parent peak at 60 *m/e* and a strong fragment peak at 45 *m/e* attributable to 2-propanol. We thank Prof. J. L. Holmes for this determination.

Anal. Calcd. for $C_6H_{14}ClNO_3 \cdot C_3H_8O$ (mol. wt., 243.7): C, 44.35; H, 9.10. Found: C, 44.69; H, 8.44.

*Methyl 3-Acetamido-2,3,6-trideoxy-4-O-methylsulfonyl-β-*D*-arabino-hexopyranoside (**12**)*

A solution of **9** (109 mg) in pyridine (5 ml; dried over sodium hydride) was cooled to −70°, and methanesulfonyl chloride (0.3 ml) was added. The reaction mixture was allowed to stand for 2 days at −10–0°. Water (0.1 ml) was then added to the brown solution which, after 15 min, was evaporated with several additions of 1% sodium bicarbonate solution in order to remove most of the pyridine. The remaining aqueous solution was extracted with chloroform (40 ml in several portions), the extract was dried with sodium sulfate and evaporated to a dark, crystalline mass (154 mg). Passage through a column of silicic acid (8 g), which was eluted first with benzene and then with benzene–ethanol (50:1), gave unidentified impurities in the benzene fractions while the mixed solvent fractions furnished 26 mg of **12** containing a trace of a contaminant (faster moving on t.l.c.) and subsequently 100 mg of chromatographically pure **12** (total yield, 83%). Upon one or two recrystallizations from ethyl acetate – petroleum ether **12** had m.p. 153–155° decomp., $[\alpha]_D$ −16.5° (*c*, 1, chloroform), unchanged on further recrystallization. Omitting the column chromatography we obtained from crude **12**, by recrystallization with use of decolorizing carbon, pure **12** in somewhat lower yields.

Anal. Calcd. for $C_{10}H_{19}NO_6S$ (mol. wt., 281.3): C, 42.70; H, 6.81; S, 11.40. Found: C, 42.78; H, 7.34; S, 11.10.

*Methyl 3-Acetamido-2,3,6-trideoxy-β-*D*-lyxo-hexopyranoside (**13**)*

A solution of mesylate **12** (91 mg), sodium acetate trihydrate (170 mg), and water (0.5 ml) in 2-methoxyethanol (5 ml) was refluxed for 40 min. The reaction mixture was evaporated to dryness and the residue was chromatographed on silicic acid (5 g) by elution with benzene–ethanol (20:1). Crystalline **13** (46 mg; 70%) was obtained and melted, in a sealed capillary, at 208–212° after one and at 210–212° after a second and a third recrystallization from ethyl acetate; $[\alpha]_D$ +27.7° (*c*, 1, water). The compound sublimed *in vacuo*.

Anal. Calcd. for $C_9H_{17}NO_4$ (mol. wt., 203.2): C, 53.19; H, 8.43; N, 6.89. Found: C, 53.16; H, 8.40; N, 6.83.

*3-Acetamido-2,3,6-trideoxy-*D*-lyxo-hexose (**14**)*

*(a) From **13***

The glycoside **13** (37 mg) was hydrolyzed with acetic acid as described for the hydrolysis of **9** to **10**. The reducing sugar **14** crystallized from ethyl acetate in a yield of 28 mg (81%), m.p. 143–145°. After one recrystallization **14** had m.p. 145–146°, $[\alpha]_D$ +101° (ca. 4 min.) → +94.2° (10 min, constant) (*c*, 0.5, water). When the rotational sample was recovered by evaporation of the water, it melted at 151–153°.

Anal. Calcd. for $C_8H_{15}NO_4$ (mol. wt., 189.2): C, 50.79; H, 7.99. Found: C, 51.00; H, 7.99.

*(b) From **18***

The glycoside **18** (12 mg) was dissolved in 0.1 *N* sodium hydroxide solution (0.5 ml). After 15 min it was determined by t.l.c. (solvent *a*) that fast-moving **18** had disappeared completely, giving rise to a slower spot that travelled like the de-*O*-acetylated glycosides **9** and **13**. After another 10 min the solution was diluted with a few milliliters of water and stirred with 2 ml of cation exchanger, Rexyn 101(H^+), for 20 min at 60°. Thin-layer chromatography then revealed complete disappearance of the product of alkaline hydrolysis and showed the presence of a single spot moving at the still lower speed of **14**. The resin was filtered off and washed well with water, and the filtrate was treated with activated charcoal and evaporated to give 5 mg of white crystals. Recrystallization from ethyl acetate gave **14** (3 mg), m.p. 144–146°,

†In chloroform.
‡Anhydrous compound.
§Hydrate.
‖Melting point 145–146°.
¶Melting point 152–153°.

undepressed upon admixture of **14** from (*a*); $[\alpha]_D$ +117° → +95.7° (20 min, constant) (*c*, 0.11, water). Crystals recovered from the aqueous solution melted at 152–153°.

Attempted Preparation of D-*Daunosamine Hydrochloride*

The glycoside **13** (44 mg) was hydrolyzed, first with 0.2 *N* hydrochloric acid at 80° for 2 h and at 100° for 1.5 h, and thereafter with increased acid strength (0.43 *N*) at 100° for 1 h. Thin-layer chromatography (solvent *b*) then indicated complete conversion of **13** into material that remained at the starting point. Evaporation of the hydrolyzate gave a syrup which was dried to glassy consistency in a desiccator. The substance failed to crystallize from a variety of solvents. It reduced hot Fehling solution and showed $[\alpha]_D$ +63.7° (*c*, 1.7, water). Reported (4) for crystalline L-daunosamine hydrochloride, $[\alpha]_D$ −54.2° (water).

*Methyl 3-Acetamido-4-O-acetyl-2,3-dideoxy-6-O-p-tolylsulfonyl-β-*D*-lyxo-hexopyranoside (16)*

To a chilled solution of 1.12 g of methyl 3-acetamido-2,3-dideoxy-β-D-*lyxo*-hexopyranoside (**15**) (2) in dried pyridine (7.5 ml) was added a chilled solution of *p*-toluenesulfonyl chloride (1.02 g; 1.05 molar equivalents) in dry, ethanol-free chloroform (28 ml). The mixture was kept at −8° for 24 h. Acetic anhydride (0.53 ml) was then added, and the mixture was allowed to stand at −8° for another 24 h. It was then shaken briefly with a small quantity of water, diluted with excess chloroform, and washed successively with dilute sulfuric acid, sodium bicarbonate solution, and water. The organic phase was dried over magnesium sulfate and evaporated to give a syrup which was crystallized from ethyl acetate – petroleum ether. Crude **16** (1.06 g; 50%), m.p. 140–142°, was recrystallized from ethyl acetate to give fibrous needles

(0.84 g) of m.p. 148–149°, $[\alpha]_D$ +13.8° (*c*, 1, chloroform).

Anal. Calcd. for $C_{18}H_{25}NO_8S$ (mol. wt., 415.5): C, 52.03; H, 6.07; S, 7.72. Found: C, 51.94; H, 6.36; S, 7.24.

The mother liquor remaining in the crystallization of **16** gave 3 spots on t.l.c. (solvent *a*). Application to large plates allowed the separation into bands which were scraped off and extracted with acetone. The slowest band afforded crystals that were identified as the known (2) *4,6-di-O-acetate* of **15** by comparing infrared and n.m.r. spectra with those of an authentic sample. The middle band gave crystals of **16**, m.p. 148–150°. The third and fastest band furnished a syrupy *di-O-tosylate*. Its infrared spectrum showed peaks at 3350 (NH), 1650 and 1540 (amide I and II), and 1610, 1470, and 1180 cm^{-1} (tosyl). The last three bands were more intense with respect to the amide absorptions than the corresponding bands in the spectrum of **16** (Table II). There were no peaks attributable to *O*-acetyl in the 1730 and 1250 cm^{-1} regions. The n.m.r. spectrum exhibited methyl proton singlets at τ 6.60 (*O*—CH_3), 7.56 (arom. CH_3), and 8.09 (*N*—Ac). The signal at τ 7.56 was twice as intense as either one of the others. (Compare also the spectra of **3** and **16**, Table I.)

*Methyl 3-Acetamido-4-O-acetyl-2,3,6-trideoxy-6-iodo-α-*D*-lyxo-hexopyranoside (17)*

A solution of **16** (840 mg) and sodium iodide (610 mg) in dry acetone (6 ml) was heated in a bomb for 18 h at 100–110°. After the mixture had cooled, sodium *p*-toluenesulfonate (392 mg, 99%) was filtered off and the red filtrate concentrated. Water was added to the residue, and the mixture was extracted three times with chloroform. The combined extracts were washed with sodium thiosulfate solution and water, dried with magnesium sulfate, and evaporated to give a syrup (0.37 g) which did not crystallize. The syrup was dissolved in a small amount of chloroform and applied to 3 large t.l.c. plates which were developed with solvent *a*. Two bands separated. Extraction with acetone of the faster-moving, and major, band afforded a crystalline material which was recrystallized from ethyl acetate – petroleum ether to give **17** (152 mg) m.p. 167–169°, $[\alpha]_D$ +155° (*c*, 1.5, chloroform). A Beilstein test indicated the presence of halogen.

Anal. Calcd. for $C_{11}H_{18}NIO_5$ (mol. wt., 371.2): C, 35.59; H, 4.89. Found: C, 35.83; H, 5.02.

The slower band afforded a syrupy material (47 mg) that had $[\alpha]_D$ +64° (*c*, 1.5 in chloroform). It showed infrared bands at 3350 (NH), 1750 (ester CO), 1660 and 1530 cm^{-1} (amide I and II). Presumably this syrup contained the β-anomer of **17**; however, it was not investigated further.

*Methyl 3-Acetamido-4-O-acetyl-2,3,6-trideoxy-α-*D*-lyxo-hexopyranoside (18)*

A solution of **17** (130 mg) and diethylamine (0.04 ml) in methanol (8 ml) was shaken with Raney nickel-T4 (30 mg) and hydrogen for 3 h at room temperature. The solution was filtered and concentrated to a syrup which was dissolved in a small amount of chloroform and subjected to preparative t.l.c. (solvent *a*). As the main component a crystalline material (48 mg) was obtained. Recrystallization from ethyl acetate – petroleum ether gave **18** (25 mg), m.p. 189–190°, $[\alpha]_D$ +186° (*c*, 0.5, chloroform). Reported (5) for **18**: m.p. 183–185°, $[\alpha]_D$ +192° (chloroform); reported (4) for the L-enantiomer of **18**: m.p. 187–188°, $[\alpha]_D$ −204° (chloroform). A small amount of the β-anomer was present in our sample, causing low rotation and a (very weak) n.m.r. signal at τ 6.50.

Anal. Calcd. for $C_{11}H_{19}NO_5$ (mol. wt., 245.3): C, 53.86; H, 7.81. Found: C, 53.93; H, 7.85.

Cyclizations of dialdehydes with nitromethane. XIV. The isolation of four crystalline methyl 3,6-dideoxy-3-nitro-α-L-hexopyranosides[1]

HANS H. BAER AND KAREL ČAPEK[2]
Department of Chemistry, University of Ottawa, Ottawa, Canada

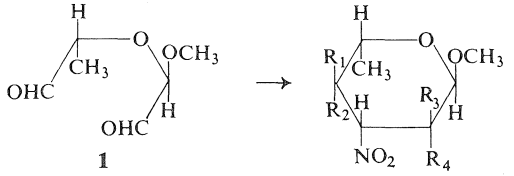
Received July 26, 1968

Cyclization of L′-methoxy-L-methyldiglycolic aldehyde (**1**) with nitromethane and sodium methoxide in methanol (40 min at room temperature) furnished four crystalline methyl 3,6-dideoxy-3-nitro-α-L-hexopyranosides in a combined yield of 75%. Chromatographic separation gave the *gluco* (**2**), *manno* (**3**), *talo* (**4**), and *galacto* (**5**) isomers in an approximate ratio of 18:8:3:1. Shortening of the reaction time to 25 min decreased the total yield to 53% at the expense of **2**, the ratio of isolated products being 8:8:2.3:1.7. The configurations of the new nitro glycosides **3**, **4**, and **5** were proven by catalytic hydrogenation followed by *N*-acetylation, which gave the known 3-acetamido derivatives.

Canadian Journal of Chemistry, 47, 99 (1969)

In the nitromethane cyclization of a periodate-oxidized methyl glycoside ("sugar dialdehyde") the resulting methyl deoxynitro glycoside contains three new asymmetric centers and consequently, eight stereoisomeric products can be expected *a priori*.[3] In practice, however, it has been found in all the cases which were examined in some detail as to the stereochemical composition of the products, that the reaction is endowed with a marked stereoselectivity. One or two of the eight configurations usually arise in considerable preponderance while another one or two occur to a minor extent, and the remaining ones are not encountered (2, 3). This picture will probably change little, and retain its general validity, even if reinvestigation of individual reactions should bring to light small proportions of additional isomers that have hitherto escaped detection. The observed stereoselectivity no doubt is governed by two factors, namely the conformational behavior of reaction intermediates and the thermodynamic stability of the final products. Stereochemical considerations (4–8) rationalizing some of the experimental results have been advanced as the latter gradually emerged over the past decade, but a comprehensive theory consistent with all observations is still lacking. It was felt that more data on the sugar dialdehyde–nitromethane cyclization need be gathered before such a theory may evolve, and the present work was undertaken in order to make a contribution in this regard.

The cyclization of L′-methoxy-L-methyldiglycolic aldehyde (**1**) (9) obtainable from methyl α-L-rhamnopyranoside was first performed by Richardson and McLauchlan (10) in whose hands it has served as a convenient preparative avenue to 3-amino-3,6-dideoxy sugars which command interest in connection with the chemistry of antibiotics (11). The authors (10) obtained from **1** and nitromethane a syrupy mixture of methyl 3,6-dideoxy-3-nitro-α-L-hexopyranosides which they reduced with Raney nickel without prior isolation of individual stereoisomers. The procedure furnished a single crystalline amine shown to possess the α-L-*gluco* configuration, and from its yields[4] of 25–31% one may realize the minimum extent to which the nitro precursor, methyl 3,6-dideoxy-3-nitro-α-L-glucopyranoside (**2**), must have been present. Repeating the nitromethane cyclization of **1**, Čapek *et al.* (12) succeeded in isolating **2** in crystalline form. In a more detailed investigation we have now isolated besides **2** the crystalline isomers with α-L-*manno*



2 $R_1 = R_3 = OH$, $R_2 = R_4 = H$
3 $R_1 = R_4 = OH$, $R_2 = R_3 = H$
4 $R_2 = R_4 = OH$, $R_1 = R_3 = H$
5 $R_2 = R_3 = OH$, $R_1 = R_4 = H$

[1]For paper XIII in this series see reference 1.
[2]On leave of absence from the Laboratory of Monosaccharides, Institute of Chemical Technology, Prague, Czechoslovakia.
[3]The possibility of additional stereoisomerism will be mentioned later on.
[4]Here and subsequently, yields are based upon the original methyl α-L-rhamnopyranoside; no unacceptable error would be introduced by equating these figures with yields based upon the dialdehyde **1**, since the latter is engendered from the rhamnoside in a virtually quantitative reaction.

(**3**), α-L-*talo* (**4**), and α-L-*galacto* (**5**) configurations, determined their proportions, and come to the conclusion that any other products do not play a significant role in the reaction mixture.

In a cyclization performed under the conditions specified previously (10), i.e. with a reaction time of 40 min at room temperature, we obtained **2** in 26% yield by direct crystallization. A thin-layer chromatogram (t.l.c.) of the mother liquor showed five spots. Column chromatography on silicic acid made possible the separation of these components. The fastest spot was due to a yellow, ether-soluble oil which was eluted from the column first and appeared to be a minor impurity amounting to less than 1% of the mother liquor dry-weight. This oil was not investigated further. The second-fastest t.l.c. spot corresponded to the α-L-*talo* isomer (**4**) which was obtained from the column in crystalline form in a yield of 7.6%. The middle, and strongest, spot did not represent a single compound but a mixture of the α-L-*manno* (**3**) and α-L-*gluco* (**2**) isomers which were present in the mother liquor in nearly equal amounts. The column furnished both **3** and **2** in yields of about 20%, although either isomer was recovered in pure form only to the extent of two-thirds of that amount while the remainder was obtained as a noncrystalline mixture of both, with a component ratio of about 1:1 determined polarimetrically. The second-to-last t.l.c. spot was due to the α-L-*galacto* isomer (**5**). This isomer was eluted from the column in yields of 2–2.5%. Finally, the slowest t.l.c. spot represented a material which, when eluted from the column, amounted to a yield of 1.5% (calculated as an isomeric nitro glycoside). However, this material did not appear to be a uniform product; it gave several spots on rechromatography and only a small part of it could be crystallized. The crystals did show infrared bands characteristic of a nitro glycoside and may have been an additional isomer,[5] but their quantity was too small for further examination.

[5]Should this be verified, a choice among the α-L-*allo*, *altro*, *gulo*, and *ido* configurations would seem logical, although glycosides bearing an axial nitro group at C-3 have not been encountered in nitromethane cyclizations (1–8), with the notable exception (4) of the β-D- and β-L-ribopyranosides. However, one would also have to consider the possibility of stereoisomers arising from epimerization of C-5. Such rather unexpected epimerizations have recently been discovered in a cyclization with nitroethane (13) and have occurred to a small degree in one cyclization with nitromethane (14).

TABLE I

Methyl 3,6-dideoxy-3-nitro-α-L-hexopyranosides

Configuration	Melting point	$[\alpha]_D^{23}$ in H_2O	Yields, % 40 min	Yields, % 25 min
Gluco (**2**)	142–145°	−162.0°	45–46	22
Manno (**3**)	73–78°*	−23.9°	18–21	20
Talo (**4**)	105–107°	−89.8°	7–8	6
Galacto (**5**)	155–158°	−216.0°	2–3	5

*This compound crystallized as a monohydrate; it liquefied with loss of water on drying *in vacuo* at room temperature.

Physical constants and isolated yields of the four stereoisomeric methyl 3,6-dideoxy-3-nitro-α-L-hexopyranosides (**2**–**5**) are listed in Table I. The table contains also the yields, obtained after chromatographic separation, of a second cyclization experiment that was conducted under identical conditions except for a shorter reaction time of 25 min. The total of isolated, crystalline products was less in this case, namely 53% *versus* 75% in the 40 min experiment. Moreover, there was an interesting variation in the ratio of products, the *gluco* and *manno* isomers on the one hand and the *talo* and *galacto* isomers on the other being now found in equal amounts. It has been recognized previously (6, 15) that nitro glycosides formed initially may epimerize as the reaction in an alkaline medium goes on, and this circumstance explains variations in the product composition as a function of time. The course of the epimeric equilibration of the sodium nitronates of **2**, **3**, **4**, and **5** will be the subject of a later communication (16), but the result of the present study, namely the observed predominance of *gluco* and *manno* products in early stages of the cyclization and the occurrence of minor proportions of *talo* and *galacto* isomers, is in full harmony with the results obtained (6) in the series of methyl 3-deoxy-3-nitro-α-D-hexopyranosides. By contrast, in the analogous series of β-D-hexopyranosides the *gluco* and *galacto* configurations were strongly favored and the *manno* configuration arose to a subordinate extent (17).

Whereas the configuration of **2** had been established previously (10, 12), that of each of the new isomers had yet to be determined. Compounds **3**, **4**, and **5** were therefore hydrogenated catalytically with platinum in the presence of

For personal use only.

acetic anhydride to give the corresponding methyl 3-acetamido-3,6-dideoxy-α-L-hexopyranosides. All of these were known, and identifications with authentic specimens were made by comparison of physical constants and infrared spectra.

Experimental

Unless otherwise indicated, thin-layer chromatography (t.l.c.) was performed on silica gel G (Merck A.G., Darmstadt) with the solvent system benzene–ethanol (20:1, v/v); spots were made visible by a ceric sulfate – sulfuric acid spray. Silic acid (analytical grade, 100 mesh) from Mallinckrodt was used for column chromatography. Petroleum ether refers to the fraction with boiling range 30–60°. Infrared spectra were taken from Nujol mulls on a Beckman IR-8 instrument. Optical rotations were measured at about 23° in a Perkin–Elmer 141 automatic polarimeter.

Nitromethane Cyclization[6]

Crystalline methyl α-L-rhamnopyranoside (18) (25 g, 0.14 mole) was prepared by an improved procedure (19) and oxidized with sodium metaperiodate as described (10). Examination by t.l.c. (acetone–benzene, 3:2) revealed that the oxidation was complete after 1 h. Treatment with nitromethane and sodium methoxide for 40 min was then conducted as described (10), and the syrupy mixture of nitro glycosides resulting after work-up was triturated with a few milliliters of chloroform and seeded with methyl 3,6-dideoxy-3-nitro-α-L-glucopyranoside (**2**) (12). Partial crystallization took place, and the crystals (**2**) were isolated after standing in the refrigerator overnight, washed with a small amount of cold chloroform, and recrystallized from chloroform – petroleum ether. The yield of **2** was 7.75 g (26%), m.p. 141–143°, $[\alpha]_D$ −164.3° (*c*, 1, water). Reported (12): m.p. 136–139°, $[\alpha]_D$ −164.5° (water).

Chromatographic Separation of Mother Liquor Components

The mother liquor remaining after the collection of crude **2** was evaporated to a brown syrup weighing 22.1 g.

A part (2.5 g) of the above syrup together with a small amount of benzene was absorbed in a lump of cotton wool and placed on a column (40 × 2 cm) containing 45 g of silicic acid. In the subsequent chromatography, 25-ml fractions were collected, evaporated and, if they left any residue, examined by t.l.c. Elution was started with pure benzene (250 ml), which produced no detectable residues in fractions 1–10. This was followed by benzene–ethanol (100:1) (450 ml). Fractions 11–20 were blank also and 21 and 22 contained a few milligrams of an oil that was discarded. Fraction 23 (146 mg) was a mixture of crystals and a yellow oil, and fractions 24–28 gave a total of 258 mg of dry, yellow crystals. The latter were recrystallized from ether – petroleum ether with the use of decolorizing carbon and afforded 177 mg of the *talo* isomer (**4**), m.p. 104–107°.

[6]Mr. C. W. Chiu is thanked for performing this preparation.

The mother liquor from this recrystallization was combined with the above fraction 23 and subjected to rechromatography on another (smaller) column, from which was obtained a brownish oil (60 mg, not uniform on t.l.c.), a partially crystalline fraction (62 mg, *talo* isomer + yellow, faster-moving oil, according to t.l.c.), and a crystalline fraction (73 mg, *talo* isomer **4** of m.p. 105–107°).

The main chromatography was continued with benzene–ethanol (100:1.5) to fraction 55, and benzene–ethanol (100:2) to fraction 63. Fractions 29–32 contained mixtures of **4** and (presumably) **3** totalling 23 mg; they were discarded. Fractions 33–63 all showed only the "middle" spot on t.l.c., the *manno* (**3**) and *gluco* (**2**) isomers being indistinguishable in the system employed. There were weight maxima in fractions 42 and 47. We combined fractions 33–39 (**A**, 220 mg), 40–43 (**B**, 337 mg) and 44–63 (**C**, 800 mg). Part **C**, whose individual portions had crystallized without difficulty, was recrystallized from chloroform–petroleum ether to give *gluco* isomer **2** (443 mg, m.p. 136–140°). The mother liquor therefrom was evaporated to give a syrup (**C′**, ca. 350 mg). Parts **A** and **B** did not crystallize upon seeding with **2**, but different crystals were obtained with initial difficulty. However, the materials crystallized well when triturated with a few drops of water, and the same was true for the syrup **C′**. The crystals were the monohydrate of the *manno* isomer **3**. Recrystallization from moist ethyl acetate (with careful, dropwise addition of petroleum ether) of the crude crystals obtained from **A**, **B** and **C′** gave a total of 433 mg of **3** (hydrate), m.p. 72–78°. The combined mother liquors were evaporated to a syrup which was dissolved in water, and the aqueous solution was decolorized with activated charcoal and evaporated again, to constant weight (427 mg). This residue showed only one spot on t.l.c. and had $[\alpha]_D$ −99.3° (*c*, 1.23, water). From the rotations of pure **2** and **3** (see below) it was calculated that the residue contained 207 mg of the former and 220 mg of the latter.

The chromatography was continued with benzene–ethanol (100:3). Fractions 64–73 contained the *galacto* isomer **5** only, according to t.l.c. The combined residues were treated with charcoal in ethyl acetate, and after filtration and addition of petroleum ether there crystallized **5** (82 mg), m.p. 154–158°.

Further elution with benzene–ethanol (100:5) gave, in fractions 74–80, 15 mg of a mixture of **5** and an unidentified, slow-moving component and, in addition, some material which did not move at all on t.l.c. The total dry-weight was 40 mg (syrup); crystallization and recrystallization from ethyl acetate – petroleum ether afforded 7 mg of the unidentified, slow-moving component, m.p. 193–197°, $[\alpha]_D$ −109.5° (*c*, 0.4, water).

A similar fractionation was carried out with a larger part (9.2 g) of the syrup (22.1 g) mentioned before, on a column containing 150 g of silicic acid. There was obtained crystalline **4** (694 mg,[7] m.p. 104–108°); crystalline **3** (1.756 g, as hydrate, m.p. 71–78°); crystalline **2**

[7]This was a yield of 5.7%. In contrast to the small-scale separation, which yielded 7.6%, no efforts were made here to isolate additional **4** by rechromatography of mixed fractions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(1.634 g, m.p. 139–143°); a mixed fraction of **2** and **3** (1.726 g) which on the basis of its rotation, $[\alpha]_D$ −78° (*c*, 3.1 in water) was seen to contain 675 mg of the former and 1.05 g of the latter; and crystalline **5** (234 mg, m.p. 154–157°).

Short-time Experiment

A periodate oxidation of methyl α-L-rhamnopyranoside (3.56 g, 20 mmole) followed by nitromethane condensation was carried out exactly as described (10), except that the nitromethane cyclization was interrupted by deionization after 25 min. In this case, crystallization of **2** from the crude syrup could not be induced, probably because of its lower content in the reaction mixture. The syrup was chromatographed on silicic acid (40 g) in a manner similar to the example described. The following were obtained: **4** (276 mg, m.p. 104–107°); a mixed fraction (90 mg) containing **4** and (presumably) **3**; crystalline **3** (631 mg as monohydrate, m.p. 73–78°); **2** (668 mg, m.p. 137–142°); a mixed fraction of **2** and **3** which on the basis of its rotation of $[\alpha]_D$ −90° was calculated to contain 251 mg of the former and 274 mg of the latter; and **5** (166 mg, m.p. 152–156°) plus an estimated 25 mg of **5** in a mixed fraction containing an equally small amount of an unidentified, slow-moving component.

Characterization of Products

Methyl 3,6-Dideoxy-3-nitro-α-L-glucopyranoside (2)

The fractions of crude **2** obtained chromatographically were recrystallized from chloroform – petroleum ether and then melted at 142–145° and had $[\alpha]_D$ −162 ± 0.8° (*c*, 1, water). Infrared bands were at 3550–3450 (OH) and 1555 cm^{-1} (NO_2) and the compound was identical with **2** obtained by direct crystallization.

Methyl 3,6-Dideoxy-3-nitro-α-L-mannopyranoside (3)

The hydrate of **3** melted in the range of 73–78° even after several recrystallizations from moist ethyl acetate, whereby the rotation remained unchanged, $[\alpha]_D$ −23.9° (*c*, 1.3, water). Infrared bands were at 3500–3200 (OH), 1650 (H_2O), 1550 cm^{-1}(NO_2). The analytical sample was air-dried.

Anal. Calcd. for $C_7H_{13}NO_6 \cdot H_2O$ (mol. wt., 225.2): C, 37.33; H, 6.71; N, 6.22. Found: C, 37.23; H, 6.67; N, 6.18.

Drying *in vacuo* at room temperature caused a loss in weight of 7.3% (calcd. for 1 H_2O, 8.0%) and the sample became syrupy.

Anal. Calcd. for $C_7H_{13}NO_6$ (mol. wt., 207.2): C, 40.58; H, 6.32; N, 6.76. Found: C, 40.40; H, 6.41; N, 6.94.

Upon exposure to the atmosphere the anhydrous syrup began to crystallize slowly, reforming the hydrate.

Methyl 3,6-Dideoxy-3-nitro-α-L-talopyranoside (4)

The melting point (104–107°) and rotation ($[\alpha]_D$ −89.8°, *c*, 1.1, water) remained virtually unchanged in several recrystallizations from ether – petroleum ether. Infrared bands occurred at 3530–3400 (OH) and 1550 cm^{-1} (NO_2). The analytical sample was dried *in vacuo* at room temperature as **4** sublimed rapidly at 56°.

Anal. Calcd. for $C_7H_{13}NO_6$ (mol. wt., 207.2): C, 40.58; H, 6.32; N, 6.76. Found: C, 40.47; H, 6.22; N, 6.76.

Methyl 3,6-Dideoxy-3-nitro-α-L-galactopyranoside (5)

The melting point of crude **5** was raised to 155–158°, and then remained unchanged, by recrystallization from ethyl acetate – petroleum ether. Rotations of crude and recrystallized **5** were the same, $[\alpha]_D$ −216° (*c*, 1, water). Infrared bands were at 3500–3430 (OH) and 1550 cm^{-1} (NO_2).

Anal. Calcd. for $C_7H_{13}NO_6$ (mol. wt., 207.2): C, 40.58; H, 6.32; N, 6.76. Found: C, 40.51; H, 6.14; N, 6.61.

Hydrogenations

The nitro glycosides **3**, **4**, and **5** (50 mg) were hydrogenated in methanol (5 ml) in the presence of platinum oxide (50–150 mg) and acetic anhydride (0.3 ml), at ordinary temperature and pressure. The reaction proceeded smoothly with **4**, less so with **3**, and had to be repeated with fresh reagents in the case of **5**. Evaporation then gave the acetamido derivatives.

Compound **3** gave a syrup shown by t.l.c. (benzene–acetone, 3:7) to contain some starting material and unidentified impurities besides the *N*-acetyl derivative. Passage over a silicic acid column (benzene–ethanol, 100:1, with increasing ethanol content) afforded methyl 3-acetamido-3,6-dideoxy-α-L-mannopyranoside (17 mg) which after recrystallization from ethyl acetate – petroleum ether melted at 169–171°, $[\alpha]_D$ −47.3° (*c*, 0.4, ethanol). Reported (12): m.p. 169–171.5°, $[\alpha]_D$ −50.3° (ethanol); for the D-enantiomer (20), m.p. 168–170°, $[\alpha]_D$ +49° (ethanol). Our sample and an authentic specimen gave identical infrared spectra.

Compound **4** afforded a crystalline hydrogenation product (35 mg, m.p. 185–195°) which after recrystallization from acetone or acetone–petroleum ether melted at 201–203°, $[\alpha]_D$ −108.5° (*c*, 0.5, water). Reported for methyl 3-acetamido-3,6-dideoxy-α-L-talopyranoside (10): m.p. 195–196°, $[\alpha]_D$ −104° (water); for the D-enantiomer (21), m.p. 201–202°, $[\alpha]_D$ +106.1° (water). Our product and an authentic sample of the D-enantiomer gave superimposable infrared spectra.

Compound **5** gave a hydrogenation product that contained some starting material but afforded, by recrystallizations from ethyl acetate and then from ethyl acetate – petroleum ether, 18 mg of methyl 3-acetamido-3,6-dideoxy-α-L-galactopyranoside of $[\alpha]_D$ −234.5° (*c*, 0.4, water) and m.p. 200–202°. An authentic sample (12) did not depress the melting point on admixture and gave an identical infrared spectrum. Recorded data: m.p. 202–203°, $[\alpha]_D$ −238° (water) (12); and m.p. 199–200°, $[\alpha]_D$ −219° (water) (22).

Pyranoquinolines. Part I. Syntheses and ultraviolet absorption characteristics of 6-chloro-4*H*-pyrano[3,2-*h*]quinoline-4-ones

D. R. PATEL, C. S. CHOXI, AND S. R. PATEL
Department of Chemistry, Sardar Patel University, Vallabh Vidyanagar, District Kaira, Gujarat State, India
Received May 1, 1968

6-Chloro-2-phenyl and 2-*p*-anisyl-4*H*-pyrano[3,2-*h*]quinoline-4-ones, their 2,3-dihydro and 3-hydroxy derivatives, and 6-chloro-3-benzoyl-2-phenyl-4*H*-pyrano[3,2-*h*]quinoline-4-one are synthesized by the application of appropriate flavonoid syntheses to 5-chloro-7-acetyl-8-hydroxyquinoline (**5**). **5** was formed on Friedel–Crafts acetylation of 5-chloro-8-methoxy and -8-hydroxyquinolines. Ultraviolet spectra of **5** are studied at three different pH's in aqueous ethanol and those of the pyranoquinolines are studied in ethanolic solutions and compared with those of their corresponding simple flavonoids.

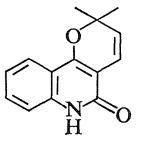
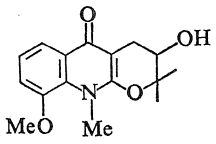
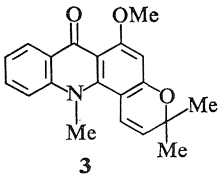
Survey of literature reveals that very few pyranoquinolines have been synthesized. Flindersine (1), isolated from *Flindersia australis* R.Br., is a pyrano[3,2-*c*]quinoline derivative (**1**) and



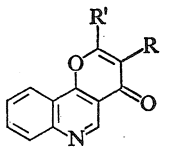
1



2



3



4

isobalfourodine (**2**) (2) isolated from *Balfouradendron riedelianum* is a pyrano[2,3-*b*]quinoline derivative. Acronycine (**3**), isolated from *A. bauerii* (3) can be regarded as a pyrano[2,3-*h*]-quinoline derivative. Elliott and Tittensor (4) have reported syntheses of 2R′-3R-4*H*-pyrano-[3,2-*c*]quinoline derivatives. The fact that the pyranoquinolines are rare was the main consideration in the selection of the work described in the present communication dealing with the syntheses of 6-chloro-2-phenyl and 2-*p*-anisyl-4*H*-pyrano[3,2-*h*]quinoline-4-ones. This provided an opportunity of studying the application of some of the well known methods of flavonoid synthesis to an *o*-hydroxyquinolinone derivative (**5**). The ultraviolet spectra of the pyranoquinolines described in this communication are studied with a view to revealing their characteristic spectral trends and correlating them with those of their parent bicyclic quinoline and flavonoid derivatives.

The Friedel–Crafts acetylation of 5-chloro-8-hydroxyquinoline (**6**), formed on chlorination of 8-hydroxyquinoline (5), was studied using different proportions of the reactants in absence of any solvent and also in presence of solvents like carbon disulfide or nitrobenzene. The product viz., 5-chloro-7-acetyl-8-hydroxyquinoline (**5**) was formed in 40% yield when the reaction was carried out by heating a mixture of 5-chloro-8-hydroxyquinoline (1 part), acetyl chloride (2 parts), and anhydrous aluminium chloride (3 parts) at 120–130° for 12 h. When Friedel–Crafts acetylation of 5-chloro-8-methoxyquinoline (**7**) was effected under similar conditions, **5** was formed in about 50% yield. **7** was formed by the application of Skraup synthesis to 2-methoxy-5-chloroaniline following the method described by Weizmann and Bograchov (6) with the only modification that acetic acid was used as a diluent. It may be interesting to note that 8-hydroxyquinoline on Friedel–Crafts acylation affords 5-acyl-8-hydroxyquinoline in 52% yield (7). The hydroxyquinolinone (**5**) dissolved in dilute alkali solution but was almost insoluble in dilute acid solution. It developed a violet color with aqueous Fe^{+3} solution.

The condensation of **5** with benzaldehyde in presence of alcoholic alkali solution was carried out at room temperature and also at 80°. The product (**8**) obtained did not respond to the characteristic color reactions of a chalcone (8) and remained unchanged on prolonged refluxing with alcoholic acid solution. This suggested that

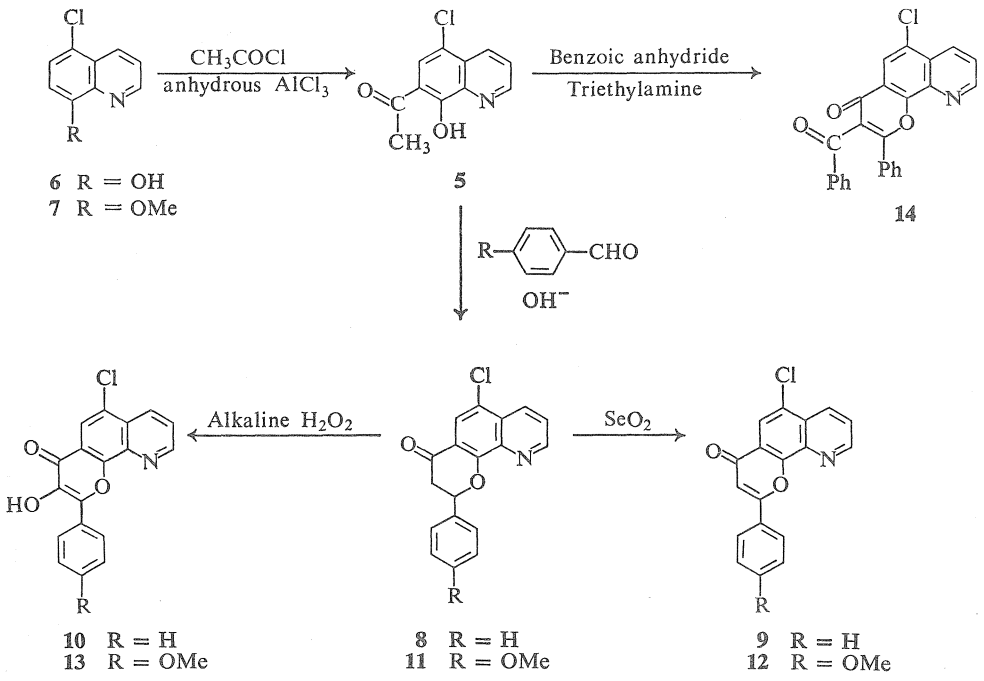


Chart I

the product **8** was not a chalcone but a flavanone derivative, 6-chloro-2-phenyl-4*H*-2,3-dihydropyrano[3,2-*h*]quinoline-4-one (**8**); this was also supported by the nature of its ultraviolet spectrum. The flavanone (**8**) was dehydrogenated on treatment with selenium dioxide (9) in dioxan solution to 6-chloro-2-phenyl-4*H*-pyrano[3,2-*h*]-quinoline-4-one (**9**). The Algar–Flynn oxidation (10) of **8** afforded 6-chloro-3-hydroxy-2-phenyl-4*H*-pyrano[3,2-*h*]quinoline-4-one (**10**). The latter compound (**10**) was also formed in very low yield when **8** was allowed to react with pentyl nitrite in alcoholic hydrochloric acid solution. These reactions have been summarized in Chart I.

6 - Chloro - 2 - *p* - anisyl - 4*H* - pyrano[3,2-*h*]-quinoline-4-ones **11**, **12**, and **13** (Chart I) were synthesized starting with **5** and anisaldehyde following the methods described for the synthesis of their corresponding desmethoxy analogues **8**, **9**, and **10** respectively. In this case too, the chalcone type of compound was not formed on condensing **5** with anisaldehyde but the flavanone derivative, 6-chloro-2-*p*-anisyl-4*H*-2,3-dihydropyrano[3,2-*h*]quinoline-4-one (**11**) was formed. All the reactions in this series ran much more smoothly giving better products than the corresponding reactions in the previous series.

Kostanecki–Robinson reaction of 5-chloro-7-acetyl-8-hydroxyquinoline (**5**) with benzoic anhydride in presence of triethylamine afforded 6-chloro-3-benzoyl-2-phenyl-4*H*-pyrano[3,2-*h*]-quinoline-4-one (**14**). The latter compound could not be deacylated when it was treated with hot 10% alkali solution. It is reported by Bhullar and Venkataraman (11) that 3-benzoyl-α-naphthoflavone having an angular structure analogous to that of **14** does not undergo deacylation on treatment with hot dilute alkali. A one-step Baker–Venkataraman transformation comprising a reaction between an *o*-hydroxyacetophenone derivative (12) with an acyl halide in presence of anhydrous potassium carbonate was applied to **5**. The latter (**5**) on treatment with benzoyl chloride in presence of anhydrous potassium carbonate in dry acetone afforded the flavone derivative (**9**). Some of these pyranoquinolines gave color reactions characteristic of flavonoids.

Thus all the above-mentioned flavonoid syntheses are applicable to 5-chloro-7-acetyl-8-hydroxyquinoline. The corresponding pyranoquinolines are formed in comparatively good yields. In this respect, **5** behaves like a simple *o*-hydroxyacetophenone derivative. This is not surprising as

TABLE I

Spectral data for 5-chloro-8-hydroxy and 5-chloro-7-acetyl-8-hydroxyquinolines

Compound	Medium	Band II λ_{max} (mμ) (log ε)	Band I λ_{max} (mμ) (log ε)
5	Acidic (pH = 1.2)	230* sh (4.10) 271 (4.49)	364 (3.50)
	Basic (pH = 14.0)	285 (4.39)	372–373 (3.95)
	Neutral (pH = 8.5)	230 In (4.10) 269 (4.41) 288 sh (3.87)	365–366 b (3.66)
6	Acidic (pH = 1.1)	226 In (3.98) 261 (4.66)	305 (3.34) 375–385 b (3.41)
	Basic (pH = 14.0)	258 (4.51)	346 (3.56) 380–385 (3.60)
	Neutral (pH = 8.4)	246 (4.56) 264 sh (3.70)	329 (3.56)

*Sh, shoulder; In, Inflection; b, broad.

the quinoline is a stable ring system and 8-hydroxyquinoline behaves like a true phenol (13). However, Pechmann condensation between 5-chloro-8-hydroxyquinoline and acetoacetic ester failed. The reaction was carried out both in presence of concentrated sulfuric acid and polyphosphoric acid. This seems to be due to absence of any activating group in a position para with respect to the point of cyclization (7-position) (14).

The ultraviolet spectra of 5-chloro-7-acetyl-8-hydroxyquinoline (**5**) were studied in aqueous alcoholic solution at three different pH's. The spectral curves are shown in Fig. 1 and the spectral data along with those of 5-chloro-8-hydroxyquinoline (**6**) are recorded in Table I. The ultraviolet spectrum of **6** was studied by Chakrabarty and co-workers (15) at different pH's for the determination of the acid dissociation constant. The ultraviolet spectrum of **5** in aqueous alcoholic solution at pH = 8.5 comprises two bands. The long wavelength band, designated as band I, forms a broad peak at 365 mμ (log ε = 3.66) and the short wavelength band, designated as band II, comprises an inflection at 230 mμ (log ε = 4.1), a sharp intense peak at 269 mμ (log ε = 4.41) and a shoulder at 288 mμ (log ε = 3.87). The spectrum of the compound **5** in the acidic medium (pH = 1.2) resembles very closely its spectrum at 8.5 pH. This suggested that the compound **5** exists mostly in the non-protonated form in acid solution and thereby indicating that it (**5**) is a very weak base. The spectrum of the compound **5** in the basic medium (pH = 14) however differs much from those in the acid and neutral media; the band II has suffered a bathochromic shift of 15 mμ and the band I has become broader and more intense than the corresponding bands in the spectra in the other two media. The bathochromic shift, broadening of the band and the increased intensity observed in the spectrum in the basic medium seems to be due to the anionic form in which the

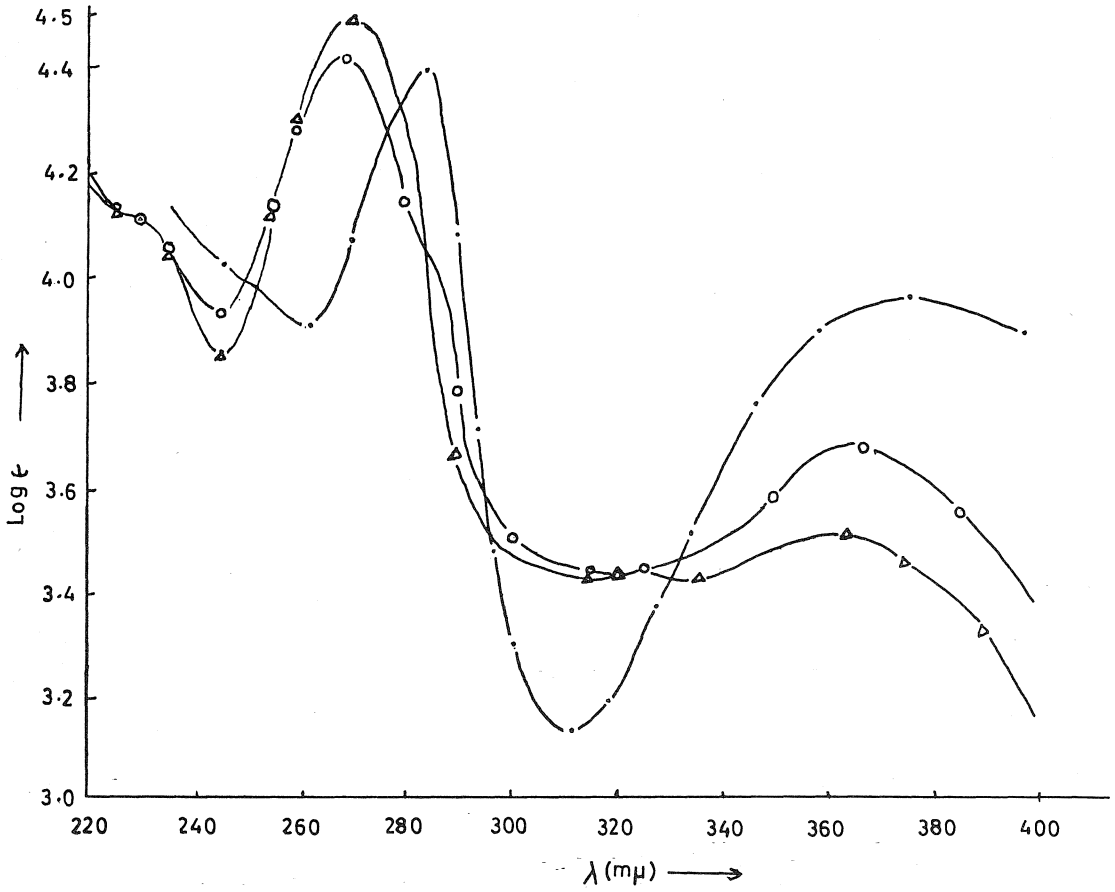

FIG. 1. The ultraviolet spectra of 5-chloro-7-acetyl-8-hydroxyquinoline (**5**) in acidic (—△—△—), basic (—•—•—), and neutral (—O—O—) media.

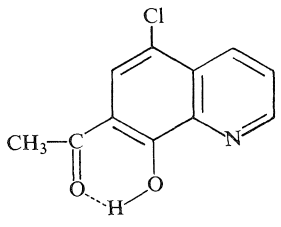
compound **5** would mostly exist in the basic medium. That the anionic form would prove a stronger chromophore than the neutral acid form has been observed in case of phenols and naphthols (16).

A comparative study of the spectrum of the compound **5** and its parent compound 5-chloro-8-hydroxyquinoline (**6**) reveals that all the bands in the spectrum of *o*-hydroxyquinolinone derivative (**5**) appear at longer wavelengths or are more intense than the corresponding bands in the spectrum of the compound **6**. This seems to be due to the strong hydrogen bond formation (chelation) between the hydroxy–hydrogen and the carbonyl–oxygen atoms (**5***a*).

The ultraviolet spectra of the pyranoquinolines (**8–14**) are studied in alcoholic solution. The



5*a*

spectral data are reported in Table II and the spectral curves are shown in Figs. 2 and 3.

It is reported that the spectrum of a flavanone comprises a strong absorption in 270–290 mμ region and a weak absorption in the form of inflection in the 320–330 mμ region; these bands have been designated as bands II and I respectively

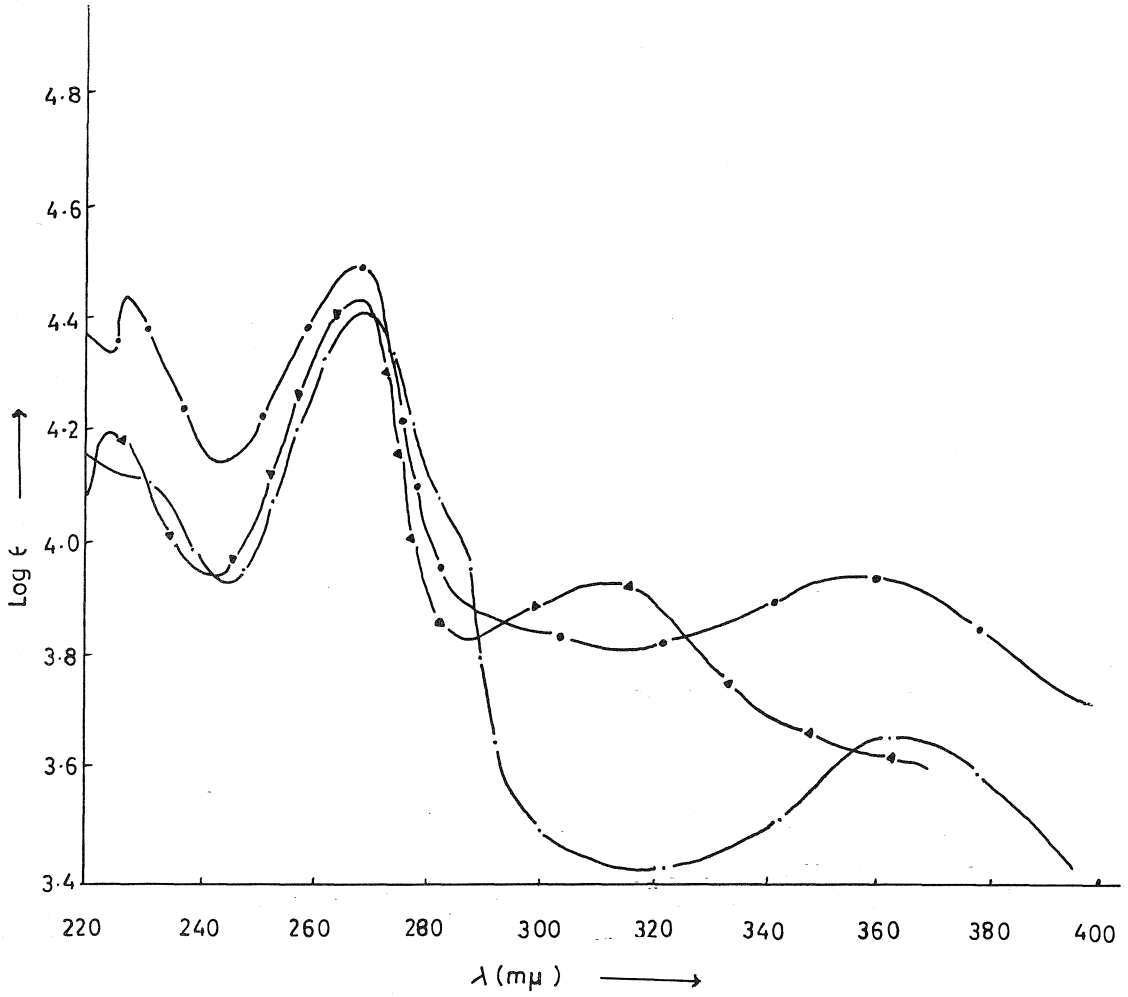

FIG. 2. The ultraviolet spectra of 5-chloro-7-acetyl-8-hydroxyquinoline (**5**) (—.—.—), 6-chloro-2-phenyl-4*H*-2,3-dihydropyrano[3,2-*h*]quinoline-4-one (**8**) (—▲—▲—), and 6-chloro-2-*p*-anisyl-4*H*-2,3-dihydropyrano[3,2-*h*]quinoline-4-one (**11**) (—.—.—).

(17). The spectrum of 6-chloro-2-phenyl-4*H*-2,3-dihydropyrano[3,2-*h*]quinoline-4-one (**8**) comprises two bands; band I appearing at 314 mμ ($\log \varepsilon = 3.93$) and band II comprising a sharp and more intense band at 268 mμ ($\log \varepsilon = 4.4$) and an inflection at 224 mμ ($\log \varepsilon = 4.19$). The band II in the spectrum of **8** resembles very closely the spectrum of the parent ketone 5-chloro-7-acetyl-8-hydroxyquinoline (**5**) (Fig. 2). This is not unexpected as in a flavanone there is no continuity of conjugation between the 2-phenyl and the carbonyl groups. The spectrum of 6-chloro-2-*p*-anisyl-4*H*-2,3-dihydropyrano[3,2-*h*]quinoline-4-one (**11**) also comprises two bands with the only difference that the band I in the spectrum of the compound **11** is more intense and appears at a longer wavelength than the corresponding band in the spectrum of its desmethoxy analogue (**8**).

The spectrum of 6-chloro-2-phenyl-4*H*-pyrano[3,2-*h*]quinoline-4-one (**9**) comprises a sharp inflection at 241 mμ and a prominent band of high intensity with a maxima near about 282 mμ. The low wavelength band II in the spectrum of a flavone has been attributed to the benzoyl grouping and any increase in conjugation in this grouping would result in a bathochromic shift and/or increase in the intensity of this band (18). In the flavone type pyranoquinoline **9**, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

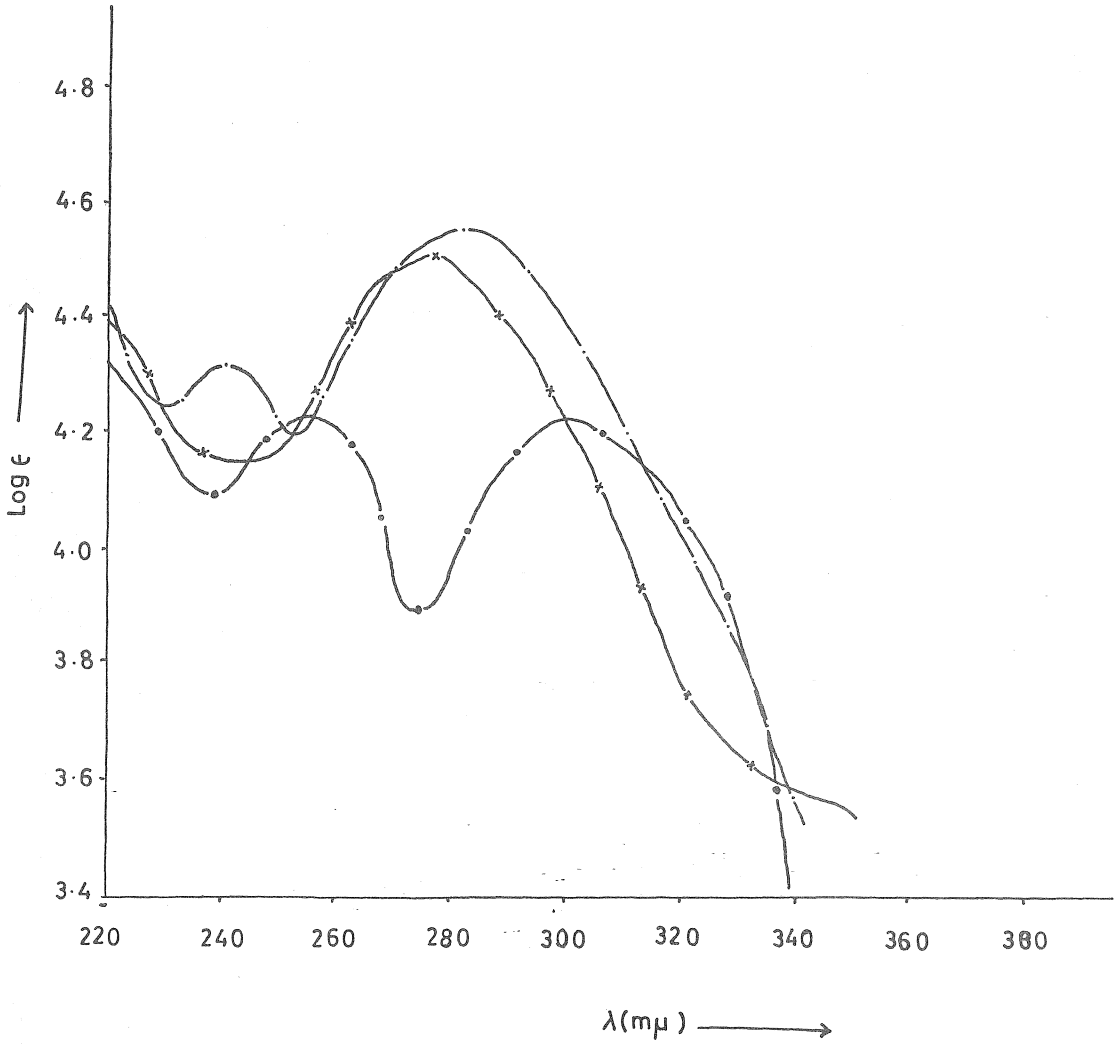

FIG. 3. The ultraviolet spectra of 6-chloroflavone (**17**) (—.—.—), 6-chloro-8-aminoflavone (**18**) (—×—×—), and 6-chloro-2-phenyl-4*H*-pyrano[3,2-*h*]quinoline-4-one (**9**) (—.—.—).

benzoyl grouping of a flavone is replaced by a quinonoyl grouping. This quinonoyl grouping being a stronger chromophore than the benzoyl grouping seems to be responsible for the prominent band II exhibited by the flavone type pyranoquinoline **9**. The long wavelength band which normally appears in the spectrum of a flavone in the region 320–380 mμ (19) is absent in the spectrum of **9**. It is likely that this band I has merged with the tail part of the intense band II and hence appears to have disappeared. The spectrum of 6-chloro-2-*p*-anisyl-4*H*-pyrano[3,2-*h*]quinoline-4-one (**12**) comprises a sharp inflection at 240 mμ and a very broad band ranging from 280 to 330 mμ with the log ε varying from 4.3 to 4.1. Due to the presence of the *p*-methoxy group in the cinnamoyl grouping, the band I in the spectrum of **12** would be more intense and would have undergone a red shift. Hence the broad 280–330 mμ band in the spectrum of **12** seems to be a continuous band comprising the end-part of the band II and whole of band I.

The spectra of the flavonol type of pyranoquinolines **10** and **13** comprise two bands. The band II in the spectra of each of these two compounds consists of an inflection at 235 mμ and a small peak at 280 mμ. The band I appears in the form of shoulder in the spectrum of **10** near

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

about 335 mμ and in the form of a broad band in the spectrum of **13**.

The spectrum of 6-chloro-3-benzoyl-2-phenyl-4*H*-pyrano[3,2-*h*]quinoline-4-one (**14**) comprises only one intense band appearing at 272 mμ (log ε = 4.58). The disappearance of one of the bands and the high intensity of the constituent band in the spectrum seems to be due to the additional —C—Ph group in 3-position.

‖
O

In order to bring forth the characteristics of the ultraviolet spectra of flavone and flavanone type pyranoquinolines which might distinguish them from their simple analogues, the ultraviolet spectra of 6-chloro, 6-chloro-8-aminoflavones, and flavanones and the corresponding pyrano-[3,2-*h*]quinoline derivatives are compared. The spectral data are given in Table II and spectral curves of only the flavone type of compounds are shown in Fig. 3. Comparative study of these spectral data reveals that in the flavanone type of compounds a continuous bathochromic shift and hyperchromic change is discernible as one passes from spectra of 6-chloro-2:3-dihydroflavone (**15**) to that of 6-chloro-2:3-dihydro-8-aminoflavone (**16**) and to that of 6-chloro-2-phenyl-4*H*-2,3-dihydropyrano[3,2-*h*]quinoline-4-one (**8**). In the flavone type of compounds, 6-chloroflavone (**17**) exhibits a two band spectrum—255 mμ (log ε = 4.23); 298 mμ (log ε = 4.22). The spectrum of 6-chloro-8-aminoflavone (**18**) comprises only one prominent and a comparatively more intense band at 275–280 mμ (log ε = 4.49). The spectrum of 6-chloro-2-phenyl-4*H*-pyrano[3,2-*h*]quinoline-4-one (**9**) comprises a similar but slightly more intense band appearing at a slightly longer wavelength and a characteristic distinguishing small peak at 241 mμ (log ε = 4.32).

This spectral analysis of pyranoquinoline derivatives thus reveals that the spectra do not exhibit any outstandingly distinguishing characteristics, except the ones which arise due to increased conjugation.

Experimental

The ultraviolet spectra of the compounds described in this communication are studied in ethanolic or aqueous ethanolic solution on Beckmann DU spectrophotometer. The ultraviolet spectra of 5-chloro-8-hydroxyquinoline and 5-chloro-7-acetyl-8-hydroxyquinoline are studied at three different pH's. The solvent composition was maintained constant in all the three media. The nearly neutral, acidic or basic solution of **5** (or **6**) was prepared by adding 20 ml of distilled water, 20 ml of 0.1 *M* HCl or 20 ml of 0.1 *M* NaOH to 80 ml of the pure ethanolic solution of the compound respectively. The ultraviolet spectra of other compounds were studied in pure ethanolic solution. In all these cases the concentrations of the reagent in solution were maintained accurately around 3×10^{-5} *M*.

5-Chloro-8-methoxyquinoline (7)

To a mixture of 2-methoxy-5-chloroaniline (20 g), arsenic oxide (18 g), glycerine (36 g), and acetic acid (40 ml) cooled in an ice-bath, concentrated sulfuric acid (50 g) was added in small lots over a period of 2 h. The reaction mixture was heated at 160–170° for 8 h, cooled, poured in ice-water, and filtered. The solid product obtained on rendering the filtrate alkaline was collected, washed, dried, and extracted in benzene. The solid product left on removal of benzene was purified by distillation under reduced pressure at 210–215° at 20 mm, m.p. 60–61° (6); yield 43%.

5-Chloro-7-acetyl-8-hydroxyquinoline (5)

A mixture of 5-chloro-8-hydroxyquinoline (1 g), acetyl chloride (2 g), and finely powdered anhydrous aluminium chloride (3 g) was left overnight at 0° and heated at 120–130° for 12 h, cooled, and decomposed with crushed ice and concentrated hydrochloric acid (2 ml). The solid product was collected, washed with water, dried in air and crystallized from aqueous ethanol (1:1) in yellow needles, m.p. 160–161°; yield 0.5 g.

5 was formed in about 50% yield when the reaction was carried out as described above using 5-chloro-8-methoxyquinoline in place of 5-chloro-8-hydroxyquinoline.

Anal. Calcd. for $C_{11}H_8O_2NCl$: C, 59.5; H, 3.6; N, 6.3; Cl, 16.0. Found: C, 59.3; H, 3.8; N, 6.0; Cl, 16.3.

6-Chloro-2-phenyl-4H-2,3-dihydropyrano[3,2-h]-quinoline-4-one (8)

A solution of **5** (0.5 g) and benzaldehyde (0.4 ml) in ethanol (15 ml) was mixed with sodium hydroxide solution (10 ml, 30%) with stirring and left at room temperature for 24 h. It was then decomposed with crushed ice and acidified with hydrochloric acid. The solid product was filtered, washed with bicarbonate solution, and then with water. It was crystallized from aqueous acetic acid (1:1) in yellow light needles, m.p. 191–192°; yield 0.3 g.

This product remained unchanged when it was refluxed with alcoholic hydrochloric acid solution for 48 h.

Anal. Calcd. for $C_{18}H_{12}O_2NCl$: C, 69.7; H, 3.87; N, 4.5; Cl, 11.5. Found: C, 69.6; H, 3.95; N, 4.7; Cl, 11.2.

6-Chloro-2-p-anisyl-4H-2,3-dihydro-pyrano[3,2-h]quinoline-4-one (11)

It was formed on condensing **5** (0.5 g) with anisaldehyde (0.4 ml) following the method described above. The product was crystallized from glacial acetic acid in yellow granules, m.p. 201–202°; yield 0.2 g.

This product remained unchanged on prolonged treatment with hot alcoholic hydrochloric acid.

Anal. Calcd. for $C_{19}H_{14}O_3NCl$: C, 67.1; H, 4.12; N, 4.1; Cl, 10.4. Found: C, 67.3; H, 4.35; N, 4.0; Cl, 10.2.

6-Chloro-2-phenyl-4H-pyrano[3,2-h]quinoline-4-one (9)

A suspension of **8** (0.25 g) and selenium dioxide (0.3 g) in dioxan (8 ml) was refluxed at 110–120° for 18 h, diluted with acetic acid (10) and refltouxed. The reac-mlatedlytion mixture was repefilte,red (thrice) remove

suspended selenium and concentrated on a water bath. The product which separated was collected and crystallized from acetic acid in pinkish white needles, m.p. 273–274°; yield 0.1 g.

Anal. Calcd. for $C_{18}H_{10}O_2NCl$: C, 70.2; H, 3.25; N, 4.5; Cl, 11.5. Found: C, 70.1; H, 3.0; N, 4.3; Cl, 11.8.

*6-Chloro-2-p-anisyl-4H-pyrano[3,2-h]quinoline-4-one (**12**)*

It was formed on treating **11** (0.25 g) with selenium dioxide (0.3 g) in dioxan (10 ml) as described above. It was crystallized from acetic acid in light-yellow needles, m.p. 303–304°; yield 0.08 g.

Anal. Calcd. for $C_{19}H_{12}O_3NCl$: C, 67.5; H, 3.55; N, 4.1; Cl, 10.5. Found: C, 67.8; H, 3.7; N, 4.0; Cl, 10.9.

*6-Chloro-3-hydroxy-2-phenyl-4H-pyrano[3,2-h]quinoline-4-one (**10**)*

It was synthesized by two methods.

*By Algar–Flynn Oxidation of **8** (Method a)*

A solution of **8** (0.2 g) in a mixture of methanol (10 ml) and 10% sodium hydroxide solution (6 ml) was cooled to 0° and mixed with hydrogen peroxide (5 ml, 20%). The reaction mixture was kept initially at 0° for 6 h and then at room temperature for 24 h. The product obtained on acidification was crystallized from acetic acid in light-yellow shining needles, m.p. 267–268°; yield 0.05 g.

*By the Action of Pentyl Nitrite on **8** (Method b)*

To a suspension of **8** (0.2 g) and pentyl nitrite (0.5 ml) in ethanol (5 ml), concentrated hydrochloric acid (5 ml) was added dropwise at room temperature and the mixture was left at room temperature for 6 h. More pentyl nitrite (0.5 ml) was added to the mixture and the reaction mixture was allowed to stand at room temperature for 6 h more. It was then diluted with water (10 ml), refluxed on a water-bath for 2 h, cooled, and neutralized with ammonia. The product was repeatedly crystallized from acetic acid in light-yellow shining needles, m.p. 267–268°; yield 0.02 g.

Anal. Calcd. for $C_{18}H_{10}O_3NCl$: C, 66.7; H, 3.09; N, 4.3; Cl, 10.9. Found: C, 66.5; H, 3.2; N, 4.3; Cl, 11.2.

*6-Chloro-3-hydroxy-2-p-anisyl-pyrano-[3,2-h]quinoline-4-one (**13**)*

It was formed on treatment of **11** (0.2 g) with hydrogen peroxide (5 ml, 20%) as described above in method *a*. It was crystallized from acetic acid in yellow powder, m.p. 295–296° (decomp.); yield 0.05 g.

Anal. Calcd. for $C_{19}H_{12}O_4NCl$: C, 64.4; H, 3.39; N, 3.9; Cl, 10.0. Found: C, 64.6; H, 3.5; N, 3.7; Cl, 10.3.

*6-Chloro-3-benzoyl-2-phenyl-4H-pyrano-[3,2-h]quinoline-4-one (**14**)*

A mixture of **5** (0.2 g), benzoic anhydride (0.8 g), and triethylamine (2 ml) was refluxed at 170–180° for 6 h, cooled and diluted with ether (10 ml). The product which separated out was collected, washed, dried, and crystallized from acetic acid in white shining needles, m.p. 281–282°; yield 0.1 g. It remained unchanged when treated with hot 10% alkali solution.

Anal. Calcd. for $C_{25}H_{14}O_3NCl$: C, 72.9; H, 3.4; N, 3.4; Cl, 8.6. Found: C, 73.1; H, 3.2; N, 3.6; Cl, 8.8.

*Baker–Venkataraman Transformation Reaction of 5-Chloro-7-acetyl-8-hydroxyquinoline: Formation of 6-chloro-2-phenyl-4H-pyrano[3,2-h]quinoline-4-one (**9**)*

A mixture of **5** (0.5 g), benzoyl chloride (0.5 ml), and anhydrous potassium carbonate (1 g) in dry acetone (35 ml) was refluxed for 24 h and distilled to remove acetone. The product which separated on treating the reaction mixture with water (25 ml) was collected, treated with concentrated sulfuric acid (15 ml) and poured on crushed ice. The solid product was filtered, washed, dried, and crystallized from acetic acid in pinkish white needles, m.p. 273–274°; yield 0.2 g. Mixture m.p. with the product obtained by the selenium dioxide dehydrogenation of the flavanone type pyranoquinoline (**8**) showed no depression.

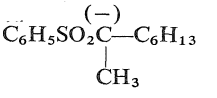
Received May 21, 1968

A survey of the experimental data on the structures of α-sulfonyl and α-sulfinyl carbanions is presented as an introduction to the present work, a theoretical study of hydrogen methyl sulfoxide (HMSO) and hydrogen methylsulfinyl anion ($HMSO^-$) by nonempirical self consistent field (s.c.f.) calculations using Gaussian basis sets. Calculations on dimethyl sulfoxide (DMSO) and its conjugate base ($DMSO^-$) are also presented and fully justify the choice of HMSO and $HMSO^-$ for the detailed work. A conformational energy surface (total energy as a function of rotation about the C—S bond and inversion of the carbanion angle) for $HMSO^-$ is presented and used to determine the stereochemical fate of a carbanion generated next to a sulfinyl group. Predictions are made concerning the probable course of proton exchange next to S—O and an explanation is offered for the experimental facts concerning exchange in sulfoxides. A very significant finding is that postulation of d-orbital conjugation is not essential to explain the asymmetry of α-sulfinyl carbanions.

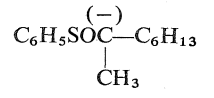
Canadian Journal of Chemistry, **47**, 113 (1969)

Introduction

Although the synthetic capabilities of carbanions are well known, their structures and symmetry properties have aroused serious attention only during the last decade and mainly as a result of the systematic studies of Cram and his co-workers (1). The method of attack has usually involved base-catalyzed hydrogen–deuterium exchange at an asymmetric carbon, the ratio of k_e, the rate constant for isotopic exchange, to k_α, the polarimetric rate constant, being used to decide whether the process occurs with retention, racemization, inversion, or isoinversion. Several generalizations have been reached concerning the way in which data, obtained from one-point pseudo first order rate constants, depend upon the structure of the substrate and the nature of the solvent. In particular, carbanions stabilized by adjacent second row element functional groups have fallen into two distinct classes: (*i*) those which undergo substitution with high retention of configuration, i.e., via an intrinsically asymmetric intermediate ($k_e/k_\alpha \gg 1$); (*ii*) those which undergo substitution via an intrinsically symmetrical intermediate ($k_e/k_\alpha \simeq 1$). In all cases k_e/k_α is strongly dependent upon the solvent composition but, in nonaqueous media, no crossover is seen. Thus **1** behaves as if it were asymmetric with asymmetric solvation effects superimposed, and **2** behaves as if it were symmetric at carbon with asymmetric solvation effects superimposed (2).



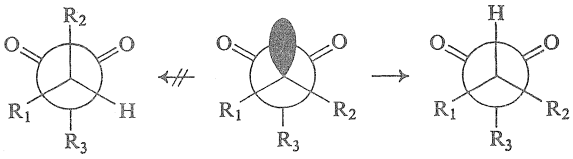
1



2

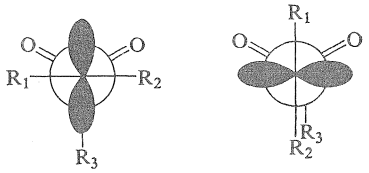
The α-sulfonyl system has been the most completely studied (3–10) without, however, general agreement having been reached on the origin of its asymmetry. Such a decision depends strongly upon the value taken for the carbanion angle as well as the conformational dependence of any interaction between the electron pair on carbon and the sulfur atom. A pyramidal configuration at carbon would retain asymmetry if there were a sufficiently high barrier to inversion irrespective of the form of the rotational energy function, i.e., **3** can protonate to give **4** but not **5** (it is assumed that protonation with inversion of configuration is indistinguishable from proton capture by an inverted carbanion).

[1]Holder of NRCC Studentships 1966–1968.
[2]To whom correspondence should be addressed.



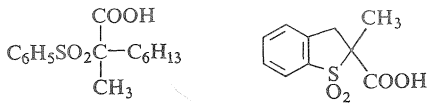
5 3 4

On the other hand, if the configuration at carbon is planar, asymmetry is possible if the structure is **6** and rotation to the symmetrical conformation **7** is restricted. Structures **6** and **7** are, respectively, the Case II and Case I conformations of Koch and Moffitt (11).



6 7

Corey and his co-workers have made a number of ingenious attempts to obtain experimental information about these possibilities. Base-catalyzed decarboxylation (6) of the α-carboxy sulfone **8**, which presumably proceeds via an α-sulfonyl carbanion that is free to adopt its most stable structure, affords phenyl 2-octylsulfone with at least 97% retention of configuration (7). In contrast, the α-carboxy sulfone **9** decarboxylates via a conformationally constrained α-sulfonyl carbanion that behaves as if it were symmetric (6) with asymmetric solvation effects superimposed (10). It was argued that the intermediate from **8** cannot be pyramidal,



8 9

i.e., with a significant barrier to inversion, for the same degree of stereospecificity would then be expected from both **8** and **9**. However, this would be true only in the event that there were no conformational dependence of the inversion barrier.

The ratios of k_e/k_α were 58 and 41, respectively, for the H/D exchange of the sulfones **10** and **11** (6). It was argued that, if asymmetric sulfonyl

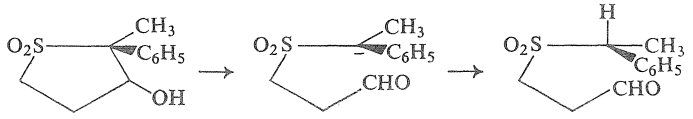
10, R = *t*-Bu

11, R = *n*-C_6H_{13}

carbanions possess the pyramidal structure, the rate of racemization of the carbanion from **10** should be far greater than that for the carbanion from **11** because of the ability of *t*-butyl to accelerate the pyramidal → planar conversion. However, if the pyramidal → planar conversion simply generated a Case II conformation, the two systems would retain asymmetry but for different reasons. Thus it seems that one is not compelled, as Corey suggests, to confer Case II planar geometry upon an α-sulfonyl carbanion.

Cram and Wingrove suggested (9) that the configuration at carbon is pyramidal and the electron pair is directed *anti* to the polar S—O bonds (electrostatic repulsion). However, in a beautifully conceived experiment, Corey and Lowry (8) demonstrated that protonation of anion **13**, generated by reverse aldol cleavage of the hydroxysulfone **12**, takes place with inversion of configuration, i.e., from the same side as the oxygen atoms. This is not shielding of the developing carbanion by the departing formyl group because similar shielding in the decarboxylation of **8** and related compounds should have led to predominant inversion rather than retention of configuration.

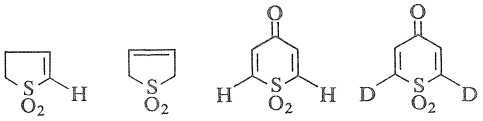
It seems then that the electron pair in **13** is directed along the acute bisector of the OSO angle. The result can be interpreted to mean either that there is highly asymmetric solvation of a planar (Case II) anion or spontaneous inversion of a pyramidal anion to that structure which has the electron pair directed along the bisector of the OSO angle. The results of Broaddus (12) may be consistent with the latter conclusion. In $NaOD/D_2O$ the most acidic proton in a mixture of **14***a* and **14***b* is the α-*vinyl* proton of



12 13

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

14*a*. It is not yet known whether this exchange occurs via the vinyl carbanion or by a reversible Michael addition. For the analogous exchange of the 4*H*-thiopyran-4-one 1,1-dioxide (**15***a* → **15***b*), the latter explanation is preferred (13).

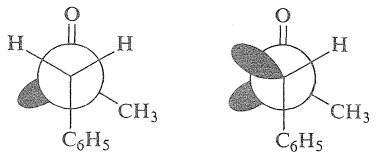


14*a* **14***b* **15***a* **15***b*

The data concerning α-sulfinyl carbanions are less detailed. Cram and Pine (14) used non-aqueous media for their studies with the diastereomeric phenyl 2-octylsulfoxides and, as mentioned earlier, they concluded that **2** is an intrinsically symmetrical species. Not only is the S—O grouping less able to confer asymmetry upon an adjacent carbanion than the SO_2 grouping, its acidifying effect upon α-protons is less. The second order rate constants for exchange of **11**-*d* at 25° were (4) 3.06×10^{-3} l mole^{-1} s^{-1} in MeOH/MeOK/DMSO and 1.45×10^{-2} l mole^{-1} s^{-1} in *t*-BuOH/*t*-BuOK. For the exchange of *R*:*S* phenyl 2-octyl sulfoxide-*d* (14, 15) *at 60°*, the rate constants were 8.5×10^{-4} l mole^{-1} s^{-1} in DMSO/MeOK and 1.8×10^{-5} l mole^{-1} s^{-1} in *t*-BuOH/*t*-BuOK. A number of earlier examples are summarized by Price and Oae (16).

In contrast to these results, dimethyl sulfoxide was found to undergo facile hydrogen exchange in NaOD/D_2O (17). Even more unexpected was the finding that benzyl methyl sulfoxide also undergoes facile hydrogen exchange in NaOD/D_2O via an asymmetric intermediate (18). It was demonstrated that at 15° *S*-benzyl methyl sulfoxide is converted sequentially, without loss of asymmetry at sulfur, to *S*,*S*-benzyl-α-*d* methyl sulfoxide, *S*-benzyl-α,α-d_2 methyl sulfoxide, and *S*-benzyl-α,α-d_2 methyl-d_3 sulfoxide (19). Analysis of the nuclear magnetic resonance (n.m.r.) spectrum of *S*-benzyl methyl sulfoxide led to the conclusions that its structure in NaOD/D_2O is **16** and that the structure of the derived asymmetric carbanion is **17**, i.e., carbanion electron pair along the bisector of the oxygen:sulfur:lone pair angle.

In this paper we show by nonempirical LCAO-MO-SCF calculations that an α-sulfinyl carbanion is intrinsically asymmetric, that the carbanion angle is pyramidal, that the most stable



16 **17**

structure has the electron pair along the bisector of the oxygen:sulfur:lone pair angle, and that d-orbital conjugation is not a significant factor in determining the asymmetry. It is demonstrated further that the rate of proton abstraction and the stereochemistry of reprotonation will depend strongly upon the orientation of the exchanging proton relative to the groups on sulfur.

Method

For practical reasons, and because it had been shown previously that meaningful results can be obtained with a minimal basis set (20), the minimal basis set of Gaussian-type functions (GTF) was used in calculations on hydrogen methyl sulfoxide (HMSO, **18**) and its carbanion ($HMSO^-$, **19**). The basis set size for **18** was 33 and for **19** it was 32 consisting of sulfur 5^s, 2^p, 1^d, oxygen 3^s, 1^p, carbon 3^s, 1^p and hydrogen 1^s. The exponents for the GTF are listed in Table I.

18 **19**

The geometry of **18** paralleled as closely as possible the experimentally determined (22) geometry of dimethyl sulfoxide (∠CSH = 100°, ∠CSO = ∠HSO = 107°, C—S = 3.43935 bohr (1.82 Å); S—H = 2.5117 bohr (1.329 Å[3]); C—H = 2.04093 bohr (1.08 Å); ∠HCH = ∠SCH = 109° 28′). Rotation of the methyl group was treated as a variable.

The geometry of the anion **19** was the same as for **18** except that both rotation about the C—S bond (Θ) and variation of the anion angles (∠SCH = ∠HCH = ϕ) were treated as variables.

The mathematical formalism for the closed shell s.c.f. as well as other calculations (dipole moment, and electron population analysis) have been reviewed recently (23) in detail. Consequently only the computational results are given here. The computations were carried out on an IBM 7094-II computer using the POLYATOM system (23). The running time for a given conformation was about 30 min. It was assumed from the beginning that the results of the calculations would be meaningful despite the presence of an S—H bond in **18** and **19**. After the initial stage of the work was completed, calculations were performed on methyl sulfinyl carbanion to test the severity of this assumption.

Hydrogen Methyl Sulfoxide

Figure 1 shows the variation of the total energy of **18** as a function of rotation about the C—S bond. The positions of the energy minima and maxima correspond neither to those of ethane ($\Theta = 0°$ and 60°, respectively) nor to those of acetaldehyde ($\Theta = 60°$ and 0°, respectively (24)), but are about midway between, $\Theta = 21°$ and 81°.

Consideration of the components which make up the total energy reveals that for HMSO only

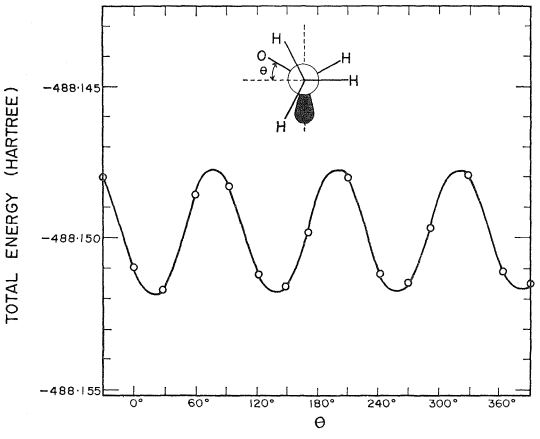

FIG. 1. Variation of the total energy of HMSO as a function of rotation about the C—S bond.

the nuclear–nuclear repulsion term displays ethane-type behavior. This can be seen in Fig. 2 where it is evident that the total energy reflects a balance between attractive (V_{ne} = nuclear–electron attraction) and repulsive (V_{ee} = electron–electron repulsion; V_{nn} = nuclear–nuclear repulsion; T = kinetic energy)[4] interactions. Although the compound exists because the large negative contribution from V_{ne} outweighs the other three, the phase of the total energy is that of the repulsive interactions which, together, counterbalance V_{ne} in deciding the geometry of the compound. The barrier heights associated with the individual terms are: V_{ne}, 58.0 kcal/mole; V_{ee}, 32.6 kcal/mole; V_{nn}, 12.6 kcal/mole, and T, 18.2 kcal/mole. For comparison purposes the corresponding quantities for ethane from s.c.f. calculations using Hartree–Fock atomic orbitals are (26): V_{ne}, 19.7 kcal/mole; V_{ee}, 9.5 kcal/mole; V_{nn}, 4.7 kcal/mole; and T, 8.2 kcal/mole. Whether the differences are due to the different basis sets used or to a property of the S—O grouping is not clear but it is noteworthy that the barrier height for the total energy of HMSO (2.68 kcal) does not differ significantly from that calculated for related systems, including ethane (26–28).

Allen and his co-workers (26–28) have proposed that the barriers in ethane, methylamine, methanol, hydrogen peroxide, hydrazine, and hydroxylamine can be understood by consideration of the one-electron ($V_{ne} + V_{nn} + T$) and two-electon (V_{ee}) components of the total energy. They find that in each case these two terms possess opposite phase. For ethane, methylamine, and methanol the phase of total energy is the same as that of the two-electron component. But for hydrazine, hydrogen peroxide, and hydroxylamine this is not the case, no simple relationship between the phase of total energy and that of either of the two components being apparent. Significantly the latter three compounds possess in each case at least one pair of electrons on each of two contiguous atoms. A very striking indication of the anomalous behavior produced by such a system is shown in Fig. 3, a reproduction of Allen's total energy data for hydrazine. *The*

[4]The kinetic energy term enters as a positive number and with the same phase as the repulsive interactions as a consequence of the virial theorem (25). According to this $-\Sigma V/2T = 1$ for an exact wave function, deviations from unity being taken as a measure of the inexactness of the actual wave function. For the minimal basis set used here, $-\Sigma V/2T = 1.0065$ (see Table II).

conformation in which the electron pairs on nitrogen are trans to each other represents an energy maximum.

Figure 4 shows an Allen plot for HMSO. The compound resembles ethane, methanol, and methylamine with the difference that the minima and maxima for total energy are slightly shifted from those of the one- and two-electron components. On the basis of this plot it would appear that the form of the barrier is not greatly affected by the presence of the SO grouping or the availability of d-orbitals.

The orbital energies for the individual atoms of HMSO have been published previously (20, 29). Table II gives the total energy and orbital energies of HMSO for conformations in which the methyl group is rotated through 0°, 30°, 60°, and 90°, and the first column of Fig. 5 shows these orbital energies graphically for the 0° conformation.

The variation of the total energy with Θ is not attributable in any simple way to the behavior of the individual molecular orbital energies. The coefficient matrices reveal that the highest occupied molecular orbital, no. 17, is largely a lone pair in an oxygen p-type atomic orbital that is directed in the plane of the bisector of the CSH angle.[5] Molecular orbital no. 16 is largely made up of a lone pair in an oxygen p-type atomic orbital that is directed perpendicular to the plane of the bisector of the CSH angle and has a small but significant contribution from a sulfur p-type orbital, suggestive of π-type bonding. Electron density contour plots of the analogous molecular orbitals of dihydrogen sulfoxide (H_2SO) (orbitals

no. 13 and 12) may be seen in Fig. 5 of ref. 20. Molecular orbital no. 15 is more highly delocalized but has largely the characteristics of a σ-type bond between sulfur and oxygen due to overlap of p-orbitals aligned with the S—O bond. Molecular orbital no. 14 is more delocalized still but is attributable, in large part, to the lone pair on sulfur. Molecular orbitals 13 and 8 constitute σ bonds between carbon and sulfur, and oxygen and sulfur respectively.

Table III contains the variation of dipole moment as a function of Θ as well as electron population analyses for the four conformations. Figures 6 and 7 display, respectively, the bond overlap populations and the net atomic charges as a function of Θ. From Fig. 6 the strength of the C—H bond, as judged from overlap populations, would be predicted to be least when it is situated approximately between oxygen and the lone pair. As Fig. 7 shows, there is a periodicity in net charge for all atoms except the hydrogens of the methyl group. Unfortunately, a quantitative estimation of the relative acidities of the hydrogens as a function of Θ cannot be inferred from the computed net charges because the minimal basis set used for hydrogen always gives the wrong sign (23, and references therein).

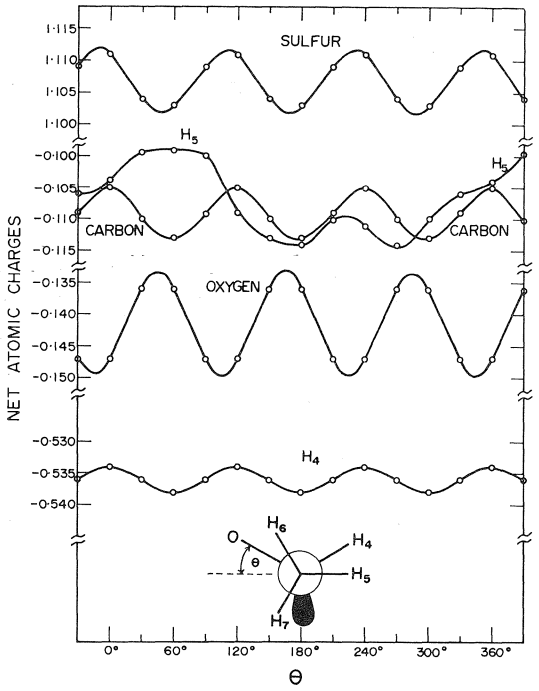

FIG. 7. Net atomic charges in HMSO as a function of rotation about the C—S bond.

Hydrogen Methyl Sulfinyl Anion

The conformation of $HMSO^-$ was defined by two independent parameters, the rotational angle Θ about the C—S bond, and the anion angle φ where $\angle H_6CH_7 = \angle SCH_6 = \angle SCH_7 = \phi$. Figure 8 shows the variation of the total energy of $HMSO^-$ as a function of Θ and φ. Horizontal

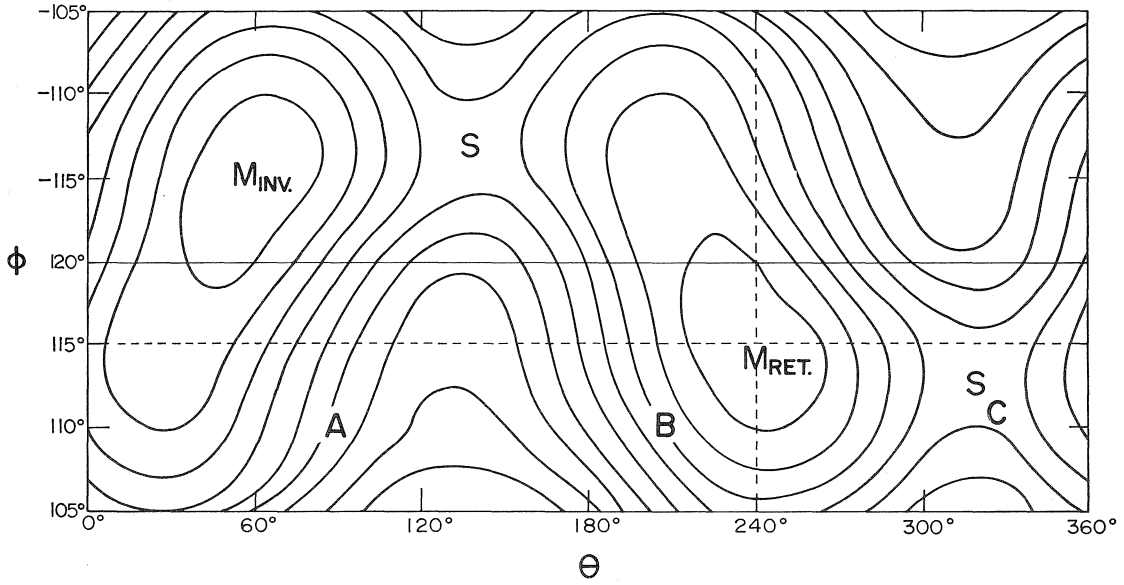

FIG. 8. Variation of the total energy of $HMSO^-$ as a function of rotation about the C—S bond (Θ) and inversion of the carbanion angle (ϕ).

movement across the surface corresponds to rotation about the C—S bond with anion angles fixed. A vertical movement across the center line represents inversion of the carbanion. Figure 9 is a projection of the three dimensional surface. Two cross-sections through the energy minimum, represented by the dashed lines of Figure 8, have already been published (Figs. 2 and 3 in ref. 30) and are reproduced in Figs. 10 and 11 along with their associated Allen plots. Figure 10 is the horizontal cross-section ($\phi = 115°$) and Fig. 11 the vertical cross-section ($\Theta = 240°$). The signs of the values of ϕ in Fig. 8 serve only to designate whether the location is on the upper or lower half of the energy surface. The signs of the ϕ values in Fig. 11 are consistent with this convention. The absolute values of ϕ represent the actual carbanion angles.

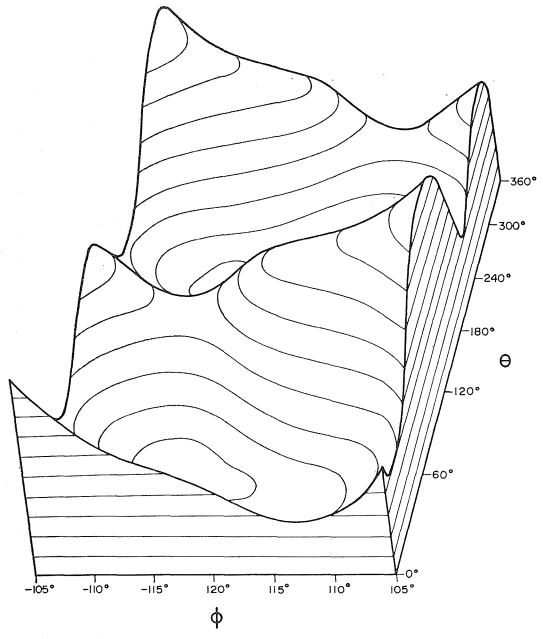

FIG. 9. A projection of the three dimensional surface of Fig. 8.

It is very clear from Fig. 11 that there is no barrier to inversion of the carbanion as was found in the case of $CH_3^{(-)}$ (31). This is, in fact, true of any of the vertical cross-sections of the energy surface as can be seen by inspection of the three-dimensional projection (Fig. 9). There are two identical minima (M) and two identical saddle points (S) on the surface so that a combination of rotation through 180° and inversion of the carbanion angle will reproduce any conformation. The energy barrier to rotation about the C—S bond in $HMSO^-$ is the difference in energy between S and M (Fig. 8) and is equal to 0.0121 Hartree (7.6 kcal/mole). This barrier is almost three times as high as the calculated barrier to

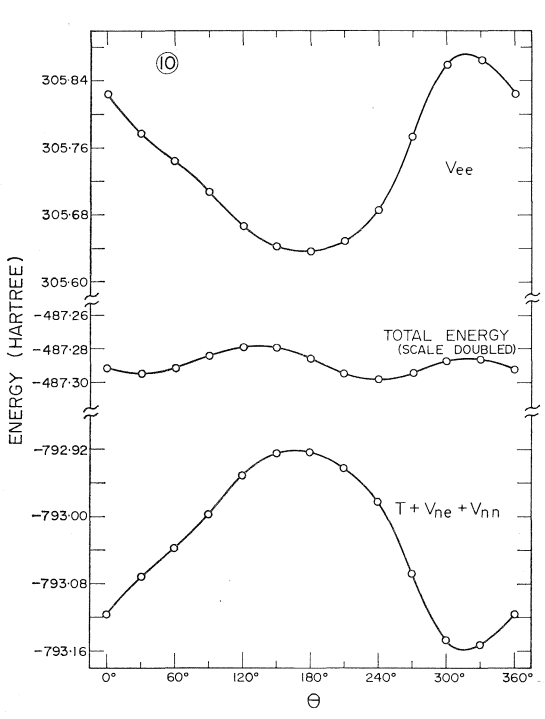

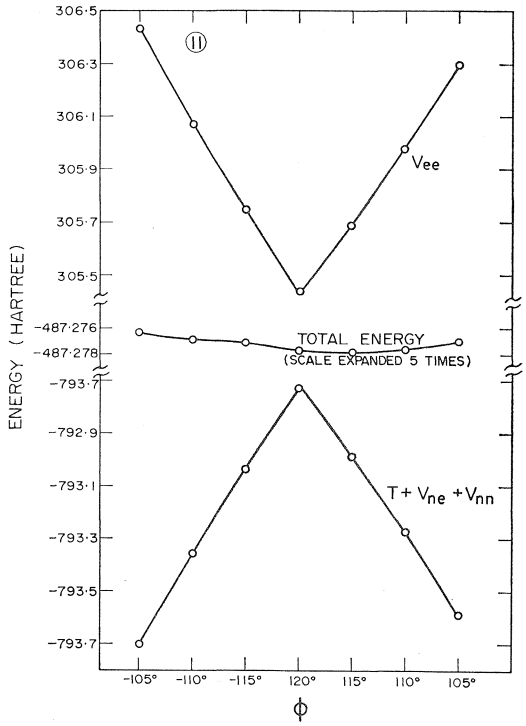

FIG. 10. Total energy of $HMSO^-$ as a function of rotation about the C—S bond ($\phi = 115°$), together with the one- and two-electron components of the total energy.

FIG. 11. Total energy of $HMSO^-$ as a function of the carbanion angle (ϕ) for the favored rotational conformer ($\Theta = 240°$), together with the one- and two-electron components of the total energy.

rotation in the hydrocarbon HMSO, and reflects increased electronic interaction between the carbanion and the sulfinyl grouping.

Probing of this interaction with the Allen plots is not very helpful. Like the systems mentioned earlier which contain electron pairs on contiguous atoms, no relationship is apparent between the phase of total energy and those of the one-electron and two-electron components. This is true for both rotation and inversion. In this respect $HMSO^-$ resembles hydrazine, methanol, and hydrogen peroxide despite the presence of the second row atom and the availability of d-orbitals.

The conformation of the anion with minimum energy is shown in Fig. 12*a*. The carbanion lone pair is situated in the plane of the bisector of the O:S:lone pair angle. The conformation which corresponds to the higher minimum of Fig. 10 has carbanion lone pair *trans* to oxygen; the two maxima of Fig. 10 correspond to carbanion lone pair *trans* to the sulfur lone pair (higher) and carbanion lone pair nearly eclipsed with the sulfur lone pair (lower).

From the energy surface (Fig. 9) it can be predicted that a carbanion generated in any conformation will spontaneously convert to that having the anion lone pair in the plane of the bisector of the O:S:lone pair angle. The ability to generate a carbanion at different points on the surface will depend on the orientation of the departing proton with respect to the groups on sulfur, as will be discussed in a following section.

Table IV lists the molecular orbital energies of the conformations of **19** shown in Figs. 12*a* and 12*b*. The latter has the conformation corresponding to the higher maximum of Fig. 10 (carbanion lone pair *trans* to the sulfur lone pair). Molecular orbitals 12, 14, and 17 have a significantly lower energy in the most stable conformation. These molecular orbitals correspond to a carbon–hydrogen bond, the sulfur–oxygen π-type bond and, surprisingly, the oxygen lone pair that is in the plane of the bisector of the HSC angle,

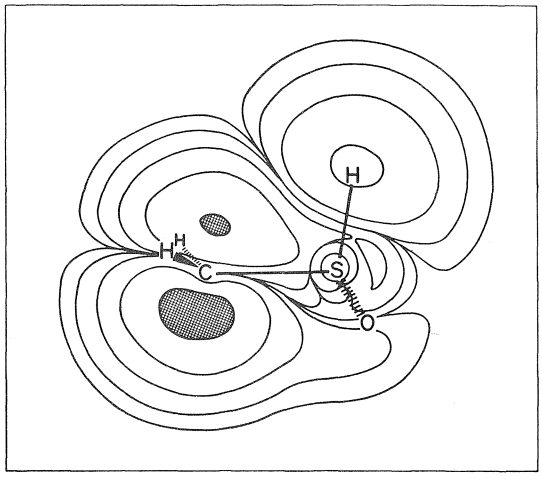

FIG. 13. An electron contour drawing of the third highest molecular orbital of $HMSO^-$ showing the elements of an sp^3 hybrid orbital on carbon.

respectively. Molecular orbital 15, which corresponds to the carbanion lone pair, is also lowered in energy, although not to the same extent as the three mentioned above. The electron contour drawing for this orbital in the plane containing the C—S bond and bisecting the HCH angle is shown in Fig. 13. Although this molecular orbital is completely delocalized, the elements of an sp^3 hybrid orbital on carbon can be recognized and are indicated by the shading of the areas of highest electron density.

The molecular orbital energies of the favored conformation of $HMSO^-$ are shown in the third column of Fig. 5.

Table V compares the electron population analyses of the conformations shown in Figs. 12*a* and 12*b*. The net charge on carbon is less and the overlap population of the S—C bond is greater in the more stable conformation. This suggests that when the carbanion lone pair is projected in a plane that bisects the oxygen:sulfur:lone pair angle there is particularly favorable delocalization of carbanionic charge into the sulfinyl group. This is qualitatively similar to the enolization process except that the anion is not flat as classical theory requires nor does the sulfinyl group need to become planar.

Figure 14 shows a contour map for the overlap population of the carbon–sulfur bond as a function of Θ and ϕ. The overlap population is maximum for the conformation ($\Theta = 240°$,

$\phi = 115°$) and minimum in the region ($\Theta = 120°$, $\phi = 110°$). Figure 15 shows a similar contour map for the overlap population of the oxygen–sulfur bond. The S—O bond overlap population is minimum in the region $\Theta = 240°$ and $\Theta = 60°$ and maximum in the region $\Theta = 120°$ and $\Theta = 300°$.

The Role of the d-Orbitals

It has become customary to associate unusual structural or chemical effects arising from the introduction of a second or third row atom into a compound with the availability of d-orbitals for bonding. One simply chooses a set of coordinate axes such that the symmetry of an atomic d-orbital is correct for overlap with an adjacent p- or sp^3-hybrid orbital and then draws some diagram to illustrate the proposed interaction. We believed, at the outset of the present work, that inclusion of sulfur d-type GTF in the minimal basis set would permit an evaluation of the importance and, indeed, the *nature* of the d-orbital interaction in an α-sulfinyl carbanion.

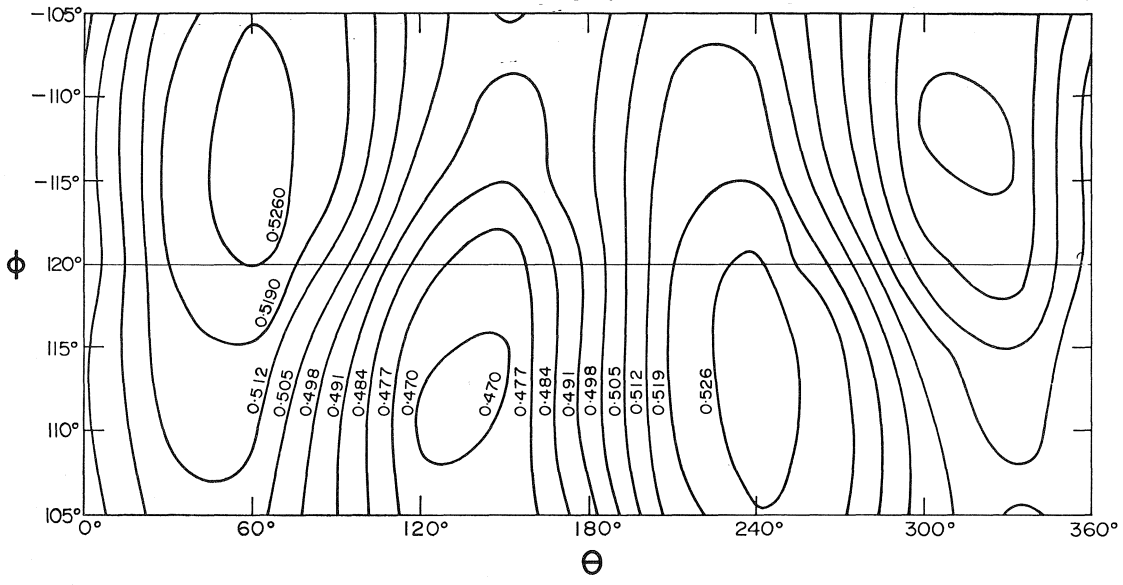

FIG. 14. A contour map for the overlap population of the C—S bond of $HMSO^-$ as a function of Θ and ϕ.

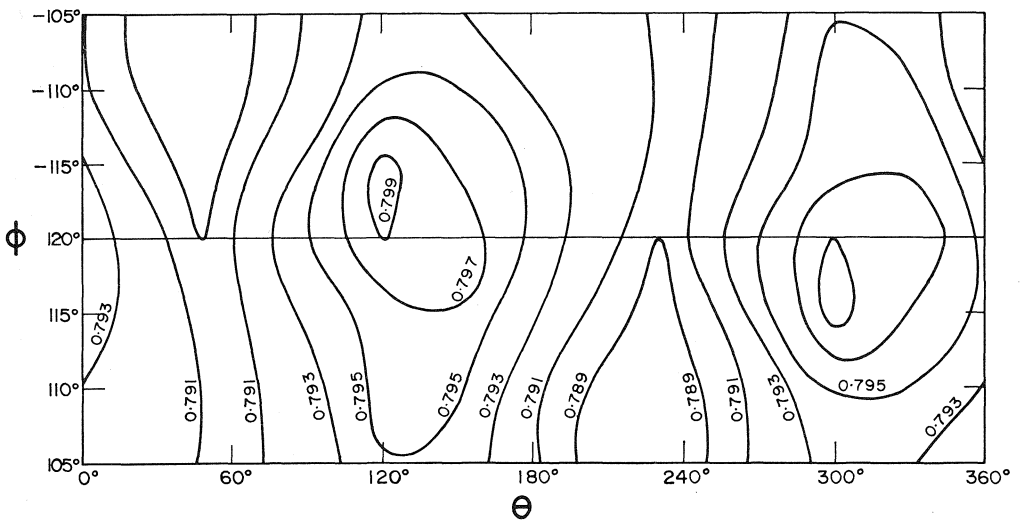

FIG. 15. A contour map for the overlap population of the S—O bond of $HMSO^-$ as a function of Θ and ϕ.

We were convinced that such an interaction would be found despite an intuitive prediction to the contrary (32). However, the intuitive prediction proved to be correct insofar as the present calculations are concerned, and we have had to revise our view to one of agnosticism. The situation is much more complicated than was originally thought, for reasons that will be discussed below.

Interestingly, the classical experimental bases for d-orbital conjugation are now also being critically reappraised for an array of structural types as new and more subtle criteria are devised (33–35), and disagreements are beginning to be made public (36–38).

Theoretical calculations on sulfur containing systems both with and without d-orbitals abound in the literature. A number of these are summarized in Table VI. The main surprise for one schooled in the pictorial approach is that there is as yet no real concensus of opinion either for or against the need to invoke contributions from the d-orbitals although the argument is a lively one. Thus, Bielefeld and Fitts (48) summarized the conclusions of Mangini and Zauli (58) as follows: "*d-orbital participation has never been proved and calculations based on the Longuet–Higgins model are fallacious.*"

In the present study six GTF have been used to describe the d-orbitals of sulfur atom rather than the usual five d-orbitals. This creates a problem because the six d-GTF do not have the proper symmetry characteristics of the spherical harmonics essential to the solutions of atomic problems. However, as explained in Appendix I of ref. 20, it is possible to effect a linear transformation of this set of six d-GTF to a single 3s-type and a set of five 3d-type (i.e. $d_{x^2-y^2}$, $d_{3z^2-r^2}$, d_{xy}, d_{xz}, and d_{yz}) functions. The same transformation can be used in any given molecular orbital to change the coefficients of the present six d-GTF to a set of one 3s and five 3d atomic orbitals.

The largest participation of d-GTF in occupied molecular orbitals occurs in the case of orbitals nos. 1 and 4 which can be associated with the sulfur 1s and 2s cores. Inspection of the virtual orbitals of the coefficient matrices for HMSO and $HMSO^-$ reveals that there are, as expected five nearly degenerate molecular orbitals which arise solely from linear combinations of the six d-type GTF. Although these are true molecular orbitals they can loosely and without ambiguity be referred to as the d-orbitals of sulfur. Table VII shows the energies of the d-orbitals of HMSO and $HMSO^-$ in the conformations indicated. It is apparent that the energies of the d-orbitals are not significantly disturbed upon formation of the carbanion.

The transformed coefficients of the two occupied (nos. 1 and 4) and the five nearly degenerate unoccupied (nos. 23–27) molecular orbitals of

TABLE VI

Survey of theoretical calculations of sulfur compounds with and without d-orbitals

Reference	Compound	Method	d-Orbitals	Conclusion
11	Diphenyl-sulfone	Symmetry considerations	Yes	Under some circumstances, expect strong conjugation with an α,β-unsaturated group
39		LCAO-MO Semi-empirical	Yes	The barrier to rotation arises from interaction of d-orbitals with p-orbitals of bonded atoms; there is competition of oxygen p's for the d-orbitals
40		Symmetry considerations	Yes	Unequal radicals compete for the d-orbitals of the central atom in tetrahedral anions
41	Thiophene, benzene	Simple HMO and symmetry considerations	Yes	(d-p)π overlap explains the "aromaticity" of thiophene
42	Thiophene	Simple HMO and symmetry considerations	Yes	—S— is about equivalent to —CH=CH—
43	Thiophene, 1,4-Dithiadiene	LCAO-MO (simple HMO)	Yes	Fairly good agreement with experiment
44		Evaluation of overlap integrels between s,p,d-orbitals using both radial and angular functions	Yes	Phosphorus and sulfur outer d-orbitals are much too diffuse for useful bonding; if used, e.g. as in SF_6, one must invoke contraction of d's
45	First row elements	Symmetry consider-ations and calculations using hydrogenic AO's and promotion energies from spectral data	Yes	Even carbon can use d-orbitals under certain circumstances, e.g., in the S_N2 transition state
46		Simple HMO	Yes	Good agreement with experimental data
47	$SO_4^=$	Extended HMO (Wolfsberg-Helmholtz, and Cusachs)	Yes	Inclusion of d-orbitals is important; they affect ordering of the energy levels in a Wolfsberg-Helmholtz calculation
48	Thiophene	An extension of the SCF-MO method, π-orbital approx.	Yes	There is limited participation of d-orbitals in the π electronic structure and a large effect on calculated electronic properties
49		Atomic d-orbital size with respect to nuclear charge and octahedral field of (+) charges	Yes	d-Orbitals can contract enough to be important in PCl_5 and SF_6
50	Bivalent sulfur	Electrostatic treatment with exchange among valence shell orbitals	Yes	There is negligible use of d-orbitals in bivalent sulfur
51	SF_6	A.O. calculation on S^{6+} with F atom potential	Yes	d-Orbitals are contracted to half their size in the free atom

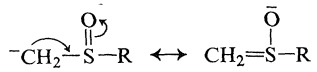
TABLE VI (*Concluded*)

Reference	Compound	Method	d-Orbitals	Conclusion
52		Electrostatic effect of H,C,F,Cl as ligand to sulfur; S core omitted	Yes	Insignificant changes in dδ and dπ orbitals, e.g. as in S—O bonds
53	Thiophene, Furan, Pyrrole	SCF-LCAO-MO (PPP)	No	Good agreement with experiment
54	Furan, Thiophene, 1,4-Dithiadiene	LCAO-MO(Pariser-Parr) self-consistent with respect to charge and electronegativity	No	No need to consider d-orbitals to explain differences in compounds studied
55	Dithienyl-thiophene	Semi-empirical SCMO (π electron and zero differential overlap)	No	Good calculated dipole moments
56	Thiophene	PPP-SCF-MO	Yes	3d, 4s, 4p Orbitals of sulfur have a negligible effect on the total energy
57	Disulfides	Semi-empirical LCAO-MO	No	The rotational energy barrier in disulfides had the correct order of magnitude

$HMSO^-$ clearly indicate (Table VIII) that in the low lying occupied molecular orbitals the d-GTF participate as s-type functions and that the five d-type functions are relegated to the virtual orbitals. Consequently, d-orbital conjugation such as structures **20** in valence bond notation, appears to be entirely out of the question.



20

It would be proper to point out, however, that the exponent that we have used for the d-GTF ($\alpha = 5.42$) may be too large to permit efficient bonding since its maximum is close to the sulfur nucleus. This point was considered earlier (Appendix II of ref. 20) in connection with the question of d-orbital participation in the bonding of H_2S. It was shown there that inclusion of a second set of d-GTF with an exponent ($\alpha = 0.25$) chosen to permit more efficient overlap made no appreciable contribution to the ground state wave function. This might have been anticipated on intuitive grounds since the sulfur is bivalent in H_2S. Greater participation of d-orbitals is expected intuitively in compounds where the coordination number of sulfur is higher than 2. A second set of d-GTF, with an exponent of 0.25, was, therefore, added to the basis set (N = 38 GTF) and a complete calculation was performed for a number of conformations of $HMSO^-$. The transformed d-coefficients of the favored conformation ($\phi = 115°$, $\Theta = 240°$) (Table IX) indicate that d-orbitals of the lower orbital exponent do mix appreciably into the higher filled molecular orbitals.[6]

TABLE VII

Orbital energies for sulfur d-orbitals in HMSO ($\Theta = 0°$) and $HMSO^-$ ($\Theta = 240°$, $\phi = 115°$).

Energy (Hartree)			
MO	HMSO	MO	$HMSO^-$
24	8.3463	23	8.6311
25	8.3483	24	8.6319
26	8.3595	25	8.6417
27	8.3640	26	8.6486
28	8.3670	27	8.6516

This demonstrates the difficulty in assigning a proper role to the d-orbitals when a small basis set is used. The same energy minimum is obtained whether the d-orbitals participate in the higher occupied molecular orbitals or not. It is clearly desirable to improve the accuracy of the present calculations. Very recently Hartree–Fock Atomic Orbitals have been obtained for sulfur (59). We hope that by use of these it will be possible to bring calculations on HMSO and $HMSO^-$ closer to the Hartree–Fock limit and provide a more meaningful basis for discussion of the problem. Whatever the outcome of these further studies it is already clear that what is significant in deciding

[6]The $\phi = 115°$, $\Theta = 240°$ conformation has minimum energy with all basis sets used so far.

*Orbital exponent $\alpha = 5.42$; basis set size = 32.

structure is not the presence or absence of d-orbital conjugation but the conformational preference of an electron pair adjacent to another electron pair or to a dipole. As noted earlier, $HMSO^-$ closely resembles hydrazine, hydroxylamine, and hydrogen peroxide and similar results are obtained in calculations on $^-CH_2SHO_2$ and $^-CH_2SH$ (60) and in experimental (61) and theoretical (57) studies on CH_3SSCH_3.[7]

Comparison of HMSO and $HMSO^{(-)}$ with Dimethyl Sulfoxide (21) and Methylsulfinyl Carbanion (22)

The minimal basis set for DMSO consists of 41 GTF and that for $DMSO^-$ consists of 40 GTF. Because of the time required for the computations, a complete study of the dimethyl sulfoxide system was not undertaken. However, a sufficient number of calculations were performed to establish that the form of the energy surface for $DMSO^-$ would be very similar to that of $HMSO^-$ One cross-section of this surface is shown in Fig. 16 which has parallel curves representing the energies of the anions $HMSO^-$ and $DMSO^-$ as a function of rotational angle about the C—S bond with the anion angle fixed at $\phi = 115°$. The maxima and minima fall at nearly identical positions and the relative barrier heights are about the same. Figure 17 shows parallel curves representing the energies of $HMSO^-$ and $DMSO^-$ as a function of the anion angle where the rotational conformation is that corresponding to $\Theta = 240°$. The essential similarity in the shapes of the curves is clear. Both are asymmetric with a minimum at about $\phi = 115°$.

In Fig. 5, where the molecular orbital energies of **18**, **19**, **21**, and **22** are plotted next to each other, the close correspondence between the energy levels of **18** and **21** and of **19** and **22** is clear.

It is our conclusion, therefore, that the calculations are unaffected by the presence of a sulfur–

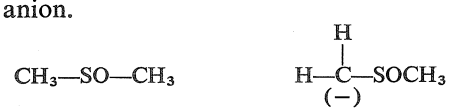
hydrogen bond in the model system HMSO and its anion.



21 22

The Stereochemistry of Proton Exchange Alpha to a Sulfinyl Group

In every conformation of HMSO the three methyl protons occupy different positions with respect to the groups on sulfur. We postulate that the abstraction of any methyl proton proceeds by a vertical energy transition which generates a carbanion whose electron pair points initially in the direction of the departing proton. Then the carbanion proceeds to its most stable structure; depending on the position on the conformational energy surface where the carbanion appears initially, this structural change may involve rotation or inversion or both. The usefulness of this concept is that if the transition state for proton abstraction possesses considerable carbanion character then it can be stated at once for any conformation what the relative rates of abstraction of the three methyl protons will be, and whether the reprotonation will occur with retention or inversion of configuration.

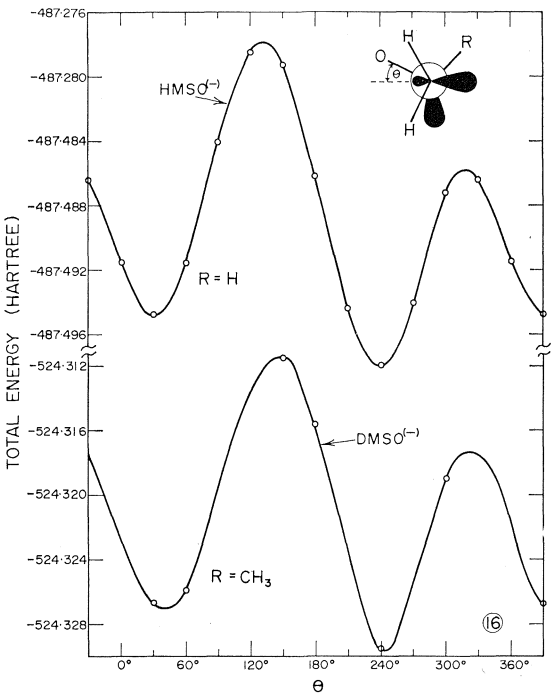

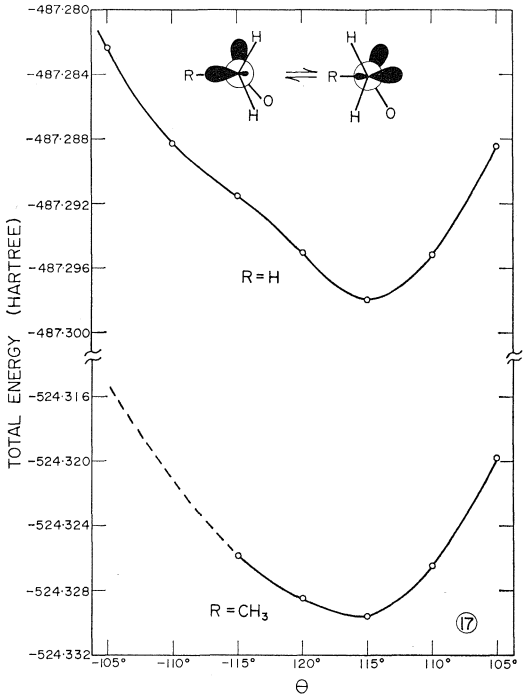

FIG. 16. Total energies of $HMSO^-$ (upper) and $DMSO^-$ (lower) as a function of rotation about the C—S bond ($\phi = 115°$).

FIG. 17. Total energies of $HMSO^-$ (upper) and $DMSO^-$ (lower) as a function of the carbanion angle ϕ for $\Theta = 240°$.

Stewart and Jones (62) have carried out hydrogen–tritium exchange studies on DMSO in water. These workers obtained a linear plot of log k against H^- with a slope of 0.939 over a range of rates varying by eight powers of ten. The result is consistent with a process in which proton transfer to the base is well advanced in the transition state. For the exchange of the methylene protons of benzyl methyl sulfoxide it has been found (63) that the kinetic isotope effect, k_H/k_D, for exchange of H_A is 1.4, and the solvent isotope effect, k_{D_2O}/k_{H_2O}, is 2.4. These effects are those expected for an unsymmetrical transition state (64) which resembles the products of an equilibrium ionization process (65). Thus, it seems valid to proceed with the assumption that the energy of the transition state for proton abstraction can be approximated by that of the carbanion (66).

$HMSO^-$ will be generated by the proton abstraction process somewhere along the cross-section of the energy surface (Fig. 9) through $\phi = 110°$. This cross-section, together with the potential curve for rotation about the C—S bond in HMSO, and the difference between the two are shown in Fig. 18, curves *a*, *b*, and *c*, respectively. From the reasoning given above, curve *c* ought to represent qualitatively the change of activation energy for the formation of $HMSO^-$ as the orientation of the proton with respect to the groups on sulfur varies. It is seen that if in HMSO one of the methyl protons were situated in the plane of the bisector of the O:S:lone pair angle ($\Theta = 240°$), this proton would be abstracted most readily.

To carry this further, consider HMSO in any conformation, say $\Theta = 90°$. Let the three different environments of the methyl protons be labelled A, B, and C as shown in Fig. 19. Abstraction of a proton from environment A generates $HMSO^-$ initially in conformation $\Theta = 90°$. Similarly abstraction from environments B and C generates $HMSO^-$ in conformations $\Theta = 210°$ and $\Theta = 330°$ respectively. Reference to curve *c*

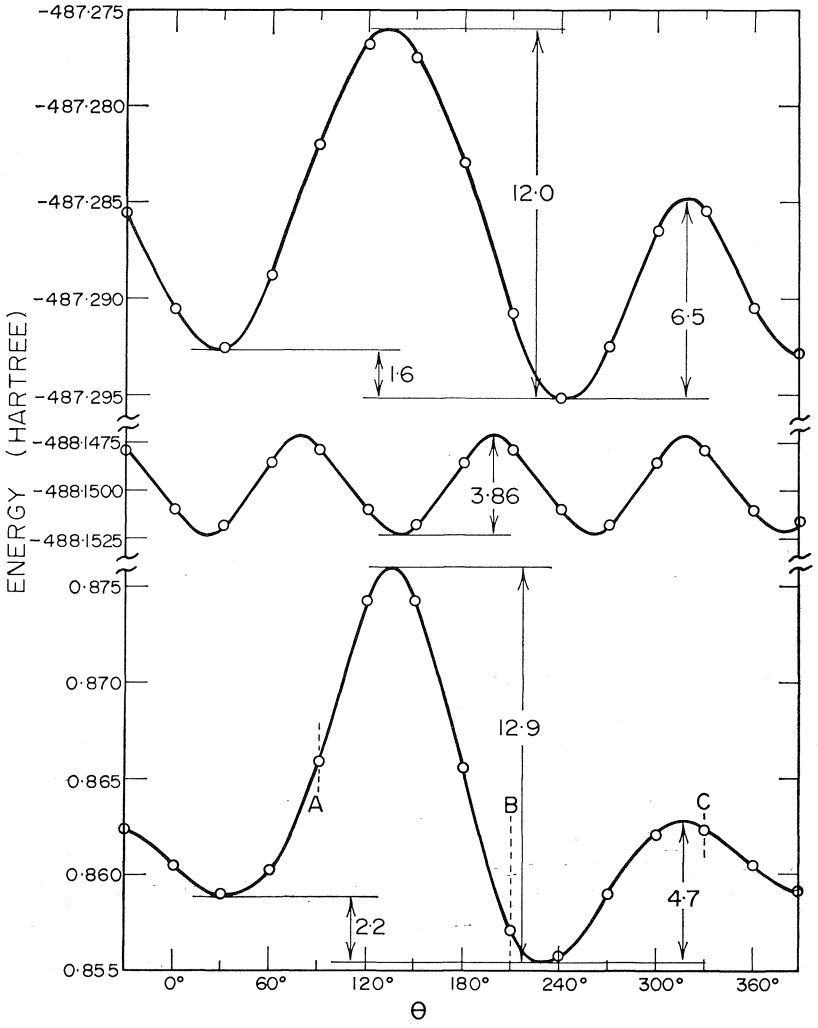

FIG. 18. Total energy of $HMSO^-$ as a function of rotation about the C—S bond for the cross-section through $\phi = 110°$ (upper curve) and the total energy of HMSO as a function of rotation about the C—S bond (middle curve). The lower curve is the difference between the upper and middle curves (energy differences are quoted in kcal/mole units).

of Fig. 18 permits the prediction that the ease of formation of $HMSO^-$ would be in the order B > C > A. The stereochemical fate of each of the resulting anions can be predicted by observing their location, labelled A, B, and C on the energy surface (Figs. 8 and 9). A will spontaneously invert, B would retain configuration, and C, being near a saddle point, may either retain or invert. These processes are shown in a three-dimensional projection in Fig. 20.

Figure 21 summarizes the procedure for predicting the stereochemical fate of a carbanion generated next to S—O. A carbanion generated in the shaded region would invert and one generated in the unshaded region would retain its configuration.

On the basis of these conclusions, we believe that hydrogen exchange in *S*-benzyl methyl sulfoxide (18, 19) can be discussed in the following manner. In conformation *a* of Fig. 22 the proton labelled A would be predicted to exchange rapidly and with retention of configuration. The

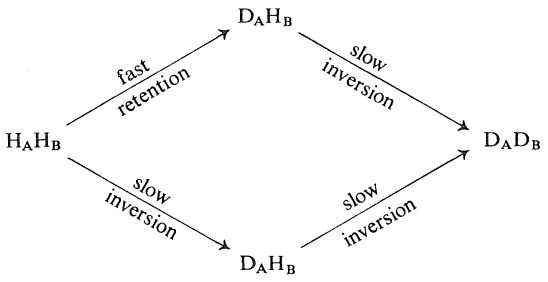
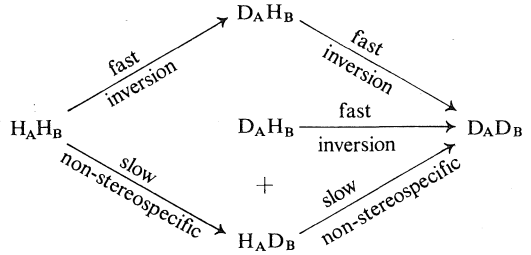
exchange of proton B would be slower and occur with inversion of configuration. In a deuterated medium the sequence of events would be,



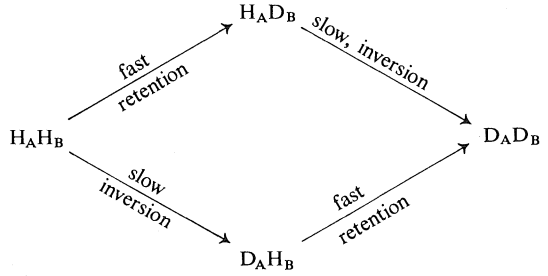
SCHEME *a*

In conformation *b*, proton B will exchange faster and with inversion; the slower exchange of proton A might occur with either retention or inversion. The sequence of events would then be



SCHEME *b*

In conformation *c*, proton B will exchange faster and with retention, while proton A will exchange more slowly and with inversion. The sequence of events would be



SCHEME *c*

Scheme *a* predicts that D_AH_B will accumulate in the medium. Scheme *c* predicts that H_AD_B will accumulate in the medium. Scheme *b* predicts that a monodeuterated species will be almost undetectable; any that would be detected would consist of H_AD_B. According to this treatment the

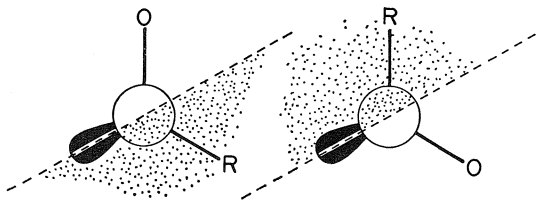


FIG. 21. A summary of the procedure for predicting the stereochemical fate of a carbanion generated next to S—O.

extent of reaction via schemes *a*, *b*, and *c* will depend upon the mole fractions of the conformations *a*, *b*, and *c* present in the medium. Since these will change as the solvent is changed the relative importance of the three schemes and thus the overall rate and stereochemistry of exchange will be affected by a change of solvent. The experimental finding, in NaOD–D_2O at 15°, is

$$H_AH_B \xrightarrow{\text{fast}} D_AH_B \xrightarrow{\text{slow}} D_AD_B$$

The result is thus consistent with Scheme *a* and with the conclusion expressed earlier (19). A forthcoming paper (63) will describe the results of experiments on conformationally constrained sulfoxides and an experiment on benzyl methyl sulfoxide which demonstrates that the conversion of D_AH_B to D_AD_B does proceed with inversion of configuration, as required by Scheme *a*.

Conclusions

Some understanding has been gained during the present work of the stereochemistry of an α-sulfinyl carbanion. Solvation effects have not been treated explicitly but, as noted in the preceding section some of the phenomena can be understood in terms of a dependence of conformer populations of the parent hydrocarbon upon the solvent. This is contrary to the view that solvation of the carbanion is a decisive factor in determining the stereochemistry of hydrogen exchange reactions.

It appears that, for a number of systems including α-sulfinyl carbanions, which contain directed electron lone pairs or highly polar bonds on adjacent atoms, conformations that place these substituents *syn or anti* to each other are energetically disfavored. The reasons for this are unknown but it is clear that the explanation of the effect is closely related to the question of the origin of rotational and inversion barriers. A result of the effect is that conformations that

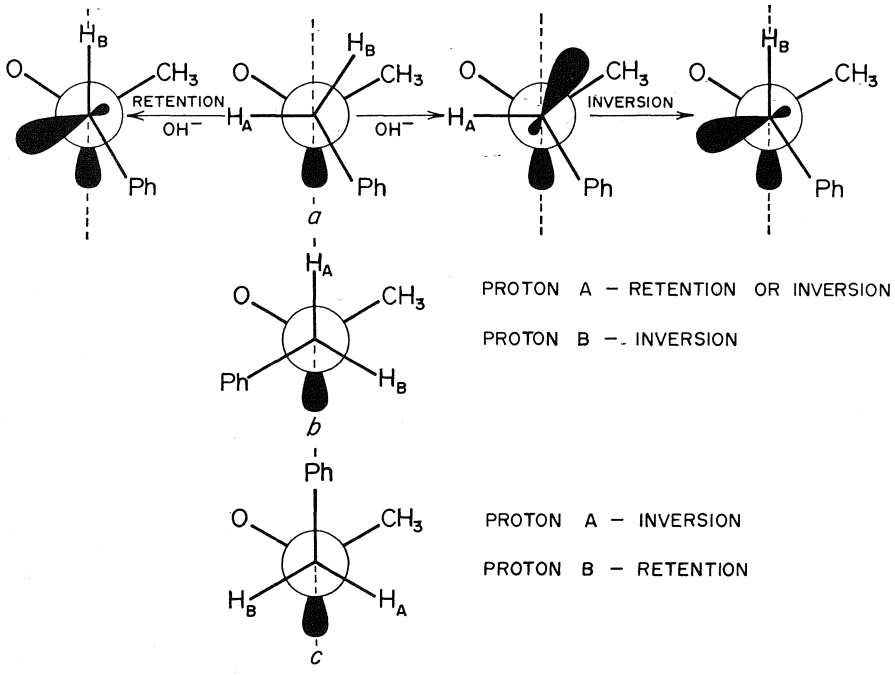

FIG. 22. Application of the theoretical results of this paper to the prediction of the rate and stereochemistry of exchange of the methylene protons of benzyl methyl sulfoxide.

place lone pairs *gauche* to each other often represent a minimum in the energy surface.

More extensive calculations than ours would be necessary to probe further the source of this anomalous behavior and to be certain of the relative positions on a conformational energy surface of structures other than the minimum. Throughout this work we have been conscious of the limitations of our basis set. The use of a minimal basis set was imposed upon us by the magnitude of the task we undertook. Even had exponents for sulfur been available from the beginning a near Hartree–Fock calculation on one conformation of $HMSO^-$ would have involved a basis set of about 120 GTF and about 24 h of 7094-II time. Forty-five separate conformations were calculated to obtain the surface shown in Fig. 9. Small basis set calculations were thus necessary forerunners to the more extensive and elaborate ones that now have to be done.

Stereoselective synthesis of (±)-eremophil-3,11-diene and related compounds. Concerning the structure of eremophilene

EDWARD PIERS AND ROBERT J. KEZIERE
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia
Received August 6, 1968

An efficient, stereoselective synthesis of (±)-eremophil-3,11-diene (**3**) is described. The key step of the synthetic sequence involves the conjugate addition of lithium dimethylcopper to the octalone **7**, which produces (±)-eremophil-11-en-3-one (**12**) in good yield. The latter is converted, *via* the tosylhydrazone derivative **13**, into compound **3**. Comparison of **3** with eremophilene indicates that the initial structural proposal for the latter sesquiterpene is in error. Evidence is presented which demonstrates that eremophilene is correctly represented by structure **4**.

Canadian Journal of Chemistry, 47, 137 (1969)

The biogenetically interesting (1) eremophilane class of sesquiterpenes possess the basic carbon skeleton **1**. Since the isolation of eremophilone (2) by Simonsen and co-workers (3), the number of known, naturally occurring eremophilane-type sesquiterpenes has, particularly in recent years, grown rapidly.[1] Structurally, one of the simplest members of this class is eremophilene, a $C_{15}H_{24}$ hydrocarbon first isolated from *Petasites officinalis* Moench. (5) and from *P. albus* (L.) Gaertn. (6). In 1964, Hochmannová and Herout (7), on the basis of nuclear magnetic resonance (n.m.r.) spectra, a fairly extensive chemical degradation, and correlation with hydroxydihydroeremophilone (**2**) (2), assigned structure **3** to eremophilene.

In connection with an interest in developing general methods for the total synthesis of various eremophilane-type sesquiterpenes, we report in this paper an efficient and stereoselective total synthesis of racemic **3**, and present evidence which invalidates the original structural proposal (7) for eremophilene. It should be immediately noted, however, that very recently, after our synthetic work had appeared in preliminary form (8), Křepinský *et al.* (9) presented spectroscopic and structural evidence which also disagreed with the initial structural proposal for eremophilene (7) and, on the basis of this evidence, assigned structure **4** to this sesquiterpene.[2] This latter assignment has very recently been confirmed by a stereoselective total synthesis of (±)-**4**.[3] We also present, in this paper, evidence which confirms that eremophilene is indeed correctly represented by structure **4**.

The starting material for our synthesis, 3-isopropenylcyclohexanone (**5**), was readily prepared, essentially by the procedure of House and co-workers (10). Thus, cuprous chloride – catalyzed conjugate addition of isopropenyl magnesium bromide to 2-cyclohexen-1-one gave the desired cyclohexanone derivative (**5**) in 71% yield. Sodium methoxide – catalyzed condensation of ketone **5** with ethyl formate in dry benzene afforded, in 75% yield, the corresponding hydroxymethylene derivative **6**, b.p. 101–102° at 4 mm, λ_{max} 283 mμ. The latter, upon treatment with 1-diethylamino-3-pentanone methiodide in the presence of sodium methoxide in methanol gave, after deformylation, ring closure, and appropriate work-up (for a similar procedure, see ref. 11), a 64% yield of the desired substituted octalone **7**, b.p. 127–131° at 0.3 mm. The spectral data obtained for this compound were in complete agreement with the assigned structure. Of particular pertinence were the ultraviolet (u.v.) spectrum (λ_{max} 249 mμ, $\varepsilon = 14\,600$) and the n.m.r. spectrum, which exhibited signals at τ 5.26 (unresolved multiplet, $=C^{12}H_2$),[4] τ 8.22 (doublet of doublets, $-C^{14}H_3$), and τ 8.25 (triplet, $-C^{13}H_3$). The chemical shifts assigned to the vinylic methyl groups ($-C^{13}H_3$ and $-C^{14}H_3$) were confirmed by a frequency-sweep decoupling

[1]At the present time, there are approximately 45 known eremophilane-type sesquiterpenoids. For a recent tabulation, see ref. 4.

4

experiment in which the olefinic protons at C-12 were strongly irradiated, whereupon the triplet at τ 8.25 collapsed to a strong, sharp singlet, while the signal at τ 8.22 remained unaffected.

The stereochemistry of the octalone **7** was assigned as shown, since, under the basic conditions involved in the preparation of this compound, the bridgehead position at C-10 would be epimerizable. Obviously, therefore, the molecule would adopt a configuration which would allow the sterically bulky isopropenyl group to adopt an equatorial orientation, with ring B in the chair conformation. This requires that the isopropenyl group be *cis* to the hydrogen at C-10.

In order to produce the characteristic eremophilane-like skeleton from the octalone **7**, it was necessary, at this stage, to introduce an angular methyl group at C-5. In particular, we wished to carry out this introduction in a stereoselective manner such that the product would contain *cis*-fused six-membered rings. At the outset, it appeared that this might be conveniently accomplished by use of the copper salt – catalyzed conjugate addition of methyl magnesium bromide (or iodide) to the α,β-unsaturated ketone system of **7**. This type of reaction had been successfully employed (12, 13) in the case of a number of 1 (9)-octal-2-ones (e.g. **8**, **9**, and **10**) and, stereochemically, resulted in each case in the formation of the corresponding *cis*-fused decalone system. It should be noted, however, that a number of years ago, Ireland and co-workers (14) reported an unsuccessful attempt to introduce, by cuprous bromide – catalyzed 1,4-addition of methyl magnesium bromide, an angular methyl group into the octalone **11**. It thus appeared that, although the conjugate addition of methyl Grignard reagent was successful with 1 (9)-octal-2-ones bearing no substituent on C-1 (as in **8**, **9**, and **10**), this reaction failed when there was a methyl group (or, presumably, another alkyl group) present on C-1 (as in **11**). Indeed, we have found, in agreement with Ireland's observation (14), that the copper-salt – catalyzed conjugate addition of methyl magnesium iodide to the octalone **7** was extremely difficult to accomplish. In fact, even the use of the reportedly (12) superior catalyst, cupric acetate in tetrahydrofuran, gave no synthetically useful result. Thus, although the latter procedure (12) afforded a crude product which exhibited a significant saturated carbonyl absorption in the infrared (i.r.) (5.85 μ), analysis of this crude material by gas–liquid chromatography (g.l.c.) showed that it was a complex mixture consisting of at least ten components. One of these components, which was formed in varying amounts (approximately 10–25% of the mixture) depending upon the experimental conditions employed, exhibited a g.l.c. retention time and i.r. spectrum (after isolation by preparative g.l.c.) identical with those of the authentic desired decalone **12**, which was eventually prepared by another method (see below). Thus, although this reaction was partially successful, the low yield of the desired compound **12**, as well as the complex nature of the reaction product, precluded its further use in our synthetic work.

In view of the above situation, we considered other routes for the conversion of octalone **7** into the decalone **12** and were attracted by a recent report by House and co-workers (15) who found that the reagents lithium dimethylcopper and "methylcopper-tri-*n*-butylphosphine complex" very selectively add a methyl group to the β carbon of an α,β-unsaturated ketone system. We therefore explored the use of these reagents for the crucial introduction of an angular methyl group in the octalone **7** and found that lithium dimethylcopper, which is prepared simply by reaction of ethereal methyllithium with cuprous iodide (molar ratio 2:1, respectively) at 0° under nitrogen, was excellent for this purpose. Thus, reaction of octalone **7** with an excess of lithium dimethylcopper in ether at 0° and under nitrogen for 2 h gave, after appropriate work-up, a 77% yield of the desired ($\pm$)-eremophil-11-en-3-one (**12**). The spectral properties of the latter were in complete agreement with the assigned structure. The compound exhibited no strong

u.v. absorption above 215 mμ, and showed a saturated carbonyl absorption (5.86 μ) in the i.r. The n.m.r. spectrum, when compared with that of the starting material (**7**), was particularly instructive, showing signals for two olefinic protons (τ 5.33, $=C^{12}H_2$), one vinyl methyl group (τ 8.29, $-C^{13}H_3$), one secondary methyl group (τ 9.11, $-C^{14}H_3$), and one tertiary methyl group (τ 9.21, $-C^{15}H_3$). In addition there appeared a one-proton quartet (1:3:3:1) at τ 7.17, readily attributable to the lone hydrogen on C-4.

The work-up procedure following the reaction of the octalone **7** with lithium dimethylcopper requires some comment. It had already been noted (15) that, in reactions of this type, hydrolysis of the excess organometallic reagent by addition of water to the ethereal reaction mixture led to the formation of significant amounts of di-addition products. This was attributed (15) to hydrolysis of the intermediate enolate formed from conjugate addition, followed by 1,2-addition of a residual unhydrolyzed "methylcopper" species to the resultant saturated ketone. These workers circumvented this difficulty by altering the isolation procedure so that the reaction mixture was poured into water or aqueous ammonium chloride with vigorous stirring. We found, however, that in the reaction of lithium dimethylcopper with octalone **7**, the latter work-up procedure did not eliminate di-addition and, in fact, produced a product which contained only a relatively small amount of the desired decalone **12**. Therefore, since we felt that the excess organometallic reagent would be destroyed much more rapidly by a stronger acid and would thus no longer be available for subsequent 1,2-addition to the saturated carbonyl of **12**, we carried out the hydrolysis by slowly pouring the reaction mixture into rapidly stirred dilute hydrochloric acid. This procedure proved successful and produced a clean product which contained, in addition to a small amount of starting material (**7**), the desired (±)-eremophil-11-en-3-one (**12**) as the only major component.

Having successfully introduced a methyl group at the bridgehead position of octalone **7**, it became important to determine the stereochemistry of the product (**12**). Although, as noted previously, the copper salt – catalyzed conjugate addition of methyl magnesium halides to various 1(9)-octal-2-ones had invariably resulted in the formation of the corresponding *cis*-fused decalone derivatives, the obscurity of the mechanism of the reaction of lithium dimethylcopper with α,β-unsaturated ketones (15, 16) required that caution be used in assuming that decalone **12** should also possess *cis*-fused six-membered rings. We therefore obtained independent and unambiguous evidence which showed that **12** had the stereochemistry shown.

(±)-Eremophil-11-en-3-one (**12**) was converted, by standard procedure, into the corresponding tosylhydrazone **13**, m.p. 159–161°. Treatment of the latter with sodium borohydride in dioxane (17) gave, in good yield, (±)-eremophil-11-ene (**15***a*). Alternatively, the hydrocarbon (**15***a*) was also obtained by Huang–Minlon reduction (18) of the semicarbazone derivative (**14**) of compound **12**. An analytically pure sample of **15***a* was obtained by preparative g.l.c. and exhibited, in the n.m.r. spectrum, signals at τ 5.38 (unresolved multiplet, $=C^{12}H_2$), τ 8.32 (triplet,

For personal use only.

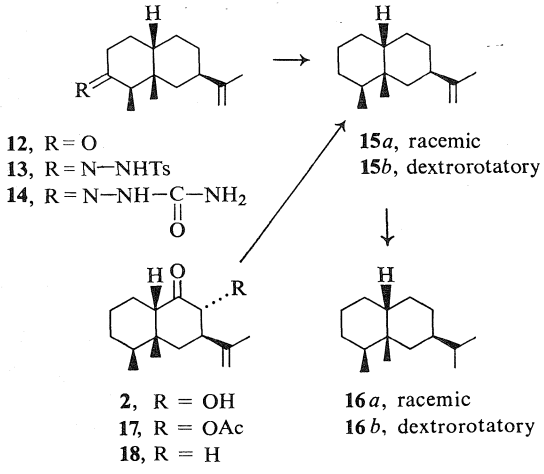
—$C^{13}H_3$), τ 9.18 (singlet, —$C^{15}H_3$), and τ 9.28 (doublet, —$C^{14}H_3$, $J_{4,14}$ = 6.5 Hz). Hydrogenation of compound **15***a* over platinum in ethanol gave, in 84% yield, (±)-7β-eremophilane (**16***a*).

Authentic (+)-eremophil-11-ene (**15***b*) and (+)-7β-eremophilane (**16***b*) were obtained by literature procedures (see ref. 19) from hydroxydihydroeremophilone (**2**),[5] a naturally occurring sesquiterpenoid of known absolute configuration (2). Thus, reduction of hydroxydihydroeremophilone acetate (**17**) with calcium in liquid ammonia afforded, in good yield, (+)-dihydroeremophilone (**18**), which, upon Huang–Minlon reduction (18), gave (+)-eremophil-11-ene (**15***b*).[6] The i.r. and n.m.r. spectra of the latter were identical with the corresponding spectra of synthetic (±)-eremophil-11-ene (**15***a*) obtained as described above. In addition, the two compounds exhibited identical g.l.c. retention times on a number of different columns. Hydrogenation of compound **15***b* over platinum in ethanol produced authentic (+)-7β-eremophilane (**16***b*) (6, 20)[7] which exhibited spectra (i.r., n.m.r.) and g.l.c. retention times identical with those of synthetic (±)-7β-eremophilane (**16***a*) (see above). These two comparisons (**15***a* with **15***b*, and **16***a* with **16***b*) conclusively demonstrated that the conjugate addition of lithium dimethylcopper to octalone **7** had, in fact, proceeded to give the desired, *cis*-fused (±)-eremophil-11-en-3-one (**12**).



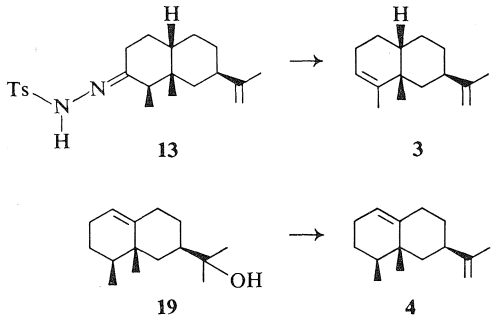
[5]We are very grateful to Professor L. H. Zalkow for a generous sample of hydroxydihydroeremophilone.

[6]Djerassi and co-workers (ref. 19) named this compound *cis*-desoxydihydroeremophilone.

[7]We thank Dr. H. Ishii for a copy of the i.r. spectrum of (+)-7β-eremophilane.

When the tosylhydrazone derivative **13** was heated with sodium ethylene glycolate (Bamford–Stevens reaction) (21), (±)-eremophil-3,11-diene (**3**) was formed in high yield. An analytical sample of this compound was obtained by preparative g.l.c. and exhibited n_D^{20} 1.5052. The n.m.r. spectrum showed a one-proton signal at τ 4.70 (unresolved multiplet, —C^3H), a two-proton signal at τ 5.35 (multiplet, =$C^{12}H_2$), and three 3-proton signals at τ 8.30 (triplet, —$C^{13}H_3$), τ 8.40 (multiplet, —$C^{14}H_3$), and τ 8.96 (singlet, —$C^{15}H_3$). The chemical shifts assigned to the vinylic methyl groups were confirmed by frequency-sweep decoupling experiments. Irradiation of the C-3 proton at τ 4.70 caused substantial sharpening of the multiplet at τ 8.40, while irradiation of the C-12 protons at τ 5.35 caused the poorly resolved triplet at τ 8.30 to collapse to a strong, sharp singlet.

Comparison of our synthetic (±)-eremophil-3,11-diene (**3**) with an authentic sample of eremophilene[8] clearly showed that the two compounds were different. Firstly, the two compounds exhibited different g.l.c. retention times. Secondly, the i.r. spectrum of (±)-eremophil-3,11-diene (**3**) differed, particularly in the "finger-print" region, from the i.r. spectrum of eremophilene. Finally, there were significant differences in the corresponding n.m.r. spectra. The n.m.r. spectrum (9) of eremophilene exhibited unresolved multiplets at τ 4.70 (1H) and τ 5.32 (2H), a triplet at τ 8.29 (3H), a singlet at τ 9.11 (3H), and a doublet (J = 6 Hz) at τ 9.15. Thus, although the n.m.r. spectra of (±)-eremophil-3,11-diene (**3**) and eremophilene were quite similar in the low-field region, the spectrum of **3** clearly showed, at high field,



[8]We are very grateful to Dr. J. Křepinský for an authentic sample of eremophilene and to Professor R. B. Bates for a copy of the i.r. and n.m.r. spectrum of this compound.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

two vinylic methyl groups and one tertiary methyl group, while the spectrum of eremophilene showed the presence of only one vinylic methyl group, one tertiary methyl group, and one secondary methyl group.

The stereoselective total synthesis of (±)-eremophil-3,11-diene (**3**), carried out as described above, clearly demonstrated that the original structural proposal (7) for the sesquiterpene eremophilene was incorrect. However, as already noted, Křepinský *et al.* (9), on the basis of new structural and spectroscopic evidence, recently assigned structure **4** to this compound. If this new proposal were correct, then eremophilene (**4**) should be related (by dehydration) to eremoligenol, a naturally occurring sesquiterpene which was isolated from *Ligularia fischeri* Turcz. and was shown to possess structure **19** (20). In fact, the dehydration of eremoligenol (**19**) had already been carried out (20) although the product was not compared with eremophilene (**4**). We were able to secure a sample of eremoligenol (**19**)[9] and found that, upon dehydration with thionyl chloride in pyridine, it gave a hydrocarbon which was identical (i.r., n.m.r., g.l.c.) with authentic eremophilene (**4**).[10] This experiment confirmed that eremophilene is indeed correctly represented by structure **4**.

It should be noted that the conjugate addition of lithium dimethylcopper to the octalone **7**, which stereoselectively produced the decalone **12**, is of particular significance, since this reaction provides a simple and efficient entry into the vicinal dimethyl system found in eremophilane-type sesquiterpenes. We are currently applying this reaction to the synthesis of sesquiterpenes belonging to the eremophilane group.

Experimental

Melting points, which were determined on a Kofler block, and boiling points are uncorrected. Ultraviolet spectra were measured in methanol solution on a Cary spectrophotometer, model 14. Routine i.r. spectra were recorded on a Perkin–Elmer Infracord model 137 spectrophotometer, while all comparison spectra were recorded on a Perkin–Elmer model 421 spectrophotometer. Nuclear magnetic resonance spectra were taken in deuteriochloroform solution on either a Varian Associates model A-60 spectrometer, a Jeolco C-60-H spectrometer, or a Varian Associates model HA-100 spectrometer, with the latter being used for decoupling experiments. Line positions are given in the Tiers τ scale, with tetramethylsilane as an internal standard; the multiplicity, integrated peak areas, and proton assignments are indicated in parentheses. Gas–liquid chromatography was carried out on an Aerograph Autoprep, model 700. The following columns (10 ft × 1/4 in.) were employed, with the inert, supporting material being 60/80 mesh Chromosorb W in each case: column A, 20% Apiezon J; column B, 20% FFAP; column C, 10% FFAP; column D, 15% QF-1; column E, 20% SE30; column F, 20% Carbowax 20M. The specific column used, along with the column temperature, are indicated in parentheses. The carrier gas (helium) flow-rate was 80–85 ml/min in each case. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver.

3-Isopropenylcyclohexanone (5)

This compound was prepared by the reaction of 2-cyclohexen-1-one with isopropenyl magnesium bromide in the presence of anhydrous cuprous chloride in dry tetrahydrofuran. The procedure employed was essentially identical with that described by House and co-workers (10). From 24.2 g of 2-cyclohexen-1-one there was obtained 24.5 g (71%) of pure 3-isopropenylcyclohexanone as a clear colorless oil, b.p. 69–72° at 7.5 mm, n_D^{26} 1.4749; lit. b.p. 80.5–84° at 8 mm, n_D^{26} 1.4743–1.4749 (10). Infrared (film), λ_{max} 5.85, 6.12, 11.20 μ; n.m.r., τ 5.22 (unresolved multiplet, 2H, $=CH_2$), 8.24 (broadened singlet, 3H, vinyl methyl).

Preparation of Hydroxymethylene Derivative 6

To a stirred slurry of sodium methoxide (31.6 g) in 160 ml of dry benzene was added a solution of ethyl formate (43.3 g) in dry benzene (160 ml). The resulting mixture was cooled to 0° and then a solution of 3-isopropenylcyclohexanone (26.4 g) in 160 ml of benzene was added dropwise, over a period of 20 min. The mixture was allowed to warm to room temperature and then stirred, under an atmosphere of nitrogen, for 50 h. Water (500 ml) was added, the mixture was thoroughly shaken, and the layers separated. The organic layer was extracted with two portions of dilute aqueous sodium hydroxide. The combined aqueous layer and alkaline extracts were cooled, acidified with concentrated hydrochloric acid, and thoroughly extracted with ether. The combined extracts were washed with water and dried over anhydrous sodium sulfate. Removal of the solvent gave a red-brown oil which, upon distillation under reduced pressure, afforded 21 g (75%) of the hydroxymethylene derivative **6** as a light-yellow oil, b.p. 101–102° at 4 mm, n_D^{20} 1.5198. Ultraviolet, λ_{max} 283 mμ; i.r. (film), λ_{max} 6.02, 6.22, 11.15 μ. The instability of this compound precluded the acquisition of satisfactory analytical data.

Preparation of Octalone 7

To a stirred solution of sodium methoxide (2.4 g) in 60 ml of dry methanol was added 11.7 g of the hydroxymethylene derivative **6**. A solution of 1-diethylamino-3-pentanone methiodide (from 15.9 g of 1-diethylamino-3-pentanone and 14.6 g of methyl iodide) in 40 ml of dry methanol was then added dropwise over a period of 20

[9]We thank Dr. H. Ishii for a sample of this compound.

[10]This reaction has also been independently carried out by R. M. Coates and J. E. Shaw, who dehydrated (±)-eremoligenol to (±)-eremophilene. See footnote 3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

min and the resulting solution was stirred at room temperature, under an atmosphere of nitrogen, for 26 h. The solution was poured into ice-cold dilute hydrochloric acid which had been saturated with ammonium sulfate. The resulting mixture was extracted thrice with ether, and the combined ether extracts were concentrated under reduced pressure. The residual material was stirred for 1 h, under nitrogen with 630 ml of 2% aqueous sodium hydroxide (deformylation). The basic mixture was extracted with ether and the ether extract was dried over anhydrous sodium sulfate. Removal of the solvent afforded a yellow oil (14.5 g) which exhibited in the i.r., a strong saturated carbonyl absorption (5.86 μ) and only a weak α,β-unsaturated carbonyl absorption (6.02 μ). Therefore, the oil was dissolved in 125 ml of dry methanol containing 0.5 g of sodium methoxide and the resulting solution was refluxed for approximately 6 h, at which time the α,β-unsaturated carbonyl absorption, in the i.r., of an acid-quenched aliquot of the reaction solution, had attained a maximum intensity. After removal of the methanol under reduced pressure, the residual material was diluted with water (50 ml), acidified with dilute hydrochloric acid, and then extracted with ether. The combined ether extracts were washed once with water and dried (anhydrous sodium sulfate). Removal of the ether yielded a pale-yellow oil which, upon distillation under reduced pressure gave, in addition to a small amount (0.6 g) of 3-isopropenylcyclohexanone, 10 g (70%) of a pale-yellow oil, b.p. 127–131° at 0.3 mm. This material contained, as shown by g.l.c. (column A, 230°), approximately 92% of the desired octalone (**7**). An analytical sample of **7** was obtained by preparative g.l.c. (column A, 230°) and exhibited n_D^{24} 1.5320. Ultra violet, λ_{max} 249 mμ (ε = 14 600); i.r. (film), λ_{max} 6.00 6.19, 11.25 μ; n.m.r., τ 5.26 (unresolved multiplet, 2H, $=C^{12}H_2$), 8.22 (poorly resolved quartet, 3H, $-C^{14}H_3$, J = 1.2 and 1.8 Hz, homoallylic coupling (ref. 22 p. 110)), 8.25 (triplet, 3H, $-C^{13}H_3$, J = 1.2 Hz, allylic coupling (ref. 22 p. 108)). The chemical shifts assigned to $-C^{13}H_3$ and $-C^{14}H_3$ were confirmed by a frequency-sweep decoupling experiment in which the olefinic protons at C-12 were strongly irradiated, whereupon the triplet at τ 8.12 collapsed to a strong, sharp singlet, while the quartet at τ 8.22 remained unaffected.

Anal. Calcd. for $C_{14}H_{20}O$: C, 82.30; H, 9.87. Found: C, 82.43; H, 10.03.

The oxime derivative of octalone **7**, after recrystallization from methanol, exhibited m.p. 163–165°.

Anal. Calcd. for $C_{14}H_{21}NO$: C, 76.66; H, 9.65; N, 6.39. Found: C, 76.84; H, 9.55; N, 6.21.

*(±)-Eremophil-11-en-3-one (**12**) and Derivatives (**13**, **14**)*

The following reaction was carried out under an atmosphere of dry nitrogen. To a stirring, ice-cold (0°) slurry of cuprous iodide (6.0 g) in 120 ml of anhydrous ether was added, by injection from a dry syringe, 39.4 ml of 1.59 *M* ethereal methyllithium. The resulting tan-colored solution, containing the lithium dimethylcopper reagent, was stirred at 0° for 5 min, and then a solution of octalone **7** (2.0 g) in 80 ml of anhydrous ether was added dropwise over a period of 20 min. The reaction mixture was stirred for an additional 2 h at 0°, and then poured into 800 ml of vigorously stirred 1.2 *N* hydrochloric acid. The resulting mixture was extracted thoroughly with ether. The combined ether extracts were washed with water and dried over anhydrous sodium sulfate. Removal of the solvent gave a light-yellow oil which, upon distillation under reduced pressure, afforded 1.9 g of a clear colorless liquid, b.p. 123.5–124.5° at 0.03 mm. This material contained, as shown by g.l.c. (column B, 215°), approximately 5% starting material (octalone **7**), 82% of the desired (±)-eremophil-11-en-3-one (**12**), and a number of minor, unidentified components. Preparative g.l.c. (column B, 215°), allowed the isolation of an analytical sample of compound **12**, n_D^{20} 1.5041. Infrared (film), λ_{max} 5.86, 6.10, 11.27 μ; n.m.r., τ 5.33 (unresolved multiplet, 2H, $=C^{12}H_2$), 7.17 (quartet, 1H, $-C^4H$, $J_{4,14}$ = 6.7 Hz), 8.29 (poorly resolved triplet, 3H, $-C^{13}H_3$), 9.11 (doublet, 3H, $-C^{14}H_3$, $J_{4,14}$ = 6.7 Hz), 9.21 (singlet, 3H, $-C^{15}H_3$).

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.61; H, 10.71.

Reaction of (±)-eremophil-11-en-3-one (**12**) with *p*-toluenesulfonylhydrazine under standard conditions afforded a good yield of the tosylhydrazone (**13**), which, after recrystallization from methanol, exhibited m.p. 159–161°.

Anal. Calcd. for $C_{22}H_{32}N_2O_2S$: C, 68.00; H, 8.30; N, 7.21; S, 8.25. Found: C, 68.22; H, 8.41; N, 7.41; S, 8.11.

Reaction of compound **12** with semicarbazide afforded the corresponding semicarbazone **14**, which was recrystallized from methanol, m.p. 191.5–193.5°.

Anal. Calcd. for $C_{16}H_{27}N_3O$: C, 69.27; H, 9.81; N 15.15. Found: C, 69.20; H, 9.98; N, 15.05.

*(±)-Eremophil-11-ene (**15a**)*

*(a) From Tosylhydrazone **13***

A stirred solution of the tosylhydrazone **13** (0.5 g) and sodium borohydride (0.3 g) in 20 ml of dioxane was refluxed, under an atmosphere of nitrogen, for 20 h. The dioxane was removed under reduced pressure and the residue was diluted with water. The resulting mixture was extracted thoroughly with pentane. The combined extracts were washed with water, dried (anhydrous sodium sulfate), and concentrated. The residual colorless oil (0.27 g) was shown by g.l.c. (column D, 130°) to contain 95% of (±)-eremophil-11-ene (**15a**), with only minor impurities. An analytical sample of **15a** was collected by preparative g.l.c. (column D, 130°) and exhibited n_D^{24} 1.4933. Infrared (film), λ_{max} 6.10, 11.28 μ; n.m.r., τ 5.38 (unresolved multiplet, 2H, $=C^{12}H_2$), 8.32 (poorly resolved triplet, 3H, $-C^{13}H_3$), 9.18 (singlet, 3H, $-C^{15}H_3$), 9.28 (doublet, 3H, $-C^{14}H_3$, $J_{4,14}$ = 6.5 Hz). This material was shown to be spectroscopically (i.r., n.m.r.) identical with (+)-eremophil-11-ene (**15b**) obtained from hydroxydihydroeremophilone (**2**) (see below).

Anal. Calcd. for $C_{15}H_{26}$: C, 87.30; H, 12.70. Found: C, 87.02, H, 12.79.

*(b) By Huang–Minlon Reduction of Semicarbazone **14***

A stirred solution of the semicarbazone **14** (2.0 g), 85% hydrazine hydrate (1.8 ml), and potassium hydroxide (1.9 g) in 20 ml of diethylene glycol was heated to 190–195° and maintained at this temperature for 24 h. The cooled solution was poured into water (100 ml) and the resulting mixture was extracted thoroughly with ether. The combined extracts were washed with water, dried

For personal use only.

(anhydrous sodium sulfate), and concentrated, yielding 1.47 g of a pale-yellow oil. The latter material showed virtually one component by g.l.c. (column C, 140°). An analytical sample, obtained by preparative g.l.c. (column C, 140°), was identical in all respects with (±)-eremophil-11-ene (**15***a*) obtained as described above.

*(±)-7β-Eremophilane (**16***a*)

This compound was obtained by hydrogenation (platinum oxide, ethanol) of (±)-eremophil-11-ene (**15***a*), at room temperature and atmospheric pressure. From 0.65 g of **15***a* there was obtained 0.6 g of (±)-7β-eremophilane. An analytical sample of the latter, obtained by preparative g.l.c. (column C, 135°), exhibited n_D^{24} 1.4820. Infrared (film), 6.82, 6.92, 7.25, 7.32 μ; n.m.r., τ 9.15 (doublet, 6H, —$C^{12}H_3$ and —$C^{13}H_3$, J = 6.0 Hz), 9.16 (singlet, 3H, —$C^{15}H_3$), 9.28 (doublet, 3H, —$C^{14}H_3$, $J_{4,14}$ = 6.8 Hz). The i.r. and n.m.r. spectra of this compound were found to be identical with the corresponding spectra of authentic (+)-7β-eremophilane (**16***b*) obtained from hydroxydihydroeremophilone (**2**) (see below).

*(+)-Dihydroeremophilone (**18**)*

Hydroxydihydroeremophilone acetate (**17**), which was obtained by acetylation (19) of hydroxydihydroeremophilone (**2**), was reduced with calcium in liquid ammonia. The procedure employed was identical with that reported by Djerassi and co-workers (19). The product, (+)-dihydroeremophilone (**18**), was obtained in 60% yield. Infrared (film), λ_{max} 5.86, 6.08, 11.20 μ; n.m.r., τ 5.26 (unresolved multiplet, 2H, =$C^{12}H_2$), 8.27 (poorly resolved triplet, 3H, —$C^{13}H_3$), 8.97 (singlet, 3H, —$C^{15}H_3$), 9.23 (doublet, 3H, —$C^{14}H_3$, $J_{4,14}$ = 5.9 Hz).

*(+)-Eremophil-11-ene (**15***b*)

This compound was obtained, according to a literature procedure (19), by Huang–Minlon reduction of (+)-dihydroeremophilone (**18**). An analytical sample of **15***b*, obtained by preparative g.l.c. (column C, 140°), gave spectra (i.r., n.m.r.) and g.l.c. retention times (four different columns: A, 180°; B, 168°; D, 120°; E, 180°) identical with those of synthetic (±)-eremophil-11-ene (**15***a*), obtained as described above.

*(+)-7β-Eremophilane (**16***b*)

Hydrogenation of (+)-eremophil-11-ene (**15***b*) (see ref. 20) at room temperature and atmospheric pressure over platinum in ethanol afforded (+)-7β-eremophilane (**16***b*). An analytical sample was obtained by preparative g.l.c. (column F, 140°). This material exhibited i.r. and n.m.r. spectra, as well as g.l.c. retention times on three different columns (D, 120°; E, 158°; B, 158°) identical with those of synthetic (±)-7β-eremophilane (**16***a*) prepared as described above.

*(±)-Eremophil-3,11-diene (**3**)*

The Bamford–Stevens reaction (21) on the tosylhydrazone **13** was carried out as follows. Sodium metal (10.0 g) was dissolved in ethylene glycol (100 ml). To this solution was added 1.5 g of the tosylhydrazone **13**, and the solution was then refluxed, under an atmosphere of nitrogen, for 2h. The solution was cooled and poured into ice-cold water. The resulting mixture was extracted thoroughly with ether. The combined extracts were washed twice with water and dried over anhydrous sodium sulfate. Removal of the ether gave a yellow oil, which upon distillation under reduced pressure afforded 0.75 g (95%) of a clear colorless liquid, b.p. 85–88° (bath temperature) at 0.38 mm, which was shown by g.l.c. (column C, 135°) to be approximately 90% pure. An analytical sample of the major component, (±)-eremophil-3,11-diene (**3**), was collected by preparative g.l.c. (column C, 135°) and exhibited n_D^{20} 1.5052. Infrared (film), λ_{max} 6.10, 6.95, 7.32, 11.28 μ; n.m.r., τ 4.70 (unresolved multiplet, 1H, —C^3H, width at half-height = 8 Hz), 5.35 (unresolved multiplet, 2H, =$C^{12}H_2$, width at half-height = 3.5 Hz), 8.30 (triplet, 3H, —$C^{13}H_3$), 8.40 (unresolved multiplet, 3H, —$C^{14}H_3$), 8.96 (singlet, 3H, —$C^{15}H_3$). The chemical shifts assigned to the vinylic methyl groups were confirmed by frequency-sweep decoupling experiments. Thus, strong irradiation of the olefinic signal at τ 4.70 (—C^3H) caused considerable sharpening of the multiplet at τ 8.40, while similar irradiation of the C-12 protons (τ 5.35) caused the triplet at τ 8.30 to collapse to a strong, sharp singlet. The i.r. and n.m.r. spectra of (±)-eremophil-3,11-diene (**3**) were clearly different from the corresponding spectra of an authentic sample of eremophilene (**4**). Also, the g.l.c. retention times (column C, 135°) of the two compounds were different.

Anal. Calcd. for $C_{15}H_{24}$: C, 88.16; H, 11.84. Found: C, 88.36; H, 11.98.

*Eremophilene (**4**) by Dehydration of Eremoligenol (**19**)*

The dehydration of eremoligenol (**19**) was carried out by a procedure identical with that described by Ishii, Tozyo, and Minato (20). From 44 mg of eremoligenol there was obtained 34 mg of crude product as a pale-yellow oil. An analytical sample of eremophilene was obtained from the crude product by means of preparative g.l.c. (column A, 180°). Infrared (film), λ_{max} 6.08, 6.85, 7.28, 11.30 μ; n.m.r., τ 4.70 (multiplet, 1H, —C^1H, width at half-height = 7 Hz), 5.32 (multiplet, 2H, =$C^{12}H_2$, width at half-height = 4 Hz), 8.29 (triplet, 3H, —$C^{13}H_3$), 9.11 (singlet, 3H, —$C^{15}H_3$), 9.15 (doublet, 3H, —$C^{14}H_3$, $J_{4,14}$ = 6 Hz). This material was shown to be identical (i.r., n.m.r., g.l.c. retention times on three different columns: A, 180°; C, 140°; F, 185°) with an authentic sample of natural eremophilene.

Preparative conversion of oximes to parent carbonyl compounds by cerium(IV) oxidation[1]

J. W. Bird and D. G. M. Diaper
Department of Chemistry, Royal Military College of Canada, Kingston, Ontario
Received August 12, 1968

Oximes and semicarbazones are oxidized by ceric ammonium nitrate to the parent carbonyl compound in good yield. Suitable solvent systems include aqueous alcohols, acetonitrile, and acetic acid. The reaction is rapid at 0° or below. This procedure for regeneration of aldehydes and ketones from these derivatives may be preferable to the well-known hydrolytic procedures in some cases. The stoichiometry of the reaction was studied by isothermal calorimetry; two equivalents of oxidant are consumed by one mole of oxime evolving approximately 40 kcal/mole. A smaller consumption of oxidant by hexane-2,5-dione dioxime was attributed to stabilization of the monoxime as a nitroso chelate. Gaseous products were studied by infrared spectroscopy and nitrous oxide was identified as the sole product absorbing between 3 and 15 μ. A reaction mechanism is proposed involving one-electron oxidation to the iminoxy radical, oxidized by a second one-electron step to the α-hydroxy nitroso compound. Dimerization and elimination of hyponitrous acid gives the carbonyl compound. Nitrocyclohexane was absent from the oxidation product from cyclohexanone oxime. Carvone oxime was oxidized to carvone without racemization or significant attack of the olefin groups.

Introduction

The formation of oxime and semicarbazone derivatives is a common method of isolating, purifying, identifying, and characterizing carbonyl compounds. This is especially true with natural products, for example the separation of ketone hormone intermediates obtained by oxidation of sterols may be done by formation of the sparingly soluble semicarbazones (1). After purification the regeneration of the original ketone or aldehyde is then encountered.

A number of good procedures exist including direct acid hydrolysis (2), acid-catalyzed exchange with pyruvic acid (1), levulinic acid (6) or formaldehyde (7), nitrous acid in acetic acid (8–10), and most recently cleavage with bisulfite (11). These procedures are all hydrolytic and several involve equilibrium reaction of hydroxylamine with a more reactive carbonyl compound. They may take a number of hours to go to equilibrium or completion. Common hydrolytic procedures especially applicable to semicarbazones include sulfuric acid in ethanol (2), sulfuric acid in dioxane (3, 4) hydrochloric and acetic acids (5), and sodium nitrite and acetic acid (8). Some of the procedures are drastic and can lead to condensation products or hydrolysis of sensitive protecting groups such as acetoxy groups.

There are occasions when a mild procedure is required which is quick and will not affect other groups present in the molecule. We believe a fast, mild, and usually satisfactory procedure has now been found in the oxidation of oximes and semicarbazones by cerium(IV).

Diaper and Richardson (12) have used the discharge of alcohol – ceric ammonium nitrate orange colors as a colorimetric quantitative determination method for oximes and other easily oxidized compounds. There has been some literature on oxime oxidations but when carbonyl compounds have been recovered the yield is poor (13).

Oxidants of the donor or peroxide type give nitro compounds. Thus oxidations with manganese dioxide in acetic acid (14, 15) result in high yields of the nitro compound. Employing trifluoroacetic acid and hydrogen peroxide results also in 50–80% yields of the nitro compounds (16, 17). Recently much work has been done on the electron spin resonance identification of iminoxy radicals produced by oxime oxidation, the usual oxidant being lead tetraacetate (18–24), although ceric ammonium nitrate in methanol has also been used (19).

Ceric ammonium nitrate as an oxidant has attracted considerable attention lately. It can be used in aqueous solutions and partly organic solutions including aqueous acetic acid. It may be used in aqueous alcohols if the temperature is kept low to minimize attack on the solvent itself. Its power as an oxidant is evident from the fact

[1]Presented at the Vancouver meeting of The Chemical Institute of Canada, June 1968.

For personal use only.

that the standard redox potential of Ce(IV)–Ce(III) is approximately 1.6 V. An interesting feature of its use as a preparative oxidant is the ability to oxidize benzyl alcohols smoothly to benzaldehydes (25) without significant further oxidation of the aldehyde to the aromatic acid. It was this fact and the earlier colorimetric work which recommended this reagent to our attention.

In our procedure low reaction temperatures were employed, but the solubility of the oxime or semicarbazone in the solvent became a factor limiting the temperature. Choice of solvents other than alcohols is limited by considerations of low-temperature solubility of reagent and substrate. Reactions were rapid and easy to follow, because the color was discharged or diminished and vigorous gas evolution occurred for a few minutes. Transient blue colors were often seen. After dilution with water, the carbonyl compound was recovered by solvent extraction.

Experimental

Solutions were concentrated under reduced pressure below 50° in a rotating evaporator. Melting points were determined on a Fisher–Johns hotstage apparatus and are uncorrected. Infrared (i.r.) spectra were determined using a Perkin–Elmer Infracord model 137. Nuclear magnetic resonance (n.m.r.) spectra were obtained using samples in $CDCl_3$ containing 6% of tetramethylsilane as an internal standard. The instrument was a Varian A-60-A spectrometer. Gas–liquid chromatography (g.l.c.) was performed on a Burrell "Kromotog" model KD gas chromatograph with a thermal conductivity detector. Columns were constructed of $\frac{3}{16}$ in. copper tubing 20 ft. long coiled with a diameter of approximately 4 in. The liquid phase was Carbowax 4000, 5% on Chromosorb P (60–80 mesh). Helium flow rates of 45–110 ml/min and temperatures of 105–170 °C were employed. Columns were conditioned for at least 18 h at 190° before use.

The internal standard method was used in the determination of the yields of recovered aldehydes and ketones. An appropriate ketone with a symmetrical, well resolved peak eluting reasonably close to the peak of interest was selected as an internal standard: thus cycloheptanone was used for determination of *d*-camphor or cyclohexanone yields, *d*-camphor for *l*-carvone, and cyclohexanone for cycloheptanone and heptaldehyde. Peak areas were measured by multiplying the peak height by the width at the middle.

A study of the stoichiometry of the reaction was made using an isothermal calorimeter. It was an all-glass ice calorimeter similar to that described by Vallee (26). In principle the reaction takes place in a tube surrounded by ice. Melting of the ice mantle causes a mercury meniscus to move along a graduated horizontal capillary, whose calibration, determined electrically, corresponded to 1.23 cal/cm. The aqueous solution of ceric ammonium nitrate (0.2–0.7 *M* in *N* HNO_3) was initially pipetted into the vessel containing methanol (25 ml) at 0°. A solution of the oxime in absolute alcohol of known concentration was sealed into a weighed fragile glass bulb and introduced. A steady drift (fore-drift) of approximately 0.1 cal/min was observed. The bulb was broken with a stirrer and rapid evolution of heat observed. At the end of 30–40 min the rate of drift (after-drift) was usually about the same as that of the fore-drift. The heat evolution was measured by finding the difference between the extrapolated fore-drift and after-drift lines at the time of mixing. Blanks (0.3–0.5 cal) were determined and subtracted from the heat measured (30–40 cal per determination). Results were expressed graphically for cyclohexanone oxime (Fig. 1) and heptaldoxime (Fig. 2). Benzophenone oxime similarly gave a graph indicating consumption of 1.87 equivalents of oxidant per mole evolving 39.8 kcal/mole. Hexane-2,5-dione dioxime used 3.47 equivalents or 1.735 equivalents of oxidant per oxime group; the evolved heat was 19 kcal per equivalent of Ce(IV). In all isothermal calorimeter experiments, solutions were so dilute that gas evolution did not occur.

Preparation of Oximes and Semicarbazones

Heptaldoxime was a commercial sample (Eastman No. 3001) and had constants in agreement with literature values. Other oximes were prepared from the carbonyl compound and hydroxylamine hydrochloride in aqueous or aqueous–alcoholic basic media as appropriate. Semicarbazones were similarly prepared using semicarbazide hydrochloride. Melting points agreed with literature values; α-*l*-carvoxime had m.p. 74–75° and $[\alpha]_D^{22}$ −39.1° (1.98 g in 18.88 g of 95% ethanol). Wallach (27) found m.p. 73.5°, $[\alpha]_D^{19}$ −43.5° (1.9799 g in 18.8826 g of 95% ethanol).

Oxidation of Oximes and Semicarbazones

In a typical experiment the oxime or semicarbazone (5 mmoles) was dissolved in ethanol (20 ml) and cooled

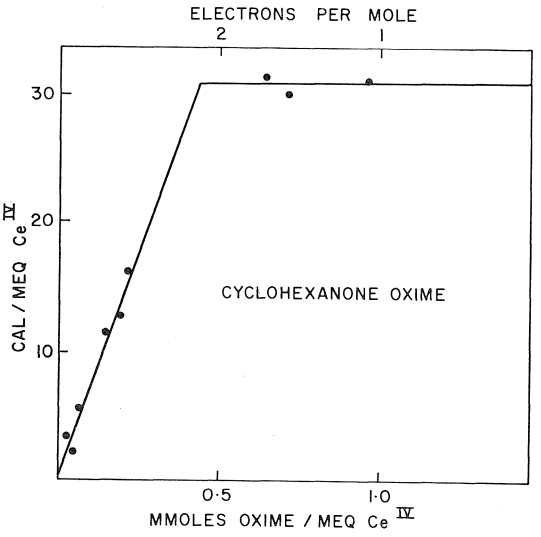

FIG. 1. Heat liberated in the reaction of ceric ammonium nitrate with cyclohexanone oxime.

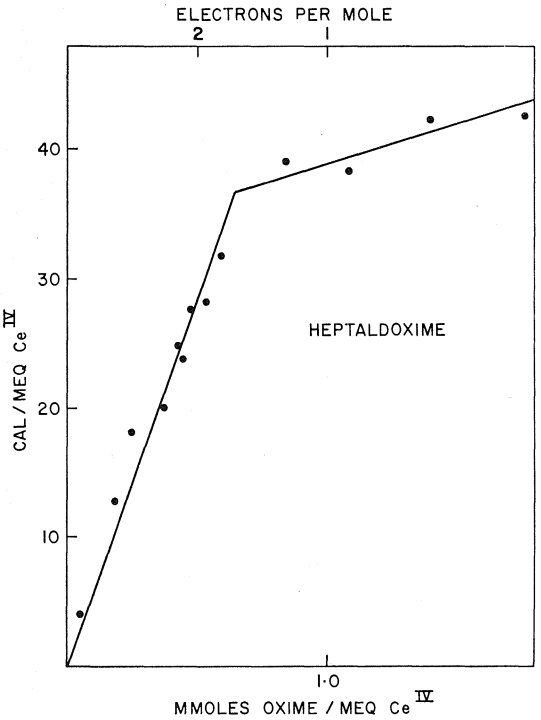

FIG. 2. Heat liberated in the reaction of ceric ammonium nitrate with heptaldoxime.

to the reaction temperature. The oxidant was prepared by mixing 20 mmoles (100% excess) of aqueous ceric ammonium nitrate (0.3 *M* in 0.5 or 1.0 *N* HNO_3, 67 ml) at 0 °C with ethanol at −40° and adjusting to the desired reaction temperature. A little care must be taken to avoid precipitation of ceric ammonium nitrate. The ceric solution was then mixed with the oxime solution, stirred manually, and maintained at the reaction temperature for 5 min. The mixture was diluted with an equal volume of ice water and immediately extracted with chloroform or other immiscible solvent (e.g. three portions of 50 ml). Extracts were dried over anhydrous $MgSO_4$, filtered, and the solvent was removed by distillation at atmospheric pressure. The yields of carbonyl compounds are summarized in Table I. Oxidation temperatures, solvents, and isolation methods were varied to attempt to optimize yields. Results are given in Table II.

Oxidation of Carvone Oxime

Carvone oxime (0.826 g, 5 mmoles) was dissolved in ethanol and cooled to −20°. To this was added the ceric oxidant solution prepared by mixing ceric ammonium nitrate (0.3 *M* in 0.5 *N* HNO_3, 40 ml, 10.2 meq) with ethanol (95%, 50 ml) at −40 °C and adjusted to −20 °C. The reaction mixture was held at −20±2° for 5 min then diluted with an equal volume of cold water and extracted immediately with pentane (three portions of 75 ml). The organic layer was washed with saturated sodium bicarbonate solution, water, dried ($MgSO_4$), and filtered. After removal of the pentane by distillation the resultant solution was divided into aliquots and analyzed by g.l.c. The average yield was 71%.

In a separate experiment to examine the purity of the recovered carvone the proportions of reactants above were doubled and the same procedure followed except that the pentane was removed by rotary evaporation below 40 °C. The resulting liquid was distilled at 10 mm and approximately 108 °C in a short-path distillation apparatus. The carvone had $[\alpha]_D^{24}$ −54.2° (*c*, 2.60, 95% ethanol). A sample of the carvone starting material was purified by vacuum distillation (123–125 °C, 33 mm) and found to have $[\alpha]_D^{24}$ −54.9° (*c*, 2.611, 95% ethanol). The n.m.r. spectra of the two carvone samples were identical with each other and with the published spectrum.

Examination of the Gaseous Product

Cyclohexanone oxime (10 mmoles) in 50% aqueous acetic acid (100 ml) was placed in a flask fitted with a dropping funnel and gas inlets and outlets. The solution was cooled to 0 °C and stirred magnetically while a solution of ceric ammonium nitrate (134 ml, 40 mmoles, 0.3 *M* in *N* HNO_3) was added dropwise. A stream of hydrogen was passed through the mixture to sweep out volatile products. They passed first into a trap cooled in solid CO_2/acetone and then into a trap cooled in liquid air (N_2O boils at −90°). After addition of the oxidant was complete (30–40 min) the reaction mixture was warmed to room temperature while stirring continued. One hour later the hydrogen stream was interrupted. The trap, cooled in liquid air, was connected to a gas cell for use with the i.r. spectrometer and flushed with hydrogen. This cell had NaCl windows 10 cm apart. The trap was allowed to warm slowly to room temperature and the volatilized contents were displaced by hydrogen into the cell. The spectrum had strong sharp absorption peaks at 4.48, 4.55, 7.75, and 7.9 μ. There were no other peaks. Similar peaks were seen in the spectra of the volatile products from cyclopentanone oxime and acetophenone oxime and from cyclohexanone oxime oxidized by ceric ammonium nitrate made up in aqueous acetic acid in place of nitric acid. A control experiment was

performed by flushing the cell with hydrogen and introducing authentic nitrous oxide from a cylinder. The spectrum was identical with that of the oxime product.

Results and Discussion

In most cases a reasonable recovery of carbonyl compound from the oxime or semicarbazone was obtained. Low yields from camphor oxime may be attributable to steric hindrance. The Ce(IV) oxidant appears to differ from oxidants of the donor type in that nitroalkane formation was not observed, and, for the cyclohexanone oxime case, it was shown by g.l.c. to be entirely absent. Identification of nitrous oxide evolved, earlier work on iminoxy radical formation, observation of blue-green colors, and the observed stoichiometry of two electrons per oxime group lead us to propose the reaction mechanism scheme outlined:

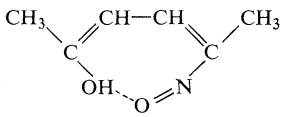
The iminoxy radical known to be the first product of oxime oxidation, is produced in a one-electron step, so a second oxidation process, involving one electron per mole, must be postulated. Hybridization of the radical has been discussed by other authors. The radical can be oxidized to a cation having a canonical structure positively charged on the carbon atom. The hydroxy-nitroso intermediate **2** has not been isolated, but an analogous compound, 4-*t*-butyl-1-acetoxy-1-nitrosocyclohexane, was observed by Lown (23) in the oxidation of 4-*t*-butylcyclohexanone oxime by lead tetraacetate. It was obtained as a blue oil and a white crystalline dimer. Compound **2** would dimerize to **3** shown in the *trans* type of structure discussed by Gowenlock (28) for dimeric unsubstituted nitroso-hydrocarbons. An α-hydroxy-nitroso compound, monomer or dimer, is analogous to other α-hydroxy chlorides and *gem* diols. By analogy with them, easy decomposition would be expected and could take place as shown to give hyponitrous acid (**4**) and the carbonyl compound. Compound **4** is a postulated intermediate in the oxidation of hydroxylamine itself to nitrous oxide.

Dimerization of the iminoxy radical through the oxygen atoms would not lead to nitrous oxide but to a peroxide; dimerization through nitrogen would violate the adjacent charge rule. Such mechanisms are therefore discarded. Another possible mechanism, hydrolysis to hydroxylamine and oxidation of the latter, is considered unlikely since oxime hydrolysis is known to be a much slower process than the oxidative cleavage studied.

While the examples given in the Tables are drawn from aliphatic, alicyclic, or aromatic classes, the reaction may be general. The carvone oxime experiment shows that it is possible for good recovery of the ketone to be achieved when the molecule contains other oxidizable groups. Moreover, retention of most of the optical activity indicated that the conditions of the reaction are sufficiently mild for general application in natural product work.

Semicarbazones in general are less rapidly oxidized than oximes and their lower solubility poses problems in the choice of solvent and conditions. The inorganic products of semicarbazone oxidation were not studied.

The stoichiometry of the oxidation was observed by isothermal calorimetry and indicated consumption of two equivalents of oxidant per mole of oxime. Slightly more than two equivalents for cyclohexanone (Fig. 1) was absorbed because of further attack on the ketone. Heptaldehyde (Fig. 2) also showed evidence of two or more simultaneous reactions in the isothermal calorimeter. The break in the curve was in the vicinity of two electrons per mole, but for high oxime to oxidant ratios the heat liberation increased. A similar slight rise, though less steep, was seen in the hexane-2,5-dione dioxime curve and consumption of the oxidant was less than two electrons per oxime group. No product isolation study was made in this case, but the solution was seen to have a strong and unusually persistent blue color. It would be expected that the product of the first stage of oxidation having one keto and one oximino group would be stabilized as structure **5** and possibly resist further oxidation.



5

Action of some bases on the tropylium cation

S. G. McGeachin
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received September 3, 1968

The tropylium cation has been treated with the hindered bases triphenylmethyl sodium, 2,6-dimethoxyphenyl lithium, and 2,4,6-tri-*t*-butylphenyl lithium to give substituted cycloheptatrienes. Where possible its reaction with tertiary amines follows Reaction Scheme 1 to give immonium salts which can be hydrolyzed to tropylated aldehydes and ketones. Its reaction with trimethylamine gives the quaternary ammonium salt which on exposure to the atmosphere is decomposed to trimethylammonium fluoborate and a mixture of tropone and ditropyl ether.

Canadian Journal of Chemistry, 47, 151 (1969)

Introduction

This study arose in attempts to deprotonate the tropylium cation with the formation of the cycloheptatrienyl carbene **1**. Two reports of the generation of this species by photochemical and thermal decomposition of the sodium salt of tropone *p*-toluene sulfonylhydrazone have appeared (1).

Cycloheptatrienylidene should be relatively stable among carbenes, for the same reasons as the tropylium cation is among carbonium ions. A number of such dipolar or nucleophilic carbenes have been generated in heterocyclic systems. Wanzlick has demonstrated, *inter alia*, the formation of the dimer **4** by reaction of benzthiazolium halides **2** with triethylamine in polar solvents (2). This reaction must proceed either by dimerization of the carbene **3** formed by deprotonation, or by its attack on a benzthiazolium cation followed by deprotonation of the resulting intermediate. The biological functions of thiamine have been shown to depend on the formation of a similar intermediate (3). It should be noted in passing that species of type **3** are better referred to as heterocyclic ylids in recognition of that major canonical form in which all atoms have formal electron octets. All the canonical forms of **1** have one atom with an electron sextet and hence the term carbene would seem appropriate in this case.

Olofson and co-workers have studied the rates of deprotonation of a wide range of five-membered heterocyclic 'olium ions (4). They have found that, aside from the positive charge, deprotonation is accelerated by an increasing number of electronegative atoms in the ring, and markedly by a sulfur atom adjacent to the carbon undergoing deprotonation. This latter is explained in terms of d–σ overlap in the resulting ylid. The tropylium cation lacking these features should therefore undergo deprotonation much more slowly than say the N,N^1-dimethylimidazolium ion ($t_{1/2}$ = 4.5 min for H—D exchange at pD8–9) (4). When it is also considered that the tropylium cation reacts very rapidly with all but the weakest bases, e.g. chloride ion, to form stable substituted cycloheptatrienes it would seem improbable that it can be deprotonated by ordinary means.

In the light of this our approach has been twofold. Firstly we have examined the action of strong bases in which the basic center is sterically hindered, in the hope that preferred attack on a ring proton rather than addition to a less accessible ring carbon atom might occur. In a similar vein we reasoned that reaction with a hindered

5

$(C_7H_7)_2CH\,CHO$

6

tertiary amine might result in direct deprotonation, or in the formation of an intermediate quaternary ammonium salt which might under certain conditions be unstable relative to the carbene and the protonated amine.

Results

Treatment of tropylium fluoborate with three increasingly hindered strong bases, triphenylmethyl sodium, 2,6-dimethoxyphenyl lithium, and 2,4,6-tri-*t*-butylphenyl lithium gave no evidence of deprotonation. The only isolated products were the corresponding substituted cycloheptatrienes in moderate yield. These were identified spectroscopically and by analysis. Addition of triethylamine to a solution of tropylium fluoborate in acetonitrile resulted in a rapid, mildly exothermic reaction. Removal of the solvent gave an oil from which there was obtained a fluoborate salt, $C_{20}H_{26}NBF_4$. The nuclear magnetic resonance (n.m.r.) spectrum of this salt, with appropriate decoupling studies, showed the presence of two tropyl groups (tropyl will be used to refer to the 1,3,5-cycloheptatrien-7-yl group), two chemically different deshielded ethyl groups, and a single low field vinylic proton coupled to a single aliphatic C—H which in turn was coupled to the C-7 protons of the tropyl groups. These findings are adequately met by the structure **5**. Confirmation of this structure came from hydrolysis either of the isolated salt or of the original reaction mixture. This resulted in a neutral substance, $C_{16}H_{16}O$, whose properties indicated it to be 2,2-ditropylacetaldehyde **6**. The formation of **5** must involve an oxidation step. The tropylium cation is well known to abstract hydride ion from suitable substrates (5). That this is operative here was demonstrated by the presence of cycloheptatriene in the reaction mixture when examined by gas–liquid chromatography.

We conclude that the tropylium cation abstracts a hydride ion from triethylamine to give the immonium salt **7**. This is then deprotonated by triethylamine to give the enamine **8** which then adds to a tropylium cation to generate a second immonium salt **9**. A further cycle of deprotonation and addition to the tropylium cation then gives the observed product. This is depicted in Reaction Scheme 1. Similar results were obtained by the use of the hindered ethyldiisopropylamine. From the reaction mixture the salt **10** was isolated. The salt **11** could not be isolated but was certainly present as hydrolysis of the reaction mixture gave two products which were separated chromatographically and found to be 2,2-ditropylacetaldehyde and 1,3-ditropyl-2-propanone, **12**.

REACTION SCHEME 1

Excellent analogy for these processes exists in the reaction of tertiary amines with the triphenylmethyl carbonium ion. Damico and Broaddus (6) have shown that dodecyldimethylamine reacts with this ion to give triphenylmethane and the amine hydrochloride as the isolated products in good yield. These findings were interpreted in terms of repeated cycles of hydride abstraction from the base, and deprotonation of the immonium salt to an enamine, with the enamine then acting as substrate for the abstraction of a second hydride ion. The net result would be the formation of the above mentioned products along with a relatively small amount of polyenamines. Depending on the extent to which the first step in Reaction Scheme 1 takes place, one might expect exclusively cycloheptatriene or any of mono-, di-, or tritropyl-acetaldehyde after hydrolysis of the triethylamine reaction. With ethyldiisopropylamine the number of possible products is even greater. Careful thin-layer chromatographic examination of the products of

For personal use only.

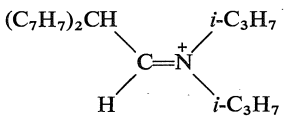
hydrolysis of these reaction mixtures has revealed only ditropylacetaldehyde in the case of triethylamine, and that plus the symmetrical ditropylacetone in the case of ethyldiisopropylamine. This result is independent of the way in which the reaction between base and tropylium cation is conducted. Slow addition over several hours of the tropylium cation to triethylamine, or the reverse, followed by the hydrolysis gave in comparable yields the product already obtained and no other.

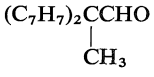
Since all of the steps in Reaction Scheme 1 are presumably reversible it is probable that the observed products are derived from the most stable immonium salts. That steric effects are of importance is inferred from the formation of 1,3-ditropyl-2-propanone as against the 1,1-derivative and from the following. When the tropylium cation was allowed to react with tri-*n*-propylamine under identical conditions, there were obtained from the hydrolysis two products in the ratio of 1:15. The minor product proved to be 2,2-ditropylpropionaldehyde **13** and the major, the corresponding monotropyl derivative **14**. We ascribe this to the destabilizing effect of a quaternary carbon *cis* to the propyl group in the intermediate **15**.



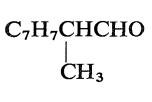
10

11

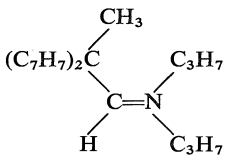
12



13



14



15

We have also investigated the action of trimethylamine since this cannot be converted to an enamine. This resulted only in formation of the quaternary ammonium salt. On the basis of the n.m.r. spectrum of the crude product, no compounds derived by hydride transfer were formed. The n.m.r. spectrum of the salt in deuteriodichloromethane was of interest in that it showed a sharp singlet at τ 7.12 for *N*-methyl protons and a slightly broadened singlet (half-width ca. 3 c.p.s.) for the seven protons of the ring at τ 3.75. In this solvent there must be an equilibrium between the quaternary salt and tropylium fluoborate – trimethylamine which makes the ring protons equivalent. The position of this absorption at considerably higher field than occurs for tropylium fluoborate in acetonitrile (τ 0.45) is in accord with this. This salt is stable in solution under nitrogen or dry air. Heating a sample under high vacuum to 150° resulted in decomposition without the formation of any volatile product. On exposure to the atmosphere the salt decomposed to trimethylammonium fluoborate and a mixture of tropone and ditropyl ether. We interpret this to be reaction with atmospheric moisture. It is reasonable that in the presence of water vapor some hydrolysis of the salt to ditropyl ether should occur. It is already known (7) that ditropyl ether disproportionates to tropone and cycloheptatriene in the presence of the tropylium cation.

Experimental

General

Melting points were taken on a Köfler melting point apparatus and are uncorrected. Analyses were performed by the Microanalytical Laboratory of this department.

7-Triphenylmethyl-1,3,5-cycloheptatriene

Triphenylmethyl sodium (8) (25 ml of a standard ethereal solution) was added to a stirred suspension of tropylium fluoborate (9) (0.353 g; 1 equivalent) in diethylene glycol dimethyl ether (25 ml) under nitrogen. The red color of the anion disappeared within a few minutes. The reaction mixture was poured into water after 10 min and the product isolated by extraction into pentane. It was chromatographed on Grade I alumina. Elution with 1:1 benzene–heptane gave triphenylmethane (50 mg) and 7-triphenylmethyl-1,3,5-cycloheptatriene (470 mg; 71%). The analytical sample recrystallized from dichloromethane–methanol and had m.p. 137–140°.

Anal. Calcd. for $C_{26}H_{22}$: C, 93.37; H, 6.63. Found: C, 93.35; H, 6.44.

Nuclear magnetic resonance spectrum ($CDCl_3$): τ 2.82 (15H, singlet), τ 3.15, 3.85, 4.73 (3 × 2H, multiplets), τ 7.07 (1H, triplet) assigned to the phenyl groups, the three pairs of vinylic protons and the C-7 proton of the cycloheptatriene ring respectively.

7-(2,6-Dimethoxyphenyl)-1,3,5-cycloheptatriene

Solid tropylium fluoborate (1.88 g) was added slowly in batches to a stirred suspension of 2,6-dimethoxyphenyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

lithium (1.55 g) in 50 ml of diethyl ether under nitrogen. After complete addition the mixture was stirred for a further 10 min, filtered, washed with water, dried, and the solvent removed. The resulting oil on crystallization from methanol gave 7-(2,6-dimethoxyphenyl)-1,3,5-cycloheptatriene (1.57 g; 65%). The analytical sample, recrystallized as plates from methanol, had m.p. 91–92°.

Anal. Calcd. for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06. Found: C, 78.89; H, 6.94.

Nuclear magnetic resonance spectrum ($CDCl_3$): τ 2.77 (1H, multiplet), τ 3.36 (4H, multiplet), τ 3.82 (2H, multiplet), τ 4.59 (2H, multiplet), τ 6.23 (6H, singlet), τ 6.48 (1H, triplet).

7-(2,4,6-Tri-t-butylphenyl)-1,3,5-cycloheptatriene

Butyl lithium (2.3*M*, 0.72 ml) was added to a stirred solution of 2,4,6-tri-*t*-butylbromobenzene (10) (0.540 g) in ether (25 ml). The mixture was refluxed gently for 1 h, cooled, and solid tropylium fluoborate (0.355 g; 1.2 molar equivalents) added. After being stirred for a further 1 h the reaction mixture was filtered, and the filtrate washed with water, and dried. The crude material was filtered through a column of silica gel (50 g) in benzene, and the resulting product crystallized from chloroform–ethanol to give 7-(2,4,6-tri-*t*-butylphenyl)-1,3,5-cycloheptatriene (352 mg; 63%). The analytical sample had m.p. 150°.

Anal. Calcd. for $C_{25}H_{36}$: C, 89.22; H, 10.78. Found: C, 89.08; H, 10.82.

Nuclear magnetic resonance spectrum ($CDCl_3$): τ 2.58 (2H, singlet), τ 3.80 (4H, multiplet), τ 5.88 (2H, multiplet), τ 6.78 (1H, multiplet), τ 8.55 (18H, singlet), τ 8.68 (9H, singlet).

N,N-Diethyl-2,2-ditropylacetaldimine Fluoborate (5)

A stirred solution of tropylium fluoborate (5.16 g) in dry acetonitrile (50 ml) was treated with triethylamine (4.05 ml). A rapid mildly exothermic reaction ensued. The mixture was allowed to stand 2 h, and then evaporated *in vacuo* to a gum. This was taken up in dichloromethane, washed with water, to remove triethylammonium fluoborate, and dried. Removal of the solvent left an oil which was crystallized from dichloromethane – ethyl acetate to give the imine fluoborate salt (2.56 g; 72%). The analytical sample, m.p. 96–97°, formed prisms from dichloromethane – ethyl acetate.

Anal. Calcd. for $C_{20}H_{26}NBF_4$: C, 65.42; H, 7.14; N, 3.90. Found: C, 65.13; H, 7.00; N, 3.94.

Nuclear magnetic resonance spectrum ($CDCl_3$): (*1*) τ 1.82 (1H, doublet, J = 11 c.p.s.), (*2*) τ 3.40, 3.70, 4.65 (3 × 4H, multiplets), (*3*) τ 6.07, 6.35 (2 × 2H, quartets, J = 7 c.p.s.), (*4*) τ 6.69 (2H, multiplet), (*5*) τ 7.03 (1H, multiplet), (*6*) τ 8.56, 8.67 (2× 3H, triplets, J = 7 c.p.s.). Decoupling indicated that proton (*1*), assigned to the aldimine CH, is coupled to proton (*5*), the aliphatic CH, which in turn is coupled to protons (*4*), the C-7 protons of the cycloheptatriene rings, with J = 8 c.p.s. Protons (*2*) were assigned to the cycloheptatriene rings and (*3*) and (*6*) to the methylenes and methyls of the *N*-ethyl groups respectively.

N,N-Diisopropyl-2,2-ditropylacetaldimine Fluoborate (10)

This was prepared by the above process in 26% yield. No other product could be isolated from the mother liquors of the crystallization. The analytical sample from dichloromethane – ethyl acetate had m.p. 156–157°.

Anal. Calcd. for $C_{22}H_{30}NBF_4$: C, 66.83; H, 7.65; N, 3.54. Found: C, 67.07; H, 7.79; N, 3.55.

Nuclear magnetic resonance spectrum ($CDCl_3$): τ 1.53 (1H, doublet, J = 10 c.p.s.), τ 3.45, 3.75, 4.62 (3 × 4H, multiplets), τ 5.75 (2H, multiplet), τ 6.65 (3H, multiplet), τ 8.47, 8.55 (2 × 6H, doublets, J = 7 c.p.s.).

Ditropylacetaldehyde (6)

A solution of tropylium fluoborate (12 g) in acetonitrile (120 ml) was treated with triethylamine (11.4 ml). After 2 h, water (60 ml) was added and the solution left for ca. 18 h. It was then poured into water (600 ml), the product isolated by extraction into ether, and distilled to give ditropylacetaldehyde (3.5 g, 66%), b.p. 112–113° at 0.01 mm pressure.

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.68; H, 7.19. Found: C, 85.54; H, 7.33.

Infrared spectrum: ν_{max} (film) 1725 cm^{-1}. Nuclear magnetic resonance spectrum ($CDCl_3$): τ 0.1 (1H, doublet, J = 3.5 c.p.s.), τ 3.37, 3.80, 4.75 (3 × 4H, multiplets), τ 7.03 (1H, triplet of doublets, J = 3.5 and 7.5 c.p.s.), τ 7.72 (2H, multiplet). The last two absorptions are assigned to the proton α to the carbonyl and the C-7 protons of the rings respectively.

1,3-Ditropyl-2-propanone (12)

By the same procedure as for the above aldehyde tropylium fluoborate (8 g) in acetonitrile (80 ml) was treated with ethyldiisopropylamine (7.85 ml). After 2 h, water (40 ml) was added to effect hydrolysis. The isolated crude product was chromatographed on silica gel (500 g). Elution with benzene gave firstly ditropylacetaldehyde (2.04 g) and then 1,3-ditropyl-2-propanone (1.80 g). The analytical sample of the ketone, m.p. 88–89°, was obtained by sublimation at 130–140°/0.05 mm.

Anal. Calcd. for $C_{17}H_{18}O$: C, 85.67; H, 7.61. Found: C, 85.39; H, 7.56.

Infrared spectrum: ν_{max} (Nujol) 1712 cm^{-1}. Nuclear magnetic resonance spectrum ($CDCl_3$): τ 3.39, 3.84, 4.86 (3 × 4H, multiplets), τ 7.27 (4H, doublet, J = 8 c.p.s.) τ 7.69 (2H, multiplet).

2-Tropylpropionaldehyde (14) and 2,2-Ditropylpropionaldehyde (13)

Tropylium fluoborate (2.1 g) in acetonitrile (20 ml) was treated with tri-*n*-propylamine (2.25 ml). The mixture was left 2 h, treated with water (10 ml), and left for a further 18 h. The crude product, isolated by dilution of the reaction mixture with water and extraction into ether, was chromatographed on silica gel (50 g). Elution with benzene gave firstly 2,2-ditropylpropionaldehyde (50 mg) followed by the more polar monotropyl-propionaldehyde (750 mg). An analytical sample of the former compound was prepared by sublimation at 130°/0.05 mm. It had m.p. 113–114.5°.

Anal. Calcd. for $C_{17}H_{18}O$: C, 85.67; H, 7.61. Found: C, 85.80; H, 7.79.

Infrared spectrum: ν_{max} (film) 1725 cm^{-1}. Nuclear magnetic resonance spectrum ($CDCl_3$): τ 0.15 (1H, singlet), τ 3.25, 3.75, 4.75 (3 × 4H, multiplets), τ 7.88 (2H, broad triplet), τ 8.59 (3H, singlet). An analytical sample of the latter compound was obtained by evaporative distillation at 80–85°/0.05 mm.

Anal. Calcd. for $C_{10}H_{12}O$: C, 81.04; H, 8.16. Found: C, 80.94; H, 8.31.

Infrared spectrum: ν_{max} (film) 1725 cm^{-1}. Nuclear magnetic resonance spectrum ($CDCl_3$): τ 0.30 (1H, doublet, $J = 2$ c.p.s.), τ 3.33, 3.75, 4.75 (3 × 2H, multiplets), τ 7.3 (1H, multiplet), τ 8.05 (1H, multiplet), τ 8.82 (3H, doublet, $J = 7$ c.p.s.).

Tropyltrimethylammonium Fluoborate

A solution of tropylium fluoborate (4.12 g) in acetonitrile (40 ml) under nitrogen was cooled in an acetone–CO_2 bath to −20°. Trimethylamine (2.52 *M*) in acetonitrile (9.5 ml) was added and the solution was allowed to rise to room temperature. Removal of the solvent *in vacuo* gave an oil which crystallized. It was recrystallized from dichloromethane – ethyl acetate under nitrogen to give tropyltrimethylammonium fluoborate, m.p. 73–78°. A satisfactory analysis was not obtained.

Nuclear magnetic resonance spectrum (CD_2Cl_2): τ 3.75 (7H, broad singlet), τ 7.12 (9H, singlet).

Twofold alkylations of ketone and aldehyde phenylhydrazones with methylene halides by means of alkali amides to form bis-*N*-derivatives[1]

FRED E. HENOCH AND CHARLES R. HAUSER
Department of Chemistry, Duke University, Durham, North Carolina 27706

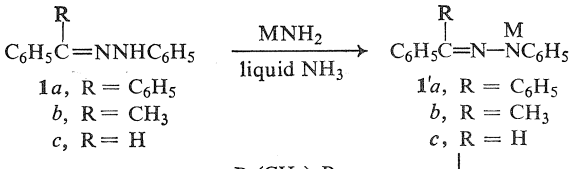
Received July 5, 1968

The phenylhydrazones of benzophenone, acetophenone, and benzaldehyde were converted by a molecular equivalent of an alkali amide in liquid ammonia to their mono-alkali derivatives, which underwent twofold alkylation with 1,3-dibromopropane or higher methylene halides or with α,α′-dichloro-*p*-xylene to form corresponding bis-*N*-derivatives. Two of the products were reduced by means of lithium in liquid ammonia to give corresponding substituted bis-hydrazines. These reactions furnish convenient methods of synthesis of such compounds.

Canadian Journal of Chemistry, 47, 157 (1969)

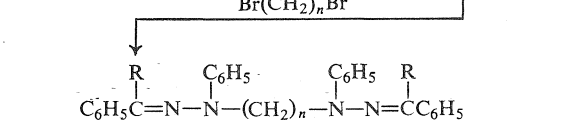
As an extension of a previous method for effecting certain *N*-alkylations of ketone and aldehyde phenylhydrazones with alkyl halides (1), we have now found that twofold *N*-alkylations of phenylhydrazones **1***a–c* can be accomplished with appropriate methylene bromides by means of alkali amides in liquid ammonia to form the bis-derivatives **2***a–f*, respectively. Similarly the intermediate alkali phenylhydrazones **1***a–b* underwent twofold alkylation with α,α′-dichloro-*p*-xylene to give the bis-derivatives **3***a–b*, respectively. The results are summarized in Tables I and II.

Table I shows that the yields of the analytically pure bis-derivatives **2***a–f* and **3***a–b* were quite satisfactory (48–81%). In certain cases the yields were slightly better with potassium amide than with sodium amide. The structures of the products were supported by analysis and absorption spectra (see Tables I and II). The most notable difference in the infrared (i.r.) spectra of the bis-derivatives from those of the starting phenylhydrazones is the lack of any absorption in the NH region. Otherwise, these spectra are similar to those of the starting phenylhydrazones except that the peaks appear at different frequencies. The nuclear magnetic resonance (n.m.r.) spectra of compounds **2***a–f* show an N—CH_2 triplet and those of **3***a–b* an N—CH_2 singlet. Their n.m.r. spectra are in complete agreement with the assigned structures.

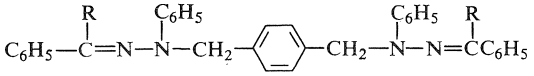


1*a*, R = C_6H_5
b, R = CH_3
c, R = H

1′*a*, R = C_6H_5
b, R = CH_3
c, R = H



2*a*, R = C_6H_5, *n* = 3
b, R = C_6H_5, *n* = 4
c, R = CH_3, *n* = 4
d, R = H, *n* = 3
e, R = H, *n* = 4
f, R = H, *n* = 10



3*a*, R = C_6H_5
b, R = CH_3

This method of synthesis would probably be suitable with, not only other phenylhydrazones, but also with other methylene bromides higher than 1,3-dibromopropane and with α,α′-dichloro-*o*-xylene (see Table I). However, the method failed with phenylhydrazone **1***a* and ethylene or methylene bromide or chloride with which the starting phenylhydrazone **1***a* was largely recovered. The results with the ethylene halides may be accounted for by β-elimination.

For personal use only.

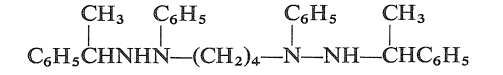
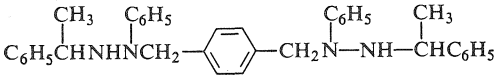
The bis-hydrazones **2***c* and **3***b* were reduced by means of lithium in liquid ammonia to form the corresponding substituted bis-hydrazines **4** and **5** in yields of 54 and 61%, respectively. The other bis-hydrazones could presumably be reduced similarly. This method has previously been employed for reduction of an α,β-unsaturated ketone (2).



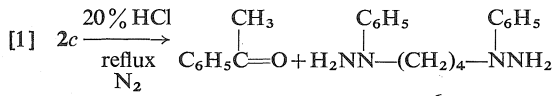
4



5

The structures of the bis-hydrazines **4** and **5** were supported by analysis and absorption spectra (see Experimental). The i.r. spectra of **4** and **5** lack the C=N peak observed in the spectra of starting bis-hydrazones **2***c* and **3***b* and have strong peaks for the NH and C—N groups. Although the n.m.r. spectrum of **4** is somewhat complicated by overlap of the methyl protons with the methylene protons and of the benzylic protons with the *N*-methylene protons, the n.m.r. spectrum for **5** shows the expected doublet for the methyl group and a quartet for the CH group adjacent to the methyl group.

The bis-hydrazones **2***c* and **3***b* were hydrolyzed with hot acid but the resulting bis-hydrazines or their acid salts appeared to be too unstable to isolate readily. For example, on refluxing a solution of **2***c* with 20% hydrochloric acid under nitrogen for 3 h, a dark tarry gum was obtained. That hydrolysis had occurred was shown by isolation of the ketone as its 2,4-dinitrophenylhydrazone (78%) and the bis-hydrazine **6** as its bis-benzaldehyde derivative **2***e* (12%) [eq. 1]:



[1]

6

It may be concluded that the twofold alkylation of phenylhydrazones and subsequent reduction of the products furnish convenient methods for the synthesis of an apparently new class of bis-hydrazones and bis-hydrazines such as **2***a–f*, **3***a–b*, **4**, and **5**. The possible twofold condensation of a bis-hydrazine such as **6** with an aldehyde or ketone does not seem suitable, since **6** appears not readily available and too unstable for a satisfactory result (see above).

Experimental

Melting points, taken on a Thomas Hoover capillary melting point apparatus, are uncorrected. Infrared spectra were recorded on a Perkin–Elmer model 237 Infracord using samples prepared as potassium bromide pellets. Nuclear magnetic resonance spectra were recorded on a Varian A-60 spectrometer using deuteriochloroform solutions containing tetramethylsilane as an internal standard[2] Elemental analyses were performed by Paul Demoen, Janssen Pharmaceutical Laboratories, Beerse, Belgium, and M-H-W Laboratories, Garden City, Michigan.

The benzophenone phenylhydrazone (3), acetophenone phenylhydrazone (4), and the benzaldehyde phenylhydrazone (5) used in this study were prepared according to literature procedures. The acetophenone phenylhydrazone should be freshly prepared.

Twofold N-Alkylations of Phenylhydrazones

To a stirred suspension of 0.025 mole of sodium amide (6) or potassium amide (7) in 350 ml of commercial, anhydrous liquid ammonia was added a molecular equivalent of the phenylhydrazone **1***a*, **1***b*, or **1***c*. The solutions of the resulting alkali salt were colored blood-red, orange-tan, and brownish-yellow respectively. After 20 min, a solution of one half of a molecular equivalent of the appropriate dihalide in 15–20 ml of anhydrous ether was added during a 4–6 min period; the color of the solution was essentially discharged and a precipitate formed. After stirring for 45–60 min, a slight excess of a molecular equivalent of ammonium chloride was added. The ammonia was allowed to evaporate, and the residue was taken up in ether and water. The layers were separated and the aqueous layer was washed twice with 100 ml of ether. The ether layers were combined and dried ($MgSO_4$) and the solvent was removed. The residue was recrystallized from an appropriate solvent. The results are summarized in Tables I and II.

Reduction of bis-Derivative 2c

To a stirred, blue solution of 0.7 g (0.1 mole) of lithium in 250 ml of commercial, anhydrous liquid ammonia was added 2.30 g (0.005 mole) of **2***c* in 100 ml of dry THF (freshly distilled from lithium aluminium hydride) during a 10 min period. After 1 h, the color of the solution had changed to a darker blue. A slight excess of ammonium chloride was then added in small equal portions during a 20 min period. The ammonia was evaporated and the reaction mixture was worked up to give a yellowish solid which was recrystallized from ethanol to give 1.43 g (54%) of hydrazine **4** (yellowish crystals), m.p. 143–144°; i.r. 3420 cm^{-1} (NH), 1600 and 1500 cm^{-1} (aromatic), 1265 and 1335 cm^{-1} (C—N), 760 and 700 cm^{-1} (out-of-plane CH bend); n.m.r. ($CDCl_3$)

Steroid derivatives of cysteamine and cysteine

OWEN H. WHEELER AND CESAR REYES-ZAMORA
Puerto Rico Nuclear Center and Department of Chemistry, University of Puerto Rico, Mayaguez, Puerto Rico

Received July 8, 1968

A number of androstenone, estrone, and pregnenone derivatives of cysteamine have been prepared by reacting the steroid amines with ethylene monothiolcarbonate. The amides of androstenone carboxylic acid with mercaptoethylamine and cysteine have also been prepared.

Canadian Journal of Chemistry, 47, 160 (1969)

The only compounds which have shown any promise in affording protection against radiation in the animal body are cysteamine (2-mercaptoethylamine) and its simple derivatives (1). Cysteine, which was one of the first compounds reported to show radiation protection, is less effective (2). However, these compounds are relatively toxic and are also easily metabolized and eliminated from the body. The object of this work was to prepare derivatives which might be less toxic and less readily metabolized, by joining cysteamine and cysteine to a steroid molecule, while still leaving the mercapto group free, since this is essential for radiation protection. The following derivatives of cysteamine have been prepared: *N*-(2-mercaptoethyl)-3-ketopregn-4-en-20β-yl amine (**1**), *N*-(2-mercaptoethyl)-3-keto-androst-4-en-17β-yl amine (**2**), *N*-(2-mercaptoethyl)estra-1,3,5(10)-trien-3-ol-17β-yl amine (**3**), and *N*-(2-mercaptoethyl)-3-ketoandrost-4-ene 17β-carboxamide (**4**). A derivative of cysteine, *N*-(3-ketoandrost-4-ene 17β-carboxyl)cysteine (**5**), has also been synthesized.

The condensation of pregn-5-en-3-ol-20-amine with an excess of ethylene monothiolcarbonate gave a good yield of *N*-mercaptoethylpregn-5-en-3-ol-20β-yl amine. Although condensations with ethylene monothiolcarbonate are usually carried out (3, 4) with an excess of amine to avoid di-substitution, no *N,N*-dimercaptoethyl derivative was formed in the present case. This same compound was formed by using one equivalent of ethyl 2-mercaptoethylcarbonate (4). An Oppenauer oxidation of *N*-(2-mercaptoethyl)pregn-5-en-3-ol-20-yl amine under standard conditions gave *N*-(2-mercaptoethyl)-3-ketopregn-4-en-20β-yl amine (**1**), without oxidizing the mercapto group, although the yield was low. The molecular weight indicated that the compound was still in the free mercapto form.

As an alternative route pregn-5-en-3-ol-20β-yl amine was oxidized with chromium trioxide in pyridine (5) to 3-ketopregn-5-en-20β-yl amine, which was obtained in an impure state and in low yield, apparently due to the formation of chromium complexes. Oxidation of the corre-

Steroid derivatives of cysteamine and cysteine

OWEN H. WHEELER AND CESAR REYES-ZAMORA
Puerto Rico Nuclear Center and Department of Chemistry, University of Puerto Rico, Mayaguez, Puerto Rico

Received July 8, 1968

A number of androstenone, estrone, and pregnenone derivatives of cysteamine have been prepared by reacting the steroid amines with ethylene monothiolcarbonate. The amides of androstenone carboxylic acid with mercaptoethylamine and cysteine have also been prepared.

Canadian Journal of Chemistry, 47, 160 (1969)

The only compounds which have shown any promise in affording protection against radiation in the animal body are cysteamine (2-mercaptoethylamine) and its simple derivatives (1). Cysteine, which was one of the first compounds reported to show radiation protection, is less effective (2). However, these compounds are relatively toxic and are also easily metabolized and eliminated from the body. The object of this work was to prepare derivatives which might be less toxic and less readily metabolized, by joining cysteamine and cysteine to a steroid molecule, while still leaving the mercapto group free, since this is essential for radiation protection. The following derivatives of cysteamine have been prepared: *N*-(2-mercaptoethyl)-3-ketopregn-4-en-20β-yl amine (**1**), *N*-(2-mercaptoethyl)-3-keto-androst-4-en-17β-yl amine (**2**), *N*-(2-mercaptoethyl)estra-1,3,5(10)-trien-3-ol-17β-yl amine (**3**), and *N*-(2-mercaptoethyl)-3-ketoandrost-4-ene 17β-carboxamide (**4**). A derivative of cysteine, *N*-(3-ketoandrost-4-ene 17β-carboxyl)cysteine (**5**), has also been synthesized.

The condensation of pregn-5-en-3-ol-20-amine with an excess of ethylene monothiolcarbonate gave a good yield of *N*-mercaptoethylpregn-5-en-3-ol-20β-yl amine. Although condensations with ethylene monothiolcarbonate are usually carried out (3, 4) with an excess of amine to avoid di-substitution, no *N,N*-dimercaptoethyl derivative was formed in the present case. This same compound was formed by using one equivalent of ethyl 2-mercaptoethylcarbonate (4). An Oppenauer oxidation of *N*-(2-mercaptoethyl)pregn-5-en-3-ol-20-yl amine under standard conditions gave *N*-(2-mercaptoethyl)-3-ketopregn-4-en-20β-yl amine (**1**), without oxidizing the mercapto group, although the yield was low. The molecular weight indicated that the compound was still in the free mercapto form.

As an alternative route pregn-5-en-3-ol-20β-yl amine was oxidized with chromium trioxide in pyridine (5) to 3-ketopregn-5-en-20β-yl amine, which was obtained in an impure state and in low yield, apparently due to the formation of chromium complexes. Oxidation of the corre-

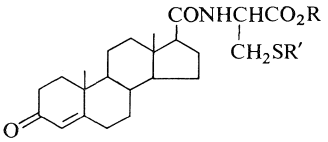
4



5 *a*; R = R′ = H
b; R = CH_3, R′ = $PhCH_2$

sponding amine hydrochloride following the method of Jones (6) gave only traces of the ketoamine. 3-Ketopregn-5-en-20β-yl amine could not be isomerized to 3-ketopregn-4-en-20β-yl amine with oxalic acid (7), but isomerization was achieved with alcoholic potassium hydroxide at room temperature.

Androst-5-en-3-ol-17β-yl amine also condensed with ethylene monothiolcarbonate to give *N*-(2-mercaptoethyl)androst-5-en-3-ol-17β-yl amine, which was oxidized under the conditions of Oppenauer to *N*-(2-mercaptoethyl)-3-ketoandrost-4-en-17β-yl amine (**2**). Estra-1,3,5(10)-trien-3-ol-17β-yl amine also reacted readily with ethylene monothiolcarbonate to give *N*-(2-mercaptoethyl)estra-1,3,5(10)-trien-3-ol-17β-yl amine (**3**).

3-Ketoandrost-4-ene 17β-carboxylic acid was converted to its acid chloride with oxalyl chloride and condensed with mercaptoethylamine to give *N*-(2-mercaptoethyl)-3-ketoandrost-4-ene 17β-carboxamide (**4**). The acid chloride was also reacted with cysteine in the presence of triethylamine to form *N*-(3-ketoandrost-4-ene 17β-carboxyl)cysteine (**5***a*). Condensation could not be effected in the presence of pyridine. Previously the acid chloride had been condensed with *S*-benzylcysteine methyl ester to afford *S*-benzyl-*N*-(3-ketoandrost-4-ene 17β-carboxyl)cysteine methyl ester (**5***b*). However, since the free cysteine derivative was prepared by direct condensation, hydrolysis and debenzylation of this last compound were not attempted.

Experimental

Analyses were performed by Dr. Jansen, Beerse, Belgium.

Pregn-5-en-3-ol-20β-yl Amine

Pregnenolone oxime (lit. (8) m.p. 218–219°) was reduced with sodium in *n*-propanol (9) to the amine hydrochloride, m.p. 304–305°. The free base was liberated with 30% aqueous sodium hydroxide, m.p. 165–167° (lit. (9) m.p. 163–166°).

N-(2-Mercaptoethyl)pregn-5-en-ol-20β-yl Amine

Pregn-5-en-3-ol-20β-yl amine (1.0 g) was dissolved in toluene (50 ml) and the solution dried by distilling off half the solvent. Ethylene monothiolcarbonate (0.165 g) was then added and the mixture refluxed for 15 h. Part of the solvent was evaporated at reduced pressure, when the product (0.97 g) crystallized and was then recrystallized from acetone, m.p. 152–154°.

As an alternative method, pregn-5-en-3-ol-20β-yl amine (0.765 g) in dry toluene (25 ml) was treated over 1 h at reflux with ethyl 2-mercaptoethylcarbonate (0.362 g) (4). The solution was refluxed for ½ h and the solvent removed *in vacuo*. The product (0.65 g) was recrystallized from acetone to m.p. 152–154°.

Anal. Calcd. for $C_{23}H_{39}NOS$: C, 73.25; H, 10.41. Found: C, 73.69; H, 10.60.

N-(2-Mercaptoethyl)-3-ketopregn-4-en-20β-yl Amine (1)

The above compound (0.55 g) was dissolved in toluene (200 ml) and cyclohexanone (30 ml). Part (70 ml) of the solvent was distilled off and aluminium isopropoxide (4.0 g) in toluene (30 ml) added dropwise while the solvent

For personal use only.

(50 ml) was distilled off. The mixture was refluxed for 15 h, Rochelle salt (5 g) was then added and the mixture steam distilled. The product was extracted from the residue with ether and recrystallized from acetone – petroleum ether (0.23 g) m.p. 186–188° (decomp.); λ_{max} 242 mμ (log ε 4.03).

Anal. Calcd. for $C_{23}H_{37}NOS$ (mol. wt., 373): C, 73.54; H, 9.93. Found (mol. wt. (Rast), 363): C, 73.35; H, 9.71.

Androst-5-en-3-ol-17β-yl Amine

Phosphorus oxychloride (1.0 ml) was added dropwise to pregnenolone oxime (0.5 g) in pyridine (7.0 ml) with stirring and cooling to 0°. The mixture was maintained at 0–5° for 1½ h and then poured into ice and dilute hydrochloric acid. The acetylamino compound was filtered off, washed with water and recrystallized from methanol water, m.p. 245–247°. The hydrolysis was carried out by refluxing overnight with 20% potassium hydroxide in ethylene glycol. The product was extracted with ether and the amine hydrochlorides (0.2 g); m.p. 362° (lit. (10) m.p. 360°) precipitated by passing in hydrogen chloride. The free amine was liberated with 30% sodium hydroxide and recrystallized from acetone (0.11 g), m.p. 161–164° (lit. (10) m.p. 162°).

N-(2-Mercaptoethyl)androst-5-en-3-ol-17β-yl Amine

Androst-5-en-3-ol-17β-yl amine was condensed as above with ethylene monothiolcarbonate. The product, m.p. 150–152°, was recrystallized from acetone.

Anal. Calcd. for $C_{21}H_{35}NOS$: C, 72.15; H, 10.09. Found: C, 72.41; H, 9.93.

N-(2-Mercaptoethyl)-3-ketoandrost-4-en-17β-yl Amine (2)

N-Mercaptoethylandrost-5-en-3-ol-17β-yl amine (0.72 g) was subjected to an Oppenauer oxidation as before giving the product (0.31 g), m.p. 193–196° (decomp.), from acetone – petroleum ether; λ_{max} 241 mμ (log ε 4.02).

Anal. Calcd. for $C_{21}H_{33}NOS$ (mol. wt., 348): C, 72.57; H, 9.57. Found (mol. wt. (Rast), 343): C, 72.83; H, 9.82.

Estra-1,3,5(10)-trien-3-ol-17β-yl Amine

Estrone oxime (0.8 g) (m.p. 231–232°) (11) in *n*-propanol (50 ml) was refluxed with small pieces of sodium (1.48 g) until they dissolved. The solvent was evaporated at reduced pressure, water added, and carbon dioxide passed in. The precipitated solid was washed with hot water and recrystallized from methanol (0.3 g), m.p. 223–226° (lit. (11) m.p. 222–223°).

N-(2-Mercaptoethyl)estra-1,3,5(10)-trien-3-ol-17β-yl Amine (3)

Estratriene-3-ol-17β-yl amine (0.237 g) and ethylene monothiolcarbonate (0.041 g) in toluene (1.3 ml) under the usual conditions, gave mixed crystals (0.18 g) of the estratriene-3-ol-17β-yl amine and *N*-(2-mercaptoethyl)-estratrien-3-ol-17β-yl amine, recrystallized from acetone, m.p. 129–130°.

Anal. Calcd. for $C_{20}H_{29}NOS \cdot C_{18}H_{25}NO$: C, 75.70; H, 9.03. Found: C, 75.78; H, 8.97.

N-(2-Mercaptoethyl)-3-ketoandrost-4-ene 17β-carboxamide (4)

3-Ketoandrost-4-ene 17β-carboxylic acid (1.0 g) prepared by hypobromite oxidation of progesterone (12), was dissolved in 0.79 *N* sodium hydroxide (39 ml). The water was evaporated and the sodium salt dried at 170° and 1 mm for 5 h. The salt was suspended in anhydrous pyridine (0.16 g) and benzene (15 ml), cooled to 5°, and treated with oxalyl chloride (4.5 ml). The mixture was allowed to stand at room temperature for 5 min and evaporated *in vacuo* at 20°. Benzene (2 ml) was added and the solution reevaporated. The residue was dissolved in benzene (12 ml), cooled to 0°, and a suspension of freshly sublimed mercaptoethylamine (0.24 g) in benzene (5 ml) added with stirring. The solution was left at room temperature overnight and then evaporated. The residue was triturated with 10% sodium carbonate. The remaining solid was recrystallized from acetone–ether to crystals (0.66 g), m.p. 148–150° (decomp.); λ_{max} 242 mμ (log ε 4.08).

Anal. Calcd. $C_{22}H_{31}NO_2S \cdot H_2O$: C, 67.14; H, 8.96. Found: C, 67.33; H, 8.08.

N-(3-Ketoandrost-4-ene 17β-carboxyl)cysteine (5a)

3-Ketoandrost-4-ene 17β-carboxylic acid (0.33 g) was converted as above to its acid chloride, and this in benzene (4 ml) added dropwise at 0° with stirring to a solution of cysteine hydrochloride (0.16 g) in triethylamine (0.15 ml) and tetrahydrofuran (5 ml). A further amount of triethylamine (0.15 ml) was added during the addition. The reaction was stirred overnight, and then poured into water (10 ml) and acidified with a few drops of hydrochloric acid. The product was recovered by ether extraction, and recrystallized from acetone–hexane, m.p. 175–180° (decomp.); λ_{max} 242 mμ (log ε 4.10).

Anal. Calcd. for $C_{23}H_{33}NOS$: C, 65.84; H, 7.92. Found: C, 65.92; H, 7.68.

S-Benzyl-N-(3-ketoandrost-4-ene 17β-carboxyl)cysteine Methyl Ester (5b)

3-Ketoandrost-4-ene 17β-carboxylic acid (0.33 g) was converted to the acid chloride and added to *S*-benzyl-L-cysteine methyl ester (0.24 g (13)), m.p. 147°, and triethylamine (0.15 ml) in benzene (5 ml) cooled to 10°. Evaporation of the solvent and trituration with ether gave the product, m.p. 115–117°.

Anal. Calcd. for $C_{31}H_{41}NO_4S$: C, 71.09; H, 7.89. Found: C, 70.93; H, 7.75.

Convenient *C*-alkylation of some acyloins

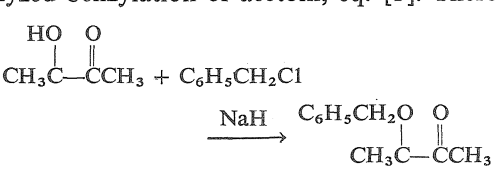
JOHAN H. VAN DE SANDE[1] AND KARL R. KOPECKY
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received August 29, 1968

Acetoin, adipoin, and benzoin are conveniently alkylated by benzyl chloride and methyl iodide in 1,2-dimethoxyethane solution using sodium hydride as the base. Only alkylation at carbon is observed. Little or no alkylation occurs at oxygen.

Canadian Journal of Chemistry, 47, 163 (1969)

A large quantity of 3-benzyloxy-2-butanone was required in these laboratories. A possible route to this compound appeared to be the base-catalyzed benzylation of acetoin, eq. [1]. There



[1] $CH_3C(HO)(C{=}O)CH_3 + C_6H_5CH_2Cl \xrightarrow{NaH} CH_3C(OCH_2C_6H_5)(C{=}O)CH_3$

appear to be few studies of base-catalyzed alkylations of acyloins. There are a number of reports of alkylation at oxygen in reactions between dianions of enediols and alkyl halides (1–4). However, alkylation at carbon has also been observed in such systems (5, 6), and appears to be general in simple cases (6). Also, acyloins give products of reaction at carbon in the base-catalyzed aldol (7) and Michael (8–10) condensation reactions with aldehydes and activated olefins, respectively, presumably via the monoanion.

A convenient procedure for the methylation of alcohols (11, 12) was adapted for the benzylation of acetoin. Addition of sodium hydride in small portions to a 1,2-dimethoxyethane solution of equimolar amounts of acetoin and benzyl chloride at room temperature resulted in a rapid reaction. The product, isolated in 45% yield, did not have spectral properties expected for 3-benzyloxy-2-butanone. The infrared spectrum (CCl_4) showed strong hydroxyl absorption at 3480 cm^{-1}. No absorptions characteristic of the CH_3—CH— group could be detected in the nuclear magnetic resonance (n.m.r.) spectrum. The material was identified as 3-benzyl-3-hydroxy-2-butanone on the basis of its n.m.r. spectrum, taken in carbon tetrachloride, which showed singlet absorptions at τ 2.86 (5.0 H) for the phenyl protons, τ 6.15 (0.93 H) for the hydroxyl proton, τ 7.13 (1.85 H) for the methylene protons, and at τ 7.95 (2.84 H) and τ 8.76 (3.24 H) for the protons of the two methyl groups. Alkylation had thus occurred at the carbon atom and there was no evidence for any product resulting from alkylation at oxygen.

A brief extension of the alkylation of acyloins was made, using the same procedure, to include methylation and benzylation of acetoin, benzoin, and adipoin. Yields of alkylated products ranged from 40% to 70%. Alkylation at the ketol carbon appeared to be the exclusive reaction in all cases except in the methylation of adipoin. In this case the presence of a singlet at τ 6.9 in the n.m.r. spectrum (CCl_4) of the crude product indicates that some *O*-alkylation might have occurred. However, the major product resulted from carbon alkylation. In the other cases no n.m.r. spectral evidence was found for the formation of any *O*-alkylated materials.

The procedure described offers a convenient method for the carbon alkylation of simple, unhindered acyloins in reasonable yield. The reaction conditions were not optimized and yields could probably be improved. The reaction appears to be general and leads to the same products as the alkylation of the dianions (6) which were generated by the acyloin condensation of esters. The present procedure is considerably more convenient.

Experimental

Melting points and boiling points are uncorrected. Infrared spectra were recorded on Perkin–Elmer model 421 and 337 spectrophotometers. Nuclear magnetic resonance spectra were determined with a Varian model A-60 analytical spectrometer using carbon tetrachloride as solvent and tetramethylsilane as an internal standard.

Sodium hydride dispersed in mineral oil was freed of the oil by washing with pentane. 1,2-Dimethoxyethane was allowed to reflux over lithium aluminium hydride for 2 h and then distilled through a 45 cm Vigreaux column.

3-Benzyl-3-hydroxy-2-butanone

The following procedure is typical of all the alkylation reactions.

Into a 500 ml 3-necked flask equipped with a dry ice condenser was placed a solution of 8.8 g (0.1 mole) of freshly distilled 3-hydroxy-2-butanone and 14.7 g (0.11 mole) of benzyl chloride in 200 ml of 1,2-dimethoxyethane. Sodium hydride, (2.5 g, 0.106 mole) was added in small portions to the stirred solution over a 20 min period. Vigorous hydrogen evolution occurred after the addition of each portion. The solution was stirred a further 2 h at room temperature and then the solvent was removed by distillation at atmospheric pressure. Ether (50 ml) was added to the residue to precipitate the remainder of the sodium chloride. The resulting mixture was filtered and the filtrate concentrated. Distillation of the residual oil afforded 7.9 g (45%) of a colorless oil, b.p. 88–91° (0.8 mm), n_D^{27} 1.5175. The features of the n.m.r. spectrum were given in the text.

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92. Found: C, 74.24; H, 8.20.

3-Hydroxy-3-methyl-2-butanone

The procedure described above was used except that solvent was removed through an efficient distillation column. From 17.6 g (0.20 mole) of acetoin, 32.7 g (0.23 mole) of methyl iodide and 5.04 g (0.21 mole) of sodium hydride 12 g (63%) of product were obtained, b.p. 136–139°, $n_D^{27.5}$ 1.4096; reported (13) b.p. 140–141°, n_D^{21} 1.415.

Methylbenzoin

The reaction was carried out as described above. The reaction mixture was poured into one liter of water and the resulting mixture extracted with three 50 ml portions of chloroform. The combined extracts were washed twice with water and dried over magnesium sulfate. The chloroform was removed under reduced pressure and the residue was crystallized from pentane. From 10.6 g (0.05 mole) of benzoin, 15 g (0.105 mole) of methyl iodide and 1.25 g (0.050 mole) of sodium hydride there were obtained 7.6 g (67%) of white crystals, m.p. 63–65°; reported (14) m.p. 65–66°.

Benzylbenzoin

The procedure described for the preparation of methylbenzoin was used. From 5.3 g (0.025 mole) of benzoin, 3.4 g (0.027 mole) of benzyl chloride and 0.63 g (0.026 mole) of sodium hydride there was obtained 3.5 g (47%) of white crystals, m.p. 113–116°; reported (15) m.p. 115–118°.

2-Hydroxy-2-methylcyclohexanone

The procedure described for the preparation of 3-benzyl-3-hydroxy-2-butanone was used. From 11.4 g (0.1 mole) of adipoin (16), 20 g (0.14 mole) of methyl iodide and 2.4 g (0.1 mole) of sodium hydride there was obtained 5.3 g (41%) of a colorless oil, b.p. 82–85° (15 mm), n_D^{27} 1.4605; reported (17) b.p. 80–95° (15 mm), n_D^{20} 1.4644.

2-Benzyl-2-hydroxycyclohexanone

The procedure described for the preparation of methylbenzoin was used. From 11.4 g (0.1 mole) of adipoin, 12.6g (0.1 mole) of benzyl chloride and 2.4 g (0.1 mole) of sodium hydride there were obtained 9.5 g (46%) of light-yellow crystals, m.p. 65–67°. The n.m.r. spectrum showed peaks at τ 2.76 (singlet, 5.0 H) for the aromatic protons, τ 6.10 (singlet, 0.82 H) for the hydroxyl proton, τ 6.93 (singlet, 0.87 H), and τ 6.97 (singlet, 0.87 H) for the non-equivalent benzylic protons and broad absorption from 7.1 to τ 8.7 (8.35 H) for the protons of the cyclohexanone ring. The compound absorbed moderately at 3540 cm^{-1} in the infrared spectrum.

P. V. DIVEKAR
Defence Research Laboratory (Materials), Kanpur, India

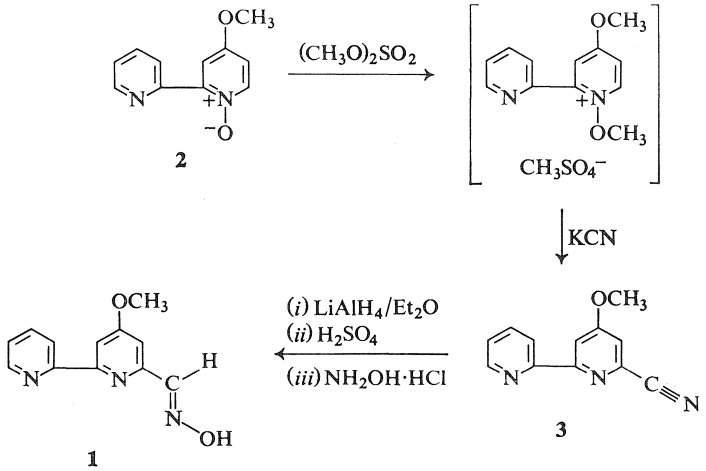
Received April 9, 1968

The synthesis of Caerulomycin starting from the known 4-methoxy-2,2′-bipyridyl-l-oxide, prepared from 2,2′-bipyridyl, is described.

Canadian Journal of Chemistry, 46, 165 (1968)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Caerulomycin (**1**), a secondary metabolite of *Streptomyces caeruleus* Baldacci, was isolated in 1959 (1) and its structure established in 1967 by Divekar, Read, and Vining (2). The 2,2′-bipyridyl along with an oxime attachment at the 6-position constitutes a novel arrangement for an antibiotic. Caerulomycin possesses powerful antifungal properties and it is also a potent plant-wilt toxin (3). Amongst a series of 2,2′-bipyridyls prepared by Jones and co-workers (4) for spectroscopic studies, was 4-methoxy-2,2′-bipyridyl-1-oxide (**2**). This timely information greatly simplified our efforts aimed at the synthesis of caerulomycin. 2,2′-Bipyridyl (5) was converted to the methoxy compound **2** (4). Compound **2** was reacted with methyl sulfate and the crude *O*-alkylated product, on treatment with potassium cyanide in aqueous dioxan, gave 6-cyano-4-methoxy-2,2′-bipyridine (**3**). Initial attempts to reduce the nitrile using sodium hypophosphite – Raney nickel (6) or lithium triethoxyaluminohydride (7) were not successful. Attention was then directed to the use of lithium aluminium hydride for this purpose. In a model experiment an ether solution of benzonitrile was treated with excess ethereal lithium aluminium hydride. The precipitated complex (believed to be $\overset{\phi}{\underset{H}{}}>=N—AlH_3Li$ (7)) on treatment with dilute sulfuric acid followed by 2,4-dinitrophenylhydrazine reagent gave a quantitative yield of benzaldehyde 2,4-dinitrophenylhydrazone. On the basis of the above experiment an ether solution of **3** was reacted with excess lithium aluminium hydride and the precipitated pink complex decomposed with 2 *N* sulfuric acid. The pH of the solution was adjusted to 8–9 with 2.5 *N* sodium hydroxide, mixed with excess neutralized hydroxylamine hydrochloride, and heated for 0.5 h, conditions which generally lead to *syn* oximes (8). Work up gave essentially pure caerulomycin; m.p. 165–169°. Two crystallizations from methanol gave a sample m.p. 174–175°, identical in all respects



with natural caerulomycin. The synthetic antibiotic was also identical with the natural one in its ability to inhibit the growth of *Candida albicans* and *Curvularia lunata*. This synthesis should make caerulomycin more accessible for biological studies.

Experimental

Melting points were taken on a Kofler block and are uncorrected. Most infrared spectra were obtained with a Perkin–Elmer model 137 recording spectrophotometer. Samples were mixed with potassium bromide and pressed into wafers. The infrared spectra of synthetic and natural caerulomycin were obtained with a Perkin–Elmer model 521 instrument. Thin-layer chromatography was carried out on 0.2 mm layers of silica gel G (Stahl) which were dried for 0.5 h at 100 °C and were developed with iodine vapor. The solvent system used was benzene:ethyl acetate (3:1). The microanalysis (C, H) was done by Mr. A. H. Siddiqui, IIT, Kanpur. Nitrogen analysis was done at C.D.R.I., Lucknow. 4-Methoxy-2,2′-bipyridyl-1-oxide (**2**) was prepared according to the published procedure (4).

6-Cyano-4-methoxy-2,2′-bipyridine (3)

A stirred solution of 4-methoxy-2,2′-bipyridyl-1-oxide (30 mg, 0.15 mmole) and methyl sulfate (38 mg, 0.3 mmole) in dioxan (0.5 ml) was heated at 100° for 2 h. Dioxan and excess methyl sulfate were removed under reduced pressure at 100° and the crude *O*-alkylated product treated with excess potassium cyanide (29 mg, 0.45 mmole) in aqueous dioxan (pH of solution 8–9). The resulting pinkish reaction mixture was stirred at room temperature for 3 h and extracted with chloroform. The chloroform extract gave crude **3** (10 mg, 30% from **2**). Thin-layer chromatography showed one spot (R_f 0.6) corresponding to nitrile obtained from natural sources. The above material after two crystallizations from ethanol gave a product m.p. 171–172°, undepressed on admixture with caerulomycinonitrile, obtained from the natural product. The infrared spectra of synthetic and authentic samples were identical.

Caerulomycin (1)

Under dry nitrogen a solution of **3** (50 mg, 0.24 mmole) in dry ether (50 ml) was mixed with a standardized ether solution of lithium aluminium hydride (18 mg in 1.2 ml of ether; 0.47 mmole). The pinkish complex was allowed to settle and the supernatant liquid rejected. The residue was treated with 2 *N* sulfuric acid and the pH adjusted to 8–9 by addition of 2.5 *N* sodium hydroxide. The solution was treated with excess neutralized hydroxylamine hydrochloride (8) (from 100 mg of reagent) and the mixture heated on a water bath for 0.5 h. Extraction with ether gave crude caerulomycin m.p. 165–169° (15.5 mg, 28%). Thin-layer chromatography showed one spot (R_f 0.3) corresponding to the natural product. Two crystallizations from methanol gave a sample m.p. 174–175°, undepressed on admixture with natural caerulomycin. The infrared spectra of synthetic and natural samples were identical in all respects.

Anal. Calcd. for $C_{12}H_{11}N_3O_2$: C, 62.90; H, 4.80; N, 18.33. Found: C, 63.19; H, 4.83; N, 17.89.

Normal coordinate analysis of titanium(IV) halide : monoethylenediamine complexes

P. J. ASHLEY[1] AND E. G. TORRIBLE[1]

Chemistry Department, Queen's University, Kingston, Ontario

Received July 16, 1968

A partial normal coordinate analysis was performed for the $Ti(en)X_4$ complexes, assuming *gauche* configuration of the ligand and overall symmetry of C_2 for the complex. Comparison of the calculated frequencies with the available experimental data supports the assumption of the chelate structure for the complexes and also confirms the previous assignments for the Ti—N stretching frequencies. Some new assignments are proposed in the 900–300 cm^{-1} region.

Canadian Journal of Chemistry, 47, 167 (1969)

Introduction

The preparation and infrared spectra of the compounds $Ti(en)Cl_4$ and $Ti(en)Br_4$ have been reported recently (1). The spectra were found to be qualitatively consistent with a chelate structure with the ethylenediamine in the *gauche* configuration. Assignments were made for both metal–nitrogen and metal–halide vibrational modes in the complex.

In this paper we report the results of a vibrational analysis based on the proposed chelate structure for the $Ti(en)Cl_4$ and $Ti(en)Br_4$ molecules.

Results

The skeleton of the proposed structure is shown in Fig. 1. In the model the ethylenediamine ligand has been coordinated in the *cis* configuration. This increased the symmetry of the complex from C_2 to C_{2v}. All the initial calculations were done for a molecule of this symmetry. However, in order to clarify certain assignments the final calculations were done for the ligand in the *gauche* configuration and hence for a molecule with C_2 symmetry, but all angles about the titanium atom were considered to be 90°. The results produced by this latter calculation are the ones reported in this paper.

[1]Present Address: Alcan Research and Development Ltd., P.O. Box 8400, Kingston, Ontario.

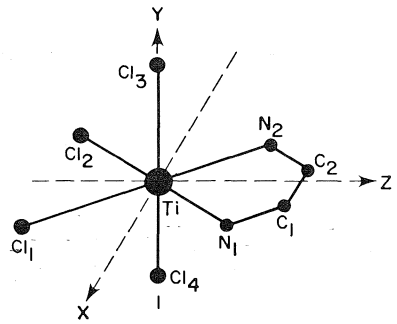

FIG. 1. C_{2v} model of $Ti(en)Cl_4$.

In the absence of known structural data, the bond lengths (Table I) used were based on corresponding dimensions in other comparable molecules.

To simplify further the calculation, the hydrogen frequencies were not calculated. There is evidence for probable coupling of the NH_2

TABLE I

Assumed bond lengths for the $Ti(en)X_4$ complexes

deformation modes with the low frequency skeletal modes (2). However, because we were unable to observe modes which absorb below 300 cm^{-1}, it was considered that for the present purpose no serious error was introduced by this simplification.

The skeleton contains nine atoms giving rise to 21 normal vibrations and 25 internal coordinates including 4 redundancies. The 25th order secular equation of the form $|\mathbf{GF} - \mathbf{E}\lambda| = 0$ was solved on an IBM 360/50 computer for the 21 normal vibrational frequencies. Four "zero frequencies" corresponding to the four redundancies were obtained. The potential function used was a simple Urey–Bradley potential function (3). The full details of the calculation are given elsewhere (4).

The calculated and observed frequencies for the complexes are listed in Table II. As an additional aid in assigning the calculated frequencies to specific vibrational modes, a potential energy distribution in each symmetry coordinate was also calculated. Table II includes an approximate description of each mode based on both the potential energy distribution and the normal coordinate analysis.

The force constants obtained from the calculation and corresponding to the calculated frequencies of Table II are listed in Table III.

Discussion

There is general agreement between the previously reported (1) and the present calculated frequencies (Table II), and the corresponding force constants are considered reasonable (5–7). However, because the observed spectra were obtained on an instrument with a lower limit of 300 cm^{-1}, only those frequencies observed above 300 cm^{-1} were available for comparison. Thus in general only the stretching force constants could be adjusted to give the best fit. The values of the bending force constants and those of the interaction terms cannot be considered final.

The assignments also agree with those previously reported (1) except for those at 442 and 315 cm^{-1} in the chloride complex and at 435 cm^{-1} in the bromide complex. For the chloride complex the calculated frequencies of 364 and 295 cm^{-1} were very sensitive to changes of the Ti—Cl stretching force constant, as also was the calculated frequency of 497 cm^{-1}. Thus the observed bands at 442, 370, and 315 cm^{-1} are assigned to Ti—Cl stretching modes. Horley and Torrible (1) originally assigned the bands at 520 and 442 cm^{-1} in the chloride to N—C—C—N bending modes on the basis of a qualitative comparison with the assignments made for free ethylenediamine (8). Our calculations now indicate that while the original assignment of the band at 520 cm^{-1} was probably correct, the band at 442 cm^{-1} in the chloride complex is a Ti—Cl stretching frequency associated with the chlorine atoms above and below the plane of molecule. A calculated Ti—Cl stretching frequency of 505 cm^{-1} for a five coordinate (C_{2v}) titanium complex, $TiCl_4.NMe_3$, has been reported (6). A shift to a lower frequency in a six coordinate complex would be expected. A comparable argument leads to a reassignment of the observed band at 435 cm^{-1} in the bromide complex to the out of plane Ti—Br stretching frequency.

TABLE III

Urey–Bradley force constants corresponding to values in Table II*

Stretching	Force constant	Bending	Force constant	Repulsion	Force constant
K(Ti—Cl)	1.55	H(Cl—Ti—Cl)	0.1	F(Cl—Cl)	0.18
K(Ti—N)	0.48	H(Cl—Ti—N)	0.1	F(Cl—N)	0.17
K(C—N)	4.1	H(N—Ti—N)	0.09	F(N—N)	0.02
K(C—C)	2.5	H(Ti—N—C)	0.09	F(Ti—C)	0.02
K(Ti—Br)	1.05	H(N—C—C)	0.32	F(N—C)	0.05
		H(Br—Ti—Br)	0.11	F(Br—Br)	0.18
		H(Br—Ti—N)	0.09	F(Br—N)	0.17

*Force constants are given in mdyn/Å.

A C—C stretching frequency was not assigned by Horley and Torrible (1). However, the bands they reported at 981 and 978 cm^{-1} for the chloride and bromide complex respectively, correspond closely to the band at 980 cm^{-1} assigned to the C—C stretching frequency by Sabatini and Califano (8) for free ethylenediamine. There is, however, some controversy regarding the assignment of the C—C stretching frequency in the ethylenediamine complexes. Bands at frequencies from 820 cm^{-1} to close to 1000 cm^{-1} have been assigned to this mode (2, 9–11). On the basis of our calculation the observed band at 880 cm^{-1} in both the Ti(en)Cl_4 and Ti(en)Br_4 complex is tentatively assigned as the C—C stretching frequency. The potential energy distribution indicated very little coupling between the C—C and C—N stretching modes, and consequently specific assignments for these vibrations have been made. A similar conclusion was also reached by Armendarez and Nakamoto for the nickel(II)oxamido complex (5).

The calculation based on the proposed chelate skeleton (Fig. 1) gives 21 possible frequencies. We have been able to compare only 9 of these values with observed values because of limited experimental data. The comparison of those frequencies indicates that the proposed chelate structure for the Ti(en)X_4 complexes is probable, and also supports the original assignments for the Ti—N stretching frequencies (1).

Acknowledgments

Grateful acknowledgement is made to the National Research Council of Canada for financial support and to the Government of the Province of Ontario for Fellowships (to P. J. A.).

The authors also wish to thank Dr. H. F. Shurvell for his assistance with the calculations and computer program.

Nickel(II) complexes with substituted ureas[1]

R. A. BAILEY, I. R. FEINS[2], AND T. R. PETERSON[3]
Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York 12181

Received August 23, 1968

A number of nickel(II) complexes with methyl-, *n*-butyl-, phenyl-, and N,N′dimethylurea ligands were prepared with a variety of anions. All exhibited octahedral coordination geometry. Of the anions, only NCS^- was in the coordination sphere. Infrared spectral studies indicate coordination of the ligands through oxygen.

Canadian Journal of Chemistry, 47, 171 (1969)

Introduction

Complexes of Ni(II) with thiourea type ligands are well known, exhibiting a variety of formulas and stereochemistries (octahedral, tetragonal, tetrahedral, planar (1)). Bonding is generally through the sulfur atom of the ligand (2). Some Ni(II) complexes with the analogous urea ligands have been prepared and shown by X-ray analysis (3, 4) or infrared spectroscopy (5) to be oxygen coordinated. The latter technique has been used frequently in the study of the coordination of ureas and thioureas, and while not always unambiguous in its results, is a useful approach. The purpose of the present study was to consider some Ni(II) complexes of substituted ureas comparable to the substituted thioureas prepared previously in order to compare the complexing in these analogous systems. The compounds have been examined in somewhat close detail by infrared and visible spectroscopy, and magnetic susceptibility techniques.

Experimental

Chemicals

All substituted ureas, anhydrous nickel halides, and nickel perchlorate hexahydrate were obtained from K and K Laboratories, Inc., and were used without further purification. Nickel nitrate hexahydrate and all other chemicals used were Fisher Reagent grade materials.

Analyses

Nickel was determined by EDTA titration using murexide indicator (6). Halogens and sulfur were determined by a modification of the Schöringer method. C, H, and N analyses were performed on a commercial Perkin–Elmer C—H—N analyzer. Sulfur and some N analyses were performed by Schwartzkopf Microanalytical Laboratories.

Spectra

Infrared spectra were obtained by the KBr pellet technique on a Perkin–Elmer 621 spectrophotometer, and checked in mulls. Visible spectra were obtained by the reflectance technique, using $MgCO_3$ as standard in a Beckman DK 2 A spectrophotometer.

Magnetic Susceptibility

Magnetic data were obtained by the Guoy technique, using $Hg[Co(SCN)_4]$ as calibrant, and corrected for diamagnetism in the usual manner (7). Measurements at a number of field strengths all gave essentially identical results. Dewar flasks containing liquid nitrogen and dry-ice – acetone were used in low temperature measurements.

Preparation of Complexes

The yellow–green complexes prepared in this study and the analytical results for them are listed in Table I. They were prepared by mixing 0.01 mole of metal salt in 50 ml hot absolute ethanol with 0.06 mole of ligand dissolved in 35 ml ethanol, boiling for 10 min, and evaporating the filtered solution to 45 ml on a steam bath. Chilling produced pale yellow–green crystals which were recrystallized three times from absolute ethanol and vacuum dried. The perchlorate compound was formed and recrystallized similarly from a solvent of 50 ml chloroform – 15 ml ethanol. The thiocyanate was made from $Ni(SCN)_2$ formed in ethanol from $NiCl_2$ and NaSCN. Frequently in these preparations a waxy, rather intractable mass was produced on cooling. The addition of a small amount of chloroform or ether reduced this to readily workable crystalline form.

Results and Discussion

The solid state electronic spectra (reflectance spectra) of the Ni(II) substituted urea complexes, which are all very similar to one another, may be assigned satisfactorily on the basis of a ligand field of O_h symmetry. The energies of the bands assigned as the three spin allowed transitions; $^3A_{2g} \rightarrow {}^3T_{2g}$ (F) at 8000–8400 cm^{-1} (ν_1),

$^3A_{2g} \rightarrow {}^3T_{1g}$ (F) at 13 200 – 13 700 cm^{-1} (ν_2), and $^3A_{2g} \rightarrow {}^3T_{1g}$ (P) at 24 200 – 24 800 cm^{-1} (ν_4), (Table II), agree well with those predicted from the energy level diagram of Liehr and Ballhausen (8) with 10 *Dq* about 8 100 cm^{-1}. Bands or shoulders at 20 700 – 22 000 cm^{-1} and 28 000 – 34 600 cm^{-1} are most probably spin-forbidden bands arising from transitions to the $^1A_{1g}$ or $^1T_{2g}$ (D), and $^1T_{2g}$ (G) or ^1E_g (G) levels which lie in these regions.

In the case of [Ni (N-methylurea)$_4$ $(NCS)_2$], the only compound of this series with fewer than six organic ligands, the 10 *Dq* value of 8300 cm^{-1} (Table II) is well within the range expected for octahedral Ni(II). The value of 10 *Dq* for this compound agrees with that predicted from the rule of average environments (9) for nitrogen bonded (but not sulfur bonded) thiocyanate (10). Further evidence for coordination of the thiocyanate group to the Ni(II) ion through nitrogen is provided by the infrared spectrum.

The Racah parameter, *B*, was calculated for each complex in the usual manner (11) from the observed positions of the three spin allowed transitions using the relation $15B = \nu_2 + \nu_3 - 3\Delta$ where Δ is the energy of the $^3A_{2g} \rightarrow {}^3T_{2g}$ transition. The values of *B* for the complexes calculated in this way (Table II) are of the order 850–900 cm^{-1}, and may be compared to the free Ni(II) ion value of 1030 cm^{-1} and a value of 880 cm^{-1} in the hexaquo complex (9). The values of *Dq* obtained for the substituted ureas in the present study are 880–850 cm^{-1}, very similar to the field strength of sulfur bonding thioureas with Ni(II) (2). The general order is found to be N,N′dimethylurea > N-phenylurea > *n*-butylurea ≈ N-methylurea.

The magnetic moments of the Ni(II) substituted urea complexes were studied at liquid nitrogen, dry-ice – acetone, and room temperatures (Table III). In no case was there a dependence of the susceptibility on field strength. The observed susceptibilities were corrected for diamagnetism and temperature independent paramagnetism (t.i.p.) in the usual manner from the relation t.i.p. = $8N\beta^2/10\,Dq$ c.g.s.u. The t.i.p. values are 200–250 $\times$ 10^{-6} c.g.s.u., approximately 6% of the room temperature susceptibility values. Plots of $1/\chi_m$ (corr.) vs. temperature gave straight lines in all cases. From these data θ values were obtained; these are small (Table III). As the significance of θ is uncertain, it has not been used in the calculation of the moment. The magnetic moments are in the range 2.9–3.2 B.M. normally found for octahedrally coordinated Ni(II) complexes (12, 13), and are close to the room temperature moments of 3.09 and 3.32 B.M. for [Ni(urea)$_6$] (ClO_4) and [Ni(N,N′dimethylurea)$_6$] $(ClO_4)_2$ previously reported by Stonestreet *et al.* (5). For most of these compounds the moments lead to values of the spin–orbit coupling constant λ' of approximately -150 to -200 cm^{-1} (from the relation $\mu = 2.83\,(1 - 4\lambda'/10\,Dq)$). Although not very accurate, these values are evidently slightly smaller than those observed with the thiourea complexes (2).

Penland *et al.* (14) and Shafer (15) have shown that urea and tetramethylurea complexes of

metal ions exhibit a decrease in the energy of the carbonyl stretching frequency of the ligand on coordination when oxygen-to-metal bonding is involved. Other carbonyl compounds, ketones, amides, etc., show similar behavior (16–18). On the other hand, coordination to the metal ion through the nitrogen atom of a urea type ligand shows a marked shift of the carbonyl stretching band to higher frequencies while the N—H stretching frequency of the bonded —NH_2 or —NHR group is decreased (14, 19). This has been shown to be the case for N-bonded Pt(II) and Pd(II) complexes containing urea ligands, as reported earlier by Penland *et al.* (14), and for a variety of Pd(II) substituted urea complexes (20). Recently Costamagna and Levitus (21) have examined the infrared spectra of a number of cobalt(II) complexes containing N-methylurea, N-ethylurea, N,N′ethyleneurea, N,N′diethylurea, and N,N′dimethylurea; and reported them to be oxygen bonded from the shifting of the carbonyl stretching band to lower frequencies along with no apparent change in position for the N—H stretching frequencies. A number of complexes of first row transition metals with N,N′dimethylurea have been reported by Stonestreet *et al.* (5) to be oxygen bonded to the metal ion, based on similar infrared evidence.

The infrared spectra of the Ni(II) complexes prepared in the present study (Table IV) suggest that in all cases oxygen is the coordinated atom. The N—H stretching frequencies are shifted slightly to higher values and sometimes split, probably because of differences in hydrogen bonding, while the carbonyl stretching frequency is usually decreased. The spectrum of the N,N′dimethylurea example is similar to those of [Co(N,N′dimethylurea)$_6$] $(NO_3)_2$ and [Co(N,N′dimethylurea)$_6$][$CoCl_4$] reported previously (21) and also considered to be oxygen bonded. This mode of bonding is further supported by the evidence of Cavalca *et al.* (23) which shows [Ni(N-methylurea)$_6$]Cl_2 to be isostructural with the oxygen bonded cobalt compound. Slight differences in the spectrum of a given complex with change of anion may be attributed to solid state effects (21, 22). Unfortunately, the infrared spectra of these organic ligands have not yet been assigned to permit bands other than the carbonyl stretching and N—H stretching frequencies to be considered unambiguously. It is probable that the C—N stretching bands in the free organic ligands lie at ca. 1150–1250 cm^{-1}. However, by analogy with the assigned spectra of urea (14) and N-methylthiourea (25), one would expect that the C—N stretching frequencies in the free ligand would shift to higher values if metal-to-oxygen bonds were present due to the increased double bond character of the C—N linkage, while metal-to-nitrogen bonding would lead to increased single bond character and decreased stretching frequency of this bond. In these complexes, this band appears shifted significantly to higher frequencies (Table IV) which would be in keeping with the presence of nickel-to-oxygen bonds if their origin is in fact due to C—N stretching.

Other significant bands in the spectra of the

[a]Tentative assignment.

substituted ureas are the amide(II) (N—H deformation plus C—N antisymmetric stretching), and amide(III) (N—H deformation and C—N stretching), which cannot be assigned at the present time. The former should shift to higher frequencies with either nitrogen or oxygen bonding, while the latter should increase in frequency with oxygen bonding but decrease if bonding is through nitrogen. None of the remaining free ligand bands decrease in frequency on coordination, but increases are noted in the 1535–1590 and 1100 cm^{-1} regions. Thus there is no evidence to support nitrogen bonding of the organic ligand in any of these compounds. While it should be emphasized that conclusions based on the infrared spectra of ligands of this complexity must always be regarded with caution, oxygen bonding is clearly indicated.

The thiocyanate groups in [Ni(N-methylurea)$_4$-$(NCS)_2$] are shown to be coordinated through the nitrogen atom by the C—N stretching frequency at 2070 cm^{-1}, the NCS bending mode at 482 cm^{-1}, and most significantly, the C—S stretching absorption at 850 cm^{-1} (24).

There are notable differences in the coordination of substituted ureas and thioureas to Ni(II). The tendency to form an octahedral NiO_6 coordination group is quite marked, while thioureas are prone to allow the anions to coordinate, and to permit other than octahedral

geometries. The ligand field strength of the O-bonding ureas is surprisingly similar to that of the S-bonding thioureas toward Ni(II). One may presume that while sulfur is a weaker electron donor than oxygen, as indicated by its usual position in the spectrochemical series, this effect is balanced by a greater covalency of the Ni—S bond in the thioureas.

The transmission of polar effects. Part IX.[1] The ionization and esterification with diazodiphenylmethane of 9-substituted 10-triptoic acids

KEITH BOWDEN AND D. C. PARKIN
Department of Chemistry, The University of Essex, Wivenhoe Park, Colchester, Essex, England

Received February 16, 1968

A series of 9-substituted 10-triptoic acids have been prepared. Their pK_a values in 80% 2-methoxyethanol–water and 50% ethanol–water at 25° and rate coefficients for esterification with diazodiphenylmethane in five alcohols at 30° have been measured. The results have been analyzed by linear free energy relations. The π-inductive effect is shown to be unimportant in such systems, while the field effect model can account for the transmission.

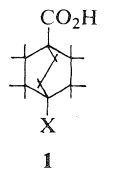
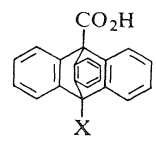
Introduction

A number of model systems have been studied to attempt a real understanding of the mode of transmission of substituent polar effects (1–6). The most important problem remaining is the estimation of the relative importance of the field and the inductive modes of transmission (3, 4). While the field effect is the coulombic action of a charged or dipolar substituent on a reaction center (7), the inductive effect derives from the polarization of the bonds connecting them (3, 4, 8). The latter can be effected through the σ- or π-bonds. Most studies (1–6), though not all (9), appear to be in favor of the field effect dominating the transmission. However, it appears likely that a π-inductive transmission may augment the field effect in favorable cases (4).

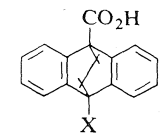
The most interesting and informative model so far studied is that of Roberts and Moreland, the 4-substituted bicyclo(2,2,2)octane-1-carboxylic acids (**1**) (1). These studies have been extended by other workers (10, 11). Analyses of the results of these and related studies (1, 2, 10, 11) appear to be in favor of the field effect transmission. The present study presents an extension of this model to include the possibility of a π-inductive transmission. The reactivity of a series of 9-substituted 10-triptoic acids (**2**) was measured in their ionization and esterification with diazodiphenylmethane (DDM) in a number of alcohols. After this study had been completed, results for a similar model, the 4-substituted dibenzobicyclo(2,2,2)-octa-2,5-diene-1-carboxylic acids (**3**), were reported (12). Our triptoic acid model is more



1



2



3

symmetrical and contains the maximum of 3 potential π-bonded transmissive links. The present report and the latter study appear to be both complimentary and consistent. In this work, the ionization and esterification with diazodiphenylmethane of a series of 9-substituted triptoic acids has been studied and the results have been correlated by linear free energy relations.

Results and Discussion

The rate coefficients for the esterification of the 9-substituted 10-triptoic acids with diazodiphenylmethane in five alcohols at 30.0° are shown in Table I. Table II shows the pK_a values of the acids in 50% w/w ethanol–water and 80% w/w 2-methoxyethanol–water.

These results have been analyzed by a linear free energy relation [1], similar to the Hammett equation and using the substituent constants σ_I (13). These constants have been derived from the pK_a values of the substituted acetic acids in

$$[1] \qquad \log (k/k_0) \text{ or } (K/K_0) = \rho_I \sigma_I$$

water at 25° as the standard reaction, with ρ_I equal to 3.95. The correlations found are shown

[1]For Part VIII; ref. 6.

*The rate coefficients, k (l mole^{-1} min^{-1}), are reproducible to ±3% or better, and are the mean of at least two determinations.

TABLE II

pK_a values of the 9-substituted 10-triptoic acids in 50% w/w ethanol–water (50% EW) and in 80% w/w 2-methoxyethanol–water (80% MCS) at 25°

	pK_a*	
9-Substituent	50% EW	80% MCS
H	5.20	6.23
Me	5.23	6.27
Cl	4.67	5.70
Br	4.67	5.69
NO_2	4.40	5.43

*The pK_a values are the mean of at least two determinations and are reproducible to ±0.03 units.

in Table III and are excellent. Data for related systems (1, 10, 12) have been correlated with σ_I values and are shown in Table IV. These correlations are also very good.

The reaction constants obtained from the present study are contrasted with those available for the acetic and bicyclo(2,2,2)octane carboxylic acid systems in Table V. It is immediately obvious that there is *no* increased transmission of the substituent polar effect in the triptoic acids, compared with the bicyclo(2,2,2)octane carboxylic acids. The transmission is very similar for both systems and in both reactions. For the ionization reaction, the reaction constants for the 2 other bicyclo(2,2,2)octene systems studied recently by Stock's group (12) are also almost the same. Thus, it appears that the π-inductive transmissive route, available in the triptoic acids, has no major role in the relay of the polar effect. *However*, this does not exclude the intervention of this route when either or both the substituent and the reaction site are bonded *directly* to a π-bonded system. In these triptoic acids, both substituent and reaction site groups are bound to saturated carbons. The π-inductive effect would have to be originally generated by a field or σ-inductive effect. In substituted cinnamic acids, for example, it is possible, and indeed probable, that such an effect can and does exist (4, 6).

A number of other possibilities are excluded by this lack of increase in the susceptibility of the system to the substituent polar effect. An

TABLE III

Reaction constants, ρ_I, for triptoic acids

Reaction	ρ_I*	log k_0	r†	n†
Esterification with DDM at 30.0°

†4-Substituted bicyclo(2,2,2)octane-1-carboxylic acids.

increased susceptibility could have arisen, in the ionization reaction, from increased dependence on polar substituent effects needed to replace sterically inhibited solvation of the carboxylate anion (4). In fact, triptoic acid does not appear to suffer significant steric inhibition of solvation, which causes strong acid-weakening for triphenylacetic acid (13*b*). This must be due to the "tying-back" of the bulky phenyl groups in triptycene. More importantly, the low dielectric cavity (7) in the triptoic acids is greatly increased compared to the bicyclo(2,2,2)octane carboxylic acids. As the transmission has not increased, a field effect must pass mainly through the core of the molecule. The medium surrounding the reaction site and substituent can still be involved in the transmission. It is important to point out that an inductive model could account for the transmission in this and related models; albeit that the transmissive coefficient, ε, (4) would have to equal about 0.44 for the triptoic acids. This is a rather large and unlikely value (3). It is important to attempt to see if the field effect model can account for the results satisfactorily. Numerous attempts (2, 4, 7, 10–12) have been made to relate the transmission of polar effects to the Kirkwood–Westheimer theory for the field effect (7). Most detailed attempts fail, but modifications to give a simpler relation have had some success. Such a model (4, 16) has been previously proposed to allow a calculation of the reaction constant ratio, ϕ, of the reaction constant of a system to that of the parent for the same reaction.

In Table VI, the field effect calculations are shown. These are based on the equation proposed by Kirkwood and Westheimer (7), shown below in eq. [2].

$$[2] \qquad \log (K/K_0) = \frac{e\mu \cos \theta}{2.303kTD'r^2}$$

When attempting a calculation of the reaction constant ratio this reduces to eq. [3], where D' is the effective dielectric constant, r the distance between the dipolar substituent and the reaction site, and θ the angle between the r and the dipolar axis. The subscript $_0$ refers to the reference system.

$$[3] \qquad \phi \text{ (calcd.)} = \frac{\cos \theta D'_0 r_0^2}{\cos \theta_0 D' r^2}$$

The chloro-substituted acids are taken as the models for the calculation (see (4, 17) for details). In Table VI, the results for a point dipole substituent spherical model are shown for 50% ethanol–water (ionization) and ethanol (DDM esterification). The important distance is that from the center of the dipole to the surface of the molecular cavity and this is taken as 1.5 Å in accordance with a suggestion by Tanford (18). The experimentally found values of the ratio, ϕ, are in good agreement with the calculations; especially considering the uncertainties involved. It is very interesting to note that these calculations predict a very small variation of the effective dielectric constant, D', with the medium for the acetic acid system. This would result in a very small variation in ρ_I for this system. This has been found especially for the ionization reaction for this system (13*b*).

The variation of the reaction constant for

esterification of the triptoic acids with the solvent closely parallels that for the acetic acids (13*b*). The solvents in the present study are all alcohols. However, the reaction constants do increase, as found before for the acetic acid system (13*b*), with decreasing dielectric constant of the alcohol. In the acetic acid system, the relation between the reaction constant and the solvent has been interpreted as being due, in the main, to solvent dependence of the reaction rather than field effect transmission through the medium. The reaction constants for the meta/para-substituted benzoic acid system shows solvent dependence which is more distinct (19). This probably results from both solvent dependence of the reaction and medium transmission of the substituent polar effect from these less proximate substituents. For triptoic acids, it seems very possible that the bulky aromatic groups would largely exclude the solvent from the "wings" of the cavity transmitting the field effect. The solvent dependence of the ionization of 4-substituted bicyclo(2,2,2)-octane-1-carboxylic acids has been investigated (20), but the results are unfortunately not well correlated by linear free energy relations and are not very certain. Their solvent dependence could be interpreted as solvent dependence of the reaction and transmission by the medium, as for meta/para-substituted benzoic acids (21).

It may be concluded, from this study, that the π-inductive effect has no major role in transmission through π-electron systems such as found in the 9-substituted 10-triptoic acids. Furthermore, a field effect will account for transmission of the polar substituent effect, mainly through the low dielectric cavity of the molecule.

Experimental

Materials

The 9-substituted 10-triptoic acids were prepared from the corresponding methyl esters by hydrolysis with potassium hydroxide in diethyleneglycol (22). The methyl esters had been synthesized by an adaption of the method of Friedman and Logullo (23). Anthranilic acid (3.05 g, 0.022 mole) dissolved in acetone (20 ml) was added to a refluxing solution of the appropriate methyl 9-substituted 10-anthroate (0.02 mole) in methylene chloride (60 ml) containing isoamyl nitrite (2.98 g, 0.025 mole) over a period of 4 h. After removal of the solvent under reduced pressure, the resulting pasty solid was dissolved in benzene and subjected to column chromatography on alumina using benzene as the eluent. The first eluate contained the methyl 9-substituted 10-triptoate and the successive eluate contained the unreacted methyl 9-substituted 10-anthroate which was recovered for recycling. The crude triptoic ester was refluxed with an equal weight of N-ethylmaleimide for 2 h in chloroform solution. After removing the chloroform under reduced pressure, the residue was dissolved in benzene and again subjected to column chromatography on alumina using benzene as the eluent. After removing the benzene, the methyl 9-substituted 10-triptoate was recrystallized from methylcyclohexane to give colorless or almost colorless crystalline solids. The conversion to the triptoate esters was between 40–60%, but this only amounted to 5–10% for the nitro-ester. The recovered anthroate esters amounted to 50–30%, but this again only amounted to 5–10% for the nitro-ester. The melting points of the 9-substituted 10-triptoic acids and methyl esters are given in Table VII, together with the required elemental analyses. The methyl 9-substituted 10-anthroates were prepared by methylation of the corresponding 9-substituted 10-anthroic acids (24) with trifluoroacetic anhydride and methanol in benzene (25), except for the nitro-ester which was prepared by direct nitration (24).

The transmission of polar effects. Part X.[1] The esterification with diazodiphenylmethane and the ionization of 9-substituted 10-anthroic and 8-substituted 1-naphthoic acids

KEITH BOWDEN AND D. C. PARKIN
Department of Chemistry, The University of Essex, Wivenhoe Park, Colchester, Essex, England
Received February 16, 1968

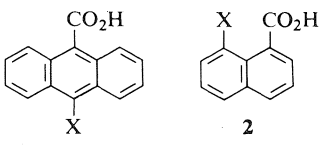
The rate coefficients for the reaction with diazodiphenylmethane in methanol, ethanol, isopropyl alcohol, *t*-butyl alcohol, 2-methoxyethanol, 2-*n*-butoxyethanol, and ethyl acetate at 30° and the pK_a values in 80% 2-*n*-butoxyethanol–water of a series of 9-substituted 10-anthroic and 8-substituted 1-naphthoic acids have been determined. The effect of substitution has been analyzed by linear free energy relations. The variation in the susceptibilities of the systems to polar substituent effects with the medium are examined. The occurrence of reversed dipolar substituent effects in the reactions of the 1,8-naphthoic acids is detected. The implications of the results for the inductive and field effect models for the transmission of polar effects are discussed.

Canadian Journal of Chemistry, **47**, 185 (1969)

Introduction

The transmission of substituent polar effects by a field effect has an implicit role for the medium. The transmissive cavity, lying between and around the substituent and the reaction site, can be composed of the low dielectric molecular cavity and the medium (1). The extent of their contributions will be determined by the molecular structure. The inductive model for transmission has no implicit role for the medium. However, polar reactions demand solvation. A lack of solvation can increase the susceptibility of the reaction to polar effects (2, 3).

It should be possible to construct and study model systems which can indicate the role of the medium. The models chosen for the present study are the 9-substituted 10-anthroic (**1**) and 8-substituted 1-naphthoic acids (**2**). These systems can be compared with meta/para-substituted benzoic acids. The anthroic system has a much more massive low dielectric molecular cavity than the benzoic system and this cavity will replace solvent in these "wing" areas. The naphthoic system has a minimal substituent–reaction site distance which should allow direct interactions at very close proximity. Both model systems have disadvantages. The anthroic acids have a highly sterically shielded reaction-site and the naphthoic acids have steric and proximity effects from the substituent on the reaction site.



1 **2**

In this study, the reactivity of a number of 8-substituted 1-naphthoic and 9-substituted 10-anthroic acids have been measured in their esterification with diazodiphenylmethane (DDM) in a series of solvents and in their ionization in 80% w/w 2-methoxyethanol–water (80% MCS). Comprehensive studies have been made on the ionization of substituted 1- and 2-naphthoic acids (4, 5), with the exception of 8-substituted 1-naphthoic acids. Reported measurements on the latter are restricted to two single measurements (6, 7). The ionization (8) and esterification with DDM in ethanol (9) of 9-substituted 10-anthroic acids have been previously investigated. In this study, the effect of substitution has been assessed by linear free energy relations and the reaction constants obtained are discussed.

Results and Discussion

In Table I the rate coefficients for the esterification of the acids with diazodiphenylmethane in the various solvents are shown. Table II shows the pK_a values of the acids in 80% w/w 2-methoxyethanol–water.

A comprehensive study of the reaction of meta/para-substituted benzoic acids with diazodiphenylmethane in a number of solvents has been made by Chapman, Shorter, and their

[1]For Part IX; see preceding paper. A preliminary account of certain aspects of these studies has appeared in Chem. Commun. 75 (1968).

*The rate coefficients, k (l mole^{-1} min^{-1}), are reproducible to ± 3% or better, and are the mean of at least two determinations. Previous workers (9–11) have found k for 1-naphthoic to be: 1.53, in ethanol; 0.356, in 2-*n*-butoxyethanol; and for 9-substituted 10-anthroic acids: 8.49, H; 8.22, Me; 12.9, Cl; 15.8, Br; in ethanol.

co-workers (13). However, measurements were required for one solvent, 2-*n*-butoxymethanol, to complete the comparison and these are reported in Table III.

A means of analyzing the results must be considered. Previously, it had been found possible to correlate the reactivity of 9-substituted 10-anthroic acids using σ^n values, excluding substituents, such as the nitro group, which were deconjugated by peri steric interactions (2, 8, 9). This type of treatment was impossible for the 8-substituted 1-naphthoic acids. It was therefore decided to take the esterification of the acids in ethanol with diazodiphenylmethane at 30° as standard *for each reaction series.* Thus, the reaction constant is arbitrarily set at a value of 0.944, i.e. the ρ for meta/para-substituted benzoic acids (13), for all systems. Then, "effective" substituent constants are calculated for each

†n is the number of substituents studied.

substituent in each system, as shown in Table IV. The results for the esterification and ionization reactions are then correlated with these values. The correlations are shown in Table V. The correlations are all very good for the anthroic acids, whereas for the naphthoic acids they are particularly poor for the esterification in ethyl acetate and the ionization reaction. However, it is apparent that the 1,8-naphthoic system shows little variation in reactivity with change in the medium for the esterification reaction. The reaction constants are contrasted with those for other systems in Table VI. A somewhat tentative interpretation of the variation of the reaction constants with the medium follows. Caution appears to be indicated as the variations are small and, sometimes, rather uncertain. The 9,10-anthroic system appears to have a medium dependence closely comparable with that shown by meta/para-substituted benzoic acids. The factors, which determine this variation, are probably the extent of transmission through the medium and the solvating power of the medium (3, 13, 16). This study suggests that, for very proximate substituent-reaction site systems, e.g. the 1,8-naphthoic, the medium dependence of the reaction constants is greatly reduced. This would agree with a field effect model for transmission. The latter system would have a transmissive cavity which is largely composed of the molecule. The occurrence of low-dielectric "wings", as in the 9,10-anthroic acids, does not greatly affect this transmission. A field effect would thus be transmitted mainly by the "core" of the molecule.

A comparison of the rate coefficients for the

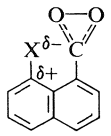
parent unsubstituted acids with those for benzoic acid (13) in the same solvents is interesting. The relation between the three acids is almost linear for all the four simple alcohols and ethyl acetate. The rate coefficients for the alkoxyethanols seem to be reduced for the naphthoic and anthroic acids relative to those of benzoic acid. A similar observation has been made previously in comparing the esterification of the two naphthoic acids and benzoic acid in ethanol and in 2-*n*-butoxyethanol (11). As the effect is very much more severe for 9-anthroic acid and 2-*n*-butoxyethanol, it appears to be an effect associated with hindered solvation of a sterically shielded carboxylic acid group by a long chain alcohol. This is probably the reason for the less satisfactory correlations observed for the naphthoic acids, where the steric environment of the site is varied.

Substituent Effects

The effects of 9-substituents on the reactivity of 10-anthroic acid have been discussed previously (2, 9). The same considerations apply to this study. The deconjugation of the carboxylic acid group by the peri-positions results in a strong acid-strengthening effect (17). The effects of 8-substituents on the reactivity of 1-naphthoic acid is more interesting. In the ionization reaction, all the 8-substituted 1-naphthoic acids are stronger than the unsubstituted acid. All these substituents cause the carboxylic acid group to be completely or very extensively deconjugated with the aromatic ring. This steric effect results in a twist of at least 60° for the carboxylic group caused by the nitro-group and in even greater twists for other substituents (18). This is confirmed by a study of Catalin models. The 8-substituents employed in this study do not appear to lead to severe steric interactions that could cause distortion of the aromatic rings (19). The deconjugation results in acid-strengthening by preferentially destabilizing the acid compared to the carboxylate anion (17). The resonance stabilization will be decreased by at least 75% for the nitro-group and more for the other substituents[2] (20). Thus, this steric effect can be considered to be constant for all the 8-substituents studied. For the 8-methyl acid, the latter effect easily overcomes the small polar acid-weakening effect of the methyl group. All the strongly dipolar and *normally* strongly acid-strengthening substituents are now no longer effective. This results from the disproportionately strong influence of the "negative" end of the dipolar substituent which is extremely close to the



3

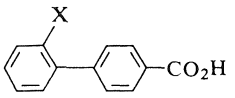
carboxylate group (**3**). This results in a reversal of the normal substituent effect which is characterized by that end of the dipole embedded in the molecule. The reversal is small due to the fine balance between the effects of each end of the substituent dipole. This reversed dipolar substituent effect has been observed in other systems (21–23). A reduced effect of the 8-nitro group, relative to the unsubstituted acid, has been noted previously in the ionization of 8-nitro-1-naphthoic (6) and 8-nitro-2-naphthoic (5) acids. An alternative explanation has been offered for the very small acid-strengthening effect of the 8-chloro substituent on 1-naphthoic acid (7), that is, steric inhibition of solvation of the carboxylate anion occurs. However, the effect of the more bulky 8-methyl group found in this study shows that cannot be the case[3]. These reversed dipolar substituent effects are shown to a lesser degree in the esterification reaction. Secondary steric

[2]The reported pK_a values in 80% MCS (12) for 1-naphthoic (6.45), 2-naphthoic (6.54), and benzoic (6.63) acids, as well as those in water, confirm that this steric effect is small for 1-naphthoic acid itself.

[3]At the same time as our preliminary account of some of these results (22), an independent investigation of 8-substituted 1-naphthoic acids was published by Hojo and co-workers (31). These workers give experimental data and discussion which agrees with and is closely related to those presented by us. However, Dewar (32) has put forward a different interpretation in a comment on our study. His interpretation involves hydrogen-bonding of the carboxylic acid hydrogens to the 8-substituents causing acid-weakening. *No* relevant *experimental evidence* is provided. What is more Dewar has apparently overlooked both Hojo's study (31) and recent studies of hydrogen-bonding in closely related carboxylic acids in carbon tetrachloride (33). Intramolecular hydrogen-bonding is *not* indicated either for *ortho*- halogeno or nitro benzoic acids or for 8-methoxy-1-naphthoic acid. The reported OH-stretching frequencies for the 8-substituted 1-naphthoic acids (31) *all* lie within the accepted limits for unbonded OH-stretching frequencies (33). Moreover, the measurements reported in this

effects have been shown to be less important in this reaction than in the ionization reaction (10, 11). However, the order of reactivity, i.e. $NO_2 > Br \approx Cl \approx Me > H$, indicates the reduced effect of the dipolar substituents. The transition state for the DDM reaction involves only partial transfer of the proton to the DDM molecule, forming an incipient ion-pair (10, 24). The ionization reaction gives the carboxylate anion and appears to demonstrate more conclusively the reversed dipolar substituent effect.

It seems very probable that a reversed dipolar substituent effect intervenes in the ionization of 2′-substituted biphenyl-4-carboxylic acids (**4**) (25). The usually strongly acid-strengthening



4

dipolar substituents have either very small acid-weakening, e.g. the halogeno and cyano groups, or acid-strengthening, e.g. the nitro group, effects. These substituents all cause significant twisting of the phenyl groups. The end of the substituent dipole embedded in the molecule no longer has a favorably positioned low dielectric cavity for transmission and is effectively opposed by the "negative" end of the dipole.

The evidence provided in this study demonstrates the variation in the solvent dependence of reactivity with the type of system. Further examples of reversed dipolar substituent effects have been noted. The field theory for the transmission of substituent polar effects appears to account for these observations.

Experimental

Materials

The 9-bromo-, chloro-, and methyl-10-anthroic acids were prepared by treatment of the 10-substituted 9-bromoanthracene with phenyl lithium, followed by carboxylation (26). 9-Nitro-10-anthroic acid was prepared by nitration of methyl 9-anthroate, followed by hydrolysis (8). Nitration of 1-naphthoic acid and separation from the 5-substituted isomer gave 8-nitro-1-naphthoic acid (27). The halogenation of the mercurated complex of 1-naphthoic acid was used to prepare 8-bromo- and chloro-1-naphthoic acids (28). 8-Methyl-1-naphthoic acid was synthesized by reduction of 1,8-naphthaldehydic acid using a modified Clemmensen reduction (29). 1-Naphthoic and 9-anthroic acids were obtained commercially. The acids were recrystallized to constant melting points which were identical or very close to those in the literature. Neutralization equivalents were determined and were within 1% of the theoretical values.

Other materials for the kinetic and equilibria measurements were prepared as described previously and had similar physical constants (3).

Measurements

Rate Coefficients for Diazodiphenylmethane Reaction

These were determined, at 30° (±0.05), in the manner described previously (3, 30) using equal acid and diazodiphenylmethane concentrations (0.006 *M*) for the anthroic acids because of their low solubility and a 10-fold excess of acid (0.06 *M*) for the naphthoic acids.

pK_a Values

Due to the low solubility of the acids in water, the pK_a values were determined in 80% w/w 2-methoxyethanol–water at 25° (±0.1), as described previously (3).

study are in media very much less likely to allow intramolecular hydrogen-bonding, and it seems extremely unlikely that Dewar's explanation is valid. The fact that we did not consider Dewar's and related studies (4, 5) on naphthoic acids to be most relevant to our preliminary communication should not detract from our interpretation. Dewar's results and analysis (4) did not provide a "clear distinction between field and inductive effects" (32), unlike those of Golden and Stock (21). The former studies do provide a useful guide which suggests the relative importance of the field and various inductive effects in similar ways to our previous studies (2, 14). We consider that the understanding of the factors governing reactivity in peri-substituted and similar systems will considerably advance the full comprehension of substituent effects in general and we are therefore pursuing these studies.

Effect of temperature on "saturation currents" in gas phase radiolysis cells: the conductance of Pyrex and other cell materials

R. M. Byrtus and G. R. Freeman
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received July 8, 1968

When gas-filled Pyrex cells were heated above about 50°, the saturation currents obtained in a gamma radiation field apparently decreased. At temperatures above 100° good saturation currents were not obtained. At temperatures below 50° the conductance of Pyrex was negligible, and "true" saturation currents were measured. At temperatures greater than 50° the Pyrex conducted appreciably, so the total current flowing in the circuit was appreciably greater than the gas phase saturation current (absorbed dose rate 10^{10}–10^{13} eV/ml s). If the outer surface of the cell was grounded, for example by ionized air, part of the current by-passed the measuring ammeter, thereby decreasing the "apparent" saturation current. The magnitude of the temperature effect was greatly decreased by wrapping the cell with teflon tape, thereby insulating it from the ionized air.

The effect of temperature on apparent saturation currents measured in quartz cells was much smaller than that in Pyrex cells, because the conductance of quartz was much less than that of Pyrex at temperatures above 50°.

When a metal cell that contains a Pyrex insulator between the electrodes is used, the temperature of the Pyrex should be kept below about 50°.

Introduction

Saturation current measurement in gas phase radiolysis cells is a useful and convenient form of dosimetry (1). However, it has been observed that "saturation currents" are temperature dependent when radiolysis cells are heated to 100 °C or more (2, 3). This dependence is not due to a temperature effect on the formation of ions, because in the temperature (up to 200°) and pressure ($\sim 10^2$–10^3 Torr) range studied the temperature coefficient of ionization is negligible (4–6). Furthermore, ion recombination coefficients and space charges at the electrodes, although they might be temperature dependent, should not appreciably influence the saturation currents (7). The observed effects are too large to be explained by the diffusion of ions to the vessel walls (8–13) and the photoelectric effect should be independent of temperature in the range studied (14).

The most likely explanation of the temperature dependence of the "saturation currents" was that it was an experimental artifact, and it was necessary to trace it.

Experimental

Argon, helium, and hydrogen, all of 99.9% minimum purity, and air were used. The gases were dried by passing them through a cold trap filled with 14–20 mesh Silica Gel and immersed in a 95% ethanol slush (−110°).

Most of the cells contained parallel plate electrodes 5 cm in diameter, spaced 2.5 cm apart. The electrodes were of aluminium, stainless steel, platinum, or Aquadag. The cell envelopes were made of Pyrex or quartz. Attempts to make vacuum-tight ceramic cells that were cleanable and that could withstand the temperature changes were unsuccessful (15). Furthermore, most of the ceramics conducted electricity to an appreciable extent in the presence of the radiation field.

Several 250 ml spherical cells were constructed of Pyrex, quartz, or stainless steel. The central electrode in each cell was a 1 cm diameter sphere of either stainless steel or aluminium. The inner surface of a Pyrex or quartz spherical cell was coated with Aquadag to serve as the outer electrode (15).

Prior to filling, the cells were evacuated and baked at 360–400° for about 4 h. They were then cooled to room temperature, flushed out several times with the gas to be irradiated, filled to the desired pressure, and sealed off.

The outside surfaces of the Pyrex and quartz cells were thoroughly washed with ethanol to remove fingerprints, which appear to be moderately good semiconductors.

The filled and cleaned cells were enclosed in a heating mantle and were irradiated with ^{60}Co gamma rays (10 000 Ci Gammacell-220 or 5 000 Ci irradiation cave). When current measurements were being taken, the power supply to the heating mantle was turned off to avoid inducing extraneous currents in the measuring circuit.

The currents were in the range 10^{-13}–10^{-4} A and were measured with a calibrated E-H Model 240 micro-microammeter.

Results and Discussion

Pyrex Cells with Parallel Plate Electrodes

It should be mentioned before proceeding that temperature effects were first observed with cylindrical cells of the design (1–3) most frequently used by radiation chemists, and that the

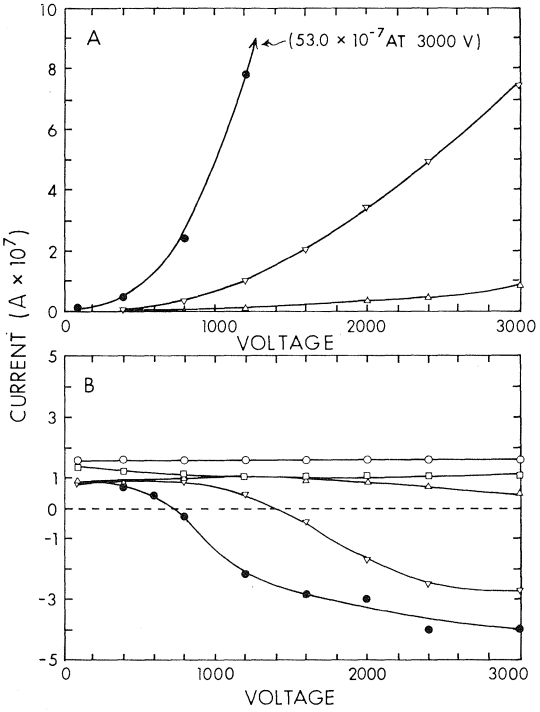

FIG. 1. Currents measured in hydrogen in Pyrex cell with aluminium electrodes (5.0 cm diameter, 2.5 cm apart); hydrogen pressure at 25° = 299 Torr; density = 3.24×10^{-5} g/cm³.

A. Background current: △, 110°; ▽, 140°; ●, 170°. In addition, the following background currents were measured: 25°, 1×10^{-11} A at 3000 V; 80°, 4×10^{-9} A at 3000 V.

B. Net positive current: ○, 25°; □, 80°; △, 110°; ▽, 140°; ●, 170°.

effects were similar to those obtained with the present parallel plate cells.

Background currents were measured in the absence of the radiation field. Typical background currents at different voltages and temperatures are shown in Fig. 1A. Net currents in the presence of the radiation field were obtained by taking the difference between the ammeter readings in the presence and absence of the radiation field. Typical net currents at different voltages and temperatures are shown in Fig. 1B. These results were obtained with a cell filled with hydrogen, but similar results were obtained with the other gases.

When the gas-filled Pyrex cells with parallel plate electrodes were heated above about 50°, the saturation currents apparently decreased. In a typical case the current at 80° was 20% smaller than at 25°, and at temperatures above 100° good saturation currents were not obtained (Fig. 1B).

The amount of decrease at a given temperature could be increased in two ways: (1) decreasing the ratio of the electrode diameter to the distance between the electrodes; (2) painting the outer surface of the cell with Aquadag and grounding it with a wire. The amount of temperature dependence could be decreased by insulating the exterior of the cell from the ionized air by wrapping the cell with teflon tape.

Saturation currents were unaffected by reducing the cell temperature from 25 to −196°, although higher voltages were required to attain them.

At the elevated temperatures, the saturation currents measured by collecting positive ions decreased more than did those measured by collecting negative ions.

The temperature effects were independent of gas pressure over the range 50–600 Torr.

The dose rate was varied in the region 10^{10}–10^{13} eV/ml s. The temperature effect increased somewhat with decreasing dose rate.

Interpretation of the Temperature Effects

At room temperature the conductance of Pyrex is negligible, and essentially all the gaseous ions of the appropriate sign are collected on the collecting electrode. The ammeter (Am in Fig. 2A) therefore registers the true saturation current. At temperatures greater than 50° the Pyrex conducts appreciably, so the total current flowing in the circuit is greater than the gas phase saturation current. Furthermore, when the Pyrex becomes a conductor the walls of the cell also act as collecting electrodes, so all the ions are not collected on the metal electrodes. If the outer surface of the cell is insulated, the total current in the circuit passes through the meter. However, if the outer surface of the cell is grounded, for example by ionized air, part of the current by-passes the meter (Fig. 2B). The fraction of the total current that by-passes the meter depends on the relative resistances of the two grounding paths (Fig. 2B). This fraction was increased by painting part of the outer surface of the Pyrex cell with Aquadag and grounding it with a wire, and was decreased by insulating the exterior of the cell from the ionized air by wrapping the cell with teflon tape.

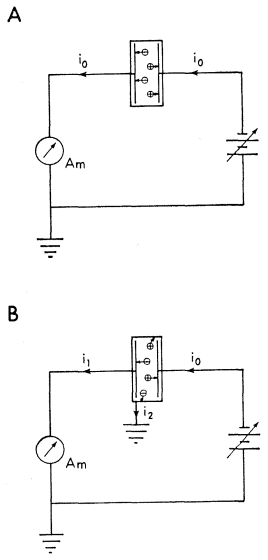

FIG. 2. Interpretation of temperature effects in Pyrex cells.

A. Current measurements when Pyrex cell wall does not conduct; $i_0 = i_s$; i_0 = total current in circuit; i_s = saturation current.

B. Current measurements when Pyrex cell wall conducts; $i_0 = i_1 + i_2 > i_s$; i_1 and i_2 each contain components due to collection of gaseous ions in the cell and to conductance of the glass.

At temperatures greater than 110° the conductance of Pyrex at high voltages was so large that, when the unwrapped cell was in the radiation field, the amount of current shunted through the ionized air was greater than the current due to the collection of gaseous ions in the cell. The net current was therefore negative under these conditions (140 and 170° curves in Fig. 1B).

At elevated temperatures the net currents measured by collecting positive ions decreased more than did those measured by collecting negative ions because Pyrex is a better conductor of positive than of negative charge (16).

The small increase of the temperature effect with decreasing dose rate indicates that space or surface charges along the cell walls tend to prevent ions from collecting on the walls. At the higher dose rates the surface charges are apparently greater, so a smaller fraction of the ions is collected on the walls.

Spherical Pyrex Cell

In the spherical Pyrex cell, the apparent saturation current increased with increasing temperature. The measured current was collected on an Aquadag coating on the inside of the Pyrex sphere. The increase in current was caused by ions from the surrounding ionized air being collected on the outer surface of the cell and being conducted through the glass. Since Pyrex conducts positive charge better than negative charge, the apparent increase in the positive saturation current was greater than that of the negative saturation current.

When the spherical cell was wrapped with teflon tape, the net current was less temperature dependent, as expected.

Conductance of Solid Plugs of Pyrex or Quartz

The preceding interpretation of the temperature effects observed with Pyrex cells is supported by measurements made with solid plugs of Pyrex and of quartz.

A 1 cm long solid plug of Pyrex or quartz was made in the center of a piece of the respective tubing (10 cm long × 1 cm diameter) by collapsing the center of the tubing with a flame. A tungsten lead was imbedded in each side of the plug, inside the tubing. The ends of the tungsten wires were separated by 2–3 mm of the glass. The surface of the plug and tubing was cleaned with ethanol to reduce surface conduction.

Currents in the range 10^{-12}–10^{-9} A were generated by the tungsten–Pyrex seals, in the absence of applied voltage. The currents were larger at the higher temperatures and also in the presence rather than in the absence of radiation. The currents generated by the tungsten–quartz seals in the absence of applied voltage were about 10^{-12} A in the absence, and 10^{-10} A in the presence of radiation (Gammacell) at all temperatures (25–170°). These currents were not reproducible and depended on the previous history of the sample (tungsten–glass seal).

At 170° and 3000 V the current passing through one Pyrex plug in the absence of a radiation field was 2.2×10^{-6} A. When the plug was lowered into the Gammacell, the current passing through the ammeter decreased to 1.9×10^{-6} A. The current through the ammeter was reduced because the ionized air in the radiation field partially grounded the plug and diverted some of the current from the meter, similar to the situation in Fig. 2B.

Insulation of a Pyrex plug from the ionized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

air, by wrapping the plug with teflon tape, forced all the current to pass through the ammeter. Under these conditions the current was larger in the presence (e.g. 5.6×10^{-6} A at 170°, 3000 V) than in the absence (3.9×10^{-6} A at 170°, 3000 V, in the same plug) of the radiation field.

The current passing through the quartz plug was 10^{-12}–10^{-11} A in the absence and $\sim 10^{-10}$ A in the presence of a radiation field (Gammacell) at all temperatures (25–170°) and applied voltages (0–3000 V). The conductance of quartz is therefore much smaller than that of Pyrex at temperatures greater than about 50°.

Quartz Cells

Since the conductivity of a quartz plug at 110 and 170° was much smaller than that of a Pyrex plug, it was expected that the apparent saturation currents would be less temperature dependent in quartz cells than in Pyrex cells. Such was the case. In fact, the apparent saturation current in a parallel plate cell decreased by only 3% when the temperature increased from 25 to 170°.

Spherical Stainless Steel Cell

The central electrode in this cell was a 1 cm diameter stainless steel ball attached to a tungsten stem. The tungsten stem was passed through a Pyrex seal, which was attached to the outside of the stainless steel vessel through a Kovar seal. The exterior of the steel vessel was insulated with a baked coating of stove cement (Sairset High Temperature Bonding Mortar, manufactured by A. P. Green, Edmonton). During experiments, the Pyrex–tungsten seal protruded outside the heating mantle, so the Pyrex remained relatively cool. The insulation between the tungsten and steel electrodes was therefore relatively good even when the cell was heated. The apparent saturation currents increased by only 4% when the cell temperature was increased from 25 to 170°.

Conclusion

Pyrex cells with no exterior insulation should only be used for gas phase ion current measurements at temperatures below 50°. For higher temperatures the exterior of the cell should be insulated from the ionized gas in the radiation field. The glass–metal seal for the collecting electrode connection should be kept at a temperature below 100°, and preferably below 50°.

Similar but less stringent precautions should be taken with quartz cells.

When metal cells are used, the insulator between the electrodes should be adequate. Since the insulator used is frequently Pyrex, its temperature should be kept below 50°.

A thermochemical study of addition complexes of zirconium and hafnium tetrahalides

FINE MAN CHUNG AND ALAN D. WESTLAND
Department of Chemistry, University of Ottawa, Ottawa 2, Canada

Received July 15, 1968

Enthalpies of addition were determined calorimetrically for the crystalline complexes $MX_4 \cdot 2L$ where M = Zr or Hf, X = Cl or Br, and L = tetrahydrofuran or tetrahydrothiophene. With oxygen as the donor atom of L, the two metal halides exhibited nearly identical acceptor power but with sulfur as donor, $HfCl_4$ proved to be the better acceptor. Hafnium(IV) shows more class *b* character than zirconium(IV).

Canadian Journal of Chemistry, **47**, 195 (1969)

There are several features of interest in connection with the elements zirconium and hafnium. The foremost amongst these is the fact that these two elements are very nearly alike in behavior. A quantitative comparison of the relative acceptor ability of the anhydrous halides would be interesting especially in comparison to similar pairs of elements, e.g. Mo and W or Pd and Pt. It has been shown (1) that $TiCl_4$ exhibits class *b* character in the terminology of Ahrland *et al.* (2). The larger size of the Zr and Hf atoms should effect a diminution in class *b* character. However, little is known as yet in this connection concerning the elements at the extreme left end of the transition series.

Some heats of reaction were determined by Hummers *et al.* for the complexing of $ZrCl_4$ and $HfCl_4$ with esters (3). Very little difference between the two acceptors was observed. We feel that this is to be expected in cases where the donor atom has a low polarizability, e.g. N, O, and F. It follows that nearly all of the aqueous chemistry of zirconium and hafnium will show little difference between the two elements. In order to test the effect of using donor atoms of higher polarizability, we have employed a thioether as well as an ether as a donor molecule in a nonaqueous system.

Anhydrous zirconium and hafnium halides react with tetrahydrofuran and tetrahydrothiophene to give 1:2 complexes. The compounds are soluble in excess of the respective ligands. Therefore, by measuring the heat of solution of the anhydrous halides in the liquid ligands and subtracting the heats of solution of the complexes, one may obtain the heats of addition. Similar studies have been carried out by Richards and Thompson using aluminium and gallium halides as acceptor molecules (4).

Results

Addition of the calculated amount of tetrahydrofuran (THF) or tetrahydrothiophene (THT) to $ZrCl_4$, $ZrBr_4$, or $HfCl_4$ suspended in benzene resulted in the formation of complexes $MX_4 \cdot 2THF$ and $MX_4 \cdot 2THT$. The analyses of the complexes are given in Table I.

The heats of addition were determined in each case. The heat quantities referred to in the following sections are defined as follows where A is the acceptor and L is the donor ligand

$$A(c) + (x + 2)L(l) \rightarrow AL_2(soln.) - \Delta H_1$$

$$AL_2(c) + xL(l) \rightarrow AL_2(soln.) - \Delta H_2$$

$$A(c) + 2L(l) \rightarrow AL_2(c) - \Delta H_c$$

$$\text{and} \quad \Delta H_c = \Delta H_1 - \Delta H_2$$

The letters c, l, and g refer to the crystalline, liquid, and gaseous states respectively.

Heats of solution, ΔH_1, are listed in Table II. Duplicate determinations are shown in each case. It can be seen that there is very little difference in the behavior of $ZrCl_4$ and $HfCl_4$ towards both THF and THT. The degree of dilution of the complex in the solutions of THF and THT is quite great with mole ratios of solute:solvent of one to several hundred. Varying the mole ratio had no observable effect upon the molar heat evolved. This can be seen from the weights of chloride which in some duplicate determinations differ by a large amount while the weight of solvent is nearly constant in all cases. The measured values are thus very close to integral heats of solution. The heats of solution of the complexes, ΔH_2, are listed in Table III.

Values of ΔH_c, listed in Table IV, refer to the mean values for the complexing process when all the participants in the reaction are in the condensed state. The process in this case entails

vaporization of the reactants, reorganization of the acceptor molecule from tetrahedral to quasi-octahedral geometry, and condensation of the product to form a lattice. It is clear that the gas phase process $A(g) + 2L(g) \rightarrow AL_2(g) - \Delta H_g$ is more amenable to interpretation. In this case it is necessary to account only for possible differences in reorganization energies for various acceptor molecules.

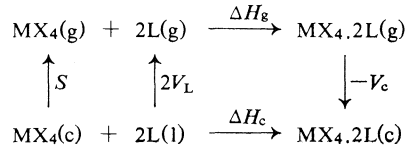

FIG. 1. Thermochemical cycle. Legend: S = heat of sublimation of metal halide. V_L = heat of vaporization of ligand (the value for tetrahydrothiophene (9.4 kcal mole^{-1}) was obtained from ref. 8. The value for tetrahydrofuran (7.1 kcal mole^{-1}) was estimated from Trouton's rule). V_c = heat of vaporization of complex.

The heat quantities involved in converting the results to those for the gaseous state are defined in Fig. 1 which shows the enthalpy cycle. The heats of sublimation of the tetrahalides are experimental values (5, 6). These are somewhat lower than the values which may be obtained from the calculated enthalpies of formation for the ideal monomeric gases (7). The discrepancy may be due to association of molecules in the form of dimers in the real vapor. The discrepancy is nearly the same for each of the tetrahalides and so may be safely neglected for the purpose of comparing the various systems.

TABLE IV

Mean heats of complexing for the formation of crystalline complexes*

Complex	$-\Delta H_c$ kcal mole^{-1}	$-\Delta H_g + V_c$ kcal mole^{-1}
$ZrCl_4 \cdot 2THF$	33.6±0.5	72.5±0.5
$ZrCl_4 \cdot 2THT$	29.8±0.9	73.3±0.9
$ZrBr_4 \cdot 2THF$	36.2±0.4	77.5±2.2
$ZrBr_4 \cdot 2THT$	8.7±0.4	54.6±2.2
$HfCl_4 \cdot 2THF$	34.6±0.2	72.6±0.3
$HfCl_4 \cdot 2THT$	33.1±0.2	75.7±0.3

*From reactants in their standard states (ΔH_c) and from reactants in the gaseous state ($\Delta H_g - V_c$).

TABLE V

Comparison of n.m.r. internal shifts with heats of adduct formation in solution

Compound	Chemical shift relative to TMS(τ) α-CH_2	β-CH_2	Internal shift (τ)	$-\Delta H_1$	$-\Delta H_g + V_c$
THF	6.72	8.78	2.06		
$ZrCl_4 \cdot 2THF$	6.24	9.14	2.90	40.2	72.5
$ZrBr_4 \cdot 2THF$	5.96	9.31	3.35	52.1	77.5
$HfCl_4 \cdot 2THF$	5.76	8.83	3.07	41.0	72.6
THT	7.47	8.45	0.98		
$ZrCl_4 \cdot 2THT$	7.44	9.01	1.57	42.0	73.3
$ZrBr_4 \cdot 2THT$	7.84	9.27	1.43	29.8	54.6
$HfCl_4 \cdot 2THT$	7.22	8.77	1.55	40.2	75.7

The heats of sublimation of the complexes are of course unknown so that we are able at best to deal with the process $A(g) + 2L(g) \rightarrow AL_2(c) - (\Delta H_g - V_c)$. Values of the heat for the reaction, $\Delta H_g - V_c$, are also listed in Table IV.

Upon complex formation, there was a change in the chemical shifts of the protons in the α and β positions in the ligand rings. The differences between the α and β chemical shifts, known as the internal shifts, are listed in Table V.

Discussion

The heats of adduct formation with THF do not vary greatly. The close agreement between the values for $ZrCl_4 \cdot 2THF$ and $HfCl_4 \cdot 2THF$ is not unexpected in the light of our knowledge of the behavior of zirconium and hafnium generally. The values which refer to gaseous reactants are in especially close agreement. The metal–oxygen bond is probably of a largely electrostatic nature so that the nearly identical sizes and charges of the Zr^{4+} and Hf^{4+} ions make the two bonds of very nearly the same strength. The heats of sublimation, V_c, for the two chloro complexes are presumably very nearly equal so that the values of $\Delta H_g - V_c$ probably parallel ΔH_g fairly closely.

The THF adduct with $ZrBr_4$ is somewhat more stable than the corresponding chloride. This is contrary to what would be expected on the basis of the relative electronegativities of the halogens as, for example, in the affinity toward N, O, and S of the gallium halides which is in the order $GaCl_3 > GaBr_3 > GaI_3$ (9, 10). Instead, the situation is similar to that encountered with the boron and aluminium halides where the usual order of acceptor strength is $MF_3 < MCl_3 < MBr_3$ (11–13). In the case of boron, the order is apparently the consequence of two factors: (*i*) the relative reorganization energies and (*ii*) the effect of π-character in the B—X bond on electronegativity of the boron atom (9, 14). It is claimed that the π-bonding ability of the halogens decreases in the order F > Cl > Br > I (11). It is reasonable to consider that these same factors are operative in our case. Of course, only one of the factors may in fact be important. The reorganization energy is probably nearly constant for the halides of an element in the fifth period for there is a decrease in the difference between the fluoride and the chloride when passing down the elements of Group IIIA, for example. The differences in the values are BX_3, 13–18; AlX_3, 3.7; GaX_3, 0.2 kcal $mole^{-1}$ (9, 15, 16). It appears that π-bonding is involved to some extent if only to cancel the effect of halogen electronegativity.

There is greater variation in the heats of complexing with THT. The bromide complex is less stable presumably because of steric hindrance which is evident from a model. This is seen also in the complexes $GaX_3 \cdot 2py$ but not in $GaX_3 \cdot py$ (17). The large values of ΔH_2 for $ZrBr_4$ complexes are probably the result of large solvation interactions between the highly polarizable bromine atoms and the outer coordination sphere. The most interesting result is the observation that the heat of formation of the hafnium complex is significantly greater than that of the others. This indicates that hafnium has more class *b* character than zirconium or, in Pearson's sense, it is a "softer acid". We conclude that the use of more polarizable ligands in association with the second and third row transition elements has the effect of enhancing differences in the behavior of related elements.

The origin of these chemical differences is to be found in the non-electrovalent features of the bonding. In particular, we note that the valence orbitals of the third row elements are more diffuse than those of the second row. Further, the effective nuclear charge of the hafnium atom should be somewhat greater than that of zirconium owing to the presence of the 4f subshell in the former atom. The hafnium nucleus would consequently have a greater polarizing ability. The difference in behavior between zirconium and hafnium is much less than the difference between aluminium and gallium. The contrast between the two pairs is understandable in terms of the relative shielding coefficients for 3d and 4f electrons respectively. Slater's rules provide for total shielding by a 4f electron but a fraction of only 0.85 for a 3d electron. These rules appear to overestimate somewhat the shielding by f-electrons.

The nuclear magnetic resonance (n.m.r.) internal shifts correlate fairly well with the thermal data as shown in Table V. Richards and Thompson observed such a correlation for complexes of Group III halides and discussed the implications and limitations of this type of experiment (4). The correlation is slightly better with $-\Delta H_l$ than with $-\Delta H_g + V_c$. If there is any significance to this, it implies that the condition of the complex in the dissolved state is important in determining both the internal shift and the heat of solution. The dissolved species may be an equilibrium mixture involving $MX_4 \cdot L$, $MX_4 \cdot 2L$, and $MX_4 \cdot 3L$, for example.

Experimental

Preparations

Zirconium(IV) chloride and hafnium(IV) chloride (nuclear grade) supplied by A. D. Mackay Inc., were purified by sublimation at 280° in a sealed tube containing nitrogen.

Anal. Calcd. for $ZrCl_4$: Zr, 39.14; Cl, 60.86. Found: Zr, 38.83; Cl, 60.95.

Anal. Calcd. for $HfCl_4$: Hf, 55.73; Cl, 44.27. Found: Hf, 54.48; Cl, 44.88.

Zirconium(IV) bromide was prepared in a sealed tube from nuclear grade zirconium sponge by allowing it to react with bromine vapor. One end of the tube containing the liquid bromine was maintained at room temperature so that the compound sublimed from the hot reaction zone into a cooler region. Excess bromine present at the end of the reaction period was removed by pumping.

Anal. Calcd. for $ZrBr_4$: Zr, 22.20; Br, 77.80. Found: Zr, 22.22; Br, 77.04.

Tetrahydrofuran (Fisher Certified Reagent) and tetrahydrothiophene (Aldrich) were purified by distillation, the middle fraction only being used.

Complexes were purified as follows:

Carefully dried, sulfur-free benzene was distilled at reduced pressure from sodium metal into a Schlenk tube immersed in liquid nitrogen. The distillate (50 ml) was allowed to attain room temperature, and dry nitrogen was then admitted. The content of an ampul of metal halide (1.5 g) was introduced into the tube and to this suspension was added ligand (1.05 molecular equivalent) dissolved in benzene (5 ml). Vigorous stirring for a few hours produced a heavy precipitate. Stirring was continued for a further 1 to 2 days to ensure complete reaction. The solvent was then reduced to $\frac{1}{3}$ the original volume by pumping, before the solid material was separated in a filtering apparatus similar to that described by Fritz *et al.* (18). The product was washed with two volumes of benzene before drying under vacuum at room temperature. As these complexes were hygroscopic they were stored in ampuls under nitrogen.

Calorimetric Measurements

A solution calorimeter similar to that described by Greenwood and Perkins (19) was used. The calibration of the associated equipment was checked by hydrolyzing $POCl_3$ in the calorimeter. In two determinations, molar heats of hydrolysis of 80.0 and 80.2 kcal $mole^{-1}$ were obtained. This is in good agreement with a published value of 79.9 ± 0.3 kcal $mole^{-1}$ (20).

The volume of THF or THT employed in the calorimeter was 100 cc. Measurements were carried out in duplicate. The calorimeter temperature was in all cases within 2° of that of the water bath which was maintained at 25 °C.

Nuclear Magnetic Resonance Spectra

The n.m.r. spectra were obtained with a Varian Associates 60 Mc/sec high resolution spectrometer. Spectra were calibrated with respect to tetramethylsilane as internal standard. The samples were dissolved in benzene to form saturated solutions.

Spectres Raman de N_2H_4 et N_2D_4 à l'état cristallin

M. GUAY[1] ET R. SAVOIE
Département de Chimie, Université Laval, Québec 10, Québec

Reçu le 21 juin 1968

Les spectres Raman de N_2H_4 et N_2D_4 cristallins ont été enregistrés à diverses températures entre -70 et -195 °C. Les dédoublements des fondamentales, le grand nombre de modes de réseau observés et la non-coïncidence probable des fréquences Raman et infrarouges sont en désaccord avec les structures cristallines obtenues par diffraction des rayons-X et des neutrons. Les résultats infrarouges et Raman suggèrent une structure à quatre molécules dans des positions générales d'une maille monoclinique de classe C_{2h}.

Raman spectra of crystalline N_2H_4 and N_2D_4 have been recorded at various temperatures between -70 and -195 °C. The splitting of the internal modes, the large number of active lattice vibrations, and the apparent non-coincidence of infrared and Raman bands cannot be explained on the basis of the crystal structures obtained from X-ray and neutron-diffraction studies. The results suggest instead a monoclinic unit cell described by one of the C_{2h} space groups and containing four molecules located in general positions.

Canadian Journal of Chemistry, 47, 201 (1969)

Introduction

La molécule d'hydrazine est d'un intérêt tout particulier du fait que sa symétrie est déterminée par l'orientation relative des groupements NH_2. La structure *gauche* (symétrie C_2) déduite par Penney et Sutherland (1) n'a pu être confirmée par diffraction des électrons (2, 3). Cependant, une analyse détaillée du spectre infrarouge de la vapeur dans la région du mode de torsion interne, centré à 376.74 cm^{-1}, a indiqué que l'angle azimuthal est voisin de 90° (4). Ce résultat a été confirmé par le spectre micro-onde (5), qui a de plus permis d'évaluer les barrières de potentiel empêchant l'inversion et la torsion interne (*trans*) à 990 et 1100 cm^{-1} respectivement. La structure *gauche* est également en accord avec le moment dipolaire de 1.75 D calculé à partir du spectre micro-onde (5, 6). Une valeur de 1.83 D avait été obtenue à partir du liquide (7). Il n'est pas impossible cependant qu'une petite fraction des molécules existent sous une autre conformation. Les nombreux spectres infrarouges (4, 8–14) et Raman (13–20) déjà publiés ne permettent pas d'éliminer cette possibilité.

Il existe une certaine confusion quant à la structure cristalline du solide. La mesure des chaleurs spécifiques et le calcul des fonctions thermodynamiques à partir des données spectroscopiques a conduit à une entropie résiduelle de 0.44 u.e. au zéro degré absolu (21). Cette valeur ne permet cependant pas de conclure à une structure désordonnée du solide puisqu'elle est moindre que l'imprécision sur la valeur calculée et celle obtenue expérimentalement. Une étude du cristal par diffraction des rayons-X, par Collin et Lipscomb (22), suggère une maille élémentaire à deux molécules et définie par le groupe spatial $C^2{}_{2h}$–$P2_1/m$. Dans cette structure, les molécules occupent des sites de symétrie C_s et doivent par conséquent exister sous la forme *cis* (éclipsée, symétrie C_{2v}) ou *trans* (symétrie C_{2h}). Cela n'implique pas que l'une de ces configurations est la plus stable dans la molécule libre puisque, dans le cristal, d'autres facteurs (liaisons hydrogène, . . . *etc.*) entrent en jeu. Une étude par diffraction des neutrons (23) a conduit à une structure légèrement différente de celle obtenue par diffraction des rayons-X. Le groupe spatial $C^2{}_2$–$P2_1$ est suggéré, avec deux molécules par maille élémentaire. Il est à noter que les seuls sites possibles dans ce groupe sont de symétrie C_1. Baglin, Bush et Durig (24) ont récemment étudié les spectres de N_2H_4 et N_2D_4 cristallins dans l'infrarouge lointain en vue de choisir entre les deux structures cristallines proposées. En se basant sur le nombre de bandes observées, ils concluent que la structure obtenue à partir de la diffraction des neutrons est la bonne. Afin de vérifier cette déduction, nous avons étudié les spectres Raman de l'hydrazine et de son analogue deutérié à diverses températures entre -70 et -195 °C.

Partie expérimentale

L'hydrazine (N_2H_4) utilisé a été obtenu à partir du produit commercial (Matheson, Coleman, and Bell, à

[1]Boursier du Conseil National de Recherches du Canada.

TABLEAU I

Corrélations entre les symétries des vibrations pour diverses structures possibles de N_2H_4 cristallin

Molécule		Site	Cristal	Site	Cristal
C_{2v}	C_{2h}	C_s	C_{2h}	C_1	C_2
A_1	A_g	A'	A_g (Raman)	A	A (Raman, i.r.)
B_2	B_u		B_u (i.r.)		
A_2	A_u	A''	A_u (i.r.)		B (Raman, i.r.)
B_1	B_g		B_g (Raman)		

97% anhydre), par séchage sur CaH_2 et distillation sous vide, suivant la méthode de Lucien (25). Un dosage de l'échantillon par une solution aqueuse d'iodate (26, 27) a révélé une pureté de 100%, à 0.2% près. Le composé deutérié a été obtenu de Merck, Sharpe, and Dohme (concentration en deutérium 97%, < 1% D_2O) et utilisé sans aucune purification.

Les échantillons ont été cristallisés dans des cellules cylindriques en Pyrex de 19 mm de diamètre qu'on laissait descendre lentement (~ 24 h) dans un bain thermostatisé maintenu à quelques degrés au-dessous du point de fusion (1.4 °C). La cristallisation a dû être amorcée dans la plupart des cas car l'hydrazine montre une tendance marquée à la surfusion. De plus, nous avons placé un anneau chauffant autour des cellules, de façon à éviter que la cristallisation ne se produise d'abord sur les parois. Pour l'enregistrement des spectres, les cellules étaient placées à l'intérieur d'un Dewar de Pyrex et refroidies par un courant d'azote gazeux, tel que décrit précédemment (28).

Les spectres ont été enregistrés avec un spectromètre Cary, modèle 81, muni d'une lampe Toronto conventionnelle. Les fentes du monochromateur étaient ajustées de 0.5 à 4 cm^{-1}, suivant l'intensité des bandes. Les fréquences rapportées plus loin sont précises à ± 2 cm^{-1} dans le cas des bandes fines.

Résultats et Discussion

Structures cristallines et spectres vibrationnels

L'analyse des spectres vibrationnels de l'hydrazine à l'état cristallin, à la lumière de la théorie des groupes (29, 30), devrait permettre de distinguer entre la structure proposée d'après la diffraction des rayons-X ($C^2{}_{2h}$) et celle obtenue par diffraction des neutrons ($C^2{}_2$). Dans le premier cas, la symétrie locale dans le cristal (C_s) implique une symétrie moléculaire C_{2v} (forme éclipsée, *cis*) ou C_{2h} (forme *trans*). Dans les deux cas, les modes vibrationnels de la molécule se transforment en espèces A' ou A'' dans l'approximation du site; celles-ci se scindent ensuite en deux composantes, l'une active en Raman et l'autre en infrarouge, par suite de l'effet de couplage dans le cristal (voir Tableau I). D'après ce modèle, chacune des vibrations internes devrait donner une seule composante tant en diffusion qu'en absorption, les bandes ayant des fréquences différentes dans les deux types de spectres puisqu'elles correspondent à des modes différents. Les trois modes de libration devraient également se comporter de cette façon, tandis que les modes de translation gênée ne devraient être actifs qu'en Raman seulement, les composantes infrarouges correspondant aux modes acoustiques, de fréquence zéro à la limite ($k = 0$). La présence de quelque neuf bandes observées par Baglin, Bush et Durig (24) dans le spectre infrarouge entre 100 et 400 cm^{-1}, au lieu des trois prévues, les a conduit à rejeter cette structure cristalline.

Si le cristal était du groupe $C^2{}_2$–$P2_1$, tel qu'indiqué par la diffraction des neutrons (23), les deux molécules de la maille cristalline devraient se situer dans les positions générales (sites de symétrie C_1). Les espèces vibrationnelles de la molécule isolée, de même que les rotations et translations, se transformeraient alors en espèces A dans la symétrie du site, pour ensuite se dédoubler en composantes de symétrie A et B dans le groupe factoriel $C^2{}_2$ (voir Tableau I). Cette structure se caractérise donc par un dédoublement de toutes les bandes, sauf celles correspondant aux modes de translation, et par la coïncidence des fréquences Raman et infrarouges. Le spectre infrarouge lointain de l'hydrazine cristallin (24) a clairement indiqué que cette structure cristalline était plus probable que celle obtenue par diffraction des rayons-X.

Région des basses fréquences

On observe dans la région des basses fréquences du spectre Raman de N_2H_4 cristallin une douzaine de bandes qui se retrouvent, décalées d'un

facteur variant de 0.73 à 0.96, dans le spectre du composé deutérié (Fig. 1 et Tableau II). De plus, la plupart des bandes infrarouges n'ont pas d'équivalent en Raman. La variation des fréquences avec la température (Tableau II) n'est pas responsable de cette disparité. Nous avons pensé que celle-ci pouvait provenir d'une mauvaise cristallisation des échantillons étudiés en infrarouge sur des films de polyéthylène (24). Afin d'éliminer cette possibilité, nous avons réexaminé le spectre infrarouge de N_2H_4, cristallisé lentement à partir du liquide entre deux fenêtres de quartz cristallin, dans la région de 40 à 200 cm^{-1}. Le spectre, obtenu avec un interféromètre (RIIC, modèle FS-720), était presque identique à celui déjà publié (24), sauf que les deux bandes de plus basses fréquences sont apparues à 108.5 et 138 cm^{-1} (comparativement à 106.7 et 136.3 cm^{-1}) et que la bande à 172 cm^{-1} était plus intense relativement à celle de 154 cm^{-1}.

En se basant sur le grand nombre de bandes dans la région de 90 à 300 cm^{-1} du spectre Raman, de même que sur la non-coincidence de leurs fréquences avec celles des bandes en infrarouge, il semble bien que nos résultats ne soient en accord avec aucune des deux structures cristallines obtenues par diffraction. De plus, compte tenu des quelque douze bandes observées en Raman, en plus de celles à d'autres fréquences en infrarouge, nos résultats indiquent que la maille primitive du cristal contient plus de deux molécules. Dans ce cas le nombre maximum de modes de réseau serait de neuf. Il se peut également que la structure du cristal soit désordonnée par suite de la présence dans le solide d'isomères de structure, comme dans le cas de N_2F_4 (31). Cette possibilité ne peut être écartée, quoiqu'elle semble assez improbable, vu la barrière de potentiel relativement élevée à la position *trans* ($\sim$ 3 kcal) (5). De plus, la finesse des bandes dans le spectre Raman suggère une structure cristalline bien ordonnée. Par conséquent, si la structure cristalline est bien monoclinique tel qu'établi par la diffraction des rayons-X et des neutrons, elle doit se situer dans un des groupes de la classe C_{2h}, avec quatre molécules dans des positions générales (site de symétrie C_1) de la maille primitive. Il est à noter que cette conclusion, basée sur la liste des positions générales et spéciales des groupes du système monoclinique (32), n'est valable que si

les molécules n'occupent qu'un seul ensemble de sites dans la maille cristalline (le contraire serait exceptionnel pour un cristal moléculaire).

L'attribution des modes de réseau de N_2H_4 et N_2D_4 cristallins (Tableau II) s'explique assez bien dans l'hypothèse d'une maille primitive de symétrie C_{2h} et contenant quatre molécules. En se référant au tableau de corrélation (Tableau I), ce modèle prédit que chacun des degrés de liberté de translation et rotation d'une molécule isolée devrait donner naissance à quatre modes vibrationnels dans le cristal, les espèces A_g et B_g n'étant actives qu'en Raman et les deux autres (A_u et B_u) en infrarouge seulement. Après avoir éliminé les trois modes acoustiques ($A_u + 2B_u$), qui correspondent aux déplacements de l'ensemble de la maille primitive suivant chacun des axes, on prédit 12 bandes en Raman (6 librations et 6 translations) et 9 en infrarouge (6 librations et 3 translations).

L'attribution des modes de réseau de N_2H_4 cristallin est facilitée par les résultats obtenus à partir du composé deutérié. En première approximation, le décalage isotopique des fréquences devrait être proportionnel à la racine carrée du rapport des masses moléculaires (0.94) ou des moments d'inertie, suivant qu'il s'agit de translation ou de libration. D'après les paramètres de structure de la molécule libre (2, 3), le rapport isotopique des fréquences devrait être de 0.72 pour les librations autour de l'axe mineur et de 0.87 pour celles autour des deux axes majeurs.

Par analogie avec le cas de H_2O_2 solide (33), on devrait retrouver dans la région de 400 à 800 cm^{-1} des spectres de l'hydrazine deux séries de bandes, correspondant aux modes de torsion interne et à ceux de libration autour de l'axe mineur de la molécule. Les deux doublets prévus en infrarouge se situent probablement à 650 cm^{-1} (492 cm^{-1} dans N_2D_4) et à 405 cm^{-1} (277/298 cm^{-1} dans N_2D_4). Les derniers ont été attribués par Baglin, Bush et Durig (24) au mode de torsion interne, à la suite d'une analyse vibrationnelle du solide. Ces auteurs ont également expliqué la bande forte à 650 cm^{-1} par une combinaison de celle à 405 cm^{-1} avec un mode de réseau. Il semble plus probable que les deux bandes fortes observées en infrarouge soient toutes deux des fondamentales, bien qu'il soit difficile de prévoir laquelle provient de la torsion interne. Dans le spectre Raman du solide, un des doublets prévus apparaît faiblement à 533/508 cm^{-1} (394/375 cm^{-1} dans N_2D_4), et l'autre n'a pas été localisé.

Les bandes de fréquences inférieures à 300 cm^{-1},

qui montrent un décalage isotopique variant entre 0.87 et 0.96, peuvent s'expliquer par des modes de translation et de libration autour des deux axes majeurs des molécules. Le spectre infrarouge s'explique assez bien selon le modèle favorisé ici (voir Tableau II). Les spectres Raman sont plus compliqués du fait que 6 modes de translation sont prévus (par comparaison avec trois seulement en infrarouge), en plus de quatre librations. On observe bien une dizaine de pics au-dessous de 300 cm^{-1}, mais les différences entre les rapports isotopiques observés et calculés indiquent que le couplage entre les divers modes de réseau est appréciable. La distinction entre modes de translation et libration, telle qu'établie dans le Tableau II, est donc très approximative.

Région des hautes fréquences

Le nombre de bandes observées dans la région de 700 à 3500 cm^{-1} des spectres Raman de N_2H_4 et N_2D_4 cristallins (Fig. 2) est de beaucoup supérieur à celui obtenu en infrarouge. Notre interprétation des spectres (Tableaux III et IV) est par ailleurs en bon accord avec celle des bandes infrarouges par Durig et ses collaborateurs (14). Cependant, l'attribution des bandes provenant des quatre modes faisant intervenir des déformations N—N—H est quelque peu incertaine à cause du couplage de certaines de ces vibrations avec celle de valence N—N. Cet effet, différent dans N_2H_4 et N_2D_4, explique certains décalages isotopiques différents de ceux prévus. Les rapports isotopiques des fréquences devraient être de l'ordre de 0.7 pour les vibrations de déformation N—N—H et de 0.9 environ pour la vibration de valence N—N. Expérimentalement, on trouve des valeurs de 0.63 à 0.85 dans le premier cas, alors que le décalage de la vibration de valence donne un rapport de 0.85. Le spectre de N_2D_4 est de plus compliqué par des bandes provenant de l'espèce isotopique N_2D_3H. Compte tenu de la teneur en hydrogène de l'échantillon (~3%), on peut estimer la concentration de cette impureté à environ 11%.

La région des hautes fréquences du spectre Raman de N_2H_4 cristallin est plus caractéristique que la région correspondante du spectre infrarouge en ce qui concerne la structure du solide.

†Intensité approximative basée sur la hauteur relative des pics dans le spectre Raman à −195 °C.

On observe en effet un dédoublement de la plupart des fondamentales, phénomène qui est particulièrement évident dans la région des modes de déformation H—N—H, où deux doublets sont présents, tant dans le spectre de N_2H_4 que dans celui de N_2D_4. Ce dédoublement des fondamentales est incompatible avec la structure déduite de l'étude par diffraction des rayons-X, pour laquelle une seule composante Raman est prédite pour chacune des fondamentales (Tableau I). La distinction entre la structure proposée à partir de la diffraction des neutrons et celle à quatre molécules par maille primitive proposée plus haut est cependant plus difficile. Dans le premier cas, et au contraire du second, il devrait y avoir coïncidence des fréquences des doublets prévus en infrarouge et observés en Raman. Une comparaison entre les fréquences des bandes infrarouges et celles des composantes Raman les plus proches (Tableaux III et IV) montre dans plusieurs cas des différences d'environ 6 cm^{-1}. Ces différences assez faibles, qui peuvent s'expliquer en partie par les imprécisions dans la mesure des fréquences, favorisent légèrement la structure à quatre molécules par maille, de préférence à celle obtenue par la diffraction des neutrons.

Dans le spectre de N_2D_4 cristallin, les vibrations de valence N—H des impuretés isotopiques N_2D_3H, pour la plupart isolées dans la matrice solide de N_2D_4, sont d'un intérêt tout particulier. On observe en effet quatre bandes (Fig. 2), situées entre 3244 et 3284 cm^{-1}. Le même phénomène se produit lorsqu'une petite quantité de N_2H_3D ($\sim 4\%$) est présente dans N_2H_4, alors que quatre bandes de valence N—D (à 2396, 2402, 2428 et 2431 cm^{-1}) apparaissent dans le

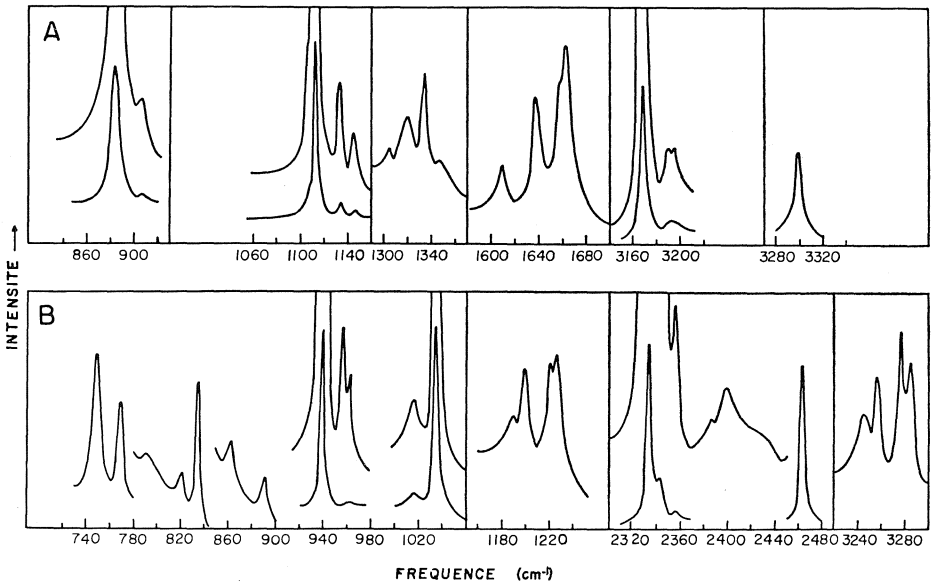

FIG. 2. Spectres Raman de N_2H_4 (A) et N_2D_4 (B) cristallins à -195 °C. Fente spectrale ≤ 3 cm^{-1}.

spectre Raman du solide. Ces pics ne sont donc pas dus à des harmoniques ou combinaisons, ou encore à un effet de couplage entre paires de molécules de l'impureté dans le cristal. On peut donc conclure que les quatre liaisons N—H (ou N—D) ne sont pas équivalentes dans le cristal, ce qui nécessite des sites de symétrie C_1. Cette observation est en contradiction avec la structure obtenue par diffraction des rayons-X (sites de symétrie C_s), mais elle ne permet pas de distinguer entre celle obtenue par diffraction des neutrons et celle que nous avons proposée plus haut. Dans l'hypothèse d'une structure où deux types d'isomères structuraux (présumément dans les configurations *gauche* et *trans*) seraient présents, on devrait attribuer deux des quatre bandes observées à chacun des isomères. Etant donné que les quatre composantes Raman ont des intensités assez semblables, il faudrait que les deux isomères existent dans des concentrations à peu près égales. Cela est assez improbable du point de vue énergétique et devrait conduire à une entropie résiduelle appréciable au zéro degré absolu ($\simeq R \ln 2 = 1.38$ u.e.).

Conclusion

L'analyse des spectres Raman de N_2H_4 et N_2D_4 cristallins, compte tenu des résultats précédemment obtenus en infrarouge, est incompatible avec les structures cristallines déduites des études par diffraction sur N_2H_4 solide. Il est cependant probable que les positions des atomes d'azote dans la maille cristalline, telles que déterminées par diffraction, sont essentiellement correctes. L'incompatibilité avec les résultats spectroscopiques est sans doute reliée à la configuration et à l'orientation des molécules dans le cristal. Une étude de la diffraction des neutrons sur N_2D_4 cristallin semble particulièrement indiquée en vue de résoudre ce problème.

Substituent effects on H—F couplings and additivity of these effects in a series of fluorobenzene derivatives

J. E. LOEMKER[1], K. M. PRYSE, J. M. READ, JR.[2], AND J. H. GOLDSTEIN
Chemistry Department, Emory University, Atlanta, Georgia

Received June 19, 1968

The nuclear magnetic resonance spectra of a series of monosubstituted fluorobenzenes have been recorded and analyzed, and the substituent effects on the H—F couplings have been determined by comparison with the corresponding H—F couplings in fluorobenzene. These substituent effects have then been successfully employed in calculating the H—F couplings for a series of di- and tri-substituted fluorobenzenes.

Canadian Journal of Chemistry, **47**, 209 (1969)

Introduction

The determination of substituent effects on the H—H couplings in benzene derivatives has recently been made possible as a result of accurate analyses of the nuclear magnetic resonance (n.m.r.) spectra of a series of monosubstituted benzenes (1) and of the ^{13}C—H satellite spectra of benzene itself (2). The additivity of these substituent effects has also been established in a series of 32 disubstituted benzenes (3–5). Other studies of the additivity of substituent effects have been reported for the meta H—H couplings in a series of unsymmetrical para-disubstituted benzenes (6) and for the H—H couplings in a series of ortho-substituted benzenes (7).

This paper describes an extension of the above studies to the H—F couplings in a series of fluorobenzene derivatives. The substituent effects have been determined here by analyzing the n.m.r. spectra of 12 monosubstituted fluorobenzenes (C_6H_4FX with X = F, Cl, Br, and NO_2) and comparing the H—F couplings obtained with the corresponding values in fluorobenzene itself (8).

Finally, the spectra of a series of 9 di- and tri-substituted fluorobenzenes were analyzed and it was found that the H—F couplings in these compounds could be estimated approximately from the previous substituent effects and the assumption of additivity.

Experimental and Calculations

All of the compounds studied were the commercially available materials, of sufficient purity as indicated by their n.m.r. spectra. In order to insure maximum reliability, all compounds were examined in the same solvent, acetone, at approximately the same concentration, 10 mole %. For the monosubstituted fluorobenzenes, the proton spectra, with one exception, were obtained at 60 MHz on a Varian A60-A spectrometer. For *p*-difluorobenzene, the proton spectrum was examined at 100 MHz and the fluorine spectrum at 94.077 MHz using a Varian HA-100. For the di- and tri-substituted fluorobenzenes, the majority of the proton spectra were obtained at 60 MHz, but in some instances, the proton spectra were obtained at 100 MHz, and the fluorine spectra at 94.077 MHz.

The calibrated frequencies were the averages of at least four spectra (two forward and two reverse sweeps) in each case, and the average deviations of the measured frequencies were approximately 0.05 Hz. All of the analyses were carried out by an iterative least-squares computer routine. The agreement between the calculated and observed spectra was 0.04 Hz or better in all cases, and the estimated reliability of the coupling parameters was within 0.05 Hz. The coupling parameters obtained are summarized in Table I (the chemical shift data have been omitted to conserve space), with the substituent effects on the H—F couplings shown in parentheses. These substituent effects are calculated using the fluorobenzene values $J_o^{HF} = 9.31$, $J_m^{HF} = 5.79$, and $J_p^{HF} = 0.34$ Hz, obtained from the 10 mole % solution of fluorobenzene in acetone. It should be noted that the para H—F couplings, unlike those of the protons, have previously been observed to have either sign relative to the ortho and meta couplings. The latter two have been shown to be of the same sign (9–13).

Table II contains the H—H, H—F, and F—F coupling parameters obtained from the analyses of the spectra for the di- and tri-substituted fluorobenzenes (again the chemical shifts have been omitted to conserve space). The corresponding additivity calculated H—F couplings are shown in parentheses, and the corresponding meta and para F—F couplings calculated from the substituent effects of Abraham *et al.* (14) are shown in square brackets.

As an example of the quality of these analyses, the observed and calculated proton spectra for 1,2,4-trifluorobenzene at 100 MHz are shown in Fig. 1.

Discussion

It is interesting to note that the ranges of the H—F couplings for the compounds studied are significantly greater than those for the H—H couplings, especially those for which long-range effects are observed. For example, the substituent effects on the para H—H couplings in the monosubstituted benzenes are all approximately −0.20 Hz (3), while those on the para H—F couplings range from −0.81 to −1.65 Hz.

Additivity of substituent effects has previously been noted for H—H couplings (3, 6, 7) and the meta and para F—F couplings (14). Hence it is worthwhile to consider whether the substituent effects on H—F couplings obtained in this study (shown in Table I) are additive in aromatic systems. These additivity calculated H—F couplings are collected in Table II.

For the H—H couplings, the largest deviation between the observed and calculated couplings was approximately 0.25 Hz, the greatest range in the observed couplings being approximately 1.3 Hz (3). For the H—F couplings given in Table II, the largest deviation between observed and calculated values is 0.50 Hz, but in most cases the deviation is considerably smaller. Since the range of substituent effects for H—F couplings is 2.4 Hz, it is apparent that the assumption of additivity is approximately as valid, on a relative basis, for the H—F couplings as for the H—H couplings. It should be mentioned that the availability of initial predicted values of the couplings based on the assumption of additivity was found to be a considerable aid in the analyses of these spectra.

The analyses of two of these compounds have been described previously, 1,5-dinitro-2,4-difluorobenzene (15, 16) and 2,4-dinitrofluorobenzene (16–18). However, the coupling values in the former studies were only reported to 0.1 Hz, at best, and are of insufficient precision for our purposes.

As has been previously noted, the H—F couplings may be subject to significant solvent effects (8, 19). An effort has been made here to minimize this source of error by the use of a uniform and relatively dilute concentration in the single solvent, acetone, chosen because some of the compounds were not sufficiently soluble in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the more inert solvents. However, some small residual uncertainty from this source may still remain.

It is felt that the regularities which have been observed here merit further study, both as a practical aid in spectral analysis and as a possible source of further insight into the mechanism whereby substituent effects operate. A linear correlation of H—F couplings with the Pauling electronegativity of the substituent in a series of monohalosubstituted fluorobenzenes has recently been observed (5). There appears to be a similar qualitative trend in the results presented here, but, in spite of the considerable amount of data obtained, the series is too limited to justify efforts toward either empirical correlations or theoretical interpretations of the substituent effects. Further studies of related compounds, however, should provide a basis for investigating these interesting questions.

Hydrogenation of methylacetylene. IV. The reaction of methylacetylene with hydrogen catalyzed by palladium, platinum, iridium, rhodium, and ruthenium catalysts[1]

R. S. Mann and K. C. Khulbe
Department of Chemical Engineering, University of Ottawa, Ottawa 2, Canada

Received June 18, 1968

The reaction between methylacetylene and hydrogen over pumice supported and unsupported palladium, platinum, iridium, rhodium, and ruthenium catalysts has been investigated between 12 and 160 °C for a wide range of reactant ratios. The order of reaction with respect to hydrogen was one and with respect to methylacetylene was zero to slightly negative. The overall apparent activation energies for supported and unsupported palladium, platinum, iridium, and rhodium were 10.5, 9.5, 12.4, 14.7, 8.6, 6.2, 10.7, and 11.7 kcal/mole respectively.

Canadian Journal of Chemistry, **47**, 215 (1969)

Introduction

In Parts I, II, and III of this series, we have reported the kinetics and products obtained from the reaction of methylacetylene with hydrogen catalyzed by pumice supported nickel (1), unsupported nickel, cobalt, and iron (2), and nickel, copper, and their alloys (3). In this concluding paper of the series, we report the reaction of methylacetylene with hydrogen catalyzed by palladium, platinum, iridium, rhodium, ruthenium, and osmium.

Experimental

The apparatus, materials, experimental procedure, and method of analysis of the products have been described previously (2). The catalysts were prepared by impregnating and evaporating the solution containing the calculated weight of Analar grade chemicals in the presence of pumice. The unsupported catalysts were prepared by evaporating the solutions. The palladium, platinum, iridium, rhodium, ruthenium, and osmium metal catalysts were prepared from $(NH_4)_2PdCl_6$, $PtCl_4$, $(NH_4)_2IrCl_6$, $RhCl_3.3H_2O$, $(NH_4)_2RuCl_6$, and $(NH_4)_2OsCl_6$, respectively.

Results

Supported and unsupported platinum, palladium, iridium, and rhodium catalysts were found to be quite active and did not get poisoned when methylacetylene or hydrogen was admitted first into the reactor. The activity remained fairly constant for several days. Ruthenium was found to be active at the beginning, and lost its activity after a few runs. Osmium catalysts showed no noticeable activity up to 200 °C.

[1]Based on the paper presented at the 51st Annual Meeting, Chemical Institute of Canada, Physical Chemistry Division, Vancouver, B.C., June 2–5, 1968.

(a) Reaction Rates

The pressure time curves obtained during methylacetylene hydrogenation (Fig. 1) over pumice supported and unsupported palladium, platinum, rhodium, and iridium catalysts, consisted of two nearly linear portions (curve AFG, Type I, Fig. 1) of different slopes for hydrogen/methylacetylene ratios ($\bar{R}$) of less than 2 at all temperatures. For hydrogen/methylacetylene ratios of 2 or more, pressure–time curve AMN (Type III, Fig. 1) was obtained for unsupported

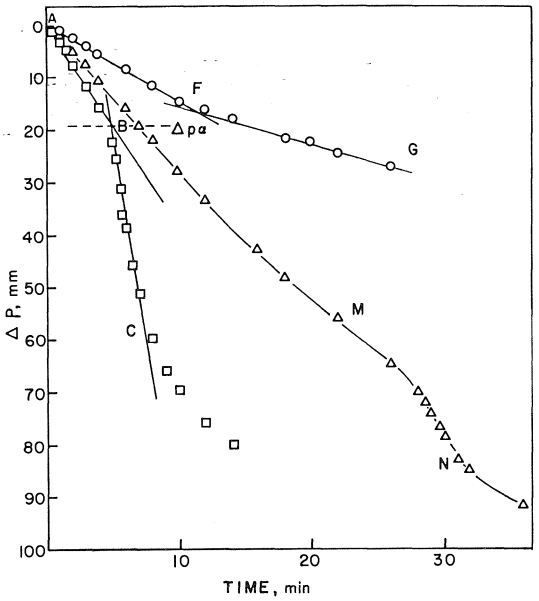

FIG. 1. Pressure–time curves. Curve ABC: Pd–pumice, $P_{C_3H_4} = 50$ mm, $P_{H_2} = 104$ mm. Curve AFG: Ir–pumice, $P_{C_3H_4} = P_{H_2} = 50$ mm, $T = 24$ °C. Curve AMN: Ir–pumice, $P_{C_3H_4} = P_{H_2} = 50$ mm, $T = 55$ °C.

TABLE I

Order of reaction and activation energies

Catalyst	Weight of catalyst (g)	Temperature range (°C)	Order with respect to hydrogen	Order with respect to methylacetylene	k, specific rate at 60 °C (min^{-1} g^{-1})	Energy of activation (kcal/mole)

*k at 40 °C.

platinum, palladium, and supported and unsupported iridium and rhodium. In the case of platinum–pumice, while for a hydrogen/methylacetylene ratio of 2, the rate of pressure fall during the course of reaction was nearly constant till nearly all the methylacetylene had reacted (curve AB), a different type of curve (curve ABC, Type II, Fig. 1) was obtained for a hydrogen/methylacetylene ratio greater than 2. Similar results were obtained for palladium–pumice catalysts, except that the acceleration was observed for all hydrogen/methylacetylene ratios greater than 1.5. Similar curves were observed by Bond and Wells (4) for acetylene hydrogenation over platinum and by Tamaru (5). In the region AB, the reaction was first order with respect to hydrogen and the main product was propylene, whereas after the rapid acceleration (BC region) the main process was the further hydrogenation of propylene to propane.

The acceleration point ($-\Delta p_\alpha$), defined as the pressure obtained by the intersection of the linear portions of the first and second stages of the reaction (Fig. 1) was observed while hydrogenating methylacetylene over pumice supported platinum ($\bar{R} > 2$) and palladium–pumice ($\bar{R} > 1.5$). No such acceleration was observed over other catalysts. The acceleration point was dependent on temperature and initial hydrogen pressure. It decreased fairly linearly with increasing temperatures and hydrogen pressures.

Since methylacetylene is more strongly adsorbed than propylene or hydrogen, an increase in the initial pressure of propylene or hydrogen would facilitate the entry of propylene into the reactive layer and further the hydrogenation of propylene to propane. This would result in an acceleration of the reaction.

Orders in hydrogen were determined from the initial rates at a fixed methylacetylene pressure of 30 mm and a wide range of hydrogen pressures (25–200 mm). Orders in methylacetylene were obtained similarly at a fixed hydrogen pressure of 60 mm and a wide range of methylacetylene pressures, 30–150 mm. The results are given in Table I. The order with respect to hydrogen was always about 1, and did not depend on temperature for all catalysts, except palladium, for which it was greater than 1. The order of reaction with respect to methylacetylene for iridium powder, and supported and unsupported rhodium was zero and temperature independent. In other cases, it varied between zero and slightly negative values (specially at $P_{C_3H_4} > 100$ mm) and was temperature dependent.

Rate coefficients, k, per gram of the metal were obtained from initial rate measurement for reactions of 30 mm methylacetylene with 25–200 mm of hydrogen between 12 and 150 °C. Plots of $\log_{10}$ (rate coefficients) against absolute temperature were very good straight lines over a wide range of temperatures. The derived apparent activation energy for the catalyst investigated is given in Table I.

(b) Selectivity

The course of reaction (50 mm methylacetylene and 50 mm hydrogen) was followed by analyzing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

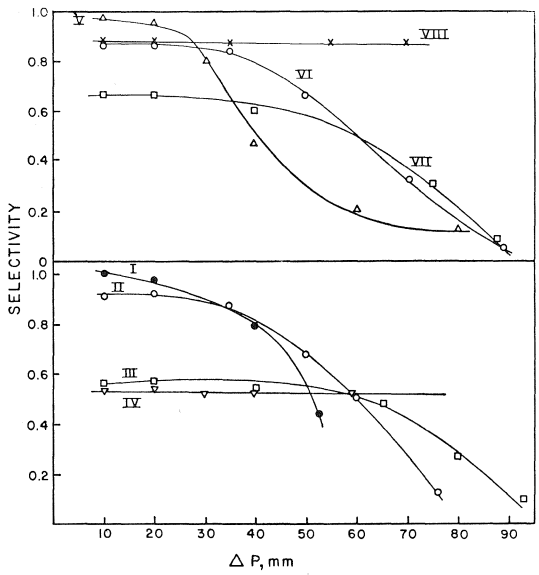

FIG. 2. Dependence of selectivity on pressure fall: $P_{C_3H_4}$ = 50 mm, P_{H_2} = 150 mm. I, Pd powder, T = 110 °C; II, Pt powder, T = 110 °C; III, Ir powder, T = 55 °C; IV, Rh powder, T = 93 °C; V, Pd–pumice, P_{H_2} = 104 mm, T = 24 °C; VI, Pt–pumice, T = 85 °C; VII, Ir–pumice, T = 115 °C; VIII, Rh–pumice, P_{H_2} = 155 mm, T = 55 °C.

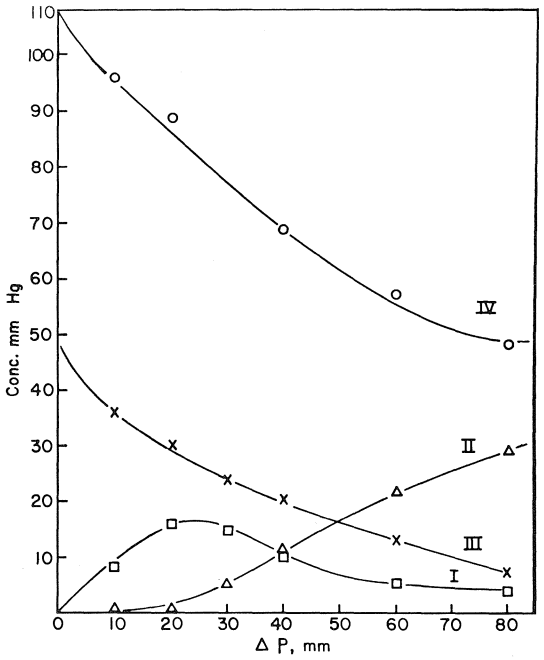

FIG. 3. Course of reaction over Pd–pumice: $P_{C_3H_4}$ = 50 mm, P_{H_2} = 104.5 mm, T = 24 °C.

the reaction products after various falls in pressure, and the selectivity, S, defined as the ratio of propylene to propylene plus propane, was determined. The selectivity was independent of pressure fall for all catalysts, except iridium, in which case it decreased with increasing pressure falls. A similar effect was observed in iron powder catalyst.

The selectivity decreased with increasing pressure falls for hydrogen/methylacetylene ratios greater than 2 for all catalysts except palladium ($\bar{R} > 1.5$). Figure 2 shows the dependence of selectivity on pressure fall. The distribution of products and unreacted hydrogen and methylacetylene at different pressure falls during the course of reaction for palladium–pumice catalyst is shown in Fig. 3. Similar results were obtained for all catalysts at hydrogen/methylacetylene ratios greater than 2.

Measurements were made of selectivity of the catalyst as a function of initial hydrogen pressure at several temperatures by using a fixed methylacetylene pressure of 50 mm and varying the hydrogen pressure. Products were analyzed when the total pressure fall was equal to 20 mm. The results are shown in Figs. 4 *a* and *b*. The selectivity of rhodium was nearly independent of initial hydrogen pressure. Similar results were observed earlier (2) for unsupported nickel and iron. For other catalysts, the selectivity was nearly constant up to a certain hydrogen/methylacetylene ratio, whereafter it decreased rapidly with increased initial hydrogen pressures. The decrease in selectivity with increased hydrogen pressures was fairly linear for supported iridium.

No significant variation in selectivity was observed with initial methylacetylene pressures (45–150 mm) for a fixed initial hydrogen pressure (60 mm).

The temperature dependence of selectivity was studied for an equimolal mixture of reactants (50 mm each). The products were analyzed at several temperatures for a total pressure fall of 20 mm. The results are summarized in Fig. 5. Selectivity was independent of temperature for all catalysts except unsupported iridium and supported platinum for which it increased with increasing temperatures. Polymerization was maximum over ruthenium and palladium and least over platinum catalysts (Table II).

Discussion

Bond and Sheridan (7) studied the kinetics of methylacetylene hydrogenation over pumice supported platinum, nickel, and palladium catalysts. A comparison of our results for platinum and palladium catalysts with those of Bond and Sheridan is given in Table III.

In the present investigations, for hydrogen/methylacetylene ratios of 2 or less, a Type I curve (curve AFG, Fig. 1) was always observed for all catalysts that were investigated. However, for hydrogen/methylacetylene ratios greater than

2, a Type III (curve AMN) was obtained for all catalysts, except pumice supported platinum and palladium. There was a slight acceleration at the end of the reaction in all cases. These curves were similar to those obtained by Bond (8) in acetylene hydrogenation over nickel for hydrogen/acetylene ratios greater than 2. In the case of pumice supported platinum and palladium, for hydrogen/methylacetylene ratios greater than 2, a different curve (curve ABC, Fig. 1) was obtained. This was similar to those observed by Bond and Wells (4, 6) for acetylene hydrogenation over alumina supported platinum and palladium, by Tamaru (5) over palladium–alumina, by Farkas and Farkas (10) over platinum, and by Cremer, Knorr, and Plieninger (11) over palladium; Mann and Khulbe (3) observed such curves in methylacetylene hydrogenation over nickel–copper alloys.

In the first stage of the reaction, the main product was propylene, whereas in the rapid acceleration (BC region) period, the main process occurring was the further hydrogenation of propylene to propane.

The differences in the shape of pressure–time curves observed by Bond (8) for acetylene hydrogenation over nickel, and by us for methylacetylene hydrogenation at hydrogen/methylacetylene ratios less than 2 may be due to (*a*) difference in the method of preparation and subsequent activation of catalyst, (*b*) use of methylacetylene pretreated catalysts, and (*c*) different comparative surface coverage by the reactants.

The metals can be placed in the following sequence of decreasing selectivity (Table II).

[*i*] supported Pd > Rh > Pt > Ru > Ir ≫ Os

[*ii*] unsupported Pd > Pt > Ru > Ir > Rh ≫ Os

The order of sequence [*i*] confirms the order of selectivities derived from the literature. It is important to note that the selectivity exhibited is primarily a function of the metal and is substantially independent of the hydrocarbon undergoing reaction and of the condition under which the reaction was carried out. In sequence [*ii*] only rhodium shows dissimilarity with [*i*]. It is pertinent to note that in the case of rhodium no significant change in the selectivity with the increase of initial hydrogen pressure was observed (Figs. 4 *a* and *b*). Rhodium has a different electronic structure to platinum, palladium, or nickel. It has 9 electrons ($4d^85s^1$) outside a closed krypton core, whereas platinum, palladium, and nickel have 10 outer electrons. The effect of support on the selectivity is very large (90%) in the case of rhodium as compared to other transition metals investigated (Table II).

The observed activity pattern per g of metal (Table I) is

[*iii*] supported metals
Pd > Ir > Rh > Pt > Ru > Os

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[*iv*] unsupported metals
Pd > Ir > Pt > Rh > Ru > Os

Thus if the activity for methylacetylene hydrogenation was the only factor governing selectivity, the observed order of selectivity would be

[*v*] supported metals
Ru > Pt > Rh > Ir > Pd

[*vi*] unsupported metals
Ru > Pt > Rh > Ir > Pd

The differences in the selectivity sequence of the metals, based primarily on the analysis of products [*i*] and [*ii*], and based on the activity [*v*] and [*vi*] is due to the strong adsorption of methylacetylene on the surface of the metals, as compared to propylene, which is formed as a reaction product. The surface of the catalyst is almost covered with methylacetylene and propylene formed in the reaction is displaced from the surface.

Under these conditions, readsorption of propylene from the gas phase cannot occur (shown by the independence of selectivity during the course of reaction at equimolal amounts of reactants); hence the reduction in the rate of formation of propane. In the early stages of the reaction, the formation of propane is due to the hydrogenation of the adsorbed propylene formed on the surface from methylacetylene and not by readsorption of propylene from the gaseous phase. It is considered that the selective hydrogenation may be due to the difference in the adsorbability of methylacetylene and propylene on the catalyst surface and not to the differences in the velocity of the hydrogenation reaction.

Bond and Sheridan (7) did not study the effect of temperature on the yields of propylene to propane. Selectivity was found to be independent of temperature for all catalysts except unsupported iridium and supported platinum. In the present investigation, the general characteristic and the products were found to be similar to those of Bond and Sheridan. However, the extent of polymerization in our case was much less. The small amount of polymerization and much lower activation energy is attributed to the method of preparation and activation of the catalyst.

The reaction of methylacetylene and hydrogen over the catalysts investigated were all pseudo first order reactions, A→B→C (Fig. 3). The negative or zero order in methylacetylene and positive order in hydrogen shows that the former was the more strongly adsorbed reactant, and that the surface coverage was high, whereas hydrogen was weakly adsorbed by comparison and its surface coverage was correspondingly low.

Since the general characteristics of the hydrogen–methylacetylene reaction over the metal catalysts investigated is the same, the mechanism of the reaction over these metals could be assumed to be the same. The following mechanism is postulated for the hydrogenation of methylacetylene, based on the mechanism of ethylacetylene hydrogenation (12)

[1] $H_3C-C\equiv CH + 2(*) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} H_3C-\underset{*}{C}=\underset{*}{CH}$

[2] $H_2 + 2(*) \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \underset{*}{H} + \underset{*}{H}$

[3] $H_3C-\underset{*}{C}=\underset{*}{CH} + \underset{*}{H} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} H_3C-\underset{*}{C}=CH_2 + 2(*)$

and

[4] $H_3C-\underset{*}{C}=CH_2 + \underset{*}{H} \xrightarrow{k_4} H_3C-CH=CH_2 + 2(*)$

Step [4] is not considered as reversible, since propylene produced in the gas phase did not readsorb due to the presence of strongly adsorbed methylacetylene, usually in much excess. Any adsorbed propylene so formed would be rapidly displaced from the surface by adsorbing methylacetylene or form a radical with active site

$$(CH_3-\dot{\underset{*}{C}}-\underset{*}{CH_2})$$

for further hydrogenation. Consequently, equating the rates of formation and removal of half hydrogenated state (C_3H_5) the rate of propylene formation is

$$\frac{dP_{C_3H_6}}{dt} = \frac{(k_4\theta_H)(k_3\theta_H)(\theta_{C_3H_4})}{k_4\theta_H + k_{-3}[*]^2}$$

The value of $\theta_{C_3H_4}$ (fractional surface covered by C_3H_4) is generally very high and approaches 1. Now if $k_4\theta_H \gg k_{-3}[*]^2$, then the reaction would be first order in hydrogen pressure. Hence, the observed order of 1 with respect to hydrogen is understandable. A slightly different mechanism may be possible in the case of palladium, where

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the order with respect to hydrogen was slightly greater than 1.

A negative order with respect to hydrocarbons has been reported by Farkas and Farkas (10), and by Bond and Sheridan (7) for platinum catalysts in the hydrogenation of acetylene and methylacetylene respectively. Bond and Wells (4, 6) also observed a negative value of the order with respect to acetylene over alumina supported platinum and palladium. The observed negative order in methylacetylene may be due to the fact that at higher pressures, the molecules form a more ordered array on the surface, thus reducing the number of vacant sites, and therefore reduce hydrogen adsorption by eq. [3]. Alternately, an increase in methylacetylene pressure may enable it to compete more effectively with hydrogen for the surface.

The order with respect to methylacetylene was temperature dependent in the case of supported and unsupported platinum, palladium, and supported iridium. Similar results were obtained by Bond and Wells in acetylene hydrogenation over alumina supported palladium. An increase in temperature would decrease the amounts of reactants on the surface. Since methylacetylene is generally more strongly adsorbed on the surface than hydrogen, it is possible that with increasing temperature, the desorption of methylacetylene would be less than hydrogen, resulting in decreased hydrogen/methylacetylene ratios on the surface. Hence, the order of the reaction with respect to methylacetylene becomes more negative with increased temperature.

Application of interferometry to reaction kinetics: hydrolysis of ethyl acetate

R. N. O'Brien and A. Glasel
Department of Chemistry, University of Victoria, Victoria, British Columbia
Received June 5, 1968

The use of multiple-beam interferometry has been extended to the study of the kinetics of the hydrolysis of ethyl acetate in acid solution. The rate of change of refractive index in the reacting solution is shown to be directly proportional to the disappearance of the reactants and the appearance of products. The rate of movement of fringes on a wedge interferometer was measured with a photomultiplier tube by recording the response of the tube on passage of a bright fringe. A continuous uniphase output gas laser was used as a light source. Extremely small refractive index changes, hence very small concentration changes, can be detected. Design characteristics of the cell are discussed.

Recently, multiple-beam interferometry has been applied by O'Brien and co-authors to the investigation of single-ion diffusion constants (1), concentration gradients at working electrodes (2), gases diffusing into liquids, and thermal conductivity (3). The hydrodynamic shear zone and diffusion layer at the rotating disc electrode (4), as well as the electrodialysis of sea water (5), have been studied interferometrically. The availability of the single mode output, continuous gas laser permits long path, wedge interferometers to be designed with the possibility of both great accuracy and great precision in measuring refractive index changes during chemical reactions. Reaction streams in commercial chemical processes have been monitored by refractometers placed in side-streams, but it is believed that this is the first time the whole reaction vessel has been used as an interferometer to measure reaction rates.

The reaction studied was the hydrolysis of ethyl acetate in HCl solution. A simple rugged optical system is presented requiring negligible optical manipulative skill and using only readily available components.

Since refractive index changes which are directly proportional to reaction progress are instantaneously recorded and very small changes can be detected, the system should be applicable to fast reactions, reactions better studied in dilute solutions, and those where spectrophotometry gives ambiguous results.

Experimental Arrangements and Theory

The reaction vessel, which also serves the dual purpose of an interferometer, consists of a teflon cyclinder bounded on each side by $1\frac{1}{2}$ in. diameter and $\frac{1}{4}$ in. thick $\lambda/4$ flat glass discs with high efficiency dichroic coating mirrors[1] on the solution side. These partially reflecting mirrors were pressed tightly against the teflon cylinder by a set of three knurled knobs on threaded pins to seal the cell and to generate a wedge for the formation of the fringe system. The teflon cylinder wall had two openings. Into one a sleeve was fitted for a vibrationless mechanical stirrer which consisted of a $\frac{1}{8}$ in. diameter teflon screw. Here the stirrer is considered vibrationless when the vibrations are sufficiently small that the wedge is not distorted, and ensure that the fringe system is not susceptible to random movement. This was readily accomplished by isolating the motor from the cell, securing the sleeve of the stirrer in a rigid brass cell holder, and by mounting a vibration absorbing spring, maintaining a slight pressure on the stirrer shaft (Fig. 1) on the cell holder. The efficiency of the stirrer was determined from the time (5 s) at which fringe perturbations were eliminated after additions to the cell. The other opening was fitted with a teflon tube for injecting solution into the cell. The volume of the cell was about 8.0 ml. The cell body was securely mounted in a heavy brass support resting on a tripod, which could be moved to adjust the angular relationships between the laser beam and the mirror plane. Figure 2 shows the cell details.

A He–Ne C. W. model 130 B Spectra–Physics gas laser[2] having an output of 1 mW in the T_{00} mode was used to provide a monochromatic and collimated beam. The laser beam

[1]These flats were obtained from the Libby-Owens-Ford Export Company.
[2]This laser may be obtained from Allan Crawford Associates Ltd.

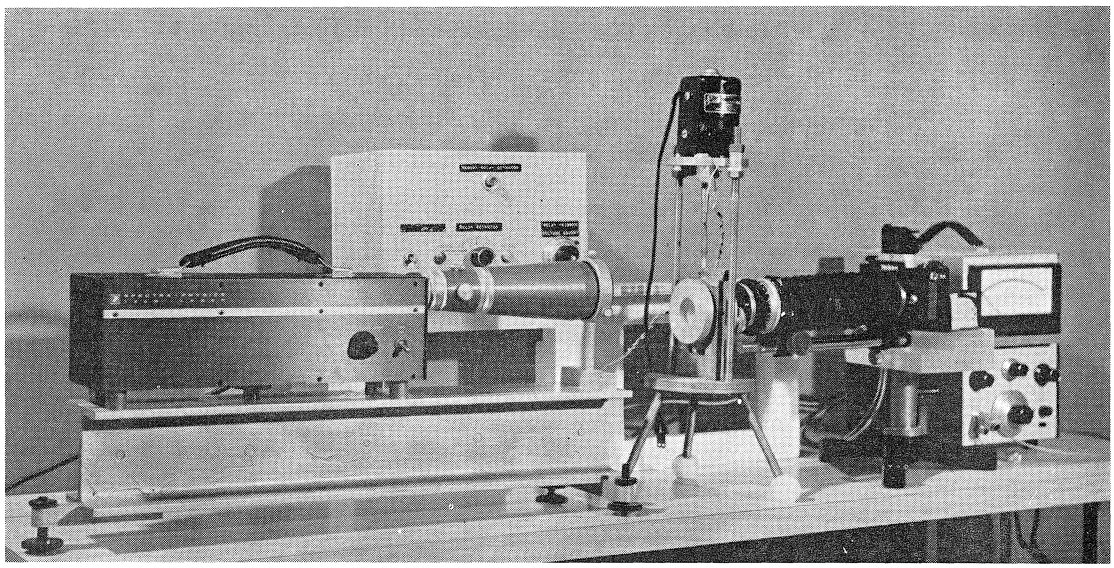

FIG. 1. Photograph showing apparatus arrangement.

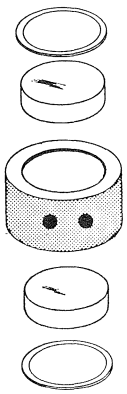

FIG. 2. An exploded view of the interferometric cell.

was passed through a Spectra–Physics spatial filter (model 332) and beam expanding telescope (model 331). The resulting beam was 50 mm in diameter with a smooth Gaussian intensity distribution. The laser system was aligned so that the beam struck the mirror plane at an angle closely approximating 90°. The two mirrors in the interferometer were both 70% reflecting in air at 6328 Å. The ratio of intensity between the bright transmission fringes and dark regions, I_{max}/I_{min}, was about 32/1, and intensity at half fringe width was about 1/9. The cell thickness was 9.57 mm. The wedge thickness, which is a distortion of the thickness of the teflon cylinder, is negligible compared to the thickness of the cell, and of the order of 0.01 mm to give about 2 fringes/mm.

A Nikon F camera (F/1.4, 50 mm) with a bellows focussing attachment provided a magnification of up to 3.5 of the interference cell. The camera was fitted with a viewfinder to allow visual examination of the fringe system for adjustment. The camera back was removed and an $RCAI_p$ 28 photomultiplier tube mounted in a box was placed behind the camera. The opening toward the photocell consisted of a pinhole in a cone having a diameter of 1.0 mm at the apex. A diffusing element consisting of a 1 cm square piece of glass frosted on one side was placed behind the pinhole facing the photomultiplier tube. After magnification of the cell by the camera, the size of the pinhole was about 1/3 to 1/5 of the fringe separation. To prevent stray light from entering the photocell compartment, a No. 24 Wratten filter (pass band 5900 $\rightarrow$; dominant λ = 6106) was placed in front of the camera. Figure 3 shows the optical path.

The electrical circuit consists of a power supply for the photomultiplier tube, a 610 A Keithly Electrometer, and a 1508 Honeywell visicorder.

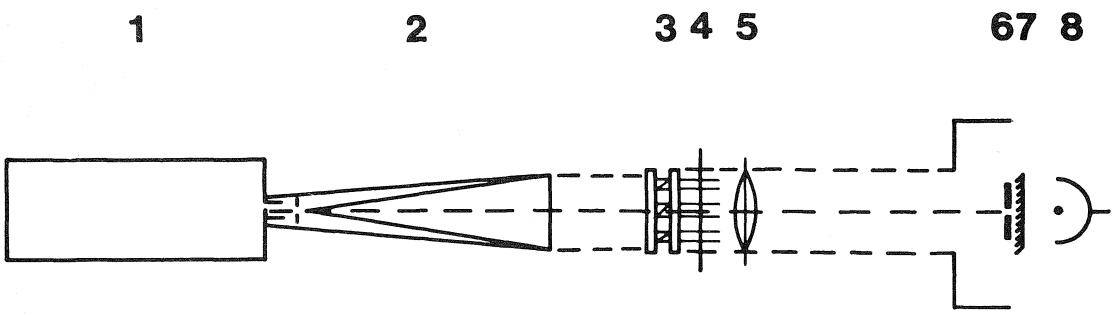

FIG. 3. Schematic diagram of light path showing: 1, He–Ne C. W. laser; 2, spatial filter and beam expanding telescope; 3, interferometer; 4, filter; 5, camera with bellows; 6, pinhole; 7, diffusing element; and 8, photomultiplier cell.

fringes when the wavefront falls on the interferometer at an angle of incidence very close to zero is given by

$$n\lambda = 2\mu d$$

where n = order of interference, λ = wavelength of light (cm), μ = refractive index, and d = thickness of cell (cm).

The relationship between refractive index change and fringe movement can be determined by noting that since d = constant for any fringe, a change in d, Δd, causes a corresponding movement of the fringe along the wedge, i.e. a change in d, Δd. The analytical expression for a movement equal to the fringe spacing is

$$\Delta d\mu + \Delta\mu d + \Delta\mu\Delta d = \frac{\lambda}{2}$$

This relationship can also be obtained by noting that the optical path length difference between successive bright fringes — or between two positions, separated by a fringe spacing, which the fringe may occupy as it moves along the wedge — is $\lambda/2$, i.e.

$$(\mu + \Delta\mu)(d + \Delta d) - \mu d = \frac{\lambda}{2}$$

This expression can be rearranged to:

$$\Delta\mu(d + \Delta d) + \Delta d\mu = \frac{\lambda}{2}$$

Since $\frac{\Delta d}{d}$ can be considered negligible for the interferometer under consideration,

$$\Delta\mu = \pm\frac{\lambda}{2d}$$

For the general case, the fringe is displaced from its reference position by the optical path length difference $F\lambda/2$ where F is the fraction of an order of displacement and may have any value, $|F| \geq 0$, giving

$$\Delta\mu = \pm F\frac{\lambda}{2d}$$

For each successive integral value of F ($F = 1, 2, 3, \cdots, N$) a refractive index change of $\lambda/2d$ displaces the fringe pattern by the fringe spacing distance. The photomultiplier tube reacting to the intensity distribution between the light and dark fringes produces a variation in voltage output with the movement of the fringe system. As a bright fringe goes past the tube, the output reaches a sharp maximum, then declines; the output is recorded on a fast recorder.

The change in refractive index occurring during the reaction is related to the change in concentration of chemical species present, the reaction being

$$\mathrm{EtAc} + \mathrm{H_2O} \xrightarrow{\mathrm{H^+}} \mathrm{HAc} + \mathrm{EtOH}$$

If the bulk refractive index at a time t_1 is given by μ_1 and the reaction is allowed to progress to time t_2, described by a bulk refractive index of μ_2, then

$$\mu_2 - \mu_1 = \Delta\mu = \sum_i \Delta\mu_i$$

where $\Delta\mu_i$ is the refractive index change for one of the participating species.

During the reaction, the refractive index change for the ethyl acetate is negative, and for HAc and EtOH positive. The refractive index change for water is assumed to be zero.

The $\Delta\mu$ (EtAc), $\Delta\mu$ (HAc), $\Delta\mu$ (EtOH) are obtained by plotting μ vs. concentration of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ethyl acetate, and vs. concentration of EtAc in HCl solutions with the reaction having gone to completion.

Since the refractive index plots of both reactants and products are linear with concentration and follow the general pattern $\mu = \mu^0 + mc$

$$\Delta\mu = \Delta m_i \Delta c_i$$

where m_i is the slope of the plot of μ vs. concentration for one species, and Δc_i the corresponding concentration change. The value μ^0 corresponds to the acid solution and is constant.

For the ethyl acetate reaction, the change of refractive index is then

$$\Delta\mu = (m_2 - m_1)\,\Delta c$$

where m_2 is the slope of products' refractive index plot, m_1 is the slope of reactants' refractive index plot, and Δc, the concentration change per fringe shift, given by

$$\Delta c = \frac{1}{(m_2 - m_1)} \frac{\lambda}{2d}$$

For every concentration change corresponding to Δc, a peak will be recorded, and the distance between the peaks gives a direct display of the rate of disappearance of reactants and formation of products.

Results

Plots of refractive index for ethyl acetate and the products of EtAc vs. concentration are given in Fig. 4 and the values of the slopes in Table I. The last column gives the corresponding calculated concentration change of EtAc per fringe shift. The product slope was obtained by addition of the EtOH and HAc slopes.

Since the rate of change of concentration for reactants and products is given by

$$\Delta c_1 \approx \frac{\Delta\mu_1}{m_1} = -ake^{-kt}\Delta t$$

and

$$\Delta c_2 \approx \frac{\Delta\mu_2}{m_2} = -ake^{-kt}\Delta t$$

the relationship for the total refractive index change is then

$$\frac{\Delta\mu_{\text{total}}}{\Delta t} = ak(m_1 - m_2)e^{-kt}$$

or

$$\log t = -\log\left[\frac{ak(m_1 - m_2)}{\Delta\mu}\right] + \frac{kt}{2.303}$$

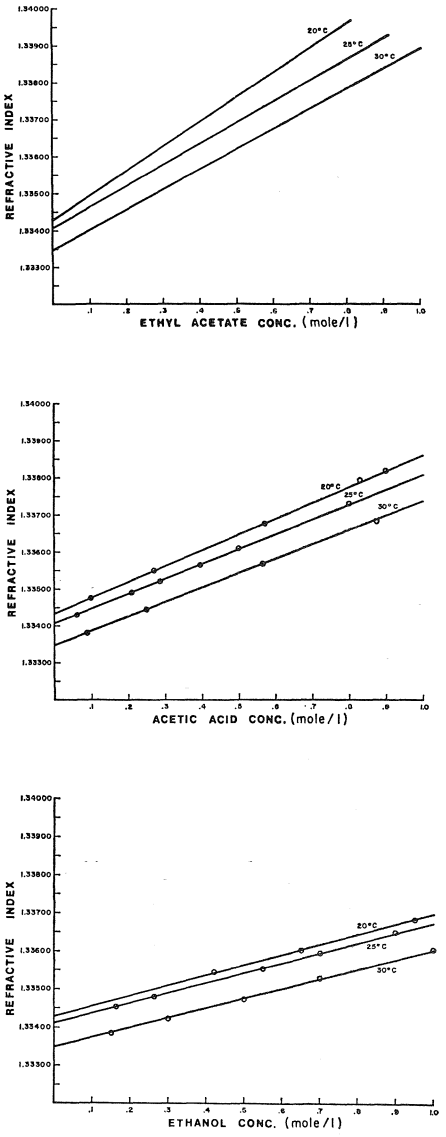

FIG. 4. Plots of refractive index versus concentration for several temperatures.

Since $\Delta\mu = \dfrac{\lambda}{2d}$

$$\log \Delta t = -\log\left[\frac{ak(m_1 - m_2)2d}{\lambda}\right] + \frac{kt}{2.303}$$

The slope of the plot of $\log \Delta t$ vs. time gives the value $k/2.303$.

Reactions were carried out at various HCl concentrations. Table II gives the results of

TABLE I

Refractive index slopes

Temperature (°C)	m_1 (EtAc slope)	m_2 (products)	Δc EtAc/fringe shift
20	6.70×10^{-3}	7.01×10^{-3}	10.68×10^{-2}
25	5.71×10^{-3}	6.67×10^{-3}	3.62×10^{-2}
30	5.50×10^{-3}	6.70×10^{-3}	2.77×10^{-2}

some of these runs. A comparative literature value is given in the last column.

The variations in the rate constants are thought to be due to experimental errors such as the uncertainty of volume injected and thermostating, rather than in the interferometric method. The temperature was checked with a thermocouple inserted into the interferometric cell and the temperature variation was found to be less than 0.5 °C throughout the run (i.e. a variation of less than 4% in rate). It should, however, be readily possible to incorporate thermostating features into the interferometric cell permitting precise temperature control. Other design features, such as volume of cell, wedge angle, etc., will require alteration depending upon the system to be studied.

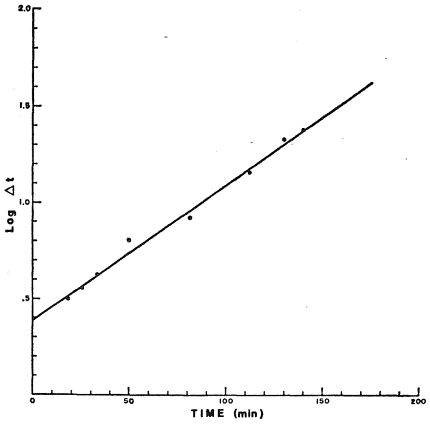

FIG. 5. Plot of log Δt versus time for $a = 0.1157$ moles/l, HCl concentration = 2.435 N, $T = 24$ °C.

From the intercept, Δc may be calculated. These values were found to differ somewhat from the independently determined value of Δc from refractive index measurements. In Fig. 5 ($k = 1660 \times 10^{-5}$ min^{-1}, $a = 0.1157$ moles/l, $T = 24$ °C) from the intercept value of 0.38

$$m_2 - m_1 = \frac{\lambda}{2dak} e^{-2.303(38)}$$
$$= 0.714 \times 10^{-3} \text{ mole}^{-1}$$

or $\Delta c = 4.64 \times 10^{-2}$ moles per fringe shift, which is comparable to the interpolated value of 4.41×10^{-2} from Table I. The refractive index data primarily serves to determine the range of concentrations to be used for the interferometer employed.

Discussion

The results show that interferometry can be used successfully in the study of reaction kinetics. The accuracy of the monitored refractive index data obtained from multiple beam interferometry is comparable to or better than refractive index readings obtained with the Precision refractometer. The change of refractive index detectable with the method described is $\lambda/2d = 3.306 \times 10^{-5}$. Long path interferometers have been designed with a cell thickness of over 2 cm. For a 3 cm cell, it would have been possible to record consecutive refractive index differences corresponding to 1 part in 10^5 during the progress of the reaction. For the hydrolysis of ethyl

For personal use only.

acetate, this would be recording 1 mmole/l per recorded peak.

The application of real-time holographic interferometry (6, 7) toward the study of reaction kinetics has also been considered. While holographic interferometry differs markedly in design and technique, a fringe system is created using a spectroscopic plate in two steps, each step forming one arm of a Mach–Zehnder interferometer. The movement of the fringe system is monitored with the use of a photomultiplier tube in the same manner as with the described multiple beam interferometer.

One advantage of the holographic system is a greater freedom in the design characteristics of the reaction vessel, while one disadvantage is the increased fringe width and usually there is decreased fringe contrast.

Gallium(III) isothiocyanate and its addition compounds

S. J. Patel and D. G. Tuck
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia
Received July 8, 1968

Gallium(III) tris-isothiocyanate trihydrate has been prepared, together with a series of compounds with monodentate ligands of the type $Ga(NCS)_3L_3$. Bidentate donors gave either $Ga(NCS)_3L_3$ or $Ga(NCS)_3L_{1.5}$. The structure and properties of these species are compared with those of other gallium(III) addition compounds, and of the corresponding indium(III) complexes.

Canadian Journal of Chemistry, 47, 229 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In the course of preparative and structural studies of indium(III) compounds and their adducts (1), indium(III) thiocyanate was isolated, and shown to be a thiocyanate-bridged polymer in the solid state (2). The addition compounds obtained with monodentate ligands were all of the type $In(NCS)_3L_3$, contrasting with the range of stoichiometries from InX_3L_3 to InX_3L (X = Cl, Br, or I) found in the indium(III) halide series (3). We have now extended the work on thiocyanates by preparing gallium(III) tris-isothiocyanate trihydrate, together with a series of compounds of $Ga(NCS)_3$ and various donor ligands. The properties of these species compare interestingly with those of related indium and gallium complexes.

Results and Discussion

Gallium(III) Tris-isothiocyanate Trihydrate

There appears to be no report of the preparation of any gallium(III) pseudohalides in the literature (4, 5). Following earlier work on indium(III) thiocyanate, gallium(III) sulfate was treated with the stoichiometric quantity of barium thiocyanate in aqueous solution; evaporation of the resultant solution yielded $Ga(NCS)_3.3H_2O$ as a stable pale-yellow solid. The anhydrous compound could not be obtained by heating to 100° in vacuo, since at about 85° the material swelled, turned yellow, and lost weight (~ 24%). The infrared spectrum of this new material showed absorption bands due to C≡N and OH, but the analytical data did not correspond to any simple stoichiometry, and the material was not investigated further.

The infrared spectrum of gallium tris-isothiocyanate trihydrate shows absorptions at 3360 s, 2076 s, 1655 sh + 1642 + 1614 m, 1425 sh + 1400 m, 1070 m, 960 w, 895 w, 580 w, 475 m, and 360 m, cm^{-1}; the compound mulled poorly and all the bands are broader than in the spectra of the adducts. We assign the strong 2076 cm^{-1} band to the C≡N stretch of the thiocyanate group, and that at 475 cm^{-1} to the N—C—S bending mode. These assignments are both consistent with Ga—NCS bonding, which suggests that the absorption at 895 cm^{-1} may be the C≡S stretch, lying slightly above the frequency region in which this mode is usually found in isothiocyanate compounds (6). The C≡N stretch is typical of that reported for N-bonded thiocyanate groups, and is significantly lower than in the anhydrous indium thiocyanate, for which a polymeric thiocyanate-bridged structure is consistent with both spectroscopic and chemical evidence (2). The broad band at 3360, and the 1655 + 1642 + 1614 cm^{-1} multiplet are presumably O—H stretching and bending modes of H_2O.

There are no bands that can be assigned to pure ν(Ga—N) or ν(Ga—O) modes. In the adducts of gallium isothiocyanate (see below), the ν(Ga—N) vibrations are in the 250–320 cm^{-1} region, in agreement with earlier work. Data on ν(Ga—O) frequencies are sparse. The totally symmetric Raman active vibration observed with an aqueous (sulfate) solution of $[Ga(H_2O)_n]^{3+}$ is at 475 cm^{-1}; the general range for this mode in aquated trivalent metal ions is 540–488 cm^{-1} (7). Hester and Plane (8), and Djordjevic (9), have reported ν_s and ν_{as} of Ga—O in $[Ga(acac)_3]$ at 460 and 525 cm^{-1} respectively. Lewis *et al.* (10) were unable to identify any unique M—O vibrations in gallium(III) halide – ether adducts, and it is very probable that there will be extensive mixing of the ν(Ga—O) and ν(Ga—N) vibrations in a monomeric $Ga(NCS)_3(H_2O)_3$ species. We therefore suggest that the band at 360 cm^{-1} is such a mode involving both ν(Ga—NCS) and ν(Ga—OH_2).

This discussion leaves unassigned the bands at 1425 + 1400, 1070, 965, and 580 cm^{-1}, of which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the last three may possibly be related to wagging and rocking modes of the Ga—OH_2 group (see for example, ref. 11).

With the preparation of gallium isothiocyanate trihydrate, for which the infrared data indicate a monomeric structure in the solid state, information is now available on the thiocyanates of all the Group IIIB elements. Boron tris-isothiocyanate (12) is a liquid (boiling point 92°/0.1 mm) soluble in benzene, chloroform, and *n*-heptane, but with a tendency to polymerize in these solvents. Aluminium thiocyanate has been known for many years (13), and the preparative method is similar to that used for the gallium and indium compounds, but no structural information is available. Gallium thiocyanate is described above, and indium thiocyanate is a thiocyanate bridged polymer (2). Thallium(III) thiocyanate has not been reported, and may in fact be unstable as a result of the redox properties of Tl(III) and CNS^-; the compounds R_2TlNCS (R = Me, Et) (14, 15) and $PhTl(NCS)_2$ (16) are, however, known.

It is worth noting that, with one exception, the Group IIIB thiocyanate species and all the adducts with donor ligands involve N-bonded thiocyanate; indium(III) thiocyanate is unique in this group in that the thiocyanate group bridges two metal atoms (2).

Adducts of Gallium(III) Isothiocyanate

A series of simple reactions between gallium(III) isothiocyanate and donor ligands in various nonaqueous media (see Experimental section) gave rise to a group of addition compounds.

The infrared spectra of the donor groups in the sodium chloride region showed that these complexes involve Ga—N bonding in the case of pyridine, γ-picoline, 2,6-lutidine, quinoline, ethylenediamine, 2,2′-bipyridyl and 1,10-phenanthroline, and Ga—O bonding in the case of dimethylsulfoxide and triphenylphosphine oxide. In general, the spectral changes establishing this bonding were within the experimental accuracy identical to those reported previously for the analogous indium(III) halide and pseudohalide adducts (2, 3). For the γ-picoline complex, not discussed previously, bands at 1606, 1224, 997, 800, and 515 cm^{-1} in the free ligand move to 1630, 1236, 1026, 810, and 552 cm^{-1} in the complex, in agreement with results reported by Goodgame and Hayward (17). For the 2,6-lutidine adduct, the principal changes are *(a)* the two bands at 1597 s and 1585 s in the free ligand move to higher energy and split to a quartet at 1659, 1644, 1635, and 1625 (all s) cm^{-1}, and *(b)*, the band at 775 cm^{-1} is replaced by new absorptions at 796 s, 787 s, and 770 w cm^{-1}. Similar changes have been reported (18) on coordination of 2,6-lutidine with copper(II) chloride and bromide. In the $Ga(NCS)_3$–quinoline complex, bands were observed at 1643 m and 1603 m, compared with 1620 and 1592 cm^{-1} in the free ligand.

TABLE I

Molar conductivities of gallium(III) tris-isothiocyanate adducts[a]

Compound[b]	Conductivity (Ω^{-1} cm^2) Nitromethane	Acetonitrile
$Ga(NCS)_3py_3$	92	137
$Ga(NCS)_3pic_3$	88	119
$Ga(NCS)_3lut_3$	128	260
$Ga(NCS)_3quin_3$	(c)	(c)
$Ga(NCS)_3(dmso)_3$	38	55
$Ga(NCS)_3(Ph_3PO)_3$	34	29
$Ga(NCS)_3bipy_{1.5}$	40	52
$Ga(NCS)_3phen_{1.5}$	35	55
$Ga(NCS)_3en_3$	(c)	(c)

[a]Concentration = 10^{-3} *M*; temperature = 25°.
[b]py = pyridine; pic = 4-methylpyridine; lut = 2,6-lutidine; quin = quinoline; dmso = dimethylsulfoxide; bipy = 2,2′-bipyridyl; phen = 1,10-phenanthroline; en = ethylenediamine.
[c]Compound insufficiently soluble.

The molar conductivities of the adducts were measured in nitromethane and acetonitrile solution, with the results shown in Table I.

The values reported for 1:1 electrolytes under these conditions are in the range 70–90 and 120–130 Ω^{-1} cm^2 in nitromethane (19) and 130–170 Ω^{-1} cm^2 in acetonitrile (20). For 1:2 electrolytes, the values are 150–200 and approximately 300 Ω^{-1} cm^2, respectively (19, 20). The values reported in Table I, therefore, imply appreciable dissociation in nonaqueous solution. As in the indium case, however, it does not follow that the compounds are to be formulated as electrolytes in the solid state (2). Following the dissociative mechanism proposed to explain the conductivity in melts of $GaCl_3L_2$ complexes (4), the dissociation is rather attributed to equilibria such as

$$Ga(CNS)_3L_3 \rightleftarrows [Ga(CNS)_2L_3]^+ + CNS^-$$

$$[Ga(CNS)_2L_3]^+ \rightleftarrows [Ga(CNS)L_3]^{2+} + CNS^- \text{ etc.}$$

in which species with coordination numbers less

[b]Ligand vibrations also present in this region.
[c]All bands very broad in this region.

than 6 are formed. The conductivities are significantly higher than for the corresponding indium(III) thiocyanate adducts, presumably because the 6-coordinate state in gallium(III) involves higher steric interference and hence weaker metal ligand bonding than in the indium case, leading to easier dissociation. This steric factor may also explain the order of conductivities for the monodentate nitrogen donor adducts, for which the order 2,6-lutidine > γ-picoline ≈ pyridine is found.

Complexes with triphenylphosphine, urea, and thiourea could not be obtained by methods identical to those used successfully for the preparation of indium(III) thiocyanate adducts of these ligands.

Infrared Structural Studies

As in the earlier work (2), an important point is the mode of bonding of the thiocyanate ligand. Inspection of the solid state infrared spectra show that for all the addition compounds, as for gallium isothiocyanate hydrate itself, the intense C≡N stretching frequency is in the region 2116–2038 cm^{-1}, implying *N*-bonding of the thiocyanate group. The evidence from the frequency of the NCS bending mode (see Table II) is in agreement with this conclusion. The only compound for which this conclusion is at all in doubt is in the interesting case of the γ-picoline adduct, for which the δ(NCS) mode is some 20 cm^{-1} below the average value in these complexes. There has been considerable discussion as to the structure of the palladium(II) thiocyanate – pyridine and γ-picoline compounds, and despite earlier views, it now appears that the mode of bonding of the thiocyanate group is the same in both cases (i.e. Pd—SCN) (see ref. 6 for details). The present result for $Ga(NCS)_3pic_3$ therefore is taken as showing some weakening of the δ(NCS) force constant due to methyl substitution at the 4-position, but not to an extent compatible with *S*-bonding of thiocyanate. The weak C≡S stretching mode could not be identified in most of the complexes because of overlying ligand vibrations.

As noted above, it is the smaller and more electronegative atom, rather than sulfur, which is bonded to the metal in gallium thiocyanate and its adducts, so that as with indium(III) (1–3), *N*-bonded thiocyanate favors high coordination numbers, even in the presence of a ligand such as triphenylphosphine oxide. This is especially striking since with gallium(III) chloride and bromide, only GaX_3L and GaX_3L_2 neutral adducts appear to have been isolated (4). A more meaningful comparison would probably be with gallium(III) fluoride, for which the only known adducts are $GaF_3.3H_2O$ and $GaF_3.3NH_3$, suggesting a coordination number of 6, which is also found in certain GaF_6^{3-} salts.

Table II also lists the absorption bands detected in the 220–320 cm^{-1} region, where ν(Ga—N) vibrations would be expected (21). Two factors prevent any detailed analysis of these absorptions in terms of the symmetry of the complexes; the unknown extent of ν(Ga—NCS) and ν(Ga–donor) coupling, and the presence of ligand absorption bands in this region in some of the compounds. It is, however, clear that the presence of ν(M—N) absorptions in the spectra are compatible with the Ga—NCS bonding discussed above.

No identification of ν(Ga—O) could be made,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

since ligand absorptions occur in the region of interest in both $Ga(NCS)_3(dmso)_3$ and $Ga(NCS)_3(Ph_3PO)_3$.

Bidentate Nitrogen Donors

As with the adducts of indium thiocyanate with 2,2′-bipyridyl and 1,10-phenanthroline, the infrared evidence for $Ga(NCS)_3bipy_{1.5}$ and $Ga(NCS)_3phen_{1.5}$ shows that the thiocyanate groups are monodentate rather than bridging. The far-infrared spectra of $In(NCS)_3bipy_{1.5}$ and $Ga(NCS)_3bipy_{1.5}$ are analogous, suggesting that the gallium and indium compounds may be isostructural. Work is still proceeding on the structure of these species (22).

The far-infrared spectrum of $Ga(NCS)_3en_3$ is completely different from that of all the other compounds prepared, and closely resembles the spectrum of $[Ni(en)_3][PtCl_4]$ (23), so that the compound is formulated as $[Ga(en)_3](CNS)_3$. As with the corresponding indium compound, insolubility in the appropriate solvents hinders any conductivity investigation of this aspect of the problem. The ethylenediamine compound is unique in this series in that it is hygroscopic; the compound as prepared (from ethylenediamine hydrate) contained about 1.5 moles of water, which could be removed by heating to 110°.

Experimental

General

Infrared spectra were obtained on both Unicam SP 200 and Beckman IR-12 instruments. Other instrumental techniques were as described earlier (2, 3).

Gallium was analyzed either gravimetrically as the oxide, or volumetrically by titration against potassium ferrocyanide in dilute acid, using 3,3′-dimethylnaphthidine as indicator (24). Thiocyanate was determined gravimetrically as silver thiocyanate, precipitated from aqueous ethanol or nitromethane solutions to avoid interference from organic ligands present.

Gallium metal was Fisher Certified material (99.99% pure). Ligands were as in previous work; γ-picoline, 2,6-lutidine, and quinoline were recrystallized before use.

Gallium(III) Isothiocyanate Trihydrate

Gallium metal was dissolved in hot conc. sulfuric acid, the resultant solution evaporated to dryness, and the residue finally heated to 250° for some hours to give anhydrous gallium(III) sulfate.

Found: Ga, 32.4; SO_4^{2-}, 67.1; $Ga_2(SO_4)_3$ requires Ga, 32.6; SO_4^{2-}, 67.4.

Stoichiometric quantities of this material were treated with barium thiocyanate (1:3) in water, barium sulfate filtered off, and the filtrate evaporated in vacuo to give a pale-yellow solid.

Found: Ga, 23.3; CNS, 58.1; $Ga(NCS)_3.3H_2O$ requires Ga, 23.4; CNS, 58.5.

Attempted recrystallization of this material led to apparent decomposition and loss of thiocyanic acid.

Found: C, 3.5; H, 3.2; N, 3.6; S, 16.9; $Ga(NCS)_3.3H_2O$ requires C, 12.1; H, 2.1; N, 14.1; S, 32.4.

Gallium(III) isothiocyanate hydrate is deliquescent, and readily soluble in water; on standing at room temperature the solution deposits a white precipitate (gallium hydroxide?) within a few hours. The compound is soluble in ethanol, methanol, acetone, acetonitrile, ethyl acetate, chloroform, nitrobenzene, and ethyl ether, but is insoluble in methylene dichloride, cyclohexane, and chloroform. As noted above, decomposition and loss of weight occurred on heating to 100°.

Trispyridine Gallium(III) Isothiocyanate

Gallium(III) isothiocyanate trihydrate in the minimum volume of methanol was treated with excess pyridine at approximately 75° for 1 h. After filtration, the filtrate was evaporated in vacuo to give a white product which was washed with ether and recrystallized from methanol. The compound is soluble in acetone, lower alcohols, nitromethane, and acetonitrile, but is insoluble in water, ether, methylene dichloride, benzene, chloroform, and cyclohexane. Melting occurred over a range of temperatures above 95°; pyridine was released on heating to 110° in vacuo. The analytical data for this, and the other adducts, are given in Table III. Tris-(4-methyl-pyridine) gallium(III) isothiocyanate (melting point (m.p.) 127°), tris-(2,6-lutidine) gallium(III) isothiocyanate (m.p. 80°), and trisquinoline gallium(III) isothiocyanate (decomposes at approximately 200°) were prepared by reactions similar to those used for the pyridine compound. The solubilities are identical with those of the latter, with the exception that the quinoline adduct is insoluble in both nitromethane and acetonitrile.

Tris(dimethylsulfoxide) Gallium(III) Isothiocyanate

A mixture of dimethylsulfoxide and gallium(III) isothiocyanate trihydrate in ethanol was heated to 60° for 1 h, after which the solution was filtered and pumped to dryness. The product, which was recrystallized from methanol, is soluble in most of the organic solvents listed above except ether, benzene, and cyclohexane. Decomposition occurs above ~ 95°.

Tris(triphenylphosphine oxide) Gallium(III) Isothiocyanate

A mixture of triphenylphosphine oxide and gallium(III) isothiocyanate trihydrate in the minimum volume of ethanol was refluxed for 17 h, filtered hot, and set aside at room temperature for one week, when pink crystals (m.p. 139°) were obtained. The color is probably due to iron impurity. Other than water and cyclohexane, the compound is soluble in all the solvents examined (see above).

Gallium(III) Isothiocyanate – 2,2′-Bipyridyl Adduct

Solutions of 2,2′-bipyridyl and gallium(III) isothiocyanate trihydrate (3:1) in ethanol gave a pale pink precipitate on mixing; this was eventually recrystallized from nitromethane (m.p. above 300°). Apart from nitrobenzene, nitromethane, and acetonitrile, the compound is insoluble in the solvents examined. The preparation and properties of the *1,10-phenanthroline adduct* were essentially identical.

Tris(ethylenediamine) Gallium(III) Thiocyanate

Addition of ethylenediamine hydrate to a solution of gallium(III) isothiocyanate hydrate in methanol gave an immediate white precipitate, soluble in excess ethylenediamine. Treatment of this solution with several volumes of dry ether yielded a resinous mass which on addition of absolute ethanol gave a white solid; this was washed with ethanol and ether, and recrystallized from ethanol. From the analytical and infrared evidence, this material is a hydrate.

Found: C, 23.8; H, 5.9; N, 27.6; Ga, 15.5; CNS, 38.4 (see Table III for values for $Ga(en)_3(CNS)_3$). This hydrate lost ~6% by weight on heating to 110° for 2–3 days. The final product had no infrared absorptions at 3450 or 1650 cm^{-1}; the slight yellow of the material suggests that some slight decomposition may have occurred in the final stages of heating and the low C and N analyses (see Table III) probably arise from this. The hydrated material, m.p. 260°, is soluble only in methanol amongst the solvents examined.

Infrared spectra of diphenylethine and diphenylethine-d_{10}[1]

CESARE PECILE AND BRUNO LUNELLI
Institute of Physical Chemistry, The University, Padua, Italy

Received April 26, 1968

The infrared spectra of diphenylethine and diphenylethine-d_{10} have been measured in the 4000–33 cm^{-1} region both for solution and solid samples. Polarized spectra of oriented crystals, (001) crystal plane, allow segregation of most bands into their respective symmetry classes. The slightness of correlation crystal field effects suggested by the comparison between crystal and solution spectra is confirmed by measurements on dilute isotopic solutions. The oriented gas model predictions are a useful guide despite some well-identified deviations.

The assignment of the infrared active fundamentals is proposed on the basis of the dichroic indications and the isotopic shifts. Most of the relevant absorption frequencies of diphenylethine and diphenylethine-d_{10} are recognized as characteristic of a monosubstituted benzene and the spectra are interpretable on the basis of two phenyl groups weakly interacting through the acetylenic bridge.

Canadian Journal of Chemistry, 47, 235 (1969)

Introduction

The interests in the spectroscopic studies of noncondensed aromatic hydrocarbons with chain structure (1) leads to the investigation of the vibrational behavior of diphenylethine (tolane) and *trans*.-1,2-diphenylethylene (stilbene), the simplest members of this class of compounds. The vibrational spectrum of tolane is far from being satisfactorily interpreted; this is because experimental information is limited (2–4) and because, as for biphenyl (5), a complete vibrational assignment is intrinsically difficult.

In this paper we present and analyze the experimental data obtained by measuring the spectra of solutions and of a well-known crystal plane of tolane and tolane-d_{10}. The vibrational assignment proposed together with the critical examination of the dichroic behavior will provide a basis for the analogous study of stilbene which is the object of the following paper.

Experimental

The tolane used (m.p. 61 °C, corr.) was a reagent grade product, purified by repeated sublimation and finally by two crystallizations from light petrol. The preparation of tolane-d_{10} was first attempted by exchange (48 h at 300 °C) with $Ca(OD)_2$ and with NaOD (4%) supported on $Ca(OD)_2$ (6). In spite of the encouraging reports on the thermal stability of tolane (7), we obtained only tars from which no more than 2% of pure compound could be recovered[2]. Tolane-d_{10} was prepared by starting with *trans*-1,2-diphenylethylene-d_{12}[3] and using a method similar to that reported for the preparation of tolane (8). The product was purified as reported above for the light compound.

The pure product has m.p. 61 °C (corr.) and displays the same very weak infrared absorption in the CH stretching region as the starting *trans*-1,2-diphenylethylene-d_{12} so that a corresponding isotopic composition can be assumed.

Single crystals of tolane and tolane-d_{10} were prepared by sublimation at about 45 °C under atmospheric pressure. X-ray analysis showed that the thin sheets always contained the *a* and *b* crystal axes. Polycrystalline oriented samples, obtained by slow cooling of the melt between KBr plates, were found to contain the same crystal plane. The direction of the *b* crystal axis in different samples was determined by optical methods.

The spectra were recorded on Beckman model IR9 and IR11 spectrometers. The crystal samples were mounted in a beam condenser unit and a silver chloride polarizer was inserted in front of the entrance slit. The crystals were rotated so that the *b* axis was first parallel and then perpendicular to the direction of the electric vector of the incident radiation.

In the 400–33 cm^{-1} spectral region no absorption was detected by using Nujol mulls; however, saturated benzene and cyclohexane solutions in a cesium iodide cell (1 mm thick) revealed some weak bands in the 400–200 cm^{-1} frequency region.

The accuracy of most of the wavenumbers is estimated to be ± 1 cm^{-1}.

Selection Rules

The schematic drawing of the tolane molecule is shown in Fig. 1; the molecular axes have been chosen according to Mulliken's convention (9).

Tolane crystallizes in the monoclinic system,

[1]This work was supported in part by the Chemistry Committee, National Research Council of Italy.

[2]Pure tolane heated in an evacuated pyrex bulb also gave (at 300 °C for 48 h) a tar from which no more than 2% of pure compound could be recovered.

space group C_{2h}^5 ($P2_1/a$), with four molecules in the unit cell (10). Its structure consists of two layers with no symmetry relation between them and an equal number of molecules in each layer. Each molecule is planar and located on a C_i symmetry site. The projection of the crystal structure on (001) is shown in Fig. 2.

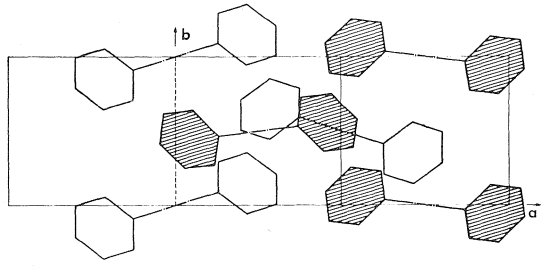

FIG. 2. Projection of the crystal structure of diphenylethine on (001). Shaded molecules belong to one of the two crystallographically independent sets.

The selection rules for the molecular point group D_{2h}, the site group C_i, and the factor group C_{2h} are reported in Table I. For the isolated molecule the normal modes of b_{1u}, b_{2u}, and b_{3u} species are infrared active; the direction of the b_{1u} transition moments is that of the "long molecular axis" Z, the b_{2u} have the "short axis" Y direction, and the b_{3u} have the "normal axis" X direction.

In the crystal, the vibrations of the molecular unit, which lies on a site of C_i symmetry, are distributed between a_g and a_u species; the modes of the a_u species of the free molecule become infrared active. The effect of dynamic interaction of the molecules set by set in the unit cell can be accounted for by factor group analysis: each u fundamental of the isolated molecule gives rise to two b_u modes with the transition moment in the ac crystal plane, and two a_u modes with the transition moment along the b axis. The g fundamentals of both the molecule and the unit cell are infrared inactive.

Table II lists the squared values of the direction cosines of the molecular axes with respect to the crystal axes a, b, and c^* calculated using the known crystal structure (10). The orientation of the molecules is such that the values in Table II are almost equal for both sets; therefore separate consideration is unnecessary for the two sets. Once we assume the oriented gas model using the data in Table II, we can predict the dichroic behavior of the absorption bands in the crystal spectrum. With plane-polarized radiation incident normally on the (001) plane, the vibrations of the b_{1u} species should display strong absorption when the electric vector is perpendicular to the b crystal axis and weak absorption when it is parallel (perpendicular bands). The b_{2u} vibrations should exhibit a reverse behavior (parallel

bands) and the b_{3u} modes should be slightly parallel.

Results and Vibrational Assignment

The polarized infrared spectra of tolane and tolane-d_{10}, *ab* crystal plane, are shown in Figs. 3 and 4. The absorption frequencies, the relative intensities, and the type of polarization are given in Tables III and IV.

The well-settled assignment of numerous monosubstituted benzenes (11–14) gives a clear indication of the number of modes insensitive to the nature of the substituent (X-insensitive) and of their location in the spectrum. These modes, excluding the CH stretching fundamentals, are $5a_1$, $7b_1$, $3a_2$, and $4b_2$ under the local C_{2v} symmetry of the phenyl ring. Such a spectral feature is also found in quite a number of molecular structures where the phenyl group is present. It is then reasonable to suppose that in the tolane molecule the spectroscopic behavior of the phenyl fragment follows the same pattern, if a strong vibrational coupling of the two phenyl rings is absent. The same regularity has been observed also for the fully deuterated monosubstituted benzenes whose infrared spectra have been reported (12–14, 16). A first inspection of solution and powder spectra of tolane and tolane-d_{10} reveals a clear fit with the above-mentioned correlative scheme.

In the whole tolane molecule the transition moments of the vibrations of the b_{1u}, b_{2u}, and b_{3u} species have the same direction as the transition moments of the phenyl fragment vibrations of the a_1, b_1, and b_2 species respectively under the local C_{2v} symmetry. Consequently, both overall and local symmetry, together with assumption of the oriented gas model, allow us to predict that the corresponding absorptions should display perpendicular, parallel, and slightly parallel polarization in the order, when the *ab* crystal plane is examined. The assumption of the oriented gas model is justified by the similarity of the crystal and solution spectra, and by the values of the correlation crystal field splittings observed, none of which exceeds 4 cm^{-1}. Dilute isotopic solutions were used to prove, where possible, that the splittings had a factor group origin. The lack of significant differences between solution and crystal spectra might also suggest an identical planar structure in the two phases; the same indication was also given by electronic spectra (17).

The presence of an inversion center (Table I) makes it impossible to know all the g modes in the lack of a complete and satisfactory Raman spectrum (4); as a consequence no attempt will be made to identify combination tones.

The frequency values used in the following discussion are those of the crystal spectra.

Vibrations of b_{1u} Species

Since the tolane and tolane-d_{10} spectra conform well to the interpretative scheme suggested by the monosubstituted benzenes, the first step in the assignment of the eleven b_{1u} infrared active fundamentals is to consider the frequencies of the modes similar to the five X-insensitive phenyl ring modes of the a_1 species.

The assignment of the bands at 1600, 1502, 1158, 1027, and 998 cm^{-1} of tolane and at 1570, 1414, 958, and 850 cm^{-1} of tolane-d_{10} to fundamentals of the b_{1u} species is almost direct. The clearly perpendicular character of the corresponding absorptions in the crystal spectra supports their segregation as b_{1u} modes. The lowest frequency X-insensitive a_1 vibration of fully deuterated monosubstituted benzenes is located in the 815–820 cm^{-1} region (5, 12–14). The corresponding mode in tolane-d_{10} is assigned at 820 cm^{-1}, overlapped by the stronger parallel band of the b_{2u} species.

The highest X-sensitive frequency in the a_1 class of monosubstituted benzenes, which in

[f]Solution in carbon disulfide.

tolane may be approximately considered an inter-ring stretching, should be localized in the region of 1200 cm^{-1}, as suggested by the assignments of benzonitrile (14), ethynylbenzene (15), and toluene (13). The spectral features of tolane at about 1200 cm^{-1} do not allow us to locate this mode. The difficulty may be due to the low intensity of this absorption, as observed in the case of ethynylbenzene where the assignment had to be based on the strong polarized Raman line. No help is offered by the spectra of tolane-d_{10}.

For the location of the two remaining X-sensitive modes the examination of C_6H_5X and C_6D_5X (X = CH_3, CN) (13, 14, 18) assignments justifies the choice of the bands at 536 and 824 cm^{-1} for tolane and at 523 and 755 cm^{-1} for tolane-d_{10}. The perpendicular polarization in the crystal spectra supports this assignment.

In the CH and CD stretching regions the isotopic shifts and the polarization, perpendicular for b_{1u} and parallel for b_{2u} modes, lead to the assignment summarized in Table V.

Vibrations of b_{2u} Species

Six out of the seven vibrations corresponding to phenyl ring X-insensitive modes of the b_1 class are found directly in the spectra of tolane (at 1572, 1443, 1332, 1281, 1179, and 1071 cm^{-1}).

[a]Bracketed frequency doublets have correlation crystal field origin.
[b]Intensity values were not corrected for band overlap. Values in parentheses refer to cases in which the overlapping is quite strong.
[c]Intensity expressed as peak absorbance, relative to a value of 100 assumed for the perpendicular component at 1570 cm^{-1}. The resulting values are rounded off to the next multiple of five. The marks +, −, 0, ≃ indicate the intensity of the parallel and perpendicular component of the weak bands; sh, shoulder.
[d]Intensity expressed as peak extinction coefficient ($mole^{-1}$ l cm^{-1}) relative to a value of 100 assumed for the band at 1569 cm^{-1}. The resulting values are rounded off to the next multiple of five; sh, shoulder; w, weak.
[e]Solution in carbon tetrachloride.
[f]Solution in carbon disulfide.

The last X-insensitive vibration, expected at about 620 cm^{-1} (11), is associated with the perpendicular absorption at 620 cm^{-1}. The perpendicular polarization is inconsistent with that predicted for a b_{2u} mode; however, in this case correlations are more dependable than dichroism, which consequently has to be considered anomalous. In tolane-d_{10} the parallel bands at 1538, 1277, and 822 cm^{-1} are directly recognized as belonging to this class and corresponding to X-insensitive b_1 modes of the phenyl fragment. The remaining three X-insensitive modes of tolane-d_{10} can be located by taking into account the frequency ranges (1040–990, 870–840, 600–590) in which they are assigned in C_6D_5X (X = F, Cl, CN, CH_3). Along these lines we propose the bands at 1036, 597, and 847 cm^{-1} despite the perpendicular polarization of the first two bands. The parallel absorption at the latter frequency is a component of the doublet 850–847 cm^{-1} which does not have a factor group origin owing to its persistence in solution.

Two more fundamentals are to be assigned in this class. One is similar to the lowest frequency X-sensitive mode and is discussed afterwards, since it is presumably located below 400 cm^{-1}; the other is found only in the light compound, and associated with the parallel peak at 467 cm^{-1}, in a spectral region suggested by the b_1 skeletal bending of ethynylbenzene (15), located at 467 cm^{-1}.

Vibration of b_{3u} Species

The four out-of-plane X-insensitive modes of the light as well as of the heavy tolane are found in the very narrow frequency ranges indicated by correlations. Although the strong b_{2u} band at 822 cm^{-1} hinders the observation of the b_{3u}

[a]Frequency values (cm^{-1}) observed in the spectra of oriented crystals. Bracketed values correspond to bands assumed to be strongly overlapped by other absorptions.

[b]As a consequence of the correspondence, used throughout the discussion, between tolane and monosubstituted benzenes vibrations, the approximate descriptions given are inferred from the results of calculations reported for C_6H_5Cl. The alignment of the frequencies of $C_{14}H_{10}$ and $C_{14}D_{10}$ has been guided by the inspection of the atomic displacements in C_6H_5Cl and C_6D_5Cl normal vibrations. For the correct description of normal vibrations of both C_6H_5Cl and C_6D_5Cl in terms of potential energy distribution, the original literature should be consulted (16).

[c]Average value of the frequencies observed in the crystal spectra for bands presenting correlation field splitting.

absorption in this position, its location cannot be questioned.

The slightly parallel dichroism predicted for b_{3u} bands is observed only for the absorptions at 758 and 690 cm^{-1} of tolane and at 550 cm^{-1} of tolane-d_{10}. In the other cases, the polarization is anomalous, and the results are of a perpendicular or parallel type.

Correlations offer a guide to assignment only for two out of the three skeletal deformations of b_{3u} species, that is for those which correspond to phenyl ring b_2 X-sensitive vibrations. One of these is located below 400 cm^{-1} and is discussed in the next section; the other is associated with the slightly parallel bands at 511 cm^{-1} in tolane and at 452 cm^{-1} in tolane-d_{10}. These frequency values compare well with the assignment at 529 in ethynylbenzene (15) and at 548 and 488 cm^{-1} in benzonitrile and benzonitrile-d_5 respectively (14). The location of the last skeletal deformation of the b_{3u} species cannot be inferred from correlative data and is left unassigned.

Vibrational Modes below 400 cm^{-1}

As reported in the experimental section, the powder spectra of both tolane and tolane-d_{10} in the region 400–33 cm^{-1} do not reveal any absorption. The only experimental data obtained in the low frequency region are the spectra of tolane in benzene and cyclohexane solutions from 400 to 200 cm^{-1} (Table III). The infrared active fundamentals still unassigned are one b_{2u} and one b_{3u} skeletal deformation. The first can be regarded as an asymmetric vibration of the tolane skeleton whose corresponding totally symmetric mode may well be identified with the frequency at 260 cm^{-1} observed in the fluorescence spectrum (1). In the infrared spectrum of tolane, it can be associated with the band at 292 cm^{-1}.

The absorption pattern between 290 and 400 cm^{-1} in the solution spectrum of tolane is not satisfactorily interpretable by using the available data. This spectral feature might be originated by accidental superposition of combination tones or by the activation in the infrared of Raman active modes, due to the existence of a twisted molecule in solution. The similarity of the solution and crystal spectra in the 4000–400 cm^{-1} region does not exclude this possibility since the extensive coincidence of the reported Raman frequencies (4) with those of the observed infrared active modes in this region makes it difficult to reveal any possible activation of the former in the infrared spectra. Clarification of this rather unusual coincidence will require more satisfactory Raman spectra than are now available.

The b_{3u} skeletal bending, which corresponds to the lowest frequency X-sensitive phenyl ring skeletal bending, was found at 170 cm^{-1} in benzonitrile (14) and at 165 cm^{-1} in ethynylbenzene (15). In the tolane spectrum, as well, it is presumably located in the same region, for which solution spectra were not obtained.

Conclusions

Most of the relevant absorption frequencies of tolane and tolane-d_{10} spectra are recognized as characteristic of a monosubstituted benzene and the spectra are interpretable on the basis of two

phenyl groups weakly interacting through the acetylenic bridge. However, more extensive investigations are required if the vibrational assignment has to be considered complete or is to be used to provide information on the degree of coupling of the phenyl ring fundamentals and on the problem of the molecular planarity in solution (5). The assignment of tolane, summarized in Table V, generally agrees with the previously reported ones (2) and is significantly supported by the parallel assignment of tolane-d_{10}.

The degree of reliability of fundamentals assignment, mainly for modes corresponding to X-insensitive phenyl ring vibrations, gives sufficient confidence to allow a critical evaluation of the observed dichroism. The experimental dichroic behavior generally agrees with the predicted one for the bands due to planar vibrations, while the anomaly is more the rule than the exception for the out-of-plane vibrations. Anomalies like these, not unusual in crystal spectra of aromatic compounds (19) and explained in an unsatisfactory way (20), must be clearly identified to know the limits of validity of dichroic indications and to study the empirical polarization specificity of phenyl ring vibrations in those cases, like stilbene, where the local symmetry of the phenyl ring and the whole molecular symmetry do not fix the same direction of the transition moments.

Infrared spectra of *trans*-1,2-diphenylethylene and *trans*-1,2-diphenylethylene-d_{12}[1]

CESARE PECILE AND BRUNO LUNELLI
Institute of Physical Chemistry, The University, Padua, Italy

Received April 26, 1968

The location of the infrared active fundamentals of *trans*-1,2-diphenylethylene and *trans*-1,2-diphenylethylene-d_{12} are discussed on the evidence given by the absorption spectra measured in the 4000–33 cm^{-1} region for solid and solution samples. This assignment is consistent with that reported in the preceding article for diphenylethine and fits the correlative scheme offered by the monosubstituted benzenes in the case of the light as well as of the heavy compound.

The polarized spectra of single crystals, (001) crystal plane, allowed examination of the dichroic behavior of the bands corresponding to planar vibrations for which no prediction is possible on the basis of the overall C_{2h} symmetry. The local symmetry C_{2v} of the aromatic fragment is not observed to prevail in such a complete and satisfactory way as to indicate the presence of an empirical polarization specificity, even though to some extent, particularly in the case of the a_1 modes of the phenyl ring, there is coincidence between the polarization observed and that predicted on the basis of the local symmetry.

Introduction

The use of polarization specificity greatly increases the amount of structural information which can be obtained from vibrational spectra of molecular crystals. The vibrational modes of isolated polyatomic molecules have the property of polarization specificity if they satisfy some basic conditions recently stated by Sverdlov (1). To exploit this property most readily, single crystals in which the molecules are ordinately oriented should be used, allowing measurement of the dichroic ratios.

However, the intensity changes which are observed to occur upon condensation and the deviations of the dichroism from the oriented gas model predictions (2) clearly indicate that the crystal field can strongly affect infrared band intensity and dichroism of the free molecule.

These still obscure facts (2) make it difficult to exploit the potential polarization specificity; therefore, a collection of empirical evidence of the existence of the specificity for molecular fragments characterized by group frequencies can offer a basis for theoretical progress and wider practical utilization of dichroic ratios. Molecules containing the phenyl group appear suitable for this empirical test.

The reported study of diphenylethine (3) has indicated that the phenyl group vibrations display frequency specificity both in the light and heavy compound, but several well-identified deviations from the predicted dichroism occur, specially in the case of the out-of-plane modes. Crystalline *trans*-1,2-diphenylethylene (stilbene) (4) is isostructural with diphenylethine (tolane) (5), a fact which allows the prediction of similar crystal field effects in the crystal spectra. The molecular symmetry of stilbene (C_{2h}) being different from that of tolane (D_{2h}), the direction of stilbene transition moments in the molecular plane is not fixed by symmetry.

In this paper we examine the infrared spectra of stilbene and stilbene-d_{12} in order to get an improved assignment which allows us to ascertain whether the empirical dichroic behavior of phenyl ring group vibrations in the spectra is determined by its local symmetry C_{2v} or by the C_{2h} symmetry of the whole molecule.

Infrared spectra (6, 7) and a partial Raman spectrum (8) of light stilbene have been reported previously.

Experimental

The stilbene used (m.p. 124 °C, corr.) was a reagent-grade product, purified by repeated crystallization from ethanol. The stilbene-d_{12} was obtained by allowing stilbene (1 g) to exchange (48 h at 300 °C) with calcium deuteroxide (10 g) in a Carius tube and repeating this procedure six times (9). The final product, purified by crystallization, gave an infrared spectrum which appeared to be identical with that of commercial stilbene-d_{12} of well-known isotopic composition[2]. Later, we exchanged stilbene with NaOD supported on $Ca(OD)_2$. We started with stilbene (300 mg), sodium (230 mg), calcium oxide (7 g), and deuterium oxide (2.4 ml) and used the method

TABLE I

Symmetry classes and selection rules for *trans*-1,2-diphenylethylene as a free molecule and in the crystalline state

Molecular symmetry C_{2h}		Site symmetry C_i	Factor group symmetry C_{2h}	
Species and activity*	Degrees of freedom		Species and activity*	Degrees of freedom
a_g (R, p)	$25(\nu_1-\nu_{25})$	a_g (R, p)	a_g (R, p)	78 (6 torsional)
b_g (R, dp)	$11(\nu_{38}-\nu_{48})$		b_g (R, dp)	78 (6 torsional)
a_u (i.r.)	$12(\nu_{26}-\nu_{37})$	a_u (i.r.)	a_u (i.r.)	78 (5 translational)+T_b
b_u (i.r.)	$24(\nu_{49}-\nu_{72})$		b_u (i.r.)	78 (4 translational)+$T_{a,c}$

*R = Raman, i.r. = infrared, p = polarized, dp = depolarized.

reported for the preparation of biphenylene-d_8 (10). Four exchanges under the same conditions gave 110 mg of pure stilbene (m.p. 124 °C, corr.). Its isotopic purity was estimated to be better than that of the sample obtained with the first method, as shown by the much weaker infrared absorptions in the CH stretching region. The series of spectra of the products of successive exchanges allowed the identification, in the spectrum of the final deuterated compound, of some weak bands which can be attributed to partially deuterated stilbenes.

Single crystals of stilbene and stilbene-d_{12}, in the form of thin sheets, were prepared by slow sublimation at about 110 °C, under atmospheric pressure. The sheet plane was shown by X-ray analysis to contain the *a* and *b* crystal axes. In the polycrystalline oriented films, obtained by slow cooling of the melt between KBr plates, the same crystal plane is developed.

The methods used to measure the standard and polarized spectra are the same as reported in the preceding work (3).

Selection Rules

Stilbene (Fig. 1) crystallizes in the monoclinic system (4), space group $C_{2h}{}^5$–$P2_1/a$. In the unit cell there are four molecules distributed into two crystallographically independent sets. Each set consists of two molecules, which lie on inversion centers. The projection of the crystal structure on (001) is shown in Fig. 2. In the crystal the molecules are planar[3] and belong to the C_{2h} point group. Molecular axes have been chosen (Fig. 1) as in the previous study of tolane (3) in order to keep the same reference system for the phenyl group vibrations.

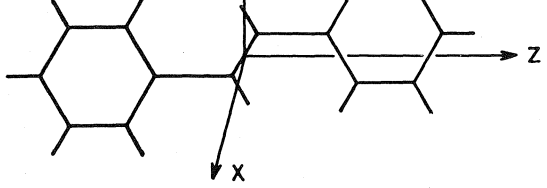

FIG. 1. Molecular structure and choice of molecular axes for *trans*-1,2-diphenylethylene, $C_{14}H_{12}$.

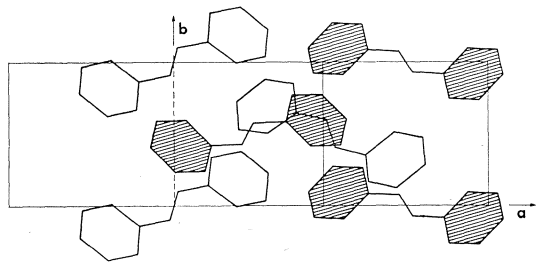

FIG. 2. Projection of the crystal structure of *trans*-1,2-diphenylethylene on (001). Shaded molecules belong to one of the two crystallographically independent sets.

The selection rules for the molecular point group C_{2h}, the site symmetry C_i, and the factor group C_{2h} are reported in Table I. The normal modes of the isolated molecule of a_u and b_u species are infrared active, while those of a_g and b_g species are Raman active. For the isolated molecule the transition moments of the a_u vibrations have the direction of the normal molecular axis *X* and those of the b_u vibrations are localized in the *YZ* molecular plane.

By using the X-ray data (4) we calculated the direction cosines of molecular axes with respect to crystal axes. Their squared values are reported

[3]A slight deviation from planarity was observed (4) for molecules belonging to one of the two independent sets.

in Table II. Since here, as in the case of tolane (3), the orientation of the molecules is such that the figures in Table II are almost equal for both sets, the two sets need no separate consideration. In the oriented gas approximation the figures in Table II (first column) represent the proportionality factors for absorption intensity of a_u molecular vibrations. The corresponding bands in the spectra of the (001) crystal plane should prove almost unpolarized. The b_u transition moments lie on the molecular YZ plane, but since their direction is not further fixed by symmetry no prediction can be made of their dichroic behavior and consequently the polarized spectra may be extremely difficult to interpret.

TABLE II

Squared values of direction cosines of molecular axes X, Y, Z, with respect to the crystal axes a, b, c^*

Crystal axis	Set I molecules			Set II molecules		
	X	Y	Z	X	Y	Z
a	0.13	0.18	0.70	0.18	0.09	0.72
b	0.30	0.67	0.03	0.30	0.70	0.00
c^* ($\perp ab$)	0.57	0.15	0.27	0.52	0.21	0.28

By assuming the local symmetry C_{2v} for the phenyl groups the polarization of the corresponding group modes can be predicted. The vibrations with transition moment along the X molecular axis (Fig. 1) are thus of b_2 type and should have the same dichroic ratio as the a_u modes of the whole molecule, being almost unpolarized upon examination of the (001) crystal plane. The vibrations of local symmetry a_1 have a transition moment directed along the Z molecular axis and the corresponding bands should display strong absorption when the electric vector is perpendicular and weak when it is parallel to the b crystal axis (perpendicular bands). The transition moment of the vibrations of local symmetry b_1 is directed along the Y molecular axis; therefore, the corresponding bands should display the reverse pattern (parallel bands).

Results and Vibrational Assignment

Figures 3 and 4 show the polarized spectra of single crystals, (001) plane, of stilbene and stilbene-d_{12}. The absorption frequencies, relative intensities, and type of polarization are reported in Tables III and IV.

For stilbene as for tolane (3), examination of the spectra reveals that most frequencies are in the positions indicated by phenyl ring assignments; therefore, the interpretative scheme is mainly based on phenyl group vibrations (11, 12). Two experimental features must be pointed out: the close resemblance between solution and crystal spectra, which might suggest planar structure in solution[4], and the slightness of correlation crystal field splittings.

The Raman spectra which we have found in the literature (8) are not extensive enough to allow a more complete and conclusive interpretation of the infrared spectra. As in the case of tolane, the Raman and infrared frequencies coincide to a great extent.

Vibrations of a_u Species

As we noted above, the phenyl ring frequencies coincide closely with the spectral pattern of stilbene and stilbene-d_{12}. Thus, application of a correlative scheme based on the assignments of monosubstituted benzenes allows ample interpretation of the spectra by using the parallelism with the modes of the phenyl ring in terms of its local symmetry C_{2v}. In this way the modes corresponding to the four b_2 X-insensitive and to one b_2 X-sensitive fundamentals can be rather safely assigned in the spectra of both stilbene and stilbene-d_{12} and need no further comments than those given on the analogous vibrations of tolane (3). The lowest frequency b_2 X-sensitive mode is left unassigned because we did not examine in solution (see Experimental) the spectral region below 200 cm^{-1} where it is presumably located (11). The three vibrations corresponding to the a_2 phenyl ring modes are easily sorted out from the spectra by comparison with the assignments of the a_2 Raman active modes of monosubstituted benzenes (11).

The very strong bands at 966 cm^{-1} in stilbene and 715 cm^{-1} in stilbene-d_{12} are characteristic of the *trans*-1,2-disubstituted ethylene structure of stilbene. Their frequency values are in close agreement with the well-known data on the CH/CD out-of-plane bending of *trans*-1,2-disubstituted ethylenes (14). The remaining two modes, which can be approximately described as skeletal deformations, can be only tentatively associated with the absorptions at 419 and 275

[4]Electronic spectra give the same indication (13).

[f]Solution in carbon disulfide.

cm^{-1} in stilbene and with the absorption at 410 cm^{-1} in stilbene-d_{12} spectra. The dichroic pattern observed for the bands (above 400 cm^{-1}) due to the a_u fundamentals is in many cases rather different from the slightly parallel character predicted for the modes of this class. The polarization of the absorptions, similar to the phenyl ring b_2 vibrations and comparable to the b_{3u} out-of-plane modes of tolane, shows the same trend and the same deviations already discussed in that case (3).

Vibrations of b_u Species

Regarding the phenyl ring frequency location, we adopted the same criteria used for tolane (3) and the results, listed in Table V, do not require further detailed comment.

The structure of *trans*-1,2-disubstituted ethylene of stilbene justifies the assignment at 1300 and at 1068 cm^{-1} of the ethylenic CH and CD bending vibrations respectively (14). The last fundamental to be considered is a skeletal deformation involving the ethylenic bridge.

[d]Intensity expressed as peak extinction coefficient ($mole^{-1}$ l cm^{-1}) relative to a value of 100 assumed for the band at 1568 cm^{-1}. The resulting values are rounded off to the next multiple of five; sh, shoulder; w, weak.
[e]Solution in carbon tetrachloride.
[f]Solution in carbon disulfide.

Taking into account fluorescence studies (15), which indicate the presence of a symmetric planar skeletal bending mode at 212 cm^{-1}, we propose the assignment of the band observed at 233 cm^{-1} in light stilbene to the infrared active asymmetric analogue of this vibration.

The unpredictable dichroism of b_u modes has been discussed above, together with the behavior which can be inferred for X-insensitive phenyl ring fundamentals by using the local symmetry of the aromatic fragment. If there is polarization specificity, the local symmetry will prevail and the modes corresponding to the vibrations of a_1 species of the phenyl fragment should display perpendicular polarization, while those corresponding to b_1 species should be parallel. Careful inspection of the spectra shows that all a_1 fundamentals, both in the light and heavy compounds, fit the expected dichroic behavior. On the other hand, the dichroism of the bands due to vibrations of the b_1 class is often anomalous (see Tables III and IV).

Conclusion

The proposed assignment for infrared active fundamentals of stilbene and stilbene-d_{12} is summarized in Table V. This assignment is supported by the new experimental information obtained from the spectra of stilbene-d_{12} and from the polarized light spectra of well-identified crystal planes of both the light and heavy compounds. The frequency values of the fundamentals

[a]Frequency values (cm^{-1}) observed in the spectra of oriented crystals. Bracketed values correspond to bands assumed to be strongly overlapped by other absorptions.

[b]As a consequence of the correspondence, used throughout the discussion, between stilbene and monosubstituted benzenes vibrations, the approximate descriptions given are inferred from the results of calculations reported for C_6H_5Cl. The assignment of the frequencies of $C_{14}H_{12}$ and $C_{14}D_{12}$ has been guided by the inspection of the atomic displacements in C_6H_5Cl and C_6D_5Cl normal vibrations. For the correct descriptions of normal vibrations of both C_6H_5Cl and C_6D_5Cl in terms of potential energy distribution, the original literature should be consulted (12).

[c]a_1, b_1, and b_2 are the symmetry species of the group vibrations of the phenyl rings under the local symmetry C_{2v}; Xs, substituent sensitive modes.

[d]Average value of the frequencies observed in the crystal spectra for bands presenting correlation field splitting.

which can be related to group vibrational modes of the monosubstituted benzenes have been localized without difficulty in nearly all the cases according to (and within the same limits of) the reported assignments of monohalogenobenzenes and their fully deuterated analogues.

The principal aim of the present study, as emphasized in the Introduction, is the ascertainment of empirical polarization specificity for those fundamentals which display frequency specificity and whose transition moment direction can be known only when the C_{2v} local symmetry of the phenyl fragment is used. The results show that, though all a_1 and a few b_1 band polarizations match the requirements for polarization specificity, the general dichroic trend is not sufficiently uniform to indicate the existence of reliable polarization specificity. This partially erratic dichroism goes beyond the anomalies observed in the case of tolane, anomalies which would not alone affect the exploitation of an existing polarization specificity.

The qualitative dichroic trend in stilbene is very similar to that reported by Daasch (16) for *trans*-azobenzene. However, we consider it untimely to draw analogous conclusions, since, even if the experimental polarization specificity were sufficiently established, the quantitative dichroic ratios are to some extent unreliable because of the instrumental errors and the influence of the solid state on the band intensity.

Acknowledgments

The authors wish to express their appreciation to Professor S. Califano for originally suggesting the present study, and to thank Dr. A. Dal Pra' for the X-ray analysis of the crystals.

Kinetics of the thermal reactions of ethylene

M. Simon and M. H. Back
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received June 20, 1968

Measurements of the yields of products and the decrease in pressure as a function of time have shown the relation between the mechanisms for the thermal reactions of ethylene proposed in two separate studies, which jointly cover the range 776–924 °K and 10–600 Torr. Specifically, the measurements relate the polymerization and decomposition processes and show the dependence on temperature and pressure of the reactions proposed.

Introduction

In two recent studies of the pyrolysis of ethylene (1, 2) a similar range and distribution of products was reported but different behavior was observed on two important aspects. As a result, two somewhat different interpretations of the mechanism of the reaction were proposed. The first study, which covered the range 798–923 °K and 10–270 Torr, reported that all products showed self-acceleration and none appeared to be formed with a non-zero initial rate. Furthermore, no changes in total pressure were observed. It was suggested that the mechanism was a degenerately branched chain reaction initiated by the breakdown of butene, one of the major products. The second study, which covered the range 776–873 °K and 150–600 Torr, reported induction periods for all products except ethane, whose yield was observed to rise linearly with time from the origin. In addition a pressure decrease was observed which was considerably in excess of that calculated from the yields of measured products. The decrease in pressure with time was an S-shaped curve. An initial rapid rate decreased to a minimum value, then increased again to a constant value, less rapid than the initial. The period of minimum rate corresponded roughly with the induction period observed for the major products. This pressure decrease was interpreted as due to a rapid radical chain polymerization and it was suggested that ethane was the only low molecular weight product of this process. The other products were suggested to arise from a slow thermal breakdown of the polymer.

The main difference in conditions between the two studies was in the range of pressure. The free radical polymerization process and the concurrent rate of formation of ethane were second order in ethylene and might therefore be expected to become less important relative to other processes as the pressure was lowered. Indeed it appeared from the results of Halstead and Quinn (1) that the decrease in pressure probably became insignificant in the neighborhood of 100 Torr and that these authors observed only the main products arising from the branched chain reaction initiated by butene. To clarify this aspect measurements of the pressure decrease have been extended to cover the range of pressures studied by Halstead and Quinn (1). At the same time some measurements of the principal products were made in the early stages of the reaction in an attempt to clarify the conditions under which an induction period is observed for the formation of ethane.

Experimental

The apparatus and analytical techniques were those described in ref. 2. Several minor improvements gave an increased precision to the results. The fluctuation in the furnace temperature was reduced to less than $\pm 0.5°$. Using a new, slightly longer (36 in.) column of the same materials, which gave somewhat better resolution, reproducibility of the product analyses was usually better than $\pm 5\%$. The purification technique for the ethylene was as described previously. For the lower pressures used in this work the yields of ethane were corrected for the ethane impurity in the ethylene (approximately 0.01 mole %). The pressure measurements were made with a Texas Instrument fused quartz spiral gauge, model 145. The gauge was provided with a digital counter. One unit in the final digit corresponded to a pressure of 0.002 Torr. This gauge was a later model than the one used in ref. 2 and also gave some improvement in precision. The temperature of the furnace was monitored during the experiments in which the pressure was measured and corrections to the pressure were made for the periodic fluctuation of the temperature. These corrections were sometimes as large as 20% of the measured ΔP. The volume of the tubing connecting the reaction vessel to the pressure gauge amounted to 4% of the volume of the reaction vessel. The correction for this dead space, which was at room temperature, was therefore 10% of ΔP at 823 °K.

Results

The pressure in the reaction vessel as a function of time is shown in Fig. 1 for three pressures at 823 °K. At 10 Torr the change in pressure was scarcely above the limit of detection of the gauge. Duplicate experiments, after correction for temperature fluctuation, showed a variation from the average of up to 5% in ΔP. All curves except those at 30 Torr (where the time taken was not sufficient) showed the S-shaped behavior which had characterized the measurements at higher pressures (2). As had been observed previously, the minimum rate occurred at longer times as the pressure was lowered.

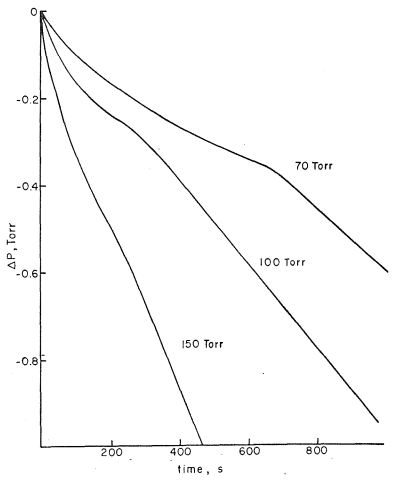

FIG. 1. Pressure as a function of time at 823 °K.

The pressure measurements are compared to the product yields in Figs. 2, 3, and 4 for three temperatures at a pressure of 100 Torr. Only the three main products, ethane, propylene, and butene are shown. The pressure decrease calculated from the yields of propylene and butene is shown for comparison with the measured ΔP. The only other product of significance at these small conversions is butadiene, inclusion of which would lower slightly the calculated ΔP curve.

In ref. 2 the rate of pressure decrease was too fast to allow a reliable measure of the initial rate. At the lower pressures studied here, however, better values could be obtained. At 823 °K and over the pressure range 30–150 Torr the order of the initial rate was 1.8. This is added support for the mechanism for the polymerization suggested in ref. 2, which predicted an order of 2.

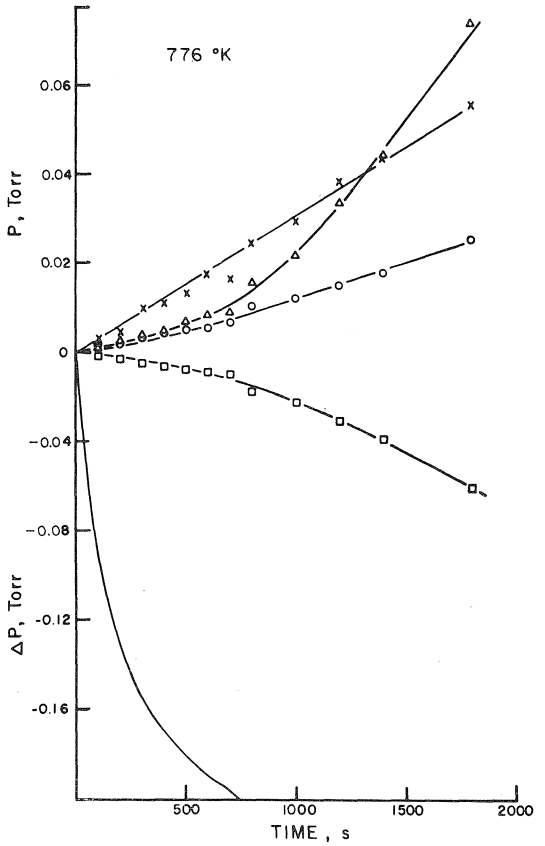

FIG. 2. Product yields and pressure as a function of time at 100 Torr: ×, ethane; △, propylene; ○, butene; □, calculated pressure decrease; and smooth curve, measured pressure decrease.

Discussion

Two points of significance are apparent from these measurements.

(1) A rapid decrease in the pressure of ethylene occurs in the initial stages of the pyrolysis without the induction period observed for most of the low molecular weight products. This decrease is readily measurable with the present techniques at pressures as low as 30 Torr, over the range of temperatures studied. Since the decrease is considerably greater than that calculated from the products measured, products of higher molecular weight than those analyzed must be formed. In ref. 2, where more extensive analysis was reported, it was estimated that these products must be of a composition corresponding to C_8 or greater.

(2) The product ethane is formed without an induction period under conditions of high

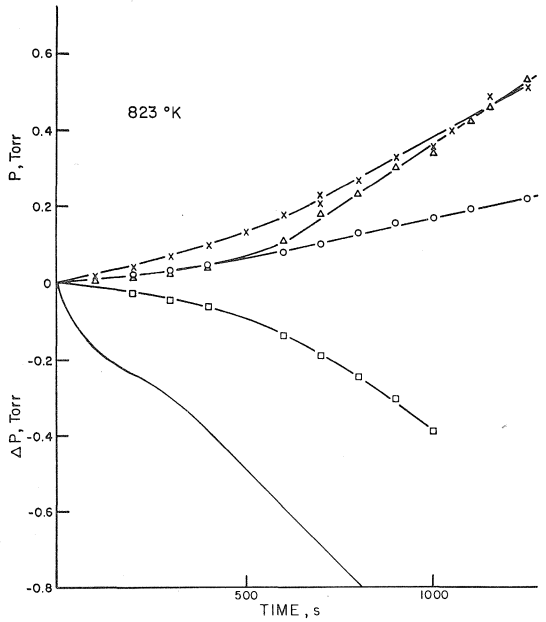

FIG. 3. Product yields and pressure as a function of time at 100 Torr: ×, ethane; △, propylene; ○, butene; □, calculated pressure decrease; and smooth curve, measured pressure decrease.

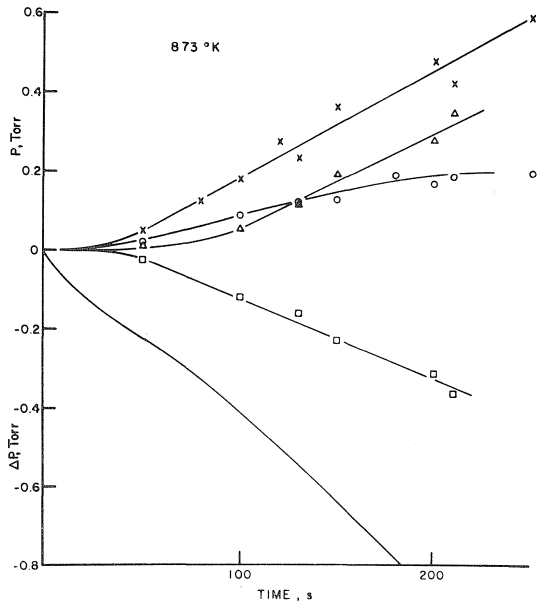

FIG. 4. Product yields and pressure as a function of time at 100 Torr: ×, ethane; △, propylene; ○, butene; □, calculated pressure decrease; and smooth curve, measured pressure decrease.

pressure and low temperature, but gradually assumes an induction period as the pressure is lowered or the temperature increased. This change in behavior is linked with the relative importance of the polymerization process. Where the polymerization is a major process the ethane yield does not show an induction period, but as the polymerization becomes relatively less important the yield of ethane also becomes very small in the initial stages. Thus the conditions of the pyrolysis in ref. 1 would give an induction period for ethane, while those of ref. 2 would tend to give a linear yield–time curve.

The general conclusion reached from these results is that the mechanisms proposed in refs. 1 and 2 are essentially complementary and one or the other becomes predominant under certain conditions of temperature and pressure. On the other hand, the measurement of the pressure decrease shows that the high molecular weight product is formed initially even at low pressures and the persistence of the S-shaped curves suggests that this polymer subsequently decomposes, possibly yielding some of the low molecular weight products.

Taking into account all the results, the following general mechanism is proposed. In the initial stages of the reaction a radical chain polymerization, initiated by the bimolecular reaction of two ethylene molecules to give a vinyl and an ethyl radical, yields a high molecular weight product and, at high pressures, measurable amounts of ethane.

$$[1] \quad C_2H_4 + C_2H_4 \rightarrow C_2H_3 + C_2H_5$$

$$[2a] \quad C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$$

$$[2b] \quad \rightarrow C_4H_9$$

$$[3] \quad C_2H_3 + C_2H_4 \rightarrow C_4H_7$$

$$[4] \quad C_4H_7 + C_2H_4 \rightarrow C_6H_{11}$$

$$[5] \quad C_nH_{2n-1} + C_2H_4 \rightarrow C_2H_5 + C_nH_{2n-2}$$

$$[6] \quad C_nH_{2n+1} + C_2H_4 \rightarrow C_2H_5 + C_nH_{2n}$$

$$[t] \quad C_2H_5 + C_2H_5 \rightarrow C_4H_{10}$$

The assumptions underlying this type of polymerization and the kinetic parameters to be expected for the products were outlined in ref. 2. At high pressures the two primary products are a polymer and ethane. If termination occurs by the combination of ethyl radicals then butane will also be a primary product, although a minor one. Amounts of butane observed were too small to be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

certain of the distinction between a primary and a secondary product.

As the pressure is lowered, reversal of the addition steps will become increasingly important, the molecular weight of the polymer will decrease, and the yield of ethane in the initial stages will also decrease. In ref. 2 it was suggested that the polymer itself decomposed giving rise to those products which were observed to have an induction period, the main ones being propylene, butene, and butadiene. The mechanism for this breakdown and formation of the products was not specified. In ref. 1 where a decrease in pressure was not observed, it was suggested that the decomposition of butene-1 initiated the branching chain reaction which produced the main products. This would be expected to occur under conditions where dissociation of radicals could compete favorably with the addition to ethylene.

The difference between the two mechanisms depends on the extent of polymerization that occurs before the dissociation of the radicals or unsaturated compounds creates an important source of radicals which in turn gives rise to the lower molecular weight products. At low temperatures and high pressures polymerization is favored and the high molecular weight unsaturated compounds would be expected to be the major source of secondary initiation. At high temperatures and low pressures, on the other hand, where higher compounds may not be formed, dissociation of butene-1 will probably be the main initiation process. It should be pointed out that although in this region the rate of formation of butene from the dissociation reaction is second order, the rate will become first order in ethylene as addition begins to compete with dissociation. Thus as the pressure is increased the polymerization process, which is second order in ethylene, will be favored.

The extent of polymerization depends not only on the relative rates of the propagation reactions—addition and decomposition—but on the relative rates of the initiation processes—the bimolecular reaction of two ethylene molecules and the dissociation of butene or higher molecular weight olefins. Using the values of Halstead and Quinn (1) for the rate constants for these initiation steps the rates of initiation were calculated at various pressures of ethylene and different extents of reaction. As the yield of butene increases during the course of the reaction, these initiation rates will eventually become equal and beyond this point the dissociation of butene will become the most important initiation step. Generally these initiation rates became equal at approximately the point in the reaction where the yield of ethane showed a rapid secondary increase in rate beyond the initial linear rise from the origin. The dissociation of butene may be the source of additional initiation which causes this increase in the rate of production of ethane. Under the conditions of the pyrolysis in ref. 2 this point in the reaction was usually well beyond the initial stages at which products were measured. Dissociation of butene may also cause the increased rate of polymerization which was observed at about the end of the induction period and it may not be necessary to suggest the formation of two types of polymers as was done in ref. 2.

The two sets of data are not in complete agreement on the conditions of temperature and pressure where the polymerization may be regarded as an important process in the initial stages of the reaction. The present data show that the decrease in pressure observed is in excess of that calculated from the products measured at a pressure as low as 30 Torr at 823 °K. Such a difference should have been observed by Halstead and Quinn (1) at least by about 70 Torr, although they did not observe a decrease in pressure even at 127 Torr. The decrease in pressure in the pyrolysis of ethylene has been measured many times and the present results are in reasonable agreement with previous measurements (3, 4), except in the shape of the initial portion of the pressure–time curve, which previous techniques were not sufficiently sensitive to detect.

Halstead and Quinn (1) also did not observe a finite initial rate of production of ethane even at 127 Torr at 823 °K, although this was observed in the present results at 100 Torr at the same temperature (Fig. 3). The cause of this discrepancy is not obvious, although we believe it is linked with the failure to observe a decrease in pressure. The rate of polymerization was independent of surface/volume ratio down to 150 Torr of ethylene (2). With good vacuum techniques the level of oxygen impurity can be kept below 1 p.p.m. and was probably not significantly different in the two systems.

An apparent disagreement between refs. 1 and 2 is the activation energy for the formation of ethane, which was 54.1 kcal/mole in ref. 1 but

42 kcal/mole in ref. 2. The difference is explained by the fact that the measurements refer to different stages of the reaction. Those of ref. 2 were the measurements of the ethane formed without an induction period, while in ref. 1 the measurements were made where the rate of formation increased with time. The activation energy for the rate of formation of butane was reported as 69.5 kcal/mole in ref. 1 and 70 kcal/mole in ref. 2. In each case butane was suggested to be formed from the termination step in the chain reaction so that the activation energy for formation of butane should equal that of the initiation. In ref. 1 the initiation was suggested to be the dissociation of butene, while in ref. 2 initiation by reaction [1] was postulated. The endothermicities of these steps are not sufficiently different that the measured activation energy would favor the occurrence of one over the other. In any case as already discussed there is probably a change from one initiation step to the other as the pressure is lowered.

Infrared spectra of photodimers of anthracene, benzo[*a*]anthracene, and tetracene

SURJIT SINGH AND C. SANDORFY
Department of Chemistry, University of Montreal, Montreal, Quebec
Received June 11, 1968

Infrared spectra of the photodimers of anthracene, anthracene-d_{10}, tetracene, and benzo[*a*]anthracene are reported in the region 4000–200 cm^{-1}. An attempt is made to correlate the observed bands with the proposed structure of the anthracene dimer. The infrared spectra indicate that the dimers of benzo[*a*]anthracene and tetracene have similar structures.

Introduction

Anthracene is known (1, 2) to form a photodimer when its deaerated solution in cyclohexane or in benzene is exposed to ultraviolet radiation. X-Ray (3) and electronic spectral (2) data show that in dianthracene the two anthracene molecules are joined at their meso positions. The top and bottom of the central rings are bent forwards and the outer rings backwards as a result of electrostatic repulsion. Mustafa and co-workers (4) prepared the dimer of benzo[*a*]anthracene and more recently Birks (5), Livingston (6), and their co-workers have reported the formation of ditetracene under similar experimental conditions. It was thought of interest to study the infrared spectra of these dimers and correlate the spectral results with the proposed structures. The infrared spectra of anthracene, benzo[*a*]anthracene, tetracene, and many other polynuclear aromatic hydrocarbons were studied by Cannon and Sutherland (7). Attempts have also been made to assign the infrared and Raman spectra of anthracene by carrying out a normal coordinate analysis (8) and polarized radiation (9) studies.

We have now prepared the photodimers of anthracene, anthracene-d_{10}, benzo[*a*]anthracene, and tetracene. The infrared spectra of these dimers are discussed using the available (7–9) assignments of monomers.

Experimental

Zone refined anthracene and anthracene-d_{10} were obtained from Dr. W. G. Schneider of the National Research Council of Canada and recrystallized pure tetracene was obtained from Professor M. S. Newman of Ohio State University, to whom our sincere thanks are due. Benzo[*a*]anthracene was purchased from Eastman Organic Chemicals. The anthracenes and tetracene were used without further purification. Benzo[*a*]anthracene was recrystallized from alcohol before use. Spectrograde benzene and cyclohexane were used without further purification. The dianthracenes were prepared by irradiating saturated cyclohexane solutions (1 g/l) of anthracene for 7 to 8 h by a Hanovia high pressure mercury–xenon arc type 6-B-1. Dimers of benzo[*a*]-anthracene and tetracene were prepared by irradiating their saturated solutions in benzene using a 1 kW tungsten lamp for 3 to 4 days. The solutions were flushed with dry nitrogen for 20–30 min before irradiating. The reactions were carried out in quartz tubes kept in Pyrex water jackets to avoid unnecessary heating of the samples. The crystalline precipitates were washed 10 to 12 times with the solvents which were used and dried in a vacuum desiccator. The ultraviolet spectra of the dimers show that di(benzo[*a*]anthracene) and ditetracene have monomer impurities which may not be more than 1%. The infrared spectra were recorded on a Perkin–Elmer 621 spectrophotometer. The samples were handled in the form of potassium bromide pellets, Nujol mulls, or solutions in 2.5 cm long cells with sodium chloride windows.

Results and Discussion

The infrared spectra of dianthracene and dianthracene-d_{20} are shown in Figs. 1 and 2. The band positions of the anthracene monomer and dimer and dianthracene-d_{20} are listed in Table I. Results from spectra taken in both KBr pellets and Nujol mulls are listed. The spectra in the C—H region were taken in saturated carbon tetrachloride and carbon disulfide solutions too.

The infrared spectrum of dianthracene shows 7 to 8 well defined bands in the C—H region (Table I). The bands are of medium or weak intensity and are observed almost at the same positions in KBr pellets and in the solution spectra. Two of the bands are considerably below the aromatic C—H stretching region (2945 and 2921 cm^{-1}). The spectra in carbon tetrachloride and carbon disulfide solutions in this region are ill defined due to strong solvent absorption.

According to the available X-ray (3) and

electronic spectral (2) results, the highest symmetry dianthracene can have is D_{2h}. By simple group theoretical considerations (10) using internal coordinates, the 20 C—H stretching vibrations can be shown to belong to the following symmetry species

$$\Gamma_D\nu(\text{C—H}) = 3A_g + 2B_{1g} + 2B_{2g} + 3B_{3g} + 2A_u + \underline{3B_{1u}} + \underline{3B_{2u}} + \underline{2B_{3u}}$$

B_{1u}, B_{2u}, and B_{3u} are the only infrared active species and are underlined. In the proposed structure of dianthracene (2) not all 20 protons are aromatic. Four protons in the meso positions of the monomer anthracene units become tertiary aliphatic protons. The normal vibrations due to these 4 C—H bonds can be shown to belong to the A_g, B_{3g}, $\underline{B_{1u}}$, and $\underline{B_{2u}}$ species. Thus 2 out of 4 aliphatic C—H vibrations are expected to be infrared active. The 10 C—H stretching vibrations in the anthracene monomer have similarly been shown to belong to the A_g, B_{1g}, B_{2u}, and B_{3u} species as follows:

$$\Gamma_M\nu(\text{C—H}) = 3A_g + 2B_{1g} + \underline{3B_{2u}} + \underline{2B_{3u}}$$

The 5 infrared active vibrations ($3B_{2u}$ and $2B_{3u}$) have been (8) assigned to the 5 bands appearing in the range 3100–2990 cm^{-1} in the anthracene spectrum. Based on the above arguments we assign the 2 low lying bands at 2945 and 2921 cm^{-1} to the aliphatic C—H stretching vibrations. The remaining 5 bands at 3070, 3059, 3035, 3012, and 3000 cm^{-1} can thus be assigned to the aromatic, =C—H stretching vibrations. It can be seen that in the spectrum of dianthracene-d_{20} also, though the bands are not as well resolved, the 2 groups of bands are present in the C—D stretching region. This gives additional support to the proposed structure of dianthracene.

The C—C stretching vibrations are quite weak as usual, and a detailed discussion of them is not warranted. About 10–15 bands of very weak to medium intensity are found in the region 2000 to 1300 cm^{-1}. Weak bands from 1700 to 2500 cm^{-1} are usually assigned to overtones and combinations (11).

The lower frequency region is more interesting. There are 4 very strong bands and about 10 medium strong bands in the spectrum of dianthracene in the region 1300–200 cm^{-1}. Dianthracene-d_{20} has a similar spectrum. While surveying the bands in Table I it appears that the bands at 1215, 1100, 1025, 810, and the broad band at 760 cm^{-1} with shoulders at 750 and 745 cm^{-1} in dianthracene experience an isotopic shift when compared to the spectrum of dianthracene-d_{20}. The ν(H)/ν(D) ratio varies between 1.2 and 1.4. All other bands undergo only a very slight shift, the ν(H)/ν(D) being 1.1 for the most shifted and 1.01 for the least shifted band. It can therefore be concluded that the bands with a shift of the order of 1.2 to 1.4 might belong to the C—H in-plane or out-of-plane bending vibrations and the other bands to the C—C bending motions or skeletal distortions. As can be seen from Fig. 1 the bands at 810 and 760 cm^{-1} are very strong, a characteristic of the C—H out-of-plane bending vibrations. The in-plane bendings are usually weaker. Anthracene shows 3 C—H out-of-plane bending vibrations

$$\Gamma_M\nu(\text{C—H}) = 2B_{2g} + 3B_{3g} + 2A_u + \underline{3B_{1u}}$$

at 954, 884, and 727 cm^{-1} in solutions (9). Another band at 870 cm^{-1} has been reported in the crystal spectrum (9). This is assumed to be due to an infrared inactive vibration, A_u, which is allowed by site symmetry. The dimer should have 6 infrared active vibrations due to out-of-plane aromatic C—H deformations and 2 infrared active out-of-plane aliphatic C—H deformation vibrations

$$\Gamma_D\nu(\text{C—H)Ar} = 2A_g + 2B_{1g} + 2B_{2g} + 2B_{3g} + 2A_u + \underline{2B_{1u}} + \underline{2B_{2u}} + \underline{2B_{3u}}$$

$$\Gamma_D\nu(\text{C—H)Al} = A_g + B_{3g} + \underline{B_{1u}} + \underline{B_{2u}}$$

The bands which we assign to the out-of-plane C—H deformations are quite broad and therefore too much emphasis cannot be laid on the number of bands expected and observed. The spectra can be further discussed on the basis of the conclusions reached by Cannon and Sutherland (7).

Cannon and Sutherland (7) suggested that for condensed ring systems containing 3 or more rings, bands near 750 cm^{-1} arise from C—H bonds that are approximately parallel to the longer axis of the molecule, and bands near 900 cm^{-1} arise from C—H bonds approximately perpendicular to the longer axis of the molecule. 9,10-Substitution has been found (7, 11) to remove the band at 884 cm^{-1} in anthracene. Therefore the band at 884 cm^{-1} has been attributed to the deformation vibration of the C—H bonds in the 9 and 10 positions.

For personal use only.

In the dianthracene spectrum we do not find any band near 900 cm^{-1}. This is in line with the fact that the C—H bonds at 9,10 positions are no more aromatic. On the other hand we see a new band at 810 cm^{-1}. The 727 cm^{-1} band of anthracene also shifts to higher frequencies. The band at ~810 cm^{-1} is probably due to the aliphatic C—H out-of-plane bending vibrations. The aromatic C—H bonds of dianthracene resemble ortho disubstituted benzene C—H bonds. It is interesting to note that the C—H out-of-plane bending vibrations in ortho disubstituted benzenes have been found (11) to lie in the range 740 to 760 cm^{-1} which is certainly higher than the anthracene C—H out-of-plane deformation vibration under consideration; this explains the shift of the 727 cm^{-1} band of anthracene to higher frequencies on dimerization.

Infrared spectra of di(benzo[*a*]anthracene) and ditetracene are shown in Figs. 3 and 4 and the positions and relative intensities of the bands observed for the monomers and dimers have been listed in Tables II and III. Both di(benzo[*a*]-anthracene) and ditetracene are found to have bands below 3000 cm^{-1} due to the above discussed aliphatic C—H stretching vibrations. This shows that the mode of linkage in the three dimers under investigation is similar. The formation of aliphatic C—H bonds is a result of dimerization. Anthracene and benzo[*a*]anthracene on dimerization can have only 4 aliphatic C—H bonds (Fig. 5*a*, 5*b*). Ditetracene can have 4 or 8 depending on whether covalent linkage takes place at 2 centers of each tetracene molecule (Fig. 5*c*(*i*)) or 4 (Fig. 5*c*(*ii*)).

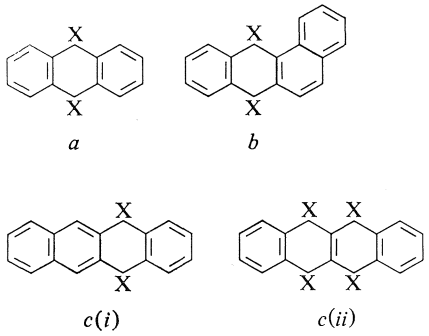

FIG. 5. Possible centers of covalent linkage in (*a*) anthracene, (*b*) benzo[*a*]anthracene, (*c*) tetracene for photodimerization.

Group theory demands 3 bands in the infrared due to aliphatic C—H stretching vibrations

$$\Gamma\nu(\text{C—H})\text{Al} = A_g + B_{1g} + B_{2g} + B_{3g} + A_u + \underline{B_{1u}} + \underline{B_{2u}} + \underline{B_{3u}}$$

if the dimer formation is through covalent linkages at 4 centers of each tetracene molecule and D_{2h} symmetry is assumed for the dimer. On the other hand if the dimerization takes place through linkages at 2 centers only, it can have either *cis* (C_{2v}) or *trans* (C_{2h}) configuration. Three out of 4 aliphatic C—H stretching vibrations are expected to be infrared active in the *cis* form ($\underline{A_1} + A_2 + \underline{B_1} + \underline{B_2}$) and 2 aliphatic stretching vibrations are expected to be infrared active in the *trans* form ($A_g + B_g + \underline{A_u} + \underline{B_u}$). Two bands appearing at 2936 and 2915 cm^{-1} can be assigned to the aliphatic C—H stretching vibrations; this makes the *trans* (C_{2h}) structure more probable than the other two structures of ditetracene.

The lower frequency part of the spectrum of di(benzo[*a*]anthracene) is quite complicated whereas that of ditetracene is comparatively simple. Tetracene has 2 strong bands at ~900 and 750 cm^{-1} which have been assigned to C—H deformation vibrations by Cannon and Sutherland (7). A strong broad band has been found in the spectrum of ditetracene at 888 cm^{-1}. Another strong band appears at 740 cm^{-1} with shoulders at 757 and 764 cm^{-1}. Two weak bands are observed at 802 and 826 cm^{-1}. It is not possible to draw any conclusion concerning the structure of ditetracene from this part of the spectrum, but the appearance of a band at 888 cm^{-1} seems to

suggest that there are aromatic C—H bonds at axes perpendicular to the longer axis of tetracene. This is in favor of the view that covalent links are formed at 2 centers of the tetracene monomers and not 4 as suggested in Fig. 5*c*(*ii*). We cannot go further without an X-ray analysis. All the spectral conclusions are confined to the spectra in solid phase because the compounds are not soluble in solvents commonly used for recording the infrared spectra in solution. But this is expected to have only a slight influence on the spectra. Raman spectra might give additional credence to the arguments.

Effect of pH and phosphate ions on the polarographic behavior of D-glucuronolactone

R. J. THIBERT AND J. R. JOHNSTON
Department of Chemistry, University of Windsor, Windsor, Ontario

Received August 12, 1968

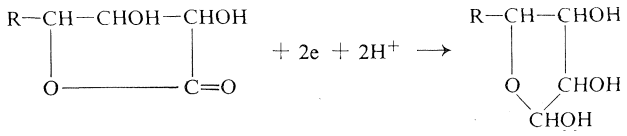
The polarographic determination of D-glucuronolactone in aqueous solution was shown to be feasible up to a concentration of 6 mg per ml in KCl, NaCl, and LiCl with gelatin as the maximum suppressor. The effect of pH and phosphate ions on the polarographic wave of D-glucuronolactone is discussed and compared to the reaction of dialkyl hydrogen phosphites and trialkyl phosphites with β-propiolactones. The effect of pH and phosphate ions on the polarographic wave of D-glucuronic acid was also investigated.

Canadian Journal of Chemistry 47, 265 (1969)

Introduction

The polarographic determination of D-glucuronolactone has not been widely investigated. Ishidate and Shimozawa (1) attempted a polarographic study of D-glucuronic acid and D-glucuronolactone, but were unable to obtain reproducible waves for either species. Thibert and Boyle (2) were able to obtain reproducible waves with D-glucuronolactone in an unbuffered medium. The concentration range studied by them was that usually encountered in biological fluids: 0–100 μg per ml. They noted, however, that any of the standard buffers completely suppressed the wave. In particular, phosphate annihilated the wave.

It is generally assumed (3, 4) that the waves produced by lactones are caused by their reduction to the corresponding sugars



Also, polyhydroxy acids give only a hydrogen wave (4).

The study of D-glucuronolactone in aqueous medium is complicated by the lactone–acid equilibrium. A fairly concentrated solution of D-glucuronolactone took 8 weeks to reach equilibrium (20% lactone, 80% acid) at room temperature (5). In the much more dilute range in which Thibert and Boyle (2) worked, it is probable that the large excess of water causes the equilibrium to be more on the acid side, and for this equilibrium to be attained more rapidly.

Dowben (6), using 0.02 *M* D-glucuronolactone solutions (i.e., about 3.52 mg lactone per ml) and at 37 °C, observed only a slight hydrolysis (about 5%) in distilled water after 24 h; about 50% hydrolysis in 0.2 *M* Tris buffer, pH 7.2, after 24 h; but 90% hydrolysis in potassium phosphate buffer, pH 7.2, after 24 h. Thus, D-glucuronolactone was hydrolyzed about 8 times more rapidly in the Tris buffer than in distilled water, and about 40 times more rapidly in the phosphate buffer than in distilled water.

This paper presents a detailed study of pH of D-glucuronolactone solutions over a wide range of concentration, and the relationship of pH to the polarographic wave. The concentration range has been extended 60-fold relative to the results reported by Thibert and Boyle (2). The effect of changing supporting electrolytes, maximum suppressor concentration, and ionic strength is reported. Detailed experiments have been made, examining the effect of adding phosphate as $H_2PO_4^-$, HPO_4^{2-}, and PO_4^{3-}. A preliminary study has also been made with D-glucuronic acid.

Experimental

Materials

Gelatin (purified, calfskin), D-glucuronolactone, both from Eastman Organic Chemicals; D-glucuronic acid, 99% from Sigma Chemical Co.; mercury (triple-distilled) from Engelhard Industries of Canada, Ltd.; LiCl, KCl, NaCl, KH_2PO_4, K_2HPO_4, K_3PO_4, NaH_2PO_4, Na_2HPO_4,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Na_3PO_4, from Fisher Scientific Co., Ltd., were all Fisher certified reagents.

All reagents were used as received from the suppliers. Solutions were prepared using deionized distilled water in all cases. This water was obtained by passing distilled water through a column containing Rexyn I-300, Research Grade resin (a mixed bed resin).

Preparation and Storage of Stock Solutions

Stock solutions of 1 mg D-glucurono-γ-lactone per ml were prepared fresh daily and were found to be stable for at least 5 h. Stock solutions of D-glucuronic acid were prepared in a similar manner.

Gelatin was generally prepared fresh daily, although on occasion a solution was stored overnight in a refrigerator. At no time was a gelatin solution used that was more than 36 h old.

The various supporting electrolytes were prepared as 1 *M* solutions and were stored in flint bottles. It was found that upon aging, the pH of these solutions increased, affecting the unbuffered solutions which were polarographed. Therefore, the solutions were prepared in 500-ml batches, and the residue (if any) was discarded after 2 weeks.

Methods

(1) Polarographic Determination of D-*Glucuronolactone*

(a) Calibration for the range 0–100 μg D-*glucuronolactone per ml*—Ten milliliters of a 1 *M* stock solution of the supporting electrolyte (KCl, NaCl, or LiCl) were added to a 50-ml volumetric flask via a burette or pipette. Two and a half milliliters of 0.1% gelatin solution (maximum suppressor) were added via a Mohr pipette (giving a final gelatin concentration of 0.005%).

The desired amount of D-glucuronolactone was then pipetted from a stock solution of 1 mg D-glucurono-γ-lactone per ml. The solution was then diluted to volume, mixed, and a small amount was quickly transferred to the polarographic cell (an H-cell). (*NOTE*: For reproducibility, the solution to be polarographed must be prepared from the stock solution of D-glucuronolactone *just* before it is to be placed in the H-cell and deaerated, because dilute solutions tend to age rapidly at lower concentrations, and even a minute or two difference in time from one run to another can cause discrepancies.)

Nitrogen was bubbled through the solution for 5 min. During this time, the H-cell was being brought to 25 °C in a thermostat. The temperature of the thermostat was maintained at 25 ± 0.1 °C by means of a Haake thermostated circulating pump.

The nitrogen was purified by passing the gas through a gas-washing bottle containing a 1:1 ammonium hydroxide solution saturated with ammonium chloride, and containing some copper turnings. Ammonia was removed by subsequent passage through a second gas-washing bottle containing a 1 *M* sulfuric acid solution. The nitrogen was then saturated with water vapor by bubbling through two more gas-washing bottles, the first at room temperature, the second at 25 °C.

Immediately after deaeration the cell was sealed and a polarogram was then run over the voltage range −1.0 to −2.0 V, with the appropriate sensitivity setting. For this purpose the Sargent (E. H. Sargent and Co.) model XXI polarograph was used. The polarographic cell was an H-cell with a saturated calomel electrode (s.c.e.) as the reference electrode. All $E_{1/2}$ values reported are with respect to the s.c.e. The characteristics of the capillary were $m = 1.785$ mg s^{-1}, $t = 3.53$ s, $m^{2/3}t^{1/6} = 1.816$ $mg^{2/3}$ $s^{-1/2}$ at −1.48 V. All polarograms were run at 50 cm mercury. No damping was used at any time.

(b) Calibration for the range 0–1000 μg D-*glucuronolactone per ml*—The procedure was the same as (*a*), except that 3.75 ml of a 0.1% gelatin solution were added to the 50-ml flask (giving a final gelatin concentration of 0.0075%). Due to the higher range of lactone concentrations, a stock solution was not prepared. Rather, the desired amount of the lactone was weighed into a small beaker and then was transferred quantitatively to the 50-ml flask. For reproducibility, the solution to be polarographed must be prepared just before it is to be placed in the H-cell and deaerated.

Other maximum suppressors were tried using method (*b*): methyl red (0.004%), methyl orange (0.001%), methylene blue (0.001%), bromophenol blue (0.001%), Triton X-100, agar, gum tregacanth, and peptone all at 0.0075%. Gelatin was by far the most successful in suppressing the maximum.

(c) Calibration for the range of concentration ⩾1 mg D-*glucuronolactone per ml*—The procedure used was the same as procedure (*b*), except that 5.0 ml of 0.1% gelatin solution were added to the 50-ml flask (giving a final gelatin concentration of 0.01%). The solution was deaerated in the H-cell for 7 min.

(2) Polarographic Determination of D-*Glucuronic Acid*

The procedure used was exactly the same as procedure (*a*) for D-glucuronolactone. Solutions of D-glucuronic acid appear to be quite stable relative to comparable solutions of D-glucuronolactone, and thus can be prepared several minutes in advance of being placed in the H-cell.

(3) pH Measurements of D-*Glucuronolactone and* D-*Glucuronic Acid*

The desired amounts of D-glucuronolactone or D-glucuronic acid, supporting electrolyte, and gelatin were placed in a 50-ml volumetric flask as described in (*1*) and (*2*), and the appropriate type of water (deionized or boiled deionized) was used to dilute the solution to volume. Approximately 15 ml of the solution were placed in a 50-ml beaker. The beaker was put into the thermostat at 25 °C and nitrogen was bubbled through the solution via a fritted glass bubbling tube for the proper length of time as in procedure (*1*) and (*2*), depending on the concentration. At a D-glucuronolactone concentration of 80 μg per ml, the pH was adjusted with 0.01 *N* HCl or 0.01 *N* KOH; at a D-glucuronolactone concentration of 1 mg per ml, pH adjustment was made with 0.1 *N* KOH or 0.1 *N* HCl.

pH measurements were made with a Radiometer type TTT1c titrator (used as a pH meter) and a Radiometer model PHA630T scale expander. The meter was standardized with buffers of pH 4.01 (0.05 *M* potassium acid phthalate) and 6.48 (Radiometer buffer solution S1001).

(4) Addition of Phosphate

$H_2PO_4^-$, HPO_4^{2-}, and PO_4^{3-} solutions were prepared as 1 mg PO_4^{3-} per ml, or 10 mg PO_4^{3-} per ml, regardless of the cation. The desired amount of phosphate was pipetted into a 50-ml volumetric flask containing gelatin,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

supporting electrolyte, and the appropriate amount of D-glucuronolactone or D-glucuronic acid. The solution was diluted to volume, mixed, and treated as detailed in methods (*1*) and (*2*). The pH of the solution was determined as detailed in method (*3*).

Results

A typical polarogram is shown in Fig. 1. There is a linear relationship between diffusion current and concentration of D-glucuronolactone, from 20 μg lactone per ml to 6000 μg lactone per ml, as is reported in Table I. From 0 to 20 μg D-glucuronolactone per ml, the relationship is not linear, but is reproducible. Above a concentration of 6000 μg per ml, the wave heights could not be reproduced. Where KCl is the supporting electrolyte, the values given are the average of triplicate determinations. When NaCl or LiCl is the supporting electrolyte, the values are the average of duplicate determinations.

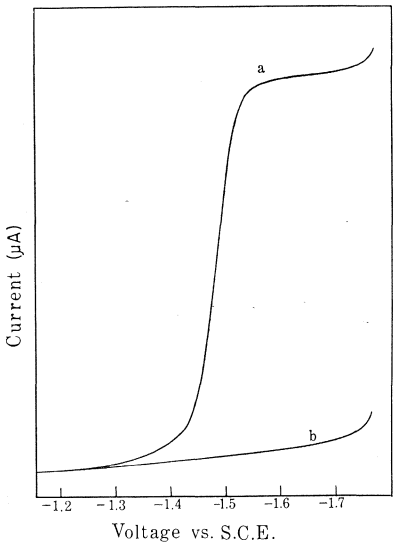


FIG. 1. A typical polarogram and a normal blank; *a*, polarogram of D-glucuronolactone; *b*, blank.

The gelatin concentration was kept as low as possible to obtain maximum sensitivity, but it was found that maxima appeared in the upper 30% of the lower and middle ranges. Therefore, when proceeding to the next highest range, the gelatin concentration was increased. Such an increase had only a small effect on the half-wave potential, but reduced the sensitivity. For example, when the D-glucuronolactone concentration was 20 μg per ml, the wave was well defined in the presence of 0.005% gelatin, but was virtually eliminated in the presence of 0.0075% gelatin. The effect of gelatin concentration on the diffusion current may be seen in Table I at the 100 and 1000 μg per ml concentrations of D-glucuronolactone.

Attempts to determine the concentration of D-glucuronic acid failed due to the wide variation of diffusion currents (±10%) at identical concentrations of the acid.

An attempt was made to determine accurately the half-wave potentials of the lactone, but due to the instability of the lactone in aqueous solution the results were not reliable. The approximate half-wave potential for D-glucuronolactone was found to be −1.48 V vs. s.c.e. for the range 0–100 μg per ml, −1.53 V vs. s.c.e. for the range 0–1000 μg per ml, and −1.60 V vs. s.c.e. for the range 0–6000 μg per ml.

The pH study of D-glucurono-γ-lactone in boiled deionized water showed that as the concentration was increased from 20 μg per ml to 20 000 μg per ml, the pH fell fairly steadily from 5.85 to 4.00 for solutions which were not deaerated, and from 6.53 to 4.07 for deaerated

*pH study of D-glucuronolactone in 0.2 *M* KCl, showing typical values. A: boiled deionized water, no gelatin; B: boiled deionized water, no gelatin, deaerated solution; C: deionized water, gelatin, deaerated solution; D: boiled deionized water, gelatin, deaerated solution.

solutions. It was found that the greater the concentration of the lactone, the more reproducible were the pH values. In the dilute range, the reproducibility is about ±0.15 pH. The pH study of D-glucuronolactone in 0.2 *M* KCl is shown in Table II. Similar results were obtained using 0.2 *M* NaCl and 0.2 *M* LiCl. The trend from one electrolyte to another was: pH KCl solutions < pH NaCl solutions < pH LiCl solutions. The reproducibility was much better than with pure aqueous solutions of D-glucuronolactone, particularly when gelatin was present; e.g., in the dilute range, the reproducibility was ±0.05 pH.

In marked contrast to this was the pH study of D-glucuronic acid in 0.2 *M* KCl – 0.005% gelatin solutions. The pH of a solution containing 10 μg D-glucuronic acid per ml was 4.59, while that of a solution containing 100 μg acid per ml was 3.59. The reproducibility of these values was similar to comparable solutions of D-glucuronolactone.

Changing the concentration of the supporting electrolyte through the range 0.1 to 0.4 *M* caused no change in pH and only a slight change in diffusion current for D-glucuronolactone; no

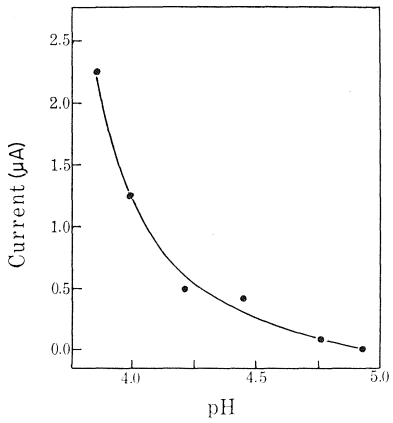

FIG. 2. The effect of pH on the diffusion current of 50 μg D-glucuronic acid per ml.

study was made with D-glucuronic acid because of the lack of reproducibility of the diffusion current.

show the effect of pH on the diffusion current of D-glucuronolactone (Fig. 4 is an expanded version of Fig. 3).

In an attempt to determine the type of wave, the height of the mercury column was varied from 30 to 50 cm. For a concentration of 80 μg D-glucuronolactone per ml, there was no change in diffusion current with change in the height of the mercury column (within experimental error), indicating that the wave is either kinetic or catalytic. For a concentration of 800 μg D-glucuronolactone per ml, there was a non-linear variation of diffusion current with the height of the mercury column. On plotting the diffusion current versus the square root of the height of the mercury column, the variation was still not linear. For a concentration of 4000 μg D-glucuronolactone per ml, the variation of diffusion current with the height of the mercury column was almost linear. The plot of diffusion current versus the square root of the height of mercury column was more linear.

As far as D-glucuronic acid is concerned, all that can be said is that the diffusion current increases with an increase in the height of the mercury reservoir.

When phosphate was added as $H_2PO_4^-$, two distinct phenomena were observed, depending on the concentration of D-glucuronolactone. At 100 μg D-glucuronolactone per ml, the wave height was considerably depressed on the addition of phosphate, even 2.5 μg PO_4^{3-} per ml had a noticeable effect on the wave height. As little as 7.5 μg PO_4^{3-} per ml reduced the wave to the residual current. The effect of adding $H_2PO_4^-$ at a D-glucuronolactone concentration of 1 mg per ml is shown in Table III. A blank made in the presence of 10 μg PO_4^{3-} per ml showed an

*All solutions contain 1 mg D-glucuronolactone per ml, are 0.2 *M* in supporting electrolyte, and are 0.0075% with respect to gelatin.

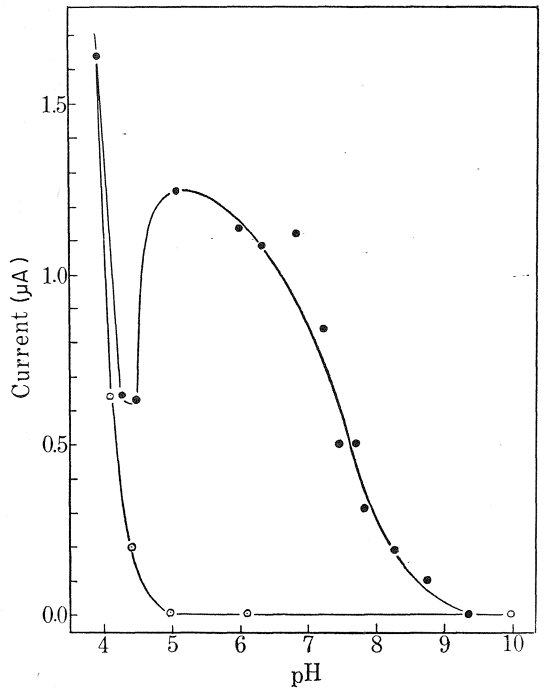

FIG. 4. The effect of pH on the diffusion current of 80 μg D-glucuronolactone per ml (an expanded version of Fig. 3); ●, D-glucuronolactone; ○, blank.

indistinct wave, and a blank containing 100 μg PO_4^{3-} per ml showed a distinct wave whose $E_{1/2}$ was −1.70 V.

The highly irregular waves mentioned in Table III resembled those made with a contaminated capillary.

When phosphate was added as HPO_4^{2-} or PO_4^{3-}, blanks with phosphate resembled normal blanks. The effect on the wave height of D-glucuronolactone solutions appeared to be a pH effect only, when the results were compared to Figs. 3 and 4. Table IV shows the effect of adding HPO_4^{2-} to solutions containing 1 mg D-glucuronolactone per ml.

Discussion

Effect of pH

Ishidate and Shimozawa (1) could not obtain reproducible waves with D-glucuronolactone or D-glucuronic acid. It is evident from Fig. 2 that the diffusion current is extremely pH sensitive when the D-glucuronic acid concentration is kept constant. Further, the pH of D-glucuronic acid solutions decreases rapidly as the concentration is increased. This is reasonable, because the acid is free and uncombined. (The pK_a of D-glucuronic acid is 3.20.) The considerable variance of the diffusion current with pH for D-glucuronic acid may account for the difficulties met by the previous investigators.

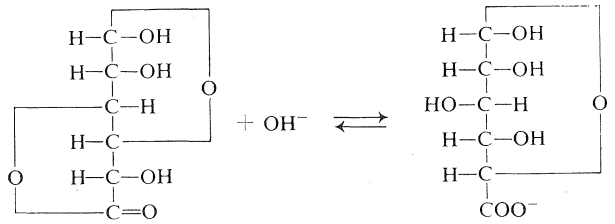
The pH of D-glucuronolactone solutions does not change nearly as much with concentration, although the trend is to lower pH values as the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

concentration increases. This is due to the lactone–acid equilibrium. As the concentration of the lactone increases, so does the concentration of the free acid, and the pH decreases. The presence of supporting electrolyte and gelatin appeared to help stabilize the pH, indicating that they are functioning to some extent as weak buffering agents. This is supported by the observation that the reproducibility of pH measurement is increased in these solutions compared to solutions of D-glucuronolactone alone. In fact it was noted that the greater the overall concentration of the solutes, the better was the reproducibility of the pH.

Below pH 5, the buffering effect of supporting electrolyte and gelatin is poor, as illustrated by the D-glucuronic acid solutions. This was also observed when HCl was added to D-glucuronolactone solutions.

Above pH 5, however, the buffering effect is assisted greatly by the lactone itself. (A blank and a D-glucuronolactone solution, treated identically, gave pH values 9.18 and 6.52, respectively.) The lactone hydrolyzes, removing OH^- ions from solution and decreasing the pH



This effect is not instantaneous, but proceeds slowly. This could be seen on the pH meter as the pH dropped slowly for several minutes before stabilizing.

Below a pH of 4, the polarographic waves of D-glucuronolactone solutions could not be distinguished from blanks at similar pH values, indicating that here the wave merely represents the reduction of hydrogen ions. The half-wave potentials of waves made with solutions containing hydrogen ion, D-glucuronolactone, or D-glucuronic acid are too close together to distinguish the species present.

The decrease in diffusion current of D-glucuronolactone as the pH was increased with KOH, as shown in Fig. 4, is no doubt due to the base hydrolysis of the lactone to the glucuronate. A similar study was made with a lactone concentration of 1 mg per ml. Here 0.1 *N* KOH was used to adjust the pH. When the base was added, the large local excess caused a partial decomposition of the lactone molecule, as indicated by the appearance of a greenish-yellow color which was first noticed at a pH of about 7 (the Lobry de Bruyn – van Ekenstein transformation of carbohydrates).

Varying the height of the mercury column in an attempt to determine the type of wave produced different results at different concentrations. It appears that at 80 μg D-glucuronolactone per ml, the wave is kinetic or catalytic; at 800 μg lactone per ml the wave is neither kinetic or catalytic, nor diffusion controlled; while at 4 mg lactone per ml, the process appears to be diffusion controlled, probably due to the large amount of reducible species being produced by the kinetic or catalytic reaction which was observed in the lowest concentration range. This would suggest that the results at the intermediate concentration (800 μg per ml) reflect a transition from a predominantly kinetic or catalytic controlled process to a predominantly diffusion controlled process. Nothing precise can be said about D-glucuronic acid other than the process is not kinetic or catalytic (the diffusion current varies with the height of the mercury column).

Addition of Phosphate

(1) As $H_2PO_4^-$

The pH studies indicate that approximately 99% of the phosphate is present as $H_2PO_4^-$, with approximately 1% present as H_3PO_4, regardless of the amount of D-glucuronolactone present.

Blank solutions exhibited a wave at high phosphate concentrations, but the half-wave potential was about 0.2 V more negative than that of D-glucuronolactone.

With a lactone concentration of 100 μg per ml, the addition of as little as 2.5 μg $H_2PO_4^-$ per ml considerably reduced the wave height, and approximately 7.5 μg $H_2PO_4^-$ per ml annihilated the lactone wave. Since the pH of these solutions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

remained fairly constant, and since the phenomenon was observed with KH_2PO_4 and NaH_2PO_4, the phosphate ion must be responsible for the change of wave height. A preliminary study with D-glucuronic acid indicated that this suppression of the wave height was not accomplished until approximately 1000 μg $H_2PO_4^-$ per ml had been added. A preliminary kinetic study indicated that the reaction between $H_2PO_4^-$ and the lactone reaches equilibrium fairly rapidly (within the mixing and deaeration time). The reaction between D-glucuronolactone and $H_2PO_4^-$ is not clear but may involve the oxygen of the lactone ring, since this is the major difference between D-glucuronic acid and its lactone.

When the D-glucuronolactone concentration was 1 mg per ml, $H_2PO_4^-$ had very little effect up to a concentration of 60 μg per ml. Above an $H_2PO_4^-$ concentration of 60 μg per ml, the highly irregular plateaux on the polarograms, resembling those made with a contaminated capillary, suggest that over an $H_2PO_4^-$ concentration range of 60 to between 100 and 200 μg per ml, and in the presence of 1 mg D-glucuronolactone per ml, the surface tension of the mercury drop becomes irregular, resulting in a non-uniform drop rate. (More work needs to be done in this regard.)

Approximately 200 μg PO_4^{3-} (as $H_2PO_4^-$) was required to completely react with the lactone. On a proportional basis, this is about twice the amount required to react with 100 μg D-glucuronolactone per ml, indicating that a greater excess of $H_2PO_4^-$ is required to cause the reaction to go to completion at the higher lactone concentration.

(2) Adding Phosphate as HPO_4^{2-} or PO_4^{3-}

At low phosphate concentrations (up to about 10 μg PO_4^{3-} per ml as HPO_4^{2-}), the pH studies indicate that the predominant species in solution is $H_2PO_4^-$. Above this level, the concentration of HPO_4^{2-} increases until at 100 μg PO_4^{3-} (as HPO_4^{2-}), the ratio $H_2PO_4^-$: HPO_4^{2-} is about 1:1, (with Na_2HPO_4, about 200 μg phosphate is required). This ratio gradually shifts in favor of HPO_4^{2-} as the phosphate concentration is increased. (At 1000 μg per ml, the ratio $H_2PO_4^-$: HPO_4^- is about 1:6 when added as K_2HPO_4, and about 1:3 when added as Na_2HPO_4.) When phosphate is added as PO_4^{3-}, the predominant species in solution is HPO_4^{2-}.

At a D-glucuronolactone concentration of 100 μg per ml, the effect of phosphate on the wave height resembled the pH effect shown in Fig. 4. This indicates that the reacting species is OH^-, and not phosphate. Similar results were observed with a lactone concentration of 1 mg per ml.

The difference in the amount of phosphate added, comparing $H_2PO_4^-$ to HPO_4^{2-} or PO_4^{3-} is extreme. For example, at a lactone concentration of 100 μg per ml, 7.5 μg PO_4^{3-} (as $H_2PO_4^-$) sufficed to obliterate the D-glucuronolactone wave but with HPO_4^{2-}, even 300 μg PO_4^{3-} could not suppress the wave to the residual current. This indicates that $H_2PO_4^-$ is an extremely reactive species.

An analogy can be made with the work of McConnell and Coover (7, 8) who reacted β-propiolactones with dialkylhydrogen phosphites and trialkyl phosphites. The latter cleaved the lactone ring at the β-carbon, but the former, having a replaceable hydrogen, cleaved the ring at the carbonyl group (the hydrogen bonds to the oxygen of the lactone ring). It is possible that $H_2PO_4^-$ (having a hydrogen which is about 10^5 more easily removed than HPO_4^{2-}) reacts with lactones in a similar manner to dialkyl hydrogen phosphites. HPO_4^{2-} (or PO_4^{3-}), like trialkyl phosphites, probably does not react at the carbonyl group due to the difficulty of hydrogen bonding with the oxygen of the lactone ring. In nonaqueous media, HPO_4^- (or PO_4^{3-}) may possibly cleave the lactone ring at the γ-carbon, but in aqueous medium, the reaction appears to be merely hydrolysis by OH^- to give the glucuronate.

Electron spin resonance study of tert-butyl halides and carbon tetrachloride, neopentane and carbon tetrachloride binary mixtures irradiated at 77 °K

F. C. THYRION[1]

Chemistry Department, Laval University, Quebec 10, Quebec

Received March 27, 1968

Tert-butyl halides and carbon tetrachloride, neopentane and carbon tetrachloride binary mixtures were irradiated at 77 °K and electron spin resonance spectra were recorded at increasing temperatures until the radicals disappeared.

Even at high concentrations of tert-butyl halides, the radicals obtained from CCl_4 predominate, indicating that CCl_4 has a high efficiency for electron capture. Maximum radical yields and the appearance of a narrow line spectrum with rising temperature were observed in $(CH_3)_3C—X - CCl_4$ mixtures (X = Cl, Br, I) in concentration ranges where only a single phase exists. This spectrum consists of 17 lines which appear to belong to one odd-numbered spectrum (7 lines due to $(CH_3)_2\dot{C}—X$ radical) and two even-numbered spectra (4 and 10 lines, the last being due to $(CH_3)_3\dot{C}$ radical). The disappearance of the CCl_4 broad band and the appearance of these radicals with increasing temperature can be interpreted as due to charge transfer from carbon tetrachloride cation to tert-butyl halide, facilitated by greater freedom of movement in the solid solutions. In contrast, neopentane and carbon tetrachloride mixtures do not display these features.

Des mélanges binaires d'halogénures de tertiobutyl et neopentane dans le CCl_4 ont été irradiés à 77 °K. Les spectres de résonance paramagnétique indiquent que la concentration des radicaux issus du tétrachlorure de carbone est prépondérante, même aux fortes concentrations en halogénures de tertiobutyl, ce qui fait ressortir la haute efficacité de capture d'électrons thermiques par les molécules de CCl_4. Lorsque les deux substances forment une solution solide à basse température, on constate un maximum dans les valeurs des rendements radicalaires et l'apparition d'un très beau spectre par élévation de température. Ce dernier comprend 17 raies appartenant à 3 espèces radicalaires différentes. La disparition de la bande attribuée à l'ion-radical CCl_4^+ et l'apparition de nouvelles espèces radicalaires par élévation de température peuvent être interprétées par le transfert de charge de CCl_4^+ sur l'halogénure de tertiobutyl. Celui-ci est favorisé par la libération progressive des mouvements moléculaires dans les solutions solides étudiées. Par contre, les mélanges de neopentane et tétrachlorure de carbone ne présentent pas ces particularités.

Canadian Journal of Chemistry, 47, 273 (1969)

Introduction

In earlier work (1), ethyl iodide and carbon tetrachloride mixtures were irradiated; radiochemical yields obtained by electron spin resonance (e.s.r.) and analysis of reaction products enabled us to show that electron capture was very efficient in alkyl halides and in carbon tetrachloride. Hamill and his co-workers (2) have also reached this conclusion in work describing the relative efficiency of electron capture for a series of solutes dissolved in suitable solvents.

It ought to be interesting to study the effects of irradiation on solutions of globular or near-globular (3) alkyl halides and carbon tetrachloride, since Powles and Gutowsky have shown that molecular motions occur even at low temperatures (4). The spectra, G values and disappearance temperatures of radicals in $(CH_3)_3C—X$ or neopentane – carbon tetrachloride solid solutions are compared with those of ethyl iodide – carbon tetrachloride mixtures (X = Cl, Br, I).

Experimental

Carbon tetrachloride (Baker Company, spectroscopic grade) was purified as previously described (1). Tert-butyl iodide (Eastman) was purified through fractional distillation under reduced pressure. Tert-butyl bromide and chloride (Eastman) and neopentane (Matheson Company) were trap to trap distilled at liquid nitrogen temperature. The solutions were prepared under vacuum by mixing known volumes of the components (total of 0.2 ml) in Suprasil tubes. Before sealing, samples were evacuated to 10^{-4} Torr. They were then rapidly cooled, and afterwards irradiated in a Gammacell 220 irradiator (A.E.C.L.) at a dose of 2.92×10^{19} eV g^{-1}. Yields are reported relative to $G = 15.6$ for the Fricke dosimeter but corrections were made in the case of $(CH_3)_3C—I$ to take into account the increase in energy absorbed by iodine atoms.

Radical or radical-ion spectra were obtained with a Varian electron paramagnetic resonance (Model

For personal use only.

4500.10A, X-band) spectrometer equipped with a variable temperature dual-cavity and cooling system. Spectra were observed at temperatures (maintained to within 0.5 °C) of 77 °K or higher. The first derivative spectra were obtained with a X–Y recorder. The radical concentrations were determined by calibration with DPPH in CCl_4. The overall sensitivity after corrections was estimated to be ±20%.

Results

Spectra in Pure CCl_4

Pure carbon tetrachloride spectrum at 77 °K consists of a very broad asymmetric band centered at $G = 2.014$, which decreases and begins to show structure at 120 °K, and is resolved better at 175 °K (Fig. 1). At this temperature, the pattern indicates a superposition of spectra. This has been ascribed to CCl_3 and CCl radicals (10 and 4 lines) by Leray (5).

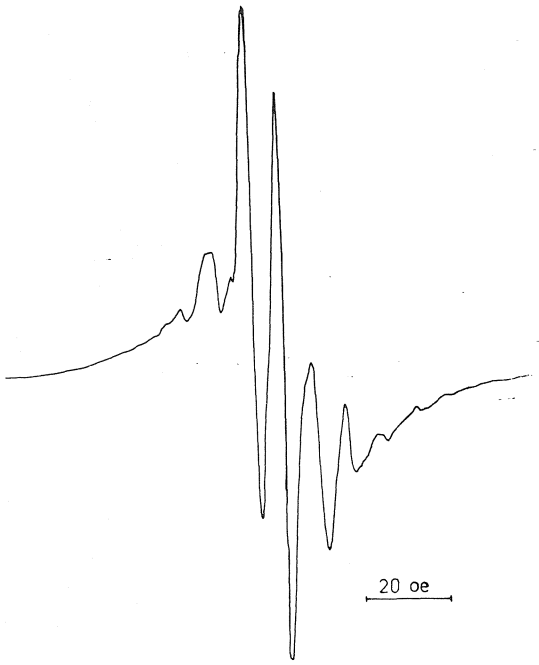

FIG. 1. Spectrum of pure CCl_4 at 192 °K.

Spectra in Tert-butyl Halides – Carbon Tetrachloride Mixtures

The spectra observed at 77 °K for solutions of tert-butyl halides and carbon tetrachloride are similar to that of pure CCl_4. However, we already observe some shoulders, at low and medium concentrations in halides which are due to a 17-line spectrum described later (Fig. 2).

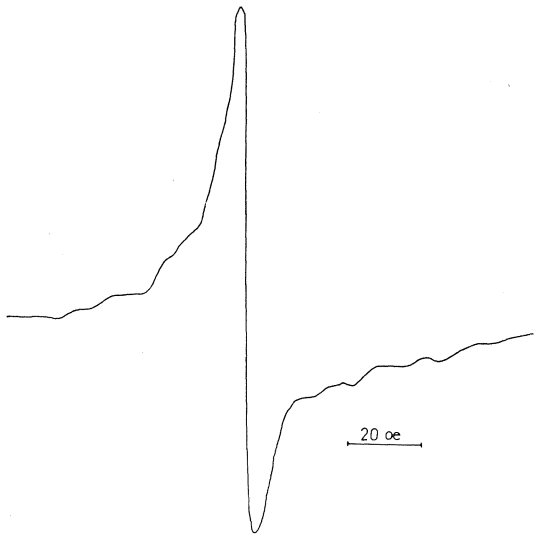

FIG. 2. Typical spectrum of tert-butyl halide – carbon tetrachloride mixtures at 77 °K.

Three cases can be considered depending on the tert-butyl halide concentration.

(*a*) In solutions with less than 35 mole % of tert-butyl halides, the spectra are similar to that of pure CCl_4. The disappearance temperatures are between 190 and 215 °K.

(*b*) In the range of 35–75 mole % tert-butyl halides (45–75% for iodide) a more resolved spectrum begins to appear at 125–130 °K. When the temperature is alternately lowered and raised, one obtains a highly symmetrical spectrum with 17 regularly spaced lines (11.6 Oe) and a 4.7 Oe line width (Fig. 3). In the case of $(CH_3)_3C—I$ mixtures, however, no symmetrical spectrum was observed. The 17-line spectrum can be resolved into two spectra with odd and even number of lines, since with increasing temperature, the former spectrum disappears faster. The peaks of the last spectrum have a relative intensity ratio of 1:6:15:20:16:6:1.2, very close to the ratio expected for the interaction of an unpaired electron with six equivalent protons. Moreover, the spectrum is quite similar to that obtained by Roncin (6) from irradiation of $(CH_3)_2CCl_2$. He assigned this to $(CH_3)_2\dot{C}—Cl$. In the even line spectrum, 8 lines with relative intensities x:2.2:7.4:15:15.2:7.8:2.3:x are observed. This spectrum should result from the superimposition of a 10-line spectrum due to the well known tert-butyl radical, and a 4-line spectrum with relative intensi-

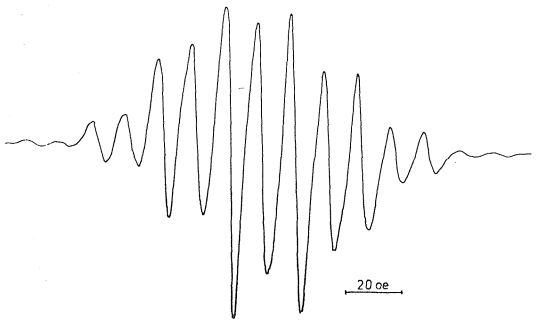

FIG. 3. Typical spectrum obtained for medium concentration $(CH_3)_3C—X - CCl_4$ mixtures, at 130 °K, (X = Cl, Br, I): spectrum of a 65 mole % $(CH_3)_3C—Cl$ mixture.

ties 1:3:3:1, which could be attributed to the CH_3 radical. Waugh (7) found that self-diffusion in solid methane was very rapid at about 60 °K. In other matrices, however, the CH_3 radical has been observed at 77 °K by several investigators (8, 9), but it seems unlikely that this radical exists up to 140 °K. If we take into account the spacing between lines and the line width observed (11.6 and 4.7 Oe), we get a nearly superimposable theoretical spectrum by assigning the following weight relationships to the three radicals: 25.6% to the 4-, 32.4% to the 10-, and 42% to the 7-line spectrum. The spectrum disappears at 140–145 °K. It is important to note that the intensity of the 17-line spectrum increases by a factor of ~ 5 on increasing the temperature from 77 to 125 °K. A comparison of the line widths at these temperatures cannot explain this enhancement.

(*c*) At higher concentrations of tert-butyl halide, a superimposition of two spectra was observed, one being the tert-butyl radical spectrum and the other being the broad band of CCl_4. At increasing temperature, the tert-butyl radical spectrum shows better resolution. The spectra disappear below the disappearance temperature observed in pure tert-butyl chloride (190 °K) and tert-butyl bromide (215 °K). Finally, a nearly equimolecular mixture of tert-butyl chloride and bromide gives the typical spectrum of the tert-butyl radical.

Annealed solid solutions of tert-butyl halides in carbon tetrachloride were also checked. The spectra of bromide and chloride did not differ from the spectra reported above. The tert-butyl iodide showed quite a different spectrum consisting of 8 broad lines with a 5.5 Oe spacing superimposed on the CCl_4 broad band. It disappears at temperatures well above those which give in destruction of radicals in a rapidly cooled mixture (Fig. 4). Complex spectra have been previously observed in polycrystalline alkyl iodides, but interpretation was difficult (10, 11).

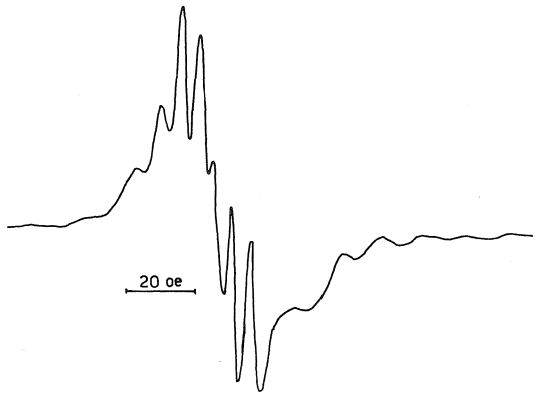

FIG. 4. Spectrum of a 36 mole % $(CH_3)_3C—I$ mixture at 130 °K, annealed before irradiation.

Spectra in Neopentane – Carbon Tetrachloride Mixtures

In all cases, the spectra appear to be a superimposition of the broad band of CCl_4 and the complex spectrum of neopentane. The latter spectrum consists of a prevailing triplet (neopentyl radical (12)) with superimposed sets of lines, and is detected even at low concentrations of neopentane.

Disappearance of Radicals

Figure 5 is a plot of the disappearance temperatures of radicals vs. mole % of solute in CCl_4. It can be noted that the curves are very similar in shape for the tert-butyl halides, but are quite different in the C_2H_5I mixtures. Neopentane is intermediate in behavior.

Yields of the Trapped Radicals

Figure 6 is a plot of $G(R)$ vs. electron % of tert-butyl halides and neopentane in carbon tetrachloride. For comparison, results previously obtained in the $C_2H_5I - CCl_4$ mixtures (1) are also indicated. A higher yield is obtained in a nearly equimolecular mixture in $(CH_3)_3—Cl$ and $(CH_3)_3C—Br$ where $G(R) = 3$. The radical yields for pure compounds are: CCl_4, 0.36; $(CH_3)_4C$, 1.42; $(CH_3)_3C—Cl$, 1.3; $(CH_3)_3C—Br$, 0.75;

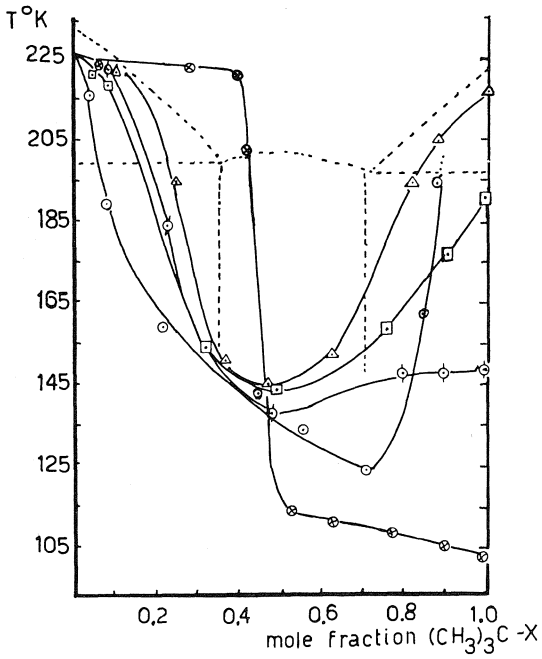

FIG. 5. Disappearance temperatures of radicals, in binary mixtures of CCl_4 with $(CH_3)_3C$—Br (△), $(CH_3)_3$-C—Cl (⊡), $(CH_3)_3C$—I (⊙), $(CH_3)_4C$ (⊙), C_2H_5I (⊗).
The dotted lines indicate the equilibrium phase diagram proposed by Conner and Smyth for the $(CH_3)_3C$—Cl – CCl_4 system (22).

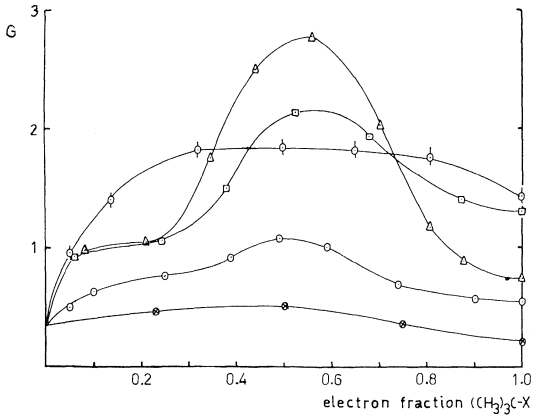

FIG. 6. Total radical yields at 77 °K in binary mixtures of CCl_4 with $(CH_3)_3C$—Br (△), $(CH_3)_3C$—Cl (⊡), $(CH_3)_3C$—I (⊙), and $(CH_3)_4C$ (⊙). Radical yields in C_2H_5I–CCl_4 mixtures are given for comparison (⊗).

and $(CH_3)_3C$—I, 0.57. The relative concentrations of radicals found in tert-butyl halides, or ethyl iodide and carbon tetrachloride systems, are similar. For instance, in 82 and 90 mole % tert-butyl bromide, the CCl_4 radical species concentrations are respectively 90 and 61% of the total concentration.

Discussion

The pure carbon tetrachloride e.s.r. spectrum at 77 °K has been reported by many investigators (13–15). It consists of a broad band which can be assigned to CCl_3 radical, CCl_4^+ or CCl_4^- radical–ions. Bennett and Thomas observed the same spectrum when CCl_3 was prepared by a chemical method (16). More recently, Shida and Hamill (17) observed, in γ-irradiated polycrystalline CCl_4 at 77 °K, a band centered at 4000 Å, which they attributed to trapped positive holes in the CCl_4 matrix. This band disappeared rapidly when the sample was warmed from 77 to 143 °K. The disappearance of this band agrees with the fact of the decay of the broad asymmetric band observed in e.s.r. spectrum. It will be assumed that CCl_4^+ is mainly responsible for it, even though Leray (5) attributed it to CCl_4^-. Indeed, Van Dunsen and Hamill (18) have indicated that it is unlikely that CCl_4^- ion can exist in polar media.

Efficient production of CCl_4^+ derives from the effective scavenging of electrons by CCl_4 itself or by tert-butyl halide, otherwise the electrons would recombine with CCl_4^+. The following set of reactions may be postulated if the positive hole migrates (17), and the electrons ejected by ionization are scavenged by the matrix:

$$[1] \qquad CCl_4 \text{—}\sim\!\!\rightarrow CCl_4^+ + e^-$$

$$[2] \qquad e^- + CCl_4 \rightarrow CCl_3 + Cl^-$$

$$[3] \qquad e^- + RX \rightarrow R + X^-$$

$$[4] \qquad CCl_4^+ + CCl_4 \rightarrow CCl_4 + CCl_4^+$$

$$[5] \qquad CCl_4^+ + RX \rightarrow CCl_4 + RX^+$$

$$[6] \qquad CCl_4^+ + X^- \rightarrow CCl_4 + X$$

$$[7] \qquad RX^+ + X^- \rightarrow R + X_2$$

$$[8] \qquad \rightarrow \dot{R}'X + Y$$

where RX represents tert-butyl halide molecule, and X^- is halide ion formed in reaction [2] or [3].

Dissociative attachment of thermal electrons by CCl_4 (reaction [2]) has been shown by several authors to be a very efficient process, more favorable than for other alkyl halides (reaction

[3]) (2). Minor contributions of tert-butyl radical are observable at high concentrations in halides at 77 °K. The same was observed in C_2H_5I–CCl_4 mixtures when the competition was effective (at about 90 mole % in C_2H_5I). Positive charge exchange between a molecule and an ion (reaction [4]) has been postulated by Shida and Hamill (17). Thermal activation restores the stabilized hole to a conducting configuration, and this migrating positive hole is assumed to interact with a tert-butyl halide molecule (reaction [5]) by simple electron transfer, since the ionization potential (i.p.) of CCl_4 (taken as 11.47 eV) (19) is somewhat higher than that of $(CH_3)_3C$—X (i.p. of $(CH_3)_3C$—Cl = 10.2 eV) (20). Further reactions [7] and [8] should produce radical species such as $(CH_3)_3\dot{C}$ and $(CH_3)_2\dot{C}$—X. If one attempts to explain the 4-line spectrum observed at 130–140 °K, it is necessary to postulate a $(CH_3)_3C$—X^+ radical–ion with an electron vacancy being well shielded in the C—C bonds. However, some authors (21) have assumed that the halogen-containing radicals give low- and high-field spectra. The existence of this ion in CCl_4 matrix should be favored by the great efficiency of CCl_4 in stabilizing ejected electrons.

The differences observed in spectra of tert-butyl halide – CCl_4 and ethyl iodide – CCl_4 mixtures with rising temperature are due to their different phase state. The onset of reorientations or rotations occurs gradually with increasing temperature in plastic crystals. Charge migration is allowed without displacement of molecules and radical recombination. In the C_2H_5I mixtures, on the contrary, the onset of these motions is abrupt, and radicals rapidly recombine. To explain the narrow line spectrum in intermediate concentration mixtures of halides with increasing temperature, it would be interesting to compare our results with those obtained by different methods, such as proton magnetic resonance studies and dielectric constant studies (4, 22). Powles and Gutowsky (4) have concluded that there is only one phase at all temperatures for tert-butyl chloride in carbon tetrachloride, at concentrations between 34.9 and 70.6 mole %. Furthermore, there are motions in the solution which do not occur at the same temperature in pure tert-butyl chloride. In this compound, the —CH_3 groups rotate even at very low temperature, and, as shown by dielectric measurements (23), the C—Cl axis is fixed at temperatures up to 220 °K. The proton magnetic resonance narrowing observed at about 100 °K (24) reveals reorientation about this axis; but below the transition at 183 °K, the three possible orientations are indistinguishable. Above 190 °K, movement is sufficient to permit diffusion and recombination of radicals. In contrast, there exists in solid solutions an effective C_3 rotation of the whole molecule, and also rotation of the three —CH_3 groups, well below 183 °K. The appearance temperature of the 17-line spectrum agrees with that corresponding to the reduction in second moment of the proton magnetic resonance spectra observed by Powles and Gutowsky in $(CH_3)_3C$—Cl – CCl_4 solid solutions (4). Furthermore, the concentration range, where the 17-line spectrum appears, corresponds exactly to the single phase limits observed by these authors. From the results reported here, tert-butyl bromide mixtures are expected to have similar properties. Tert-butyl iodide mixtures, however, do not display similar features. Some results (21) have indicated the absence of a solid solution at low temperature. When annealed samples of tert-butyl iodide – carbon tetrachloride mixtures are irradiated, their e.s.r. spectra are different from those obtained in rapidly cooled solutions. In the first case, the solid separates out in two phases below 203 °K (25), and the influence of one compound on the other is very weak. In rapidly cooled solutions, the typical spectrum of a single phase was obtained, at intermediate concentrations. This indicates a homogeneous mixture of two substances where molecular motions occur at 125 °K. This probably arises with difficulty since $(CH_3)_3C$—I molecules possess a less spherical shape than the other tert-butyl halides.

In neopentane mixtures, no definite spectral changes occur with temperature. The perfectly spherical neopentane molecule is known to rotate even at low temperatures (24), and this seems to occur in its solid solutions with CCl_4, from the narrow line width of e.s.r. spectra. Westrum and Chang pointed out, from studies of heat capacities and enthalpies of mixing, that an apparently first order transition associated with a molecular freedom of the $(CH_3)_4C$ molecules occurs in 50 and 66.5 mole % mixtures of neopentane in carbon tetrachloride at 142.5 °K (26). The persistent broad band of CCl_4 with increasing temperature suggests that positive

charge transfer between CCl_4^+ and neopentane should be less efficient.

Radical Yields

The yield of trapped radicals in pure tert-butyl halides decreases in the order: chloride > bromide > iodide. This order has already been established by several investigators (13, 27), while Shirom and Willard (28) found no difference in radical yields observed in halide containing glasses at 77 °K. The deviations relative to the mixture law observed in all the mixtures indicates a sensitization by carbon tetrachloride which is particularly effective at intermediate concentrations of bromide and chloride in carbon tetrachloride. This observation and other effects described above (appearance of the 17-line spectrum, temperature of radicals disappearance) outline the importance of phase state and molecular motions on G values. A significant argument arises from the high G value obtained in the tert-butyl bromide and chloride mixture, where a narrow line spectrum is observed, even at 77 °K, due to less restriction of molecular motions than in pure compounds. In neopentane mixtures, $G(R)$ is high for all concentration ranges. This is in good agreement with the conclusions about molecular motions described previously.

Basic dissociation constant for ethylamine by a convenient conductance method[1]

W. VAN DER LINDE[2], D. NORTHCOTT, W. REDMOND[3], AND R. E. ROBERTSON
Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received April 24, 1968

A dilution technique is described which permits a determination of the ionization constant of amines by a conductance method, in a closed system. Small amounts (5–6 g) of the amine salt are required, making the method useful in studying isotope effects. Values of K_i for ethylamine over the temperature range 1.5–45.3 °C led to calculated values at 25 °C of $\Delta G = 4528.3 \pm 0.8$ cal/mole, $\Delta H = -266 \pm 12$ cal/mole, $\Delta S = -16.08 \pm 0.04$ cal/mole deg, $\Delta C_p = -62.2 \pm 1.8$ cal/mole deg.

Problems arising in connection with the interpretation of certain deuterium isotope effects (1–3) created the need of a method for determining the ionization constant for weak electrolytes which was at once capable of the required accuracy and economical with respect to quantitative requirements of deuterated materials. The system developed to meet these requirements is described here and its capabilities are illustrated by a study of the temperature dependence of the basic dissociation constant of ethylamine over the range 1.5–45 °C. The choice of this amine was determined in part by its utility in isotopic studies and partially by the fact that no such careful study had been made previously.

In the initial stages of the work (4), attempts were made to achieve the above goals by combining a precision syringe (5) with a mixing chamber and the double conductance cell of Ives and Pryor (6), calculation of Λ_0 and K_i being made from a single set of concentration–resistance data according to the extrapolation method of Ives (7). This system proved adequate for the determination of K_b^H/K_b^D (4) but failed to give that degree of reproducibility and accuracy required for defining the temperature coefficients of the equilibrium. Minor modifications of the system did not give the required improvement (8).

Part of the difficulty may be attributed to the use of the extrapolation method for determining K_b since the value lies in the borderline region where this method becomes unreliable (9–11). In this instance, errors of about 1% between successive runs were found. Kilpatrick (11) in a detailed analysis of the factors contributing to error in the use of the extrapolation method in calculating the ionization constant of weak acids seems to suggest a lower limit of $K_i = 10^{-5}$, hence the sources of the above error may not have been due entirely to the method of calculation. This question was not explored since important changes in the design of the cell were introduced concurrently with a change to the additive method of calculating Λ_0. Fortunately, the system provides a convenient experimental approach for determining the required value of Λ_0 for the ethyl amonium chloride with a minimum of labor.

Experimental

The main features of the conductance cell will be apparent from Fig. 1. This consists of a mixing chamber bearing a fine inlet joined to the precision syringe, and two opposed conductance cells. Stirring and circulation of the stirred solution through the cells is accomplished with a glass-enclosed magnet at the bottom of the central shaft bearing stirrers and impeller blades. This is set in a frame above a rotating magnet fixed centrally below the cell. The essential feature of the cells would appear to be the constriction of the central portion such that the platinum electrodes in the foreshortened dumb-bell shaped cell were much larger than the connecting tube. Such an arrangement was found to be essentially frequency independent (500–10 000 Hz) when used in an oil bath. Grounding the unused cell through the bridge ground when making a measurement eliminated a source of interference. It is recognized that this design merely represented a return to the inherent feature of the classical dumb-bell shape of the Kohlrausch cell, which had been omitted in the Ives–Pryor design (6). The attachment of the electrodes was accomplished by mounting on glass studs and electrical connection established by sealing on a very thin platinum sheet (0.0005 in.), through

a pinched joint terminating by electrowelding to a copper wire. This was welded in turn to a tungsten terminal, the latter being topped with a nickel sleeve. The glass arms bearing the terminals were placed under vacuum, hence any leakage past the platinum pinch-joint was readily detected.

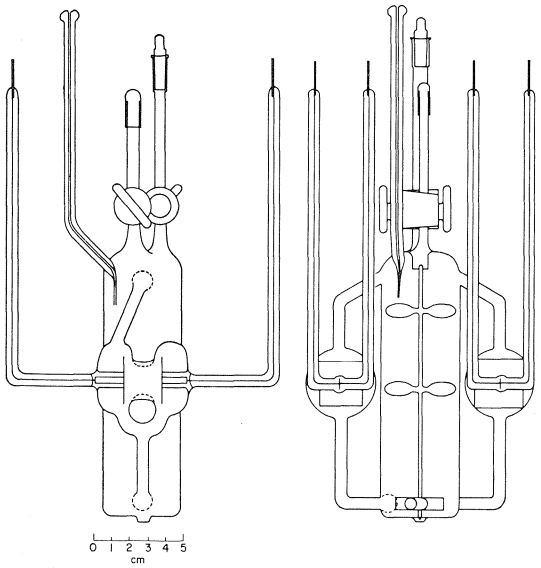

FIG. 1. Double conductance cell with mixing chamber.

One of the problems, indeed one of the major sources of error inherent in the conductance method is the property of glass walls to absorb ions from the solution. This will be most apparent in dilute solutions. Where there is no restriction on the amount of solution, repeated flushing will bring the walls into equilibrium with the solution but this possibility was inadmissible here. To minimize wall effects pretreatment of the cells was carefully standardized between runs. This consisted of leaving the cell stand with the solution of the amine overnight, rinsing and throughly steaming out for 10 min followed by pumping to dryness and filling with purified nitrogen. At this stage the cell was weighed to 1 mg on a balance sensitive to 0.5 mg/1 kg load, and filled to a point above the sidearms with distilled water under a positive pressure of purified nitrogen, in order to prevent the entrance of CO_2. Unless the water had a nominal value of 5×10^{-8} ohm^{-1} cm^{-1} (10 °C), experience showed that useful results could not be obtained.

Using the same procedures, values of the cell constant for the "hypothetical" cell (i.e. the difference of the two measured cells) were found to be $0.27905 \pm 0.0^{4}2$ for four determinations and after 8 weeks $0.27906 \pm 0.0^{4}3$ on two determinations (12).

[4]We are grateful for the skilled workmanship and practical advice available to us through our glass-blower, Mr. Jack van den Hoff.

The titrimeter was a more compact form of an earlier model previously described and was capable of delivering up to 10 ml in small increments, with high accurancy (5).

KCl

Analytical grade KCl was recrystallized from conductivity water twice and fused in a platinum boat in an electric furnace (13).

NaCl

NaCl (analytical grade) was precipitated from a saturated solution in conductivity water by bubbling in HCl, and the resulting crystals were filtered off, dried in an electric oven, and fused as above.

Ethylammonium Chloride

The amine-hydrochloride was prepared by bubbling dry HCl gas through an ethereal solution of the pure amine and filtering under dry nitrogen. Recrystallization from dry *n*-butanol and drying under vacuum gave a white fluffy crystalline hydrochloride. This was kept in a desiccator and either used directly (Λ_0) or as a source of amine (K_i). To get amine solutions (0.2 molar) the requisite amount of hydrochloride and KOH were added to a reaction vessel on a vacuum-line and the system repeatedly evacuated and flushed with dry, purified nitrogen. The addition of conductivity water to the reaction cell led to the regeneration of the amine which was swept into a trap cooled with liquid N_2. The amine was distilled from bulb-to-bulb, the middle fraction being stored for use. The purity was checked by mass spectral analysis and showed no significant amounts of other amines. The amine solution was made up in a special flask (Fig. 2*b*) containing 125 cc conductivity water, and the flask was thoroughly degassed. The required approximate amount of amine was transferred to the flask, air being excluded at all times. Transfer of the amine solution from the make-up flask to the titrimeter and guard-bubblers is done after flushing the system repeatedly with N_2 through loosely clamped joints during the successive filling of the bubblers C, B, and the reservoir A (Fig. 2*a*). The concentration of the amine was determined by titration from the precision titrimeter against standard HCl solution using a glass electrode and pH meter to detect the end point.

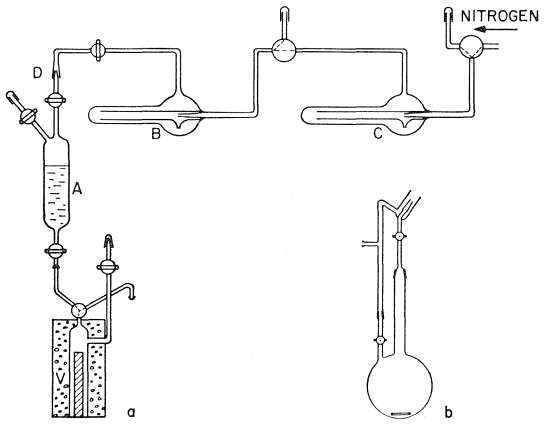

FIG. 2. Titrimeter filling train.

Conductance water was obtained from a still of the Stuart–Wormwell type, (14), the initial distillation being from $KOH/KMnO_4$ (3–4 g each in 5 l), the output being condensed into the final still where distillation takes place from $NaHSO_4$ (0.1 g/3 l). The vapors from the latter pass through an all-glass spray-suppressor of the same general design as in the original system whence partial condensation takes place in a stream of purified nitrogen on a silica condenser. Water was discarded until a nominal value of specific conductance of less than 5×10^8 ohm^{-1} cm^{-1} at 10 °C was established as determined by a cell forming part of the collection system. It was found that this value could be maintained by storage overnight in a polypropylene container, an integral part of the closed system.

In order to eliminate the error[5] introduced through the simultaneous determination of Λ_0 and of K_b (10, 11), a preliminary determination of the Λ_0 values for ethylammonium chloride was made over the experimental range of interest. While the reproducibility of Λ_0 by our method falls short of what can be obtained by the most careful workers (12), the minor variations in Λ_0 were not judged important for our purpose. The inherent convenience of being able to determine Λ/c for 20–30 different concentrations in a closed system in 1–2 h is self-evident.

Conductance–concentration data for determination of Λ_0 and K_b were obtained by adding increments of the stock solution of the salt, in this case $C_2H_5NH_3Cl$ (for Λ_0) or of the amine $C_2H_5NH_2$ from the titrimeter into a weighed amount of conductance water in the cell. The cumulated concentration of solute in the cell for each incremental addition could be calculated using the equation

$$[1] \qquad M_s = \frac{f \times d_s \times 1000 d_0 \left(\frac{M_0}{1000 d_s}\right) c}{\text{mol. wt.} \times (W_0 + f \times d_s \times c)}$$

where

f = titrimeter factor in ml/1000 counts,
d_s = density of titrant solution,
d_0 = density of conductivity water,
M_0 = concentration of titrant in moles/l,
W_0 = weight of conductivity water originally in cell,
c = number of counts on the titrimeter,
M_s = concentration of substrate in moles/l in the conductivity cell, and
mol. wt. = molecular weight of solute.

It will be apparent that in such a system precautions will have to be taken to minimize zero-point errors and the effects of unavoidable diffusion from the titrimeter capillary. The first was reduced by carefully calibrating the "syringe-units" required to fill the delivery tip from an arbitrary calibration line on the delivery capillary leading to the cell. This could be further corrected by adding small increments, noting the incremental changes in resistance and extrapolating back to "zero-reading". Either method was adequate under optimum conditions, the correction method being preferred when there was some doubt about the reading at the calibration line. At higher temperatures and with volatile amines, only the calibration method was useful. Diffusion between points could be effectively eliminated by "backing-off" a few counts after each addition, thus filling the fine tip of the capillary with the same solution as in the bulk. Such precautions as allowing for steady resistance reading before further additions are obvious. In practice this occurred in less than 1 min.

Temperature Control

Temperature control of about 0.001 °C was achieved by surrounding a small stirred oil bath by a large grounded water bath of conventional design and control to 0.002 °C.

Conductance Bridge

A Dekatron, D272A decade transformer with a norminal accuracy of 0.5 p.p.m. provided the measuring arm of a bridge against standard resistances of known values and capacitances. The frequency source was a GR.1311-A Audio oscillator with a GR.1231-P5 filter. The detector system was a GR.1232-A tuned amplifier and null detector, the final balance being determined on an oscilloscope.

Λ_0 of NaCl and KCl

As a test of the system, Λ_0 for NaCl and KCl was determined by loading the syringe with the respective solutions (0.2 M) and determining concentration–resistance relationships at 25 °C for two series on two successive days for NaCl and over a wider period for KCl. The individual Λ_0 values were found for NaCl from a LMS fit to the Onsager equation [2]

$$[2] \qquad \frac{1000 K_x \left(\frac{1}{R_i} - \frac{1}{R_0}\right)}{(C_i - C_0)} = \Lambda_0 + A \frac{(C_i^{3/2} - C_0^{3/2})}{(C_i - C_0)}$$

where R_i and R_0 are the measured resistance at concentrations C_i and C_0. A is the limiting Λ/c slope, K_x is the cell constant, and Λ_0 is the intercept.

A modification is included to correct for any errors in zeroing the titrimeter, possible adsorption at the walls of the cell at lowest concentrations (the assumption being the major part of such adsorption in so far as it exists, will be established quickly), and as a check on the water correction. Thus Λ_0 was calculated first setting $C_0 = 0.0$ and taking the resistance of water as R_0, then the calculation was repeated using low initial readings of C and R in eq. [2]. The values of Λ_0 so determined were usually within experimental error of the original value but if an error from the above sources was present it would be detected by a change in Λ_0. An illustration of the operation of this procedure is given in Table I.

Values of Λ_0 so determined for NaCl were 126.57, 126.29, 126.47, and 126.89 giving an average value of 126.57 ± 0.17. Shedlovsky (15) gives a value of 126.45 later confirmed by Benson and Gordon (16). The experimental error in the above method is somewhat larger but there is the compensation of economy in time, 2 h being

[5]Professor J. M. W. Scott of Memorial University, St. John's, first drew this possibility to our attention.

TABLE I

Data to illustrate zero point correction

C/1000*	Concentration (mole/l)	Λ_0†
0.0	0.0	126.47
0.1	0.2157×10^{-4}	126.48
0.31	0.6681×10^{-4}	126.40
0.50	1.076×10^{-4}	126.50

*C = titrimeter units.
†Units of Λ_0 throughout the paper are $cm^2\ ohm^{-1}\ equivalent^{-1}$.

sufficient to determine Λ_0 after temperature equilibrium is established.

The values of Λ_0 for KCl were found over a period of 3 months to be 149.94, 149.88, 149.72, and 150.23 giving an average value of 149.94 ± 0.12 compared to the literature value of 149.93 (149.87–149.98 depending on the author (12)).

Determination of Λ_0 for Ethylammonium Chloride

Following the procedures outlined above, the resistance of 30 solutions of increasing ethylammonium chloride concentration were determined. The value of Λ_0 calculated as above from the data in Table II at 25.005 °C is 245.6 with a standard deviation of 0.076%. This is typical of what was obtained through the series though we do not believe that it represents the ultimate precision inherent in the method. Corresponding values for other temperatures are recorded in Table IV.

TABLE II

Concentration–equivalent conductance data* for ethylammonium chloride at 25.005 °C

Concentration (moles/l × 10^{-3})	Conductance	
	Observed†	Calculated

0.77258	119.36	119.30

*These data represent about ⅓ of the actual data.
†Left hand side of eq. [2].

By applying the Kohlrausch equation

$$[3]\quad \Lambda_0 R_0NH_3{}^+OH^- = \Lambda_0 R_0NH_3{}^+Cl^- + \Lambda_{0\,OH^-} - \Lambda_{0\,Cl^-}$$

and determining the values of $\Lambda_{0_{OH^-}}$ and $\Lambda_{0_{Cl^-}}$ from the equation

$$[4]\quad \Lambda_{0_t} = \Lambda_{0_{(25°)}} + A(t-25) + B(t-25)^2 + C(t-25)^3$$

the corresponding values of A, B, C, and $\Lambda_0{}^{25}$ are obtained and are given in Table III (17).

TABLE III

Constants for temperature dependence of Λ_0

	$\Lambda_0{}^{25}$	A	$B \times 10^2$	$C \times 10^4$
Cl^-	76.35	1.54037	0.465	−0.1285
OH^-	199.18	3.3604	0.306	−0.4828

The corresponding values of Λ_0 for ethylammonium hydroxide can be determined for each temperature for which K_b is to be determined. The resulting Λ_0 values were fitted to a Λ_0 vs. $(t-25)$ relationship of the conventional form to give the equations: Λ_0–temperature relation for ethylammonium hydrochloride, [5], and Λ_0–temperature relation for ethylammonium hydroxide [6].

$$[5]\quad \Lambda_0 = 122.772 + 2.5822\,(t-25) + 0.0071757\,(t-25)^2 - 0.00015079\,(t-25)^3$$

$$[6]\quad \Lambda_0 = 245.777 + 4.3945\,(t-25) + 0.004948\,(t-25)^2 - 0.00018098\,(t-25)^3$$

Determination of K_b

After the necessary values of Λ_0 for ethylammonium chloride were obtained, the syringe was loaded with an amine solution taking particular precaution to exclude CO_2, and a new series of concentration–resistance readings determined. These data were then fitted to the Shedlovsky–Kay equation (19),

$$[7]\quad \frac{1}{\Lambda S(z)} = \frac{1}{\Lambda_0} + \frac{C\Lambda S(z) f^2}{K{\Lambda_0}^2}$$

where

$$S(z) = 1 + z + \frac{z^2}{2} + \cdots$$

and

$$z = \left(\frac{\alpha\Lambda_0 + \beta}{\Lambda_0{}^{3/2}}\right)\sqrt{(\Lambda C)}$$

$$-\log f^2 = a\sqrt{(cx)}$$

$$a = \frac{3.649 \times 10^6}{(DT)^{3/2}}$$

and

$$x = \frac{\Lambda S(z)}{\Lambda_0}$$

A linear least squares analysis of these data gives a straight line, the slope of which is $1/K_i{\Lambda_0}^2$ and the intercept $1/\Lambda_0$, the value of Λ_0 being that determined in the previous experiments. Values of K_b so determined for a series of temperatures are given in Table V.

Values of the corresponding acid dissociation constant (K_{bh}) for the dissociation

$$EtNH_3{}^+ \rightleftharpoons EtNH_2 + H^+$$

*{[K_b (observed) − K_b (calculated)]/K_b (observed)} × 100.

can be readily calculated from the relation $K_b = K_w/K_{bh}$. A series of values of $-\log K_{bh}$ using values of K_w determined by Harned and Robinson (20) are given in Table VI.

TABLE VI

Summary of dissociation constants for ethylamine K_b and ethylammonium ion K_{bh} from 0 to 40 °C

T (°C)	$-\log K_b$	$-\log K_{bh}$
0	3.354_9	11.5886
10	3.327_4	11.2074
20	3.318_0	10.8486
25	3.319_3	10.6772
30	3.324_4	10.5086
40	3.344_8	10.1900

The data in Table VI permit the temperature dependence of the ionization constant K_b for the equilibrium

$$C_2H_5NH_2 + H_2O \rightleftharpoons C_2H_5\overset{+}{N}H_3 + \overset{-}{O}H$$

to be fitted to an equation of the type

$$R \ln K_b = A + B/T + C \ln T + DT + \cdots\cdots$$

using the method of Clarke and Glew (21). The accuracy of these data warrant fit to 3 terms only, i.e. equivalent to setting $d\Delta C_p/dT = 0$, contrary to reasonable theoretical expectations. The thermodynamic constants for a series of temperatures together with standard errors are given in Table VII for a series of temperatures. Values of K_b at intermediate temperatures can be interpolated from the equation

$$[8] \quad \log K_b = 87.52367 - 3994.444/T - 31.29822 \log T$$

with an error comparable to those given in Table VI provided sufficiently accurate log-tables are used.

Discussion

In Table VIII values of K_b obtained in this work are compared with those of previous workers. Everett and Wynne-Jones have commented that potentiometric methods tend to be low. However, their suggestion that conductivity methods may yield correspondingly high results because of the failure to extrapolate to infinite dilution does not apply here.

The calculated standard error is given below each constant and illustrates the change in error across the experimental temperature range, or alternately the inadequacy of the three constant equation.

A better indication of the capability of the system may be made by a comparison of the

errors in the derived constants given in Table VII with the corresponding values obtained by treating the data of Everett and Wynne-Jones (25) by the same analysis (Table IX). There it is seen that the indeterminacy in the values is approximately the same. It may also be noted that the difference between the values for monomethylamine and monoethylamine are not very different, in agreement with normal expectations.

Since it is the intent of this paper to illustrate the experimental potential and convenience of our conductance system for determining Λ_0 and K_i, no comment will be made at this time on the possible theoretical implications of the results reported.

Formation of diphenyl nitroxide in diphenylamine inhibited autoxidations[1]

K. ADAMIC[2], M. DUNN[3], AND K. U. INGOLD
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received July 23, 1968

The formation of diphenyl nitroxide in diphenylamine inhibited, α,α′-azo-bis-isobutyronitrile initiated, autoxidations at 65° has been studied by electron spin resonance. Diphenylamine is oxidized to a diphenylamino radical which is then converted to the nitroxide by an oxygen atom transfer from a peroxy radical. The initial rates of conversion of diphenylamine to diphenyl nitroxide and the maximum nitroxide concentrations attained are generally greater for oxidations with tertiary peroxy radicals than for oxidations with primary or secondary peroxy radicals. The lower efficiency of nitroxide formation by primary and secondary peroxy radicals is attributed to a cage disproportionation between alkoxy radical and nitroxide which leads to the formation of a carbonyl compound and diphenyl hydroxylamine. This reaction cannot occur with tertiary radicals. The rate of formation of diphenyl nitroxide is greater for tertiary peroxy radicals which give stable tertiary alkoxy radicals. Nitroxide formation is inhibited by secondary, but not by tertiary, hydroperoxides.

Canadian Journal of Chemistry, **47**, 287 (1969)

One of the most important developments in our understanding of the inhibition of oxidation by amines was the discovery by Thomas and coworkers (refs. 1–4, see also refs. 5–7) that relatively stable diaryl nitric oxide radicals (nitroxides) are produced in fairly high concentrations during inhibition with diarylamines. They are believed to be formed by the reaction sequence

$$ROO^{\cdot} + Ar_2NH \rightarrow ROOH + Ar_2N^{\cdot}$$

$$ROO^{\cdot} + Ar_2N^{\cdot} \rightarrow RO^{\cdot} + Ar_2NO^{\cdot}$$

A similar reaction sequence with dialkyl amines leads to the production of dialkyl nitroxides (3, 8).

Although there have been many studies of the kinetics of the inhibition of autoxidation by amines[4] (cf. 9, 10 and references cited therein) the kinetics of nitroxide formation in these systems has been the subject of only one serious investigation. In 1962 Thomas and Tolman (4) used electron spin resonance (e.s.r.) spectroscopy to follow the formation of diphenyl nitroxide in the diphenylamine inhibited oxidation of cumene at 68.5°. Unfortunately, the importance of chain transfer reactions between inhibitor radicals and hydroperoxide products was not appreciated at that time and some of the results were incorrectly interpreted in terms of complex formation between peroxy radicals and inhibitors. The overall process of inhibition is now so much better understood that we decided to re-investigate the formation of diphenyl nitroxide in diphenylamine inhibited oxidations. Cumene and a number of other hydrocarbons were used as oxidizing substrates.

Experimental

Apparatus

In order to obtain an essentially continuous record of the free radical concentration the reagents were circulated through the cavity of a Varian E-3 e.s.r. spectrometer. The apparatus is shown schematically in Fig. 1. It is built of Pyrex except for a 3 mm i.d. quartz tube running through the spectrometer cavity. The reagents (55–60 ml) are normally saturated with oxygen[5] and circulated at a rate of ~ 10 ml/s by a reciprocating 10 ml

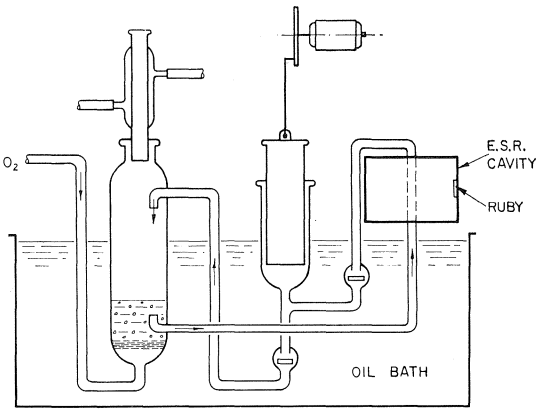

FIG. 1. Diagram of experimental apparatus.

hypodermic syringe associated with two glass float valves. The apparatus is immersed in an oil bath thermostated at 69° which ensures that the circulating reactants are held at 65 °C.

Procedure

A 55 ml aliquot of the hydrocarbon to be oxidized was poured into the main reservoir. A chlorobenzene solution of diphenylamine, Ph_2NH, (typically 0.5 ml of a 0.1 *M* solution) was immediately added and the circulating pump started. The e.s.r. spectrometer was tuned and a background spectrum obtained. A chlorobenzene solution of α,α′-azo-bis-isobutyronitrile, AIBN, (typically 5 ml of a 0.3 *M* solution) was then pipetted into the reservoir, the completion of its addition being considered to represent the start of the reaction (time zero). The radical concentration was monitored at frequent intervals, the minimum time between readings being 30 s. Not less than 5 ml of chlorobenzene were used in all the experiments. In some runs no hydrocarbon was present, the reactants being 50–55 ml of chlorobenzene, Ph_2NH, 0.05–5 ml of a hydroperoxide, and AIBN, added in that order.

To obtain reproducible results it was necessary to add the Ph_2NH before the AIBN. Two complications can arise if the reverse mode of addition is employed. In the first place, some hydrocarbons which oxidize by way of tertiary peroxy radicals (e.g. cumene) quickly develop a steady e.s.r. signal due to these peroxy radicals. Although this signal disappears as soon as the Ph_2NH is added and although it is reasonably well distinguishable from the diphenyl nitroxide signal[6], it can interfere with the integration of the first derivative. The second complication arises with hydrocarbons which oxidize to give primary or secondary peroxy radicals. Although these hydrocarbons give a very small steady-state peroxy radical signal[7], the hydroperoxides formed in these oxidations appear to react quite rapidly with nitroxide radicals. The formation of these hydroperoxides in the system prior to the introduction of the Ph_2NH leads to lower rates of formation and much smaller maximum concentrations of nitroxide radicals than for systems which are initially free from hydroperoxide. This difficulty does not arise with hydrocarbons forming tertiary hydroperoxides, as these do not seem to react with nitroxides nearly so rapidly as secondary hydroperoxides.

Calibration of the Radical Concentration

In place calibration of the system was done with freshly prepared 2,2-diphenyl-1-picrylhydrazyl (DPPH) solutions in chlorobenzene (10^{-4} *M* at 65 °C). The radical concentrations were determined by double integration of the first derivative e.s.r. signal using a Honeywell GPI-10 general purpose integrator. A small single crystal of synthetic ruby was attached to the inside of the cavity with a dab of Apiezon grease and its signal at ~ 2 kG was used to correct for variations in spectrometer sensitivity due to solvent induced variations in cavity Q (17).

Determination of the Rate of Chain Initiation (R_i)

The rate of free radical formation by the AIBN was determined by allowing it to react with known concentrations of stable nitroxide radicals in chlorobenzene. The reaction was carried out in the absence of oxygen by flushing the system continuously with helium. The radicals 4,4′-dimethoxydiphenyl nitroxide and 2,2,6,6-tetramethyl-4-pyridone nitroxide were stable for several thousand seconds at 65° in the absence of AIBN. 4,4′-Dinitrodiphenyl nitroxide was not stable under these conditions. Upon the addition of AIBN the e.s.r. signal due to the stable nitroxides declined linearly with time (i.e. the destruction of nitroxide is zero order in nitroxide). With 2.5×10^{-2} *M* [AIBN] the rate of chain initiation was found to be 5.2×10^{-7} *M* s^{-1} which, when combined with the known rate constant for the decomposition of AIBN at this temperature (1.8×10^{-5} s^{-1} (9)), gives a value of 58% for the efficiency of chain initiation.

Materials

Commercial diphenylamine was purified by zone refining. Ethylbenzene, cumene, and *sec*-butylbenzene were Phillips Research grade materials. The other hydrocarbons were of C.P. grade and were further purified by distillation under vacuum. Fisher certified chlorobenzene was used as an "inert" diluent. The hydrocarbons and chlorobenzene were passed through alumina immediately before use in order to remove any trace of hydroperoxide (14). The preparation and purification of the hydroperoxides has been described in previous publications from this laboratory (18).

Results

A typical set of nitroxide accumulation curves are shown in Fig. 2. The substrate is α-methylstyrene and the AIBN concentration is 2.5×10^{-2} *M*. It can be seen that as the Ph_2NH concentration is reduced the maximum concentration of diphenyl nitroxide decreases, but the initial rate of nitroxide formation increases and appears to approach a limiting value at the lowest Ph_2NH concentrations. The initial rate of nitroxide formation can also be increased at constant Ph_2NH concentration by increasing the AIBN concentration.

A measure of the efficiency of nitroxide formation can be obtained by dividing the measured rate of nitroxide formation, ρ, by the known rate of chain initiation, R_i. Values of ρ/R_i at an AIBN concentration of 2.5×10^{-2} *M* are summarized in Tables I and II. These tables also include the maximum nitroxide concentration $[Ph_2NO^{\cdot}]_{max}$ and the time taken to reach the maxima for the reactions with 8.3×10^{-4} *M* $[Ph_2NH]$. The initial chain lengths, ν, (Table I) were calculated

[6]The *g* values for peroxy radicals are in the range 2.014–2.016 (13, 14) while the *g* values for nitroxide radicals are below 2.010 and are generally in the range 2.003–2.008 (see, for example, ref. 15).

[7]Because of the rapid self-reaction of these peroxy radicals compared with the rate for the self-reaction of tertiary peroxy radicals (16).

Values of k_2 at 65° were assumed to be 5 times as great as the values measured at 30° in this laboratory by the rotating sector method (16). The rate constant for reaction 3 with poly-(peroxystyryl)peroxy radicals is about 4×10^4 M^{-1} s^{-1} (10).

Peroxy radicals can be produced not only by the oxidation of hydrocarbons but also by the free-radical induced decomposition of hydroperoxides, i.e.

$$ROOH + X^{\cdot} \rightarrow ROO^{\cdot} + XH$$

The hydroperoxide was added to chlorobenzene containing the amine and this was followed by the addition of AIBN. The results obtained by this procedure using 1.0–0.01 *M* [hydroperoxide], 8.3×10^{-4} *M* $[Ph_2NH]$, and 2.5×10^{-2} *M* [AIBN] are summarized in Table III. Similar results were obtained in *t*-butylbenzene and in

§No nitroxide detectable.

chlorobenzene – *t*-butylbenzene mixtures. It is obvious from the data in this table that secondary hydroperoxides strongly inhibit the formation of nitroxide. None is detected in the presence of as little as 0.02 M [9,10-dihydroanthracyl-9-hydroperoxide]. Tetralin hydroperoxide at 0.1 M depresses ρ/R_i and the maximum radical concentration compared with the values found for these quantities in tetralin or chlorobenzene (cf. Table I). After the maximum nitroxide concentration is attained the radical concentration remains virtually constant for a prolonged period. This steady nitroxide concentration is roughly inversely proportional to the concentration of the added tetralin hydroperoxide. The addition of tetralin hydroperoxide to oxidizing tetralin during the reaction but before the attainment of the maximum radical concentration produces a sharp decrease in the nitroxide concentration. After about 300–600 s the nitroxide concentration steadies at a relatively low value.

In contrast to these results with secondary hydroperoxides, the tertiary hydroperoxides produce high ρ/R_i values and the curves for nitroxide formation resemble those obtained in oxidizing hydrocarbons. The values of ρ/R_i for cumene hydroperoxide are larger than for cumene and, in fact, if the AIBN is added to cumene before the amine, a higher value of ρ/R_i is obtained than when the usual procedure is followed. Thus, at $[Ph_2NH] = 8.3 \times 10^{-4}$ M, $\rho/R_i = 0.37$ if the AIBN is added 2–3 min before the Ph_2NH, whereas a value of 0.22 is obtained (Table I) when the amine is added first. This difference is clearly due to the formation of cumene hydroperoxide (probably $\sim 5 \times 10^{-3} - 1 \times 10^{-2}$ M) before the amine is added.

Discussion

Diphenylamine stops slightly more than two reaction chains per molecule in oxidizing cumene (4, 19). The changes in nitroxide concentration with time shown in Fig. 2 indicate that the nitroxide is essentially all consumed by the end of the induction period, as has been previously reported (4). That is, the induction period is approximately given by $2[Ph_2NH]/R_i$ which, for $R_i = 5.2 \times 10^{-7}$ $M\,s^{-1}$, is 650, 1270, and 3200 s at $[Ph_2NH] = 1.7$, 3.3, and 8.3×10^{-4} M, respectively.

Although secondary and, presumably, primary hydroperoxides tend to inhibit the formation of nitroxide this should not affect the measured values of ρ/R_i which are given in Table I. This is because the normal experimental procedure ensures that no hydroperoxide is present at the beginning of the reaction. On the other hand, the maximum concentration of nitroxide which is obtained may be influenced by the substrate because of the nature of the hydroperoxide it forms in reactions [2] and [3]. That is, we might expect to get lower maximum nitroxide concentrations for substrates giving primary or secondary hydroperoxides than for those giving tertiary hydroperoxides. With the exception of ethylbenzene, this generally seems to be the case (cf. Table I). The exception may perhaps be attributable to the short chain length in ethylbenzene which implies that a large fraction of the hydroperoxide formed during reaction will be the

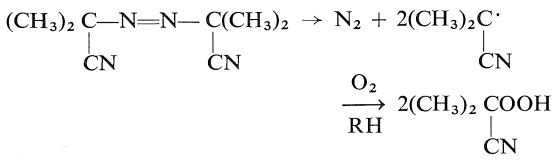
For personal use only.

tertiary hydroperoxide formed from the initiator rather than the secondary 1-phenylethyl hydroperoxide.



The following scheme represents the simplest sequence of reactions that is consistent with our results:

[1] $\text{AIBN} \xrightarrow{O_2} 2e\text{IOO}^{\cdot}$ (Rate R_i)

[2] $\text{ROO}^{\cdot} + \text{RH} \xrightarrow{O_2} \text{ROOH} + \text{ROO}^{\cdot}$

[2a] $\text{RO}^{\cdot} + \text{RH} \xrightarrow{O_2} \text{ROH} + \text{ROO}^{\cdot}$

[3] $\text{ROO}^{\cdot} + \text{Ph}_2\text{NH} \rightleftarrows \text{ROOH} + \text{Ph}_2\text{N}^{\cdot}$

[4] $\text{ROO}^{\cdot} + \text{Ph}_2\text{N}^{\cdot} \rightarrow \text{RO}^{\cdot} + \text{Ph}_2\text{NO}^{\cdot}$

[4a] $\text{ROO}^{\cdot} + \text{Ph}_2\text{N}^{\cdot} \rightarrow$ Molecular products

[5] $\text{ROO}^{\cdot} + \text{ROO}^{\cdot} \rightarrow$ Molecular products

[6] $\text{ROO}^{\cdot} + \text{Ph}_2\text{NO}^{\cdot} \rightarrow$ Molecular products

[7] $\text{R}^{\cdot} + \text{Ph}_2\text{NO}^{\cdot} \rightarrow$ Molecular products

[8] $\text{Ph}_2\text{N}^{\cdot} \rightarrow ?$

[9] $\text{ROOH} + \text{Ph}_2\text{NO}^{\cdot} \rightleftarrows \text{ROO}^{\cdot} + \text{Ph}_2\text{NOH}$

The AIBN decomposes to give *iso*-butyronitrile radicals with an efficiency e, and these react with oxygen to give $\text{IOO}^{\cdot}$ radicals which attack the substrate RH or the amine. In this scheme it is understood that all reactions involving $\text{ROO}^{\cdot}$ and $\text{RO}^{\cdot}$ radicals may equally well involve $\text{IOO}^{\cdot}$ or $\text{IO}^{\cdot}$ radicals and must, of course, involve only these radicals in the non-oxidizable substrates, chlorobenzene and *t*-butylbenzene. The relative importance of the radicals from the initiator will increase as the chain length decreases, as occurs when an oxidizable substrate is diluted with chlorobenzene (see Table II).

At high diphenylamine concentrations the initial rate of nitroxide formation is low because most of the $\text{ROO}^{\cdot}$ radicals are trapped by the amine in reaction [3] and they are therefore not available to take part in reaction [4]. Since the $\text{Ph}_2\text{N}^{\cdot}$ radical does not accumulate under these conditions it must be able to react in some way other than reactions [4] or [4*a*]. The unknown mode or modes of reaction are represented by reaction [8].

At very low diphenylamine concentrations the initial rate of nitroxide formation is low because some peroxy radicals are destroyed in the normal termination process, reaction [5]. Maximum rates of nitroxide formation occur at intermediate amine concentrations which are primarily determined by the rate constant of reaction [5]. That is, the rate constant of reaction [5] is generally considerably greater for primary and secondary than for tertiary peroxy radicals (16). In agreement with this, the ρ/R_i values pass through maxima at $[\text{Ph}_2\text{NH}] \geqslant 3 \times 10^{-4}\ M$ for the substrates giving primary and secondary peroxy radicals whereas the substrates giving tertiary peroxy radicals and the non-oxidizing substrates all have maximum ρ/R_i values at amine concentrations below $1.7 \times 10^{-4}\ M$.

In the diphenylamine inhibited decomposition of the hydroperoxides the value of ρ/R_i decreases as the hydroperoxide concentration is increased (Table III). This suggests the occurrence of a direct reaction between the hydroperoxide and the amino radical (reaction [−3]) and/or the occurrence of a direct reaction between the hydroperoxide and the nitroxide (reaction [9]). Reaction [−3] was previously proposed by Thomas to explain the fact that the rate of the diphenylamine (or phenol) inhibited oxidation of cumene increased with increasing concentration of cumene hydroperoxide (20). However, in amine inhibited oxidations, reaction [−3] is not kinetically distinguishable from reaction [9], the analogous reaction with nitroxide (see ref. 9, footnote 4). Although our present measurements on the formation of nitroxide cannot determine the relative importance of reactions [−3] and [9] some reasonably direct evidence for the occurrence of the latter reaction has been obtained in experiments with the free radical 4,4′-dimethoxydiphenyl nitroxide. This radical is stable in chlorobenzene at 65°. Hydroperoxide was added to a $1.8 \times 10^{-3}\ M$ solution of the nitroxide in the absence of AIBN and oxygen. The secondary hydroperoxides (0.1 M) produced an immediate rapid decrease in the nitroxide concentration (50% consumption in 500 s with 9,10-dihydroanthracyl-9-hydroperoxide and in 2000 s with tetralin hydroperoxide). In contrast, the addition of the tertiary hydroperoxides, *t*-butyl, cumyl,

2-phenylbutyl-2, and 1,1-diphenylethyl, at the same concentration caused little or no loss of nitroxide for a period of 1000–3000 s or more. Thereafter, the nitroxide concentration started to decrease but it decreased at a lower rate than with either of the secondary hydroperoxides. The most probable reaction between a nitroxide and a secondary hydroperoxide would seem to be a hydrogen atom transfer to give a hydroxylamine and a peroxy radical (i.e. reaction [9]). However, there is no very obvious reason why such a reaction should not also occur with tertiary hydroperoxides. The difference between the two classes of hydroperoxides may perhaps be attributed to differences in the importance of reaction [−9] which result from differences in the rate constants for the self-reactions of the secondary or tertiary peroxy radicals produced in reaction [9]. That is, since reaction [−9] is extremely rapid (11) the dimethoxydiphenyl nitroxide concentration must be determined to some extent by the amount of hydroxylamine which has been formed in reaction [9] and by the peroxy radical concentration. In the presence of a secondary hydroperoxide the concentration of the peroxy radicals produced in reaction [9] will be small because of their rapid disappearance by reaction [5]. Reaction [−9] will therefore be relatively unimportant and the rate of loss of dimethoxydiphenyl nitroxide will be large. On the other hand, the slow self-reaction of tertiary peroxy radicals means that in the presence of a tertiary hydroperoxide the nitroxide will be lost slowly since it is being reformed by reaction [−9].

Differences in the rate constants of the self-reactions of secondary and tertiary peroxy radicals may also be partly responsible for the difference in the rates of formation and maximum concentrations of diphenyl nitroxide in the presence of secondary and tertiary hydroperoxides.

In a system saturated with oxygen at 1 atm pressure the steady-state concentration of R· radicals is so much less than the concentration of ROO· radicals that it might be supposed that reaction [7] could play no part in the overall process. However, it is known that the autoxidation of hydrocarbons can be inhibited by aliphatic nitroxide radicals such as 2,2,6,6-tetramethyl-4-pyridone nitroxide under conditions similar to those used in the present work (11). This nitroxide reacts rapidly with R· radicals ($k_7 \geqslant 1 \times 10^7\ M^{-1}\ s^{-1}$ (11)) but slowly, or not at all, with ROO· radicals (11, 21–23). When this nitroxide was added ($10^{-4}\ M$) to oxygen saturated chlorobenzene containing AIBN ($2.5 \times 10^{-2}\ M$) in the present apparatus it was consumed at about $\frac{1}{5}$ of the rate of chain initiation. Since aromatic nitroxides react equally rapidly with R· radicals (2, 4, 11, 21–23) it seems likely that reaction [7] represents an important route for the destruction of diphenyl nitroxide[8]. However, it is not the only route since aromatic nitroxides do react with peroxy radicals. For example, k_6 is about $5 \times 10^4\ M^{-1}\ s^{-1}$ at 65° for 4,4′-dimethoxydiphenyl nitroxide (11) and probably has a similar value for diphenyl nitroxide (cf. footnote 4 in ref. 11). The rate constant for the reaction of Ph_2NO· with peroxy radicals is of comparable magnitude to that for the reaction of Ph_2NH with peroxy radicals ($4 \times 10^4\ M^{-1}\ s^{-1}$ (10)). It is therefore easy to understand why quite high concentrations of nitroxide can accumulate in oxygen saturated systems.

According to the reaction scheme given above, the maximum value of ρ/R_i is 1.0. This assumes that reactions [4*a*] and [5] do not occur and that all the RO· radicals formed in reaction [4] regenerate ROO· radicals *via* reaction [2*a*] or the analogous reaction [2*b*]

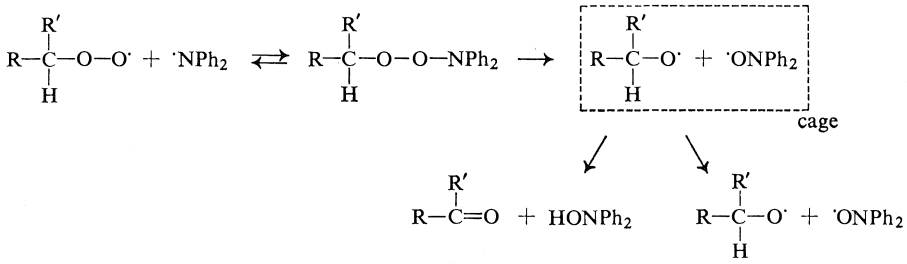
$$[2b] \qquad RO\cdot + ROOH \rightarrow ROH + ROO\cdot$$

That is, $\rho/R_i = 1.0$ if all Ph_2N· radicals are converted to Ph_2NO· and all RO· regenerate ROO·. Experimentally, with diphenylamine at 65°, we have never found a value of $\rho/R_i > 0.58$ which suggests that not all ROO· + Ph_2N· reactions lead to the formation of a nitroxide radical. It is for this reason that reaction [4*a*] is included in the reaction scheme.

From the results in Table I it can be seen that the maximum values of ρ/R_i are in the range 0.11–0.19 for hydrocarbons giving primary and secondary peroxy radicals. The hydrocarbons oxidizing to give tertiary peroxy radicals have maximum ρ/R_i values greater than the largest measured values (0.20 for α-methylstyrene, 0.23

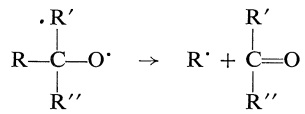
[8]Reaction [7] should be much less important in the diphenylamine inhibited decomposition of hydroperoxides than in diphenylamine inhibited oxidations since R· radicals are not formally involved in the induced decomposition of hydroperoxides. The higher ρ/R_i values obtained in *t*-hydroperoxides compared with those obtained in *t*-hydrocarbons are consistent with this idea.

for *sec*-butylbenzene, and 0.33 for cumene). For the inert substrates, in which the tertiary 2-cyanopropyl-2-peroxy radical may be expected to predominate, the ρ/R_i values are greater than 0.14 (*t*-butylbenzene) and 0.17 (chlorobenzene). The ρ/R_i values in Table III are greater for tertiary than for secondary hydroperoxides, rising to a maximum of 0.58 with *t*-butyl hydroperoxide. A plausible explanation for the higher ρ/R_i ratios obtained with tertiary peroxy radicals is that the primary and secondary peroxy radicals undergo a hydrogen atom exchange in the cage to give a carbonyl compound and a hydroxylamine. That is,

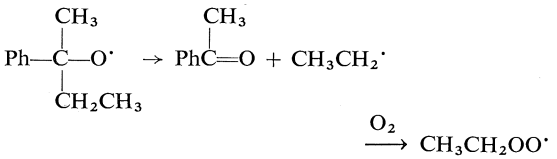


Such a hydrogen atom transfer is obviously impossible for a tertiary peroxy radical and they are, therefore, more efficient than primary or secondary peroxy radicals at converting diphenylamine into diphenyl nitroxide.

Under standard conditions, the variations in ρ/R_i appear to be greater among the different tertiary peroxy radicals than among the secondary peroxy radicals. Some of the differences in the ρ/R_i values can probably be attributed to differences in the stabilities of the alkoxy radical which is formed in conjunction with the nitroxide in reaction [4]. That is, a stable alkoxy radical will tend to regenerate its parent peroxy radical directly by reaction [2*a*] or [2*b*], whereas an unstable alkoxy radical will be more likely to undergo β-scission to form a carbonyl compound and a carbon centered radical,



It is possible that some alkoxy radicals are actually so unstable that they undergo scission while still in the solvent cage with the nitroxide. For primary and secondary alkoxy radicals (which are generally less stable than most tertiary alkoxy radicals), β-scission will usually lead to the formation of a primary peroxy radical. The types of peroxy radicals present in the amine inhibited reaction will therefore not be greatly changed from the types present in the uninhibited oxidation. However, the β-scission of many tertiary alkoxy radicals also gives primary peroxy radicals, e.g.



and these presumably will tend to decrease the value of ρ/R_i. The results in Tables I, II, and III support the idea that decreased β-scission tends to increase ρ/R_i. For example, the series 1,1-diphenylethyl, 2-phenylbutyl-2, cumyl, *t*-butyl, corresponds to decreasing rates of alkoxy radical β-scission and to increasing values of ρ/R_i. The rate of β-scission must also be high for the 2-cyano-2-propoxy radical (IO$^{\cdot}$) and the alkoxy radical from the α-methylstyrene–oxygen copolymer. In this last case (and also with styrene), the formation of a polymeric alkoxy radical normally leads to its rapid and complete depolymerization to acetophenone (or benzaldehyde), formaldehyde, and the radical that initiated the polymerization.

In summary, the initial rates of conversion of diphenylamine to diphenyl nitroxide and the maximum nitroxide concentrations attained are generally greater for oxidations with tertiary peroxy radicals than for oxidations with primary or secondary peroxy radicals. The more efficient tertiary peroxy radicals are those giving the more stable tertiary alkoxy radicals. The formation of the nitroxide is inhibited by secondary, but not by tertiary, hydroperoxides.

Formation of radicals in the amine inhibited decomposition of *t*-butyl hydroperoxide[1]

K. ADAMIC[2] AND K. U. INGOLD

Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received July 23, 1968

The radicals formed in the amine inhibited, α,α′-azo-bis-isobutyronitrile initiated, decomposition of *t*-butyl hydroperoxide at 65° have been examined by electron spin resonance. In the absence of amine a strong peroxy radical signal is obtained. Amines with structures that do not correspond to those of conventional antioxidants (i.e. primary and secondary aliphatic amines and tertiary amines) generally have little or no effect on this signal. Nitroxide radicals are generated from secondary aromatic (diaryl and alkaryl) amines. The rate of conversion of these amines to nitroxides reached a maximum of 50–60% of the rate of chain initiation for some diphenylamines. A maximum concentration of nitroxide of about half the initial amine concentration was obtained with 4,4′-dimethyldiphenylamine.

N,N,N′,N′-Tetramethyl-*p*-phenylenediamine is very rapidly oxidized by *t*-butyl hydroperoxide to give Wurster's Blue cation and, presumably, a *t*-butoxy radical. This amine is therefore an initiator of oxidation rather than an inhibitor as has commonly been supposed.

Primary aromatic amines do not appear to form simple aryl nitroxides. It is proposed that arylamino radicals (ArNH) are directly oxidized to nitroso compounds by peroxy radicals.

Canadian Journal of Chemistry, 47, 295 (1969)

Quite a large number of aromatic and aliphatic nitroxide radicals have been prepared by oxidizing amines with peroxy radicals (see e.g. 1–5) and hydroperoxides (see e.g. 6, 7). However, there have been no attempts to compare the rates of formation of the various nitroxides under standard conditions although this information has an obvious bearing on the mechanism of the inhibition of autoxidation by amines. The preceding paper (8) describes a quantitative study of the oxidation of diphenylamine to diphenyl nitroxide by a number of peroxy radicals. The present paper extends this work to a variety of amines. The *t*-butylperoxy radical was generally used as the oxidizing species since it proved to be most efficient at converting diphenylamine to diphenyl nitroxide.

Experimental

The experimental apparatus and general procedure were described in the preceding paper (8). The amines used in this work were reagent grade materials which were purified by standard methods. The *t*-butylperoxy radicals were produced by the α,α′-azo-bis-isobutyronitrile, AIBN, induced decomposition of *t*-butyl hydroperoxide (8). The conditions used for most of this work were: [amine] = 8.3×10^{-4} *M*, [$(CH_3)_3COOH$] = 0.02 *M*, [AIBN] = 2.5×10^{-2} *M*, in oxygen saturated chlorobenzene at 65 °C. The reagents were added to the chlorobenzene in the order, amine, hydroperoxide, AIBN, the beginning of the reaction being considered to be the moment of completion of the AIBN addition.

Results

An electron spin resonance (e.s.r.) signal due to *t*-butylperoxy radicals is observed in the absence of amine. The peroxy radical concentration reaches a maximum[3] of $\sim 2 \times 10^{-5}$ *M* at about 200 s and then decreases rather slowly as the hydroperoxide is consumed ([ROO·] = 1×10^{-5} *M* at ~4000 s).

An amine that terminates all oxidation chains and reacts with two peroxy radicals per molecule will be consumed in about 3200 s under the standard experimental conditions (8). It is, therefore, not surprising to find that a peroxy radical signal appears after about 3200 s in oxidations containing amines known to be inhibitors or with structures similar to those of known inhibitors (i.e., principally primary and secondary aromatic amines). The peroxy radical signal appears at about this time whether or not a nitroxide signal was visible earlier[4]. A maximum peroxy radical concentration of ~ 0.9–1.1×10^{-5} *M* was generally attained at ~3000–5000 s. However, *N,N′*-dimethyl-*p*-phenylenediamine,

[1]Issued as NRCC No. 10413.

[2]NRCC Postdoctorate Fellow, 1967–1968.

[3]Since $R_i = 5.2 \times 10^{-7}$ *M* s^{-1} (8) this concentration corresponds to a rate constant for the self-reaction of *t*-butylperoxy radicals of $5.2 \times 10^{-7}/(2 \times 10^{-5})^2 = 1.3 \times 10^3$ M^{-1} s^{-1}.

[4]Similarly, a peroxy radical signal appears after about 3000 s if the reaction is inhibited with the same concentration of phenol or 2,4,6-tri-*t*-butylphenol, or half the standard concentration of 4,4′-methylene-bis-2,6-di-*t*-butylphenol. With these phenols no e.s.r. signal was detected in the first 3000 s of reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

N,N,N'-trimethyl-*p*-phenylenediamine, and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine develop peroxy radical signals at 2500–4000 s which do not build up to their maxima ($\sim 8 \times 10^{-6}$ *M*) until 8000–10 000 s (see Fig. 1). Presumably these *p*-phenylenediamines (or their oxidation products, see below) react readily with about two peroxy radicals per molecule to form products that are not very reactive but are still able to trap about two additional peroxy radicals. In contrast to the *N*-methyl derivatives, the peroxy radical signals in the presence of *p*-phenylenediamine itself and the *N,N'*-diphenyl derivative appear at $\sim$ 3000 s and rise very rapidly to their maximum values ($\sim 1.1 \times 10^{-5}$ *M*). This behavior was expected of the diphenyl derivative which is a very efficient antioxidant and is known to react with two peroxy radicals per molecule (9).

A number of amines show a peroxy radical signal from the beginning of the reaction. Essentially identical curves for the build up and decay of peroxy radicals were obtained in the absence of amine and in the presence of triphenylamine, piperidine, quinoline (see Fig. 1), *N*-methyl diphenylamine, 2-anilino-1,4-naphthoquinone[5], or *t*-butylamine. As we might expect from their structures, these six amines do not appear to react with peroxy radicals under the present experimental conditions. With 1,6-hexanediamine and tribenzylamine the curves of peroxy radical concentration against time are of the same general shape as in the absence of amine, but the maximum radical concentration was only about half as great. With 2-anilino-1,4-naphthoquinone-4-anil[5] the maximum concentration of peroxy radicals (9×10^{-6} *M*) was reacted after $\sim$1500 s. Presumably, these last three amines react rather slowly with peroxy radicals. The changes in peroxy radical concentrations with time suggest that they are not consumed in the usual 3000–5000 s period and, therefore, most peroxy radicals must be destroyed by the normal bimolecular reaction.

Peroxy radicals were also formed from the beginning of the reaction with aniline, *p*-toluidine, and dibenzylamine. The radical concentrations rise rapidly in the first 200 s and then level off for about 1000–1500 s before increasing again and passing through maxima at 4000–5500 s (see Fig. 1).

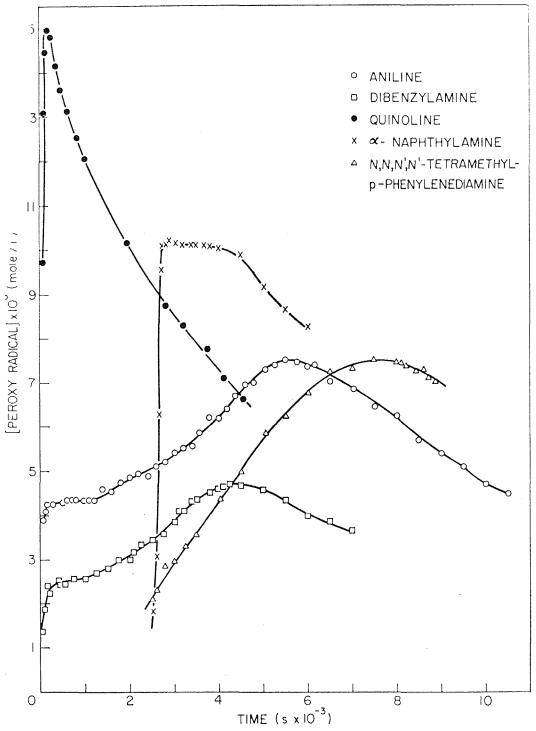

FIG. 1. The formation of peroxy radicals in amine (8.3×10^{-4} *M*) inhibited, AIBN (2.5×10^{-2} *M*) induced, decomposition of *t*-butyl hydroperoxide (1.7×10^{-3} *M*) in chlorobenzene at 65°.

Those amines which gave significant concentrations of nitroxide radicals[6] are listed in Table I. The initial rate of production of nitroxide, ρ/R_i (8), and the maximum concentration are given in this Table.

No radical signal was detected under the standard conditions for the first 3000 s with *p*-anisidine, *p*-phenylenediamine, *N,N'*-diphenyl-*p*-phenylenediamine, or α-naphthylamine (see Fig. 1). The usual peroxy radical signal develops after 3000 s.

Very small concentrations of radicals (maximum concentration $< 1 \times 10^{-6}$ *M*) were detected in reactions with *N,N'*-dimethyl-*p*-phenylenediamine, *N,N,N'*-trimethyl-*p*-phenylenediamine, and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine. These radicals did not seem to be nitroxides as they appeared at slightly higher magnetic fields (lower *g* values) than the nitroxides. The radical from the tetramethyl-*p*-

[5]A product of the oxidation of *N*-phenyl-2-naphthylamine with peroxy radicals (10).

[6]A radical concentration of about 1×10^{-6} *M* was close to the limit of detection in the present system.

TABLE I

The formation of nitroxide radicals in amine inhibited decomposition of *t*-butyl hydroperoxide*

Amine	$\rho/R_i \times 100$	$[\text{Nitroxide}]_{max} \times 10^5$ (M)
Diphenylamine	56	19
4-Nitrodiphenylamine	54	11
4,4′-Dinitrodiphenylamine	64	15
4,4′-Dimethyldiphenylamine	55	40
4-Methoxydiphenylamine	32	25
4,4′-Dimethoxydiphenylamine	41	28
N-Phenyl-1-naphthylamine	1.0	0.4
N-Phenyl-2-naphthylamine	1.5	0.4
1,1′-Bis(*N*-phenyl-2-naphthylamine)	12	4.5
N-Methylaniline	$\lesssim$10	0.3
N-Methyl-*p*-toluidine	$\lesssim$10	0.4
N-Methyl-*m*-toluidine	$\lesssim$10	0.3

*At 65° ($[(CH_3)_3COOH] = 0.02\ M$, $[AIBN] = 0.25\ M$, $[amine] = 8.3 \times 10^{-4}\ M$, in chlorobenzene).

phenylenediamine was identified as Wurster's Blue cation $(CH_3)_2NC_6H_4N(CH_3)_2^{\cdot +}$ in experiments at relatively high reactant concentrations. With 10 times the usual amine concentration (i.e., $8.3 \times 10^{-3}\ M$) the addition of 50 times the usual amount of *t*-butyl hydroperoxide (i.e., 1.0 M) resulted in the immediate development of a deep blue solution with an e.s.r. spectrum which, though rather poorly resolved, was consistent with that of Wurster's Blue cation (11, 12). No AIBN was required to develop the signal and, in fact, the addition of AIBN had little or no effect on the formation and decay of the cation radical. The maximum radical concentration ($6–7 \times 10^{-5}\ M$) was reached within 100 s; it decayed rather slowly reaching half its maximum concentration after about 3000 s. Under similar conditions, more transitory blue colors, which are assumed to be due to similar cation radicals, appeared with dimethyl- and trimethyl-*p*-phenylenediamine. The maximum radical concentrations ($2 \times 10^{-5}\ M$ for dimethyl- and $4 \times 10^{-5}\ M$ for trimethyl-*p*-phenylenediamine) were recorded on the first measurement 30 s after the start of the reaction. The concentrations of both radicals fell to $\sim 1 \times 10^{-5}\ M$ at 200 s and $\sim 3 \times 10^{-6}\ M$ at 800 s. Similar experiments with *p*-phenylenediamine and *N*,*N*′-diphenyl-*p*-phenylenediamine generated neither a blue color nor an e.s.r. signal.

Discussion

Amines with structures which do not correspond to conventional antioxidants, i.e., tertiary amines and primary and secondary aliphatic amines, generally show a peroxy radical signal whose behavior is similar to that observed in the absence of amine. Clearly such amines do not react with peroxy radicals at an appreciable rate under the present experimental conditions.

The behavior of the peroxy radical signals found in the presence of aniline, *p*-toluidine, and dibenzylamine (Fig. 1) suggests that these amines are consumed in the same length of time as the more efficient antioxidants. Since these amines probably react with two peroxy radicals per molecule they must stop essentially all the reaction chains and completely suppress bimolecular termination between *t*-butylperoxy radicals. However, these amine-peroxy radical reactions must either be reversible or be slow compared with the rate for more powerful antioxidants. Aniline and *p*-toluidine can presumably give amino radicals. Benzylamine may form either an amino radical (2) or a benzylic radical. The latter would yield a secondary peroxy radical which could trap *t*-butylperoxy radicals quite efficiently (13–15).

The rate of nitroxide formation and the maximum concentration of nitroxide are, quite understandably, greatest for those amines which give particularly stable nitroxides—specifically, diphenylamine and its ring substituted derivatives[7], i.e.

[4] $\quad ROO^{\cdot} + Ph_2N^{\cdot} \rightarrow RO^{\cdot} + Ph_2NO^{\bullet}$

However, in no case does the rate of nitroxide formation equal the rate of chain initiation which is its theoretical limiting value (8), i.e., in no case is $\rho/R_i = 1.0$. Although this feature of the reaction might be due to a number of causes, our studies on the oxidation of *N*-phenyl-2-naphthyl-

[7]The reactions are numbered in the same way as in the preceding paper (8).

amine with peroxy radicals suggest that the reaction of peroxy radicals with aromatic amino radicals may involve attack on the ring as well as on the nitrogen atom (10). That is, the reaction

[4*a*] $ROO^{\cdot} + Ph_2N^{\cdot} \rightarrow$ Molecular products

may take the following course,

[4*b*] $ROO^{\cdot} + Ph_2N^{\cdot} \longrightarrow$ 
$\longrightarrow ROH +$ 
The rates of nitroxide formation from methyl and methoxy substituted diphenylamines are somewhat lower than from diphenylamine itself which suggests that reaction [4*a*] is accelerated relative to reaction [4] by electron donating *para*-substituents. Since peroxy radicals are electrophilic, it is not unreasonable to suppose that their rate of attack on the ring will be accelerated by electron donating substituents on the ring. The low ρ/R_i values for *N*-phenyl-1- and -2-naphthylamines suggest that the attack of peroxy radicals on naphthyl rings is considerably faster than their attack on phenyl rings.

With the three *N*-methyl anilines the maximum concentration of nitroxides is low but the initial rate of formation is high: too high, in fact, to measure accurately during the very short time that the rate of nitroxide formation is presumably constant. In all three cases the nitroxide concentration reaches 50% of its maximum value by the time the first measurement is made 30 s after the (arbitrarily defined) start of the reaction, and reaches 80–90% of its maximum value after 100 s. The initial rate of nitroxide formation may actually be as high as for the diphenylamines. The low maximum concentrations of phenyl methyl nitroxides must be due to their high reactivity in the present reaction system.

The absence of nitroxides from tertiary amines and from other amines which are unlikely to react with peroxy radicals is readily understood. The absence of a nitroxide from *N*,*N*′-diphenyl-*p*-phenylenediamine can be explained by its known oxidation by peroxy radicals to *N*,*N*′-diphenyl-*p*-quinonediimine (9)

[4*c*] $ROO^{\cdot} +$ 
$\longrightarrow ROOH +$ 
The tertiary amine *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine is an interesting compound as its structure suggests that it should have little or no antioxidant activity. This compound was first reported to be an inhibitor by Boozer and Hammond (16) and its inhibitory activity has subsequently been confirmed by Yates and Ihrig (17). Our own rather limited conventional inhibition studies (18) have shown that this phenylenediamine behaves completely differently to other amine inhibitors. When it is used to inhibit the AIBN initiated oxidation of hydrocarbons such as styrene or tetralin there is a rather short induction period which is followed by an *extremely* rapid absorption of a relatively small amount of oxygen. This reaction ceases abruptly and further oxygen is only absorbed slowly. The rapid absorption of oxygen appears to be due to a chain initiating reaction involving the phenylenediamine and peroxide, presumably,

$$(CH_3)_2NC_6H_4N(CH_3)_2 + ROOH \rightarrow [(CH_3)_2NC_6H_4N(CH_3)_2]^+ OH^- + RO^{\cdot}$$

The short induction period may be due to traces of impurities in the diamine which have conventional antioxidant properties. The abrupt cessation of oxygen absorption occurs when all the diamine has been oxidized to the Wurster cation. Subsequent reactions of the cation must yield products with antioxidant activity, perhaps by the loss of a methyl group.

Dimethyl- and trimethyl-*p*-phenylenediamine behave quite normally in conventional inhibition studies (19) presumably because they can inhibit oxidation by the usual transfer of an amino hydrogen to a peroxy radical. This transfer is extremely fast with these two amines (19) and the hydroperoxide concentration will therefore be prevented from reaching a level where direct reaction with the phenylenediamines becomes important.

The most interesting group of amines that failed to give nitroxides in significant yields are the primary aromatic amines (*p*-anisidine, α-naphthylamine, and *p*-phenylenediamine). The absence of nitroxides cannot be due to the low reactivity of these amines towards peroxy radicals

[3*a*] $ROO^{\cdot} + ArNH_2 \rightarrow ROOH + Ar\dot{N}H$

since they are all known to be powerful oxidation inhibitors and, furthermore, since they do not show a peroxy radical signal at the beginning of

the reaction (cf. aniline and *p*-toluidine). Although the absence of nitroxides cannot be due to any inherent lack of stability of the ArN(H)O· radical[8] the possibility remained that these radicals would be unstable under our experimental conditions[9]. However, under the usual conditions, phenylhydroxylamine (8.3×10^{-4} *M*) gave readily detectable amounts of nitroxide, the concentration reaching a maximum of 1.6×10^{-6} *M* and being fairly constant from 150–1500 s. α-Naphthylhydroxylamine did not give a detectable signal under the usual conditions but 8.3×10^{-3} *M* was rapidly oxidized by 1.0 *M* [*t*-butylhydroperoxide] to give a radical (maximum concentration 6×10^{-6} *M*) which is presumably α-naphthyl nitroxide[10]. This radical decayed rather slowly (concentration $\sim 2 \times 10^{-6}$ *M* at 1500 s). No e.s.r. signal was detected from α-naphthylamine under similar conditions even after the addition of the usual quantity of AIBN. These results all suggest that the conversion of ArṄH radicals to ArN(H)O· radicals by reaction with peroxy radicals has a very low efficiency. We would like to suggest that oxidation occurs by the alternate pathway,

$$[4d] \quad \mathrm{ArṄH} + \mathrm{ROO}\cdot \rightarrow [\mathrm{ArN}\overset{\mathrm{H}}{\mathrm{O}}\mathrm{OR}] \rightarrow \mathrm{ArNO} + \mathrm{ROH}$$

The analogous reaction,

$$[4e] \quad \mathrm{PhNO}\overset{\mathrm{H}}{\mathrm{O}}\mathrm{H} \rightarrow \mathrm{PhNO} + \mathrm{H_2O}$$

is probably important in the base catalyzed oxidation of aniline to azobenzene (25). The direct formation of aromatic nitroso compounds by reaction [4*d*] provides an attractively simple explanation for the absence of aryl nitroxides in primary aromatic amine inhibited oxidations.

Acknowledgment

We should like to thank Dr. D. F. Bowman for the preparation of the phenylhydroxylamine and α-naphthylhydroxylamine.

[8]Phenyl nitroxide can readily be prepared by the action of various inorganic oxidizing agents on phenylhydroxylamine (20) and by a number of other methods (see e.g., 21–23).

[9]An early report by Baird and Thomas (2) suggested that the nitrogen containing radical formed by the oxidation of aniline with peroxy radicals was phenyl nitroxide or, rather, a time average between PhṄOH and PhN(H)O·. The e.s.r. spectrum has since been assigned to a radical with the probable structure PhN(O·)ON(H)Ph which is formed by the coupling of two oxidized aniline species (24). In our apparatus we could not detect a nitroxide signal from aniline under the standard experimental conditions. However, a very weak signal, probably due to PhN(O·)ON(H)Ph, was obtained by increasing the aniline concentration to 1.0 *M* and the AIBN concentration to 0.1 *M*. A similar type of radical was detected with 0.01 *M* [*p*-anisidine], 1.0 *M* [*t*-butylhydroperoxide], and 0.05 *M* [AIBN].

[10]A 10 line spectrum was obtained with 1.25 G modulation. This may be derived as a partially resolved 18 line spectrum assuming hyperfine splittings $A_{H-N} \approx 13$ G, $A_N \approx 9$ G, and a further 1:2:1 splitting of ~ 3 G from the equivalent 2- and 4- aromatic protons (23).

Nuclear charge dispersion in the fission of ^{232}Th by protons of energy 20–85 MeV[1,2]

P. P. BENJAMIN[3], D. A. MARSDEN[4], N. T. PORILE[5], AND L. YAFFE
Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Quebec

Received July 29, 1968

^{232}Th was irradiated with protons of energy 20–85 MeV and the independent yields of ^{130}Cs, ^{132}Cs, ^{134}Cs^{m}, ^{134}Cs^{g}, ^{136}Cs, ^{138}Cs, ^{86}Rb, and the cumulative yields of ^{137}Cs and ^{138}Xe were measured radiochemically. Charge dispersion curves were constructed at various energies and, as in previous studies, the broadening with increasing energy and shift of the most probable charge towards stability were observed. The most probable charge of a fission fragment of a given mass number lies closer to the line of β-stability in the case of thorium fission than in uranium. Detailed calculations in an attempt to correlate the experimental data with equal charge displacement (e.c.d.) and unchanged charge displacement (u.c.d.) charge distribution postulates were attempted. The results are not conclusive, lying in between the two, but favoring u.c.d. at the higher energies.

Canadian Journal of Chemistry, **47**, 301 (1969)

Introduction

Very few independent yields have been determined in the proton-induced fission of ^{232}Th. Pate, Foster, and Yaffe (1) obtained independent yields for various isotopes of iodine and tellurium for the fission of thorium induced by protons of energy 8–87 MeV. They were able to obtain charge dispersion curves, studied the behavior of these with energy, and attempted to draw conclusions about the mechanism of the charge distribution in fission. The work was extended by Kjelberg, Taniguchi, and Yaffe (2) who obtained fractional yields of ^{72}Ga, ^{82}Br, ^{112}Ag, and ^{140}La at the same bombarding energies.

Other workers (3–5), have obtained independent yields from the proton fission of uranium and drawn conclusions regarding the mechanism of the charge distribution, particularly the role of the neutron-to-proton ratio in the target and the resulting fission product.

It was of interest to determine independent yields in the same mass region as these previous workers, but with thorium as a target, and to compare the results as a function of the neutron-to-proton ratios of the two targets.

Experimental

(a) Irradiations

All irradiations were performed in the internal circulating beam of the McGill synchrocyclotron. The energy spread of the beam was known to ±2 MeV. Thorium metal foil (~ 80 mg/cm^2) was used as the target material. In all experiments, but the one at 20 MeV, foils were in stacks of three to compensate for recoil. A monitor foil, again with a guard foil on each side except for the 20-MeV experiment, was sandwiched to and placed upstream from the target. The leading edges of all foils were carefully aligned. The proton beam was monitored by the reaction ^{65}Cu(p,pn)^{64}Cu for all energies and also by the reaction ^{27}Al(p,3pn)^{24}Na at energies above 60 MeV. The values used were those of Meghir (6) and are given in Table I. Where single foils were used the results were corrected for recoil losses by means of the data of Noshkin and Sugihara (7). Recoil loss of ^{86}Rb was assumed to be the same as that of ^{83}Br (8%) and a value of 5% was estimated for the Cs isotopes.

The length of irradiations varied from 5 to 30 min and the energy range covered was 20 to 85 MeV.

Methods of measurement and relevant properties of nuclides

Nuclide	Half-life*	Radiation measured	Branch abundance	Instrument used
^{130}Cs	30 min	β^+	0.46	511–511 coincidence
^{132}Cs	6.5 d	673-keV γ	0.99	Scintillation spectrometer
$^{134}Cs^g$	2.1 y	797-keV γ / 801-keV γ	0.83	,,
$^{134}Cs^m$	2.9 h	e^-, β^-	1	$4\pi\beta$ and end-window proportional counters
^{136}Cs	12.9 d	β^-	1	,,
^{137}Cs	30 y	661-keV γ	0.84	Scintillation spectrometer
^{138}Cs	32.2 min	β^-	1	End-window proportional counter
^{86}Rb	18.6 d	β^-	1	,,

*The abbreviations used are: min for minutes, h for hours, d for days, and y for years.

(b) Chemical Separation

(i) Cesium

The procedure used was essentially that of Evans (8). The thorium foil was dissolved in concentrated hydrochloric acid and a few drops of ammonium silicofluoride were added to dissolve the last traces of residue. Carriers were added (Cs, 20 mg; Rb, 20 mg; Ba, 5 mg; 2 mg each of Sr, La, Ce, Y, and Zr) and the insoluble hydroxides and carbonates precipitated with 12 *N* sodium hydroxide and 2 *N* sodium carbonate solutions. The supernate was scavenged with lanthanum hydroxide, acidified with hydrochloric acid, cooled, and $Cs_3Bi_2I_9$ precipitated by the addition of BiI_3–HI reagent. The supernate was used for the subsequent rubidium separation. The Cs activity was purified by repeated precipitations as the bismuth iodide and finally either left as a precipitate or dissolved and made up to standard volume for activity measurement. The chemical yield determination was as the chloroplatinate.

(ii) Rubidium

The solution containing the Rb fraction was scavenged by $Cs_3Bi_2I_9$ precipitations. The excess reagent was removed by boiling with nitric acid to drive off the iodine and precipitation of bismuth as the oxynitrate. Rubidium was precipitated as Rb_2PtCl_6, washed with ethanol, the complex reduced to platinum with formic acid, and the excess formic acid destroyed by boiling with hydrochloric acid. Cesium bismuth iodide was precipitated and repeated until it showed no cesium activity. The rubidium was finally reprecipitated as the chloroplatinate, weighed for chemical yield determination, and the activity measured.

(iii) Aluminium

No chemical separation of sodium from aluminium was necessary. The aluminium foil was dissolved in the minimum amount of hydrochloric acid, made to volume, and aliquots taken for $4\pi\beta$ activity measurements. The samples were placed on VYNS films, dried, and covered with similar thin VYNS films to prevent absorption of moisture by the aluminium chloride.

(iv) Copper

The copper was separated from other activities by the ion-exchange method of Kraus and Moore (9). The chemical yield of copper was determined by direct titration with ethylenediamine tetraacetic acid with murexide as indicator (10).

(c) Activity Measurements

The methods of measurement of the various isotopes of cesium and ^{86}Rb are given in Table II. Unless otherwise stated, the data given were taken from Nuclear Data Sheets (11). Corrections, where applicable, were made for counter efficiency, self-absorption, external absorption, and resolution losses in the usual manner. The errors associated with these corrections are reflected in the general error associated with the cross section value quoted. The correction for the self-absorption of the conversion electrons from $^{134}Cs^m$ was arrived at by use of the decay scheme calculations of Baerg *et al.* (12).

(d) Decay Curve Analysis

The data obtained from the proportional counters were easily resolved into three components due to ^{138}Cs (32 min), ^{134}Cs (2.9 h), and ^{136}Cs (13 days) and a long-lived tail which by gamma analysis was found to consist of $^{134}Cs^g$ and ^{137}Cs. The radiations of ^{132}Cs, $^{134}Cs^g$, and ^{137}Cs were measured by γ-scintillation spectrometry. The area under the 670-keV photopeak of ^{132}Cs was obtained after the ^{136}Cs contribution had been subtracted from the entire spectrum. The contributions due to $^{134}Cs^g$ and ^{137}Cs were obtained from γ-ray measurements made about 1 year after irradiation.

The ^{24}Na and ^{64}Cu activities were determined by $4\pi\beta$ and γ-scintillation spectrometry respectively and gave pure single-component curves.

(e) Calculations

Formation cross-sections, σ, were obtained by application of equations readily available (3). Thorium and aluminium are monoisotopic so no corrections for isotopic abundance had to be introduced, but in the case of copper the isotopic abundance of copper was taken as 31%.

In the case of ^{138}Cs, a correction for its formation from its parent ^{138}Xe during irradiation and prior to separation has to be applied to obtain the independent yield of ^{138}Cs. The separation time was taken as that of foil dissolution since the xenon was removed by bubbling.

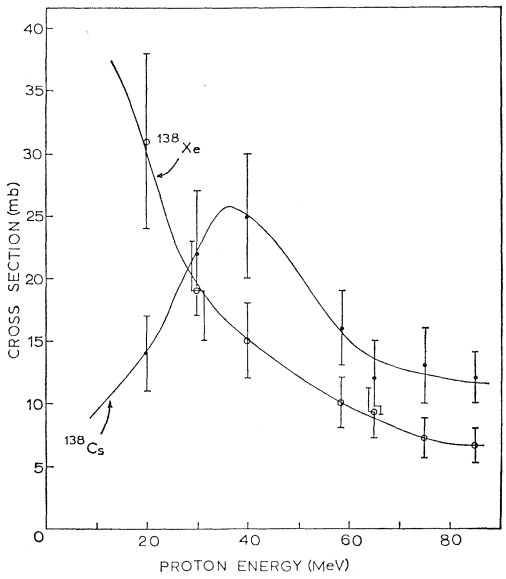

FIG. 1. Excitation functions for ^{138}Cs and ^{138}Xe: ○, cumulative yields of ^{138}Xe; ●, independent yields of ^{138}Cs.

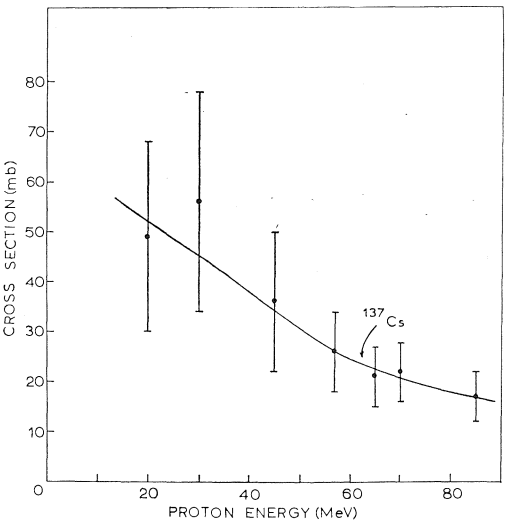

FIG. 2. Excitation function for ^{137}Cs (cumulative).

In all the other cases where the independent yield was obtained the nuclides were "shielded" by stable isobars. In the case of ^{138}Cs two short irradiations were performed at each energy. In one, the target was dissolved as quickly as possible at the end of bombardment while the other was processed about 1 h after irradiation. The data yielded two equations which were solved simultaneously to obtain the independent and cumulative cross-sections of ^{138}Cs and ^{138}Xe respectively.

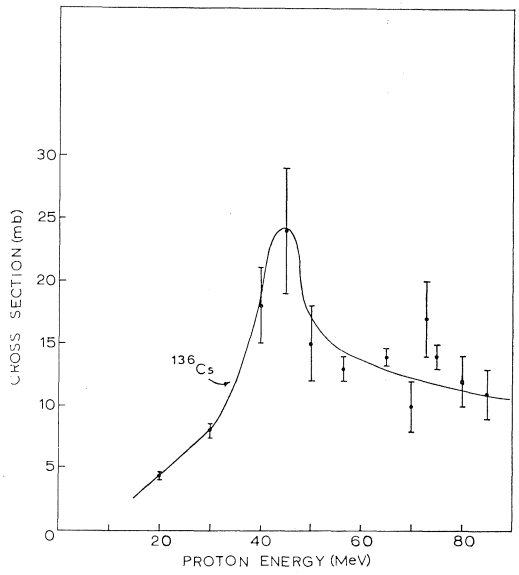

FIG. 3. Excitation function for ^{136}Cs (independent).

Uncertainties in determination of disintegration rates, chemical yields, pipetting, superficial densities, and decay curve analyses were obtained with a resulting probable error of ±20% in the case of ^{138}Cs, ^{138}Xe, ^{136}Cs, ^{134}Cs^{m}, ^{86}Rb; ±25% for ^{130}Cs and ^{132}Cs; and ±30% for ^{134}Cs^{g} and ^{137}Cs. Uncertainties in decay schemes and branching ratios were not included in the estimate. Where more than one determination at any energy was made the standard deviation from the mean value is given. The deviations were quite comparable to the estimated errors for the individual determination.

Results and Discussion

(a) Cross Sections and Excitation Functions

The cross sections obtained are shown in Table III and are plotted as a function of energy in Figs. 1–6 inclusive. As observed by other workers (3, 4) the excitation functions of the neutron-excess isotopes normally associated with low-energy fission reach a peak at relatively low energies, e.g. ^{136}Cs at 45 MeV, while the excitation functions of the more neutron-deficient isotopes increase in the energy range studied. As done by previous workers (3, 4) for uranium fission, the energies at which the excitation functions reach their maxima are plotted against the neutron-to-proton (N/Z) ratio of the nuclide and shown in Fig. 7. The data in the present paper alone are too sparse for a meaningful plot. They have been reinforced with data obtained by Forster *et al.* (13) for ^{133}Xe and ^{135}Xe in the

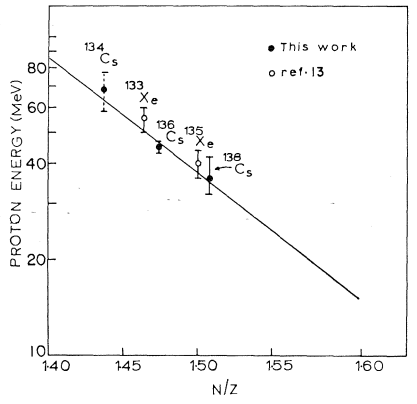

FIG. 7. Energies at which excitation functions reach their maxima.

fission of ^{232}Th. The limits on the data shown in Fig. 5 for ^{134}Cs are too great to allow the excitation function to be very closely defined. The dotted curve shows where the curve would be expected to reach its maximum (as obtained from Fig. 7) and this is not inconsistent with the data.

The curve in Fig. 7 for the fission of ^{232}Th is not as steep as that obtained in the same energy range (4) for ^{238}U fission, the slope of the latter being approximately twice as great. However, more data are needed before more meaningful conclusions can be drawn. It is apparent though that the energy at which ^{138}Cs has its greatest probability of formation is roughly the same (30 and 36 MeV) for ^{238}U and ^{232}Th respectively. However, ^{134}Cs has its greatest probability of formation at 100 MeV and 68 MeV for ^{238}U and ^{232}Th, respectively.

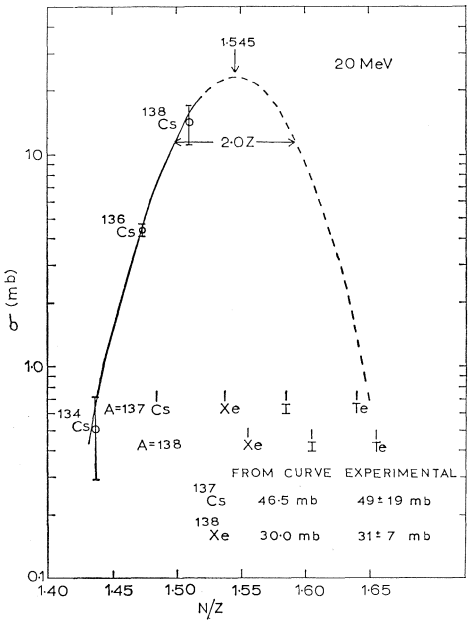

FIG. 8. Charge dispersion curve at 20 MeV.

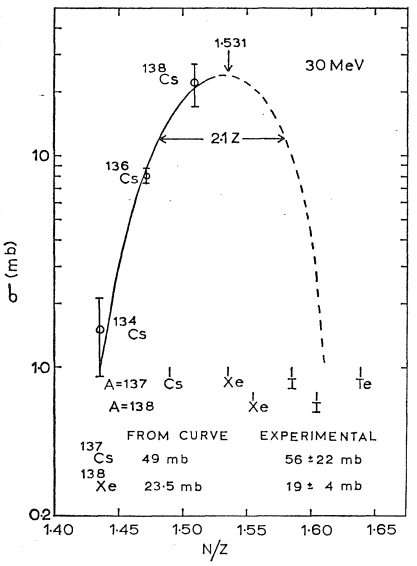

FIG. 9. Charge dispersion curve at 30 MeV.

Once again it is apparent that the N/Z value is an extremely useful parameter. From previous considerations (3) and the data in Fig. 7 one would expect the excitation function for ^{86}Rb to reach a maximum at energies far beyond those investigated here.

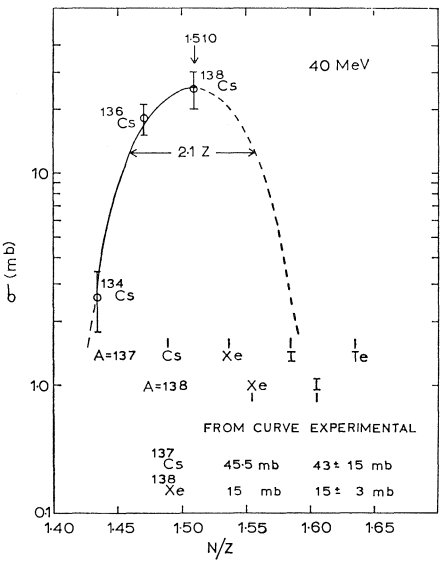

FIG. 10. Charge dispersion curve at 40 MeV.

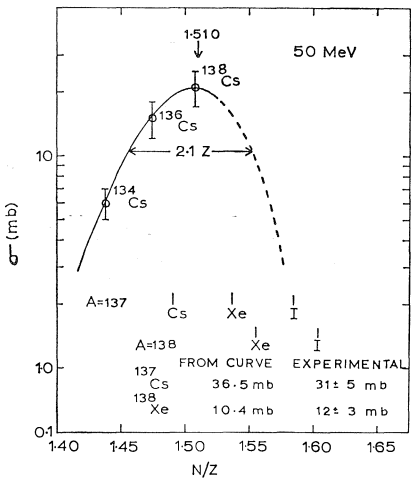

FIG. 11. Charge dispersion curve at 50 MeV.

(b) Charge Dispersion

Charge dispersion curves were constructed for bombarding energies of 20, 30, 40, 50, 57, 65, 75, and 85 MeV and are shown in Figs. 8–15 inclusive. The data consisted of the independent yields experimentally determined. The right-hand portion of the curve was fitted so that the independent yields read off the curve totalled to the cumulative yields for ^{137}Cs and ^{138}Xe experimentally determined. It has been shown (1, 3) that this constraint uniquely defines this

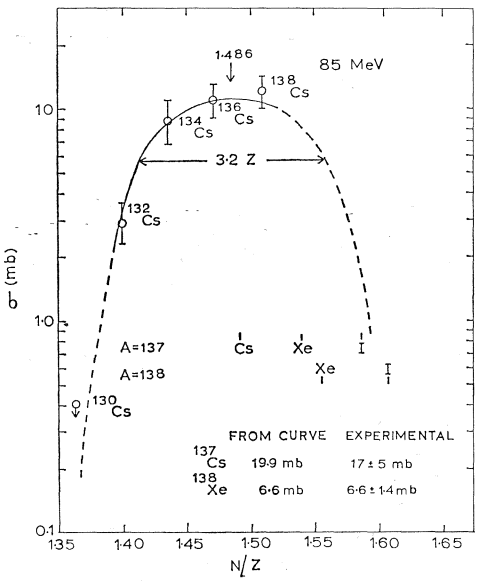

FIG. 15. Charge dispersion curve at 85 MeV.

portion of the curve. A basic assumption in plotting such a curve is that the mass-yield curve is sensibly flat at the appropriate energy for the narrow mass region under consideration.

In Fig. 16 and Table IV are shown the variation of the full-width at half-maximum (f.w.h.m.) with bombarding energy. As in previous work, both with Th (1) and U (4, 13) initially (up to around 50 MeV) the f.w.h.m. remains essentially constant and then increases with bombarding energy. This would seem to indicate two separate reaction mechanisms occurring, e.g. compound nucleus formation at the lower energies, and direct interaction at the higher.

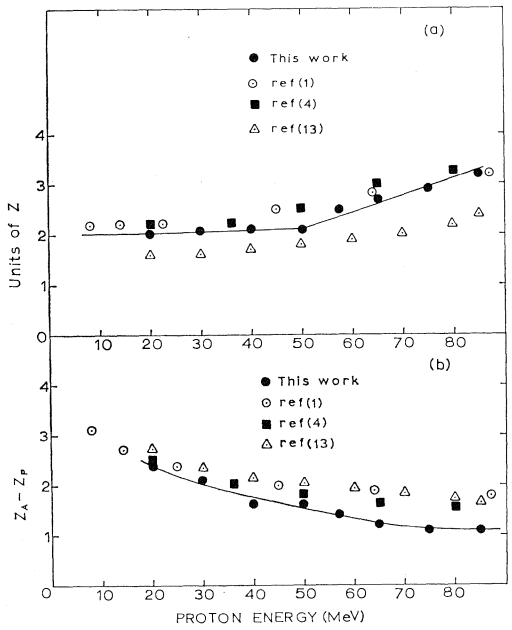

FIG. 16. (*a*) Variation of full-width at half-maximum of charge dispersion curves with bombarding energy. (*b*) Displacement of most probable charge, Z_p, towards beta stability, Z_A, with increase in bombarding energy.

In Fig. 16 is also given the plot of $Z_A - Z_p$ with increase in bombarding energy, where Z_A is the most stable charge for mass number A (14) and Z_p the most probable charge formed in fission. The movement of Z_p towards stability with increase in energy, as also shown by others, is clearly evident.

An attempt has been made to calculate the most probable charge of a fission fragment in the mass region of interest on the basis of the equal charge displacement (e.c.d.) (15) and unchanged charge displacement (u.c.d.) (16) postulates. These values are then compared with the experimentally determined Z_p values for $A = 136$.

Compound nucleus formation is assumed at proton bombarding energies of 20, 50, and 57 MeV and the results of published calculations on the prompt nuclear cascade (17, 18) were used as well as the data of Vandenbosch and Huizenga (19) on fission–spallation competition for proton energies of 80 and 85 MeV. The experimental results of Davies and Yaffe (4) on the proton-induced fission of uranium over a similar energy range were included in the present analysis for purposes of comparison.

TABLE IV

Parameters of charge dispersion curves

Proton energy (MeV)	Full-width at half-maximum ΔZ	Displacement from stability ($Z_A - Z_p$)
20	2.0	2.4
30	2.1	2.1
40	2.1	1.6
50	2.1	1.6
57	2.5	1.4
65	2.7	1.2
75	2.9	1.1
85	3.2	1.1

According to the e.c.d. postulate, the most probable charge $(Z_p)_i$ of a fission fragment of initial mass number A_i is given by

$$[1] \quad (Z_p)_i = Z_{A_i} - \tfrac{1}{2}[Z_{A_i} + Z_{(A_F - A_i)} - Z_F]$$

where A_F and Z_F denote the mass number and nuclear charge of the fissioning nucleus; $Z_{(A_F - A_i)}$ and Z_{A_i} are the most stable charges of the two complementary fission fragments with mass numbers A_i and $(A_F - A_i)$, respectively. Values of Z_{A_i} are those of Coryell (14).

According to the u.c.d. postulate, the most probable charge is given by

$$[2] \quad Z_{p_i} = \left(\frac{Z_F}{A_F}\right) A_i$$

Calculations were performed for a variety of fissioning nuclei to allow for prefission neutron emission and the Z_p values arrived at in this fashion refer to the primary fragments which may subsequently evaporate neutrons to lead to the observed fission products. If the fragments emit n neutrons after fission to give the final mass number A_f (experimentally studied), then Z_p for A_f is calculated from eqs. [1] and [2] with $A_i = A_f + n$.

To obtain n, the following assumptions were made:

(*i*) On the average 2 fission neutrons are emitted promptly regardless of excitation energy or the fission mode (20). These are equally divided between the two fragments and originate from the deformation energy of the fissioning nucleus.

(*ii*) The excitation energy of the fissioning nucleus is divided between the fragments in the ratio of their masses.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(*iii*) The average number of neutrons evaporated from the primary fragments is obtained using an average neutron binding energy of 7 MeV (21) plus an estimated average neutron kinetic energy of 2 MeV (22).

On these assumptions the fissioning nucleus divides into two fragments such that one has a mass number

$$[3] \qquad A_H = 136 + 1 + \left(\frac{E_F^*}{9} \times \frac{A_H}{A_F}\right)$$

where A_F is the mass number of the fissioning nucleus and E_F^* is its excitation energy in MeV. The equation can be rearranged to give

$$[4] \qquad A_H = \frac{137}{\left(1 - \frac{E_F^*}{9A_F}\right)}$$

The excitation energy E_C of the compound nucleus is given by the sum of the kinetic and binding energy of the impinging proton. The residual excitation energy, E_r, after emission of a neutron is given by

$$[5] \qquad E_r = E_C - (B_n + \bar{E}_k)$$

where B_n is the neutron binding energy, $\bar{E}_k = 2\tau$ is the average kinetic energy of the neutron, τ being the nuclear temperature. The proton and neutron binding energies are taken from Levy (21) and the calculation is carried through until the excitation value reaches an energy below the neutron binding energy. The excitation energies of the various nuclei formed from the compound nuclei by successive evaporation of neutrons and the estimated initial fragment masses are given elsewhere (23).

The probability G for fission of a given nucleus at these energies is given by

$$[6] \qquad G = \Gamma_F/(\Gamma_n + \Gamma_F)$$

where Γ_F and Γ_n are fission and neutron evaporation widths (charged particle evaporation is considered unlikely at these energies (17)). The dependence of G on the fissioning nucleus is quite pronounced and the data used are those of Vandenbosch and Huizenga (19) in order to get the fission probability of each fissioning nucleus. It was assumed that the formation probability of the compound nucleus (^{233}Pa) was 1, and Z_p values, calculated on the basis of e.c.d. and u.c.d., were weighted by the fission probability of each fissioning nucleus and the average $\bar{Z}_p$ determined for bombarding energies of 20, 50, and 57 MeV for thorium, and 20 and 50 MeV for uranium.

For ^{232}Th and ^{238}U, bombarded with protons of energies 85 and 80 MeV respectively, the experimental data were compared with an analysis starting with the results of the prompt cascade for 82-MeV protons incident on ^{238}U (17). The difference in energy of bombardment was neglected and appropriate shifts in charges and masses of the reaction products made to allow for the difference in mass and charge of the targets.

A total of 1258 cascades was followed in the prompt interaction calculation in addition to 78 events in which nuclear transparency is indicated. The excitation spectrum was also obtained from ref. (17). The cascade products, relative frequencies and their average excitation energies are given in ref. (23). Charged particle evaporation was neglected (18). For each cascade product the spectrum of residual excitation energies was divided into a number of bins and an average excitation energy taken for each bin. This procedure simplified the calculation without introducing any significant distortion of the results. The evaporation reaction, as in the low-energy cases, was allowed to proceed until a value below the neutron binding energy was reached.

Fission was assumed to compete with neutron evaporation in these cascade products as in the low-energy reactions. The average Z_p value of the fission fragment (final mass number $A = 136$), calculated for each cascade product, was weighted with the relative frequencies of each cascade reaction and the final weighted average of Z_p was compared with the experimental values.

The results for both the low and higher energy calculations are given in Table V. The maximum

TABLE V

Comparison of calculated and experimental Z_p values for $A = 136$

Target	Proton energy (MeV)	Z_p e.c.d.	Z_p u.c.d.	Z_p Experimental

uncertainty in the estimation of the primary fragment mass number is estimated to be ± 1 mass unit. This would introduce an uncertainty of ± 0.4 charge units in both the e.c.d. and u.c.d. calculations. In addition, in the case of the e.c.d. calculations, an uncertainty of about $\pm 0.5\,Z$ units in the Z_A values would make the e.c.d. values have a total uncertainty of ± 0.63 charge units. For the experimental Z_p values an uncertainty of $\pm 0.25\,Z$ units is estimated for $E \leqslant 50$ MeV and $\pm 0.5\,Z$ for $E \geqslant 50$ MeV.

Because of these limits, it is difficult to draw any definite conclusions. However, some general trends can be noted. The experimental values of Z_p lie between the e.c.d. and u.c.d. predictions for both uranium and thorium up to about 57 MeV, although they are somewhat closer to the u.c.d. predictions. At 80 and 85 MeV the values are much closer to those predicted by u.c.d. than e.c.d. However, it should be borne in mind that at these energies the charge dispersion curves are becoming much broader and the uncertainty in defining Z_p experimentally becomes greater. As the excitation energy increases both the e.c.d. and u.c.d. values of Z_p increase, showing slightly greater values of Z_p for thorium than uranium fission at comparable energies. The experimental data conform with these trends.

Aagard *et al.* (24) found, in a study of mass numbers about 130 formed in the fission of uranium by 170-MeV protons, that their data fell between the u.c.d. and e.c.d. values calculated by Rudstam and Pappas (25). Colby and Cobble (26) found that their data on the α-induced fission (20–40 MeV) of ^{233}U, ^{235}U, and ^{238}U correlated better with u.c.d. than e.c.d. Pate (27), with data obtained (1) in ^{232}Th fission by protons, concluded that fission up to energies as high as 480 MeV proceeds predominantly by a process consistent with the e.c.d. postulate.

The present analysis differs from that of Pate. He assumed that $\Gamma_F/(\Gamma_n + \Gamma_F)$ was energy-dependent. The present treatment assumes energy independence and incorporates published values of $\Gamma_F/(\Gamma_n + \Gamma_F)$ at every stage of neutron evaporation after the prompt interaction.

(c) $^{134}Cs^m/^{134}Cs^g$ Isomer Ratio

The cross section for the independent formation of ^{134}Cs includes contributions from metastable ^{134}Cs^m (spin and parity 8−, $t_{1/2} = 2.9$ h) as well as ^{134}Cs^g (spin and parity 4+, $t_{1/2} = 2.05$ years). Independent cross sections have been determined for the formation of both states and thus the isomer ratio can be calculated as a function of energy. The results are shown in Fig. 17. It is seen that the isomer ratio increases from approximately unity at the lowest energy to nearly three at the highest. It should be pointed out, however, that the experimental values are subject to an uncertainty of nearly a factor-of-two due primarily to the large error in the determination of the disintegration rates of ^{134}Cs[8].

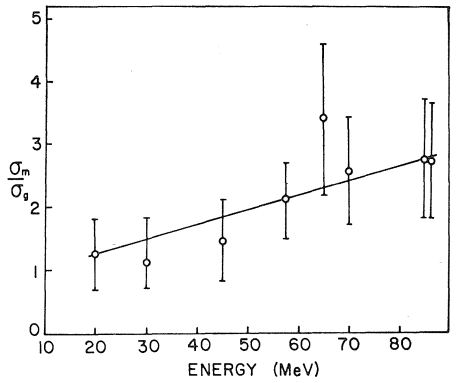

FIG. 17. Ratio of formation cross sections of the metastable and ground states of ^{134}Cs as a function of proton bombarding energy.

The isomer ratio of independently-formed fission products may be used to determine the intrinsic angular momentum of the primary fragments. A number of such determinations have been reported recently for low- or intermediate-energy fission (28–32). In common with these previous calculations we assume that the angular momentum distribution of a primary fragment, $P(J)$, is proportional to $(2J + 1)$ $\exp - J(J \pm 1)/\langle J^2 \rangle$ where $\langle J^2 \rangle$ is the mean square angular momentum. This functional form has been postulated by Nix and Swiatecki (33) on the basis of the liquid drop model. The calculation of the isomer ratio of the final products then follows the method of Vandenbosch and Huizenga (34). It is assumed that the primary fragment emits either 1 or 2 neutrons, having an average kinetic energy of 2 MeV (22). Following neutron emission the excited product is allowed to emit either 3 or 4 dipole photons (34). The last γ-ray populates either the metastable or ground state of ^{134}Cs, depending on which transition involves the smallest spin change. The calculation was performed with a value of the spin cutoff

TABLE VI

parameter, σ, of 3–5 (34). The neutron transmission coefficients were obtained from the compilation by Feld *et al.* (35).

The results of the calculation are summarized in Table VI. It is seen that the value of $\langle J^2\rangle^{1/2}$ required to fit the experimental value of σ_m/σ_g obtained at incident energies of 20–25 MeV is approximately 9–10. The angular momentum of the primary fragments arises, at least in part, from the angular momentum of the compound nucleus as modified by the emission of pre-fission neutrons. In addition, previous comparisons of experimental and calculated isomer ratios (28–32) indicate that substantial amounts of intrinsic angular momentum can be generated in the fission act, in agreement with a prediction by Strutinskii (36).

We have assessed the relative importance of these two factors by calculating the angular momentum of the fissioning nucleus and then determining the isomer ratio expected on the assumption that the primary fission fragment has the same angular momentum as the fissioning nucleus. The calculation was performed for protons of 19- and 24-MeV incident energy. The proton transmission coefficients were taken from the tabulation by Feshbach *et al.* (37). It was expected, on the basis of the available excitation energy, that up to 3 neutrons could be emitted from the compound nucleus if fission followed neutron emission, or that up to 2 neutrons could be emitted by the primary fragment if fission preceded evaporation. The calculation was performed for both these extreme assumptions using the above mentioned parameters. Typical results for bombardment by 19-MeV protons are summarized in Table VII. It is seen that the value of $\langle J^2\rangle^{1/2}$ of the fissioning nucleus is approximately 4.5, regardless of whether fission occurs prior to or after neutron emission. This value is much smaller than the value $\langle J^2\rangle^{1/2} = 10$ required to fit the experimental isomer ratio and, as expected, the ratio calculated on the basis of the angular momentum of the fissioning nucleus is much too small. The same conclusion also follows from the calculation for 24-MeV protons. The present results thus bear out Strutinskii's prediction (36).

Although the angular momentum of the compound nucleus does not appear to be the primary factor determining the isomer ratio in fission, it does nonetheless play an important role. This can be seen by comparing a particular isomer ratio obtained in fission induced by different projectiles with varying bombarding energies. The angular momentum generated in fission should be the same in all these cases and the variation in the number of emitted neutrons

TABLE VIII

Correlation of experimental ^{134}Cs isomer ratio with root-mean-square angular momentum of $\langle J^2 \rangle^{1/2}$ of different compound nuclei

Compound nuclei	Energy (MeV)	$\langle J_c^2 \rangle^{1/2}$	$\sigma_{^{134}Cs^m}/\sigma_{^{134}Cs^g}$ isomer ratio	Reference number
$^{233}U + \gamma$	16	1	0.75	29
$^{238}U + P$	20	4	20	38
$^{232}Th + P$	20	4.2	1.2	Present work
$^{237}Np + d$	21	6	1.6	29
$^{238}U + P$	45	8.6	6	38
$^{232}Th + P$	45	8.7	1.4	Present work
$^{232}Th + P$	65	11	3.4	Present work
$^{238}U + P$	65	11	4	38
$^{237}Np + {}^4He$	42	11	4.7	29
$^{235}U + {}^4He$	42	11	3.3	29

should only lead to a minor effect on the isomer ratio. If the differences in the spins of the various targets and projectiles are neglected, one should then see a correlation between the isomer ratio and the orbital angular momentum brought into the compound nucleus by the bombarding particle.

The $^{134}Cs^m/^{134}Cs^g$ ratio constitutes a good case in point since it has been determined in a variety of fission reactions (28, 38). The results of this comparison are summarized in Table VIII. The root-mean-square value of the angular momentum of the compound nucleus was obtained by use of the sharp cutoff approximation (39). It is seen that, except for the surprisingly large values of σ_m/σ_g reported by Davies and Yaffe (38) at low energies, a reasonably good correlation between $\langle J^2 \rangle^{1/2}$ and the isomer ratio is found.

Acknowledgments

The authors wish to express their appreciation to Professor R. E. Bell, Director, Foster Radiation Laboratory, McGill University for his ready permission to use the cyclotron and to Mr. R. H. Mills who cheerfully performed the irradiations.

Kinetics and mechanisms of the reaction between carbon monoxide and copper(II) in aqueous solution

J. J. BYERLEY
Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario

AND

E. PETERS
Department of Metallurgy, University of British Columbia, Vancouver 8, British Columbia

Received June 24, 1968

The kinetics of the reduction of copper(II) to copper(I) by carbon monoxide in aqueous solutions have been investigated at 120 °C and carbon monoxide pressures up to 1360 atm. The reaction is homogeneous and proceeds by two paths, one of which is virtually independent of carbon monoxide pressure due to the formation of a stable cuprous carbonyl complex $Cu(CO)^+$. The second reaction path contains both a pH-dependent and pH-independent component. The rate-determining step in both paths appears to be the decomposition of a carbon monoxide insertion complex by a cupric ion. Complexing ligands such as acetate were observed to have a minor inhibiting effect on the overall reaction.

Introduction

Carbon monoxide reduces a number of metal ions under pressurized conditions and elevated temperatures. The kinetics and mechanisms of many of these reactions, for example, silver(I) (1–3), nickel(II) (4), cobalt(II) (5), and mercury(II) (6), are described in the literature.

The reaction of copper(II) with carbon monoxide was first studied by Bauch, Pawlek, and Plieth (1) who reported a first-order dependence on carbon monoxide and a second-order dependence on dissolved copper. McAndrew and Peters (7) using a pressure drop technique (8–10) reported that the overall reaction takes place in 2 stages; the first stage which may be represented by the stoichiometry

$$[1] \quad 2Cu(II) + 3CO + H_2O \rightleftarrows 2Cu(CO)^+ + CO_2 + 2H^+$$

is followed by a second stage described as a further reduction to metallic copper, hydrolysis or disproportionation depending on prevailing chemical conditions.

In a previous paper the present authors (11) indicated that at low initial copper levels the process would proceed only through the first stage providing the carbon monoxide pressure was maintained at a sufficiently high value to stabilize the cuprous ion. Under these conditions it was found that the kinetics of the homogeneous reactions described by reaction [1] were expressible by a 2 term rate law

$$[2] \quad \frac{-d[Cu(II)]}{dt} = k_1 \frac{[Cu(II)][Cu(I)]}{[H^+]} + k_2 \frac{[Cu(II)]^2}{[H^+]} P_{CO}$$

The reaction mechanism postulated from the kinetic evidence centered on the formation of carbon monoxide insertion complexes such as

$$(Cu—\overset{\overset{O}{\|}}{C}—OH)^+$$

It is now possible, through a combination of the earlier information and new data, especially that obtained at high carbon monoxide pressures, to provide a much more comprehensive understanding of the reaction.

Experimental

All chemicals were reagent grade and used without further purification. Carbon monoxide (99.5% minimum) was supplied by the Matheson Company. The copper(II) solutions employed in the kinetic study were prepared by diluting standardized stock solutions. Most experiments were carried out in acetate buffered solutions.

The progress of the reaction of copper(II) with carbon monoxide was followed spectrophotometrically using a titanium alloy cell which fitted directly into the sample compartment of a DK-2 ratio-recording spectrophotometer. This cell has been described in detail in the literature (12). The spectrophotometer was modified somewhat to permit the recorder pen carriage to be driven at constant speed while the wavelength scroll remained fixed at a desired wavelength (approximately

For personal use only.

750 mμ for cupric acetate; the absorption peaks are temperature dependent). This arrangement produced a continuous record of optical density change as the copper(II) species was reduced.

The experimental procedure consisted of filling the reaction cell (total liquid volume 1 cc) with copper(II) solution using a hypodermic syringe. The remaining volume in the cell was flushed with nitrogen and carbon monoxide through the exhaust valve on the side of the vessel. With the cell placed in the sample compartment of the spectrophotometer, the temperature was raised to 120 °C under a pressure of about 20 atm of carbon monoxide. A thermistor temperature controller provided temperature regulation to within ±0.3 °C. When the reaction temperature was reached, the desired carbon monoxide pressure was applied, and the solution was immediately agitated for 2 min by a magnetic plunger. The reaction thus being initiated was allowed to proceed without further agitation[1] since the solubility of carbon monoxide at the applied pressures (68 to 1360 atm) was at least 5 times that required for complete reduction of the dissolved cupric salt.

Experimental Results

The General Form of the Rate Law

Three typical experimental curves with optical density replaced by copper(II) concentration showing the reduction of cupric acetate by carbon monoxide are given in Fig. 1. This characteristic "S" shape was observed for all experiments in the acetate buffered system except when certain extreme chemical conditions were applied. Under these conditions (discussed later) it was possible to virtually eliminate the initial downward curvature. Curves of the type shown in Fig. 1 were consistently found to yield maximum slopes at the point where 50% of the copper(II) had been reduced regardless of the initial copper(II) concentration. The rate at this mid-point was found to be the most reproducible stage of the experiment (normally within 5%) and thus was selected as the reaction parameter for most experiments.

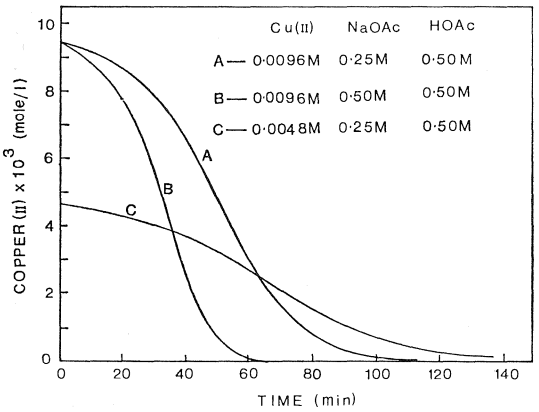

FIG. 1. Typical experimental curves for the reduction of copper(II) by carbon monoxide: P_{CO} = 68 atm; temperature = 119.4 °C.

[1]Agitation during the course of the reaction did not produce any detectable change in the rate of the reaction.

Examination of the experimental curves shown in Fig. 1 indicates a definite dependence of reaction rate on copper(II) and acid concentrations. Although a consideration of these variables (along with the carbon monoxide dependence) has resulted in a preliminary rate law formulation, given in the paper cited earlier, it is appropriate to repeat briefly this discussion to facilitate a clear understanding of the final rate law.

Figure 2 shows the results of graphically differentiating curves of the type shown in Fig. 1. These curves which are nearly symmetrical about the 50% reduction point, indicate a rate law of the form

$$[3] \qquad -\frac{d[Cu(II)]}{dt} = A[Cu(II)][Cu(I)] + B[Cu(II)]^n$$

In this expression the product of the concentrations of 2 copper species is the dominant term

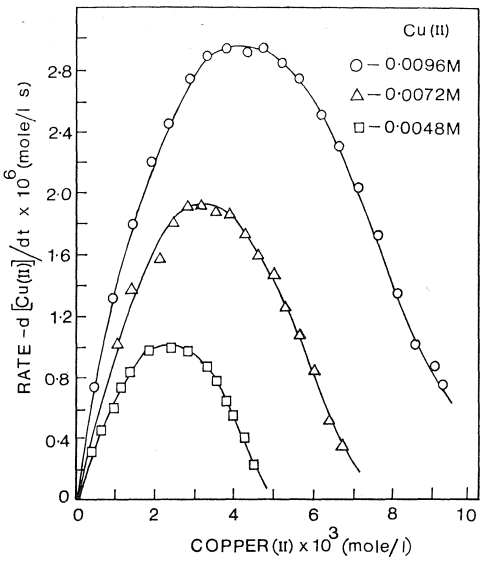

FIG. 2. Differential plot showing $-d[Cu(II)]/dt$ vs. [Cu(II)] for 3 initial copper(II) concentrations: 0.25 *M* NaOAc; 0.50 *M* HOAc; P_{CO} = 68 atm; temperature = 119.4 °C.

whereas the second term is added to account for the initiation of the reaction which must be dependent on copper(II) alone.

Further evidence to support the form of eq. [3] is found through maximum rate measurements. The maximum rate still retains some contribution from the rate due to the second term but this may be neglected. Figure 3 shows a plot of maximum rate for a series of experiments using different initial copper concentrations. A linear dependence on [Cu(II)][Cu(I)] is apparent. The zero intercept arises because at the point of measurement the concentration of copper(II) is about equal to the concentration of copper(I).

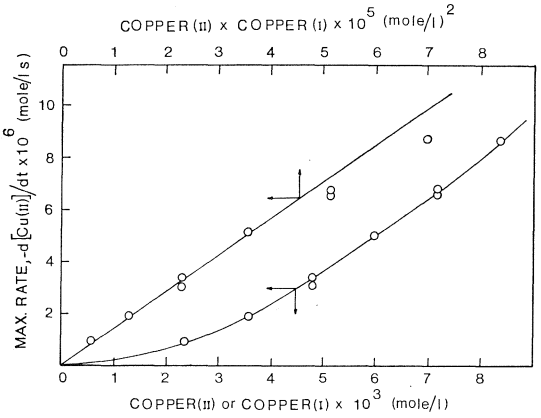

FIG. 3. Dependence of maximum rate on [Cu(II)] and [Cu(II)][Cu(I)] at 50% reduction: 0.25 *M* NaOAc; 0.50 *M* HOAc; P_{CO} = 68 atm; temperature = 119.4 °C.

The dependence of maximum rate on the reciprocal of acetic acid concentration is shown in Fig. 4. In view of this result, eq. [3] may be rewritten in the following form

$$[4] \quad -\frac{d[Cu(II)]}{dt} = A'\frac{[Cu(II)][Cu(I)][OAc^-]}{[HOAc]} + B'\frac{[Cu(II)]^n[OAc^-]}{[HOAc]}$$

Under the conditions prevailing in this series of experiments only the form of the dominant first term appears justified although it does not seem unreasonable to expect the same acid behavior to be reflected in the second term. Further discussion of this point will be given later. By using the expression for the ionization constant of acetic acid, eq. [4] may be rewritten in terms of a new set of rate constants

$$[5] \quad -\frac{d[Cu(II)]}{dt} = k_1'\frac{[Cu(II)][Cu(I)]}{[H^+]} + k_2'\frac{[Cu(II)]^n}{[H^+]}$$

where $k_1' = A'K_i$, $k_2' = B'K_i$, and K_i is the ionization of acetic acid.

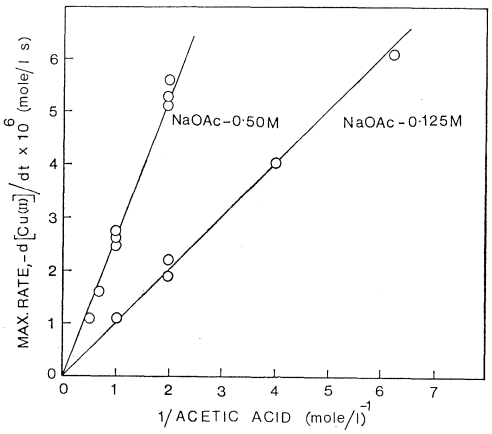

FIG. 4. Dependence of maximum rate on 1/[HOAc]: 0.0096 *M* initial Cu(II); P_{CO} = 68 atm; temperature = 119.4 °C.

The composition of the solution used in these experiments is such that free cupric ions would form a negligible part of the total copper(II) concentration while the concentrations of $Cu(OAc)^+$ and $Cu(OAc)_2$ are present in significant concentrations. Figure 4 may be used to illustrate the inhibiting effect of increasing acetate complexing on the reaction rate by simply selecting a point on each curve of equivalent [NaOAc]/[HOAc] ratio. This result indicates that the diacetate complex which increases in concentration on addition of sodium acetate apparently has a somewhat lower reactivity than the monocetate. A portion of the decrease in rate at constant [NaOAc]/[HOAc] is probably due to a salt effect which would cause an increase in the ionization constant of acetic acid and thus an increase in hydrogen ion concentration. No attempt was made to resolve the complexing effect from the rate constants although experiments carried out in perchlorate media, which is considered a very weak complexing ligand, correlated quite well with rates obtained by extrapolating acetate data to "zero" complexing.

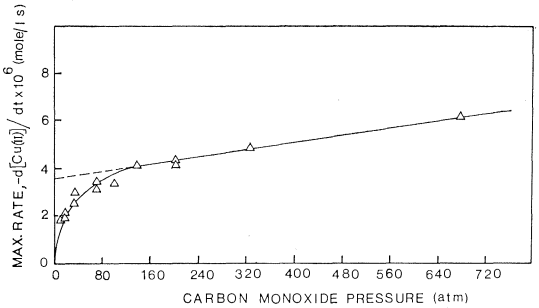

FIG. 5. Effect of carbon monoxide pressure on maximum rate: 0.0096 *M* initial Cu(II), 0.25 *M* NaOAc; 0.50 *M* HOAc; temperature = 119.4 °C.

Effect of Carbon Monoxide Pressure

The effect of carbon monoxide pressure on the reaction rate is recorded in Fig. 5. This plot indicates that the rate of reaction increases very little over the pressure range of about 60 to 680 atm. In view of the fact that the maximum rate is rather insensitive to large carbon monoxide pressure variation, it is reasonable to assume that the pressure-dependence is primarily related to the second term of the rate law. This can be interpreted in terms of a stable cuprous carbonyl (10) complex given by the equilibrium

$$[6] \qquad Cu^+ + CO \overset{K}{\rightleftharpoons} Cu(CO)^+$$

The concentration of $Cu(CO)^+$ can be written as

$$[7] \qquad [Cu(CO)^+] = \frac{K[Cu^+_t][CO]}{1 + K[CO]}$$

where $[Cu^+_t]$ is the total monovalent copper. Since K is known to be large, eq. [7] loses the pressure-dependence and $[Cu(CO)^+] \simeq [Cu^+_t]$. Thus, with the equilibrium of eq. [6] shifted far to the right, the pressure effect would pertain only to the term not involving Cu(I). The effect of pressure on the first term would only become significant when the CO pressure is so low as to shift the $Cu^+ - CO$ equilibrium to the left. The form of Fig. 5 implies that when the CO pressure is above $\sim$ 60 atm a linear dependence on CO pressure can be assigned to the second term of the rate expression. Equation [5] can be written as

$$[8] \qquad -\frac{d[Cu(II)]}{dt} = k_1' \frac{[Cu(II)][Cu(I)]}{[H^+]} + k_2'' \frac{[Cu(II)]^n}{[H^+]} P_{CO}$$

The form of eq. [8] suggests a method of resolving the rates due to the first and second terms. The intercept of Fig. 5 is an estimate of the rate due to the first term. The additional rate at a particular carbon monoxide pressure is the contribution from the second term. Thus a closer inspection of the 2 individual terms in the rate expression and a resolution of their rate constants is possible under high pressure conditions.

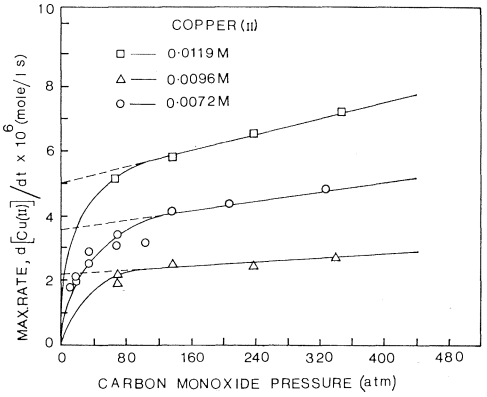

FIG. 6. Resolution of pressure-dependent and pressure-independent terms using [Cu(II)] as the variable: 0.25 *M* NaOAc; 0.50 *M* HOAc; temperature = 119.4 °C.

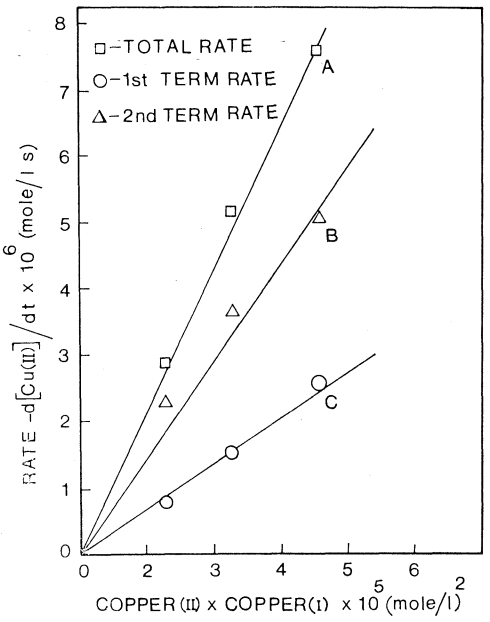

FIG. 7. Dependence of total rate, first term rate and second term rate on [Cu(II)][Cu(I)] or $[Cu(II)]^2$, total rate and second term rate measured at 400 atm (Fig. 6): 0.25 *M* NaOAc; 0.50 *M* HOAc; temperature = 119.4 °C.

Recorded in Fig. 6 is a series of experiments similar to those shown in Fig. 5 except that 3 different initial copper concentrations were investigated. Figure 7 presents the graphical data taken from Fig. 6. Curves A and B are plots of the total rate at 400 atm and the first term rate vs. [Cu(II)][Cu(I)] and give the expected linear relationships and zero intercepts. Curve C is a plot of the rate due to the second term and is also linear in [Cu(II)][Cu(I)] which is equivalent to $[Cu(II)]^2$ at 50% reduction. Equation 8 may thus be rewritten in the form

$$[9] \quad -\frac{d[Cu(II)]}{dt} = k_1' \frac{[Cu(II)][Cu(I)]}{[H^+]} + k_2'' \frac{[Cu(II)]^2}{[H^+]} P_{CO}$$

where $k_1' = 5.43 \times 10^{-6}$ s^{-1} ($\pm 10\%$) and $k_2'' = 5.70 \times 10^{-9}$ s^{-1} atm^{-1} ($\pm 20\%$), concentration of NaOAc = 0.25 *M*, temperature = 119.4 °C.

Another series of experiments was carried out in which the $[H^+]$ was varied instead of the [Cu(II)]. These results are shown in Fig. 8. Curve A of Fig. 9 is a plot of the total rate of the reaction at a CO pressure of 400 atm. The curve does not pass through the origin which suggests a pH-independent component of the reaction. This result was not evident in the data obtained from the acid series at 68 atm of carbon monoxide. Thus the pH-independent component must be contained only in the second term of the rate law. Curve B shows the expected inverse linearity of the first term along with a zero intercept. In view of these results the kinetics may be described by a 3 term rate expression

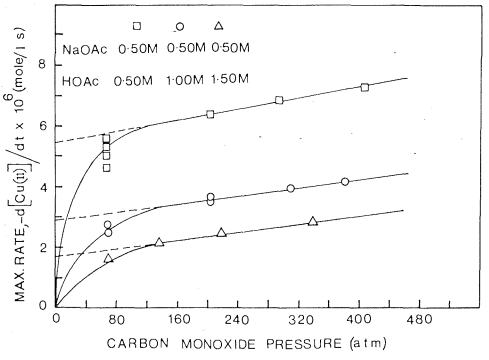

FIG. 8. Resolution of pH-dependent and pH-independent terms: 0.0096 *M* initial Cu(II); temperature = 119.4 °C.

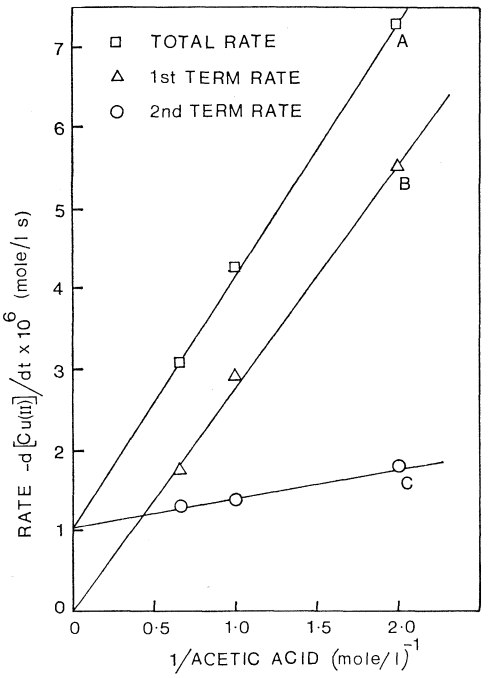

FIG. 9. Dependence of total rate, first term rate, and second term rate on 1/[HOAc], total rate and second term rate measured at 400 atm (Fig. 8): 0.0096 *M* initial Cu(II), 0.50 *M* NaOAc; temperature = 119.4 °C.

$$[10] \quad -\frac{d[Cu(II)]}{dt} = k_1 \frac{[Cu(II)][Cu(I)]}{[H^+]} + k_2 \frac{[Cu(II)]^2}{[H^+]} P_{CO} + k_3 [Cu(II)]^2 P_{CO}$$

where the rate constants as obtained from the data in Fig. 9 are given as follows: $k_1 = 4.24 \times 10^{-6}$ s^{-1} ($\pm 10\%$), $k_2 = 1.40 \times 10^{-9}$ s^{-1} atm^{-1} ($\pm 20\%$), $k_3 = 1.15 \times 10^{-4}$ s^{-1} M^{-1} atm^{-1} ($\pm 15\%$), concentration of NaOAc = 0.50 *M*, temperature = 119.4 °C.

Through the use of the pressure variable it is possible to enhance the contribution of the pressure-dependent terms which at modest pressure account for less than 10% of the maximum reaction rate. Estimation of the second term rate constant k_2'' has, up to now, been made on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

basis of maximum rates which can produce large errors. Initial rate measurements at low pressure were also found to suffer from large errors not only because of the inherent difficulty associated with initial rate measurement but also because the reaction is changing very rapidly from a pure cupric dependence to a cupric–cuprous dependence. A series of experiments were performed at carbon monoxide pressures from 68 to 1360 atm. The experimental curves are reproduced in Fig. 10. The gradual elimination of the characteristic "S" shape can be explained in terms of a superposition of curves, a convex curve due to the second-order dependence of copper(II) in the second term and an "S" curve with a very slow initial downward curvature increasing only when the copper(I) level becomes significant. As the second term contribution becomes large with increasing carbon monoxide pressure the initial downward curvature disappears.

Using a one term approximation of eq. [9], that is

$$[11] \quad -\frac{d[Cu(II)]}{dt} = k_2'' \frac{[Cu(II)]^2}{[H^+]} P_{CO}$$

the average value of k_2'' was found to be 5.02×10^{-9} s^{-1} atm^{-1}. This average does not include the evaluation of k_2'' taken from the experiment at 68 atm. It should be noted that the value of the ionization constant of acetic acid is affected by hydrostatic pressure. This pressure dependence which has been reported by Hamann and Strauss (13) shows that the ionization constant varies from 1.75×10^{-5} to 5.4×10^{-5} at 25 °C in the pressure range 1 to 3000 atm. This factor has been taken into account when calculating k_2''.

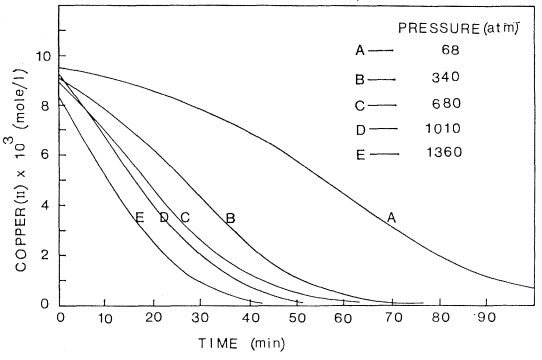

FIG. 10. Alteration of experimental curves by increasing carbon monoxide pressure: 0.0096 *M* initial Cu(II), 0.125 *M* NaOAc; 0.50 *M* HOAc; temperature = 119.4 °C.

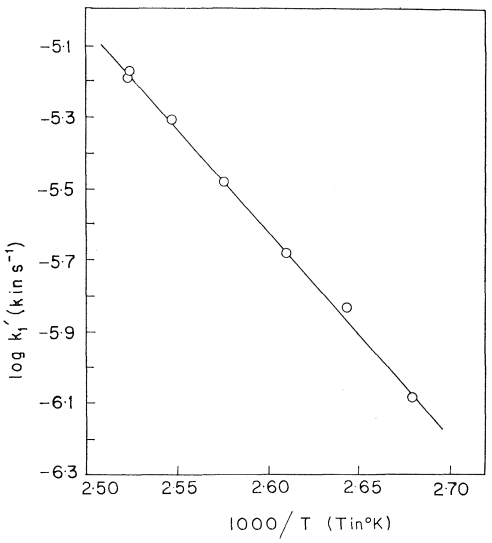

FIG. 11. Arrhenius plot for the reduction of Cu(II) by carbon monoxide: 0.0096 *M* initial Cu(II), 0.25 *M* NaOAc; 0.25 *M* HOAc; P_{CO} = 68 atm.

The Temperature Dependence

The effect of temperature on the reduction of copper(II) was investigated over the temperature range 100 to 123 °C. The rate constants plotted in Fig. 11 are those which pertain to the dominant term since they were obtained from maximum rate measurements. No attempt was made to separate the temperature dependence of the smaller terms. From the slope of this Arrhenius plot, an experimental activation of 25.8 ± 1.0 kcal/mole was calculated.

Reaction Mechanism

A reaction mechanism may be postulated which is compatible with the kinetic evidence summarized in the 3 term rate law given by eq. [10]. This mechanism which defines 2 reaction paths may be represented as follows

PATH A

$$[12a] \quad Cu(II) + CO + H_2O \underset{\text{rapid equilibrium}}{\overset{K_a}{\rightleftharpoons}} (Cu{-}\overset{OH}{\overset{|}{C}}{=}OH)^{2+}$$

[12*b*] $$(\mathrm{Cu{-}C(OH){=}OH})^{2+} + \mathrm{Cu(II)} \xrightarrow{k_a} \mathrm{CO_2} + 2\mathrm{Cu(I)} + 2\mathrm{H^+}$$

[12*c*] $$\mathrm{Cu(II)} + \mathrm{CO} + \mathrm{H_2O} \underset{\text{rapid equilibrium}}{\overset{K_b}{\rightleftharpoons}} (\mathrm{Cu{-}C(=O){-}OH})^{+} + \mathrm{H^+}$$

[12*d*] $$(\mathrm{Cu{-}C(=O){-}OH})^{+} + \mathrm{Cu(II)} \xrightarrow{k_b} \mathrm{CO_2} + 2\mathrm{Cu(I)} + \mathrm{H^+}$$

PATH B

[12*e*] $$\mathrm{Cu^+} + \mathrm{CO} \xrightarrow[\text{fast}]{} \mathrm{Cu(CO)^+}$$

[12*f*] $$\mathrm{Cu(CO)^+} + \mathrm{H_2O} \underset{\text{rapid equilibrium}}{\overset{K_c}{\rightleftharpoons}} (\mathrm{Cu{-}C(=O){-}OH}) + \mathrm{H^+}$$

[12*g*] $$(\mathrm{Cu{-}C(=O){-}OH}) + \mathrm{Cu(II)} \xrightarrow{k_c} \mathrm{CO_2} + \mathrm{CuH^+} + \mathrm{Cu(I)}$$

[12*h*] $$\mathrm{CuH^+} + \mathrm{Cu(II)} \xrightarrow[\text{fast}]{} 2\mathrm{Cu(I)} + \mathrm{H^+}$$

The rate law derived from this reaction sequence corresponds to

$$[13] \quad -\frac{\mathrm{d[Cu(II)]}}{2\mathrm{d}t} = k_c K_c \frac{[\mathrm{Cu(II)}][\mathrm{Cu(CO)^+}]}{[\mathrm{H^+}]} + k_b K_b \frac{[\mathrm{Cu(II)}]^2}{[\mathrm{H^+}]} P_{\mathrm{CO}} + k_a K_a [\mathrm{Cu(II)}]^2 P_{\mathrm{CO}}$$

Equation [13] is identical to eq. [10] if $k_c K_c = k_1$, $k_b K_b = k_2$, $k_a K_a = k_3$, $[\mathrm{Cu(CO)^+}] = [\mathrm{Cu(I)}]$, and the stoichiometry is taken into account.

The first term does not appear to have a pH-independent component. According to the proposed mechanism the observed pH-independent reaction results from the doubly charged intermediate

$$(\mathrm{Cu{-}C(OH){=}OH})^{2+}$$

where the carbon co-ordinates 2 hydroxyl groups. An analogous equilibrium to reaction [12*a*] could exist

[14] $$\mathrm{Cu(CO)^+} + \mathrm{H_2O} \overset{K}{\rightleftarrows} (\mathrm{Cu{-}C(OH){=}OH})^{+}$$

resulting in a singly charged intermediate. The absence of the pH-independent contribution suggests that either this structure is extremely labile and does not exist long enough to react with copper(II), or the attack of the intermediate by copper(II) is too slow to contribute an observable effect.

There are 2 important features evident in the proposed mechanism, the insertion of a carbon monoxide molecule between a metal ion and co-ordinated water molecule, and the decomposition of the insertion complex by another metal ion.

The postulation of a carbon monoxide insertion intermediate is not new. The reduction of silver(I) (2, 3, 9) in both acidic and basic solutions incorporate carbon monoxide insertion complexes into the mechanisms which subsequently undergo decomposition by a metal ion. In the reduction of mercury(II) (6, 14) and nickel(II) (4) by carbon monoxide and the metal ion-catalyzed reduction of MnO_4^- (6, 14), similar intermediates have been postulated. There is no kinetic evidence for the attack of these intermediates by metal ions to facilitate their decomposition as in the case of silver(I) and copper(II) reductions.

In the development of the reaction mechanism

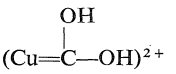
not only have insertion complexes been suggested, but also the carbonyl complex (10) $Cu(CO)^+$. In order to account for the pressure-independent character of the first term of the rate law, a fast reaction involving the complexing of Cu^+ with carbon monoxide has been proposed. This is in contrast to the pressure-dependency of the second term, where carbon monoxide participates in a pre-equilibrium. The Cu^+ ion does possess the characteristics necessary for carbonyl formation and indeed shows a great affinity for carbon monoxide. The existence of a stable carbonyl clearly distinguishes the Cu(II)–CO reduction mechanism from the earlier mechanisms proposed for silver(I), mercury(II), and the catalyzed reduction of MnO_4^-.

The explanation of the pH-independent term of the rate law appears in the mechanisms in the form of an intermediate exhibiting a protonated carboxyl group. Although the attachment of 2 OH^- groups to the same carbon atom lacks stability, the presence of a species such as Cu^{2+} could have sufficient electrophilic character to promote stabilization. Further stability of this intermediate may also be gained by admitting resonance structures such as



The slow step in both reaction paths is the attack of the insertion complexes by copper(II). In path B the slow step implies the transfer of an H atom or hydride ion H^-. It seems reasonable to assume that the copper ion forming the CuH^+ intermediate comes from the insertion complex whereas the attacking copper(II) acts as the electron acceptor[2]. Removal of a hydride ion from H_2 to form CuH^+ has already been postulated for the mechanism of hydrogen reduction of copper(II) and thus is not without support (15). The postulation of CuH^+ permits the use of one Cu^{2+} ion in the rate-determining step as allowed by the rate law whereas the overall stoichiometry would require two Cu^{2+} ions.

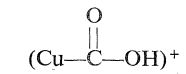
The alternate products to CuH^+ are copper atoms and a proton. The available thermodynamic data indicates that the formation of such species is energetically inconsistent (81.5 kcal/mole) with the activation energy of 26 kcal/mole observed for the reduction of copper(II) by molecular hydrogen in which CuH^+ is the proposed intermediate (16, 17).

The final decomposition of CuH^+ by reaction with another copper(II) species is regarded as fast and does not affect the kinetics. In strong acid solutions it would be expected to compete with another reaction between CuH^+ and hydrogen ions which would yield molecular hydrogen, i.e.

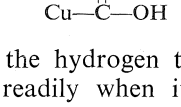
[15]

This reaction was never observed in acetate solutions and would be difficult to obtain because of the slow nature of the overall reaction in strongly acid solutions due to the reciprocal dependence of the rate on hydrogen ion concentration.

The principle difference in the rate-determining step of path A is that the intermediate species



(or the protonated form) has a net positive charge. The charged intermediate would be a stronger acid than the neutral species

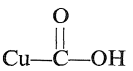


thus allowing the hydrogen to come off as a proton more readily when it is attacked by copper(II). The result is a simple oxidation–reduction reaction. In contrast to the reduction of silver(I) by carbon monoxide in acetate solution the present reaction exhibited only minor sensitivity to the acetate ligand. No attempt was made to resolve this variable nor is it considered in the reaction mechanism.

Acknowledgment

The authors gratefully acknowledge the financial support from the National Research Council of Canada.

[2]At first glance the species



appears to be an acid and upon dissociation a proton would be produced. However, the intermediate is sufficiently electron rich so that in the presence of a suitable recipient 1 or even 2 electrons may accompany the proton in which case the result is either hydrogen atom or hydride ion transfer.

Isomerization of butene over a chromia–alumina catalyst

H. C. CHEN[1], R. R. HUDGINS, AND P. L. SILVESTON
Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario

Received May 15, 1968

Isomerization runs were performed in a micro-reactor at 325 °C over a range of butene partial pressure of 84 to 763 mm Hg and at a total pressure of approximately 1 atm. The isomerization rate of 1-butene passed through a maximum with increasing 1-butene partial pressure; the isomerization rate of *cis*- and *trans*-2-butene increased asymptotically with increasing *cis*- and *trans*-2-butene partial pressures respectively. Stereoselectivity was observed in the isomerization of each butene, and was found to be independent of pressure. Catalyst deactivation resulted in loss in stereoselectivity. Results suggest that surface reactions control isomerization and proceed simultaneously on different active sites.

Despite the commercial importance of chromia–alumina catalysts for dehydrogenation–isomerization reactions, our understanding of the reaction mechanism on the catalyst and the transport-kinetic rate-controlling steps is incomplete. This paper furnishes new kinetic data on the isomerization of butenes over a commercial chromia–alumina catalyst taken with the intent of establishing rate-controlling steps and helping to elucidate the catalytic mechanism. This study extends earlier work (1) on butane dehydrogenation using the same catalyst, and supplements the work of Amenomiya and Cvetanović (2), the latter being the only account of butene isomerization on chromia–alumina reported to date.

Under the conditions employed, *cis–trans* isomerization of 2-butene and a double bond shift occur. Isobutylene is not found normally, and was not found in this study.

Catalytic isomerization of butenes exhibits a high degree of stereoselectivity which is dependent upon the catalyst (2–9), temperature, and conversion (6, 11). Foster and Cvetanović (6) show that alkaline catalysts favor double bond migration, whereas typically acidic catalysts favor *cis–trans* isomerization. Neutral and metal catalysts exhibit less stereoselectivity. Higher temperatures also reduce stereoselectivity. Selectivity observations have led to the view that isomerization proceeds via a carbanion radical on alkaline catalysts, whereby the stereoselectivity is due to lack of rotation of the allylic carbanion (6, 8, 10). A carbonium ion mechanism has been proposed for the acidic catalysts by Lucchesi *et al.* (7) and is given support by other investigators (9–11). In particular, Hall and co-workers using isotope and tracer techniques (9) provide considerable evidence for a carbonium ion intermediate on silica–alumina. Their studies (9) on activated γ-alumina lead them to suggest that more than one mechanism is operative. Brouwer (5) attributes olefin isomerization on γ-alumina to a carbonium ion mechanism for *cis–trans* isomerization and a hydrogen switch mechanism for a double bond shift. The interpretation of a carbonium ion mechanism for the steric isomerization and an allylic intermediate (though not necessarily ionic) for the double bond shift is suggested by Ogasawara and Cvetanović (8) for Na_2CO_3 impregnated alumina. It is offered, as well, as an interpretation for the chromia–alumina system by Amenomiya and Cvetanović (2).

Chromia is believed to occur in co-precipitated or impregnated catalysts as 10 to 150 Å semicrystalline nodules (12, 13). Foster and Cvetanović (6) find both unsupported chromia and K_2CrO_4 catalyze butene isomerization and are stereoselective. Burwell *et al.* (14) also report olefin isomerization on chromia. According to Harnsberger *et al.* (12), the alumina support is inactive for dehydrogenation at 500 °C. However, Carra and Ragaini (23) in their study of butene isomerization over alumina supported palladium, report some isomerization activity above 240 °C. Nonetheless, it is reasonable to assume that the bulk of the isomerization occurs on the chromia nodules.

Experimental

Apparatus

Details of the apparatus, calibration of rotameters, thermocouples, gas chromatograph, and analysis of products are described elsewhere (1), except for slight

modifications to the micro-reactor. The micro-reactor employed is shown in Fig. 1.

Calibration of the gas chromatograph was done with standard hydrocarbon mixture No. 37 (Lot 14) from Phillips Petroleum Company, Texas, U.S.A. Propylene carbonate (30% by weight) on 60–80 mesh chromosorb was used for the column.

A commercial chromia–alumina catalyst (approximately 21% Cr_2O_3, 0.46% Na_2O) supplied by Davison Division of W. R. Grace and Co., Baltimore, Md., U.S.A., was used after crushing to provide 40–50 mesh catalyst grains. Properties of this catalyst are detailed elsewhere (1). Compressed nitrogen (prepurified grade) and butene gases of C.P. grade purity (99% minimum) were obtained from Matheson of Canada, Ltd. Analyses by gas chromatography revealed no detectable impurities.

Procedures

Deactivation made it necessary to regenerate the catalyst periodically. It was also necessary to activate the ground fresh catalyst before use. Activation was accomplished by passing pure butene over the fresh catalyst at reaction temperature. On regeneration, the catalyst activity increased. Subsequent regenerations did not alter the activity; as a result, the same batch of catalyst was used for all measurements. Regeneration was carried out by first purging the reactor with pure nitrogen, treating with air for 2 h at 325 °C, and then flushing the reactor again with nitrogen.

The experimental objective was to obtain rate and selectiveness ratios (defined as the ratio of rates of formation of any two butene isomers from the third) for various butenes as a function of butene partial pressure and time of deactivation. Thus, the partial pressure of butene was varied by changing the relative flows of nitrogen and butene while keeping the total flow constant. Butene flow was controlled by a $\frac{1}{4}$-in. toggle valve located upstream from the tee where butene and nitrogen were mixed. In a typical run, this toggle valve was opened for several minutes to allow for flushing and for a quasi steady-state to be reached on the catalyst surface. After several minutes, a gas sample was collected and analyzed immediately by an on-line gas chromatograph. During analysis, only nitrogen passed over the catalyst. The time on stream (with butene in the feed) was accumulated for each series of readings to give conversion as a function of the time butene passed over the catalyst. Initial rates and selectiveness ratios were obtained by extrapolating to zero time on stream.

Results

Butene isomerization rates and selectiveness ratios were obtained for a range of partial pressures from 84–763 mm Hg at approximately 1 atm total pressure and 325 ± 2 °C. Nitrogen was the diluent. Results reported are extrapolations to zero time on stream. Figures 2, 3, and 4 for *trans*-2-butene, *cis*-2-butene, and 1-butene respectively, show the rate of disappearance of the isomer as a function of isomer partial pressure. The selectiveness ratios for different reactant partial pressures are shown as a function of time on stream in Figs. 5, 6, and 7, for *trans*-2-butene, *cis*-2-butene, and 1-butene respectively. It is seen that selectivity is affected by catalyst deactivation but not by butene partial pressures.

Reproducibility and Sources of Error

At the same reactant partial pressure, 2 or 3 series of experiments were performed to test reproducibility. A series is a set of reaction rates measured at different times on stream after a regeneration of the catalyst. Reproducibility was good in almost all cases. Figure 8, a typical plot

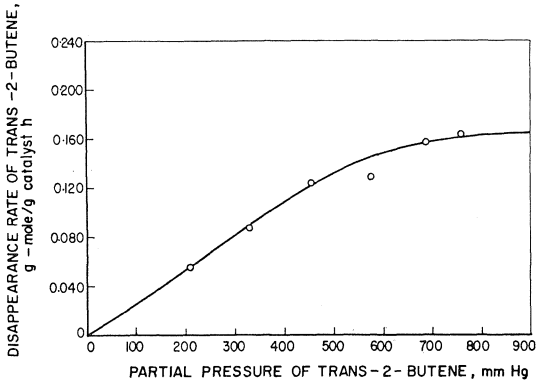

FIG. 2. Rate of disappearance of *trans*-2-butene.

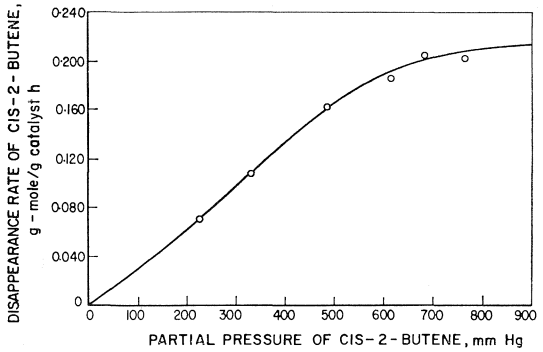

FIG. 3. Rate of disappearance of *cis*-2-butene.

of conversion data vs. time on stream, shows a slight spread of points for different series. If the spread was greater than shown, extrapolation was carried out using the points of highest activity. Occasionally a series would show a significantly lower activity than the others, probably owing to incomplete regeneration. Such a series was disregarded and extrapolation was based on data points with high activity. In the worst case, use of the low activity data would have resulted in a rate only 11% less than that obtained with the high activity data.

The standard deviation in conversion at various times on stream, and of replicate data points, rarely exceeded 15% and averaged about 10%. Thus, reproducibility was deemed satisfactory.

Isomerization was treated as irreversible and conversion was considered differential. Thus, rates could be calculated directly from conversion and mass flow rate of the reactant. Conversion in the reactor averaged about 8%, which is well below equilibrium conversion corresponding to an equilibrium distribution at 325 °C of 20.0, 33.5, and 46.5% for 1-butene, *cis*-2-butene, and *trans*-2-butene respectively (3). It is shown elsewhere (15) that the irreversible and differential assumption introduced a negligible error.

To test the contribution of homogeneous thermal isomerization, a series of runs was made at a low flow rate with about 50% butene mixture using a roll of stainless steel screen to replace the catalyst in the micro-reactor. No perceptible conversion was detected by gas chromatography. This result agrees with the literature

(16, 17), which reports that homogeneous thermal reactions are negligible for the experimental conditions used in the study.

Catalytic cracking of butenes was also negligible as shown by the presence of only trace amounts of cracking products in the chromatographic analyses, and a satisfactory carbon balance considering only butenes.

The results reported in Figs. 2–7 were obtained using a 40–50 mesh catalyst. The average diameter based on mesh opening was 0.35 mm. As a check for the influence of pore diffusion, a series of runs was made for *cis*-2-butene using a 60–70 mesh catalyst (average diameter 0.22 mm). A comparison of rates obtained by extrapolating differential conversions versus time on stream to zero time gave the results summarized in Table I. If pore diffusion played a significant role, a 59% increase in rate should have been detected for this size change. The rate difference is negligible; therefore, pore diffusion is not important in this study.

According to Petersen (18), if intraparticle resistance to mass transfer is unimportant, so too is

60–70	0.41	26 200	0.107

external resistance to mass transfer. Furthermore, the sharp reduction in conversion with catalyst deactivation, shown in Fig. 8, suggests that reaction or adsorption rates and not mass transfer rates were measured in this study. A calculation of the partial pressure difference between the gas and catalyst surface indicated a difference of the order of 10^{-2} atm which confirms that mass transfer can be neglected in interpreting the kinetic measurements.

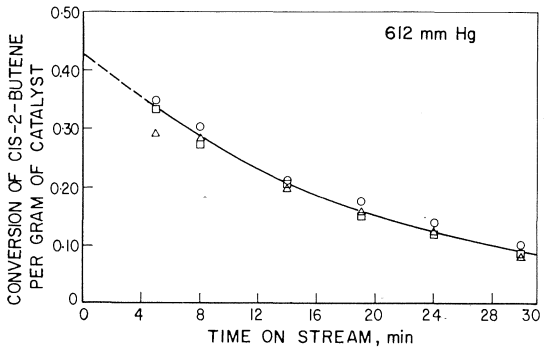

FIG. 8. Conversion data for *cis*-2-butene and extrapolation to zero time on stream, using 612 mm Hg of *cis*-2-butene. ○, Reading numbers 300–305 (series 1); □, reading numbers 306–311 (series 2); △, reading numbers 312–317 (series 3).

Modelling and Interpretation of Results

The salient features of the experimental results are:

(*1*) The apparent asymptotic behavior of the rate of disappearance of *cis*- and *trans*-2-butene as the isomer partial pressure increases (Figs. 2 and 3).

(*2*) The maximum found in the rate of disappearance of 1-butene over the same range of partial pressures (Fig. 4).

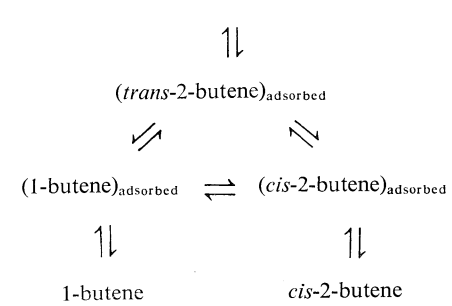
(*3*) Stereoselectivity showing *cis*- and *trans*- equally favored in the double bond shift, and *cis–trans* isomerization favored over a double bond shift (Figs. 5–7).

(*4*) Lack of a pressure effect on selectivity (Figs. 5–7).

(*5*) A trend towards equilibrium distributions of isomers as the catalyst deactivates.

Any rate-controlling step or kinetic mechanism proposed for the system must be consistent with these observations.

Amenomiya and Cvetanović (2) postulate that isomerization over chromia–alumina follows a reaction scheme:



and assume that the rate is described by $kKp/(1+Kp)$, where k is a rate constant, K, an adsorption equilibrium constant, and p, the partial pressure of the butene reactant. This model is adequate for the description of 2-butene isomerization, but will not yield a maximum in rate. This maximum was found for 1-butene (Fig. 4).

The model proposed by Amenomiya and Cvetanović corresponds to a Langmuir–Hinshelwood model for rate-controlling surface reaction occurring at a single active site or desorption of a product. The highly idealized Langmuir–Hinshelwood models (19, 20) should, according to Boudart (21), adequately describe reaction rates measured at one temperature for moderate ranges of pressure and concentration. These conditions are met in this study and models for various rate-controlling steps have been compared to the data as a means of indicating the controlling step. Details are given by Chen (15). Isomerization can be treated as irreversible and interconversion between products neglected for the conversion range used. The Langmuir–Hinshelwood models for different rate-controlling steps are:

(*a*) desorption of product or surface reaction involving a single active site

$$[1] \qquad r = \frac{Ap}{1 + Bp}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(*b*) adsorption of reactant on a single active site

$$[2] \qquad r = Cp$$

(*c*) surface reaction involving dual sites or dissociative adsorption involving dual sites

$$[3] \qquad r = \frac{Dp}{(1 + Ep)^2}$$

An expansion of eq. [3], gives

$$[4] \qquad r = \frac{Dp}{1 + Fp + Gp^2}$$

In the above equations, p is the reactant partial pressure, and A to G are constants representing collections of equilibrium constants and rate coefficients. The contributions of adsorption terms for reaction products were neglected, because adsorption equilibrium constants were believed to be all about the same size while experimental conversions were low. Also the contributions of adsorption terms for the nitrogen diluent were neglected; this is common practice. This assumption is supported by measurement by Uesugi (22) of the adsorption of N_2 on the catalyst at 325 °C. His measurements indicate that N_2 accounts for less than 0.5% of monolayer coverage for the highest diluent partial pressures used.

Equations [1]–[4] were rearranged to give linear forms and fitted to the data by the method of linear least squares. The variance of the fit was compared to an estimate of experimental error of 11% (see discussion of reproducibility above) to test the adequacy of the models. Another test was provided by the fact that all constants of the models should be positive.

This fitting procedure found that eq. [1] gave an adequate fit of the 2-butene data with both A and B positive. Equations [1] and [2] failed to give an adequate fit of the 1-butene data as might be expected; eq. [3], although allowing for the shape of Fig. 4, also failed to give a good fit and; for eq. [4], one of the constants in the denominator was found to be negative in the region between confidence limits. The inconclusiveness of the statistical test may be due to insufficient data, but could also result from the assumption that isomerization occurs via a single mechanism. Carra and Ragaini (23) propose parallel mechanisms for the isomerization of 1-butene.

The model results suggest that surface reaction of chemisorbed intermediates controls butene isomerization. This is in accord with the findings of other investigators (5, 9, 8, 11), albeit for other catalysts. Desorption control is normally dismissed if isomerization is stereoselective (8). However, if the reaction proceeds through a geometrically stable allylic intermediate, stereoselectivity is possible for desorption control. In this case, desorption control may be rejected because it is unlikely that 2-butene isomerization is desorption controlled while 1-butene is surface-reaction controlled.

Figures 5–7 show selectiveness ratios of (1-butene)/(*trans*-2-butene) = 0.77, (1-butene)/(*cis*-2-butene) = 0.77, (*trans*-2-butene)/(*cis*-2-butene) = 1.00, at zero time on stream. The equilibrium distribution at 325 °C corresponds to ratios of 0.43, 0.60, and 1.42, respectively. Chromia–alumina is thus stereoselective and favors double bond migration over a *cis–trans* shift for 2-butene, and the formation of *cis*-2-butene from 1-butene. Amenomiya and Cvetanović (2) found a similar stereoselectivity for unpromoted chromia–alumina between 210 to 260 °C. A difference in catalyst prevents a quantitative comparison of selectivity. Foster and Cvetanović (6) report that *cis* is favored over *trans* for isomerization of 1-butene, and that 1-butene is favored over *cis–trans* for 2-butene isomerization on unsupported chromia at 250 °C. Chromia on alumina and unsupported chromia exhibit a selectivity in between those found by Foster and Cvetanović to characterize acidic and basic catalysts. Their stereoselectivity is similar to that found for activated carbon. Chromia is not considered to be a strong acid catalyst. A carbonium ion mechanism, however, is invoked by Habeshaw and Hill (24) for polymerization of ethylene on chromia supported on silica or silica–alumina gels. A number of mechanisms are proposed to account for the transfer of hydroxyl protons from the support to the chromia surface. This transfer may also occur with an alumina support. Acid sites have been measured on potassium promoted chromia–alumina by Voltz *et al.* (25). The marked decrease in site density when the catalyst is reduced clearly associates the majority of sites with the chromia. Burwell and co-workers (14) find *cis–trans* and double bond isomerization of hexenes occurs readily at 200 °C on unsupported chromia and suggest an allylic carbanion intermediate.

Activated alumina (6, 9) is acidic and favors

cis–trans isomerization of 2-butene over double bond migration. This is not observed for this catalyst, confirming the assumption that the support is inactive.

The product distribution obtained here is identical to that predicted by the isomerization model of Hightower and Hall (9), which invoked a common 2-butyl carbonium ion for both *cis–trans* and double bond migration. However, agreement seems fortuitous since their (1-butene)/(*cis*-2-butene) = (1-butene)/(*trans*-2-butene) = 0.75 ratios are for room temperature only. The major failing of the 2-butyl carbonium ion intermediate model is that it does not predict a change in selectivity on deactivation.

Leftin and Hermana (11) propose configurationally different allylic carbonium ion intermediates for double bond migration to yield *cis* and *trans*-2-butene. This model also fails to predict the deactivation effect unless some complex and unlikely assumptions are made. If, for example, preferentially deactivated sites favor the *cis* precursor, intraconversion of the allylic configurations will occur readily, and is less affected by deactivation than the double bond migration.

Ogasawara and Cvetanović (8) suggest that geometric and double bond isomerization occur by simultaneous mechanisms. A carbonium ion mechanism is responsible for *cis–trans* isomerization, and either an allylic radical or ion, or the concerted hydrogen switch mechanism, is responsible for the double bond shift. This is more satisfactory than Brouwer's postulate of either carbonium or hydrogen switch occurring at the same site. The Brouwer model also fails to predict the observed decrease in *cis–trans* selectivity on deactivation. If one assumes separate sites for the simultaneous mechanisms with an activity hierarchy

$$\text{1-butene} \rightleftharpoons \textit{cis}\text{-2-butene} > \text{1-butene}$$

$$\textit{trans}\text{-2-butene} > \textit{cis} \rightleftharpoons \textit{trans}$$

and preferential deactivation of the most active sites, the observed behavior would result.

The proposal of Carra and Ragaini of parallel mechanisms for 1-butene isomerization is particularly attractive event though it was originally put forward to explain isomerization over metal catalyst (23). The first mechanism involves π-adsorbed butene forming a carbonium ion, interacting with another site to shift a hydrogen atom, and give σ-bonding on two metal sites. Desorption yields only *cis*-2-butene. The parallel mechanism involves a single site and the formation of an allyl radical, and, according to Carra and Ragaini, is not stereoselective. If one assumes that intraconversion of the intermediates or a separate *cis–trans* isomerization is possible to account for the 2-butene results, and that the stereoselective sites for 1-butene are preferentially deactivated, the proposal is fully in accord with the selectivity, deactivation, and rate model results.

Analysis of line-width effects in the electron spin resonance spectra of monoprotonated semiquinones

T. E. GOUGH
Department of Chemistry, University of Waterloo, Waterloo, Ontario
Received April 17, 1968

Electron spin resonance spectra of monoprotonated *p*-benzosemiquinone, 2:6-dimethyl-*p*-benzosemiquinone, and durosemiquinone dissolved in tetrahydrofuran at −70 °C are reported. Under such conditions restricted rotation of the hydroxyl group causes the ring positions meta to the site of protonation to appear as non-equivalent, though this effect is not observed for monoprotonated durosemiquinone. The spectra of monoprotonated *p*-benzosemiquinone in tetrahydrofuran exhibit both anisotropic and alternating line-width trends; equations are presented which allow the separation of these two effects and the determination of the energy of activation for the rotation of the hydroxyl group as between 31 and 40 kJ/mole. Spectra of monoprotonated 2:3- and 2:5-dimethyl-*p*-benzosemiquinones in 1:2 dimethoxyethane at 20 °C are also reported.

Introduction

Ultraviolet irradiation of neutral solutions of quinones results in the formation of monoprotonated semiquinone radicals of general formula HO—Ar—O·, which have been characterized by their electronic (1, 2) and electron spin resonance (3–5) spectra. The latter show that protonation of the semiquinone causes a redistribution in unpaired electron density; positions ortho to the hydroxyl group carry a small negative spin density (of the order of −0.02) while the meta positions carry an appreciable positive spin density (of the order of +0.2). The signs of these spin densities have been inferred from valence-bond calculations (3) and from the fact that, when due consideration is given to their signs, the mean of the ortho and meta splitting constants closely approximates the splitting constant of the semiquinone anion. The magnitude of the perturbation produced by protonation depends upon the polarity of the solvent (as defined by Kosower (6)), less polar solvents giving larger perturbations of the semiquinone's spin density distribution. The hydroxylic proton's hyperfine splitting pattern is broadened to high field, indicating (7) a negative splitting constant for this proton. To date, all electron spin resonance studies have been performed at room temperature, when the hydroxyl group is rotating sufficiently rapidly to give the radicals an effective C_{2v} symmetry.

Studies performed on several other hydroxy-substituted radicals (8–11) have shown the possibility of observing the effects of the restricted rotation of hydroxyl groups upon the resonance spectra. Under suitable conditions, rotation of the hydroxyl group modulates the hyperfine splitting constants of the radical and gives rise to an alternating line-width effect which may be used to determine the frequency factor and energy of activation of the rotational process. Quantitatively, the method of Carrington (12) has been most widely used for this purpose; the Bloch equations, modified to include the effects of exchange (13), are solved for a series of trial values of the rotational correlation time. The results are then used to simulate theoretical spectra which are compared with the experimental spectrum. However, the rotational correlation time is not the only variable to be assigned; in addition, it is necessary to determine a value for the transverse relaxation time, and, when these two quantities are comparable, considerable errors in the evaluation of the rotational correlation time can be encountered.

An alternative approach to the evaluation of kinetic data is to use, not the complete solution of the modified Bloch equations, but the approximate solutions for slow and rapid exchange rates. Within these approximations, the excess width of a line may be related to the correlation time of the process causing the broadening. The peak to peak amplitude of the first derivative of a Lorentzian line is inversely proportional to the square of the line-width: this amplitude is, therefore, sensitive to line-broadening and so it is the experimental quantity most often used to evaluate the exchange rate. However, to do this, the proportionality constant linking the amplitude and the width must be eliminated. This has been done

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

by using amplitude ratios, either of the same line in the presence and absence of the broadening mechanism (14), or of two lines in the spectrum affected to different extents by the broadening mechanism (15). The results obtained using the approximate methods are in good agreement with those from the complete solution of the Bloch equations (15).

If the experimental spectra are recorded under conditions when their anisotropic components are incompletely averaged, additional broadening, varying from line to line, will be superimposed on the effects of the exchange process. Freed and Fraenkel (16, 17) have shown that such anisotropic effects can be described by equations involving the spectral indices characterizing each line; the peak to peak amplitudes of the lines were used to determine their widths, the proportionality factor being eliminated by defining the widths relative to a standard line.

In the present work, the results of the approximate solutions of the Bloch equations modified to include two-site exchange are combined with Freed and Fraenkel's description of anisotropic broadening to give equations applicable to spectra showing considerable anisotropic and alternating line-width effects.

Experimental

Quinones were purified by vacuum sublimation, and solvents were fractionated and dried by standard methods. Solutions were prepared in the open laboratory, not in a vacuum apparatus. This procedure is not recommended when the accurate measurement of splitting constants and their dependence upon temperature is required (18). However, the present paper deals primarily with the measurement of amplitudes. The stationary concentration of radicals attained was rather low, and so slow sweeps, and hence frequent replacement of the sample, were necessary. For this reason, preparation of the solutions was performed in the open laboratory. The sample was irradiated using a Westinghouse H38-4GS 100 W lamp. Electron spin resonance (e.s.r.) spectra were recorded on a Varian E-3 spectrometer equipped with a variable temperature accessory. Temperatures were measured using a copper–constantan thermocouple inserted into the sample immediately before and after each scan. The temperature was found to vary by less than 1 °C during each scan, after which the sample was replaced by a fresh solution.

Results

The general structural formula of the radicals under investigation, and the numbering system used is given in Fig. 1.

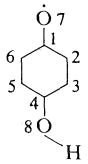

FIG. 1. General structural formula of monoprotonated semiquinones and the numbering system used. For the dimethyl-substituted radicals, the numbering system corresponds to the numbering system of the parent quinone.

The most suitable solvent for the observation of monoprotonated semiquinones at reduced temperatures was tetrahydrofuran; however, results similar to those described have been obtained for solutions in acetone, 1:2-dimethoxyethane and methanol.

Spectra of monoprotonated *p*-benzo- , duro- , and 2:6-dimethyl-*p*-benzosemiquinones at −70 °C were analyzed in terms of the splitting constants given in Table I. Spectra were recorded for sample temperatures as low as −110 °C, but no evidence was found for inequivalence of the positions ortho to the hydroxyl group for any of these radicals. Further, for monoprotonated durosemiquinone no evidence was found for inequivalence of the protons meta to the hydroxyl group.

Increasing the temperature to +20 °C caused the differences in the meta splitting constants of monoprotonated *p*-benzo- and 2:6-dimethyl-*p*-benzosemiquinones to be removed by rapid rotation of the hydroxyl group. At intermediate temperatures line-width alternation caused by incomplete averaging of the meta splitting constants was observed: for monoprotonated *p*-benzosemiquinone, spectra obtained between −18 and −65 °C were used to estimate the activation energy of the rotation of the hydroxyl group (see below). Above −18 °C the radical concentration diminished appreciably during the course of a 30 min scan, while below −65 °C line-width effects due to incomplete averaging of the anisotropic hyperfine and *g*-tensor interactions (16, 17) obscured the line-width alternation.

The incomplete averaging of these anisotropic interactions resulted in the following line-width trends; patterns associated with hydroxylic protons broadened to high field, patterns associated with ring protons broadened to low field, and patterns associated with methyl groups did not broaden asymmetrically to any appreciable extent. The line-width trends for the hydroxylic

TABLE I

2:3-Dimethyl-*p*-benzoquinone	1:2 Dimethoxyethane	20	4.95	−1.10	0.48	−5.68	−1.60
2:5-Dimethyl-*p*-benzoquinone	1:2 Dimethoxyethane	20	5.90	1.10	−0.70	−4.93	−1.37

*Values tabulated are ±0.02 G. Numerical subscripts correspond to the numbering system of Fig. 1. Underlined values are methyl groups splitting constants.

†Parameters used: $Q_{CH} = -24.0$ G, $\lambda = 1.20$, $h_{C_3} = 0.05$, $h_{O_7} = h_{O_8} = 1.17$, $k_{C_1O_7} = 1.91$, $k_{C_4O_8} = 1.01$; for definitions of h and k, see ref. (27).

protons are in the same direction as the corresponding trends observed for diprotonated semiquinone cations (11) whereas the trends for the ring protons are in the opposite sense. This discrepancy underlines the dangers inherent in the evaluation of signs of splitting constants from line-width trends, especially those of aromatic CH fragments (7).

A typical spectrum of monoprotonated *p*-benzosemiquinone, recorded under slow-rotation conditions, is shown in Fig. 2; all 24 components of the spectrum are readily distinguishable, and both the alternation and the trends in line-width can be seen. The sharpest line in the spectrum has a peak-to-peak line width of 110 mg and is thus almost as narrow a line as can be obtained with the 4 in. magnet of the E-3 spectrometer.

Table I also contains the experimental splitting constants of monoprotonated 2:3- and 2:5-dimethyl-*p*-benzosemiquinones, which have not been hitherto reported. The dependence of these spectra upon solvent parallels that for other similar radicals (3–5), less polar solvents leading to greater perturbation of the semiquinone's spin density distribution. The results obtained using 1:2-dimethoxyethane as solvent are given in Table I, since these spectra showed a minimum of overlapping lines, thereby allowing a more accurate determination of the hyperfine splitting constants. No evidence was obtained for two isomers of either of these radicals, suggesting that the hydroxyl group does not rotate freely but tends to point away from the adjacent methyl group (cf. ref. 11).

Discussion

In order to evaluate the activation energy for the rotation of the hydroxyl group of monoprotonated *p*-benzosemiquinone from the spectra the following procedure was adopted. For each line a quantity A, equal to the peak-to-peak amplitude of the first derivative curve divided by the degeneracy of the line, was recorded. Assuming a Lorentzian line-shape, A is related to W, the half-width at half-height, by eq. [1]

$$[1] \qquad A^{-\frac{1}{2}} = S \cdot W$$

where S is a proportionality constant determined by radical concentration and spectrometer sensitivity. Previous workers (14, 15, 17) have eliminated S through the use of relative values of A referred to some standard line. However, in the present studies, the signal-to-noise ratio was often so low that, for a series of spectra run under identical conditions, the results were strongly dependent on the choice of reference line. Accordingly, a more statistically valid approach was employed.

Three major contributions to the line-width were considered. These were broadening from mechanisms independent of the spectral indices, $\tilde{M}$, characterizing a line, broadening from anisotropic dipolar and g-tensor interactions, and broadening from the modulation of isotropic hyperfine splitting constants due to rotation of the hydroxyl group. The most important broadening independent of spectral indices was, under the experimental conditions employed, caused

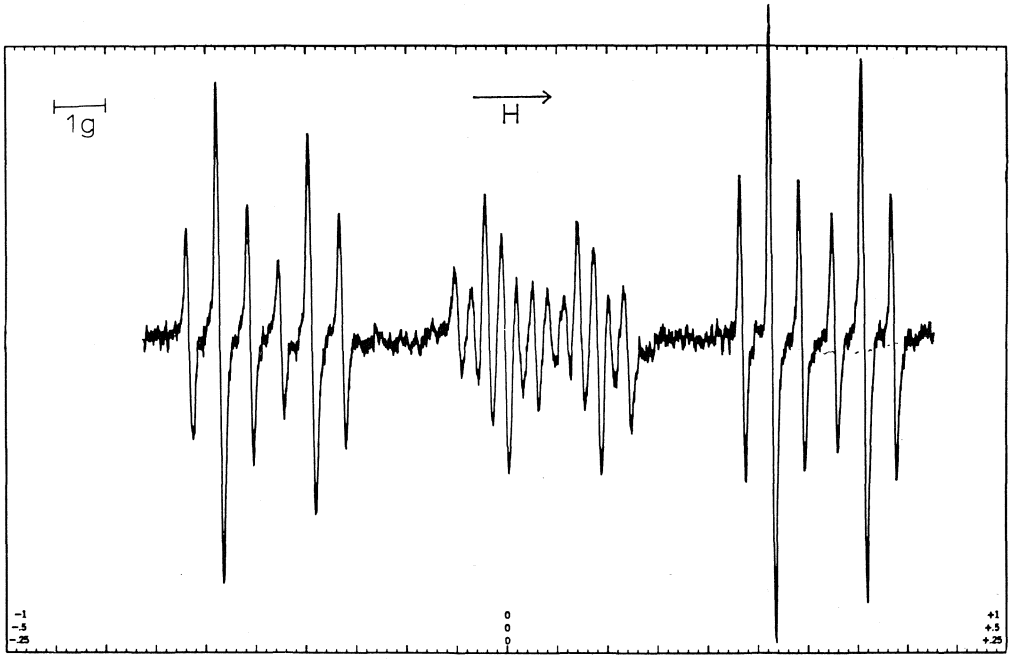

FIG. 2. Electron spin resonance spectrum of monoprotonated *p*-benzosemiquinone in tetrahydrofuran at −60 °C, when rotation of the hydroxyl group is slow. Magnetic field increases from left to right.

by inhomogeneity of the applied magnetic field. Therefore, for each line of a spectrum there will be a constant contribution, denoted by $S \cdot B$, to $A^{-\frac{1}{2}}$; further $S \cdot B$ will be a constant from scan to scan, even though the individual values of S and B may vary with changes in radical concentration and instrument settings.

Contributions to the width of a line from anisotropic dipolar and *g*-tensor interactions may be expressed as functions of the spectral indices[1] characterizing that line (16, 17). For the spectra under consideration, anisotropic effects were described satisfactorily by terms linear in the spectral indices. Since all protons in the radical are nonequivalent (in the terminology of Fraenkel (19)) the spectral indices describing the lines can only take values of $\pm\frac{1}{2}$. Therefore, terms involving the squares of the spectral indices, being independent of spectral indices, contribute to $S \cdot B$ and are not capable of independent evaluation. Terms involving the products of the spectral indices were found to be statistically insignificant, except at sample temperatures below −70 °C when line-width alternation was unimportant. The anisotropic effects, therefore, make contributions to $A_i^{-\frac{1}{2}}$ of the form $S \sum_j C_j \tilde{M}_{i,j}$ where the subscript i denotes the ith line of the spectrum, and the subscript j denotes the jth proton of the molecule. Using the numbering system of Fig. 1, C_3 was always set equal to C_5 and, when the rotation of the hydroxyl group was fast, C_2 was set equal to C_6.

Rotation of the hydroxyl group modulates the splitting of protons 2 and 6 and so gives finite contributions to $A_i^{-\frac{1}{2}}$ for all lines having $\tilde{M}_{i,2}$ not equal to $\tilde{M}_{i,6}$. These contributions may therefore be described by a term of the form $S \cdot P \cdot (\tilde{M}_{i,2} - \tilde{M}_{i,6})^2$ where P is determined by the rate of rotation.

Combining all three contributions to $A_i^{-\frac{1}{2}}$ by assuming their effects to be additive, forms eq. [2]

$$[2] \quad A_i^{-\frac{1}{2}} = S \cdot B + S \sum_j C_j \tilde{M}_{i,j} + S \cdot P \cdot (\tilde{M}_{i,2} - \tilde{M}_{i,6})^2$$

(a) Slow Rotation Approximation

Twenty four lines, giving 24 values of $A_i^{-\frac{1}{2}}$, were obtained and from these values and eq. [2] standard statistical methods were used to evaluate B, C_2, C_3, C_6, C_8, and P (subscript 8 refers

[1] $\tilde{M}_{i,j}$, the spectral index, is equal to $M_{i,j}$, the spin quantum number, after any necessary sign changes have been made to place positive $\tilde{M}_{i,j}$ to high field.

to the hydroxylic proton). By these means, the broadening due to line-width alternation was separated from the other two broadening mechanisms.

For lines broadened by the modulation of hyperfine splitting constants, the effective transverse relaxation time, T_2', is, within the slow rotation approximation (20), given by

$$[3] \qquad (T_2')^{-1} = T_2^{-1} + \tau^{-1} = W$$

where τ is the rotational correlation time. Comparing eqs. [2] and [3]

$$[4] \quad \tau^{-1} = S \cdot P \cdot (\tilde{M}_{i,2} - \tilde{M}_{i,6})^2 = S \cdot P = k$$

where k is the rate constant for the rotation. S may vary from scan to scan, but since $S \cdot B$ is a constant we may write

$$[5] \qquad k = S \cdot B \cdot \frac{P}{B}$$

Expressing k in terms of the Arrhenius equation, we have

$$[6] \qquad Z \exp(-E_a/RT) = S \cdot B \cdot \frac{P}{B}$$

where Z is the frequency factor and E_a the energy of activation. Taking natural logarithms

$$[7] \qquad \ln \frac{P}{B} = \ln \frac{Z}{SB} - \frac{E_a}{RT}$$

and so a plot of $\ln P/B$ versus $1/T$ should afford a straight line with slope $-E_a/R$.

(b) Fast Rotation Approximation

Eighteen lines were obtained from which the five constants B, C_2, C_3, C_8, and P were determined as above. Using a derivation analogous to that of [7] but imposing the rapid rotation approximation (20)

$$[8] \qquad \ln \frac{B}{P} = \ln \frac{8ZSB}{(\Delta a)^2} - \frac{E_a}{RT}$$

where Δa is the difference in splitting constants between positions 2 and 6. In this approximation therefore, a plot of $\ln B/P$ against $1/T$ should be a straight line of slope $-E_a/R$.

Values of B, C_j, and P are given in Table II. These values have, of course, no absolute significance, but indicate the relative importance of the anisotropic and the alternating line-width effects at the various temperatures.

The appropriate graphs corresponding to eqs. [7] and [8] are shown in Fig. 3. Values for E_a of 31.4 and 33.2 kJ/mole were obtained from the slow and rapid approximations, respectively. Estimates of the accuracy of these energies are difficult to make; the internal consistency of the method appears to be good, the root mean square error in fitting the rapid rotation values of $\ln B/P$ to the line drawn being only 0.024 units. In order to check on the value of E_a, an independent determination was made using the complete solution of the Bloch equations modified (13) to include a two-jump exchange process. Spectra were calculated for trial values of the rotational exchange rate and compared with the experimental traces: anisotropic effects were allowed for by averaging corresponding experimental intensity ratios in the high and low field halves of the spectrum before comparison with the simulated plots. By this method the comparable value of $E_a = 40.2$ kJ/mole was obtained. The simulation

method required considerably more computer time, however, each trial spectrum taking approximately 10 s execution and 90 s plotting time. Further, it was usually necessary to compute four trial spectra for each experimental one. In contrast, the total execution time to generate all points in Fig. 3 was less than 4 s.

An additional advantage of eq. [8] is that it allows evaluation of E_a without any knowledge of Δa. The assumption is made that Δa is a constant, but this assumption is also made when employing the complete solution of the modified Bloch equations. Equation [8] is, therefore, suitable for determining the energy of activation when it is not possible to obtain slow-exchange spectra; e.g. the dinitro-durene anion in dimethylformamide (21), thereby eliminating the necessity of estimating Δa as, in this case, 20 G (22).

The values obtained for E_a for the rotation of the hydroxyl group of monoprotonated *p*-benzosemiquinone are in agreement with the value of 42 ± 12 kJ/mole previously observed for the hydroquinone cation (9). It is, therefore, somewhat surprising that it was not possible to observe the effects of the rotation of the hydroxyl group of monoprotonated durosemiquinone since comparable experiments have been successful for the duroquinol cation (10).

Molecular Orbital Calculations

Spin densities were calculated according to McLachlan's self-consistent field theory (23) using a program written by Fritsch, Layloff, and Adams (24). The parameters used to include the oxygen hetero-atoms were obtained as described for similar calculations performed to simulate the spin density distributions in semiquinone–alkali metal ion-pairs (25). The inequivalence between positions 2 and 6 was satisfactorily reproduced by increasing empirically the Coulomb integral of carbon atom 3 (9–11): the calculated inequivalence between positions 3 and 5, while small should have been detectable, at least as a line-width alternation phenomenon; such was not the case. The inequivalence between positions 2 and 6 may also be reproduced by introducing a finite resonance integral between oxygen atom 8 and carbon atom 5 (26). Such a procedure predicts a greater difference between positions 3 and 5 than does increasing the Coulomb integral of carbon atom 3 and is, therefore, even less satisfactory. Until carbon-13 hyperfine splitting constants are determined for such systems, the evaluation of a unique set of parameters best describing the molecule does not seem feasible.

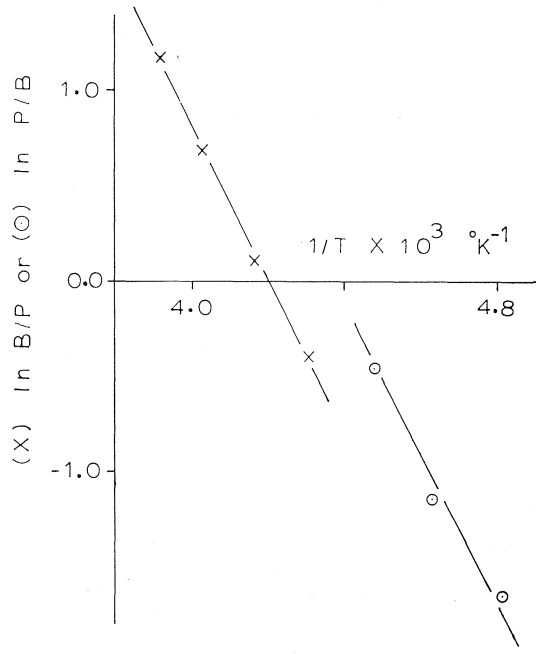

FIG. 3. Plot used to determine the energy of activation of the rotation of the hydroxyl group of monoprotonated *p*-benzosemiquinone in tetrahydrofuran (⊙ = slow rotation approximation; × = rapid rotation approximation).

Arsinohydrazines: reactions of hydrazine and substituted hydrazines with organo-arsine derivatives

L. K. PETERSON AND K. I. THÉ
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia
Received September 16, 1968

Reactions between organo-arsine derivatives $(CF_3)_2AsX$ and $(CF_3)_3As$ and hydrazine or substituted hydrazines are discussed as synthetic routes to a new class of hydrazinoarsine compounds. The systems $[(CF_3)_2As]_x\ N_2H_{4-x}$ are unstable with respect to elimination of CF_3H and N_2, but stability increases with increased methylation of the nitrogen atoms. The new compounds described are: N-methyl,N′-bis-(trifluoromethyl)arsinohydrazine, $MeNHNHAs(CF_3)_2$, (**1**) (highly unstable at room temperature); N,N-dimethyl,N′-bis(trifluoromethyl)arsinohydrazine, $Me_2NNHAs(CF_3)_2$, (**2**) (m.p. 3.00° ± 0.15°, b.p. 20°/14.6 mm); and trimethylhydrazino-bis(trifluoromethyl)arsine, $Me_2NNMeAs(CF_3)_2$, (**3**) (m.p. −41.5° ± 0.5°, b.p. 15°/6.30 mm). The observed order of stability was **2** > **3** ≫ **1**.

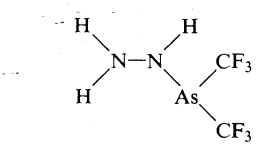
Discussion

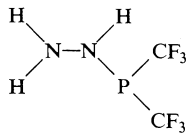
In an effort to increase the number of available compounds based on a N—N—As skeleton, with varying electronic and steric or structural characteristics, we have investigated synthetic routes involving reaction between hydrazine and substituted hydrazines and organo-arsine derivatives. The N—N—As system is of interest as a Lewis base and potential chelating agent toward acceptor species (1, 2). The N—N hydrazine moiety is in itself of interest from the point of view of bonding, structure, and potential bidentate character (3–7). The modification of these characteristics, and the variation in the N—N bond energy and stability with differing metalloidal substituents, has not been widely studied.

This paper is concerned with the family of perfluoroalkyl-arsinohydrazines $(CF_3)_xAs(NRNR'R'')_{3-x}$ with R, R′, and R″ = H or Me, and $x = 0-3$. Studies of analogous alkyl-arsinohydrazines are in progress. The N atoms may be expected to function as differential Lewis bases, while the As atom may exhibit both σ donor and π acceptor behavior, both strongly influenced by the electronegative CF_3 groups. The hydrazine unit, with lone pairs of electrons on adjacent N atoms, is relatively unstable with respect to oxidation processes which result ultimately in the production of the stable N_2 molecule. One might expect enhanced stability with substituents that permit intramolecular dative π bonding, as discussed for phosphinohydrazines, for example (2).

Our studies show that bis(trifluoromethyl)arsinohydrazines are sensitive to the replacement of H on nitrogen by methyl groups. Reaction between hydrazine and $(CF_3)_3As$ or $(CF_3)_2AsCl$ yielded large quantities of fluoroform, nitrogen, and colored (brown, black) residues, as well as oily, low volatile liquids. During handling on the vacuum line, the latter decomposed into colored residues and CF_3H and N_2. While it seems that all of the CF_3—As bonds are ultimately cleaved, only partial elimination of the hydrazine moiety, as N_2, occurs; the fate of the remaining hydrazine linkages cannot easily be established. We may infer, however, that an intermediate, such as **4**, is highly unstable.



4



5

The corresponding studies with mixtures of $(CF_3)_3P$ or $(CF_3)_2PI$ and hydrazine indicated that reaction does not occur unless a basic medium, such as trimethylamine, is present (2). The intermediate phosphinohydrazines, such as **5**, suffer loss of CF_3H, condensing to form waxy, intractable materials, but elimination of N_2 was not found. These observations are in keeping with the fact that simple covalent compounds of arsenic have lower thermal stability than those of phosphorus (8). In addition, N→P π bonding (9) in the N—N—P system should modify the electron density about the skeleton of the molecule, reducing repulsion energies in a way such as to improve its stability against the

For personal use only.

elimination of the N≡N unit. This stabilizing effect was shown to be less significant for the nitrogen–arsenic bond, in the systems $(CF_3)_2$-AsNRP$(CF_3)_2$, (R = H, Me), where bond cleavage, with HCl or NH_3, occurred preferentially at the N—As, rather than at the N—P, bond (10).

Methylhydrazine reacts with $(CF_3)_3As$ and $(CF_3)_2AsCl$ in much the same way as hydrazine itself, yielding, at room temperature, highly colored decomposition products together with CF_3H, N_2, and involatile oily liquids. Trifluoroethane was not observed.

Under carefully controlled conditions, however, the unstable compound N-methyl,N′-bis(trifluoromethyl)arsinohydrazine MeNHNHAs$(CF_3)_2$, **1**, was isolated. The vapor phase molecular weight (M_{obsd}, 259; M_{calcd}, 258) and the ^1H nuclear magnetic resonance (n.m.r.) spectrum established this formulation. The latter consisted of three absorptions in a 1:3:1 ratio, corresponding to the protons H—NAs (at τ 7.30, reference internal $SiMe_4$), H_3C—NN (τ 6.76), and H—NN (τ 4.95). The assignments were based upon comparisons with the spectra of methylhydrazine and NN-dimethyl-N′-bis-(trifluoromethyl)arsinohydrazine (1). Significantly, there was no evidence suggesting the formation of the isomeric compound, $(CF_3)_2$-AsNMeNH_2, a result contrary to the observation that alkylation of hydrazines occurs at the most highly substituted nitrogen atom (11). For the alkylation process, a preference for the transition state **6** rather than **7** has been postulated (9):

6 **7**

In a somewhat similar situation, however, alkylalanes react at the least substituted nitrogen atom of dimethylhydrazine, suggesting that steric factors prohibit attack at the alternative, substituted site (12). It seems likely that similar factors would operate with $(CF_3)_2AsCl$, giving rise to MeNHNHAs$(CF_3)_2$, rather than its isomer.

The effect of the next methyl group is dramatic; thus NN-dimethylhydrazine with the appropriate haloarsine reacts smoothly to give a high yield of NN-dimethyl-N′-bis(trifluoromethyl)-arsinohydrazine, $Me_2NNHAs(CF_3)_2$, **2**, a compound which decomposes quite slowly at room temperature (1). The solvolysis of $(CF_3)_3As$ with Me_2NNH_2 was not a feasible synthetic route to compound **2**. The trimethylamine needed to promote CF_3H elimination also facilitated the decomposition of the desired product.

The next member of the series, the new compound trimethylhydrazino-bis(trifluoromethyl)-arsine, $(CF_3)_2AsNMeNMe_2$, **3**, was obtained in high yield from a low temperature reaction between trimethylhydrazine and $(CF_3)_2AsCl$ in ether (or cyclohexane) as solvent. The p.m.r. spectrum consisted of two resonance absorptions in a 2:1 ratio, corresponding to two equivalent CH_3 groups (at τ 7.80, reference internal $SiMe_4$), and one distinct CH_3 group (τ 7.35). The ^{19}F resonance consisted of a quartet indicative of long range proton–fluorine coupling involving the N—CH_3 group (δ, midpoint, 53.2 p.p.m.; J_{H-F}, 0.8 c.p.s., reference internal $CFCl_3$). Compound **3** is reasonably stable at room temperature, but decomposes more rapidly than $Me_2NNHAs(CF_3)_2$.

Experimental

Votatile materials were handled in a vacuum system, while involatile, air-sensitive substances were manipulated in a nitrogen-filled dry box. Reactions were carried out in sealed Pyrex tubes, fitted, where necessary, with *in situ* filtration facilities. Appropriate spectra were determined with Varian A56/60 (n.m.r.), Beckman I.R. 12 (infrared), and Hitachi Perkin–Elmer RMU-6E (mass spectra) spectrometers.

Tris(trifluoromethyl)arsine and bis(trifluoromethyl)-iodoarsine were prepared by the method of Brandt *et al.* (13). Conversion of the iodoarsine to the chloro compound was effected by reaction with mercuric chloride. Final purifications were achieved by means of low temperature fractional distillation, under vacuum, using a 36 in. vacuum-jacketed, all-glass column. Dimethylhydrazine and hydrazine were dried over anhydrous barium hydroxide, and were distilled under nitrogen, the latter at reduced pressure. Trimethylhydrazine was prepared by the method of Class *et al.* (14), and freed from dimethylhydrazine by low temperature column distillation, under vacuum. Solvents were rigorously dried, and distilled, before use.

Reactions of Hydrazine with $(CF_3)_3As$ and $(CF_3)_2AsCl$

A mixture of equal molar proportions of hydrazine and $(CF_3)_3As$, allowed to warm from −196° to room temperature, reacted to give a proportionate amount of CF_3H, corresponding to all of the available CF_3 groups, and N_2, representing about half of the original proportion of hydrazine, together with an intractable black residue

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with the approximate composition $As_2N_2H_3$. Reactions with $(CF_3)_2AsCl$ were carried out at low temperatures (−78 to −33°), in dilute ethereal solution. Initial precipitates of N_2H_5Cl were contaminated with black residues, while other decomposition products included N_2 and CF_3H. Materials of low volatility were obtained in our fractionation trains, but these rapidly decomposed into involatile, black residues, with elimination of N_2 and CF_3H.

Reactions of Methylhydrazine with $(CF_3)_3As$ and $(CF_3)_2AsCl$

A mixture of methylhydrazine and a threefold excess of $(CF_3)_3As$ reacted readily at room temperature, giving an amount of CF_3H corresponding to the cleavage of one CF_3 group from $(CF_3)_3As$. Unstable yellow liquids were also found. Reactions with $(CF_3)_2AsCl$ were carried out under carefully controlled conditions, using dilute ethereal solutions and low temperatures (−78 to −33°). The hydrazine hydrochloride salt was filtered off, and fractionation revealed a pale yellow liquid, held at −33°, with an n.m.r. spectrum and a vapor phase molecular weight (M_{obsd}, 259; M_{calcd}, 258) corresponding to $MeNHNHAs(CF_3)_2$, **1**. The infrared spectrum of compound **1** is given in Table I. At room temperature, compound **1** rapidly turned black, eliminating N_2 and CF_3H.

Reactions of N,N-Dimethylhydrazine with $(CF_3)_3As$ and $(CF_3)_2AsCl$

A mixture of dimethylhydrazine and $(CF_3)_3As$ showed no evidence of reaction after 48 h at room temperature, but at 80°, both CF_3H and N_2 were readily formed. Attempts to promote solvolysis (hydrazinolysis) of the As—CF_3 bond at room temperature by means of added trimethylamine were unsuccessful, but at 80°, both CF_3H and N_2 were again formed. In neither case could the desired arsinohydrazine be detected; in both cases of reaction, colored residues (yellow to black) indicated the ultimate thermal decomposition of intermediate species.

With $(CF_3)_2AsCl$ and dimethylhydrazine, in ether solution, reaction proceeded smoothly to give $Me_2NNHAs(CF_3)_2$, **2**, in good yield (1). The melting point of samples sealed into capillary tubes was 3.00 ± 0.15°, while vapor pressure measurement with a mercury tensimeter indicated the volatility b.p. 20°/14.6 mm. Infrared data are given in Table II.

Reaction of Trimethylhydrazine with $(CF_3)_2AsCl$

A mixture of trimethylhydrazine (0.1798 g) and $(CF_3)_2AsCl$ (0.3345 g) in ether solution (1.8656 g) was allowed to react at −78° for 14 h and at −33° for 2 h. Separation procedures yielded an "ether fraction"

Electric moments, sulfur bonding, and conformations of substituted thiochloroformate esters in benzene solutions

A. QUEEN, T. A. NOUR[1], AND E. BOCK
Parker Chemistry Laboratory, University of Manitoba, Winnipeg, Manitoba

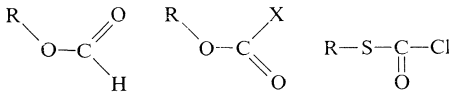
Received July 18, 1968

The dipole moments of a series of aryl and alkyl thiochloroformate esters have been determined in benzene solution at 25 °C and compared with the corresponding values for chloroformate and fluoroformate esters. The results have been interpreted in terms of conjugative and hyperconjugative electron release by the hydrocarbon group to the d-orbitals of the sulfur atom in the thio compounds. Vector model, bond moment calculations indicate that, as in the cases of the chloroformate and fluoroformate esters, the preferred conformations of the thiochloroformates are those in which the hydrocarbon group and the halogen atom are *cis* to each other.

Canadian Journal of Chemistry, **47**, 343 (1969)

Introduction

Dipole moment measurements made in this laboratory have led us to conclude (1), in agreement with other workers (2–4), that the most favorable configuration of alkyl formates is that in which the alkyl group and carbonyl oxygen are *cis* to each other (**1**). In contrast, the corresponding chloroformate and fluoroformate esters seem to prefer the arrangement that brings the halogen atom into the *cis* position with respect to the alkyl group (**2**; X = Cl or F) (5, 6). This surprising difference, brought about by the replacement of a hydrogen atom in (**1**) by a halogen atom, has led us to extend our studies to the analogous thiochloroformate esters (**3**).



(**1**) (**2**) (**3**)

One of the present authors has previously commented (7) on the fact that the dipole moments of thioethers are larger than those of the corresponding oxygen compounds, although the opposite is true for hydrogen sulfide and water and for thiols and alcohols (Table I). It was suggested that the difference could be explained in terms of conjugative or hyperconjugative electron release to the sulfur atom, which uses its d-orbitals to accept these electrons. The data in Table I show that there is insufficient information available for ethers and thioethers containing secondary and tertiary alkyl groups to allow any conclusion to be reached regarding the importance of hyperconjugation in these compounds. Although this does not apply to alcohols and thiols, it is difficult to interpret the data in terms of hyperconjugation, despite the obvious dependence of the dipole moments of the thiols on the branched natures of the alkyl groups. For example, the changes in the values of $\Delta\mu$(S—O) seem to be in the wrong direction. It is possible that hydrogen bonding effects complicate the situation for alcohols.

Thiochloroformate esters possess several features likely to enhance electron-pair acceptance by sulfur. Hydrogen bonding is small and the chlorocarbonyl group withdraws electrons both inductively and conjugatively. In agreement with this argument, it was previously noted (7) that the dipole moment of phenyl thiochloroformate is significantly greater than that of phenyl chloroformate, consistent with conjugative electron release from the aromatic ring to the sulfur atom.

In order to test the importance of electron-pair acceptance by sulfur, we have measured the dipole moments of methyl, ethyl, propyl, isopropyl, butyl, and tertiary butyl thiochloroformates in benzene solution. The dipole moment of the phenyl ester has been redetermined with a carefully purified sample of the compound and, for purposes of comparison, we have also measured the corresponding values for isopropyl chloroformate, isopropyl fluoroformate, and *p*-chlorophenyl thiochloroformate.

Experimental

Solvent

Fisher certified reagent benzene was used as solvent.

[1]University of Manitoba Postdoctorate Fellow, 1967–1968.

Solutes

Isopropyl chloroformate and methyl thiochloroformate were prepared by reacting isopropanol and methanethiol, respectively, with a large excess of phosgene (9, 10). Isopropyl fluoroformate was obtained from the corresponding chloroformate by reacting it with an equivalent amount of thallous fluoride (11). The other compounds were commercial samples[2]. All the compounds were fractionally distilled through a short column packed with glass helices and their purities then checked by means of vapor phase chromatography. Isopropyl fluoroformate was further purified by vapor phase chromatography. Experimental data are recorded in Table II.

Procedure

The dipole moment apparatus and experimental procedure have been previously described (16).

[2]Obtained from K. and K. Laboratories, Inc., Plainview, New York.

Results and Discussion

The experimental data are summarized in Table III, and Table IV lists the solution dipole moments calculated by Smith's method (17), using eq. [1].

$$[1] \qquad \mu = \frac{27kT}{4N} \cdot \frac{M_2}{d_1(\varepsilon_1 + 2)^2} \cdot (\alpha - \nu)$$

where the symbols have the same meanings as those used in our earlier papers (6). In order to facilitate comparisons, this table also includes previously determined values of the dipole moments of the corresponding chloroformate and fluoroformate esters.

The results in Table IV show that both the fluoroformate and thiochloroformate esters have larger dipole moments than the chloroformates. However, it can be seen that while the values for the fluoro compounds are quite uniformly

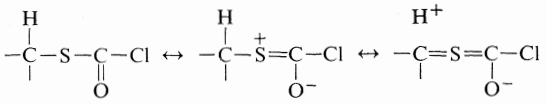
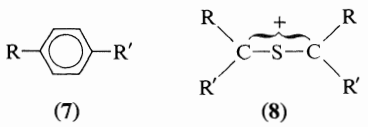
greater than those of the chloroformates by about 0.2 D, this parallelism does not hold for the oxygen and sulfur compounds. In the alkyl series, the differences in the dipole moments of these latter compounds appear to depend on the number of hydrogen atoms bonded to the α-carbon atom of the alkyl group. The magnitude of the difference, Δμ(S—O), progressively decreases as the number of such hydrogens decreases, strongly suggesting that hyperconjugative electron release to the sulfur atom occurs in the thiochloroformates (**4**, **5**, **6**).



(**4**) (**5**) (**6**)

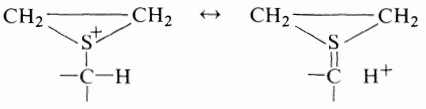
The much greater effect of conjugative electron release can be deduced from the fact that phenyl thiochloroformate has a dipole moment that is 0.47 D greater than that of the corresponding oxygen compound. It is furthermore significant that phenyl thiochloroformate has a higher dipole moment than methyl thiochloroformate, while the corresponding two oxygen analogues have practically the same moment. In the latter case, resonance effects similar to that represented by structure (**6**) do not exist.

These results are interesting in the light of the conclusion of Bordwell and Boutan (18) that divalent sulfur in certain substituted phenols and carboxylic acids (**7**; R = OH or COOH, R′ = CH_3—(CO)—S, —SCN) shows little tendency to act as an electron-pair acceptor. Similar conclusions were reached (19) from a study of the rates of hydrolysis of substituted aryl chloromethyl sulfides. On the other hand, Campbell and Rogers (20) have concluded, on the basis of dipole moment measurements, that electron-pair acceptance by sulfur does occur in the para-substituted phenylthiocyanates (**7**; R = —SCN, R′ = NH_2, $N(CH_3)_2$, OCH_3).



(**7**) (**8**)

Caserio, Pratt, and Holland (21) have recently obtained evidence from their studies of the nuclear magnetic resonance (n.m.r.) spectra of α,β-unsaturated alkylsulfides for electron acceptance by sulfur. Undoubtedly, the same effect accounts for the remarkable stabilities of the sulfonium methylides (**8**; R and R′ = CH_3 and C_2H_5) (22). Variations in the rates of hydrolysis of alkyl-2-chloroethyl sulfides have been explained (23) in terms of hyperconjugative stabilization of the cyclic intermediates (**9**, **10**) and our studies of the rates of hydrolysis of the present thiochloroformate esters in water (24) support the conclusions we have reached from dipole moment measurements. Other examples of d-orbital bonding by sulfur are known (25–28).



(**9**) (**10**)

A vector model, bond moment calculation, similar to those previously carried out for methyl chloroformate (5) and methyl fluoroformate (6), indicates that the preferred conformation of methyl thiochloroformate is that in which the chlorine atom and the alkyl group are *cis* to each other. The bond moments H—C = 0.4 D, C=O = 2.4 D, C—Cl = 1.5 D are those given by Smith (29). In view of the possibility of hyperconjugative electron release to the sulfur atom, the group moment CH_3—S = 1.2 D was calculated from dipole moment (30) and bond angle (31) data for dimethyl sulfide; viz. 1.45 D and 99°, respectively. It was assumed that the H—C and CH_3 moments were equal and, hence, that the C—S bond moment could be obtained by subtracting the C—H bond moment from the value calculated for CH_3—S. While the value so obtained for the C—S bond moment is probably too small, it can easily be shown that a larger value would reduce the calculated dipole moment of methyl thiochloroformate, a conclusion that reinforces our arguments. In the absence of appropriate data for methyl thiochloroformate itself, the bond angles used in Fig. 1 are based on values obtained for thiolacetic acid (32). It can be seen that, irrespective of the value assumed for the angle ψ, the dipole moment decreases as the angle θ increases from 0 to 180°. If the contribution from the CH_3—S bond to the vector *A* is ignored, the group moment of S—(CO)—Cl may be calculated to be 1.22 D, centered on the carbonyl carbon atom at an angle of 152° 49′ to the

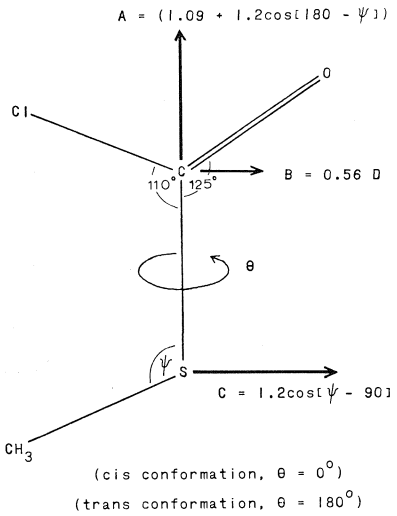

FIG. 1. Vector model for methyl thiochloroformate.

direction of the S—C bond. This is shown as a dotted line in Fig. 1. The maximum value of the dipole moment of methyl thiochloroformate will correspond to the situation where $\theta = 0°$ and $\psi = 152° 49'$. The calculated value for this situation is 2.4 D. It is unlikely that ψ is as large as $152° 49'$ since the corresponding angle in methyl formate is only $114° 47'$ (4) and the bond angles are usually smaller in thioethers than in ethers (28, 31, 33). Assuming a more reasonable value of 110° for the angle ψ, the calculated dipole moments for the *cis* and *trans* conformations are 2.3 D and 1.6 D, respectively[3]. While both values are smaller than the experimental value of 2.69 D, these figures would seem to indicate a preference for the *cis* conformation. As already pointed out, the use of dimethyl sulfide as a model for calculating the CH_3—S group moment is likely to give too small a value; furthermore, this value does not take into account the fact that hyperconjugation is probably more important in methyl thiochloroformate than in dimethyl sulfide. However, an improbably large moment of about 2.5 D would have to be assumed for the CH_3—S group in order to raise the calculated dipole moment of the *trans* conformer to the experimental value of 2.69 D.

We have carried out another calculation using our data for phenyl thiochloroformate and its *p*-chlorophenyl analogue. Making the reasonable assumption tha the chlorine atom attached to the aromatic ring affects the dipole moment of the molecule mainly by virtue of its electron withdrawing properties and using the accepted value of 1.58 D for the aryl–Cl bond moment (29), we have calculated the angle between the aryl–S bond and the dipole moment vector of the phenyl—S—(CO)—Cl unit to be 140°. The two extreme *cis* and *trans* conformations are shown in Fig. 2. It can be seen that the *trans* arrangement requires the phenyl—S—C bond to be at least 140° which is unlikely and the *cis* arrangement is, therefore, preferred.

The proton magnetic resonance spectra of the chloroformate and thiochloroformate esters in carbon tetrachloride solutions have been compared by Hutton and Schaefer[4]. Although the

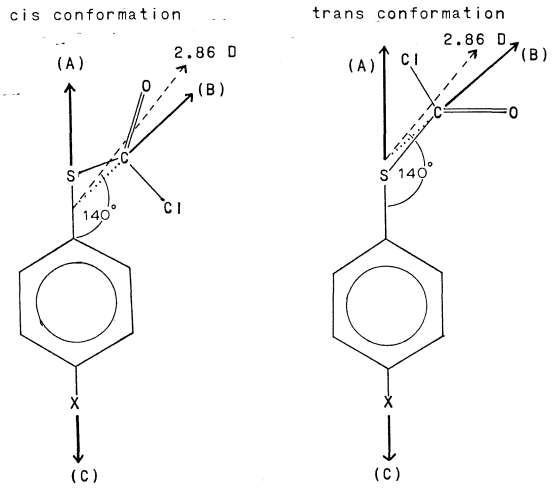

FIG. 2. Vector models for phenyl thiochloroformate (X = H, $C = 0$ D) and *p*-chlorophenyl thiochloroformate (X = Cl, $C = 1.58$ D). ***A*** is the group moment for C_6H_5—S, ***B***, that for S—(CO)—Cl, and ***C***, that for C_6H_5—X.

[3]A referee has objected to the use of bond moments based on the value of 0.4 D for the carbon–hydrogen bond in the sense $\overset{+}{H}$—$\overset{-}{C}$. Some doubt exists not only as to the magnitude of this moment but also to its direction and there is some theoretical evidence that, in many aliphatic compounds, the value 0.3 D in the sense $\overset{-}{H}$—$\overset{+}{C}$ may be more appropriate. Smith (29) has discussed the situation in detail and listed other bond moments based on this latter value. The calculated dipole moments are not greatly changed by using these alternative bond moments, the values for the *cis* and *trans* conformations, assuming that the angle $\psi = 110°$, being 2.15 and 1.58 D, respectively.

chemical shifts of the protons on the β, γ, and δ carbon atoms of the alkyl groups are very similar in both series of compounds, the same is not true for the protons attached to the α carbon atoms. These protons of the thioesters resonate about 80 cycles to higher field than the corresponding protons in alkyl chloroformates. Much smaller differences are found when the n.m.r. spectra of thiols and alcohols are compared. These observations are consistent with hyperconjugation in the alkyl thiochloroformates but the detailed interpretation of the n.m.r. spectra is not straightforward. Further work is in progress to determine the coupling constants for the present compounds and their fluoro analogues.

Acknowledgments

We thank Drs. T. Schaefer and H. Hutton for helpful discussion of our results and the National Research Council of Canada for financial assistance.

Reactions of ethylene with rhodium(III) chloride. Part II.[1] Catalyzed substitution at rhodium(III)

B. R. JAMES, M. KASTNER, AND G. L. REMPEL
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received June 26, 1968

Ethylene has been found to catalyze at ambient temperatures the production of $RhCl_2(H_2O)_4^+$ species from freshly made solutions of $RhCl_3.3H_2O$ in water. A mechanism involving trace amounts of chlororhodate(I) species is indicated.

Canadian Journal of Chemistry, **47**, 349 (1969)

We have been studying the reaction of rhodium(III) chloride trihydrate with ethylene in both aqueous and non-aqueous solvents (1) and have found that the rhodium products may be derivatives of the tri-, uni-, or zero-oxidation state depending on the conditions.

A fresh solution of $RhCl_3.3H_2O$ in water or perchloric acid is a complex mixture containing both monomeric and polymeric species (2). The initial electronic spectrum slowly changes, showing decreasing absorption over the whole range from 350–600 mμ. After several weeks at 80° the spectrum becomes steady (λ_{max} = 355 mμ, ε = 70; and λ_{max} = 464 mμ, ε = 65) which, according to the data reported for the various rhodium(III) chloride complexes (3), indicates a mixture of mainly the $RhCl_2(H_2O)_4^+$ and $RhCl_3(H_2O)_3$ species. If ethylene, however, is bubbled through the fresh Rh(III) solution at room temperature, the initial spectrum changes rapidly to a steady one showing peaks at 350 mμ (ε = 60) and 455 mμ (ε = 75) which is close to that of the $RhCl_2(H_2O)_4^+$ species (3). Wilkinson and co-workers (4) have reported a similar observation using molecular hydrogen and suggested a catalytic substitution process via intermediate hydride species; we have found that rhodium metal usually appears when H_2 is used.

Attempts to investigate the kinetics and mechanism of the ethylene reaction were made by following continuously as a function of time the decrease in absorption at 550 mμ, where the molar absorptivity for the fresh solution was about 115 and for either the 2:1 or 3:1 chloro complexes is about 10. Figure 1 shows such an investigation at 7° for a 7×10^{-3} *M* solution of $RhCl_3.3H_2O$. The "noise" appearance of the plot is due to interference on the absorption by the continuous stream of gas bubbles. The plots were rather irreproducible, the sharp decrease in optical density occurring anywhere between about 200 and 500 s for repeated experiments, but all exhibited the autocatalytic character. The irreproducibility may be due to diffusion problems with ethylene saturation and/or the presence of traces of O_2 (see later); mixing of the Rh(III) and presaturated ethylene solutions gave similar plots. The autocatalytic character was not due to any reaction involving the observed product $RhCl_2(H_2O)_4^+$, or $RhCl_3(H_2O)_3$. Separate experiments using fresh 5×10^{-2} *M* Rh(III) solutions showed that no measurable amount ($< 5 \times 10^{-4}$ *M*) of ethylene was consumed in the process. No such catalyzed substitution reactions were observed when starting with (*a*) a fresh

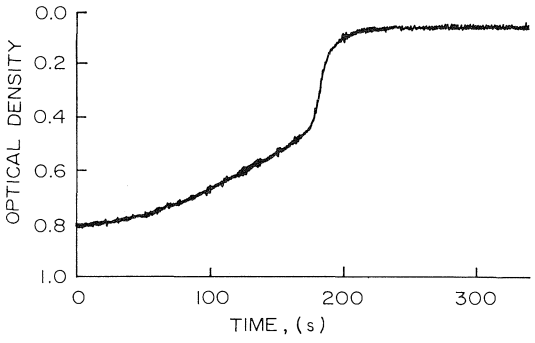

FIG. 1. Optical density at 550 mμ as a function of time, on bubbling C_2H_4 through a 7×10^{-3} *M* aqueous solution of $RhCl_3.3H_2O$ at 7°; 1 cm cell.

[1]For Part I, see ref. 1.

solution of 10^{-2} *M* $Na_3RhCl_6.12H_2O$, which initially gives the spectrum (3) of $RhCl_6^{3-}$ and changes to a mixture of the 2:1 and 3:1 chloro complexes over a few hours at room temperature; (*b*) a thermal equilibrated solution of the 2:1 and 3:1 chloro complexes; (*c*) any other thermal equilibrated solution containing the complexes (3) $RhCl_n(H_2O)_{6-n}^{(n-3)-}$.

Investigations involving pH measurements have proved to be complex, which is not too surprising in view of the complex nature of such solutions (2). However, the initial pH of a 10^{-2} *M* solution of $RhCl_6^{3-}$ is about 4.0 indicating little hydrolysis, whereas that of $RhCl_3.3H_2O$ is about 2.7. We suggest that compared with solutions (*a*), (*b*), and (*c*), the fresh $RhCl_3.3H_2O$ solution contains more appreciable amounts of Rh(III) species with coordinated hydroxy groups either as such or as bridging ligands in polymeric species, and it is thought that the presence of these aids the production of small amounts of Rh(I) species through the mechanism previously postulated for the ethylene reduction of metal ions (1, 5)

$$[1]\quad \overset{OH}{\underset{|}{Rh(III)}} + C_2H_4 \rightarrow \overset{OH}{\underset{|}{Rh}}\!\!-\!\!\underset{CH_2}{\overset{CH_2}{\|}} \rightarrow -RhCH_2CH_2OH \quad (\sigma\text{-complex})$$

$$\rightarrow Rh(I) + CH_3CHO + H^+$$

The reduction occurs via a 2 electron transfer in the σ intermediate produced by migration of the coordinated hydroxide. Rh(I) species are labile while the Rh(III) species here are substitution inert, and the catalyzed substitution process forming $RhCl_2(H_2O)_4^+$ could result through formation of a chloride bridged intermediate with a subsequent 2 electron transfer

$$[2]\quad Cl\text{—}Rh(I)\text{—}Cl\text{—}Rh(III)Cl_2 \rightarrow Cl\text{—}Rh(III)\text{—}Cl\overset{\diagup\diagdown}{\underset{\diagdown\diagup}{}}Rh(I)Cl_2$$

Such bridged intermediates seem well established for Rh(III)–Rh(I) systems (6–8). Breakage of the labile bond yields $Cl_2Rh(III)$ and $Rh(I)Cl_2$; this Rh(I) species can then react further with more Rh(III). The Rh(III) species formed will depend on the number of chlorides attached to Rh(I) in the bridged intermediate and this would seem to be 2.

The autocatalytic nature of the reaction is explained by the build up of concentration of the Rh(I) species, which, however, must remain quite small since none could be detected according to the stoichiometry of reaction [1], and also no metallic rhodium was formed. The disproportionation reaction,

$$[3]\quad 2Rh(I) \rightleftharpoons Rh(0) + Rh(II)$$

is probably important but no quantitative data are available for this process. Rh(I) intermediates are appealing since C_2H_4 is known to reduce Rh(III) to Rh(I) species in non-aqueous solvents (1, 9) and at higher temperatures ($\sim 50°$) in aqueous solution, metal production occurs, presumably through reaction [3]. These findings are in agreement with those of Rund (8) who reports that concentrations of Rh(I) complexes as low as 10^{-6} *M* are sufficient to catalyze substitution reactions of Rh(III). These systems are probably very sensitive to the presence of traces of oxygen, which would oxidize any chlororhodate(I) species present, and this could account for the inconsistency of the kinetic data. The presence of an oxidizing agent, such as quinone, in solution completely inhibited the catalytic substitution reactions; quinone is also known to be reduced by weak field rhodium(III) hydrides in aqueous solution (10), but a hydridic mechanism seems less likely.

Quantitative kinetic data for this catalyzed substitution process will be difficult to obtain, although on comparison with the ethylene reduction of Rh(III) in dimethylacetamide solution (1), the step involving ethylene coordination in [1] is likely to be rate determining.

Effect of temperature on yields in the radiolysis of nitrous oxide with high intensity electron pulses[1]

A. W. Boyd, C. Willis, and O. A. Miller
Research Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

Received July 23, 1968

Nitrous oxide has been irradiated with single electron pulses at a dose rate of 0.8×10^{27} eV/g s at temperatures between 24 and 500 °C. The gas yields showed no dependence on temperature below 200 °C but above this $G(N_2)$ increased and $G(O_2)$ decreased. The yields were found to be independent of dose up to 4×10^{20} eV/g.

Canadian Journal of Chemistry, **47**, 351 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

A disadvantage of nitrous oxide as a gas phase dosimeter is the dependence of the nitrogen yield on temperature. Jones and Sworski (1) using Van de Graaff electrons and a dose rate of $\sim 10^{18}$ eV/g s found that the yield of nitrogen increased from $G(N_2) = 10$ to $G(N_2) = 20$ between 24 and 200 °C. Gorden and Ausloos (2) using γ-rays at 1.3×10^{17} eV/g s and isotopically substituted N_2O found that $G(N_2)$ increased by a factor of nearly 8 between 40 and 376 °C.

In a previous publication (3) we reported a nitrogen yield of $G(N_2) = 12.4$ in the radiolysis of N_2O at 24 °C using electron pulses from a Febetron 705. In this work the gas was irradiated in a metal cell with a 0.0127 cm stainless steel window. With this cell the dose per pulse was 2.3 Mrads at 2 cm from the Febetron tube window. This dose was measured using calorimeters consisting of thin aluminium disks. The yield of nitrogen with these pulses, which give an average dose rate of 1.8×10^{27} eV/g s, was independent of pressure within 5% from 0.5 to 5.0 atm.

In these irradiations (3) the temperature of the N_2O might have been raised as much as 25° by one of these pulses so that the effective temperature of the N_2O during irradiation was uncertain. Because of this uncertainty we have determined the effect of temperature in N_2O radiolysis with the Febetron.

In the present work the N_2O was contained at 1 atm in a 100 ml cylindrical quartz cell of 4.2 cm diameter and 7.5 cm long. One end of the cell was flattened to form a thin (0.05 cm) window for electrons, the other was fitted with a breakseal. With the cell placed so that the window was 2 cm from the Febetron tube window the dose in the N_2O was 1 Mrad per pulse (taking $G(N_2) = 12.4$ (3)) giving a dose rate of 0.8×10^{27} eV/g s. The cell was contained in an annular furnace. The temperature was measured using thermocouples embedded in the inner wall of the furnace. Medical grade nitrous oxide (Liquid Air Company Ltd.) was used directly from the bottle after several freeze–pump–thaw cycles to remove any non-condensable impurities. The irradiation products were measured by freezing out with a liquid nitrogen cold trap and pumping the non-condensable gases into a standard volume (3). The measured volume of gas was analyzed by mass spectrometry.

The N_2 and O_2 yields as a function of temperature are shown in Fig. 1. As can be seen, both yields are constant from 24 to 200 °C.

Pyrolysis was negligible below 375°. Above this temperature corrections for pyrolysis were

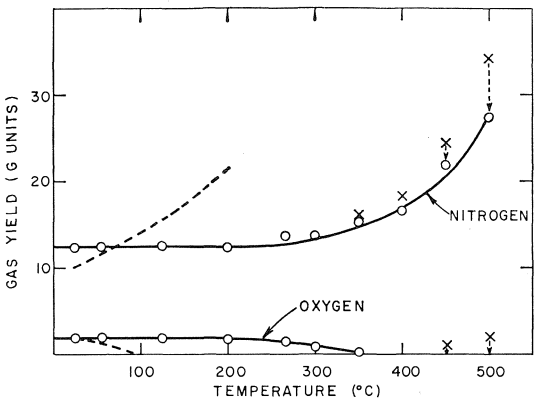

FIG. 1. Temperature dependence of product yields from N_2O radiolysis at high dose rates.
Circles are yields corrected for pyrolysis at 0.8×10^{27} eV/g s; crosses are uncorrected yields at 0.8×10^{27} eV/g s; and dashed lines denote yields at 10^{18} eV/g s taken from ref. (1).

[1]Issued as A.E.C.L. No. 3179.

made by subtracting from the irradiated samples the amounts of N_2 and O_2 formed in identical unirradiated samples which had been heated for the same time.

The dose dependence of the N_2 and O_2 yields was determined by varying the number of pulses. Between 6×10^{19} eV/g (1 pulse) and 4×10^{20} eV/g (7 pulses) there was no change in yields.

The temperature dependence shown in Fig. 1 is markedly different from the results obtained at low dose rates (1, 2). The energy of activation corresponding to the increase in the nitrogen yield (corrected for pyrolysis) with temperature between 200 and 500 °C is $\sim$ 13 kcal/mole.

At room temperature there is no apparent effect of dose rate on the yields of nitrogen and oxygen (within 20%) between 10^{16} eV/g s (1) and 10^{27} eV/g s (3). This, and the independence of the nitrogen yields at 10^{27} eV/g s over the wide range of temperature, 20–200 °C, make nitrous oxide a satisfactory dosimeter at very high dose rates.

Catalytic hydrodesulfurization of thiophene. VII. Comparison between thiophene, tetrahydrothiophene, and *n*-butanethiol[1]

S. Kolboe[2]
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received December 13, 1967

The desulfurization rates in hydrogen of thiophene, tetrahydrothiophene, and *n*-butanethiol over molybdenum disulfide, an alumina supported cobalt molybdate, and a chromia catalyst have been measured.

Measurements of the interconversion rates of the three sulfur compounds were also carried out.

Canadian Journal of Chemistry, 47, 352 (1969)

Refinements introduced in the previous paper of this series (1) strongly suggested a more detailed evaluation and comparison of the catalytic reactions of thiophene, tetrahydrothiophene, and *n*-butanethiol over different catalysts.

Experimental

Apparatus and Experimental Technique

The apparatus and experimental technique employed were the same as in the previous paper (1).

Materials

The additional materials used were tetrahydrothiophene and *n*-butanethiol (both from Eastman, used as received). The tetrahydrothiophene contained 0.14% thiophene and 0.002% of a compound which may have been butanethiol. The butanethiol was identical with the sample used in Part V of this series (2). The catalysts used were pure MoS_2 heat treated to 650 °C, a commercial alumina-supported cobalt molybdate (Girdler, G.35A), and chromia, designated as catalysts V, VII, and VIII in the previous publication (1) and characterized there in more detail.

Results and Discussion

Generally speaking the desulfurization rate of thiophene and tetrahydrothiophene was about the same on all catalysts in contrast to the desulfurization of butanethiol which was 15–40 times faster under the chosen conditions (see Table I). Results on the product distribution are given in Table II.

It was shown previously that the hydrogenation of gas phase butenes was negligible under the prevailing desulfurization conditions and that the isomerization rate was very small, but the hydrogenation of butadiene to butenes was quite important (1). Similar tests carried out for tetrahydrothiophene and butanethiol led to the same results. The numbers given in Table II therefore reflect the primary product distribution when it is taken into account that the amount of butadiene is too low and that the amount of the

	n-Butane	36.0	59.0	85.0

*Conditions same as in Table I, except thiophene partial pressure equals 20 Torr. The product distribution from thiophene is essentially independent of the thiophene pressure from 4 to 20 Torr.

butenes therefore is slightly high. The product distribution varies with the catalyst as well as the sulfur compound. Chromia gives much more butane than the other catalysts. Thiophene and tetrahydrothiophene yield product distributions which are qualitatively similar. Surprisingly, the saturated compound tetrahydrothiophene yields more butadiene than the unsaturated thiophene over all catalysts. It also yields more 1-butene and the *trans* to *cis* ratio is higher. *n*-Butanethiol yields mainly 1-butene and *n*-butane.

Some experiments were carried out in order to obtain information on the possible interconversions and their rates. It has previously been established that tetrahydrothiophene under conditions similar to the ones used here can be transformed into thiophene (2). The transformation of *n*-butanethiol to thiophene and tetrahydrothiophene was not investigated as these reactions are thermodynamically unfavorable (3). Also the fact that the butanethiol is desulfurized much faster than the two other compounds makes these reactions less interesting. The results are given in Table III. An interesting parallel is seen between the activity of a catalyst for hydrogenating thiophene to tetrahydrothiophene and the relative amounts of butane formed over the catalyst (Table II). The hydrogenation of thiophene to tetrahydrothiophene did not show such a marked dependence upon conversion as the desulfurization reactions (1).

One may conclude that no organo-sulfur compounds are gas phase intermediates when thiophene, tetrahydrothiophene, or butanethiol are reacting under steady state conditions, low conversions, and a fairly low hydrogen pressure. (For pertinent literature references see paper I of this series (4).) It also seems unlikely that thiophene or tetrahydrothiophene reacts via a ring hydrogenation or dehydrogenation and then

†Measured at 400 °C, not accurately measurable at 288 °C because of thiophene impurity, but it is less than 0.02 at 288 °C.

‡Not definitely identified as butanethiol but having the correct retention time.

reacts further without leaving the surface because the product distribution from thiophene and tetrahydrothiophene are not equal.

The available data do not permit positive conclusions regarding the mechanism of the desulfurization reaction or detailed deductions about the reaction route. A rough scheme can be proposed, however, which is believed to be consistent with the observations. According to this scheme the desulfurization reaction is a dehydrosulfurization reaction rather than a hydrodesulfurization reaction. That is, it is proposed that the desulfurization step consists of the splitting off of an H_2S entity, analogous to the dehydration of an alcohol. More specifically, it is proposed that when the C—S bond in a group $(R \cdot (CH_n) \cdot (CH_n)—S—)_{ads}$ is ruptured, the following group results $[R \cdot (CH_{n-1}) \cdot (CH_n)]_{ads}$.

The resulting C_4-containing molecule is 1-butene when butanethiol reacts, 3-butenethiol when tetrahydrothiophene reacts, and 1-butene-3-yne-1-thiol when thiophene reacts. When the reactants are thiophene or tetrahydrothiophene the above reaction can proceed once more, splitting the second C—S bond whereby thiophene produces an adsorbed diacetylene and tetrahydrothiophene an adsorbed butadiene. Parallel with the second C—S splitting a hydrogenation of the unsaturated C_4-residue may go on. The residues produced in the above way will then probably be bonded to the catalyst surface with each of the free valencies. The last assumption is consistent with the fact that the C_4-compounds formed from the desulfurization reaction are not bonded to the surface in the same way as the corresponding C_4-compound when adsorbed from gas phase. This was shown in the previous publication (1). The products to be expected from the various C_4-compounds are:

Butanethiol

Butane, if the butene is hydrogenated before it is desorbed, otherwise butene. The butene is most likely to be 1-butene, but it may well be expected to show some isomerization before desorption.

Tetrahydrothiophene

The primary adsorbate may desorb as such or it may be hydrogenated once or twice during its stay on the surface, thus producing butadiene, butenes, and *n*-butane. Desorption of a molecule after rupture of the first C—S bond, but prior to rupture of the second C—S bond, may lead to small amounts of *n*-butanethiol or *n*-butenethiol.

Thiophene

The primary adsorbate (acetylenic residue) is not likely to desorb as such, because acetylene is known to be very strongly adsorbed. One may therefore expect that no (measurable) desorption will take place until it has been partially hydrogenated so that there are no acetylenic bonds left. Thiophene should therefore yield the same products as tetrahydrothiophene.

It was shown in Table II that a higher yield of butadiene was obtained from tetrahydrothiophene than from thiophene. This appears surprising at first sight, but may not really be so. If the probability is about the same for an olefinic bond being hydrogenated as for an acetylenic bond, a substantial part of the C_4-molecules from thiophene will never exist as adsorbed butadiene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

molecules. The well-known fact that acetylene usually is selectively hydrogenated before an olefin when both are present does not invalidate this argument because the acetylene is much more strongly adsorbed, and displaces the olefin from the catalyst surface (5).

It is a well-known fact that the desulfurization reaction of thiophene can only be made to proceed in the presence of hydrogen. The proposed scheme is consistent with this observation, as the surface would soon be covered by acetylenic residues in the absence of hydrogen.

Photochemical decomposition of methanethiol. II. The wavelength dependence of the hydrogen atom energy[1]

JOHN M. WHITE AND G. P. STURM, JR.[2]
The University of Texas at Austin, Austin, Texas 78712

Received November 5, 1968

Data are presented which indicate that the energy distribution of the hydrogen atom produced in the photolysis of methanethiol varies with wavelength in the region 2288 to 2537 Å.

Canadian Journal of Chemistry, 47, 357 (1969)

Introduction

Recently several papers have appeared which deal with the photolysis of methanethiol in the presence of various substrates (1–5). Two, in particular, provide evidence for important effects of translationally excited hydrogen atoms in the $CH_3SH - C_2H_4$ systems (2) and the $CH_3SH - D_2$ systems (4) respectively. We wish to report here an extension of the $CH_3SH - D_2$ experiments from which it is concluded that the energy distributions of hydrogen atoms produced in photolyses of CH_3SH at 2537 and 2288 Å differ significantly. This conclusion is in disagreement with that of Steer and Knight (2), who conclude, from $CH_3SH - C_2H_4$ photolyses, that 2537 and 2288 Å radiation give rise to essentially the same hydrogen atom energy distribution.

Experimental Procedure and Results

We have photolyzed $CH_3SH - D_2$ mixtures at room temperature and wavelengths 2537 or 2288 Å, and measured the $2H_2/HD$ ratio in the products by mass spectrometry. No variation of $2H_2/HD$ with fractional decomposition of CH_3SH over the range 0.04 to 0.2 was noted. At 2537 Å, the CH_3SH pressure ranged from 45 to 54 Torr while the D_2 pressure varied from 13 to 442 Torr. In most photolyses at 2288 Å the CH_3SH pressure was in the range 18 to 24 Torr and the D_2 pressure varied from 9 to 180 Torr. In a few experiments at 2288 Å, the CH_3SH pressure was varied over the range 10 to 40 Torr. Other experimental details have been given previously (4).

Figure 1 shows the product ratio $2H_2/HD$ as a function of the CH_3SH/D_2 reactant ratio. Fitting the data to a linear function by least squares furnishes an intercept of 5.30 ± 0.47 and a slope of 6.90 ± 0.23 at 2537 Å. At 2288 Å the slope is 4.88 ± 0.13 and the intercept is 1.96 ± 0.12. The uncertainties quoted are the standard deviations. Experiments in which the CH_3SH pressure was varied as described above are included in Fig. 1; clearly the product ratio depends only on the reactant ratio with no additional dependence on CH_3SH pressure.

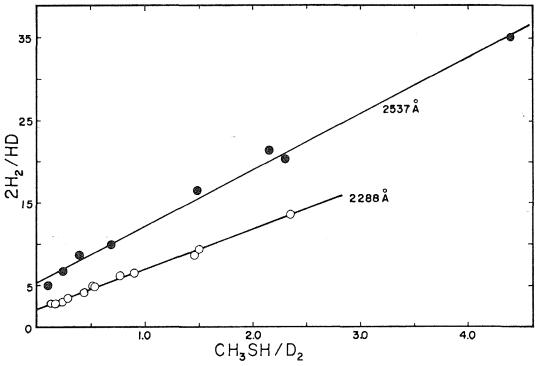

FIG. 1. Variation of the $2H_2/HD$ product ratio with the CH_3SH/D_2 reactant ratio in photolyses of methanethiol–deuterium mixtures at 2537 Å (●), and 2288 Å (○).

Discussion

The following mechanism satisfactorily accounts for the observed results:

[1] $CH_3SH + h\nu \rightarrow CH_3S + H^*$

[2] $H^* + CH_3SH \rightarrow H_2 + CH_3S$

[3] $H^* + D_2 \rightarrow HD + D$

[4] $H^* + CH_3SH \rightarrow H + CH_3SH$

[5] $H^* + D_2 \rightarrow H + D_2$

[6] $H^* + M \rightarrow H + M$

[7] $H + CH_3SH \rightarrow H_2 + CH_3S$

[1]Supported in part by the Petroleum Research Fund of the American Chemical Society and The Robert A. Welch Foundation.

[2]N.A.S.A. Trainee.

[8] $D + CH_3SH \rightarrow HD + CH_3S$

[9] $CH_3S + CH_3S \rightarrow CH_3SSCH_3$

In this mechanism H* denotes translationally excited hydrogen atoms whose energy distribution may be a function of the photolysis wavelength and the cross sections for reactions [2] through [6]. H denotes thermal hydrogen atoms whose energy distribution is a function only of the macroscopic reaction vessel temperature. Steady-state analysis of the mechanism[3] furnishes

$$\frac{2[H_2]}{[HD]} = \frac{(k_2 + k_4)}{k_3}\frac{[CH_3SH]}{[D_2]} + \frac{k_5}{k_3} + \frac{k_6}{k_3}\frac{[M]}{[D_2]}$$

In the present experiments, the last term may be neglected, since the pressures are sufficiently high to preclude wall thermalization, and no gaseous thermalizing species are present other than CH_3SH and D_2 which are accounted for by [4] and [5]. We therefore interpret the slopes in Fig. 1 as being equal to $(k_2 + k_4)/k_3$ and the intercepts as k_5/k_3.

It should be pointed out that, as discussed previously (4), the reaction of thermal hydrogen atoms with D_2 is negligible under the conditions of these experiments. A significant variation with wavelength of the energy distribution of the hydrogen atoms is suggested by the observed increase in the intercept with increasing photolysis wavelength. Since k_5 decreases while k_3 increases with the average hydrogen atom energy (6), the hydrogen atoms reacting at 2288 Å appear to have on the average significantly more energy than those produced at 2537 Å. The variation of the slopes may also be accounted for by similar qualitative arguments. Since the thermal activation energy for abstraction of D from D_2 is larger than for abstraction of H from CH_3SH (7, 5), the rate coefficient for the hot atom reaction [3] is expected to show a stronger energy dependence than reaction [2] in the range of energies being dealt with here ($\lesssim 2$ eV). Therefore it is concluded that $(k_2 + k_4)/k_3$ should decrease as the energy of the hydrogen atoms increases. This is consistent with the above interpretation of the intercepts and the observed slopes.

The apparent discrepancy in these results and those of Steer and Knight may be accounted for in the following way. Photolyses using D_2 as a detector molecule for hot hydrogen atoms may be expected to provide a more sensitive test for differences in translational excitation than photolyses using C_2H_4 or CH_3SH as a detector. Steer and Knight (2) found that in thermalized systems $k_7/k_{10} = 1.15 \pm 0.10$. The hot atom counterpart of this ratio is 2.32 ± 0.11 (2).

[10] $H + C_2H_4 \rightarrow C_2H_5$

The corresponding ratios in the $CH_3SH - D_2$ systems are k_7/k_{11} and k_2/k_3. The ratio k_7/k_{11} is estimated to be greater than 10^{+3} near 300 °K (4).

[11] $H + D_2 \rightarrow DH + H$

Furthermore, the cross section for [11] or [3] is expected to be a sensitive function of the hydrogen atom energy in the region of interest here (6, 9). The data shown in Fig. 1 confirm this statement; the small magnitude of the slopes arises because k_2/k_3 is more than 100 times smaller than its thermal counterpart k_7/k_{11}. Because of this strong variation, we conclude that D_2 is significantly more sensitive to changes in the hydrogen atom energy distribution than is either CH_3SH or C_2H_4.

[3]It should be noted that it is not necessary to require $k_7 = k_8$. The important assumption is that the only detectable reaction of thermal D and H atoms is with CH_3SH.

The preparation and properties of $[Ru(en)_3]^{3+}$ have been described (1–3) and salts of *cis*-$[Ru(en)_2X_2]^{2+}$ (X = Cl, Br) have been reported recently (4). We now wish to report a facile synthesis of $[Ru(en)_3]^{3+}$ *via* the oxidation of $[Ru(en)_3]^{2+}$ with concentrated nitric acid[2].

A small amount of concentrated nitric acid was added to a suspension of $[Ru(en)_3][ZnCl_4]$ in concentrated aqueous en.2HNO$_3$ to form $[Ru(en)_3]^{3+}$ in solution. The oxidation is quite rapid and is complete within 5 min at room temperature. The hydrated bromide salt[3], $Ru(en)_3Br_3.5H_2O$, may be precipitated from the solution by the addition of aqueous sodium bromide. This salt may then be converted to $[Ru(en)_3]I_3$ by the addition of sodium iodide (saturated solution) to a concentrated aqueous solution of the bromide salt. It should be pointed out that the colors of these salts are dependent on the anion present; the bromide salt is yellow while the iodide salt is dark purple. A similar effect of the counter anion has been observed with various hexaaminеruthenium(III) salts (6). The iodide salt is paramagnetic with μ_{eff} = 2.2 B.M. at 297 °K confirming the presence of ruthenium (III) (7).

The electronic spectrum of $[Ru(en)_3]I_3$ in aqueous solution has been investigated; surprisingly, the spectrum is not stable and changes with time. Despite this behavior, a very good estimate of the spectral parameters may be obtained by *quickly* recording the spectrum of a freshly prepared sample. The spectral data are presented in Table I together with assignments for the observed absorption bands. A value of 29 000 cm^{-1} for the crystal field splitting parameter, $10Dq$, has been calculated from these data using the energy level data of Tanabe and Sugano for d^5 ions (8). This value of the crystal field splitting parameter is consistent with $10Dq$ = 19 500 cm^{-1} reported for the isoelectronic, low-spin, $[Fe(en)_3]^{3+}$ (9). It may be noted that $10Dq$ for $[Ru(en)_3]^{3+}$ is only slightly larger than that reported for $[Ru(en)_3]^{2+}$ (3, 10). Further aspects of the chemistry of these and related complexes are being investigated.

Studies of specifically fluorinated carbohydrates. Part III. A new method for the addition of the elements of "BrF" and of "IF" to unsaturated carbohydrate derivatives

L. D. HALL[1] AND J. F. MANVILLE[2]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received June 3, 1968

A smooth addition of the elements of "BrF", to D-glucal triacetate (**1**), occurs when bromine is reacted with **1** in the presence of silver monofluoride and a suitable solvent. This reaction affords a major product 2-bromo-2-deoxy-α-D-mannopyranosyl fluoride triacetate, together with smaller quantities of 2-bromo-2-deoxy-α-D-glucopyranosyl fluoride triacetate and the corresponding β-D-anomer. The structures of these products have been elucidated by fluorine and proton magnetic resonance studies, and confirmed by several independent syntheses. The same three products are obtained when "BrF" is generated *in situ* from *N*-bromosuccinimide and HF; however, under these conditions 2-deoxy-α-D-*arabino*-hexopyranosyl fluoride triacetate is also formed in ca. 7% yield. The Br_2/AgF reagent has also been reacted with several 3,4-dihydro-2*H*-pyran derivatives and with other glycals. In all cases the major product(s) corresponds to the *trans* addition of "BrF". Similar results are obtained for the addition of the elements of "IF" to all of the above derivatives.

Canadian Journal of Chemistry, **47**, 361 (1969)

Introduction

In the two previous papers (1) of this series, we described studies of glycopyranosyl fluorides which gave us some insight as to the stereospecific dependencies of the ^{19}F nuclear magnetic resonance (^{19}F n.m.r.) parameters of fluorine attached to the anomeric center of a pyranose sugar. We also indicated the potential which ^{19}F n.m.r. spectroscopy has, as a "stereospecific probe", for studying the conformational symmetries of carbohydrate derivatives. In view of the proven sensitivity of ^{19}F chemical shifts with respect to the environment of a fluorine substituent, it occurred to us that ^{19}F n.m.r. spectroscopy might have a unique potential for studying the course of certain electrophilic addition reactions of unsaturated carbohydrate derivatives. The present study is concerned, in part, with the development of this hypothesis and, in part, with an investigation of the potential of unsaturated carbohydrate derivatives as precursors for specifically fluorinated carbohydrates.[3]

Bowers and co-workers (3) described the *in situ* generation, and addition to alkenes, of the elements of "XF" (where X = Cl, Br, or I) by reaction of the appropriate *N*-haloamide with HF in the presence of the alkene. Pattison and co-workers (4) subsequently applied this procedure to a variety of unsaturated systems and Kent and co-workers (5) also described its application to several glycal derivatives. In spite of the evident success of these studies we felt that the use of anhydrous HF would preclude the general application of the Bowers reagent to unsaturated carbohydrate derivatives and as a result, developed the reaction sequence outlined below. The sequence is basically an extension of the concept developed originally for the addition of "BrOMe" to alkenes (6) and subsequently applied to carbohydrate derivatives by Lemieux and co-workers (7).

Flow Sheet 1

Following the usual procedure for electrophilic addition reactions (8) we anticipated reaction of the alkene with bromine to give the appropriate bromonium (or carbonium) ion, plus the bromide anion. Our variant required the immediate removal of this bromide anion, as silver bromide, by reaction with silver monofluoride. Reaction of the concomitantly-formed fluoride anion with the bromonium intermediate, which had been generated in the initial stage of the reaction, should then afford the desired "BrF" adduct. As will be shown below, this hypothetical sequence proved to be successful for "XF" additions (where X = Br, I) to a variety of α,β-unsaturated cyclic ethers.

Subsequent to our studies, a detailed literature search showed that the utilization of the above sequence for effecting the addition of "IF" to cyclohexene had previously been the subject of some controversy. Bergmann and Shahak (9) used an excess of cyclohexene as the reaction solvent and characterized the product as 3-iodocyclohex-1-ene. Schmidt and Meinert (10) used acetonitrile as solvent and reported the isolation of *trans*-2-iodo-cyclohexylfluoride. However, an unsuccessful attempt to repeat this work (11) resulted in the isolation of *N*-acetyl-2-iodo-cyclohexylamine. We have recently shown (12) that when a mixture of acetonitrile and/or benzene is used as solvent, the "IF" adduct of cyclohexene can be obtained in high yield; the reaction follows an exclusively *trans* addition.

Results and Discussion

When an acetonitrile solution of D-glucal triacetate (**1**) was stirred with silver monofluoride, and a solution of bromine (10%, in benzene) was added dropwise, an immediate precipitation occurred. Subsequent work-up of the reaction mixture afforded a syrup, a solution of which showed *three* separate fluorine resonances (Fig. 1) whose shifts were characteristic of pyranosyl

fluorides; there was no evidence for any products having fluorine attached to a secondary carbon (13, 14). The major component (**A**) of this mixture readily crystallized and, as will be shown below, it has the structure 2-bromo-2-deoxy-α-D-mannopyranosyl fluoride triacetate (**2**). A second derivative (**C**), found to be 2-bromo-2-deoxy-α-D-glucopyranosyl fluoride triacetate (**4**), crystallized out more slowly. The third component (**B**) has not to date, been obtained in crystalline form, but it has been shown to be 2-bromo-2-deoxy-β-D-glucopyranosyl fluoride triacetate (**3**). Evidence leading to the structural elucidation of these compounds will now be discussed.

The ^{19}F resonance ($\phi_c = +144.9$) of compound **C**, Fig. 1*c*, showed in addition to the characteristic *geminal* ^{19}F–^{1}H coupling (51.7 Hz) a large (25.1 Hz) *vicinal* ^{19}F–^{1}H coupling, which immediately indicated that this fluorine was *trans-diaxial* with respect to the proton at C-2; therefore, this compound must have the α-D-configuration. Analysis of the proton magnetic resonance (p.m.r.) spectrum, Fig. 2*b*, confirmed that this compound had the D-*gluco* configuration (large *vicinal* couplings of ca. 9 Hz between H-2, H-3; H-3, H-4; and H-4, H-5) and confirmed the α-configuration at C-1 ($J_{1,2} = 2.5$ Hz). On this basis, **C** has the structure 2-bromo-2-deoxy-α-D-glucopyranosyl fluoride triacetate.

The impure sample of derivative **B**, gave a p.m.r. spectrum consistent with the D-*gluco* configuration ($J_{2,3} = 9.0$ Hz) and with the β-configuration at C-1 ($J_{1,2} = 8.0$ Hz). The fact that the ^{19}F chemical shift of this derivative was to low field ($\phi_c = +136.0$) of that of the corresponding α-anomer ($\phi_c = +144.9$) is also consistent (1) with their respective anomeric configurations. The ^{19}F–^{1}H couplings observed in the ^{19}F spectrum (Fig. 1*b*) of this compound are again consistent with the above assignment (*geminal* coupling, 50.3 Hz; *vicinal*, 10.0 Hz). Thus, **B** has the structure, 2-bromo-2-deoxy-β-D-glucopyranosyl fluoride triacetate.

The ^{19}F n.m.r. spectrum of compound **A**, (Fig. 1*a*) exhibited a resonance at ϕ_c +123.1 which had a *vicinal* ^{19}F–^{1}H coupling of 2.9 Hz, which indicated a *gauche* relationship between these substituents. Although the p.m.r. spectrum indicated that this derivative has the D-*manno* configuration ($J_{2,3} = 3.95$ Hz), the *vicinal* H_1–H_2 coupling (1.5 Hz) offered no unequivocal evidence concerning the anomeric configuration. However, the observation that the ^{19}F shift was essentially temperature invariant ($\Delta\phi_c = 0.16$ p.p.m. between $+30°$ and $-80°$), indicated that this derivative has the α-configuration. We had previously observed (1) that the ^{19}F shift of β-D-hexopyranosyl fluorides are temperature dependent whereas those of the α-anomers are essentially invariant. Evidently the replacement of the oxygen substituent at C-2 by a bromine atom does not significantly alter this behavior: thus the ^{19}F shift of **3**, which is assigned the β-D-gluco configuration, changed by 3.2 p.p.m., whilst that of **4**, which is the corresponding α-anomer, changed by only 0.1 p.p.m. over the same temperature range. Thus, a straightforward application of the ^{19}F n.m.r. and p.m.r. methods afforded a facile identification of the three reaction products (**2**, **3**, **4**).

Since this was our first application in the carbohydrate area of this new method of generating "BrF", and also of ^{19}F n.m.r. as a method of structural elucidation in the carbohydrate area, it was felt desirable to confirm the above structural assignments by independent syntheses. The first of these started with the syntheses of 1-*O*-benzoyl-2-bromo-2-deoxy-α-D-mannopyranose triacetate (**5**) and the corresponding β-D-*gluco* isomer **6**. The proof of structure of these two derivatives follows from the known (15) stereochemistry of the Prevost reaction and from consideration of their p.m.r. spectra. These two derivatives were then reacted separately with anhydrous liquid HF, under conditions which are known (16, 17) to afford the most thermodynamically stable glycopyranosyl fluoride, which in the present series is the α-anomer. Reaction of the D-*manno* derivative **5** afforded as the sole product a crystalline material identical in all respects with the derivative previously assigned the α-D-*manno* configuration (**2**). Under identical reaction conditions, the D-*gluco* derivative **6** gave material which was the same in all respects with the compound previously assigned the α-D-*gluco* configuration (**4**). In one such reaction a second, minor component was detected by ^{19}F n.m.r. spectroscopy which gave an identical spectrum with that of the material tentatively assigned the β-D-*gluco* configuration (**3**). Since this derivative isomerized readily to the α-anomer (**4**), this provided further evidence (17) that **3** is the β-D-*gluco* derivative.

Although the above reactions provided reasonable proof for the structures of the two α-anomers, it was desirable to obtain a more satisfactory

synthesis for the β-D-*gluco* derivative (**3**). Partial success of this objective was attained as follows. Reaction of the β-D-*gluco*-bromo-benzoate (**6**) with HBr in glacial acetic acid afforded the corresponding glucopyranosyl bromide (18). The p.m.r. spectrum of this crude product showed that no starting material remained and that the bromide had the α-D-*gluco* configuration. This bromide was then reacted, without purification, with silver monofluoride in acetonitrile solution. This reaction afforded in high yield, as the sole glycosyl fluoride {^{19}F n.m.r. showed that none of the *cis* product (α-anomer) was formed}, material having spectral properties identical with those of the β-D-glucosyl fluoride (**3**). Initially, this syrupy material was contaminated with some of the bromo-benzoate (**6**) which was partially removed by crystallization. However, all attempts to crystallize **3** have failed, even though it contains less than 5% of impurities (p.m.r.); thin-layer chromatography (t.l.c.) shows only one spot. A similar reaction sequence, starting with the D-*manno* bromo-benzoate (**5**) gave as the sole glycosyl fluoride (^{19}F n.m.r.) the α-D-mannosyl fluoride (**2**). This reaction demonstrates that the bromine at C-2 participates during these exchange reactions. Again the fluoride was contaminated with its bromo-benzoate precursor; however, since the crude bromide did not contain any starting material (p.m.r.), the bromo-benzoate (**5**) must have been formed during the exchange reaction itself (see later). The mannosyl fluoride (**2**) was obtained pure after fractional crystallization.

To characterize further the α-D-*manno* derivative (**2**) attempts were made to remove the bromine substituent from C-2 by hydrogenolysis, which should afford the known (19) 2-deoxy-α-D-*arabino*-hexopyranosyl fluoride triacetate (**9**). Although a pure specimen could not be isolated from an atmospheric hydrogenolysis (palladium catalyst), it was present in the reaction product to the extent of ca. 40% as evidenced by both ^{19}F n.m.r. and p.m.r. spectroscopy. The ^{19}F n.m.r. spectrum showed, apart from a small amount of the starting material remaining, and the desired product **9**, *no other glycosyl fluoride resonances*. Interestingly the p.m.r. spectrum showed that the major by-product of the hydrogenolysis was D-glucal triacetate (**1**). Since the bromo-fluoro derivative (**2**) could be recovered in high yield after stirring with diethylamine and palladium–charcoal at 100° for 2 h, this by-product could not have come directly from **2**.

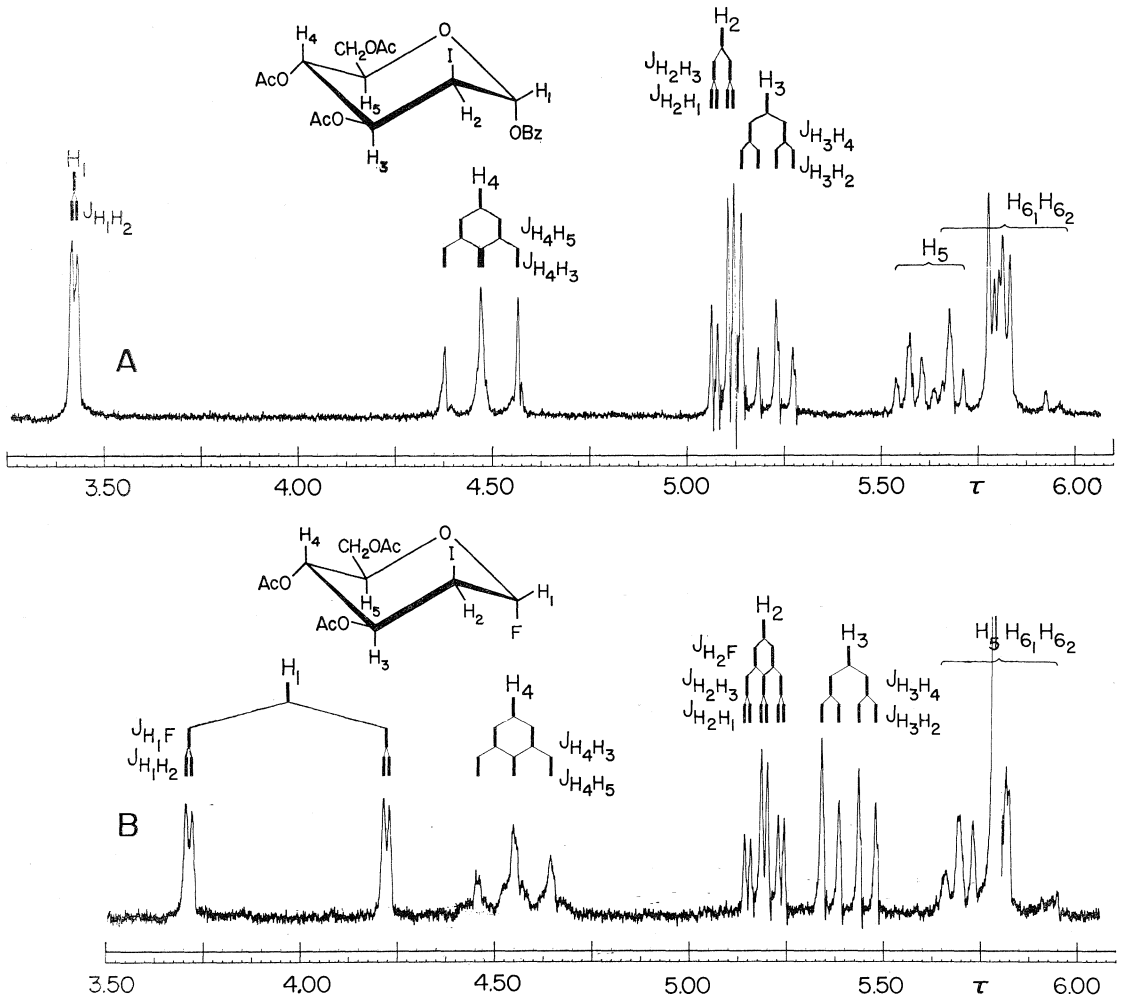

FIG. 3. Partial p.m.r. spectra (100 MHz) of acetone-d_6 solutions of:— (**A**), 1-*O*-benzoyl-2-deoxy-2-iodo-α-D-mannopyranose triacetate (**13**) and (**B**), 2-deoxy-2-iodo-α-D-mannopyranosyl fluoride triacetate (**10**).

The demonstrated success of the Br_2/AgF reagent for effecting the addition of "BrF" to D-glucal triacetate (**1**), prompted us to extend this approach to the addition of "IF" to **1**. Flow Sheet 2 outlines the reactions which were studied and the products which were isolated. Since the basic format of this part of the work parallels that described above for the addition of "BrF", a detailed discussion will not be given. The details are outlined in the Experimental section and the product ratios are given in Table I. It is sufficient to state here that the products isolated in crystalline form were shown to be 2-deoxy-2-iodo-α-D-mannopyranosyl fluoride triacetate (**10**), 2-deoxy-2-iodo-α-D-glucopyranosyl fluoride triacetate (**12**); an impure sample of syrupy 2-deoxy-2-iodo-β-D-glucopyranosyl fluoride triacetate (**11**) was also isolated. The ^1H spectrum of the α-D-*manno* derivative (**10**) is shown in Fig. 3*b*, together with that of the corresponding 1-*O*-benzoate (**13**) (Fig. 3*a*) for comparison.

At this point, a comparison will be made of the procedure for adding the elements of "XF" outlined above and the Bowers method (3) together with a discussion of points of mechanistic interest.

Kent and co-workers (5) have studied the Bowers addition of "BrF" and "IF" to D-glucal

triacetate. This reaction has been repeated during the present study and with the aid of ^{19}F n.m.r. spectroscopy, the products (shown in Table I), together with their ratios, have been found. The major components, which Kent reported as the β-D-*manno* derivatives were found to be identical with the α-D-mannopyranosyl fluorides (**2** and **10**) described in this paper. It is evident that the published (5) description of these derivatives as possessing the β-D-manno configuration, will have to be corrected; as a direct result it is necessary for Kent's proof of a "*cis*" mechanism to withstand closer examination. It is noteworthy that in the Bowers addition of "BrF" to D-glucal triacetate (**1**) a product arising from the addition of HF across the double bond is formed, namely, 2-deoxy-α-D-*arabino*-hexopyranosyl fluoride triacetate (**9**). The formation of this product was not anticipated since Pedersen (20) had shown that treatment of **1** with anhydrous HF affords 4,6-di-*O*-acetyl-2,3-dideoxy-D-*erythro*-hexosyl fluoride. However, neglecting the above "by-product", the product ratios, resulting from these two different methods for generating "XF", are extremely close; thus for **1**, the two methods may follow a similar mechanism.

Before discussing any details of this mechanism it is necessary to consider the stereospecificity of some of the reactions encountered during the proof of structure of the "BrF" adducts. The most important of these concerns the fluorine exchange reactions of the glycosyl bromides involved in the conversion of **5** to **2** and of **6** to **3**. In both instances this reaction proceeds to give exclusively that glycosyl fluoride having the fluorine *trans* to the C_2-halogen substituent. It is particularly significant that the conversion of **6** to **3** *does not* lead to the formation of any of the α-anomer, which is formed, in ca. 9% yield, during the "XF" addition reaction itself. This finding immediately excludes the possibility, which we have thus far ignored, that the "XF" addition itself merely involves the formation of the 1,2-dibromide(s) (18) which subsequently react(s) with the silver fluoride to give the glycosyl fluoride(s).

The conversion of **5** exclusively to **2** demonstrates conclusively that a halogen atom (bromine) at C-2 of a pyranose carbohydrate controls the course of the exchange reaction at C-1, when silver fluoride is used to effect this exchange. This exchange proceeds with 100% retention of configuration at C-1, possibly via an S_Ni mechanism, in which the bromine at C-2 participates in the ejection of the halide from C-1, forming a halonium type intermediate, which subsequently reacts with the incoming nucleophile, F^-.

This observed participation of halogen (bromine) at C-2 in exchange reactions at C-1 has an important significance as to the proposed mechanism (5, 21) for electrophilic addition reactions of glycals. Lemieux and Fraser-Reid (7) proposed for such reactions that the initiating step is the formation of a cyclic halonium ion and that the actual transition state ". . . . can be expected to be a resonance hybrid of the following canonical structures" (for example)

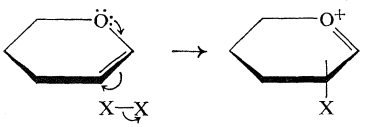
A B C

This statement is acceptable insofar that **A** could clearly afford a *trans* product, whilst both **B** and **C** could lead to either *trans* or (more importantly) *cis* products. However, it is difficult to see why a cyclic halonium ion (**A**) formed during a direct "XF" addition should be in resonance with **B** and **C**, whereas the cyclic halonium ion postulated for the halogen exchange reaction is apparently (by lack of formation of *cis* products) not in resonance with either **B** or **C**. Several possible rationales can be offered for this apparent dilemma, although it must be emphasized that no definitive experimental evidence is presently available. One is that it is totally inappropriate to compare the "XF" addition reaction with the exchange reaction. However, since particular attempts were made during this work to keep the reaction conditions of these two sequences as near identical as possible, this seems to beg the issue. A second rationale is that in the case of electrophilic additions, the initially formed ion has the form (**C**); its formation could result from anchimeric assistance from the ring oxygen as indicated below. This ion could then react directly with F^- to give either *cis* or *trans*



C

products. Alternatively, it could change to, or be in resonance with, the carbonium ion (**B**) which would also lead to *cis* or *trans* products; or it could change to **A** which, by analogy with the AgF exchange reactions, would necessarily lead exclusively to the *trans* product. To account for the exclusive formation of *trans* products during AgF exchange reactions, it would be necessary to postulate that reaction of a halonium ion such as **A** with F^- be very fast compared with the possible equilibrium between **A** and **B** or **C**.

In view of the paucity of really definite data it is not worthwhile pursuing this discussion further at this time. It is, however, interesting to note the similarity between the product ratios for the "XF" additions described in this study and those previously reported by Lemieux and Fraser-Reid (7) for "XOR" additions; in many instances the basic characteristics of the "XF" and "XOR" reactions would appear to be similar. If this is generally the case, it seems reasonable to suggest that studies of "XF" addition reactions may serve as convenient models for gaining insight as to the nature of the more general "XOR" additions. Thus, advantage can be taken of the wide dispersion of ^{19}F chemical shifts to monitor the product ratios and to determine in a facile and unequivocal fashion the configurations of the products arising from these reactions.

Already one situation has been encountered where such a "model" study proved to be useful. During the course of reactions leading to the stereoselective syntheses of the "XF" adducts, it was necessary to effect the addition of "XOBz" to D-glucal triacetate (**1**). Following closely the method of Lemieux and Levine (15) the two products arising from *trans* addition of "IOBz" were isolated. However, the observation, by ^{19}F n.m.r. spectroscopy, of ca. 9% of the α-D-*gluco* adduct from an "IF" addition to **1**, prompted the reinvestigation of the original "IOBz" addition. Inspection of the crude reaction mixture by p.m.r. spectroscopy revealed the presence (ca. 8%) of an anomeric resonance corresponding to the α-D-*gluco* derivative. Following a similar reaction sequence, "BrOBz" addition to **1** resulted in significant amounts (ca. 26%) of the *cis*, or α-D-*gluco*, adduct (**7**).

It is, therefore, clearly established that electrophilic addition reactions can result in *cis* addition to the double bond of acetylated glycals, although the *cis* product is usually a minor component. This result should be compared with those found for electrophilic addition reactions to cycloalkenes, in which *trans* additions are generally (though not exclusively) observed (8, 12) for those reactions proceeding via an ionic mechanism. It follows that the ring oxygen of the glycals must significantly alter the nature of the reaction, thus allowing the formation of *cis* products.

It is convenient at this time to discuss the use of ^{19}F n.m.r. for determining the nature and ratio of the products arising from "XF" addition reactions to other α,β-unsaturated cyclic ethers. Since most of these products were not in an analytically pure state and were identified mainly

on the basis of their ^{19}F n.m.r. parameters, these results have not been used during the discussion of possible mechanisms for the "XF" addition reaction. The results arising from these reactions are summarized in Table II. The ^{19}F n.m.r. parameters for these reaction products will be found in the Experimental section.

The "XF" addition reactions of dihydropyran (**16**) resulted in the formation of *two* products; these are the trans-diaxial (α-*manno*)[4] and *cis* (α-*gluco*)[4] isomers. Their identification is straightforward since the *cis* isomers (**20, 22**) displayed large (ca. 25 Hz) *vicinal* ^{19}F–^{1}H couplings, indicative of a *trans-diaxial* arrangement, whereas, the *trans* isomers (**19, 21**) showed small (ca. 1.5 Hz) couplings. The product ratios found for the "XF" reactions (AgF + X_2) are as expected, 80% *trans*. The unusually large percentage of *cis* (**20**) formation found for the Bowers reaction may reflect the fact that there is now equilibrium control over the product ratio.

The "XF" additions (X_2 + AgF) to the "C-5" substituted dihydropyrans[4] **17** and **18** resulted in formation of *two trans* isomers and a smaller percentage of the *cis* isomer (α-*gluco*). These results are qualitatively the same as those found previously for D-glucal triacetate (**1**). The high percentage of *cis* product (**31**) arising from the "BrF" (Bowers) reaction to **18** could be a result of isomerization of the *trans-diequatorial* isomer (β-*gluco*) to the more stable *cis* isomer (α-*gluco*) as the former could not be detected.

Results of "XF" (X_2 + AgF) addition to three other glycals are summarized in Table III. Tentative identification of these reaction products followed from comparison with the results found for D-glucal triacetate **1** and their ^{19}F n.m.r. parameters which can be found in the Experimental section. The product ratios arising from "XF" addition to D-galactal triacetate (**35**) appear to reflect the fact that there is now an axially oriented acetoxy substituent at C-4 {low percentage of the α-D-*talo* isomers **38** and **41**} and

[4]We have used the expressions "α-*gluco*" and "α-*manno*" in order to facilitate comparison of these results with those described earlier. Strictly, this nomenclature is incorrect, as also is the reference to "C-5 substituted dihydropyrans".

these results are in agreement with those reported by Lemieux and Fraser-Reid (7) for "XOR" addition reactions.

Identification of the reaction products arising from "XF" addition to the pentals (**36**) and (**37**) are tentative. They were identified on the basis of their *vicinal* ^{19}F–^{1}H couplings and the fact that the *trans-diaxial* isomers are expected to be the preferred ones. Nevertheless, there is one very interesting result that does not depend on the precise identification of the individual products. It was noted that "XF" (X = Br,I) additions to D-xylal diacetate **37** results in the formation of all *four* diastereoisomers, whereas, only three are formed in the case of D-arabinal diacetate **36**. This result may reflect the difference in the ground state conformations of these two molecules, which are shown in Table III, (these conformations were deduced from detailed analysis of their p.m.r. spectra). The conformation of D-arabinal diacetate is such that both acetate substituents are in stereo-electronically favorable orientations; the one at C-3 is *pseudo-axial* {allylic effect (22)} and the acetate at C-4 is *equatorial*. In contrast, D-xylal diacetate has the acetate at C-4, *axially* oriented, in the ground state conformation. As soon as either of these glycals react with halogen, the allylic effect of the double bond will be removed: for D-arabinal diacetate the resulting (carbonium?) ion will be in an energetically stable ground state; however, for D-xylal diacetate, the ion will have at least two substituents axially oriented and will therefore be energetically metastable with respect to the inverted ($^{4}C_{1}$-D) conformer. In the event that the rate of conformational inversion exceeds the rate of attack by F^{-}, it is clearly possible for the intermediate ion to form products from either of its

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

two possible conformers and hence to form four, rather than three, adducts.

The addition of "IOBz" to D-arabinal diacetate and to D-xylal diacetate resulted in syrupy mixtures of three and four products, respectively. Only one component, from the D-arabinal addition reaction was obtained crystalline. It proved to be 1-*O*-benzoyl-2-deoxy-2-iodo-β-D-ribopyranose diacetate (**50**) (p.m.r. evidence; see Experimental section). Since further attempts to obtain these materials in crystalline form are to be made, we shall not discuss them further at this time. It is unfortunate that the isomeric sets of derivatives have similar mobilities on t.l.c. plates.

In conclusion, we have shown that ^{19}F n.m.r. spectroscopy provides a facile method for identifying the products arising from the addition of the elements of "XF" to unsaturated carbohydrate systems. We further suggest that advantage can be taken of the considerable steric sensitivity of ^{19}F chemical shifts to use "IF" additions as models for other "IOR" addition reactions; we are continuing to develop this approach and to study the effect of solvent changes on the product ratios. It is regrettable that the concept of *cis* addition of the elements of "XF" to glycals should have as its foundation the incorrect assignment of a structure (the α-D-*manno* derivatives (**2**) and (**10**)), since the result is evidently quite general and of some importance as far as electrophilic addition reactions to α,β-unsaturated cyclic ethers are concerned. Since the acceptance of a preliminary communication of these results (2), Dr. Kent has informed us[5] that he has independently revised the structure for "BrF" adduct (**2**) derived from D-glucal triacetate (**1**), and now concurs with the α-D-*manno* configuration.

A detailed discussion of the n.m.r. parameters of the derivatives whose syntheses have been described in this paper will be given later in this series.

Experimental

The general methods and nuclear magnetic resonance (n.m.r.) measurements followed the format outlined previously (1).

Electrophilic Addition Reactions of D-*Glucal Triacetate (**1**) Addition of the Elements of "BrF"*

(a) Generated from Br_2 and AgF—D-Glucal triacetate (**1**)[6] (1.36 g) in dry acetonitrile (ca. 25 ml) was stirred vigorously with powdered silver monofluoride[7] (4 g). A solution of bromine (0.85 g, 10% w/v in benzene) was then added dropwise. After completion of the bromine addition (ca. 10 min), the solution was stirred for a further 20 min and then filtered from the copious precipitate of silver halide. To this solution were added 5 ml of saturated aqueous sodium chloride, the precipitated silver chloride was removed, the filtrate was concentrated to ca. 10 ml and chloroform (30 ml) was added. The chloroform solution was extracted successively with aqueous sodium thiosulfate, aqueous sodium bicarbonate and water. After drying (Na_2SO_4), evaporation produced a clear syrup (1.8 g, 97%). Inspection (by proton magnetic resonance (p.m.r.)) of the crude reaction product showed that no starting material remained and ^{19}F n.m.r. showed the presence of *three* glycopyranosyl fluorides which were subsequently identified as:—2-bromo-2-deoxy-α-D-mannopyranosyl fluoride triacetate (**2**) 70%, ϕ_c +123.2, $J_{1,F}$ 50.2 Hz; $J_{2,F}$ 2.85 Hz; 2-bromo-2-deoxy-β-D-glucopyranosyl fluoride triacetate (**3**) 21%, ϕ_c +136.0, $J_{1,F}$ 50.3 Hz; $J_{2,F}$ 10.0 Hz and 2-bromo-2-deoxy-α-D-glucopyranosyl fluoride triacetate (**4**) 9%, ϕ_c +144.9, $J_{1,F}$ 51.5 Hz; $J_{2,F}$ 25.2 Hz.

After work-up, the reaction mixture was dissolved in boiling diethyl ether and on cooling the solution deposited crystals (0.98 g), m.p. 137–142°; addition of light petroleum afforded a second crop of the same material (0.13 g), total yield 1.11 g; 56%. Recrystallization from ethanol afforded pure **2** as prismatic crystals m.p. 138–140°, $[\alpha]_D^{22}$ −32.0° (*c*, 2.06).

Anal. Calcd. for $C_{12}H_{16}O_7BrF$: C, 38.8; H, 4.3; F, 5.1. Found: C, 39.0; H, 4.5; F, 5.0.

The mother liquors remaining after isolation of **2** were evaporated and the resulting syrup dissolved in ethanol and cooled to −5°; after several weeks an impure sample of **4** was obtained (0.12 g, 6%). Recrystallization, twice from aqueous ethanol afforded pure **4** as fine needles; m.p. 120–121°, $[\alpha]_D^{22}$ +134.5° (*c*, 1.80).

Anal. Calcd. for $C_{12}H_{16}O_7BrF$: C, 38.8; H, 4.3; F, 5.1. Found: C, 39.0; H, 4.45; F, 4.95.

The residual syrup from above was shown (by n.m.r.) to contain mainly the β-D-*gluco* isomer (**3**) together with smaller quantities of the other isomers (**2**) and (**4**). Fortunately this syrup was sufficiently pure for detailed n.m.r. analysis; it has so far failed to crystallize.

Reinvestigation of the above reaction, using only benzene as solvent, yielded the same three isomers, but in quite different ratios and the overall yield of adducts was only 83%; the α-D-*manno* isomer (**2**), 42%, the β-D-*gluco* isomer (**3**), 42% and the α-D-*gluco* isomer (**4**) 16%.

(b) Generated from N-bromosuccinimide and anhydrous liquid HF—Following the procedure outlined by Kent *et al.* (5*a*), this reaction was repeated several times, using slightly different reaction times. The yields reported are

[5]P. W. Kent. Private communication, December 27, 1967.

[6]**1** was a commercial sample from the Aldrich Chemical Co., Milwaukee, Wisconsin, which was purified by recrystallization from aqueous ethanol.

[7]The silver monofluoride was a commercial sample from Harshaw Chemical Co. Cleveland, Ohio, and was ground to a fine powder before use.

average results. Anhydrous hydrogen fluoride (10 g) was added to anhydrous diethyl ether (18 g) in a polythene bottle cooled to ca. −78° (solid-CO_2/acetone). *N*-Bromosuccinimide (4.0 g) and D-glucal triacetate (**1**) (5.0 g) were added, portionwise, to the stirred solution, over the course of ca. 10 min. After 0.5–2 h at −78°, the temperature was raised to 0° for a further 0.5–2 h. After dilution with anhydrous diethyl ether, the solution was decomposed by pouring directly into an ice-cold, saturated aqueous solution of sodium bicarbonate. The ethereal layer was subsequently extracted with water, dried (Na_2SO_4), and evaporated. Investigation (p.m.r.) of the crude reaction product showed that no starting material remained and ^{19}F n.m.r. showed the presence of *four* glycopyranosyl fluorides which were identified on the basis of their ^{19}F chemical shifts and ^{19}F–^1H coupling constants, as the α-D-*manno* isomer (**2**) ca. 55%, the β-D-*gluco* isomer (**3**) ca. 30% and the α-D-*gluco* isomer (**4**) ca. 9%; the fourth resonance has been identified (19) as 2-deoxy-α-D-*arabino*-hexopyranosyl fluoride triacetate (**9**) ca. 8%, ϕ_c +131.1, $J_{1,F}$ 51.2 Hz; $J_{2e,F}$ 5.0 Hz; $J_{2a,F}$ 38.0 Hz.

The syrupy mixture was dissolved in diethyl ether and on cooling, the solution deposited **2** (1.85 g, 32%). Recrystallization from 1:5 v/v chloroform – light petroleum afforded pure **2** m.p. and mixture m.p. 139–140°, with the compound obtained above. The remaining compounds from this reaction were not isolated as they had been previously characterized in this study.

The α-D-*manno* isomer **2** was heated under reflux for 24 h in acetonitrile containing a molar excess of silver monofluoride and was recovered unchanged. It was also unaffected when resubjected to treatment with *N*-bromosuccinimide and anhydrous HF as described above.

Partial hydrogenolysis of **2**, at atmospheric pressure (10% palladium–charcoal catalyst, diethylamine as acid acceptor) in methanol solution gave (n.m.r. evidence) the 2-deoxy fluoride (**9**) together with unreacted starting material (**2**) and D-glucal triacetate (**1**). The α-D-*manno* derivative (**2**) was unaltered when heated under reflux in methanol solution containing diethylamine and palladium–charcoal catalyst.

Addition of the Elements of "IF"

(a) Generated from I_2 and AgF—Following the same procedure (as described above for the generation of "BrF" from Br_2 and AgF), D-glucal triacetate (**1**) (1.36 g) was reacted with I_2 (1.25 g) and AgF (2 g) to form a clear syrup in 98% yield. This syrup contained (^{19}F n.m.r.) *three* glycopyranosyl fluorides: 2-deoxy-2-iodo-α-D-mannopyranosyl fluoride triacetate (**10**) 60%, ϕ_c + 116.9, $J_{1,F}$ 51.7 Hz; $J_{2,F}$ 3.9 Hz; 2-deoxy-2-iodo-β-D-glucopyranosyl fluoride triacetate (**11**) 34%, ϕ_c +132.3, $J_{1,F}$ 49.9 Hz; $J_{2,F}$ 9.3 Hz and 2-deoxy-2-iodo-α-D-glucopyranosyl fluoride triacetate (**12**) 6%, ϕ_c + 139.8, $J_{1,F}$ 50.5 Hz; $J_{2,F}$ 27.8 Hz.

The α-D-*manno* isomer (**10**) was obtained crystalline from an ether solution of the reaction mixture and was crystallized from ethanol to give pure **10** as prismatic crystals (yield 1.0 g, 47%); m.p. 155–156°, $[\alpha]_D^{22}$ −46.1° (*c*, 2.54).

Anal. Calcd. for $C_{12}H_{16}O_7FI$: C, 34.45; H, 3.85; F, 4.55. Found: C, 34.7; H, 4.0; F, 4.65.

The mother liquors remaining from crystallization of **10** were concentrated to a syrup which was dissolved in ethanol. The α-D-*gluco* isomer (**13**) was obtained from this solution after several weeks of standing at 0°. Recrystallization from aqueous ethanol afforded fine needles (yield 0.10 g, 4.8%); m.p. 143–144°, $[\alpha]_D^{22}$ +180.5° (*c*, 2.72).

Anal. Calcd. for $C_{12}H_{16}O_7FI$: C, 34.45; H, 3.85; F, 4.55. Found: C, 34.6; H, 4.0; F, 4.65.

The mother liquors were found (n.m.r.) to contain mainly the β-D-*gluco* isomer (**11**). Column chromatography (silica gel, 1% MeOH in CH_2Cl_2 as eluant) yielded a clear syrup which was sufficiently pure for detailed n.m.r. analysis. To date, this compound has not been obtained crystalline.

Upon reinvestigation of this reaction, using only benzene for solvent, the same three isomers were obtained (yield 79%) in the following ratio: the α-D-*manno* isomer (**10**) 33%, the β-D-*gluco* isomer (**11**) 45%, and the α-D-*gluco* isomer (**12**) 22%.

(b) Generated from N-iodosuccinimide and anhydrous liquid HF—Following the procedure of Wood *et al.* (5*b*), a partially crystalline mass was obtained which contained (^{19}F n.m.r.) the same *three* glycopyranosyl fluorides in the following ratios: the α-D-*manno* isomer (**10**) 71%, the β-D-*gluco* isomer (**11**) 3%, and the α-*gluco* isomer (**12**) 23% together with a small (3%) unidentifiable resonance at ϕ_c +125.3. None of the deoxy isomer (**9**) could be detected.

Addition of the Elements of "BrOBz"

D-Glucal triacetate (**1**) (1.36 g) was dissolved in benzene (25 ml) to which was added silver benzoate[8] (2.5 g); 8.5 ml of a bromine solution (10% w/v in benzene) were added dropwise to the stirred suspension. After a further 20 min, the suspension was filtered and the filtrate was then extracted successively with aqueous sodium bicarbonate and water. The benzene solution was dried (Na_2SO_4) and evaporated to a clear syrup (2.23 g).

Inspection (by p.m.r.) of this crude reaction product indicated four anomeric resonances, which were attributed to the four isomeric "BrOBz" adducts. They were formed in the following yields: the α-D-*manno* isomer (**5**) 31%, τ H_1 = 3.44, $J_{1,2}$ 1.8 Hz; α-D-*gluco* isomer (**7**) 26%, τ H_1 = 3.43, $J_{1,2}$ 3.5 Hz; β-D-*gluco* isomer (**6**) 42%, τ H_1 = 3.94, $J_{1,2}$ 9.1 Hz; and β-D-*manno* isomer 2%, τ H_1 = 3.56, $J_{1,2}$ 3.5 Hz.

This crude reaction product was dissolved in a minimum of boiling ethanol and left at room temperature overnight, during which time crystals (1.61 g, 68%) were deposited. These were shown (by p.m.r.) to be an almost equal mixture of the two *trans* isomers (**5**) and (**6**).

The mother liquors were cooled to ca. 0° and after several weeks fine needle shaped crystals were deposited (0.55 g, 23%); recrystallization from aqueous ethanol afforded pure 1-*O*-benzoyl-2-bromo-2-deoxy-α-D-glucopyranose triacetate (**7**) m.p. 112–113°, $[\alpha]_D^{25}$ +213° (*c*, 0.89).

Anal. Calcd. for $C_{19}H_{21}O_9Br$: C, 48.2; H, 4.45; Br, 17.0. Found: C, 48.0; H, 4.5; Br, 17.0.

---

[8]Silver benzoate was formed by reacting equimolar aqueous solutions of silver nitrate and sodium benzoate; the crude precipitate was washed with copious amounts of water, filtered (suction), and dried at 120° for 8 h.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The mixture of **5** and **6** was separated in the manner of Lemieux and Levine (15) and was each recrystallized from aqueous ethanol. 1-*O*-Benzoyl-2-bromo-2-deoxy-α-D-mannopyranose triacetate (**5**) had m.p. 168–169°, $[\alpha]_D^{28}$ +62.3° (*c*, 1.54).

Anal. Calcd. for $C_{19}H_{21}O_9Br$: C, 48.2; H, 4.45; Br, 17.0. Found: C, 48.0; H, 4.5; Br, 17.1.

1-*O*-Benzoyl-2-bromo-2-deoxy-β-D-glucopyranose triacetate (**6**) had m.p. 161–162°, $[\alpha]_D^{28}$ +15.3° (*c*, 0.72).

Anal. Calcd. for $C_{19}H_{21}O_9Br$: C, 48.2; H, 4.45; Br, 17.0. Found: C, 48.05; H, 4.6; Br, 17.1.

When the above reaction was repeated using acetonitrile to dissolve the D-glucal triacetate (**1**), the same four products were observed (by n.m.r.) in the following ratios; the α-D-*manno* isomer (**5**) 20%, the β-D-*gluco* isomer (**6**) 35%, the α-D-*gluco* isomer (**7**) 40% and the β-D-*manno* isomer 6%.

Addition of the Elements of "IOBz"

The two isomeric *trans* 1-*O*-benzoyl-2-deoxy-2-iodo-D-pyranose triacetates, **13** and **14**, were obtained by a variant of the method described by Lemieux and Levine (15). 1.36 g of **1** in benzene solution, was used and the iodine (1.35 g) was dissolved in benzene (10% w/v) and added dropwise to the stirred solution.

Investigation (by n.m.r.) of the crude reaction product showed the presence of a third product, not reported by Lemieux and Levine. It was assigned to 1-*O*-benzoyl-2-deoxy-2-iodo-α-D-glucopyranose triacetate (**15**) (τ H-1 = 3.42; $J_{1,2}$ 3.0 Hz). The product ratios as determined by p.m.r. were:— α-D-*manno* isomer (**13**) 46%, the α-D-*gluco* isomer (**15**) 8%, and the β-D-*gluco* isomer (**14**) 46%.

This reaction was repeated, using an acetonitrile solution of D-glucal triacetate (**1**). The same products were observed in the following ratios: the α-D-*manno* isomer (**13**), 64%; the β-D-*gluco* isomer, (**14**) 28%; and the α-D-*gluco* isomer (**15**) 8%.

The α-D-*gluco* isomer (**15**) was not isolated from the mother liquors. The α-D-*manno* isomer (**13**) had m.p. 160–161°, lit. (15) m.p. 159.5–160°, $[\alpha]_D$ +45.3° and the β-D-*gluco* isomer (**14**) had m.p. 150–151°, lit. (15) m.p. 150–151.5°, $[\alpha]_D$ +2.2°.

Stereoselective Syntheses of Products Formed during the Addition Reactions of D-*Glucal Triacetate*

2-Bromo-2-deoxy-α-D-mannopyranosyl fluoride triacetate (2)—1-*O*-Benzoyl-2-bromo-2-deoxy-α-D-mannopyranose triacetate (**5**) (0.25 g) was converted to the 2-bromo-2-deoxy-α-D-mannopyranosyl bromide triacetate (18) which was immediately dissolved in acetonitrile (20 ml) containing silver monofluoride (1 g). The solution was then shaken for ca. 20 min (no more precipitate was formed after ca. 15 min). Work-up, following the procedure described previously (1) for halogen exchange reactions, produced a clear syrup which contained (^{19}F n.m.r.) only *one* fluoride (**2**); however, p.m.r. showed the presence of ca. 20% of the starting material (**5**).

This syrup was dissolved in ethanol and the benzoate (**5**) was precipitated (0.050 g, m.p. 171–174°) leaving a colorless solution which contained mainly the desired fluoride. This solution was evaporated, dissolved in 3 ml of chloroform, petroleum ether (20 ml) was added and the solution cooled to ca. 5°. Crystals of **2** m.p. 137–142° were deposited which were recrystallized from aqueous ethanol (0.102 g, 51%) m.p. 138–140°.

The fluoride (**2**) was also prepared, as described (1) for the formation of α-D-glucopyranosyl fluoride tetraacetate, from the benzoate (**5**) (0.05 g) by action of anhydrous liquid HF. The desired compound (**2**) was obtained in 63% yield; m.p. and mixture m.p. with samples obtained previously, 139–140°.

This compound was identical in every respect with the product obtained in the bromofluorination reactions described above.

2-Bromo-2-deoxy-β-D-glucopyranosyl fluoride triacetate (3)—1-*O*-Benzoyl-2-bromo-2-deoxy-β-D-glucopyranose triacetate (**6**) (0.25 g) was converted as described above to the 2-bromo-2-deoxy-α-D-glucopyranosyl bromide triacetate, which was immediately dissolved in acetonitrile (20 ml) containing silver monofluoride (1 g). Starting material (0.053 g, 21%) was isolated from this reaction leaving the desired fluoride (**3**) (0.095 g, 62%). This product, however, has not been obtained either pure or crystalline. ^{19}F n.m.r. showed only the desired fluoride, none of the corresponding *cis* isomer (**4**) could be detected

2-Bromo-2-deoxy-α-D-glucopyranosyl fluoride triacetate (4)—1-*O*-Benzoyl-2-bromo-2-deoxy-β-D-glucopyranose triacetate (**6**) (0.25 g) was converted, in the manner described (1) for the formation of α-D-glucopyranosyl fluoride tetraacetate, with anhydrous hydrogen fluoride, into the desired fluoride (**4**) (0.11 g, 58%) with m.p. and mixture m.p. with sample obtained previously, 120–121°.

2-Deoxy-2-iodo-α-D-mannopyranosyl fluoride triacetate (10)—1-*O*-Benzoyl-2-deoxy-2-iodo-α-D-mannopyranose triacetate (**13**) (0.25 g) was reacted in the usual manner with anhydrous hydrogen fluoride to give the desired fluoride (**10**), (0.10 g, 50%) with m.p. and mixture m.p. with a sample previously obtained, 153–155°.

2-Deoxy-2-iodo-α-D-glucopyranosyl fluoride triacetate (12)—1-*O*-Benzoyl-2-deoxy-2-iodo-β-D-glucopyranose triacetate (**14**) (0.25 g) was subjected, in the usual manner, to react with hydrogen fluoride. The desired fluoride (**12**) was formed in a yield of 60%; m.p. and mixture m.p. with a sample obtained previously, 142–144°.

The above halogenofluorinations (bromine and iodine) were also performed on the following model compounds; vinyl acetate, 3,4-dihydro-2*H*-pyran (**16**), the acetate of 3,4-dihydro-2*H*-pyran-2-methanol (**17**), and the *p*-toluenesulfonate of 3,4-dihydro-2*H*-pyran-2-methanol (**18**). In each case, the product had halogen at C-2 and fluorine at C-1[9]: with the exception of those from the tosylate (**18**), the products were unstable liquids or oils which could not be isolated in a pure state. However, it was possible to determine their product ratios by ^{19}F n.m.r.

Reactions of Vinyl Acetate[10]

(a) Bromofluorination, "BrF" generated from Br_2 and AgF—This bromofluorination afforded only *one* fluorine

[9]These reaction products are given trivial names. It is felt that these trivial names adequately describe the reaction products and facilitate greatly the comparison between these reaction products and those described previously for the D-glucal triacetate adducts. See also footnote[4] given in the discussion.

[10]Vinyl acetate was a commercial sample from the Aldrich Chemical Co., Inc., Milwaukee, Wisconsin.

For personal use only.

containing product; ϕ_c +121.9, (doubletted triplet) J_{gem} ca. 50 Hz, J_{vic} ca. 15 Hz. Solely on the basis of the ^{19}F n.m.r. data, it was concluded that the product had the structure $CH_2BrCHFOAc$.

*Reactions of 3,4-Dihydro-2H-Pyran (**16**)*[11]

(a) Bromofluorination, "BrF" generated from Br_2 and AgF—This bromofluorination of **16** afforded *two* fluorine containing products: the *trans* isomer (**19**) 84%, ϕ_c +122.8, $J_{1,F}$ 51.3 Hz, $J_{2,F}$ 4.6 Hz and the *cis* isomer (**20**) 16%, ϕ_c +149.4, $J_{1,F}$ 52.2 Hz, $J_{2,F}$ 26.3 Hz.

(b) Bromofluorination, "BrF" generated from N-bromosuccinimide and anhydrous liquid HF—Following the general procedure as outlined for the reaction of D-glucal triacetate (**16**) afforded a yellow syrup which contained (^{19}F n.m.r.) the same *two* fluorine resonances: these were assigned to the *trans* isomer (**19**) 55–60% and *cis* isomer (**20**) 40–45%.

(c) Iodofluorination, "IF" generated from I_2 and AgF—The iodofluorination of **16** also yielded *two* compounds; the *trans* isomer (**21**) ca. 95%, ϕ_c +117.5, $J_{1,F}$ 51.3 Hz, $J_{2,F}$ 5.2 Hz and the *cis* isomer ca. 5%, ϕ_c +143.5, $J_{1,F}$ 51.1 Hz, $J_{2,F}$ 27.2 Hz.

(d) Iodofluorination, "IF" generated from N-iodosuccinimide and anhydrous liquid HF—When this iodofluorination reaction was attempted, a black tar was obtained, which did not contain any fluorine organic products.

*Reactions of the Acetate of 3,4-Dihydro-2H-Pyran-2-Methanol (**17**)*[12]

(a) Bromofluorination, "BrF" generated from Br_2 and AgF—The bromofluorination of the acetate (**17**), b.p. 104–106°, 15 mm led to the formation of the *trans-diaxial* (α-*manno*) isomer (**23**) 57%, ϕ_c +119.7, $J_{1,F}$ 51.1 Hz, $J_{2,F}$ 4.0 Hz; the *trans-diequatorial* (β-*gluco*) isomer (**24**) 20%, ϕ_c +126.9, $J_{1,F}$ ca. 52 Hz and the *cis* (α-*gluco*) isomer (**25**) 18%, ϕ_c +147.1, $J_{1,F}$ 51.6 Hz, $J_{2,F}$ 26.0 Hz. (A minor unidentified resonance at ϕ_c +121.9 was also detected.)

(b) Iodofluorination, "IF" generated from I_2 and AgF—The iodofluorination of **27** resulted in the formation of the *trans-diaxial* (α-*manno*) isomer (**26**) 78%, ϕ_c +114.5, $J_{1,F}$ 51.4 Hz, $J_{2,F}$ 5.0 Hz; the *trans-diequatorial* (β-*gluco*) isomer (**27**) 17%, ϕ_c +122.3 $J_{1,F}$ ca. 50 Hz and the *cis* (α-*gluco*) isomer (**28**) ca. 5%, ϕ_c ca. +141. (This resonance was too weak for an accurate determination of ϕ_c or of the coupling constants.) No other ^{19}F resonances were discernible.

*Reactions of the p-Toluenesulfonate of 3,4-Dihydro-2H-Pyran-2-Methanol (**18**)*

(a) Bromofluorination, "BrF" generated from Br_2 and AgF—The bromofluorination of **18**, (m.p. 46.5–47.5°) afforded the *trans-diaxial* (α-*manno*) isomer (**29**) 66%, ϕ_c +120.1, $J_{1,F}$ 50.5 Hz, $J_{2,F}$ 3.7 Hz; the *trans-diequatorial* (β-*gluco*) isomer (**30**) 25%, ϕ_c +125.8 $J_{1,F}$ ca. 51 Hz and the *cis* (α-*gluco*) isomer (**31**) 6%, ϕ_c +147.5, $J_{1,F}$ 52.0 Hz, $J_{2,F}$ 26.0 Hz, together with two other very minor, unidentified resonances.

(b) Bromofluorination, "BrF" generated from N-bromosuccinimide and anhydrous liquid HF—The bromofluorination of **18** (5 g) afforded a crystalline mass (1.4 g, 20%): m.p. 106–110°. ^{19}F n.m.r. showed this reaction product to consist of almost equal portions of the *trans-diaxial* (α-*manno*) isomer (**29**) ca. 55%, and the *cis* (α-*gluco*) isomer (**31**) ca. 45%. Successive recrystallizations (7 times) failed to separate these two isomers; m.p. 121–122.5°.

Anal. Calcd. for $C_{13}H_{16}O_4BrFS$: C, 42.5; H, 4.35; F, 5.2. Found: C, 42.4; H, 4.4; F, 5.25.

(c) Iodofluorination, "IF" generated from I_2 and AgF—The iodofluorination of **18** afforded three products. They were identified (by ^{19}F n.m.r.) as the *trans-diaxial* (α-*manno*) isomer (**32**) 76%, ϕ_c +114.8, $J_{1,F}$ 51.5 Hz, $J_{2,F}$ 5.1 Hz; the *trans-diequatorial* (β-*gluco*) isomer (**33**) 18%, ϕ_c +121.0, $J_{1,F}$ ca. 50 Hz and the *cis* (α-*gluco*) isomer (**34**) 5%, ϕ_c ca. +141.

*Reactions of D-Galactal Triacetate (**35**)*

(a) Bromofluorination, "BrF" generated from Br_2 and AgF—In the manner described for "BrF" addition to **1**, D-galactal triacetate[13] (**35**) (1.36 g) was reacted in acetonitrile solution with bromine and silver monofluoride. A 98% yield of a light amber syrup was obtained, which so far has failed to crystallize; ^{19}F n.m.r. showed that *three* glycopyranosyl fluorides were formed. Their structures were tentatively assigned, on the basis of their ϕ_c values and first order ^{19}F–^{1}H coupling constants, and by analogy with the products obtained from D-glucal triacetate as: 2-bromo-2-deoxy-α-D-talopyranosyl fluoride triacetate (**38**) 34%, ϕ_c +121.4, $J_{1,F}$ 49.8 Hz, $J_{2,F}$ 4.6 Hz, 2-bromo-2-deoxy-β-D-galactopyranosyl fluoride triacetate (**39**) 43%, ϕ_c +135.6, $J_{1,F}$ 49.7 Hz, $J_{2,F}$ 10.0 Hz and 2-bromo-2-deoxy-α-D-galactopyranosyl fluoride triacetate (**40**), 24%, ϕ_c +145.0, $J_{1,F}$ 50.5 Hz, $J_{2,F}$ 25.1 Hz. {Compare with those results reported by Kent *et al.* (21*b*).}

(b) Iodofluorination, "IF" generated from I_2 and AgF—A 96% yield of a clear syrup was obtained, which has failed to crystallize. Again ^{19}F n.m.r. showed that *three* glycopyranosyl fluorides had been formed. Tentatively, these have the structures 2-deoxy-2-iodo-α-D-talopyranosyl fluoride triacetate (**41**), 25%, ϕ_c +114.6, $J_{1,F}$ 50.5 Hz, $J_{2,F}$ 6.3 Hz; 2-deoxy-2-iodo-β-D-galactopyranosyl fluoride triacetate (**42**) 41%, ϕ_c +130.8, $J_{1,F}$ 49.8 Hz, $J_{2,F}$ 10.2 Hz and 2-deoxy-2-iodo-α-D-galactopyranosyl fluoride triacetate (**43**) 34%, ϕ_c +139.4, $J_{1,F}$ 50.0 Hz, $J_{2,F}$ 27.6 Hz.

*Reactions of D-Arabinal Diacetate (**36**)*[14]

(a) Bromofluorination, "BrF" generated from Br_2 and AgF—Following the established procedure a syrup was obtained from **36** (1.0 g) in 93% yield, which has not crystallized. ^{19}F n.m.r. showed only *three* anomeric fluorine resonances. They were tentatively assigned as: 2-bromo-2-deoxy-α-D-arabinopyranosyl fluoride diacetate (**44**) 62%, ϕ_c +126.4, $J_{1,F}$ 50.5 Hz, $J_{2,F}$ 3.5 Hz; 2-bromo-2-deoxy-β-D-ribopyranosyl fluoride diacetate

[11]3,4-Dihydro-2*H*-pyran, was a commercial sample from Eastman Organic Chemicals, Rochester, New York.

[12]3,4-Dihydro-2*H*-pyran-2-methanol was a gift from Shell Chemical Co., New York.

[13]D-Galactal triacetate (**35**), was a commercial sample from Koch Light Laboratories Ltd., England and was used as received.

[14]D-Arabinal diacetate (**36**), was prepared by Miss Zinat Mia, according to the procedure of Humoller (23); had b.p. (1 mm) 90°; lit. (23) b.p. 0.3 mm) 79°; $[\alpha]_D$ +266°.

(**45**), 20%, ϕ_c +127.9, $J_{1,F}$ 50.4 Hz, $J_{2,F}$ 3.4 Hz and 2-bromo-2-deoxy-α-D-ribopyranosyl fluoride diacetate (**46**), 18%, ϕ_c +147.6, $J_{1,F}$ 51.3 Hz, $J_{2,F}$ 25.1 Hz. {Compare with the results of Kent *et al.* (21*a*).}

(b) Iodofluorination, "IF" generated from I_2 and AgF—An 82% yield of a clear syrup was obtained from **36** (1.0 g) which so far has failed to crystallize. ^{19}F n.m.r. showed only three anomeric resonances. These resonances were tentatively assigned as: 2-deoxy-2-iodo-α-D-arabino-pyranosyl fluoride diacetate (**47**) 49%, ϕ_c +121.6, $J_{1,F}$ ca. 50 Hz, $J_{2,F}$ ca. 5 Hz; 2-deoxy-2-iodo-β-D-ribopyranosyl fluoride diacetate (**48**) 38%, ϕ_c +123.9, $J_{1,F}$ 51.0 Hz, $J_{2,F}$ 6.5 Hz and 2-deoxy-2-iodo-α-D-ribopyranosyl fluoride diacetate (**49**) 13%, ϕ_c +141.9 $J_{1,F}$ 50.7 Hz, $J_{2,F}$ 27.6 Hz.

(c) Iodobenzoylation—Following the same procedure as described for D-glucal triacetate (**1**), Miss Zinat Mia effected the addition "IOBz" to **36** in benzene solution and obtained a semi-crystalline syrup which was found (by p.m.r.) to contain three anomeric resonances.

One isomer was obtained crystalline, from an ethanol solution and was recrystallized twice from aqueous ethanol to afford hard needles of 1-*O*-benzoyl-2-deoxy-2-iodo-β-D-ribopyranose diacetate (**50**), m.p. 129–130° $[\alpha]_D^{27}$ −26.5° (*c*, 1.46).

Anal. Calcd. for $C_{16}H_{17}O_7I$: C, 42.85; H, 3.8; I, 28.3. Found: C, 42.6; H, 3.9; I, 28.1.

This component (**50**) accounted for 45% of the reaction product.

Reactions of D-*Xylal Diacetate (**37**)*[15]

(a) Bromofluorination, "BrF" generated from Br_2 and AgF—Following the established procedure a clear syrup was obtained from **37** in 91% yield which has to date failed to crystallize. ^{19}F n.m.r. showed that all *four* isomeric "BrF" adducts were formed. They are (the structures are tentative):— 2-bromo-2-deoxy-α-D-lyxo-pyranosyl fluoride diacetate (**51**) 55%, ϕ_c +126.7, $J_{1,F}$ 50.1 Hz, $J_{2,F}$ 3.5 Hz; 2-bromo-2-deoxy-β-D-xylopyranosyl fluoride diacetate (**52**) 32%, ϕ_c +128.0, $J_{1,F}$ 51.0 Hz, $J_{2,F}$ 9.0 Hz; the β-D-*lyxo* or the α-D-*xylo* isomer (**53**) 5%, ϕ_c +144.1, $J_{1,F}$ 50.8 Hz, $J_{2,F}$ 26.8 Hz and the α-D-*xylo* or the β-D-*lyxo* isomer (**54**) 8%, ϕ_c +146.5, $J_{1,F}$ 50.3 Hz, $J_{2,F}$ 25.1 Hz.

(b) Iodofluorination, "IF" generated from I_2 and AgF—Following the established procedure a colorless syrup was obtained, which has failed to crystallize. ^{19}F n.m.r. again showed that all *four* isomeric "IF" adducts were formed.

The resonances were tentatively assigned as: 2-deoxy-2-iodo-α-D-lyxopyranosyl fluoride diacetate (**55**) 46%, ϕ_c +120.4, $J_{1,F}$ 50.0 Hz, $J_{2,F}$ 3.5 Hz; 2-deoxy-2-iodo-β-D-xylopyranosyl fluoride diacetate (**56**) 43%, ϕ_c +122.5, $J_{1,F}$ 51.1 Hz, $J_{2,F}$ 9.2 Hz; the α-D-*xylo* or β-D-*lyxo* isomer (**57**) 8%, ϕ_c +138.0, $J_{1,F}$ 50.8 Hz, $J_{2,F}$ 29 Hz and the β-D-*lyxo* or α-D-*xylo* isomer (**58**) 3%, ϕ_c +141.1, $J_{1,F}$ 50.8 Hz, $J_{2,F}$ 29 Hz.

(c) Iodobenzoylation—When "IOBz" was reacted with **37** (1.0 g) in the manner described above for the reaction with D-glucal triacetate in acetonitrile solution, a light-yellow syrup was obtained (2.1 g, 94%). It was not possible to obtain any crystalline products from this reaction and although p.m.r. showed the presence of four anomeric resonances, they could not be assigned.

[15]D-Xylal diacetate (**37**), was prepared, with the assistance of Mrs. Liane Evelyn following the procedure of Weygand (24); had m.p. 37–39°, lit. m.p. 40°, $[\alpha]_D$ −314.7°.

Note added in proof: Since the preparation of this manuscript Campbell *et al.* (25) have reported an X-ray study of the major product from their addition of "BrF" to D-glucal triacetate. On this basis they have revised their original assignment of the β-D-*manno* configuration to the, correct, α-D-*manno* configuration. Their structure of the corresponding "IF" adduct must be similarly corrected.

Studies of specifically fluorinated carbohydrates. Part IV. Addition of the elements of "ClF" to D-glucal triacetate[1]

L. D. HALL[2] AND J. F. MANVILLE[3]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received June 3, 1968

Reaction of chlorine with a suspension of D-glucal triacetate and silver monofluoride in an acetonitrile/benzene solution, affords a mixture of the four possible 2-chloro-2-deoxy-D-glycopyranosyl fluoride triacetates. The structures of these derivatives have been established by nuclear magnetic resonance studies and confirmed by independent syntheses. The major product is 2-chloro-2-deoxy-β-D-glucopyranosyl fluoride triacetate. These results are compared with those from the related "BrF" and "IF" additions.

Introduction

In the previous paper of this series (2) we described the synthesis of the "BrF" and "IF" adducts of D-glucal triacetate (**1**) by several independent routes, all of which located the halogen (Br or I) at C-2 and the fluorine at C-1. We shall now discuss, as an extension of that study, the addition of the elements of "ClF" to **1**. It will be shown that the addition of this electrophile to **1** differs from that of either "BrF" or "IF" in several important details.

Results and Discussion

Reaction of D-glucal triacetate (**1**) with halogen (Br_2 or I_2) in the presence of silver fluoride resulted (2) in the formation of three of the four possible stereoisomers of the 2-deoxy-2-halo-D-glycosyl fluoride system: none of the β-D-*manno* isomer could be detected. When an acetonitrile/benzene solution of D-glucal triacetate (**1**) was stirred vigorously with silver monofluoride and chlorine gas was bubbled into the suspension, an immediate precipitation occurred. Subsequent work up of the reaction mixture afforded a syrup, which gave (^{19}F nuclear magnetic resonance-^{19}F n.m.r.) *four* separate "glycosyl fluoride" resonances; no secondary fluorine resonances (3) were discernable. This was the first time in our experience that an "XF" reaction to D-glucal triacetate (**1**) has resulted in the formation of all four diastereoisomers, the fourth being (presumably) the β-D-mannopyranosyl fluoride (**5**).

A minor component from the syrupy reaction product crystallized after several days at ca. 0°; it proved to be the α-D-mannosyl fluoride (**2**). The major component, the β-D-glucosyl fluoride (**3**) was obtained crystalline after seeding with an authentic sample made by the AgF exchange method (*vide infra*). Remaining in the mother liquors were the α-D-*gluco* (**4**) and β-D-*manno* (**5**) isomers. These were not separated, although the α-D-glucosyl fluoride (**6**) was subsequently obtained *via* the reaction of HF on the α-D-*gluco* chloro-benzoate (**7**).

The proof of structure for the three crystalline fluorides followed the general format previously described (2) for the "BrF" derivatives. Since the α-D-*mannosyl* fluoride (**2**) was not characterized by independent syntheses the n.m.r. evidence leading to its structural elucidation will be presented in some detail.

The ^{19}F resonance (ϕ_c +127.8) of this compound exhibited a *vicinal* ^{19}F–^{1}H coupling of ca. 2 Hz, which indicated a *gauche* relationship between these substituents. Also, the proton magnetic resonance (p.m.r.) spectrum (Fig. 1) indicated that this compound had the D-*manno* configuration ($J_{2,3}$ = 3.6 Hz); however, the anomeric configuration could not be determined with absolute certainty since there would necessarily be a *gauche* relationship between H-2 and both H-1 and F-1 for either the α- or β-anomers. The close similarity between the spectrum of this derivative and that obtained previously (2) for 2-bromo-2-deoxy-α-D-mannopyranosyl fluoride triacetate supported the α-configuration and consideration of the chemical shift of H-5 (τ 6.08,

[1]For a preliminary communication, see ref. (1).

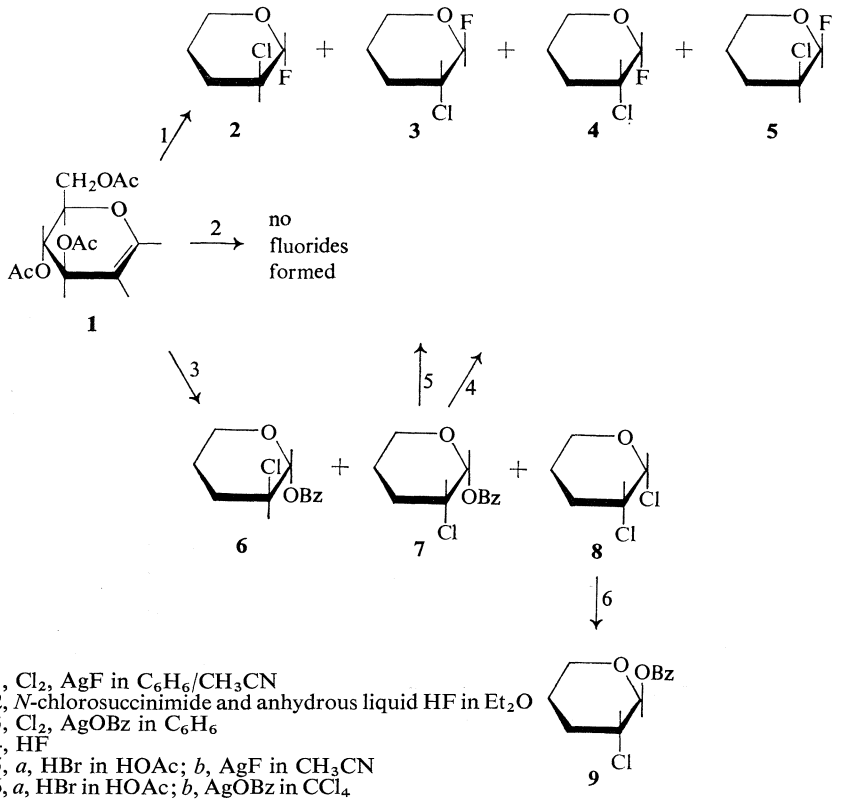
[3]Recipient of a British Columbia Sugar Refining Co. Scholarship, 1965–1966 and a NRCC Studentship, 1966–1967. Present address: Forest Products Laboratory, N.W. Marine Drive, Vancouver 8, British Columbia.



benzene-d_6) further supported the assigned α-configuration at C-1. (The shift of H-5 for the β-D-*gluco* derivative (**3**) is τ 6.53, benzene-d_6, whilst that of the α-D-*gluco* isomer (**4**) is τ 6.06, benzene-d_6.)

The p.m.r. spectrum of the α-D-*gluco* derivative (**4**) was essentially the same as that found (2) for the bromo-analogue and the observation of a large (24 Hz) *vicinal* ^{19}F–^{1}H coupling left no doubt as to its structure. Since the β-D-*gluco* derivative (**3**) is the only "XF" adduct of **1** which has this configuration and which we have obtained crystalline thus far, its p.m.r. spectrum has been included in this paper; that of the corresponding 1-benzoate (**9**) is included for comparison purposes.

The independent syntheses of some of these "ClF" adducts were planned to follow the addition of the elements of "ClOBz" to **1** with subsequent conversion of the 1-*O*-benzoyl derivatives to the corresponding glycosyl fluorides. It has previously been observed that, in contrast to either bromine or iodine, the chlorine cation adds to D-glucal triacetate to give preferentially D-*gluco* adducts; chlorine itself is reported (4, 5) to lead to greater than 80% formation of the α-D-glucosyl chloride. In accord with this generalization, the major product from the attempted addition of "ClOBz" to **1** was the α-D-*gluco* chloro-benzoate (**7**) together with, somewhat unexpectedly, the α-D-glucosyl chloride (**8**). Although small quantities of the α-D-*manno* chloro-benzoate (**6**) could be isolated, none of the *trans* β-D-*gluco* isomer (**9**) could be recovered; however, the p.m.r. spectrum of the reaction product indicated that ca. 5% of this isomer was formed. The dichloride (**8**) was found to be extremely stable with respect to reaction with AgOBz, with which it could be treated under reflux in CCl_4 solution, and recovered unchanged. In fact, it was necessary to convert **8** to the corresponding glucosyl bromide, by reaction with HBr in acetic acid, before successful conversion to the β-D-*gluco* chloro-benzoate (**9**) could be effected.

In accord with the above result from the

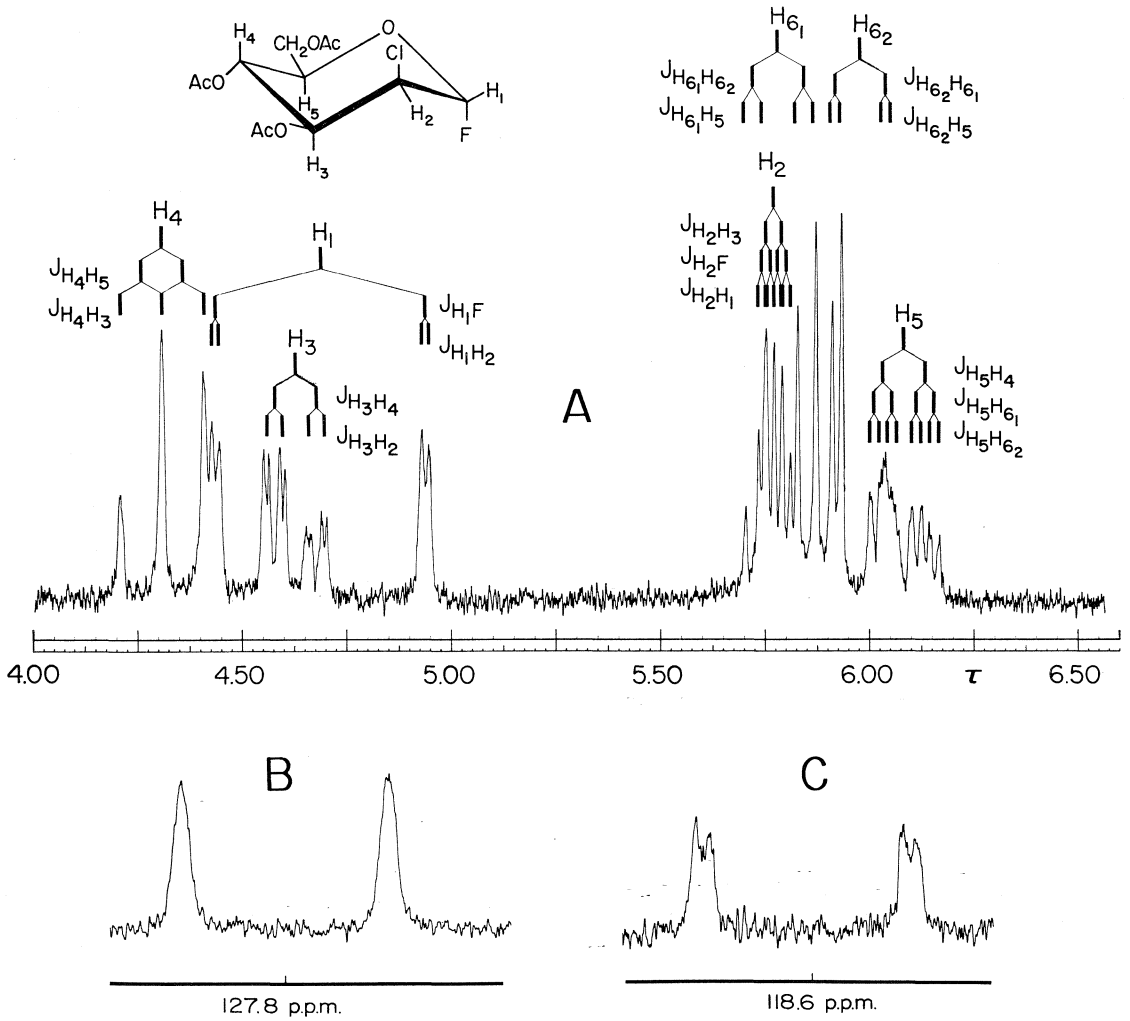

FIG. 1. (*a*) Partial 100 MHz proton magnetic resonance spectrum of 2-chloro-2-deoxy-α-D-mannopyranosyl fluoride triacetate (**2**) in benzene-d_6 solution; (*b*) ^{19}F n.m.r. spectrum of **2** in chloroform-*d* solution; (*c*) ^{19}F n.m.r. spectrum of 2-chloro-2-deoxy-β-D-mannopyranosyl fluoride triacetate (**5**) in chloroform-*d* solution.

"ClOBz" addition, reaction of **1** with "ClF" affords mainly the D-*gluco* isomers (**3**) and (**4**), and in contrast with previous experience, the major product has the β-D-*gluco* configuration. The β-D-anomer (**3**) is in fact the one expected for the *gluco*-series since *trans* addition would be expected to predominate over *cis* addition and anomerization is not generally observed for "XF" addition reactions (2). It is, therefore, most likely that the formation of the α-D-*gluco*-dichloride (**8**) (*cis* product) during reaction of **1** with Cl_2, reflects the instability of the *trans* isomer (equatorial chlorine), which anomerizes to the more stable α-anomer (axial chlorine) during the course of the chlorination reaction.

Reaction of the α-D-*gluco* chloro-benzoate (**7**) with anhydrous HF afforded as sole product material identical to that to which the α-D-glucosyl fluoride structure (**4**) had been assigned. The same chloro-benzoate (**7**) afforded the β-D-glucosyl fluoride (**3**) when reacted with HBr in acetic acid, followed by halogen exchange with silver monofluoride. This particular conversion was important since it demonstrated that a chlorine substituent at C-2 was capable of participating in C-1 halogen exchange reaction in an

analogous fashion to that previously established for bromine (2).

Attempts to utilize the same set of reaction sequences for the stereospecific syntheses of either of the mannosyl fluorides (**2**) or (**5**) were hindered by lack of sufficient quantities of the α-D-*manno* chloro-benzoate derivative (**6**). Nevertheless some results were obtained as follows. The mixture of products obtained from direct chlorination of **1** was dissolved in benzene: acetonitrile (2:1 v/v) and this solution shaken at room temperature with silver monofluoride. The halogen exchange reaction was observed (by ^{19}F n.m.r.) to be very slow and after 30 h at room temperature only ca. 5% of the dichlorides had been converted to the *trans* chloro-fluorides (**2**) and (**3**). Interestingly, the α-D-*manno* isomer (**2**) was formed at a much faster rate than the corresponding β-D-*gluco* isomer (**3**), in spite of the predominance of the α-D-glucosyl chloride in the original starting material. Presumably this enhanced reactivity of the mannosyl chloride reflects the fact that the C_2-halogen substituent of this derivative is *trans-diaxial* with respect to the C_1-chlorine substituent and is hence able to participate more readily in the halogen exchange reaction. Nevertheless, the overall slow rate of halogen exchange for these dichloride derivatives confirms their high chemical stability.

It is unfortunate that it was not possible to isolate a pure sample of the β-D-*manno* chloro-fluoride (**5**) since the formation of a product having this configuration, from D-glucal triacetate, has not previously been reported (4). Nevertheless we believe that the ^{19}F n.m.r. data are uniquely consistent with this configurational assignment. The small (3.6 Hz) *vicinal* ^{19}F–^{1}H coupling indicates not only that the F-1 and H-2 substituents have a *gauche* relationship but also, that either F-1 or H-2 are antiparallel to an electronegative substituent (7). This requirement could only be satisfied by a derivative having the D-*manno* configuration. The *geminal* ^{19}F–^{1}H coupling (49.4 Hz) accords with this conclusion; both the D-*gluco* isomers have geminal couplings of ca. 51 Hz.

Several interesting points were revealed during the stereospecific syntheses of the β-D-*gluco* chloro-fluoride (**3**) and chloro-benzoate (**9**). The stereospecific reaction sequence designed to produce only the β-D-glucosyl fluoride **3** from **7** resulted in a mixture consisting of three components; these were, starting material (**7**) which had not been converted into the intermediate bromide, the β-D-*gluco*-benzoate (**9**) and the anticipated β-D-*gluco*-fluoride (**3**) which was the *only glycosyl fluoride* formed. Fractional crystallization successfully separated all three components. The formation of the β-D-*gluco*-chloro-benzoate (**9**) demonstrates that the "starting" material found in the previous (2) exchanges, (X = Br) had been formed during the exchange reaction itself and was not unreacted starting material. The participation of chlorine in an AgF exchange reaction is clearly confirmed by this reaction sequence since only *trans* products were formed. It is interesting to note that Olah and co-workers have recently (6) obtained evidence for the ability of chlorine to participate in the formation of cyclic "chloronium" ions.

Attempts were made during this study to effect the addition of the elements of "ClF" to **1** using *N*-chlorosuccinimide with anhydrous liquid HF. Surprisingly, no fluorinated products could be detected (by ^{19}F n.m.r.).

The syntheses described in this paper complete the sequence of "XF" additions to **1**, for X = Cl, Br, I. The n.m.r. parameters of the derivatives synthesized in this and the previous (2) paper will be discussed in the next paper of this series.

Experimental

The general methods and nuclear magnetic resonance measurements followed the format previously described (7).

Addition of the Elements of "ClF" to ***1***

(a) Generated from Cl_2/AgF—Following closely[4] the procedure outlined previously for the addition of "BrF" from Br_2/AgF (2), an amber syrup was obtained in 91% yield which contained (^{19}F n.m.r.) all *four* isomeric "ClF" adducts. These were shown to be: 2-chloro-2-deoxy-α-D-mannopyranosyl fluoride triacetate (**2**) 16%, ϕ_c +127.8, $J_{1,F}$ 49.5 Hz; $J_{2,F}$ ca. 2 Hz; 2-chloro-2-deoxy-β-D-mannopyranosyl fluoride triacetate (**5**) 16%, ϕ_c +118.6, $J_{1,F}$ 49.4 Hz; $J_{2,F}$ 3.6 Hz; 2-chloro-2-deoxy-α-D-glucopyranosyl fluoride triacetate (**4**), 6%, ϕ_c +147.6, $J_{1,F}$ 51.2 Hz; $J_{2,F}$ 24.0 Hz; and 2-chloro-2-deoxy-β-D-glucopyranosyl fluoride triacetate (**3**) 62%, ϕ_c +138.9, $J_{1,F}$ 51.0 Hz; $J_{2,F}$ 10.6 Hz.

Over the course of several days at ca. 0°, an ethanolic solution of the reaction product precipitated the α-D-*manno* isomer (**2**) (0.17 g, 10%). Recrystallization from

[4]The only modification required was that benzene (20 ml) was added to the acetonitrile solution and the chlorine gas was bubbled into the stirred solution. Excess chlorine was subsequently removed with a stream of dry air.

aqueous ethanol afforded pure **2**; m.p. 120–121°, $[\alpha]_D^{25}$ −23.4° (*c*, 0.96, $CHCl_3$).

Anal. Calcd. for $C_{12}H_{16}O_7ClF$: C, 44.1; H, 4.9; F, 5.9. Found: C, 44.3; H, 5.1; F, 5.6.

The mother liquors, when seeded with an authentic sample of **3** yielded 0.83 g (51%) of the β-D-*gluco* isomer which when recrystallized from aqueous ethanol afforded crystalline plates; m.p. 77–78°, $[\alpha]_D^{25}$ +124° (*c*, 1.13, $CHCl_3$).

Anal. Calcd. for $C_{12}H_{16}O_7ClF$: C, 44.1; H, 4.9; F, 5.9. Found: C, 44.15; H, 5.1; F, 5.8.

The remaining compounds (**4**) and (**5**) were not obtained crystalline from this reaction.

(b) Generation from N-chlorosuccinimide and anhydrous liquid HF—The reaction of D-glucal triacetate (**1**) with anhydrous liquid HF and *N*-chlorosuccinimide did not lead to any fluorine containing material (^{19}F n.m.r.).

Addition of the Elements of "ClOBz" to 1

D-Glucal triacetate (**1**) (5.6 g) was dissolved in dry benzene (70 ml) containing silver benzoate (5.6 g) and chlorine gas was bubbled in until an excess was present as evidenced by the color of the solution. After 20 min the excess chlorine was removed by a stream of dry air. The resulting solution was filtered and successively extracted with aqueous sodium thiosulfate, aqueous sodium bicarbonate and water. The benzene solution was dried (Na_2SO_4) and evaporated to a clear syrup (8.9 g, 105%).

The reaction product was dissolved in ethanol and after standing at −5° overnight, deposited crystals (1.3 g, 15%) m.p. 150–153°. Recrystallization twice from ethanol afforded 1-*O*-benzoyl-2-chloro-2-deoxy-α-D-glucopyranose triacetate (**7**) as needles, m.p. 153–154°, $[\alpha]_D^{28}$ +195.0° (*c*, 0.50, $CHCl_3$).

Anal. Calcd. for $C_{19}H_{21}O_9Cl$: C, 53.2; H, 4.9; Cl, 8.3. Found: C, 53.3; H, 5.05; Cl, 8.25.

The mother liquors remaining after isolation of **7**, deposited light needles (0.37 g, 4.2%) of 1-*O*-benzoyl-2-chloro-2-deoxy-α-D-mannopyranose triacetate (**6**). Recrystallized from ethanol afforded pure **6**, m.p. 169–170°, $[\alpha]_D^{28}$ +79.3° (*c*, 0.52, $CHCl_3$).

Anal. Calcd. for $C_{19}H_{21}O_9Cl$: C, 53.2; H, 4.9; Cl, 8.3. Found: C, 53.0; H, 4.95; Cl, 8.4.

Proton magnetic resonance (p.m.r.) analysis showed that a major component remaining in solution was 2-chloro-2-deoxy-α-D-glucopyranosyl chloride triacetate (**8**). It was identified from comparison of its p.m.r. spectrum with that published by Lemieux and Fraser-Reid (4). No attempt was made to purify further this compound.

Stereoselective Syntheses

2-Chloro-2-Deoxy-α-D-Glucopyranosyl Fluoride Triacetate (4)

1-*O*-Benzoyl-2-chloro-2-deoxy-α-D-glucopyranose triacetate (**7**) (0.50 g) was converted to the desired fluoride (**4**) by the action of anhydrous hydrogen fluoride, (yield 0.23 g, 60%) m.p. 87–95°. Three recrystallizations from aqueous ethanol afforded needle-like crystals of the fluoride (**4**); m.p. 95–97°, $[\alpha]_D^{25}$ +203° (*c*, 1.13, $CHCl_3$).

Anal. Calcd. for $C_{12}H_{16}O_7ClF$: C, 44.1; H, 4.9; F, 5.9. Found: C, 44.05; H, 5.1; F, 5.65.

2-Chloro-2-Deoxy-β-D-Glucopyranosyl Fluoride Triacetate (3)

1-*O*-Benzoyl-2-chloro-2-deoxy-α-D-glucopyranose triacetate (**7**) (0.50 g) was converted to the corresponding bromide. Proton magnetic resonance showed that the desired bromide had formed in ca. 86% yield, and that the remainder was unreacted starting material. The crude bromide was dissolved in acetonitrile (25 ml) and silver monofluoride (1 g) was added. This mixture was shaken for ca. 20 min (until no more silver halide was precipitated). Standard work-up produced a partially crystalline product (0.38 g), which was found (by p.m.r.) to consist of three components. They were identified as starting material (**7**), the corresponding β-D-benzoate (**9**), and the desired β-D-fluoride (**3**). ^{19}F Nuclear magnetic resonance showed that only one fluoride (**3**) had formed, none of the corresponding *cis* fluoride (**4**) could be detected.

This syrupy material was dissolved in ethanol (20 ml) and cooled to ca. 5°; after 12 h the 1-*O*-benzoyl-2-chloro-2-deoxy-β-D-glucopyranose triacetate (**9**) crystallized, and was removed from solution. Recrystallization from ethanol afforded fine needles, m.p. 160–161°, $[\alpha]_D^{25}$ +35.5 (*c*, 1.46, $CHCl_3$).

Anal. Calcd. for $C_{19}H_{21}O_9Cl$: C, 53.2; H, 4.9; Cl, 8.3. Found: C, 53.1; H, 5.1; Cl, 8.1.

The mother liquors, after removal of **9**, were left a further 24 h at ca. 5°, during which time the chloro-benzoate (**7**) was precipitated. This filtrate was then diluted with petroleum ether (15 ml) and cooled to ca. −5° and after several days impure crystals of the fluoride (**4**) were obtained. These crystals were recrystallized from aqueous ethanol three times but were not obtained pure (m.p. 75–82°); p.m.r. showed that they were contaminated with chloro-benzoate (**7**). These crystals were nevertheless suitable for seeding the solution obtained from the chloro-fluorination reaction described previously.

1-O-Benzoyl-2-Chloro-2-Deoxy-β-D-Glucopyranose Triacetate (9)

D-Glucal triacetate (**1**) (1.36 g) was dissolved in 25 ml CCl_4 and cooled to 0°. Chlorine was bubbled into the solution until an excess was present; after 25 min air was passed through the solution to remove the excess chlorine. This solution was then heated under reflux for 45 min with silver benzoate (2 g). Only the dichloride starting material was observed (p.m.r. evidence).

This dichloride was then dissolved in hydrogen bromide/acetic acid (35% w/w) and left for 4 h at room temperature. Standard work-up yielded a syrup which was heated under reflux with AgOBz in CCl_4 for 1 h. The solution was filtered and concentrated. Crystals (1.50 g, 70%) were obtained which were recrystallized from aqueous ethanol. These light needles proved to be the desired benzoate (**9**); the m.p. and mixture m.p., with a sample previously obtained, were 160–161°.

The high stability of the chlorine adducts of D-glucal triacetate was further demonstrated with the following reaction. The material obtained from the chlorination of **1** was dissolved in a solution of benzene and acetonitrile (2:1 v/v) containing silver monofluoride. This chlorine exchange reaction was observed to be very slow, after 30 h at room temperature ca. 5% of the dichlorides had been converted into the *trans* chloro-fluorides (**2**) and (**3**).

Interestingly it was observed that the D-*manno* isomer(s) exchanged preferentially.

Note Added in Proof:—Since the preparation of this manuscript Igarashi *et al.* (8) have re-investigated the addition of chlorine to D-glucal triacetate (1) and have been able to obtain all four diastereoisomers. They noted that the two *cis* isomers were predominant from the chlorination of **1** in CCl_4. It was concluded, therefore, that this reaction "mainly proceeds by way of a four-centered transition state or a concerted mechanism". It is interesting to note that the major product from this reaction is the α-D-gluco isomer, whereas that from the "ClF" addition is the β-D-gluco isomer. Possibly this reflects the different nature of the intermediates in these two reactions and/or the important role played by the solvent during addition reactions of glycols.

Aromatic oxidation by cobaltic acetate in acetic acid

KOICHIRO SAKOTA,[1] YOSHIO KAMIYA,[2] AND NOBUTO OHTA[2]
Department of Fuel Technology, Faculty of Engineering, Tokyo University, Bunkyo-ku, Tokyo, Japan
Received May 9, 1968

A detailed kinetic study of oxidation of toluene and its derivatives by cobaltic acetate in 95 vol% acetic acid is reported. The reaction was found to be profoundly affected by a steric factor and rather insensitive to the C—H bond energy. The order of reactivities of various alkylbenzenes is quite reversal to that of hydrogen abstraction reactions. The reaction was of first-order with respect to toluene, of second-order with respect to cobaltic ion and of inverse first-order with respect to cobaltous ion. The oxidation by cobaltic ion seems to proceed via an initial reversible electron transfer from toluene to cobaltic ion, yielding $(\phi CH_3)^+$ which is oxidized into benzyl acetate by another cobaltic ion. The apparent activation energy for toluene was found to be 25.3 kcal mole^{-1}, and the same activation energy was found for ethylbenzene, cumene, diphenylmethane, and triphenylmethane.

There have been many papers discussing the mechanism of an initiation step in autoxidation. But the detailed explanation of the roles played by the transition metal ions as catalyst has not been fully given. The main role established in autoxidation is to decompose hydroperoxide (1) into radicals which can abstract hydrogen from reactants, namely via the Harber–Weiss mechanism. Recently the other roles of transition

$$M^{n+} + ROOH \rightarrow RO\cdot + OH^- + M^{n+1}$$

$$M^{n+1} + ROOH \rightarrow ROO\cdot + H^+ + M^{n+}$$

metal ions have been studied. One of them is the oxidation by higher valence state ion itself involving hydrogen abstraction.

$$M^{n+1} + RH \rightarrow M^{n+} + R\cdot + H^+$$

Bawn and Sharp explained their kinetic results on the autoxidation of benzaldehyde and acetaldehyde in terms of this hydrogen-abstraction mechanism. The overall oxidation could be appreciably accelerated by this reaction only if the reoxidation of cobaltous ion were fast. The reactions where a ligand undergoes oxidation by the central ion via electron transfer have been reported and are of much interest. The acceleration effect of methyl ethyl ketone (2) and acetaldehyde (3) on the autoxidation of *p*-toluic acid could be explained on the basis of oxidation of *p*-toluic acid by cobaltic ion. Oxidation of toluene in 50% aqueous methyl cyanide by cobaltic perchlorate (4) is reported to follow the kinetic scheme below.

$$\phi CH_3 + Co^{3+}{}_{aq} \rightarrow \phi CH_2\cdot + Co^{2+}{}_{aq} + H_3O^+$$

$$\phi CH_2\cdot + Co^{3+}{}_{aq} \rightarrow \phi CH_2OH + Co^{2+}{}_{aq} + H_3O^+$$

Here it should be mentioned that cobaltic acetate is a weak oxidant for the hydrocarbons as compared with cobaltic sulfate and cobaltic perchlorate. Oxidation of *p*-methoxy toluene by manganic acetate in glacial acetic acid (5) is reported to proceed via an electron transfer as follows.

$$ArCH_3 + Mn(OAc)_3 \rightleftarrows [(ArCH_3)^+, AcO^-] + Mn(OAc)_2$$

$$[(ArCH_3)^+, AcO^-] \rightarrow ArCH_2\cdot + AcOH$$

$$ArCH_2\cdot + Mn^{3+} \rightarrow ArCH_2{}^+ + Mn^{2+}$$

$$ArCH_2{}^+ + AcOH \rightarrow ArCH_2OAc + H^+$$

Oxidation of toluene by cobaltic acetate in acetic acid is supposed to follow the similar mechanism to that by manganic acetate. But some changes in the mechanism are expected when manganic ion is replaced with cobaltic ion because of the differences in redox potentials and so on.

It is of interest to obtain the value of the rate constant of oxidation by cobaltic acetate in acetic acid in the absence of molecular oxygen and to clarify the mechanism, because cobalt ions exhibit a strong catalysis in the autoxidation of many hydrocarbons in acetic acid.

Results and Discussion

Kinetic studies were carried out on toluene and its derivatives mainly at 40 °C in 95% acetic

acid solution. Oxygen was carefully excluded and every run was made under purified argon atmosphere, because hydrocarbons are easily autoxidized under the conditions employed here. The reactions were followed by potentiometric titration of cobaltic acetate and cobaltous acetate separately. The reactions were carried out under conditions where the concentration change of hydrocarbons is substantially small in comparison with the initial concentration. The plots of concentration of cobaltic ion against reaction time gave no simple relations. However, a function was found which established a satisfactory linear relation against reaction time. It is convenient at this point to introduce the symbols used here. They are as follows: x, a, y, Θ and t are the concentrations of cobaltic acetate, of cobaltic acetate plus cobaltous acetate, of hydrocarbon to be oxidized (in M), the portion of cobaltic acetate to the total concentration of cobalt ions, and reaction time (in min), respectively. A typical plot of Θ vs. t as well as the plot of $1/\Theta + \log \Theta$ vs. t are shown in Fig. 1. The latter plot of $1/\Theta + \log \Theta$ gave a satisfactory straight line. Therefore,

$$[1] \qquad 1/\Theta + \log \Theta = kt + \text{constant},$$

where k is the slope of the line.

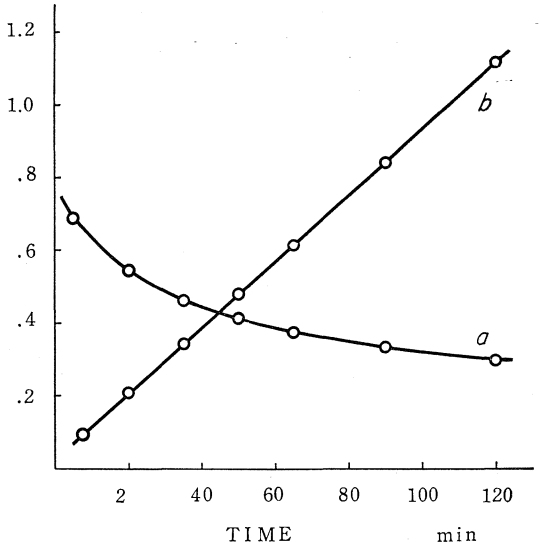

FIG. 1. A typical kinetic run, plots of Θ and $1/\Theta + \log \Theta$ vs. t at 40 °C, $[\phi CH_3] = 1.88$ mole l^{-1}, [cobalt] = $2 \cdot 10^{-2}$ mole l^{-1}; $a : \Theta$; $b : 1/\Theta + \log \Theta$.

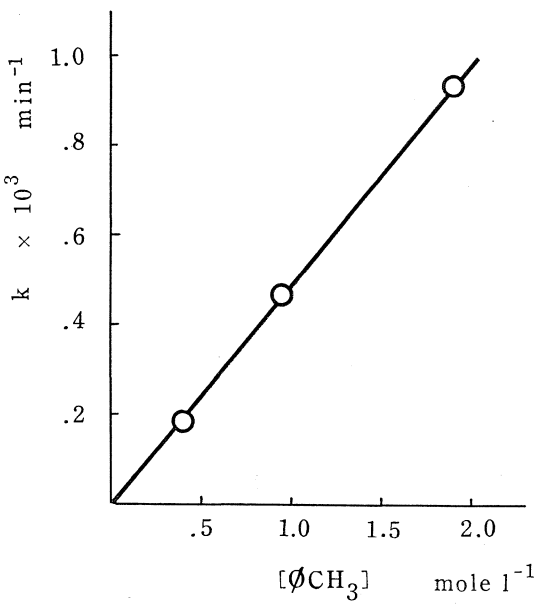

FIG. 2. Plots of k vs. initial concentrations of toluene.

Taking the derivative of both sides of eq. [1], we get

$$[2] \qquad -d\Theta/dt = k \cdot \Theta^2 \cdot (1-\Theta)^{-1}$$

Since $x = a \cdot \Theta$,

$$[3] \qquad -dx/dt = k \cdot x^2 \cdot (a-x)^{-1}$$

In other words, the oxidation by cobaltic acetate was found to follow the kinetic law below.

$$[4] \quad -d[Co^{3+}]/dt = k \cdot [Co^{3+}]^2 \cdot [Co^{2+}]^{-1}$$

k which was established as the slope of the line was found to be proportional to the initial concentration of toluene as shown in Fig. 2. Using these results, we get

$$[5] \quad -d[Co^{3+}]/dt = k_{obs} \cdot [\phi CH_3] \cdot [Co^{3+}]^2 \cdot [Co^{2+}]^{-1},$$

where $k = k_{obs} \cdot [\phi CH_3]$.

The stoichiometry of this reaction was found as follows.

$$\phi CH_3 + 2\ Co^{3+} \rightarrow \phi CH_2OAc + 2\ Co^{2+} + AcOH$$

The integral of both sides of eq. [5] with the value of two for dx/dy $(= d[Co^{3+}]/d[\phi CH_3])$ gives,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[6] $a/((2b - a)x) + 2b/(2b - a)^2 \cdot \log x/(x - a + 2b) = k_{obs} \cdot t/2 + \text{constant}$,

where b is equal to y at time $t = 0$.

When the assumption $b \gg a$ and $b \gg x$, is satisfied, eq. [6] can be simply expressed as eq. [7].

[7] $a/x + \log x = b \cdot k_{obs} \cdot t + \text{constant}$

Since $x = a \cdot \Theta$, eq. [7] is equivalent to eq. [1]. Under the conditions where the assumption $b \gg a$ and $b \gg x$ is not satisfied, k_{obs}'s was established from eq. [6] using an Okitac computer. The oxidation of *p*-methoxytoluene by manganic acetate in acetic acid has been reported (5) to follow the kinetic law [8],

[8] $-\mathrm{d}[Mn^{3+}]/\mathrm{d}t = k' \cdot [CH_3O—C_6H_4CH_3] \cdot [Mn^{3+}] \cdot [Mn^{2+}]^{-1}$

By using Θ and with the assumption of $b \gg a$ and $b \gg x$, eq. [8] is rewritten as follows:

[9] $\Theta + \log 1/\Theta = (b \cdot k'/a) \cdot t + \text{constant}$

If this reaction does follow the kinetic law [8], the slope of the line, k $(=b \cdot k'/a)$ established by the plot of $(\Theta + \log 1/\Theta)$ vs. t must be inversely proportional to the total concentration of cobalt ions. And k_{obs} $(=k/b)$ must also be of the same dependence as k. If the reaction follows the kinetic law [5], the slope of the line, k and k_{obs} $(=k/b)$ must be independent of the total concentration of cobalt ions. It is convenient to mention at this point that the functions $(1/\Theta + \log \Theta)$ and $(\Theta + \log 1/\Theta)$ behave similarly to each other according to the change of Θ. The expansions of both functions in terms of α are:

$$1/\Theta + \log \Theta = 1 + 1/2\,\alpha^2 + 2/3\,\alpha^3$$

$$\Theta + \log 1/\Theta = 1 + 1/2\,\alpha^2 + 1/3\,\alpha^3,$$

where $\alpha = 1 - \Theta$.

These expansions suggest that it is not only necessary to carry out the runs to the extent where the decrease in Θ is large enough, but also to examine the dependence of k_{obs} (or k) on the total concentration of cobalt ions in order to determine which law is obeyed in this reaction, eq. [1] or eq. [9]. Figure 3 shows a plot of k_{obs} against the total concentration of cobalt ions (line *a*). Here again a linear plot was obtained, implying that the kinetic law [1] is operative. But the line had a small negative slope and was not completely independent of the total concentration of cobalt ions. This may be easily explained in terms of a cobalt monomer–dimer equilibrium (6), i.e., $2\,M \overset{K}{\rightleftarrows} D$, where only the monomeric species being active (7) in this reaction. It is also known that cobaltous ion has little tendency to form polymeric species contrary to cobaltic ion. The concentration of monomeric cobaltic ion is equal to $(\sqrt{1 + 8Kx} - 1)/4K$, where K is the equilibrium constant. Substitution of this term into eq. [5] and taking the integral of the equation result in eq. [10].

[10] $(1 + 8Kx)/4 + (1 + 8kx)^{1/2} + (1 - 4Kx)((1 + 8Kx)^{1/2} - 1) = k_{obs} \cdot b \cdot t$

The rate constants corrected in terms of a monomer–dimer equilibrium are obtained using eq. [10] with the aid of a computer using a method of least squares. The employed value of K was 0.3 M^{-1}. The plot of these corrected constants gives a linear line parallel to an abscissa, in Fig. 3 (line *b*). When hydrocarbons are absent, the decrease of the concentration of cobaltic ion in acetic acid solution was not observed under the reaction conditions employed here. Then the reactions where water or acetic acid is oxidized to yield hydroxy or alkyl radicals need not be considered. The outstanding point is that rates are inversely proportional to the concentration of cobaltous ion as was shown in eq. [5]. This inverse dependence is easily explained when a reversible step is assumed. Only the electron transfer below can readily explain a reversible step.

[11] $\phi CH_3 + Co^{3+} \rightleftarrows (\phi CH_3)^+ + Co^{2+}$

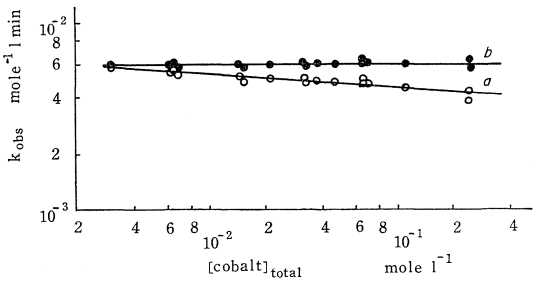

FIG. 3. Dependence of rate constant on the total concentration of cobalt ions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The further fate of the incipient ion, ϕCH_3^+ is the next question. The incipient ion may either undergo self-decomposition into a benzyl radical and a proton or react with cobaltic ion when the life time of toluene ion is long enough. It is determined by the degree of the stability of toluene ion and the oxidizing power of cobaltic ion in acetic acid. The second-order dependence on the concentration of cobaltic acetate supports the reaction path below. A disproportionation step is not

$$[12]\quad \phi CH_3^+ + Co^{3+} \rightarrow \phi CH_2OAc + Co^{2+}$$

probable, since the existence of Co^{4+} ion in this reaction is vague and its participation is still more unlikely.

Kinetic studies led to the formulation of the reaction as initial electron transfer from toluene to cobaltic ion to give the toluene cation. Toluene cations then react with cobaltic ion to give benzyl acetate. The tentative mechanism which is consistent with the experimental results is as follows:

$$[13]\quad Co^{3+}(AcO)_3 + \phi CH_3 \rightleftarrows Co^{2+}(AcO)_2 + [(\phi CH_3)^+, AcO^-]$$

$$[14]\quad [(\phi CH_3)^+, AcO^-] + Co^{3+}(AcO)_3 \xrightarrow{k_2} \phi CH_2OAc + Co^{2+}(AcO)_2 + AcOH$$

This will lead to the kinetic expression below.

$$[15]\quad -d[Co^{3+}]/dt = 2k_1k_2[\phi CH_3] \cdot [Co^{3+}]^2/(k_{-1}[Co^{2+}] + k_2[Co^{3+}])$$

When the electron transfer step is rate-determining, $k_1[Co^{3+}]\cdot[\phi CH_3]$ is smaller than $k_2[(\phi CH_3)^+, AcO^-]\cdot[Co^{3+}]$. When $k_2[(\phi CH_3)^+, AcO^-]\cdot[Co^{3+}]$ is much smaller than $k_{-1}[(\phi CH_3)^+]\cdot[Co^{2+}]$, then we obtain eq. [16] from eq. [15],

$$[16]\quad -d[Co^{3+}]/dt = 2k_1k_2k_{-1}^{-1}[\phi CH_3]\cdot[Co^{3+}]^2\cdot[Co^{2+}]^{-1},$$

which is identical with eq. [5].

Rate constants were estimated by means of the Hammett relationship (Fig. 4). The ρ value obtained vs. σ^+ was −0.7. Negative value of ρ shows that electron withdrawing substituents retard the reaction in agreement with the oxidation of substituted toluenes by organic and halogen radicals. The ρ values for abstraction of benzylic hydrogen atoms by trichloromethyl (8), *t*-butoxy (9), *p*-chlorobenzoylperoxy (10), and bromine (11) radicals are reported to be −1.46, −0.68, −1.668, and −1.38, respectively. Although the ρ of −0.7 does not exclude the possibility that the C—H bond rupture (hydrogen or hydride abstraction) is rate-determining (k_2), it is very easily explained when the electron transfer step (k_1) is rate-determining. When the C—H bond rupture process is the rate-determining step, the reaction has a large negative value of ρ and depends strongly on the C—H bond energy. And the order of the rate constants also holds as tertiary hydrogen > secondary hydrogen > primary hydrogen. The Arrhenius plot for oxidation by cobaltic ion is shown in Fig. 5. The same apparent activation energies (25.3 kcal/mole) were found for toluene, ethylbenzene, cumene, diphenylmethane, and triphenylmethane. The effect of the strength of the bond being broken on the rate is summarized in Table I. The order of relative reactivities per active hydrogen was found to be reversal to that of the C—H bond energy. The replacement of hydrogen atoms in a side chain of toluene with a methyl or a phenyl group did not change the apparent activation energy. But the rate constant was profoundly affected in an inverse way to the cases of oxidation by radicals. These results are not explicable in terms of the C—H bond rupture process, but support that the electron transfer process is rate-determining. The C—H bond is considered to be scarcely elongated in the rate-

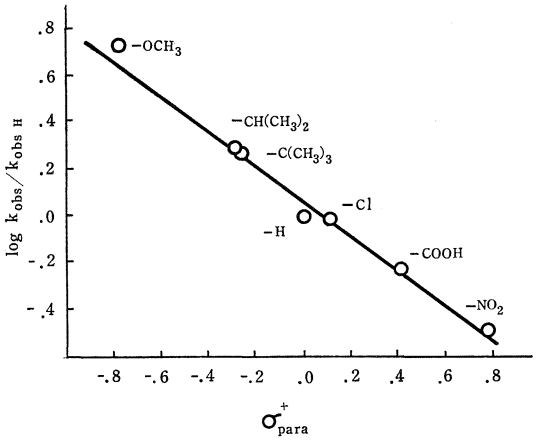

FIG. 4. Substituent effect in oxidation of toluene by cobaltic acetate at 40 °C.

NOTE: Only benzylic hydrogens are considered labile.

determining step. And the distortion which reduces the internal rotations of hydrocarbon is a main factor in that step. The difference in reactivities toward cobaltic acetate may be ascribed to that of the entropy decrease of the hydrocarbon in the transition state. If hydrogen atom in methyl group of toluene is replaced by a group with many more internal degrees of freedom, the activation process will also be accompanied by a greater loss of internal motions. This results in unfavorable decrease of activation entropy, which explains, for example, fivefold decrease in the rate of cumene relative to toluene. Hydrogen abstraction from cumene by cumylperoxy radical proceeds thirty times faster than that from toluene in contrast to this oxidation by cobaltic ion. The reaction [12] may be expressed more adequately as follows:

$$[(\phi CH_3)^+, AcO^-] + Co^{3+}(AcO)_3$$
$$\rightarrow [[(\phi CH_3)^+ + OAc^-] \leftrightarrow$$
$$[(\phi CH_2\cdot) + HOAc]] + Co^{3+}(AcO)_3$$
$$\rightarrow [(\phi CH_2\cdot) + Co^{3+} + HOAc]$$
$$\rightarrow \phi CH_2OAc + Co^{2+}(OAc)_2 + AcOH$$

If the above is accepted as a proper interpretation of the course of the reaction [12], let us turn to the problem concerning the initiation mechanism of autoxidation tentatively proposed as follows:

$$RH + Co^{3+} \rightarrow R\cdot + Co^{2+} + H^+$$

When a sufficient amount of molecular oxygen is present, benzylperoxy radical which can initiate the chain of autoxidation can possibly be expected to be produced instead of (or together with) benzyl acetate in this reaction.

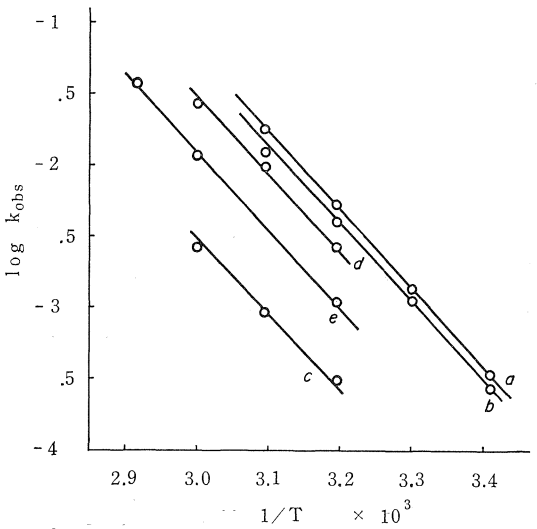

FIG. 5. Effect of temperature on rate of consumption of cobaltic acetate; *A* : toluene; *b* : ethylbenzene; *c* : cumene; *d* : diphenylmethane; *e* : triphenylmethane (solvent : AcOH/ϕH = 1 (v/v)).

Experimental

Analytical Method

The concentration of cobaltic acetate was determined by potentiometric titration (7). A known volume of the solution was added to a 1 *M* sulfuric acid solution containing a known excess of standard ferrous ammonium sulfate. After standing until the initial green color disappeared (ca. 5 min), the solution was back-titrated with standard ceric sulfate solution. Titration curves were obtained with the aid of a Yokogawa "PKH-11A" pH meter. A procedure for cobaltous acetate (15) was also a potentiometric one. Cobaltous acetate was oxidized in an ammoniacal solution containing ammonium citrate with potassium ferricyanide. The excess potassium ferricyanide was back-titrated with standard cobaltous acetate solution. Other methods, such as polarography and potentiometric titration with EDTA did not give satisfactory results.

Materials

The preparations of cobaltic acetate and perchlorate

have been reported by many authors. In the case of acetic acid solution there are two ways to avoid the difficulties caused by low electric conductivity. One is to add electrolyte, such as sodium acetate and the other is to use acetic acid – water solution as solvent. We adopted 95 vol% acetic acid solution. This amount of water did not disturb elucidation of the mechanism of oxidation by cobaltic acetate. And cobaltic acetate was found to be stable enough to carry out the reaction in this solution. Anodic oxidation was used for the preparation of the cobaltic acetate at room temperature at ca. 10 V. The electrolysis cell was made of polyethylene and separated into two rooms with an ion exchange film "Selemion CMV" made by Asahi Glass Co., one with a platinum electrode and another with a stainless steel electrode.

Procedure

The reaction vessel is a ca. 60 ml glass flask with two necks, one at the top and another at the side of the flask. The vessel was connected through a Tygon tube to a vacuum line and an argon reservoir. The solution was de-gassed as usual and the vessel was filled with purified argon. After thermal equilibrium had been attained, samples of the solution were withdrawn through a side neck at appropriate intervals with a current of purified argon. The volume of each sample was 5 ml. Determination of cobaltic and cobaltous acetate was carried out by potentiometric titration.

Some aspects of the formation of hex-2-enopyranosides from methyl 2,3-di-*O*-methanesulfonyl-α-D-glucopyranosides

BERT FRASER-REID[1] AND (MRS.) BAHYA BOCTOR
Chemistry Department, University of Waterloo, Waterloo, Ontario
Received August 6, 1968

The elimination of vicinal sulfonyloxy groups from methyl 2,3-di-*O*-methanesulfonyl-α-D-glucopyranosides with the formation of hex-2-enopyranosides using potassium iodide, and zinc in refluxing dry dimethyl formamide has been investigated. The specific use of a zinc–copper couple has been found to be highly advantageous to the yield and reproducibility of the reaction, and the elimination proceeds successfully whether acid or base labile groups are present at carbon-4 or -6. Both the 4,6-di-*O*-benzoyl (**3***b*) and the 6-*O*-benzoyl (**3***d*) precursors give methyl 6-*O*-benzoyl-α-D-*erythro*-hex-2-enopyranoside (**4***d*) as the major product, the latter also being obtainable by selective benzoylation of methyl α-D-*erythro*-hex-2-enopyranoside (**4***c*). The reaction of the dibenzoate therefore occurs with some deacylation at carbon-4, but it is noteworthy that this is not accompanied by any epimerization. A similar pattern of reaction apparently occurs with the 4,6-di-*O*-acetyl derivative (**3***a*). The conformations of the starting di-*O*-methanesulfonyl esters are discussed and suggestions for the n.m.r. assignments of the groups are made.

For certain projects underway in this laboratory it is necessary to have available in fairly large quantities various substituted methyl hex-2- or hex-3-enopyranosides. These compounds are of interest because of their possible biological significance (1), and because of their projected utility for the synthesis of "rare and modified" sugars (2) as well as higher saccharides (3). Of the two classes of olefins, the hex-2-enopyranosides such as **4** are better known, having been first prepared over 30 years ago (4).

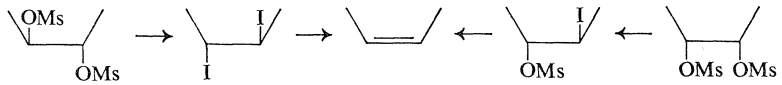
At the time this work was undertaken the main routes to the hex-2-enopyranosides were (*a*) the high temperature reaction of alcohols with acylated glycals which proceeds with concomitant rearrangement of the double bond and displacement of the carbon-3 function (5, 6) and (*b*) the elimination of vicinal sulfonyloxy groups by potassium ethyl xanthate (7). We considered it desirable to have a method of preparation applicable to a wide variety of substrates. The elimination method (*b*) cannot be utilized for the preparation of **4***a*, for example, because when the compound **3***a* was treated for 1 h with xanthate, the recovered material had undergone extensive decomposition including the loss of the glucosidic methoxyl group, and contained none of the desired olefin. On the other hand the high temperature rearrangement (5, 6) gives mixtures of anomers,[2] and since acid is liberated during the reaction, the method might prove inapplicable in the presence of acid sensitive groups. Moreover, this method may not be adaptable to the synthesis of the hex-3-enopyranosides of interest to us. Recently Lemieux, Fraga, and Watanabe (1) developed a third synthetic route to compounds such as **2** which involves the conversion of an epoxide to the iodohydrin, and treatment of the latter with a sulfonyl chloride, whereupon rapid elimination of the iodo- and sulfonyloxy-groups occurs. Since this sequence begins with an epoxide, this method would not be applicable to the formation of olefins such as **4***a* or **4***b*, in which the possibility of oxide ring migration could occur in the precursor (8, 9).

The olefin-forming reaction of Corey and Winter (10) which has been successfully used for the formation of **2** from methyl 4,6-*O*-benzylidene-α-D-mannopyranoside-2,3-thionocarbonate appears promising, but the prohibitive cost[3] of methyl α-D-mannopyranoside places this procedure beyond our economic resources for large

[1]All correspondence should be addressed to this author.

[2]A recent communication (3) indicates that conditions have been found for enhancing the stereospecificity and yield of these reactions for the preparation of compounds such as **4***a*.

[3]Rare Chemicals, K & K Laboratories, Plainview, New York.

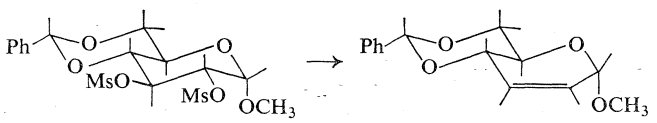


SCHEME 1

scale preparations. The related 2,3-*trans* thionocarbonate has recently been synthesized (11)[4] from less expensive α-D-glucoside precursors, but the stereospecificity of the Corey reaction makes it impossible for such a compound to furnish the olefin **2**.

The elimination of vicinal sulfonyloxy groups first reported by Tipson and Cohen (12) seemed to have none of the disadvantages cited above. This reaction, employing zinc dust and sodium iodide in refluxing dimethyl formamide, was used successfully with 3,4-disulfonate esters of 1,2:5,6-di-*O*-isopropylidene-D-mannitol. Furthermore, results on *cis* and *trans* 1,2-ditosyloxycyclohexane (13) suggested that this method might apply whether the vicinal sulfonyloxy groups existed in a *cis* or *trans* relationship. If *trans*, both groups might be replaced to give the *trans* diiodide which would rapidly form olefin (14). If *cis*, replacement of one group would give a *trans* iodomesylate which according to Cristol *et al.* (15), Newth (16), and Lemieux *et al.* (1), should also readily undergo elimination to the olefin. Of additional importance is the observation of Kochi and Singleton (17) that the solvent used in this reaction, dimethyl formamide, is particularly effective for promoting certain reductive eliminations. We now report on the use of this method for the synthesis of some hex-2-enopyranosides.

The conversion of **1** to **2** was chosen for preliminary investigation since **1** is readily available (18) and **2** has been well characterized (7, 19). A cursory study of this transformation has been reported (7) but in view of our desire to develop a method capable of relatively large scale operation[5] we pursued the investigation further. The reaction could be monitored conveniently by observing the nuclear magnetic resonance (n.m.r.) changes for the glycosidic methoxyl and the methanesulfonyl groups.



1 **2**

Since a product of the reaction is the Lewis acid zinc iodide, it is desirable to exclude water which would otherwise hydrolyze the reactive glycosidic group. Use of potassium iodide tended to improve the rate and yield of the reaction, in spite of the greater solubility (20) in organic solvents of the generally used sodium salt (7, 12, 21). Of additional significance to us is the fact that the potassium salt is less expensive (22).

In our early work, the results were very dependent upon the zinc used, and were generally erratic and unreproducible. Use of zinc–copper couple caused a remarkable improvement, and also enhanced the yield and rate of reaction. Initially the compound, **1**, potassium iodide and zinc–copper couple were used in the mole ratio 1:10:10 and the reaction proceeded to completion in 10 h, but reduction of the ratio to 1:10:5 and then to 1:5:5 did not alter the rate or the yield of the reaction. However, a further reduction to 1:2.5:5 did diminish the rate, and hence a ratio of 1:5:5 was adopted. Reasonably pure material (**2**) was isolated in about 30% yield from these large scale preparations without resorting to chromatographic fractionations (cf. 7).

[4]We are grateful to Dr. Stout for providing us with a sample of this material and for making this information available prior to its publication.

[5]If the published reaction conditions (7) were adopted, the "large scale preparation" reported below would require 3000 g of sodium iodide, 1400 g of zinc, and 5000 ml of dimethyl formamide.

Having established the general experimental procedure, we turned our attention to the diacyl derivatives **3***a* and **3***b*, readily available from **1** *via* **3***c* by conventional methods. The diacetate **3***a* underwent elimination in one-seventh the time required by **1**, presumably because the *trans*-fused benzylidene ring of **1** restricts the facility with which the equatorial sulfonyloxy groups are displaced. This constraint is absent in **3***a* and the compound may react from the unfavorable 1C conformation (Scheme 2), in which the sulfonyloxy groups, now diaxially oriented, are well disposed for displacement by iodide ion. This effect is also in evidence in eliminations of the dibenzoate, **3***b*, and monobenzoate, **3***d*, which require reaction periods of $2\frac{1}{2}$ h and 1 h, respectively. Judging from the color change in the reaction, the diol **3***c* seems to achieve elimination within 10 min.

Elimination from the diacetyl derivative **3***a* gave a product containing two hex-2-enopyranosides of R_f 0.50 ("**A**") and 0.43 ("**B**") on thin-layer chromatograms. The adverse n.m.r. ratio of methoxyl to acetoxyl protons (1:1.6), the presence of a n.m.r. signal removable by exchange with D_2O, and infrared evidence, indicated that some deacetylation had occurred. Reacetylation converted the slower moving component, "**B**", into the faster "**A**", while deacetylation gave a new hex-2-enopyranoside, "**C**". "**A**" was identified as the olefinic diacetate **4***a* (5) and "**C**" as the corresponding diol **4***c*. Prolonged reaction resulted in complete deacetylation, but the diol **4***c* accumulated in the aqueous phase during work-up and could not be conveniently recovered therefrom. Thus, the preferred route to **4***c* is *via* deacylation of **4***a* or **4***b* and not by elimination from **3***c* (see Experimental).

It was of interest to determine whether the acyl group was being lost from carbon-4 or carbon-6, assuming that deacetylation was initiated by dimethylamine produced upon thermal decomposition of dimethyl formamide (23). Because debenzoylation is a slower process than deacetylation[6] the dibenzoate was subjected to elimination for $2\frac{1}{2}$ h. The major product was a non-crystalline monobenzoyl olefin, which could also be derived by selective benzoylation of the diol **4***c*. Partial acylation customarily occurs at the primary hydroxyl group (24) in pyranosides such as **3***c*, but it was feared that the allylic hydroxyl group of **4***c* might possess abnormally high reactivity towards benzoyl chloride. Conclusive evidence that this was not the case was obtained since the 6-*O*-monobenzoyl derivative **3***d* underwent elimination to give the same olefin as that obtained in the two processes detailed above. It is to be noted that acyl groups preferentially migrate from a secondary to a primary hydroxyl group (8), and although the secondary hydroxyl group involved here is allylic, it was hoped that the

[6]Using the triethylamine – methanol – water system, de-esterification of **4***a* is complete in 1 h, while **4***b* requires upwards of 7 h (see Experimental).

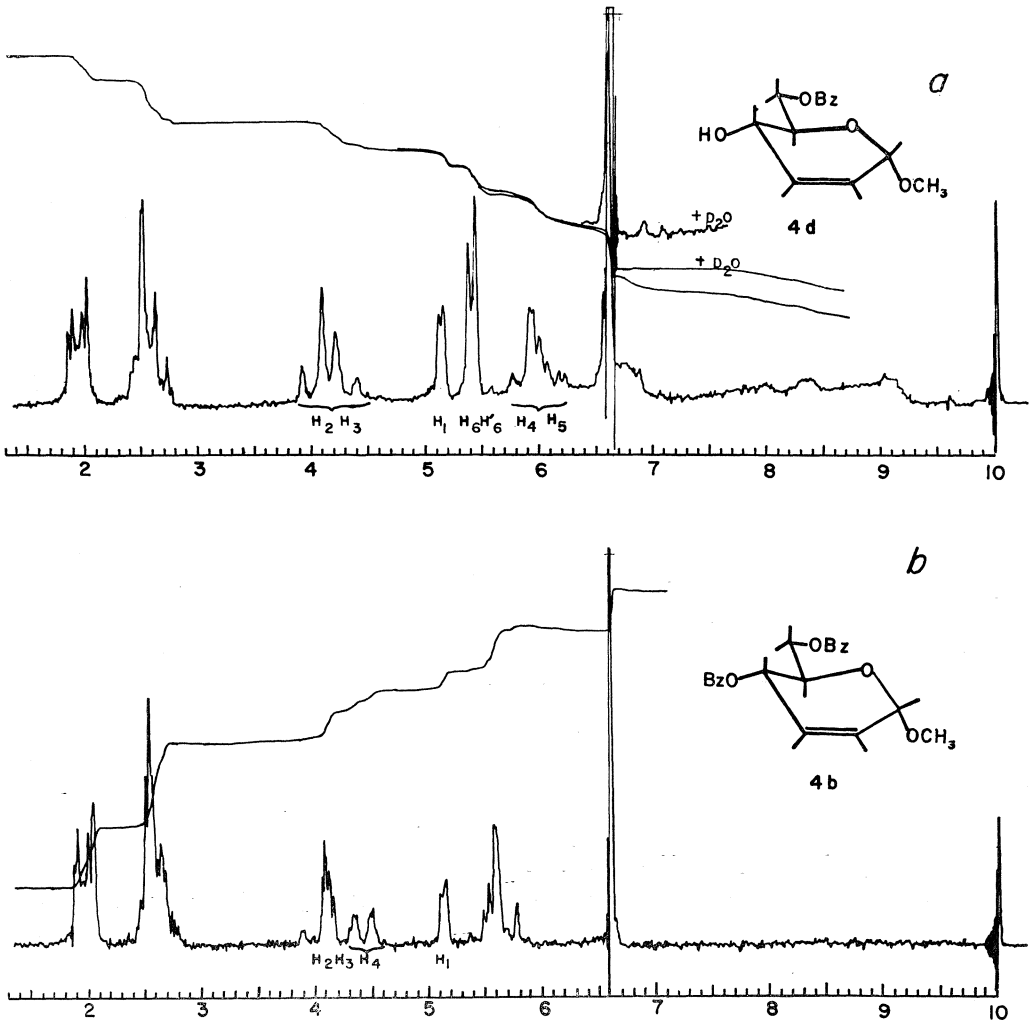

FIG. 1*a*. The nuclear magnetic resonance spectrum (60 Mc.p.s.) of methyl 6-*O*-benzoyl-α-D-erythro-hex-2-enopyranoside (**4***d*) in $CDCl_3$. *b*. The nuclear magnetic resonance spectrum (60 Mc.p.s.) of methyl 4,6-di-*O*-benzoyl-α-D-erythro-hex-2-enopyranoside (**4***b*) in $CDCl_3$.

established pattern would prevail and preclude migration of the 6-*O*-benzoyl group to the 4-position. This appears to have been the case.

The n.m.r. spectrum, Fig. 1*a*, provides independent evidence for the structure of **4***d*. The signal in the vicinity of τ 6 is acceptably located for an allylic proton (cf. 25), and in the dibenzoate, **4***b* (Fig. 1*b*), this signal is shifted 1.47 p.p.m. to lower field as is to be expected for the geminal proton upon benzoylation of a secondary hydroxyl group (26). The two benzyloxymethyl protons (H_6, H_6') of **4***d* are conveniently assigned as shown (26). Migration of the 6-*O*-benzoyl group to carbon-4 would produce a molecule in which the 4-hydrogen would resonate around τ 4.5 (cf **4***b*), and possessing a complex pattern for the hydroxy methyl function. Neither of these features is present in Fig. 1*a*. The structure of **4***d* is therefore secure. By analogy, the major product derived from the diacetate **3***a*, is therefore presumed to be **4***e*.

The foregoing discussion confirms the presence but not the *configuration* of the free hydroxyl group at carbon-4. If instead of the presumed

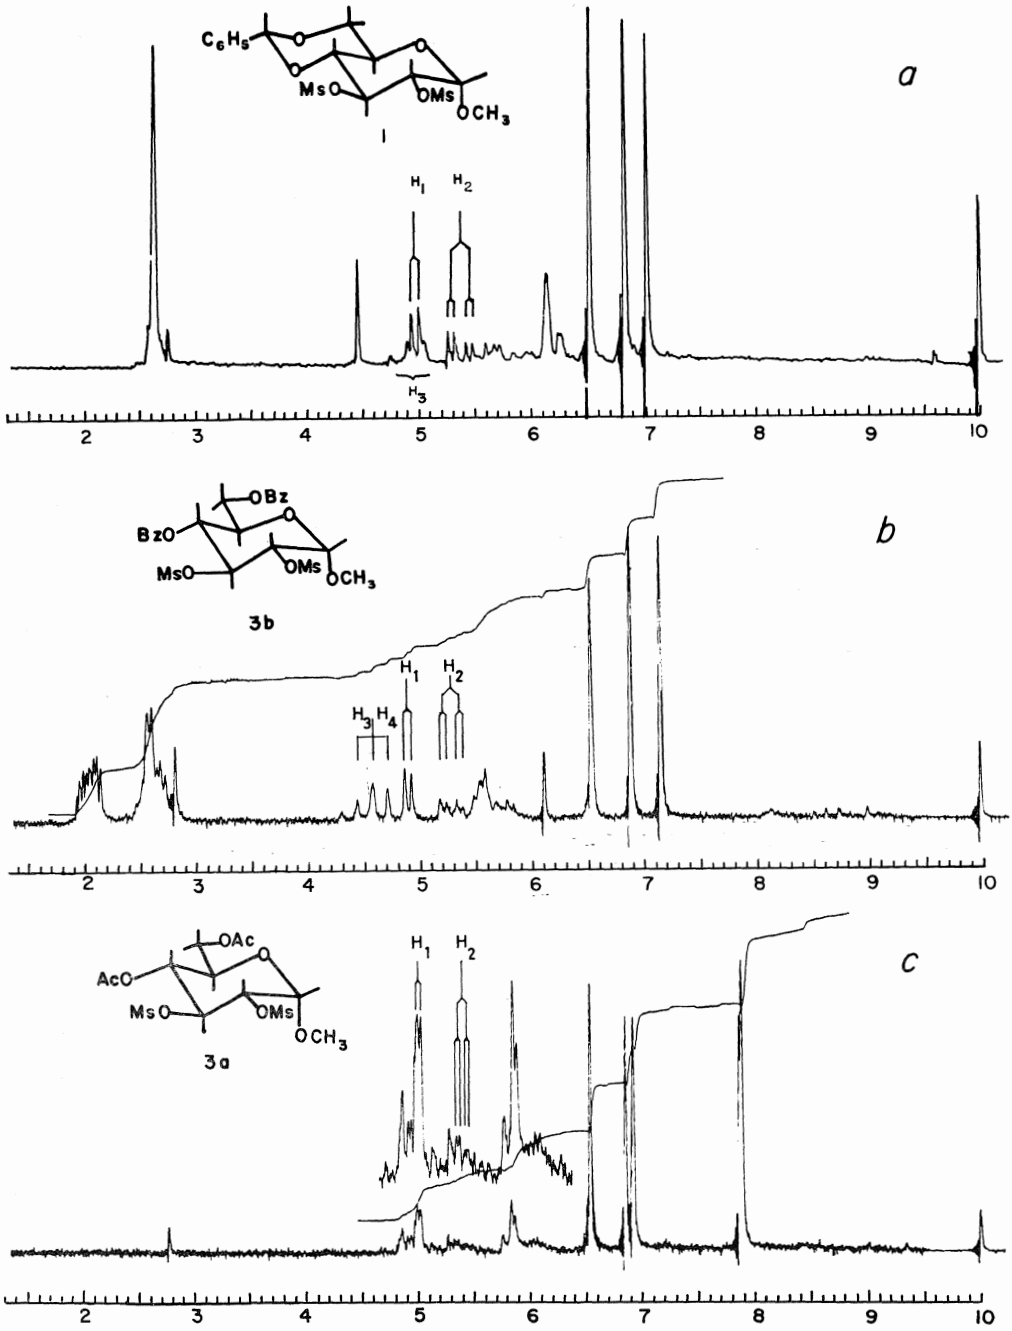

FIG. 2*a*. The nuclear magnetic resonance spectrum (60 Mc.p.s.) of 4,6-*O*-benzylidene-2,3-di-*O*-methanesulfonyl-α-D-glucopyranoside (**1**) in $CDCl_3$. *b*. The nuclear magnetic resonance spectrum (60 Mc.p.s.) of 4,6-di-*O*-benzoyl-2,3-di-*O*-methanesulfonyl-α-D-glucopyranoside (**3***b*) in $CDCl_3$. *c*. The nuclear magnetic resonance spectrum (60 Mc.p.s.) of 4,6-di-*O*-acetyl-2,3-di-*O*-methanesulfonyl-α-D-glucopyranoside (**3***a*) in $CDCl_3$.

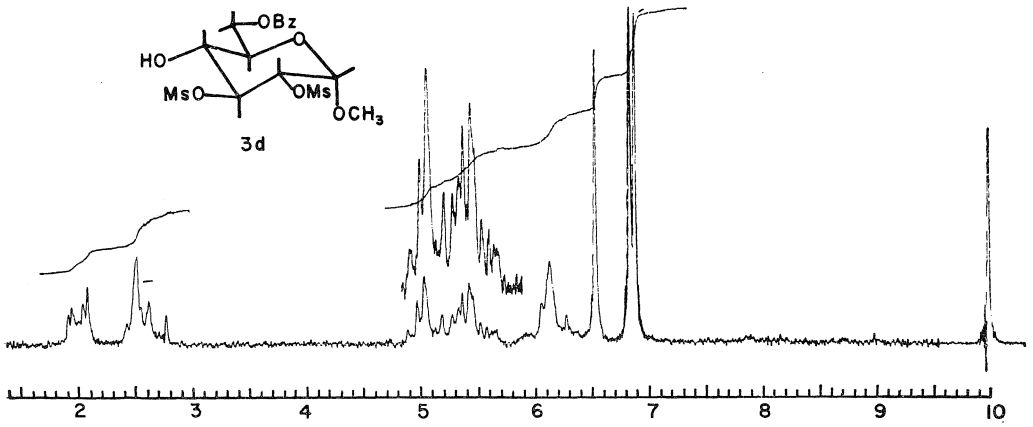

FIG. 3. The nuclear magnetic resonance spectrum of methyl 6-*O*-benzoyl-2,3-di-*O*-methanesulfonyl-α-D-gluco-pyranoside (**3***d*) in $CDCl_3$.

deacylation, an inversive displacement of the allylic acyl group occurred, the olefin obtained would be the *threo* rather than the *erythro* hexenopyranoside. Such an event warranted particular attention in view of the facility with which epimerization was found to occur at the allylic center of certain related hexenopyranosides (27). Fortunately inversion of configuration at carbon-4 of these systems is accompanied by dramatic changes in optical rotation. Thus the diacetate (**4***a*) derived by acetylation of **4***e* had an optical rotation of $+143.5°$ in full agreement with the reported value (4, 5), and vastly different from that ($-174°$) for the corresponding *threo* hex-2-enopyranoside (6).

Treatment of the monobenzoyl olefin **4***d* with benzoyl chloride in pyridine gave the dibenzoate **4***b* as a crystalline material.

Of some interest are the n.m.r. spectra shown in Fig. 2. The most striking feature in the spectra is the difference in the OSO_2CH_3 resonances of the various compounds. For the diacetate, **3***a* (Fig. 2*c*), these are separated by about 4.5 c.p.s. while in the dibenzoate **3***b* (Fig. 2*b*), the separation is about 17 c.p.s. The latter value is close to that (14 c.p.s.) found for **1** (Fig. 2*a*). These effects are presumably due to interactions introduced in the pyranose ring by the different substituents at carbons-4 and -6. The resonances for the annular protons would also be expected to reflect any changes. The assignments shown in Fig. 2 follow patterns now well entrenched for n.m.r. analysis of carbohydrate derivatives (28–31). The pronounced doublet at τ 4.96 ($J = 3.8$ c.p.s.) in Fig. **2***a* is ascribable to the anomeric proton of compound **1**, and the quartet centered at τ 5.37 with spacings of 3.8 and 9.8 c.p.s. can therefore be assigned to the 2-hydrogen. The broad multiplet around τ 4.8, partly obscured by the signal for the anomeric hydrogen, arises from a deshielded proton, strongly coupled to its neighbors. This is to be expected for the 3-hydrogen. Comparable analysis of compounds **3***a* and **3***b* results in the assignments shown in Fig. 2.

The constant chemical shift of the 2-hydrogens in compounds **1**, **3***a*, and **3***b* (Fig. 2) suggests that the geminal methanesulfonyl groups might also resonate at a relatively constant frequency. For this reason the lower-field OSO_2CH_3 signals occurring in these compounds at τ 6.85, 6.81, and 6.88, respectively, may be presumed to arise from the group attached at carbon-2. It is not surprising that the resonance of the group at carbon-3 should show greater perturbation than that at carbon-2 upon varying the substituents at carbon-4 (32). These effects are again observed for the related 6-*O*-monobenzoate, **3***d* (Fig. 3), obtained by selective benzoylation of **3***c*. The multiplet around τ 6.1 is to be expected for a proton geminal to a free secondary hydroxyl group (26). Upon benzoylation of such a hydroxyl group, the geminal proton should be shifted downfield by about 1.5 p.p.m. (26). This is seen to be correct by comparison with the dibenzoate **3***b* (Fig. 2*b*). Following the reasoning

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

above, the signal at τ 6.83 in compound **3***d* (Fig. 3) is probably assignable to the OSO_2CH_3 group at carbon-2 while the carbon-3 group, now not as shielded as in its counterpart **3***b*, would resonate at τ 6.88. Further study of these shielding and conformational effects is warranted but is outside the scope of the present communication.

The elimination of vicinal methanesulfonyloxy groups using zinc–copper couple and potassium iodide in refluxing dimethyl formamide can therefore be utilized whether or not acid or base sensitive groups are present in the molecule. The deacylation which occurs predominantly at carbon-4 may prove valuable, and it is reassuring to note that this reaction takes place without isomerization. Further work is underway to explore the applicability of the reaction for the preparation of other hexenopyranosides, and polyhydroxylated olefins in general.

Experimental

Melting points were determined on a Kofler block and are uncorrected. Nuclear magnetic resonance (n.m.r.) spectra were recorded using a JEOLCO C-60-H spectrometer with tetramethylsilane as internal standard. For analytical thin-layer chromatography Merck, Silica Gel HF_{254} was used and for preparative work the GF_{254} variety was employed. Solvent systems used for development were (*a*) benzene–chloroform (1:1), (*b*) ethyl acetate – petroleum ether (35–60 °C) (2:3) and ethyl acetate – petroleum ether (35–60 °C) (1:1). *N,N*-Dimethyl formamide was dried by refluxing over, followed by distillation from, calcium hydride. Zinc–copper couple was prepared as that used in the Simmonds–Smith reaction (33). Microanalyses were performed by Mr. A. B. Gygli, 329 St. George Street, Toronto, Ontario.

Methyl 4,6-O-Benzylidene-α-D-erythro-hexenopyranoside (2)

(i) Preliminary Experiments

(a) In a typical experiment, methyl 4,6-*O*-benzylidene-2,3-di-*O*-methanesulfonyl-α-D-glucopyranoside, **1**, (9 g, 0.02 mole) (18) was added to an efficiently stirred mixture of potassium iodide (17 g, 0.1 mole) and zinc–copper couple[7] (6.5 g, 0.1 g-atom) in 50 ml of dimethyl formamide. The solution was refluxed and at the intervals indicated, samples of the refluxing mixture were removed with a sawn-off pipette and poured into ice water. The slurry was washed with chloroform[8] filtered through a bed of Celite and the filter cake washed with a mixture of chloroform and water. The chloroform phase was washed with sodium thiosulfate solution, with water, then dried with calcium chloride and evaporated to dryness using a rotary evaporator. Most of the dimethyl formamide accumulated in the aqueous phase, but traces were removed by attaching the evaporator to a high vacuum pump. The degree of conversion of **1** to **2** was determined by comparison of the n.m.r. signal for the methoxyl groups at τ 6.52 with the OSO_2CH_3 groups at τ 6.85 and τ 7.02. This was determined to be as follows: 1 h, 43%; 3 h, 60%; 6 h, 73%; 8 h, 89%; 10 h, 100%.

(b) When the molar ratio of the di-*O*-methanesulfonate, potassium iodide and zinc–copper couple was changed from those used in part (*a*) to 1:10:5 or to 1:10:10 the reactions were also complete in 10 h.

(c) When the ratio of the reactants was reduced from that used in part (*a*) to 1:2.5:5 respectively, there was 73% conversion after 10 h.

(d) When previously dried sodium iodide (15 g, 0.1 mole) was substituted for potassium iodide under the conditions used in part (*a*), the observed conversion was as follows: 1 h, 23.5%; 3 h, 42.4%; 6 h, 67.5%; 8 h, 76.4%; 10 h, 92%; 12 h, 100%.

(ii) Large Scale Preparation

Compound **1** (180 g, 0.41 mole) was added to a mixture of potassium iodide (360 g, 2.2 moles) and zinc–copper couple (132 g, 2.0 g-atom) in dry dimethyl formamide (1 l). After refluxing with rapid stirring for 10 h, the hot solution was poured into 3500 ml ice-water mixture, chloroform (1 l) added, and the mixture stirred for 15 min. The insoluble material was removed by filtration and the filter cake was stirred with an equal mixture of chloroform and water. After repeating the latter process twice, the chloroform phases were combined and treated in a manner similar to that described above. The dried (calcium chloride) solution on evaporation afforded a brown residue which was dissolved in ethanol and boiled with charcoal for 30 min. The filtrate was concentrated and upon cooling deposited 30.5 g (29% yield) of material. After two recrystallizations from ethanol it melted at 121–122° and did not depress the melting point of an authentic sample (7). The syrup obtained from the mother liquors was eluted through a column of deactivated alumina (7) with petroleum ether (35–60 °C). Evaporation and crystallization from methanol gave an additional 2.3 g of material raising the overall yield to 32%.

Methyl 2,3-Di-O-methanesulfonyl-α-D-glucopyranoside, 3c

Methyl 4,6-*O*-benzylidene-2,3-di-*O*-methanesulfonyl-α-D-glucopyranoside, **1**, (30 g, 0.067 mole) was refluxed for 3 h with 360 ml of dioxane–water mixture (2:1) containing 10 ml of 10% sulfuric acid. The cooled solution was neutralized with sodium bicarbonate, and then extracted twice with petroleum ether to remove benzaldehyde. The aqueous layer was evaporated to dryness and traces of water removed by co-distillation with ethanol. Finally, the residue was boiled with ethanol and the inorganic salts collected by filtration. On concentration of the filtrate and cooling, **3***c* (22 g, 92%) crystallized from solution. Recrystallization from ethanol gave material (**3***c*) of melting point 150–151° $[\alpha]_D^{25}$ +82.4° (*c*, 1.06 in methanol).

Anal. Calcd. for $C_9H_{18}O_{10}S_2$: C, 30.86; H, 5.14. Found: C, 30.78; H, 5.19.

[7]Use of unactivated zinc gave a slower reaction (e.g. 21% after 1 h) and the results were also found to be unreproducible.

[8]It is to be noted that **2** unlike **1** is very insoluble in ether. Use of this solvent for extraction therefore led to erroneous estimates of the degree of conversion.

Methyl 4,6-Di-O-acetyl-2,3-di-O-methanesulfonyl-α-D-glucopyranoside, 3a

Compound **3***c* (24 g, 0.07 mole) was dissolved in pyridine (100 ml) and treated overnight with 60 ml of acetic anhydride. The excess anhydride was destroyed by addition of methanol to the ice-cold solution. The residue obtained upon evaporation was freed of pyridine by azeotropic distillation with toluene, and the resulting syrup was set to crystallize from methanol. The material obtained melted over a wide range, and n.m.r. analysis indicated that it contained methanol of crystallization. As an alternative work-up procedure, the acetylation mixture was poured into ice water, whereupon **3***a* crystallized out in an analytically pure condition; m.p. 79.5–80.5° $[\alpha]_D^{25}$ +91.7° (*c*, 1.04 in chloroform).

Anal. Calcd. for $C_{13}H_{22}O_{12}S_2$: C, 35.94; H, 5.07. Found: C, 35.71; H, 5.06.

Methyl 6-O-Benzoyl-2,3-di-O-methanesulfonyl-α-D-glucopyranoside, 3d

To a solution of compound **3***c* (20 g, 0.057 mole) in pyridine (100 ml) which had been cooled in an ice-salt bath, benzoyl chloride (6 ml, 7.17 g, 0.051 mole) was added slowly. The mixture was allowed to warm up to and stand at room temperature overnight. The benzoylated material, **3***d*, obtained in a manner analogous to that described for **3***b*, was a crystalline material of melting point 122–123° $[\alpha]_D^{25}$ = +63.2° (*c*, 0.79 in chloroform).

Anal. Calcd. for $C_{23}H_{22}O_{11}S_2$: C, 42.30; H, 4.89. Found: C, 42.61; H, 5.20.

Reductive Elimination of Methyl 4,6-Di-O-acetyl-2,3-di-O-methanesulfonyl-α-D-glucopyranoside, 3a. Methyl α-D-Erythro-hex-enopyranoside, 4c, and its 4,6-Di-O-acetate, 4a

Compound **3***a* (36 g, 0.083 mole) was refluxed in dimethyl formamide (200 ml) with zinc–copper couple (26.4 g, 0.42 g-atom) and potassium iodide (72 g, 0.43 mole). The reaction monitored previously by n.m.r. had been shown to progress as shown in Table I.

TABLE I

Reductive elimination of **3***a*

	Ratio of groups*		
Time (min)	OSO_2CH_3	OCH_3	$OCOCH_3$
20	1	2.6	5.7
40	1	4.7	9.0
60	1	5.0	9.3
75	1	7.3	12.0

*Nuclear magnetic resonance determination.

Beyond this time secondary reactions set in which resulted in deacetylation of the product. The residue obtained upon evaporation of the aqueous layer from work-up showed the presence (t.l.c.) of considerable olefinic diol, **4***c*. A reaction period of 1½ h was selected as optimal.

The product isolated in the same manner as **2** afforded 9.3 g of material which on thin-layer chromatograms (solvent system *b*) revealed two components of R_f 0.5 ("**A**") and 0.43 ("**B**"). The latter was the major component. Treatment of a 4.3 g portion of the reaction product with acetic anhydride and pyridine in the usual way gave "**A**" as the sole component. Distillation of the re-acetylated product at 110° and 0.5 mm afforded 2.15 g (ca. 25% from **3***a*) of material having identical spectral characteristics as an authentic sample of **4***a*.[9] Its optical rotation $[\alpha]_D^{25}$, was +143.5° (*c*, 0.87 in benzene) in good agreement with the literature values of +143° (34) and +139 (5) for **4***a*.

The mixture of "**A**" and "**B**" (1.0 g) was stirred with methanol – water – triethylamine (5:4:1) mixture for 1 h, after which time the liquids were removed on a rotary evaporator. Water–methanol mixture (1:1) was twice evaporated from the residue to ensure hydrolysis of any quaternary amides. A different hex-2-enopyranoside "**C**" (0.61 g) of R_f 0.36 in ethyl acetate was obtained. The non-crystalline material had an optical rotation of $[\alpha]_D^{20}$ +127.8° (*c*, 1.01 in methanol). "**C**" could be acetylated to **4***a*, selectively benzoylated to **4***d*, or fully benzoylated to **4***b*. "**C**" is therefore **4***c*.

Methyl 6-O-Benzoyl-α-D-erythro-hex-2-enopyranoside, 4d

(a) By Reductive Elimination of Compound 3b

Compound **3***b* (30 g, 0.054 mole) along with potassium iodide (42 g, 0.25 mole) and zinc–copper couple (16 g, 0.25 g-atom) was refluxed in 120 ml dimethyl formamide for 2½ h, this period of time having been previously determined in the manner already described, as being optimal for the conversion. The product (5.71 g) contained one major hexenopyranoside of R_f 0.54 (solvent system *c*) on thin-layer chromatograms. A portion of the product (0.307 g) was applied to a preparative chromatogram for development in solvent system *c*, and the appropriate zone was located by exposure to ultraviolet light. The band was separated and eluted with ethyl acetate to afford 0.121 g of non-crystalline material.

(b) By Reductive Elimination of Compound 3d

Methyl 6-*O*-benzoyl-2,3-di-*O*-methanesulfonyl-α-D-glucopyranoside, **3***d*, (9.5 g, 0.021 mole) in 45 ml of dimethyl formamide was treated with potassium iodide (16 g, 0.95 mole) and zinc–copper couple (6.0 g, 0.95 g-atom) under reflux, and the reaction followed in the usual way. The percent completion was: 30 min, 30%; 40 min, 45%; 1 h, 83%. The ratio of methoxyl to aromatic protons at these times was respectively as follows: 1:1.8; 1:1.7, and 1:2.1. At 1½ and 2 h the ratios were 1:2.7, and 1:2.6. A reaction time of 1 h was adopted, since it was evident that the methoxyl group was being lost during the reaction.

The product obtained by the customary work-up procedure weighed 1.07 g. Of this, 0.430 g was fractionated by preparative layer chromatography as described in part (*a*) above to give 0.140 g of the material of interest.

(c) From Selective Benzoylation of 4c

A pyridine (15 ml) solution of methyl α-D-erythro-hex-2-enopyranoside, **4***c*, (0.65g, 0.004 mole) was treated at ice-salt temperature with benzoyl chloride (0.44 ml,

[9]We are grateful to Dr. R. J. Ferrier for providing us with the authentic sample.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

0.525 g, 0.0037 mole). After being allowed to warm up gradually to room temperature and stand there overnight, the reaction mixture was subjected to the customary work-up procedure. The reaction product (0.492 g) contained one major component which was isolated by preparative layer chromatography as in part (*a*) above. Thereby 0.202 g of material of R_f 0.54 (solvent system *c*) was recovered.

The substance obtained by the different routes described in parts (*a*), (*b*), and (*c*) had identical R_f (0.54) in solvent system *c*, and identical infrared and n.m.r. (Fig. 1*a*) spectra. It was a non-crystalline material of optical rotation $[\alpha]_D^{25}$ +58.1° (*c*, 0.74 in chloroform) which was judged to be the title compound, **4***d*.

*Methyl 4,6-Di-O-benzoyl-α-*D*-erythro-hex-2-enopyranoside*, **4***b*

In one experiment, the product derived from the reductive elimination of compound **3***b* (see part (*a*) immediately above) was dissolved in pyridine and treated with excess benzoyl chloride. Work-up in the manner described above gave 6.5 g of a syrup essentially homogeneous by t.l.c. Prolonged cooling of a methanolic solution caused the deposition of 5.44 g (27%) of the olefinic dibenzoate **4***b*. Its melting point was 72–73°, $[\alpha]_D^{25}$ +189.5° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_{21}H_{20}O_6$: C, 49.48; H, 4.66. Found: C, 49.27; H, 4.87.

Treatment of a sample of **4***b* with methanol – water – triethylamine (5:4:1) required 7 h for conversion to the diol **4***c*.

Stereochemical dependence of vicinal H—C—O—H coupling constants

ROBERT R. FRASER, M. KAUFMAN, AND PETER MORAND
Department of Chemistry, University of Ottawa, Ottawa, Canada

AND

G. GOVIL[1]
Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received August 15, 1968

The exact analysis of the ABC type absorption due to the —CH_2OH group of 3β-acetoxy-5β,6β-oxidocholestan-19-ol provides two vicinal HCOH coupling constants for dihedral angles of 80° and 160°. A least squares fit of these and previous data in the literature to a "Karplus" relation provides values for the coefficients in such an equation. The theoretical justification for such a relation has been obtained by extended Hückel molecular orbital calculations for methanol with different dihedral angles. The practical limitations in, and applications of the relation are discussed. An effect of solvent on the vicinal coupling constants is also noted and discussed.

Introduction

The Karplus relation between the magnitude of the vicinal proton–proton coupling constant for the H—C—C—H fragment (J_{HCCH}) and the dihedral angle (ϕ) between the planes passing through H—C—C and C—C—H has been of invaluable aid in the solution of stereochemical problems (1). In its most general form, such a relation can be written as a power series limited to the second power in cos ϕ

[1] $$J_{HCCH} = A\cos^2\phi + B\cos\phi + C$$

with $A \sim 13.0$, $B \sim -1.5$ and $C \sim -0.3$ Hz. A similar angular dependence of the proton–proton coupling (J_{HCOH}) for the H—C—O—H fragment has been proposed by a number of authors (2–5) and in several papers the relation between J_{HCOH} and ϕ has been discussed on empirical grounds (6–8). However, while a functional behavior of the type given by eq. [1] for J_{HCCH} has been predicted on the basis of valence bond and molecular orbital (MO) theories and confirmed experimentally,[2] the basis for postulating the same functional form for J_{HCOH} is purely intuitive, requiring the assumption that replacement of one of the carbons by oxygen does little to disturb such a relation. Thus Bauld and Rim (4) believe that $J_{HCCH}(\phi)$ and $J_{HCOH}(\phi)$ are quantitatively comparable. Stolow and Gallo (5) on the other hand assume that $C = 0$ and solve for A and B from values of J_{HCOH} in two molecules with known stereochemistry. The experimental measurements available prior to the present paper (4, 5) were just sufficient to solve for A, B, and C and allowed no test of applicability of eq. [1] for J_{HCOH}. In this paper we wish to report our observations on the spectrum produced by the CH_2OH group of a steroidal epoxyalcohol. The coupling constants obtained from an exact analysis of this ABC system add two more measurements for testing of the Karplus relation for J_{HCOH}. The functional dependence of J_{HCOH} on cos ϕ has also been examined using calculations based on molecular orbital theory.

Molecular Orbital Calculation of J_{HCOH}

A survey (9) of the various theoretical methods employed in calculations of *vicinal* and *geminal* proton–proton coupling constants in ethane as a function of ϕ, indicates that the method employed by Fahey *et al.* (10) using extended Hückel theory (EHT) is more satisfactory than other methods. We therefore decided to perform similar calculations on methanol. Since the basic theory and details of calculation are the same as given in (10) we will not discuss them here. The 1s orbitals on the four hydrogens and the 2s and 2p orbitals on carbon and oxygen were chosen as the basis set and Slater exponents of 1.2, 1.625, and 2.275 for hydrogen, carbon and oxygen, respectively, were used. The chosen Coulomb integrals of various atomic orbitals [H (1s) = −13.60, C (2s)

[1]NRCC Postdoctorate Fellow 1967–1968.

[2]It might be mentioned that the theoretical results for J_{HCCH} are generally lower than the experimental values and therefore the theoretically estimated, A, B, and C are different from those obtained by a least squares fitting of the experimental data [see for example reference (9)].

TABLE I

Calculated values of J_{HCOH} as a function of ϕ

ϕ	J in Hz
0	1.64
30°	1.46
60°	1.12
90°	0.92
120°	0.95
150°	1.13
180°	1.24

$= -21.43$, C (2p) $= -11.42$, O (2s) $= -35.30$, O (2p) $= -17.28$ eV] are the same as used by other workers (11, 12). The calculated values of the contribution of the contact term to the coupling constant J_{HCOH} as a function of ϕ are given in Table I. It can be seen that a functional form of the type given by eq. [1] is predicted by theory, but the calculated values are in general much lower than the observed ones. Thus for methanol in its equilibrium conformation, J is predicted to be 1.16 Hz as compared to the observed value of 5.3 Hz (22). Although a similar behavior is found for ethane (10) [$J_{calculated} = 5.2$ Hz, $J_{observed} = 8.0$ Hz] the discrepancy between the calculated and observed values is much larger for CH_3OH. Several factors might be responsible for this, among them the choice of wrong Coulomb integrals for oxygen, the neglect of the contributions of spin-dipolar and spin-orbital interactions to J_{HCOH} and the neglect of all but the one and certain two electron terms in the calculation of the contact term. For these reasons it is felt that attempts at further refinement of the calculations are unwarranted.

3β-Acetoxy-5β,6β-oxidocholestan-19-ol(2)

During an investigation of synthetic routes to the A/B ring of strophanthidin, the intermediate 3β-acetoxy-5β,6β-oxidocholestan-19-ol, **2** was prepared by the peracid oxidation of 3β-acetoxycholest-5-en-19-ol, **1**. As expected (13, 14), **2** was the major product (72%) of this reaction. In addition the isomeric 5α,6α-epoxide, **3** was formed in 14% yield. Epoxides **2** and **3** were isolated separately by chromatography on silica gel. The configurations of **2** and **3** can be ascertained from their nuclear magnetic resonance (n.m.r.) spectra. The spectrum of **3** in deuteriochloroform showed a broad multiplet for the axial proton at C-3. It appeared at τ 5.08, a chemical shift at lower field than was observed for the proton at C-3 in either **1** (τ 5.38) or **2** (τ 5.18). This deshielding effect in **3** is indicative of an alpha orientation for the epoxide (15, 16). In addition the absorption at τ 7.02 in the spectrum of **3** appears as a doublet of spacing 3.5 Hz and is consistent only with an α epoxide ring (16). The n.m.r. spectrum of **2**, which we will describe in detail shortly, offers strong evidence for the β-orientation of the epoxide ring. Chemical proof of

TABLE II

Parameters obtained from the ABC analysis of the CH_2OH group of **2**

ν_A	ν_B	ν_C	J_{AB}	J_{AC}	J_{BC}	Solvent
240.8	217.0	193.4	−11.5	2.5	9.2	Acetone–$CDCl_3$ (2:1)
244.3	209.5	182.9	−11.8	0.3	10.4	Benzene
250.3	217.8	182.4	−11.5	0.1	10.5	$CDCl_3$

structure for **2** and **3** has also been obtained and will be described in detail in a separate paper (17).

Analysis of Spectra of 2

The n.m.r. spectrum of **2** in deuteriochloroform showed a typical ABC pattern in the region of τ 5.8–7.0 which is attributed to the CH_2OH group at C-19. All peaks had a half-band width of about 1 Hz which did not change on cooling the sample to −40°. The two peaks at highest field (spacing of 10.3 Hz) disappeared when a drop of D_2O was added to the solution and therefore represent the OH proton. The spectrum of **2** measured in benzene was very similar to that in deuteriochloroform. When a 2:1 mixture of acetone and deuteriochloroform was used as solvent the pattern changed to the extent that the OH absorption appeared as a quartet. The region of interest in this spectrum, τ 5.9–7.3 is shown in Fig. 1. Twelve peaks due to the ABC pattern are observed, the thirteenth transition of observable intensity being obscured by the doublet due to the proton at C-6. The strong close-spaced quartet is the signal for the $^{13}CH_3$ side band of acetone solvent.

The spectra in each of these three solvents were subjected to computer analysis using the LAOCOON II program (18) on an IBM 360–65 computer. The results of these analyses are given in Table II. Because of the line widths encountered in all spectra, the parameters obtained from the analysis are only accurate to 0.2 Hz or better, although the average agreement between observed and calculated transitions was 0.06 Hz. In general in a solution of an ABC spectrum more than one set of parameters can give agreement with the observed line positions and intensities (19), within experimental accuracies. To make a proper choice from such solutions and establish the relative signs of the three coupling constants, spin-tickling experiments (20) were performed to show that the relative signs given in Table I are indeed correct.

It was observed for example, that spin-tickling of C2 splits B1 and A4 into sharp doublets. Similarly irradiation of A4 showed that it is connected 'regressively' with the transitions B4 and C2. These experiments show that J_{AB} has opposite sign as compared to the two J_{HCOH} couplings, J_{AC} and J_{BC}. Further, in view of the absolute negative sign of the geminal proton–proton coupling constants in related compounds [see for example reference (10)] both the J_{HCOH} couplings can be assigned positive values. These results are in agreement with the observations of Hruska *et al.* (21) on 2-methyl-2-nitro-1,3-propanediol where the sign of the geminal versus the vicinal J's averaged over all the rotational isomers, has been determined.

The spectral characteristics of the CH_2OH group are unusual in the sense that the H—C—O—H splittings can be observed in a variety of solvents. Normally either scrupulously purified solvent and solute (22) or dry dimethyl sulfoxide (23, 24) must be used in order to retard the rate of exchange of the OH proton sufficiently to allow observation of vicinal coupling. The particularly slow OH exchange in **2** can be attributed to the presence of an intramolecular hydrogen bond to the β-epoxide group.[3] In contrast epoxide **3** lacks the proper orientation and shows no H—C—O—H coupling in its n.m.r. spectrum in deuteriochloroform.

Angular Dependence of Observed J_{HCOH}

The measurement of two vicinal H—C—O—H coupling constants involving the same OH proton provides us with the opportunity to examine their stereochemical dependence with greater precision than was previously possible since the two diastereotopic protons at C-19 have interdependent dihedral angles with respect to the OH proton.

[3]A 1% (w/v) solution of **2** in carbon tetrachloride showed only one band at 3560 cm^{-1} in the hydroxyl region. This band is in the region of intramolecularly hydrogen-bonded O—H vibrations.

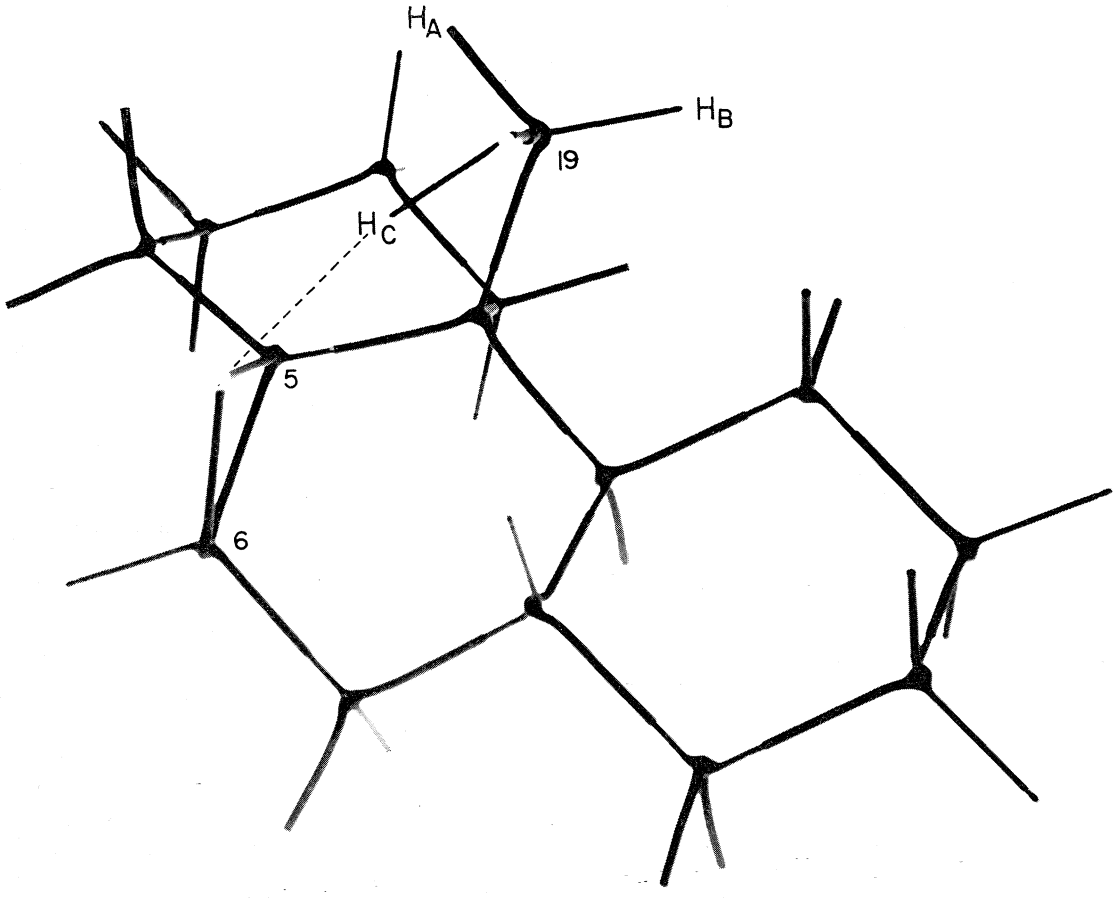

FIG. 2. The Dreiding molecular model of 3β-acetoxy-5β,6β-oxidocholestan-19-ol which indicates the most likely conformation for the CH_2OH group.

Dreiding models of **2** indicate the most likely conformation for the CH_2OH group to be that shown in Fig. 2. In this conformation the dihedral angles between the OH and the two C—H protons are estimated (±10°) to be 160° and 80°. The values of J_{HCOH} for **2** in deuteriochloroform have been combined with all the previous known values of $J_{HCOH}(\phi)$ in Table III. A least squares fitting of eq. [1] with the observed data gives

$$[2] \quad J_{HCOH} = 10.4 \cos^2 \phi - 1.5 \cos \phi + 0.2$$

The fit of the observed values with eq. [2] is also given in Table III. It appears that a Karplus type of behavior does account for the variations of J_{HCOH}.

In applying eq. [2] to any conformational problem, one must remember its limitations, which more or less are the same as that for J_{HCCH} (25). No account for changes of hybridization and electronegativity due to substitution effects in solving eq. [2] have been made, and like in J_{HCCH} such effects might be appreciable (22, 26, 27). An extreme example of the effect of hybridization on the observed J values is provided by protonated formaldehyde where *cis* and *trans* coupling constants of 8.5 and 18.5 (26), and 8.7 and 21.1 (27) Hz have been reported by two groups of workers. Although the substitution effects on J_{HCOH} couplings in tetrahedral systems are likely to be much smaller than the extreme case of protonated formaldehyde, the knowledge of similar effects on J_{HCCH} indicates that eq. [2] can probably predict J_{HCOH} to no better than 1 or 2 Hz.

Solvent Effect on J_{HCOH}

There is one more point which deserves mention, namely the solvent effect on J_{HCOH}. It is seen from Table II that the values of J_{HCOH} in going from deuteriochloroform to acetone/deuteriochloroform change significantly. Thus J_{AC} increases by 2.2 Hz while J_{BC} decreases by 1.2 Hz. It is possible that when a fixed dihedral angle is maintained, J_{HCOH} might change with solvent. Such effects in sp^3 hybridized systems are usually small. For example, the difference between the coupling constant of methanol in carbon tetrachloride and dimethyl sulfoxide is only 0.1 Hz (22). An alternative explanation for the solvent effect on the coupling constants should also be considered. This explanation involves a change in the population of rotamers.

In order to examine this possibility we refer back to Fig. 2. As one rotates the O—H_C bond about the C—O axis the potential energy of the whole molecular system goes through three minima. These occur at $\phi_{AC} \sim 80$, 180, and 300°[4] where ϕ_{AC} is the dihedral angle between the planes containing H_COC and H_ACO. In nonpolar solvents like $CDCl_3$ and C_6H_6 the possibility of intramolecular hydrogen bonding leads to a very stable configuration at $\phi_{AC} = 80°$. Thus, almost no molecules exist in the form for which $\phi_{AC} = 180$ or 300°. In the presence of acetone however, the O—H_C group can also form hydrogen bonds with the solvent. Such bonds are favored in conformations corresponding to $\phi_{AC} = 180$ and 300° for steric reasons. Thus the concentration of such structures might change significantly with a change in solvent. Calling the conformations with $\phi_{AC} = 80$, 180, and 300° I, II, and III respectively, one calculates using eq. [2]

$$J_{AC}^{I} = 0.2 \quad J_{AC}^{II} = 12.1 \quad J_{AC}^{III} = 2.0$$

$$J_{BC}^{I} = 10.2 \quad J_{BC}^{II} = 2.0 \quad J_{BC}^{III} = 2.0$$

If the interconversion between I, II, and III is rapid then one would observe only an average coupling constant

$$[3] \qquad J_{\alpha\beta} = \sum_{i=I,II,III} p^i \, j^i \alpha\beta / \sum_i p^i$$

where p^i is the population of the structures I, II, and III. (Since no bond cleavage takes place during internal rotation, such a process need not lead to 'washing' of spin-multiplets.) We have calculated values for J_{AC} and J_{BC} assuming a decrease in the proportion of conformer I along with equal increments in II and III. We find the best agreement with the experimental values for an 8:1:1 mixture of conformers I, II, and III. The calculated values for J_{AC} and J_{BC} in this case are 1.6 and 8.5 Hz compared with the experimental values in acetone–deuteriochloroform of 2.5 and 9.2 Hz. This agreement does not appear to be sufficient to rule out the aforementioned possibility of a solvent effect on J in conformer I alone. Both effects may be operative. In any event careful consideration must be given to solvent effects when employing a Karplus-type relation between J_{HCOH} and ϕ.

Experimental

Microanalyses were done by A. Bernhardt, Mülheim, Germany. Melting points were determined in capillary tubes on a Hoover Uni-Melt apparatus and are uncorrected. A Perkin–Elmer model 141 polarimeter was used to determine the optical rotation of the compounds in chloroform solution at room temperature. Petroleum ether refers to that fraction with b.p. 30–60°.

Florisil (60–100 mesh, Floridin Co.) and silica gel ("SilicAR" CC–7, 200–325 mesh) were used for column

[4]Stolow and Gallo (5) have pointed out that an asymmetry in the curve is expected due to hydrogen bonding. Consequently, the minimum in potential energy for the bonded conformer does not occur at the expected interval of 120° for ϕ but instead assumes a conformation most favorable for hydrogen bonding.

chromatography. Silica gel G (according to Stahl, E. Merck Co., Germany) was used for thin-layer chromatography.

The n.m.r. spectra were recorded on a Varian HA-60-IL nuclear magnetic resonance spectrometer.

Epoxidation of 3β-Acetoxycholest-5-en-19-ol(1)

A solution of 3.20 g of 3β-acetoxycholest-5-en-19-ol (28) in ether was treated with an excess of monoperphthalic acid in ether for 2 h at room temperature. The reaction solution was washed with a 20% aqueous solution of sodium sulfite and dried over magnesium sulfate. The ethereal solution was then eluted on a Florisil (500 g) column to remove completely the phthalic acid. A crude product was obtained in this manner in which three components were detected by thin-layer chromatography.

This mixture was separated by column chromatography using silica gel as the adsorbant and benzene as eluent. The first substance (0.15 g) collected from the column has the same R_f value as the starting material by thin-layer chromatography and was not characterized further. The second fraction (2.27 g) was identified as *3β-acetoxy-5β,6β-oxido-cholestan-19-ol*, **2**. An analytical sample obtained by crystallization from petroleum ether – ether had m.p. 129–130.5°, $[M]_D = -30°$ (*c*, 2.3 mg/ml).

Anal. Calcd. for $C_{29}H_{48}O_4$: C, 75.60; H, 10.50. Found: C, 75.42; H, 10.51.

The third solid material (0.45 h) to be eluted from the column was identified as 3β-acetoxy-5α,6α-oxidocholestan-19-ol, **3**. Crystallization from methanol gave an analytical sample, m.p. 184–186°, $[M]_D = -267°$ (*c*, 2.5 mg/ml). The n.m.r. spectrum in $CDCl_3$ showed a singlet at τ 5.0 (3α-H; $w/2 = 20$ Hz), a singlet at τ 6.05 (C-19 methylene group), a doublet centered at τ 6.99 (6β-H; $J_{a,a} = 3.4$ Hz), and a singlet at τ 8.0 (3—OAc).

Anal. Calcd. for $C_{29}H_{48}O_4$: C, 75.60; H, 10.50. Found: C, 75.77; H, 10.50.

Some enzymic syntheses of ^{15}N-L-aspartic acid and ^{15}N-L-glutamic acid

J. A. ZINTEL, A. J. WILLIAMS, AND R. S. STUART
Biosynthetic Isotopic Research Laboratories, Merck, Sharp and Dohme of Canada Limited, Montreal, Quebec
Received September 10, 1968

Some methods for the preparation of ^{15}N-L-aspartic acid and ^{15}N-L-glutamic acid using enzyme catalyzed reactions are described. ^{15}N-L-Aspartic acid is prepared by the addition of ammonia to fumaric acid, catalyzing the reaction with aspartase which was partially purified from *E. coli*. ^{15}N-L-Glutamic acid with a high $^{15}N/^{14}N$ ratio is prepared by transamination with ^{15}N-L-aspartic acid catalyzed by aspartate aminotransferase. ^{15}N-L-Glutamic acid with a low $^{15}N/^{14}N$ ratio is prepared by a glutamic acid dehydrogenase catalyzed exchange of L-glutamic acid with ^{15}N-ammonia. These enzymes are commercially available. Since efficient utilization of ^{15}N is obtained, aspartic acid or glutamic acid may be prepared with any desired $^{15}N/^{14}N$ ratio.

Introduction

During the last few years new methods for the detection and analysis of stable isotopes have greatly increased their utility as tracers in biological sciences. For example, Tanabe and Detre (1) verified the biosynthetic pathway of griseofulvin by growing *Penicillium urticae* on ^{13}C-labeled acetate, isolating griseofulvin, and determining the position and abundance of each labeled carbon by nuclear magnetic resonance spectroscopy. This process eliminated the degradative work which would have been required with radioactive carbon. Using mass spectrometry, Bose *et al.* (2) identified the nitrogen precursors of gliotoxin isolated from an organism grown on ^{15}N-glycine or ^{15}N-phenylalanine. Since continuing research into nitrogen metabolism would be aided by making readily available some nitrogen labeled substrates, we have initiated a program to synthesize ^{15}N-L-amino acids.

Two of the best procedures for the synthesis of amino acids are the direct amination of α-halogen carboxylic acids and the Gabriel synthesis with potassium phthalimide. Neither of these syntheses is satisfactory for preparing amino acids with a high $^{15}N/^{14}N$ ratio, as the former requires a large excess of ammonia and the latter requires the preparation of ^{15}N-potassium phthalimide. In addition, chemical syntheses yield racemic mixtures which must be resolved if the L-isomer is to be used in biological studies (it has been pointed out that use of D,L mixtures has sometimes led to misleading results (3)). In any case, use of D,L mixtures wastes half of the isotope since, in general, only the L form is metabolized. These difficulties encountered in chemical syntheses of amino acids have been obviated by using enzyme catalyzed reactions. Aspartase has absolute stereochemical specificity for L-aspartic acid (4) and aspartate aminotransferase has absolute stereochemical specificity for both L-aspartic acid and L-glutamic acid (5). In this report, we describe syntheses of ^{15}N-L-glutamic acid and ^{15}N-L-aspartic acid with good yields and low isotopic loss.

Experimental

Chemicals

Aspartate aminotransferase (E.C. 2.6.1.1) and β-nicotinamide adenine dinucleotide (NAD) were obtained from Sigma Chemical Co., St. Louis, Missouri; glutamate dehydrogenase (GDH) (E.C. 1.4.1.2) from Boehringer Mannheim, New York; pyridoxal phosphate from Nutritional Biochemicals, Cleveland, Ohio; ^{15}N-ammonium chloride from Merck, Sharp & Dohme of Canada Limited, Montreal, Quebec; bacteriological grade alumina (A-305) from Canada Colors and Chemicals, Montreal, Quebec; and Whatman glass filter paper from Reeve Angel, Clifton, New Jersey. α-Ketoglutaric acid was a product of Matheson, Coleman and Bell. All other chemicals were standard reagent grade.

Thin-layer Chromatography

All thin-layer chromatography (t.l.c.) of amino acids was done on silica gel (K301R) chromogram sheets manufactured by Eastman Kodak. The sheets were developed with butanol/glacial acetic acid/water solvent (80:20:20 v/v) and the amino acids were visualized by spraying with 0.2% ninhydrin in butanol. Amino acids were estimated by comparing the spot size to standards.

Purification of Amino Acids

A single procedure was used for purifying glutamic and aspartic acids from any reaction mixture. The boiled, charcoal-treated amino acid reaction mixture was absorbed on a column (3.8 × 28.5 cm) of Dowex 50W × 8, 50–100 mesh, charged in the hydrogen form. The column was washed with at least 300 ml of distilled water and then

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

amino acids were eluted with 0.75 *N* ammonium hydroxide solution. Fractions containing amino acids were combined, flash evaporated to dryness, dissolved in 300 ml of water, and absorbed on a column (4.5 × 38.0 cm) of Amberlite CG-45 type II in the acetate form. After washing the column with 500 ml or more of 0.05 *M* acetic acid, glutamic acid was eluted with 0.15 *M* acetic acid and then aspartic acid was eluted with 0.25 *M* acetic acid (6). The amino acid solutions were flash evaporated to dryness (40°), dissolved in a minimum volume of hot water, and crystallized from solution by adding 0.5 volumes of absolute ethanol. The product was collected by filtration, dried, and weighed. Mass spectrometric isotopic analyses were done on a Hitachi RMU-6D with an M/G-150 direct introduction system.

Isolation of Aspartase

Escherichia coli cells (N.T.C. 9001) were grown on agar in standard Roux culture bottles as described by Wu and Rittenberg (7). In a typical isolation, cells from 19 Roux bottles were used. All steps in the isolation were done at 0–5°. The cells from each Roux bottle were suspended in 10 ml of 0.001 *M* sodium phosphate buffer solution, pH 7.4, combined, and the suspension was centrifuged at 10 000 × g for 10 min. The supernatant was discarded, the cells were suspended in 20 ml of the same buffer, and ground in a mortar with two volumes of alumina. The ground cell paste was diluted with 100 ml of buffer and centrifuged as before. Streptomycin was added (in the form of a 5% solution of streptomycin sulfate) to the supernatant to a final concentration of 1%. After 30 min, the suspension was centrifuged at 10 000 × g for 10 min, the precipitated nucleic acids were discarded, and the supernatant was dialyzed for 18 h against 3 l of tap water. The dialyzate was acidified to pH 4.4 with 10% acetic acid and stored overnight. The suspension was centrifuged as before, the supernatant was discarded, and the pellet dissolved in 45 ml of 0.001 *M* sodium phosphate buffer, pH 7.4; it was necessary to readjust the pH of the solution to 7.4 by adding 0.1 *N* sodium hydroxide solution. Insoluble material was removed by centrifugation at 10 000 × g for 10 min. The clear supernatant constituted the aspartase preparation used in syntheses. When stored at 4°, the aspartase preparation was found to be stable for at least one month.

Synthesis of ^{15}N-L-Aspartic Acid

To 63 ml of 0.05 *M* sodium phosphate buffer, pH 7.4, was added 10.5 g of sodium fumarate, 2.8 g of ammonium chloride (96.5 atom % ^{15}N), and 24.5 ml of aspartase preparation. The mixture was incubated at 37° for the required time, usually 72 h, and then boiled for a few minutes to inactivate the enzymes. ^{15}N-L-Aspartic acid was purified by column chromatography. After crystallization from water–ethanol, 5.4 g of L-aspartic acid were obtained, a yield of 78% based on ^{15}N-ammonium chloride. The product was determined by mass spectrometry to have the same isotopic composition (96.5 atom % ^{15}N) as the ammonium chloride used: $[\alpha]_D^{22}$ +42.5 (*c*, 2.00 in 2 *N* HCl). Non-labeled L-aspartic acid standard: $[\alpha]_D^{22}$ +46.6 (*c*, 2.00 in 2 *N* HCl).

Synthesis of ^{15}N-L-Glutamic Acid by ^{15}N Exchange

Five grams (0.034 moles) of L-glutamic acid and 1.92 g (0.034 moles) of ammonium chloride (96.7 atom % ^{15}N) were dissolved in 500 ml of distilled water. The pH of the solution was adjusted to 8.3 by dropwise addition of 4 *M* sodium hydroxide solution, chilled, and 150 mg NAD and 1 mg GDH (specific activity 2.9 EU/mg protein) were added. This mixture was incubated at 37° for 48 h after which time it was adjusted to pH 3.2 with 85% lactic acid and shaken for 45 min with 200 mg of Darco X charcoal. The suspension was filtered on glass filter paper and the filtrate was flash evaporated (40°) to dryness. The residue was dissolved in a minimum volume of hot water, 0.5 volumes of absolute ethanol added, and L-glutamic acid was allowed to stand at 5° for two days. The crystals were collected by suction filtration, washed with 20 ml of hot absolute ethanol, and dried at reduced pressure over P_2O_5. A 91% (4.8 g) recovery of L-glutamic acid was obtained which had an isotopic content of 50 ± 1 atom % ^{15}N; $[\alpha]_D^{22}$ +46.9 (*c*, 2.00 in 2 *N* HCl). Non-labeled L-glutamic acid standard: $[\alpha]_D^{22}$ +45.9 (*c*, 2.00 in 2 *N* HCl).

Synthesis of ^{15}N-L-Glutamic Acid from α-Ketoglutaric Acid

Glucose dehydrogenase was obtained from beef liver using the procedure of Strecker (8) up to and including the acid precipitation step.

To 250 ml of 0.05 *M* sodium phosphate buffer, pH 7.6, were added 50 ml of glucose dehydrogenase preparation, 200 mg of NAD, 5.0 g of glucose, 100 mg of ammonium chloride (96.5 atom % ^{15}N), 50 mg of monosodium α-ketoglutarate, and about 3 mg of glutamic acid dehydrogenase (specific activity 2.9 EU/mg protein). The reaction was followed by measuring the change in absorbance of the mixture (usually at 280 mμ) due to formation or disappearance of $NADH_2$. After 2 h, when the absorbance of the reaction mixture was constant, an additional 50 mg of monosodium α-ketoglutarate were added and the pH was readjusted to 7.6 with 1 *M* sodium hydroxide solution. Over the next 90 min, three 50 mg portions of α-ketoglutarate were added. Then 100 mg of ^{15}N-ammonium chloride and 300 mg of α-ketoglutarate were added, the pH was adjusted to 7.6, and the reaction mixture was stirred slowly overnight at room temperature. A final lot of 150 mg of ^{15}N-ammonium chloride and 200 mg of monosodium α-ketoglutarate were added and the pH was adjusted as before. After 6 h, the solution was boiled for a few min and then stored at 0° until glutamic acid was purified by chromatography. The yield was 450 mg or 47% based on ^{15}N-ammonium chloride. However, considerable isotopic dilution occurred and the product was only 30.0 ± 1 atom % ^{15}N.

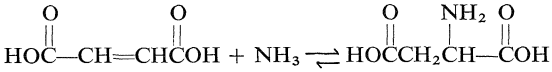
Synthesis of ^{15}N-L-Glutamic Acid Using Aspartate Aminotransferase

To 75 ml of distilled water was added 1.5 g of ^{15}N-L-aspartic acid (96.5 atom % ^{15}N) and 2.1 g of α-ketoglutaric acid. The suspension was stirred slowly and the reactants were dissolved by adding 4 *M* sodium hydroxide solution until the pH was 7.6. A few mg of pyridoxal phosphate, 50 mg of CG-45 (in acetate form), and 2 mg of aspartate aminotransferase were added. The mixture was incubated at 25°; the pH was checked hourly and adjusted to 7.6 with 1 *M* hydrochloric acid solution. After 6 h the solutions was acidified to pH 6.5 with 10% acetic acid solution

and the reaction mixture was stirred slowly overnight. After 18 h, the pH was again made 7.6 with 4 *M* sodium hydroxide solution and maintained at this value for 6 h. After the solution was acidified to pH 5.0 with 10% acetic acid solution, the reaction mixture was stirred for 30 min with 200 mg of Darco X charcoal and filtered on glass paper. Glutamic and aspartic acids were purified by chromatography. The yield was 700 mg or 42% based on aspartic acid and the isotopic content of L-glutamic acid was 96.5 atom % ^{15}N, $[\alpha]_D^{22}$ +49.2 (*c*, 2.00 in 2 *N* HCl). Non-labeled L-glutamic acid standard: $[\alpha]_D^{22}$ +45.9 (*c*, 2.00 in 2 *N* HCl).

Results and Discussion

A procedure for synthesizing ^{15}N-L-aspartic acid was reported by Wu and Rittenberg (7) using a resting cell suspension of *E. coli* as a source of aspartase to catalyze the addition of ammonia to fumaric acid as is shown below:



They reported a 60% yield of ^{15}N-L-aspartic acid based on ^{15}N-ammonia as ammonium chloride and very little isotopic dilution; we have found that this procedure gave highly variable yields and often gave considerable isotopic dilution. However, these difficulties were overcome by catalyzing the reaction with partially purified *E. coli* aspartase. In several experiments run with different batches of aspartase, the lowest yield was 70% in a reaction starting with 0.4 g of ammonium chloride (a more typical yield was 78% which was obtained in a larger reaction using 2.8 g of ammonium chloride). In no case did isotopic dilution occur, thus, this procedure is very suitable for preparing L-aspartic acid with any desired $^{15}N/^{14}N$ ratio.

Since the utility of this synthesis of ^{15}N-L-aspartic acid is dependent on a partial purification of aspartase from *E. coli*, each step in the purification was chosen so that it could be duplicated easily. Each batch of aspartase was checked by running a small scale synthesis and estimating by t.l.c. on silica gel the amount of aspartic acid synthesized. For a synthesis on the scale described, volumes from 20 to 30 ml of aspartase preparation were used and a convenient reaction rate was always obtained.

A direct synthesis of ^{15}N-L-glutamic acid was also devised. In the reaction illustrated below, glutamic acid dehydrogenase (GDH) catalyzed the addition of ammonia to α-ketoglutaric acid with a concomitant oxidation of $NADH_2$ to NAD. To eliminate the requirement for a large amount of $NADH_2$, $NADH_2$ was regenerated *in situ* from NAD by an alcohol dehydrogenase (ADH) catalyzed oxidation of ethanol to acetaldehyde. An advantage of this system is that both enzymes are available commercially from biochemical supply houses in highly purified form. However, the yields from this reaction were very low as the large excess of ethanol that was required to drive the reaction in the direction shown, brought about rapid denaturation of the enzymes. Greater success was attained when $NADH_2$ was regenerated by using glucose dehydrogenase to catalyze the oxidation of glucose to gluconic acid. Using this latter system a typical yield was 50% based on ammonium chloride; but in a reaction using 96.5 atom % ^{15}N-ammonium chloride, the L-glutamic acid synthesized was found to contain only 30 atom % ^{15}N. This dilution could be eliminated by dialyzing both enzyme preparations prior to use. However, glucose dehydrogenase must be isolated from beef liver and great care is required in carrying out the reaction; hence this procedure for the preparation of ^{15}N-L-glutamic acid was inferior to others that were developed.

The preparation of ^{15}N-L-glutamic acid with an isotopic content of 50 atom % ^{15}N or less was best achieved through a very simple exchange reaction with ^{15}N-ammonia and L-glutamic acid catalyzed by GDH and NAD. L-Glutamic acid and ^{15}N-ammonium chloride were dissolved in a buffer solution, GDH and a trace of NAD were added, and the mixture was incubated at 37°

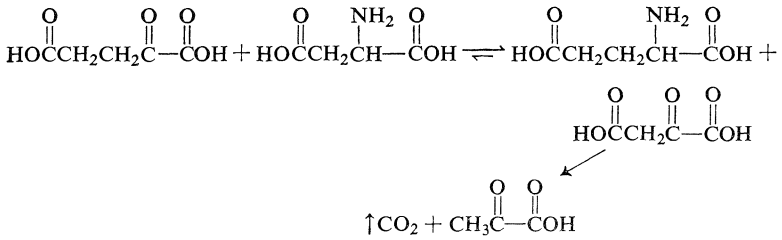
two days, after which over 90% of the L-glutamic acid was recovered in pure form, having an isotopic content equal to the theoretical value calculated by assuming complete equilibration of nitrogen.

Transamination reactions in which the enzyme source was either a whole cell suspension or a cell homogenate have been used to synthesize non-labeled amino acids (9–14). Our experience has shown that such syntheses are more reproducible and result in no detectable isotopic dilution if the enzyme is at least partially purified from proteins and metabolites. As pure aspartate aminotransferase may be obtained from biochemical supply houses, a transamination synthesis of L-glutamic acid was developed, which is shown by the following reaction:



The synthesis requires ^{15}N-L-aspartic acid, but as mentioned earlier, this was prepared in good yield by the aspartase catalyzed addition of ^{15}N-ammonia to fumaric acid; in addition, almost quantitative transfer of amino nitrogen was achieved by decarboxylating oxalacetic acid during transamination.

To ensure decarboxylation of oxalacetic acid, the reaction was run in a dilute buffer solution which was initially adjusted to pH 7.6, but as transamination proceeded the pH decreased to about 6 and a slow acid-catalyzed decarboxylation occurred. Also, a primary amine resin, CG-45, was added to the reaction as primary amines are specific catalysts for decarboxylating β-keto acids. Although at pH 6 the contribution of CG-45 to the net decarboxylation was low, its use was warranted as it was removed easily by filtration at the end of the reaction period. In the example given of this reaction, a preparation with ^{15}N, a 42% yield was obtained. A 77% yield was obtained from the same scale reaction using non-labeled L-aspartic acid. Since, at the end of the ^{15}N reaction period, very little aspartic acid was detected by t.l.c., the low yield was probably due to mechanical loss during isolation and not due to an isotope effect. A yield of 75% can be expected.

Each of these enzyme catalyzed syntheses of ^{15}N-L-amino acids was reproducible, gave the L-isomer in good yield, and was superior to conventional chemical syntheses. We think that ^{15}N-L-aspartic acid is best prepared from the aspartase reaction, ^{15}N-L-glutamic acid with a low $^{15}N/^{14}N$ ratio is best prepared by the glutamic acid dehydrogenase catalyzed exchange reaction, and ^{15}N-L-glutamic acid with a high $^{15}N/^{14}N$ ratio is best prepared by transamination with ^{15}N-L-aspartic acid. It is possible that ^{15}N-L-glutamic acid could also be prepared by combining the aspartase synthesis with the aspartate aminotransferase reaction so that it would not be necessary to isolate ^{15}N-L-aspartic acid as an intermediate. One approach, which would minimize the chances of forming L-alanine by transamination with pyruvic acid, would be to add α-ketoglutarate and aspartate aminotransferase to an aspartase synthesis reaction that was nearing completion. These enzyme reactions also have potential for a very large scale production of amino acids if the enzymes are stabilized by attaching them to an insoluble inert support, such as beads of Sephadex G-200; Axén and Porath (15) have published a procedure for attaching enzymes to Sephadex G-200. By attaching aspartase to Sephadex beads, a continuous synthesis of L-aspartic acid could be made by simply percolating a solution of fumaric acid and ammonium chloride through a column of aspartase beads held at 37°. Similarly, L-glutamic acid could be synthesized by using a mixed bed column of aspartase beads and aspartate aminotransferase beads.

Received September 6, 1968

The electrolysis of monosaccharides in alkaline, non-aqueous media caused a sequential descent of the series as a result of the elimination of one-carbon units from the reducing end of the molecule, without the formation of chromatographically detectable quantities of oxidized derivatives.

Canadian Journal of Chemistry, 47, 417 (1969)

Introduction

Since the initial detection of acids from the electrolysis of sucrose (1) and glucose (2) relatively few studies of electrochemical reactions of carbohydrates have been published. The synthetic applications other than the electrochemical synthesis of D-gluconic (3–6) and other aldonic acids (7–10), D-glucitol and D-mannitol (11, 12), and periodate oxystarch (13) remain largely unexploited.

The electrolysis of carbohydrates in aqueous solution usually involves both hydrolytic and oxidative reactions in which carbonyl (4, 14, 15) and/or carboxyl (1, 3–9, 16) groups are introduced into the parent compound. Thus, polysaccharides and proteins may be depolymerized, and the monomers degraded to lower molecular weight products (1, 14, 17–23).

Occasionally the literature has reported the electrochemical reduction of aldoses (16, 24) and other carbohydrates (25), and of aliphatic and aromatic aldehydes (26–28). The mechanism of such a reduction of glucose, which produced as side-products small amounts of mannitol and 2-deoxyglucitol, was elucidated by Wolfrom *et al.* (29, 30).

The qualitative and quantitative study reported herein was instigated to determine the effect on simple carbohydrates of electrolysis in a system in which the generation of a significant concentration of methoxyl free radicals could be anticipated (31).

Discussion

Paper chromatographic analysis of the products of electrolysis revealed the stepwise degradation of the parent compound to a mixture of lower aldoses (Table I). In accord with earlier studies (14), these reactions exhibited a high initial rate. In one typical experiment, a detectable amount of the secondary reaction, arabinose → erythrose, was obtained after 10 min electrolysis of D-glucose. D-Galactose underwent a more efficient degradation than D-glucose and gave a higher yield of pentose (cf. ref. 20).

A large volume of gas containing both H_2 and CO_2 was evolved during the reaction, principally from the cathode. Whereas it is likely that the H_2, and much of the CO_2, came from the electrolysis of methanol (31), the lack of quantitative recovery of carbohydrate suggested that some of the parent compound was completely oxidized to CO_2 (18).

Experiments in which maltose, because of its low solubility in methanol, was electrolyzed in water to which sodium methoxide was added, disclosed rapid and extensive cleavage of the glycosidic bond. Paper chromatographic analysis revealed no identifiable oxidation product of maltose; glucose and arabinose were the earliest degradation products detected (see Table I). These observations are consistent with an initial

hydrolysis of the glycosidic bond followed by the usual electrolytic degradation of glucose, and with the synthesis of 3-*O*-α-D-glucopyranosyl-D-arabinose (32) followed instantly by hydrolysis to D-glucose and D-arabinose. The elucidation of the route(s) is under investigation.

As adduced from qualitative paper chromatographic analysis, the same products were obtained by electrolysis with each of sodium methoxide, sodium ethoxide, sodium hydroxide, and potassium hydroxide (see Table I).

In this study an amperage lag of 0.1–0.5 min occurred at the start of electrolysis before the amperage rose to a maximum value (usually after 0.1–0.5 h) and thereafter slowly declined. The porosity of the graphite electrodes and/or the formation of an insulating residue on the cathode surface may explain in part this decline. However, the reversal of polarity, which caused the residue to flake off of the new anode, and/or the cleaning of the electrode surface, failed to restore maximum current. Some current-conducting component appeared to have been consumed or otherwise irreversibly removed from the system.

The non-aqueous system was peculiar in that it formed aldoses in the absence of chromatographically detectable quantities of aldonic acids (3–9, 14, 16) and other oxidized derivatives (4, 14, 15). Nevertheless the most probable mechanism of sequential degradation would involve the formation of an aldonic acid as the first, or an early, step in the electrolysis, since these are known to form from (16, 17), and to degrade to (14, 20, 33), aldoses during electrolysis. Neuberg's (14) discovery of ozones in the electrolysis of aldoses may mean that an α-keto compound is formed (34) either prior to, or after, the carboxyl group, thus giving an α-ketoaldonic acid which can decarboxylate to an aldose having one less carbon atom (35). Consistent with such a theory are the alkaline oxidative degradation of D-glucose to D-arabonic acid (36) and L-arabinose to L-erythronic acid (37), the formation in alkali of carbonyl derivatives of carboxylic acids (31), and the detection of a keto acid from the electrolysis of erythronic acid (21). If such acidic intermediates participate in these reactions the aldoses must be strongly favored in any equilibria involving the oxidized compounds, and/or the oxidation must be very slow relative to decarboxylation so that at any instant the concentration of the intermediate is below present levels of detection.

Electrolysis offers a facile, and potentially useful method for the sequential degradation of sugars, and sugar derivatives (14, 33) to lower homologues. The method is of broad application (Table I, see ref. 33) and avoids the necessity of synthesizing special derivatives (38) for subsequent chemical degradation. Both the mechanism of the process, and conditions whereby higher yields of a desired product can be obtained, remain to be established, however, even in its present state of development it is a practical means of obtaining certain unusual sugars such as D-arabinose and D-threose in semi-micro amounts, as has been clearly established by the isolation of milligram quantities of the pure products by preparative paper partition chromatography. There seems to be no reason to question the ability of still more recent separatory techniques to provide equal or superior resolution and recovery of the individual components on a macro scale.

Experimental

General Methods

All evaporations were carried out at 35–45 °C under reduced pressure, unless stated otherwise. Melting points were determined with a Fisher–Johns Melting Point Block (Fisher Scientific Co.) and are uncorrected. The water used for optical rotation studies of free sugars contained a trace of ammonium hydroxide to catalyze the formation of an equilibrium mixture of anomers.

Paper chromatography by the descending technique, using Whatman no. 1 and 3MM paper, was effected with one or more of the following solvent systems (39): (*a*) 1-butanol:ethanol:water, 4:1:5; (*b*) 1-butanol:pyridine:water, 6:4:3; (*c*) pyridine:ethyl acetate:water, 2:5:7; (*d*) 1-butanol:acetic acid:water, 2:1:1; (*e*) 2-butanone–water azeotrope; (*f*) ethyl acetate:acetic acid:formic acid:water, 18:3:1:4. Chromatograms were visualized (39) with ammoniacal silver nitrate, or with *p*-anisidine–trichloroacetate.

Electrolysis Cell and Power Supplies

The cell was a standard 800 ml (13 × 9.5 cm) beaker which was slightly reshaped to remove the pouring lip. Two holes were drilled in a stopper (size 15) to accommodate 4.0 cm diameter graphite electrodes approximately 0.5 cm apart. Each electrode was fitted with a brass terminal at the exterior end. A third hole was drilled in the stopper in which was inserted a 19/38 to 24/40 standard taper adapter which received a reflux condensor.

A power supply from a Reco Electric Desalter (Research Equipment Corp.) with a maximum output of 3.0 A at 50 V, or a transistorized rectifier module (fused at 2 A) attached to a Powerstat variable resistance (The Superior Electric Co.), supplied direct current for the experiments. The Powerstat control without rectifier was used to supply alternating current (60 Hz).

General Electrolytic Method

In almost all experiments, the sugar sample and the solvent were introduced into the dry, sealed electrolysis cell. The electrodes extended 3.5–4.5 cm below the surface of the reaction mixture. The electrolyte (Na, NaOH, KOH, or $NaOCH_3$) was dissolved whereupon the voltage was applied to give maximum current. Electrolysis was continued for widely variable lengths of time.

Miscellaneous Electrolyses

A relatively large number of experiments were investigated only by qualitative paper partition chromatographic analysis. The results of a series of typical experiments are recorded in Table I.

Electrolysis of D-*Glucose*

A sample (15.0 g) of D-glucose (anhydrous powder) was suspended in 200 ml methanol to which 0.05 g freshly cut sodium then was added. The solution was electrolyzed for 44 h using direct current (d.c.). The current rose to a maximum of 1.1 A at 45 V after 0.5 h and then declined slowly to a terminal value of 0.15 A at 47 V. Aliquots were removed 3, 5, 15, 24, and 44 h after the start of the experiment and were found by paper partition chromatography in solvents *a*, *b*, and *c* to contain glucose, arabinose, erythrose, and some unidentified material. Evaporation of the solvent gave 8.2 g of heavy, amber syrup.

A sample (0.3587 g) was resolved quantitatively by preparative paper chromatography in solvents *a* and *b*. The components having R_f values greater than that of erythrose were reduced with sodium borohydride whereupon glycerol was detected. The individual components were isolated and identified in the following manner.

D-Glucose: glucose (0.2208 g, yield: 51.0%) $[\alpha]_D^{24}$ +54.0° (*c*, 1 in H_2O) (40), was converted to the characteristic *N*-*p*-nitrophenyl-β-D-glucosylamine, m.p., and mixture m.p. 184.5–186 °C (41).

D-Arabinose: this component (0.0528 g, yield: 12.4%) $[\alpha]_D^{25}$ −101° (*c*, 0.8 in H_2O) (42), afforded D-arabinose benzoylhydrazone, m.p. and mixture m.p. 189–190 °C (hot, 95% ethanol) (43).

D-Erythrose: this fraction (0.0430 g, yield: 9.9%) $[\alpha]_D^{24}$ −15.5° (*c*, 1 in H_2O) (44–46), was reduced in aqueous solution $NaBH_4$. Erythritol was characterized as the tetra-*p*-nitrobenzoate, m.p., and mixture m.p. 249–251 °C. An authentic sample had the same m.p.

Glyceraldehyde: the components migrating faster than erythrose on the paper chromatograms were eluted with water, reduced with $NaBH_4$, and rechromatographed after removal of borate (47). Glycerol (0.0181 g, yield: 4.2%) was identified as the tri-*p*-nitrobenzoate, m.p., and mixture m.p. 191–192.5 °C (48).

The remaining eluates were combined and evaporated to a light-amber syrup (0.0161 g, yield: 3.7%).

Control Experiment

A duplicate solution of D-glucose in sodium methoxide–methanol was refluxed for the period during which electric current was allowed to flow.

Chromatographic analysis of the reaction product in solvents *a* and *d*, revealed the presence of glucose with traces of mannose and arabinose.

Electrolysis of D-*Galactose*

D-Galactose (9.1 g) was electrolyzed in 200 ml methanol to which was added 0.04 g sodium. A direct current was passed through the solution for 20 h using graphite electrodes. The current rose to a maximum of 0.9 A at 44 V after 0.25 h and thereafter declined to the terminal value of 0.55 A at 46 V. Evaporation of the reaction mixture gave 8.6 g of viscous syrup.

A sample (0.1631 g) was resolved by paper chromatography in the manner described for glucose, except that the components migrating ahead of lyxose were eluted, combined, reduced, and rechromatographed. The individual components were identified on the basis of the following data:

D-Galactose: galactose (0.0466 g, yield: 27.0%), $[\alpha]_D^{25.5}$ +78.4° (*c*, 1.2 in H_2O) (40), was converted in the usual manner to D-galactose *unsym.*-methylphenylhydrazone, m.p. and mixture m.p. 186–187 °C (43).

D-Lyxose: this component (0.0413 g, yield: 24.0%) $[\alpha]_D^{24.2}$ −12.6° (*c*, 1 in H_2O) (42), afforded the 2,5-dichlorophenylhydrazone of D-lyxose, m.p. and mixture m.p. 140–142.5 °C (hot aqueous ethanol) (49).

D-Threitol: threitol (0.0293 g, yield: 17.0%) $[\alpha]_D^{25.2}$ +4.5° (*c*, 4.75 in H_2O) (50–51), was converted in the usual manner to di-*O*-benzylidene-D-threitol, m.p. 222–223.5 °C, mixture m.p. 224–225 °C (52).

Glycerol: this component (0.0094 g, yield: 5.4%) was identified as described above (48).

The unidentified residue weighed 0.0329 g, yield: 19.1%. A control experiment was performed in the usual manner.

Analysis of Electrode Gases

The electrolysis of 10 g D-glucose in 200 ml methanol in which 0.05 g sodium had been dissolved, was allowed to proceed for 6 h to displace air initially present in the cell. The evolved gas was passed into a clear solution of $Ba(OH)_2$. The formation of a white precipitate was accepted as a presumptive test for CO_2.

A similar experiment was performed on a smaller scale using an "H" tube to separate the anode and cathode. Cathodic gases were collected under water. The water vapor was frozen out with Dry Ice – acetone and the gases analyzed in a mass spectrometer.[6] Hydrogen was identified as a major component of the mixture.

Studies of stereochemical influences upon anti-histaminic activity. The synthesis, configuration, and anti-histaminic properties of some isomeric aminobutenes[1]

A. F. CASY AND A. P. PARULKAR
Faculty of Pharmacy, University of Alberta, Edmonton, Alberta

Received August 23, 1968

The acid-catalyzed dehydration of 4-dimethylamino-2-*p*-methoxyphenyl-1-phenylbutan-2-ol yields all four possible 4-amino-1,2-diarylbutenes. Pure samples of each isomer have been isolated, double bond positions and configurations being established from proton magnetic resonance and ultraviolet spectroscopic data. A stereoselective route to *cis* aminobut-1-enes has been further investigated. The anti-histaminic properties of the reported butenes together with some related compounds are given and structural influences upon activity discussed.

Canadian Journal of Chemistry, 47, 423 (1969)

In 1950 Stoll and co-workers reported the anti-histaminic properties of some 4-amino-1,2-diarylbutenes formed by dehydration of 1,2-diaryl-4-*t*-aminobutan-2-ols (**1**), certain members having activities approaching that of Antergan (1). Since the aminobutenes were not characterized satisfactorily, the elimination of water from the butanols **1** has been further investigated and the double bond position and configuration of a series of so-derived isomeric aminobutenes established by spectroscopic means and the most active product of the Geigy workers shown to be a ternary mixture (2–4). In this paper further pharmacological data upon this mixture and upon a number of isomerically pure 4-aminobut-1-enes and -but-2-enes are given and tentative structure activity relationships drawn from the results.

Chemistry

All the compounds tested (Tables II and III) were obtained by fractional crystallization of 4-aminobutene hydrochloride mixtures derived by acid-catalyzed elimination of the corresponding *t*-alcohols **1**. Those alcohols with 3-methyl substituents (**1***b*) gave but-1-enes exclusively (**2**) while the nor-analogues (**1***a*) gave all four possible isomers, namely *cis* and *trans* **3** and **4** (2, 3). An additional series of 2-*p*-methoxyphenylbutenes was synthesized by the sequence **5** through **8** and the four aminobutenes separated by fractional crystallization of their hydrochloride salts. Amongst these isomers, but-1-enes were differentiated from but-2-enes by the multiplicities of their vinylic proton magnetic resonance (p.m.r.) signals (but-1-ene signals were singlets and but-2-ene signals were triplets, $J = 7$ Hz), whilst configurational assignments rested upon association of the lower field vinylic chemical shift with the more planar of the two isomers (in both but-1-enes and but-2-enes the vinylic proton is subject to a greater degree of aromatic deshielding in the more planar isomer) (3, 4) (Table I). Models show the *trans* (Ph/Ar) but-1-ene **4***b* and the *cis* (Ar/H) but-2-ene **3***b* to be more planar forms. Ultraviolet (u.v.) data

TABLE I

Spectral data of 4-dimethylamino-2-*p*-methoxyphenyl-1-phenylbutenes

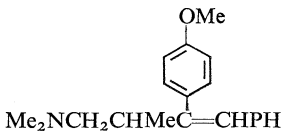
7 **8**

Ar = *p*-MeO·C_6H_4

supports these assignments, the absorption maxima and extinction coefficients of *trans* **4***b* and *cis* **3***b* being at longer wavelengths and more intense respectively than those of the corresponding *cis* and *trans* isomers (Table I). These spectral results are in accord with data obtained for related isomers (3). The *cis* but-1-ene **4***b* showed an additional wavelength band (peak at 228 mμ) apparent only as a shoulder near 227 mμ in the *trans* isomer, the more complex *cis* spectrum resembling those of the 3-methyl congeners **9** (*trans*, maxima at 232 mμ, ε 17 200 and 256 mμ, ε 12 130; *cis* broad band between 222 mμ, ε



9

14 600 and 263 mμ, ε 10 990) (4). The butenes *cis* **4***b* and *cis* and *trans* **9** are all highly crowded molecules in which no single chromophore is likely to be favored and this may be the reason why they give u.v. spectra that are more complex than those of the *trans* but-1-ene **4***b* and the but-2-enes **3** where favored planar conformations are clear upon inspection of models.

An alternative route to but-1-enes, exemplified by the sequence **10** through **13**, has previously been shown to lead to a *cis* isomer (3). Further study shows these reactions to be stereoselective respecting:

$$\mathrm{PhCH_2COPh} \xrightarrow[\mathrm{NaNH_2}]{\mathrm{RCl}} \mathrm{PhCH(R)COPh} \xrightarrow{\mathrm{LAlH_4}} \mathrm{PhCH(R)CHOHPh}$$
10 **11** **12**

$$\xrightarrow{\mathrm{KHSO_4}} \mathrm{RCPh{=}CHPh} \qquad \mathrm{PhCH{=}C(OR)Ph}$$
13 **14**

R = $Me_2N(CH_2)_2$

(*a*) reduction of the ketone **11**. The p.m.r. spectrum of the total alcoholic product in $CDCl_3$ displayed sharp signals for the 1-methine, 2-methine, and NMe_2 protons (doublet $J = 7$, quartet $J = 7$, and singlet at 283, 177, and 121 Hz from TMS respectively) indicative of the preponderance of one diastereoisomer, and

(*b*) the dehydration step **12** to **13**. The p.m.r. spectrum of the total product of elimination showed vinylic signals at 390 and 407 Hz (from TMS) characteristic of *cis* and *trans* **13** respectively (3), present in the ratio of approximately 2 to 1 (cf. the same elimination of the α-ethyl analogue of **11** which led chiefly to *trans* α-ethylstilbene) (4).

Both *C*- and *O*-alkylated products were isolated upon alkylation of desoxybenzoin with 2-dimethylaminoethyl chloride in benzene, the enol ether **14** being characterized by its vinylic p.m.r. signal (a sharp singlet near 350 Hz) and infrared (i.r.) (doublet, 1670 and 1635 cm^{-1}) and u.v. (λ_{max} 287 mμ; ε 27 540; hydrochloride in ethanol) features typical of conjugated enol ethers (5, 6). The ratio of *O*- to *C*-alkyl product was about 7 to 1.5, a result in contrast with alkylation experiments upon desoxybenzoin using simple alkyl halides in which only minor amounts of *O*-alkylated products were detected (4). The proportion of the *C*-alkyl derivative **11** was raised when the reaction was repeated using dimethylsulfoxide as solvent, the total alkylation product consisting of about 40% **11**, 50% **14**, and 10% starting material as assessed from p.m.r.

integrals of characteristic signals. The configuration of the *O*-alkyl derivative **14** is unknown but is probably *trans* Ph/Ph on the grounds of its very intense u.v. absorption band.

Preliminary Pharmacological Results and Discussion

The anti-histaminic potencies of a series of aminobutenes, as measured by their ability to antagonize the histamine-induced contraction of the guinea-pig ileum, are given in Tables II and III. Thanks are due to Drs. R. T. Brittain and R. G. W. Spickett of Allen and Hanburys, Ware, U.K. for arranging these tests. Tentative structure–activity relationships drawn from results of the initial series (Table II) are as follows:

First, amongst the diphenylbutene samples (Table II, Nos. 1–3) the ternary mixture is by far the most active; it has a pA_2 value of 9.4 comparable with those of highly active anti-histaminic agents (7). This mixture is composed of the *cis* and *trans* but-1-enes **4***a* and the *cis* but-2-ene **3***a*, and since the but-1-enes are much less active than the mixture [the *cis* isomer **4***a*, not included in these tests, has previously been shown to have a low order of activity (8)], it may be deduced (assuming

synergism is not operative in the mixture) that the *cis* but-2-ene **3***a* is the most active of the four isomers derived from the butanol **1***a* (Ar = Ar′ = Ph). Pure *cis* **3***a*, unavailable at the time of these tests, has now been isolated and a study of its anti-histaminic properties is in hand.

Secondly, a 3-methyl substituent reduced activity in *trans* but-1-enes (Table I, Nos. 1 and 4). In the same series the 1, 2-diphenyl and 1-*p*-tolyl, 2-phenyl members have comparable activities (Nos. 4 and 5) while the 1-2(2-pyridyl) and 1-(*o*-tolyl) analogues are of significantly reduced potency (Nos. 6 and 7). Replacement of 2-phenyl in No. 4 by 2-thienyl is advantageous (No. 9) but substitution of 2-phenyl by *p*-methoxyphenyl gives a less potent compound (No. 10).

Thirdly, among the two but-1-ene pairs Nos. 7/8, and 10/11, the *cis* member is more potent than the *trans* isomer.

These initial results indicative of the antagonism of histamine by aminobutene derivatives being stereoselective in nature, encouraged us to examine a second series, data for which (Table III) is summarized below:

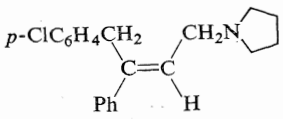
First, *o*-fluoro and particularly *o*-chloro substituents in the phenyl group at C-1 of *trans* **2** (Ar = Ar′ = Ph) reduce activity (Table III, No. 1–3); cf. similar influence of *o*-methyl in previous series (Table II, Nos. 4 and 7).

Secondly, amongst the *p*-methoxyphenyl derivatives (Table III, Nos. 4–7), the *trans* but-1-ene **4***b* and the *cis* but-2-ene **3***b* are far more active than corresponding geometrical isomers, the duration of action of *cis* **3***b* being particularly prolonged. *Cis* **3***b* (pA_2 6.94) is substantially less potent than the standard drug mepyramine (pA_2 8.67).

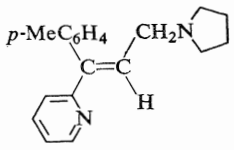
These results further emphasize the influence of steric factors upon activity among anti-histaminic aminobutenes and confirm that the disposition of functions about the double bond in a *cis* (Ar/H) 1,2 diarylbut-2-ene appear to be optimal for activity. It is significant that pyrrobutamine, an aminobut-2-ene already marketed as an anti-histaminic agent (9), has the same *cis* configuration **15** (unpublished p.m.r. results).

Differences in the anti-histaminic properties of geometrical isomers have previously been reported for Triprolidine **16** and its *trans* (2-pyridyl/H) analogue (10). The former compound and the *cis* but-2-enes **3***a*, **3***b*, and **15** possess the common structural feature **17** rigidly orientated in the same manner and it is attractive to postulate that their histamine-blocking actions are of like nature involving similar drug-receptor association modes.

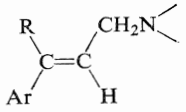
Kier (11) has recently proposed favored *anti* and gauche $\overset{+}{N}H_3$/Ar conformations for histamine based on molecular orbital calculations, and has suggested that the similar N to N interatomic distances of the *anti* conformer and triprolidine may be of significance regarding the latter compound's antagonistic properties. The present demonstration of stereospecific action among anti-histaminic agents which lack a pyridine substituent, suggests that the distance between the side chain nitrogen atom and the center of the aromatic ring attached to C-1 more truly represents the critical parameter for activity in these compounds. The problem of explaining the activity difference between triprolidine and its *trans* Ph/H isomer remains (since both forms may satisfy the aryl–nitrogen distance requirement), and further structure–activity data upon triprolidine analogues and related aminobutenes are being sought to provide more evidence upon this question.



15



16



17

Experimental

The proton magnetic resonance (p.m.r.) spectra were recorded on a Varian A-60 spectrometer using $CDCl_3$, CCl_4, or D_2O as solvent. Chemical shifts are expressed in Hz from the TMS standard.

β-*Dimethylamino-p-methoxypropiophenone*

A mixture of *p*-methoxyacetophenone (22.5 g), dimethylamine hydrochloride (15.75 g), paraformaldehyde (5.8 g), concentrated hydrochloric acid (0.4 ml), and ethanol (38 ml) was heated under reflux for 20 h. The cooled product was diluted with acetone (150 ml) when the *hydrochloride* of the β-*aminoketone* **6** (36 g), m.p. 186–186.5° separated.

Anal. Calcd. for $C_{12}H_{18}ClNO_2$: C, 59.1; H, 7.45; N, 5.7. Found: C, 58.7; H, 7.2; N, 5.3.

4-Dimethylamino-2-p-methoxyphenyl-1-phenylbutan-2-ol and its Elimination

The β-aminoketone **6** (24.5 g) in ether (50 ml) was added to benzylmagnesium chloride in ether (125 ml) prepared from benzyl chloride (29.7 g) and magnesium (6.7 g), the mixture heated under reflux for 3 h, and then decomposed with NH_4Cl–ice. The organic layer was dried (Na_2SO_4) and evaporated to give the impure butanol **7** (29 g), characterized as the *hydrochloride*, m.p. 195–196° from ethanol–ether.

Anal. Calcd. for $C_{19}H_{26}ClNO_2$: C, 67.9; H, 7.8; N, 4.2. Found: C, 67.6; H, 7.7; N, 4.0.

A mixture of the butanol **7** hydrochloride (9.5 g), concentrated hydrochloric acid (25 ml), and glacial acetic acid (70 ml) was heated under reflux for 4 h. The product was concentrated under reduced pressure and the free base recovered as usual. The p.m.r. spectrum of the total butene mixture in $CDCl_3$ displayed 4 vinylic signals (2 broad singlets and 2 triplets) and 4 closely placed OMe and NMe_2 singlets near 225 and 183 Hz from TMS respectively. Fractional crystallization of the base hydrochloride from ethanol–ether gave the following isomers (listed in order of separation):

The *trans but-1-ene* **4***b hydrochloride* (800 mg), m.p. 227–228°.

Anal. Calcd. for $C_{19}H_{24}ClNO$: C, 71.8; H, 7.6; N, 4.5. Found: C, 72.2; H, 7.8; N, 4.2.

The *trans but-2-ene* **3***b hydrochloride* (290 mg), m.p. 186.5–187.5°. Found: C, 72.05; H, 8.1.

The *cis but-2-ene* **3***b hydrochloride* (320 mg), m.p. 203–204°. Found: C, 71.9; H, 7.4.

The *cis but-1-ene* **4***b hydrochloride* (400 mg), m.p. 178.5–179.5°. Found: C, 71.9; H, 7.8.

Alkylation of Desoxybenzoin with 2-Dimethylaminoethyl Chloride

Sodamide (2.5 g) was added to desoxybenzoin (10.8 g) in benzene (20 ml) and the mixture heated under reflux for 3 h, cooled, and treated with 2-dimethylaminoethyl chloride (6.75 g), freshly liberated from the hydrochloride. After a further reflux period of 16 h, the reaction mixture was cooled, filtered, and concentrated *in vacuo*. The residue gave a distillate (13.1 g), b.p. 145–172°/1.2 mm and its p.m.r. spectrum in CCl_4 showed it to consist of about 70% of the *O*-alkyl-derivative **14** (integral of the vinylic singlet at 361 Hz), 15% of the *C*-alkyl isomer **11** (integral of the methine triplet at 283 Hz), and 15% desoxybenzoin (integral of the methylene singlet at 244 Hz). The total product in cold ether was acidified with ethereal HCl, and the precipitated salt collected, washed with ether, and fractionally crystallized from ethanol to give the *C-alkylamine* **11** *hydrochloride* (1 g), m.p. 250–253°.

Anal. Calcd. for $C_{18}H_{22}ClNO$: C, 71.2; H, 7.25; N, 4.6. Found: C, 70.8; H, 7.15; N, 4.3.

The *O-alkylisomer* **14** *hydrochloride* (7.2 g), m.p. 185–185.5°. Found: C, 71.2; H, 7.2; N, 4.4. Characteristic p.m.r. signals in D_2O: singlet 345 Hz (vinylic proton) and deformed, object–mirror image, triplets centered at 214 Hz (OCH_2) and 190 Hz (NCH_2) (in the base, CCl_4 solvent, these methylene signals are approximate first order triplets, $J = 7$ Hz). Repetition of the alkylation reaction with dimethyl sulfoxide as solvent (sodio derivative of desoxybenzoin formed as before then solvent benzene replaced by DMSO) and a heating period of 16 h at 80°, gave the *C*- and *O*-alkyl isomers in a ratio of 4:5.

Conformational analysis of 1,4-disubstituted cyclohexanes. III. *trans*-1,4-Di(trifluoroacetoxy)cyclohexane[1]

GORDON WOOD, E. P. WOO,[2] AND M. H. MISKOW[3]
Department of Chemistry, University of Windsor, Windsor, Ontario

Received September 13, 1968

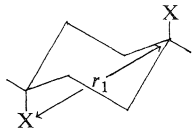
By the low temperature nuclear magnetic resonance integration method the standard free energy difference between the diequatorial and the diaxial forms of *1-H,4-H-trans*-1,4-di(trifluoroacetoxy)-cyclohexane-d_8 was found to be 77 ± 5 cal/mole. The conformational free energy ($-\Delta G°$) of the trifluoroacetoxy group in the monosubstituted cyclohexane was 485 ± 4 cal/ mole at the same temperature. The non-additivity of the $-\Delta G°$ values is discussed in terms of transannular electrostatic interaction.

Canadian Journal of Chemistry, 47, 429 (1969)

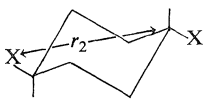
Introduction

Studies on the additivity of conformational energies of 1,4-substituents on cyclohexanes are quite uncommon. Generally, when one of the substituents is an alkyl group, it is assumed that additivity holds (1). However, recent work from our laboratory (2, 3) has shown that if two polar groups are *trans* to each other, marked deviations from additivity are observed. Thus, the relative proportion of the two conformers of *cis*-1,4-bromochlorocyclohexane present at low temperature was shown to be nearly equal as expected from additivity of conformational energies. However, the conformational composition of a series of *trans*-1,4-dihalocyclohexanes was shown to differ considerably from the predicted values; indeed, the experimental preference for the diequatorial form was only one-fifth of the expected values.

One plausible explanation of non-additivity involves electrostatic interactions. Polarization of the C—X bonds results in partial charges on these atoms. The attractive interaction between C-1 and 4-X and between C-4 and 1-X is greater in the diaxial form than in the diequatorial form



1



2

(**1** vs. **2**);[4] for example, if X = Cl, r_1 = 3.9 Å, and r_2 = 4.8 Å. This postulate accommodates our results as well as some observations in the literature.[5] We report here some further results which are in agreement with the proposal.[6]

We have studied the conformational equilibrium of *1-H,4-H-trans*-1,4-di(trifluoroacetoxy)-cyclohexane-d_8 (**3**) at low temperature by integration of the separate axial and equatorial proton signals. The trifluoroacetoxy group was chosen for its high electronegativity (3.77 vs. 3.25 for chlorine and 2.96 for bromine according to the scale of Cavanaugh and Dailey (5)). Higher electronegativity in the group X should favor the diaxial form and thus result in an increase in the deviation from additivity.[7]

Results and Discussion

The nuclear magnetic resonance (n.m.r.) spectrum of **3** followed the usual pattern of cyclohexyl compounds on cooling. The coalescence

[1]See refs. 2 and 3 for the previous papers in this series.

[3]Holder of NRCC Studentships, 1966–1968.

[4]The repulsive interaction between 1-X and 4-X favors the diequatorial form, but because the potential energy varies as $1/r^2$ this interaction will not be as large as the attractive one.
[5]Note that *trans*-1,2-dihalocyclohexanes also exist in approximately equal mixtures of diaxial and diequatorial forms (4). While this result may be caused by electrostatic interactions, it is by no means clear what role steric effects play here.
[6]While this work was in progress, a similar proposal was put forward by Prof. R. Stolow to explain anomalous results in 4-hydroxycyclohexanones (see later discussion).
[7]Determination of the position of conformation equilibrium in 1,4-disubstituted cyclohexanes where only one group is polar would constitute an interesting test for this postulate. We have prepared *cis*-4-methylcyclohexyl chloride for this purpose, but so far have not been able to detect the signal from the axial C-1 proton. Results on *cis*-4-methylcyclohexylamine suggest that additivity is followed at least approximately in this compound (6).

temperature was ca. −90°. Upon further cooling to −103°, two separate signals were obtained (peak widths at half-height were 3.5 Hz). Integration of the peak areas allowed calculation of the free energy difference between the diequatorial and diaxial form. A value of 77±5 cal/mole in favor of the former was found. At the same temperature this method gave a value for $-\Delta G°$ of 485±4 cal/mole for trifluoroacetoxycyclohexane-2,2,6,6-d_4. Assuming additivity, the free energy difference between the two conformers of **3** should be 970 cal/mole. The importance of this deviation can be appreciated if one remembers that the predicted value corresponds to a 95:5 ratio of conformers and the actual value corresponds to a 55:45 ratio at the temperature studied.

Several results in the recent literature may involve an electrostatic interaction of the kind proposed here. Notable among these is the report that the conformational equilibrium constant for 4-hydroxycyclohexanone is very nearly unity (7). Thus the apparent $-\Delta G°$ value for hydroxyl is reduced from its usual value of 0.7 kcal/mole or higher (8) to zero. Similar results were reported by Stolow *et al.* (9) from equilibration of *cis*- and *trans*-2-*t*-butyl-4-hydroxycyclohexanone.

Equilibration of 4-chlorocyclohexanol resulted in a slight preponderance (54.5%) of the *cis* isomer (10). Although further study is required to establish the cause of this result, it is clear that application of the $-\Delta G°$ values for the individual groups fails to predict it. The protonation of cyclohexane-1,4-bisnitronate ion also gave 55% of the *cis* isomer. Although this result was originally attributed to steric hindrance to axial protonation of the half-protonated form (11), some doubt has recently been cast on this explanation (12). It seems likely to us that electrostatic interaction across the ring is responsible for both of these results, although in the latter case the interaction would have to be operative in the transition state if this reaction is kinetically controlled.

Our conclusion is that interaction between polar groups across a cyclohexane ring is a general phenomenon which frequently determines the position of conformation equilibrium and the stereochemical outcome of reactions for such compounds.

Experimental

Nuclear magnetic resonance spectra were recorded with a JEOL 60 MHz instrument in 10–15% acetone-d_6 solutions. Tetramethylsilane was used as the internal standard. Twelve integrations were performed on the diester and fourteen on the monoester. A computer program was used for all the calculations. The relative peak areas of each integration were converted to the corresponding equilibrium constant. A standard deviation was obtained for each set of data, from which the reported errors were computed.

Preparative gas–liquid chromatography (g.l.c.) was carried out with an F and M 720 instrument. The column (8 ft × 0.5 in.) was packed with Lac 728. Melting points were determined on a Fisher–Johns apparatus and are uncorrected. All samples were purified by preparative g.l.c immediately before use.

Cyclohexane-1,4-dione-d_8[8]

To a solution of 0.5 g of PCl_5 and 25 ml of D_2O (99.7%) was added 5.0 g of cyclohexane-1,4-dione. After standing at room temperature for 5 days, the solution was extracted with four 10 ml portions of methylene chloride. The combined organic phase was dried with anhydrous Na_2SO_4 and filtered. Removal of the solvent afforded 4.7 g of white solid which was dissolved in a solution of 35 ml of D_2O containing 1 g of PCl_5. Four days standing at room temperature followed by the usual isolation procedure yielded 3.3 g of white crystalline solid, m.p. 78–80° (lit. m.p. 78° for the hydrogen analogue (14)). Integration of the relative peak areas of the residual hydrogen and a known amount of dioxane showed 94% isotopic purity.

Cyclohexane-1,4-diol-2,2,3,3,5,5,6,6-d_8

The procedure of Lemieux and Lown (15) for the reduction of the dione was followed, and gave 2.6 g of viscous brown oil which was used in the next step without purification.

1-H,4-H-trans-1,4-Di(trifluoroacetoxy)cyclohexane-d_8

The brown oil obtained above was dissolved in 10 ml of tetrahydrofuran and cooled in an ice-bath. Trifluoroacetic anhydride (4 ml) was added dropwise with stirring. After standing at 0° for 1 h, the solution was poured onto ice and saturated with potassium carbonate. The organic layer was separated and the aqueous layer extracted with 10 ml of ether. After drying and removal of the solvent, a viscous brown oil was obtained which was shown by g.l.c. (110°) to consist of two main components in the ratio 70:30. Collection of the larger peak (retention time, 18 min) gave a white crystalline solid, m.p. 57.5–58°, and the second (retention time, 27 min) yielded a colorless liquid. The retention times were identical to those of the hydrogen analogues prepared in the same manner. The structure of the *trans* isomer was confirmed by saponification of the hydrogen analogue (m.p. 57–58°), according to the method of Owen and Robins (16), to the *trans*-diol, m.p. 140–142° (lit. m.p. 141° (16)).

Trifluoroacetoxycyclohexane-2,2,6,6-d_4

Deuteration and subsequent reduction of cyclohexanone was performed according to the method of Premuzic

[8]The potassium carbonate-catalyzed exchange procedure reported by Bhatt *et al.* (13) consistently gave a dark brown gum.

and Reeves (17). The trifluoroacetate was prepared by essentially the same method as above except that ether was used as solvent.

The total synthesis of optically active annotinine

K. Wiesner, Lizzie Poon, I. Jirkovský, and M. Fishman
Natural Product Research Center, University of New Brunswick, Fredericton, New Brunswick
Received October 21, 1968

The total synthesis of the first *Lycopodium* alkaloid annotinine in the optically active form is described. The key step in this synthesis was the photochemical addition of allene to the tricyclic vinylogous imide (**3**) which yielded the photoadduct (**6**).

Canadian Journal of Chemistry, **47**, 433 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In the years 1956–1957 we have deduced the structure of the first *Lycopodium* alkaloid annotinine (**1**) (1). The only feature of the formula (**1**) which did not follow from the chemical evidence was the configuration of the methyl group. The complete stereochemistry of annotinine was later revealed by an X-ray crystallographic structure determination of annotinine bromohydrin (2). It seemed to us that the *Lycopodium* alkaloids in general and annotinine in particular offer an interesting synthetic challenge. A simple and successful solution of the problems involved would require the design of new synthetic methods and these would presumably be capable of a wider application.

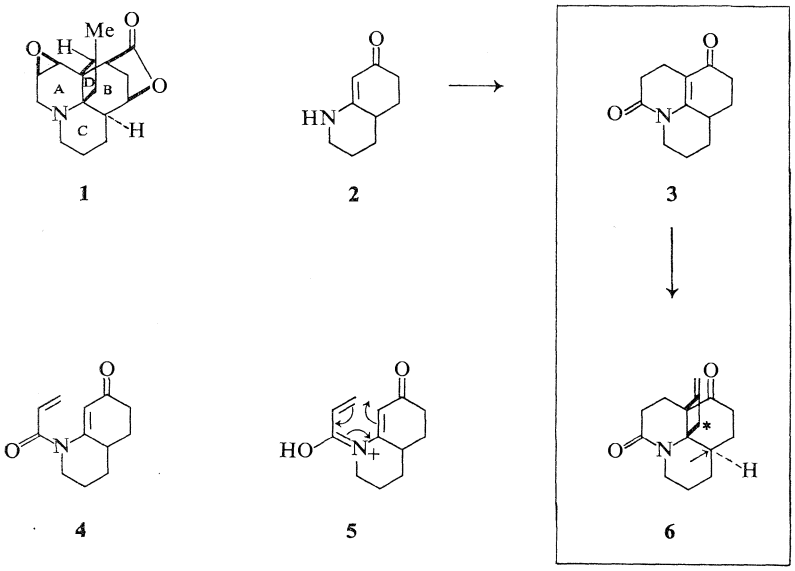
A stereospecific synthesis would also provide chemical evidence for the configuration of the annotinine methyl group and we felt that we owe to this classical structural problem a rigorous and complete chemical solution.

At the outset of our synthetic studies one of us (K.W.) proposed two general approaches to the various *Lycopodium* systems: (1) The reaction of Grignard reagents with properly constituted vinylogous amides and (2) The photo-addition of allene to properly constituted vinylogous imides. It was the second approach which seemed promising for a very simple tailor-made annotinine synthesis and after a verification of the novel photo-reaction on model compounds (3) we indeed succeeded in synthesizing racemic annotinine in 1967 (4). In the following year we have made considerable improvements in the later stages of the synthesis and also achieved a resolution of a suitable intermediate into optical antipodes. Consequently, we wish to give in the present communication a full account of the preferred synthetic route to optically active annotinine.

Our starting material was the bicyclic vinylogous amide (**2**), which may be easily prepared from acrylonitrile and methyl acrylate (5). This compound is destined to form rings B and C of annotinine. The first task in our synthesis was now to fuse ring A to the system and to obtain the tricyclic vinylogous imide (**3**). We have envisaged that this objective might be accomplished by the treatment of (**2**) with acrylonitrile or methyl acrylate in the presence of various basic catalysts. However, only small amounts of the product (**3**) were produced under these conditions. Finally it was found that heating of the bicyclic starting material (**2**) with a small excess of acrylic acid to 135 °C gives an excellent yield of the desired tricyclic product (**3**). Compound (**3**) was crystalline and showed characteristic ultraviolet and infrared spectra.[1] (Ultraviolet: $\lambda_{max} = 298$ mμ; $\log \varepsilon = 4.1$; Infrared ($CHCl_3$): maxima at 1695, 1645, 1610 cm^{-1}). A possible rationalization of the process leading to (**3**) is the initial formation of the vinylogous imide (**4**) which may protonate on the amidic oxygen and undergo a thermal cyclization as portrayed in the formula (**5**).

The next step (**3**) → (**6**) was of crucial importance, since on its outcome depended the success of the entire synthesis. We have hoped to accomplish it by a photochemical addition of allene to (**3**) at low temperature. *A priori* it was not at all certain that only one compound would result in this process. Isomers with the exocyclic double bond located at the asterisked carbon and diastereoisomers at the carbon marked with the arrow were clearly possible products of the novel photo-addition. In fact, a single compound was formed in high yield and it was shown to possess the structure (**6**) (*vide infra*). The photoadduct was homogeneous, crystalline, and yielded analytical

[1]Only specially relevant spectral data are mentioned in the theoretical part; for more spectral data and full characterization of compounds see Experimental.



1 2 3 4 5 6

and spectroscopic data consistent with the formula (**6**). (Infrared ($CHCl_3$): 1700 (ketone), 1640 (lactam), 908 cm^{-1} (exocyclic methylene); Nuclear magnetic resonance (n.m.r.): narrow doublet (2 H) $\tau = 5$ p.p.m. (vinylic hydrogen).

The next compound required, both for the purpose of the structure proof of (**6**) and to carry on the synthesis, was the ketal (**7**). It was prepared in a quantitative yield by ketalization of (**6**) in benzene with *p*-toluenesulfonic acid and ethylene glycol. The ketal (**7**) was crystalline and it was fully characterized. The transformation of the ketal (**7**) to the diketone (**10**) was carried out in our laboratories by H. Dugas in connection with another problem.[2] The process involved an epoxidation of (**7**) to (**8**), reduction of the epoxide with lithium borohydride to the tertiary alcohol (**9**), and finally the treatment of compound (**9**) with aqueous acid, which yielded by deketalization and simultaneous retroaldol reaction the diketone (**10**). The sequence (**7**) → (**10**) proves unambiguously the relative position of the keto group and the exocyclic methylenic group in the photoadduct (**6**) and thus it proves the structure of this compound.

The only point which is still in question is the configuration of the asymmetric center marked with the arrow in formula (**6**). For the purposes of the annotinine synthesis this configuration is unimportant, since the asymmetric center involved becomes epimerizable and equilibrates in one of the subsequent steps.

Nevertheless, we believe that the configuration of our photoadduct is in fact as shown in the formula. Several cases of related stereospecific photo-additions to α,β-unsaturated carbonyl compounds studied in our laboratories can be rationalized without exception by the hypothesis (7) that the stereochemistry of the photo-addition is not controlled by the stability of the product, but by the tendency of the excited state to exist preferentially in the most stable configuration. If the excited state is assumed to have carbonium character in the position α to the carbonyl group and an orbital with an electron pair in the β position, then its most stable configuration in the present case would be the one shown in formula (**13**), in which the orbital and the adjacent hydrogen (indicated by arrows) are axial *trans*. The addition of allene to this species would then yield an adduct with the configuration as in (**6**). Experimental evidence which supports this configuration and which is based on infrared spectroscopy of various transformation products of compound (**10**) may be found in H. Dugas' thesis (6).

With all the important structural features of the photoadduct established, we may now return to the description of our main synthetic pathway. At this point it is advantageous to effect a stereo-

[2]This transformation is described in the Ph.D. Thesis of H. Dugas and it will be published separately.

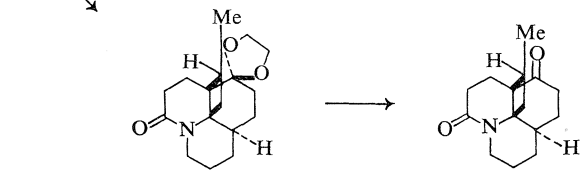
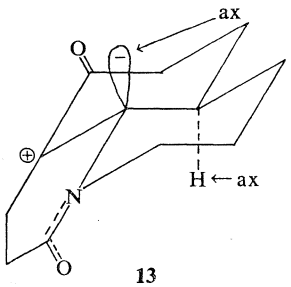
7 8 9 10



11 12



13

specific hydrogenation of the exocyclic methylenic double bond in the photoadduct. A derivative particularly suitable for this purpose is the ketal (**7**). In this compound the double bond is shielded by the plane of the dioxolane ring and consequently it hydrogenates stereospecifically from the opposite direction to yield exclusively the dihydro derivative (**11**). Compound (**11**) was crystalline and homogeneous and it was fully characterized. By deketalization it yielded the crystalline and homogeneous ketolactam (**12**).

This last compound (**12**) was now reduced with sodium borohydride in aqueous tetrahydrofuran to the alcohol (**14**) in a quantitative yield. Compound (**14**) was crystalline and it was fully characterized. The configuration of the hydroxyl in this product is assumed to be *cis* to the cyclobutane ring. The keto group of compound (**12**) is strongly hindered from the side of the cyclobutane ring and it is assumed that in the reduction process the borohydride approaches from the less

hindered side. The alcohol (**14**) was converted into the mesylate (**15**) with methane sulfonyl chloride in pyridine in a 92% yield. The mesylate

For personal use only.

crystallized from benzene and was fully characterized. Attempts to achieve an elimination of the mesyl group under various basic conditions gave only modest yields of the desired olefin (**16**) accompanied by equal quantities of the rearrangement product (**17**). Finally it was found that treatment of the mesylate (**15**) with potassium tertiary butoxide in absolutely anhydrous dimethyl sulfoxide yielded the desired compound (**16**) as a crystalline single product in a yield of 83%. The n.m.r. spectrum of (**16**) showed a multiplet (2 H) centered at $\tau = 4.45$ p.p.m. for the two olefinic protons. The shift of the methyl group doublet (3 H) from $\tau = 8.66$, 8.76 p.p.m. in the n.m.r. spectrum of the mesylate (**15**) to $\tau = 9.06$, 9.18 p.p.m. in the n.m.r. spectrum of the olefin (**16**) constitutes independent evidence for the configuration of the methyl group, which in compound (**16**) is located in the shielding region of the double bond.

We believe that there may be some theoretical significance in the fact that we have not succeeded in finding any other basic conditions which would yield only elimination unaccompanied by rearrangement besides the conditions given above. It is well known that Hofmann eliminations are not prone to rearrangement. In a recent summarizing article it was pointed out that eliminations of halides and sulfonates with potassium tertiary butoxide in DMSO follow (in cases unlike ours, where there is a choice) the Hofmann rule rather than the Zajcev rule and thus, in this respect, resemble Hofmann eliminations (8). The lack of rearrangement found by us and the special directional behavior of this type of sulfonate eliminations might well have a common cause and be due to the nature of the transition state of this reaction.

Oxidation of the olefin (**16**) with selenium dioxide in glacial acetic acid yielded the oily acetate (**18**) in a 67% yield. It was characterized by spectroscopy and was homogeneous in t.l.c. Basic hydrolysis of the acetate proceeded in quantitative yield and the alcohol (**19**) was oxidized to the α,β-unsaturated ketone (**20**) with chromium trioxide in pyridine. Compound (**20**) was crystalline and showed an infrared and an ultraviolet spectrum in agreement with the structure assigned to it. [Infrared ($CHCl_3$): 1690, 1660, 1620 cm^{-1} (conjugated ketone, double bond, and lactam); ultraviolet: $\lambda_{max} = 230$ mμ, $\log \varepsilon = 4.0$]. In the n.m.r. spectrum of (**20**) a quadruplet (2 H) centered at $\tau = 3.58$ p.p.m. was assigned to the two vinylic protons. The configuration of the hydrogen next to the ketone in formula (**20**) is left unassigned, since we have not investigated whether this configuration has undergone epimerization on work-up and chromatography of the reaction mixture. The optically active form of (**20**) is known, since many years ago we prepared it by degradation of annotinine (1*b*). We did not possess a reference sample, but it was a matter of some satisfaction that the infrared spectra of the "natural" and synthetic materials were identical in every detail.

With an efficient method for the preparation of the α,β-unsaturated ketone (**20**) in hand, the stage is set for the introduction of the annotinine carboxyl. The ketone (**20**) was subjected to a hydrocyanation reaction in dimethyl formamide (9), which gave two diastereoisomers of compound (**21**) in a total yield of 82%. The two compounds were purified by chromatography, but not separated from each other. The mixture was characterized by the mass spectrum, which displayed a correct molecular ion and by its infrared spectrum. (Infrared ($CHCl_3$): 2230, 1720, 1650 cm^{-1} [nitrile, ketone, lactam]). It gave two spots of equal intensity on a thin-layer chromatogram.

The nitrile mixture (**21**) was now converted by refluxing with methanol and sulfuric acid into the crystalline methyl ester (**22**). After chromatography and crystallization the yield of this material was 46%. We have described (1*b*) the optically active form of this compound 10 years ago and it is readily available from annotinine.

The synthetic racemate (**22**) was found to be identical with the "natural" optically active compound (**22**) by t.l.c., i.r. spectrum in potassium bromide and carbon tetrachloride and by mass spectrometry. The configuration of the synthetic compound (**22**) follows from this identity, since for the "natural" material the stereochemistry portrayed in formula (**22**) was rigorously proved (1*b*). It clearly corresponds to the most stable configuration and the proof cited above is independent of the fact that the conformational analysis of the system is difficult and unconvincing.

The synthetic racemic ester (**22**) was now hydrolyzed to the crystalline racemic acid (**23**) and this last material was converted into the diastereoisomeric brucine salts by treatment with one equivalent of brucine. The less soluble di-

astereoisomer was obtained pure by crystallization from acetone–methanol mixtures and melted constantly at 158–160 °C. Decomposition of this salt yielded the crystalline optically active acid (**23**), which was esterified with diazomethane to the totally synthetic optically active ester (**22**). After recrystallization this compound melted at 198–200 °C, and did not depress the identical melting point of the "natural" ester (**22**). Both materials showed also practically superimposable rotatory dispersion curves, a clear proof of the complete optical purity of the synthetic compound (Fig. 1). Infrared (CCl_4 and KBr) and mass spectra of both materials were also identical in every detail.

The next problem which had to be solved was the conversion of the optically active ester (**22**) to the lactam-lactone (**27**). This task involved the inversion of two asymmetric centers and the creation of a third one. In our preliminary communication (4*b*) we have described a route via the selenium dioxide dehydrogenation of (**22**) to (**24**), a step which proceeded in a very low yield and was known already from the time of our structural studies (1*a*, *b*). Hydrogenation of (**24**) proceeded stereospecifically and yielded the ester (**25**). Basic hydrolysis of (**25**) accompanied by epimerization of the carboxyl gave the acid (**26**). This compound finally yielded the lactam-lactone (**27**) by lactonization in benzene – dimethyl formamide with *p*-toluenesulfonic acid with a new epimerization of the carboxyl.

We have now succeeded in elaborating a more efficient method, which completely avoids the low yield step (**22**) → (**24**). The ester (**22**) was converted into the crystalline enol-acetate (**28**) in a yield of 91% after recrystallization. The n.m.r. and i.r. spectra of this material defined the structure as given in the formula. (Nuclear magnetic resonance: singlets (3 H) each τ = 6.29 and 7.84 p.p.m. (ester and acetate methyls), no vinylic hydrogen; Infrared ($CHCl_3$): 1750, 1640 cm^{-1} (esters and lactam)). The enol-acetate (**28**) was now subjected to a reduction with sodium borohydride in absolute tetrahydrofuran and methanol. The result of this reduction was a mixture of the hydroxyester (**29**) and an isomeric hydroxyester presumably (**30**). The two compounds were purified by chromatography, but not separated from each other. They were characterized by the correct molecular ion in mass spectrometry, and by the infrared spectrum. The reason for the

For personal use only.

assumption, that the second isomer may be represented by the formula (**30**) is the fact that both the reduction products of compound (**28**) were distinctly different (t.l.c.) from the analogous borohydride reduction product of the keto-ester (**22**).

The mixture of the esters (**29**) and (**30**) was hydrolyzed to the corresponding carboxylic acids (**26**) and (**31**) and these materials were, without separation, subjected to lactonization in dry benzene with *p*-toluenesulfonic acid. Work-up and chromatography gave the crystalline lactone (**27**) in a yield of 38%. It was proved to be identical with the product of the same structure which may be simply prepared directly from annotinine (10) by mixed melting point, infrared spectrum in chloroform, mass spectrum, and thin-layer chromatography.

Under the lactonization conditions used, the hydroxy acid (**31**) remained unchanged and was isolated in approximately the same yield as the lactone. Since the acid (**31**) could be presumably esterified and oxidized back to the keto-ester (**22**), the presently described process for the conversion of (**22**) to (**27**) could be made reasonably efficient. As it is, even without the reconversion of (**31**) to (**22**), the overall yield from the enol-acetate (**28**) to the lactam-lactone (**27**) was 25%.

The formulae (**28**), (**30**), and (**31**) leave the configuration of the carboxyl unassigned, because it is unproved. The remaining structures represent compounds known from our degradative work and their complete configurations have been fully documented, cf. (1*c*). We believe that the reduction process of (**28**) to the mixture (**29**) and (**30**) proceeds as follows: (1) Alcoholysis of the enol-acetate (**28**) to the corresponding enolate ion. (2) Kinetically controlled protonation of the enolate ion to a keto-ester epimeric with the ester (**22**) on the asymmetric carbon α to the keto group. (3) Non-stereospecific reduction of the keto group in this hypothetical intermediate, before it can isomerize to the more stable ester (**22**).

The final task which we face at this point is the conversion of the lactam-lactone (**27**) to annotinine (**1**). The reaction sequence, which we worked out to this end, is portrayed in the formula Scheme V. All the intermediates in this sequence may be reached also in the opposite direction, i.e. by unexceptional degradation reactions of annotinine. Since some of these compounds have not been described in the literature, it is convenient to discuss the degradation series first.

The potassium permanganate oxidation of annotinine to oxoannotinine (**34**) is well known (cf. 1*c*). It is also well known that the treatment of (**34**) with hydrochloric acid yields oxoannotinine chlorohydrin, which may be dehydrated to oxoanhydroannotinine chlorohydrin by phosphorus oxychloride. These two chlorine containing derivatives have well established structures (cf. 1*c*), and are chlorine analogues of the two bromo compounds (**33**) and (**32**). The heating of oxoannotinine (**34**) with aqueous hydrobromic acid (19%) gave a good yield of the bromohydrin (**33**), which crystallized directly from the reaction mixture on cooling and was fully characterized.

Compound (**33**) was then subjected to dehydration with phosphorus oxychloride to the anhydro derivative (**32**). Also this material was crystalline

For personal use only.

and fully characterized and analyzed. It is interesting that the infrared spectrum of (**32**) was superimposable on the spectrum of the previously known chloro analogue. The mass spectra of both materials were identical except for the shift due to the difference in the atomic weight of bromine and chlorine.

With all the intermediates characterized, we may now discuss the reverse process, i.e. the conversion of the lactam-lactone (**27**) to annotinine (**1**). Compound (**27**) was dissolved in carbon tetrachloride and brominated with *N*-bromosuccinimide under irradiation with visible light and reflux. Chromatography on silica gel followed by crystallization allowed the isolation of compound (**32**) in a yield of 16%. Identity of the totally synthetic compound (**32**) and the same product prepared from annotinine (*vide supra*) was established by mixed melting point, infrared spectrum (KBr), mass spectrum, and thin-layer chromatography. The conversion of compound (**32**) to the bromohydrin (**33**) was accomplished by an acid-catalyzed hydration in hot aqueous hydrobromic acid. An equilibrium between various possible compounds was probably established under these conditions, and it was our good fortune that the desired product (**33**) crystallized gradually from the reaction mixture thus shifting the equilibrium in its favor. The synthetic compound (**33**) was purified by recrystallization and rigorously identified with the material prepared from oxoannotinine (**34**) by mixed melting point, t.l.c., mass, and infrared (KBr) spectroscopy.

With the successful preparation of the bromohydrin (**33**) the last serious obstacle in the total synthesis of annotinine was removed. The bromohydrin (**33**) yielded predictably oxoannotinine (**34**) (for the analogous reaction in the chloro series cf. 1*c*) on refluxing with sodium bicarbonate in aqueous acetone. Also in this step the product crystallized directly from the reaction mixture and was purified by recrystallization. Identity of the synthetic compound (**34**) and the material obtained by oxidation of annotinine was rigorously established (mixed m.p., t.l.c., i.r. (KBr), mass spectrum). Having synthesized oxoannotinine, we have formally completed the total synthesis of the natural alkaloid annotinine itself. The conversion of oxoannotinine to annotinine by an unusual hydrogenolysis with platinum oxide in methanolic hydrochloric acid has already been described by Betts and MacLean (11). Because we wished to actually perform the entire synthesis and also because of the unusual nature of the reported last step, we have repeated the hydrogenation of oxoannotinine according to the directions of the above authors. Annotinine was indeed obtained in a yield of 56% and rigorously identified. Besides annotinine we isolated some starting material and oxoannotinine chlorohydrin. Since this last compound is convertible to oxoannotinine by bicarbonate (*vide supra*) the yield obtainable in MacLean's hydrogenolysis is actually very high. Thus the total synthesis of the first natural *Lycopodium* alkaloid is complete.

Experimental

Preparation of the Tricyclic Vinylogous Imide (3)

The bicyclic compound (**2**) (1.4 g) and acrylic acid (0.67 g) were heated to 135 °C for 2 h. After this the mixture was cooled to 50 °C and chloroform (100 ml) was added to it. The chloroform solution was then washed five times with 5% hydrochloric acid (30 ml), dried, and evaporated to dryness. It yielded 1.2 g (63%) of compound (**3**), m.p. 81–83 °C, homogeneous in t.l.c.

Anal. Calcd. for $C_{12}H_{15}NO_2$ (mol. wt., 205): C, 70.24; H, 7.32. Found (mass spectroscopy, 205): C, 70.35; H, 7.23.

Infrared ($CHCl_3$): 1695, 1645, 1610 cm^{-1}. Ultraviolet: $\lambda_{max} = 298$ mμ ($\log \varepsilon = 4.1$.).

Preparation of the Photoadduct (6)

The tricyclic compound (**3**) (102 g) was dissolved in distilled tetrahydrofuran (4 l) and cooled to −70 °C. Allene was added in great excess (about 500 ml) and the mixture was irradiated by a mercury lamp with a Pyrex glass jacket, through which methanol cooled to −70 °C was circulated. The irradiation was continued for 20 h. After evaporation of the solvent the photoadduct (**6**) was purified by crystallization from ethyl acetate. After several crystallizations the yield was 66 g (54%), m.p. 155–157 °C.

Anal. Calcd. for $C_{15}H_{19}NO_2$ (mol. wt., 245): C, 73.47; H, 7.76. Found (mass spectroscopy, 245): C, 73.35; H, 7.78.

Infrared ($CHCl_3$): 1700 (ketone), 1640 (lactam), 908 cm^{-1} (exocyclic methylene). Nuclear magnetic resonance: narrow doublet (2 H), $\tau = 5$ p.p.m. (vinylic hydrogen).

Preparation of the Ketal (7)

The photoadduct (**6**) (10 g) was dissolved in dry benzene (500 ml) to which ethylene glycol (54 g) and *p*-toluenesulfonic acid (3.8 g) were added. The solution was refluxed overnight with a water separator. After this the solution was cooled, washed with water, dried, and evaporated to dryness. The ketal (**7**) was recrystallized from ether to a m.p. of 95–97 °C. The yield was 11.5 g (97%).

Anal. Calcd. for $C_{17}H_{23}NO_3$: mol. wt. 289. Found (mass spectroscopy/mol. wt.): 289.

Infrared ($CHCl_3$): 1630 (lactam), 910 cm^{-1} (exocyclic

For personal use only.

methylene). Nuclear magnetic resonance: quadruplet (2 H) τ = 4.80, 5.04 p.p.m. (vinylic hydrogen), singlet (4 H) τ = 6.05 p.p.m. (dioxolane hydrogen).

Hydrogenation of (7) to (11)

The ketal (**7**) (11.5 g) was hydrogenated in 400 ml of ethanol with 2 g of prehydrogenated platinum oxide for 2 h. The product (**11**) was recrystallized from ether to a m.p. of 162–164 °C. The yield was 11.2 g (96%).

Anal. Calcd. for $C_{17}H_{25}NO_3$: mol. wt., 291. Found (mass spectroscopy): mol. wt. 291.

Infrared ($CHCl_3$): 1615 cm^{-1} (lactam). Nuclear magnetic resonance: singlet (4 H) τ = 6.03 p.p.m. (dioxolane hydrogen), doublet (3 H) τ = 8.69, 8.83 p.p.m. (*C*-methyl).

Deketalization of (11) to (12)

Compound (**11**) (11.2 g) was dissolved in acetone (500 ml) and *p*-toluenesulfonic acid (2.6 g) was added to the solution. The mixture was then heated under reflux overnight. The acetone was evaporated *in vacuo*, chloroform (200 ml) was added and the solution was washed, dried, and evaporated to dryness. The product (**12**) was recrystallized from ethyl acetate to a m.p. of 165–167 °C. The yield was 9 g (95%).

Anal. Calcd. for $C_{15}H_{21}NO_2$ (mol. wt., 247): C, 72.85; H, 8.56; N, 5.66. Found (mol. wt., mass spectroscopy, 247): C, 72.37; H, 8.63; N, 5.68.

Infrared (CCl_4): 1700 (ketone), 1660 cm^{-1} (lactam). Nuclear magnetic resonance: doublet (3 H) τ = 8.94, 9.05 p.p.m. (*C*-methyl).

Reduction of (12) to (14)

The keto lactam (**12**) (9 g) was dissolved in tetrahydrofuran (400 ml) and sodium borohydride in water (40 ml) was added. The reaction mixture was stirred for 2 h, after which the tetrahydrofuran was evaporated *in vacuo* and chloroform (200 ml) was added. The solution was washed, dried, and evaporated to dryness. The product (**14**) was recrystallized to a m.p. 182–183 °C from benzene. The yield was 8.6 g (96%).

Anal. Calcd. for $C_{15}H_{23}NO_2$ (mol. wt., 249): C, 72.37; H, 9.29; N, 5.62. Found (mol. wt., mass spectroscopy, 249): C, 72.48; H, 9.52; N, 5.76.

Infrared ($CHCl_3$): 3600 (hydroxyl), 1620 cm^{-1} (lactam). Nuclear magnetic resonance: doublet (3 H) τ = 8.71, 8.83 p.p.m. (*C*-methyl).

Preparation of the Mesylate (15)

The alcohol (**14**) (1 g) was dissolved in pyridine (10 ml) and methane sulfonyl chloride (0.65 g) was added. The reaction mixture was stirred for 15 h at room temperature and worked up in the usual manner. The product (**15**) was recrystallized from benzene to a m.p. of 162–164 °C. The yield was 1.23 g (92%).

Anal. Calcd. for $C_{16}H_{25}NO_4S$: C, 58.76; H, 7.65; N, 4.28. Found: C, 59.61; H, 7.60; N, 4.23.

Infrared ($CHCl_3$): 1620 (lactam), 1375, 1175 cm^{-1} (OSO_2). Nuclear magnetic resonance: singlet (3 H) τ = 6.92 p.p.m. (—O_3S—CH_3), doublet (3 H) τ = 8.66, 8.76 p.p.m. (C—CH_3).

Preparation of the Olefin (16)

The mesylate (**15**) (100 mg) was dissolved in absolutely dry dimethyl sulfoxide and freshly sublimed potassium tertiary butoxide (42 mg) was added. The mixture was heated for 15 h to 70 °C with *absolute* exclusion of moisture. The reaction mixture was then poured into ice-water and extracted with cloroform. After washing and drying the chloroform was evaporated to dryness and the residue chromatographed on a column of silica gel (10 g). Elution with chloroform yielded the olefin (**16**). It was recrystallized from benzene–ether to a m.p. of 76–77 °C. The yield was 83%. Elution of the column with 1% methanol in chloroform yielded 15 mg of the starting material (**15**).

A large amount of the mesylate (**15**) was transformed to (**16**) in a series of small runs not exceeding 200 mg, since the yields in larger runs were lower for reasons unknown.

Anal. Calcd. for $C_{15}H_{21}NO$ (mol. wt., 231): C, 77.89; H, 9.15; N, 6.06. Found (mol. wt., mass spectroscopy, 231): C, 78.16; H, 9.24; N, 5.94.

Infrared ($CHCl_3$): 1615 cm^{-1} (lactam). Nuclear magnetic resonance: multiplet (2 H) τ = 4.45 p.p.m. (vinylic hydrogen), doublet (3 H) τ = 9.06, 9.18 p.p.m. (C—CH_3).

Oxidation of (16) to (18)

The olefin (**16**) (100 mg) was dissolved in glacial acetic acid (5 ml) and a solution of freshly sublimed selenium dioxide (100 mg) in water (1 ml) was added. The mixture was heated under reflux overnight, filtered, and evaporated to dryness. The residue was taken up in chloroform, washed, dried, and evaporated to dryness again to yield the crude mixture of the epimeric acetates (**18**). It was purified for spectroscopic examination by chromatography (yield 67%), but was used in the crude form for further work.

Anal. Calcd. for $C_{17}H_{23}NO_3$: mol. wt., 289. Found (mass spectroscopy): mol. wt., 289.

Infrared ($CHCl_3$): 1745 (acetate), 1630 cm^{-1} (lactam). Nuclear magnetic resonance: multiplet (2 H) τ = 4.45 p.p.m. (vinylic hydrogen); singlet (3 H) τ = 7.89 p.p.m. (acetate methyl), doublet (3 H) τ = 9.00, 9.15 p.p.m. (*C*-methyl).

Hydrolysis of (18) to (19)

The acetate (**18**) was hydrolyzed by heating under reflux with a large excess of 1% methanolic potassium hydroxide for 5 h. After work-up in the usual manner the crude alcohol (**19**) was obtained in a yield of 90%. It was immediately oxidized to the ketone (**20**).

Preparation of the α,β-Unsaturated Ketone (20)

To an ice-cold solution of the crude alcohol (**19**) (100 mg) in pyridine (7 ml), chromium trioxide (100 mg) in pyridine (7 ml) was added. The ice bath was removed and the mixture was stirred at room temperature for 15 h. The reaction mixture was worked up as usual and the crude material chromatographed on a column of silica gel (10 g). The product (**20**) was eluted by chloroform and recrystallized to a m.p. of 150–152 °C from benzene–ether. The yield was 50 mg (50%).

Anal. Calcd. for $C_{15}H_{19}NO_2$ (mol. wt., 245): C, 73.43; H, 7.81; N, 5.72. Found (mol. wt., mass spectroscopy, 245): C, 73.40; H, 7.96; N, 5.65.

Infrared ($CHCl_3$): 1690 (ketone), 1660 (double bond), 1620 cm^{-1} (lactam). Ultraviolet: λ_{max} = 230 mμ (log ε = 4). Nuclear magnetic resonance: quadruplet (2 H)

centered at τ = 3.58 p.p.m. (vinylic hydrogen), doublet (3 H) τ = 8.97, 9.10 p.p.m. (*C*-methyl).

*Preparation of the Nitrile (**21**)*

The α,β-unsaturated ketone (**20**) (150 mg) was dissolved in dimethyl formamide (50 ml) and potassium cyanide (80 mg) and ammonium chloride (50 mg) in water (5 ml) was added. The mixture was heated for 48 h to 140–150 °C. After this time the solvent was removed *in vacuo* and the residue was dissolved in chloroform. After washing and drying the chloroform soluble material was chromatographed on a column of neutral alumina (20 g). Chloroform eluted 135 mg (82%) of the nitriles (**21**). The material gave two spots in t.l.c. and no attempt was made to separate the two diastereoisomers.

Anal. Calcd. for $C_{16}H_{20}N_2O_2$: mol. wt., 272. Found mol. wt. (mass spectroscopy): 272.

Infrared ($CHCl_3$): 2230 (nitriles), 1720 (ketone), 1645 cm^{-1} (lactam).

*Preparation of the Racemic Ester (**22**)*

The nitriles (**21**) (135 mg) was heated under reflux with methanol (8 ml) and concentrated sulfuric acid (2 ml) for 48 h. The mixture was then poured on ice and extracted with chloroform. After washing and drying the chloroform soluble material was chromatographed on silica gel (8 g). Elution with 20% ether in benzene gave the racemic ester (**22**). It was recrystallized from benzene–ether to a m.p. of 190–192 °C. The yield was 70 mg (46%).

Anal. Calcd. for $C_{17}H_{23}NO_4$: mol. wt., 305. Found mol. wt. (mass spectroscopy): 305.

Infrared (CCl_4): 1740 (ester), 1730 (ketone), 1650 cm^{-1} (lactam). Nuclear magnetic resonance: singlet (3 H) τ = 6.23 p.p.m. (—O—CH_3), doublet (3 H) τ = 8.53, 8.65 p.p.m. (C—CH_3). For comparison with the optically active "natural" compound (22) see theoretical part.

*Preparation of the Racemic Acid (**23**)*

The racemic ester (**22**) was saponified by heating under reflux with 5% methanolic potassium hydroxide overnight. After work-up in the usual manner the racemic acid (**23**) was recrystallized from methanol to a m.p. of 224–226 °C.

Anal. Calcd. for $C_{16}H_{21}NO_4$ (mol. wt., 291): C, 65.74; H, 7.24; N, 4.79. Found mol. wt. (mass spectroscopy): 291: C, 64.70; H, 7.07; N, 4.62.

Infrared (KBr): 1740 (carboxyl), 1730 (ketone), 1610 cm^{-1} (lactam).

*Preparation of the Synthetic Optically Active Acid (**23**)*

The racemic acid (**23**) (145 mg) was dissolved in acetone (10 ml) and a few drops of methanol were added. To this solution brucine (200 mg) in acetone (10 ml) was added and the volume of the solvent was reduced to 5 ml. Crystals appeared after standing for 2 h and they were recrystallized several times from methanol–acetone until the constant m.p. of 158–160 °C was reached. The yield of the pure constant melting brucine salt was 100 mg. This material was dissolved in a small volume of methanol and 10% sulfuric acid (30 ml) was added to the solution. Continuous extraction of the mixture with ether yielded 45 mg of the optically active acid (**23**). It was recrystallized from methanol to a m.p. of 240–242 °C. Its mass and infrared (KBr) spectra were identical with the spectra of the racemic acid (**23**).

*Preparation of the Synthetic Optically Active Ester (**22**)*

The pure synthetic optically active acid (**23**) (70 mg) was esterified with diazomethane and the optically active ester (**22**) was obtained in quantitative yield. It was recrystallized from benzene–ether to a constant m.p. of 198–200 °C.

Anal. Calcd. for $C_{17}H_{23}NO_4$: C, 66.95; H, 7.59; N, 4.59. Found: C, 66.54; H, 7.54; N, 5.17.

All the spectral data for the optically active ester (**22**) and the racemic ester (**22**) were identical. The synthetic optically active ester (**22**) was found to be identical with the material of the same structure prepared from annotinine by melting point, mixed melting point, t.l.c., i.r. spectrum in KBr and CCl_4, mass spectrum, and rotatory dispersion curve (see Fig. 1).

*Preparation of the Enol-acetate (**28**)*

The optically active keto-ester (**22**) (160 mg) and *p*-toluenesulfonic acid (30 mg) were dissolved in acetic anhydride (10 ml) and heated under reflux for 6 h. The acetic anhydride was then distilled off *in vacuo* and the residue was taken up in chloroform. The chloroform solution was washed, dried, and evaporated to dryness. The pure compound (**28**) was obtained by recrystallization from benzene. It melted at 162–163 °C. The yield was 165 mg (91%).

Anal. Calcd. for $C_{19}H_{25}NO_5$ (mol. wt., 347): C, 65.69; H, 7.25; N, 4.01. Found mol. wt. (mass spectroscopy): 347: C, 65.75; H, 7.39; N, 3.99.

Infrared ($CHCl_3$): 1750 (esters), 1640 cm^{-1} (lactam); Nuclear magnetic resonance: singlet (3 H) τ = 6.29 p.p.m. (—O—CH_3), singlet (3 H) τ = 7.84 p.p.m. (—O—C—CH_3), doublet (3 H), τ = 8.87, 9.00 p.p.m. (C—CH_3).

*Preparation of the Lactam–Lactone (**27**)*

The enol-acetate (**28**) (200 mg) was dissolved in dry tetrahydrofuran (20 ml) and a solution of sodium borohydride (200 mg) in absolute methanol (4 ml) was added. The crude reduction product obtained by working up in the usual manner was chromatographed on silica gel (20 g). Elution with 5% methanol in chloroform gave 140 mg (78%) of the mixture of the isomeric hydroxy esters (**29**) and (**30**).

Anal. Calcd. for $C_{17}H_{25}NO_4$: mol. wt., 307. Found: mol. wt. (mass spectroscopy), 307.

The above material was hydrolyzed by heating under reflux with 5% methanolic potassium hydroxide (40 ml) for 24 h. The acids (**26**) and (**31**) were isolated in the usual manner. The yield was 110 mg (90%). This material (200 mg) was subjected without purification to the lactonization reaction. It was dissolved in dry benzene (200 ml) and *p*-toluenesulfonic acid (60 mg) was added. The solution was refluxed for 3 days with a water separator. After this time the benzene was distilled off, the residue was taken up in chloroform and washed with 1% aqueous potassium hydroxide and with water. The chloroform layer was then dried and evaporated to dryness. The pure lactone (**27**) was eluted from a column of silica gel (10 g) with ether and it was crystallized from ether and methanol to a m.p. of 179–180 °C. The yield was 72 mg (38%).

Anal. Calcd. for $C_{16}H_{21}NO_3$ (mol. wt., 275): C, 69.80; H, 7.69; N, 5.09. Found (mol. wt. (mass spectroscopy) 275): C, 69.37; H, 7.64; N, 4.69.

Infrared ($CHCl_3$): 1770 (lactone), 1620 cm^{-1} (lactam); nuclear magnetic resonance: doublet (3 H) $\tau = 8.73$, 8.84 p.p.m. (C—CH_3). The synthetic compound (**27**) was identical with the material of the same structure prepared from annotinine by melting point, mixed melting point, t.l.c., i.r. spectrum (KBr) and ($CHCl_3$), and mass spectrum.

*Preparation of Compound (**32**) by Total Synthesis*

The lactone (**27**) (500 mg) was dissolved in carbon tetrachloride (300 ml) and *N*-bromosuccinimide (540 mg) was added to the solution. The reaction mixture was irradiated with a strong visible light source and refluxed for 30 min. The solution was then washed extensively with water, dried, and evaporated to dryness. The residue was chromatographed on a column (60 g) of silica gel. The product (**32**) was eluted by 30% chloroform in benzene and recrystallized from methanol to a constant m.p. of 212 °C. The yield of the pure compound (**32**) was 100 mg. (16%).

Anal. Calcd. for $C_{16}H_{18}NO_3Br$: C, 54.78; H, 5.15; Br, 22.71. Found: C, 55.54; H, 5.14; Br, 23.27.

Mass spectrum: *m/e* 309, 311 (M-42). Infrared (KBr): 1785 (lactone), 1655, 1630 cm^{-1} (lactam and double bond); nuclear magnetic resonance: doublet (3H) $\tau =$ 8.62, 8.74 p.p.m. (C—CH_3), singlet (1 H) $\tau = 3.31$ p.p.m. (vinylic hydrogen). The synthetic compound (**32**) was identical with the material of the same structure obtained by degradation of annotinine (*vide infra*) by melting point, mixed melting point, t.l.c., i.r. (KBr), and mass spectrum.

*Preparation of Compound (**33**) by Total Synthesis*

The synthetic compound (**32**) (300 mg) was dissolved in 10% hydrobromic acid (200 ml) and heated to 100 °C overnight. The crystalline precipitate of compound (**33**) which was gradually formed during the night was filtered off and recrystallized from methanol to a constant m.p. of 260–262 °C. The yield of the pure product was 30%.

Anal. Calcd. for $C_{16}H_{20}NO_4Br$: C, 51.91; H, 5.45; Br, 21.57. Found: C, 52.01; H, 5.42; Br, 20.31.

Infrared (KBr): 1765 (lactone), 1630 cm^{-1} (lactam). The synthetic compound (**33**) was identical with the material of the same structure prepared from annotinine (*vide infra*) by melting point, mixed melting point, t.l.c., i.r. spectrum (KBr), and mass spectrum.

*Preparation of Oxoannotinine (**34**) by Total Synthesis*

The bromohydrin (**33**) (200 mg) was dissolved in acetone (25 ml) and a solution of sodium bicarbonate (75 mg) in water (2 ml) was added. The reaction mixture was heated under reflux for 4 h. After this time the acetone was removed by distillation and water was added. The crystalline product (34) was filtered off and purified by crystallization from methanol to a constant m.p. of 233–234 °C. The yield was 156 mg (78%).

Anal. Calcd. for $C_{16}H_{19}NO_4$: C, 66.42; H, 6.62; N, 4.84. Found: C, 66.51; H, 6.69; N, 4.82.

The synthetic compound (**34**) was identified with the known oxoannotinine (10) by melting point, mixed melting point, t.l.c., i.r. (KBr and $CHCl_3$), and mass spectrum.

*Hydrogenolysis of Oxoannotinine (**34**) to Annotinine (**1**)*

This experiment is a repetition of the reaction described by Betts and MacLean (11). To a solution of oxoannotinine (**34**) (600 mg) in methanol (100 ml) six drops of concentrated hydrochloric acid were added. The solution was hydrogenated at room temperature for 20 h with prehydrogenated platinum oxide (200 mg) at a pressure of 60 p.s.i. The catalyst was filtered off and the solution was evaporated to dryness. Water was then added and the insoluble crystalline material (165 mg) filtered off. It was identified after recrystallization from methanol by melting point (286 °C) and i.r. spectrum (KBr) as the known oxoannotinine chlorohydrin. The aqueous filtrate was basified with ammonia and extracted with chloroform. After washing and drying the chloroform extract was chromatographed on silica gel (30 g). Elution with chloroform yielded annotinine, which was recrystallized from methanol to a melting point of 234–235 °C. The yield was 250 mg (56%). The material was identified with an authentic sample of annotinine by melting point, mixed melting point, t.l.c., and i.r. spectrum (KBr). Later fractions of the chromatogram yielded a small amount of oxoannotinine (20 mg). It was identified by mixed melting point (233–234 °C) and i.r. spectrum (KBr) with an authentic sample.

*Preparation of the Bromohydrin (**33**) from Oxoannotinine (**34**)*

A solution of oxoannotinine (**34**) (2 g, prepared by oxidation of annotinine (10)) in 19% hydrobromic acid (260 ml) was heated for 2 h to 100 °C. The product (**33**) crystallized directly from the reaction mixture and was purified by recrystallization from methanol to a melting point of 260–262 °C. The yield was 1.8 g (72%).

Anal. Calcd. for $C_{16}H_{20}NO_4Br$: C, 51.91; H, 5.45; Br, 21.57. Found: C, 51.98; H, 5.41; Br, 21.49.

The i.r. and mass spectra of compound (**33**) prepared in this manner were identical with the corresponding spectra of the synthetic material (*vide supra*).

*Dehydration of (**33**) to (**32**)*

The bromohydrin (**33**) (500 mg) was heated under reflux with phosphorus oxychloride (30 ml) for 2 h. The oxychloride was distilled off *in vacuo* and the residue was dissolved in chloroform, washed with water, dried and evaporated to dryness. Chromatography on a column of neutral alumina (10 g) with chloroform as eluant gave the product (**32**). It was recrystallized from methanol to a constant melting point of 212–214 °C. The yield was 122 mg (26%).

Anal. Calcd. for $C_{16}H_{18}NO_3Br$: C, 54.78; H, 5.15; Br, 22.71. Found: C, 55.55; H, 5.30; Br, 23.20.

The i.r. and mass spectra of compound (**32**) prepared in this manner were identical with the corresponding spectra of the synthetic material (*vide supra*).

Acknowledgments

We wish to thank the National Research Council of Canada, the Research Corporation, New York, the Ciba Company Limited, Dorval, Quebec, and the Hoffmann–La Roche Company, Nutley, New Jersey, for supporting the various

fundamental studies which eventually led to the present synthesis as well as the synthesis proper. We also wish to thank Dr. J. G. McCluskey for his participation in various unpublished model studies. We wish to thank also Dr. W. A. Ayer, University of Alberta, Edmonton, for recording the optical rotatory dispersion curves.

Specifically ring-labelled (±)-pelletierine

R. N. Gupta and Ian D. Spenser
Department of Chemistry, McMaster University, Hamilton, Ontario

Received September 9, 1968

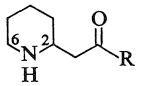
A synthesis of 2-^{14}C- and of 6-^{14}C-(±)-pelletierine and (±)-α-phenacylpiperidine is described, starting from 2-^{14}C- and 6-^{14}C-(±)-lysine, respectively.

Canadian Journal of Chemistry, **47**, 445 (1969)

It has been suggested that pelletierine (**1**)[1] is the biogenetic precursor of the *Lycopodium* (2) and the *Lythraceae* (3) alkaloids, and that the *Lobelia* alkaloid lobinaline is derived from α-phenacylpiperidine (**2**) (4). For investigations of the biosynthesis of these alkaloids we required samples of the postulated precursors, specifically labelled either at C-2 or at C-6 of the piperidine nucleus.

A number of syntheses of (±)-pelletierine and its phenyl analogue have been described, but none of these lend themselves to the preparation of the desired radiomers. In several of the syntheses (5–10) the piperidine nucleus of the products is generated by reduction of a pyridine nucleus. Suitably labelled samples of the required pyridine derivatives which serve as starting materials are not readily accessible.

In another, biogenetically modelled (11), synthetic approach (12–19), the piperidine ring of the products is supplied by Δ^1-piperideine, which, in turn, may be readily prepared from piperidine (20) or from cadaverine (1,5-diaminopentane) (16, 21, 22). Since piperidine and cadaverine are symmetrical molecules, a radiochemical synthesis starting with 2-^{14}C-piperidine or 1-^{14}C-cadaverine would yield an equimolar mixture of 2-^{14}C- and 6-^{14}C-Δ^1-piperideine and hence of 2-^{14}C- and 6-^{14}C-(±)-pelletierine or its phenyl analogue. Other attempts to prepare Δ^1-piperideine failed (23) or gave the product in very poor yield (13, 24, 25).



1 R = CH_3 Pelletierine
2 R = C_6H_5 α-Phenacylpiperidine

We have now obtained the desired singly labelled radiomers of (±)-pelletierine and of (±)-α-phenacylpiperidine in 45–50% overall yield, starting from 2-^{14}C- or from 6-^{14}C-(±)-lysine (cf. ref. 25). Lysine was oxidized with *N*-bromosuccinimide (26), and the product of this reaction, presumably Δ^1-piperideine, was condensed, without isolation, with acetoacetic acid or benzoylacetic acid (14, 19). The products, (±)-pelletierine and (±)-α-phenacylpiperidine, respectively, were purified and isolated as hydrochlorides.

Radioactive (±)-pelletierine, obtained from 6-^{14}C-(±)-lysine, was degraded by conventional methods to establish the site of labelling.

All activity of the compound was recovered in the formaldehyde (isolated as the dimedone derivative), obtained from C-6 of the piperidine ring of the labelled (±)-pelletierine. The (±)-pelletierine from 6-^{14}C-(±)-lysine is thus 6-^{14}C-(±)-pelletierine.

In an analogous manner 2-^{14}C-(±)-pelletierine was prepared from 2-^{14}C-(±)-lysine, 4,5-$^3H_2$-(±)-pelletierine from 4,5-$^3H_2$-(±)-lysine, and 6-^{14}C-(±)-α-phenacylpiperidine from 6-^{14}C-(±)-lysine.

Evidently no randomization of activity occurs between C-6 and C-2 of Δ^1-piperideine, the intermediate in the synthesis.

Experimental

Starting Materials

Solutions of the sodium salts of acetoacetic acid and benzoylacetic acid were prepared by hydrolysis, at room temperature, of the corresponding ethyl esters with the calculated volume of 0.5 *N* sodium hydroxide (19). The labelled samples of (±)-lysine (2-^{14}C-(±)-lysine monohydrochloride, nominal specific activity 3.3 mC/mmole, New England Nuclear Corporation; 6-^{14}C-(±)-lysine, nominal specific activity 9.2 mC/mmole, Commissariat à L'Energie Atomique, France; 4,5-$^3H_2$-(±)-lysine monohydrochloride, nominal specific activity 0.25 C/mmole, Radiochemical Center were commercial products.

(±)-Pelletierine (cf. ref. 14, 26)

N-Bromosuccinimide (178 mg, 1 mmole) was added to a solution of lysine monohydrochloride (92 mg, 0.5 mmole in 10 ml water) in a small flask. The flask was

[1] 2-Piperidylpropanone (**1**), known for many years as isopelletierine, is now referred to as pelletierine, following the suggestion of Gilman and Marion (1).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

rotated by means of a rotary evaporator, under mild suction, while immersed in a water bath at 40°. When the solution had become colorless (20 min) it was transferred quantitatively, with repeated washing (2 × 1 ml water), by means of a Pasteur pipette into a dropping funnel which had been calibrated to deliver approximately 0.5 ml/h. The solution was added at room temperature over a period of 24 h to a solution of sodium acetoacetate (2 mmoles) (*vide supra*) in citrate buffer, pH 6.9 (5 ml), which was continuously stirred under nitrogen. The dropping funnel was washed (1 ml water), and the washings were allowed to drop into the reaction mixture. When addition was complete, the reaction mixture was cooled (5°), basified with cold aqueous potassium hydroxide (10% w/v), and the product was extracted into chloroform (5 × 1 ml). The chloroform extract was dried (Na_2SO_4), the solution was removed from the desiccant by means of a Pasteur pipette, a drop of concentrated hydrochloric acid was added, and the mixture was evaporated to dryness. The residue was dissolved in chloroform (0.5 ml) and applied to a column (10 × 1 cm) of neutral alumina (activity I). The column was eluted with ethyl acetate (10 ml) and the eluate discarded. Ethyl acetate containing 5% methanol (200 ml) then eluted the product (27). The eluate was evaporated and the residue dissolved in a little methanol. Addition of ether yielded (±)-pelletierine hydrochloride (42 mg, 47% based on lysine), m.p. 144–145° (reported m.p. 141–143° (15), 144–145° (5, 18)), identical (mass spectrum,[2] m.p., mixture m.p.) with an authentic sample, prepared from 1-[2-pyridyl]-propan-2-one (9).

The labelled samples of (±)-pelletierine hydrochloride were synthesized in the manner outlined above from labelled lysine (2-^{14}C-(±)-lysine, 0.5 mC; 6-^{14}C-(±)-lysine, 0.5 mC; 4,5-$^{3}H_2$-(±)-lysine, 5 mC). So that the active runs could be carried out on the same scale as the pilot run, unlabelled (±)-lysine was added to the labelled lysine samples to yield ^{14}C-labelled lysine of specific activity 1 mC/mmole, and ^{3}H-labelled lysine of specific activity 10 mC/mmole. The resulting labelled samples of (±)-pelletierine hydrochloride were of corresponding specific activity. Products of higher specific activity would be obtainable by scaling down the preparation, or by starting with higher total activities.

The radiochemical purity of the products was established by paper chromatography (1-butanol – acetic acid – water, 2:1:1) and radioscanning. The products showed a single radioactive component, R_f 0.76.

(±)-α-Phenacylpiperidine (cf. ref. 14)

The scale and method of preparation were analogous to those described for (±)-pelletierine, except that benzoylacetic acid was used in place of acetoacetic acid. (±)-α-Phenacylpiperidine hydrochloride, R_f 0.87 (1-butanol – acetic acid – water, 2:1:1), m.p. 165–167° (reported melting point 170–172° (18)) was obtained in 51% yield. The mass spectrum of the salt, introduced into the mass spectrometer by the direct inlet system, showed a signal *m/e* 203. The free base did not show this signal of the molecular ion.

Degradation of Labelled (±)-Pelletierine, Obtained from 6-^{14}C-(±)-Lysine

A small sample (total activity approximately 3×10^5 counts min^{-1}) of the (±)-pelletierine hydrochloride, obtained from 6-^{14}C-(±)-lysine, was dissolved in methanol and was added to a solution of unlabelled (±)-pelletierine hydrochloride (350 mg) in methanol. The solution was concentrated, ether was added, and (±)-pelletierine hydrochloride crystallized. This was recrystallized to constant activity (Found: $(13.0 \pm 0.3) \times 10^4$ counts min^{-1} mmole^{-1}).

This sample of (±)-pelletierine hydrochloride (300 mg) was dissolved in methanol (10 ml), the solution was cooled to 0°, and excess sodium borohydride (0.6 g) was added in portions. The mixture was kept for 12 h at room temperature, methanol was evaporated, and ice cold 10% hydrochloric acid was added to the residue until the solution was acidic. Aqueous potassium hydroxide solution (10%) was added and the alkaline solution was extracted with chloroform. The chloroform extract was dried (Na_2SO_4) and evaporated, and the residue was sublimed at 0.5 mm and 70–90°, to yield 1-(2-piperidyl)-propan-2-ol (240 mg, 80% yield), m.p. 50–55° (reported m.p. for the diastereoisomeric mixture ((±)-sedridine plus (±)-allosedridine) approximately 50° (7); 60–64° (9)).

The product was dissolved in methanol (10 ml); methyl iodide (2 ml) and anhydrous sodium bicarbonate were added and the mixture was stirred at room temperature. After 24 h more methyl iodide (2 ml) was added and stirring continued for 24 h. The solid was filtered off and washed with methanol, and the filtrate evaporated to dryness. The residue was redissolved in dry methanol (10 ml) and filtered. An equal volume of water was added to the filtrate, the solution was warmed on the steam bath, freshly precipitated silver oxide (300 mg) was added, and the mixture was kept for 4 h in the dark with occasional stirring. It was then filtered, the solvents were evaporated, the oily basic residue was distilled at 0.5 mm and 110–140°, and the distillate collected in a trap which was cooled in ice.

Ozonolysis of a portion of the distillate failed to yield formaldehyde, indicating that Hofmann degradation yields only 8-dimethylaminooct-3- or -4-en-2-ol, and no 4-dimethylaminooct-7-en-2-ol. This mode of reaction is similar to that of sedamine (28).

The major portion of the Hofmann base was dissolved in methanol, palladium on charcoal (5%, 100 mg) was added, and the mixture was stirred under hydrogen at atmospheric pressure until there was no further uptake of hydrogen. The mixture was filtered, methanol was evaporated, and the oily residue distilled at 0.5 mm and 100–120°, yielding the product, 8-dimethylaminooctan-2-ol (mass spectrum : molecular ion *m/e* 173), as an oil.

The oily product was dissolved in a mixture of equal volumes of methanol and ether (10 ml); methyl iodide (1 ml) was added, the mixture was allowed to stand 12 h, and was then evaporated to dryness. The residue was washed with dry ether, and was dissolved in 50% aqueous methanol (5 ml). The solution was heated, freshly precipitated silver oxide (200 mg) was added, and the mixture was kept for 4 h in the dark. It was filtered, solvents were

[2]The signal *m/e* 141 (molecular ion of the free base) was observed when isopelletierine hydrochloride was introduced into the direct inlet system of the mass spectrometer.

evaporated, the oily residue was distilled at 0.5 mm and 120–150°, and the distillate was collected in a trap which was cooled in solid carbon dioxide/acetone. The distillate was dissolved in ethyl acetate (3 ml), and the solution was washed with dilute hydrochloric acid to remove basic components. Glacial acetic acid (2 ml) was added to the organic layer, the solution was cooled in an ice–salt mixture and a slow current of ozonized oxygen was passed through it for 15 min. Water (50 ml) and zinc dust (100 mg) were then added, and the mixture was distilled until 40 ml distillate had been collected. 5,5-Dimethyl-1,3-cyclohexanedione (dimedone) (50 mg) was added to the distillate, the mixture was warmed to evaporate ethyl acetate, and was then kept for 6 h at 0°, when crystallization of formaldehyde dimethone (10 mg) was complete. The product was recrystallized from aqueous methanol to constant activity (Found: $(13.8 \pm 0.3) \times 10^4$ counts min^{-1} $mmole^{-1}$).

Determination of Radioactivity

Radioactivity was assayed on samples of finite thickness on aluminium planchets, using a Nuclear Chicago Corp. gas flow system. The usual corrections for background and self-absorption were applied. For plating, a 1% solution of collodion in dimethyl formamide was used as the solvent.

Alkaloids of *Lycopodium lucidulum* Michx. Structure and properties of alkaloid L.23

W. A. AYER AND B. ALTENKIRK
Department of Chemistry, University of Alberta, Edmonton, Alberta

AND

R. H. BURNELL AND M. MOINAS
Department of Chemistry, Laval University, Quebec City, Quebec

Received September 9, 1968

The minor alkaloids present among the strong bases of *Lycopodium lucidulum* have been reinvestigated. Manske and Marion's alkaloid L.23 has been shown to be epimeric with lycodoline at C-12 and the nitrogen. A correlation between the two alkaloids has been achieved. The presence of a σ-coupled p interaction in the ultraviolet spectrum of lycopodine, lycodoline, and related compounds is described. A Cotton effect due to this chromophore has been detected by means of circular dichroism. The optical rotatory dispersion and circular dichroic properties of lycopodine, 12-epilycopodine, lycodoline, and alkaloid L.23 are discussed in terms of the absolute configuration assigned to these alkaloids.

The alkaloids of *Lycopodium lucidulum* Michx. were first investigated by Manske and Marion in 1946 (1). They reported the isolation of nicotine, lycopodine (**1**), alkaloid L.13,[1] and six other bases which were designated alkaloids L.20, L.21, L.22, L.23, L.24, and L.25. In previous papers dealing with this species we have reported on the structures of alkaloids L.20 (**2**) (2) and L.21 (**3**) (3) and have noted the occurrence of lycodoline (alkaloid L.8) (**4**) (2) in *L. lucidulum*. Further examination of the strong bases (2) has led to the isolation of lycodine (**5**), flabelliformine (**6**), alkaloid L.23,[2] and a compound $C_{16}H_{25}O_2N$, m.p. 230–233°, previously isolated from *L. clavatum* var. *megastachyon* (4). The molecular formula of this alkaloid corresponds to that assigned to alkaloid L.25 which was isolated and characterized as its perchlorate, m.p. 297°. The perchlorate of the compound we have isolated melts at 238–240°. In this paper we report on the structure of alkaloid L.23 and discuss the ultraviolet, optical rotatory dispersion, and circular dichroism spectra of this and related compounds.

Alkaloid L.23, which has also been isolated from *L. selago* (5) and which is probably identical with the pseudoselagine of Achmatowicz and Rodewald (6), has structure **7** and thus is epimeric with lycodoline (**4**) at C-12 (and consequently also at the nitrogen). The structure was established in the following manner. The infrared spectrum ($CHCl_3$) shows carbonyl absorption at 1690 cm^{-1}, a concentration independent band at 3510 cm^{-1} indicative of an intramolecularly hydrogen bonded hydroxyl, and intense "Bohlmann bands" at 2810, 2760, and 2680 cm^{-1} indicative of a *trans*-quinolizidine system (7). The nuclear magnetic resonance spectrum revealed the presence of the secondary *C*-methyl group (poorly resolved doublet at τ 9.04) and suggested that the hydroxyl group was tertiary (no signal other than that for OH (τ 6.4, readily exchanged for deuterium) below τ 6.7. The finding that the alkaloid is resistant to acetylation is consistent with this observation.

The mass spectrum of alkaloid L.23 (Fig. 1*a*) confirms the molecular formula assigned earlier (1) and is strikingly similar (see Fig. 1) to that of lycodoline (**4**, Fig. 1*b*). The mass spectral fragmentation pattern for lycodoline has previously been discussed (8). The similarity of the two spectra suggests that the compounds are stereoisomers and since alkaloid L.23 appears to contain a *trans*-quinolizidine system (Bohlmann bands) it appeared likely that the two were stereoisomeric at least at C-12 and nitrogen. The ultraviolet spectrum of lycodoline (**4**) (Table I) shows a maximum at 221 mμ (ε 1500). This absorption band is not present in the spectra of salts of lycodoline and is also absent in the ultraviolet spectrum of alkaloid L.23, which shows only end absorption in this region. It has

[1]A sample of the perchlorate of alkaloid L.13, provided by Dr. Marion, proved to be identical with lycopodine perchlorate.

[2]Identical with an authentic sample kindly provided by Dr. L. Marion.

been shown (9) that β-aminoketones in which the unshared pair on nitrogen, the α,β σ-bond and the π orbital of the carbonyl are parallel (**8** illustrates the present case) give rise to a non-classical E. T. band in the 220–260 mμ region of the ultraviolet. As may be seen in Table I, all of the lycopodine-like alkaloids with a carbonyl group at C-5 and in which the nitrogen lone pair is equatorial to ring A show an absorption band in this region whereas 12-epilycopodine (**9**) and alkaloid L.23 do not. Ultraviolet spectroscopy may therefore be used as an adjunct to infrared spectroscopy (Bohlmann bands) in assigning the configuration at the nitrogen in these alkaloids. As is discussed later, optical rotatory dispersion and/or circular dichroism may be used to the same end.

In order to establish that alkaloid L.23 differed from lycodoline (**4**) only in the stereochemistry at C-12 and the nitrogen, it was necessary to establish a direct correlation between the two. Dehydration of alkaloid L.23 with either phenyl-

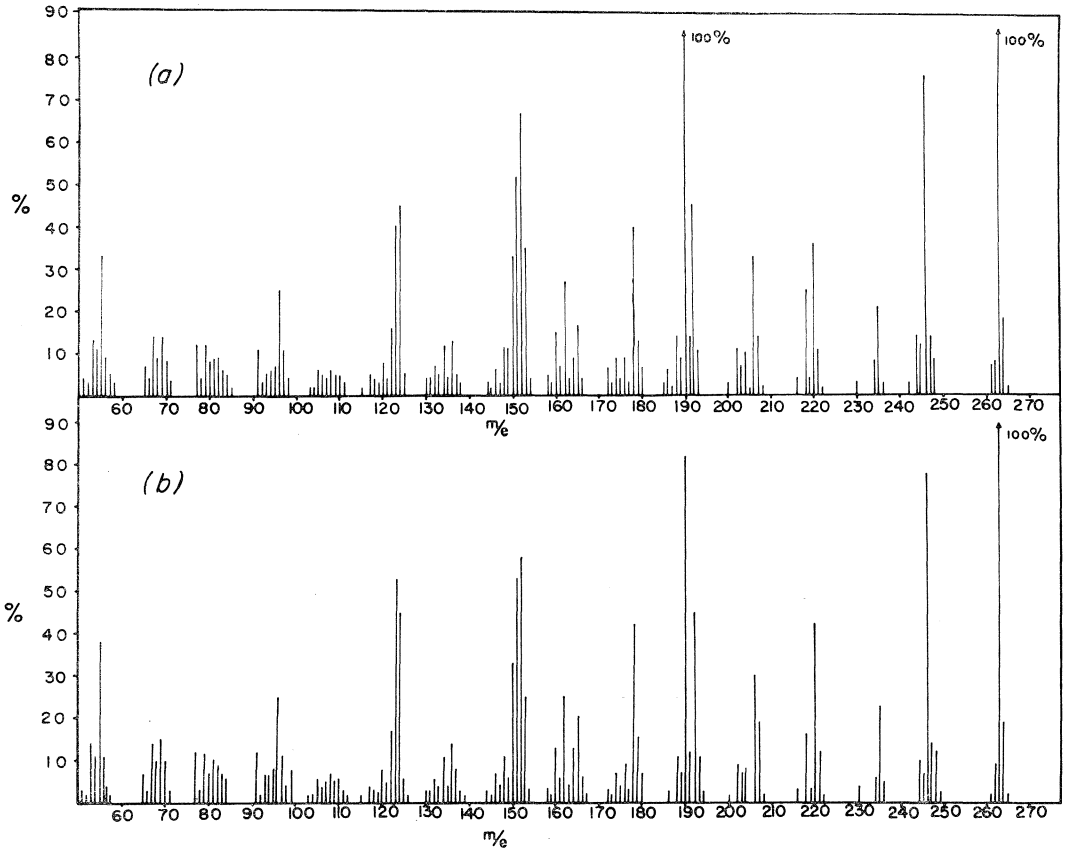

FIG. 1. Mass spectrum of (*a*) alkaloid L.23, (*b*) lycodoline.

phosphonic dichloride in pyridine or with phosphorus pentoxide in toluene gave, albeit in low yield, anhydrolycodoline (**10**) (10, 11), isolated as its hydrochloride. Alkaloid L.23 is the second naturally occurring alkaloid of this group to possess the "epi" configuration at C-12, the other being sauroxine (**11**) (12).

Anhydrolycodoline has been transformed into lycopodine (10) and thus alkaloid L.23 belongs to the same enantiomeric series as lycopodine (**1**) and lycodoline (**4**). The absolute configuration of lycopodine was assigned by application (13, 14) of the octant rule (15) and of the axial haloketone rule (2). As is predicted by the octant rule, both lycopodine and lycodoline (octant diagrams **12***a* and **12***b*, respectively) show positive Cotton effects (Table II) associated with the $n\rightarrow\pi^*$ transition of the keto group. As may be seen in the octant diagram **13***a* for alkaloid L.23, the octant rule predicts a positive Cotton effect in this case as well. *Alkaloid L.23 however shows a negative Cotton effect* (Table II). The salts of alkaloid L.23 also show a negative Cotton effect, although of lesser magnitude than that of the free base. In the case of lycopodine and lycodoline, salt formation causes a reversal of the sign of the Cotton effect (2, 16). Epilycopodine (octant diagram **13***b*), like alkaloid L.23 shows a negative Cotton effect for both the salt and the free base. It appears, therefore, that the sign of the Cotton effect depends on the configuration at C-12 and nitrogen and only in the case of the free bases with the lycopodine configuration does the octant rule correctly predict the sign of the Cotton effect. Circular dichroism (c.d.) measurements (Table II) show that lycopodine displays two Cotton effects above 200 mμ, a positive centered at 288 mμ and associated with the $n\rightarrow\pi^*$ transition and a negative centered at 223 mμ associated with the σ-coupled p interaction discussed above. The

†Values taken from ref. 10.

large negative rotation at 250 mμ (−15 000°) in the optical rotatory dispersion (o.r.d.) curve is thus the result of the overlapping of the troughs of the two Cotton curves. Protonation of the nitrogen removes the shorter wavelength Cotton effect in the c.d. curve and the one at longer wavelength becomes negative. The c.d. curve for alkaloid L.23 shows a single, negative, Cotton effect. It is thus obvious that the octant rule cannot be safely applied in these cases at least until the effect of nitrogen, charged and uncharged, is fully understood. The argument used previously in the case of lycopodine (2), i.e., that charged nitrogen makes an anti-octant contribu-

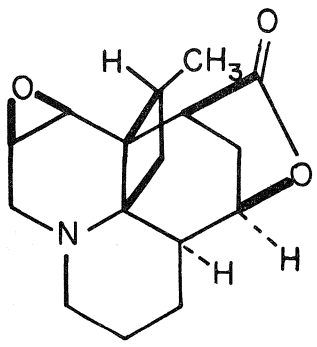
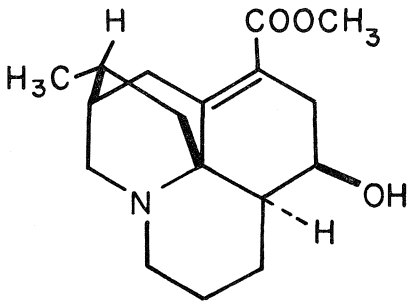
tion, does not explain the negative Cotton effect observed for L.23 and epilycopodine.

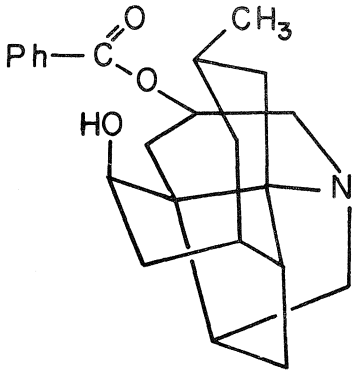
It is now necessary to consider the possibility that lycopodine is the anomalous case, that this is the system which shows the unusual charge transfer band, and that the absolute configurational assignment should be reversed. The following observations lead us to believe that the originally assigned (13, 14) configuration is probably correct. Both 6-α-bromolycopodine (**12***c*) and its hydrobromide show Cotton effects which are much more positive than those of the corresponding unbrominated compounds (2). Application of the axial halo ketone rule should be independent of the effect of the nitrogen. Application of the Horeau method (17) to dihydrolycopodine (**14**) and α-dihydrolycopodine (**15**) gives results in agreement with the absolute configuration portrayed (18). The absolute configurations of annotinine (**16**) (13), annopodine (**17**), (19), and alopecurine (**18**) (22) have been determined, the latter two by the X-ray method, and although they have different skeletons they belong to the same absolute stereochemical series as that



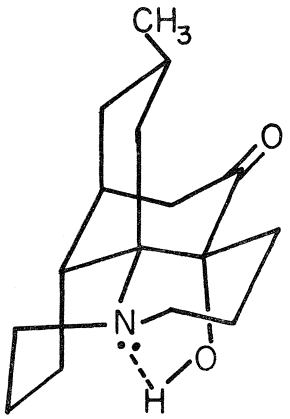
16



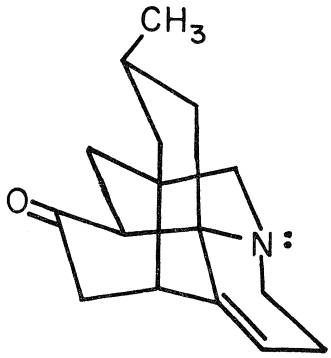
17



18



19



20

assigned to lycopodine. Because of the uncertainties created by the o.r.d. and c.d. studies, the determination of the absolute configuration of a lycopodine derivative by the X-ray method is in progress.

It has been suggested (20) that flabelliformine exists in conformation **19** rather than **6** since the hydroxyl group is intramolecularly hydrogen bonded (infrared evidence) and it is inferred that this hydrogen bonding involves the nitrogen as receptor rather than the carbonyl. Since o.r.d., c.d., and u.v. measurements appear to offer a means of determining the orientation of the lone pair on the nitrogen in this system, we have examined the spectra of flabelliformine. The ultraviolet spectrum (Table I) shows an inflexion at 228 mμ. A much clearer indication of the presence of this chromophore is obtained from the c.d. spectrum (MeOH) which shows a strong ($\Theta = -18\,000$) negative Cotton effect at 225 mμ in addition to a positive Cotton effect ($\Theta = -8\,600$) at 293 mμ. The c. d. spectrum is very similar to that of lycopodine and lycodoline (Table II). The o.r.d. spectrum (extrema 316 mμ (+2250°) and 257 mμ (−13 500°)) is also similar to that of lycopodine. Flabelliformine hydrochloride shows a negative Cotton effect. We feel therefore that flabelliformine exists mainly in conformation **6**, at least in methanol. As noted previously, anhydrolycodoline also shows a strong positive Cotton effect ($a = +13\,300°$ (10)). This suggests that conformation **20** makes an important contribution to the description of the stereochemistry of anhydrolycodoline. Conformation **10** was previously assigned (10) on the basis of the "Bohlmann bands" present in the infrared spectrum. As with flabelliformine, the infrared assignments were made on spectra determined in aprotic solvents and the o.r.d. and c.d. measurements were made in protic solvents.

Experimental

Optical rotatory dispersion, circular dichroism and ultraviolet spectra were recorded on a Durrum–Jasco Recording Spectropolarimeter, model 5. Most of the spectra were recorded in methanol in 1 cm and 1 mm cells. The concentrations used for the o.r.d. and c.d. measurements were about 0.01 *M*. The mass spectra shown in Fig. 1 were recorded on an AEI MS-2H mass spectrometer using a heated inlet system at 185°. The high resolution mass spectra were determined on an AEI MS-9 mass spectrometer.

Isolation Procedure

The "strong bases" of *Lycopodium lucidulum* Michx. (35 g) obtained as previously described (3), were subjected to seven funnel countercurrent distribution between chloroform (400 ml fractions, moving phase) and potassium hydrogen phthalate buffer (pH 5). After completion of the distribution, each fraction was made strongly basic and extracted into chloroform: fraction 1, 4.3 g; fraction 2, 4.1 g; fraction 3, 5.6 g; fraction 4, 2.6 g; fraction 5, 1.6 g; fraction 6, 3.0 g; fraction 7, 13 g. Fraction 7, containing the weak bases was combined with the "weak base" fraction from the original separation (3).

Fraction 3 was subjected to chromatography over alumina (activity II–III, 170 g). Elution with benzene (200 ml) and benzene–ether (1:1, 500 ml) gave lycopodine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

For personal use only.

(0.4 g). Elution with ether (500 ml) gave a mixture (0.23 g) of lycodoline and flabelliformine. The components were separated by preparative t.l.c. and identified by comparison with authentic samples. Elution with ether–chloroform (500 ml) and chloroform (500 ml) gave, after evaporation of the solvents, mixed crystals of lycodoline and alkaloid L.23. These were separated by fractional crystallization from acetone. Lycodoline crystallized first leaving alkaloid L.23 in the mother liquor. Alkaloid L.23 was recrystallized from a small volume of acetone, m.p. 163–164° both alone and when admixed with an authentic sample of alkaloid L.23 provided by Manske and Marion (1). $[\alpha]_D^{26} - 43°$ (*c*, 0.13, EtOH). Pertinent details of the infrared, nuclear magnetic resonance, and ultraviolet spectra are discussed in the text. The mass spectrum is shown in Fig. 1*a*.

Anal. Calcd. for $C_{16}H_{25}O_2N$: mol. wt., 263.1885. Found: mol. wt., 263.1888 (mass spectrometry).

Fractions 2 and 4 gave further quantities of alkaloid L.23.

Chromatography of fraction 6 over alumina and elution with benzene–ether gave a mixture of lycopodine and lycodine. Separation was achieved by reducing the mixture with sodium borohydride and then separating the lycodine from the dihydrolycopodine by chromatography over alumina. Further elution of fraction 6 with chloroform–methanol gave a compound,[3] m.p. 230–233°, identical (melting point, mixture melting point, infrared spectrum) with that previously isolated (4) from *L. clavatum* var. *megastachyon*. High resolution mass spectrometry showed that this compound has the molecular formula $C_{16}H_{25}O_2N$ (Calcd. mol. wt., 263.1885; Found 263.1885). The infrared spectrum of this compound shows OH absorption but no carbonyl absorption. The perchlorate melts at 238–240° (decomp.).

Anhydrolycodoline from Alkaloid L.23

Alkaloid L.23 (60 mg) was dissolved in pyridine (4 ml) containing phenylphosphonic dichloride (4 ml) and the solution was heated to 60° for 17 h. The reaction mixture was cooled and poured onto ice. The resulting solution was made basic by the addition of sodium hydroxide pellets and then extracted several times with chloroform. Evaporation of the chloroform left an oil (40 mg) which showed two spots on t.l.c., one corresponding to starting material and the other to anhydrolycodoline. Chromatography over alumina and elution with benzene gave an oil (ca. 2 mg) which with hydrogen chloride in methanol gave crystals of anhydrolycodoline hydrochloride, m.p. 273–275° (decomp.). The infrared spectrum was identical with that of an authentic sample. The o.r.d. spectrum of the free base was virtually identical with that of anhydrolycodoline prepared by dehydration of lycodoline (10).

Further elution of the chromatogram with benzene–ether and ether gave first a mixture of anhydrolycodoline and alkaloid L.23 (ca. 10 mg) and then alkaloid L.23 (20 mg).

The dehydration was also accomplished by heating alkaloid L.23 in toluene in the presence of phosphorus pentoxide. In this case, the yield of anhydrolycodoline was again poor and very little starting material was recovered.[4]

[3]We previously reported a melting point of 261–263° for this compound.

Acknowledgments

We wish to thank Dr. L. Marion of the University of Ottawa for samples of several alkaloids, A. N. Hogg and A. Budd for determining the mass spectra, R. N. Swindlehurst for the infrared and nuclear magnetic resonance spectra, and J. Hoyle for the optical rotatory dispersion and circular dichroism measurements. The financial support of the National Research Council of Canada is gratefully acknowledged.

Lignans of Western Red Cedar (*Thuja plicata* Donn). VIII. Plicatinaphthol

HAROLD MACLEAN AND B. F. MACDONALD

Forest Products Laboratory, Department of Forestry and Rural Development of Canada, 6620 N.W. Marine Drive, Vancouver 8, British Columbia

Received August 21, 1968

The isolation and structure of a new lignan, 1,6-dihydroxy-2-(hydroxymethyl)-7-methoxy-4-(3′,4′-dihydroxy-5′-methoxyphenyl)-3-naphthoic acid lactone (plicatinaphthol, **2**), in which the 4-aryltetrahydronaphthalene structure of plicatin (**1**) has been aromatized to a 4-arylnaphthol nucleus are described. Proof of structure of the parent compound and its tetramethyl, tetraacetyl, and tetraethyl derivatives is presented both by analytical and spectral techniques, in addition to the synthesis of the tetramethyl derivative starting from podophyllotoxin.

Canadian Journal of Chemistry, **47**, 457 (1969)

The lignans of Western Red Cedar (*Thuja plicata* Donn) fall into two classes, the five dibenzyl butyrolactones of the thujaplicatin series (1–4) and plicatic acid and plicatin (**1**), the 4-aryltetrahydronaphthalene derivatives (5, 6). These lignans are novel in that they all contain a guaiacyl ring in conjunction with either a monomethylated pyrogallol or a syringyl group. A new 4-arylnaphthol derivative, 1,6-dihydroxy-2-(hydroxymethyl)-7-methoxy-4-(3′,4′-dihydroxy-5′-methoxyphenyl)-3-naphthoic acid lactone, which has been given the trivial name plicatinaphthol (**2**), is now reported.

Other 4-arylnaphthols previously reported are diphyllin (7), justicidin A (8), dehydropodophyllotoxin (**6**) (9), and taiwanin E (10), the latter two suspected as being produced by acetone photolysis oxidation in the separation procedure (10). Plicatinaphthol is not an artifact, as it can be obtained directly from the wood meal by neutral solvent extraction in the dark, although in small amounts.

Separation was accomplished in two ways. After the hot-water extract of cedar heartwood meal had been chloroform extracted, the residual water solution was extracted with ethyl acetate. The ethyl acetate solubles were column chromatographed, either on cellulose or first on polyamide followed by cellulose. Plicatinaphthol is strongly absorbed by silica gel from which it cannot be totally reclaimed.

Plicatinaphthol (**2**) is an optically inactive crystalline compound having strong blue fluorescence under long (365 mμ) and weak blue fluorescence under short (254 mμ) ultraviolet light. The broad melting-point range of 260–270 °C with decomposition for plicatinaphthol has been previously noted for dehydropodophyllotoxin (**6**) (11). Carbon–hydrogen and methoxyl analyses indicated $C_{20}H_{16}O_8$. A double-focusing, high-resolution mass spectrum showed the parent ion to be the base peak at M^+ 384.0835 confirming the analytical results. A low-resolution mass spectrum showed, in addition to the large parent-ion

base peak, major fragmentation peaks at M − 16 (loss of oxygen), M − 58 (loss of lactone), M − 75 (loss of lactone and phenolic hydroxyl), M − 89 (loss of lactone and methoxyl group), followed by a series of small peaks indicative of a peeling of the hydroxyl and methoxyl groups (12) resulting in a complex pattern. Other major peaks, the M^{++} peak at 192, an unexplained peak at 176, and the pendant-ring split-off peaks, are clearly visible at 139–140. Since oxidation with alkaline nitrobenzene (13) produced only a small yield of vanillin and no syringaldehyde, the possibility of a syringyl group in the pendant ring was eliminated. Chromatography on molybdic acid – treated paper with butanol – acetic acid – water shows a considerably reduced R_f value (0.62) as found previously for other lignans containing pyrocatechol groups, when compared to untreated paper (0.74).

Plicatinaphthol is insoluble in deuteriochloroform and sparingly soluble in deuterioacetone. Positive identification of its four phenolic peaks by nuclear magnetic resonance (n.m.r.) was made more difficult owing to rapid exchange with the deuterioacetone solvent. However, n.m.r. spectra of the tetramethyl (**3**), tetraacetyl (**5**), and tetraethyl derivative (**4**) all indicated four hydroxyl groups and were confirmatory both as to species and number of protons, the aromatic protons appearing as two one-proton singlets for C-5 and C-8 and a two-proton singlet for C-2′ and C-6′ similar to plicatic acid (5), since no additional aromatic protons were introduced by the aromatization to plicatinaphthol. These n.m.r. data are in agreement with the substitution pattern shown for plicatinaphthol (**2**). Ultraviolet (u.v.) spectra were typical for a naphthalene nucleus (14) in all compounds. Infrared (i.r.) spectra were as expected for both the parent compound and the three derivatives, although the lactone band in plicatinaphthol is very broad and shifted to longer wavelengths when compared to dehydropodophyllotoxin (**6**) owing, probably, to intermolecular hydrogen bonding effects of the four phenolic groups. Diphyllin, which has the naphthol–lactone structure with the lactone carbonyl in the inverted position, i.e., in association with the naphthol group (7, 8), shows a hindered carbonyl absorbing at much lower wavelength still, 1705 cm^{-1}, compared to 1724 cm^{-1} for plicatinaphthol.

Similar to dehydropodophyllotoxin, the lactone ring of the tetramethyl plicatinaphthol could not be opened by 10% sodium hydroxide solution on a steam bath (17).

The tetraethyl derivative (**4**) was oxidized in alkaline permanganate as outlined in a previous paper (4) and 3,4-diethoxy-5-methoxybenzoic acid detected by both paper and thin-layer chromatography (t.l.c.) in conjunction with a known sample establishing the phenol substitution pattern of the pendant ring.

These data leave in doubt the position of an hydroxyl at C-1 or C-8 (as in the peltatins (15)) and the placement of the carbonyl of the lactone ring at either C-2 or C-3. A synthesis of the tetramethyl derivative of plicatinaphthol was successfully undertaken by preparing dehydropodophyllotoxin (**6**) from podophyllin resin (16, 17), opening the methylenedioxy ring with boron trichloride (18), and remethylating. Earlier attempts to cleave the methylenedioxy grouping were unsuccessful. A Birch reaction (19) failed apparently due to solubility considerations and a boron trifluoride reaction (20) resulted in excessive decomposition. After the boron trichloride treatment, t.l.c. showed five more products than the compound expected from cleaving the methylenedioxy ring, none of which were the original dehydropodophyllotoxin. As remethylation produced only the one major product, the boron trichloride reagent apparently cleaved additional methoxyl groups. The resultant product after remethylation was identical with the tetramethyl derivative (**3**) of plicatinaphthol by mixture melting point and quantitative i.r. spectral comparison.

In conclusion, the structure of plicatinaphthol (**2**) is therefore 1,6-dihydroxy-2-(hydroxymethyl)-7-methoxy-4-(3′,4′-dihydroxy-5′-methoxyphenyl)-3-naphthoic acid lactone.

Experimental

The following equipment was used: melting points, Fisher–Johns heated block (uncorrected); infrared (i.r.) spectra, Perkin–Elmer 521 grating spectrometer (KBr disks); ultraviolet spectra, Beckman DK-2 spectrophotometer (ethanol); nuclear magnetic resonance (n.m.r.) spectra, Varian HA-100 (tetramethylsilane, $\delta = 0$ as internal standard in the solvents shown). The following services were used: analyses, Clark Microanalytical Laboratories, Urbana, Illinois; mass spectrum, Morgan–Schaffer Laboratory, Montreal; high-resolution mass spectrum (parent ion), University of British Columbia. Thin-layer chromatography (t.l.c.) values were obtained with silica gel G

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(Merck) as adsorbent, benzene – ethanol – acetic acid (90:10:1) as developer with ultraviolet light followed by nitric acid – sulfuric acid (1:1) spray and heat as detector. Paper chromatograms were developed with butanol – acetic acid – water (60:15:25) or with 2% aqueous acetic and detected with potassium ferricyanide – ferric chloride reagent (mixed 1% solutions).

Plicatinaphthol (2)

The reserved aqueous layer from the hot-water extract of Western Red Cedar heartwood (1 kg moisture-free basis), which had been extracted with chloroform as outlined in a previous paper (4), was extracted with ethyl acetate (3 × 500 ml). After evaporation of the ethyl acetate solvent (yield 10.2 g), part of the residue (2 g) was dissolved in ethanol (20 ml) and added to a cellulose column (60 cm × 5 cm) using water as eluting solvent. Fractions were monitored by paper chromatography (2% acetic acid). After approximately 3 l elution, the following 1.5 l contained plicatinaphthol (R_f 0.09). After evaporation, fractions containing contaminant R_f 0.20 were purified by triturating with chloroform. After crystallization from ethanol, plicatinaphthol (150 mg) was obtained, m.p. 260–270 °C decomp.

An alternate method made a gross separation of the ethyl acetate residue on a polyamide (Woelm) column with *n*-butanol – formic acid (9:1) as eluting solvent. The fractions were monitored by paper chromatography (2% acetic acid) (R_f 0.09) or t.l.c. (R_f 0.10). The fractions containing plicatinaphthol were further purified on a cellulose column. Nitrobenzene oxidation (13) yielded vanillin only (4%).

Spectra: λ_{max} in mμ (log ε), 263.5 (4.59) (shifting to 275 in alkaline media), 312 (3.89), 323 (3.88), 365 (3.68): ν_{max} 3400 (broad hydroxyl), 1724 (lactone), 780 (tri-substituted phenyl) cm^{-1}; n.m.r. (deuterioacetone), 9.05, 8.28, 7.61, 7.44 (1H each, broad singlets, phenols), 7.70, 7.10 (1H each, singlets, C-5 and C-8), 6.44 (2H, singlet (width at half height 1.5 Hz), C-2′ and C-6′), 5.33 (2H, singlet, lactone methylene), δ 3.79 and 4.02 (3H each, singlets, methoxyls) (all phenol peaks were shifted to higher field by warming to 50 °C); mass (high resolution), M^+ 384.0835 (Calcd. for $C_{20}H_{16}O_8$: 384.0845), mass (low resolution), parent ion = base peak 384, M − 16 (18%), M − 58 (6%), M − 75 (5%), M − 89 (12%), M^{++} peak at 192 (4%), 176 (4%), 139 (6%), and 140 (6%).

Tetramethyl Plicatinaphthol (3)

Plicatinaphthol (100 mg) was dissolved in methanol (40 ml) with warming. On cooling, diazomethane in ether (5 ml) was added each hour for 5 h at room temperature with stirring and allowed to stand overnight. The product (t.l.c. R_f 0.46) was evaporated to dryness, crystallized from methanol to yield 2-(hydroxymethyl)-1,6,7-trimethoxy-4-(3′,4′,5′-trimethoxyphenyl)-3-naphthoic acid lactone (**3**) (60 mg), m.p. 259–260 °C.

Anal. Calcd. for $C_{24}H_{24}O_8$ (mol. wt., 440): C, 65.22; H, 5.46; OCH_3, 42.2. Found (mol. wt., 440; mass spectrum): C, 65.05; H, 5.49; OCH_3, 40.05.

Spectra: λ_{max} in mμ (log ε), 261 (4.66), 310 shoulder (3.90), 320 (3.93), 351 (3.58); ν_{max}, no hydroxyl band, 1760 (lactone) cm^{-1}; n.m.r. (deuteriochloroform) (all peaks are sharp singlets), 7.56 and 7.11 (1H each, C-5 and C-8), 6.58 (2H, C-2′ and C-6′), 5.54 (2H, lactone methylene), 4.13, 4.06, 3.97, and 3.78 (3H each, methoxyl), and δ 3.84 (6H, methoxyl C-3′ and C-5′).

Tetraacetyl Plicatinaphthol (5)

Plicatinaphthol (195 mg) was dissolved with warming in acetic anhydride (25 ml) and left standing for 3 h. The reaction mixture was heated on a steam bath for 1 h, *p*-toluenesulfonic acid (75 mg) added, and the mixture heated for an additional hour. It was cooled overnight and added slowly to ice water (400 ml) with stirring. After filtering, the crude acetate (110 mg) was purified by alumina chromatography using gradient elution with benzene–ethanol solvent. The column was monitored by t.l.c. (R_f 0.38) and the product crystallized from ethanol – ethyl acetate (40:15) by addition of water (7 ml) to yield 1,6-diacetoxy-2-(hydroxymethyl)-7-methoxy-4-(3′,4′-diacetoxy-5′-methoxyphenyl)-3-naphthoic acid lactone (**5**) (68 mg), m.p. 234–235 °C.

Spectra: ν_{max}, no hydroxyl band, 1765 (lactone), shoulders at 1750, 1740, 1730, and 1710 (acetyl) cm^{-1}; n.m.r. (deuteriochloroform), all peaks sharp singlets, 7.61 and 7.27 (1H each, C-5 and C-8), 6.86 (2H, width at half height 1.5 Hz, C-2′ and C-6′), 5.25 (2H, lactone methylene), 3.96 and 3.83 (3H each, methoxyls), 2.54 and 2.29 (3H each, acetyls), and δ 2.36 (6H-acetyl).

Tetraethyl Plicatinaphthol (4)

Plicatinaphthol (50 mg) in acetone (30 ml) containing anhydrous potassium carbonate (5 g) was treated with diethyl sulfate (1 ml per hour) for 5 h. After filtration and solvent removal the reaction product was purified by column chromatography on alumina by benzene–ethanol gradient elution to yield, after crystallization from ether, 1,6-diethoxy-2-(hydroxymethyl)-7-methoxy-4-(3′,4′-diethoxy-5′-methoxyphenyl)-3-naphthoic acid lactone (**4**) (23 mg), m.p. 156–157 °C; t.l.c. R_f 0.60.

Spectra: ν_{max}, no hydroxyl band, 1760 (lactone) cm^{-1}; n.m.r. (deuteriochloroform), 7.52 and 7.05 (1H each, singlets, C-5 and C-8), 6.56 (2H, singlet, C-2′ and C-6′), 5.48 (2H, singlet, lactone methylene), 4.48–3.76 (8H, multiplet centered at 4.12 partially obscured by methoxyl, ethoxyl methylenes), 4.06 and 3.83 (3H each, singlets, methoxyl), δ 1.67–1.32 (12H, unsymmetrical quartet centered at 1.49, ethoxyl methyls).

Synthesis of Tetramethyl Plicatinaphthol (3) from Podophyllin Resin

Podophyllotoxin was extracted from crude podophyllin resin by the method of Hartwell and Detty (16). Dehydropodophyllotoxin (**6**) was prepared from podophyllotoxin by the method of Gensler and Johnson (17). Dehydropodophyllotoxin (150 mg) in dichloromethane (30 ml) was cooled in a dry ice–acetone mixture and freshly distilled boron trichloride (30 ml) was added (18). The reaction mixture was allowed to come to room temperature overnight after which it was heated gently to expel boron trichloride. The solvents were evaporated at reduced pressure to yield an amorphous solid. Methanol containing ca. 1% water was added and then evaporated to remove final traces of boron trichloride. The residue was triturated with water containing a few drops of dilute hydrochloric acid with warming and the solution evaporated to dryness. Thin-layer chromatography showed six reaction products (70 mg), none of which were the original

dehydropodophyllotoxin. On methylation with diazomethane in methanol in the usual manner a single product, crystallizing from the reaction mixture, was obtained, which on recrystallization from methanol, yielded 2-(hydroxymethyl)-1,6,7-trimethoxy-4-(3′,4′,5′-trimethoxyphenyl)-3-naphthoic acid lactone (**3**) (30 mg) identical by quantitative i.r. spectrum and mixture melting point with tetramethyl plicatinaphthol.

Evidence for the formation of *exo* and *endo* aziridines in the reaction of *cis–endo* and *cis–exo*-bicyclo[2·2·1]-5-heptene-2,3-dicarboxylic anhydride and benzenesulfonyl azide[1,2]

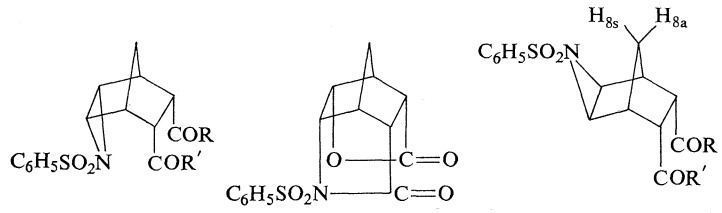
A. C. Oehlschlager[3] and L. H. Zalkow

School of Chemistry, Georgia Institute of Technology, Atlanta, Georgia 30332, and Department of Chemistry, Oklahoma State University, Stillwater, Oklahoma 74075

Received August 16, 1968

Benzenesulfonyl azide has been found to react with *cis–endo* and *cis–exo* bicyclo[2·2·1]-5-heptene-2,3-dicarboxylic anhydride to give in both cases, predominantly the more hindered *endo* aziridine in addition to the *exo* aziridine in apparent violation of the "*exo*-addition rule" (3). The stereochemistry of the aziridine rings were determined by nuclear magnetic resonance analysis and by conversion of the *endo*-aziridine-*exo*-anhydride to 2-*endo*-benzenesulfonamidobicyclo[2·2·1]heptane. The *endo*-aziridine-*endo*-anhydride has been previously (4) converted into a lactone-*N*-benzenesulfonyl-lactam.

Canadian Journal of Chemistry, 47, 461 (1969)



1 R = R′ = O
3 R = R′ = OCH_3

2

4 R = R′ = OCH_3

We have previously reported (4) that benzenesulfonyl azide reacts with bicyclo[2·2·1]-5-heptene-*endo*-cis-2,3-dicarboxylic anhydride in refluxing carbon tetrachloride to give the *endo* aziridine **1**, which was converted in two steps into **2**. After removal of crystalline **1**, the mother liquors were esterified with diazomethane in methanol–ether and then chromatographed on alumina. In addition to **3**, the dimethyl ester derived from **1**, there was thus obtained the previously unreported *exo* aziridine **4** in about 20% yield.

The infrared spectrum of **4** showed the presence of ester (1740 cm^{-1}) and benzenesulfonamido (1325, 1200, 1160 cm^{-1}) groups but the absence of N—H and C=N absorptions. The nuclear magnetic resonance (n.m.r.) spectrum of **4** showed two protons, by integration, at low field (δ 3.13) which could be assigned to carbons bearing nitrogen. Since this signal was much sharper (width at half-height, $w_{1/2h}$ = 2 c.p.s.), then the corresponding signal (δ 2.63, $w_{1/2h}$ = 6.5 c.p.s.) in **3** the *exo* aziridine structure was suggested. Additional support for the assignment of an *exo* aziridine structure to **4** was found in the positions of the C-8 protons in the n.m.r. Thus one proton (C-8*a*) appeared as a doublet: $J_{8a,8s}$ = 10.5 c.p.s.) at δ 0.90 whereas the other (C-8s) appeared at δ 1.70. By contrast, in **3** the C-8 protons gave similar doublets but centered at δ 1.54 and δ 1.98. Tori *et al.* (5) have shown that an *exo* aziridine ring produces an anisotropic shielding effect on the 8-*anti* proton. Additional support for structure **4** has been provided (6) by the conversion of **4** to the lactone **5**, which differs from the previously reported (6) **6** in not being readily converted into **2**. Finally, the carbomethoxy groups and the bridgehead protons in **4** are each magnetically equivalent, indicating that no epimerization of the carbomethoxy groups occurred in the reaction.

The reaction of benzenesulfonyl azide with bicyclo[2·2·1]-5-heptene-*exo–cis*-dicarboxylic anhydride in refluxing carbon tetrachloride also led to the formation of two isomeric products

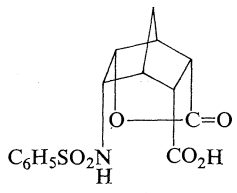
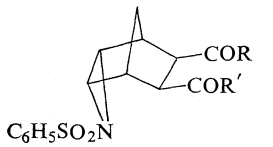
5



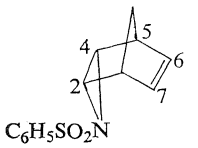
6



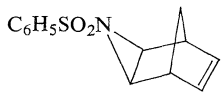
7*a* R=R′=O
7*b* R=R′=OCH_3

which could be separated in a manner similar to that described above. The predominant product (≃74%), which crystallized from the reaction mixture in benzene, was originally assigned (4) the *exo* aziridine structure. This product is now known to be the *endo* aziridine **7***a*. Thus the n.m.r. spectrum of **7***b*, the dimethyl ester derived from **7***a*, showed a broad signal ($w_{1/2h}$ = 6.5 c.p.s.) for the C-6, C-7 protons centered at δ 3.50. However, a more definitive proof of the stereochemistry of the aziridine ring in **7** was sought and provided as follows.

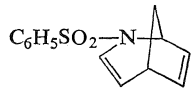
Anhydride **7***a* was converted into the corresponding *exo–cis* dicarboxylic acid in boiling water. That no epimerization occurred under these conditions was shown by conversion of a small amount of the diacid into **7***b* with methanolic diazomethane. On treatment with lead tetraacetate in pyridine the diacid gave **8**. The unsaturated aziridine **8** was found to differ from the previously reported (7) **9**, the latter being very unstable and readily rearranging to **10**. Hydrogenation of **8**



8
11 6,7-dihydro

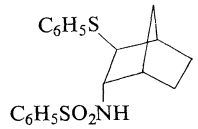


9
12 6,7-dihydro

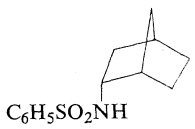


10

gave **11** which again differed from the previously reported (8) *exo* aziridine **12**. In particular, the C-2 and C-4 protons in **11** appeared as a broad signal ($w_{1/2h}$ = 6 c.p.s.) whereas in **12** they appear as a sharper singlet ($w_{1/2h}$ ~2 c.p.s.). Finally, treatment of **11** with potassium thiophenoxide gave **13** which on reductive removal of the thiophenoxy group gave the known (9) 2-*endo*-benzenesulfonamidobicyclo[2·2·1]heptane, **14**. The preparation of **14** from **7** shows that



13

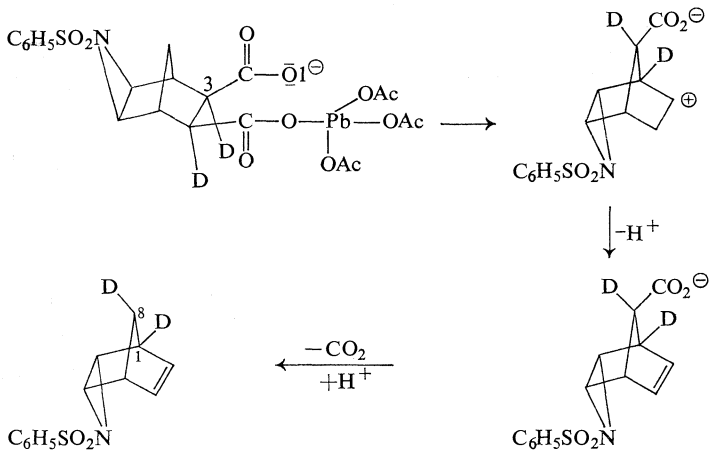


14

the aziridine ring in **7** is *endo* if no skeletal rearrangement has occurred. However, it is not unreasonable that during decarboxylation skeleton rearrangement did occur and that **7** therefore possesses an *exo* aziridine ring as illustrated in Scheme I. It is well known (10) that cationic intermediates are generated during oxidative decarboxylations using lead tetraacetate and the bicyclo[2·2·1]heptane ring system is particularly prone to rearrangment in reactions in which a nuclear cationic charge is generated (11). In such a rearrangement (illustrated in Scheme I), the original carbon atoms C-6 and C-7 end up at positions C-1 and C-8. To determine if rearrangement occurred carbon atoms C-6 and C-7 were labeled with deuterium as follows. Maleic anhydride-d_2 and cyclopentadiene were condensed in a Diels–Alder reaction to give 2,3-*exo*-dideuterio-2,3-*endo*-dicarboxybicyclo[2·2·1]-5-heptene anhydride, which was partially converted into 2,3-*endo*-dideuterio-2,3-*exo*-dicarboxybicyclo-[2·2·1]-5-heptene anhydride on heating at 200°. The latter, on treatment with benzenesulfonyl azide in refluxing carbon tetrachloride, gave 2,3-dideuterio-**7** which contained 71±2% deuterium at C-6 and C-7. Hydrolysis in D_2O gave the corresponding acid, which on oxidative decarboxylation with lead tetraacetate gave **8** which contained 72±2% deuterium at C-6 and C-7. Thus no skeletal rearrangement occurred during the decarboxylation.

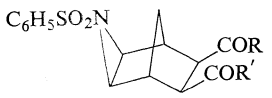
The n.m.r. spectrum of the dimethyl ester of the minor product (~22%) from the reaction of benzenesulfonyl azide and bicyclo[2·2·1]-5-heptene-*exo–cis*-2,3-dicarboxylic anhydride has

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

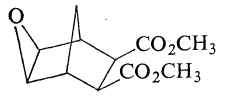


SCHEME I

been assigned structure **16** on the basis of the following evidence. The protons at C-6 and C-7 appeared as a sharp singlet ($w_{1/2h}$ = 2.5 c.p.s.) at δ 3.03, characteristic of *endo* protons and therefore an *exo* aziridine ring. Because of the presence of *exo*-carbomethoxy groups in **16**, the deshielding of the 8-*anti* proton by the *exo* aziridine ring is not so apparent in this case. The n.m.r. spectrum of **16** was very similar to that of



15 R = R′ = O
16 R = R′ = OCH_3



17

17. Thus in **16** the protons at C-1, C-2, C-4, and C-5 appeared as a narrow signal at δ 2.82, while in **17** these protons gave a similar signal at δ 2.80. In **16** the C-8 protons showed an AB quartet (J = 11 c.p.s.) with the two doublets centered at δ 1.47 and 1.75 while in **17** the two doublets (J = 10.5 c.p.s.) appeared at δ 1.33 and 1.64.

Detailed studies of the reactions of aryl and aryl-sulfonyl azides with bicyclo[2·2·1]heptene derivatives have provided an insight into the mechanism by which bicyclo[2·2·1]-5-heptene *endo* and *exo–cis*-2,3-dicarboxylic anhydrides react with benzene sulfonyl azide to give both *exo* and *endo* aziridine products (6). These investigations indicate the reaction involves the conversion of an initially formed, unstable *exo*-1,2,3-Δ^2 triazoline adduct **18** to a diazoimine intermediate **19** which rearranges with loss of nitrogen (via **20**) to the observed *exo* and *endo* aziridine products.

Experimental

Melting points were taken on a Fisher–Johns apparatus and are uncorrected. Infrared (i.r.) spectra were recorded with a Beckman IR-5 spectrophotometer, n.m.r. spectra were obtained with the Varian A-60 spectrometer, using tetramethylsilane (TMS) as an internal standard (δ = 0) and using deuteriochloroform, carbon tetrachloride, or carbon disulfide as a solvent. Carbon and hydrogen analyses were performed by Midwest Microlabs, Inc., Indianapolis, Indiana.

Reaction of Benzenesulfonyl Azide with Bicyclo[2·2·1]-5-heptene-endo–cis-2,3-dicarboxylic Anhydride

A solution of bicyclo[2·2·1]-5-heptene-2,3-*endo–cis*-dicarboxylic anhydride (4.4 g, 26.8 mmole) and benzenesulfonyl azide (6.0 g, 32.8 mmole) in 65 cm^3 carbon tetrachloride was refluxed for 48 h. The solvent was removed *in vacuo* and **1** (4.13 g, 13.0 mmole) crystallized from benzene–acetone to give m.p. 206–210°. The crystalline product had m.p. 215–216° (lit. (4), m.p. 215–216.5°)

after recrystallization from acetone. The mother liquors were combined and concentrated. The concentrate was treated with excess diazomethane in ether–methanol. The esterified mixture was concentrated and chromatographed directly on 250 g of Merck acid-washed alumina. Elution with 0.5 l of benzene gave 0.71 g of benzenesulfonyl azide. Elution with 1 l of benzene–chloroform (9:1) gave dimethyl bicyclo[2·2·1]-5-heptene-2,3-*endo–cis*-dicarboxylate (0.252 g, 1.2 mmole). Elution with 1 l (8:2), 0.5 l (7:3), and 0.7 l benzene–chloroform (6:4) gave **4** (1.76 g, 4.8 mmole). The analytical sample, prepared by crystallization from methanol, had m.p. 113–114°; ν_{max}(KBr) 1740, 1325, 1200, 1160, and 880 cm^{-1}; n.m.r. (in $CDCl_3$) δ 0.90 (*anti* C-8 proton, doublet, J = 10.5 c.p.s.), 1.70 (*syn* C-8 proton, doublet, J = 10.5 c.p.s.), 2.83 (protons at C-1 and C-5), 3.13 (protons at C-2 and C-4), 3.53 (protons at C-6 and C-7), 3.67 (6 protons of dimethyl ester), and 7.5–8.1 (5 aromatic protons).

Anal. Calcd. for $C_{17}H_{19}O_6NS$: C, 55.88; H, 5.24. Found: C, 56.22; H, 5.45.

Continued elution with 0.4 l of benzene–chloroform (6:4) gave **3** (0.86 g, 2.4 mmole) which had m.p. 129–130° after recrystallization from ether (lit. (4), m.p. 130–131°). Elution with 2 l of chloroform gave 0.77 g of an unidentified oil containing N—H absorption in the i.r. and whose n.m.r. spectrum showed several methoxyl signals. Thin-layer chromatographic analysis showed this material to be a mixture of several very polar components.

Reaction of Benzenesulfonyl Azide with Bicyclo-[2·2·1]-5-heptene-exo–cis 2,3-dicarboxylic Anhydride

A solution of bicyclo[2·2·1]-5-heptene-*exo–cis*-2,3-dicarboxylic anhydride (4.77 g, 29 mmole) and benzenesulfonyl azide (5.95 g) in 62 cm^3 of carbon tetrachloride was refluxed for 48 h during which time a gummy solid precipitated. The solvent was stripped *in vacuo* and the precipitate partially crystallized from benzene to give **7** (4.18 g, 13.1 mmole), m.p. 167–168°, (lit. (4), 168–168.5°). The mother liquors were concentrated and treated with excess diazomethane in ether–methanol. The esterified mixture was chromatographed on 500 g of Merck acid-washed alumina. Elution with 0.5 l benzene gave 0.69 g of benzenesulfonyl azide. Continued elution with 1.5 l of benzene gave 0.65 g (3.1 mmole) of dimethylbicyclo-[2·2·1]-5-heptene-*exo–cis*-dicarboxylate. Elution with 1 l (9:1), 1 l (8:2), and 1 l (7:3) benzene–chloroform gave 0.245 g of a mixture which was shown by n.m.r. analysis to contain 1.5 1 mmole of dimethylbicyclo[2·2·1]-5-heptene-*exo–cis*-dicarboxylate and 0.6 mmole of **8**. Elution with 1 l (6:4) benzene–chloroform gave 2.94 g of a mixture of 4.3 mmole of **8** and 3.7 mmole of **16**. Elution with 1 l (1:1) benzene–chloroform gave 1.12 g of a mixture of 1.05 mmole **8** and 2.05 mmole **16**. Crystallization of the last mentioned eluate from ether gave 0.35 g of **16**, m.p. 149–149°; ν_{max}(KBr) 1740, 1365, 1322, 1220, and 1160 cm^{-1}; n.m.r. (in $CDCl_3$) δ 1.47 (*anti* C-8 proton, doublet, J = 11 c.p.s.), 1.75 (*syn* C-8 proton, doublet, J = 11 c.p.s.), 2.82 (protons at C-1, C-2, C-4, and C-5), 3.03 (protons at C-6 and C-7), 3.68 (6 protons of dimethyl ester), and 7.5–8.0 (5 aromatic protons).

Anal. Calcd. for $C_{17}H_{19}O_6NS$: C, 55.88; H, 5.24. Found: C, 56.11; H, 5.07.

Elution with 1 l (1:9) benzene–chloroform gave 0.35 g of an unidentified oil which showed N—H absorption in the i.r. and several methoxyl signals in the n.m.r. spectrum. Thin-layer chromatographic analysis showed this to be a mixture of several polar components.

*Decarboxylation of 7: Preparation of N-Benzenesulfonyl-3-azatricyclo[3·2·1·$0^{2,4\ endo}$]-5-octene (**8**)*

Aziridine **7** (2.37 g) was dissolved in 100 cm^3 of hot water over a period of 20 min. Upon cooling 2.08 g of aziridine diacid precipitated and had m.p. 180–182°. The dimethyl ester was prepared using diazomethane and after recrystallization from petroleum ether had m.p. 102–103° (lit. (4), m.p. 102–103)°.

The aziridine diacid (1.49 g) was dissolved in 50 cm^3 dry pyridine at 50° under nitrogen. Lead tetraacetate (4.33 g) was added and the temperature was raised to 80° over a period of 20 min. The reaction mixture was cooled and the pyridine evaporated under vacuum. The residue remaining was taken up in 50 cm^3 of chloroform which was washed with 30 cm^3 of dilute hydrochloric acid and filtered. The chloroform portion was decanted, dried over anhydrous magnesium sulfate, and evaporated to give ca. 0.9 g of a dark oil. Thin-layer chromatography on Silica Gel-G (15 cm) in chloroform gave three small spots below R_f 0.25 and one large spot at R_f 0.60. Chromatography of this residue on 29 g of Merck acid-washed alumina gave 0.67 g (58%) of **8** m.p. 90–92°, eluted in benzene. The analytical sample of **8** was prepared by recrystallization from ethanol and had m.p. 92–93.5°; ν_{max}(KBr) 1305, 1155, 715 cm^{-1}; n.m.r. (in $CDCl_3$) δ 1.76 (2 protons at C-8), 2.87 (protons at C-1 and C-5), 3.55 (protons at C-2 and C-4, triplet, J = 1.8 c.p.s.), 5.86 (protons at C-6 and C-7, triplet, J = 1.5 c.p.s.), and 7.3–8.1 (5 aromatic protons).

Anal. Calcd. for $C_{13}H_{13}NO_2S$: C, 63.13; H, 5.30. Found: C, 63.04; H, 5.29.

*Preparation of N-Benzenesulfonyl-3-azatricyclo-[3·2·1·$0^{2,4\ endo}$]-octane (**11**)*

The unsaturated aziridine **8** (0.24 g) was hydrogenated in the presence of 0.2 g of 10% palladium-on-charcoal catalyst in 50 cm^3 of methanol under hydrogen at atmospheric pressure. The theoretical volume of hydrogen was absorbed in 15 min. Removal of the catalyst by filtration followed by evaporation of the methanol gave 0.21 g of **9**, b.p. (0.03 mm) 150±5°; ν_{max}(film) 1310, 1160, and 910 cm^{-1}; n.m.r. (in CS_2) δ 1.2–1.5 (5 protons), 1.83 (1 proton, doublet, J = 9.5 c.p.s.), 2.31 (protons at C-1 and C-5), 3.29 (protons at C-2 and C-4, triplet, J = 2 c.p.s.), and 7.4–8.0 (5 aromatic protons).

*Preparation of 2-exo-Thiphenoxy-3-endo-benzenesulfonamidobicyclo[2·2·1]heptane (**8**)*

A solution of 0.83 g of **11** and thiophenol (0.70 g) in 7 cm^3 of 0.1 *N* potassium *tert*-butoxide in *t*-butyl alcohol was refluxed overnight. The reaction mixture was poured onto water and neutralized with 5% hydrochloric acid. The aqueous solution was extracted with ether which was then dried over anhydrous magnesium sulfate. Evaporation of the ether extract gave 1.15 g of **13** which, after washing with petroleum ether, had m.p. 114–115°; n.m.r. (in nitrobenzene containing CF_3COOH); δ 1.1–1.9 (6 protons), 2.08 (proton at C-1, broad multiplet), 2.25 (proton at C-4, broad multiplet), 2.98 (proton at C-2, quartet, $J_{2,3}$ = 4 c.p.s., $J_{2,7\text{-}anti}$ = 2 c.p.s.), and 3.54 (proton at C-3, triplet, $J_{2,3} = J_{3,4}$ = 4 c.p.s.).

Anal. Calcd. for $C_{19}H_{21}NO_2S_2$: C, 63.48; H, 5.89. Found: C, 63.37; H, 6.05.

Conversion of ***13*** *to 2-endo-Benzenesulfonamidobicyclo-[2·2·1]heptane (****14****)*

The thiophenol addition product **13** (0.71 g) was refluxed for 15 h with a slurry of 6 g of Raney nickel (W-2) in 15 cm³ of isopropyl alcohol. The solution was filtered and the catalyst was washed several times with ethanol. Evaporation of the alcohol filtrate gave 0.18 g of **14**, m.p. 104–105°. The mixture melting point with authentic **14** which had m.p. 104–105°, prepared as described previously (9), was undepressed. Mixture melting point with 7-benzenesulfonamidobicyclo[2·2·1] heptane, m.p. 103–104°, prepared as described earlier (9), gave m.p. 90–93°. Authentic 2-*exo*-benzenesulfonamidobicyclo[2·2·1]heptane gave m.p. 89–91°, well below that of **14**.

Preparation of N-Benzenesulfonyl-3-azatricycolo [3·2·1·$0^{2,4\ endo}$]-octane-6,7-endo-dideuterio-6,7-exo-dicarboxylic Anhydride

A mixture (3.9 g) of 2,3-*exo*-dideuterio-2,3-*endo*-dicarboxybicyclo[2·2·1]-5-heptene anhydride and the protio species were prepared by the reaction of maleic anhydride-d_2 and cyclopentadiene according to the procedure of Van Sickle and Rodin (12). Analysis of the mixture by n.m.r. showed 70 ± 5% deuterium in the 2,3 positions.

Heating 3.3 g of the *endo* anhydride in an open flask at 200° for 2 h gave a mixture of *endo* and *exo* anhydrides from which 0.72 g of the *exo* anhydride crystallized in benzene (13). Gas–liquid chromatography using a 0.25 in. × 10 ft column of 5% SE-30 on acid-washed Chromosorb at 180° with helium flow rate of 80 cm³ per min showed the *exo* anhydride to be uncontaminated with the *endo* anhydride. Analysis by n.m.r. showed the *exo* anhydride to contain 71 ± 2% deuterium in the 2,3-positions.

A solution of 0.65 g deuterated *exo* anhydride and 0.59 g benzenesulfonyl azide in 10 cm³ of carbon tetrachloride was refluxed for 36 h. The carbon tetrachloride was decanted and the residue was crystallized thrice from benzene to give 0.4 g of **7**-6,7-$d_{1,4}$, m.p. 167–168°. Analysis by n.m.r. showed 71 ± 2% deuterium at C-6 and C-7.

Preparation of N-Benzenesulfonyl-3-azatricyclo-[3·2·1·$0^{2,4\ endo}$]-6,7-dideuterio-5-octene

Aziridine **7**-6,7-$d_{1,4}$ (0.4 g) was dissolved in 15 cm³ of hot 80% D_2O over a period of 30 min. Evaporation of the aqueous portion *in vacuo* gave 0.41 g of the corresponding diacid which after drying over phosphorus pentoxide for 12 h had m.p. 181–183°; ν_{max}(KBr) 1750 cm^{-1}.

The aziridine diacid (0.41 g) was dissolved in 13 cm³ dry pyridine under nitrogen at 50° and 1.19 g of lead tetraacetate was added. The reaction mixture was stirred at 75° for 20 min and then worked up by the usual procedure. Chromatography of the reaction mixture directly on Merck acid-washed alumina gave 35 mg of **8**-6,7-$d_{1,4}$, m.p. 90–91°, eluted in benzene. Analysis of **8**-6,7-$d_{1,4}$ by n.m.r. showed 72 ± 2% deuterium at C-6 and C-7.

Received May 21, 1968

The reactions between aminochromes and thiols have been reinvestigated. In general aminochromes react with thiols to give mixtures of products including: 5,6-dihydroxyindoles; thio-substituted 5,6-dihydroxyindoles (the mercapto residue is now considered to be in the 4-position of the indole nucleus and not the 7-position as previously reported); and relatively unstable addition products formed between the aminochrome and the thiol. The mechanisms by which these compounds are formed are discussed. The characterization of three thio-substituted 5,6-dihydroxyindoles by nuclear magnetic resonance spectroscopy is described. The nuclear magnetic resonance spectra of a number of 5,6-diacetoxyindole derivatives are reported.

Canadian Journal of Chemistry, **47**, 467 (1969)

Solutions of adrenochrome (**1**) are readily decolorized by a wide variety of thiols (1–9). The nature of the products obtained from aminochromes in reactions of this type and the mechanisms by which they were formed have been the subjects of several recent investigations (6–13). As a result of these studies it was concluded that (6–9) aminochromes react with thiols to form three different types of product: (**A**) 5,6-dihydroxyindoles; (**B**) thio-substituted 5,6-dihydroxyindoles; and (**C**) addition products of the aminochrome with the thiol which appear to be structurally similar to the adrenochrome–sodium bisulfite addition product (cf. 14). It has been reported that in the case of the reaction between adrenochrome (**1**) and glutathione the type **A**, **B**, and **C** products are respectively: (**A**) 5,6-dihydroxy-1-methylindole (**2**); (**B**) 7-*S*-glutathionyl-5,6-dihydroxy-1-methylindole (**3**); and (**C**) 9-*S*-glutathionyl-2,3,6,9-tetrahydro-3,5-dihydroxy-1-methyl-6-oxoindole (**4**).

Reactions of this type may be of biological importance since the attachment of melanin pigment molecules to proteins could involve interaction of the thiol groups of the protein molecule with aminochrome units, which were either formed as intermediates in the melanization process or were present as integral parts of the melanin macromolecule. The presence of sulfide linkages in melanoproteins was first suggested in 1950 (15), however the manner by which such linkages could form has only recently been systematically investigated (cf. 10–12, 16, 17). Bouchilloux and Kodja studied the reactions that occurred between several oxidized catechol derivatives and the thiol-substituted aminoacids glutathione and cystein (10–12), and observed that a number of products were formed when glutathione reacts with dopachrome (**5**) including 5,6-dihydroxyindole-2-carboxylic acid (**6**), 5,6-dihydroxyindole (**7**), and a compound described as 4-*S*-glutathionyl-5,6-dihydroxyindole (**8**) (12). Mason and Peterson also reported the formation of thio-substituted 5,6-dihydroxyindoles by the interaction of suitable thiols with oxidized 5,6-dihydroxyindole (or 3,4-dihydroxyphenylalanine), (16).

The possibility that aminochrome–thiol addition products (cf. 4) may play a different significant physiological role has been considered. Inchiosa suggested that the inhibition of cardiac actomyosin ATPase by an adrenaline derivative involves the formation of a specific addition product between an oxidation product of adrenaline,

SG = glutathione residue

(isomeric with adrenochrome) and the thiol groups in the myosin molecules (13). Mattok and Heacock had previously suggested that the formation of adrenochrome–thiol adducts (such as **4**) offered the possibility that suitable thiols could act as "carriers" for the highly reactive aminochromes in physiological systems (6, 7).

The structures of the thio-substituted 5,6-dihydroxyindole derivatives (cf. **3** or **8**) were proposed on the basis of chromatographic and spectroscopic evidence (cf. 6–12) and on mechanistic considerations (6–8). Whilst structures of the type **3** or **8** were not incompatible with the evidence available, the question of the precise position of the thiol residue was not satisfactorily resolved. It was therefore decided, firstly to investigate the influence of substituents in the 4- and 7-positions of the aminochrome nucleus on their reactions with thiols in general, and secondly to attempt the isolation and unambiguous characterization of one of the thio-substituted 5,6-dihydroxyindole derivatives.

Aqueous solutions of adrenochrome (**1**); 4-methyladrenochrome (**9**); and 7-methyladrenochrome (**10**) were treated, in turn, with a slight excess of each of several different thiols. After filtration the reaction mixtures were examined spectroscopically and paper chromatographically (cf. 5–9). 4-Methyladrenochrome (**9**) reacts with these thiols to give essentially two products. The main product (R_f, 0.34)[8] appeared to be 5,6-dihydroxy-1,4-dimethylindole (**11**). A second, minor, product (R_f, ca. 0.49–0.55) was also detected in most cases. However, no products

[8]Unless otherwise stated the R_f values quoted in this paper were obtained by means of descending paper chromatography, using 2% acetic acid in water as the running solvent, and Ehrlich's reagent for visualization.

with R_f values > 0.8 were observed in any of the reaction mixtures derived from **9**. The chromatographic pictures obtained from the reaction mixtures derived from 7-methyladrenochrome (**10**) were somewhat different. Two main products were observed in most cases, neither of which appeared to be 5,6-dihydroxy-1,7-dimethylindole (**12**); one had an R_f value of ca. 0.55 whilst a second product (R_f, ca. 0.8), which reacted quite slowly with Ehrlich's reagent, was detected.

All the reaction mixtures absorbed maximally in the 275–300 mμ region. The reaction mixtures prepared from **1** or **10** had absorption maxima at 300 mμ, whilst those from **9** absorbed maximally at 276 mμ (shoulder at 290 mμ). The adrenochrome (**1**) reaction mixtures also showed absorption maxima at 350 mμ, whilst those from its 7-methyl derivative (**10**) absorbed at 380 mμ; however, no significant absorption was detected in the 300–400 mμ region in the products derived from 4-methyladrenochrome (**9**). For comparison purposes solutions of 5,6-dihydroxy-1-methylindole (**2**), 5,6-dihydroxy-1,4-dimethylindole (**11**), and 5,6-dihydroxy-1,7-dimethylindole (**12**) were prepared by the reduction of **1**, **9**, and **10** respectively by sodium hydrosulfite. The R_f values of authentic samples of **11** and **12** were 0.36 and 0.31 respectively.

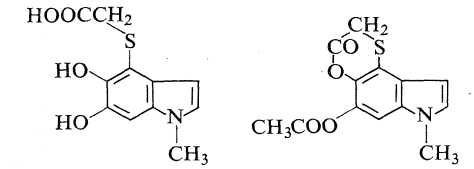
The above-mentioned results suggest that the type and distribution of products obtained by the action of thiols on the aminochromes **9** and **10** are different both from each other and from the corresponding products obtained from **1**. Only traces of 5,6-dihydroxy-1,7-dimethylindole (**12**) were formed by the action of glutathione on **10**. The major product (R_f, 0.56) which contained the thiol residue could not, in view of the substituent originally present in the 7-position, be a 7-thio derivative; this fact alone indicated that the previous formulation of this type of product as a 7-thio derivative (cf. **3**) (cf. 6–9) was incorrect. An examination of the products obtained by the action of glutathione on 4-methyladrenochrome (**9**) tended to confirm this thesis. 5,6-Dihydroxy-1,4-dimethylindole (**11**) (R_f, 0.33) was the major product formed in this case and only traces of a second product (R_f, 0.50) were detected. Substituents in the 4-position of the aminochrome nucleus therefore prevent the formation of thio-substituted 5,6-dihydroxyindoles, similar to those which can be obtained from **1** and **10** (cf. **3** or **8**). These facts suggest that the thiol residue is attached to position-4 of the indole nucleus in the type **B** products and that the product obtained from adrenochrome (**1**) by the action of glutathione, previously described as 7-*S*-glutathionyl-5,6-dihydroxy-1-methylindole (**3**) (cf. 6, 7), is actually the isomeric product 4-*S*-glutathionyl-5,6-dihydroxy-1-methylindole (**13**). The minor product (R_f, 0.50) obtained from **9** may be the 7-*S*-glutathionyl-5,6-dihydroxyindole derivative **14**.

4-*S*-Glutathionyl-5,6-dihydroxy-7-iodo-1-methylindole (**15**) was reported to be one of the major products obtained by the action of glutathione on 7-iodoadrenochrome (**16**) (8); the current results suggest that this structure is the correct one for this compound. Reaction mixtures derived from **1** by the action of thiols always showed strong absorption at ca. 350 mμ; however, this absorption was observed at ca. 380 mμ in the case of the products derived from **10**. This latter value is close to that previously reported for one of the 7-iodoadrenochrome–glutathione reaction products (8). In general 7-substituted aminochromes exhibit absorption maxima at longer wavelengths than the parent compounds [e.g. **1**: λ_{max}, 487 mμ; **16**, λ_{max}, 535 mμ; **10**: λ_{max}, 534 mμ (cf. 18, 19)]. An absorption maximum of ca. 380 mμ would therefore be expected for the 7-methyladrenochrome-glutathione addition product (**17**). However, this type of compound is not formed from 4-methyladrenochrome (**9**), since reaction mixtures derived from **9** by the action of thiols show no absorption at ca. 350 mμ. The fact that this type of compound is not formed in this case may be due to steric hindrance by the 4-methyl substituent to reaction by the thiol at the bridgehead 9-position.

Preliminary attempts to isolate one of the thio-substituted 5,6-dihydroxyindole derivatives, obtained from **1** by the action of thiol-containing aminoacids, were not successful. However, a derivative of a compound of this type has been isolated from the products obtained by the action of thioglycollic acid on adrenochrome (**1**). The reduction of adrenochrome by thioglycollic acid was first described in 1945 (2), and the nature of the products formed was subsequently investigated by Heacock and Scott (5). It appeared that two major products (R_f values: 0.42 and 0.48) and one minor product (R_f, 0.18) were formed. One of the major products (R_f, 0.42) was 5,6-dihydroxy-1-methylindole (**2**) and could be

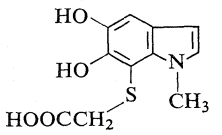
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

separated from the other major product (R_f, 0.48) since the latter was soluble in aqueous sodium bicarbonate, whilst **2** was not. The product (R_f, 0.48) exhibited color reactions expected for the indole ring system, the *o*-diphenol group, the carboxy group, and divalent sulfur [alkaline sodium nitroprusside spray reagent (20)]. This substance, presumably **18** or **19**, and in view of some of the evidence presented above, probably the latter, could only be obtained as a yellow oil. A crystalline acetyl derivative was obtained on treatment of the crude product with acetic anhydride and pyridine. The acetyl derivative was not acidic and its infrared spectrum showed no absorption in the NH/OH stretching region, but did show absorption in the carbonyl region at 1765 and 1775 cm^{-1}. The ultraviolet spectrum confirmed that the indole ring system was still intact. Microanalytical data and mass spectrometry indicated an empirical formula of $C_{13}H_{11}NO_4S$. These facts suggested that an intramolecular cyclization reaction had occurred at the same time as the acetylation, to give a structure such as **20** or **21**. An analogous internal cyclization reaction had been observed earlier when the corresponding product obtained by the action of thioglycollic acid on *p*-benzoquinone (21, 22) was allowed to stand in a vacuum desiccator in the presence of phosphorus pentoxide (21).

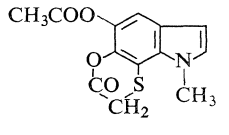


19

21



18



20

Nuclear magnetic resonance (n.m.r.) spectroscopy has been widely used for the elucidation of structural problems in the indole series and it appeared that this technique should provide a convenient method for determining which of the structures **20** or **21** was correct for the acetyl derivative, since the problem was essentially one of distinguishing between the presence or absence of the 4- and 7-protons in the indole ring system. The signals due to the protons in the 2- and 3-positions of the indole nucleus are easily recognized (cf. 23–25). Recently, long range coupling has been observed between the protons in the 3- and 7-positions in the indole nucleus (26–31); this coupling (ca. 0.8–1.0 Hz) is of greater magnitude than any of the other possible long range couplings, ignoring couplings involving the proton at position-1, which are not relevant in the present case. The majority of the other couplings are $\leqslant$ 0.3 Hz and are scarcely detectable (30). The exceptions [$J_{2,6} \sim$ 0.4–0.5 Hz and $J_{4,7} \sim$ 0.5–0.8 Hz (30)] would not be observable in compounds such as **20** and **21**.

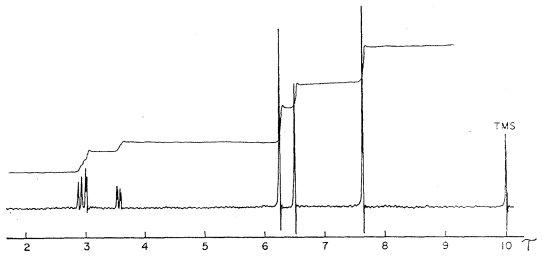


FIG. 1. The nuclear magnetic resonance spectrum of 6-acetoxy-4-*S*-carboxymethylthio-5-hydroxy-1-methylindole lactone (**21**) in $CDCl_3$ with tetramethylsilane as an internal standard.

The n.m.r. spectrum of the acetyl derivative which is shown in Fig. 1 shows that formula **21** is the correct structure for this compound. The signals due to the *C*—CH_3 (τ, 7.65), *N*—CH_3 (τ, 6.5), and *S*—CH_2— (τ, 6.25) (cf. 32) can clearly be seen in the spectrum. In the aromatic proton region the signal due to the 3-proton appears as a doublet of doublets centered at τ, 3.55 with splittings of 3.0 Hz ($J_{2,3}$) and 0.8 Hz ($J_{3,7}$). The 2-proton is observed as a doublet centered at τ, 2.9 ($J_{2,3}$ = 3.0 Hz) whilst the 7-proton appears as a doublet centered at τ, 3.0 ($J_{3,7}$ = 0.8 Hz).

The n.m.r. spectra of a number of related indole compounds with two or more substituents in the benzene ring have been recorded and the relevant τ values and coupling constants for the protons in the 2-, 3-, 4-, and 7-positions are given in Table I. The aromatic proton regions of the n.m.r. spectra of four of these compounds are shown in Fig. 2 and it can clearly be seen that the assignments made for compound **21** are probably correct. In general the signal due to the 4-proton in the

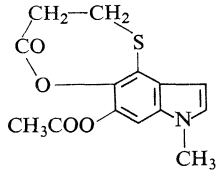
*The spectra were recorded in $CDCl_3$ with tetramethylsilane as an internal reference.
†The N-CH_3 signal was always observed as a well defined singlet at τ, 5.8–6.4.
‡(d) = doublet; (dd) = doublet of doublets; (s) = singlet.
§The methine proton was observed as a complex multiplet centered at τ, 5.4 and 5.5 respectively in the cases of 5,6-diacetoxy-1-isopropylindole and 6-acetoxy-4-carboxymethylthio-5-hydroxy-1-isopropylindole lactone, whereas in the case of the 7-iodo compound, 5,6-diacetoxy-7-iodo-1-isopropylindole the methine proton was observed as a complex multiplet centered at τ, 4.00, presumably due to the deshielding effect of the 7-iodo substituent.

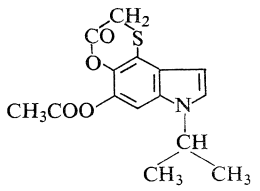
spectra of 5,6-disubstituted indole derivatives is observed as a well defined singlet downfield from the other aromatic proton signals (see Fig. 2, spectra of 5,6-diacetoxy-1,7-dimethylindole and 5,6-diacetoxy-7-iodo-1-methylindole), whereas the signal due to the 7-proton is usually seen as a doublet (provided the 3-position is free) with a splitting ($J_{3,7}$) of ca. 0.8–1.0 Hz (see Fig. 2, spectra of 5,6-diacetoxy-1-methylindole and 5,6-diacetoxy-1,4-dimethylindole).

The ultraviolet absorption patterns of solutions of **21** change on alkalinization in the manner that would be expected if the lactone ring opened (see Fig. 3). The long wavelength absorption maximum shifts from 298 mμ (shoulder at 307 mμ) in neutral solution to 337 mμ in alkaline solution; on acidification of the alkaline solution the peak is observed at 320 mμ, suggesting that the lactone ring does not reform. This latter shift (i.e. 337 mμ → 320 mμ) is probably due to the change in absorption associated with the ArO^- → ArOH change. The ultraviolet spectrum of **21** did not change appreciably with time, in alkaline solution (see Fig. 3). In view of the known instability of 6-hydroxyindoles, relative to the corresponding 5-hydroxy isomers, in alkaline solution, this observation tends to confirm that the unacetylated phenolic group is in the 5-position, (after the lactone ring has been opened), rather than in the 6-position, of the indole nucleus.

β-Mercaptopropionic acid readily reduces adrenochrome (**1**) in solution; in this case the major products are 5,6-dihydroxy-1-methylindole (**2**) and 4-*S*-(β-carboxyethylthio)-5,6-dihydroxy-1-methylindole. On treatment with an acetic anhydride – pyridine mixture the latter compound also undergoes an intramolecular cyclization to form a cyclic lactone (i.e. **22**), analogous to **21**, which in this case, contains a seven-membered ring. The structure of this lactone was confirmed by the micronalytical data and by n.m.r. and mass spectroscopy.



22



25

Preliminary paper chromatographic studies indicated that *N*-ethylnoradrenochrome (**23**) and *N*-isopropylnoradrenochrome (**24**) react analogously to adrenochrome (**1**) with thioglycollic

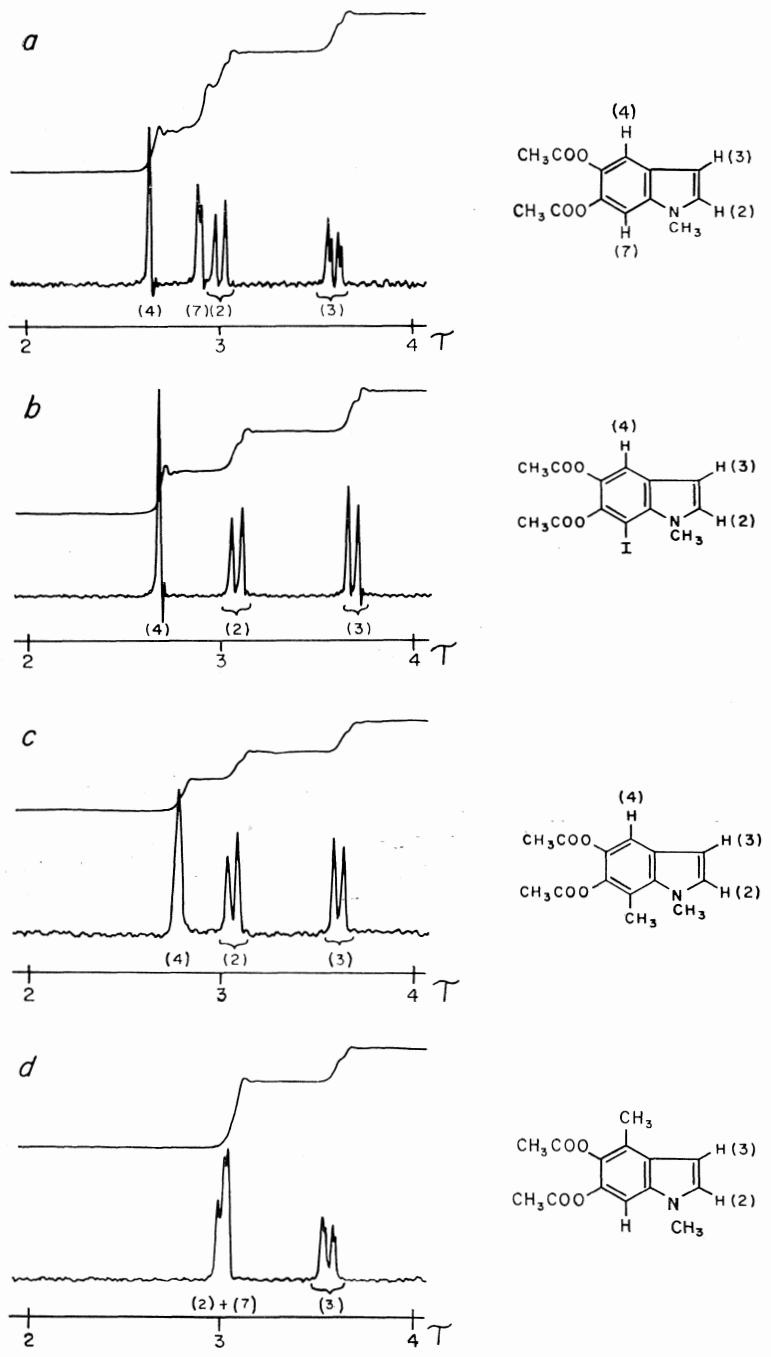

FIG. 2. The nuclear magnetic resonance spectra (in the region τ, 2.00 to τ, 4.00) of: 5,6-diacetoxy-1-methylindole (*a*); 5,6-diacetoxy-7-iodo-1-methylindole (*b*); 5,6-diacetoxy-1,7-dimethylindole (*c*); 5,6-diacetoxy-1,4-dimethylindole (*d*). The spectra were recorded in $CDCl_3$ with tetramethylsilane as an internal standard.

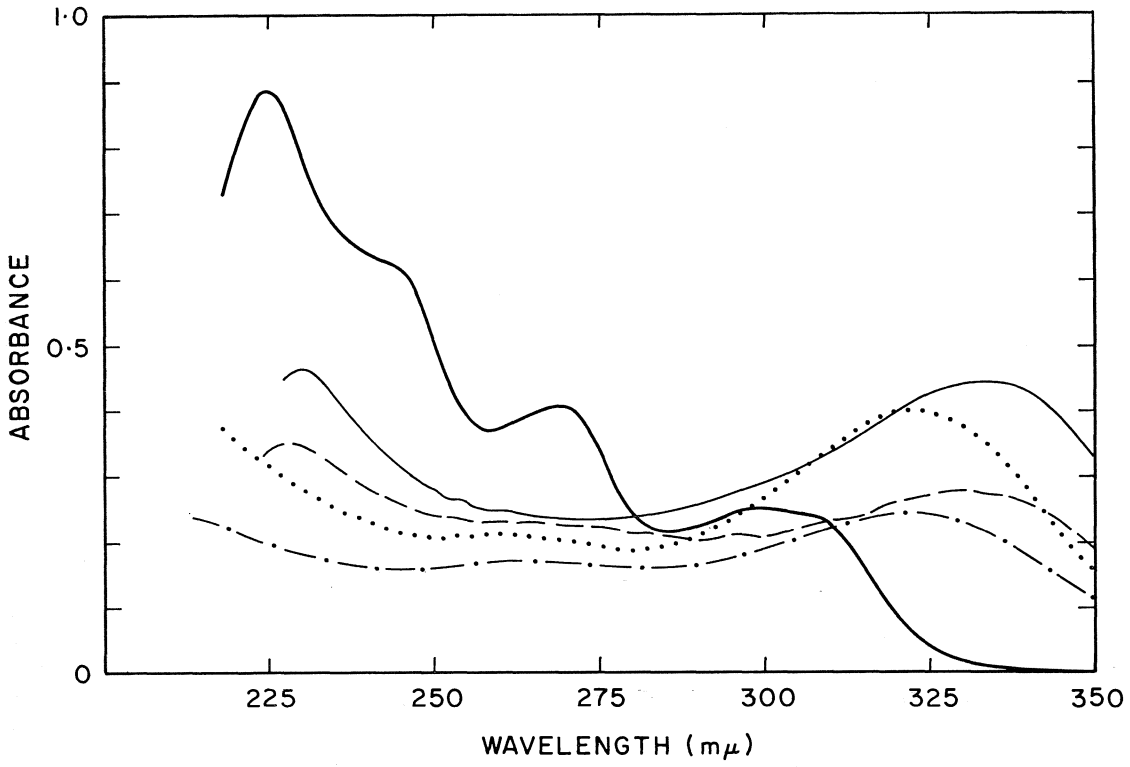

FIG. 3. Absorption spectra of: (*a*) **21** in ethanol (———); (*b*) **21** in ethanol directly after the addition of a few drops of aqueous NaOH (———); (*c*) **21** in ethanol 18 h after addition of the alkali (— — —); (*d*) solution (*b*) acidified (. . . . .); (*e*) solution (*c*) acidified (—·—·—).

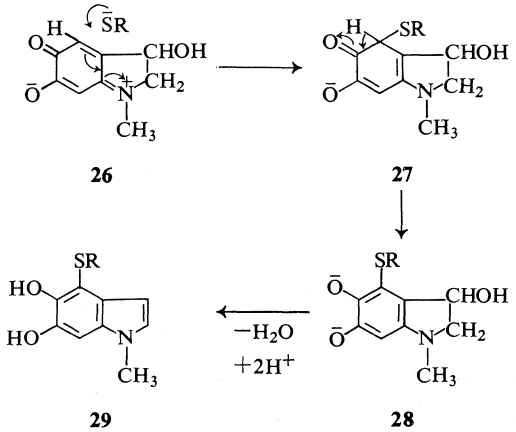
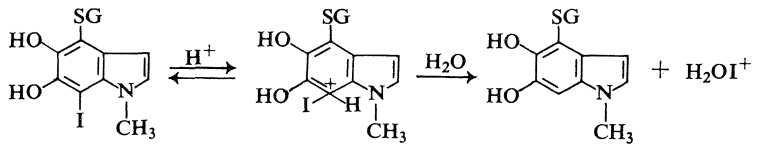
acid to form the appropriate 1-alkyl-5,6-dihydroxyindole; 1-alkyl-4-*S*-carboxymethylthio-5,6-dihydroxyindole; and an unknown product, in each case. In the latter case the lactone analogous to **21** (i.e. **25**) was isolated and characterized unambiguously.

It was suggested that the main products obtained by the interaction of thiols with aminochromes were formed either by direct reduction, or by 1,4-addition of the thiol to the two α,β-unsaturated carbonyl systems apparently present in the aminochrome molecule. These were the systems involving the C-5 carbonyl group and either the C_6—C_7 or the C_4—C_9 double bond (6–8) and gave, in the case of the adrenochrome–glutathione reaction, the products **3** and **4** respectively. It would now appear that whilst the second of these alternatives satisfactorily accounts for the formation of **4**, the former reaction probably does not occur. A reaction sequence involving an initial nucleophilic attack at the adrenochrome C-4 carbon by the mercaptide anion, as shown below (i.e. **26** → **27** → **28** → **29**) would, however, satisfactorily account for the formation of 4-thio-substituted 5,6-dihydroxyindole derivatives such as **8** or **13**. The formation of quinone thioethers by nucleophilic substitution reactions has



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



15 **30** **13**

previously been described (34). It has also been shown that, like glutathione (cf. 7), thioglycollic acid does not react with 5,6-dihydroxy-1-methylindole (**2**) under the conditions employed in this investigation; thus the initial nucleophilic attack by the mercaptide anion must be on the aminochrome molecule.

It would now appear that some of the mechanisms previously proposed for the formation of the products that are observed in 7-iodoadrenochrome–glutathione reaction mixtures (8) require revision. 4-*S*-Glutathionyl-5,6-dihydroxy-7-iodo-1-methylindole (**15**), one of the major products, could be formed from 7-iodoadrenochrome (**16**) by a mechanism analogous to that described above (cf. Scheme 4). The product previously described (8) as 7-*S*-glutathionyl-5,6-dihydroxy-1-methylindole (**3**) is in all probability the isomeric 4-*S*-glutathionyl derivative (i.e. **13**), formed by the acid-catalyzed deiodination of **15** [cf. acid-catalyzed deiodination of some aromatic iodo compounds by the mechanism suggested by Batts and Gold (35)]. Such a mechanism (i.e. **15** → **30** → **13**), would account for the preponderance of deiodinated products observed among the products obtained from 7-iodoadrenochrome (**16**) by the action of glutathione as the free acid as compared to those produced by glutathione as the monosodium salt (8).

Experimental

The infrared spectra were recorded on a Perkin–Elmer model 237 recording spectrophotometer; the ultraviolet (u.v.) absorption spectra were obtained on either a Beckman DK-2 or a Bausch and Lomb "Spectronic 505" recording spectrophotometer and the nuclear magnetic resonance spectra were recorded on a Varian A-60-A instrument.

*Reactions of Adrenochrome (**1**), 4-Methyladrenochrome (**9**), and 7-Methyladrenochrome (**10**) with Some Thiols*

Materials

Adrenochrome (36), 4- and 7-methyladrenochrome (19), *N*-ethylnoradrenochrome (33), *N*-isopropylnoradrenochrome (33), and adrenochrome methyl ether (33) were prepared by methods described in the literature. Glutathione, its monosodium salt, and homocysteine were obtained from the Nutritional Biochemicals Corporation; thioglycollic acid and β-mercaptopropionic acid from the Eastman Kodak Company.

Reaction Mixtures

The reactions were all carried out at room temperature. Aqueous solutions (1 ml) of each of the aminochromes (2 mg/ml) were treated, in turn, with a slight excess (i.e. until the red color of the solution was permanently discharged) of some of the thiols mentioned above. The reaction mixtures were filtered and examined by paper chromatography and by ultraviolet–visible spectroscopy.

Paper Chromatography

Descending chromatography was carried out on Whatman No. 1 paper with 2% acetic acid in water as the running solvent. In all cases the solvent was allowed to descend ca. 35–40 cm, which required 2.5–3.0 h. The developed chromatograms were allowed to dry in air at room temperature; they were then examined for fluorescence in u.v. light and then sprayed with one of the following chromogenic reagents:[9] Ehrlich's reagent, cinnamaldehyde, *p*-dimethylaminocinnamaldehyde, ninhydrin, and Gibb's reagent.

Spectroscopy

Spectra were obtained from suitably diluted solutions of the reaction mixtures or ether extracts, and were recorded on a Beckman DK-2 spectrophotometer.

The results of the chromatographic and spectroscopic examination of the reaction mixtures are shown in Tables II and III.

*6-Acetoxy-4-S-carboxymethylthio-5-hydroxy-1-methylindole Lactone (**21**)*

Freshly prepared silver oxide (30 g) was added portionwise, during a period of about 3–4 min to a stirred solution of adrenaline bitartrate (7.0 g) in water (150 ml). The temperature of the reaction mixture was not allowed to exceed 30° during the addition of the oxidant. The resulting deep red suspension was filtered through a Dowex-1 (×10) (Cl^-) resin bed[10] (diameter = 4.5 cm; height = 2.5 cm) and thioglycollic acid (4 ml) added dropwise, with stirring, to the filtrate. The resulting opaque and brownish-green solution was acidified with conc. hydrochloric acid (3 ml) and extracted with ether[11] (6 × 100 ml). The combined ether extracts, which contained both 5,6-dihydroxy-1-methylindole and 4-*S*-car-

[9]The chromogenic reagents were prepared by the usual methods described in the literature (cf. ref. 37).

[10]The resin was prepared by extensive washing with: (*1*) 3 *N* hydrochloric acid and (*2*) water, until neutral to litmus.

[11]Peroxide-free ether was used throughout this investigation.

boxymethylthio-5,6-dihydroxy-1-methylindole, were extracted with saturated aqueous sodium bicarbonate (6 × 100 ml). Concentrated hydrochloric acid (50 ml) was added slowly with stirring to a two-phase system composed of the combined sodium bicarbonate extracts and ether (100 ml). Small quantities of ether were added from time to time to replace losses due to evaporation. After addition of the acid was complete, the ether layer was separated and the aqueous mother liquors further extracted with ether (5 × 100 ml). The original ether layer and extracts were combined, dried (Na_2SO_4), and filtered. A mixture of acetic anhydride (7.5 ml) and dry pyridine (7.5 ml) was added to the filtrate and the reaction mixture allowed to stand overnight at room temperature, after which time the ether was removed *in vacuo*, below 30°, and the resulting solution added, dropwise, with stirring to an ice–water mixture (500 ml). The crude acetyl derivative, which was obtained as a pale-yellow gummy solid, was dissolved in a benzene–light petroleum[12] mixture (3:1), and adsorbed on a silica gel[13] column (diameter = 2 cm; height = 15 cm). The column was eluted with the same solvent and a series of fractions (50 ml) collected until the eluant gave a positive reaction with Ehrlich's reagent. Concentration, *in vacuo*, below 30°, of the first four Ehrlich negative fractions merely gave traces of unidentifiable gummy products which were discarded. Further elution of the column with the same solvent (300 ml) and (700 ml) gave crude **21** as white crystalline solids (137 mg;

[12]British Drug Houses Analar grade (b.p, 60–80°).
[13]Obtained from the Koch–Light laboratories (200/300 mesh size).

New synthesis of formaldehyde-d_2[1,2]

J. G. Atkinson, D. W. Cillis, and R. S. Stuart
Isotopic Laboratories, Merck Sharp and Dohme of Canada, Ltd., Montreal, Quebec

Received August 6, 1968

A new and improved synthesis of formaldehyde-d_2 on a molar scale has been developed *via* the reactions:

$$CH_2Br_2 + D_2O \rightarrow CD_2Br_2 \rightarrow CD_2(OAc)_2 \rightarrow CD_2O$$

The yield from deuterated methylene bromide is 50%, and the deuterium content is over 98%.

Une nouvelle synthèse, à l'échelle molaire, du formaldéhyde-d_2, fondée sur les réactions suivantes, est rapportée:

$$CH_2Br_2 + D_2O \rightarrow CD_2Br_2 \rightarrow CD_2(OAc)_2 \rightarrow CD_2O$$

Le rendement à partir du bromure de méthylène deuterié est 50%, et le taux de deutérium dépasse 98%.

Canadian Journal of Chemistry, **47**, 477 (1969)

Introduction

Formaldehyde-d_2 is a reagent of considerable utility as the starting point for further syntheses of deuterium labelled compounds (2) and for the study of reaction mechanisms (ref. 3 p. 213). The need for this material has grown considerably, and as part of a program to develop improved syntheses of labelled compounds, we have investigated and developed a new synthetic approach by which we have prepared up to 15 moles of formaldehyde-d_2.

The most satisfactory previous synthesis of formaldehyde-d_2 was that of Bannard, Morse, and Leitch (4) which consists of the lead tetraacetate cleavage of ethylene-d_4 glycol to yield pure, polymeric formaldehyde-d_2 in 75% yield. This procedure has the major disadvantage that the deuterated precursor is itself rather expensive, and, in addition, it is operationally difficult to carry out on a molar scale or larger. Elwyn *et al.* (5) have also described a synthesis in 33% yield by decarboxylation of dihydroxymaleic acid in heavy water followed by periodate cleavage of the resulting glycolaldehyde-d_4. Very recently, Olofson and Zimmerman (6) have reported a new synthesis of benzaldehyde-d_1 and formaldehyde-d_2 by exchange of a bisiminium cation with deuterium oxide, although the formaldehyde-d_2 was isolated only as a derivative. These latter preparations have the disadvantage that the product is obtained initially as a relatively dilute aqueous solution containing large amounts of inorganic salts so that a lengthy steam distillation is required in order to obtain pure material. Renaud and Leitch (7) have also recently described a novel preparation based on the Polonovsky reaction of trimethyl-d_9-amine oxide.

Results

The first step in the present synthesis was based on the discovery by Blanchard and Simmons (8) that methylene iodide could be exchanged in a basic solution of ethanol-OD and deuterium oxide. We have re-investigated this system extensively and have found that both methylene bromide and methylene iodide undergo ready exchange with refluxing, basic heavy water without the need of a co-solvent. By repeated exchange the deuterium content can be brought up to 99 atom % D and the partially depleted heavy water can be re-used in subsequent preparations.

$$CH_2Br_2 \xrightarrow{D_2O/OD^-} CD_2Br_2$$

$$CH_2I_2 \xrightarrow{D_2O/OD^-} CD_2I_2$$

Hydrolysis is very slow under these conditions and after 6–8 exchanges, 65–75% yields of fully deuterated halide were obtained. The exchange presumably proceeds through the dihalomethyl anion which reacts with D_2O much more rapidly

[1]Synthetic aspects of stable isotope chemistry. V. For Part IV, see ref. 1.

[2]Presented in part at the Second International Conference on Methods of Preparing and Storing Labelled Molecules, Brussels, Belgium. November 28–December 3, 1966.

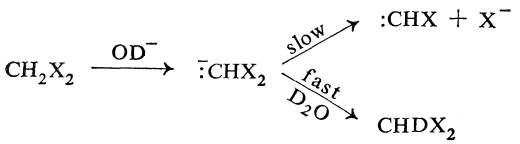
For personal use only.

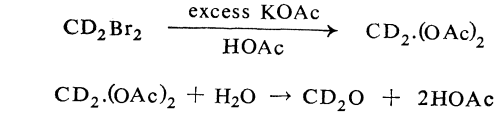
than it decomposes to a halocarbene, thus accounting for the relatively high recovery even after a number of exchanges. By analogy with the addition of the trichloromethyl anion to aldehydes (9) and acid anhydrides (10), it might be expected that the dihalomethyl anion could be trapped by electrophilic species other than D^+, and such experiments would be of potential synthetic interest.[3]



Many attempts at the direct conversion of the methylene halides to formaldehyde confirmed their resistance to hydrolysis. This is a "textbook" reaction, but upon heating methylene iodide with water at 180° only carbon and iodine were obtained. Heating in a glass bomb with water and $Ba(OH)_2$, PbO, or Ag_2O caused the bomb to explode in each case. Heating with concentrated H_2SO_4 at 100° resulted in the liberation of iodine, and no reaction was observed with refluxing aqueous mixtures of silver oxide, silver carbonate, or silver acetate with either halide.

A two-step conversion to formaldehyde-d_2 was then developed when it was found that the methylene-d_2 halides would react with silver acetate or potassium acetate under anhydrous conditions to yield methylene-d_2 diacetate in 60-65% yields. The optimum conditions involved the reaction of 3–4 moles of potassium acetate with one mole of halide in refluxing acetic acid containing 5% of acetic anhydride. Methylene-d_2 bromide is preferred over the iodide because if any of the latter is left unreacted it is difficult to separate from methylene-d_2 diacetate. Methylene-d_2 diacetate is easily and rapidly hydrolyzed to formaldehyde-d_2 in over 80% yield. The formaldehyde solution thus obtained is very concentrated and contains only volatile materials, so that upon evaporation to dryness, pure polymeric formaldehyde-d_2 is readily obtained.

A very careful check on the deuterium content of the intermediate methylene-d_2 diacetate and



the formaldehyde-d_2 showed that the latter had the same isotopic purity as the starting deuterated methylene halide. Thus, no back-exchange occurs in either of the hydrolytic steps.

Appendix

Several other much less successful approaches to the preparation of deuterated formaldehyde were investigated at some length and are included for the sake of completeness.

Leitch (11) has prepared acetaldehyde-1-d_1 from nitroethane-1,1-d_2 by hydrolysis of the sodium salt. When this reaction, or the modification introduced by Schechter and Williams (12) was applied to nitromethane, little if any formaldehyde was produced. Since this reaction would have led to an aqueous solution of formaldehyde-d_2 containing large amounts of inorganic salts, it was not investigated further.

Dimethyl sulfoxide is known to react with electrophilic reagents to yield derivatives which can be hydrolyzed to formaldehyde (13). We have investigated the reaction of dimethyl-d_6-sulfoxide with hydrogen chloride gas in a hot benzene solution. With the protio compound, formaldehyde sublimed out of the reaction mixture in 45% yield, but from dimethyl-d_6-sulfoxide less than 10% yield of formaldehyde-d_2 resulted, the major product being dimethyl-d_6 sulfide.

The nature of the reduction reaction was not further investigated,[4] but it provides an interesting example of how an isotope effect may influence a multi-directional reaction when a C—H or C—D bond must be broken in one of the reaction paths.

A Polonovsky-type reaction between acetic anhydride and dimethyl-d_6-sulfoxide led to α-acetoxy dimethylsulfide-d_5 in 80% yield, hydrolysis of which led to formaldehyde-d_2 in less than 25% yield. The low yield was found to be due to the formation of the very stable dimethyl-d_6-

[3]*Note added in proof*: The trapping of dihalomethyl lithium species with carbonyl compounds has recently been reported (15).

[4]The reduction of sulfoxides to sulfides by iodide ion is a well-known reaction, see ref. 14.

thioacetal of the aldehyde. This approach was abandoned because of the low yield and the presence of sulfur impurities in the formaldehyde-d_2 which were difficult to remove.

$$CD_3 \cdot SO \cdot CD_3 + Ac_2O \rightarrow CD_3 \cdot S \cdot CD_2 \cdot OAc + DOAc$$

$$2CD_3 \cdot S \cdot CD_2 \cdot OAc + H_2O \rightarrow CD_2O + (CD_3 \cdot S)_2 \cdot CD_2 + 2HOAc$$

Experimental

Nuclear magnetic resonance (n.m.r.) spectra were run on a Varian A60-A instrument and mass spectra were performed by the Morgan-Schaeffer Corporation, Montreal, Quebec.

Methylene-d_2 Bromide

A heterogeneous mixture of 500 g of methylene bromide and 210 g of a 10% solution of sodium deuteroxide in deuterium oxide was stirred and refluxed for 24 h. The organic layer was separated and further exchanged with successively decreasing amounts of 10% sodium deuteroxide (160, 150, 130, 100, 100, and 100 g). The organic layer was finally distilled through a short Vigreux column. A water–methylene-d_2 bromide azeotrope was first collected, followed by the bulk of the dry methylene-d_2 bromide. The azeotropic mixture was dried by passage over phosphorous pentoxide on a vacuum line and combined with the dry material from the distillation, to give a yield of 319 g (63%). Nuclear magnetic resonance and mass spectral analyses showed the methylene-d_2 bromide to contain 99 atom % D.

Methylene-d_2 Diacetate

To a mechanically stirred solution of methylene-d_2 bromide (176 g, 1.0 moles) in 600 ml glacial acetic acid containing 30 g of acetic anhydride was added potassium acetate (294 g, 3.0 moles) at such a rate as not to prevent stirring. On heating the mixture to reflux, all of the potassium acetate dissolved and after 1 h potassium bromide began to crystallize from the solution. Stirring and refluxing was continued for 24 h, after which time the solution was allowed to cool with continued stirring in order to avoid cake formation. To the cooled reaction mixture was added 1500 ml of ether, and the precipitate was filtered off and washed with ether until no odor of acetic acid remained.[5]

The filtrate and washings were combined and distilled at atmospheric pressure to remove the ether and the bulk of the acetic acid. If more solid was seen to crystallize at this point, the dilution with ether and filtration were repeated. If not, the distillation was continued at 12 mm pressure and, after removal of acetic acid and acetic anhydride, a fraction was collected at 61–63 °C to yield 83 g (0.62 moles, 62%) of methylene-d_2 diacetate. The deuterium content of the methylene group was found by n.m.r. analysis to be 99%.

Formaldehyde-d_2

A mixture of methylene-d_2 diacetate (240 g, 1.79 moles), 45 ml of water, and 5 ml of concentrated hydrochloric acid was refluxed for 17 h. Upon cooling of the solution, some polymeric formaldehyde-d_2 crystallized out and was filtered off. The filtrate was taken to dryness in vacuum to leave the bulk of the product as a white solid. A second distillation of the solvent mixture was necessary to recover all of the product. The combined crops of formaldehyde-d_2 were dried at 0.5 mm and 100 °C in order to remove the last traces of acetic acid and gave a yield of 49.4 g (1.54 moles, 86%); m.p. 172–174 °C, which corresponds to that of α-polyoxymethylene (ref. 3 p. 158).

The dimedone derivative had a m.p. 188–190 °C and mixture m.p. of 188–189 °C.

Analysis of Formaldehyde-d_2

A mixture of polymeric formaldehyde-d_2 (0.50 g, 15.6 mmoles), methanethiol (10 g, 208 mmoles), and ether (15 ml) was stirred for 18 h in a stoppered flask. After removal of the volatile materials, formaldehyde-d_2 dimethylthioacetal was distilled at 38–40 °C/5 mm in a yield of 1.2 g (10.9 mmoles, 70%). Nuclear magnetic resonance analysis showed the methylene group to contain 98.5 atom % D.

[5]This operation must be carried out as quickly as possible to minimize exposure since methylene diacetate reacts very rapidly with atmospheric moisture with a resulting lowering of yield.

Biosynthesis of aristolochic acid[1]

F. Comer, H. P. Tiwari, and I. D. Spenser
Department of Chemistry, McMaster University, Hamilton, Ontario

Received August 12, 1968

The biosynthesis of aristolochic acid-**1** (**1**) was studied in *Aristolochia sipho*. Tyrosine, dopa, dopamine, and noradrenaline serve as specific precursors. The nitro group of aristolochic acid is derived from the amino group of tyrosine. The aristolochic acids are yet another group of natural products related to norlaudanosoline.

Canadian Journal of Chemistry, **47**, 481 (1969)

The aristolochic acids (e.g. **1**), a group of substituted 10-nitro-1-phenanthroic acids, have been found to occur in many species of the genus *Aristolochia* (2–5), as well as in other members of the family Aristolochiaceae (6). A biogenetic relationship between these compounds and the aporphine alkaloids has been suspected on structural grounds (2, 3, 7). An aporphine alkaloid, magnoflorine, does indeed accompany aristolochic acids in various *Aristolochia* species (5, 7).

The biosynthetic derivation of the aporphine skeleton from norlaudanosoline or related benzylisoquinoline precursors is now well established (8–10). The benzylisoquinoline precursors, in turn, originate from tyrosine (e.g. ref. 11).

We have examined the incorporation of tyrosine and of a number of its biochemical relatives into aristolochic acid-**1** (**1**). Our results are consistent with the view that the aristolochic acids arise from aporphines by oxidative cleavage of the hetero ring.

In a series of experiments [β-^{14}C]-DL-tyrosine, [β-^{14}C,^{15}N]-tyrosine, [α-^{14}C]-DL-dihydroxyphenylalanine (dopa), [2-^{14}C]-dihydroxyphenylethylamine (dopamine), and [2-^{14}C]-DL-noradrenaline were administered to plants of *Aristolochia sipho* (Dutchman's pipe) by the wick technique (12). In each experiment aristolochic acid-**1** was extracted from roots and rhizomes of the plants, and was purified to constant activity. The details of these experiments are summarized in Table I. Little, if any, of the desired product was detected in the green parts of the plant.

The labelled samples of aristolochic acid-**1** were diluted with carrier and degraded to locate the sites of activity, by reaction sequences shown in Scheme 1. The specific activities of the degradation products are recorded in Table II.

All activity of the samples of aristolochic acid-**1**, derived from the experiments with [2-^{14}C]-dopamine (Expt. 4) and with [2-^{14}C]-DL-noradrenaline (Expt. 5) was confined to the carboxyl group (**1** minus **2**).

All activity of the aristolochic acid obtained from the plants which had been fed with [α-^{14}C]-dopa (Expt. 3) was located at C-10 (**3** minus **4** minus C_1 units).[2] Attempts to isolate C-10 directly, in the form of bromopicrin, failed. Treatment of aristolochic acid-**1** with bromine, under conditions which give good yields of bromopicrin from simple nitrophenols (13), gave only traces of the desired degradation product.

The samples of aristolochic acid-**1**, derived from the experiments with [β-^{14}C]-tyrosine (Expts. 1 and 2) contained label at more than one site. In each case approximately 70% of the activity was located at the carboxyl group (**1** minus **2**). Since the specific activity of the lactone (**4**) was identical with that of the nitrophenanthrene (**2**), none of the activity was present at C-10, or at the peripheral C_1 units of the aristolochic acid-**1**. Lack of material precluded completion of the final step in the degradation, hydrolysis, and decarboxylation of the lactone, after protection of the phenolic groups. Even so, it can be assumed that the remaining 30% of the activity was located at the carboxyl group, the one remaining extranuclear carbon atom of the lactone, and hence at C-9 of aristolochic acid-**1**,

[1]A preliminary account of part of this work has been published (1).

[2]In many natural products C_1 units in general, and *O*-methyl and methylenedioxy groups in particular, have been shown to be derived from one and the same source, the *S*-methyl group of methionine (11). Since the methylenedioxy carbon was devoid of activity (formaldehyde), it can be inferred that the *O*-methyl group was also inactive.

Degradation of aristolochic acid–**1**

the predicted site. The absence of activity in the lactone, obtained by degradation of the aristolochic acid-**1** derived from [α-^{14}C]-dopa (Expt. 3), strengthens this inference.

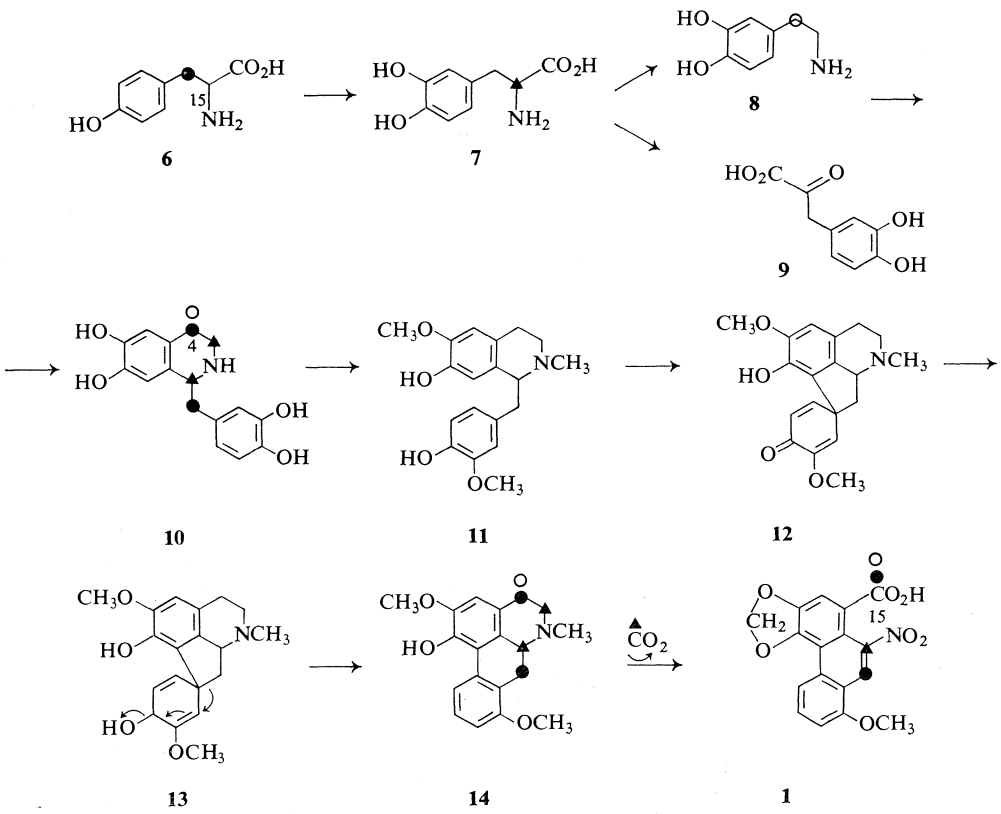
The observed pattern of incorporation of radiocarbon from the labelled samples of tyrosine (**6**), dopa (**7**), and dopamine (**8**) into aristolochic acid-**1** (**1**) corresponds to the distribution which would be predicted if norlaudanosoline (**10**) were an intermediate on the pathway from the administered precursors to the product (cf. Scheme 2). In an independent, concurrent, investigation Schütte, Orban, and Mothes (5) demonstrated that norlaudanosoline (**10**) does indeed serve as a specific precursor of aristolochic acid-**1**.

The evidence is strong that tyrosine supplies both C_6–C_2 units in the skeletons of the many structural variants amongst the alkaloids related to norlaudanosoline (11). It is also well-documented that dopamine supplies only one of these units (11). Dopa has long been regarded as a stage of the pathway. Specific incorporation of dopa into a natural product related to norlaudanosoline is now demonstrated for the first time. A biogenetic sequence from tyrosine to aristolochic acid-**1**, consistent with the results of the tracer experiments, is shown in Scheme 2. Orientaline (**11**), orientalinone (**12**), orientalinol (**13**), and an aporphine (**14**) are shown as hypothetical stages of the postulated pathway, which involves a phenol-oxidation step and a dienol–benzene rearrangement (8, 9).

On the basis of this sequence it would be predicted that the nitro group of aristolochic acid originates from the amino group of tyrosine. The result of a feeding experiment with [β-^{14}C,^{15}N]-tyrosine (Expt. 2) (Tables II and III) provides evidence in support of this view. Aristolochic acid-**1** obtained from this experiment was specifically labelled with ^{14}C (Table II, Expt. 2) and enriched in ^{15}N (Table III).

If an intact C_6–C_2–N unit derived from tyrosine had been incorporated, the ^{15}N/carboxyl-^{14}C ratio of the isolated aristolochic acid (found $(0.69 \pm 0.08) \times 10^{-6}$) should have been identical with the ^{15}N/^{14}C ratio of the L-tyrosine pool of the plant (found $(1.05 \pm 0.04) \times 10^{-6}$) (represented by the re-isolated protein-bound tyrosine). In fact ca. 30% of the ^{15}N relative to ^{14}C had been lost in the course of conversion of tyrosine into aristolochic acid-**1** (Table III). Since the route from tyrosine to the product runs via dopa, an amino acid which is known to undergo reversible transamination in plants (14), this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



SCHEME 2
Origin of aristolochic acid-**1**

loss is not surprising.[3] It is significant that the ^{15}N enrichment of the amino acids, other than tyrosine, which were isolated from the experimental plants (found 0.011 ± 0.002 atom % excess) was markedly lower than the ^{15}N enrichment of the aristolochic acid (found 0.041 ± 0.005 atom % excess) (Table III).

The outcome of a further experiment is difficult to reconcile with the sequence shown in Scheme 2.

Administration of [2-^{14}C]-noradrenaline to *A. sipho* yielded aristolochic acid-**1**, specifically labelled in the carboxyl group (Expt. 5). If noradrenaline were an obligatory precursor of the acid, Scheme 2 would have to be modified to include 4-hydroxynorlaudanosoline and the correspondingly hydroxylated derivatives of orientaline (**11**) and of the later intermediates (**12–14**). It would be enticing to speculate that it is the presence of a benzylic hydroxyl group which predisposes an aporphine intermediate to oxidative conversion into an aristolochic acid.[4] Since noradrenaline is derived from tyrosine by way of dopa (**7**) and dopamine (**8**), the observed incorporation pattern of these compounds is consistent with this alternative; however, the incorporation of norlaudanosoline is not.

It is tempting to regard the specific incorporation of noradrenaline into aristolochic acid-**1** as evidence for a normal biosynthetic pathway. But incorporation, even though specific, does not constitute proof of an obligatory precursor–product relationship. The specific incorporation (5) of norlaudanosoline into aristolochic acid-**1** lends weight to the possibility that entry of nor-

[3]Comparison of the $^{15}N/^{14}C$ ratios of the administered $((1.66 \pm 0.07) \times 10^{-6}$, see Experimental) and protein-bound $((1.05 \pm 0.04) \times 10^{-6}$, see Table III) L-tyrosine indicates that this amino acid also undergoes transamination within the plant.

[4]Attempts to convert 4-hydroxyanonaine into aristolochic acid-**2** by chemical oxidation have so far been unsuccessful however (15).

*The specific activity shown is that at the carboxyl carbon atom. This was determined as the difference of the specific activities of aristolochic acid-**1** (**1**) (2.79±0.06) × 10^4 counts $min^{-1}mmole^{-1}$ and of the nitrophenanthrene (**2**) (0.76±0.03) × 10^4 counts $min^{-1}mmole^{-1}$ (c.f. Table II, Expt. 2).

adrenaline constitutes an aberrant pathway to a normal tissue component. Noradrenaline has not hitherto been detected in *A. sipho*. If the enzyme which normally catalyzes the condensation of dopamine with the α-keto acid (**9**) lacked absolute specificity, a dopamine analogue not normally present in the plant might be used as a substrate, if forced upon the system, to yield an abnormal intermediate which, in subsequent enzymatic steps of similar non-specificity, might be converted to a normal component.

Further evidence is required to decide whether the observed specific incorporation of noradrenaline into aristolochic acid-**1** in *A. sipho* represents the norm or whether this result was obtained as a consequence of a biochemical uncertainty principle.

Experimental

*Isolation of Aristolochic Acid-**1** (**1**) (16)*

Dried and finely powdered roots and rhizomes of *Aristolochia sipho* (28 g) were wetted with aqueous sulfuric acid (0.5%) and extracted first with petroleum ether and then with dichloromethane. The petroleum ether extract was discarded. The dichloromethane extract was evaporated to dryness and the residue digested with a saturated solution of sodium bicarbonate (10 ml). The mixture was filtered, the filtrate was freed from non-acidic material by extraction with ether, and was then acidified with hydrochloric acid (5%). Aristolochic acid-**1** which precipitated was washed with water, dried, and recrystallized from ethanol. Thin-layer chromatography (t.l.c.) of a sample of this product on alkaline cellulose revealed the presence of a red impurity near the origin of the developed plate. The product was, therefore, further purified by preparative t.l.c. (6) using cellulose plates which had been sprayed with a buffer solution (pH 9.2) consisting of sodium carbonate (0.05 *M*) and sodium bicarbonate (0.05 *M*), and had then been dried at room temperature. Aristolochic acid-**1** was applied in ethanol solution and the plates were developed with water-saturated butanol:dimethylformamide (5:1). Sodium aristolochate was extracted from the cellulose with ethanol. The solvent was evaporated, the residue was suspended in chloroform, and aristolochic acid regenerated by addition of dilute hydrochloric acid. The product was recrystallized from ethanol; yield 48 mg, m.p. 280° (decomp.) (reported m.p. 281–286° (decomp.) (17), 274–278° (decomp.) (18)).

The infrared (17) and ultraviolet (19) spectra of this product agreed with those reported. Decarboxylation of this product (*vide infra*) gave a nitrophenanthrene derivative whose behavior on t.l.c. on alumina (benzene:petroleum ether (30–60°), 1:1) matched that of an authentic sample of 1-methoxy-5,6-methylenedioxy-9-nitrophenanthrene, obtained by decarboxylation of a sample of aristolochic acid-**1**, isolated from *Aristolochia indica* (20).

*Methyl Aristolochate-**1** (17, 18)*

Aristolochic acid-**1** (15 mg) was dissolved in warm dioxane (1 ml). After cooling, diazomethane in ether was added and the mixture allowed to stand 2 h. Solvent was evaporated, the residue dissolved in chloroform (15 ml), and unchanged acid extracted into saturated sodium bicarbonate solution. The chloroform layer was washed with water (5 ml), dried (Na_2SO_4), and concentrated. On addition of hot methanol the ester crystallized as yellow needles (12 mg); m.p. 282° (reported m.p. 281° (17) 280–282° (18)); mass spectrum, molecular ion *m/e* 355. The ester was very sparingly soluble in most solvents. Several attempts to hydrolyze the ester failed to regenerate aristolochic acid-**1** (cf. 17).

*Aristolactam-**1** (5) (20)*

A mixture of aristolochic acid-**1** (95 mg) and zinc dust (300 mg, activated by brief treatment with 2 *N* hydrochloric acid, washed with water, ethanol and ether, and dried at 70° for 2 h) in glacial acetic acid (10 ml) was refluxed gently for 20 min. The solution was filtered and diluted with water to yield the product (80 mg, m.p. 310–315°) as a yellow precipitate. Sublimation at 10^{-3} mm and 240–250° raised the m.p. to 317–318°; reported m.p. 319° (17).

1-Methoxy-5,6-methylenedioxy-9-nitrophenanthrene (2) (17, 18)

Aristolochic acid-**1** (**1**) (120 mg) was heated 10 min with copper powder (40 mg) in freshly distilled quinoline (5 ml). After cooling, ether (25 ml) was added and copper was filtered off. The filtrate was washed repeatedly with hydrochloric acid (6 *M*), until the acid extract was no longer colored, and then with aqueous sodium hydroxide (1%), until the alkaline extract was no longer colored. The ether solution was washed with water, dried (Na_2SO_4), and concentrated. The residue was dissolved in chloroform and applied to a column of alumina (grade I) which had been slurried in petroleum ether (30–60°). Elution of the column with petroleum ether (30–60°) – benzene (95:5 v/v) gave a small amount of a low melting impurity. Benzene then eluted a broad yellow band of the desired product. Benzene was evaporated and the residue crystallized from chloroform/ethanol, to yield orange needles of 1-methoxy-5,6-methylenedioxy-9-nitrophenanthrene (65 mg), melting at 212° (reported m.p. 212 (17) 206–212° (18)).

3-Methoxy-5′,6′-methylenedioxybiphenyl-2,2′-dicarboxylic Acid (3) (17)

A mixture consisting of the nitrophenanthrene (**2**) (60 mg) in tetrahydrofuran (15 ml) and aqueous sodium hydroxide (10% w/v, 5 ml) was refluxed very gently with continuous stirring. Hydrogen peroxide (30%, 100 ml) was added dropwise over a period of 6 h, at which time the solution had become colorless. Tetrahydrofuran was distilled off *in vacuo*, the alkaline solution was then boiled 10 min, cooled, washed with ether, acidified with hydrochloric acid, and the product extracted into ether (5 × 10 ml). The combined ether extracts were washed with water, dried (Na_2SO_4), and concentrated. The residue crystallized on addition of chloroform, and was recrystallized from ethanol/chloroform, when the dicarboxylic acid (16 mg) was obtained as colorless plates, m.p. 242° (reported m.p. 243° (17)). A small sample of the product was converted to the dimethyl ester, m.p. 115° (reported m.p. 114° (17)), mass spectrum: molecular ion *m/e* 344.

3,2′,3′-Trihydroxybiphenyl-2-carboxylic Acid Lactone (4) (17)

A mixture of the dicarboxylic acid (**3**) (12 mg) and resorcinol (30 mg) in concentrated hydrochloric acid (1 ml) was heated for 4 h at 130° in a sealed tube. The solution was evaporated to dryness and the residue sublimed at 3×10^{-3} mm. Resorcinol sublimed at 80–90°. The product, which sublimed at 120–125°, was recrystallized from ethanol; yield 3 mg, m.p. 205° (reported m.p. 204° (17)); mass spectrum: molecular ion *m/e* 228.

Hydrolytic Cleavage of the Methylenedioxy Group of Aristolochic Acid-1

A solution of aristolochic acid-**1** (**1**) (15 mg) and dimedone (5,5-dimethyl-1,3-cyclohexanedione) (50 mg) in concentrated hydrochloric acid (1 ml) was heated in a sealed tube at 120–130° for 18 h. The cooled reaction mixture was diluted with water (10 ml) and extracted with ether. The ether extract was washed with sodium bicarbonate solution and with water, and was then dried over sodium sulfate and evaporated. The residue was purified by preparative t.l.c. on silica gel GF_{254} using benzene:ethyl acetate 9:1. The dimedone derivative of formaldehyde was crystallized from aqueous methanol and obtained as white silky needles, melting at 189–190°; yield 4 mg.

Administration of ^{14}C-Labelled Compounds to Aristolochia sipho, and Isolation and Degradation of Radioactive Aristolochic Acid-1

Six two-year-old plants of *A. sipho* were used in each feeding experiment. The labelled tyrosine was dissolved in dilute hydrochloric acid (0.01 *M*, 10 ml), and the labelled samples of dopa, dopamine, and noradrenaline were dissolved in dilute hydrochloric acid (0.01 *M*, 10 ml) containing ascorbic acid (5 mg). In each experiment equal portions of the tracer solution were administered to individual plants by aspiration into the stem through a cotton wick (12). The plants were left in contact with tracer for 3 days. The labelled compounds which were administered to the plants in separate experiments are listed in Table I. In each case aristolochic acid-**1** was isolated from the dried roots and rhizomes of the plants and the samples so obtained were recrystallized to constant activity from ethanol. Chemical and radiochemical yields are shown in Table I.

Each labelled sample of aristolochic acid-**1** was diluted with carrier, and the diluted samples were degraded by the reactions described above. The products were purified to constant activity. The specific activities of the degradation products are recorded in Table II.

Radioactivity was assayed on samples of finite thickness on aluminium planchettes, using a Nuclear Chicago Corp. gas flow counter (model 1052) in a low background sample changer (C115). Counts were recorded on a printing timer (C111B) in association with a scaler (181B). For plating of the samples a 1% solution of collodion in dimethylformamide was used as the solvent. The usual corrections for background and self-absorption were applied. Limits shown in the Tables are the standard deviation of the mean.

Experiment with [β-^{14}C,^{15}N]-Tyrosine

The doubly-labelled tyrosine used in this experiment was a mixture of [β-^{14}C]-DL-tyrosine (2.7 mg, specific activity $(3.43 \pm 0.05) \times 10^9$ counts min^{-1} $mmole^{-1}$, Nuclear Chicago Corporation) and [^{15}N]-L-tyrosine (87.9 mg, 89.7 ± 0.4 atom % excess ^{15}N above natural abundance, Schwarz BioResearch Inc.). This yielded a product with a specific activity of $(1.02 \pm 0.02) \times 10^8$ counts min^{-1} $mmole^{-1}$ and an ^{15}N content of 86.7 ± 0.4 atom % excess ^{15}N above natural abundance, i.e. with an $^{15}N/^{14}C$ ratio $(0.85 \pm 0.01) \times 10^{-6}$.

The mixture was dissolved in 0.01 *M* hydrochloric acid (25 ml). A small sample of this solution (20 μl) was added to a solution of unlabelled L-tyrosine (181 mg) in 0.01 *M* hydrochloric acid. Neutralization gave a precipitate which was recrystallized from water. The specific activity of this diluted tyrosine was $(2.36 \pm 0.05) \times 10^4$ counts min^{-1} $mmole^{-1}$ and the ^{15}N content was 0.0391 ± 0.0016 atom % excess ^{15}N above natural abundance. The specific activity and the $^{15}N/^{14}C$ ratio $(1.66 \pm 0.07) \times 10^{-6}$ of this sample are consistent with the complete loss of [β-^{14}C]-D-tyrosine in the course of dilution and recrystallization of the original sample.

The tracer solution was administered by wick to eleven *A. sipho* plants. The plants were kept in contact with

For personal use only.

tracer for 3 days. The dried roots and rhizomes of the plants (76 g) were extracted with petroleum ether and then with dichloromethane. Aristolochic acid (45 mg) was obtained from the dichloromethane extract, in the manner described above.

The plant material was freed from non-protein amino acids by extraction, first with cold aqueous ethanol (70% v/v) and then with boiling water. Protein-bound tyrosine was then isolated as follows. The plant material was digested by refluxing with 6 *N* hydrochloric acid (500 ml) for 20 h. The solution was filtered and the filtrate neutralized by addition of saturated sodium hydroxide solution. The amino acids were collected on Dowex 50W-X4 (100 g, H^+ form) by keeping the resin, tied in a bag of dialysis tubing ($1\frac{1}{8}$ in. diameter), suspended in the aqueous solution for 2 days. The resin was then transferred into a column, was washed with water, and the amino acids were eluted with 2 *N* ammonia. The eluate was evaporated to dryness *in vacuo*. Quantitative amino acid analysis of this residue showed that it contained 25 mg of tyrosine. L-Tyrosine (50 mg) was added to the residue as carrier, the mixture was dissolved in *N* hydrochloric acid (4 ml), and the solution was filtered and neutralized with *N* sodium hydroxide. Tyrosine (65 mg), which crystallized, was mixed further with carrier L-tyrosine (70 mg), and the sample was redissolved in *N* hydrochloric acid. The solution was lightly charcoaled, filtered, and neutralized, and the product was recrystallized from hot water. The L-tyrosine (87 mg) so obtained was analyzed for ^{15}N and ^{14}C (Table III).

A sample of amino acids other than tyrosine was obtained as follows. The mixture of amino acids from which radioactive tyrosine had been precipitated with carrier L-tyrosine was hydrolyzed further with 6 *N* hydrochloric acid for 20 h. The solution was neutralized by addition of a saturated solution of sodium hydroxide. The amino acids were collected on a Dowex 50W-X4 column (55 g, H^+ form) and eluted with 2 *N* ammonium hydroxide. The eluate was evaporated to dryness and a solution of barium hydroxide was then added. The solution was distilled to remove any ammonia, and barium ions were then removed by precipitation of barium carbonate with carbon dioxide. The solution was filtered and charcoaled three times to remove any tyrosine. The solution was evaporated to dryness to give a residue shown to be devoid of tyrosine by amino acid analysis. This mixture of amino acids was analyzed for ^{15}N.

Assay of [^{15}N]-Labelled Compounds

The ^{15}N content of the [^{15}N]-labelled compounds was determined mass spectrometrically on nitrogen gas samples prepared by oxidation of the ammonia formed by Kjeldahl digestion (21, 22). The sample of aristolochic acid-**1**, obtained from plants to which [β-^{14}C,^{15}N]-labelled tyrosine had been administered, was reduced to aristolactam-**1** (**5**) (*vide supra*) prior to digestion. The ^{15}N-content of the nitrogen gas samples obtained from aristolactam-**1**, from the doubly-labelled tyrosine and the sample of amino acids other than tyrosine, isolated from the plants to which [β-^{14}C,^{15}N]-tyrosine had been administered, and from the doubly-labelled L-tyrosine, obtained from the original tracer solution by carrier dilution and recrystallization, was measured by double collection and balancing of the signals from the ions of mass 28 and 29 by the null method (23). The ^{15}N-content of the nitrogen gas samples derived from the precursor ^{15}N-L-tyrosine was measured, conventionally, by repeated scanning of the signals from mass 28 and 29 and normalization to the line standard. In every case ^{15}N analysis was carried out on duplicate samples and sufficient material was digested to yield 1–2 ml nitrogen gas (at N.T.P.) from each sample.

Acknowledgments

Mass spectrometric measurements were carried out by Mr. J. Monster, Department of Chemistry, and amino acid analyses by Mr. M. Abdulla, Department of Biochemistry, McMaster University. This work was supported by a grant from the National Research Council of Canada.

Diethyl malonate as leaving group: Facile synthesis of some 1,3,4-benzotriazepines and benzotriazepinones

C. Podesva, G. Kohan, and K. Vagi
Delmar Chemicals Limited, Lasalle, Quebec

Received August 16, 1968

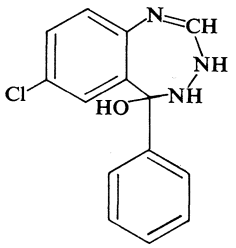
Reaction between 2-(2′,2′-bis-carboethoxyvinylamino)-benzophenones, resulting from the condensation of 2-aminobenzophenones with diethyl ethoxymethylenemalonate, and hydrazine hydrate yields 5-hydroxy-5-phenyl-1,3,4-3*H*-4,5-dihydrobenzotriazepines or their double bond isomers. These products on acetylation afford *O*,*N*,*N*-triacetates, which on treatment with ammonia are transformed into 4-phenylquinazolines. Structure proof of these substances is reported.

Canadian Journal of Chemistry, **47**, 489 (1969)

When diethyl ethoxymethylenemalonate was heated together with 2-amino-5-chlorobenzophenone, the expected 2-(2′,2′-bis-carboethoxyvinylamino)-5-chlorobenzophenone (**1**) was readily formed. Other 2-aminobenzophenones as well as methyl anthranilate and methyl 5-chloroanthranilate reacted in the same manner. The infrared (i.r.) spectra of these substances were in good agreement with the assigned structures, exhibiting α,β-unsaturated ester absorptions at 1680 cm^{-1} together with the benzophenone carbonyl absorption at 1640 cm^{-1}. The reaction products are summarized in Table I.

When **1** was allowed to react with hydrazine hydrate in methanolic solution at room temperature, a high yield of a crystalline material could be isolated whose elemental analysis corresponded to a formula of $C_{14}H_{12}ClN_3O$. Obviously, this substance must have been formed from the starting material by the elimination of the diethyl malonate moiety and by the addition of one molecule of hydrazine. Its i.r. spectra (KBr) exhibited a sharp peak at 3325 cm^{-1}, a peak of medium intensity at 2780 cm^{-1} together with a weaker peak at 2600 cm^{-1}, thus disclosing very strong hydrogen bonding (1, 2), plus a strong peak at 1640 cm^{-1}. On acetylation of this product with acetic anhydride in pyridine an *O*,*N*,*N*-triacetate was formed (ν_{max} (KBr) 1730, 1665, and 1645 cm^{-1}), which on controlled alkaline hydrolysis afforded an *N*,*N*-diacetate having a free hydroxyl (ν_{max} (KBr) 3230, 1670, and 1620 cm^{-1}). In the light of this, the i.r. absorption at 1640 cm^{-1} in the original product must be assigned to a C=N grouping rather than a C=O.

From the presence of the C=N and OH together with three N atoms in the molecule and in view of the nature of starting material it was concluded that the initial product had to possess a 1,3,4-benzotriazepine skeleton. The hydroxyl group could be attached either to C-5 and the position of the double bond then would be as shown in structure **7** or between C-2 and N-3, or to C-2 with the double bond between N-4 and C-5.



7

The position of attachment of the hydroxyl was established in a somewhat unexpected way. On attempted selective saponification of the ester function in the above mentioned *O*,*N*,*N*-triacetate with aqueous methanolic ammonia, a high yield of a crystalline substance was isolated which was identified as 4-phenyl-6-chloroquinazoline (**8**) by comparison of physical properties and i.r. spectra

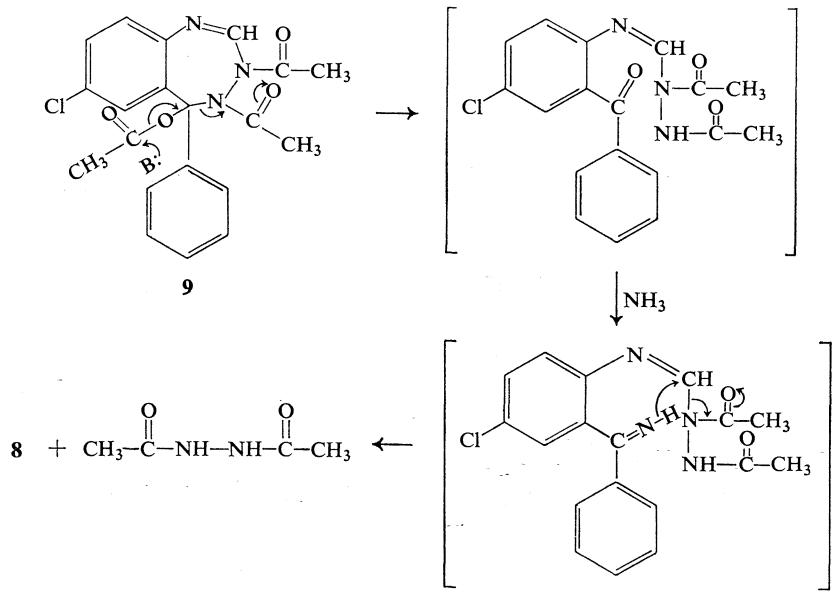
‖Sometimes a different crystalline form having a m.p. of 185–187°, but having the same i.r. spectrum was obtained.

with a sample prepared by an independent synthesis.

The same product was also obtained when the diester **1** was subjected to a similar treatment using methanolic ammonia, and also when the *N,N*-diacetate was kept for some time in aqueous methanolic ammonia solution in presence of catalytic amount of triethylamine. (It is noteworthy, that whereas in the case of the triacetate the reaction was completed in about 30 min, the uncatalyzed reaction with the *N,N*-diacetate proceeded very slowly. A likely explanation is, that in the first case the liberated electron pair on the alcoholic oxygen immediately became involved in the transfer shown in the postulated mechanism (*vide infra*), whereas once protonated a stronger base than ammonia was needed to produce the necessary anion). On the other hand, when the non-acetylated material was treated with aqueous methanolic ammonia under the same conditions, the starting material was recovered unchanged, thus showing that in order for elimination to occur the hydrazine portion had to be acetylated. A plausible mechanism for the formation of **8** from the triacetate formulated as **9** can be represented as follows:



9

It can be seen, that the above mechanism postulates elimination of hydrazine in the form of a symmetrical diacetate. On the other hand, if a similar elimination is considered for the diacetylated 2-hydroxy isomer, an unlikely ammonolysis of an *N*-acetyl would be anticipated and hydrazine would have to be eliminated in the form of a monoacetate. As we were able, however, to isolate from the reaction mother liquors a high yield of 1,2-diacetylhydrazine, identified by comparison of its physical properties and i.r. spectra with a sample prepared by an independent synthesis, the correctness of the above mechanism is rigorously proved and at the same time the sites of the acetylation as well as the position of the double bond in the acetates clearly established, as shown in structures **9** and **10**. Consequently, for the nonacetylated product, structure **7** would appear to be the most likely one. As, however, a double bond migration might have taken place during the acetylation, a double bond isomer of **7** cannot be excluded. Attempts to solve this question by nuclear magnetic resonance (n.m.r.) spectra were frustrated by insufficient solubility of this substance in deuterated solvents.

When compounds **2**–**4** listed in Table I, were brought in contact with hydrazine hydrate under the same conditions as **1**, they afforded readily the corresponding 1,3,4-benzotriazepines listed in Table II. Similarly compounds **5** and **6**, when allowed to react with hydrazine hydrate, yielded the corresponding 1,3,4-benzotriazepine-5-ones

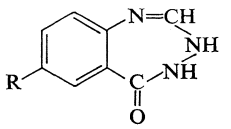
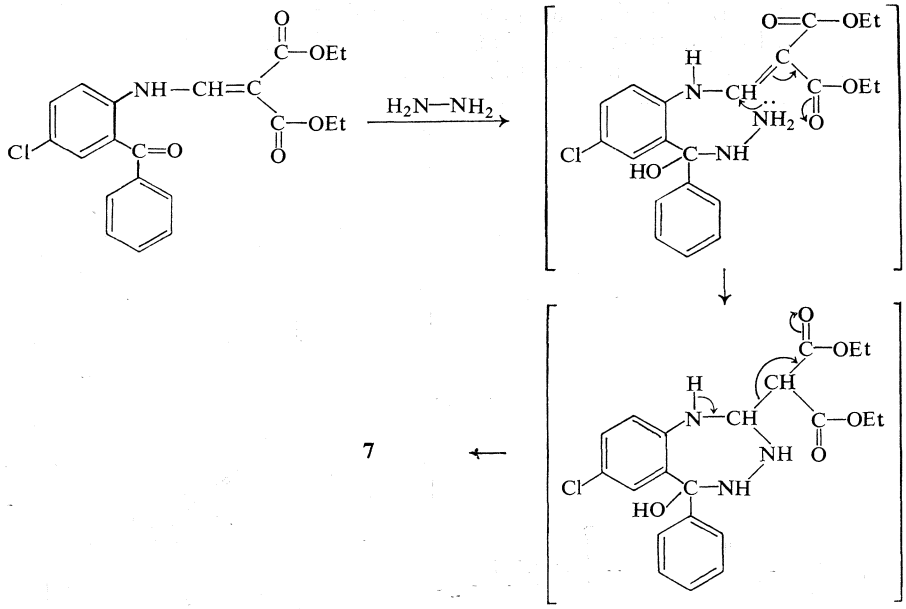
For personal use only.

14 and **15**. (We placed the double bonds in **14** and **15** between N-1 and C-2 by analogy with the benzotriazepines listed in Table II, nevertheless, we do not have any rigorous proof for this assignment. Ultraviolet spectra proved to be of little value due to the lack of appropriate models).



14, R = H
15, R = Cl

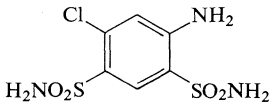
The reaction mechanism by which 1,3,4-3*H*-4,5-dihydrobenzotriazepines are formed from the appropriate 2-(2′,2′-bis-carbethoxyvinylamino)-benzophenones and hydrazine hydrate is readily conceivable and can be represented as follows:



7

Because the above reactions were carried out using an excess of hydrazine hydrate, the question arose as to whether the leaving group is indeed diethyl malonate or rather pyrazolidine-3,5-dione resulting from the hydrazinolysis of the diester. For that reason the reaction was repeated using only one mole equivalent of hydrazine hydrate. Isolation of about the same yield of the benzotriazepine as in the previous experiments clearly showed that the leaving group is indeed the diethyl malonate.

The general applicability of the above described method for introduction of a =CH— group between two nitrogens was further tested by treating 1-amino-3-chlorobenzene-4,6-disulfonamide **16** with diethylethoxymethylenemalonate. The expected 6-chloro-7-sulfamyl-1,2,4-benzothiadiazine-1,1-dioxide **17**, identified by comparison of physical properties and i.r. spectra with an authentic sample prepared by independent synthesis was obtained in high yield. The above described method has therefore a wide applicability and constitutes a method of choice whenever the use of formic acid, ethyl orthoformate etc. is excluded for one reason or other.



16

Condensation of Diethyl Ethoxymethylenemalonate with 2-Aminobenzophenones and Anthranilic Esters

General Procedure

A mixture of approximately equal weights of the appropriate amine and diethyl ethoxymethylenemalonate was kept at a temperature of about 110° (140° in case of anthranilic esters) for 30 min. After cooling to about 80° the reaction mixture was diluted with some ethanol and the reaction product was allowed to crystallize in an ice box overnight. The crystalline material was collected by filtration and recrystallized from the appropriate solvent.

Synthesis of 5-Hydroxy-5-phenyl-1,3,4-3H-4,5-dihydrobenzotriazepines

General Procedure

An approximately 10% ethanolic solution of the diester was stirred at room temperature overnight in presence of 1–3 mole equivalents of hydrazine hydrate. The crystalline reaction product was collected by filtration, washed with water, and recrystallized from the appropriate solvent.

*1,3,4-3H-4,5-Dihydrobenzotriazepine-5-one (**14**)*

A solution of **5** (2 g) in ethanol (10 ml) was left standing at room temperature for 4 days in presence of 100% hydrazine hydrate (1 g). The crystalline precipitate was collected by filtration, washed with some ethanol (0.94 g, 94%), and recrystallized for analysis from isopropanol, m.p. 214–215°.

Anal. Calcd. for $C_8H_7N_3O$: C, 59.61; H, 4.38; N, 26.07. Found: C, 59.74; H, 4.51; N, 25.84.

*7-Chloro-1,3,4-3H-4,5-dihydrobenzotriazepine-5-one (**15**)*

A solution of **6** (7.1 g) in ethanol (50 ml) containing 100% hydrazine hydrate (3 g) was allowed to stand at room temperature for overnight. The crystalline precipitate was collected by filtration (3 g, 77%), washed with some ethanol, and recrystallized for analysis from chloroform – methanol mixture, m.p. 230–232°.

Anal. Calcd. for $C_8H_6Cl\ N_3O$: C, 49.11; H, 3.09; Cl, 18.13; N, 21.48. Found: C, 49.00; H, 2.84; Cl, 18.31; N, 21.43.

Acetylation of 7

A mixture of **7** (54.7 g, 0.2 mole), acetic anhydride (122.4 g, 1.2 mole), and dry pyridine (170 ml) was allowed to stand at room temperature for 48 h. The reaction mixture was evaporated to dryness *in vacuo* and water was added to the residue. The reaction product was extracted into 2 × 150 ml of chloroform and the solution washed first with 5% HCl, then with 15% aqueous solution of $NaHCO_3$, and eventually with water. The solvent was removed *in vacuo* and the residue crystallized first from ethanol, then from methanol. The yield of **9** was 42 g (52.5%), m.p. 103–104°.

Anal. Calcd. for $C_{20}H_{18}Cl\ N_3O_4$: C, 60.07; H, 4.53; Cl, 8.86; N, 10.50. Found: C, 60.15; H, 4.72; Cl, 9.05; N, 10.68.

Saponification of 9

To a solution of **9** (8 g, 0.02 mole) in methanol (20 ml), previously warmed to about 45°, was added alcoholic KOH till a pH of about 10 was reached. After allowing the warm solution to stand for about 30 min, cold water (300 ml) was added; the precipitated solid was collected by filtration, washed with water, and dried at 60° (6 g, 85.7%). The analytically pure **10**, m.p. 170–172°, was prepared by crystallization from tetrahydrofuran – ether mixture.

Anal. Calcd. for $C_{18}H_{16}Cl\ N_3O_3$: C, 60.42; H, 4.51; Cl, 9.91; N, 11.74. Found: C, 60.61; H, 4.55; Cl, 10.07; N, 11.91.

*4-Phenyl-6-chloroquinazoline (**8**)*

Method a

To a solution of **9** (18 g, 0.0045 mole) in methanol (50 ml) was added aqueous NH_3 till a pH of 9.5 was reached. After standing for 30 min at a temperature of about 30°, the reaction mixture was cooled to 0° and the precipitated **8** (9.72 g, 90%) was collected by filtration and purified by crystallization from methanol, m.p. 137–139°.

Anal. Calcd. for $C_{14}H_9Cl\ N_2$: C, 69.89; H, 3.77; Cl, 14.74; N, 11.64. Found: C, 70.10; H, 3.94; Cl, 15.04; N, 11.59.

This product was found identical by comparison of physical properties and i.r. spectra with the product obtained by a method described by Palazzo for the preparation of 4-phenylquinazoline (3), using 2-amino-5-chlorobenzophenone instead of 2-aminobenzophenone. The filtrate from the above experiment was evaporated to dryness *in vacuo* and the residue (4 g, 80%) was recrystallized from methanol, m.p. 138–139°. It was found identical with 1,2-diacetylhydrazine prepared by the method of Stollé (4), by comparison of physical properties and i.r. spectra.

Method b

A solution of **1** (2 g, 0.005 mole) in anhydrous methanol (150 ml) previously cooled in an ice bath was saturated with NH_3 gas. After standing at room temperature over the weekend, the reaction mixture was concentrated to a small volume under reduced pressure and the crystalline precipitate was collected by filtration (0.6 g, 50%) and recrystallized from methanol, m.p. 137–139°, undepressed on admixture of the product obtained by Method *a*. Infrared spectra of these two products were superimposable.

Method c

A solution of **10** (0.7 g, 0.00195 mole) in a mixture of methanol (70 ml) and water (20 ml) containing a few drops of triethylamine was saturated with HN_3 gas and allowed to stand at room temperature overnight. The reaction mixture was concentrated to a small volume under reduced pressure, diluted with water, and the reaction product was extracted into chloroform. The solution was evaporated to dryness *in vacuo* and the residue treated with a small amount of methanol. The crystalline reaction product was collected by filtration (0.15 g, 31%) and identified as **8** by m.p., mixture m.p., and by comparison of i.r. spectra.

When the above experiment was carried out in absence of triethylamine, most of the starting material was recovered even after 48 h standing.

*6-Chloro-7-sulfamyl-1,2,4-benzothiadiazine-1,1-dioxide (**17**)*

A mixture of **16** (5.4 g, 0.02 mole) and diethyl ethoxymethylenemalonate (4.32 g, 0.02 mole) was heated to 210° for 10 min. After cooling the solid product was triturated with methanol, collected by filtration, and purified by recrystallization from methanol – ethyl acetate mixture. The yield was 3 g (51%), m.p. 343°, undepressed

on admixture of a sample prepared by a previously described method (5). The i.r. spectra of these two products were superimposable.

Conversion of uridine 2′,3′-carbonates to anhydrouridines

K. K. OGILVIE AND D. IWACHA[1]
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received September 25, 1968

Uridine 2′,3′-carbonates are readily converted to 2,2′-anhydrouridines in hot dimethyl formamide with base catalysis. 3′,5′-Di-*O*-trityluridine is converted to 3′,5′-di-*O*-trityl-2,2′-anyhdro-1-β-D-arabinofuranosyluracil with diphenyl carbonate in the presence of sodium bicarbonate in hot dimethyl formamide.

Canadian Journal of Chemistry, **47**, 495 (1969)

In a recent publication, Hampton and Nichol (1) reported the formation of 2,2′-anhydro-1-β-D-arabinofuranosyluracil (**2***a*) when uridine (**1***a*) was treated with diphenyl carbonate and sodium bicarbonate in hot *N*,*N*-dimethyl formamide (DMF). Replacement of uridine by other ribonucleosides in this reaction yielded 2′,3′-cyclic carbonates. These authors suggested that either uridine 2′,3′-carbonate (**3***a*) or 2′-phenoxycarbonyluridine (**4***a*) was probably the intermediate in the reaction (1). In an analogous case Ruyle *et al.* (2) found that 5′-*O*-trityluridine 2′,3′-thionocarbonate was readily converted to 5′-*O*-trityl-2,2′-anhydro-1-β-D-arabinofuranosyluracil when heated with imadazole in toluene. Since uridine 2′,3′-carbonates (**3***a*, *b*) were readily available as a result of another study (3) it was of interest to us to test them under the reaction conditions used by Hampton and Nichol.

As expected we found that both uridine 2′,3′-carbonate (**3***a*) and 5′-*O*-trityluridine 2′,3′-carbonate were readily converted to the anhydrouridines **2***a* and **2***b* respectively when heated in DMF with sodium bicarbonate or sodium carbonate. The cyclic carbonates were not converted to their anhydroforms when heated alone in DMF or in DMF containing phenol.

For comparison we obtained 3′,5′-di-*O*-trityluridine (**1***c*) and 2′,5′-di-*O*-trityluridine by a variation of the procedure of Yung and Fox (4) and subjected them to the diphenyl carbonate reaction of Hampton and Nichol. The 3′,5′-di-*O*-trityluridine was smoothly converted to 3′,5′-di-*O*-trityl-2,2′-anhydro-1-β-D-arabinofuranosyluracil (**2***c*) when heated with diphenylcarbonate and sodium bicarbonate in DMF. However 2′,5′-di-*O*-trityluridine was not converted to the 2,3′-anhydrouridine analogue under these conditions, but gave instead a good yield of 2′,5′-di-*O*-trityl-3′-*O*-phenoxycarbonyluridine. This result was not unexpected in view of previous observations (5) that 2,2′-anhydrouridines form much more readily than 2,3′-anhydrouridines.

These results confirm that uridine 2′,3′-carbonates **3***a* and **3***b* are probable intermediates in the conversion of uridine derivatives **1***a* and **1***b* to their anhydroforms using diphenyl carbonate in dimethyl formamide with base catalysis. However, when the 3′-position is blocked (**1***c*) other intermediates, most likely **4***c*, must occur.

Experimental

Materials

Thin-layer chromatography was carried out on Eastman Chromagram Sheets 6060 by the ascending technique. Thick-layer chromatography was carried out on glass plates (15 × 20 cm) coated with a 2 mm thick layer of silica gel DSF-5 (Mondray Chemicals Ltd.). Elemental analysis were performed by MicroTech Laboratories, Skokie, Illinois.

Melting points were obtained on a Fisher–Johns melting point apparatus and are reported uncorrected.

Uridine 2′,3′-carbonate (m.p. 122–126 °C) and 5′-*O*-trityluridine 2′,3′-carbonate (m.p. 134–135 °C) were prepared as previously described (3).

3′,5′-Di-*O*-trityluridine was prepared from uridine by the method of Yung and Fox (4). The isolation procedure was modified in that the 3′,5′- and 2′,5′-ditrityl mixture produced was separated by thick-layer chromatography using ether as developing agent. 2′,5′-Di-*O*-trityluridine (m.p. 216–218 °C) traveled fastest (R_f 0.76) while the 3′,5′-di-*O*-trityluridine (m.p. 134–138 °C) had an R_f value of 0.63 in ether.

5′-*O*-Trityluridine (m.p. 115–117 °C) was prepared by the procedure of Lohrman and Khorana (6).

2,2′-Anhydro-β-D-arabinofuranosyluracil (anhydrouridine m.p. 245–247 °C) was obtained from uridine by the

[1]NRCC Scholarship Recipient, 1968–1969.

method of Hampton and Nichol (1); the ultraviolet spectrum in 95% ethanol had λ_{max} 248 mμ (ε 8680), and λ_{max} 224 mμ (ε 10 600) and λ_{min} 236.5 mμ (ε 7560) and λ_{min} 210 mμ (ε 7130).

5′-O-Trityl-2,2′-anhydro-1-β-D-arabinofuranosyluracil (2b) from 5′-O-Trityluridine

5′-*O*-Trityluridine (0.67 g, 1.37 mmole) and diphenyl carbonate (0.39 g, 1.8 mmole) were dissolved in dimethyl formamide (1.5 ml). Sodium bicarbonate (0.01 g) was added and the mixture was heated at 150 °C for 30 min, cooled to room temperature and poured onto ether. A gummy precipitate formed and was collected and recrystallized from ethanol to yield 0.40 g (62%) of **2***b*, m.p. 218–220 °C (7), infrared spectrum (KBr disk): 6.15, 6.6, 6.8, and 14.2 μ; ultraviolet spectrum (95% ethanol): λ_{max} 249 mμ (ε 6630) and 224 mμ (sh); thin-layer R_f values were 0.70 (ethanol) and 0.55 (tetrahydrofuran). The product was identical to a sample prepared by the reaction of anhydrouridine (**2***a*) with trityl chloride in pyridine at room temperature.

Reactions of Uridine 2′,3′-carbonates in Dimethyl Formamide at 150 °C

(a) 5′-*O*-Trityluridine 2′,3′-carbonate (**3***b*, 204 mg, 0.4 mmole) was heated with diphenyl carbonate (114 mg, 0.64 mmole) and sodium bicarbonate (25 mg) in dimethyl formamide (0.2 ml) at 150 °C for 30 min. The solution was cooled and upon addition of ether a gummy precipitate formed which was collected and crystallized from ethanol to yield 110 mg (59%) of 5′-*O*-tritylanhydrouridine (**2***b*) m.p. 218–220 °C (mixed melting point 218–220 °C). Thin-layer R_f values were 0.55 (tetrahydrofuran) and 0.70 (ethanol). Spectral properties were identical to those of the sample prepared above.

(b) **3***b* (51 mg, 0.1 mmole) and sodium bicarbonate (3 mg) were heated in dimethyl formamide (0.05 ml) at 150 °C for 30 min. The reaction mixture was worked up as in *a* to yield 40 mg of **2***b* (85%) m.p. 219–220 °C.

(c) Reaction *b* was repeated except that sodium carbonate (2 mg) was used in place of sodium bicarbonate. A yield of 38 mg (81%) of **2***b* was obtained, m.p. 218–220 °C.

(d) Reaction *c* was repeated except that **3***a* (30 mg) was used in place of **3***b* and a yield of 18 mg (72%) of **2***a* was obtained, m.p. 245–247 °C, mixed melting point 246–248 °C; Spectral properties were identical to those of the sample prepared above.

(e) **3***b* (51 mg) was dissolved in dimethyl formamide (0.05 ml) and after 30 min heating at 150 °C the products were separated by thick-layer chromatography using ethyl acetate. Two compounds appeared (R_f 0.42 and 0.84) and these were eluted to yield 5′-*O*-trityluridine 2′,3′-carbonate 25 mg, 48%; R_f 0.84 (ethyl acetate) and R_f 0.25 (ether (1); m.p. 133–135 °C; infrared spectrum (KBr disk) showed major bands at 5.57, 6.0, and 14.2 μ) and uridine 2′,3′-carbonate (10 mg, 37%; m.p. 122–126 °C; thin-layer R_f values of 0.42 (ethyl acetate) and 0.00 (ether); the infrared spectrum (KBr disk) showed prominent peaks at 5.56 and 5.95 μ).

(f) Reaction *e* was repeated except that phenol (3 mg) was added and heating was continued for 3 h. After 30 min thin-layer chromatography in ethyl acetate showed two separate spots of nearly equal intensity at R_f 0.79 (**3***b*) and 0.38 (**3***a*). After 3 h the reaction was worked up by thick-layer chromatography to yield 25 mg (92%) of uridine 2′,3′-carbonate (**3***a*), m.p. 120–125 °C.

3′,5′-Di-O-trityl-2,2′-anhydro-1-β-D-arabinofuranosyluracil (2c)

3′,5′-Di-*O*-trityluridine (40 mg, 0.055 mmole) and diphenyl carbonate (19 mg, 0.086 mmole) were heated with sodium bicarbonate (2 mg) in dimethyl formamide (0.05 ml) at 150 °C for 30 min. On cooling to room

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

temperature ether (2 ml) was added and the solution was applied to two thick layers plates which were developed in ethyl acetate. A band appeared at R_f 0.35 and was eluted to yield 27 mg (67%) of **2***c*, m.p. 141–143 °C; in 95% ethanol the compound showed two shoulders at 249 mμ (ε 6740) and 223 mμ; the infrared spectrum (KBr disk) displayed prominent peaks at 6.06, 6.82, and 14.3 μ.

Anal. Calcd. for $C_{47}H_{32}N_2O_6$: C, 77.35; H, 5.25; N, 3.84; Found: C, 77.33; H, 5.12; N, 3.99.

2′,5′-Di-O-trityl-3′-O-phenoxycarbonyluridine

2′,5′-Di-*O*-trityluridine (200 mg, 0.27 mmole) was heated with diphenyl carbonate (95 mg, 0.43 mmole) and sodium bicarbonate (10 mg) in dimethyl formamide (0.25 ml) at 150 °C for 30 min. The solution was cooled to room temperature, diluted with ether, and separated from a small amount of insoluble material. On addition of hexane a precipitate formed which was collected by filtration and recrystallized from ether–hexane to yield 175 mg (77%) of 2′,5′-di-*O*-trityl-3′-*O*-phenoxycarbonyluridine as a white solid, m.p. 156–159 °C. The infrared spectrum (KBr disk) displayed major peaks at 5.63, 5.85, and 14.2 μ.

Anal. Calcd. for $C_{54}H_{44}N_2O_8$: C, 76.40; H, 5.22; N, 3.30. Found: C, 76.41; H, 5.31; N, 3.20.

Photolysis of a diterpene nitrosamine

W. B. Watkins[1]
Department of Pharmacology, South Parks Road, Oxford, England

AND

R. N. Seelye
Cancer Laboratories, Cornwall Hospital, Auckland, New Zealand

Received August 16, 1968

Photolysis of the diterpene nitrosamine, 4-*N*-nitroso-4-*N*-methyl-12-methoxy-16-norpodocarpa-8,11,-13-trien-4-amine in cyclohexane solvent gave the corresponding amine as the major product.

Canadian Journal of Chemistry, **46**, 497 (1968)

The photolysis of nitrites has now become an established method, in the steroid field, for the functionalization of suitably placed saturated carbon atoms (1). In recent years work has been carried out to investigate the products resulting from the photolytic decomposition of the spectroscopically similar nitrosamines (2). In Chow's latest work (3) he has further established that simple acyclic and alicyclic *N*-nitrosodialkylamines undergo photolysis in the presence of acid to give amidoximes and the parent secondary amine.

In this present paper we have further investigated the scope of the latter reaction by studying the photolysis of the polycyclic nitrosamine, 4-*N*-nitroso-4-*N*-methyl-12-methoxy-16-norpodocarpa-8,11,13-trien-4-amine (**8**). The stereochemistry of podocarpic acid **1** is such that the axial carboxyl group at C-4 is *cis* to the C_{10}-angular methyl, the latter being forced close to the former by the steric compression offered by ring C. In this system, a nitrosamine group at C-4 might thus be expected to oxygenate the methyl at C-10.

Treatment of the acid chloride of 12-methoxypodocarpa-8,11,13-trien-16-oic acid **2** (4) with sodium azide gave the isocyanate **4** which on reduction with excess lithium aluminium hydride

[1]To whom all correspondence should be addressed.

temperature ether (2 ml) was added and the solution was applied to two thick layers plates which were developed in ethyl acetate. A band appeared at R_f 0.35 and was eluted to yield 27 mg (67%) of **2***c*, m.p. 141–143 °C; in 95% ethanol the compound showed two shoulders at 249 mμ (ε 6740) and 223 mμ; the infrared spectrum (KBr disk) displayed prominent peaks at 6.06, 6.82, and 14.3 μ.

Photolysis of a diterpene nitrosamine

W. B. Watkins[1]
Department of Pharmacology, South Parks Road, Oxford, England

AND

R. N. Seelye
Cancer Laboratories, Cornwall Hospital, Auckland, New Zealand

Received August 16, 1968

Photolysis of the diterpene nitrosamine, 4-*N*-nitroso-4-*N*-methyl-12-methoxy-16-norpodocarpa-8,11,-13-trien-4-amine in cyclohexane solvent gave the corresponding amine as the major product.

Canadian Journal of Chemistry, **46**, 497 (1968)

The photolysis of nitrites has now become an established method, in the steroid field, for the functionalization of suitably placed saturated carbon atoms (1). In recent years work has been carried out to investigate the products resulting from the photolytic decomposition of the spectroscopically similar nitrosamines (2). In Chow's latest work (3) he has further established that simple acyclic and alicyclic *N*-nitrosodialkylamines undergo photolysis in the presence of acid to give amidoximes and the parent secondary amine.

In this present paper we have further investigated the scope of the latter reaction by studying the photolysis of the polycyclic nitrosamine, 4-*N*-nitroso-4-*N*-methyl-12-methoxy-16-norpodocarpa-8,11,13-trien-4-amine (**8**). The stereochemistry of podocarpic acid **1** is such that the axial carboxyl group at C-4 is *cis* to the C_{10}-angular methyl, the latter being forced close to the former by the steric compression offered by ring C. In this system, a nitrosamine group at C-4 might thus be expected to oxygenate the methyl at C-10.

Treatment of the acid chloride of 12-methoxypodocarpa-8,11,13-trien-16-oic acid **2** (4) with sodium azide gave the isocyanate **4** which on reduction with excess lithium aluminium hydride

[1]To whom all correspondence should be addressed.

in ether afforded the *N*-methyl amine **5**. Nitrosation of **5** in aqueous acetic acid gave the nitrosamine **8** in yields up to 61%. On irradiation of the *N*-nitrosamine **8** in the absence of acid, the absorption of the NNO at 352 mμ rapidly disappeared with the formation of the secondary

amine **5** together with polymeric material. This reaction is yet another example in which homolysis of **8** to the radical **9** and subsequent disproportionation to **5** appears to occur in preference to hydrogen abstraction from the C-10 methyl. Chow (3) has similarly found that photolysis of *N*-nitroso-*trans*-decahydroquinoline gave the parent amine as the only product.

Experimental

Infrared spectra were measured on a Perkin–Elmer Infracord model 237 spectrophotometer and the ultraviolet spectra were measured on a Perkin–Elmer model 137-UV spectrophotometer. Nuclear magnetic resonance spectra were recorded on a Varian A60 spectrophotometer with tetramethylsilane as an internal reference. Photolyses were carried out in an atmosphere of nitrogen using a Hanovia lamp (450–500 W). Melting points were taken on a Köfler block and are uncorrected. Microanalyses are by Dr. A. D. Campbell and associates, University of Otago, New Zealand.

12-Methoxypodocarpa-8,11,13-trien-16-oyl Chloride (3)

Phosphorus pentachloride (10 g) was slowly added to powdered 12-methoxypodocarpa-8,11,13-trien-16-oic acid **2** (10 g) (4) and the mixture heated for 1 h at 80°. The resultant oil was washed until neutral to give the acid chloride **3** (9.9 g, 90%) as a yellow gum, b.p. 179–183°/0.3 mm; ν_{max} (film) 1802 cm^{-1} (C=O).

4-N-Methyl-12-methoxy-16-norpodocarpa-8,11,13-trien-4-amine (5)

A cold (ca. 15°) solution of sodium azide (2.8 g) in water (11 ml) was added to a stirred solution of **3** (10.7 g) in acetone (50 ml) and stirring continued for 1 h. The mixture was diluted with water, extracted with benzene and the benzene extract refluxed for 2 h to give the isocyanate **4** (9.1 g, 91%) as an oil; ν_{max} (CCl_4) 2270 cm^{-1} (N=C=O).

A solution of **4** (7.4 g) in dry ether (100 ml) was added in portions to a stirred suspension of lithium aluminium hydride (5.8 g) in ether (100 ml) and then refluxed for 1 h. The excess hydride was decomposed with ethyl acetate and the ethereal layer washed to give **5** (5.7 g, 80%) as rods, m.p. 48–50°, b.p. 146°/0.4 mm; ν_{max} (film) 3400 (N—H), 2800 cm^{-1} (N—Me); δ ($CDCl_3$) 0.98 (N*H*Me), 1.10 (C_{15}—Me), 1.34 (C_{17}—Me), 2.28 (N—Me), 3.78 (ArOMe), 6.50–7.10 (C-11,13,14-aromatics).

Anal. Calcd. for $C_{18}H_{27}NO$: C, 79.07; H, 9.95; N, 5.12; O, 5.85. Found: C, 79.13; H, 9.95; N, 5.00; O, 6.10.

Hydrochloride **6** had m.p. (sealed tube) 290–295° (decomp.).

Anal. Calcd. for $C_{18}H_{28}NOCl$: C, 69.76; H, 9.10; N, 4.52. Found: C, 70.06; H, 9.02; N, 4.57.

Acetyl derivative **7**, needles from ethanol–water m.p. 108–109°; ν_{max} (CCl_4) 1681 cm^{-1} (C=O); δ (CCl_4) 1.29 (C_{15}—Me), 1.34 (C_{17}—Me), 1.99 (acetyl methyl), 2.89 (N—Me), 3.70 (ArOMe), 6.46–6.90 (C-11,13,14-aromatics).

Anal. Calcd. for $C_{20}H_{29}NO_2$: C, 76.15; H, 9.27; N, 4.44. Found: C, 76.30; H, 9.44; N, 4.23.

4-N-Nitroso-4-N-methyl-12-methoxy-16-norpodocarpa-8,11,13-trien-4-amine (8)

The amine **5** (21.9 g) was dissolved in 25% (v/v) aqueous acetic acid (400 ml), glacial acetic acid (10 ml), and ether (200 ml). A saturated aqueous solution of sodium nitrite (6.9 g) was added over a period of 30 min and stirring continued for 2½ h. The solid product was filtered off and after recrystallization from ethanol gave **8** (14.8 g, 61%), as needles m.p. 131–131.5°; λ_{max} (EtOH) 279, 287, 352 mμ (ε = 3240, 2900, 72); δ ($CDCl_3$) 0.94 (C_{15}—Me), 1.49 (C_{17}—Me), 3.05 (N—Me), 3.79 (ArOMe), 6.60–7.10 (C-11,13,14-aromatics).

Anal. Calcd. for $C_{18}H_{26}N_2O_2$: C, 71.49; H, 8.67; N, 9.26; O, 10.58. Found: C, 71.61; H, 8.83; N, 9.40; O, 10.85.

Photolysis of Nitrosamine 8

The nitrosamine **8** (4.9 g) was photolyzed in cyclohexane (9 L) at 80° for 1½ h to give a pale-yellow reaction mixture. The ethereal extract of the photolyzate was acidified with dilute hydrochloric acid and the aqueous phase then made basic to yield the secondary amine **5** (3 g) which was identified by comparison of its infrared and nuclear magnetic resonance spectra with those of an authentic sample. Concentration of the remaining ethereal extract gave the nitrosamine **8** (230 mg), while the residual photolyzate consisted of polymeric material.

Structure of lucidioline. An alkaloid of *Lycopodium lucidulum*

W. A. AYER AND B. ALTENKIRK
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received October 21, 1968

The alkaloid lucidioline is shown to have structure **1**. The transformation of lucidioline into desacetyllycoclavine (**8**) is described.

Canadian Journal of Chemistry, 47, 499 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Recently we described the isolation of an alkaloid $C_{16}H_{25}O_2N$ from *Lycopodium lucidulum* (1). This compound had previously been isolated from *L. clavatum* var. *megastachyon* (2). We now wish to report that this alkaloid, for which we suggest the trivial name lucidioline, possesses structure **1**.

Inspection of the infrared and nuclear magnetic resonance (n.m.r.) spectra of lucidioline and its simple derivatives (see Experimental) revealed that the oxygens are present as hydroxyl groups, the nitrogen is tertiary, and the molecule contains a trisubstituted double bond. The presence of a secondary *C*-methyl group was obvious from the n.m.r. spectra. With these as the functional groups, the molecule is tetracyclic.

The mass spectrum of lucidioline (Fig. 1) proved to be very informative. The base peak in the spectrum is at *m/e* 203 and corresponds to the ion $C_{14}H_{21}N^+$, as shown by high resolution measurements. An intense metastable peak centered at 156.8 indicates that the ion *m/e* 203 is formed directly from the molecular ion (calculated for 263 → 203, 156.5). This corresponds to the loss of $C_2H_4O_2$ and indicates that *the two hydroxyl groups are on adjacent carbon atoms.* The base peak in the mass spectra of Lycopodium alkaloids containing the skeleton **2** is usually derived by loss of the "bridging" ring (carbons 8, 14, 15, and 16) and the hydrogen from C-12 to form a stabilized ion of type **3** (3), except in cases where there is no hydrogen at C-12 (1, 3). We felt that structure **4** offered a good explanation for the observed mass spectral fragmentation pattern, a possible origin of the ion *m/e* 203 being illustrated in the sequence 4 → 5 → 6 → 7. Accordingly we set about to correlate lucidioline with a compound of known structure.

Hydrogenation of lucidioline over platinum in methanol resulted in the uptake of one molar equivalent of hydrogen and gave a product which consisted of two components in the ratio of about 19:1. The minor component could not be isolated in pure form; however, on thin-layer chromatoplates it was indistinguishable from desacetyllycoclavine (**8**) (2). When the hydrogenation was carried out in the presence of perchloric acid, the same two components were

obtained but now in approximately equal amounts. The two were separated by chromatography. The component of higher R_f value proved to be identical with desacetyllycoclavine (**8**), establishing that lucidioline is a *dehydro* desacetyllycoclavine. Since the double bond in lucidioline is trisubstituted and since the methyl group is not located on the double bond, only the 11, 12-, or

For personal use only.

the 3,4-position are possible for the double bond. The second product formed in the hydrogenation was isomeric with desacetyllycoclavine. Acetylation gave a di-*O*-acetyl derivative which shows prominent "Bohlmann bands" in the infrared, indicative of the presence of a *trans*-quinolizidine system (4) in this compound. This indicated that the dihydro compounds are epimeric at C-12 (and at nitrogen) and identifies this carbon as one terminus of the double bond. Lucidioline thus has structure **1** and the second hydrogenation product is **9**.

Oxidation of lucidioline with Jones' reagent gave an oily unstable product which from its ultraviolet spectrum appeared to be a diosphenol.

Experimental

Isolation of Lucidioline

Lucidioline was isolated as previously described (1), m.p. 230–233°. The mass spectrum is shown in Fig. 1. Exact mass measurements: *m/e* 203. Calcd. for $C_{14}H_{21}N$: 203.1674. Found: 203.1672. *m/e* 202. Calcd. for $C_{14}H_{20}N$: 202.1596. Found: 202.1595. Infrared spectrum: ν_{max}(Nujol) 3400, 2600–3300 (intermolecularly H-bonded OH), 1678 (C=C). Nuclear magnetic resonance spectrum (CD_3COOD): τ 4.38 (1H, doublet, $J \simeq 5$ c.p.s., olefinic proton), 9.08 (3H, doublet, splitting 6 c.p.s., $CHCH_3$).

The *hydroperchlorate* was formed in methanol and recrystallized from methanol, m.p. 238–240° (decomp.).

Hydrogenation of Lucidioline

(a) In Methanol

Lucidioline (50 mg) in methanol (50 ml) was hydrogenated over Adams' catalyst (25 mg) at 50 p.s.i. for 3 h. After the catalyst and solvent were removed the product (50 mg) solidified. Thin-layer chromatography (t.l.c.) indicated the presence of a major and a very minor component. The major component was isolated by crystallization from acetone–methanol and after sublimation melted at 247–251°. Calculated molecular weight for $C_{16}H_{27}O_2N$, 265. Found, 265 (mass spectroscopy). The base peak in the mass spectrum appeared at *m/e* 208. This compound, **9**, was further characterized as its diacetyl derivative (below).

The mother liquors from the crystallization were separated by preparative t.l.c. The minor component could not be obtained in crystalline form. Its t.l.c. behavior was identical with that of desacetyllycoclavine.

(b) In the Presence of Perchloric Acid

Lucidioline (47 mg) in methanol (50 ml) containing 70% perchloric acid (2 drops) was hydrogenated over Adams' catalyst (25 mg) as above. After the catalyst was removed and the solution concentrated, aqueous ammonia was added, and the solution was extracted with chloroform. Evaporation of the chloroform gave a semicrystalline solid (45 mg) comprising two components (determined by t.l.c.) in approximate equal amounts. Separation was achieved by chromatography over basic alumina (2 g, activity II–III) using ethyl acetate (20 ml fractions) as the eluting solvent. Fractions 3 to 5 were homogeneous (t.l.c.) and crystallized to give desacetyllycoclavine (**8**, 8 mg), identical (m.p., infrared spectrum, mass spectrum, t.l.c. behavior) with an authentic sample (2). Fractions 6 and 7 (15 mg) contained both components. Fractions 8 to 20 yielded 19 mg of the 12-*epi*-desacetyllycoclavine (**9**).

Acetylation of 9

12-*Epi*-desacetyllycoclavine (**9**) was kept in a mixture of pyridine (2 ml) and acetic anhydride (2 ml) at room temperature for 3 days. After work-up an oil (44 mg) was obtained. This was purified by chromatography over alumina. The material (38 mg) thus obtained was homogeneous as determined by t.l.c. but could not be induced to crystallize. The analytical sample was purified by evaporative distillation.

Calculated molecular weight for $C_{20}H_{31}O_4N$: 349.2253. Found: 349.2253 (high resolution mass spectroscopy).

The base peak in the mass spectrum appeared at *m/e* 230. Infrared spectrum (CCl_4): no OH or NH absorption, 2750 and 2800 (Bohlmann bands), 1735 cm^{-1} (OAc). Nuclear magnetic resonance spectrum (CCl_4): τ 5.07 (1H, doublet, $J \simeq 7$ c.p.s., C*H*OAc), 5.45 (1H, singlet, $W_{1/2}$, 3 c.p.s., C*H*OAc), 7.98 and 8.02 (two 3-proton singlets, $OCOCH_3$), 9.08 (3H, doublet, splitting 6 c.p.s., $CHCH_3$).

Oxidation of Lucidioline

Lucidioline (14 mg) was dissolved in acetone (15 ml) and Jones' reagent (0.5 ml) added dropwise. After a few minutes methanol (10 drops) was added and then most of the solvent removed under reduced pressure. The residue was dissolved in water, aqueous ammonia added, and the solution was extracted with chloroform. Evaporation of the chloroform left an oil (5 mg) which could not be induced to crystallize. Ultraviolet spectrum: λ_{max}(EtOH) 280 mμ (ε 8000); λ_{max}(EtOH, $^-$OH) 323 mμ (ε 7000). Infrared spectrum: ν_{max}($CHCl_3$) 1670 and 1635 cm^{-1}.

Preparation of diphenylamines via the Chapman rearrangement

OWEN H. WHEELER, FERNANDA ROMAN, MARCELINA V. SANTIAGO, AND FRANCISCO QUILES
Department of Chemistry and Puerto Rico Nuclear Center, University of Puerto Rico, Mayaguez, Puerto Rico

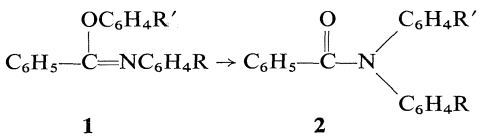
Received August 16, 1968

The optimum conditions have been determined for preparing substituted diphenylamines using the Chapman rearrangement. The rearrangement was best carried out in boiling tetraglyme. Phenyl *N*-phenylcinnamidate rearranged at a lower temperature than the corresponding benzimidate.

Canadian Journal of Chemistry, 47, 503 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The Chapman rearrangement (1, 2) of phenylbenzimidates (**1**) to benzoyldiphenylamines (**2**) affords a general method (3) for the synthesis of substituted diphenylamines, and is often the only method available (4). The rearrangement is usually carried out by heating the fused imidate to an elevated temperature (280–300°), although this gives a low yield in some cases. Nitrobenzene, diphenyl (5), or diphenyl ether (6) have been used as solvent, but are inconvenient for isolating the product.



1 **2**

It has now been found that the rearrangement can be carried out in nearly quantitative yield by refluxing the benzimidate in tetraethylene glycol dimethyl ether (tetraglyme) (b.p. 276°). The benzoyldiphenylamines were readily isolated by adding water. The reaction could also be carried out in triethylene glycol (b.p. 285°), although with charring and in a lower yield (75–80%). The rearrangement was incomplete in triglyme (b.p. 225°).

The benzimidates (**1**) were prepared by the reaction of a benziminyl chloride with a sodium phenoxide. These chlorides were most conveniently prepared from the benzoylaniline, using a small excess of thionyl chloride (8, 9). The use of phosphorus pentachloride (10, 11) resulted in considerable polymerization on distilling the chloride. The benziminyl chloride in ether was then condensed with the phenol in methanol containing an equivalent of sodium methoxide (1, 4, 12). Dioxane and pyridine have also been used (5, 7) as solvents. It was found that there was no advantage in using sodium methoxide in dimethyl formamide and benzene. Lower yields were obtained with sodium methoxide in tetraglyme, triglyme, or in triethylene glycol. The condensation of the benziminyl chloride in tetraglyme and the rearrangement of the resulting benzimidate without isolation gave only a low yield of product.

A number of substituted benzimidate and benzoyldiphenylamines were prepared (see Table I) in good yield. *N*-Phenylcinnamamide was also prepared by the direct condensation of cinnamic acid and aniline in high yield (91%). The amide was easily converted to the corresponding iminyl chloride by reacting with thionyl chloride. The iminyl chloride reacted smoothly with sodium phenoxide in methanol to give phenyl *N*-phenylcinnamimidate which was rearranged in triglyme in 85% yield, at a lower temperature (225°) than that utilized for the rearrangement of the other compounds studied. Presumably the additional resonance contribution of the cinnamyl group facilitated the rearrangement.

Experimental

Phenylbenziminyl Chloride

Recrystallized benzanilide (19.7 g) was gently heated to reflux with thionyl chloride (15.5 g) for 1 h. The excess thionyl chloride was removed by evacuating at the water pump and the product (28 g, 91%) was distilled, b.p. 115°/6 mm, m.p. 40–41° (lit. (8), m.p. 40°).

Benzo-*p*-toluide (21 g) gave in the same manner *N*-*p*-tolylbenziminyl chloride (32 g, 97%), b.p. 141–144°/10 mm, m.p. 51–52° (lit. (13), b.p. 186°/10 mm).

4-Chlorophenyl-N-phenylbenzimidate
*(**1**; $R = H_1R^1 = pCl$)*

p-Chlorophenol (2.32 g) was added to anhydrous methanol (25 ml) containing sodium (0.42 g). Phenylbenziminyl chloride (3.96 g) in ether (15 ml) was added with stirring. The solution was stirred at room temperature overnight, diluted with water, and extracted with ether. The ether solution was washed with 10% sodium hydroxide and water. The product (3.93 g, 80%), m.p. 91–92° (lit. (2), m.p. 92–93°) was recrystallized from methanol.

The other benzimidates (see Table I) were prepared in the same manner.

N-Benzoyl-4-chlorodiphenylamine
(2; R = H, R¹ = pCl)

4-Chlorophenyl-*N*-phenylbenzimidate (1.5 g) in tetraglyme (15 ml) was heated under reflux for 4 h. The cooled solution was then poured into water, and the solid recrystallized from ethanol (1.3 g, 87%), m.p. 110° (lit. (2), m.p. 110°).

The other diphenylamines (see Table I) were prepared similarly.

N-Phenyl-N-phenylcinnamimidate

A mixture of cinnamic acid (15 g) and aniline (12 g) was heated under reflux at 180° for 2 h. The excess aniline was distilled off *in vacuo*, and the residue of *N*-phenylcinnamamide (22.1 g, 91%) was washed with water and dried, m.p. 149–150° (lit. (14), m.p. 151–152°).

A mixture of *N*-phenylcinnamamide (22 g) and thionyl chloride (12 g) was submitted to the same procedure as before. Distillation of the product gave a light-brown liquid, b.p. 170–175°, 5 mm. On cooling a solid was obtained (25 g, 80%), m.p. 60–61°.

N-Phenylcinnaminyl chloride (2.8 g) was reacted with phenol (1.1 g) in the presence of sodium methoxide (0.6 g) as before to give an oily product. This was chromatographed on alumina and the product eluted with hexane and benzene giving crystals (1.7 g, 48%), m.p. 65–66°, from benzene–hexane. Infrared: 1600 cm^{-1} (CON), 1480 cm^{-1} (C=N), and 1250 cm^{-1} (C—O—Ar).

Anal. Calcd. for $C_{21}H_{17}NO$: C, 84.25; H, 5.72; N, 4.69. Found: C, 84.36; H, 5.66; N, 4.75.

N-Cinnamoyldiphenylamine

Phenyl-*N*-phenylcinnamimidate (1.2 g) was heated under reflux in triglyme (15 ml) for 3 h. The product (1.0 g, 84%) was recrystallized from ethanol, m.p. 153–155° (lit. (13), m.p. 154–156°).

Synthesis of some para-substituted 3,3,3-triarylpropionic acid derivatives

T. J. ADLEY AND D. R. CLARKE
Department of Chemistry, Sir George Williams University, Montreal, Quebec

Received June 26, 1968

The syntheses of representative compounds of the type $4\text{-}XC_6H_4(4'\text{-}YC_6H_4)C_6H_5CCH_2CO_2R$ are described.

Canadian Journal of Chemistry, 47, 505 (1969)

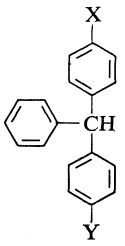
Introduction

We wish to report the synthesis of a number of new substituted triphenylpropionic acid derivatives of the type $4\text{-}XC_6H_4(4'\text{-}YC_6H_4)C_6H_5CCH_2CO_2R$. In a recent publication Snyder (1) has pointed out that the ^1H nuclear magnetic resonance (n.m.r.) spectra of compounds of this class might be of interest, since any magnetic non-equivalence observed for the methylene protons could be attributed to an "asymmetry effect".[1]

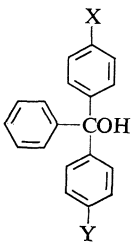
Examples of substituted triarylpropionic acid derivatives of the series $4\text{-}XC_6H_4(4'\text{-}XC_6H_4)\text{-}C_6H_5CCH_2CO_2R$ have been reported (4), but the aryl substituents have generally been of a type which did not readily permit their selective conversion to the required class of compounds.

Results and Discussion

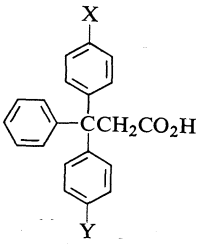
The sequence of reactions employed in the synthesis of (±)methyl 3-[4-anilino-4′-nitrophenyl-phenyl]-propionate (**4***b*) is outlined in Reaction Scheme 1.



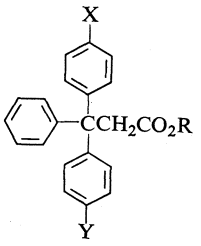
1 (*a*) X = Y = NH_2
1 (*b*) X = Y = NO_2



2 (*a*) X = Y = NO_2
2 (*b*) X = NH_2, Y = NO_2
2 (*c*) X = $NHCOCH_3$, Y = NO_2



3 (*a*) X = $NHCOCH_3$, Y = NO_2
3 (*b*) X = NH_2, Y = NO_2



4 (*a*) X = NH_2, Y = NO_2, R = CH_2CH_3
4 (*b*) X = NH_2, Y = NO_2, R = CH_3

REACTION SCHEME 1

4,4′-Diaminotriphenylmethane (**1***a*) (5) could be selectively oxidized with hydrogen peroxide to the corresponding 4,4′-dinitro compound (**1***b*) (6). Treatment of **1***b* with chromium trioxide

[1]Snyder (1) also suggested that since the barrier to free rotation of the methyl group in methyl acetylene is extremely low (less than 0.1 kcal $mole^{-1}$) (2), the contribution of an "asymmetry effect" to magnetic non-equivalence could be unambiguously assessed by an examination of the n.m.r. spectra of compounds of the series $ACH_2C{\equiv}CCXYZ$. We have synthesized two compounds of this class (3) but their n.m.r. spectra reveal no multiplicity for the methylene protons attributable to magnetic non-equivalence.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

gave the alcohol 4,4′-dinitrotriphenylmethanol[2] (**2***a*) (8). The partial reduction of **2***a* → **2***b* was carried out in 64% yield by addition of sodium polysulfide and sulfur to a refluxing solution of the dinitro compound in aqueous ethanol. The n.m.r. spectrum of **2***b* clearly indicated the presence of two AA′BB′ systems centered at δ 6.91 and 8.0. The only analogous examples of reductions of this type were carried out by Litvinenko and Levchenko, who successfully reduced 4,4′-dinitrodiphenylmethane (9*a*) and 4,4′-dinitrobenzophenone (9*b*) to the corresponding monoamino derivatives in yields of the order of 50%, using phenylhydrazine and sodium disulfide, respectively. Treatment of **2***b* with acetic anhydride gave the amide **2***c* which failed to crystallize, but was readily identified by its infrared (i.r.) and n.m.r. spectra.

Patai and Dayagi reported (4) that the tendency of substituted triarylmethanols to undergo condensation with malonic acid depended on the nature of the aryl substituents. They found that nitro substituted triarylmethanols have little tendency to give carbonium ions and fail to react, whereas carbonium ions formed from more active alcohols (i.e., those containing electron donating substituents), may undergo intramolecular cyclization to form fluorene derivatives (10). Patai and co-workers (11) found that much milder conditions were required for the condensation of triphenylmethyl chloride with active methylene compounds and the extent of side reactions and the amount of by-products were reduced considerably. Our attempt to synthesize 4,4′-dinitrotriphenylmethyl chloride[3] by the reaction of acetyl chloride with the corresponding triarylmethanol derivative (13) gave 4,4′-dinitrobenzophenone in high yield. A precedent for this unusual rearrangement has recently been reported by Starnes (14*a*, 14*b*) who observed a similar rearrangement when certain triarylmethanols were treated with lead tetraacetate.

Despite the difficulties reported for condensation reactions of nitro substituted triarylmethanols (4) we found that fusion of **2***c* with malonic acid at 170° readily furnished the acid **3***a* in 76% yield. The n.m.r. spectrum of this compound indicated the presence of a singlet (CO_2H) at δ 9.84 and a singlet (CH_2) at δ 4.22. The i.r. absorption band at 1715 cm^{-1} substantiated the presence of the acid. Of the methods attempted, hydrolysis of **3***a* to the amino acid **3***b* was found to proceed most smoothly with a solution of 10% aqueous hydrochloric acid in ethanol, although some of the ethyl ester **4***a* was formed in the process. Esterification of the amino acid **3***b* with dimethyl sulfite after the method of Cruickshank and Sheehan (15) produced the methyl ester (**4***b*) in nearly quantitative yield. The n.m.r. spectrum of **4***b* showed a singlet (CH_2) at δ 3.80 and a singlet (CH_3) at δ 3.46.

Experimental

Melting points were determined on a Mettler FP1 Melting and Boiling Point Apparatus and are uncorrected. Elemental analyses were performed using an F and M model 185 CHN analyzer.

Thin-layer chromatographic (t.l.c.) determinations were on Eastman Chromatogram Sheets 6060 coated with silica gel containing fluorescent indicator.

Infrared (i.r.) spectra were recorded on a Perkin–Elmer 225 Grating Spectrophotometer and Beckman IR-8 Spectrophotometer.

Mass spectra were determined on a Hitachi RMU-6E single-focus mass spectrometer using an ionizing voltage of 70 eV and a source temperature of 250°.

The ^1H nuclear magnetic resonance (n.m.r.) spectra were recorded on Varian A-60A and HA-100 spectrometers operating at 60 and 100 MHz respectively. The chemical shifts are in parts per million from tetramethylsilane as internal reference and are recorded on the δ scale.

*4,4′-Diaminotriphenylmethane (**1***a*)*

This compound was prepared in 45% yield according to the procedure of Baeyer and Villeger (5). The solid obtained had a m.p. of 110° in agreement with the value quoted when benzene of crystallization is present.

*4,4′-Dinitrotriphenylmethane (**1***b*)*

4,4′-Diaminotriphenylmethane (**1***a*) (15 g, 0.055 mole) was added to a mixture of 180 ml H_2O_2 (30%), concentrated H_2SO_4 (12 ml), and acetic acid (400 ml) (6). The reaction mixture which immediately turned light-brown was slowly heated to 70° at which point heating was discontinued. After approximately 30 min a solid precipitated from solution and heat was reapplied. The reaction mixture was then maintained between 70–80° overnight. After cooling a yellow-brown product was removed by filtration, washed with water, and dried. A small additional quantity of crude material could also be obtained by the addition of water to the filtrate. Recrystallization from *n*-propyl alcohol – benzene (1:1) gave the required product, m.p. 169–170° (9.3 g, 51%). An analytical sample was prepared by sublimation at 3 mm, 160° (bath) to give yellow prisms, m.p. 169–170°; ν_{max} (KBr) 1605, 1595, 1515

[2]This compound has been previously reported by Deno *et al.* (7). No experimental details on its preparation or physical properties were given.

[3]4,4′-Dinitrotriphenylmethyl chloride has been synthesized by Ziegler and Mathes (12), in a six-step synthesis from *p*-nitrobenzyl chloride.

(C—NO_2), and 1347 cm^{-1} (C—NO_2); δ ($CDCl_3$) 7.2–8.6 (13 proton multiplet in which an AA′BB′ pattern was observed), 5.9 (one proton singlet, CH); mass spectrometry indicated the presence of a molecular ion at *m/e* 334.

Anal. Calcd. for $C_{19}H_{14}N_2O_4$: C, 68.26; H, 4.22; N, 8.38. Found for **1***b*: C, 68.57; H, 3.97; N, 8.56.

4,4′-Dinitrotriphenylmethanol (2a)

4,4′-Dinitrotriphenylmethane (**1***b*), (10 g, 0.03 mole) was added to a previously cooled solution (0°) of chromium trioxide (6 g, 0.06 mole) and water (6 ml) in acetic acid (40 ml) (8). The reaction mixture was slowly brought to reflux temperature and the disappearance of the methine proton was monitored by removing 5 ml aliquots and examining the n.m.r. spectrum of the product after work-up. The reaction was generally complete after 12 h. Upon cooling a solid precipitated which was removed by filtration, washed with water, and dried. The solid could be recrystallized from $CCl_4 - C_6H_6$ (1:1). Subsequent recrystallization from *n*-propanol gave white crystals of **2***a*, m.p. 133°, (7.96 g, 76%); ν_{max} (KBr) 3565 cm^{-1} (O—H); δ ($CDCl_3$) 7.1–8.6 (13 proton multiplet, benzenoid protons), 3.68 (1 proton singlet, O—H).

Anal. Calcd. for $C_{19}H_{14}N_2O_5$: C, 65.14; H, 4.03; N, 8.00. Found for **2***a*: C, 65.26; H, 4.33; N, 7.86.

(±)-4-Amino-4′-nitrotriphenylmethanol (2b)

4,4′-Dinitrotriphenylmethanol (**2***a*) (5.0 g, 0.14 mole) was dissolved in 5 ml of ethanol and heated to reflux. To this was added dropwise a solution of sodium polysulfide (2.5 g) and sulfur (0.7 g) in aqueous ethanol. Refluxing was continued for 15 min. The reaction solution was then cooled and poured into ten times its volume of ice-water. The yellow solid obtained was removed by filtration and dried *in vacuo*. Recrystallization from *n*-propanol gave a yellow solid which was sufficiently pure to use in subsequent reactions, (2.92 g, 64%). In order to prepare an analytical sample the product was purified by chromatography on neutral alumina (Brockman Activity 1, 80–200 mesh) eluting with benzene followed by benzene–chloroform (1:1). The syrupy product was crystallized from *n*-propanol. Repeated recrystallization from the same solvent gave crystals of **2***b* m.p. 122.5–123°; ν_{max} (KBr) 3458 (OH), 3380 and 3306 (NH), 1615 (NH bending), 1503 and 1340 cm^{-1} (C—NO_2); δ ($CDCl_3$) 6.56–8.42 (13 proton multiplet, benzenoid; two AA′BB′ systems, centered at 6.91 and 8.0 p.p.m. were clearly observed, 3.6 (singlet 3 protons, OH and NH_2 overlapping). Mass spectrometry showed the presence of a molecular ion at *m/e* 320.

Anal. Calcd. for $C_{19}H_{16}N_2O_3$: C, 71.24; H, 5.03; N, 8.75. Found for **2***b*: C, 71.16; H, 4.98; N, 8.59.

(±)-4-Acetanilidyl-4′-nitrophenyl-phenyl-methanol (2c)

(±)-4-Amino-4′-nitrotriphenylmethanol (**2***b*) (20 g, 0.063 mole) was acetylated at room temperature with acetic anhydride (19.1 g, 0.12 mole) in the presence of a few drops of pyridine. After pouring the reaction mixture into water, the product was extracted with chloroform. The solution was washed first with a saturated aqueous $NaHCO_3$ solution, then with water, and dried over anhydrous sodium sulfate. Concentration under reduced pressure yielded a glass which when heated with ligroin gave an amorphous solid. Chromatography of **2***c* on neutral alumina (Brockman Activity 1, 80–200 mesh) eluting with benzene–diethyl ether (3:1) gave a brown glass which could not be induced to crystallize (18.8 g, 83%); ν_{max} (KBr) 1670 cm^{-1} (C=O); δ ($CDCl_3$) 8.2 (1 proton singlet NH), 6.8–8.0 (13 proton multiplet, benzenoid protons), 4.02 (1 proton singlet, OH), and 1.88 (3 proton singlet, CH_3); mass spectrometry indicated the presence of a molecular ion at *m/e* 362.

(±)-3-[4-Acetanilidyl-4′-nitrophenyl-phenyl]-propionic Acid (3a)

To (±)-4-acetanilidyl-4′-nitrophenyl-phenyl-methanol (**2***c*) (2 g, 0.006 mole) was added malonic acid (8 g, 0.08 mole) (4). The solids were fused at 170° for 36 min. After cooling, the product was extracted with a saturated aqueous solution of $NaHCO_3$ and precipitated by the addition of dilute HCl. After filtration the product was dried and recrystallized from benzene. Subsequent recrystallization from ethanol–benzene (1:1) and ethanol, gave a white amorphous solid **3***a*, m.p. 174°, 1.7 g (76%); ν_{max} (KBr) 1715 (C=O, acid), 1665 cm^{-1} (C=O, amide); δ (CF_3CO_2H) 9.84 (1 proton singlet, acid proton), 8.80–7.40 (14 proton multiplet, benzenoid protons overlapping with N—H), 4.22 (2 proton singlet, CH_2), 2.70 (3 proton singlet, CH_3). Mass spectrometry indicated the presence of a molecular ion at *m/e* 404.

Anal. Calcd. for $C_{23}H_{20}N_2O_5$: C, 68.31; H, 4.99; N, 6.93. Found for **3***a*: C, 68.45; H, 5.17; N, 7.01.

Hydrolysis of the Amide 3a and Esterification of the Product to (±)Methyl 3-[4-anilino-4′-nitrophenyl-phenyl]-propionate (4b)

(±)-3-[4-Acetanilidyl-4′-nitrophenyl-phenyl]-propionic acid (**3***a*) (4 g, 0.01 mole) was dissolved in 100 ml of hot aqueous ethanol. An aqueous solution of 10% HCl (40 ml) was then added dropwise. Refluxing was continued until t.l.c. showed complete disappearance of **3***a*. After cooling, ammonium hydroxide (Sp. G.0.90) was added until pH 5.9, whereupon a yellow solid precipitated. Chromatography of the product on partially deactivated alumina (Brockman, Neutral Activity 1 (100 g) to which had been added 5 g water) yielded upon elution with chloroform (±)ethyl 3-[4-anilino-4′-nitrophenyl-phenyl]-propionate (**4***a*), identified by its ^1H n.m.r. and i.r. spectra. The amino acid could be removed from the column by the addition of ammonium hydroxide (Sp. G.0.90). Careful addition of HCl (36.5%) to the ammoniacal solution caused precipitation of the amino acid at pH 5.9. After drying *in vacuo* the solid had a m.p. 120–125°. It was identified as (±)-3-[4-anilino-4′-nitrophenyl-phenyl]-propionic acid (**3***b*) from its i.r. and n.m.r. spectra. The hydrochloride of **3***b* (2 g, 0.005 mole) was esterified with dimethyl sulfite (5 g, 0.045 mole) (15) to give the methyl ester hydrochloride as a glass in quantitative yield. The free amine **4***b* was obtained by treatment of an aqueous ethanolic solution of the hydrochloride of **4***b* with ammonium hydroxide (Sp. G.0.90). The compound failed to recrystallize from any of the usual solvents. Chromatography of **4***b* on neutral alumina (Brockman Activity 1, 80–200 mesh) gave after elution with carbon tetrachloride followed by benzene a yellow glass, which could not be induced to crystallize. Its i.r. spectrum showed ν_{max} 3490 (N—H), 3395 (N—H), 1735 (C=O), 1620 (N—H bending), 1512 (C—NO_2),

1348 cm^{-1} (C—NO_2); δ ($CDCl_3$) 6.50–8.38 (13 proton multiplet, benzenoid; two AA′BB′ systems were clearly discernible), 3.80 (4 protons, a sharp spike for CH_2 superimposed on a broad peak, NH_2), 3.46 (3 proton singlet, CH_3). The 100 MHz n.m.r. spectrum failed to reveal any multiplicity in the signal for the methylene group. A mass spectrum indicated the presence of a molecular ion at *m/e* 376.

Anal. Calcd. for $C_{22}H_{20}N_2O_4$: C, 70.20; H, 5.36; N, 7.44. Found for **4***b*: C, 70.14; H, 5.64; N, 7.58.

Total synthesis of the *Ormosia* alkaloid skeleton

H. J. LIU, Z. VALENTA, J. S. WILSON, AND T. T. J. YU
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received November 29, 1968

A total synthesis of dilactam (**3**) possessing the complete pentacyclic skeleton of the *Ormosia* alkaloids has been completed.

Canadian Journal of Chemistry, **47**, 509 (1969)

The determination of the structure of the *Ormosia* alkaloid jamine by X-ray crystallography (1) led directly to the structure of ormosanine and, through a study of the reduction of the dehydrogenation product (**1**) (2, 3), to the structure and stereochemistry of additional alkaloids of this type (4). Since the alkaloid piptanthine (**2**) together with four isomeric bases has already been prepared by a controlled reduction of **1** (4) and since most of the stereochemical and functional variation in compounds of this class occurs in rings A, B, and E, it was deemed desirable to develop a synthetic approach in which ring E would be aromatic to the penultimate stage and in which ring A would be added last. The following total synthesis of the crystalline racemic dilactam (**3**) satisfies these requirements.

The known compound (**4**) (5), m.p. 126–127°, was reduced with Pd–C in ethanol to give an 80% yield of the oily lactam ester (**5**), a mixture of at least two isomers.[1] Treatment of crude **5** with sodium hydride and ethyl acrylate in dimethyl formamide at 110° for 12 h gave the keto-ester (**6**), m.p. 155–156°, in 53% yield. In order to establish its stereochemistry, **6** was hydrolyzed with 10% aqueous sulfuric acid to give **7**, m.p. 173–176°. Vigorous reduction of **7** with lithium aluminium hydride gave the corresponding hydroxyamine which showed strong Bohlmann bands (6) in the 2800 cm^{-1} region of the i.r. spectrum ($CHCl_3$). Based on previous study (4), this clearly establishes that the C_6—H is *cis* to the C_7—C_9 bridge. Treatment of **6** with selenium dioxide and acetic acid in boiling *tert*-butyl alcohol gave the unsaturated keto-ester (**8**), m.p. 200–201°, in 78% yield; this was then converted to ketone (**9**), m.p. 193–194°, in 71% yield on boiling with 10% aqueous sulfuric acid.

Since standard methods applied for construction of ring A using **7**, **8**, and **9** proved unpromising, the following novel synthetic application of the versatile photo-addition of olefins to α,β-unsaturated ketones[2] was developed. Irradiation of **9** in vinyl acetate and tetrahydrofuran (Hanovia 100 W High-Pressure Hg vapor lamp, Pyrex filter) at 25° for 2 h gave a 60% yield of a mixture composed of four isomers of acetate (**10**). Bromination of crude **10** with pyridinium bromide perbromide in glacial acetic acid gave a mixture of four bromo-ketones (**11**) in 78% yield. Treatment of crude **11** with sodium carbonate in aqueous methanol followed by chromatography on silica gel gave a 76% yield of pure keto-aldehyde (**12**), i.r. maxima at 2730, 1730, 1680, 1640, 1585, and 1575 cm^{-1}, nuclear magnetic resonance signals at 0.32 and 2.25 τ (singlet). Although a fragmentation reaction (8) in compound (**11**) could in principle take place in two different ways, fragmentation in the sense of the dotted arrow in formula (**11**) was in fact not observed.

Reduction of **12** with lithium aluminium tri-*tert*-butoxy hydride in tetrahydrofuran to alcohol (**13**) (89% yield) was followed by conversion with methanesulfonyl chloride in pyridine to **14** (97%) and by a treatment of the mesylate with lithium

[1]All reported compounds showed satisfactory spectral properties, including correct molecular ions in mass spectrometry. For brevity, only spectral data of special significance are given. All crystalline compounds gave correct elemental analysis. Unless otherwise stated, all oily compounds were purified by column chromatography on silica gel and were homogeneous in thin-layer chromatography.

chloride in boiling acetone to give the chloride (**15**) in 84% yield. Spectroscopic and analytical evidence has indicated that treatment of **15** with sodium cyanide does not give the desired nitrile (**18**), but in fact involves the addition of the cyanide ion to the β-position of the α,β-unsaturated ketone with the concomitant formation of a cyclopropane ring. In order to prevent this interesting reaction, **15** was first converted to the ketal **16** with ethylene glycol and *p*-toluenesulfonic acid in boiling benzene in 98% yield. As expected, **16** underwent normal displacement with sodium cyanide in dimethyl sulfoxide at 125° to give nitrile (**17**) in 98% yield. Deketalization of **17** with 10% sulfuric acid in tetrahydrofuran gave **18** (95% yield), which was converted to the keto-ester (**19**) in 85% yield on treatment with alcoholic hydrogen chloride followed by hydrolysis of the resulting imino-ester on a column of silica gel.

Finally, prolonged treatment of **19** with ammonia in ethanol gave the desired dilactam (**3**), m.p. 245–247°, in 65% yield (*m/e* 353, i.r. maxima at 3310, 1715, 1638, 1590 and 1575 cm^{-1}). The stereochemistry of the A/B ring-juncture in **3** follows from the fact that the addition of ammonia to the unsaturated ketone in **19** can be expected to take place from the side opposite to the bulky tertiary lactam grouping and from the coupling constant of the C_{11}-H atom (J_{AB} = 4 c.p.s.; 5.2 τ) which is in agreement with a *cis*-juncture.

The totally synthetic dilactam (**3**) has the correct stereochemistry at C-6 for the synthesis of the dipyridine (**1**) and at C-6 and C-11 for the synthesis of the alkaloid ormojanine (3). The efficient conversion of **3** to compounds of natural origin and the general scope of the fragmentation reaction **11** → **12** are under active study.

Facile elimination accompanying some methyl sulfoxide oxidations. Formation of unsaturated carbohydrates

G. M. CREE,[1] D. W. MACKIE, AND A. S. PERLIN
Department of Chemistry, McGill University, Montreal, Quebec

Received October 16, 1968

Oxidation of some partially-acetylated carbohydrates with methyl sulfoxide, activated by sulfur trioxide – pyridine and triethylamine, leads to facile elimination of the elements of acetic acid and the formation of novel, unsaturated, derivatives.

Canadian Journal of Chemistry, **47**, 511 (1969)

Pfitzner and Moffatt (1) found that the treatment of various nucleotides and nucleoside derivatives with a mixture of methyl sulfoxide (DMSO), dicyclohexylcarbodiimide, and orthophosphoric acid, results in rapid oxidation of unprotected hydroxyl groups of the sugar moieties and, in some instances, in extensive elimination of substituents. Thymidine, for example, yielded the free base and inorganic phosphate, probably because DMSO oxidation of the 3^1- hydroxyl group was followed by acid-catalyzed β-elimination (1). Other compounds, however, were oxidized smoothly without decomposition. Originating in these observations, DMSO oxidation now finds wide use for the preparation of carbonyl compounds from alcohols (2), although accompanying elimination reactions appear to be rarely encountered.

In examining the reaction of various carbohydrate derivatives with a modified oxidant developed by Parikh and Doering (3)—which consists of DMSO, sulfur trioxide, pyridine, and triethylamine—we have found that some compounds undergo both oxidation and elimination rapidly and efficiently. In such instances the reaction provides a high-yield route to novel types of unsaturated carbohydrates.

For example, methyl 2,3,4-tri-*O*-acetyl-α-D-mannopyranoside (**1**) was treated with the oxidant (3) for 15 min. The reaction mixture was diluted with chloroform, washed successively with cold, saturated tartaric acid and sodium bicarbonate, and concentrated, affording a crystalline solid (**2**) in 75% yield; m.p. 57 °C.

Anal. Calcd. for $C_{11}H_{14}O_7$ (mol. wt., 258): C, 51.16; H, 5.47. Found (M^+, 258): C, 51.1; H, 5.4.

The proton magnetic resonance spectrum of **2** ($CDCl_3$) indicates that it is an aldehyde (δ 9.2, one H, singlet), and that it contains two *O*-acetyl groups, one *O*-methyl group, and one H on each of C-1 to C-4. Together with other spectral data λ_{max} 250nm,ε 3600 (CH_3OH); 1720 cm^{-1} (HC=O), 1660 cm^{-1} (C=C) and chemical tests (reaction with semicarbazide; bromine uptake following borohydride reduction), this evidence shows that **2** is a 6-*aldehydo* derivative containing a 4,5-double bond, i.e., methyl 2,3-di-*O*-acetyl-6-*aldo*-4-deoxy-β-L-*erythro*-hex-4-enopyranoside. Its formation from **1** is attributed to DMSO oxidation of the primary carbinol group followed by elimination of H-5 and the 4-acetoxyl group, the latter step perhaps being catalyzed by the triethylamine present.[2]

[1]Harold Hibbert Memorial Postdoctorate Fellow, 1967–1968.

[2]Although this may involve a *cis*-elimination, a referee has pointed out that prior epimerization at C-5 could result in a *trans*-elimination. As shown herein, however, a compound in which the H and OAc eliminated are *trans* originally is less reactive than its epimer.

Elimination also accompanied the oxidation of 1,2,3,4-tetra-*O*-acetyl-β-D-glucopyranose. Under the same reaction conditions, the latter afforded an 83% yield of a chromatographically-pure syrup[3] (**3**); δ, 9.2 (one H, singlet), three *O*-acetyl singlets, and one H signal for each of C-1 to C-4 ($CDCl_3$); λ_{max} 245 nm, ε 2750 (CH_3OH); 1725 cm^{-1} (HC=O), 1662 cm^{-1} (C=C); semicarbazone, m.p. 205–207 °C.

Anal. Calcd. for $C_{13}H_{17}N_3O_8$ (mol. wt., 343): N, 12.24. Found (M^+, 343): N, 12.38.

Similarly, methyl 2,3,4-tri-*O*-acetyl-α-D-glucopyranoside gave syrupy **4** in 82% yield. The overall spectral characteristics of **4** paralleled those of **2** and **3** sufficiently closely to indicate that this product also is an α,β-unsaturated 6-aldehyde, i.e., the expected L-*threo* isomer corresponding to **2**.

Facile elimination has been found also with partially-acetylated derivatives in which the free hydroxyl group is secondary or an anomeric hydroxyl. Thus, 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranose yielded 81% of a syrupy product (**5**); 1755 cm^{-1} (broad multiplet, C=O), 1670 cm^{-1} (C=C); one H signal for each of C-3 to C-5, two H signals for C-6, δ 2.10–2.15 (two *O*-acetyl singlets), δ 2.3 (enol acetate singlet)($CDCl_3$); *m/e* 244 ($M - COCH_2$), *m/e* 226 ($M - CH_3COOH$), *m/e* 184 ($M - CH_2CO - CH_3COOH$), etc. Since 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranose also yielded the same product, although at only about one-third the rate of the D-*gluco*-epimer, **5** undoubtedly is an α,β-unsaturated lactone (i.e., 2,4,6-tri-*O*-acetyl-3-deoxy-D-*erythro*-hex-2-en-2-ol-1 → 5 lactone) the formation of which must involve elimination of H-2 and the 3-acetoxyl group. *Two* elimination reactions accompanied the oxidation of 1,3,4,6-tetra-*O*-acetyl-α-D-glucopyranose, which afforded an unsaturated diacetate (**6**) in 61% yield; m.p. 95 °C, $[\alpha]_D$ 0° (5, CH_3OH).

Anal. Calcd. for $C_{10}H_{10}O_6$ (mol. wt., 226): C, 53.10; H, 4.46. Found (M^+, 226): C, 53.5; H, 4.4.

[3]All syrupy products were contaminated with small quantities of odorous by-products which were difficult to remove by distillation.

λ_{max} 252 nm, ε 1060 (CH_3OH); 3082 cm^{-1}, 980 cm^{-1} ($C=CH_2$); 1781 cm^{-1} (enol Ac), 1760 cm^{-1} (OAc), 1678 cm^{-1} (doublet C=O, C=C); δ 7.85 (1H, singlet), 7.05 (1H, singlet), 4.90 (2H, singlet), 2.30 (enol Ac, singlet), 2.15 (OAc, singlet) ($CDCl_3$). Tentatively, **6** is formulated as the conjugated 3,5-diene-2-one that would be derived by successive α,β- and γ,δ-eliminations.

1,2:3,4-Di-*O*-isopropylidene-α-D-galactopyranose, when oxidized under the same conditions, did not undergo elimination but readily yielded the 6-*aldehydo* diketal (4) in 85% yield. Similarly, 1,2:4,5-di-*O*-isopropylidene-D-*erythro*-hexopyranos-2,3-diulose (5–7) was prepared in 65% yield by oxidation of 1,2:4,5-di-*O*-isopropylidene-D-fructopyranose. In both reactions, only a trace of the contaminating methyl thiomethyl ether was produced, and the work-up of the reaction mixtures appeared to be more satisfactory than in parallel experiments (4–7) with other modifications of the DMSO oxidant. Also, in preliminary experiments with partially-substituted *O*-benzyl and *O*-trimethylsilyl ethers satisfactory oxidation without elimination has been observed, but 1,2:3,5-di-*O*-methylene-α-D-glucofuranose suffered extensive decomposition to unidentified products. Since the methylene groups themselves are not attacked by the reagent, this breakdown probably was initiated by formation of the 6-aldehydo compound.

Received November 28, 1968

The temperature dependence of the nuclear magnetic resonance spectra of U, C, 5′-UMP, 5′-CMP, UpU, and CpU indicates a specific deshielding of the base proton at position-6 by an hydroxyl, phosphodiester, or phosphate group at position-5′, and demonstrates that in these compounds the bases exist in the *anti* conformation. Similar experiments on the wobble pair UpUpU and UpUpC suggest that the spatial arrangements of both trinucleoside diphosphates are identical, and that in these arrangements the bases are predominantly in the *anti* conformation.

La variation avec la température de spectres de résonance magnétique nucléaire de U, C, 5′-UMP, 5′-CMP, UpU, et CpU indique un effet spécifique de déblindage des protons des bases à la position-6 par des groupements-5′ hydroxyls, phosphodiesters, ou phosphates, et démontre que dans ces composés les bases ont la conformation *anti*. Des expériences semblables sur le couple de "wobble" UpUpU et UpUpC suggèrent que les structures des deux composés soient identiques, et que dans ces structures les bases aient surtout la conformation *anti*.

Canadian Journal of Chemistry, **47**, 513 (1969)

The fundamental unit of genetic information in messenger RNA is a trinucleotide sequence (1). In the genetic code more than one such sequence can represent a particular amino acid, i.e. for phenylalanine the codons are UpUpU and UpUpC.[4] In order to account for the recognition of degenerate codons by the trinucleotide in the anticodon position of transfer RNA, Crick proposed that the conditions for binding of the third base are less stringent than those for the first two, i.e. the third base is allowed to "wobble" (2). As part of a study of trinucleotide-transfer RNA interactions we have investigated the 220 MHz nuclear magnetic resonance spectra of UpUpU and UpUpC, and related nucleotides, nucleosides, and dinucleoside phosphates. We present here evidence that the environments of the corresponding bases in UpUpU and UpUpC are identical, and that the bases are present in the *anti* conformation relative to the 5′-position.

In Fig. 1 we show the 220 MHz spectra due to the protons at position-6 in the uracil and cytosine moieties of UpUpU and UpUpC at 15 and 53 °C. The individual U and C resonances can be identified by means of the spin–spin splitting due to the protons at position-5 (8.0 Hz for U, 7.5 Hz for C). In the 15 °C spectrum of UpUpU it is apparent that the magnetic environments of two of the uracil bases are equivalent; in the corresponding spectrum for UpUpC the two uracil bases are magnetically equivalent to one another, as well as to the two equivalent uracil bases in UpUpU. Similarly, in the 53 °C spectra of UpUpU and UpUpC, the uracil resonances of both codons fall in almost identical positions. This suggests strongly that the orientations of the bases in UpUpU and UpUpC are identical. Further evidence for this comes from the temperature dependence of the chemical shifts of the protons at position-6, illustrated in Fig. 2. The resonances due to the two U bases of UpUpU and UpUpC, which were equivalent at 15 °C,

show identical temperature dependences (indicated by circle and triangles in Fig. 2, open for UpUpU, filled for UpUpC). The third U resonance of UpUpU has a temperature dependence very similar to that of the C resonance in UpUpC; we assign this third U resonance (indicated by open squares in Fig. 2) to the uracil at the 3′ wobble end of UpUpU. This assignment is valuable for a study of the relative binding constants of the three bases of UpUpU and UpUpC to the anticodon region of $tRNA^{Phe}$.

In order to elucidate the source of these temperature-dependent chemical shifts in terms of molecular structure, we have examined the n.m.r. spectra of the relevant 5′-nucleotides, nucleosides, and dinucleoside phosphates under the same conditions. For each of U, C, 5′-UMP, and 5′-CMP the resonances due to the protons at position-6 moved to higher magnetic field (lower chemical shift) with increasing temperature, at rates comparable to those shown in Fig. 2, whereas the resonances due to the protons at position-5 did not vary appreciably with temperature. Similar behavior was observed for both bases of each of UpU and CpU. Schweizer *et al.* have demonstrated that substitution of a charged phosphate group at position-5′ in U or C causes a specific downfield shift (deshielding) of the resonance due to the proton at position-6, while causing no appreciable change in the resonance due to the proton at position-5 (3). They presented strong evidence that this was due to the bases being in the *anti* conformation relative to the 5′-position—that is, with the base rotated about the glycosyl bond so that the 5,6 side of the pyrimidine ring is directed towards the 5′-position. In this conformation the proton at position-6 of the pyrimidine ring is much nearer the 5′-position than is the proton at position-5 of the pyrimidine ring. A comparison of earlier 30 °C nuclear magnetic resonance spectra of pUpU and UpU (4) suggests that the effect of a monocharged 5′-phosphodiester linkage is similar to that of a 5′-hydroxyl group. The observed temperature dependences reported here for 5′-UMP and 5′-CMP are consistent with the removal of a specific deshielding effect by a gradual conversion of the conformations from *anti* to *syn*. Our observation that U, C, UpU, and CpU all exhibit behavior similar to that of 5′-UMP and 5′-CMP indicates that the 5′-hydroxyl group also has a specific deshielding effect on the protons at position-6, which is considerably weaker than that due to a doubly-charged 5′-phosphate but comparable to that due to a singly-charged 5′-phosphodiester group. Thus, the temperature dependences of the resonances due to the U and C moieties of UpUpU and UpUpC suggest that in the trinucleoside diphosphates at physiological temperatures all the bases are predominantly in the *anti* conformation.

A comparison of earlier 30 °C nuclear magnetic resonance spectra of pUpU and UpU (4) suggests that the effect of a monocharged 5′-phosphodiester linkage is similar to that of a 5′-hydroxyl group. The observed temperature dependences reported here for 5′-UMP and 5′-CMP are consistent with the removal of a specific deshielding effect by a gradual conversion of the conformations from *anti* to *syn*. Our observation that U, C, UpU, and CpU all exhibit behavior similar to that of 5′-UMP and 5′-CMP indicates that the 5′-hydroxyl group also has a specific deshielding effect on the protons at position-6, which is considerably weaker than that due to a doubly-charged 5′-phosphate but comparable to that due to a singly-charged 5′-phosphodiester group. Thus, the temperature dependences of the resonances due to the U and C moieties of UpUpU and UpUpC suggest that in the trinucleoside diphosphates at physiological temperatures all the bases are predominantly in the *anti* conformation.

Synthetic approach to ryanodine; the use of *O*-spirodienone lactone in organic synthesis

Daniel Berney and Pierre Deslongchamps[1]
Département de Chimie, Université de Sherbrooke, Sherbrooke, Québec

Received November 19, 1968

The key steps for this synthetic approach are the preparation of *o*-spirodienone lactone **15**, its reaction with methylvinyl ketone which gave **16** and **17**, and the conversion of **16** and **17** into compound **19** by base. Finally ozonolysis of **26** followed by internal condensation gave compound **28**.

Canadian Journal of Chemistry, **47**, 515 (1969)

The insecticide ryanodine **1** isolated from *Ryana speciosa* Vahl is the ester of pyrrole-α-carboxylic acid with ryanodol **2**. The structure elucidation of this complex insecticide and one of its key degradation products, anhydroryanodol **3** was solved by Valenta and Wiesner and their

co-workers (1). Recently, an X-ray analysis on ryanodol-*p*-bromo benzyl ether achieved by Srivastava and Przybylska (2) has confirmed the proposed structure for ryanodine except that the configuration of the isopropyl side chain was found to be the opposite.

In this communication, we wish to describe a synthetic approach which appears to be an attractive scheme for the syntheses of ryanodine and its closely related degradation product **3**.

5,6-Dimethoxyindane **4** which is readily available from veratraldehyde (3) was treated with bromine in carbon tetrachloride at room temperature and gave bromoindane **5**. Reaction of **5** with magnesium in ether in presence of methyl iodide gave the expected Grignard derivative of **5** which by reaction with triethyl orthoformate followed by acid hydrolysis gave methoxyphenolaldehyde **6**[2,3,4] (m.p. 118–119 °C, 75% yield from 4).

Reaction of **6** with boron tribromide in dichloromethane (4) gave the *o*-phenol **9** (m.p. 178 °C, 80% yield). Treatment of **9** with bromoacetyl bromide in benzene and pyridine gave bromoacetate **10** (m.p. 110 °C, 70% yield) which was transformed into lactone aldehyde **11** (m.p. 131–132 °C, 75% yield) in boiling tetrahydrofuran containing potassium carbonate.[5]

Wolff–Kischener reduction of lactone aldehyde **11** gave lactone **14** (m.p. 74–75 °C; 80% yield). Treatment of lactone **14** with one mole of sodium hydroxyde in acetonitrile–water followed by the addition of one mole of *N*-bromosuccinimide yielded the stable *o*-spirodienone lactone **15** (m.p. 97–98 °C; 90% yield; mol. wt. (mass spectroscopy) 220; ν_{max} 1790, 1665, 1640, and 1600 cm^{-1}; λ_{max} (EtOH) 355 mμ (3100); τ 3.97 (1H, singlet, H-1), 5.25 and 5.60 (2H, double doublet, J = 15 c.p.s., H-2 and H-3) and 8.10 (3H, singlet, CH_3)).

Compound **15** was refluxed for 5 min in methylvinyl ketone and gave the tricyclic compounds **16** and **17** (ratio 1 ~ 1) which could be separated by preparative thin-layer chromatography. **16** (oil; mol. wt. (mass spectroscopy) 290; ν_{max} 1810, 1740, and 1720 cm^{-1}; τ 5.34 and 5.74 (2H, double doublet, J = 14 c.p.s., H-3 and H-4), 6.44 (1H, doublet, J = 2 c.p.s., H-1), 6.93 (1H, octuplet, J = 2, 6, and 9 c.p.s., H-2), 7.87 (3H,

[2]All new crystalline compounds gave satisfactory analytical and mass spectral (mol. wt.) data. Infrared (dichloromethane), ultraviolet, and nuclear magnetic resonance (deuteriochloroform with tetramethylsilane as internal standard) spectra are consistent with the structures proposed. All yields reported have been calculated after purification by crystallization.

[3]A specific cleavage of one methoxyl group has occurred during the Grignard reaction. Discussion concerning this unexpected result will be included in our article.

[4]Reduction of **6** with lithium aluminium hydride gave phenol alcool **7** (m.p. 100 °C) which was transformed into the carbonate **8** (m.p. 146 °C) by reaction with phosgene in benzene containing pyridine. This result shows that the methoxyl group remaining in **6** is at C-6.

[5]A rigorous chemical proof for lactone aldehyde **11** was obtained in the following way. Lactone aldehyde **11** was transformed into compound **12** (m.p. 99–100 °C) by methylation with dimethyl sulfate in aqueous base followed by esterification with diazomethane. Alkylation of the known methoxy phenol aldehyde **6** with ethyl bromoacetate in tetrahydrofuran containing potassium carbonate gave compound **13** (m.p. 83–84 °C) which by hydrolysis in aqueous base followed by diazomethane esterification gave a compound which was found identical with compound **12**.

singlet, CH_3CO) and 8.75 (3H, singlet, CH_3)), and **17** (m.p. 113–115 °C; mol. wt. (mass spectroscopy) 290; ν_{max} 1810, 1740, and 1720 cm^{-1}; τ 5.34 and 5.68 (2H, double doublet, J = 14 c.p.s., H-3 and H-4), 6.36 (1H, doublet, J = 2 c.p.s., H-1), 6.83 (1H, octuplet, J = 2, 6, and 9 c.p.s., H-2), 7.83 (3H, singlet, CH_3CO) and 8.74 (3H, singlet, CH_3)).

Treatment of an ethereal solution of the mixture **16** and **17** with aqueous base gave the liquid triketone **18**.[6] Treatment of compound **18** with aqueous tetrahydrofuran containing sodium hydroxide at room temperature gave the tetracyclic hydroxydiketone **19** (m.p. 69–70 °C; mol. wt. (mass spectroscopy) 232; ν_{max} 3520, 1745, and 1720 cm^{-1}; τ 6.66 (1H, doublet, J = 4 c.p.s., H-1), 7.50 (2H, singlet, H-2, and H-3)[7] and 8.73 (3H, singlet, CH_3)). Compound **19** was best prepared in 70% overall yield by treating directly the crude mixture **16** and **17** with the basic treatment described above. Consequently, by a simple three-step procedure (**14** → **15** → **16** and **17** → **19**), a high yield of the complex tetracyclic hydroxydiketone **19** can be obtained from the simple aromatic compound **14**.[8] Compound **19** was transformed into the keto-acetate **21** (m.p. 128–130 °C, 90% yield) by a 15 min reflux in pyridine – acetic anhydride and was selectively ketalized with ethylene glycol, benzene, and *p*-toluenesulfonic acid to give ketal acetate **22** (m.p. 149–152 °C; 90% yield). Reaction of ketal acetate **22** with lithium borohydride in tetrahydrofuran at room temperature followed by addition of lithium aluminium hydride and reflux gave the *trans*-diol **23**[9] (m.p. 145–147 °C; 80% yield). Reaction of *trans*-diol **23** with pyridine in acetic anhydride at room temperature for 3 h gave the liquid acetate **26**.

[6]The formation of **18** from **16** and **17** combined with the spectral data confirms the position of the methyl ketone side chain in **16** and **17** as shown but does not determine the configuration of this side chain. The methyl ketone side chain has been shown to be *syn* to the double bond by several deuterium exchange experiments. Those results will be included in our article.

[7]The singlet at 7.50 τ was shown to correspond to H-2 and H-3 by deuterium exchange experiments.

[8]Compound **15** is crystalline and stable at room temperature; consequently, the *o*-spiro lactone ketal blocking group has a high stabilizing effect since the corresponding *o*-quinone **20** is unstable at room temperature. Furthermore, such blocking group on the *o*-quinone permits a very stereospecific Diels–Alder reaction with an unsymmetrical dienophile. The preparation of compound **20** will be reported in our article.

[9]A chemical reduction of ketal acetate **22** with sodium in liquid ammonia containing ethanol gave two compounds which were separated by column chromatography. The minor product was the *trans*-diol **23** and the major product, the *cis*-diol **24** (m.p. 115–117 °C). The diol **24** was shown to be the *cis* isomer in the following way: reaction of **24** with phosgene in benzene containing pyridine gave the carbonate **25** (m.p. 102–103 °C; 85% yield).

The entry into a ring skeleton related to ryanodine and its degradation product **3** was achieved in the following way: ozonolysis of **26** in methanol at room temperature followed by catalytic reduction with palladium-on-charcoal gave crude diketone **27** which underwent internal aldol condensation by filtration through silica gel to give dihydroxyketo acetate **28** (m.p. 176–177 °C; 55% yield from **23**; ν_{max} 3450, 1735, and 1700 cm^{-1}; τ 4.75 (1H, doublet, J = 2 c.p.s., H-1)[10], 6.10 (4H, multiplet, OCH_2CH_2O), 7.78 (3H, singlet, CH_3CO) and 9.00 (3H, singlet, CH_3)).

[10]H-1 appears as a doublet due to W coupling (5) with H-2. By irradiation at 8.2–8.4 τ, the doublet at 4.75 τ collapsed into a singlet.

Compound **28** gave the six-membered carbonate **29** by reaction with phosgene in benzene containing pyridine (m.p. 204–205 °C; 85% yield; ν_{max} 1755, 1740, and 1715 cm^{-1}).

Compound **28** contains in principle all the necessary functional groups for the complete elaboration of rings A, B, C, D, and E of ryanodine and its degradation product **3**. Work in this direction and in the synthesis of new polycyclic systems of the type **19** by using different dienophiles with **15** is now in progress.

Mass spectrometric studies of chemical reactions in shock waves: the thermal decomposition of nitrous oxide

S. C. BARTON[1] AND J. E. DOVE

Department of Chemistry, University of Toronto, Toronto 5, Ontario

Received June 19, 1968

Apparatus for the mass spectrometric study of rapid gas reactions in reflected shock waves is described. This apparatus has been applied to the thermal decomposition of 2% N_2O in Kr at total gas concentrations of about 1.6×10^{-6} mole cm^{-3}, in the temperature range 1800 to 2800 °K. The principal products of the reaction were found to be N_2, O_2, NO, and O. The rate coefficient for the unimolecular decomposition of N_2O was calculated from the experimental data, and the rates of the secondary reactions between O and N_2O were estimated. The possibility of the occurrence of a "weak collision" mechanism in the unimolecular reaction of N_2O is discussed.

Canadian Journal of Chemistry, **47**, 521 (1969)

Introduction

It is now well established that the primary reaction of the thermal decomposition of nitrous oxide is

$$N_2O \rightarrow N_2 + O$$

This is a unimolecular reaction of a simple molecule whose structural parameters are relatively well known. This system, therefore, appears very suitable for testing theories of unimolecular reaction, and a number of theoretical studies have, indeed, already been made (1–8). However, a complication is the fact that the direct decomposition to ground state products is spin-forbidden:

$$N_2O(^1\Sigma) \rightarrow N_2(^1\Sigma) + O(^3P)$$
$$\Delta H_0^0 = +38.68 \text{ kcal}$$

The spin-allowed process is considerably more endothermic (9–11):

$$N_2O(^1\Sigma) \rightarrow N_2(^1\Sigma) + O(^1D)$$
$$\Delta H_0^0 = +84.05 \text{ kcal}$$

It is therefore generally considered that the decomposition involves crossing from the potential surface of the singlet ground state molecule to the potential surface of a triplet intermediate which then decomposes to ground state products (12, 13). The minimum energy required for this process is likely to be appreciably less than the 84 kcal $mole^{-1}$ needed for the spin-allowed decomposition. However, in the absence of detailed information about the potential surfaces, the actual value cannot be accurately predicted. This is in contrast to very many other decomposition reactions, where the minimum energy required for reaction can often be assumed without serious error to be equal to the dissociation energy of the bond which is broken. It is, therefore, particularly of interest in the case of N_2O to measure the energy of activation experimentally. To help in the theoretical interpretation of the results, it is also desirable to look for a possible dependence of the Arrhenius activation energy on concentration and temperature.

Accurate experimental study of the primary unimolecular process is made difficult by the occurrence of a number of secondary reactions, some of which also consume nitrous oxide. Johnston (14) has made a careful analysis of the results obtained below 1050 °K by a number of previous workers, and has concluded that the

AP, common output of velocity gauge pulses and display oscilloscope timing pulses; B+, "+ gate B" output; BV, buffer volume; D, diaphragm; DO, mass spectrum display oscilloscope (Tektronix 543B); DP, diffusion pump; DT, mass spectrometer drift tube; DTP, delayed trigger pulse output or input; EH, external drive for oscilloscope horizontal amplifier; EM, electron multiplier; IG, ion accelerating grids; IS, ion source; M, gas manifold; MSTP, mass spectrometer trigger pulse output or input; OT, external trigger pulse input; PA, preamplifiers for shock velocity gauge signals; RO, raster oscilloscope (Tektronix 535A); S, sawtooth waveform output; SG, output from staircase waveform generator; ST, shock tube (driven section); STD, shock tube (driver section); STP, display oscilloscope trigger pulse output; TG, timing marker generator (Radionics TWM2-A); TP, trigger pulse input; VA, main amplifiers for shock velocity gauge signals; VG, shock velocity gauge; VGP, shock velocity signal input; WA, wideband amplifier.

minimum critical energy for the primary process is about 60 kcal mole^{-1}. This figure, and the rate coefficients which he obtained, are now widely accepted and have been used in most of the subsequent work on the reaction. Some objections have, however, been raised to Johnston's analysis (12). Moreover, in a later paper, Johnston and White (15) found that the available data on N_2O decomposition did not meet consistency tests which they applied. They concluded that the rate constants were still in doubt and that the data then available should not be used for a close test of reaction rate theories.

We have measured the rate and Arrhenius activation energy of the unimolecular reaction at low total concentration over a large range of temperatures, using shock tube techniques. At the time that our work was begun, only one study had been made in a higher temperature range (16), and there appeared to be doubts about the quantitative nature of the results. Since then, several other high temperature studies have appeared (7, 17–21). However, there is still conflict about some of the main experimental findings, and the theoretical interpretation of the results is in considerable doubt.

Experimental

The apparatus, shown schematically in Fig. 1, consisted of a shock tube coupled to a time-of-flight mass spectrometer. Gas was sampled directly from the reflected shock region into the ion source of the mass spectrometer. The changes in gas concentration during the reaction period were monitored by recording the mass spectra from cathode ray oscilloscopes. This type of experimental arrangement, in which the time-of-flight mass spectrometer is used to follow very rapid reactions, was pioneered in the laboratory of Professor G. B. Kistiakowsky at Harvard (22, 16, 23); important developments have also been made in other laboratories (19, 20, 24–26).

Shock Tube

The stainless steel shock tube was of 2.54 cm inside diameter and 570 cm in length, with a driver section of 25 cm diameter and 35 cm in length. This configuration of driver almost completely eliminates the effects of the rarefaction wave from the driver gas, which might otherwise affect the gas in the reflected shock region during the observation period (27, 28). The main section of the

For personal use only.

shock tube, which contained the experimental gas at an initial pressure of typically 5 Torr, was separated from the driver (containing, e.g., 400 Torr of helium) by a thin aluminium diaphragm. To initiate the shock wave, this diaphragm was cut by a spring-driven four-bladed knife. Metal diaphragms broken in this manner generally "petal" without losing any fragments. This avoids the necessity for dismantling the shock tube after each experiment to remove pieces of diaphragm material; the mass spectrometer vacuum would have to be broken at the same time.

Because of the possibility of serious deviations from ideal shock tube behavior, we have made careful experiments in which the shock wave pressure was monitored by a Kistler Model 603 pressure transducer[2] mounted in the end plate of the shock tube. For shock waves in argon or krypton, we found that the pressure remained steady for 380 to 1100 μs after shock reflection, depending on the gas used and the Mach number of the shock wave. The steady pressure regime was terminated by the arrival of a disturbance which we believe to be a wave reflected from the contact surface. The arrival of this wave always occurred well after the longest time for which kinetic data were taken by us under those conditions. However, the time of arrival was much earlier than would be calculated on the assumption of ideal behavior of the driver, as has been found by some other workers (28).

Shock Velocity Measurement

The velocity of the shock waves was measured by using 5 gold thin-film resistance thermometers at accurately known positions along the shock tube. The signals from these, after being amplified by circuits having a gain of 100 000 and a rise time of 0.5 μs, were used to trigger bistable multivibrators. The outputs of the multivibrators were combined in an "or" gate circuit and displayed on a raster trace (Fig. 2) produced by a Radionics Model TWM2-A waveform generator[3] and a Tektronix type 535A oscilloscope. In this way, the shock velocity between any pair of stations could be measured to within 0.5%. The shock attenuation was then calculated and was used to determine, by a short extrapolation, the velocity and arrival time of the shock wave at the end plate of the shock tube.

Gas Sampling

Gas was sampled continuously from the end of the shock tube directly into the ion source of the mass spectrometer. The sampling orifice was a round hole or a short re-entrant nozzle in a disc of gold or stainless steel foil of 0.0025 to 0.005 cm thickness, mounted on the end plate of the shock tube. The diameter of the hole used was 0.010 to 0.013 cm. The end plate of the shock tube also acted as the base of the ion source, and the ionizing electron beam was about 0.2 cm beyond the sampling hole.

Mass Spectrometer

The time-of-flight mass spectrometer (29, 30) was a Bendix Model 12 with type 14-101 "fast reaction" ion source; it had been specially modified to produce mass spectra at any chosen repetition frequency in the range 10 to 100 kHz. The ion currents, after amplification in the electron multiplier of the mass spectrometer, were further amplified in 2 Hewlett–Packard 460A wideband amplifiers and recorded photographically from oscilloscopes.

In order to obtain a representative sample of the reacting gas, it is necessary to use an orifice whose diameter is large compared with the mean free path in the shock-heated gas (31, 23). The large inflow of gas from such an orifice demands a fairly big pumping system for the mass spectrometer. The ion source was pumped by an Edwards F603 6-in. oil diffusion pump with cold cap and water-cooled CB06 baffle. With about 5 Torr of gas in the shock tube, the steady reading of a Bayard–Alpert ionization gauge attached to the ion source was about 4×10^{-5} Torr. The flow of gas into the ion source increased sharply on arrival of the shock wave. In order to keep the rate of pressure rise within reasonable bounds, 2 ballast volumes of 15 l each were added to the ion source. The openings to these 2 ballast volumes were 9 cm in diameter and were respectively 4.5 cm above and below the sampling orifice. Since our experiments were completed within at most a few hundred μs after shock arrival, these ballast volumes reduced the rate of pressure rise just as effectively as the addition of extra pumps. The flight tube, 1 m in length, was separated from the ion source by a baffle containing an opening of 0.5 cm × 1.2 cm (situated 13 cm from the sampling orifice), and was differentially pumped by a 4-in. mercury diffusion pump with refrigerated baffle and liquid nitrogen trap. When

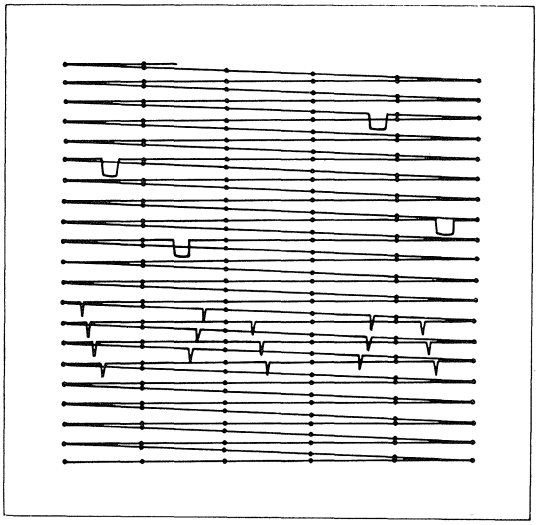

FIG. 2. Trace from raster oscilloscope display.

Zero time is at the top left. The approximately rectangular pulses are from the shock velocity gauges. The sharp narrow pulses near the bottom of the trace indicate the times at which the oscilloscopes were triggered to record the mass spectra. The bright dots are crystal-controlled timing markers.

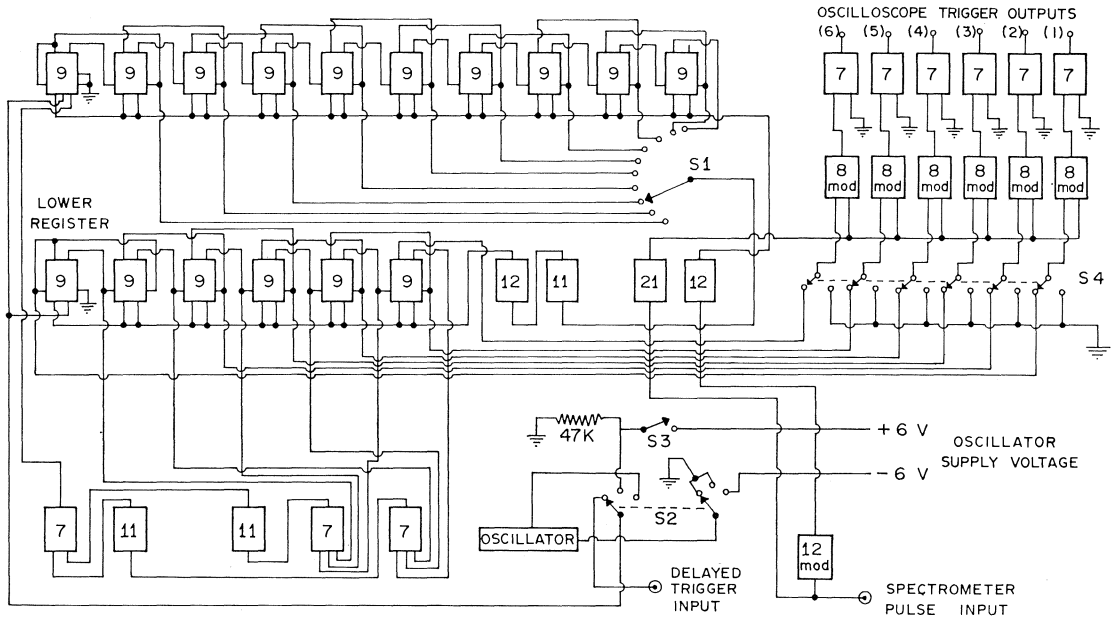

FIG. 3. Block schematic diagram of the control electronics for recording the mass spectrometric data. The figures on the circuit blocks are "PSC" numbers from ref. 33; where the circuit has been slightly modified, "mod" is added below the PSC number.

the shock tube was filled to pre-shock pressure, this pumping system kept the pressure in the flight tube at least an order of magnitude less than in the ion source. Between experiments, the mass spectrometer was pumped down to about 10^{-7} Torr.

Data Recording

A major problem is the accurate recording of the great amount of data which is produced in a very short time by the mass spectrometer. The ideal system would record the data directly in digital form, ready to be fed into the computer. Unfortunately this is at present prohibitively expensive, since it needs a recording system with a bandwidth of at least 30 MHz. We therefore record our mass spectra by photographing them from the screens of several oscilloscopes. The special electronic circuitry (32), which we have devised for this purpose, is shown schematically in Fig. 3. It has proved very successful and reliable.

The principle of operation is as follows. The mass spectrometer operates continuously at the chosen frequency. The external circuitry selects, at the appropriate time, a group of successive mass spectra to be recorded in time-resolved fashion. This is accomplished by gating and counting the trigger pulses which are being produced automatically by the mass spectrometer, and feeding them in a predetermined manner to the "external trigger" inputs of the oscilloscopes.

The heart of the recording electronics in Fig. 3 is the combination of 2 counting registers. These consist of binaries arranged in modified T connection (33, 34). In operation, the sequence of events is started by a pulse from one of the velocity gauges, suitably delayed by an accurate electronic delay circuit. The upper register then counts mass spectrometer trigger pulses until a certain number, preset by switch S1, has been reached. The registers are interconnected in such a manner that the first binary of the lower register is turned to state "0" by the initial trigger pulse and is returned to state "1" when the preset count is reached. The second lower binary then switches to state "0", and the upper register again counts the preset number of mass spectrometer pulses; the second lower binary then returns to "1". This continues until each of the binaries of the lower register has operated, after which the circuit stops automatically.

The waveform from the first binary of the lower register is used to gate the oscilloscope trigger pulses so that they can trigger the first recording oscilloscope for the required number of traces. The second binary acts similarly for the second oscilloscope, and so on. Our system can use up to 6 oscilloscopes with 1 to 10 spectra displayed on each. Typically, we record 4 to 6 mass spectra on each of 3 or 4 oscilloscopes. Tektronix 543B oscilloscopes are used since they have good bandwidth and a 6 cm high display area. Spectra are photographed onto Polaroid 10 000 ASA film.

The main remaining requirement is a staircase (step waveform) generator which displaces the oscilloscope trace vertically upwards between each triggering. The type of display which is obtained is shown in Fig. 4.

An additional feature which is extremely useful is that pulses showing the times of triggering of each oscilloscope are combined with the velocity gauge signals and recorded on the raster trace (Fig. 2). Since the time

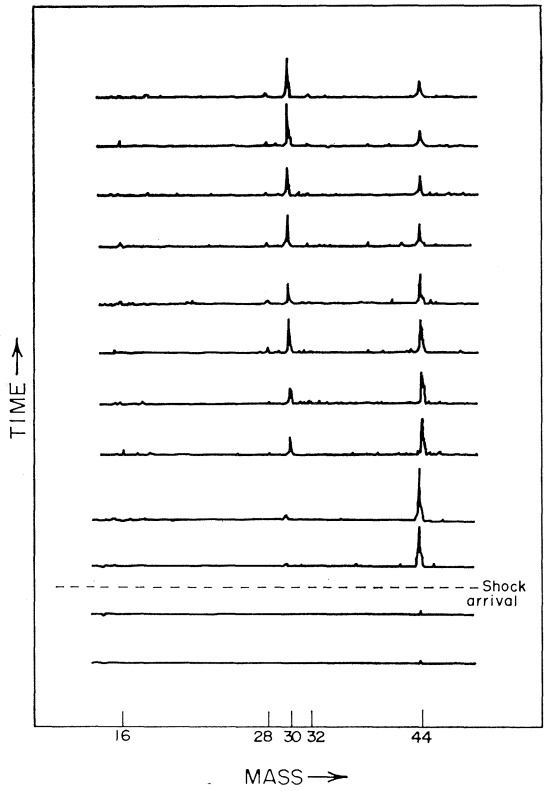

FIG. 4. Oscilloscope records of mass spectrum showing arrival of shock wave and subsequent reaction, with decrease of reactant N_2O (m/e = 44) and increase of N_2, NO, and O_2 (m/e = 28, 30, 32).

interval between the mass spectrometer electron beam pulse and the oscilloscope trigger pulse is known from calibration experiments, the raster records enable the times at which the mass spectrometric concentration measurements were made to be precisely established with respect to the start of chemical reaction (arrival of the shock wave). Strictly, a small additional correction is also required for the time that the gas takes to travel from the sampling orifice to the electron beam.

The system also includes a low-frequency internal oscillator, to trigger the electronics repetitively for setting-up purposes.

A definite problem with any system which uses oscilloscopes for data recording is the limited dynamic range available in any one trace. This difficulty is accentuated in the present application, by the characteristics of the mass spectral traces, which consist of very narrow pulses rising from a relatively slow-moving horizontal scan. The rise time of the pulses is so short that almost the maximum beam intensity of the cathode ray tube (c.r.t.) is required to make the pulses visible on the film at all. At this intensity, the base line is heavily over-exposed and thickened, and very small mass peaks are completely obscured. To minimize this problem, we feed a portion of the mass spectrum signal, suitably amplified and synchronized, as a "bright-up" signal to the c.r.t. cathodes. The c.r.t. beam can then be used well below maximum intensity and is automatically turned up to full brightness for the duration of any large mass spectrum peak.

Gas Mixtures

Gas mixtures were prepared in a conventional glass high vacuum system by manometric measurement of partial pressures, and were stirred before use. The purity of all the gases was checked by mass spectrometric analysis.

Krypton of Matheson "research" grade was used without further purification; the main impurities were Xe and N_2, each 25 p.p.m. Nitrous oxide of Matheson "regular" grade (98%, the main impurity being air) was purified by repeated fractional distillation after condensation with liquid nitrogen, only the middle fraction being retained each time. Oxygen, required for calibration experiments, was prepared by heating "research" grade potassium permanganate, and was then dried and purified by fractional distillation. Nitrogen, used for calibration experiments only, was Matheson "high purity" grade (99.9% minimum purity), and was dried by passing through a liquid nitrogen trap before use. Nitric oxide, also used only for calibration, was Matheson "C.P." grade (99.8% minimum) and was condensed in liquid nitrogen, degassed, and distilled once.

Shock Parameter Calculations

The temperature, pressure, and density of the unreacted gas mixture behind the reflected shock wave were calculated from the extrapolated incident velocity. The standard conservation equations (35) were solved by an iterative procedure, using a Fortran program on an IBM 7094 computer. Enthalpies were obtained from ref. 9 and were fitted to fifth order polynomials in T. Ideal shock reflection was assumed.

After the chemical reaction has begun, the temperature of the gas may change as a result of endothermicity or exothermicity. In order to calculate this change, a detailed knowledge of the reaction mechanism is needed, as discussed below.

Results

Experiments were carried out at temperatures between 1780 and 2790 °K with total gas concentrations of 1.4×10^{-6} to 1.8×10^{-6} mole cm^{-3}. The reactant mixtures contained 2.1% N_2O. Krypton was chosen as the diluent, rather than argon, mainly because its mass spectral peaks are well outside the region of main interest and therefore do not interfere. The predominant peaks of the reacting gas were determined to be of mass 44, 32, 30, and 28, corresponding to N_2O, O_2, NO, and N_2 respectively. No peak was found at mass 46 (NO_2).

Mass Spectrometric Data

The full sensitivity of the mass spectrometer could not be used with the large gas influx of

these experiments, otherwise the electron multiplier which was used as a detector would have been overloaded and driven beyond its range of linear response. The overall sensitivity was therefore reduced by operating the ionizing electron beam at an energy of 18 V (rather than the more conventional 50 to 70 V). The use of such a relatively low voltage had two major advantages. The formation of fragment ions or doubly-charged ions was almost completely eliminated, thus simplifying the interpretation of the mass spectra. Also, the ionization of the inert diluent, which has a relatively high ionization potential, was reduced much more than that of most of the gases of kinetic interest.

Because any mass peak on a given trace results from a finite, and sometimes small, number of detected ions, statistical fluctuations of peak height occur. These fluctuations are superimposed on any change of concentration due to chemical reaction, and are one of the factors limiting the accuracy of any single experiment. Fluctuations of this general type tend, of course, to be noticeable in any experiment where data have to be obtained in a very short time interval.

The primary kinetic data consisted of plots of peak height of N_2O^+, O_2^+, N_2^+, and NO^+ versus time from shock arrival. These mass spectral peak heights were assumed to be proportional to gas concentrations. We found it impracticable to obtain absolute (and constant) sensitivity factors for converting peak heights to concentrations. The measurement of absolute concentrations was, however, possible using relative sensitivity factors and the known initial concentration of N_2O. These relative sensitivity factors were determined under conditions as close as possible to those used in the kinetic investigations. Mass spectra of various gas mixtures of known composition were recorded under shock wave conditions. This procedure was used because an apparent temperature dependence of the mass spectra of some larger molecules has been found under similar conditions in other work (95). Also, diffusive separation of the gases may take place during their expansion into the ion source (36, 37), and this effect may be temperature dependent. Our experimentally-obtained sensitivity factors may reasonably be assumed to take these effects into account. The sensitivity to N_2 was rather low, mainly because of the high ionization potential of that molecule (15.6 eV). Hence the results for N_2 concentration are less accurate and more subject to statistical fluctuation than for the other gases.

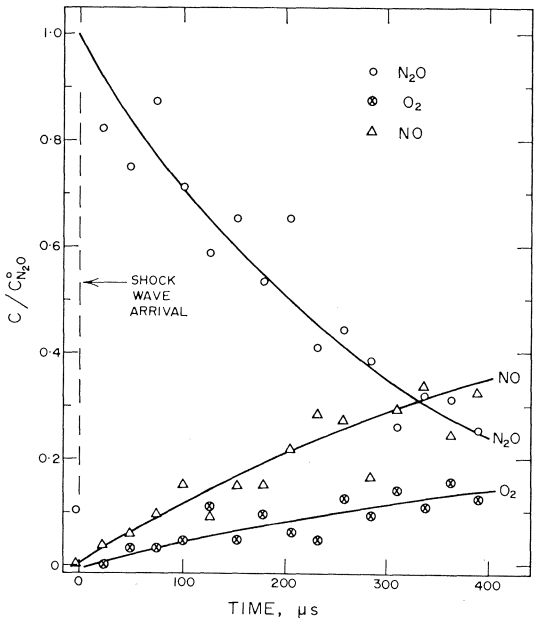

FIG. 5. Experimental concentration profiles of N_2O, NO, and O_2. The concentrations have been normalized by dividing by the initial concentration of N_2O. T_5 = 2370 °K.

The concentration profiles obtained in a typical successful experiment are shown in Fig. 5.

Overall Rate of Decomposition of N_2O

The results of previous workers indicate that the unimolecular reaction will be of the second order under our conditions. Then, neglecting for the moment the occurrence of possible secondary reactions, the rate of disappearance of N_2O will be given by

$$-\frac{d[N_2O]}{dt} = k_0[M][N_2O],$$

and hence

$$\log_{10}[N_2O] = \log_{10}[N_2O]_0 - k_0[M]t/2.303$$

[M] is the total concentration and is assumed to remain constant during a given experiment.

A typical plot of the logarithm of the N_2O peak height against time is shown in Fig. 6. These plots could be fitted fairly well to a straight line whose slope was used to obtain a value of k_0.

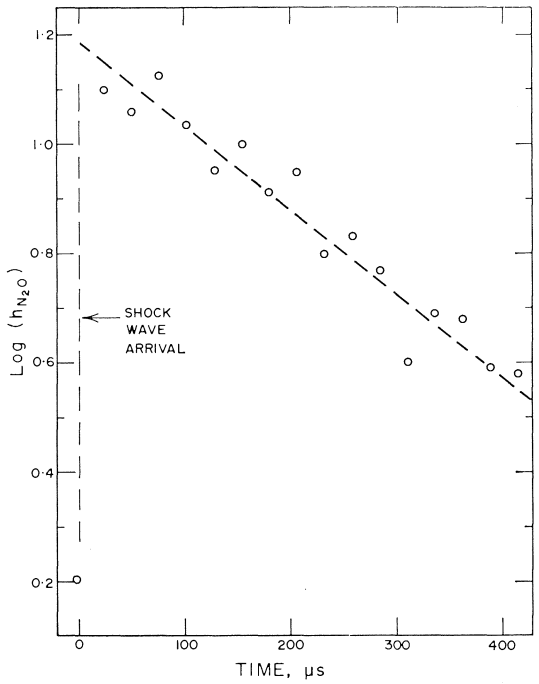

FIG. 6. Logarithm of the experimentally observed mass spectrometric peak height of N_2O (in arbitrary units), plotted as a function of time from shock arrival.

The values of k_0 at various temperatures were then fitted to an Arrhenius form by a least mean squares procedure, resulting in

$$k_0 = 5.8 \times 10^{12} \exp(-37\,000/RT)$$

in cm^3 mole s units (which are used throughout this paper), and with the energy of activation in cal $mole^{-1}$. The relation of this overall rate constant to the rate constant for the unimolecular reaction will be discussed later.

Discussion

The Reaction Mechanism

This and other investigations suggest that the reactions which may be important in the mechanism at high temperatures include:

[1] $N_2O + M \rightarrow N_2 + O + M$

[2] $O + N_2O \rightarrow N_2 + O_2$
$\Delta H_0^0 = -79.3$ kcal

[3] $O + N_2O \rightarrow 2NO$
$\Delta H_0^0 = -36.3$ kcal

[4] $NO + N_2O \rightarrow NO_2 + N_2$
$\Delta H_0^0 = -33.1$ kcal

[5] $O + NO + M \rightarrow NO_2 + M$
$\Delta H_0^0 = -71.8$ kcal

[−5] $NO_2 + M \rightarrow NO + O + M$

[6] $O + O + M \rightarrow O_2 + M$
$\Delta H_0^0 = -118.0$ kcal

[7] $O + NO_2 \rightarrow O_2 + NO$
$\Delta H_0^0 = -46.2$ kcal

[8] $NO_2 + N_2O \rightarrow NO + O_2 + N_2$
$\Delta H_0^0 = -7.5$ kcal

We have made calculations using the literature values of the rates of the two termolecular processes, reaction [5] (38–43) and reaction [6] (44) which show that both of these will be negligibly slow under the relatively low density conditions of our experiments. Calculations on reaction [4] using literature data (16, 18, 45, 46) show that its rate will be at most of the order of 1% of that of reaction [1] and hence it also can be neglected. These calculations are supported by the fact that we did not observe NO_2 in any of our experiments. Consequently we have omitted reactions [4], [5], and [6], and all processes involving NO_2, from the analysis of our own data.

Relative Values of k_2 and k_3

It is convenient next to evaluate k_3/k_2 from our data. It may readily be shown that in any experiment, $[NO]/[O_2] = 2k_3/k_2$. The average value of this quantity in all our experiments was 2.0 ± 0.7. Therefore we find $k_3/k_2 = 1.0 \pm 0.35$, in very good agreement with Belford *et al.* (20) who obtained 1.2 ± 0.2. The standard deviation which we quote represents deviations attributable to small fluctuations in the ion source conditions with consequent variations in the relative sensitivity to NO and O_2. There may be a small trend of k_3/k_2 with temperature, since we find 0.85 ± 0.3 in the range 1960–2100 °K, 1.0 ± 0.4 from 2100 to 2500°, and 1.15 ± 0.3 from 2500 to 2800°. However the trend, if any, lies within the standard deviations of the various values. We note that Belford found no trend with temperature, but that Kaufman *et al.* (46) found a difference of 1 kcal $mole^{-1}$ in the activation energies of the two reactions, which would predict a very small trend in the same direction as ours.

The results of experiments below 1960° were not used in the evaluation of k_3/k_2, since the amount of product formed during the observation time was too small to permit accurate measurement of $[NO]/[O_2]$.

Relative Values of k_1 and $(k_2 + k_3)$

The mechanism to be considered thus consists of reactions [1], [2], and [3]. The differential equations to which these give rise,

$$[9] \quad -\frac{d[N_2O]}{dt} = k_1[M][N_2O] + (k_2 + k_3)[O][N_2O]$$

$$[10] \quad \frac{d[O]}{dt} = k_1[M][N_2O] - (k_2 + k_3)[O][N_2O]$$

do not seem to have any straightforward analytic solution which would give the concentrations as an explicit function of time (47). However, it can readily be seen that if the secondary reactions [2] and [3] are very slow, the overall rate of disappearance of N_2O will be the rate of the unimolecular reaction. If reactions [2] and [3] are very rapid, a steady state in oxygen atoms will quickly be set up, and the overall rate will be twice the unimolecular rate. Therefore, in order to obtain the rate of reaction [1], we expect that we shall have to apply a correction factor, whose value lies between $\frac{1}{2}$ and 1, to the observed rate.

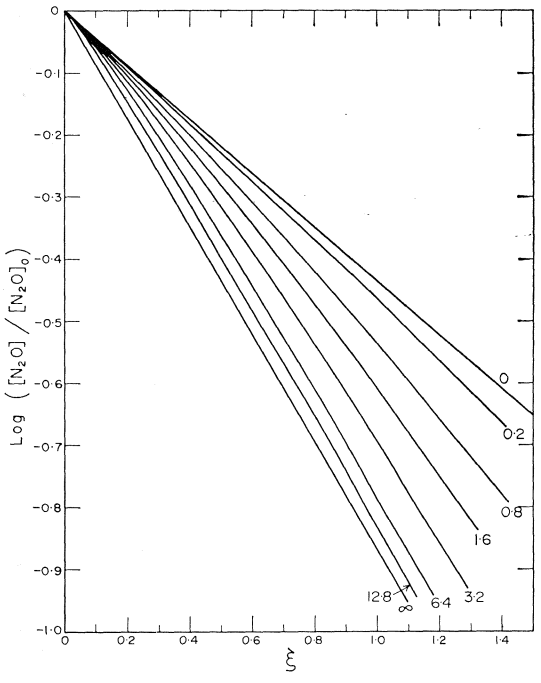

FIG. 7. Concentration profile obtained by computer solution of eqs. [9] and [10]. Logarithm of dimensionless N_2O concentration is plotted against dimensionless reaction time $\xi = k_1[M]t$, for various indicated values of $Y = (k_2 + k_3)[N_2O]_0/k_1[M]$.

Careful inspection of the experimental records, and preliminary calculations based on the literature data on reactions [2] and [3] (46, 48–51) indicated that we could not safely assume that a steady state in O atoms was rapidly established in all of our experiments. Therefore, in order to evaluate k_1, and also, if possible to obtain information about the rates of the secondary reaction, the reaction scheme needs to be considered in detail. In order to reach conclusions of general validity, it is convenient to transform the rate equations into dimensionless form. We define the following two quantities

$$\xi = k_1[M]t$$

and

$$Y = \frac{(k_2 + k_3)[N_2O]_0}{k_1[M]}$$

where $[N_2O]_0$ is the initial concentration. ξ is a dimensionless reaction time; it expresses the elapsed time in terms of $1/k_1[M]$, the time constant for reaction [1]. The equations then become

$$-\frac{d}{d\xi}\frac{[N_2O]}{[N_2O]_0} = \frac{[N_2O]}{[N_2O]_0} + Y \cdot \frac{[N_2O]}{[N_2O]_0} \cdot \frac{[O]}{[N_2O]_0}$$

and

$$\frac{d}{d\xi}\frac{[O]}{[N_2O]_0} = \frac{[N_2O]}{[N_2O]_0} - Y \cdot \frac{[N_2O]}{[N_2O]_0} \cdot \frac{[O]}{[N_2O]_0}$$

The solutions of these equations express the dimensionless concentrations $[O]/[N_2O]_0$ and $[N_2O]/[N_2O]_0$ in terms of the dimensionless time ξ, and depend only on the initial conditions and on the value of Y. We have solved these equations by numerical integration on a computer, using the initial conditions $[O]/[N_2O]_0 = 0$ and $[N_2O]/[N_2O]_0 = 1$, for Y values in the range 0.2 to 25.6. Some results of these computations are shown in Figs. 7 to 10. These graphs can be converted into plots in real time by a straight-forward linear scaling of the ξ-axis, if a value of $k_1[M]$ is known or assumed.

We now seek to establish values of Y, and hence of $(k_2 + k_3)/k_1$, by comparing the computed solutions with our experimental data. This may be done in several ways such as (*i*) comparing the shape of log $[N_2O]$ vs. time plots

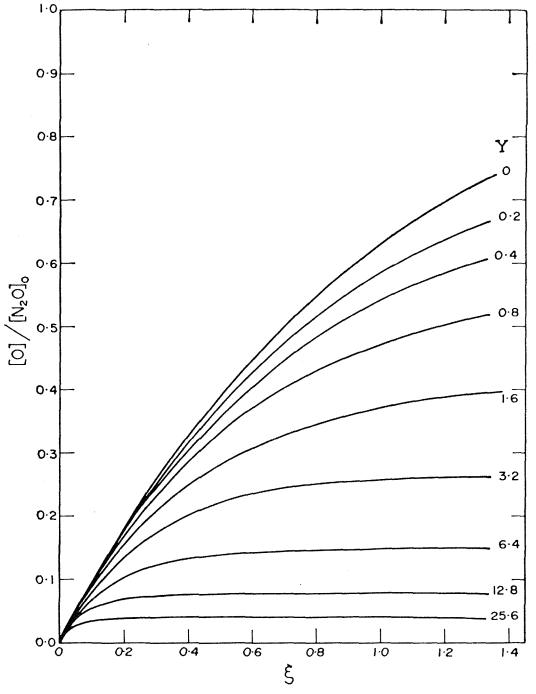

FIG. 8. Computed dimensionless O atom concentration plotted against dimensionless reaction time, ξ, for various values of *Y*.

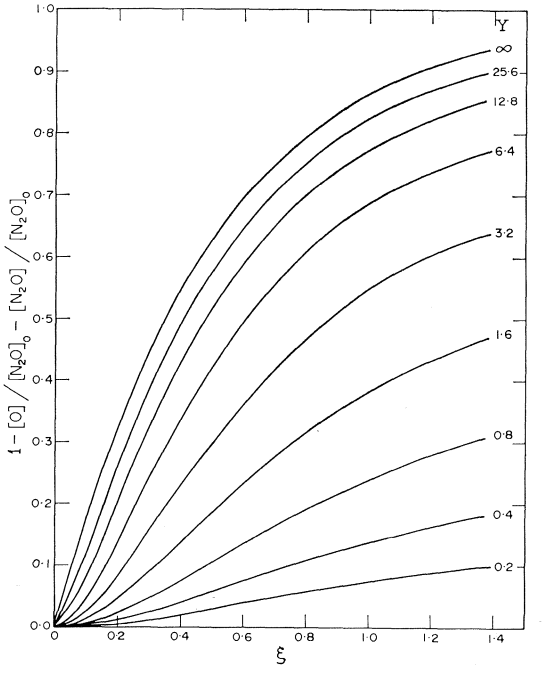

FIG. 9. Computed values of $s = 1 - [O]/[N_2O]_0 - [N_2O]/[N_2O]_0$ plotted as a function of ξ for various values of *Y*. *s* represents the fractional amount of total oxygen, originally present as N_2O, which has been converted to secondary products (NO and O_2) at any given time.

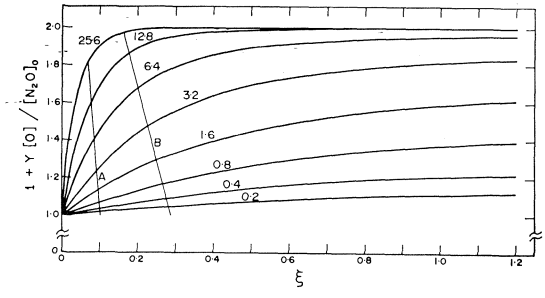

FIG. 10. Computed values of $1 + Y[O]/[N_2O]_0$ plotted against ξ for various values of *Y*. This graph can also be regarded as a plot of $d(\ln [N_2O])/dt$ against ξ, or as a plot of the ratio of the total rate of disappearance of N_2O to the unimolecular rate. The lines A and B represent times at which 10 and 25% of the initial N_2O have reacted.

(cf. Fig. 7), (*ii*) by observing the O-atom concentration (cf. Fig. 8), or (*iii*) by studying the formation of secondary products (cf. Fig. 9). Evidently none of these methods will be successful if *Y* is very small or very large, since the experimental results then become very insensitive to the actual value of *Y*.

A number of our log $[N_2O]$ plots appeared to be appreciably curved in such a manner as to suggest an acceleration in rate due to a build-up of O atoms. However, it is not easy to determine values of *Y* from such curves, partly because of statistical scatter in the experimental concentration plots; even a moderate scatter will tend to mask the curvature of any of the lines of Fig. 7. A more fundamental difficulty is that such curvature can arise in 2 quite distinct ways. If *Y* happens to be moderately small, the O atom concentration builds up gradually and this causes curvature of the log $[N_2O]$ plot, as explained above. The overall reaction is then approximately thermoneutral, as we show later, so that there is no appreciable temperature effect on the rate of N_2O disappearance. On the other hand, if *Y* is large, the O atom concentration quickly approaches a steady state but the overall reaction is exothermic. The temperature will rise as the reaction proceeds, so that in this case also there will be an increase in the relative rate of reactant consumption, and curved plots

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of log $[N_2O]$ will again occur. Considerable care is therefore needed in the analysis of the results, in order to separate the effects of exothermicity from those of the secondary reactions. Because of the danger of employing a circular argument in the interpretation, we did not rely on the N_2O plots alone for our determinations of Y. However, we did note that if the apparent curvature was assumed to be mainly due to build-up of O atoms, then a value of Y of about 6 at 2300 °K was indicated in our experiments. This is in quite good agreement with values obtained in a different manner, as described below.

In principle, a more satisfactory method of finding Y is to study the O atom concentration directly. Provided that Y is sufficiently large (cf. Fig. 8), the value of $[O]/[N_2O]_0$ tends to the stationary value $1/Y$. Unfortunately it is not easy to obtain a reliable mass spectrometric calibration factor for O atoms, in order to make concentration measurements. In any case, the mass spectrometric peaks for $m/e = 16$ were small and hence very subject to statistical fluctuation and unsuitable for quantitative evaluation. The sensitivity of the mass spectrometer to O atoms under our conditions is expected to be relatively low, because of the small cross section and relatively high ionization potential of this species, because of mass spectrometer discrimination against light atoms, and because of the possibility of loss of O from the sampled beam by diffusive separation (36). Using an estimated sensitivity for O atoms of 0.2 relative to O_2, we found a Y value of about 10 in the temperature range 2550 to 2750 °K. This rather rough estimate is also in satisfactory agreement with the results described below.

The third method of evaluating Y is to study the disappearance of N_2O and to compare it with the formation of NO and O_2. The mass spectrometer has good sensitivity to these 3 species, and relative sensitivity factors are of course known from our experiments. The method includes, essentially, an evaluation of the O atom concentration from the difference between the amount of N_2O decomposed and the NO and O_2 formed, though the actual calculation is not cast in exactly that form. Evidently such a calculation will only be successful if the quantity to be found is sufficiently large, compared with the probable errors in the quantities whose difference is to be taken. Fortunately this condition appears to be reasonably well fulfilled in our experiments, so that an approximate value of Y can be obtained. The calculation was actually made by matching our experimental data with the appropriate concentration profiles from the computed solutions of the rate equations (cf. Fig. 7 and 9). From each experiment we obtained plots of log $[N_2O]/[N_2O]_0$ and $s = ([NO] + 2[O_2])/[N_2O]_0$ against time. The quantity s represents the fraction of total oxygen which is present as secondary products, and is, therefore, to be directly compared with the computed profile of $1 - [O]/[N_2O]_0 - [N_2O]/[N_2O]_0$. Since the forms of the curves of log $[N_2O]/[N_2O]_0$ and s against time have different dependences on Y, only for one particular value of Y is it possible to match both of the experimental curves to their computed counterparts. A value of Y was found in this manner for each experiment. The results are plotted as log (Y) against $1/T$ in Fig. 11. One experiment that gave an extremely large value of Y has been omitted from the graph; presumably this high value was caused by an uncontrolled fluctuation in the ion source conditions, which would change the effective relative sensitivity factors.

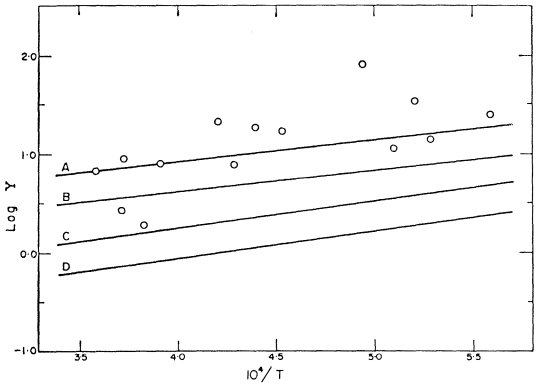

FIG. 11. Experimental values of log Y, obtained in the present work. The lines A and B are logarithmic plots of $(k_2 + k_3)[N_2O]_0/0.5k_0[M]$ and $(k_2 + k_3)[N_2O]_0/k_0[M]$, using data of Fenimore and Jones (49) for k. The lines C and D are similar plots using the data of Fishburne and Edse (51) for $(k_2 + k_3)$.

There are 2 previous determinations of the rates of the secondary reactions in a temperature range close to that of the present work. Fenimore and Jones (49) have measured k_3 over the range

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

1400 to 2200 °K and find a value of 1×10^{14} exp $[(-28\,000 \pm 3\,000)/RT]$ cm^3 mole^{-1} s^{-1}. Fishburne and Edse (51) find that $(k_2 + k_3) = (2.3 \pm 0.4) \times 10^{13}$ exp $[(-25\,000 \pm 800)/RT]$ from 1700 to 2300 °K. If it is assumed that $k_2 \simeq k_3$, then the rates found by Fenimore and Jones are about 4 times as great as those of Fishburne and Edse.

Our values of Y can be compared with the earlier work in the following way. We believe that k_1 lies between $0.5k_0$ and k_0. Therefore Y should lie between $(k_2 + k_3)[N_2O]_0/0.5k_0[M]$ and $(k_2 + k_3)[N_2O]_0/k_0[M]$. The 2 lower lines in Fig. 11 are these two quantities plotted using $(k_2 + k_3)$ from Fishburne and Edse's data, and using $[N_2O]_0$, [M], and k_0 from our own experiments. The 2 upper lines are the corresponding quantities using Fenimore and Jones' data for $(k_2 + k_3)$, assuming that $k_2 = k_3$. To agree with Fishburne and Edse, our data points should lie between the 2 lower lines, whereas to agree with Fenimore and Jones, they should lie between the 2 upper ones. In fact, in the latter case the correction factor to k_0 is found to be fairly near to 0.5, so that the points should lie close to the upper line if Fenimore and Jones' value is correct. Our data are rather scattered, since the measurement is a difficult one, depending upon differences between measured quantities. Nevertheless, it will be seen that the value of Fenimore and Jones is strongly favored by our results.

It should be pointed out that the method just described for finding Y will not be very seriously affected by minor changes in temperature due to slight endothermicity or exothermicity of the reaction. It would be expected that the value of Y obtained would simply be an average over a small temperature range. Since Y depends on a ratio of rate constants, its temperature dependence is not particularly large. Of course, large temperature changes would considerably distort the shapes of the curves and would affect the results, probably making it difficult to obtain a match for any value of Y.

There has been no agreement among previous workers on the N_2O pyrolysis, about the rates of reactions [2] and [3]. Two groups (7, 17, 20) have previously considered that their rate data fitted the results of Fenimore and Jones, though they did not report any actual determination of the secondary rates. Several other workers have favored lower values for the rates of the secondary reactions (16, 18, 19). However the results of Kaufman, Gerri, and Bowman (46) for reactions [2] and [3], which were at one time held to favor the lower values, have now been reconciled with the data of Fenimore and Jones (49, 50, 52).

Determination of k_1

When the mechanism and the values of k_2 and k_3 are known, k_1 can be found by correcting the observed rate for the effects of exothermicity or endothermicity and secondary reactions. We will assume for the present that the thermal effects are small, and will justify this assumption later.

To correct for the secondary reactions, we use the experimental results in conjunction with the computed solutions of the rate equations. Essentially we fit a curve of the appropriate shape to the N_2O concentration points for a given experiment, by making a suitable linear scaling of the ξ-axis. A value of $k_1[M]$ is then derived from the scale factor which has to be applied to ξ. The shape of curve to be used is found from the computer solution for the relevant value of Y. This value of Y could have been our own value, determined as described in the previous section. However, we decided instead to use the value of Fenimore and Jones for k_3, and to assume that $k_2 = k_3$, as found in our own experiments.

In order to obtain Y from $(k_2 + k_3)$, we needed also an estimate of k_1. Therefore we employed a method of successive approximations, using $(k_2 + k_3)[N_2O]_0/0.6k_0[M]$ as our first estimate of Y. This was used to obtain a more accurate value of k_1, and a new value of Y was then found. Two complete iterations were found to be quite sufficient for k_1 to converge to a closely constant value. Additional calculations showed that, for given values of k_2 and k_3, the final value of k_1 by this successive approximation procedure was not appreciably dependent on the value of Y that was initially assumed; this is reasonable, because of the relative insensitivity of the correction to the value of Y.

Corrected values of log k_1 are plotted against $1/T$ in Fig. 12. The line is a least mean squares fit of the data to an Arrhenius form, and can be expressed as

$$k_1 = 10^{12.86 \pm 0.09} \exp [(-40\,700 \pm 900)/RT]$$

Using the above correction procedure, we

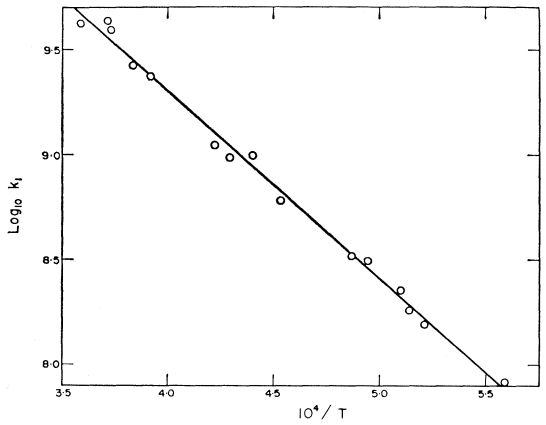

FIG. 12. Arrhenius plot of experimental values of k_1 obtained in the present work.

found that the value of k_1/k_0 was not the same in all experiments, though it was generally about 0.55 to 0.6. The final value of k_1 is somewhat affected by the values assumed for the rates of the secondary reactions. Therefore we also tried the effect of using Fishburne and Edse's values (51), which are about $\frac{1}{4}$ of those of Fenimore and Jones, for the secondary rates. The experimental curves then did not fit the computed ones quite as well, but it was still possible to obtain a corrected value of k_1 which ranged from about $0.6k_0$ at the lower end of the temperature range of our work to about $0.8k_0$ at the higher temperatures.

Throughout these calculations, we had set [M] equal to the total initial concentration of the shock-compressed gas. The results of Volmer and Bogdan (53) below 1000 °K show that the efficiencies of various monatomic and diatomic gases in energizing N_2O are not extremely different from that of N_2O itself; the differences may well be smaller still at higher temperatures (54). Therefore, we believe that our rate constant can, without serious error, be considered that for Kr as M. We believe also that our rates should be comparable, without large correction, to those in otherwise similar experiments which use argon as diluent.

Thermal Effects

Reaction [1] is endothermic by at least 38 kcal, so that the overall reaction will always be endothermic in the initial stages. The secondary reactions [2] and [3] are, however, exothermic. The overall endo- or exothermicity will therefore be decided by the relative effects of these 3 reactions. In considering this point, it is useful to note that at the low densities and short reaction times of the present work, d[O]/dt cannot become negative. This can be seen by consideration of eqs. [9] and [10], or from Fig. 8. Thus O atoms are always present, even when the decomposition of N_2O is essentially complete; for small values of Y, the predicted proportion of O atoms is quite large (Fig. 8).

Calculations show that in the range studied by us, the overall reaction is in fact very nearly thermoneutral, and that thermal effects are therefore probably quite negligible. As an example, at 1900 °K, where $Y = 12$, about 10% of the N_2O has decomposed when $\xi = 0.0777$. The reaction can then be written as

$$N_2O \rightarrow 0.900\ N_2O + 0.048\ O + 0.087\ N_2 + 0.026\ NO + 0.013\ O_2$$

$$\Delta H^0 = 1.37 \text{ kcal}$$

corresponding to a temperature change of $-6°$ due to endothermicity in a 2% mixture. When 40% of the N_2O has decomposed, the temperature change is calculated to be $+1.5°$. At 2600°, the temperature changes at 10 and 40% reaction are calculated to be -9 and $-8°$ respectively. Incidentally, in calculating these temperature changes we actually used values of Y obtained from Fenimore and Jones' data and our own final k_1. However, essentially the same conclusion would have been reached if we had used our own values of Y, derived by methods (*ii*) and (*iii*) above without the assumption of negligible thermal effects, so that our conclusion that temperature changes are small is not reached by circular argument.

In experiments at much higher densities, where the recombination reactions are fast, the figures given here will not apply and the overall reaction will tend to be much more exothermic.

Discussion of k_1 Values

Our values of k_1 are compared with those of several other workers (7, 18, 20) in Fig. 13. Fishburne and Edse (F.E.) (18) quoted first order rate constants for the total rate of N_2O disappearance. Their constants have accordingly been divided by total gas concentration and multiplied by 0.5 (approximately the expected value of k_1/k_0) to bring them to a convenient form for comparison. Of their data, only the results for their lowest total concentration, 13×10^{-6} mole cm^{-3}, are shown on this

graph. It will be seen that as regards the magnitude of the observed rates at about 2000° there is fair agreement among the various workers. However, there is not very good agreement about the temperature coefficient of the rate, and in particular the results of Olschewski, Troe, and Wagner (O.T.W.) (7) (see also Jost, Michel, Troe, and Wagner (17)), show a substantially larger temperature dependence than any of the other results in Fig. 13.

Making a more detailed comparison, we note that F.E. found, as is usual in unimolecular reactions, that the Arrhenius activation energy is appreciably dependent on total gas concentration. As shown in Fig. 14, our own result for the activation energy appears consistent with the trend found by F.E. It should be pointed out, however, that the usual theories of unimolecular reaction predict that the energy of activation should level out again at low concentrations, and it is not clear from Fig. 14 whether this is happening. The difference between high and low pressure activation energies also appears rather large, as discussed below. On the other hand,

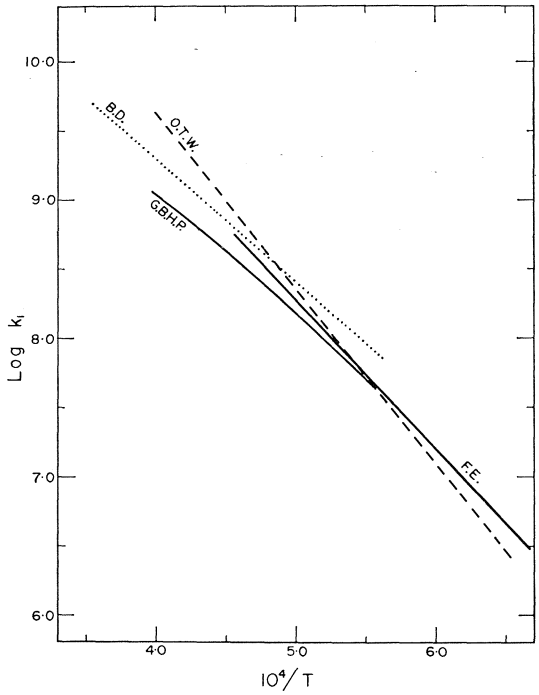

FIG. 13. Comparison of various experimental values of k_1 in the temperature range 1600 to 2800 °K. B.D., this work. F.E., Fishburne and Edse (18). G.B.H.P., Gutman, Belford, Hay, and Pancirov (20). O.T.W., Olschewski, Troe, and Wagner (7).

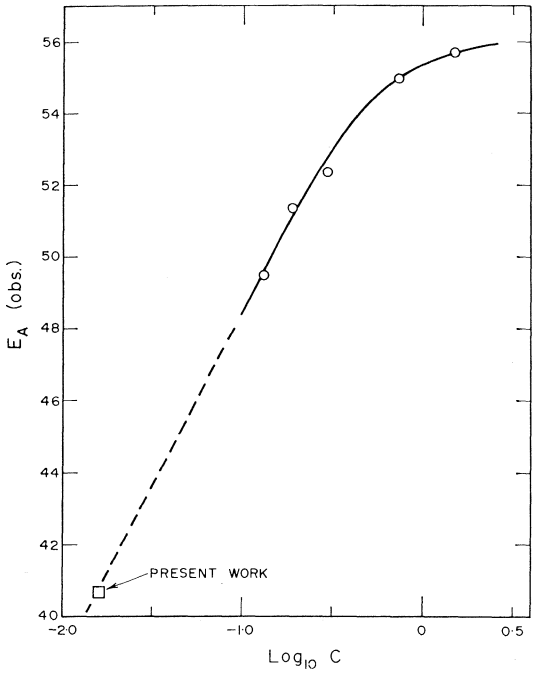

FIG. 14. Experimentally observed Arrhenius activation energies, plotted as a function of concentration. The circles are data of Fishburne and Edse (18).

it must also be admitted that there is relatively little experimental evidence to show whether the expected levelling out of the activation energy at low concentrations does in general occur under high temperature conditions such as those used in our work. When F.E.'s k_1 is plotted against total concentration, for a fixed temperature, a curve which is always concave upwards is obtained, as is expected on theoretical grounds (55). Again our result lies on a plausible extrapolation of their curve, as is shown for one representative temperature in Fig. 15. Accordingly we conclude that our values of k_1 are in general reasonably consistent with those of F.E., though some points remain to be clarified. Also, Kistiakowsky and co-workers (56) have briefly reported some work on N_2O decomposition, and find agreement with F.E.

Gutman, Belford, Hay, and Pancirov (G.B.H.P.) (20) expressed their k_1 in a different functional form

$$k_1 = 1.2 \times 10^7 (T)^{\frac{1}{2}} (60\,000/RT)^{5.09} \times \exp(-60\,000/RT) \text{ cm}^3 \text{ mole}^{-1}\text{s}^{-1}$$

However, their Arrhenius activation energy can be written as $E_A = 60\,000 - 4.59RT$, and this

gives a temperature coefficient very close to ours. For example, at 2200 °K, in the middle of our temperature range, the value obtained from their results is 39.9 kcal mole^{-1}, compared with our figure of 40.7. Our rate constants are, however, consistently about 1.8 times as large as theirs. In looking for a possible explanation of this discrepancy, we note that G.B.H.P. expected that the reaction would be appreciably exothermic. Therefore, to eliminate interference from exothermicity and from possible thermal boundary layer effects, they extrapolated their rate constants to zero time. The extrapolated constant was interpreted as $2k_1$, and was accordingly divided by 2 before plotting. Figure 10 shows a graph of k'/k_1 against dimensionless reaction time. k' is the effective overall rate constant for N_2O destruction. Clearly any procedure which efficiently extrapolates the rate constant towards zero time will tend to give k_1 rather than $2k_1$. However, the Y values of G.B.H.P. would be rather large; we estimate for their conditions 60 at 1500° and 13 at 2500°, so that the extrapolation would have to be carried rather close to the shock front in order to give a result substantially smaller than $2k_1$.

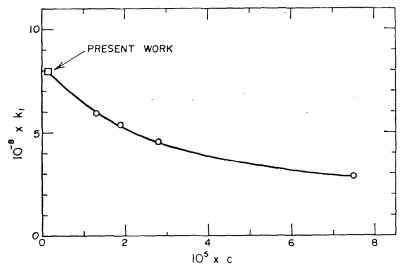

FIG. 15. Experimentally observed rate constants at 2200 °K, plotted as a function of concentration. The circles are taken from the data of Fishburne and Edse (18) and represent $0.5k/c$, where k is their measured first order rate constant for overall consumption of N_2O, and c is the total gas concentration.

The remarks of the previous paragraph will need some modification if the results of Fishburne and Edse (51) are used for the secondary reactions. Then the Y values will be considerably smaller, and almost any extrapolation towards zero time will give an apparent rate coefficient less than $2k_1$. In such a case, as mentioned above, our own results for k_1 would also have to be revised upwards by a small amount.

Comparing our results with O.T.W. (7), we find good agreement in the actual rates at about 2000 °K. At higher temperatures, O.T.W. find much higher rates than the other groups. This difference, which leads also to a difference in the energy of activation, is a major discrepancy which we have not been able to understand. It might be suggested that some of the gases used were impure. It is difficult to see how in our work an impurity could have passed unnoticed in the mass spectrometric records and yet have been present in sufficient amount to *reduce* our high temperature rates enough to account for the difference. O.T.W. used rather low concentrations of reactant, and this would tend to make their results susceptible to the presence of small amounts of catalytic impurity. It is clear, however, that they took considerable pains with cleanliness and purity. Moreover, their rate constants do not show the degree of scatter that might be expected if impurities were being accidentally introduced.

One other aspect of the comparison with O.T.W. is hard to understand. They report seeing effects due to non-stationary O atom concentrations only if the initial N_2O percentage was lowered to 0.02%. Accepting the values of F.J. for the secondary rates or, *a fortiori*, those of Fishburne and Edse (51), we would have expected non-stationary effects at much higher percentages of N_2O. For example, with 1% N_2O at 2500 °K, F.J.'s and O.T.W.'s rates imply a Y value of about 1.6. Figures 7 to 10 show that the non-stationary effects should be quite noticeable. With lower percentages of N_2O, the effects would be very marked, even at considerably lower temperatures. O.T.W.'s results may imply that all currently available values of k_2 and k_3, including our own, are too small. Alternatively, some re-interpretation of their results may be necessary. However, we do not believe that the differences between our results and those of O.T.W. can be due mainly to such non-stationary effects.

Drummond and Hiscock (21) have recently reported a unimolecular rate and activation energy for N_2O that closely agree with O.T.W. Unfortunately this does not help to resolve the difference between our results and those of O.T.W., because Drummond and Hiscock also report that if they were to correct their own results for the effects of temperature changes in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the reacting mixture, they believe that the activation energy would be reduced to a value close to 40 kcal mole^{-1}. This latter value would, of course, agree with ours.

Low pressure unimolecular rate constants are often expressed in the simplified classical Kassel form. If we do this with our results, we obtain, assuming a minimum critical energy of 60 kcal mole^{-1},

$$k_1 = 10^{7.475}(T)^{\frac{1}{2}}(60\,000/RT)^{4.96} \times \exp(-60\,000/RT)$$

However, we are somewhat dubious of the theoretical significance or value of using this form of the rate constant, since it implies six contributing classical oscillators for a light molecule with only 4 vibrations. Moreover, this expression is already an approximation which is only valid when $6RT \ll 60\,000$ cal mole^{-1}. Since the inequality is not very well obeyed in the present case, we must use (57) the more complete form

$$k = PZ \sum_{r=0}^{s-1} \frac{1}{r!}\left(\frac{E_0}{RT}\right)^r \exp(-E_0/RT)$$

where s is the number of contributing oscillators. Because the addition of the extra terms reduces the overall temperature dependence of the expression, one needs to use $s = 7$ to represent the results. This number of oscillators can scarcely have any direct physical significance.

Several other recent experimental studies of the high temperature dissociation of triatomic molecules have found energies of activation that could not be accounted for in terms of reasonable numbers of Kassel oscillators. A summary of data is given in Table I. For CO_2 and CS_2, as well as N_2O, direct dissociation into ground state products is spin-forbidden. For none of these cases is the minimum critical energy known *a priori*. However, the minimum critical energy E^* must be at least as great as the bond dissociation energy D for a truly unimolecular process, and may be much greater than D. In the case of CO_2, quite unreasonable numbers of Kassel oscillators are required to account for the results, even if $E^* = D$. For CS_2, the number of oscillators can be just within reason, but only if E^* is assumed to be very close to D. Of the spin-allowed processes, NOCl also requires too many oscillators; for SO_2, the number of oscillators may be normal, assuming that $E^* = D$.

TABLE I

Experimental data on high temperature energies of activation for dissociation of some triatomic molecules

Molecule	E_A* (kcal mole^{-1})	T (°K)	Reference	D† (kcal mole^{-1})

*E_A = Arrhenius energy of activation. Where the rate constant was not quoted in Arrhenius form, E_A has been evaluated at the temperature corresponding to the mean value of $1/T$.
†D = dissociation energy, into ground state products, of the bond which is broken. Data are taken from refs. 9–11, 70, and 71.
‡Quoted in the original paper as a "high pressure" value for energy of activation.
§This work.

Several of these results suggest an analogy with the thermal dissociation of diatomic molecules, where Arrhenius activation energies much lower than the energy of dissociation are frequently observed. These low values of the activation energy are very likely to be due to the occurrence of deviations from a Boltzmann distribution of vibrational energy amongst molecules which have insufficient energy to dissociate (72, 73). Similar deviations (20) might occur also for small polyatomic molecules at high temperatures.

The existence of deviations from Boltzmann equilibrium amongst molecules having *more than* the minimum critical energy is, of course, well known in unimolecular reactions, and is one of the principal topics of the theory of such reactions. The possibility of similar deviations amongst molecules of energy less than E^* seems to have been generally ignored or discounted because of the use of the "strong collision" assumption. According to this assumption, relatively large amounts of energy are exchanged during the collisions which energize molecules to levels above E^*. This in turn implies that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

energization can occur with appreciable probability from each of many different levels below E^*. Then, in order to explain with this model any large non-equilibrium effect on the reaction rate, we would have to propose that a substantial proportion of these levels can simultaneously be considerably out of Boltzmann equilibrium. Because of the very large number of vibrational levels in a polyatomic molecule, such widespread disequilibrium is highly unlikely.

If we examine the evidence for the strong collision assumption, it appears that direct experimental evidence of collisional transfer of large amounts of energy from highly energized molecules has been obtained only for much more complex molecules than N_2O (74–80). There is indeed already some indication that for small molecules, the strong collision mechanism does not operate (81). Certainly, in the case of diatomic molecules, it is generally assumed that most of the energy transfer occurs by transitions among neighboring levels (82). Moreover, in the shock tube experiments which are considered here, the triatomic species is in high dilution. Therefore most of the energizing collisions are expected to be between a molecule and an atom, rather than between two molecules. An atom as collision partner would in general be less likely to exchange large amounts of energy than a molecule of the same mass, simply because the atom has fewer degrees of freedom available for such an exchange.

If we assume that a "weak collision" mechanism operates in N_2O, direct energization to states above E^* will occur only from a relatively few states which have energy just less than E^*. At very low pressures and high temperatures, these levels will become heavily depleted by the unbalanced demand from above. Energy transfer among levels below E^* will then tend to become a rate-determining factor, and the low pressure rate will be less than that predicted for a strong collision mechanism. Incidentally, though O.T.W. do suggest a weak collision mechanism for N_2O, they use an equilibrium energy distribution function to calculate energization rates, and therefore their treatment does not appear to be applicable to the study of possible disequilibrium below E^*.

Unfortunately, if the strong collision assumption is not used, the theoretical treatment of energization rates becomes much more difficult. In order to calculate unimolecular reaction rates in the fall-off and low pressure regions, detailed information about intermolecular energy transfer will be needed. At present, the data for a calculation of the actual energy distributions during unimolecular reaction in such a system are not available. Even when such data are obtained, it is likely that each reaction will have to be treated as a separate different case. The observations quoted in Table I already hint at such a situation.

Experimental Errors

There are several possible sources of error which might give rise to systematic deviations in our experimental results. These possible sources of error include non-ideal behavior of the shock waves, thermal boundary layer effects, and accumulation of sampled gas in the ion source region.

Non-ideal behavior of reflected shocks has been reported by a number of workers (see, e.g., refs. 83–92). However, the deviations from ideality are relatively small in the case of gas mixtures whose specific heat ratio, γ, is close to 1.67, as in the present work. It appears that for such mixtures, the actual shock temperatures may be about 30° lower than calculated (89). However, there is not complete agreement in the literature about the extent or even the direction of the deviation. Consequently we have not attempted to correct our reported temperatures for this effect. A systematic deviation of 30° would change our reported rate constant at 2000 °K by about 10%, and would have only a negligible effect on the observed energy of activation.

The possibility that a substantial proportion of the sampled gas might come from the thermal boundary layer near the end wall of the shock tube has been considered by a number of workers (16, 19, 20, 23, 56, 93). The general conclusion has been that in the range of temperatures and reaction times used in our work, interference by the thermal boundary layer is not very serious. In particular, Belford and coworkers (20) have reported an observed cooling rate of less than 5° per 100 μs at 2000°, and 50° per 100 μs at 2500 °K. These cooling rates would not be sufficient to affect our reaction rates very seriously. Moreover, these estimates of cooling rates were based on an observed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

deceleration of the rate of reaction, and included an allowance for the expected exothermicity. If, as we believe, the reaction is less exothermic than they estimated, the true cooling rate would be less than mentioned above. Also, our sampling orifice was larger than that used by Belford, so that the influence of the thermal boundary layer on our results would in any case be expected to be less. Thus we conclude that, on evidence currently available, our results are probably not seriously affected by the thermal boundary layer. Nevertheless our opinion is that the general question of the effects of the thermal boundary layer on sampling in systems of this type is not by any means entirely closed, and that it would be desirable to find additional methods of studying these effects, particularly at temperatures above 2500 °K.

If substantial amounts of sampled gas build up in the ionization region of the mass spectrometer, the observed concentration profiles could be distorted. Calculations[4] of the gas flow in this region, based on the known geometry of the ion source, indicate that this effect is negligible. In these calculations, the gas flow from the orifice was treated as a freely expanding jet (36). Part of this flow was backscattered by the ion grids. The backscattered gas was then assumed to leave the ionization region by molecular flow. We have not made detailed calculations of the possibility of effects due to ion–molecule reactions, or elastic scattering of ions during flight to the detector; however, the calculations of Diesen and co-workers (94) show that such effects would almost certainly not cause appreciable errors under our conditions. This conclusion is supported by the fact that we did not observe any systematic deviations which could be attributed to elastic scattering or to ion–molecule reactions or to reactions of metastable krypton atoms, during our calibration experiments.

Acknowledgments

This work was supported by the National Research Council of Canada, Imperial Oil Limited, and the Ontario Research Foundation. S.C.B. thanks the National Research Council of Canada for the award of a Studentship. J.E.D. wishes to acknowledge his great indebtedness to Dr. George B. Kistiakowsky, in whose laboratory he began work on this area of research. We thank the Institute of Computer Science, University of Toronto, for the use of their facilities, and Drs. R. L. Belford, J. Troe, D. McL. Moulton, and J. V. Michael for helpful correspondence and discussion.

Molar excess Gibbs free energies of benzene – *m*-xylene mixtures[1]

T. BOUBLÍK[2] AND G. C. BENSON
Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received September 25, 1968

Vapor–liquid equilibria for the system benzene – *m*-xylene were measured in a circulation still at 25, 37, and 50 °C. Excess free energy data were analyzed in terms of Flory's theory of non-polar mixtures.

Canadian Journal of Chemistry, **47**, 539 (1969)

Introduction

Values of the excess enthalpies and excess volumes of the three systems formed by mixing benzene with *o*-, *m*-,and *p*-xylene (at 25 °C) were presented in a previous publication (1). It was found that the Flory theory (2) of non-polar mixtures provided a reasonable framework for interpretation of these results. However, a similar treatment (3) of data for aromatic–alicyclic systems showed that, although the theory appears to correlate enthalpy and volume changes fairly well, excess free energies are generally overestimated. Analogous behavior has been observed for mixtures of *n*-alkanes by Orwoll and Flory (4) who suggested that the equation for the excess free energy in the original formulation of the theory should be amended to include an empirical interaction entropy contribution.

The present paper continues our investigation of the thermodynamic properties of benzene–xylene systems by reporting results for the vapor–liquid equilibrium of benzene – *m*-xylene mixtures at 25, 37, and 50 °C. Excess free energies derived from these data are considered in the light of the Flory theory and its recent modification.

Experimental

Materials

Spectroquality benzene from Matheson, Coleman and Bell was used without further purification since gas chromatographic analysis failed to show any significant impurities. Values of the density, refractive index (μ_D), and vapor pressure, determined for this material at 25 °C, were 0.87340 g cm^{-3}, 1.49777, and 95.20 Torr respectively.

The *m*-xylene (primary material also Matheson, Coleman and Bell spectroquality reagent) was purified chromatographically using a 4 in. column packed with 20% PEG 20M on Chromosorb W. At 25 °C the density of the final product was equal to 0.85988 g cm^{-3} and μ_D was equal to 1.49464.

Description of Apparatus

The vapor–liquid equilibrium was studied by the dynamical method. The equilibrium still (capacity 120 cc), shown schematically in Fig. 1, is similar to that described by Dvořák and Boublík (5). The design of the temperature chamber and separator ensures good thermal equilibrium, and stirrers in both the vapor condensate and liquid sampling vessels prevent the occurrence of density gradients.

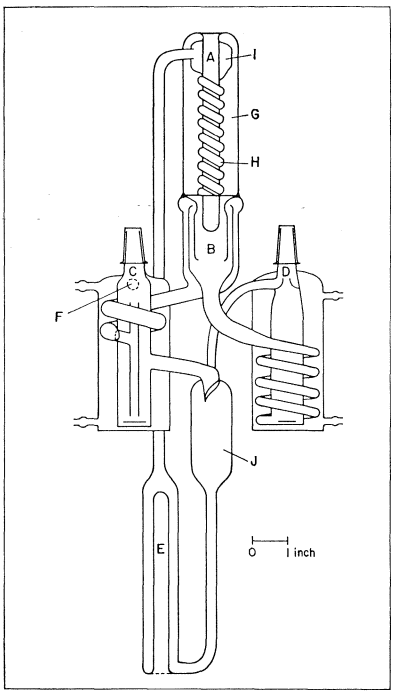

FIG. 1. Vapor–liquid equilibrium still. A, thermometer well; B, separator; C, D, vapor and liquid samplers; E, heater; F, connection to the pressure vessel; G, evacuated mantle; H, spiral tube carrying vapor and liquid from expansion chamber I to separator and ensuring good thermal contact with thermometer well; J, collector for condensate and liquid.

The still and a water ebullioscope were attached to a large pressure vessel which could be maintained at any required pressure. The equilibrium value of the pressure was calculated from the boiling point of the water in the ebullioscope. The latter could be determined with an accuracy of 0.005 °C using a standardized Leeds and Northrup platinum resistance thermometer in a Mueller bridge circuit. The temperature in the still was measured to 0.02 °C with a mercury thermometer which had been calibrated against the resistance thermometer.

Analysis

The usual methods of analysis based on density or refractive index are unsatisfactory for the present system since they would necessitate measuring relatively small differences in the values of these properties. Gas chromatography has proved to be useful in determining the compositions of benzene – alkylbenzene systems where similar conditions prevail (6) and this technique was adopted in the present investigation.

Preliminary tests indicated that an equilibrium state was reached within the still after it had been operating for about 1½ h under steady conditions. Samples of the liquid phase and vapor condensate were removed with syringes and analyses carried out using a Perkin–Elmer gas chromatograph with hot wire detector and a column containing 4% squalane on Chromosorb (G-AW-DMCS). With the output from the thermal conductivity bridge connected to an integrating recorder, the mean of 10 analyses was reproducible to 0.1 mole %. A calibration curve was established over the whole concentration range; the compositions of the equilibrium phases were then determined as the mean of 10 analyses. The overall accuracy of the compositions is estimated to be 0.3 mole %.

Results

Pressures and compositions (expressed as mole fractions x_1 and y_1 of benzene in the liquid and vapor respectively) measured for the equilibrium phases at 25, 37, and 50 °C are listed in Table I. Activity coefficients γ_i were calculated from the equilibrium data using the relation

$$[1]\quad RT \ln \gamma_i = RT \ln (y_i p / x_i p_i^0) + (B_{ii} - v_i^0)(p - p_i^0) + (1 - y_i)^2 p\delta$$

where R is the gas constant, T the absolute temperature, p the pressure of the system, and x_i and y_i are the mole fractions of component i in the liquid and vapor phases. The vapor pressure and molar volume of pure component i are denoted by p_i^0 and v_i^0 respectively. The quantity δ is related to the virial coefficients (B_{11} and B_{22}) of the pure species and to the cross term (B_{12}) between the species by the equation

$$[2]\quad \delta = 2B_{12} - B_{11} - B_{22}$$

Vapor pressures of the component liquids were calculated from the Antoine equation with values of the coefficients taken from the API tables (7). Values of the molar volumes were based on the experimental densities at 25 °C and on data at other temperatures from refs. (7) and (8). Haggenmacher's formula (9) was used to estimate values of the virial coefficients from critical data (7); the simple mixing rules outlined by O'Connell and Prausnitz (10) were adopted in the case of the cross coefficient. Table II summarizes the results of these calculations.

50.0	−1440	−2664	161

*Units: $cm^3\ mole^{-1}$.

where the constants c_j were calculated for each temperature by a least squares method with weights assigned according to estimated errors of the primary experimental data. In point of fact the values of ln γ_i were fairly small and differences between the experimental results (i.e. from eq. [1]) and those calculated from the fit of G^E (i.e. from differentiation of eq. [4]) were relatively large. The experimental accuracy did not warrant using more than one coefficient in eq. [4] and a single value of this ($c_1 = 113 \pm 19$) described the free energy behavior of the system within the limit of the experimental error over the temperature range studied. This is illustrated by the comparison of calculated and experimental values of y_1 and p given in Table I. Use of a single temperature independent coefficient in eq. [4] should not be interpreted as indicating that the excess entropy is zero but only that the temperature variation of G^E is less than the error of its determination from the present measurements.

Application of Flory's Theory

As originally presented (2) Flory's theory permits the evaluation of the excess properties of a binary system from the properties of the pure components, provided the value of one parameter, X_{12}, characterizing the interaction of unlike species in the mixture, is known. In practice this parameter is generally estimated from data for the mixture.

In our earlier work on benzene – isomeric xylene systems (1), the values of X_{12} which minimized the integral

$$[5]\quad \sigma_H^2(X_{12}) = \int_0^1 (H^E_{exptl} - H^E_{Flory}(X_{12}))^2 dx_1$$

were determined. The integrand in this equation represents the square of the difference between the experimental excess enthalpy and the value obtained from the Flory theory (see eq. 34′ of ref. (2)) for any particular value of X_{12}. Using the values of X_{12} obtained in this way for the three benzene–xylene systems, excess volumes of the right order of magnitude were calculated and the observed order meta > ortho > para was reproduced, although differences between the systems were underestimated.

The expression for the excess free energy derived by Flory (2) on the basis of an ideal combinatory entropy, is

$$[6]\quad G^E_{Flory}(0) = \sum_1^2 x_i\left[v_i^* p_i^*(\tilde{v}_i^{-1} - \tilde{v}) + 3v_i^* p_i^* \tilde{T}_i \ln\left(\frac{\tilde{v}_i^{1/3} - 1}{\tilde{v}^{1/3} - 1}\right)\right] + x_1 v_1^* \theta_2 X_{12} \tilde{v}^{-1}$$

where p_i^*, T_i^*, and v_i^* are characteristic values of the pressure, temperature, and hard-core volume per mole which can be calculated from the molar volume, coefficient of expansion, and isothermal compressibility of pure component i at a given temperature. From these the reduced volume per mole of segments $\tilde{v}_i$, and the reduced temperature $\tilde{T}_i$ are readily obtainable. At zero pressure the reduced volume per mole of segments in the solution $\tilde{v}$, and the reduced temperature defined by

$$[7]\quad \tilde{T} = (\phi_1 p_1^* \tilde{T}_1 + \phi_2 p_2^* \tilde{T}_2)/(\phi_1 p_1^* + \phi_2 p_2^* - \phi_1 \theta_2 X_{12})$$

satisfy the simple equation of state

$$[8]\quad \tilde{T} = (\tilde{v}^{1/3} - 1)/\tilde{v}^{4/3}$$

In eqs. [6] and [7] ϕ_i and θ_i are the segment fractions and site fractions which can be calculated from the relations

$$[9]\quad \phi_2 = 1 - \phi_1 = x_2/(x_2 + x_1 r_1/r_2)$$

and

$$[10]\quad \theta_2 = 1 - \theta_1 = \phi_2/(\phi_2 + \phi_1 s_1/s_2)$$

where r_i is the effective number of segments in a molecule of component i, and s_i is the mean number of contact points per segment.

As in our previous calculation it is assumed that

$$[11]\quad r_1/r_2 = v_1^*/v_2^*$$

and

$$[12]\quad s_1/s_2 = (v_2^*/v_1^*)^{1/3}$$

Using the above relations and the properties of

benzene and *m*-xylene at 25° as summarized in ref. (1) along with the value of $X_{12} = 11.51$ J cm^{-3} derived therein, the values of G^E plotted as a broken curve in Fig. 2 were calculated. These values are considerably higher than the experimental results represented by the solid curve in Fig. 2; for an equimolar solution the difference amounts to nearly a factor of 8. This may be compared with our earlier calculations (3) for benzene–cyclopentane, benzene–cyclohexane, and toluene–cyclohexane where discrepancies in the excess free energies amounting to factors of the order of 2 were found.

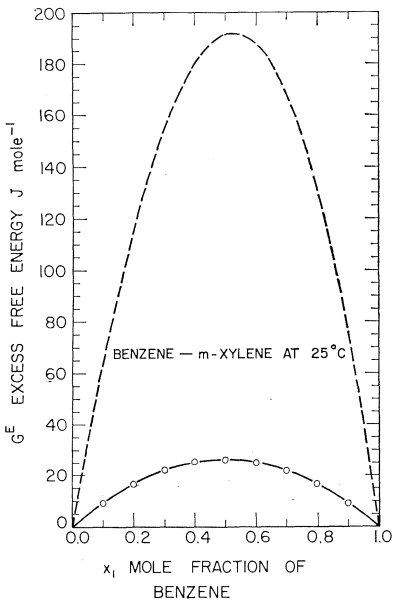

FIG. 2. Excess Gibbs free energy of the system benzene–*m*-xylene at 25 °C. Solid curve represents experimental results obtained from data for vapor–liquid equilibria. Broken curve calculated from Flory theory with $Q_{12} = 0$; the points ⊙ at 0.1 intervals in x_1 are theoretical values calculated with $Q_{12} = 0.02824$ J cm^{-3} deg^{-1}.

Recently Orwoll and Flory (4) pointed out that interaction between neighboring species can be expected to contribute to the entropy of the mixture as well as to the enthalpy. To allow for this contribution they added an empirical term containing a second adjustable parameter Q_{12} to the original free energy equation. The resulting expression

$$[13] \quad G^E_{\text{Flory}}(Q_{12}) = G^E_{\text{Flory}}(0) - x_1 v_1^* \theta_2 T Q_{12}$$

was fitted to our experimental data for G^E by minimizing the integral

$$[14] \quad \sigma_G^2(Q_{12}) = \int_0^1 [G^E_{\text{exptl}} - G^E_{\text{Flory}}(Q_{12})]^2 dx_1$$

It was found that the experimental data could be represented within the experimental error by eq. [13] using a value of $Q_{12} = 0.02824$ J cm^{-3} deg^{-1}. Values calculated in this way at 0.1 intervals in x_1 are indistinguishable from the experimental curve in Fig. 2.

In the same way the excess free energies of aromatic–alicyclic systems considered previously (3) can be fitted quite well using values of $Q_{12} =$ 0.03362, 0.04807, and 0.02675 J cm^{-3} deg^{-1} for benzene–cyclopentane, benzene–cyclohexane, and toluene–cyclohexane respectively. Thus it appears that the use of Q_{12} as a second adjustable parameter in the Flory theory leads to a useful representation of excess free energy data.

Acknowledgment

We are grateful to Mr. C. J. Halpin for purifying the *m*-xylene and for technical assistance throughout the course of this investigation.

Excess thermodynamic properties of isopropanol–*n*-decanol mixtures[1]

JASWANT SINGH[2], H. D. PFLUG[3], AND G. C. BENSON
Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received October 2, 1968

Molar excess Gibbs free energies, obtained from static vapor pressure measurements on isopropanol–*n*-decanol mixtures over the temperature range 20–50 °C, are reported. Results of direct determinations of heats and volumes of mixing at 25 °C are also presented.

Canadian Journal of Chemistry, **47**, 543 (1969)

Introduction

Previous studies of the thermodynamic properties of binary alcohol mixtures (1–5) have been continued by investigating the system isopropanol–*n*-decanol. The new measurements comprise determinations of total vapor pressures over the range 20–50 °C and of heats and volumes of mixing at 25 °C.

Experimental

(i) Vapor Pressures

Static vapor pressures for systems of known total composition and known total volume were measured with a precision quartz gauge (Texas Instruments). Details of the experimental procedure and of the method of calculating the compositions of the individual liquid and vapor phases have been described in earlier communications (3–4).

Assumptions similar to those made in ref. (3) were also adopted in the present investigation. Thus, the equation of state employed for the vapor phase was

$$[1] \qquad V^g = n^g\left(\frac{RT}{p} + B + Dp^2\right)$$

where V^g is the volume of n^g moles of material and B and D are the second and fourth virial coefficients respectively. For isopropanol vapor, Kretschmer and Wiebe (6) have found that this form is more appropriate than one involving second and third virial coefficients. In all of the vapor phases studied, the mole fraction of decanol, y_2, was small (< 0.015) and the second and fourth virial coefficients were approximated by the values for pure isopropanol. Also, since the vapor pressure of decanol was relatively small at all of the temperatures considered, the partial pressure, p_2, of decanol in the vapor phase was estimated from that of pure decanol, p_2^0, by means of the Raoult expression

$$[2] \qquad p_2 = x_2 p_2^{\,0}$$

where x_2 is the mole fraction of decanol in the liquid phase in equilibrium with the vapor.

(ii) Excess Enthalpies and Excess Volumes

The enthalpy and volume changes for mixing isopropanol with *n*-decanol were measured at 25 °C by continuous dilution techniques. The same calorimeter and dilatometer were used as in our previous studies (1, 2).

(iii) Materials

Purification of the *n*-decanol used in this investigation has been described in ref. (3). The isopropanol (Eastman Organic Chemicals) was purified chromatographically with a column containing PEG 4000 supported on Chromosorb W. Density measurements on the alcohols at 25 °C yielded values of 0.7808_6 and 0.8268_7 g cm^{-3} for isopropanol and decanol respectively.

Results and Discussion

Vapor pressures of pure isopropanol were fitted with an Antoine form of equation

$$[3] \qquad \log_{10} p\,(\text{Torr}) = 8.1838 - 1591.08/[218.028 + t\,(^\circ\text{C})]$$

The standard error of the estimate is 0.047 Torr. Values of the vapor pressure of isopropanol calculated at rounded temperatures are given in Table I along with the observed vapor pressures of decanol. The values of other properties of the pure alcohols needed for analysis of the vapor pressure measurements on mixtures are also collected in Table I. The molar volumes at 25 °C are based on the densities quoted above; the variation of the molar volumes with temperature was derived from the work of Costello and Bowden (7). Equations given by Kretschmer and Wiebe (6) were used to calculate the virial coefficients of isopropanol; this usage involved an extrapolation to temperatures 40 °C lower than investigated experimentally.

Results for the liquid–vapor equilibrium of isopropanol–decanol mixtures at 20, 25, 30, 35, 40, and 50 °C are summarized in Table II (x_1

and y_1 are the mole fractions of isopropanol in the liquid and vapor phases respectively). The activity coefficients of isopropanol in the liquid phase were calculated from the equation

$$[4] \quad \ln \gamma_1 = \ln\left(\frac{y_1 p}{x_1 p_1^0}\right) + \frac{(p - p_1^0)(B_{11} - V_1^0)}{RT} + D_{1111}\frac{(4y_1^3 - 3y_1^4)[p^3 - (p_1^0)^3]}{3RT}$$

A least squares procedure was used to fit these values with the form

$$[5] \quad \ln \gamma_1 = \frac{x_2^2}{RT}\sum_{r=1}^{n} C_r(1 - 2rx_1)(x_2 - x_1)^{r-2}$$

which corresponds to representation of the excess free energy by the relation

$$[6] \quad G^E = x_1 x_2 \sum_{r=1}^{n} C_r(x_2 - x_1)^{r-1}$$

At each temperature an adequate fit of the data by eq. [5] was obtained with four coefficients. The values of these are given in Table III along with $\sigma_{\ln \gamma}$ and σ_G, the standard errors of estimates of $\ln \gamma_1$ and G^E by eqs. [5] and [6].

Results of the calorimetric and dilatometric measurements are given in Table IV. These data are represented by the equations

$$[7] \quad H^E\,(\text{J mole}^{-1}) = x_1x_2[1183.23 - 305.38(x_2 - x_1) + 231.43(x_2 - x_1)^2 - 192.6(x_2 - x_1)^3]$$

and

$$[8] \quad V^E\,(\text{cm}^3\ \text{mole}^{-1}) = x_1x_2[0.10552 + 0.08710(x_2 - x_1) + 0.01035(x_2 - x_1)^2 - 0.01656(x_2 - x_1)^3]$$

with standard errors of 1.17 J mole^{-1} and 0.0003 cm^3 mole^{-1} respectively.

The curve for G^E shown in Fig. 1 was calculated from eq. [6] with coefficients for 25 °C taken from Table III; eq. [7] was used to construct the curve for H^E. In principle, excess entropies (and enthalpies) can be obtained from the variation of the excess free energy with tem-

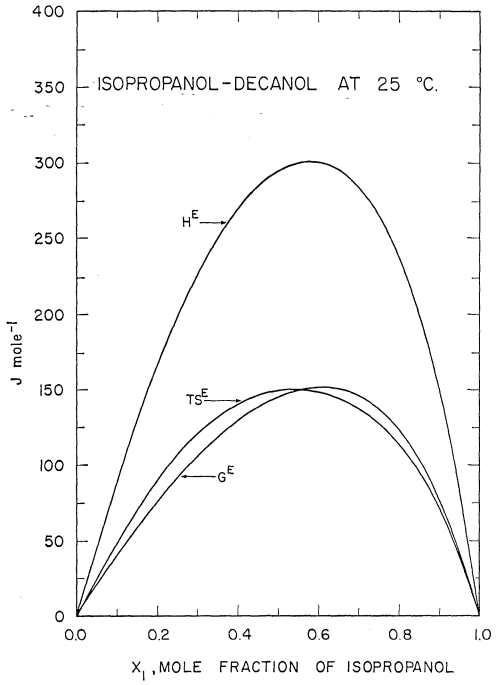

FIG. 1. Excess thermodynamic properties of isopropanol–decanol mixtures at 25 °C, G^E is derived from vapor pressures; H^E represents calorimetric results; TS^E is calculated from eq. [9].

perature. However values obtained in this way are subject to relatively large errors. For the present system, values of H^E at 25 °C calculated from the free energy data are all larger than the calorimetric results; the difference amounts to 58 J mole^{-1} for an equimolar solution. Similar discrepancies were noted for the ethanol–decanol and *n*-propanol–decanol systems (3, 4). Accordingly the TS^E curve shown in Fig. 1 was calculated from the relation

$$[9] \qquad TS^E = H^E - G^E$$

using the values of H^E measured calorimetrically.

The excess free energies of isopropanol–decanol mixtures at 25 °C are slightly lower than those of the *n*-propanol–decanol mixtures studied previously (4). However, the present heats of mixing, and as a consequence the TS^E values, are noticeably larger than those for the *n*-propanol system[4]. This suggests that the formation of the isopropanol mixtures results in the breaking of more hydrogen bonds and is accompanied by greater structural changes than in the case of *n*-propanol. On the other hand the excess volumes for isopropanol–decanol mixtures are considerably smaller than those for *n*-propanol–decanol (8) (0.026 cm^3 mole^{-1} compared to 0.089 cm^3 mole^{-1} for equimolar mixtures).

[4]In an equimolar mixture of isopropanol–decanol (at 25 °C) G^E = 145.6 J mole^{-1}, H^E = 295.8 J mole^{-1}, and TS^E = 150.2 J mole^{-1}. The corresponding values for the *n*-propanol–decanol system are 158.0, 252.0, and 94.0 J mole^{-1} respectively.

Acknowledgments

We are indebted to Mr. P. J. D'Arcy and to Mr. C. J. Halpin for invaluable technical assistance throughout the course of this investigation.

Conductance and viscosity of *n*-alkylamine hydrobromides in water at 25 °C: influence of hydrophobic hydration

JACQUES E. DESNOYERS, MARCEL AREL, AND PAUL-ANDRÉ LEDUC
Department of Chemistry, University of Sherbrooke, Sherbrooke, Quebec

Received April 30, 1968

The equivalent conductivities and viscosities of the homologous salts RNH_3Br, where R varies from H to *n*-octyl, have been measured in water at 25 °C. The data in the submicellar region can be represented adequately by the semi-empirical relations

$$\Lambda = \Lambda_0 - A_\Lambda c^{1/2} + B_\Lambda c \text{ and } \eta/\eta_0 - 1 = A_\eta c^{1/2} + B_\eta c + D_\eta c^2$$

The parameters $B_\eta{}^+$ and $\lambda_0{}^+$ are both functions of the effective size of the organic ions in solutions, while the parameters D_η and B_Λ can be interpreted through structural salting-in of the hydrophobic cations. Viscosities and conductivities can be used equally well to study the micelle formation of *n*-octylamine hydrobromide.

Canadian Journal of Chemistry, **47**, 547 (1969)

Introduction

Recent reviews (1–5) on the properties of aqueous solutions have stressed the importance of structural changes induced by the solute. Small ions attract water molecules (hydrophilic hydration), most large organic ions and molecules strengthen the hydrogen bonds of the neighboring water molecules (hydrophobic hydration), and intermediate ions break the structure of water. Much of the information on hydrophobic hydration was provided by the quaternary ammonium salts with the general formula R_4NX, since these salts are reasonably soluble in water and their hydrophobic character can be varied by changing the size and nature of the R group. The homologous salts RNH_3Br have also proven to be very informative (6, 7) since the true distance of closest approach is approximately the same with all the larger homologs, and this series goes from a relatively simple (NH_4Br) to a micellar salt (*n*-octylamine hydrobromide). These salts are therefore very useful in examining the influence of certain factors, such as association and hydration, on the concentration dependence of physico-chemical properties of electrolyte solutions.

The principal conclusion we have reached in previous studies (1, 6, 7) of the concentration dependence of hydrophobic ions is that activity coefficients, excess entropies, and volumes are ruled to a large extent by structural salting-in and salting-out effects: attractive forces (salting-in) between two hydrophobic ions and repulsive forces (salting-out) between a hydrophobic and a hydrophilic ion are induced by structural changes in water (8). The purpose of the present work is to extend these studies to viscosities and conductivities; a systematic investigation of aqueous RNH_3Br solutions, when R is lengthened, should disclose the influence of structural interactions on the concentration dependence of these properties.

Experimental

The preparation and purification of the amine salts have been described elsewhere (7). In all measurements, water was redistilled from an alkaline permanganate solution using an all-glass still and was equilibrated with atmospheric CO_2. All solutions were made by weight (molalities) and converted to molarities c from the known densities (7). These densities were also used for calculating viscosities. For the viscosity measurements the solutions were in addition filtered through a fine sintered glass disk. All measurements were made at 25.000 ± 0.003 °C.

Conductivities

The resistances were obtained with an Industrial Instrument Conductivity Bridge (model RC-18) using a Scientific Glass Apparatus cell (model E-4100-4). The platinum electrodes were platinized following the method of Jones and Bollinger (9). The cell constant was determined in the usual manner (10) from KCl solutions. Corrections were made for the conductivity of water and for the slight dependence of the resistance on frequency. As a check of the technique, the equivalent conductivity of NaCl was determined as a function of concentration. Extrapolation to infinite dilution by the method described later in the text gives a value $\Lambda_0 = 126.43$ conductance units which compares well with the value quoted by Robinson and Stokes (10) as 126.45. In general a reproducibility of 0.05 conductance units has been realized.

Viscosities

A viscometer of the Ubbelohde type, similar to the one described by Tuan and Fuoss (11), was fitted with a plexiglass jacket in which thermostated water was circulated. The instrument was supported perpendicularly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

by a steel rod mounted on a bearing system, the viscometer could thus be easily inverted to initiate a run.

The viscometer was kept wet when not in use to insure cleanliness. Whenever adsorption of impurities in capillary became noticeable, the viscometer was cleaned with alkaline ethanol solution and then with a 1:1 mixture of hot sulfuric and nitric acid. The flow time of water was 811.05 ± 0.08 s at 25 °C which indicates a reproducibility of 0.01%. To avoid errors from the formation of drops at the end of the capillary the viscometer was slanted at a fixed angle of about 7° during all measurements. The flow time correction mentioned by Kay *et al.* (12) for solutions of large organic ions was not found necessary.

The viscometer was calibrated with the equation $\eta/d = at + b/t$, where a and b are constants determined from the known densities and viscosities of water at 20, 25, and 30 °C (13). As a check, the viscosities of NaCl, KCl, NaBr, and KBr solutions were measured at 25 °C in the region 0.05 to 0.7 molar, and the relative viscosities were given by

$$\eta/\eta_0(\text{NaCl}) = 1 + 0.0060c^{\frac{1}{2}} + 0.0810c + 0.0033c^2$$

$$\eta/\eta_0(\text{KCl}) = 1 + 0.0050c^{\frac{1}{2}} - 0.0117c + 0.0015c^2$$

$$\eta/\eta_0(\text{NaBr}) = 1 + 0.0061c^{\frac{1}{2}} + 0.0458c + 0.0106c^2$$

$$\eta/\eta_0(\text{KBr}) = 1 + 0.0050c^{\frac{1}{2}} - 0.0461c + 0.0108c^2$$

The B_η coefficients are all slightly more positive than the literature values (13); this is presumably a consequence of the different methods of plotting. Still the differences are: $B_\eta(\text{NaCl}) - B_\eta(\text{KCl}) = 0.0927$ and $B_\eta(\text{NaBr}) - B_\eta(\text{KBr}) = 0.0919$ l mole^{-1}. This additivity test indicates that the B_η coefficients are probably reliable to ±0.001.

Results and Discussion

It was shown (7) that the apparent molal volumes ϕ_v of the salts RNH_3Br can be represented below the critical micelle concentration (c.m.c.) by a relation of the type

$$[1] \qquad \phi_v = \phi_v^0 + A_v c^{\frac{1}{2}} + B_v c$$

where A_v can be calculated from the limiting Debye–Huckel theory. The apparent molal volume at infinite dilution ϕ_v^0 and the parameter B_v can be obtained from a plot of $\phi_v - A_v c^{\frac{1}{2}}$ versus c. By analogy with eq. [1] we may possibly expect similar relations for Λ and η

$$[2] \qquad \Lambda = \Lambda_0 - A_\Lambda c^{\frac{1}{2}} + B_\Lambda c + \cdots$$

and

$$[3] \qquad \eta/\eta_0 - 1 = A_\eta c^{\frac{1}{2}} + B_\eta c + D_\eta c^2 + \cdots$$

Since the left-hand side of eq. [3] is not a reduced function of c, an extra term in c^2 is required to retain the analogy between eqs. [1], [2], and [3].

The conductance data is now commonly interpreted from the Fuoss–Onsager equation which bears the form

$$[4] \qquad \Lambda = \Lambda_0 - A_\Lambda c^{\frac{1}{2}} + Ec \log c + Jc$$

The term in $c \log c$ is essential for the treatment of the data in very dilute solutions, but the approximations leading to this term are not valid (10) at intermediate concentrations where most of our measurements were made. It is probably for this reason that the present data could not be fitted adequately with eq. [4] while the semi-empirical eq. [2] was applicable over most of the concentration range as it will be shown. Kay (15) has shown that the effect of the log term is to raise Λ_0 by about 0.06 conductance units; since our experimental error is about 0.05 conductance units, eq. [2] is acceptable as a basis for extrapolation.

If eqs. [2] and [3] are applicable to our system, then the parameters A_Λ and A_η must be the theoretical values predicted from the interionic theory since the Debye–Huckel theory is valid at infinite dilution. There is, therefore, no need to determine A_Λ and A_η experimentally. A plot of $\Lambda + A_\Lambda c^{\frac{1}{2}}$ versus c and $(\eta/\eta_0 - 1 - A_\eta c^{\frac{1}{2}})/c$ versus c should be essentially linear at low concentration with the slopes B_Λ and D_η and the intercepts Λ_0 and B_η respectively. It was established (7) that B_v is related to the mutual salting-in of the organic cations; the analogous parameters B_Λ and D_η can also be expected to depend on these structural salting-in effects.

Equivalent Conductivities

The equivalent conductivities have been measured[1] at 25 °C for the salts RNH_3Br where R varies from H to *n*-octyl. Since the parameter A_Λ of eq. [2] is a function of Λ_0 (10), a first approximation for Λ_0 is obtained from a plot of Λ against $c^{\frac{1}{2}}$. The parameter A_Λ is then calculated, and a better value for Λ_0 is obtained from the method of plotting described above. This procedure may be repeated as often as desired but one or two cycles were usually found sufficient to obtain reliable Λ_0. The final plots are shown in Fig. 1 and the derived parameters Λ_0 and B_Λ obtained by a least-square fit are given in Table I. The

complete curve for *n*-octylamine hydrobromide is shown in Fig. 2.

The parameters Λ_0 and ϕ_v^0 should both be functions of the effective size of the hydrated ions in solution. Near hydrophobic solutes there is little free space (7), and ϕ_v^0 (RNH_3^+) should be proportional to r^3, where r is a mean effective radius of the ion. Similarly, if Stokes law is applicable to hydrophobic ions, λ_0^+ should be inversely proportional to r. After subtraction of the Br^- contribution to ϕ_v^0 and Λ_0, ϕ_v^0 (Br^-) = 30.9 ml $mole^{-1}$ (16) and λ_0^- (Br^-) = 78.14 (10), $1/\lambda_0^+$ was plotted against the cube-root of ϕ_v^0 (RNH_3^+) in Fig. 3. Except for NH_4^+, all points fall on a straight line given by the relation

$$[5] \qquad 1/\lambda_0^+ = 0.0083\,(\phi_v^0)^{1/3} - 0.0082$$

This behavior illustrates the self-consistency of the conductivity and density measurements and indicates that both λ_0^0 and ϕ_v^0 are related to the effective size of the ions in solution. The significance of these functions in terms of hydration models has been discussed elsewhere (7, 16, 17).

The slopes B_Λ in Fig. 1 are all positive but decrease with chain length. These slopes are more difficult to interpret than Λ_0 since none of the existing theories of conductance can be considered reliable in the concentration range we are concerned with, and little correlation has been made between hydrophobic hydration and the concentration dependence of Λ. The parameter B_Λ

should be a function of Λ_0, the distance of closest approach and all other sources of deviations between the limiting Onsager theory and the experimental data. In an attempt to eliminate the dependence of B_Λ on Λ_0, *apparent* distances of closest approach $\mathring{a}$ were calculated (see Table I) assuming that the B_Λ coefficient was equivalent to the J parameter of the Fuoss–Onsager theory (14). At 25 °C

$$[6] \quad J = 0.4583\Lambda_0\left(\frac{\mathring{a}}{3.575} + \frac{\mathring{a}^2}{25.57} - \frac{\mathring{a}^3}{365.6} - \ln \mathring{a} - 0.2052\right) + 13.79 + 18.15\,\mathring{a} - 17.66\,(\ln \mathring{a} - 0.0956)$$

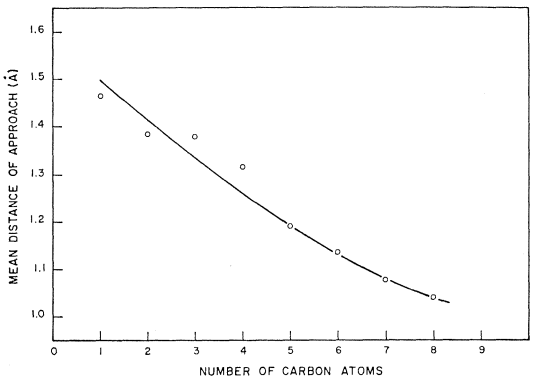

FIG. 4. Apparent distances of closest approach of *n*-alkylamine hydrobromides as a function of chain length.

The derived ion-size parameters were plotted as a function of the chain length in Fig. 4. Similar $\mathring{a}$ and trends are also obtained if other extensions of the Onsager theory, such as those mentioned by Robinson and Stokes (10), are used[2].

As a first approximation, the true distance of closest approach of this homologous series should be constant, since, except for the lower members, the hydrophilic hydration of the $-NH_3^+$ group is similar. As seen from Fig. 4, the apparent distances of closest approach, on the other hand, decrease markedly with chain length and reach unrealistically low values. The same observations have been made by Evans and Kay (17) in their study of symmetrical quaternary ammonium salts; all values of $\mathring{a}$ are of the order of 1 Å, but while the ion-size parameters increase with the size of the cations R_4N^+ with the chlorides, they remain approximately constant with the bromides and decrease with the iodides.

Evans and Kay (17) attribute the anomalous $\mathring{a}$ to some type of ion association. Levien (18) and Evans and Broadwater (19) reach similar conclusions. We prefer to interpret the small size of $\mathring{a}$ and its variations with the size of the cations to structural attractive and repulsive forces. In a recent review (1), it was shown that structural salting-out predominates between strong hydrophobic cations (large R_4N^+) and strong hydrophilic anions (F^- and Cl^-), while structural salting-in of hydrophobic cations is observed when the anions are only weakly hydrophilic (I^-). The data of Evans and Kay is in complete agreement with this model; with R_4NCl structural salting-out causes $\mathring{a}$ to increase with the size of the cations (with the fluorides the effect should be even more pronounced), while with R_4NI the influence of I^- is small and structural salting-in between R_4N^+ ions is observed. The structural salting-in is larger with the larger cations and for the same reason $\mathring{a}$ is smallest with (*n*-butyl)$_4$NI. Therefore structural salting-in causes a decrease in $\mathring{a}$ and structural salting-out causes an increase. The results with the RNH_3Br salts are also consistent with this model. The Br^- has little effect, and, as the chain increases in length, the hydrophobic character increases and so does the mutual structural salting-in between the cations. This is

[2]It has been pointed out by one of the referees that it is incorrect to compare the $\mathring{a}$ parameters obtained from the Fuoss–Onsager theory with those from any other theory which neglects the c log c term. We have verified this by fitting Λ of $MeNH_3Br$, $EtNH_3Br$, and *n*-$BuNH_3Br$, where sufficient data below 0.01 molar are available, with the Fuoss–Onsager equation. The derived $\mathring{a}$ parameters are respectively 2.8, 2.5, and 2.4 Å compared with the values 1.47, 1.38, and 1.32 Å of Table I. These new values are closer to but still lower than the expected distance of closest approach. In addition, they still decrease as the length of the hydrophobic chain increases. Therefore the conclusions reached in this paper are to a large extent independent of the equation used to obtain $\mathring{a}$.

It should be noted also that the Λ_0 parameters obtained from the Fuoss–Onsager equation, using the data below 0.01 molar for the above salts, are all as expected, larger than the Λ_0 of Table I by a factor which varies between 0.05 to 0.2 conductance units. Because of the larger uncertainty in the data below 0.01 molar we prefer to use the Λ_0 derived from eq. [2] for the study of trends in this homologous series.

reflected in a decreasing $\mathring{a}$. The conductance data of trialkyl sulfonium iodides in water (19) can also be interpreted in a similar way.

Structural salting-in is an attractive force between hydrophobic solutes and may lead to association as a limiting case, e.g. micelle formation, hydrophobic bonding (20). However, as evidenced from the concentration dependence of ϕ_v for RNH_3Br salts (7), structural salting-in may occur without association. Therefore, an abnormal decrease in the ion-size parameter of hydrophobic solutes may be taken as an indication of predominance of attractive forces over the long-range coulombic forces but does not necessarily mean association. With the ϕ_v of hydrophobic solutes, structural salting-in and association act in opposite direction. Unfortunately, in the case of conductance, both have similar effects. For example, association is clearly indicated in the case of *n*-octylamine hydrobromide above the c.m.c. (Fig. 2). Therefore much caution should be taken before interpreting as association negative deviations from the Onsager or Fuoss–Onsager theories when hydrophobic solutes are involved.

Structural effects such as structural salting-out and salting-in are very pronounced with large quaternary ammonium salts. They are also present to a lesser extent in all aqueous electrolyte solutions (1, 21). It therefore seems of little value to attempt interpreting quantitatively the concentration dependence of Λ in water unless structural effects are taken into account.

The present method of plotting equivalent conductivities is very useful for the study of micelle formation. Usually Λ is plotted as a function of $c^{\frac{1}{2}}$ and a slight change in slope is seen at the c.m.c. In Fig. 2, the range over which a micelle is formed is very well defined and corresponds closely to that obtained from density measurements (7).

Viscosities

The viscosities of the homologous series have been measured at 25 °C and are plotted as a function of concentration in Figs. 5 and 6. The parameter A_η was calculated from Falkenhagen's theory (13) using the above λ_0^+ and λ_0^-. The derived parameters B_η and D_η are given in Table IV.

Most works on electrolyte theories have neglected the D_η term of eq. [3]. The reason is that the method of plotting the data, $(\eta/\eta_0 - 1)/c^{\frac{1}{2}}$ versus $c^{\frac{1}{2}}$, does not reveal this term at low concentration. With a correction for the A_η term the ordinate in Figs. 5 and 6 becomes analogous to the reduced viscosity used with polymer solutions and more confidence can be given to the B_η coefficient; the D_η coefficient is obtained at the same time from

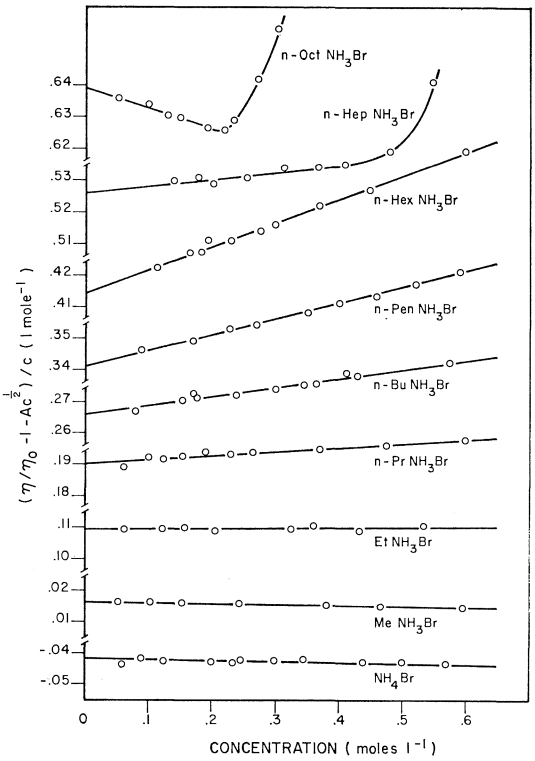

FIG. 5. Viscosities of *n*-alkylamine hydrobromides in water at 25 °C.

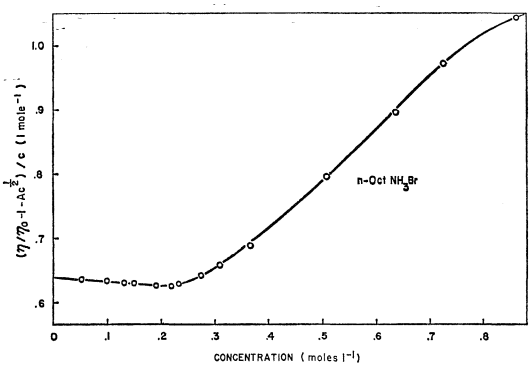

FIG. 6. Viscosity of *n*-octylamine hydrobromide in water at 25 °C.

the slope. The B_η coefficient should be proportional to the effective size of the ions (13). A straight line (or smooth curve) is therefore expected if B_η is plotted against ϕ_v^0. As seen from Fig. 7 a linear relation given by

$$[7] \qquad B_\eta = 4.9\ \phi_v^0 - 0.03$$

is observed except for the two highest homologs; these two salts fall above the line. This break is unexpected since it was not observed in Fig. 3. The anomaly with *n*-heptylamine and *n*-octylamine hydrobromides is even more obvious when the D_η parameters are examined in Fig. 5 and Table II; the slopes increase in a regular fashion except for the two higher homologs. To elucidate this irregularity, the viscosities of the symmetrical salts R_4NBr were examined (22) and D_η was found to increase in a regular way with the size of the cation. Therefore hydrophobic hydration seems to give a positive contribution to D_η. This would indicate that the behavior of B_η up to *n*-hexylamine hydrobromide is normal and reveals the presence of structural salting-in.

Ion association cannot be responsible for the behavior of *n*-heptylamine and *n*-octylamine hydrobromides since association causes an increase in viscosity as witnessed by the micelle formation in Fig. 6. A more plausible explanation is that the flow becomes non-Newtonian when the chain reaches a certain length. An attempt was made to verify this hypothesis by repeating the viscosities of these salts with a viscometer with a shorter flow time. Unfortunately the experimental error was larger with this viscometer and the results were not conclusive. Measurements with a very sensitive Couette type viscometer would possibly solve this dilemma. Until such measurements are made available, the data for these two salts must be considered doubtful. They are still included since the anomaly before the c.m.c. does not seem to affect the determination of micelle formation and good agreement is found between Figs. 2 and 6.
