Since neither water nor tert-butyl alcohol has large molecular moments, the high dielectric constants of these substances in the pure state arise because the short-range association forces favor molecular orientations which lead to cooperative reinforcement of dipole fields. This is expressed by Kirkwood (40) in terms of a correlation parameter, g, which has, in such cases, a value greater than unity. The value of this parameter in the Onsager model is considered by Kirkwood to be equal to unity, since in this model only the effect of electrostatic forces on hindered rotation was taken into account. For normal liquids, devoid of specific, short-range association forces, $g = 1$, and the interaction between a dipole molecule and its surroundings is then similar to that which would exist if the surroundings were replaced by material of the same macroscopic dielectric constant (41). Therefore, one may have the opinion that since the Onsager equation is derived on such a basis for which $g = 1$, or on the assumption that hydrogen bonding is purely electrostatic in nature, which is hardly acceptable (42), the application of our equation of polar solutes in polar solvents to any system for which g exceeds unity would be as inappropriate as the application of Debye's equation to any associated liquid. According to this view, the success of our equation can be regarded as only coincidental in those cases where it affords the correct result.

Our measurements (Table III)[1] and those of others (43) show a tremendous reduction of the dielectric constant of tert-butyl alcohol in the pure state with increase of temperature. Dannhauser and Cole (43) associate this with a rapid fall in g towards 1, arising from a decrease in the mean chain length. That the addition of water to tert-butyl alcohol at 30 and 40 °C should initially cause a reduction of the dielectric constant, i.e.

$$\lim (d\varepsilon_{12}/dC_2)_{C_2 \to 0}$$

is negative (Table I), is reflected in a failure of the modified form of Onsager's equation. Associating this reduction of dielectric constant with a rapid fall in the Kirkwood g-factor of the alcohol, the effect of added water at each of these two temperatures is apparently the same as a shift towards higher temperature in the pure alcohol. The fact that, when water is dissolved in the alcohol at 50 °C, the dielectric constant of the solution increases as expected and

$$\lim (d\varepsilon_{12}/dC_2)_{C_2 \to 0}$$

is sufficiently positive to give the right dipole moment (Table I) may lead one to suggest that perhaps g has become effectively unity between 40 and 50 °C. The fall in the g value of tert-butyl alcohol on the addition of water at 30 and 40 °C may be explained by assuming that the association which occurs between solute and solvent molecules involves complexes long-lived enough to be oriented as polymeric units in response to the low-frequency field, and thus the dielectric constant is reduced. When the temperature is raised to 50 °C the complexes formed are probably very short-lived, so that they cannot contribute directly to the static dielectric constant by orientation as molecular entities and, consequently, the observed increase of the dielectric constant can be accounted for. Also as a consequence of the short-lived complexes in this system at 50 °C, the interactions involved may be regarded as effectively smeared out into spherical symmetry, and then the dipole-in-a-cavity model or the modified form of Onsager's equation for a polar solute in a polar solvent becomes appropriate. This means that the short-range intermolecular forces are perhaps much less important at 50 than at 30 or 40 °C.

On the other hand, the observed decrease of the dielectric constant of *n*-butyl alcohol on the addition of acetone at 30 to 50 °C or the negative value of $\lim (d\varepsilon_{12}/dC_2)_{C_2 \to 0}$ (Table I), which is also reflected in a failure of the equation, may be

[1]Detailed tables of original data have been deposited with the Depository of Unpublished Data, National Science Library, National Research Council, Ottawa, Canada. Photocopies are available free of charge, on request to the Depository.

explained by assuming that acetone probably serves to reduce the high Kirkwood *g*-factor of *n*-butyl alcohol (2.6 at 30 °C) by chain termination.

It may therefore be thought that the modified form of Onsager's equation can usefully define limiting cases, but must fail when short-range interactions assume predominant importance. The fact that this relationship still holds so well for those cases which are also complicated hydrogen-bonded systems is, however, far from clear.

Kinetics of the anation reaction of nickel(II) and 1,10-phenanthroline in methanol–water mixtures

M. L. SANDUJA AND W. MACF. SMITH
Department of Chemistry, Queen's University, Kingston, Ontario
Received May 22, 1969

The kinetics of formation of the monophenanthroline complex of nickel(II) has been studied spectrophotometrically in water–methanol mixtures of 0 to 97 weight % of methanol, at ionic strength 0.050, at varying acidities at 25 °C. Values for the rate constants for the acid independent and acid dependent reactions together with values for the equilibrium acid ionization quotient of phenanthrolium ion over the range of solvent mixtures have been determined. The values of the acid independent rate constant show little dependence on solvent compositions up to 76% methanol, then decrease and show no correlation with trends in the ionization quotient of phenanthrolium ion. The acid dependent rate constant shows only a modest dependence on solvent composition over most of the range of solvent compositions except in the range of highest methanol content where it is not significantly different from zero.

Introduction

Investigations of anation reactions of metal ions in mixed solvents are understandably sparse. A variety of cationic species with different compositions for the inner solvation sphere are present in mixed solvents and quantitative assessment of data consequently difficult. However, trends in kinetic behavior which could be correlated even semi-quantitatively with trends in solvent properties and the populations of solvated species may point out features which studies in single solvents would miss. With this approach we have examined the reaction of nickel(II) with 1,10-phenanthroline in methanol–water mixtures over a wide range of compositions and over a range of low acidities. To permit interpretation of our primary data we have also obtained values for the equilibrium acid ionization quotient for phenanthrolium ion at ionic strength 0.050 and the same range of solvent compositions involved in the kinetic measurements.

Pearson and Ellgen (1) have examined the reaction of nickel(II) with bipyridine in methanol and in methanol–water mixtures containing up to 25 volume % of water and also the reaction of nickel(II) with 1,10-phenanthroline in 100 % methanol. Their results support the view that the mechanism in methanol is the same as that operative in water, i.e., that the rate controlling step is solvent loss from the inner solvation sphere of nickel ion, which is part of an outer sphere complex involving the metal ion and the potential ligand. On the basis of the "ion-pair interchange" mechanism, if the concentration of outer sphere complexes (ion-pairs) is small compared to the concentrations of the unassociated metal and species L, the expression for the rate of reaction should be

$$[1] \qquad -\frac{d}{dt}[NiL^{2+}] = k_o K_o [Ni^{2+}][L] \doteq k_f [Ni^{2+}][L]$$

where K_o is the association constant for outer sphere complex formation and k_o is the first order rate constant for reorganization of the outer to the inner sphere complex. The data for reactions in water (2) and in methanol (1) support the view that k_o is nearly independent of ligand type and proportional to the rate constant for solvent loss from the solvated Ni(II) species. Pearson and Ellgen found that in solution containing 3 volume % of water the rate constant of the reaction with bipyridine was about 3 times that in pure methanol, and attribute this increase to an increase in the effective value of k_o, which is associated with enhanced values of solvent loss from each of the partly aquated nickel ion species, $Ni(CH_3OH)_{6-x}(H_2O)_x^{2+}$, present.

Our choice of phenanthroline as ligand was determined largely by experimental convenience. The association constant for the monocomplex with nickel(II) is high and reaction proceeds essentially to completion under all conditions of this work. Also, the concentration of free phenanthroline, which is kinetically much more active than phenanthrolium ion, may be held at low values by maintaining moderate values for the hydrogen ion concentration and consequently the rates of reaction can be reduced to the range measurable by conventional techniques. On the

For personal use only.

other hand, there are possible complications in interpretation because of the rather complex dependence of overall rate constant on hydrogen ion concentration (3) and of the bidentate nature of the monocomplex. We have obtained values for the acid independent rate constant by simple extrapolation and have followed Wilkins and co-workers (4) in assuming that the rate determining step in the acid independent reactions is the formation of the monodentate intermediate.

Experimental

All substances used were of reagent grade (G. F. Smith or Fisher). Reagent grade methanol was distilled using a Widmer column and the center cut, along with triply distilled water, used in preparing the solutions. All solutions involving methanol were prepared freshly on the day of the determination.

The kinetic measurements were made spectrophotometrically with stop-watch timing. The concentrations of nickel(II) ranged from 2×10^{-2} to 2×10^{-3} M, that of total phenanthroline from 2×10^{-4} to 2×10^{-5} M. In most runs the concentration of nickel(II) was 2×10^{-3} M, that of phenanthroline 2×10^{-5} M. Solutions of the two reactants, adjusted to the appropriate acidity and ionic strength, were ejected from thermostatted syringes into a 5 cm optical cell thermostatted in a DK–1 spectrophotometer and the variation with time of the absorbance at λ310 mμ recorded. At the wavelength λ310 mμ the essential absorbing species are phenanthroline, phenanthrolium ion, and the monocomplex. The extinction coefficient of the complex is substantially less than that of phenanthrolium ion, which constitutes over 99% of the uncomplexed phenanthroline in all solutions, and a substantial decrease in absorbance occurs as reaction proceeds. The overall change in absorbance for reacting solutions of given initial concentration of nickel and total phenanthroline was independent of acidity in each solvent medium, in accord with the assumption of substantially complete transformation of phenanthroline to the complex. As the nickel(II) concentration was in 100-fold excess over that of phenanthroline, the reaction was pseudo first order and the slope of the plot of log $(D - D_\infty)$ against time is identifiable with

$$[2] \qquad -k_f \frac{[\mathrm{Ni}]_0}{2.303} \frac{Q_a}{Q_a + [\mathrm{H}^+]}$$

where D represents the optical density of the solution, k_f is the value of

$$-\frac{d}{dt}[\mathrm{Niphen}^{2+}]/[\mathrm{Ni}^{2+}][\mathrm{phen}]$$

where [phen] represents the concentration of the free base phenanthroline and Q_a is the equilibrium acid ionization quotient of phenanthrolium ion.

Q_a was determined electrometrically using a radiometer pH meter 4. Solutions containing known concentrations of phenanthroline and phenanthrolium perchlorate adjusted to appropriate ionic strength were assessed for hydrogen ion concentration in cells involving an aqueous calomel and a glass electrode using the techniques developed by Grunwald and co-workers (5). Calibration curves relating E_{cell} with $-\log [H^+]$ were prepared using solutions of perchloric acid adjusted to the same ionic strength as the test solutions. The slopes and associated standard errors of the plots of E_{cell} against $-\log [H^+]$ at 25 °C for solutions containing 45, 54.2, 75.94, 87.0, and 97.0 weight % methanol were, respectively, 0.0589 ± 0.0017, 0.0585 ± 0.0003, 0.0586 ± 0.0003, 0.0590 ± 0.0013, 0.0591 ± 0.0001 V (per pH_c). Extrapolation of these curves by at most 1.4 units of $-\log [H^+]$ was necessary to attain to the values of E_{cell} developed by the phenanthroline solutions. The slopes of the plots of E_{cell} vs. $-\log [H^+]$ in this region were assessed using benzoic acid – sodium benzoate buffers and for solutions with methanol content in the solvent of 54.2 and 75.94 weight % the slopes were 0.0583 ± 0.0005 and 0.0588 ± 0.0004. For the solutions of higher methanol content the ratio [phenanthrolium ion]/[phenanthroline] was assessed spectrophotometrically as well as from "make-up" compositions and the two values agreed to within 1.5%.

The concentration of $[H^+]$ for the kinetic experiments was estimated from "make-up" composition and the values checked with electrometric measurements. Agreement was within ±2%.

Results and Discussion

Values for the rate constant k_f were assessed as indicated above using plots of log $(D_\infty - D)$ against time and relation [1] The results are displayed in Fig. 1. Over the range of acidity investigated, the values of the rate constant k_f increase linearly with the concentration of hydrogen ion.

We consider that the intercept at $[H^+] = 0$ of the line of regression through the points is the value of the rate constant (k_f^0) of the reaction involving phenanthroline as the free base. Our value for k_f^0 for 100% water is 4.2×10^{-3} $\mathrm{mole}^{-1}\,\mathrm{l}\,\mathrm{s}^{-1}$ which compares favorably with the value 3.9×10^{-3} obtained by Wilkins and co-workers (4) by stop-flow methods using solutions near neutrality, where the phenanthroline was present almost entirely as the free base.

Values for the acid independent rate constant k_f^0, for the slopes (S) of the lines of regression, and for the equilibrium acid ionization quotient Q_a for phenanthrolium ion are presented in Table I. The trend in the values of Q_a is notable, the values rising sharply over the range of methanol content 35 to 54 weight % and dropping substantially in the highest range of methanol content.

Over the range where the values of Q_a are rising fairly sharply the slopes (S) are undergoing a sharp decrease. As emphasized below, this de-

§From ref. 1.

crease in slope may be directly related to the rise in Q_a and need not imply any marked change in kinetic features of the acid dependent path of this reaction. The values k_f^0 deviate only slightly from constancy for solutions of methanol content from 0 up to 76%. For methanol content greater than 76% there is a significant but not marked decrease in the value of k_f^0. Our value of 1.7×10^3 for solutions 97% in methanol (at ionic strength 0.05) is nearly five times greater than the value 0.35×10^3 determined by Pearson and Ellgen (1) for 100% methanol solution and ionic strength 0.20. A corresponding though not so marked increase in rate constant was observed by Pearson and Ellgen for the reaction between nickel(II) and bipyridine.

Our data for a given solvent mixture may be formally systematized in terms of two parallel reaction paths

$$Ni^{2+} + phen \xrightarrow{k_f^0} Ni\,(phen)^{2+}$$

$$Ni^{2+} + Hphen^{+} \xrightarrow{k_f^1} Ni\,(phen)^{2+} + H^{+}$$

with

$$\frac{d}{dt}[Niphen^{2+}] = k_f^0[Ni^{2+}][phen] + k_f^1[Ni^{2+}][Hphen^{+}] = \left(k_f^0 + k_f^1 \frac{[H^+]}{Q_a}\right)[Ni^{2+}][phen]$$

$k_f^0 + k_f^1[H^+]/Q_a$ is identifiable with k_f, so the slope of the plot of k_f against $[H^+]$ is k_f^1/Q_a or $k_f^1 = Q_a \times$ slope.

The values of $Q_a \times$ slope $(= k_f^1)$ are also included in Table I. It may be noted that the change in the values of k_f^1 over the range 34 to 59% methanol, over which Q_a is changing markedly, is small. There does seem to be a significant decrease of k_f^1 for solutions of higher methanol content, although the small magnitude and the wide confidence limits of the slope prevent precise estimates of k_f^1. Indeed for solutions with methanol content 87 and 97%, the slight positive slopes of the lines of regression on the graph are not significant.

The essential features of the kinetic results in the table are: *a*, near independence of k_f^0 on solvent composition over the range 0 to 76% methanol followed by a significant decrease in value as the water content is further decreased, with the effect of the removal of the last few % of water being quite pronounced; *b*, values for k_f^1 which rise to a significant but not pronounced maximum in the region of 35% methanol content and which are substantially less than those of k_f^0 by a factor of about 10^{-3} except in the solvents of highest methanol content where the values drop markedly and are not significantly different from zero.

If the "ion-pair exchange" mechanism applies over the entire range of solvent compositions, the near constancy of k_f^0 over the range 0 to 76 weight % of methanol could be the consequence of the effective values of K_0 and k_0 remaining constant or of compensating change in each. Pearson and Ellgen (1) suggested that with uncharged ligands K_0 should be approximately the same in water and in methanol. The fact that the ratio of the values of k_f^0 for the nickel phenanthroline anation in water and in methanol is about 11/1 (3, 1) and the ratio of the rate constants for solvent exchange from nickel(II) ions in the two solvents is about 30/1 (6, 7) may be taken as at least consistent with this view. K_0 relates to an essentially physical process which should not be sensitively dependent on the exact composition of the solvation sphere, and it may be expected that there would be little change in the values of K_0 in the mixed solvents from the values in the pure solvents. Consequently one may consider the variation in k_f^0 as paralleling the variations in k_0.

On this basis our data imply that the effective rate constant for transformation of the various nickel(II)–phenanthroline outer complexes (various because of the variety of the solvation spheres of nickel(II)) in solvents up to 76% by weight methanol stays very close to that of fully aquated nickel(II) ion in 100% water solvent. On the other hand, our data, along with that of Pearson and Ellgen for behavior in 100% methanol, imply close to a 5-fold drop in k_0 as the water content of the solvent decreases from 3 to 0 %, whereas the decrease in water content from 100 to 3% yields a somewhat smaller relative decrease. Reliable data on the nature of the solvated nickel(II) species in methanol–water are not available but Luz and Meiboom (8) were able to assess the population of various cobalt(II) species in such solvent mixtures at −60 °C. In 97%

methanol the predominant species appear to be $[Co(CH_3OH)_5(H_2O)]^{2+}$ and $[Co(CH_3OH)_6]^{2+}$ with the former constituting about 2/3 of the total cobalt(II). At 87% methanol the predominant species are the mono-, bi-, and tri-aquated cobalt(II) ions with the bi-aquated form in the highest concentration. Our data imply that k_f^0 and presumably k_0 for the reaction of nickel(II) with phenanthroline in solvents of methanol content 97 and 87% have values about 2/5 and 2/3 the values in 100% water. In the absence of quantitative information about the distribution of solvated nickel(II) species it is not possible to make worthwhile quantitative interpretations, but if one assumes that the distribution of nickel(II) species very roughly approximates that of cobalt(II) species in methanol–water mixtures at −60 °C, it is apparent that the effective value of k_0 for the mono- plus bi-aquated species would be close to 2/3 the value for the fully aquated ions.

An acceptable mechanism for the acid dependent contribution to the reaction must explain the trends in k_f^1 with solvent composition summarized above and also the decrease in the slope of the plot of k_f against $[H^+]$ at high concentrations of H^+ which, though not implied by our data, does occur (3). A mechanism explaining the fall-off in slope at higher hydrogen concentrations could involve Ni^{2+} and $Hphen^+$ yielding a monodentate intermediate, Ni—$phen^{2+}$, which becomes involved significantly in the reverse reaction with H^+ only at high hydrogen ion concentrations. If the mechanism is of the "interchange" rather than the "dissociative" type (9), the outer sphere ion pairs which collapse to give the intermediate would be collision complexes of short life involving the normally solvated nickel(II) species and $Hphen^+$. The Fuoss relation (10), while admittedly not applicable for precise quantitative calculations, should give approximate indication of the magnitudes of K_0 and of the value of the ratio (K_0 for Ni^{2+} and $Hphen^+$)/(K_0 for Ni^{2+} and phen). This ratio should *decrease* with increase in methanol content of the solvent, and for essentially aqueous solution at ionic strength 0.050 and a distance of closest approach of 5 Å, would be of the order of 1/10 rather than 1/1000 which is the value suggested by the observed ratio of the rate constants and a simple ion-pair interchange mechanism in which the rate controlling step in bidentate complex formation is the formation of the monodentate intermediate. Taken along with the observed increase in the value of k_f^1 with increase in methanol content in the range 0 to 35% methanol, this suggests that a simple ion-pair interchange mechanism in which the overall rate of reaction is effectively that of collapse of the ion-pair with a rate constant approximating that for solvent loss from nickel(II) ions is not applicable to the acid dependent reactions.

It seems possible that the low values of k_f^1 are associated with a mechanism involving a protonated monodentate intermediate which (unlike the unprotonated monodentate intermediate at low acidities) reverts to reactants much more rapidly than it converts via a deprotonated intermediate to the bidentate product, e.g. $k_{-1} \gg k_2$ in the scheme

$$Ni^{2+},phenH^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ni\text{-}phenH^{3+} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Ni{-}phen^{2+} + H^+ \rightarrow Ni{<}phen^{2+}$$

where $Ni^{2+},phenH^+$ represents the ion-pair and $Ni{<}phen^{2+}$, the bidentate complex. Steric resistance to the formation of a monodentate intermediate involving the rigid monoprotonated phenanthroline might be expected. However, there appears to be no positive evidence which precludes the formation of such a species which might involve the ligand bent back from the nickel with a strained bond to the one coordinating nitrogen. Moreover, the relatively low values for the acid dissociation rate constants of amines (11) suggest that the assumption that $k_2 \ll k_1$ is reasonable. If the step with rate constant k_2 is the slow step then general base catalysis may be anticipated, but our data are too restricted to allow reliable assessment of this implication.

Perhaps the most pertinent of our findings about the acid dependent reaction is that its contribution to the overall reaction appears to approach insignificance in the most methanolic solvents. This may be taken to imply that the reactivity of phenanthrolium ion with the solvated

nickel(II) species decreases much more sharply than does that of phenanthroline as the water of the solvent becomes the minor component. The decrease in K_0 for the nickel(II)–phenanthrolium ion-pair with increase in methanol content could contribute to such a decrease. The precision of the values for k_f^1 in the highly methanolic solvents is too low to permit judgment as to whether the drop in k_f^1 is too great to be explicable on this basis.

Crystal structures of $NaNiIO_6$, $NaMnIO_6$, and $KMnIO_6$

I. D. BROWN

Institute for Materials Research, McMaster University, Hamilton, Ontario

Received May 16, 1969

$NaNiIO_6$ (a = 4.962, c = 5.148 Å, space group $P312$) is shown from X-ray powder patterns to be isostructural with trigonal $KNiIO_6$. Approximate coordinates for the oxygen atoms are given. $NaMnIO_6$ (a = 4.972, c = 5.136 Å) and $KMnIO_6$ (a = 5.009, c = 6.000 Å) are probably also isostructural but the broadening of the X-ray powder lines in these compounds makes a complete analysis impossible. Powder patterns for all three compounds are given.

$KNiIO_6$ and $NaNiIO_6$ were first prepared by Rây and Sarma (1). More recently Reimer and Lister (2) have characterized the manganese analogues and have shown by means of X-ray powder diffraction patterns that they are isomorphous with the corresponding nickel complexes. Also using X-ray powder diffraction, Vannerberg and Blockhammar (3) and Eddy and Vannerberg (4) have shown that $KNiIO_6$ consists of hexagonal sheets of linked NiO_6 and IO_6 octahedra with the potassium atoms lying in the octahedral holes between the sheets.

The samples used in this work were those prepared by Reimer and Lister (2). All four complexes are highly insoluble in water and it was not possible to obtain crystals large enough for a single crystal X-ray diffraction study. Consequently, X-ray powder patterns of each compound were recorded using a Philips horizontal diffractometer equipped with a focusing LiF monochromator. Filtered copper radiation was used throughout. The powder pattern of $KNiIO_6$ agreed with that observed by Vannerberg and Blockhammar (3). The powder patterns of the other three compounds could be indexed by assuming that they were isostructural. The crystal data, which were refined by least squares analysis, are summarized in Table I and the diffraction patterns are given in Tables II and III. Both the nickel complexes gave diffraction patterns which could be indexed out to high angles, but the lines in the manganese complexes were very broad and weak and could not be recorded much beyond a Bragg angle of 30 or 40 degrees. However, enough was visible to confirm that their unit cells were almost identical to the corresponding nickel complexes. The cause of the broadening of the lines was not examined but the fact that the degree of broadening was roughly proportional to the l index suggests that the crystals in the sample were 00.1 plates about 150 Å in thickness.

The diffractometer was used to record integrated intensities from the $NaNiIO_6$ sample in

reflection. An estimated standard error (σ) was assigned to each measurement and the data were corrected for the Lorentz effect and the polarization occurring in both the sample and monochromator. The structure of $NaNiIO_6$ was assumed to be the same as that of $KNiIO_6$. Models in which the Ni and I atoms were in turn placed in 1(a) gave considerably worse agreement. Unfortunately, in the space group $P312$, which Vannerberg and Blockhammar (3) found for $KNiIO_6$, only those reflections with either h, k, or l equal to zero can be measured unambiguously. The intensities measured for the remainder were the sum of the intensities of the hkl and $hk\bar{l}$ reflections which are not equivalent. Consequently, the initial refinement involved only the use of the $h0l$ and $hk0$ reflections. The position of the oxygen atom was chosen to give reasonable bond distances (Na—O = 2.4 Å, Ni—O = 2.1 Å, I—O = 1.9 Å), and the scale and individual isotropic temperature factors were varied in a least squares refinement which minimized the sum of the squares of the differences between the observed and calculated structure factors, F_o and F_c, respectively, weighted according to the estimated standard errors. The resulting weighted agreement index (R) was 0.14 and an application of the χ^2 test, using the estimated standard errors as a measure of the expected deviation in individual measurements, led to a probability[1] $P(\chi^2)$ of 5%. The scale, isotropic temperature factors, and the coordinates of the oxygen atom were then refined, at each stage the values of $F_o(hkl)$ and $F_o(hk\bar{l})$ being chosen so that $F_o^2(hkl) + F_o^2(hk\bar{l})$ agreed with the observed intensity and $F_o(hkl)/F_o(hk\bar{l})$ was the same as $F_c(hkl)/F_c(hk\bar{l})$ for the previous round. After several rounds, no further significant changes occurred, R was equal to 0.105 and $P(\chi^2)$ was equal to 76%. The final set of parameters is given in Table IV.

The results of this study are not, unfortunately, as accurate as could be wished. All four compounds appear to be isostructural but the broad lines in the powder patterns of $KMnIO_6$ and $NaMnIO_6$ do not permit refinement of their structures. The refinement of the structure of $NaNiIO_6$ leads to temperature factors which are rather small, two being negative, although not significantly so. The Ni—O and I—O distances, whose errors are estimated to be at least 0.13 Å, do not differ significantly from the values found in $KNiIO_6$ (Table IV) nor does the Na—O distance differ significantly from the value of 2.35 Å expected from the sum of the crystal radii (5). As was observed by Vannerberg and Blockhammar (3), the X-ray diffraction analysis shows no sign of the water which has been found in the chemical analyses of all these complexes. It can be assumed that since the crystallites composing the sample are very small, the water is adsorbed onto the crystal surfaces and is not true water of crystallization.

Gas phase radiolysis of hydrogen chloride, hydrogen bromide, and nitrous oxide with intense electron pulses[1]

C. WILLIS AND A. W. BOYD
Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

AND

D. A. ARMSTRONG
Department of Chemistry, University of Calgary, Calgary, Alberta

Received June 11, 1969

Hydrogen chloride and hydrogen bromide have been irradiated with single electron pulses at a very high intensity (10^{27} eV g^{-1} s^{-1}) with a Febetron 705. At room temperature the yields of hydrogen from hydrogen chloride and hydrogen bromide, for pressures between 700 and 1200 Torr, are $G(H_2) = 8.1 \pm 0.2$ and $G(H_2) = 9.9 \pm 0.3$, respectively. These are the same as the yields observed at low dose rates. Detailed lifetime calculations, however, show that the mechanism is significantly different at the higher dose rate. Scavenger experiments with chlorine in hydrogen chloride show that the negative ion intermediates form thermal hydrogen atoms.

The value of $G(N_2) = 12.4 \pm 0.2$ from nitrous oxide at a dose rate of 10^{27} eV g^{-1} s^{-1} is confirmed and the use of nitrous oxide as a dosimeter for pulsed electron beams is discussed. The higher nitrogen yield at Febetron dose rates appears to be due to changes in the reactions of electrons.

Canadian Journal of Chemistry, 47, 3783 (1969)

Introduction

The radiation chemistry of gases using pulsed electron beams with dose rates of 10^{26} to 10^{28} eV g^{-1} s^{-1} is a relatively new field. We have previously described the radiolysis of nitrous oxide, ethylene (1), and ammonia (2) and discussed the use of nitrous oxide as a dosimeter at these dose rates (1, 3). The nitrogen yield, $G(N_2) = 12.4$ molecules per 100 eV, was significantly higher than the value of $G(N_2) = 10.0$ accepted for low dose rates (4). The present study was undertaken to examine the radiolysis of hydrogen chloride and hydrogen bromide at high dose rates and to investigate the reason for the difference in nitrogen yields from nitrous oxide. Diatomic gases, such as hydrogen chloride and hydrogen bromide, provide model systems for studying fundamental processes and their radiolytic mechanisms at low dose rates (5, 6) are currently much better understood than that of nitrous oxide.

The average energy of the primary electrons used in the irradiations at 10^{27} eV g^{-1} s^{-1} will not be much larger than that of the electrons traversing a gas in typical γ-ray radiolyses, and differences in linear energy transfer will be negligible. Primary ionization and excitation events will be the same. Differences between normal γ-ray radiolyses and those at very high dose rates, therefore, must arise from the much higher concentrations of reactive intermediates produced. Recombination times of ions and neutral intermediates will be very much shorter and may be reflected by changes in mechanism which can further elucidate the primary processes occurring.

Experimental

Pulsed Electron Accelerator and Dosimetry

The pulsed electron accelerator was a Febetron 705 which gives short pulses of 1.0 to 1.7 MeV electrons with a maximum current of about 5000 A. Details have been given elsewhere (1, 7, 8).

The dosimetry was based on a nitrogen yield of $G(N_2) = 12.4$ for the radiolysis of nitrous oxide at 1 atm. This value was obtained by comparing the yields from nitrous oxide with the dose per pulse measured by adiabatic calorimetry (1). The yield is independent of temperature from 20–200 °C (3). The dose absorbed in hydrogen chloride and hydrogen bromide was calculated from the measured dose in nitrous oxide using the relative stopping power for 1 MeV electrons derived from the Bethe equation (9).

Gas samples were contained in quartz cells (2) with ~0.5 mm quartz electron windows. The actual pulse shape and duration in these cells is somewhat uncertain. However, the voltage range of the transmitted pulse is estimated to be 0.4 to 1.1 MeV with its half-duration as 30 ns. The average energy of the electrons is estimated to be 1 MeV.

Materials and Analytical Procedures

All gases were obtained from Matheson Company.

The hydrogen chloride (Technical Grade 99.0%) and hydrogen bromide (99.8%) were purified as previously described (10). Nitrous oxide (98.0%), sulfur hexafluoride (98.0%), and chlorine (High Purity Grade 99.5%) were taken from the cylinders and subjected to freeze–pump–thaw cycles to remove non-condensible impurities.

Analysis of the gaseous products was achieved by immersing the irradiated cell in liquid nitrogen and pumping off the noncondensible gases into a McLeod gauge. After the volume of gas had been measured, its composition was determined by mass spectrometry.

Results

Radiolysis of the Pure Gases

Nitrogen yields from nitrous oxide and hydrogen yields from hydrogen chloride and hydrogen bromide, determined at pressures in the range 600 to 1500 Torr, are given in Table I.

Effect of Chlorine on the Hydrogen Yields from Hydrogen Chloride

Hydrogen yields from the Febetron radiolysis of hydrogen chloride – chlorine mixtures are plotted as a function of $[Cl_2]/[HCl]$ in Fig. 1. They are the same, within experimental error, for hydrogen chloride pressures of 700 and 1200 Torr, but differ significantly from those observed at low dose rates under similar conditions of temperature and pressure. The latter are included in Fig. 1 for comparison.

TABLE I

Product yields in Febetron radiolysis of nitrous oxide, hydrogen chloride, and hydrogen bromide

Gas	Pressure (Torr)		G values
			$G(N_2)$
N_2O	760		12.4*
	790		12.5
	900		12.4
	1367		12.5
	1498		12.4
		Mean =	12.4 ± 0.2
			$G(H_2)$
HCl	609		8.2
	604		7.9

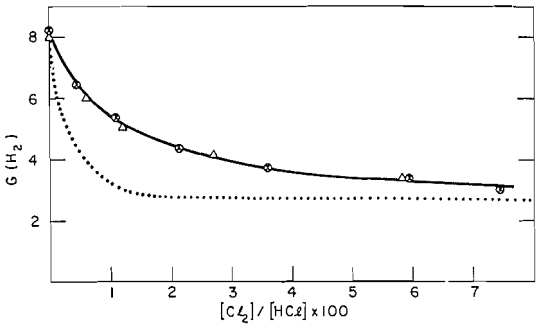

FIG. 1. Effect of chlorine addition on hydrogen yield from HCl at 10^{27} eV g^{-1} s^{-1}: Δ, 700, ⊗, 1200 Torr HCl; dotted line gives yields observed at low dose rates from 19.

Effect of SF_6 on the Hydrogen Yields from Hydrogen Chloride

The values of $G(H_2)$ for the Febetron and X-ray radiolysis (11) of hydrogen chloride at 1200 Torr and varying proportions of SF_6 are compared in Fig. 2. A difference between the two dose rates may be noted.

Effect of SF_6 on the Nitrogen Yields from Nitrous Oxide

Figure 3 shows a plot of $G(N_2)$ vs. $[SF_6]/[N_2O]$

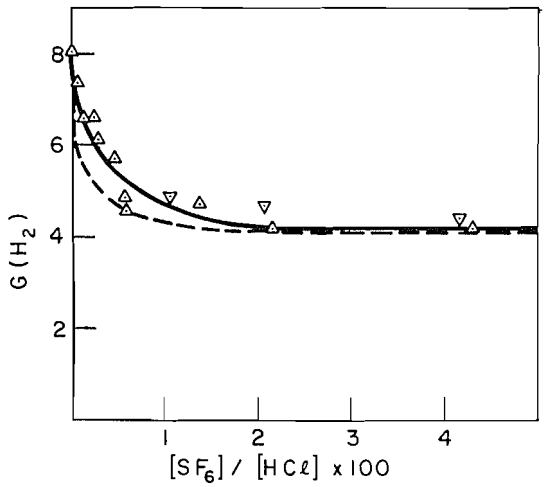

FIG. 2. Effect of sulfur hexafluoride on hydrogen yield from HCl at 10^{27} eV g^{-1} s^{-1}: ▽, 700, Δ, 1200 Torr HCl; dotted line gives yields observed at low dose rates from ref. 11.

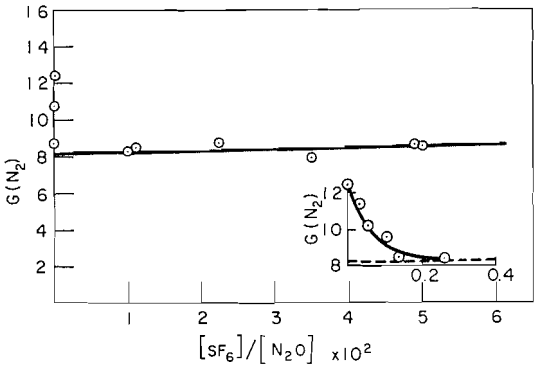

FIG. 3. Effect of sulfur hexafluoride on nitrogen yield from N_2O at 10^{27} eV g^{-1} s^{-1} at 700 Torr N_2O. The inset shows the nitrogen yields in the fall-off region at very low SF_6 concentrations of 0–0.6 mole %.

at a nitrous oxide pressure of 700 Torr. The inset figure shows the nitrogen yield at very low concentrations of SF_6 in the fall-off region.

Discussion

Hydrogen Chloride

The total hydrogen yield from the X-ray and γ-ray radiolysis of hydrogen chloride is $G(H_2) = 8.0 \pm 0.3$ (5). The present investigation shows that the hydrogen yield at 10^{27} eV g^{-1} s^{-1}, at room temperature, is the same; $G(H_2) = 8.1 \pm 0.2$. In accord with the W value of 25.0 ± 0.3 eV per ion pair (10), the yield of HCl^+ ions and electrons, e^-, from primary ionization is 4.0 ± 0.1 per 100 eV.

[1] $$HCl \rightarrow HCl^+ + e^-$$

HCl^+ undergoes the ion molecule reaction

[2] $$HCl^+ + HCl \rightarrow H_2Cl^+ + Cl$$

Experiments with SF_6 in γ-ray and X-ray radiolyses have shown (5) that each electron produces 1 molecule of hydrogen. The reduction of $G(H_2)$ from 8.1 to 4.1 in Fig. 2 indicates that this is also true at Febetron dose rates. The remaining 4 molecules of hydrogen per 100 eV are due mainly to the formation of hydrogen atoms from neutral excited molecules

[3] $$HCl \rightarrow HCl^* \rightarrow H + Cl$$

At low dose rates there is a yield of hydrogen, $G_{H_2} = (G_{H'}) = 2.2 \pm 0.2$ (5), which cannot be scavenged by chlorine or bromine. This means that some of the hot hydrogen atoms formed in reaction [3] undergo reaction [4]

[4] $$H + HCl \rightarrow H_2 + Cl$$

before being moderated to thermal energies. However, there is a thermal hydrogen atom yield, G_γ, of 1.7 per 100 eV. These must come from the collisional moderation of H

[5] $$H + HCl \rightarrow H + HCl$$

and threshold dissociation processes which need not be considered in detail here. The yields of H_2 and H from reactions [4] and [5] will clearly be unaffected by dose rate.

Figure 4 shows a reciprocal plot of the hydrogen yields from the Febetron radiolysis of hydrogen chloride – chlorine mixtures at 700 and 1200 Torr of hydrogen chloride. This is based on the expression

$$\frac{1}{\Delta G(H_2)} = \frac{1}{G_H}\left(1 + \frac{k_{H+HCl}[HCl]}{k_{H+Cl_2}[Cl_2]}\right)$$

which assumes that hydrogen chloride and chlorine are competing for thermal hydrogen atoms in reactions [6] and [7]

[6] $$H + HCl \rightarrow H_2 + Cl$$

[7] $$H + Cl_2 \rightarrow HCl + Cl$$

For simplicity, only the best line for the 700 Torr results is given. It gives $G_H = 5.7$ and $k_6/k_7 = 1.10 \times 10^{-2}$. The best line for the 1200 Torr data gives $G_H = 5.5$ and $k_6/k_7 = 1.03 \times 10^{-2}$. The mean value of k_6/k_7 is 1.07×10^{-2}. The agreement with $1.08 \pm 0.15 \times 10^{-2}$ from photochemical experiments (12) means that at 10^{27} eV g^{-1} s^{-1} chlorine reacts only with thermal hydrogen atoms. Since the yield of these, 5.6 ± 0.2 per 100 eV, is equal to the yield of thermal hydrogen atoms from neutral dissociations ($G_\gamma = 1.7$) plus $G_e = 4.0$, each electron must produce a

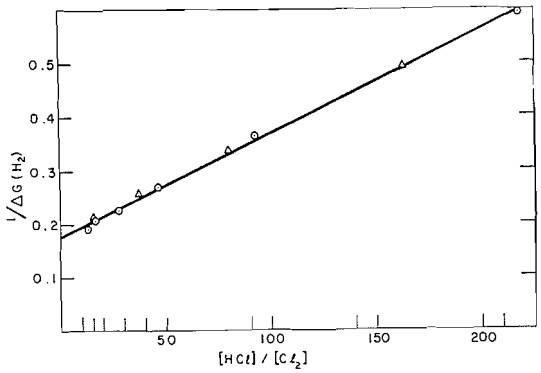

FIG. 4. Reciprocal plot for hydrogen yields in presence of added chlorine: Δ, 700, ○, 1200 Torr HCl.

thermal hydrogen atom. Hence combinations of free electrons with H_2Cl^+

[8] $$e + H_2Cl^+ \rightarrow H + HCl$$

and HCl^+

[9] $$e + HCl^+ \rightarrow H + Cl$$

cannot be important, since they are highly exothermic and should produce hot hydrogen atoms. Chlorine cannot scavenge free electrons below 1.6 eV (13) and thus the occurrence of reactions [8] and [9] should enhance $G_{H'}$. The observed value at Febetron dose rates is 2.5 ± 0.2 $(=8.1 - 5.6)$, which agrees within experimental error with 2.2 ± 0.2 at low dose rates.

Experiments reported elsewhere (14) have shown that secondary electrons acquire energy from the transient electric field due to the space charge of the intense electron beam of the Febetron. The effects of this are most serious at pressures below 500 Torr where the electrons gain sufficient energy to give enhanced decomposition through reaction [10]. In the pressure

[10] $$e\ (\text{k.e.} > 6\ \text{eV}) + HCl \rightarrow e^- + HCl^*$$

range 600–1200 Torr the energy gained by an electron per mean free path is much less, and enhanced yields are not observed. However, even at these pressures the electrons would not be expected to be completely thermal. This is shown in Fig. 2 by the fact that larger concentrations of SF_6 are required to reduce the hydrogen yield at Febetron dose rates than at low dose rates. Since

[11] $$e + SF_6 \rightarrow SF_6^-$$

k_{11} decreases sharply as the energy of the electron rises above 0.03 eV (15–17), its effective value in Febetron radiolysis will be significantly less than in an X-ray or γ-ray radiolysis where there is no electric field. The total electron capture cross section for hydrogen chloride apparently does not decrease as markedly with energy (18). This may in part be due to the resonance capture process

[12] $$e + HCl \rightarrow H + Cl^-$$

which sets in at 0.65 eV (18). However, the cross section for this process is small ($\sigma_{\varepsilon_{max}} = 2 \times 10^{-17}$ cm^2). Therefore, most electrons are probably captured in the low energy processes which are observed at normal dose rates.

From a study (5*a*, 19) of the effects of chlorine on the hydrogen yields at low dose rates it was concluded that 1.4 electrons per 100 eV gave hydrogen atoms by reaction [13] (20)

[13] $$e + 3HCl \rightarrow HCl_2^- + HCl + H$$

while the remaining 2.5 per 100 eV formed a negative ion intermediate, HCl^-

[14] $$e^- + 3HCl \rightarrow HCl^- + 2HCl$$

The structure of this species is as yet unknown, but in view of the low electron affinity of hydrogen chloride (< 0.3 eV) (5*a*), it would probably be better represented as the electron dimer complex (Cl—H···e···H—Cl) for which Raff and Pohl (21) have estimated a binding energy of 0.8 eV. At normal dose rates HCl^- reacts with hydrogen chloride to produce hydrogen

[15] $$HCl^- + HCl \rightarrow H + HCl_2^-$$

[6] $$H + HCl \rightarrow H_2 + Cl$$

or, if chlorine is present, it can be scavenged in reaction [16]

[16] $$Cl_2 + HCl^- \rightarrow Cl + HCl_2^- \text{ or } Cl_2^- + HCl$$

Assuming that reaction [16] goes on every collision, the chlorine results (5*a*) give the minimum lifetime of HCl^- in pure hydrogen chloride at room temperature and 1 atm pressure as 200 ns.

The effects of chlorine on hydrogen yields from hydrogen chloride at low dose rates and Febetron dose rates are compared in Fig. 1. The reduction of $G(H_2)$ at much lower chlorine concentrations in the low dose rate experiments is due to the scavenging of HCl^- in reaction [16]. From our analysis of the reciprocal plot in Fig. 4 it is obvious that this does not occur at Febetron dose rates. Hence if HCl^- is formed under these conditions it must be reacting with positive ions

[17] $$HCl^- + H_2Cl^+ \rightarrow H + 2HCl$$

[18] $$HCl^- + HCl^+ \rightarrow H + Cl + HCl$$

too rapidly to be scavenged by chlorine at the concentrations shown in Fig. 1. Furthermore, the above analysis of the experiments with added chlorine requires that these reactions produce thermal hydrogen atoms. To assess their importance relative to reactions [15] and [16] we have calculated the concentrations of products and of atomic and ionic intermediates during and after a Febetron pulse, using a computer program WR16 (22). This was based on all the relevant foregoing reactions, except the resonance capture

process [12], and the following additional ionic and free radical reactions

[19] $HCl_2^- + H_2Cl^+ \rightarrow 3HCl$

[20] $HCl_2^- + HCl^+ \rightarrow Cl + 2HCl$

[21] $H + H + HCl \rightarrow H_2 + HCl$

[22] $H + Cl + HCl \rightarrow HCl + HCl$

[23] $Cl + Cl + HCl \rightarrow Cl_2 + HCl$

Reaction [19] is, of course, the neutralization process and reaction [23], the atom combination process, which occur at low dose rates. The primary yields used in the program were those derived from low dose rate studies: $G_{H'} = 2.2$, $G_\gamma = 1.8$, $G_{HCl^+} = 4.0$, and $G_{Cl} = 6.2$ (from reactions [3] and [4]). The pulse shape was approximated by a step function with 2 ns steps. The calculated concentrations are shown in Fig. 5 for the Febetron radiolysis of hydrogen chloride at 830 Torr in a quartz cell at 25 °C.

Theoretical considerations (23) show that the rate constant for the clustering of HCl^+ ions in hydrogen chloride at high pressures ($\sim$ 1 atm) will be of the order of $3 \times 10^{11}\ M^{-1}\ s^{-1}$ or larger. This is large enough that even at 10^{27} eV $g^{-1}\ s^{-1}$ all ions will have been clustered before neutralization occurs, although the clusters may not have reached equilibrium size as would be the case at low dose rates. A formal distinction between clustering of HCl^+ and the rate of the ion–molecule reaction [2]

[2] $HCl^+ + HCl \rightarrow H_2Cl^+ + Cl$

to give H_2Cl^+ is impossible at high pressures, and we assume k_2 equal to the rate constant for clustering. This and all other relevant rate constants are summarized in Table II.

From the computer calculated concentrations it follows that the mean ion combination lifetime is less than 10 ns, confirming that reactions [15] and [16] will not compete with reaction [17]. Using the peak concentrations of HCl^+, e, HCl^-, and HCl_2^-, reactions [9], [18], and [20] can be shown to be negligible. Similarly, less than 2% of the free electrons should give direct neutralization in reaction [8]. This is consistent with the

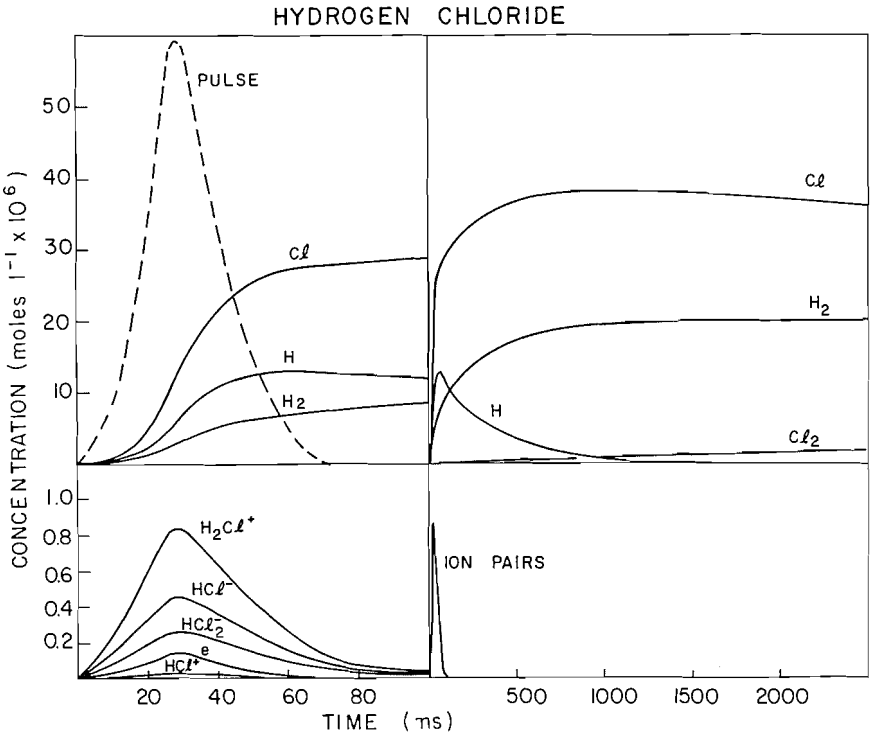

FIG. 5. Calculated ionic and atomic concentrations in hydrogen chloride during and following a Febetron pulse at 25 °C and 830 Torr pressure. Total dose = 1.5×10^{20} eV l^{-1}. The pulse intensities can be taken from the ordinate axis. The units for these are 10^{26} eV $l^{-1}\ s^{-1}$: i.e., the maximum intensity is 5.95×10^{27} eV $l^{-1}\ s^{-1}$.

[a]All rate constants are given in equivalent two-body rate constants for 830 Torr hydrogen chloride.
[b]This is estimated from the data of ref. 23 to be the minimum rate constant for clustering of HCl^+ at 800 Torr. k_2 is assumed equal to it.
[c]See ref. 24.
[d]$k_7 = 10^2 \times k_6$ from ref. 12.
[e]All negative ion – positive ion combination coefficients are taken to be 6×10^{14} M^{-1} s^{-1} consistent with recent experimental data on ion lifetimes in irradiated hydrogen chloride (30). Free electron – positive ion combination coefficients are assumed to be a factor of 6 slower as usually observed (31).
[f]The sum of k_{13} and k_{14} was calculated from the SF_6 scavenging results at low dose rates (5*a*, 20) using $k_{11} = 1.8 \times 10^{14}$ (15). At 800 Torr hydrogen chloride it is equivalent to a second order rate constant of 6×10^{10} M^{-1} s^{-1}. The ratio of k_{13}/k_{14} is taken from ref. 5*a*.
[g]Reaction [16] is assumed to go on every collision and $k_{15}/k_{16} = 10^{-3}$ from ref. 5*a*.
[h]k_{21} was taken to be $2 \times k_{H+H+Ar}$, taken from ref. 32*c*.
[i]k_{22} was taken to be 1.0×10^9 M^{-1} s^{-1} by analogy with rate constants for related reactions given in ref. 32*a* and *c*.
[j]k_{23} was assumed to be $2 \times k_{Br+Br+Ar}$, taken from ref. 32*b*.

equivalence of $G_{H'}$ at low and high dose rates as discussed above. Even if the difference in $G_{H'}$ of 0.3 is real, this only accounts for 5% of the electrons. The absence of a significant change in $G_{H'}$ under these circumstances lends further support to the formation of the unscavengeable hydrogen in reactions [3] and [4] rather than in ion combination reactions (5*b*).

The above calculations did not explicitly include the resonance capture process (reaction [12]). However, since Cl^- will rapidly cluster to form HCl_2^- it is formally equivalent to reaction [13]. Also its rate constant for 0.8 eV electrons (i.e. at maximum cross section) does not exceed k_{13}. Its only effect, therefore, would be to decrease the proportion of HCl^- relative to HCl_2^-, but this should not invalidate the conclusions drawn above.

The concentration of hydrogen at infinite time corresponds to a predicted $G(H_2) = 7.98$, confirming that reactions [7], [21], and [22] are negligible at 25 °C and 10^{27} eV g^{-1} s^{-1}. The excellent agreement between $G(H_2) = 8.1 \pm 0.3$ observed in the X-ray and γ-ray radiolysis, at similar pressures, was therefore to be expected.

At −80 °C, $k_6 = 2.64 \pm 0.04 \times 10^6$ M^{-1} s^{-1} which is a factor of 30 smaller than the room temperature value (24). Using this value of k_6 in the computer program, the predicted hydrogen yield was $G(H_2) = 5.4$. This is in good agreement with a value we have measured at −80 °C of $G(H_2) = 5.3 \pm 0.3$. The reduction cannot be attributed to reaction [7] because of the very slow rate of formation of chlorine (see Fig. 5), and is due almost entirely to reaction [22]. Our choice of rate constant for reaction [22] is thus supported.

Hydrogen Bromide

The reactions occurring in irradiated hydrogen bromide are very similar to those occurring in hydrogen chloride (6). Those of importance are summarized in Table III. Using these and data from low dose rate radiolyses, the concentrations of products and intermediates for a Febetron irradiation have been calculated and are shown in Fig. 6. The significant differences between hydrogen chloride and hydrogen bromide are due to the much greater rates at which electrons and hydrogen atoms react with hydrogen bromide.

This is illustrated clearly in Fig. 6 by the lower calculated concentrations of the free electron and hydrogen atom. The concentration of the hydrogen atoms follows the pulse and the behavior is very similar to that of ions. As in the case of hydrogen chloride, the computer calculations show that $G(H_2)$ should be the same at Febetron and low dose rates. Excellent agreement is in fact found between $G(H_2) = 9.9 \pm 0.3$ at 10^{27} eV g^{-1} s^{-1} and 9.8 ± 0.2 (6*a*) and 9.7 ± 0.2 (6*b*) for the X-ray and γ-ray radiolysis at low dose rates.

The agreement between the yields from both hydrogen bromide and hydrogen chloride at 10^{27} eV g^{-1} s^{-1} and those observed at low dose

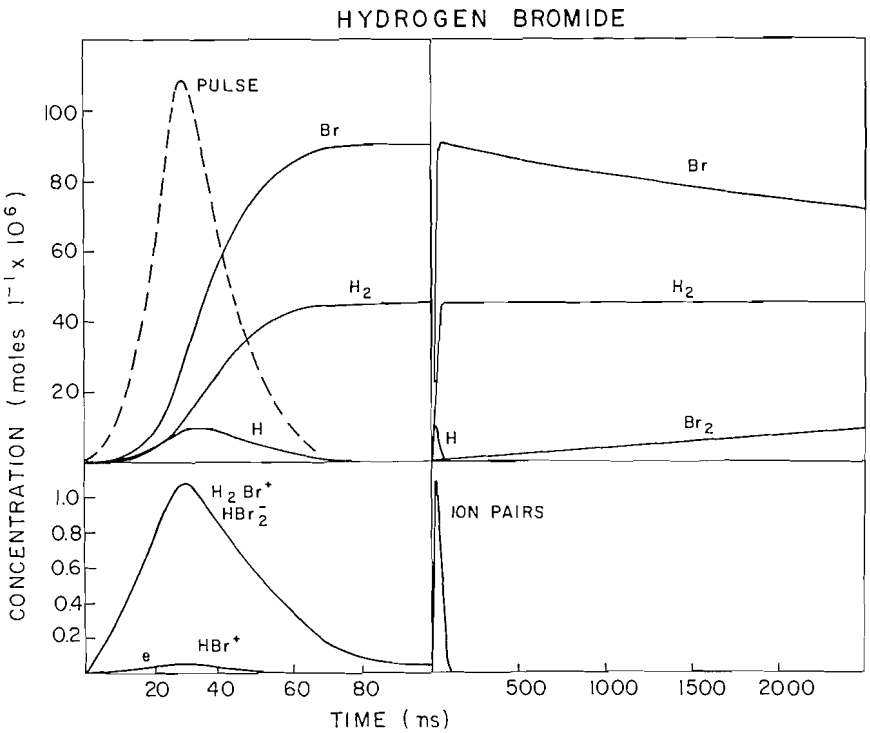

FIG. 6. Calculated ionic and atomic concentration in hydrogen bromide during and following Febetron pulse at 25 °C and 830 Torr pressure. Total dose = 2.76×10^{20} eV l^{-1}. The pulse intensities can be taken from the ordinate axis. The units for these are 10^{26} eV l^{-1} s^{-1}, i.e., the maximum intensity is 1.08×10^{28} eV l^{-1} s^{-1}.

rates strongly supports the value of $G(N_2) = 12.4 \pm 0.2$ from nitrous oxide which is used for the dosimetry at the high dose rates.

Nitrous Oxide

The yields reported in Table I and previous work (11, 14) show that the nitrogen yield from the Febetron radiolysis of gaseous nitrous oxide is $G(N_2) = 12.4 \pm 0.2$, independent of pressure from 600 to 3500 Torr. Figure 3 shows the effect of SF_6 on the Febetron radiolysis of nitrous oxide at 700 Torr. The yield of nitrogen extrapolated to zero concentration of SF_6 is $G(N_2) = 8.2 \pm 0.3$. It is in good agreement with $G(N_2) = 8.0 \pm 0.2$ reported for the plateau yield with SF_6 for ^{60}Co γ-ray radiolysis (25). This implies that it is differences in the electron reactions which cause the nitrogen yield at Febetron dose rates to be 12.4 instead of 10.0 molecules per 100 eV as at low dose rates.

It is known that the capture of thermal electrons in N_2O is a three-body process

[31] $$e + 2N_2O \rightarrow \text{Products}$$

with a rate constant of $2.2 \times 10^9\ M^{-2}\ s^{-1}$ (26, 27). At 700 Torr of N_2O the lifetime of electrons with respect to this reaction is therefore 250 ns. Assuming a rate constant of $6 \times 10^{13}\ M^{-1}\ s^{-1}$ for reaction [32]

[32] $$e + N_2O^+ \rightarrow \text{Products}$$

the electron–ion combination time for a typical low dose rate (^{60}Co) radiolysis would be 0.01 s or longer. Therefore at low dose rates all electrons would be consumed in reaction [31]. Unfortunately the situation is complicated by the fact that reaction [31] may produce O_2^- and NO^- as well as N_2O^-. Furthermore, charge transfer and other ionic reactions with the products are likely to occur and the ions of greatest thermodynamic stability will be the ones that recombine. For example, N_2O^+ may react with NO

[33] $$N_2O^+ + NO \rightarrow N_2O + NO^+ \qquad \Delta H = -3.5 \text{ eV}$$

and negative ion reactions are also possible.

Assuming rate constants of the order of $5 \times 10^9\ M^{-1}\ s^{-1}$, these ionic reactions will give mean lifetimes of the order of 10^{-4} s as soon as the product concentrations have reached the typical detection limit of 10 p.p.m. in N_2O at 700 Torr. This lifetime is much shorter than the recombination time, therefore these reactions will occur in N_2O at low dose rates in the same way that ozone must react with O_2^- (or O_4^-) in the radiolysis of

[34] $$O_3 + O_2^- \rightarrow O_3^- + O_2$$

oxygen at low dose rates. The ozonide ion has in fact been observed (28) in the mass analysis of the negative ions in irradiated oxygen.

Reaction [11] has a rate constant of $1.8 \times 10^{14}\ M^{-1}\ s^{-1}$ (15) and at 3×10^{-3} mole % of sulfur hexafluoride, in 700 Torr of N_2O, the lifetime of electrons for this reaction would be about 3 ns, which is $\sim$ 100 times shorter than their lifetime in reaction [31]. The suppression of $G(N_2)$ by SF_6 at low dose rates can therefore be attributed to the replacement of reaction [31] by reaction [11], and will obviously be complete at an SF_6 concentration of 10^{-2} mole %.

From the foregoing discussion, it is apparent that there is at present insufficient information on the ionic reactions in nitrous oxide to permit calculations of the type performed for hydrogen chloride and hydrogen bromide at 10^{27} eV g^{-1} s^{-1}. However, the concentrations of ions will be similar to those shown in Fig. 5 for hydrogen chloride, and, taking $k_{32} = 6 \times 10^{13}\ M^{-1}\ s^{-1}$ as above, the mean electron lifetime with respect to reaction [32] is found to be 3 ns. Hence this reaction would occur to the exclusion of reaction [31]. Also there would be insufficient time for charge transfer from primary ions to products. Thus the greater reduction of $G(N_2)$ by SF_6 at 10^{27} eV g^{-1} s^{-1} can be explained by the fact that the ionic reactions are different from those at low dose rates.

The results in the inset of Fig. 3 show the fall-off in $G(N_2)$ at low concentrations of SF_6. The reduction is halfway to the plateau at 0.1 mole % of SF_6. This is over 10 times the SF_6 concentration calculated above to be equivalent to an electron lifetime of 3 ns. As in the case of HCl, the discrepancy is attributed to the fact that under Febetron conditions the electrons are not thermal and that k_{11} decreases sharply with electron energy. It should also be noted that the resonance capture of electrons by nitrous oxide

[35] $$e^- + N_2O \rightarrow N_2 + O^-$$

occurs at a much lower energy (29) than reaction [12] in hydrogen chloride. Hence, in the presence of electrical fields generated in the Febetron, radiolysis reaction [35] should be a significant electron loss process. The O^- ion will disappear in reaction [36]

[36] $$O^- + N_2O^+ \rightarrow \text{Products}$$

The importance of reactions [35] and [36], relative to reaction [32], will decrease as the mean energy of the electrons is decreased. This will occur as the nitrous oxide pressure is raised. The absence of a pressure dependence of $G(N_2)$ over the range 600 to 3500 Torr implies that the reaction sequence [35]–[36] gives a similar stoichiometry for nitrogen to reaction [32].

An important point relating to the use of N_2O as a dosimeter is that $G(N_2)$ should change from 10.0 to 12.4 in the dose rate range 10^{22} to 10^{25} for 1 atm of nitrous oxide. This arises from the competition between reactions [31] and [32]. Therefore, it will not be practical to use nitrous oxide at these pressures as a dosimeter in this range of dose rates which is typical of many pulsed lineacs and Van de Graaffs.

Absolute rate constants for hydrocarbon autoxidation. XIV. Termination rate constants for tertiary peroxy radicals[1]

J. A. HOWARD, K. ADAMIC[2], AND K. U. INGOLD
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received May 23, 1969

Absolute rate constants for chain termination by ten *t*-peroxy radicals have been measured at 30° by the rotating sector technique, the photochemical pre- and after-effect method, and by electron spin resonance. The different methods generally give results in good agreement with one another. The termination rate constants vary from a low of $\sim 4 \times 10^2\ M^{-1}\ s^{-1}$ for *t*-butylperoxy to a high of $\sim 3 \times 10^4\ M^{-1}\ s^{-1}$ for 1,1-diphenylethylperoxy radicals.

Introduction

In the liquid phase the self-reaction of *t*-alkylperoxy radicals occurs by the following reaction sequence (1–8)

$$[1] \quad \mathrm{ROO\cdot} + \mathrm{ROO\cdot} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{ROOOOR} \quad \left(K_1 = \frac{k_{-1}}{k_1}\right)$$

$$[2] \quad \mathrm{ROOOOR} \xrightarrow{k_2} [\mathrm{RO\cdot}\ \ \mathrm{O_2}\ \ \cdot\mathrm{OR}]_{\mathrm{cage}}$$

$$[3] \quad [\mathrm{RO\cdot}\ \ \mathrm{O_2}\ \ \cdot\mathrm{OR}]_{\mathrm{cage}} \xrightarrow{k_3} \mathrm{ROOR} + \mathrm{O_2}$$

$$[4] \quad [\mathrm{RO\cdot}\ \ \mathrm{O_2}\ \ \cdot\mathrm{OR}]_{\mathrm{cage}} \xrightarrow{k_4} \mathrm{RO\cdot} + \mathrm{O_2} + \cdot\mathrm{OR}$$

For most organic substrates, RH, which are oxidized by a chain process involving primarily the attack of tertiary peroxy radicals on RH, the measured rate constant for chain termination corresponds to a rather complex kinetic expression (3, 6). The reason for this is that although the *t*-alkoxy radicals produced in reaction [4] may attack the substrate to regenerate *t*-ROO· radicals, they may also undergo β-scission to give a carbonyl compound and a new radical. This new radical will generally be a primary or secondary radical and, after the addition of oxygen, it may react with RH to continue the chain or with a *t*-ROO· to terminate the chain. The latter process can have a profound influence on the overall rate constant for chain termination because it will generally have a much higher rate constant than termination by the reaction of two *t*-peroxy radicals (6).

We have previously shown that it is possible to trap all the RO· radicals produced in reaction [4] and convert them to ROO· radicals by the addition of a sufficient concentration of the appropriate hydroperoxide (5, 6).

$$[5] \quad \mathrm{RO\cdot} + \mathrm{ROOH} \rightarrow \mathrm{ROH} + \mathrm{ROO\cdot}$$

Under these conditions, the measured rate constant for chain termination, $2k_t$, corresponds to $(2k_2/K_1)(k_3/(k_3 + k_4))$. Our initial measurements of $2k_t$ for a few *t*-peroxy radicals (5) indicated that this composite rate constant was not independent of the nature of the group R. That is, at 30° our measured values of $2k_t$ ranged from $\sim 1 \times 10^3\ M^{-1}\ s^{-1}$ for *t*-butylperoxy, to $\sim 6 \times 10^3\ M^{-1}\ s^{-1}$ for cumylperoxy, to $\sim 6 \times 10^4\ M^{-1}\ s^{-1}$ for 1,1-diphenylethylperoxy radicals. There are three separate factors that might produce this variation in $2k_t$: (*i*) a variation in K_1, the equilibrium constant for tetroxide formation, (*ii*) a variation in k_2, the rate constant for irreversible decomposition of tetroxide, and (*iii*) a variation in the ratio $k_3/(k_3 + k_4)$ which measures the fraction of alkoxy radical pairs which undergo combination in the cage. The present set of three papers describes work leading to the conclusion that differences in k_2 are the prime cause of the differences in $2k_t$. This, the first paper, describes the measurement by three independent methods of $2k_t$ at 30° for ten *t*-peroxy radicals. The second paper describes the radical induced decomposition of some *t*-hydroperoxides from which it is possible in certain cases to derive the ratio $k_3/(k_3 + k_4)$. The final paper is concerned with the measurement of K_1 and k_2 at low temperatures by the electron spin resonance procedure pioneered by Bartlett and Guaraldi (4).

[b]0.6 *M* [Hydroperoxide] in CCl_4 initiated with 3.3×10^{-2} *M* [TBH].
[c]Calculated from $k_p/(2k_t)^{1/2}$ and the mean value of $k_p(=0.11_7\ M^{-1}\,s^{-1})$ for all peroxy radicals.
[d]At 35°; ref. 12.
[e]The present value is believed to be more accurate than that originally reported (5).

Experimental

Procedures

Cumene was oxidized in the presence of a sufficient concentration of the appropriate tertiary hydroperoxide to ensure that the *t*-peroxy radicals from the hydroperoxide were the only terminating radicals. The absolute rate constants for the self-reactions of the *t*-peroxy radicals in cumene were measured by the rotating sector (r.s.) technique (9) and by the photochemical pre- and/or after-effect (p.e.) (10). The precautions necessary to obtain reliable rate constants by the r.s. method have been described previously (9, 11). The increase or decrease in the rate of reaction under non-steady state conditions resulting from a sudden increase or decrease in the rate of chain initiation (p.e. method) is particularly useful with *t*-peroxy radicals because of the comparatively small values of the termination rate constants (12).

Tertiary peroxy radicals are also well suited to the measurement of their steady concentration $[ROO\cdot]_s$ by electron spin resonance spectroscopy (the e.s.r. method). At a rate of initiation, R_i, the termination rate constant is defined by the relation

$$R_i = 2k_t[ROO\cdot]_s^2$$

In the e.s.r. experiments, decomposition of the tertiary hydroperoxides was initiated by the thermal decomposition of *t*-butyl hyponitrite (TBH) (13).

All work described in this paper was done at 30 °C.

Materials

Cumene (Phillips Research Grade) was used immediately after passage through activated basic alumina. *t*-Butyl hydroperoxide was purified by crystallization. Cumene hydroperoxide and 2-neopentyl-2-propyl hydroperoxide (Lucidol) were purified via their sodium salts. 2-Phenylbutyl-2-hydroperoxide was prepared by the emulsion oxidation of *sec*-butylbenzene and was purified via its sodium salt (14). 1,1-Diphenylethyl hydroperoxide was prepared from 1,1-diphenylethanol and 30% H_2O_2 (15). The remaining hydroperoxides were synthesized by reaction of the appropriate *t*-alcohols with 100% H_2O_2 and a trace of sulfuric acid (16)[3]. Great care was taken to ensure that the liquid hydroperoxides were free from H_2O_2 by repeated washings with water. The presence of H_2O_2 gave high values for $2k_t$, presumably because hydroperoxy radicals were involved in chain termination.

α,α′-Azo-bis-cyclohexylnitrile (ACHN) and α,α′-azo-bis-isobutyronitrile (AIBN) were the photo-initiators in the p.e. method. ACHN was the photo-initiator in the r.s. method. Rates of chain initiation were measured with 2,6-di-*t*-butyl-4-methoxyphenol.

Results and Discussion

Rate constants for the oxidation of cumene in the presence of ten *t*-hydroperoxides are given in Table I. The oxidizability of cumene, $k_p/(2k_t)^{1/2}$, depends on the added hydroperoxide, decreasing by an order of magnitude between *t*-butyl hydroperoxide and 1,1-diphenylethyl hydroperoxide. The three methods used to measure the termination rate constants give results which are in reasonable agreement with one another except for the 1,1-diphenylethylperoxy radical. The e.s.r. signal due to the 1,1-diphenylethylperoxy radical was rather small and the measured steady state concentration of this peroxy radical could be in serious error. The measurement of $2k_t$ by the e.s.r. method might also be affected by low concentrations of oxygen in the reaction mixture. It is worth noting that the 1,1-diphenylethoxy radical

[3]This reaction should be carried out with extreme caution. Although none of the reaction mixtures described here detonated, an attempted synthesis of 2-*t*-butyl-2-propyl hydroperoxide exploded violently.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

behaves rather differently to other alkoxy radicals (see following paper).

The measured termination rate constants confirm our previous observation (5) that $2k_t$ is not the same for all *t*-peroxy radicals. In most cases the values of k_p given in Table I have been calculated from $k_p/(2k_t)^{1/2}$ and the average values of $2k_t$. The $2k_t$'s determined by the e.s.r. method for 1-methylcyclopentylperoxy, 2-phenyl-2-butylperoxy, and 1,1-diphenylethylperoxy radicals were not included in the averages because they were not considered accurate. Since there is no obvious correlation between k_p and the structure of the peroxy radical, it seems most probable that the variations in $k_p/(2k_t)^{1/2}$ are due entirely (or almost entirely) to changes in $2k_t$. Because the ratio $k_p/(2k_t)^{1/2}$ can be measured a great deal more accurately than its component rate constants, we feel justified in calculating a "best value" for $2k_t$ based on values of $k_p/(2k_t)^{1/2}$ and the average value of k_p for all the peroxy radicals studied ($0.11_7\ M^{-1}\ s^{-1}$). These best values of $2k_t$ increase by almost two orders of magnitude along the series of *t*-peroxy radicals from *t*-butyl to 1,1-diphenylethyl. This change is too large to be wholly attributed to any change in the fraction of the alkoxy radicals which combine in the cage (i.e., in $k_3/(k_3 + k_4)$). However, the importance of alkoxy radical cage combination relative to diffusion from the cage would be expected to increase as the size of the alkoxy radicals increases. It is therefore conceivable that some of the variation in $2k_t$ is due to changes in $k_3/(k_3 + k_4)$. Our measurements of this ratio for a few selected radicals are described in the following paper.

Absolute rate constants for hydrocarbon autoxidation. XV. The induced decomposition of some *t*-hydroperoxides[1]

J. A. HOWARD AND K. U. INGOLD
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received May 23, 1969

The radical induced decomposition of several *t*-hydroperoxides at 30° has been studied. In the self reaction of *t*-alkylperoxy radicals the ratio of the rates of alkoxy radical diffusion from the cage to combination in the cage is essentially independent of the size of the *t*-alkyl group.

The rate constant for abstraction from hydroperoxides of the hydroperoxidic hydrogen by alkoxy radicals is about $4 \times 10^6\ M^{-1}\ s^{-1}$ at 30°. This reaction has a deuterium isotope effect, $k_H/k_D \approx 5$.

The 1,1-diphenylethoxy radical undergoes a 1,2-phenyl shift to yield the 1-phenyl-1-phenoxyethyl radical more rapidly that it undergoes β-scission.

Canadian Journal of Chemistry, 47, 3797 (1969)

Introduction

Previous workers have shown that *t*-butyl hydroperoxide (1–3) and cumene hydroperoxide (4) undergo radical induced chain decompositions in solution with chain lengths of about 5–10 in solvents of normal viscosity at ambient temperatures. The decomposition of *t*-butyl hydroperoxide (in an inert solvent) can be represented by[2]

$$\text{Initiator} \rightarrow \text{ROO}\cdot$$

[1] $$\text{ROO}\cdot + \text{ROO}\cdot \rightleftarrows \text{ROOOOR}$$

[2] $$\text{ROOOOR} \rightarrow [\text{RO}\cdot \quad \text{O}_2 \quad \cdot\text{OR}]_{\text{cage}}$$

[3] $$[\text{RO}\cdot \quad \text{O}_2 \quad \cdot\text{OR}]_{\text{cage}} \rightarrow \text{ROOR} + \text{O}_2$$

[4] $$[\text{RO}\cdot \quad \text{O}_2 \quad \cdot\text{OR}]_{\text{cage}} \rightarrow \text{RO}\cdot + \text{O}_2 + \cdot\text{OR}$$

[5] $$\text{RO}\cdot + \text{ROOH} \rightarrow \text{ROH} + \text{ROO}\cdot$$

The rate of hydroperoxide decomposition and the rate of oxygen evolution, R_{O_2}, are given by eqs. [I] and [II]

$$[\text{I}] \qquad -\frac{d[\text{ROOH}]}{dt} = R_i(1 + k_4/k_3)$$

$$[\text{II}] \qquad R_{O_2} = \frac{R_i}{2}\left(1 + \frac{k_4}{k_3}\right) = -\tfrac{1}{2}\frac{d[\text{ROOH}]}{dt}$$

where R_i is the rate of chain initiation. At a known rate of initiation either of these rates yields the ratio of non-terminating to terminating rate constants for *t*-butylperoxy radicals (k_4/k_3).

The decomposition of certain other *t*-hydroperoxides is more complicated because the *t*-alkoxy radicals formed in reaction [4] can undergo β-scission to give carbonyl compounds and alkyl radicals

[6] $$\text{R}_1\text{R}_2\text{R}_3\text{O}\cdot \rightarrow \text{R}_1\text{R}_2\text{C}{=}\text{O} + \text{R}_3\cdot$$

The stability of the incipient ketone and alkyl radical determines the mode of β-scission. Cumyloxy radicals, for example, give acetophenone and methyl radicals

[6a] $$\text{Ph(CH}_3)_2\text{CO}\cdot \rightarrow \text{PhCOCH}_3 + \text{CH}_3\cdot$$

The methylperoxy radicals formed in the presence of oxygen may react with cumene hydroperoxide (chain transfer)

[7] $$\text{CH}_3\text{OO}\cdot + \text{Ph(CH}_3)_2\text{COOH} \rightarrow \text{CH}_3\text{OOH} + \text{Ph(CH}_3)_2\text{COO}\cdot$$

or with cumylperoxy radicals (chain termination)

[8] $$\text{CH}_3\text{OO}\cdot + \text{Ph(CH}_3)_2\text{COO}\cdot \rightarrow \text{Non-radical products}$$

The kinetics for the decomposition of *t*-hydroperoxides which undergo β-scission are greatly simplified if sufficient hydroperoxide is present to suppress chain termination by reactions such as [8]. The rate of decomposition of the *t*-hydroperoxide is described by eq. [I] but the rate would be difficult to measure because of the accumulation of the alkyl hydroperoxide formed in reaction [7]. The rate of oxygen evolution and ketone formation ($R_{C=O}$) are given by

$$[\text{III}] \qquad R_{O_2} = \frac{R_i}{2}\left(1 + \frac{k_4}{k_3}\right) - R_{C=O}$$

$$[\text{IV}] \qquad R_{C=O} = \frac{R_i k_4 k_6}{k_3 k_5([\text{ROOH}] - k_6/k_5)}$$

[1]NRCC No. 10 897.
[2]The reactions are numbered in the same way as in the preceding paper.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Under ideal conditions, the measurement of R_{O_2} and $R_{C=O}$ enables both k_4/k_3 and k_6/k_5 to be determined.

The radical induced decompositions of some *t*-hydroperoxides are not described by the above reactions because the *t*-alkoxy radicals undergo various intramolecular rearrangements. Two examples of these more complicated decompositions are described.

Experimental

Materials

The preparation of the hydroperoxides used in this work was described in the preceding paper (5).

1-Phenylethyl phenyl ether was prepared from 1-phenylethyl chloride and phenol (6). It was crystallized and zone refined before use. Only one peak was observed by gas–liquid chromatography (g.l.c.).

1,1-Diphenylethyl peroxide, m.p. 149–151°, was prepared from 1,1-diphenylethyl hydroperoxide by the procedure of Bassey *et al.* (7). This compound has not been previously prepared.

1,1-Diphenylethane was prepared by the catalytic reduction of 1,1-diphenylethylene and its purity was better than 99.5%.

Procedures

The induced decompositions of the *t*-hydroperoxides (0.1–0.5 *M*), at various rates of chain initiation, were studied in carbon tetrachloride in the presence of oxygen at atmospheric pressure. The reactions were initiated by the thermal decomposition of *t*-butylhyponitrite (TBH). The calculated rates of chain initiation ($1.8 \times 2.7 \times 10^{-6}$ [TBH] (8)) were confirmed by measurement of the rates of the TBH initiated oxidations of hydrocarbons with well established values of $k_p/(2k_t)^{1/2}$ (e.g. cumene and tetralin). The rates of oxygen evolution were monitored by a Dynesco pressure transducer (DPT 85–2) and were corrected for nitrogen evolution from the TBH. Rates of ketone formation were followed by infrared analysis (1650–1750 cm^{-1} region) of aliquots.

1,1-Diphenylethane and 1-phenylethyl phenyl ether were oxidized both thermally and photochemically. The products from the oxidation of these compounds and from the decomposition of 1,1-diphenylethyl hydroperoxide and 1,1-diphenylethyl peroxide were identified by thin layer chromatography and g.l.c. All reactions were carried out at 30 °C unless stated otherwise.

Results and Discussion

Ratio of Diffusion (k_4) to Cage Combination (k_3) for t-Alkoxy Radicals

Kinetic data for the induced decomposition of six *t*-hydroperoxides at 0.2 *M* are presented in Table I. Within experimental error the ratio k_4/k_3 for *t*-alkoxy radicals is constant for all the hydroperoxides studied. This implies that most of the variation in the termination rate constants ($2k_t$) between different *t*-peroxy radicals is due to differences in K_1 or k_2 (see preceding paper).

The Alkoxy Radical – Hydroperoxide Reaction

The ratio of the rate constants for *t*-alkoxy radical β-scission (k_6) to abstraction from the parent hydroperoxide (k_5) were calculated from eq. [IV]. Values of k_6/k_5 for five alkoxy radicals are given in Table II and are compared with the ratios of β-scission (k_d) to abstraction from cyclohexane (k_a) for the same alkoxy radicals (9.) Absolute values of k_5 have been calculated from the ratios k_6/k_5 and k_d/k_a since k_5 should equal k_d for each alkoxy radical (10).

The values of k_a have been assumed to be constant and equal to $3 \times 10^4\ M^{-1}\ s^{-1}$, the value for the *t*-butoxy radical (11). The absolute values of k_5 are in the range $1–7 \times 10^6\ M^{-1}\ s^{-1}$ and this variation almost certainly reflects experi-

†C. Walling, in a paper presented to the 156th ACS National Meeting (1968), reported that this value of k_d/k_a is probably too low. A value 3–5 times greater would improve the consistency of the k_5 values.
‡C. Walling and A. Padwa (20) did not report a k_d/k_a value for this alkoxy radical. Our work suggests that it undergoes β-scission about twice as readily as the 1-methylcyclohexyloxy radical.

mental errors in the determination of k_6/k_5 and k_d/k_a rather than actual differences in k_5.

The average value of k_5 is $3.7 \times 10^6\ M^{-1}\ s^{-1}$ and is about three orders of magnitude larger than the rate constant (k_9) for abstraction of the hydroperoxidic hydrogen from cumene hydroperoxide (COOH) by the tetralylperoxy radical (TOO·) (12)

[9] $\quad TOO\cdot + COOH \rightarrow TOOH + COO\cdot$

Reaction [9] has a large deuterium isotope effect ($(k_9)_H/(k_9)_D \sim 17$) which was estimated by measurement of k_9 in the presence of light and heavy water (12). The same procedure for the induced decomposition of cumene hydroperoxide gave an isotope effect of about 5 for abstraction of the hydroperoxidic hydrogen from cumene hydroperoxide by the cumyloxy radical (reaction [5]). This value agrees with other isotope effects for similar symmetric H-atom abstraction reactions (12).

1,1-Diphenylethoxy Radical

Because alkoxy radicals produced by the induced decomposition of some *t*-hydroperoxides undergo intramolecular reactions, rate constant ratios, k_4/k_3, could not be measured. The 1,1-diphenylethoxy radical provides an intriguing example of this effect. This radical is of further interest since its termination rate constant is the highest we have measured for a *t*-peroxy radical (5).

Although it was expected that β-scission of the 1,1-diphenylethoxy radical would give mainly benzophenone

[10] $\quad Ph_2(CH_3)CO\cdot \rightarrow Ph_2CO + CH_3\cdot$

none of this ketone was formed during the induced decomposition of the hydroperoxide. Instead, acetophene, phenol, and *p*-benzoquinone (and presumably other oxidation products of phenol) were produced. Similar products have recently been found by Kropf *et al.* in the oxidation of 1,1-diphenylethane at 100 °C and in the copper phthalocyanine catalyzed decomposition of the hydroperoxide (13). We found that the same products were formed during the oxidation of 1,1-diphenylethane (at 30 °C) and also by photolysis (3650 Å) of 1,1-diphenylethyl peroxide in CCl_4 in the presence of oxygen[3].

These results suggest that β-scission might occur by the alternative route

[11] $\quad Ph_2(CH_3)CO\cdot \rightarrow PhCOCH_3 + Ph\cdot$

with the phenyl radical as the source of phenol and quinone. However, this reaction can probably be ruled out because chlorobenzene was not detected when the oxidation of 1,1-diphenylethane or the induced decomposition of 1,1-diphenylethyl hydroperoxide were carried out in

[3]Thermal decomposition of the peroxide at 120° in CCl_4 yielded some benzophenone which implies that reaction [10] can occur at this temperature. The product yields (calculated on the basis of the number of alkoxy groups) in the presence and absence of oxygen were: acetophenone, 10% and 30%; phenol, 30% and 30–50%; benzophenone, 8% and 4%; 1,1-diphenylethylene, 3% and 30%. The last named product may arise by dehydration of 1,1-diphenylethanol (formed by hydrogen abstraction by the ethoxy radical) or perhaps by a concerted decomposition of the peroxide which does not involve free radicals

$$Ph_2(CH_3)COOC(CH_3)Ph_2 \rightarrow PhCOCH_3 + Ph_2C{=}CH_2 + PhOH$$

Traces of chlorobenzene were also formed in these reactions, which suggests that reaction [11] may occur at this temperature.

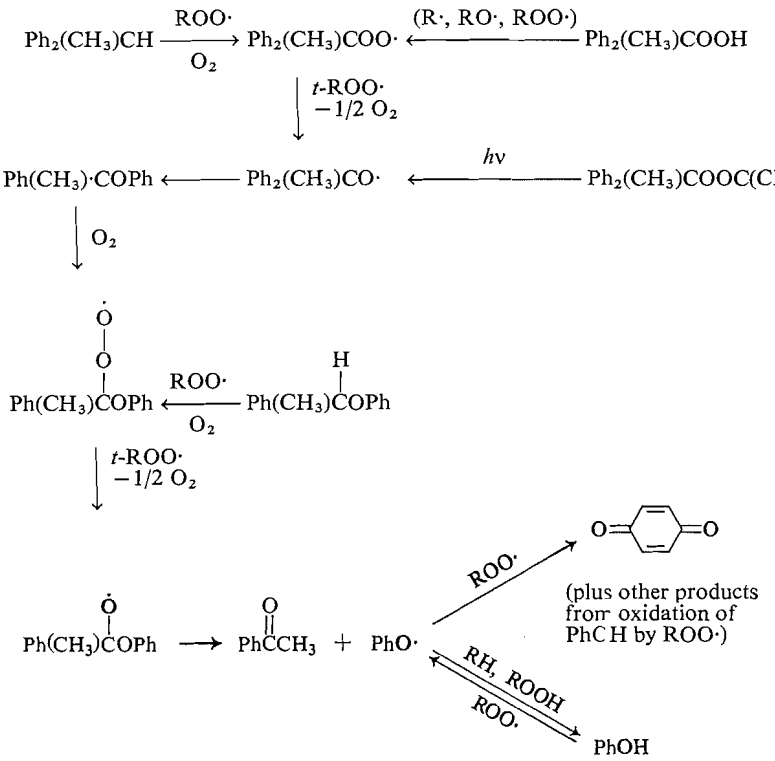

SCHEME I. The formation of acetophenone, phenol, and *p*-quinone.

dilute solution in CCl_4. The attack of phenyl radical on CCl_4, reaction [12]

[12] $\quad Ph\cdot + CCl_4 \rightarrow PhCl + CCl_3\cdot$

is extremely rapid (14) and reaction [11] would lead to the production of chlorobenzene. Our results are consistent with the reactions given in Scheme I. That is, the diphenylethoxy radical isomerizes to the 1-phenyl-1-phenoxyethyl radical more rapidly than it undergoes β-scission. The ethyl radical then adds to oxygen and, by a non-terminating reaction with a second *t*-peroxy radical, is converted to the 1-phenyl-1-phenoxyethoxy radical which then undergoes β-scission to give acetophenone and the resonance stabilized phenoxy radical[4]. Oxidation of the phenoxy radical by a peroxy radical yields *p*-quinone and its reduction by hydrogen abstraction from a suitable donor, such as the hydroperoxide (15), yields phenol.

[4]An alternative reaction sequence involving hydrogen abstraction by the phenoxyethoxy radical followed by direct decomposition to acetophenone and phenol cannot be ruled out by the present data.

The 1,2-phenyl shift of the diphenylethoxy radical is analogous to the rearrangement of triarylmethoxy radicals (16–19), e.g.

[13] $\quad Ph_3CO\cdot \rightarrow Ph_2\dot{C}OPh$

The intermediacy of the phenoxyethyl radical in the above reactions is supported by the formation of acetophenone, phenol, and oxidation products of phenol during the oxidation of 1-phenylethyl phenyl ether.

2-Neopentyl-2-propoxy Radical

Induced decomposition of 0.35 *M* 2-neopentyl-2-propyl hydroperoxide gave $R_{O_2}/R_i = 0.5$, $R_{C=O}/R_i = 0.04$ and the rather low value of 0.08 for k_4/k_3. We believe that these values result from the facile intramolecular hydrogen abstraction of the 2-neopentyl-2-propoxy radical. It has previously been shown that alkoxy radical intramolecular abstractions from the δ-position (i.e., via a 6-membered cyclic transition state) are very fast (20). The hydrogens on the *t*-butyl group of the 2-neopentyl-2-propoxy radical are in this favorable position

[14] 
The resultant primary alkyl radical will add to oxygen to give the corresponding hydroperoxide (reaction [9]). The overall result is that this alkoxy radical yields a product which absorbs oxygen without simultaneously forming a ketone. The kinetic analysis used to derive eqs. [III] and [IV] is therefore not valid.

Although no evidence was found for intramolecular abstraction from the γ position of an alkoxy radical (20), the induced decomposition of 2-isopropyl-2-propyl hydroperoxide (at 0.2 M, $R_{O_2}/R_i = 0.13$, $R_{C=O}/R_i = 1.6$, $k_4/k_3 = 2.5$) suggests that the 2-isopropyl-2-propoxy radical may abstract a hydrogen from the γ position. 1-Methylcyclopentyl hydroperoxide also gave a low value for k_4/k_3 (at 0.26 M, $R_{O_2} = 0.44$, $R_{C=O} = 0.45$, $k_4/k_3 = 0.8$). In this case the ketone group produced by β-scission may be partly destroyed by recyclization of the 5-acetylpentyl radical to give a pyran ring system, i.e.

[15] 
The reactions of alkoxy radicals derived from both these hydroperoxides clearly deserve further investigation.

Absolute rate constants for hydrocarbon autoxidation. XVI. Reactions of peroxy radicals at low temperatures[1,2]

K. ADAMIC[3], J. A. HOWARD, AND K. U. INGOLD
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received May 23, 1969

The equilibrium constants for the formation of some *t*-alkyl tetroxides and the rate constants for irreversible decay of the tetroxides have been measured by electron spin resonance spectroscopy at low temperatures. The equilibrium constant appears to be virtually independent of the nature of the alkyl groups. It is concluded that differences in the rate of constants for chain termination by *t*-peroxy radicals at ambient temperatures are due chiefly to the differences in rate constants for irreversible tetroxide decomposition. The activation parameters for this reaction indicate that it occurs by one bond rather than two bond scission.

Canadian Journal of Chemistry, **47**, 3803 (1969)

Introduction

Bartlett and Guaraldi (1) have shown that di-*t*-butyl tetroxide is stable at temperatures below about $-80°$. The tetroxide was prepared both by the irradiation of di-*t*-butylperoxycarbonate in frozen methylene chloride at $-196°$ and by the oxidation of *t*-butyl hydroperoxide with lead tetraacetate at $-90°$ in the same solvent. The equilibrium constant, $K_1 (= k_{-1}/k_1)$ and the rate constant for tetroxide decomposition k_2, were determined by using electron spin resonance (e.s.r.) spectroscopy to monitor changes in the peroxy radical concentration[4].

$$[1] \qquad \mathrm{ROO\cdot} + \mathrm{ROO\cdot} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \mathrm{ROOOOR}$$

$$[2] \qquad \mathrm{ROOOOR} \xrightarrow{k_2} [\mathrm{RO\cdot}\ \ \mathrm{O_2}\ \ \cdot\mathrm{OR}]_{\mathrm{cage}}$$

$$[3] \qquad [\mathrm{RO\cdot}\ \ \mathrm{O_2}\ \ \cdot\mathrm{OR}]_{\mathrm{cage}} \xrightarrow{k_3} \mathrm{ROOR} + \mathrm{O_2}$$

$$[4] \qquad [\mathrm{RO\cdot}\ \ \mathrm{O_2}\ \ \cdot\mathrm{OR}]_{\mathrm{cage}} \xrightarrow{k_4} \mathrm{RO\cdot} + \mathrm{O_2} + \cdot\mathrm{OR}$$

Di-*t*-butyl tetroxide has also been prepared by the photolysis of azo-isobutane in the presence of oxygen (2) and by the reaction of *t*-butyl hydroperoxide with iodosobenzene and iodosobenzene diacetate (3). The low temperature photolysis of azo-isobutyronitrile (AIBN) and azo-cyclohexylnitrile (ACHN) in the presence of oxygen has also been reported to yield tetroxides (2). At temperatures below about $-30°$, di-*t*-butyl trioxide and dicumyl trioxide are stable (4). They are believed to be formed by the trapping of the RO· radicals formed in reaction [4] by peroxy radicals

$$[16] \qquad \mathrm{RO\cdot} + \mathrm{ROO\cdot} \underset{> -30°}{\rightleftharpoons} \mathrm{ROOOR}$$

Our interest in the self-reactions of peroxy radicals comes from our measurements of the rate constants for chain termination in hydrocarbon oxidation. Part XIV of this series (5) describes the measurement of termination rate constants in the presence of concentrations of tertiary hydroperoxides sufficient to trap all the RO· radicals formed in reaction [4] and convert them to ROO· radicals

$$[5] \qquad \mathrm{RO\cdot} + \mathrm{ROOH} \rightarrow \mathrm{ROH} + \mathrm{ROO\cdot}$$

Under these conditions the termination rate constant, $2k_t$, corresponds to $(2k_2/K_1)(k_3/(k_3 + k_4))$. Values of $2k_t$ at 30° for tertiary peroxy radicals range from $\sim 4 \times 10^2\ M^{-1}\ s^{-1}$ for for *t*-butylperoxy radicals, to $\sim 3 \times 10^3\ M^{-1}\ s^{-1}$ for cumylperoxy, to $\sim 3 \times 10^4\ M^{-1}\ s^{-1}$ for 1,1-diphenylethylperoxy radicals. This range cannot be accounted for by any variation in the ratio of alkoxy radical combination in the cage to diffusion from the cage (6). Bartlett and Guaraldi's experimental approach appeared to provide a simple method for determining whether the variation in $2k_t$ was due primarily to changes in K_1 or k_2. The present paper describes an e.s.r. study of the low temperature reactions of some representative peroxy radicals.

Experimental

Radical Formation

Peroxy radicals were prepared by three different methods, all of which, for *t*-butylperoxy at least, gave very similar results in the temperature range in which the equilibrium constant for tetroxide formation was determined. However, at the higher temperatures where the irreversible decomposition of tetroxide was studied, similar results were not obtained by the different methods. In this region, the most satisfactory procedure involved photolysis of 10^{-2} *M* azoalkanes in oxygen saturated CF_2Cl_2 (freon 12, f.p. $-155°$) at liquid nitrogen temperatures (2). With this procedure the rates of peroxy radical decay were very reproducible and were exactly second order. In contrast, the photolysis of hydroperoxides under similar conditions gave rather irreproducible decay rates which were not always second order. These effects are probably due, in part, to the fact that the RO· radicals are scavenged both by reaction [16] (which leads to the loss of an ROO· radical) and by reaction [5] (which leads to the formation of an ROO· radical). The relative importance of these two processes obviously depends on the relative concentrations of ROO· and ROOH and will, therefore, vary during a decay experiment. The ROOH concentration will itself depend on its initial concentration and on the amount photolyzed in the radical generation. It is also possible that the highly reactive ·OH radical produced in the photolysis forms secondary radicals which in some way interfere with the peroxy radical decay.

Peroxy radicals were also prepared by the rapid cooling from 30° of *t*-butyl hyponitrite (2.5×10^{-2} *M*) induced decompositions of 0.1 *M* hydroperoxide solutions in CF_2Cl_2 and in isopentane. Although this method was quite satisfactory for the determination of the equilibrium constant the radical decays were not exactly second order.

Solvents

In most of the present work CF_2Cl_2 was used as the solvent. A few experiments were also done in isopentane. Methylene chloride, the solvent used by Bartlett and Guaraldi (1), was less satisfactory than either CF_2Cl_2 or isopentane, because its freezing point ($-97°$) is in the middle of the temperature range of the experiments. Although there does appear to be some kind of equilibrium between the peroxy radicals and tetroxide in solid methylene chloride (1) in our hands, the measured equilibrium constants were not very reproducible and appeared to depend on the rate at which the methylene chloride was solidified.

Radical Concentrations

The peroxy radicals were monitored in the V-4557 variable temperature accessory of a Varian E-3 e.s.r. spectrometer. The signal at ~2 kG from a single crystal of synthetic ruby was used to correct for variations in cavity Q (7). The radical concentrations were determined at each temperature[5] by double integration of the first derivative e.s.r. signal using a Honeywell G.P.I.-10 general purpose integrator. The calibration of concentration was done over the entire temperature range with 2,2-diphenyl-1-picrylhydrazyl (DPPH) and 2,2,6,6-tetramethylpyridone nitroxide solutions. This is necessary because the second integral for these stable radicals (normalized to the ruby signal) varied with temperature (Fig. 1).

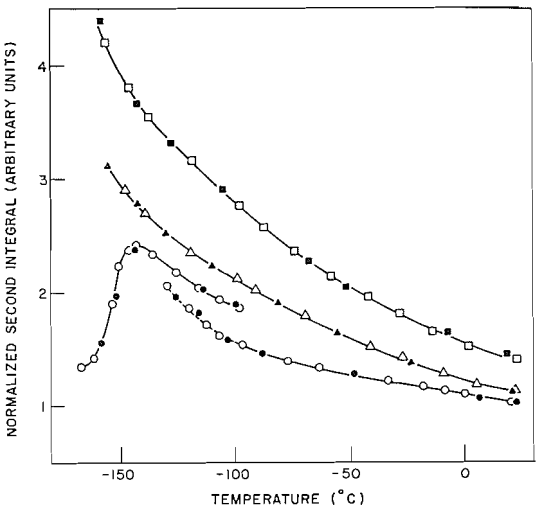

FIG. 1. Calibration curves for the stable radicals in the different solvents; ○, methylene chloride; △, isopentane; □, freon 12 (CF_2Cl_2). Open points refer to nitroxide and solid points to DPPH.

Results

The effect of temperature on the concentration of peroxy radicals is illustrated schematically in Fig. 2. The picture is generally similar to that previously found by Bartlett and Guaraldi (1).

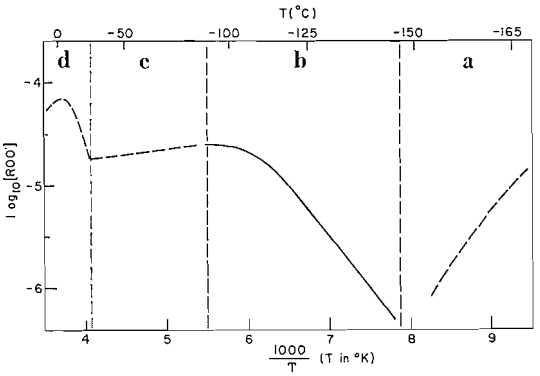

FIG. 2. The temperature dependence of the concentration of *t*-alkylperoxy radicals. The line is dotted in regions *a*, *c*, and *d* because the peroxy radical concentration at a given temperature can vary significantly during the time involved in an experiment.

[5]The line width for peroxy radicals is strongly temperature dependent (8), even at temperatures below $-90°$. For example, the line width for *t*-butylperoxy radicals at $-90°$ (4.2 ± 0.2 G) is twice as great as at $-148°$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The region *a* is characteristic of peroxy radicals generated by photolysis at −196°. As the temperature is increased the radical concentration decreases owing to the formation of tetroxide. The disappearance of the radicals in the solid matrix as they are slowly converted to tetroxide occurs even at temperatures as low as −170 to −180°. The ease of this reaction has been commented on previously (9). At these low temperatures the e.s.r. line shape is not symmetrical but the asymmetry is not connected with the presence of a second radical (9). The asymmetry has been previously analyzed in terms of a single radical whose *g* value is anisotropic but has an axis of symmetry (9, 10*c*). The asymmetric line shape depends not only on the radical concentration (10) but also on the temperature. Provided little tetroxide is formed the line shape is reversible with temperature. There is no signal in the region *a* if tetroxide is allowed to form. That is, a sample containing peroxy radicals which is cooled from higher temperatures into region *a* does not give an e.s.r. signal.

For most practical purposes peroxy radicals can be considered to be in equilibrium with the tetroxide in region *b*. There is, in actual fact, a slow disappearance of radicals in this region but it is not until region *c* that radical loss becomes significant on the time scale (and at the concentrations) of the present experiments. In region *b* the concentrations of radicals and tetroxide are related to one another by

$$[\mathrm{ROO}\cdot] + 2[\mathrm{RO_4R}] = [\mathrm{ROO}\cdot]_{max}$$

where $[\mathrm{ROO}\cdot]_{max}$ is the radical concentration at complete dissociation. The equilibrium constant is given by

$$K_1 = \frac{[\mathrm{ROO}\cdot]^2}{[\mathrm{RO_4R}]} = \frac{2[\mathrm{ROO}\cdot]^2}{[\mathrm{ROO}\cdot]_{max} - [\mathrm{ROO}\cdot]}$$

Its variation with temperature can be represented by the van't Hoff relation

$$K_1 = e^{\Delta S_1/R}\, e^{-\Delta H_1/RT}$$

where ΔS_1 is the change in entropy and ΔH_1, the change in enthalpy.

The behavior of *t*-butylperoxy radicals in the temperature range where they are in equilibrium with tetroxide is illustrated in Fig. 3. The data in this figure were obtained in a single experiment. The individual points on each of the three curves were obtained in a completely random manner. After curve I was obtained, about 90% of the radicals were allowed to decay at ~ − 50° and curve II was obtained. The sample was then warmed to about −20° (region *d*) at which temperature trioxide decomposition was sufficiently rapid that the radical concentration *increased* (see Fig. 2). The sample was recooled and curve III was obtained. This general procedure for changing the radical concentration by warming the sample into region *c* (smaller) and *d* (greater) was employed in a majority of the experiments in order to increase the number of individual measurements of ΔS_1 and ΔH_1.

The values found for ΔS_1 and ΔH_1 from curves such as those in Fig. 3 are summarized in Table I. The errors are standard deviations from the average value for several different experiments. With cumene hydroperoxide and 2-phenyl-2-butyl hydroperoxide, ΔS_1 values were not measured because irreversible decomposition of the tetroxide started to occur at a temperature below which it was fully dissociated into peroxy radicals, i.e., $[\mathrm{ROO}\cdot]_{max}$ could not be determined.

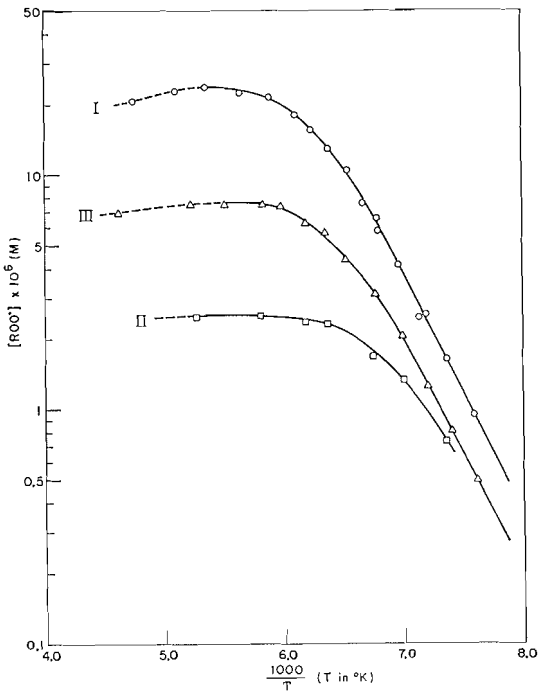

FIG. 3. The *t*-butylperoxy radical – *t*-butyl tetroxide equilibrium. The radicals were prepared by low temperature photolysis of azo-isobutane.

[a]"Best values" at 30° (5, 9).
[b]From RNNR in CF_2Cl_2.
[c]From ROOH in CF_2Cl_2.
[d]From ROOH in isopentane.
[e]ΔS_1 was not measured because irreversible decay started to occur at a temperature below that at which the tetroxide was fully dissociated into peroxy radicals.

For some of the more unstable tetroxides, region *c* extends to lower temperatures. The presence of a tetroxide can only be inferred by the fact that a short-lived peroxy radical signal appears when the irradiated samples are warmed rapidly into region *b*. Thus, with 1,1-diphenylethyl hydroperoxide the intensity of the 1,1-diphenylethylperoxy radical signal rose with temperature throughout region *b*. The tetroxide was definitely formed reversibly but its irreversible decomposition was too rapid for ΔH_1 to be determined.

Although Mill and Stringham (2) apparently obtained tetroxides from azo-bis-isobutyronitrile (AIBN) and azo-bis-cyclohexylnitrile (ACHN), we had great difficulty in detecting any peroxy radicals when these compounds were irradiated in CF_2Cl_2. In some experiments a small asymmetric signal, probably due to peroxy radicals, was detected at −165°. This signal disappeared at −130° and reappeared as a symmetric signal at −100°, lasting only for about 200 s at this temperature[6]. These small signals had only about 1% of the intensity of the signals from azo-isobutane and azo-cumene and were not always observed. Instead, a radical signal with three lines of approximately equal intensity and separation was generally obtained from AIBN and ACHN. This triplet appeared on warming the irradiated sample to about −110° and was not reversible with temperature. It was moderately stable up to about −90° but disappeared rapidly at −60° (half life ~200 s). The triplet had splittings of 30.0 ± 0.1 G on the low field side and 30.4 ± 0.1 G on the high field side. The line width was 2.0 ± 0.3 G with 0.5 G modulation. The maximum radical concentration was $\sim 1 \times 10^{-7}$ *M*. This radical has not been identified but it is worth noting that it was not detected when AIBN was irradiated in the absence of oxygen. On warming the samples to 0° a second very weak triplet was observed. The splittings were ~8–9 G suggesting that this radical may be a nitroxide.

The photolysis of 2-cyano-2-propyl hydroperoxide, which should give the same *t*-peroxy radical as the photolysis of AIBN and oxygen, did not give a peroxy radical signal. Preliminary experiments on the oxidation of cumene in the presence of 2-cyano-2-propyl hydroperoxide gave $k_p/(2k_t)^{\frac{1}{2}} \sim 0.33 \times 10^{-3}\ M^{-\frac{1}{2}}\ s^{-\frac{1}{2}}$, $k_p \sim 0.18\ M^{-1}\ s^{-1}$, and $2k_t \sim 3 \times 10^5\ M^{-1}\ s^{-1}$. It is possible that a *t*-peroxy radical with a termination rate constant of about $10^5\ M^{-1}\ s^{-1}$ would not be seen under our experimental conditions.

Cyclohexyl hydroperoxide gave a peroxy radical signal in region *b*. Although short-lived,

[6]The irradiation of AIBN in the e.s.r. cavity at −95° (cf. ref. 2) gave no detectable signal in 900 s. In contrast, a peroxy radical signal was easily detected within 50 s of the irradiation of azo-isobutane under the same conditions.

the intensity of the signal did increase with an increase in temperature. However, the radical concentration decreased too rapidly for confirmation of the reversibility of tetroxide formation. Di-*sec*-alkyl tetroxides have not previously been directly detected. Mill and Stringham originally reported (2) and we have confirmed that peroxy radicals cannot be detected in photolyzed azo-isopropane samples. There is no obvious reason for the difference in the low temperature behavior of cyclohexylperoxy radicals and isopropylperoxy radicals because, at 30°, the rate constants for their self-reactions are similar (11).

With azo-bis-1-propanol diacetate, $(CH_3C(O)OCH_2C(CH_3)_2N)_2$, the concentration of peroxy radicals was too low to measure ΔH_1, although a tetroxide was definitely formed reversibly.

In region *c*, where the tetroxide is almost completely dissociated, the radical concentration decreases with time according to a second order rate law (1). As was mentioned in Experimental section, the radical decay is accurately second order for radicals derived from the azoalkanes (see also Fig. 4) but it is rather irreproducible and frequently is not exactly second order for the radicals from hydroperoxides. Now the measured bimolecular rate constant, $k_{e.s.r.}$, will be equal to $2k_2/K_1$ provided the RO· radicals formed in reaction [4] have no effect on the ROO· radical concentration and provided $k_{-1} \gg k_2$. In the experiments in which hydroperoxides were used the RO· radicals can be scavenged by ROO· (reaction [16], $k_{e.s.r.} = (2k_2/K_1)(1 + k_4/(k_3 + k_4))$) and by ROOH (reaction [5], $k_{e.s.r.} = (2k_2/K_1)(k_3/(k_3 + k_4))$). The rather poor reproducibility of $k_{e.s.r.}$ values in the hydroperoxide experiments chiefly reflects variations in the relative contributions of reactions [5] and [16] to RO· scavenging. The excellent reproducibility of the $k_{e.s.r.}$ values in the azoalkane experiments presumably reflects the exclusive scavenging of RO· in reaction [16]. The activation parameters for reaction [2] (see Table I) have therefore been calculated only from the azoalkane data. In these calculations, it was assumed that $k_{e.s.r.} = 4k_2/K_1$ on the basis that k_4/k_3 is about 6–7 at 30° (6 and references cited therein) and that although this ratio decreases slightly with temperature the value of $k_4/(k_3 + k_4)$ will probably still be reasonably close to unity in the temperature range in which $k_{e.s.r.}$ is measured (cf. ref. 4).

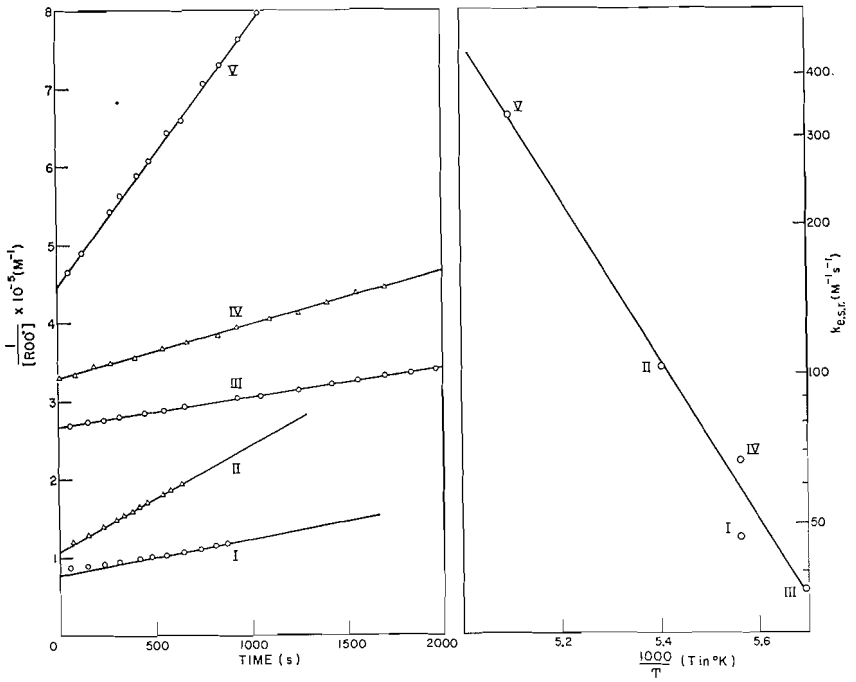

FIG. 4. The irreversible decay of cumyl tetroxide. The cumylperoxy radicals were prepared by low temperature photolysis of azocumene.

Discussion

The values of ΔS_1 and ΔH_1 for the tetroxides listed in Table I are in excellent agreement with the values obtained by Bennett, Brown, and Mile for a number of other *t*-alkyl tetroxides prepared by the low temperature photolysis of *t*-butyl peroxide in oxygen saturated branched chain hydrocarbons (12). These parameters are also in reasonably good agreement with the original estimate that ΔS_1 should be ~ 25 cal deg^{-1} mole^{-1} and $\Delta H_1 \sim 5$ kcal/mole (13). These estimates were made by Benson on thermochemical grounds before tetroxides had been observed experimentally.

Within our limits of experimental accuracy the values of ΔS_1 and ΔH_1 are identical for the different tetroxides. This implies that differences in behavior of *t*-alkylperoxy radicals in the termination of oxidation chains at 30° ($2k_t$) are due chiefly to differences in the rate constants for irreversible tetroxide decomposition, k_2. Evidence favoring this conclusion is also provided by the fact that both cumyl tetroxide and 1,1-diphenylethyl tetroxide undoubtedly decomposed more rapidly than the *t*-alkyl tetroxides. The activation parameters for *t*-butyl tetroxide and cumyl tetroxide decomposition suggest that rate differences are due to differences in activation energy rather than activation entropy.

The chain termination rate constants for *t*-butylperoxy and cumylperoxy radicals at 30° can be calculated from the relation $2k_t = (2k_2/K_1)(k_3/(k_3 + k_4))$ using the values of K_1 and k_2 found in this work and the values of k_4/k_3 given in the preceding paper (6). Assuming that K_1 is the same for both radicals, the azoalkane photolytic results give $\Delta H_1 = 9.0$ kcal/mole, $\Delta S_1 = 33$ cal deg^{-1} mole^{-1} and $(K_1)_{30°} = 5.2\ M$. For *t*-butylperoxy radicals at 30°, $k_2 = 1 \times 10^4$ s^{-1} (Table I) and $(k_3 + k_4)/k_3 = 8.0$ giving $2k_t = 5 \times 10^2\ M^{-1}$ s^{-1}, in excellent agreement with the "best" value of 4.0×10^2 (5). For cumylperoxy radicals, $k_2 = 1.6 \times 10^5$ and $(k_3 + k_4)/k_3 = 7.3$, giving $2k_t = 8 \times 10^3\ M^{-1}$ s^{-1}, which is in good agreement with the measured values ($6–8 \times 10^3\ M^{-1}$ s^{-1}) but is rather larger than the "best" value of $2.6 \times 10^3\ M^{-1}$ s^{-1}. Considering the temperature range over which K_1 and k_2 have been extrapolated, the agreement between the calculated and measured rate constants is very satisfactory.

The pre-exponential factors in the Arrhenius equation for reaction [2] are such as to indicate that only one bond in the tetroxide is cleaved in the rate determining step.

$$\text{ROOOOR} \xrightarrow{k_2} \text{RO}\cdot + \cdot\text{OOOR} \rightarrow \text{RO}\cdot + \text{O}_2 + \cdot\text{OR}$$

That is, the *A* factors for simple one bond fission are expected (14) to be in the range 10^{15}–10^{17} s^{-1}, while lower values are obtained if two O—O bonds are cleaved at the same time. The pre-exponential factors found in the present work (together with the value of Bennett *et al.*, $10^{17.5}$ s^{-1}, for the tetroxide derived from 2,2,3-trimethylbutane (12)) contrast with earlier values of $10^{9.3}$ (1) and 10^{12} s^{-1} (2), which implied that reaction [2] occurred by concerted cleavage of the 1,2 and 3,4 O—O bonds. The activation energies of reaction [2] are also consistent with Benson's estimate that the 1,2 O—O bond strength is about 20 kcal/mole (13). Further support for single bond fission of the tetroxide comes from Fessenden's recent identification of the $CF_3OOO\cdot$ radical (15). However, we could not detect any peroxy radicals in the photolysis of *t*-butyl hyponitrite, which implies that oxygen is not readily trapped by a *t*-butoxy radical even at liquid nitrogen temperatures.

Absolute rate constants for hydrocarbon autoxidation. XVII. The oxidation of some cyclic ethers[1]

J. A. HOWARD AND K. U. INGOLD
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received June 30, 1969

The propagation and termination rate constants have been determined for the autoxidation of 1,4-dioxan, tetrahydropyran, tetrahydrofuran, 2,5-dimethyltetrahydrofuran, and phthalan. The rate constants for α-hydrogen atom abstraction from some of the ethers by the tetralylperoxy radical and from tetralin by some ether peroxy radicals have been measured and compared. The chain transfer rate constants have been estimated for the reaction of the cumylperoxy radical with α-hydroperoxytetrahydrofuran, α-hydroperoxytetrahydropyran, and α-ethoxyethyl hydroperoxide.

Introduction

It has been known for some time that ethers react with molecular oxygen at ambient temperatures to form peroxides and hydroperoxides (1–3). The free radical initiated oxidation of tetrahydrofuran (EH) has been shown to yield α-hydroperoxytetrahydrofuran (4) and to obey the kinetic expression (5)

$$[\mathrm{I}] \qquad \text{Rate of oxidation} = -\frac{d[O_2]}{dt} = \frac{k_p[EH]R_i^{1/2}}{(2k_t)^{1/2}}$$

where k_p and $2k_t$ are the propagation and termination rate constants and R_i is the rate of chain initiation. It is, therefore, possible to describe the oxidation of tetrahydrofuran, at oxygen pressures above about 100 mm Hg, by a reaction scheme which is similar to that used to describe the oxidation of many organic substances

$$[1] \qquad I_2 \xrightarrow[O_2 + EH]{k_i} EOO\cdot \qquad (R_i = 2ek_i[I_2])$$

$$[2] \qquad EOO\cdot + EH \xrightarrow{k_p} EOOH + E\cdot$$

$$[3] \qquad E\cdot + O_2 \longrightarrow EOO\cdot$$

$$[4] \qquad EOO\cdot + EOO\cdot \xrightarrow{2k_t} \text{Non-radical products}$$

where E· is the tetrahydrofuranyl radical, EOO· the tetrahydrofuranylperoxy radical, and I_2 is the free radical chain initiator. This scheme can almost certainly be used to describe the autoxidation of many other cyclic ethers.

There are no directly measured absolute rate constants for the oxidation of ethers reported in the literature. However, Gosborne and Seree de Roch (5) have estimated the termination rate constants for *n*-butyl, isopropyl, benzyl, and α-methylbenzyl ethers, tetrahydrofuran, and 2-methyl tetrahydrofuran to be about $10^6\ M^{-1}\ s^{-1}$ by the co-oxidation method (6). These results imply a fundamental difference between hydrocarbon and ether oxidations since the termination rate constants for secondary and tertiary hydrocarbons have been shown to vary considerably (7). In this paper we report our measurements of the absolute propagation and termination rate constants for the oxidation of a number of readily oxidizable cyclic ethers.

Experimental

Tetrahydrofuran, tetrahydropyran, 1,4-dioxan, 2,5-dimethyltetrahydrofuran, tetralin, cumene, *t*-butyl hydroperoxide, and chlorobenzene were commercial materials purified to > 99.5% by standard techniques. Phthalan was prepared by dehydration of phthalyl alcohol (8). The preparation of tetralin hydroperoxide has been described previously (9). α-Hydroperoxytetrahydrofuran and 2-hydroperoxy-2,5-dimethyltetrahydrofuran were prepared by the α,α′-azo-bis-isobutyronitrile initiated oxidation at 30° of tetrahydrofuran and 2,5-dimethyltetrahydrofuran, respectively. α-Hydroperoxytetrahydropyran, α-ethoxyethyl hydroperoxide, and 2-hydroperoxy-2-methyltetrahydrofuran were prepared by the reaction of 50% H_2O_2 with 2,3-dihydropyran, ethyl vinyl ether, and 2-methyl-4,5-dihydrofuran, respectively (10).

The rates of oxidation were determined from the consumption of oxygen as monitored by a Dynisco pressure transducer (DPT 85–2). The reaction cell and the transducer were both thermostatted at 30°. The output from the transducer was displayed on a Sargent recorder (Model SRG). The absolute rate constants were generally measured by the rotating sector technique. The photochemical pre- and after-effect method (11) was used for the determination of the absolute rate constants (i.e.,

$k_p/2k_t$) for the oxidation of 2,5-dimethyltetrahydrofuran and some oxidations in the presence of 2-hydroperoxy-2,5-dimethyltetrahydrofuran and 2-hydroperoxy-2-methyltetrahydrofuran. The rate constants for attack on an ether by a peroxy radical not derived from the ether have been determined by oxidation of the ether in the presence of the appropriate hydroperoxide (e.g. tetralin hydroperoxide served as a source of tetralylperoxy radicals (9)).

α,α′-Azo-bis-cyclohexyl nitrile was the photoinitiator and α,α′-azo-bis-isobutyronitrile and *t*-butylhyponitrite were the thermal initiators. The rates of chain initiation were measured using 2,6-di-*t*-butyl-4-methoxyphenol as inhibitor. The hydroperoxide yields for the oxidation of the pure ethers were determined by iodometric titration.

The carbonyl compounds formed in many of the oxidations were investigated by infrared analysis (1650–1750 cm^{-1} region).

Results and Discussion

The propagation and termination rate constants for the oxidation of tetrahydrofuran at 30° are given in Table I. α-Hydroperoxytetrahydrofuran (0.38 *M*) has no effect on the rate constants for the oxidation of the parent ether.

The rate constants for the oxidation of tetrahydrofuran in the presence of a number of ether hydroperoxides and hydrocarbon hydroperoxides are given in Table II.

α-Hydroperoxytetrahydropyran, α-ethoxyethylhydroperoxide, and tetralin hydroperoxide have little or no effect on the rate of oxidation of tetrahydrofuran. The termination rate constants for the secondary peroxy radicals derived from the ether hydroperoxides (E′OOH) and from tetralin hydroperoxide (TOOH) are very similar. These peroxy radicals also have a similar reactivity in H-atom abstraction from tetrahydrofuran. The transfer reaction between the added hydroperoxide and tetrahydrofuranylperoxy radicals (EOO·) does indeed take place, since the carbonyl compounds formed in the oxidations in the presence of the hydroperoxides correspond to the carbonyl compounds formed in the free radical induced decomposition of the hydroperoxides, i.e.

$$\text{EOO}\cdot + \text{ROOH (or E′OOH)} \rightarrow \text{EOOH} + \text{ROO}\cdot \text{ (or E′OO}\cdot\text{)}$$

This implies that the majority of the chain terminating radicals in the oxidations are derived from the added hydroperoxide.

For *t*-butyl hydroperoxide concentrations in the range 4–8 *M* the rate of oxidation of tetrahydrofuran is increased by a factor of about 14. This change in rate combined with the fact that the measured termination rate constant is similar

TABLE I

Rate constants for the oxidation of tetrahydrofuran (12.3 *M*) at 30°

$R_i \times 10^8$ ($M\,s^{-1}$)	$R_s \times 10^6$ ($M\,s^{-1}$)	$k_p/(2k_t)^{1/2} \times 10^4$ ($M^{-1/2}\,s^{-1/2}$)	k_p ($M^{-1}\,s^{-1}$)	$2k_t \times 10^{-7}$ ($M^{-1}\,s^{-1}$)
20	4.2	7.8	4.3	3.0

α-Ethoxyethyl	0.36	5.5	11	1.2	10	7.0

to the value found previously for *t*-butylperoxy radicals serves to confirm that the chain transfer reaction takes place. The propagation rate constant is a factor of 10 lower than the values found for the secondary peroxy radicals. This result is in agreement with our earlier conclusions that tertiary peroxy radicals are less reactive than secondary peroxy radicals in chain propagation (9, 12).

The propagation and termination rate constants for the oxidation of tetralin in the presence of three secondary ether hydroperoxides (Table III) are similar to one another and to the values found for tetralin alone or in the presence of tetralin hydroperoxide. Infrared analysis of the termination products again demonstrated that the similar rate constants are not due to the absence of the transfer reaction. These results supplement the results in Table II and confirm that secondary peroxy radicals from ethers and hydrocarbons have similar termination rate constants and similar reactivities towards H-atom abstraction.

The rate of oxidation of cumene is reduced by small concentrations of tetrahydrofuranyl, tetrahydropyranyl, and α-ethoxyethyl hydroperoxides (Table IV and Fig. 1). The rate is also reduced by the addition of tetrahydrofuran (Fig. 1). Similar reductions in the rate of oxidation of cumene have been reported for tetralin hydroperoxide (13) and tetralin (14). We have determined "cross" propagation rate constants for the attack of tetralylperoxy radicals (TOO·) on cumene (CH), i.e. k_p^{TC}

$$\mathrm{TOO\cdot + CH \xrightarrow{k_p^{TC}} TOOH + C\cdot}$$

and for the attack of cumylperoxy radicals (COO·) on tetralin (TH), i.e., k_p^{CT}

$$\mathrm{COO\cdot + TH \xrightarrow{k_p^{CT}} COOH + T\cdot}$$

by a study of the co-oxidation of cumene and tetralin and the oxidation of each of these hydrocarbons in the presence of the hydroperoxide of the other hydrocarbon (9). The results of the present work show that tetralylperoxy and tetrahydrofuranylperoxy radicals have similar reactivities towards H-atom abstraction, which means that $k_p^{TC} \approx k_p^{EC}$. Moreover, it can be concluded that the rate constants for the attack of cumylperoxy radicals on tetrahydrofuran and on tetralin are approximately equal (i.e., $k_p^{CT} \approx k_p^{CE}$). Since tetralin and tetrahydrofuran produce comparable retardations of the oxidation of cumene (Fig. 1) it seems likely that the "cross" termination rate constants, $2k_t^{CT}$ and $2k_t^{EC}$, are of similar magnitude[2]

$$\mathrm{TOO\cdot + COO\cdot \xrightarrow{2k_t^{CT}} Non\text{-}radical\ products}$$

$$\mathrm{EOO\cdot + COO\cdot \xrightarrow{2k_t^{EC}} Non\text{-}radical\ products}$$

We have demonstrated (9) that the rate constant for the peroxy radical – hydroperoxide transfer reaction, k_{trans}^{CTOOH}

$$\mathrm{COO\cdot + TOOH \xrightarrow{k_{trans}^{CTOOH}} COOH + TOO\cdot}$$

may be calculated from measurements of the retardation of the oxidation of cumene by low

[2]For small amounts of added tetralin (or tetrahydrofuran) the co-oxidation rate expression (9) reduces to

$$-\frac{d[O_2]}{dt} = \frac{(k_p^{CC}[CH] + 2k_p^{CT}[TH])R_i^{1/2}}{\left(2k_t^{CC} + \frac{4k_t^{CT}k_p^{CT}[TH]}{k_p^{TC}[CH]}\right)^{1/2}}$$

so that if $k_p^{TC} \approx k_p^{EC}$ and $k_p^{CT} \approx k_p^{ET}$, then $2k_t^{CT} \approx 2k_t^{EC}$.

TABLE IV

Effect of some ether hydroperoxides on the oxidation of cumene

Hydroperoxide	Concentration $\times 10^4$ (M)	Rate $\times 10^6$* ($M\,s^{-1}$)	k_{trans} ($M^{-1}\,s^{-1}$)
None	—	3.87	—
Tetrahydrofuranyl	5.1	3.37	34
Tetrahydrofuranyl	7.7	2.52	44
Tetrahydrofuranyl	24.7	1.77	35
Tetrahydropyranyl	5.0	2.84	42.5
Tetrahydropyranyl	10	2.18	52
α-Ethoxyethyl	10	1.94	66

*$R_i = 1.38 \times 10^{-7}\,M\,s^{-1}$.

concentrations of tetralin hydroperoxide combined with the appropriate absolute rate constants for "uncrossed" and "crossed" propagation (k_p^{CC}, k_p^{TC}) and termination ($2k_t^{CC}$, $2k_t^{CT}$,$2k_t^{TT}$). Since the appropriate rate constants for tetrahydrofuran appear to be very similar to those for tetralin (see above) the weaker retarding effect of tetrahydrofuran hydroperoxide relative to tetralin hydroperoxide (Fig. 1) implies that $k_{trans}^{CEOOH} < k_{trans}^{CTOOH}$. This is not entirely unexpected since the hydroperoxidic hydrogen of the ether hydroperoxide is involved in a stronger intermolecular (and/or intramolecular) hydrogen bond and we have shown that intermolecular hydrogen bonds reduce k_{trans}^{CTOOH} (9). If it is assumed that the appropriate rate constants for tetrahydrofuran and tetralin are exactly equal then $k_{trans}^{CEOOH} = 38\,M^{-1}\,s^{-1}$, compared with $k_{trans}^{CTOOH} = 600\,M^{-1}\,s^{-1}$. The same assumptions for the rate constants for tetrahydropyran and for diethyl ether give transfer constants of 47 and 66 $M^{-1}\,s^{-1}$, respectively, for the attack of cumylperoxy radicals on their α-hydroperoxides.

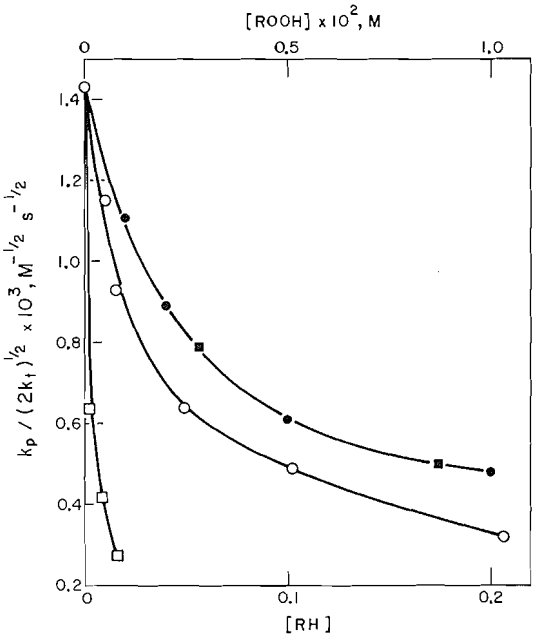

FIG. 1. Variation in the oxidizability of cumene with added tetrahydrofuran, ●; tetralin, ■; α-hydroperoxytetrahydrofuran, ⊙; and tetralin hydroperoxide, □. (N.B. The larger concentration scale refers to tetrahydrofuran and tetralin.)

The rate constants for the oxidation of 1,4-dioxan, tetrahydropyran, and phthalan are given in Table V. These three cyclic ethers give α-hydroperoxides as the primary reaction products in nearly 100% yields and the kinetics for their oxidation obey eq. [I]. The directly measured rate constants for the oxidation of tetrahydropyran are rather inaccurate because of the short chain length involved in the oxidation of this ether. The oxidations of tetrahydrofuran and of tetralin in the presence of α-hydroperoxytetrahydropyran give an average value of 2.1×10^7 $M^{-1}\,s^{-1}$ for the termination rate constant for α-tetrahydropyranylperoxy radicals. This value should be more accurate than the value obtained with neat tetrahydropyran because of the longer chain lengths of the oxidations (Tables II and III). The oxidation of 1,4-dioxan gives $2k_t = 5 \times 10^7$ $M^{-1}\,s^{-1}$ which is close to the values for tetrahydrofuranyl peroxy and tetrahydropyranyl peroxy radicals. The termination rate constant for phthalan ($1.2 \times 10^8\,M^{-1}\,s^{-1}$) is somewhat greater than for the three aliphatic cyclic ethers.

The propagation rate constants for the cyclic ethers increase in the order 1,4-dioxan ~ tetrahydropyran < tetrahydrofuran < phthalan.

TABLE V

The rate constants for the oxidation of 1,4-dioxan, tetrahydropyran, and phthalan

*Based on the concentration of oxygen absorbed.
†These k_p values are based on $2k_t = 2.1 \times 10^7\,M^{-1}\,s^{-1}$, the average of the values measured in tetralin and tetrahydrofuran containing α-hydroperoxytetrahydropyran.
‡In chlorobenzene.

Since this difference is not due to any difference in the reactivity of the peroxy radicals, it must be due to differences in the reactivity of the ethers. Although the propagation rate constants for dioxan and tetrahydropyran are similar, dioxan has twice as many hydrogens α to oxygen. Dioxan has been reported to have a low reactivity towards the *t*-butoxy radical and it was shown that the hydrogens attached to a carbon which is β to oxygen are deactivated relative to the secondary hydrogens in a fully saturated hydrocarbon (15). The low reactivity of dioxan towards oxidation must result from the fact that although all the hydrogens are activated by an α-oxygen they are also deactivated by a β-oxygen.

Tetrahydrofuran is more reactive than tetrahydropyran towards the *t*-butoxy radical (15) and the phenyl radical (16), as well as towards peroxy radicals. The difference in reactivity towards the *t*-butoxy radical has been attributed to the greater availability of electrons (as judged by ether basicity) in the 5-membered ring (15), the rate being enhanced by electron donation because the *t*-butoxy radical is an electrophilic species. However, this explanation cannot apply to phenyl radicals because they are essentially nonpolar (16). It seems possible that the differences in reactivity result from the fact that steric repulsion between the α and β hydrogens will be released to a greater extent by abstraction of hydrogen from the 5-membered ring than from the less strained 6-membered ring.

The high reactivity of phthalan is not unexpected since the reactive C—H bond is weakened both by an α-phenyl group and by an α-alkoxy group.

Under our usual experimental conditions, the chain length for the oxidation of the tertiary aliphatic cyclic ether, 2,5-dimethyltetrahydrofuran, is quite high (~ 700). At low conversion the α-hydroperoxide is formed in approximately 100% yield. There appears to be little or no difference between the rates of oxidation of the racemic mixture and the meso form[3]. The rate constants for the oxidation of this ether are given in Table VI. It is apparent that its facile oxidation is due to the low value of the termination rate constant ($4.6 \times 10^4\,M^{-1}\,s^{-1}$). This rate constant is in the range normally observed for the peroxy radicals involved in the oxidation of tertiary hydrocarbons, i.e., 10^3–$10^5\,M^{-1}\,s^{-1}$ (17). The propagation rate constant per α hydrogen is about twice as high as for tetrahydrofuran. That is, the tertiary hydrogen is more readily abstracted than the secondary hydrogen. Although this is the order usually observed for the abstraction of secondary and tertiary hydrogens from similar molecules by free radicals, exceptions have been noted in hydrocarbon oxidations. For example, the propagation rate constant for the oxidation of cumene is lower than that for the oxidation of ethylbenzene (18).

The rates of oxidation of cumene and many other tertiary hydrocarbons are increased by the addition of their hydroperoxides because there

[3]The racemic mixture and the meso form are resolved by gas–liquid chromatography and appear to be consumed at the same rate.

is a decrease in the overall termination rate constant (19). This change in the rate constant results from the suppression of termination processes involving products of the β-scission of the *t*-alkoxy radicals formed in the self-reaction of the main chain carrying *t*-peroxy radicals (9, 20–22). We attempted to investigate this phenomenon for the oxidation of 2,5-dimethyltetrahydrofuran by studying the oxidation of the ether in the presence of its hydroperoxide and in the presence of 2-hydroperoxy-2-methyltetrahydrofuran. Both the hydroperoxides, however, *reduce* the rate of oxidation of the ether at a constant rate of initiation (Table VII). The absolute rate constants for these oxidations could not be measured very accurately because of the thermal instability of the ether hydroperoxides[4]. The measured propagation and termination rate constants are listed in Table VII merely to illustrate the impossibility of interpreting the decrease in $k_p/(2k_t)^{1/2}$ (which can be measured fairly accurately) in terms of a change in k_p or in $2k_t$. 2-Hydroperoxy-2,5-dimethyltetrahydrofuran (DOOH) inhibits the oxidation of cumene (Table VIII) in which it appears to be thermally stable. If it is assumed that the peroxy radical derived from this hydroperoxide has a reactivity similar to that of the cumylperoxy radical[5], then its termination rate constant is about 3×10^6 M^{-1} s^{-1}. Although DOOH is less stable in tetralin than in cumene, it was possible to obtain an approximate value of 3.6×10^6 M^{-1} s^{-1} for DOO· radicals in this hydrocarbon. In this connection, it is worth noting that our samples of DOOH and 2-hydroperoxy-2-methyltetrahydrofuran did not give a peroxy radical signal detect-

[4]For example, the ratio of the dark rate to the photochemical rate is 0.3 for the oxidation of 8.0 M 2,5-dimethyltetrahydrofuran containing 0.4 M 2-hydroperoxy-2,5-dimethyltetrahydrofuran.

[5]That is, assuming $k_p^{DC} = 0.18$ M^{-1} s^{-1}.

able by electron spin resonance spectroscopy under conditions where tertiary hydroperoxides from hydrocarbons (with $2k_t \approx 3 \times 10^4\ M^{-1}$ s^{-1}) give reasonably large peroxy radical signals (23, 24).

The results with 2-hydroperoxy-2-methyl-, and 2-hydroperoxy-2,5-dimethyl-tetrahydrofuran suggest that these two hydroperoxides may both contain impurities which give peroxy radicals (possibly secondary peroxy radicals) having high termination rate constants. Although such impurities were not detected they need not be present in high concentration, since small amounts of secondary hydroperoxides and secondary ethers or hydrocarbons drastically reduce the rate of oxidation of a tertiary substrate (see above and refs. 13 and 14).

The rate constants for the cyclic ethers oxidized in this work are summarized in Table IX.

Isomer ratios of ^{90}Y and ^{91}Y in the fission of ^{235}U and ^{238}U by protons of energies 20–85 MeV[1]

A. H. KHAN[2], G. B. SAHA, AND L. YAFFE
Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Quebec
Received June 13, 1969

Isomer ratios of ^{90}Y and ^{91}Y formed in the fission of ^{235}U and ^{238}U induced by protons of energies 20–85 MeV have been determined. For both ^{90}Y and ^{91}Y the isomer ratios are always higher in ^{235}U fission than in ^{238}U fission. Isomer ratios of ^{90}Y in ^{238}U fission and those of ^{91}Y in ^{235}U and ^{238}U fission remain almost constant in the energy range of 20–85 MeV, whereas those of ^{90}Y in ^{235}U fission increase with increasing bombarding energy. A theoretical calculation of these ratios indicates that the primary fragments leading to the formation of these isomers possess 2–3 $\hbar$ units of angular momentum.

Introduction

Huizenga and Vandenbosch (1, 2) have developed a statistical model formalism for the calculation of isomer ratios in nuclear reactions. Several authors (3–5) have used this calculation as a basis for comparison with experimentally-determined isomer ratios in spallation reactions where the angular momentum of the initial nucleus was unique, and in general obtained good agreement.

The theoretical interpretation of isomeric yields in fission in terms of the formalism of Huizenga and Vandenbosch is much more complicated than in simple nuclear reactions, because the initial spin distributions of the primary fragments are not known. However, on the basis of an assumed spin distribution of the primary fragments, one can calculate the isomer ratios in fission. From a comparison between the calculated and the experimental values one can then estimate the average spin of the primary fragment.

Several studies (6–14) have been made of the isomer ratios in the heavy-mass region in fission of different targets at various energies. In many of these studies (6–8, 12, 13), calculations of isomer ratios have been made on the basis of an assumed functional form for the primary spin distribution, and various values for different parameters entering into the calculation. Saha and Yaffe (12) also included in the calculation the competition between fission and neutron emission in medium-energy fission. From all these studies it has been concluded that angular momentum is generated in the fission process and also that a fraction of the initial angular momentum appears as orbital angular momentum and the rest as the intrinsic spin of the primary fragments.

Very few isomer ratio data for the light-mass fission products are known compared to the heavy-mass products. Haller and Andersson (15) measured the isomer ratio of ^{80}Br in the fission of uranium by protons of energies 70–100 MeV and found an increase in the ratios with increasing energy. Hagebo (16) determined the isomer ratios of ^{95}Nb in the fission of lead, bismuth, thorium, and uranium of natural composition by 15–157 MeV protons. These results indicated that the isomer ratios for all targets increase with increasing energy and at a given energy, the isomer ratio is highest for lead targets and lowest for uranium targets. From a calculation based on the statistical model he obtained a very low value of 1–2 $\hbar$ for the primary fragment spin in low-energy fission of uranium.

Rudy *et al.* (17) have recently found that about 12 $\hbar$ of angular momentum are necessary for the primary fragment to explain the observed isomer ratio of ^{95}Nb in ^{235}U fission with 10-MeV protons. This is in contradiction to the value of 1–2 $\hbar$ reported by Hagebo (16), and the discrepancy has been attributed to possible experimental error in the measured ratio found by Hagebo.

No work on isomeric yield ratios of ^{90}Y and ^{91}Y in fission has been reported so far. It was considered interesting to determine these isomer ratios and correlate them with those in the heavy-mass region and also compare them with those

[1]This research received financial assistance from the National Research Council of Canada.
[2]Present Address: Chemistry Division, Atomic Energy Centre, P.O. Box 164, Ramna, Dacca, East Pakistan.

found for ^{95}Nb. We have measured the isomer ratios of ^{90}Y and ^{91}Y in the fission of ^{235}U and ^{238}U by protons of energies 20–85 MeV. A comparison of the ratios for the two targets has been made in an attempt to obtain information about the dependence of the isomer ratios on target spin. A calculation has been performed to estimate the average spin of the primary fragment which has been compared with those in the heavy-mass region.

Experimental

The details of the experimental procedures are given elsewhere (18). Only a brief outline is given below.

The two target materials were natural uranium (99.3% ^{238}U) and ^{235}U (94%). The thickness of target foils varied from 0.001 to 0.003 in. The intensity of the proton beam was monitored with the ^{65}Cu(p,pn)^{64}Cu reaction (19). All bombardments were performed in the internal circulating proton beam of the McGill synchrocyclotron. The duration of irradiation varied from 2 to 20 min.

After irradiation the target was dissolved and the chemical separation of yttrium was made as described (18). The activities of 3.2-h ^{90}Y^{m} (202-keV isomeric transition) and 50-min ^{91}Y^{m} (551-keV isomeric transition) were measured with a 3 × 3 in. NaI(Tl) crystal coupled to a 400-channel pulse-height spectrometer. The beta activities of 64-h ^{90}Y^{g} and 59-day ^{91}Y^{g} were measured by gas-flow end-window proportional counters. While ^{90}Y isomers could be considered shielded because of the long-lived precursor (28-yr ^{90}Sr), the activities of ^{91}Y^{m} and ^{91}Y^{g} had to be corrected for the growth from their precursor, 9.7-h ^{91}Sr (about 40% and 7%, respectively, for a typical irradiation time of 10 min and a separation time of 15 min).

The activities measured were corrected for the chemical yield, branching ratio, and counter efficiencies, and were used to calculate absolute cross sections of both isomers of ^{90}Y and ^{91}Y. The measured cross sections and the isomer ratios are given in Tables I and II. The errors in isomer ratios were estimated from the uncertainties in the activity measurements and the counter efficiencies.

Results and Discussion

From Table I it can be seen that in ^{235}U fission the cross sections of ^{90}Y^{m} increase rather sharply with increasing bombarding energy, compared to those of ^{90}Y^{m+g}, whereas the relative energy dependence of the excitation functions of ^{91}Y^{m} and ^{91}Y^{m+g} is almost the same. The excitation

functions of both $^{91}Y^{m}$ and $^{91}Y^{m+g}$ in ^{235}U fission show maxima at about 70 MeV. In the case of ^{238}U fission (Table II), the cross sections of $^{90}Y^{m}$ increase more rapidly than those of $^{90}Y^{m+g}$ with increasing bombarding energy. On the other hand, the cross sections of both $^{91}Y^{m}$ and $^{91}Y^{m+g}$ in ^{238}U fission vary with energy almost in similar fashion. The relative formation probabilities of both metastable and ground states and their energy dependence will be discussed in the following sections.

The experimental isomer ratios, $\sigma_m/(\sigma_m + \sigma_g)$, of ^{90}Y have been illustrated in Fig. 1 and those of ^{91}Y in Fig. 2 for both ^{238}U and ^{235}U targets in the energy range of 20–85 MeV. Figure 1 shows that for ^{90}Y isomers, the ratio $\sigma_m/(\sigma_m + \sigma_g)$ increases very slowly with increasing energy in ^{238}U fission, whereas it is highly energy dependent in the case of ^{235}U fission, for example, increasing from a value of 0.05 at 20 MeV to about 0.23 at 85 MeV. On the other hand, in the case of ^{91}Y isomers, as can be seen in Fig. 2, the ratios are almost constant within experimental error in both ^{235}U and ^{238}U fission, although they are higher in the latter

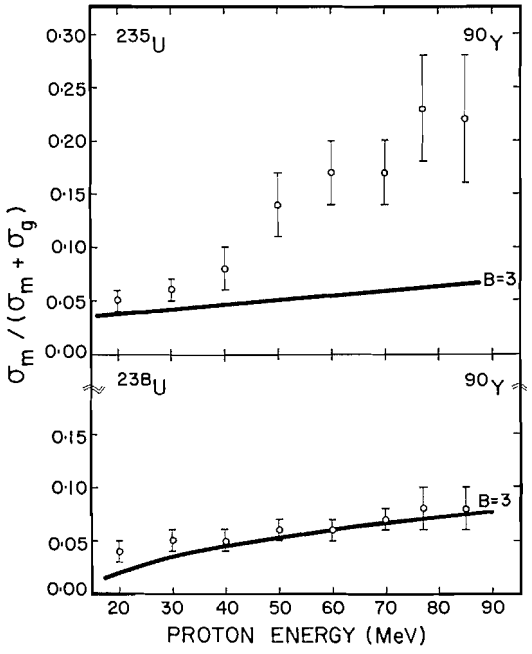

FIG. 1. Experimental and calculated isomer ratios of ^{90}Y in the fission of ^{235}U and ^{238}U: ○, experimental; —, calculated.

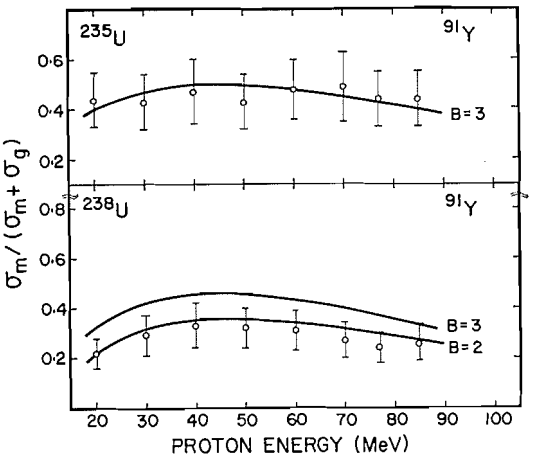

FIG. 2. Experimental and calculated isomer ratios of ^{91}Y in the fission of ^{235}U and ^{238}U: ○, experimental; —, calculated.

than in the former case. It can thus be seen that the observed isomer ratios are somewhat affected by the nature of the target and also the projectile energy. We shall discuss these effects briefly.

(a) Effect of Target

It has been observed by Forster and Yaffe (8) from their study of isomer ratios of ^{133}Xe in various fissioning systems that the spin and type of target do not appreciably affect the isomer ratios. At proton energies up to 115 MeV, Hagebo's (10) measured isomer ratios of ^{117}In were about the same for ^{232}Th ($I = 0$), ^{238}U ($I = 0$), and ^{209}Bi ($I = 9/2$). However, in another work (16) on ^{95}Nb, the isomer ratios were smaller in ^{238}U fission than in ^{232}Th, ^{209}Bi, and ^{208}Pb fission. On the other hand, isomer ratios of ^{134}Cs were almost the same in the fission of ^{233}U (6, 13), ^{235}U (13), ^{238}U (9), ^{232}Th (14), and ^{239}Pu (12), indicating no significant effect of the target on the ratios. From an examination of the calculated results Forster and Yaffe (8) concluded that many factors in the complex fission process overshadow the effect of small changes in target spin.

With all these diversified data it is difficult to correlate the ^{90}Y and ^{91}Y data with those observed in the heavy-mass region. For both ^{90}Y and ^{91}Y isotopes, isomer ratios are always higher in ^{235}U fission than in ^{238}U fission. This follows the same trend as observed by Hagebo (16) for ^{95}Nb isomers. Since fission is considered

to be a high angular momentum process, it is surprising to see how a difference of 3.5 units of spin between ^{235}U and ^{238}U can affect the formation of two isomeric states. This difference in isomer ratios might be a reflection of different fission mechanisms in two targets leading to these isomers.

(b) Effect of Projectile Energy

The isomer ratios for ^{90}Y and ^{91}Y, except those of ^{90}Y in ^{235}U fission, remain almost constant in the energy range of 20–85 MeV. While the isomer ratios of ^{134}Cs (9, 12–14) show very little energy dependence, those of ^{117}In (10) and ^{95}Nb (16) vary strongly with energy. On the other hand, the isomer ratios of ^{80}Br (15) were found to increase only slightly with energy.

At higher energies, several factors become important. As the projectile energy is increased, direct interactions become important, with the transfer of less energy and less angular momentum to the target. At higher projectile energies the orbital angular momentum of fragments may increase and consequently the primary fragments may share less spin. Also neutron and gamma cascades of high multiplicity, largely quadrupole radiations would remove a relatively large amount of angular momentum from fragments formed with very high spin. A combination of all these factors may lead to constant isomer ratios of ^{91}Y in both ^{235}U and ^{238}U fission and of ^{90}Y in ^{238}U fission at all energies. However, the energy dependence of ^{90}Y in ^{235}U fission cannot be readily understood from the above arguments. Several authors (6, 7) have, however, maintained that as the spin of the fissioning nucleus increases with increasing bombarding energy, most of it appears as the intrinsic spin of the primary fragments leaving only a little for orbital angular momentum. Thus the isomer ratio is expected to increase with energy until the initial spin of the fissioning nucleus becomes a limiting value due to direct interaction. However, this explanation for the energy dependence of the isomer ratios of ^{90}Y in ^{235}U fission is obviously at variance with the interpretations given above for the ratios of ^{90}Y and ^{91}Y in ^{238}U fission and for those of ^{91}Y in ^{235}U fission.

(c) Theoretical Estimation of the Average Spin of the Primary Fragments

The theoretical calculation of isomer ratios of ^{90}Y and ^{91}Y in ^{235}U and ^{238}U fission has been made according to the prescription of Saha and Yaffe (12). According to this prescription the formation probability of a product is weighted by the mass-yield, the fractional chain yield, and the fissionability of the fissioning nuclei, and also by the evaporation probability of different fragments yielding the product of interest. The details of the calculation have been given elsewhere (12, 13) and only pertinent points will be mentioned here.

Compound nucleus formation was assumed at energies up to 50 MeV and a direct interaction above this energy. The excitation energy of the compound nucleus was calculated from the energetics of the reaction, while at 60–85 MeV, the average excitation energy of the residual nucleus was taken from Metropolis *et al.* (20). A fission–evaporation competition was considered to follow the initial compound nucleus formation or direct interaction. After evaporation of each neutron the excitation energy, U', of the residual nucleus was calculated as $U' = U - B_n - 2T$ where U is the excitation energy of the preceding nucleus, B_n is the binding energy, and $2T$ is the kinetic energy of the emitted neutron. T is the nuclear temperature given by $U = aT^2 - 4T$ where a is the level-density parameter. We assumed the value of a to be 10.5 MeV^{-1} (21). The pairing energy was taken to be 1.1 MeV in order to correct for the odd–even nature of the residual nuclei. The neutron binding energy and the fission barrier were taken from the mass table of Myers and Swiatecki (22). The fission branching ratio, $G = \Gamma_f/(\Gamma_f + \Gamma_n)$, was calculated for each fissioning nucleus using the equations of Huizenga and Vandenbosch (21).

A number of complementary fragment pairs were selected corresponding to the light-mass region of $A = 90$–96 for each fissioning nucleus. The total energy of these fragments was then calculated from mass-excess values of Myers and Swiatecki (22). The average kinetic energy, taken from Milton and Fraser (23), was subtracted from the total energy released in a particular mode of fission, and the excitation energy was assumed to be shared by two complementary fragments in the ratio of their masses.

Neutron evaporation from each of the light-mass primary fragments was considered in the same way as discussed above in the case of the fissioning nuclei. Only those primary fragments which, after neutron evaporation, could lead to ^{90}Y and ^{91}Y were sorted. The evaporation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

probability of these fragments was assumed to be unity. The fractional chain yields of these fragments were calculated on the basis of a Gaussian charge distribution and the mass-yields were assumed to be the same for all masses in this mass region for all fissioning nuclei.

The relative formation probabilities of two isomeric states were calculated from each of the selected fragments with the use of the computer code of Hafner, Huizenga, and Vandenbosch (24). The initial spin distributions of the primary fragments were taken as (6)

$$[1] \quad P(J) = (2J + 1) \exp [-J(J + 1)/B^2]$$

where $P(J)$ is the probability of a fragment having spin J and B is related to the root-mean-square of the spin.

The transmission coefficients for neutron emission from the fragments were calculated using Auerbach's (25) computer code. The number of gamma rays were calculated from the residual energy after neutron emission using the relationship of Vonach *et al.* (4). The isomer-deciding gamma ray was assumed to be emitted when the residual energy was 1 MeV or less. Only dipole radiations were considered.

The spin cut-off parameter σ is given as $\sigma^2 = It/\hbar^2$ (26) where I is the moment of inertia of the nucleus and t is the thermodynamic temperature. At high excitation energy the moment of inertia of a nucleus equals that of a rigid body. In general, neutron emission takes place in the high excitation energy region and gamma-ray emission in the low excitation energy region of the deexcitation process. Therefore, σ_n was calculated from $\sigma_n^2 = I_R t/\hbar^2$ and σ_γ as $\sigma_\gamma^2 = I_{eff} t/\hbar^2$. The values of I_{eff} were taken from Dudey and Sugihara (3).

The spins of $^{90}Y^m$ and $^{90}Y^g$ are 7+ and 2−, respectively, with an intermediate 3− excited state. The penultimate spin distributions of the residual nuclei were, therefore, divided at $J = 5$. Similarly for $^{91}Y^m$ ($\frac{9}{2}+$) and $^{91}Y^g$ ($\frac{1}{2}-$), the spin distribution was divided at $J = 5/2$.

Because of the relatively low values of the experimental isomer ratios, the calculation was performed for values of $B = 2$ and 3. The calculated values are illustrated by solid lines in Figs. 1 and 2. The open circles are the experimental values. It is seen that, except for ^{90}Y in ^{235}U fission, the experimental values are well reproduced with $B = 3$ for ^{90}Y in ^{238}U fission and ^{91}Y in ^{235}U fission, whereas $B = 2$ gives a better fit for ^{91}Y in ^{238}U fission. Obviously a larger value of B is required to account for the increasing isomer ratios of ^{90}Y in ^{235}U fission with increasing bombarding energy. However, for reasons given previously, we have not attempted further to calculate these isomer ratios.

In the study of isomer ratios of the heavy-mass products in photofission (6) and thermal fission (7), the spin of the primary fragment was found to be about 5–7 $\hbar$. At higher energies (20–85 MeV) Saha *et al.* (12, 13) obtained 12–16 $\hbar$ in the study of isomer ratios of ^{134}Cs in ^{239}Pu, ^{235}U, and ^{233}U fission.

Such a low B value of 2–3 $\hbar$ in the mass region of $A = 90$–94 obviously does not agree with the values obtained for heavy fragments and a great deal of ambiguity exists in the light-mass region. For example, as pointed out earlier, Hagebo (16) reported a very low value of 1–2 $\hbar$ for the spin of the primary fragment for ^{95}Nb isomers in 15-MeV proton fission of ^{238}U and Rudy *et al.* (17) obtained a value of 12 $\hbar$ for these isomers in the 10-MeV proton fission of ^{235}U. The latter authors attributed this discrepancy to the large uncertainty in the data of Hagebo (16).

The only systematic error in the present work might be in the decay schemes if they were not correct. Barring this we can conclude that a value of 2–3 $\hbar$ may well be characteristic for the spin of the light-mass primary fragments in ^{235}U and ^{238}U fission at medium energies. If one accepts the Strutinski hypothesis (27) that angular momentum is generated in the fissioning act, these data would indicate an unequal sharing of the angular momentum between the light and heavy fragments in fission.

Hoffman (28) calculated the average angular momentum of fragments on the basis of an electrostatic torque applied to uniformly charged spheroidal fragments at the moment of scission and obtained a value of 5–7 $\hbar$ per fragment in thermal fission. He further predicted that those fragments having relatively low kinetic energy and those close to nuclear shells (where fragment distortion is very small) will have little or no induced angular momentum. The yttrium fragments contributing to ^{90}Y and ^{91}Y should have neutron number $N = 51$–54. This may account in part for the low value of the primary fragment spin.

Reactions of ruthenium(III) ammine complexes. I. Competing acid hydrolysis and redox reactions of pentaammineruthenium(III) ions

T. ELIADES, R. O. HARRIS, AND P. REINSALU
Chemistry Department, Scarborough College, University of Toronto, West Hill, Ontario

Received April 3, 1969

A study of acid hydrolysis of acidopentaammines of ruthenium(III) shows that aquation is not the only reaction taking place. For the halopentaammines, both in the presence and absence of light, reduction occurs with the formation of ruthenium(II) and free halogen. When azide, instead of halide ion, is coordinated to the metal, ruthenium(II) nitrogen complexes can be prepared. The solid state decomposition of $[Ru(trien)(N_3)_2]^+$ ion to $[Ru(trien)N_3N_2]^+$ is described.

Canadian Journal of Chemistry, 47, 3823 (1969)

Introduction

Studies in acid and base hydrolysis reactions for complexes of the type $[M(III)(NH_3)_5X]^{2+}$ are well established for the cobalt group metals but little corresponding work has been done in the iron group. Iron ammine complexes are unstable, losing ammonia in the solid, and the osmium(III) pentaammines have been well characterized only recently (1). For ruthenium, acid and base hydrolysis studies on the chloropentaammineruthenium(III) ion have been reported (2). A similar study on the bromopentaammine ion could not be carried out because of unexplained behavior in its electronic spectrum. The only reported ultraviolet (u.v.) – visible spectrum of the iodopentaammine ion (3) shows changes with time that are difficult to explain in terms of replacement of the iodide by solvent water or by sulfate ion, the spectrum being recorded in 2 *M* sulfuric acid. Finally, the azidopentaammine ion, either in solution or as a salt, has been reported (4) to give the ruthenium(II) complex ion, $[Ru(II)(NH_3)_5N_2]^{2+}$. In view of the diverse nature of their reactivity, it was decided to study these compounds further.

Experimental

Starting material for the preparation of the pentaammines was ruthenium trichloride obtained from Engelhard Industries, Inc., New Jersey. All other chemicals were reagent grade or better.

Hexaammineruthenium(III) Oxalate

The most convenient way into the pentaammine series is by refluxing a hexaammineruthenium(III) salt in hydrochloric acid to give the chloropentaammineruthenium(III) dichloride. The nitrate salt is the most easily prepared hexaammine from commercial ruthenium trichloride by the method of Lever (5) but it has the disadvantage that it often gives dark brown decomposition products when refluxed in acid. The chloride and sulfate salts can be made from the nitrate but since the nitrate is the most insoluble salt of the 3, the yields of the other 2 are always poor. It was found that the addition of a saturated solution of potassium oxalate to a slurry of the nitrate in water caused the solid to dissolve to give a light yellow solution from which precipitated almost immediately the white hexaammineruthenium(III) oxalate. This was filtered from the ice-cooled solution, washed with water, alcohol, and ether, and dried in air; yield 60–70%.

Chloropentaammineruthenium(III) Dichloride

This was prepared from the hexaammine oxalate by the method of Gleu and Rehm (6). Samples used for kinetics were recrystallized twice from dilute hydrochloric acid as orange–yellow crystals, which were washed with water and alcohol until the filtrate showed no trace of chloride ion. The salt was dried under vacuum at 100°; yield 95%.

Anal. Calcd. for $[Ru(NH_3)_5Cl]Cl_2$:total Cl, 36.4; ionized Cl, 24.2; H, 5.17; N, 23.9; Ru, 34.6. Found: total Cl, 36.8; ionized Cl, 24.8; H, 5.24; N, 24.5; Ru, 34.5.

Bromopentaammineruthenium(III) Dibromide

Similar preparations of the bromopentaammine from the hexaammine gave lower yields. The alternative method suggested by Gleu and Rehm (6) was found to give almost quantitative yields; yield 90%.

Anal. Calcd. for $[Ru(NH_3)_5Br]Br_2$: total Br, 56.3; ionized Br, 37.6; H, 3.55; N, 16.4; Ru, 23.7. Found: total Br, 56.1; ionized Br, 37.8; H, 3.53; N, 15.6; Ru, 24.0.

Iodopentaammineruthenium(III) Diiodide

The almost black crystals of the iodopentaammine were prepared in a similar manner to the bromopentaammine dibromide; yield 90%.

Anal. Calcd. for $[Ru(NH_3)_5I]I_2$: total I, 67.2; ionized I, 44.8; H, 2.67; N, 12.4; Ru, 18.1. Found: total I, 67.2; ionized I, 44.8; H, 2.95; N, 11.8; Ru, 17.8.

Aquopentaammineruthenium(III) 2-Naphthalenesulfonate Tetrahydrate

Chloropentaammine dichloride (1.0 g) was dissolved in dilute ammonia solution (10 ml) and the solution warmed for several min. The light red solution was ice-cooled and a saturated solution of 2-naphthalenesulfonic acid was added dropwise to pH 3.0. From the resulting light yellow

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

solution, colorless crystals of the aquopentaammine salt precipitated. These were recrystallized from dilute naphthalenesulfonic acid, washed with alcohol and ether, and dried in air; yield 40%.

Anal. Calcd. for $[Ru(NH_3)_5H_2O](C_{10}H_7SO_3)_3 \cdot 4H_2O$: C, 40.1; H, 5.13; N, 7.80; Ru, 11.2. Found: C, 40.7; H, 5.33; N, 8.34; Ru, 10.9.

The aquopentaammine salt is unstable in the solid state with respect to replacement of the complexed water by the outside ion unless this is very bulky. A number of other anions such as perchlorate and methanesulfonate were used as precipitating agents. The absorption spectra of freshly prepared solutions of these salts in 0.01 *M* methanesulfonic acid have an absorption band at 268 mμ with ε_{max} of 770 ± 15 which agrees with previously recorded values (7). Addition of dilute ammonium hydroxide to such solutions yielded the hydroxypentaammineruthenium(III) ion with an absorption band at 295 mμ and ε_{max} of 2.0 × 10^3.

cis-Diazidotriethylenetetramineruthenium(III) Iodide

cis-Dichlorotriethylenetetramineruthenium(III) chloride (0.5 g), prepared by the method of Broomhead and Kane-Maguire (8), was added to 10 ml water containing 1 g of sodium azide. The mixture was stirred at room temperature until all the complex ion had dissolved. At this time, the resulting deep red solution was ice-cooled. Addition of potassium iodide gave a precipitate of a deep red solid which was filtered off but not dried. The moist precipitate was transferred to 25 ml water containing Dowex 1X8–100 resin (chloride form). The precipitate dissolved after a few minutes stirring, when the solution was filtered. Addition of potassium iodide to the filtrate gave the desired deep red product. This was filtered off, washed with water and ethanol, and air dried (yield 0.15 g, 23%). The initial precipitate of iodide salt always contains free azide ion. Dried samples of this tended to explode whereas no such tendency was found in the purified iodide salt.

Anal. Calcd. for $[Ru(C_6H_{18}N_4)(N_3)_2]I$: C, 15.7; H, 3.93; N, 30.6; I, 27.8; Ru, 22.0. Found: C, 16.3; H, 3.99; N, 29.0; I, 27.1; Ru, 22.2.

Analyses for carbon, nitrogen, and hydrogen were by Bernhardt microanalytical laboratories, Max Planck Institute, West Germany. Ruthenium analyses were carried out by heating the complex in a stream of hydrogen and weighing the residue as ruthenium metal. Halide analyses were done potentiometrically.

Instruments used were a Perkin–Elmer 521 infrared spectrophotometer (Nujol mull between KBr plates), a Bausch and Lomb 505 spectrophotometer (1 cm fused silica cells). A Gouy balance supplied by Alpha Scientific Laboratories, Inc., was used for the magnetic susceptibilities.

Absorption spectra were obtained in the range 200 to 800 mμ for the ruthenium(III) complexes $[Ru(NH_3)_5Cl]^{2+}$, $[Ru(NH_3)_5Br]^{2+}$, $[Ru(NH_3)_5I]^{2+}$, $[Ru(NH_3)_5H_2O]^{3+}$ in dilute methanesulfonic acid and for $[Ru(NH_3)_5OH]^{2+}$ in dilute ammonia solutions. The position of absorption maxima and molar extinction coefficients are summarized in Table I. The data for the chloro- and bromo-pentaammineruthenium(III) salts agree with previously reported values (3). That for the iodopentaammineruthenium(III) ion does not agree with the value given by Hartmann and Buschbeck but this was indicated to be doubtful. The hydroxypentaammine ion was not isolated from solution but was formed by the addition of dilute ammonia to solutions of the aquopentaammine ion.

All the pentaammines are very sensitive to base, decomposition with loss of ammonia in sodium hydroxide being rapid. In ammonia, however, they react to form the hydroxypentaammine which is moderately stable even in hot concentrated ammonia. The spectra of the aquo- and hydroxy-ions are sufficiently different for relative amounts of each to be determined in solutions containing both. This was used as a method of finding the pK_a of the aquo-complex. A sample of the aquopentaammine salt was dissolved in a known amount of freshly boiled, doubly distilled water. Varying aliquots of standard methanesulfonic acid were added to known samples of the stock complex solution which were then made up to a fixed volume. The pH of the solutions and their spectra were then recorded (Fig. 1). The absorption curve for $[Ru(NH_3)_5OH]^{2+}$ ion was taken in moderately strong ammonia and it can be seen that this last spectrum does not go through the isosbestic point for the series at 265 mμ. Whether this is due to some slight decomposition or to ionic effects in solution is not known. At 313 mμ the molar extinction coefficient for $[Ru(NH_3)_5OH]^{2+}$ is 1.65 × 10^3 and for $[Ru(NH_3)_5H_2O]^{3+}$ it is 1.14 × 10^2. Since the aquopentaammine has an absorption at this

wavelength, the ratio A/B in Fig. 1 does not measure directly the ratio $[HX]/[X^-]$, where $HX = [Ru(NH_3)_5H_2O]^{3+}$, $X^- = [Ru(NH_3)_5OH]^{2+}$, but a small correction can be applied knowing the molar extinction coefficient for the aquo ion. It follows from the equation

$$pH = pK_a + \log [HX]/[X^-]$$

neglecting any activity coefficients, that by plotting the ratio of the corrected A/B against the pH of the solution, pK_a can be found. The data are contained in Table II. A value of 3.7 ± 0.1 at 21° was calculated. Other methods using the pH of weighed samples of acid in water, and the values from the half equivalence point in potentiometric titrations against 2×10^{-3} N NaOH give, for several determinations, a result of 3.9 ± 0.1. These figures agree with the value of 4.2 for the pK_a at 25° quoted by Basolo and co-workers (2). It is noteworthy that ruthenium(III) aquopentaammine is a significantly stronger acid than the aquopentaammines of Co(III), Rh(III), and Cr(III).

Kinetic Studies

The acid hydrolysis reactions were carried out in approximately 10^{-2} M methanesulfonic acid solutions, sufficiently acid to suppress completely any loss of protons by the product. Concentrations of complex were of the order of 10^{-4} M. To measure the rate of hydrolysis, sealed 5 ml samples of the solution were removed at noted intervals from a constant temperature bath and the reaction "frozen" in ice. The optical density (o.d.) of the sample was then measured directly at room temperature. The spectra obtained from a typical series of readings for the hydrolysis of the chloropentaammine ion are shown in Fig. 2.

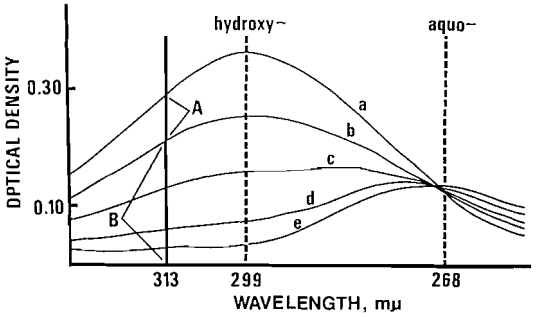

FIG. 1. Spectra of $[Ru(NH_3)_5H_2O]^{3+}$ at various pH. (*a*) 10.0, (*b*) 3.98, (*c*) 3.59, (*d*) 2.73, (*e*) 1.0.

3.98	0.44	0.9	3.64
3.59	1.42	1.1	3.74
2.73	7.33	2.9	3.60

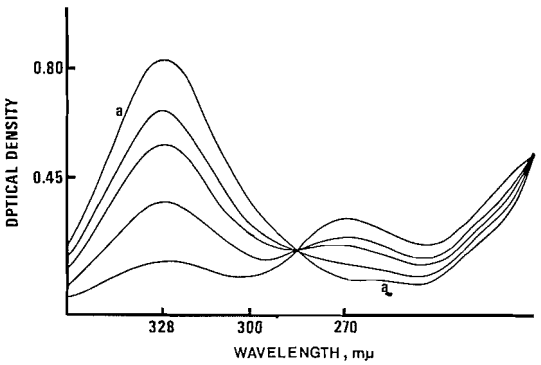

FIG. 2. Absorption spectra changes during aquation of $[Ru(NH_3)_5Cl]^{2+}$ in 7.0×10^{-2} M $MeSO_3H$ at 49.5°. Curve *a* is at $t = 0$. Successive curves are at 4.3, 8.0, 17.0, 52.0 h.

From preliminary runs, it was evident that the reaction

$$[Ru(NH_3)_5Cl]^{2+} + H_2O \rightarrow [Ru(NH_3)_5H_2O]^{3+} + Cl^-$$

does not go to completion but reaches a position of equilibrium, the presence of an isosbestic point at 286 mμ indicating a simple reaction. The position of equilibrium was at approximately 80% reaction for the chloropentaammine and 90% reaction for the corresponding bromopentaammine hydrolysis reactions. In such cases, approach to equilibrium can be considered to a first approximation as a reversible first order process

$$A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} B$$

By plotting $\log (o.d._o - o.d._e)/(o.d._t - o.d._e)$ against time, where $o.d._o$, $o.d._e$, and $o.d._t$ are optical densities at zero time, at equilibrium, and at time t (in s), respectively, k_1 can be determined. Good first order plots were obtained up to 3 half-lives of the reaction. All kinetic runs were carried out in triplicate.

Results

Kinetics

Data for acid hydrolysis of the chloropentaammine ion are listed in Table III. The results show the hydrolysis reaction to be independent of added anion and acid strength but that a slight decrease in rate constant is found with increasing ionic strength. Temperature dependence of the rate constants was plotted in the usual way. An enthalpy of activation of 22.2 kcal and an entropy of activation of -10 e.u. being calculated, in good agreement with the values of 22.6 kcal and -11 e.u. reported by Basolo and co-workers (2).

Acid hydrolysis of bromopentaammineruthenium(III) ion was followed under the same conditions. The spectra for the disappearance of

the bromopentaammine absorption band at 398 mμ with time are not as straightforward as those for the chloropentaammine ion. From Fig. 3 it can be seen that the main differences are that no isosbestic point is observed in the system although there is a region of cross-over in the spectra in the region of 310–280 mμ, and that the aquopentaammine maximum at 268 mμ does not increase regularly with time, corresponding to the disappearance of the bromopentaammine band but first increases, slightly decreases, and finally continually increases. Lastly, as the system approaches equilibrium, a new band with ε_{max} at 247 mμ appears.

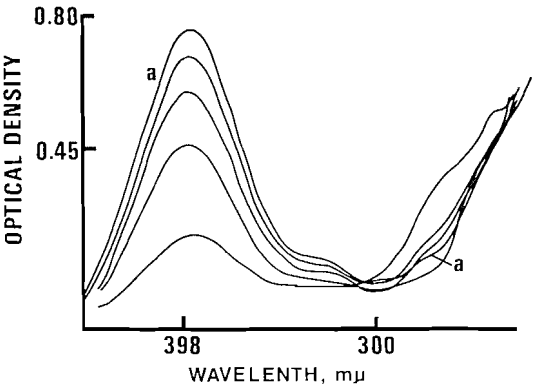

FIG. 3. Absorption spectra changes during reaction of $[Ru(NH_3)_5Br]^{2+}$ in 3.5×10^{-2} *M* $MeSO_3H$ at 49.5°. Curve *a* is at $t = 0$. Successive curves are at 1.75, 4.0, 8.0, 18.0 h.

The rate of disappearance of the bromopentaammine absorption band was studied as before, and the relevant rate constant data are shown in Table IV. Again the rate constant for the disappearance is independent of added anion and acid strength, but is slightly decreased with increasing ionic strength. However, the interpretation of these results is difficult since the lack of isosbestic point in the system indicates that other reactions are taking place. The starting material or the products, bromide ion and aquopentaammine ion, could be involved in these reactions. Solutions of bromide ion over a wide range of concentration in methanesulfonic acid show no spectral changes with time. Aquopentaammine ion can complex with methanesulfonic acid to give methanesulfonatopentaammine ion with an absorption band at 330 mμ and ε_{max} of approximately 2×10^3. Such a product would have been difficult to detect in the chloropentaammine system where the main absorption band of the chloropentaammine ion is at 328 mμ. However,

solutions of aquopentaammineruthenium(III) methanesulfonate in 10^{-2} *M* methanesulfonic acid show no detectable spectral changes with time. The starting material could react in solution with other than the solvent but it was found that the addition of possible nucleophiles (Table IV) produces, if anything, a decrease in the measured rate constant. If, however, bromopentaammine could react by an alternative first order process, this would maintain pseudo first order reactivity overall. Such a system would produce spectra with time that still contain an isosbestic point unless the products of this secondary reaction undergo further reaction.

A possible reaction route is photolytic decomposition. Preliminary kinetic runs using iodopentaammineruthenium(III) diiodide were found to contain large amounts of triiodide ion after a very short period of time, the intense absorption of this ion in the visible region making it difficult to obtain kinetic data from the spectra. A general reaction can be written[1]

$$[M(III)(NH_3)_5X]^{2+} + h\nu \rightarrow [M(II)(NH_3)_5]^{2+} + X\cdot$$

The free radical may react in several ways. With iodopentaamminecobalt(III) ion, iodine is produced (9)

$$[Co(NH_3)_5I]^{2+} \rightarrow Co(II) + 5NH_3 + I\cdot$$

In the corresponding reaction with bromopentaamminecobalt(III) ion, bromine has not been detected. This may be because bromine would oxidize the liberated ammonia. However, for ruthenium, Endicott and Taube have shown (7) that in $[Ru(II)(NH_3)_5H_2O]^{2+}$, the Ru(II)—$NH_3$ bonds remain intact in up to 10^{-2} *M* acidic solution for at least 1 h. It should therefore be possible to detect bromine if it were being formed by this type of reaction.

Kinetic runs with bromopentaammine dibromide were made therefore under various conditions. They were carried out in darkened sample tubes, under nitrogen and with small amounts of allyl alcohol present. Allyl alcohol reacts rapidly and irreversibly with bromine and itself has no absorption down to 200 mμ. Both bromine and tribromide ion have a strong absorption maximum at 264 mμ, very close to the relatively weak absorption maximum of the aquopentaammine ion at 268 mμ. Data from the various conditions are summarized in Table V. Figure 4 shows the spectra obtained with time in the acid hydrolysis reaction with added allyl alcohol, under nitrogen and carried out in darkened sample tubes. This series of spectra was chosen since it shows an initial isosbestic point at 323 mμ which eventually is lost as the new band at 247 mμ begins to appear.

shows two main bands at 485 mμ (ε_{max} 2.4 × 10^3) and 377 mμ (ε_{max} 2.0 × 10^3). Pentaammines, *cis*- and *trans*-tetraammines of ruthenium(III) can be distinguished by their visible spectra. In the pentaammines, one relatively intense absorption band is found (Table I). In the *cis*-tetraammines, this is split into two bands, of roughly the same intensity, one band at higher and the other at lower wavelength to the original pentaammine band (3). In the corresponding *trans*-isomer, only one band is found, roughly twice the intensity of the pentaammine band and at almost exactly the same wavelength (10). On this basis the diazido complex would be considered the *cis*-isomer.

(ii) Infrared Spectrum

Supporting evidence that this is the *cis*-isomer comes from its infrared (i.r.) spectrum. In the 2100–2000 cm^{-1} region, 2 bands are found, at 2046 and 2002 cm^{-1}, both assigned to asymmetric stretches of the coordinated azides. From Table VI, it can be seen that similar diazido complexes show 2 bands in this region if they are *cis*, whereas the more symmetrical *trans*-diazido complexes only show one.

Salts of $[Ru(trien)(N_3)_2]^+$ slowly decompose with time. The deep red compound changes to a grey–white powder, during which time the magnetic moment of 1.87 B.M. drops to zero. The complete change takes place over several weeks at room temperature but can be completed within 24 h if the salt is kept at 75°. The decomposition can be monitored by following changes in the i.r. spectrum. Figure 5 shows the changes with time of the two azido bands in the 2100–2000 cm^{-1} region. The disappearance of the lower azido band at 2002 cm^{-1} is accompanied by the appearance of a new band at 2096 cm^{-1}. It is assumed that the final product is [Ru(II)trien N_2N_3]I. Its slow rate of formation is in direct contrast to the similar rapid formation of $[Ru(II)(NH_3)_5N_2]^{2+}$ from $[Ru(III)(NH_3)_5N_3]^{2+}$ (4).

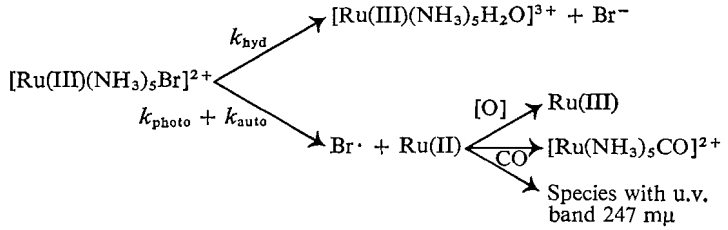
Discussion

Kinetics

The only reaction found for the chloropentaammine ion in dilute acid is hydrolysis. However, reaction of the bromopentaammine is complicated by the appearance of redox reactions. From the spectra and rate data obtained, the overall reactions appear best represented by the following scheme



where k_{hyd} is the first order rate constant for the hydrolysis reaction, k_{photo} is the first order rate constant for the light-induced redox reaction, and k_{auto} is the first order rate constant for the self induced redox reaction. The overall observed rate constant for the disappearance of the bromo-

For personal use only.

pentaammine ion is then first order. Both products of the redox reaction react further. Unless precautions are taken to immediately remove these redox products, no isosbestic point will appear in the spectrum as it changes with time. The ruthenium(II) probably reacts immediately with the solvent to give $[Ru(II)(NH_3)_5H_2O]^{2+}$ but this is also reactive. It is, for example, fairly easily air-oxidized. Its presence was confirmed by carrying out a reaction with carbon monoxide bubbling through the solution. Precipitation of the final products with potassium bromide gave a solid whose i.r. spectrum contained a band at 1940 cm^{-1}, indicative of $[Ru(NH_3)_5CO]Br_2$ (11). An identical reaction for $[Ru(III)(NH_3)_5Cl]^{2+}$ with carbon monoxide bubbling through the solution gave only the hydrolysis reaction, showing that the carbon monoxide itself was not reducing the ruthenium(III).

Although several kinetic runs were carried out under nitrogen, which also can attack $[Ru(II)(NH_3)_5H_2O]^{2+}$ (12), no evidence was obtained for the formation of $[Ru(NH_3)_5N_2]^{2+}$. This may be merely an indication of the relative rates of attack of these 2 species on the ruthenium(II) complex. The following observations are relevant to the above scheme.

(*i*) Addition of allyl alcohol to the reaction removes any bromine formed. There is therefore no interference with the absorption of 268 mμ for the hydrolysis product, $[Ru(NH_3)_5H_2O]^{3+}$. This band is found to increase uniformly with time in the presence of allyl alcohol. No isosbestic point is observed although deviation from it is small. Interference is believed to come from reoxidation of Ru(II) since reactions under nitrogen show an isosbestic point (see (*iii*)).

(*ii*) If the reaction is carried out in the dark, the observed rate constant for the disappearance of bromopentaammine ion falls to 2.66×10^{-5} s^{-1} from 2.86×10^{-5} s^{-1} at 55° (Table V), since k_{photo} has been eliminated. However, bromine is still produced in solution.

(*iii*) If the reaction is carried out under nitrogen to eliminate air-oxidation of Ru(II), in the dark to eliminate photoreduction, and in the presence of allyl alcohol to remove the interference of bromine, an isosbestic point is obtained in solution (Fig. 4). The rate constant, 2.56×10^{-5} s^{-1} at 55°, is the sum ($k_{hyd} + k_{auto}$).

(*iv*) The band at 247 mμ appears in all spectra, even in the one where carbon monoxide was bubbled through the solution. The band appeared after the reaction had proceeded for some time and continued to increase after the hydrolysis reaction had come to effective equilibrium. The exact nature of the species is not known but it is thought to be some polymeric ruthenium(II) species formed slowly from the ruthenium(II) produced in the redox reaction.

(*v*) Trace amounts of ruthenium(II) have been reported (12) to catalyze reactions of ruthenium(III). To show that the ruthenium(II) produced had no effect upon the rate of hydrolysis of ruthenium(III) bromopentaammine ion, kinetic runs containing up to 10% ruthenium(II) hexaammine dichloride relative to the ruthenium(III) present were carried out. No appreciable effect upon the rate of reaction was noted[2].

From the results summarized in Table V, it is evident that the redox reactions only occur to a small extent. The photoinduced reaction at 55° is only about 7% of the total reaction. Comparison of spectra, under various conditions, shows that the amount of bromine produced in the autoredox reaction at 55° is somewhat smaller. We therefore estimate that the true hydrolysis rate constant is approximately 10–15% lower than that observed in runs carried out without any precautions.

Spectra

The strong band ($\varepsilon_{max} \sim 2000$) in the visible spectra of the ruthenium halopentaammines has been assigned by Jorgenson (13) to a transfer of a π-electron on the halogen to the unfilled d^5 subshell on the metal. The position of the band should be related to the ease of removal of an electron from the halogen, and the data in Table I support this. The order of ease of removal would be $I^- > Br^- > Cl^-$ and the order found for the wavelength at the band maximum in the halopentaammines is $-I > -Br > -Cl$. From the rate data, decomposition of the intermediate formed, $[Ru(II)(NH_3)_5 \ldots X]^{2+}$ occurs most readily if X is iodine, and least if chlorine. The same type of intermediate is expected to occur with azidopentaammine except that there is now possibility of decomposition within the free radical formed to give a nitrogen molecule in situ before the metal–ligand bond has time to break. Decomposition of $[Ru(III)(NH_3)_5N_3]^{2+}$ in solution does give $[Ru(II)(NH_3)_5N_2]^+$ (4) but the

[2]We would like to thank the referees for this suggestion.

reaction is too fast to follow conveniently. Solid state decomposition at room temperature is slow, but within the beam of the i.r. spectrophotometer it is again too fast to follow conveniently. The corresponding reactions of $[Ru(III)(trien)(N_3)_2]^+$ were found to be slower. From reactions carried out in solution, a ruthenium(II) nitrogen complex could be isolated but analyses for total nitrogen were always low. It is known (11) that the corresponding carbonyl series, $[Ru(II)(NH_3)_4CO\ X]^+$, where X is Cl or Br, is difficult to prepare in aqueous solution, because of the rapid hydrolysis to give $[Ru(II)(NH_3)_4CO\ H_2O]^{2+}$. The evidence suggests that similar behavior can be expected in the $[Ru(II)(NH_3)_4N_2\ X]^+$ series, so that the low analyses for nitrogen are due to hydrolysis of the coordinated azide from $[Ru(II)(NH_3)_4N_2\ N_3]^+$. The experiments were therefore carried out on solid samples to show that only one azide was decomposing.

It is difficult to say exactly why this azide decomposition in $[Ru(III)trien(N_3)_2]^+$ is slower than in $[Ru(III)(NH_3)_5N_3]^{3+}$. From the position of the absorption band, it would seem that the energy required to produce the intermediate is roughly the same. However, small changes in the σ- and π-donation by other ligands to the metal may have a significant role in deciding whether the intermediate once formed will return to its original state, or undergo ligand rearrangement to give a nitrogen-containing complex. Recently, Basolo and co-workers (14) have prepared the similar *cis*-azidonitrogenbisethylenediamineruthenium(III) hexafluorophosphate salt by solid state decomposition of the diazido compound. The rate of decomposition appears to be intermediate between that of the ammonia and triethylenetetramine complexes.

Infrared spectroscopic investigations of zeolites and adsorbed molecules. Part V. Carbon dioxide

C. L. ANGELL AND M. V. HOWELL
Union Carbide Research Institute, P.O. Box 278, Tarrytown, N.Y. 10591

Received May 7, 1969

When bivalent cation-exchanged, but not univalent or decationized, Type X or Y zeolites are heated at 500° in the presence of carbon dioxide, two or three bands appear in the 1600 to 1300 cm^{-1} region of the infrared spectrum. These bands are stable even at 700°, and their frequencies are cation-dependent. They are assigned to a unidentate surface carbonate species, which (in the case of CaY) blocks about 20% of the surface cations.

Introduction

The adsorption of carbon dioxide on a number of metal oxides, e.g., beryllium oxide (1), nickel oxide (2), alumina (3), zinc oxide (4), and magnesium oxide (5), has been investigated by means of infrared spectroscopy. In all these cases the formation of carbonate-like species was indicated. Evans and Whateley (5) investigated the spectra of carbon dioxide adsorbed on magnesium oxide in the range of 4000 to 750 cm^{-1} and identified both uni- and bidentate forms of surface carbonate species. The behavior of carbon dioxide adsorbed on zeolites has been investigated by Habgood and co-workers (6, 7). They observed physical adsorption of carbon dioxide on the X zeolites containing bivalent cations and showed that the asymmetric stretching band near 2350 cm^{-1} depended on the cation. Angell (8) extended this to the Y zeolites containing alkaline-earth cations and showed that the shift of the asymmetric stretching band can be correlated with the electrostatic field strength due to the cation. Habgood and co-workers (6, 7) found additional bands in the region 1750 to 1250 cm^{-1} on monovalent cation-containing X zeolites. These were ascribed to carbon dioxide chemisorbed on surface oxygen to give a bent carbonate-like structure. However, no similar species were observed when the alkaline-earth ion exchanged X zeolites were exposed to carbon dioxide at room temperature. Ward and Habgood (7) interpreted this as indicating that the surface bivalent cations are located in Sites S_{II} only, while the surface monovalent cations also occupy the more exposed Sites S_{III}, where it is likely that the reaction of carbon dioxide would result in carbonate-like species.

In the present work we are reporting the strong interaction of carbon dioxide with bivalent cation-containing X and Y zeolites[1] on exposure to carbon dioxide at high temperatures ($\sim$ 500°). The role of the cation in promoting the interaction of the carbon dioxide with the zeolite surface is discussed.

Experimental

The compositions of the zeolite samples used in this work have been given previously (Part I, Table I (9)). The short path length infrared cells, the preparation of the pellets, and the activation techniques have also been described in Part I (9). In air-activation, the pellets were placed at the bottom of the cell, which was left open at the top. The samples were then heated slowly to 500° and kept at this temperature for 2 h. (No special effort was made to improve the air circulation around the pellets.) At the end the cell was evacuated at 500° and cooled in vacuum. Activations at 700° were carried out in cells with bottoms made of quartz. The infrared spectra were obtained on the following spectrophotometers: a Perkin–Elmer Model 21 prism spectrometer, a Beckman Model IR 10 grating spectrometer, and a Perkin–Elmer Model 225 grating spectrometer. The carbon dioxide and the carbon monoxide were obtained from Matheson Company. Carbon dioxide impurity in the carbon monoxide was removed by cooling the cylinder to liquid nitrogen temperature. Quantitative carbon monoxide adsorption data were obtained on a Cahn vacuum microbalance. The technique of simultaneous measurement of infrared spectra and gas adsorption has been described previously (10). The infrared spectrometer used in the experiments with the microbalance was a Perkin–Elmer Model 112 single beam, double pass spectrometer converted to grating operation.

Results

When bivalent cation-exchanged Y zeolites

[1]Throughout this article the Type X and Type Y zeolites are designated NaX and NaY, respectively; see U.S. Patents No. 2 882 244 and 3 130 007. Forms in which sodium has been exchanged with other cations are designated as CaY, etc. The term "decationized Y" will mean NH_4Y which was heat treated to decompose the NH_4 ions; see U.S. Patent No. 3 130 006.

were activated at 500° in ordinary laboratory air, two or three bands appeared in the 1600 to 1300 cm^{-1} region. These bands did not occur when the same samples were activated at 500° in vacuum. Once these bands have appeared in the spectrum, activation in a vacuum at 500° does not remove them. To establish the cause of these bands, various bivalent cation-exchanged Y zeolites were activated in an atmosphere of pure oxygen or pure nitrogen. In neither case was the formation of these bands observed. However, when samples of the same zeolites, activated under vacuum at 500°, were heated at 500° with 10 Torr carbon dioxide, the same bands appeared that were observed after air activation. In this way the origin of the bands was definitely tied to the presence of carbon dioxide during the heating process. For most of our subsequent experiments these bands were generated by activation in air at 500 °C, since the small amount of carbon dioxide in ordinary air was apparently sufficient to create bands the same size as those obtained from samples heated in an atmosphere of carbon dioxide. Although the possibility of interaction between carbon dioxide and oxygen could not be excluded, the spectra showed no evidence that such did occur. In contrast to the bands observed by Bertsch and Habgood (6) on monovalent cation-containing X zeolites, which appeared at room temperature, our spectra only showed bands due to physically adsorbed carbon dioxide. However, the other bands did appear on heating at 500°. Experiments on CoY, MnY, and MgY exposed to carbon dioxide at 500° indicated that these bands did not diminish at all on heating in vacuum at 700° for a prolonged period.

All the bivalent cation-exchanged zeolites studied gave these bands, except the sample of NiY. Among the monovalent cation-exchanged zeolites, NaY and AgY did not produce any bands in this range when heated with carbon dioxide at 500°. NaX at room temperature showed the same bands as observed by Habgood and Bertsch (6), and after heating at 500° and then cooling, these bands were still present. However, evacuation at 500° immediately removed these bands, indicating a much weaker chemisorption of carbon dioxide. A sample of 90% exchanged ammonium Y which was activated at 500° in vacuum did not produce any bands in the 1600 to 1300 cm^{-1} region when exposed to carbon dioxide at 500°.

The frequencies of the bands observed with bivalent cation-exchanged zeolites are given in Table I. Figure 1 shows the appearance of these bands on air-activated CaY, ZnY, MgY, and CoY.

The interaction of various adsorbed molecules with these carbonate-type bands was studied on CoY zeolite. When water was adsorbed on a CoY sample containing these bands, both the 1575 and the 1380 bands were removed completely. A band appeared at 1620 cm^{-1} and the band at 1450 cm^{-1} became much larger (see Fig. 2). Removal of the water by evacuation at 300° completely restored the original bands. Adsorption of heavy water did not produce the 1620 cm^{-1} band, but did result in the complete removal of the 1575 and 1380 cm^{-1} bands. Evacuation at 300° and removal of the heavy water again resulted in the reappearance of the bands in their original positions. Similar results were obtained on adsorption of ammonia; the 1575 and 1380 cm^{-1} bands were completely removed and a strong band appeared at about 1450 cm^{-1}. On removal of the ammonia at 300° the original bands were restored. Adsorption of benzene on a ZnY sample, air-activated at 500°, did not change the two

outer bands of the carbonate complex, although a very strong band appeared at 1480 cm^{-1}. This band is one of the fundamentals of benzene.

For the quantitative measurement of the number of bivalent cations available on the surface, a calcium Y sample was vacuum-activated in the Cahn microbalance system at 500°. The spectrum of the sample did not show any carbonate-type bands. After this, a carbon dioxide isotherm was measured at room temperature up to about 400 Torr carbon dioxide pressure. The infrared spectrum showed no carbonate-type bands even under the highest pressure of carbon dioxide. The sample was then heated at 500° in 400 Torr carbon dioxide for 4 h. After cooling, the infrared spectrum showed the two characteristic carbonate type bands at 1493 and 1435 cm^{-1}. The sample was then heated in vacuum at 500° till constant weight was reached. The weight increase corresponded to 1.62 cc of carbon dioxide per gram of zeolite. After this, the simultaneous measurements of the gas adsorption isotherm of carbon monoxide and the optical density isotherm for the cation-specific carbon monoxide band were carried out as described previously (10). Comparing these data with the data obtained from the adsorption of carbon monoxide on a sample[2] of the same CaY vacuum activated at 500°, the constants in Table II were obtained by calculations described previously (11).

It can be seen that there has been very little change in the Langmuir combining constant (k_1) or the slope of the linear part of the adsorption curve (C), but the number of adsorption sites has decreased. The high temperature carbon dioxide

[2]Note that this CaY is that given in ref. 9: 77% exchanged, not the 84% exchanged CaY mentioned in ref. 11.

TABLE II

Adsorption of carbon monoxide on CaY zeolite*

Sample treatment	k_1	C	n_0 cc/g	n_0'	Sites/unit cell
Vacuum-activated	0.285	0.0166	9.35	0.242	5.31
Heated in CO_2	0.280	0.0145	7.23	0.188	4.11

*The effective adsorption is expressed in number of carbon monoxide molecules per gram zeolite, n_0, or as the proportion of total cations reacted with the carbon monoxide, n_0'.

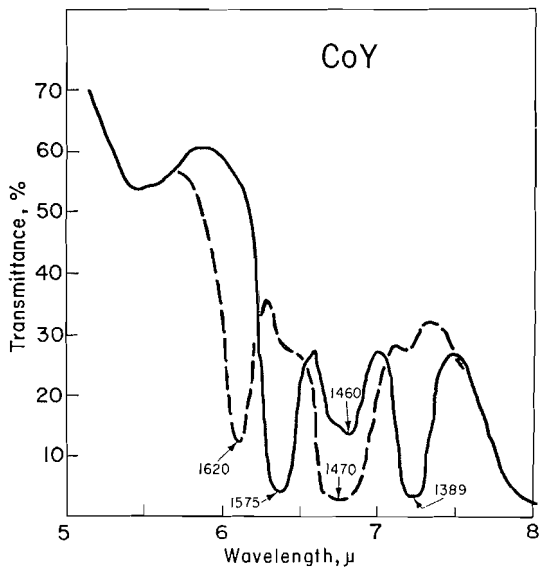

FIG. 2. Interaction of water with the carbonate-type bands on CoY Zeolite; —, sample air-activated at 500°; - - -, same, with small amount of water.

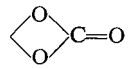
uptake of 1.62 cc/g corresponds to 0.92 CO_2 molecules per unit cell. This is in reasonably good agreement with the decrease of sites (5.31 − 4.11 = 1.20), as indicated by the cation specific CO capacity after exposure to carbon dioxide.

These results indicate that one adsorbed carbon dioxide molecule is responsible for the blocking of approximately one surface site. Since the sites measured by carbon monoxide adsorption are the surface cations (11), the above results also mean that the high temperature adsorption of carbon dioxide in some way blocks the surface cations in an approximate ratio of one CO_2 molecule per surface cation.

Discussion

Evans and Whateley (5) have summarized the characteristic infrared bands of groups that can be formed by the interaction of carbon dioxide with metal oxide surfaces. They list the frequencies of the carbonate ion (CO_3^{2-}), of unidentate carbonate (—O—CO_2), of bidentate carbonate



and of the bicarbonate ion, (HO—CO_2^-). Comparison with our results leaves little doubt that the bands observed in the 1600–1300 cm^{-1} region of the spectra of zeolites exposed to carbon dioxide are due to the unidentate carbonate type species. The interaction, therefore, consists of a carbon dioxide molecule chemisorbing in a bent configuration on a surface oxygen to form the unidentate type carbonate species. The appearance of a band at 1460 cm^{-1} in some cases would indicate that in addition some carbonate ion species are also formed.

Our results lead to three important conclusions. First, since even heating at 700° does not remove this group, the unidentate carbonate formed on the zeolite surface is extremely stable, comparable in stability to the zeolite structure itself. Second, it must be the bivalent cations on the surface that cause this chemisorption of carbon dioxide, since the same reaction does not occur on zeolites with monovalent cations. Finally, the chemisorbed carbon dioxide is on the zeolitic surface in proximity to the cations, since the frequencies of the carbonate-type grouping are cation-dependent (see Table I). The quantitative aspect of carbon dioxide adsorption on CaY shows that the adsorbed molecules block some, but not all, of the available surface cations. This indicates that about 20% of the calcium cations may differ in some way from the other surface cations. Distribution of the surface cations between Sites S_{II} and Sites S_{III} is a distinct possibility, since the carbon monoxide adsorption method used for the quantitative measurement of the available surface cations does not differentiate between these two surface positions.

Ward and Habgood (7) have suggested that the reason why the monovalent cation exchanged X zeolites do form carbonate-like structures when exposed to carbon dioxide at room temperature, while the alkaline-earth cation exchanged X's do not, is that in the first case the cations can occupy both Sites S_{II} and the more exposed Sites S_{III}, while in the bivalent cation cases the cations most likely occupy only Sites S_{II}. Cations in Sites S_{III} are less shielded than those in Sites S_{II} and have stronger electric fields in their vicinity. It was therefore assumed that only cations in Sites S_{III} interact with carbon dioxide at room temperature.

Although it might be easy for the carbon dioxide to adsorb on any surface cation in the end-on configuration (see refs. 7, 8), it must be more difficult to adsorb parallel-to-the-surface in the configuration necessary for surface carbonate formation, and this apparently happens only on the more exposed Site S_{III} cations. This explains our results on NaY, where no carbonate formation was observed: NaY has very few (8) cations in Sites S_{III}, compared to NaX (38), assuming the normal distribution of cations as 16 in Sites S_I, 32 in Sites S_{II}, and the rest in Sites S_{III}[3]. The above mechanism would also explain why the bivalent cation zeolites require heating to 500° in the presence of carbon dioxide before these bands form: a considerable activation energy would be needed for the carbon dioxide molecules to reach the bivalent cations in Sites S_{II} in a symmetrical coordination, or to make the cations mobile enough to be able to move into Sites S_{III}. On the other hand, it does not explain the lack of formation of high temperature carbon dioxide bands with the monovalent cation zeolites. To explain this difference between mono- and bivalent cations in the formation of the chemisorbed carbonate complex, we have to assume that it is the much stronger electrostatic field of the bivalent cation which is necessary for the reaction. This strong field polarizes the carbon dioxide molecule, presumably adsorbed on the cation, and it is this highly polarized form of the molecule which is then able to react with the neighboring oxygen of the structure to yield the carbonate-type grouping. The final product then is a carbon dioxide molecule very strongly attached to a surface oxygen which is quite close to a cation; so close that it can block the adsorption of other molecules (e.g. carbon monoxide) on the cation and the cation can in turn influence the vibrational frequencies of the carbonate group.

The interaction of adsorbed molecules with the carbonate-type bands can be explained as follows: when water is adsorbed on a CoY (see Fig. 2), it hydrogen-bonds with the surface carbonate species and this shifts both bands to lower frequencies: the 1575 cm^{-1} band to about 1470 cm^{-1} and the 1380 cm^{-1} band to a position where it cannot be detected due to the strong zeolite absorption. The 1620 cm^{-1} band is the bending frequency of the water molecule and of course does not appear when heavy water is adsorbed. When the water is removed, the bands shift back to their original positions. The same hydrogen-bonding effect is responsible for the similar changes in ammonia adsorption. On the other hand, the bands are not affected by benzene, since benzene is not a hydrogen-donor and thus does not form hydrogen bonds. These effects confirm our suggestion that the carbonate-type grouping is on the zeolitic surface.

To assess the practical significance of our findings we have to consider that, although the total chemisorption of carbon dioxide of the type that is stable at high temperature is quite small (1.6 cc of carbon dioxide per gram of zeolite), it is definitely associated with and, to some degree, blocks available surface cations. This fact should be taken into consideration whenever reactions are carried out which are thought to occur through interaction with the surface cations. Exposure to ordinary air in the high temperature activation process makes it possible for the small amounts of carbon dioxide present to interact with the zeolite to form this highly stable, chemisorbed species.

[3]The formation of Na_6^{5+} centers in NaX (11) indicates that there might be even more Na^+ ions in Sites S_{III} than given here.

Radiolysis of gaseous isobutylene by ^{60}Co γ-rays. II. Irradiation of isotopic mixtures: iso-C_4H_8 + iso-C_4D_8

J. A. HERMAN AND G. COLLIN[1]

Centre de Recherche pour les Atomes et les Molécules et Département de Chimie, Université Laval, Québec

Received May 29, 1969

The radiolysis of the isotopic mixture: iso-C_4H_8 + iso-C_4D_8 shows that, at 48 Torr pressure, about 40% of isobutane is formed in an ion–molecule reaction between isobutyl ion and the monomer. Half of the propene produced in radiolysis is formed in ion–molecule reactions, the H^- transfer reaction to $C_3H_5^+$ ion being the most important process. Small fractions of CH_4, C_2H_2, C_2H_4, allene, and propyne are also formed in ionic processes, but the main part results from unimolecular decomposition processes of the excited isobutylene.

La radiolyse du mélange isotopique iso-C_4H_8 + iso-C_4D_8 indique qu'à 48 Torr, environ 40% d'isobutane est formé dans une réaction ion–molécule qui fait intervenir, selon toute vraisemblance, l'ion isobutyle. Environ la moitié du propène est formé dans des réactions ioniques, dont le transfert de H^- à l'ion $C_3H_5^+$ est le plus important. Le restant du propène apparaît à la suite de décomposition monomoléculaire de la molécule parent. De faibles proportions de CH_4, C_2H_2, C_2H_4, allene et propyne sont aussi formées dans des processus ioniques, mais la majeure partie de ces produits est le résultat de décomposition monomoléculaire de l'isobutylène excité.

Introduction

In a recent paper (1), we reported yields of products formed during the radiolysis of gaseous isobutylene in the presence and absence of additives, and we suggested some mechanisms leading to the formation of isobutane and the C_2 and C_3 products. However, the evidence for these mechanisms was based mainly on mass balance and energetic considerations. The case of isobutane formation is of special interest; at a sample pressure of 40 Torr, the total yield per 100 eV of absorbed energy is 2.1 ± 0.2 molecules, and the addition of nitric oxide as a radical scavenger diminishes the yield by ~60%, thus indicating an important non-radical contribution to the formation of this molecule. This was explained (1) by assuming the following sequence of reactions

[1] $\text{iso-}C_4H_8^+ + \text{iso-}C_4H_8 \rightarrow t\text{-}C_4H_9^+ + C_4H_7$

[2] $t\text{-}C_4H_9^+ + \text{iso-}C_4H_8 \rightarrow C_4H_7^+ + \text{iso-}C_4H_{10}$

According to Lias and Ausloos (2) and Miyazaki and Shida (3), the tertiary butyl ion cannot produce iso-C_4H_{10} by a hydride transfer reaction with neopentane, because of the endothermicity of such a reaction ($\Delta H = 0.55$ eV). In the present case, the endothermicity of reaction [2] is smaller than that of a reaction between t-$C_4H_9^+$ ion and neopentane. However, even if the energy balance is more favorable, it is necessary to assume that the tertiary butyl ion is internally excited, in order to react in process [2]. The necessary excitation energy of the tertiary butyl ion may be provided in reaction [1], which is slightly exothermic as estimated from the available data (4, 5). Recent studies of Volpi and coworkers (6) on the variation of the mass spectrum of isobutylene with pressure showed that the $C_4H_9^+$ ion (which was assumed to have a tertiary structure) reacts with the parent molecule in an ion–molecule chain

[3] $t\text{-}C_4H_9^+ \xrightarrow{M} C_9H_{17}^+ \xrightarrow{M} C_{12}H_{25}^+ \xrightarrow{M} C_{4n}H_{8n+1}^+$

The "polymerization" chain probably propagates via an alkyl carbonium ion of tertiary structure, which is thermodynamically more stable. Another sequence involves the $C_5H_9^+$ ion

[4] $C_5H_9^+ \xrightarrow{M} C_9H_{17}^+ \xrightarrow{M} C_{13}H_{25}^+$

In the region of 10^{-2} Torr pressure, the 2 sequences account for more than 95% of the total ion intensity. With increasing pressure other ions appear of the general formulas $C_nH_{2n-1}^+$ and $C_nH_{2n-3}^+$.

It is clear that the proposed ion–molecule reaction [2], accounting for the formation of isobutane, is in disagreement with the mass-spectrometric investigation of Volpi and co-workers

*Yields are calculated relative to G(allene) 1.01 ± 0.05 at 48 Torr, and 0.76 ± 0.05 at 95 Torr.

(6). Therefore, in order to elucidate the possible ionic mechanism of isobutane formation, we carried out a set of radiolysis experiments on mixtures of perprotonated and perdeuterated isobutylenes in the presence of a suitable radical scavenger. Another series of radiolyses was conducted in an electric field; from such experiments one can differentiate, to some extent, between ionic and excited neutral decomposition reactions (7).

Experimental

Purification of reagents, the irradiation cell, the dosimetry, and the product analysis were previously described (1), and therefore only experimental details relevant to the present study are outlined below. The principal difference in the present analytical procedure, compared to that of ref. 1, is the systematic use of a gas–liquid chromatograph (g.l.c.) equipped with a flame ionization detector. A 30 ft. squalane chromatographic column was used for the separation of the radiolysis products. Previously (1), we separated the gases in a LeRoy still before injecting them into the g.l.c. equipped with a thermoconductivity detector, and in such a procedure some compounds (i.e. C_2H_2) were partially lost. All G values are calculated relative to the yield of allene in an unscavenged radiolysis experiment, because the formation of this compound is dose and dose-rate independent at a given pressure, and it is also insensitive to radical scavengers.

Ammonia from Matheson Co. was purified by trap-to-trap distillation at −195 °C. Isobutylene-d_8 from Merck, Sharp and Dohme Ltd was purified further by g.l.c. before its use. It contained 5.35% of isobutylene-d_7, as shown by mass spectrometry. In order to compensate for the presence of iso-C_4D_7H, a statistical correction was made to the calculation of yields of all hydrocarbons. The isotopic mixtures were prepared in the following ratio: (iso-C_4H_8:iso-C_4D_8:NO) = (50:50:8) in all experiments where nitric oxide was used as radical scavenger. After irradiation, the products were separated by g.l.c. and trapped at −195°. Immediately after, they were transferred for further analysis to the high resolution mass spectrometer, Hitachi Perkin–Elmer RMU-6.

The experiments involving an electric field were performed in irradiation cells of the same shape and dimensions as those described in (1). They were coated from inside with graphite, the inner electrode being a wire of tungsten.

Results

In Table I are presented the G values at 48 and 95 Torr for isobutane and the major decomposition products of isobutylene. The G values calculated in the present case are comparable to those obtained previously (1). At 48 Torr pressure, $G(CH_4)$ is somewhat higher, but the yields are smaller for C_2H_2 and C_3H_6. The present results show that G(propyne) is always a little smaller than the corresponding value of allene. It is worthwhile to note that, with the present analytical procedure, the $G(C_2H_2)$ does not show the strong pressure dependence as described in Part I.

As noted in Part I, the presence of radical scavengers, oxygen and nitric oxide, have no effect on C_2H_2, C_2H_4, propyne, and allene formation, but have a strong effect on CH_4 and iso-C_4H_{10} and, to a lesser extent, on C_3H_6 formation. The presence of ammonia, which acts as a proton scavenger, also has no effect on the yields of H_2, CH_4, C_2H_2, C_2H_4, and the C_3H_4 isomers, but has an important one on G(iso-C_4H_{10}) and a smaller one on $G(C_3H_6)$. Moreover,

Ethylene	49.5	3.1	3.2	2.8	41.4						
Allene	53.0	0.6	0.9	0.1	44.7						
Propyne	52.7	1.0	—	2.2	44.0						
Propene	34.7	11.3	6.4	4.7	6.2	10.6	26.1				
Isobutane	?	?	?	?	?	?	?	~0	155	123	100

*iso-C_4H_8:iso-C_4D_8:NO = 50:50:8; pressure of the mixture = 48 Torr.

the formation of isobutane is almost completely suppressed by the combined action of O_2 and NH_3.

In the presence of an electric field, the yields of C_2H_4 and C_3H_6 are affected little (C_3H_6) or not at all (C_2H_4), whereas the yields of propyne and allene increase very strongly (Fig. 1).

The relative isotopic compositions of products formed during radiolysis of isotopic mixtures at 40 Torr are presented in Table II. In the case of isobutanes, only $-d_{10}$, $-d_9$, and $-d_8$ species could be estimated. Their relative composition was inferred from the abundance of propyl ions in the mass spectrum. The lack of adequate standard mass spectral patterns of partially deuterated butanes made a detailed quantitative analysis of the isobutane fractions only approximate. The isobutane-d_9 was assumed to have only the $(CD_3)_3CH$ structure. In comparison with the abundances of $-d_{10}$, $-d_9$, and $-d_8$ isobutanes, the $-d_7$ fraction seems to be very small.

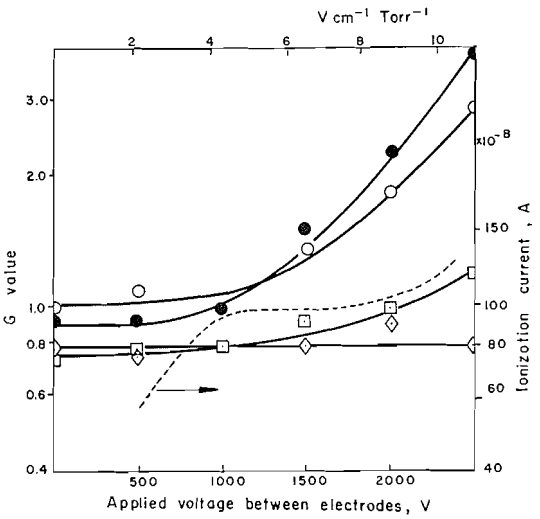

FIG. 1. Radiochemical yields of ethylene (◇), propene (□), propyne (○), and allene (●) as a function of the electric field. The dashed line represents the ionization current in the cell.

In order to check the ionic mechanism for formation of isobutane, we performed radiolyses of mixtures of neopentane and isobutylene. The mixture (neo-C_5H_{12}:iso-C_4D_8:O_2) = (100:5:0.4) has a G(isobutane)$_{total}$ = 0.01 relative to the energy absorbed by neopentane, but a G' (isobutane) = 1.5 ± 0.5 if calculated relative to the energy absorbed by isobutylene-d_8 only. In the case of irradiation of a mixture (neo-C_5D_{12}:iso-C_4H_8:O_2) = (50:50:14), only perprotonated isobutane is formed and its yield, G(iso-C_4H_{10}) = 0.82 is relative to the energy absorbed by the isobutylene.

Discussion

Formation of Isobutane

The action of radical scavengers and of ammonia in the radiolysis of isobutylene indicates that isobutane is formed in part in radical reactions (~60%) and in ion–molecule processes (~40%). The formation of iso-C_4H_{10} in radical reactions proceeds via disproportionation between tertiary butyl radicals (8–11), the t-C_4H_9· being formed efficiently by thermal hydrogen addition to the tertiary carbon in isobutylene. The addition of nitric oxide has a more pronounced effect on the formation of iso-C_4H_{10} than does oxygen (Table I), and that can be attributed to the charge transfer between iso-$C_4H_8^+$ (ionization potential (i.p.) = 9.23 eV) and NO (i.p. = 9.25 eV) (12)

[5] iso-$C_4H_8^+$ + NO → iso-C_4H_8 + NO^+

However, reaction [5] is relatively slow (13) and it is therefore possible that, even at 30% NO, not all iso-$C_4H_8^+$ ions have been intercepted. Incidentally, reaction [5] is another proof of the ionic character of the mode of formation of that part of the isobutane which is not scavengable by oxygen.

Recent studies on the photolysis of gaseous isobutylene by 10.0 and 11.6–11.8 eV photons (14) have shown that 3 isobutane molecules are produced for every 10 isobutylene ions, and that this ionic mechanism is the only one which accounts for the nonradical formation of isobutane. If we admit that this ratio also described the situation for oxygen or ammonia scavenged radiolysis experiments, then it is possible to calculate the yield of these iso-$C_4H_8^+$ parent ions which did not decompose before the first reactive collision. At 48 Torr, G(iso-$C_4H_8^+$) = 2.7 or 2.2, depending which of the two effects, oxygen or ammonia, is taken into account. The smaller G value calculated from radiolysis experiments in the presence of ammonia (Table I) results most probably from the fact that the concentration of ammonia is not sufficiently important in order to intercept all iso-$C_4H_8^+$ ions before the formation of isobutane. At 95 Torr, G(iso-$C_4H_8^+$) = 1.7, as calculated from radiolysis experiments done in the presence of oxygen (Table I). However, the increase of pressure from 48 to 95 Torr is not sufficient to change appreciably the yields of parent ions, and it is more probable that the present difference in G(iso-$C_4H_8^+$) is the result of experimental incertitude. Tentatively, we shall admit a G(iso-$C_4H_8^+$) = 2.5 ± 0.3 at 48 Torr.

According to a mass spectrometric investigation (15) in the case of iso-C_4H_8, the proton transfer

[6] $\text{iso-}C_4H_8^+ + \text{iso-}C_4H_8 \rightarrow C_4H_9^+ + C_4H_7$

is essentially the only mode of reaction between the parent ion and iso-C_4H_8. It is well established that the t-$C_4H_9^+$ ions are efficiently intercepted by NH_3 (3, 16), but it is also possible that the iso-$C_4H_8^+$ parent ions are intercepted by ammonia. The effect of NH_3 in the radiolysis of isobutylene is comparable to that of water vapor (17) and of nitric oxide in the radiopolymerization of gaseous iso-C_4H_8 (18). However, if 0.1% of NO inhibits 95% of the polymerization yield (18), 30% of NO inhibits only 85% of the isobutane production. Similar observations are applicable to the ammonia effect in this system. Therefore, if the polymer and the ionic isobutane have the same common precursor, the reaction sequences are different. In order to check the role of the t-$C_4H_9^+$ ions in the formation of iso-C_4H_{10}, we irradiated mixtures of neopentane-d_{12} and isobutylene-d_0 with oxygen as radical scavenger (see Results). Irradiated neopentane is recognized to produce tertiary butyl ions by fragmentation of the parent molecule (19, 20), and if an ion–molecule reaction occurs between t-$C_4D_9^+$ and iso-C_4H_8, the isobutane-d_9 should be formed by H^- transfer. The results of such an experiment show clearly that the afore-mentioned reaction does not take place and that the proposed mechanism, reaction [2], is wrong (1).

Volpi and co-workers (6) reported that reaction [6] is followed by consecutive processes [3] and [4] which lead to the polymer formation in the gas phase. When the pressure increases above 10^{-2} Torr, the intensity of the polymeric ions $(C_nH_{2n+1})^+$ and $(C_nH_{2n-1})^+$ drops rapidly, while a new generation of ions of the general formula $(C_nH_{2n-1})^+$ and $(C_nH_{2n-3})^+$, which could result from an H_2 transfer, simultaneously appear

[7] $(C_nH_{2n+1})^+ + \text{iso-}C_4H_8 \rightarrow (C_nH_{2n-1})^+ + \text{iso-}C_4H_{10}$

Isotopic analysis of the unscavenged isobutane fraction (Table II) shows the presence of C_4D_{10}, C_4D_9H, and $C_4D_8H_2$, and such an isotopic composition is in qualitative agreement with mechanism [7]. The thermodynamic considerations are also favorable; the heat of formation of $(C_nH_{2n+1})^+$ and $(C_nH_{2n-1})^+$ ions do not differ appreciably when n is large ($n > 10$), and reaction [7] is then exothermic by 28 kcal/mole. A similar mechanism was assumed for the formation of propane by an H_2 transfer process in the photoionization of propene (21). However, the $(C_nH_{2n+1})^+$ ions formed in the radiolysis of neo-C_5D_{12}:iso-C_4H_8:O_2 = 50:50:14 mixture might contain at most 9 deuterium atoms if originating from a t-$C_4D_9^+$ ion. Therefore, one can expect that isobutane formed in reaction [7] might contain 1 or 2 deuterium atoms, but this is not the case (see Results).

There is still the possibility that a part of the $C_4H_9^+$ ions produced in reaction [6] retain the isobutyl structure, and that these ions react with the monomer by hydride transfer

[8] $(CH_3)_2CHCH_2^+ + \text{iso-}C_4H_8 \rightarrow \text{iso-}C_4H_{10} + C_4H_7^+$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Reaction [8] would also be in qualitative agreement with the observed isotopic composition. If reaction [8] contributes to the formation of isobutane, then the iso-C_4D_9H fraction formed in radiolysis of iso-C_4D_8:iso-C_4H_8:NO mixture (Table II) is a mixture of $(CD_3)_3CH$ and $(CD_3)_2CDCHD_2$ structures. The calculation of the mass spectrum of partially deuterated isobutanes is cumbersome, the reason being the lack of adequate standard mass spectral patterns, but if we assume that the isobutanes-d_{10}, -d_9, and -d_8 are a mixture of $[(CD_3)_3CD]:[(CD_3)_3CH]:[(CD_3)_2CDCHD_2]:[(CD_3)_2CDCDH_2] = 1:1:1:1$, the calculated results fit the experimental mass spectrum better than these in which we ignore the third structure. However, the formation of the isobutyl ion from the ground state of the parent ion, iso-$C_4H_8^+$, is slightly endothermic ($\Delta H = 5$ kcal/mole); thus the necessary energy required for such a reaction should be provided by the excited parent ion. This was verified in photolysis by 10.0 eV photons (krypton resonance line) of isobutylene in a great excess of argon with oxygen added as a radical scavenger (14). In these conditions, the production of isobutane decreases very strongly, which means that the ionic precursor of isobutane is deactivated by argon.

This last observation indicates that the isobutyl ions are responsible for the formation of isobutane, whereas the tertiary butyl ions lead to the ionic polymerization as suggested by Volpi and co-workers (6). The length of the kinetic "ionic polymerization" chain is either sufficiently long, or the process is relatively slow, in order that small concentrations of NH_3, H_2O, or NO ($< 10^{-2}\%$) inhibit the formation of the polymer (18). On the other hand, the formation of isobutane by a rapid H^- ion transfer to the isobutyl ion explains the much lower sensitivity of the process [8] to the presence of NO or H_2O.

Propene, Allene, and Propyne

The radiolytical yield of propene formation is about 6 times higher than the corresponding yield in photolysis experiments at 11.6–11.8 eV (14). It follows that formation of C_3H_6 involves either a substantial increase of processes already operating at photon energies of 8.4 to 11.8 eV, or the occurrence of new mechanisms, or both together. The relatively high abundance of -d_0 and -d_6 propenes indicates an elimination of a methylene group from isobutylene

[9] $$(CD_3)_2CCD_2^* \rightarrow CD_2 + C_3D_6$$

The C_3D_5H and C_3H_5D formation might result from the decomposition of the excited isobutyl radical formed in a hot deuterium/hydrogen addition

[10] $$D + (CH_3)_2CCH_2 \rightarrow (CH_3)_2CDCH_2^* \rightarrow CH_3 + CH_3CDCH_2$$

Both mechanisms were postulated as being responsible for the propene production in photolysis at 1460, 1236, and 1067–1048 Å (14). However, the d_2, d_3, and d_4 propenes are not formed in the photolysis, and their production in radiolysis experiments suggests another reaction path for propylene formation. In the photolysis of isobutylene by 1067–1048 Å photons, there is practically no fragmentation of the parent ion (14); therefore, the formation in radiolysis of d_2, d_3, and d_4 propenes must proceed by an ionic mechanism involving fragmentation of the parent ion followed by ion–molecule reaction with isobutylene. The small decrease of the yield of propene in the presence of NH_3 (Table I) is a supplementary indication of such a process.

The total yield of ions formed per 100 eV of absorbed energy is 4.2 (22). If one assumes the correctness of the $G(\text{iso-}C_4H_8^+) = 2.5 \pm 0.3$, it follows that the yield of fragment ions is 1.7 ± 0.3. The most important ion in the isobutylene mass spectrum is the $C_3H_5^+$ species, which accounts for around 31% of all ions produced by 70 eV electrons in the mass-spectrometric source at very low pressure. At 48 Torr, the relative abundance of this ion over all other fragment ions from isobutylene is at least the same or higher, and $G(C_3H_5^+) > 0.5 \pm 0.1$. Abramson and Futrell (15) concluded that about 70% of the $C_3H_5^+$ ions react with isobutylene in a formal H^- transfer process

[11] $$C_3H_5^+ + \text{iso-}C_4D_8 \rightarrow C_3H_nD_{6-n} + C_3D_{2n}H_{5-n}^+$$

but, in fact, reaction [11] proceeds via a strong complex, where many hydrogens are exchanged. At first sight, reaction [11] could explain the formation of all partially deuterated propenes, but a more careful examination of the results shows some discrepancies between the Abramson and Futrell values and ours. In the tandem mass-spectrometry experiments (15) the formation of the $C_3D_3H_3$ is favored, while, in the present case, it is the less important species. Several factors might be responsible for this discrepancy, but the pressure effect is probably the most important. At 40 Torr, the stabilization of a strong (long

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

lived) intermediate complex is very likely, and it might undergo further condensation process. Therefore, a process such as [11] will contribute only to a small extent to the propene formation, and its yield can be estimated as 0.12 from the ammonia effect.

If an ion–molecule process similar to [11] takes place in the present system, it will probably result from an encounter between $C_3H_5^+$ and iso-C_4H_8, where only a weak (short lived) intermediate complex is involved and the result is a true H^- transfer reaction

[12] $C_3H_5^+ + \text{iso-}C_4H_8 \rightarrow C_3H_5D + C_4D_7^+$

An estimation of $G[10] + G[12] = 0.35$ can be made, where isotope effects were not taken into consideration (Tables I and II). The photolysis data provide an upper limit of $G[10] \leqslant 0.10$ (14); it follows then, that the yield per 100 eV of hydride transfer reaction [12] is around 0.25. Therefore, the total yield of propene formed in ionic processes (reactions [11] and [12]) is about 0.4, and this value explains in part the important difference of $G(C_3H_6)$ between radiolysis and photolysis experiments.

In the presence of an electric field, $G(C_3H_6)$ increases slightly but seems to follow the increase of the ionization current in the "plateau" region. This increase of $G(C_3H_6)$ results from the enhancement of process [9] as electrons gain more kinetic energy with increasing field strength.

The action of the electric field (Fig. 1) on allene and propyne production and the isotopic analysis (Table II) of these products indicate that they are formed in elimination processes of the excited isobutylene molecule. This is consistent with the previously proposed mechanism (1)

[13] $\text{iso-}C_4H_8^* \begin{cases} \nearrow H_2C{=}C{=}CH_2 + H + CH_3 \text{ (or } CH_4) \\ \searrow HC{\equiv}C{-}CH_3 + H + CH_3 \text{ (or } CH_4) \end{cases}$

The C_3H_4 species can originate by secondary fragmentation either from $C_3H_5^{\cdot}$ or $C_4H_7^{\cdot}$ radicals. This is not unexpected, because the energy requirements to form these radicals from isobutylene are almost equal[1]. However, radiolysis experiments carried out in order to determine the nature of the radical intermediates in isobutylene at −90 °C showed that the major radical species is 2-methylallyl (67%), while the yield of 1-methylvinyl is small (2%) (24). This suggests that the $C_3H_5^{\cdot}$ species undergoes fast secondary fragmentation

[14] $CH_3C{=}CH_2^* \begin{cases} \nearrow H_2C{=}C{=}CH_2 \\ \searrow H_3C{-}C{\equiv}CH \end{cases}$

and does not accumulate within the system, whereas the $C_4H_7^{\cdot}$ is stabilized. However, the last argument might be fallacious, because there is no experimental evidence that process [14] is taking place in the condensed phase.

About 2.5% of allene and propyne are partially deuterated (Table II). Such species are not formed in photolysis experiments (14); therefore, we concluded that ion–molecule processes are responsible for their production. The partially deuterated allene and propyne might originate in the following process involving $C_3H_3^+$ ions (whose relative abundance in the American Petroleum Institute mass spectrum of iso-C_4H_8 is 13.6%)

[15] $C_3H_3^+ + \text{iso-}C_4D_8 \rightarrow C_3H_3D + C_4D_7^+$

As in the case of C_3H_5 ion, process [15] can be a true H^- transfer reaction, or involves a long lived intermediate complex where reshuffling of hydrogens is very likely.

Methane, Acetylene, and Ethylene

The fact that the unscavenged methane in radiolysis of C_4H_8–C_4D_8–NO mixtures (Table II) consists mainly of CH_4 and CD_4 demonstrates that this molecule is nearly exclusively formed in unimolecular processes. Either the primary process

[16] $(CH_3)_2CCH_2^* \rightarrow CH_4 + CH_3CCH$

or a secondary fragmentation such as

[17] $\begin{matrix} H_3C \\ \diagdown \\ \quad C{=}CH_2 \\ \diagup \\ H_2C \end{matrix} \rightarrow CH_4 + CH_2CCH$

could account for the observed results. The small $-d_1$ and $-d_3$ contributions to the methane can be explained by addition of a hot hydrogen atom to isobutylene and subsequent fragmentation of the excited molecule. The decomposition of an excited parent ion is also a process which contributes to the production of "molecular" meth-

[1]Heats of reaction are based on thermodynamic data presented in ref. 23.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ane. Such a decomposition process occurs in an interval less than 10^{-10} s before a first collision happens; therefore, even an important increase of pressure does not seriously interfere with this process. Nevertheless, the present results do not allow us to calculate the contribution of each of these unimolecular decomposition reactions to the formation of molecular methane.

Acetylene formed in the radiolysis of isotopic mixtures consists of perprotonated and perdeuterated molecules and indicates, therefore, that unimolecular fragmentation process is responsible for its formation. On the other hand, the yield of ethylene, which also consists mainly of $-d_0$ and $-d_4$ species, is close to that of acetylene. In fact, the yields of perprotonated and perdeuterated acetylene and ethylene are equal within experimental error. Moreover, the equal decrease in the yields of C_2H_2 and C_2H_4 with increasing pressure of isobutylene (Table I) give evidence that these products have a common excited precursor with an appreciable lifetime. A mechanism such as

[18] $(CH_3)_2CCH_2^* \rightarrow H_2 +$ 
followed by

[19] 
$\rightarrow C_2H_2 + C_2H_4$

is in harmony with established mechanisms (25, 26) for the formation of both perprotonated and perdeuterated acetylene and ethylene. The fact that during radiolysis in the presence of an electric field there is no increase in the C_2H_2 and C_2H_4 yields (Fig. 1) does not necessarily rule the occurrence of processes [18] and [19]. Indeed, electrons accelerated by the electric field do not gain enough energy to excite the isobutylene to such a level where processes [18] and [19] could take place. However, the excitation reached by isobutylene in collision with accelerated electrons is sufficient to detach a methyl group, which requires only 5.83 eV (23).

There are some minor contributions of other processes leading to the production of ethylene and acetylene, as demonstrated by the formation of partially deuterated species. These species are not formed in photolysis experiments at 1067–1048 Å (14); we assume that they originate in ion–molecule reactions in the same manner as partially deuterated propenes, allenes, and propynes. The $C_2H_3^+$ ion is an important fragment in the 70 eV electron mass spectrum of isobutylene ($\sim 6.4\%$). It reacts with isobutylene in the following processes

[20] $C_2H_3^+ + \text{iso-}C_2H_8 \rightarrow C_2H_4 + C_4H_7^+$

[21] $\rightarrow C_2H_2 + C_4H_9^+$

and their cross-sections are relatively important (15). Assuming that "ionic" ethylene is produced in process [20], where the intermediate complex has a sufficient lifetime for reshuffling of hydrogen atoms, the yield of partially deuterated ethylenes is then $G[20] = 0.08$. Another important fragment in the mass spectrum of iso-C_4H_8 is the $C_2H_4^+$ ion ($\sim 6.6\%$). This species reacts quantitatively with isobutylene in a charge transfer process (15) leading to the "molecular" ethylene. Such a process should be insensitive to an increase of the pressure (within the limits of the present study), as it does not require the formation of a strong intermediate complex.

Conclusions

(*a*) The formation of the unscavenged isobutane proceeds via an ion–molecule reaction involving most probably isobutyl ions, whereas the tertiary butyl ions lead to the ionic polymerization.

(*b*) Assuming the same ionic yield for unscavenged isobutane formation in radiolysis as in photolysis at 1067–1048 Å (14), the yield per 100 eV of fragment ions is then 1.7 ± 0.3.

(*c*) About half the production of propene proceeds through an ionic process, $G(C_3H_6, \text{ionic}) \sim 0.4$.

(*d*) All other decomposition products, CH_4, C_2H_2, C_2H_4, allene, and propyne show small ionic contributions to their formation. However, the total ionic contribution of these species, including that of propene, is less than the yield of fragmentions. We conclude, therefore, that a part of these ionic reactions leads to condensation products in similar processes to those described by Volpi and co-workers (6).

Pyrolysis of hydrocinnamic acid[1,2]

A. T. C. H. TAN[3] AND A. H. SEHON[4]
Department of Chemistry, McGill University, Montreal, Quebec

Received January 15, 1969

The pyrolysis of hydrocinnamic acid was investigated by the toluene-carrier technique over the temperature range 910–985 °K. The overall decomposition was first-order with respect to hydrocinnamic acid, and could be represented by reactions [1] and [2], respectively,

[1] $$C_6H_5CH_2CH_2COOH \xrightarrow{k_1} C_6H_5CH_2 + \cdot CH_2COOH$$

[2] $$C_6H_5CH_2CH_2COOH \xrightarrow{k_2} C_6H_5CH_2CH_3 + CO_2$$

Both reactions [1] and [2] were found to be homogeneous first-order processes, and the rate constants may be represented by the following expressions

$$k_1 = 1.1 \times 10^{12} \exp(-55\,000/RT) \quad s^{-1}$$

$$k_2 = 1.0 \times 10^{15} \exp(-69\,000/RT) \quad s^{-1}$$

The activation energy of reaction [1] is identified tentatively with $D(C_6H_5CH_2—CH_2COOH)$.

Canadian Journal of Chemistry, 47, 3845 (1969)

Introduction

In a previous study (1) the $\cdot CH_2COOH$ radical was produced by the rupture of the C_6H_5-S—CH_2COOH bond in the pyrolysis of phenylmercaptoacetic acid using the toluene-carrier technique. It was found that the $\cdot CH_2COOH$ radicals either abstracted a hydrogen atom from toluene to form acetic acid or decomposed to give other ill-defined fragments. The pyrolysis of hydrocinnamic acid was studied in the present investigation with a view to producing this radical from another source and in the hope of throwing additional light on the mechanism of the reactions of this radical.

It was anticipated that due to the resonance stabilization of the benzyl radical, the weakest bond in hydrocinnamic acid would be the C_6H_5-CH_2—CH_2COOH bond. Thus, on dissociation of this bond, one benzyl radical would be produced for each $\cdot CH_2COOH$ radical formed. It is a well-known fact that the benzyl radicals tend to dimerize to form dibenzyl. Consequently, if all the $\cdot CH_2COOH$ radicals abstracted hydrogen from toluene, the rate of formation of acetic acid would be equal to the rate of production of dibenzyl and either of these rates would measure the rate of dissociation of the corresponding C—C bond in hydrocinnamic acid. The activation energy of the decomposition reaction could then be identified with the bond dissociation energy, if the assumption is made that the activation energy of the reverse reaction is zero. On the other hand, if not all the $\cdot CH_2COOH$ radicals were removed by abstraction of hydrogen atoms from toluene, this study would provide the opportunity to study the decomposition reaction of this radical.

Experimental

Hydrocinnamic acid was the highest purity product of Eastman Organic Chemicals, Rochester, N.Y. Mass spectrometric analysis revealed that it was contaminated with a substance of molecular weight 198 in a fraction of 1%. It was used without further purification. The toluene was supplied by Gulf Petroleum Company, Pittsburgh, Pa. It was stirred for 20 h with calcium chloride and distilled through an efficient column; the fraction boiling at 110.5 °C was used in this study.

The pyrolysis of hydrocinnamic acid in a stream of toluene was studied over the temperature range 910–985 °K. The apparatus and procedure used were identical with those employed for the pyrolysis of phenylmercaptoacetic acid (1). Toluene was passed through the reaction vessel for 5 min both before and after the reaction to ensure that no pyrolysis of toluene alone occurred under the present experimental conditions.

The set-up and experimental conditions for gas chromatographic analysis were described in a previous paper (1). A column of apiezon L on firebrick operated at 66 °C and a 30% TCP (Tricresylphosphate) on firebrick column operated at 120 °C were used to separate the products condensed at dry ice – acetone and liquid air temperatures, respectively.

The methods of analysis for the products were identical with that described in ref. 1, with the exception that the contents of the dry ice – acetone and liquid air traps from typical experiments in the present investigation were also analyzed by mass spectrometry. The products of the decomposition that were determined quantitatively are shown in Table I. In column 8 of Table I is given the total amount of substances trapped at liquid air temperature, which consisted of carbon dioxide, toluene, ethylene, and trace amounts of ketene.

Gas chromatographic analysis of the materials trapped at −78 °C revealed the presence of acetic acid, ethylbenzene, styrene, and unreacted toluene. In some experiments trace amounts of acetone and benzene were also detected by mass spectrometry.

Infrared analysis of the substances trapped at −188 °C demonstrated that carbon dioxide was the main product. In addition, small amounts of ethylene and ketene were characterized by the two peaks at 950 (2) and 2150 cm^{-1} (3), respectively. Mass spectrometric analysis of the contents in this trap from 12 experiments indicated the presence of more than 90% of carbon dioxide in most experiments, a few % of unreacted toluene which had not been completely trapped out at −78 °C, and less than 1% of ethylene. In some experiments trace amounts of water, C_2 (other than ethylene), and higher hydrocarbons were also detected.

The noncondensable gases consisted of 42–70% of carbon monoxide, the remainder being hydrogen and methane.

The sum of carbon dioxide, acetic acid, and carbon monoxide was almost equal to the amount of hydrocinnamic acid decomposed. The ratio of the two quantities varied from 0.85 to 1.1, except in experiment 41, where this ratio was as low as 0.69. This run was performed at 935 °K, i.e., at the lower end of the whole temperature range used, at which the extent of decomposition was small and consequently the experimental error larger than in other experiments.

The quantity of dibenzyl was equivalent to 55–93% of the acid decomposed, and was approximately 65% in most experiments. The ratio of carbon dioxide to acid decomposed was from 0.30 to 0.47, being about 0.4 in most experiments.

Ethylbenzene and styrene were trapped together in a large excess of toluene. Since the latter two compounds represented about 0.5% of the toluene, it was rather difficult to determine their quantities accurately.

Discussion

Mechanism of Decomposition

The products of the pyrolysis suggest that the thermal decomposition of hydrocinnamic acid might occur primarily by the two simultaneous processes [1] and [2], involving a free radical and a molecular dissociation reaction, respectively.

$$[1]\quad C_6H_5CH_2CH_2COOH \xrightarrow{k_1} C_6H_5CH_2\cdot + \cdot CH_2COOH$$

$$[2]\quad C_6H_5CH_2CH_2COOH \xrightarrow{k_2} C_6H_5CH_2CH_3 + CO_2$$

Thus, reaction [1] would represent the dissociation of the C—C bond resulting in the formation of the benzyl and $\cdot CH_2COOH$ radicals, and reaction [2] would represent the molecular dissociation yielding ethylbenzene and carbon dioxide. From the relative amounts of the products formed, reaction [1] appears to predominate over the temperature range studied.

If each of the $\cdot CH_2COOH$ radicals produced in reaction [1] were to abstract one hydrogen atom from toluene

$$[3]\quad \cdot CH_2COOH + C_6H_5CH_3 \rightarrow C_6H_5CH_2\cdot + CH_3COOH$$

and all the benzyl radicals dimerized to dibenzyl

$$[4]\quad 2C_6H_5CH_2 \rightarrow (C_6H_5CH_2)_2$$

one would expect to have the following stoichiometry

$$[C_6H_5CH_2CH_2COOH \text{ decomposed}] = [CH_3COOH] + [CO_2]$$

$$[C_6H_5CH_2CH_3] = [CO_2]$$

and

$$[(C_6H_5CH_2)_2] = [CH_3COOH]$$

However, the results indicated that

$$[C_6H_5CH_2CH_2COOH \text{ decomposed}] > [CH_3COOH] + [CO_2]$$

$$[(C_6H_5CH_2)_2] > [CH_3COOH]$$

Therefore, it must be concluded that reaction [3] was not sufficiently rapid to remove all the $\cdot CH_2COOH$ radicals. This conclusion is supported by the fact that other products were also formed in this reaction system.

Calculation of $D(C_6H_5CH_2—CH_2COOH)$

If the rate of the overall decomposition were first-order with respect to hydrocinnamic acid, the overall rate constant k_o could be calculated by using the following rate expression

$$k_o = \frac{1}{t} \ln \frac{A}{A - X}$$

where t is the time of contact in s, A the amount of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

hydrocinnamic acid introduced, and $A - X$ represents the amount of hydrocinnamic acid recovered in trap "U" surrounded with ice. Furthermore, if the two modes of decomposition, as represented by reactions [1] and [2], were first-order reactions, and if reactions [3] and [4] were very fast by comparison with reaction [1], one could obtain the rate constants k_1 and k_2 for reactions [1] and [2], respectively, by the following expressions

$$k_1 = \frac{[(C_6H_5CH_2)_2]}{[A]} k_o [1 - \exp(-k_o t)]^{-1}$$

$$k_2 = \frac{[CO_2]}{[A]} k_o [1 - \exp(-k_o t)]^{-1}$$

where $[(C_6H_5CH_2)_2]$ and $[CO_2]$ represent the amounts of dibenzyl and carbon dioxide formed in time t, respectively.

According to the proposed mechanism, the only source for carbon dioxide would be reaction [2]. Therefore, the rate of formation of CO_2 would be a measure of the rate of reaction [2]. The difference between the total amount of hydrocinnamic acid decomposed and the amount of carbon dioxide would thus correspond to the amount of acid decomposed via reaction [1]. The rate constants k_1 and k_2 thus calculated for 12 experiments are shown in Table I.

The rate constant of the overall decomposition of hydrocinnamic acid, k_o, at a given temperature was not affected, within experimental accuracy, by the variation of the partial pressure of acid by a factor of 9, of the toluene pressure by a factor of 2, and of the time of contact by a factor of 5. These results are also shown in Table I. It is also evident from Table I that the increase in surface/volume ratio by a factor of 27 had practically no effect on the rate constant k_o. The effects of the variation of the partial pressures of the acid and toluene, of the time of contact, and of the surface/volume ratio on k_1 and k_2 are shown in Table I. From these results it is deduced that the overall decomposition of hydrocinnamic acid, as well as the two modes of its decomposition, [1] and [2], were homogeneous, first-order reactions. The plots of log k_o vs. $1/T$, log k_1 vs. $1/T$, and log k_2 vs. $1/T$ are shown in Figs. 1, 2, and 3, respectively. The plots are linear over the temperature range studied. From these plots the corresponding parameters in the Arrhenius equation, $k = A \exp(-E/RT)$, were calculated as given below.

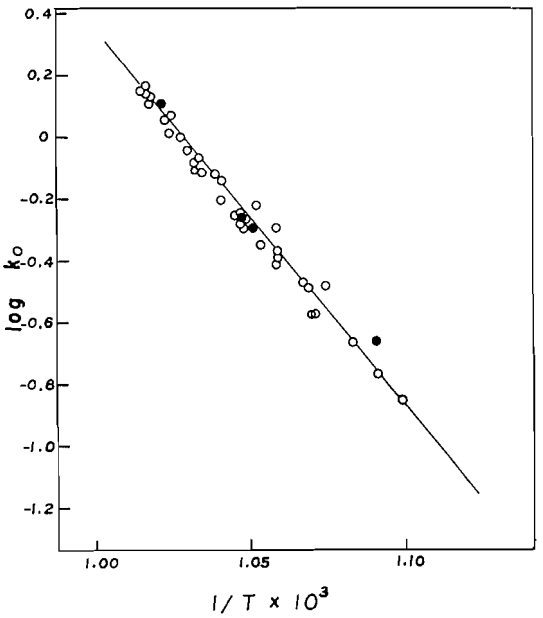

FIG. 1. Plot of log k_o vs. $1/T$. Experiments done in the packed reaction vessel are indicated by the filled circles.

For the overall decomposition

$$E_o = 56 \quad \text{kcal/mole}$$

$$A_o = 3.0 \times 10^{12} \quad \text{s}^{-1}$$

for reaction [1]

$$E_1 = 55 \quad \text{kcal/mole}$$

$$A_1 = 1.1 \times 10^{12} \quad \text{s}^{-1}$$

and for reaction [2]

$$E_2 = 69 \quad \text{kcal/mole}$$

$$A_2 = 1.0 \times 10^{15} \quad \text{s}^{-1}$$

The A factor of 1.1×10^{12} s^{-1} for reaction [1] is within the range of 10^{12}–10^{14} s^{-1} associated with most unimolecular reactions. However, A_1 is only 0.14 and 0.003 of the A factors for the pyrolyses of phenylacetic acid (4) and ethylbenzene (5), respectively. The experimentally estimated activation energy for reaction [1] is of the right order of magnitude when compared with the value of 55 kcal/mole (4) associated with the decomposition of phenylacetic acid, but is considered somewhat low if compared with the value

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

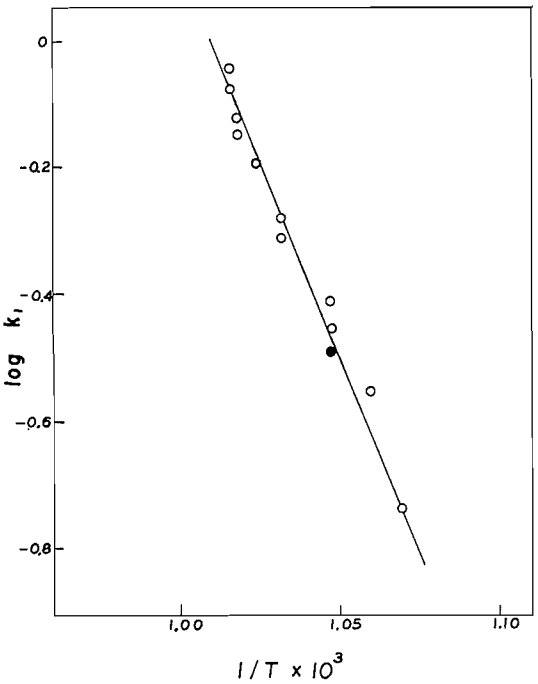

FIG. 2. Plot of log k_1 vs. $1/T$. Experiment done in the packed reaction vessel is indicated by the filled circle.

of 70 kcal/mole (5) assigned to $D(C_6H_5CH_2—CH_3)$. Keeping in mind the complexity of the decomposition of hydrocinnamic acid and the assumptions made in the estimation of k_1, it is possible to visualize that in addition to reaction [2], side reaction or reactions producing carbon dioxide might have occurred to a small extent; the linearity of the Arrhenius plot may not be noticeably affected though the activation energy calculated from it may be erroneous. Owing to this uncertainty, the identification of E_1 with the $D(C_6H_5CH_2—CH_2COOH)$ is only tentative.

The Secondary Reactions

The $\cdot CH_2COOH$ radicals may abstract hydrogen according to reaction [3] stated previously, or may decompose according to reaction [5]

[5] $$\cdot CH_2COOH \rightarrow CH_2CO + \cdot OH$$

The ·OH radicals would be expected to disappear by reaction [6]

[6] $$\cdot OH + C_6H_5CH_3 \rightarrow C_6H_5CH_2\cdot + H_2O$$

Water was detected in the liquid air trap by mass spectrometry. However, its amount was small and it could have been due to extraneous sources rather than to reaction [6] exclusively. Nevertheless, under the experimental conditions used in this investigation, reaction [6] appears to be the most probable reaction of the ·OH radical; this has also been suggested by other workers (4).

The detection of ketene among the products supports reaction [5]. However, the amount of ketene is too small to account for the difference between the amounts of the $\cdot CH_2COOH$ radicals produced, as reflected by the amount of dibenzyl formed, and that of acetic acid. This indicates that some ketene underwent further reaction. On concentration grounds alone, dimerization of ketene is considered unlikely. Failure to detect diketene among the products of the pyrolysis of ketene (6, 7) supports this proposal.

Carbon monoxide has been found to be the major product of the pyrolysis of ketene, both using the static system at 510–590° (6), 396–563° (7), 500–550° (8), and 570° (9) and the flow system at 1120° (10). The ratio of carbon monoxide to methane varied between 2.1 (8) and 6.1 (9), and that of carbon monoxide to ethylene ranged from 2.1 (10) to 18.6 (8) at temperatures larger than 500°. The CO to $(CH_4 + C_2H_4)$ ratio in all reports is about 2 (7–10). The discrepancies in

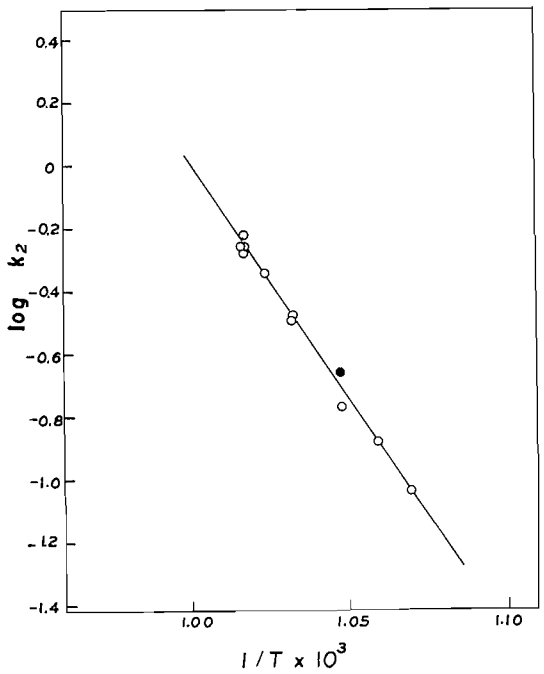

FIG. 3. Plot of log k_2 vs. $1/T$. Experiment done in the packed reaction vessel is indicated by the filled circle.

CO/CH_4 and CO/C_2H_4 may be due to analytical error, as trap-to-trap distillation used in the determination of these compounds may not be perfect, although changes in the mechanism of decomposition under various experimental conditions may also play an important role. The fact that the $CO/(CH_4 + C_2H_4)$ is about 2 in the present investigation suggests that further reaction of ketene produced in reaction [5] is probably responsible for the formation of carbon monoxide, methane, and ethylene. Moreover, the further reaction of ketene might also explain the formation of C_2 and higher hydrocarbons (6, 7, 10).

Carbon dioxide was also detected among the products in the pyrolysis of ketene using a static system by Young (6), Akeroyd (9), and Guenther and Walters (7), but not by Williamson (8), at temperatures lower than 590°. In a flow system at 1120°, carbon dioxide was absent (10). Guenther and Walters (7) studied the temperature dependency of the ketene decomposition products volatile at −78° and found that the mole % of carbon dioxide decreased with increasing temperature from 52.5 at 498° to 20 at 563°, whereas the mole % of carbon monoxide increased from 19.1 at 498° to 48 at 563°. The lowest temperature used in the present study was about 50° higher than the highest temperature used in the decomposition of ketene where carbon dioxide was detected (6, 7, 9). On the basis of the results of the pyrolysis of ketene (7, 8, 10), it appears that the amount of carbon dioxide which might have been produced from ketene decomposition in the present system was probably negligible. This conclusion is supported by the linearity of the Arrhenius plots.

The following reaction would account for the formation of hydrogen and styrene

[7] $$C_6H_5CH_2CH_3 \rightarrow C_6H_5CH{=}CH_2 + H_2$$

Reaction [7] occurred also in the pyrolysis of ethylbenzene using the toluene-carrier technique (11). Further reactions of ketene is also a possible source for hydrogen (6, 7, 9, 10).

The presence of trace quantities of benzene in some experiments may be explained by (*a*) benzene might exist as an impurity in the original toluene that had not been removed completely by the distillation treatment, (*b*) benzene may be formed by the molecular decomposition of ethylbenzene (5), and (*c*) benzene may be formed by the pyrolysis of toluene to a small extent. Under the experimental conditions used in the present investigation, reason (*a*) perhaps is the most probable one.

The source of trace quantities of acetone is not clear. Since acetone was used to clean the removable traps in the system, one would be tempted to suspect it might have originated from the system.

In view of the complex nature of the decomposition of hydrocinnamic acid and the incomplete analysis of the products, it is advisable to postpone further consideration of the mechanism until additional data are available.

Acknowledgments

The distribution coefficients of 2-thenoyl trifluoroacetone (TTA) between the organic and aqueous phase containing mixtures of ClO_4^-, NO_3^-, Cl^-, SCN^-, and SO_4^{2-} ions indicate that the activity coefficients of TTA in the aqueous phase are given by $\ln \gamma = \Sigma ks_i Cs_i$ where ks_i and Cs_i are the salting-out parameter and molar concentration of the ith component, respectively. The salting-out effect on TTA follows the usual pattern for a non-electrolyte, i.e. $SO_4^{2-} > Cl^- > Br^- > ClO_4^- > SCN^-$ for anions and $Li^+ > Na^+ > H^+$. In the solvent extraction equilibria, the extraction behavior of the neutral species $M(TTA)_n$ may not be similar to that of TTA and thus stability constants determined by this method, wherein there are large changes of anion composition in the aqueous phase to maintain the ionic strength constant, may be in error. The ion exchange equilibria have also been investigated by determining distribution coefficients, D, of metal ions in trace concentrations in mixed electrolyte solutions. The large, poorly hydrated ions are salted into the resin phase in the presence of anions like ClO_4^- having the property of breaking the water structure. In mixed electrolytes containing perchlorate, nitrate, and chloride ion mixtures, the D values are difficult to rationalize on the basis of the activity coefficients of ions alone. The stability constants for the formation of $CaCl^+$, $CaNO_3^+$, $BaCl^+$, and $BaNO_3^+$ determined by the ion exchange method at $\mu = 1$ are not in agreement with those obtained by the spectroscopic method.

Canadian Journal of Chemistry, 47, 3851 (1969)

Introduction

Ion exchange and 2-thenoyl trifluoroacetone (TTA) extraction methods have been widely used for the determination of stability constants of complexes in aqueous systems (1–6). During the course of work on the determination of stability constants of the actinide elements, in particular Am(III), it was observed that the values obtained by the TTA method differed from ones obtained by the ion exchange and solubility methods (7, 8). In these methods one of the assumptions is that the activity coefficients of the distributed species in the two phases do not alter when ionic composition in the aqueous phase is changed for maintaining a constant ionic strength. This is generally achieved by taking mixed electrolytes like SO_4^{2-}, NO_3^-, Cl^-, or ClO_4^- in varying composition assuming one of them, usually ClO_4^-, complexes least. While there have been various suggestions to refine the ion exchange method by determining distribution coefficients in different cross-linked resins (9), there exist no studies wherein the distribution coefficients have been determined in mixed electrolytes. It is expected that the distribution coefficient of the metal ion will remain constant if there is no ion association or complexing in the aqueous phase. Similarly, the variation in activity coefficients of TTA in the aqueous phase is not known in the presence of the mixed electrolytes. In this paper are reported the results of the study of the distribution of TTA and metal ions in the organic and the aqueous phases, and also of the metal ions in the ion exchange resin, in the presence of mixed electrolytes, and maintaining constant ionic strength.

Experimental

All sodium salts and acids used were AnalaR grade except sodium perchlorate which was prepared by neutralizing sodium hydroxide (AnalaR) with standard perchloric acid. Lithium salts used were C.P. grade (E. Merck) except lithium sulfate which was AnalaR grade. TTA obtained from Peninsular Chemical Research Inc. was recrystallized from AnalaR benzene. The resin used was air-dried Amberlite IR-120 (52–100 mesh) in acid form. In the experiments with resins of varying cross-linkage, Dowex-50 was used.

The acids were standardized against sodium hydroxide solution. The accuracy of standardization was checked using standard sodium carbonate solution. The pH of the solution was measured by using a glass electrode and Beckman (Model G) pH-meter. Perchloric acid was used to maintain a constant ionic strength of 1. Sodium or lithium perchlorate was used for maintaining a constant ionic strength of 1 with pH = 3.0. The complexing anions were added by replacing perchloric acid by hydrochloric, nitric, or sulfuric acid when the hydrogen ion concentration was 1 M, whereas at pH = 3.0 sodium or lithium perchlorate was replaced by the corresponding chloride, nitrate, or sulfate to maintain constant ionic strength.

Americium-241 was obtained from The Atomic Energy Research Establishment, Harwell, England and

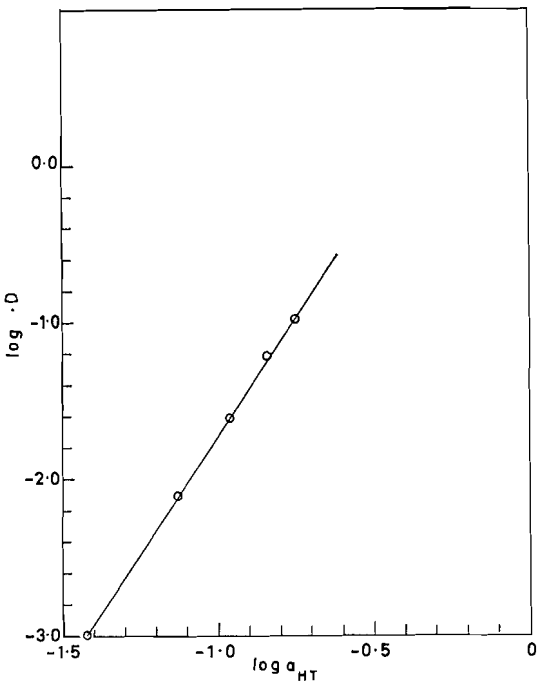

FIG. 1. Distribution coefficients of Am(III) vs. the activity of TTA.

used after purification. ^{24}Na, ^{86}Rb, ^{45}Ca, ^{133}Ba, and ^{181}Hf tracers were produced in the Apsara reactor and ^{137}Cs was separated from the fission product mixture. The radiochemical purity of all these isotopes was checked by γ-ray spectroscopy.

In the TTA extraction experiment with ^{241}Am, 5 ml aqueous solution of ionic strength 1, pH = 3.2, and 1 *M* in chloride ion containing tracer americium(III) was contacted with an equal volume of pre-equilibrated solution of TTA in benzene. The ^{241}Am concentration in both the phases was determined radiometrically using an NaI(Tl) scintillation counter.

Equal volumes of an aqueous phase with constant ionic strength and hydrogen ion concentration, but varying salt composition and 0.2 *M* TTA in benzene, were equilibrated for 1 h, which was found to be the equilibration time. The concentration of TTA in the equilibrated aqueous phase was determined spectrophotometrically by measuring optical density at 292 mμ (ε 292 = 7875). All the experiments were done in duplicate and the results of these duplicates usually agreed within 2% with a maximum difference of ±5%.

Distribution coefficients of Hf^{4+} between 2 *M* $HClO_4$ and 2 *M* HCl and TTA in different solvents, namely toluene, hexane, and carbon tetrachloride, were determined. Each experiment was done 4–6 times and the values given are the average ones.

The experimental details used in ion exchange are described in our earlier paper (7). In the case of ^{24}Na, ^{137}Cs, and ^{86}Rb, the distribution coefficient being quite small, it could be reproduced within only ±10% although in some cases 8 duplicates were done to get reliable values.

Results

The variation of distribution coefficients of Am(III) with the activity of TTA is shown in Fig. 1. The activity coefficients of TTA in benzene were taken from King and Reas (10).

The variation of concentration of TTA in the aqueous phase having constant hydrogen ion concentration and constant ionic strength but varying salt composition is shown in Figs. 2, 3, and 4. The change in solubility of TTA in aqueous phase at pH = 3 and ionic strength of 1 in Cl^-–ClO_4^- mixtures, determined by equilibrating the aqueous solution with solid TTA for 65 h, is shown in Fig. 5. The distribution coefficients, *D*, of Hf^{4+} in 2 *M* $HClO_4$ and 2 *M* HCl solution with TTA in various solvent are given in Table I.

The distribution coefficients, *D*, are presented in Tables II and III for Na^+, Rb^+, Cs^+, Ca^{2+}, and Ba^{2+} in tracer concentrations in ion exchange resin and aqueous solutions having varying Cl^-–ClO_4^-, NO_3^-–ClO_4^- mixtures of constant ionic strength of 1. Table IV gives the values of *D* for Am(III) in Cl^-–ClO_4^- solutions and different cross-linked resins.

Discussion

Solvent Extraction

The extraction of the metal ion, Am^{3+}, from the aqueous phase into the organic phase in the presence of TTA can be depicted by the following equilibria, if it is assumed that AmT_3 is the only species extracted into the organic phase

$$Am^{3+} + nHT \rightleftharpoons AmT_n^{(3-n)+} + nH^+$$

$$AmT_3(aq) \rightleftharpoons AmT_3(org)$$

$$HT(aq) \rightleftharpoons HT(org)$$

and the equilibrium and extraction constants are defined as follows

$$[1] \quad \beta_n = \frac{[AmT_n^{(3-n)+}][H^+]^n \gamma_{AmT_n^{(3-n)+}}}{[Am^{3+}][HT]^n \gamma_{Am^{3+}} \gamma_{HT}^n}$$

$$[2] \quad K' = \frac{[HT(org)]\gamma_{HT(org)}}{[HT(aq)]\gamma_{HT(org)}}$$

$$[3] \quad K'' = \frac{[AmT_3(org)]\gamma_{AmT_3(org)}}{[AmT_3(aq)]\gamma_{AmT_3(aq)}}$$

where γ is the activity coefficient of the species as denoted by the subscript. The terms for organic phase only are further denoted by another subscript (org) hereafter. γ_{H^+} terms have not been included.

TABLE I

Distribution coefficients, D, of Hf^{4+} in TTA in solvents

Solvent	TTA Concentration (M)	D_0 in 2 M $HClO_4$	D_a in 2 M HCl	D_0/D_a
Carbon tetrachloride	0.0278	1.160±0.02	0.265±0.01	4.38±0.1
Hexane	0.0280	1.066±0.02	0.329±0.015	3.24±0.1
Toluene	0.0287	1.323±0.08	0.244±0.010	5.42±0.1

TABLE II

Distribution coefficients, D, of alkali metal ions in ion exchange resin

Anion concentration (M)	Na^+		Rb^+		Cs^+	
	Cl^-	NO_3^-	Cl^-	NO_3^-	Cl^-	NO_3^-
0 0	3.71±0.7	3.71±0.7	4.24±0.2	4.24±0.2	8.51±0.5	8.51±0.5
0.25	4.25±0.5	4.25±0.2	5.61±0.2	6.05±0.2	8.00±0.5	
0.50	3.71±0.3	4.25±0.2	8.35±0.2	5.55±0.2	10.95±0.7	9.3 ±0.9
0.75	4.45±0.5	3.84±0.4	9.71±0.7	6.42±0.2	13.24±0.3	
1.00	5.12±0.3	3.78±0.2	12.54±0.8	11.29±0.5	16.42±0.4	10.4 ±0.9

The distribution coefficient is defined as

$$[4] \qquad D_0 = \frac{[AmT_3(org)]}{\sum_{n=0}^{n} [AmT_n^{(3-n)+}]}$$

The expression for D_0 can be rewritten by substituting terms for $[AmT_n^{(3-n)+}]$ and $[AmT_3(org)]$ from eqs. [2] and [3]

$$[5] \qquad D_0 = \frac{K''\beta_3}{\gamma_{AmT_3(org)} \sum_{n=0}^{3} \beta_n \dfrac{[H^+]^{3-n}}{[HT]^{3-n}\gamma_{AmT_n^{(3-n)+}}\gamma_{HT}^{3-n}}}$$

Similarly, in the presence of complexing anion, X^{-1}, the following equilibria are considered

$$Am^{3+} + jX^{-1} \rightleftharpoons AmX_j^{(3-j)+}$$

$$AmT_n^{(3-n)+} + jX^{-1} \rightleftharpoons AmT_nX_j^{(3-n-j)+}$$

and the equilibrium constants

$$[6] \qquad \beta_j = \frac{[AmX^{(3-j)+}]\gamma_{AmX^{(3-j)+}}}{[Am^{3+}][X^-]^j\gamma_{Am^{3+}}\gamma_X^j}$$

$$[7] \qquad \beta_{nj} = \frac{[AmT_nX_j^{(3-n-j)+}]\gamma_{AmT_nX_j^{(3-n-j)+}}}{[AmT_n^{(3-n)+}][X^-]^j\gamma_{AmT_n^{(3-n)+}}\gamma_X^j}$$

where $\beta_{0j} = \beta_j$, $\beta_n = \beta_{n0}$, and $\beta_0 = \beta_{00} = 1$.

The distribution coefficient, D_a, in the presence of complexing anion is similarly given by the following expression, assuming neutral species like AmT_2X as well, are extracted.

$$[8] \qquad D_a = \frac{K''\beta_3}{\gamma'_{AmT_3(org)} \sum_{n=0}^{3} \sum_{j=0}^{j} \beta_{nj} \dfrac{[H^+]^{3-n} \cdot X^j \cdot \gamma'^j_X}{[HT]^{3-n}\gamma'^{3-n}_{HT} \cdot \gamma'_{AmT_nX_j^{(3-n-j)+}}}} + \frac{K'''\beta_{21}}{\gamma'_{AmT_2X(org)} \sum_n \sum_j \beta_{nj} \dfrac{[H^+]^{2-n}X^{j-1}\gamma'^{j-1}_X}{[HT]^{2-n}\gamma'^{2-n}_{HT}\gamma'^{(3-n-j)+}_{AmT_nX_j}}}$$

Activity Coefficients of TTA (γ_{HT})

The activity coefficients of TTA in the aqueous phase were examined by the solubility and distribution methods (11), so as to enable evaluation of D_0 and D_a. In two experiments, one involving 1 M ClO_4^- and the other involving ClO_4^- and another anion (Cl^-, NO_3^-, SO_4^{2-}, Br^-, or SCN^-) having total ionic strength of 1 in the aqueous phase, the concentration of TTA in the reference phase (benzene) was kept constant, and the following equation applies

$$\gamma_0 C_0 = b\gamma_R C_R = \gamma_i C_i$$

where

γ_0 = the activity coefficient of TTA in ClO_4^- medium in the aqueous phase

γ_i = the activity coefficient of TTA in the mixed solution in the aqueous phase

γ_R = the activity coefficient of TTA in the organic phase

C_0, C_i, and C_R = concentration of TTA in the respective phases

b = constant

$$\frac{C_0}{C_i} = \frac{\gamma_i}{\gamma_0}$$

Similarly, for the solubility of TTA in the aqueous phase in contact with solid TTA, the following relationship holds

$$S_0\gamma_0 = S_i\gamma_i$$

where S_0 = solubility of TTA in 1 M ClO_4^- and S_i = solubility of TTA in the mixed solution.

The results as shown in Figs. 2–5, indicate that

$$\frac{C_0}{C_i} = \frac{S_0}{S_i}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

for the same pair of systems. It can also be deduced that

$$\ln \gamma_i = k_s . C_s$$

where k_s is a salting-out parameter and there is no contribution due to self-interaction of the non-electrolyte in the solution. The salting-out effect follows the order

$$SO_4^{2-} > Cl^- > Br^- > ClO_4^- > SCN^-$$

and

$$Li^+ > Na^+ > H^+$$

which is the usual one observed for non-electrolytes (11). The activity of TTA in the aqueous phase can thus be directly related to its activity in the organic phase. The activity coefficients of TTA in benzene have been determined by King and Reas (10) and can be used for further evaluation of eqs. [5] and [8].

The expressions for D_0 and D_a have terms in polynomials of $[H^+]$ and [HT]. The determinations of D_0 and D_a at various [HT(org)] in the presence of mixtures of electrolytes, viz. ClO_4^-, ClO_4^-, and Cl^- showed that both D_0 and D_a varied with $[HT(org)]^3\ \gamma_{HT(org)}{}^3$ when the $[H^+]$ concentration was maintained constant, as shown in a typical plot of log D vs. log $a_{HT(org)}$ (Fig. 1). Similarly, the results of Khopkar and Sharma showed that D_0 and D_a varied with $[H^+]^3$ when [HT] was maintained constant (7*b*). It is thus verified that the terms in eqs. [5] and [8] involving $[H^+]^{3-n-j}$ and $[HT]^{3-n-j}$ for $n \geqslant 1$ do not contribute significantly in the expression for D_0 and D_a. In other words, the concentrations of species like $AmT_n^{(3-n)}$ for $n \geqslant 1$ are small as compared to $AmX_j^{(3-j)+}$ under the experimental conditions. Furthermore, the earlier assumption that AmT_3 is the only species extracted into the organic phase holds good and no mixed species like AmT_nX_{3-n} are extracted. The expression for the ratio D_0/D_a reduces as follows when they are determined at the same $[H^+]$ and [HT]

$$[9] \qquad \frac{D_0}{D_a} = \frac{\gamma'_{AmT_3(org)}}{\gamma_{AmT_3(org)}} \times \sum_{j=0}^{j} \frac{\gamma_{Am^{3+}}}{\gamma'_{AmX_j^{(3-j)+}}} \beta_j X^j \gamma'_X{}^j$$

The determination of ratio D_0/D_a enables evaluation of β_j by the solvent extraction method provided the activity coefficients of the species are assumed to be constant. The metal ion is present in tracer concentration in solution and thus the assumption that $\gamma_{AmT_nX_j^{(3-n-j)+}}$ are constant is often justified. However, $\gamma_{sAmX_j^{(3-j)+}}$ and γ'_X may not be constant when large changes are effected in aqueous phase. The values of β_j are thus reported for specified experimental conditions in the aqueous phase, since it is difficult to determine the activity coefficient of the ionic species in mixed electrolytes. The extraction behavior of neutral species like AmT_3 is also assumed to be ideal according to eq. [3]. In order to verify this, the Hf–TTA system, earlier studied by us (12), was chosen for ease of handling radioactivity. The values for the ratio D_0/D_a were determined in 2 *M* $HClO_4$ and 2 *M* HCl solutions using different inert solvents. In such solvents, the values of D_0 and D_a are likely to vary (13), but according to eq. [9] the ratio D_0/D_a should not alter since the aqueous phase activity coefficients of the ionic species are not affected by the solvents in the organic phase. The activity coefficients of the neutral species present in very low concentration in the organic phase should remain constant. The value of D_0/D_a for the solvents differ significantly (Table I). The reason for the variation is not clearly understood. It can be attributed to the change in the extraction behavior of the neutral species. Nevertheless, the stability constants determined by this method, wherein large changes are effected in the anionic composition in the aqueous phase, may not be correct.

Ion Exchange Equilibria

In ion exchange equilibria, the metal ion is distributed between the aqueous and resin phases and the following equilibrium applies

$$M^{n+} + n\overline{RH} \rightleftharpoons \overline{MR}_n + nH^+$$

and

$$[10] \qquad K_d = \frac{[\overline{MR}_n][H^+]^n \gamma_{\overline{MR}_n}}{[M^{n+}][\overline{RH}]^n \gamma_{M^{n+}} \gamma_{\overline{RH}}{}^n}$$

where $[\overline{MR}_n]$ and $[\overline{RH}]$ are concentrations of metal- and hydrogen-form of resin. (If $[\overline{MR}_n]$ is very small, i.e. metal ion is present in tracer concentration, the ion exchanger is mainly present as $\overline{RH}$.) Here γ again represents the activity coefficient of the species designated by the subscript.

$$D_0 = \frac{[\overline{MR}_n]}{[M^{n+}]}$$

or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$[11] \qquad D_0 = \frac{K_d[\overline{RH}]^n \gamma_{M^{n+}} \gamma_{\overline{RH}}^n}{[H^+]^n \gamma_{\overline{MR}_n}}$$

Similarly, in the presence of complexing anions

$$[12] \qquad D_a = \frac{[\overline{MR}_n] + [\overline{MXR}_{n-1}]}{\sum_{j=0}^{j} [MX_j^{n-j}]}$$

Following eq. [6] and

$$MX_j^{(n-j)+} + (n-j)\overline{RH} \rightleftharpoons MXR_{n-j} + (n-j)H^+$$

we have

$$[13] \quad K_{d_j} = \frac{[\overline{MXR}_{n-j}][H^+]^{n-j} \gamma'_{MXR_{n-j}}}{[M^{(n-j)+}][\overline{RH}]^{n-j} \gamma'_{M^{(n-j)+}} \gamma'^{n-j}_{\overline{RH}}}$$

and

$$[14] \quad D_a = \frac{K_d[\overline{RH}]^n \gamma'_{M^{n+}} \gamma'^{n}_{\overline{RH}}}{[H^+]^n \gamma'_{\overline{MR}_n} \sum_{j=0}^{j} \beta_j \frac{X_j^j \gamma_x^j}{\gamma'^{3-j}_{MX}}} + \frac{K_{d_1}[\overline{RH}]^{n-1} \gamma'_{MX^{(n-j)+}}}{[H^+]^{n-1} \gamma'_{\overline{MXR}_n} \sum_{j=0}^{j} \beta_j \cdots}$$

γ' is the activity coefficient in the mixed electrolyte solution.

By examining the variation of D values with respect to $[H^+]$ it can be verified that the second term does not contribute significantly (7). K_{d_1} is much smaller in magnitude as compared to K_d for most of the systems. If constant hydrogen ion concentration is maintained and the D values are determined for constant amount of resin, the expression for D_0/D_a becomes

$$[15] \quad \frac{D_0}{D_a} = \frac{\gamma_{\overline{RH}}^n \gamma'_{\overline{MR}_n}}{\gamma'^{n}_{\overline{RH}} \gamma_{\overline{MR}_n}} \sum_{j=0}^{j} \beta_j \frac{\gamma_{M^{n+}}}{\gamma'_{MX_j^{(n-j)+}}} X^j \gamma_x^j$$

The expression is similar to the one derived for solvent extraction equilibria except for the activity coefficients in the resin phase of the two species in the presence of mixed electrolyte systems. In the absence of any data, they are usually assumed to be constant. This assumption is examined by choosing cations which are not complexed appreciably in the presence of anions like Cl^- and NO_3^-. The alkali metal ions do not form contact ion pairs in ClO_4^- or NO_3^- media in 1 M solutions as indicated by Raman spectra (14–16). At constant ionic strength and $[H^+]$, and the metal ion in tracer concentration, the distribution coefficients should vary according to eq. [15], as the activity coefficients of metal ion in mixed electrolytes change assuming $\beta_1 = 0$. It can be seen from Table II that there are significant but small variations in the D values for Na^+ but very large variations are found for Cs^+ and Rb^+ ions. These large variations can partly be attributed to the changes in the activity coefficients of metal ions in the aqueous phase since they are present in tracer concentration in solution. If they do change to such an extent, the values of β_j obtained by these methods will have large uncertainties. The activity coefficients in the resin phase are perhaps affected by the presence of differing composition of electrolytes in the aqueous phase contrary to the earlier concepts (17–20). Diamond (21) and Diamond and Whitney (22) have discussed the behavior of these ions on the basis of water structure forming or breaking properties of hydrated ions. The structure forming ions are preferentially taken into the resin phase. Na^+ and H_3O^+ ions are considered structure forming ones, whereas ClO_4^- is considered as structure breaking type, and Cl^- and NO_3^- fall in between the two. The large, poorly hydrated ions in the presence of ClO_4^- ions are forced into the resin phase and thus the D values for these ions in 1 M ClO_4^- are large. However, in the mixtures, the behavior cannot be rationalized and at present it can be explained only qualitatively on the above basis. The structure forming ions may not show such behavior.

The D values for Ca^{2+} and Ba^{2+} ions depict a typical behavior indicating considerable ion association or complexing with Cl^- and NO_3^- ions. The stability constants, β_1, for the formation of $CaCl^+$ and of $CaNO_3^+$ are calculated to be 0.6 (Table III) whereas values of β_1 for $BaCl^+$ and $BaNO_3^+$ are 0.2 and 1.4, respectively. The Raman spectra in the Ca^{2+}–NO_3^- system indicate that for the formation of contact ion pairs in the nitrate system, β_1 is 0.16 and 0.12 in high ionic strength. Hester and Plane (14, 15) and Irish and Walrafen (16) do not find evidence for the formation of the complex in 1 M solution, which is not in agreement with the results obtained by the ion exchange method. It appears that this method for the determination of stability constants of weak complexes may not give accurate results when large changes are effected in the aqueous phase.

The stability constants determined for Am(III)

with chloride ions were reinvestigated by using different cross-linked resins. There does not seem to be much change in the value of ~ 1, but in all the resins with 8 determinations for each D value, there are very small deviations from the expected values, which makes us doubt the accuracy of this method. The activity coefficients of species in the resin phase perhaps do not remain constant when large changes in the salt composition are effected in the aqueous phase. The different values of β_j obtained by the two methods can perhaps be attributed to either the extraction behavior of the neutral species or changes in the distribution coefficients D_0 in ion exchange when there are large changes in the aqueous phase composition.

In summary, the experimental methods for the determination of stability constants of weak complexes require large changes in electrolyte composition in aqueous phase. The activity coefficients of the species under such changes may not be constant. The evaluation of stability constants from the experimental data may have large errors if the activity coefficients of the species are assumed to be constant. In the distribution methods, the activity coefficients in the non-aqueous phase may also alter when the salt composition is varied in aqueous phase and thus give rise to additional errors in the values of the stability constants. The disagreement between the values of stability constants obtained by the solvent extraction and ion exchange methods can be attributed to the changes in the activity coefficients of the distributed species in the non-aqueous phases when salt composition in the aqueous phase is altered.

Crystal and molecular structure of $CuSiF_6 \cdot 4H_2O$

M. J. R. CLARK, J. E. FLEMING[1], AND H. LYNTON
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received June 12, 1969

The structure of $CuSiF_6 \cdot 4H_2O$ has been shown to consist of chains of $[Cu(H_2O)_4F_2]$ and $[SiF_6]$ octahedra linked through a common fluorine atom. The space group is monoclinic $P2_1/a$, with cell dimensions $a = 7.22 \pm 0.01$ Å, $b = 9.64 \pm 0.01$ Å, $c = 5.36 \pm 0.01$ Å and $\beta = 105.2 \pm 0.3°$. There are 2 molecules in the unit cell and the copper and silicon atoms occupy centers of symmetry. Atomic parameters have been obtained from a block diagonal least squares refinement using anisotropic temperature parameters. The final agreement residual for 574 observed reflections is $R = 0.083$.

Introduction

In a previous paper (1) the authors were able to show that a compound identified in the literature as $CuBF_3O \cdot 5H_2O$ was in fact $CuSiF_6 \cdot 4H_2O$. Details of the preparation and analysis of this compound have been given.

Two general classes of simple fluosilicates are known, the anhydrous compounds such as Na_2SiF_6 and $BaSiF_6$, and the hexahydrates such as $MgSiF_6 \cdot 6H_2O$ and $FeSiF_6 \cdot 6H_2O$. Both the anhydrous and hydrated salts are thought to have discrete $[SiF_6]^{2-}$ octahedra. The metal ions in the hexahydrates are believed to be coordinated octahedrally to the 6 water molecules. $CuSiF_6 \cdot 4H_2O$ would appear to be a hydrated compound intermediate in character.

Crystallographic and Intensity Data

The crystal data are given in Table I. The compound is monoclinic and the systematic absences establish the space group as $P2_1/a$. Unit cell dimensions were measured with a single crystal equi-inclination diffractometer. The density measurements indicate 2 molecules of $CuSiF_6 \cdot 4H_2O$ in the unit cell.

All intensity data were collected from a small needle-shaped crystal mounted on the [101] axis inside a lithium borate capillary tube. Using the multiple film pack technique, equi-inclination Weissenberg photographs were obtained of all layers accessible with Cu Kα radiation. The total number of independent reflections is calculated to be 727, of which 43 are systematically absent. The structure analysis utilized 574 intensities which were above the minimum intensity limit for observation.

TABLE I
Crystal data for $CuSiF_6 \cdot 4H_2O$

System	Monoclinic
Space group	$P2_1/a$
Systematic absences	$h0l: h = 2n + 1$ $0k0: k = 2n + 1$
Molecular weight	277.7
Unit cell dimensions	
a	7.22 ± 0.01 Å
b	9.64 ± 0.01 Å
c	5.36 ± 0.01 Å
β	$105.2 \pm 0.3°$
Volume	360 Å^3
Measured density (by flotation)	2.56 g cm^{-3}
Calculated density (assuming 2 molecules in the unit cell)	2.56 g cm^{-3}

The intensities of all reflections were estimated by visual comparison with a calibrated strip prepared using a suitable reflection from the intensity crystal. Lorentz polarization factors were applied to all intensity data. No corrections were made for absorption.

Structure Analysis

A three dimensional Patterson synthesis established the sites for the copper atoms as special positions $2a$—000 and $\frac{1}{2}\frac{1}{2}0$, and the silicon atoms as special positions $2d$—$\frac{1}{2}0\frac{1}{2}$ and $0\frac{1}{2}\frac{1}{2}$. A three dimensional Fourier synthesis then gave the coordinates of all the fluorine and oxygen atoms.

The refinement was by successive cycles of block diagonal least squares[2], employing only the observed reflections. The quantity minimized was

O(2)	882	461	1998	223	600	−5

*All values have been multiplied by 10^5.
$T = \exp -[h^2\beta_{11} + k^2\beta_{22} + l^2\beta_{33} + kl\beta_{23} + hl\beta_{13} + hk\beta_{12}]$

$\sum\omega(F_o - F_c)^2$. The matrices used were 3 × 3 for the positional parameters and 6 × 6 for the anisotropic thermal parameters of each atom. The weighing scheme $\omega = 1/(a + |F_o| + c|F_o|^2)$ was employed with the following values: $a = 4.00$ and $c = 0.020$. Scattering factor curves used were those given in International tables (3).

No corrections were made for extinction, and in the last cycle, no parameter shift exceeded 0.3 estimated standard deviation (e.s.d.). The final agreement residual, $R = \sum|F_o - F_c|/\sum|F_o|$, for observed reflections was $R = 0.083$.

Results and Discussion

There are 2 molecules of $CuSiF_6 \cdot 4H_2O$ in the unit cell, the copper and silicon atoms being situated on centers of symmetry. The silicon atoms are surrounded octahedrally by 6 fluorine atoms and the copper atoms surrounded octahedrally by 4 water molecules and 2 fluorine atoms. The 2 octahedra form chains along the [101] direction linked by the common fluorine atom F(3), Fig. 1. The angle Cu—F(3)—Si is 152.15 (0.29)°.

The final atomic coordinates are given together with their e.s.d. in Table II. The temperature parameters are given in Table III. Tables IV and V give the intramolecular distances and angles, together with their e.s.d. A final set of structure factors has been placed in the Depository of Unpublished Data[3].

The closest approach distances between non-bonded atoms are O(1)—O(2), 2.762(9) Å, and F(1)—F(3), 2.366(7) Å between atoms in the same chain, and O(1)—F(2), 2.682(8) Å between atoms in adjacent chains. Each water molecule has as nearest non-bonding neighbors 2 other water molecules at 2.762(9) and 2.808(8) Å, and 2 fluorine atoms at 2.682(8) and 2.763(7) Å for O(1), and 2.750(7) and 2.760(8) Å for O(2). These distances are within the range expected for hydrogen bonding. The hydrogen atoms were not located in the structure analysis. Each water molecule has in addition 3 other fluorine atoms

Kinetics of the pyrolysis of *n*-butane

JOHN TOROK[1] AND SAMUEL SANDLER
Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario

Received June 19, 1969

The thermal decomposition of *n*-butane was investigated at temperatures ranging from 330 to 420 °C. This extension of the temperature range for such studies was made possible by the use of a highly sensitive analytical system, consisting of a gas–liquid chromatograph equipped with a hydrogen-flame-ionization detector which permitted the determination of the major products of the reaction at reactant conversions as low as 0.0002%. At temperatures below 400 °C the reaction order was both temperature and pressure dependent, a lower order, approaching 0.5, being favored at lower temperatures and higher pressures. The contribution to the reaction mechanism of a chain-termination step consisting of the combination of 2 secondary butyl radicals explains the observed phenomena.

Canadian Journal of Chemistry, 47, 3863 (1969)

Introduction

Recent investigators of the thermal decomposition of *n*-butane (1, 2) have been concerned with the reaction in the temperature range of 420–590 °C. On the other hand, studies of the sensitized decomposition have generally been conducted at temperatures below 340 °C. Thus, though this reaction has been studied extensively, no thorough investigation at the intermediate temperatures had been made prior to the present one.

Although the pyrolysis of *n*-butane is one of the better understood free-radical chain reactions, it is still necessary to point out, as in a recent publication by the present authors (3), that the main chain-ending step of this reaction at temperatures above 420 °C is still obscure. The present work is mainly concerned with the elucidation of the chain-termination mechanism at temperatures below 420 °C.

Purnell and Quinn (1) have made the most significant contribution of the last 2 decades to the clarification of the mechanism of this reaction. They identified most of the products, including the minor ones, thoroughly investigated the temperature and pressure dependence of the distribution of the major products, and determined that the decomposition of the ethyl radical was in its pressure-dependent region.

Due to the large apparent activation energy for this reaction (about 63 kcal/mole) the reaction rate rapidly decreases with a decrease in reaction temperature. Thus, this extension of the temperature range over which the pyrolysis of *n*-butane could be studied required, and was made possible only as a result of, the development of a highly sensitive analytical system. Gas–liquid chromatography in conjunction with hydrogen-flame-ionization detection was used to determine the major products of the reaction at conversions as low as 0.0002%.

[1]Present address: Norton Research Corporation, Chippawa, Ontario.

Experimental

A conventional static reaction system was used. The reactor and auxiliary glass vessels were connected to a vacuum system capable of maintaining pressures near 10^{-5} Torr.

Phillips Petroleum Co. Research Grade *n*-butane was treated to remove traces of isobutane, propane, and butene impurities. It was first adsorbed at ambient temperature on Linde molecular sieve, Type 5A, and the unadsorbed vapors containing isobutane were pumped off and discarded. The adsorbed *n*-butane and propane were then desorbed at 170 °C, a temperature at which olefins would still be retained, and passed through a bed of Type 4A molecular sieve at ambient temperature to remove propane. The reactant now contained no hydrocarbon impurities detectable by sensitive gas–liquid chromatography.

Traces of oxygen and other fixed gases were carefully removed by prolonged degassing of the condensed reactant at −107 °C. This was followed by repeatedly bubbling the gas through a 100 mm column of aluminum amalgam (4) to further lower the oxygen content to a negligible value.

The reaction bulb was housed and heated in an electronically controlled 3 section oven capable of maintaining a constant temperature along the length of the reactor, within ±0.3 °C. Two 80 ml quartz reaction vessels were used. The bodies of the reactors were cylindrical, 2.5 cm in diameter and 21 cm in length. Each contained a coaxial thermowell terminating at the center of the reactor. One of the reactors was unpacked and had a surface-to-volume ratio (s/v) of 2.1 cm^{-1}. The other

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was packed with enough quartz tubing to yield a value of s/v of 7.7 cm^{-1}. The effect of using reaction times between 15 s and 2 h, and pressures in the range 16 to 600 mm Hg, could be usefully investigated with this apparatus.

At any desired stage of the reaction, the reactor contents were expanded into a previously evacuated bulb. Subsequently, the bulb contents were compressed over mercury and a portion transferred into the 2 ml sample loop of a Varian–Aerograph Model 600-D gas chromatograph equipped with a high sensitivity hydrogen-flame-ionization detector.

The gas–liquid chromatographic analysis was limited to the 4 major hydrocarbon products of the reaction, since it was not possible to obtain quantitatively significant quantities of the minor products at the low conversion conditions of this study. Furthermore, since a hydrogen-flame-ionization detector was needed at its ultimate sensitivity to detect the major products, product hydrogen could not be detected. Three identical column trains were prepared. Each train contained a 25 ft long, 0.25 in. o.d. copper tube column packed with 60–80 mesh Chromosorb P acid-washed fire brick coated with 29% by weight of dimethylsulfolane (DMS). To this was attached a 6 in. column packed with 60–80 mesh Chromosorb W fire brick coated with 15% by weight of Carbowax 20M. The purpose of the latter was to hold back any DMS tending to bleed from the first column.

The 3 column trains were connected to a common carrier-gas source and any one of them could be connected to the inlet of the hydrogen-flame-ionization detector. Following the elution of methane, ethane, ethylene, and propylene, respectively, from one column, another was connected to the detector for the next analysis. This procedure reduced analysis time and eliminated the necessity for burning excessive amounts of the unreacted butane in the detector. Due to the large sample size required to obtain measurable quantities of reaction products, the column had to be overloaded insofar as *n*-butane was concerned. However, this did not affect the reaction product peaks eluted ahead of *n*-butane, and the latter could be purged from the column to air while one of the other columns was being used for the analysis of another sample.

The analysis for *n*-butane itself was neither feasible nor required, so long as the sample size injected was reproducible and the same sample loop was used for calibration. The calibration was performed on samples of known and very low concentrations of the major hydrocarbon reaction products. Since conversions were always extremely low, reaction rates could be calculated directly from a carbon balance based on the product analysis, assuming that all significant carbon containing products had been determined and that the conversion–time relationship was linear in the region investigated.

Results

The poor reproducibility of the results obtained at temperatures below approximately 380 °C was a major problem in this investigation. Various cleaning and coating procedures (5) served only to enhance this problem. Clean reactors, freshly fabricated by the glass blower but otherwise untreated, gave the most reproducible results and were used for all final runs.

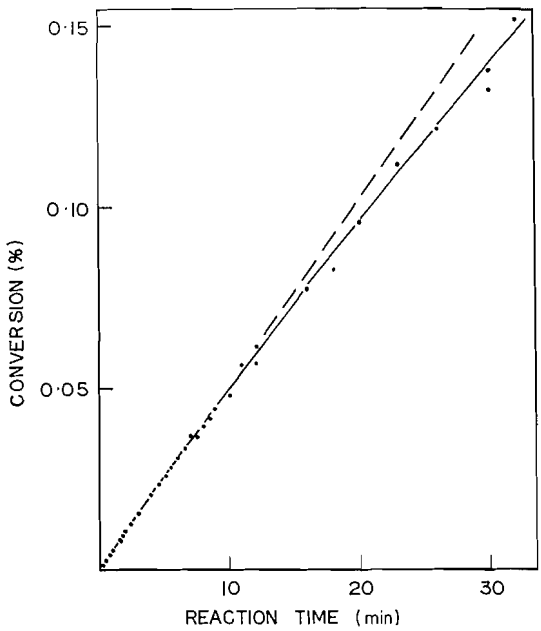

FIG. 1. Reactant conversion as a function of reaction time at 393 °C and 200 mm Hg.

Figure 1 demonstrates the effect of residence time on conversion at 393 °C and 200 mm Hg pressure. The following points may be noted from this figure. (*i*) The reaction has no observable induction period. This coincides with the observation of Purnell and Quinn (1), but is not consistent with the findings of Sagert and Laidler (2), who observed a short induction period. (*ii*) After an initial period of several minutes, corresponding to a conversion of less than 0.05%, the reaction rate decreases slightly with reaction time. The broken line is the extension of the initial linear portion of the curve.

At conversions rising to 0.15% product selectivities (defined as moles of product/100 moles of butane decomposed) were found to be independent of conversion.

Figure 2 demonstrates as well the independence of the product selectivities of the reaction pressure at a temperature of 370 °C. It is also apparent that the selectivities for methane and propylene on the one hand, and ethane and ethylene on the other, are equivalent.

Several runs were conducted at temperatures

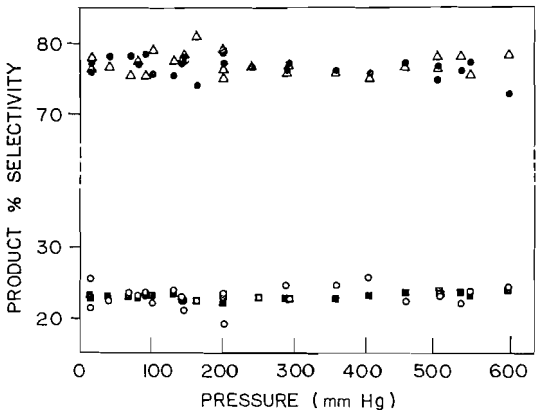

FIG. 2. Product selectivity as a function of reaction pressure at 370 °C. Reaction time range 8–25 min. △, methane; ■, ethane; ○, ethylene; ●, propylene.

above 420 °C to establish some connection with the work of previous investigators. Product selectivities in this temperature range were quite comparable to those obtained by Purnell and Quinn (1). An Arrhenius-type plot of the product selectivities is given in Fig. 3. The slope and position of the line drawn were calculated by the method of least squares and correspond to the equation

$$[\mathrm{I}] \quad \frac{[C_2H_4] + [C_2H_6]}{[CH_4] + [C_3H_6]} = 1.8 \exp\left(-2300/RT\right)$$

This is comparable with the result obtained by Purnell and Quinn as expressed in the equation

$$\frac{[C_2H_4] + [C_2H_6]}{2[CH_4]} = 1.3 \exp\left(-2000/RT\right)$$

Overall Reaction Order

The temperature and pressure dependence of the overall order were thoroughly investigated. At temperatures above 410 °C, the order was found to be both temperature and pressure independent and approximately 1.5.

A log–log plot of the relative rate of pyrolysis at 370 °C against reaction pressure is given in Fig. 4. In this plot the rates are measured relative to the reaction rate at the reference pressure of 194 mm Hg. Every second run was conducted at the reference pressure, while intermediate runs were executed at randomly selected pressures ranging from 16 to 620 mm Hg. The relative rate in Fig. 4. is defined as the rate of reaction at the specified pressure divided by the rate of the succeeding reaction conducted at 194 mm Hg. This treatment of the experimental data was necessary since the results of successive runs at temperatures below 380 °C were much more reproducible than those of runs further separated in time. Points in Fig. 4 were fitted with both linear and curvilinear regressions. A statistical analysis of the 2 regressions indicated that the

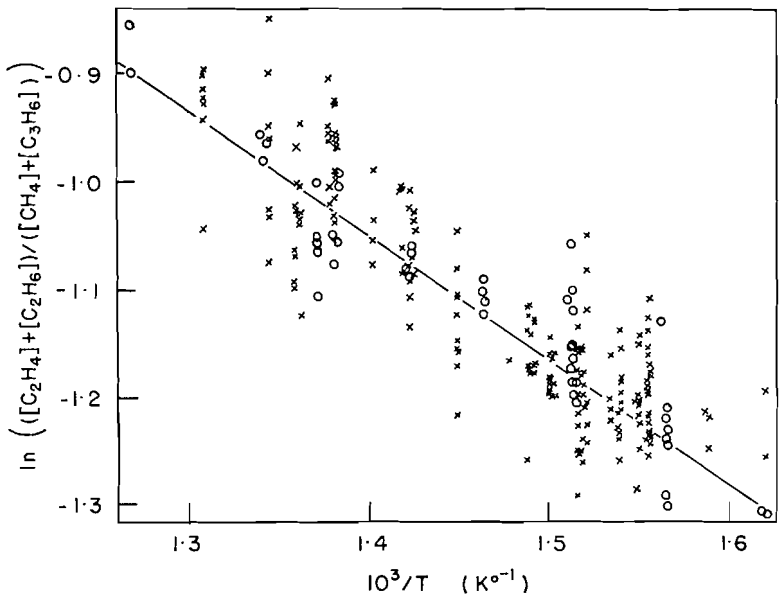

FIG. 3. Arrhenius plot for product selectivities. ○, packed reactor; X, unpacked reactor.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

departure from the linear regression is significant. The slope of a log (rate) vs. log (pressure) curve (at constant temperature) is equivalent to the overall order of reaction. Thus, at 370 °C, the overall reaction order is in its pressure dependent region, a higher order being favored at lower pressures.

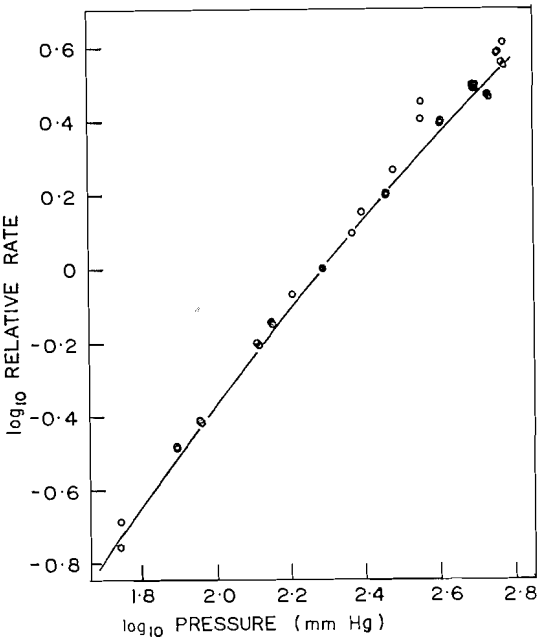

FIG. 4. Logarithm of relative rate as a function of the logarithm of the pressure for the pyrolysis at 370 °C. (Relative rate is defined as the reaction rate at the specified pressure divided by the reaction rate at 194 mm Hg pressure.)

Figure 5 demonstrates the variation of reaction order with temperature. At each temperature, successive runs were conducted at reaction pressures alternating between 94 and 200 mm Hg. From the rates of successive pairs of runs, a reaction order was calculated and plotted against temperature. The differences in the results obtained with packed and unpacked reactors were not significant. The broken line in the figure is a third-degree polynomial least squares fit of all the points. The solid curve is calculated and is described later.

A plot of the natural logarithm of the reaction rate as a function of the reciprocal of the reaction temperature for runs in the unpacked reactor is given in Fig. 6. The upper line is a linear regression for runs at 200 mm Hg, the lower line for runs at 94 mm Hg reaction pressure. The activation energies calculated from the slopes of these regressions are 63.5 and 60.3 kcal/mole, respectively.

Discussion

In a previous publication (3), the authors proposed the following mechanism for this pyrolysis at temperatures above 410 °C.

Initiation

[1] $C_4H_{10} \rightarrow 2C_2H_5\cdot$

Propagation

[2] $p\text{-}C_4H_9\cdot \rightarrow C_2H_4 + C_2H_5\cdot$

[3] $s\text{-}C_4H_9\cdot \rightarrow C_3H_6 + CH_3\cdot$

[4] $C_2H_5\cdot + C_4H_{10} \rightarrow C_2H_6 + s\text{-}$ or $p\text{-}C_4H_9\cdot$

[5] $CH_3\cdot + C_4H_{10} \rightarrow CH_4 + s\text{-}$ or $p\text{-}C_4H_9\cdot$

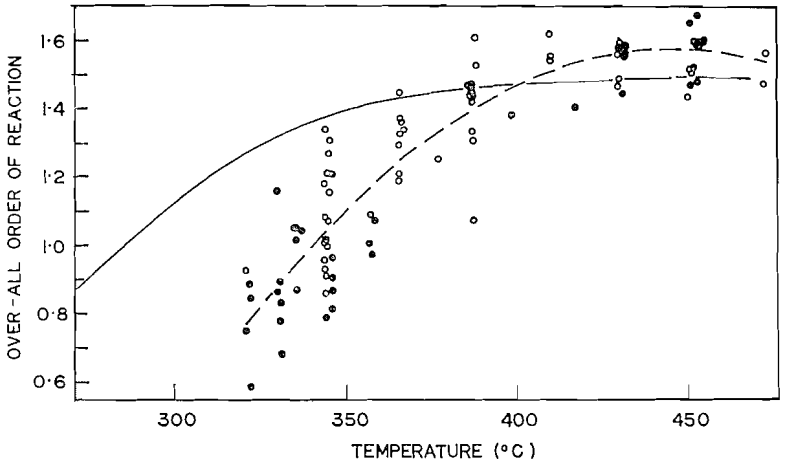

FIG. 5. Variation of overall reaction order with temperature. ———, theoretical curve; - - -, 3rd degree polynomial fit to data; ○, packed reactor; ●, unpacked reactor.

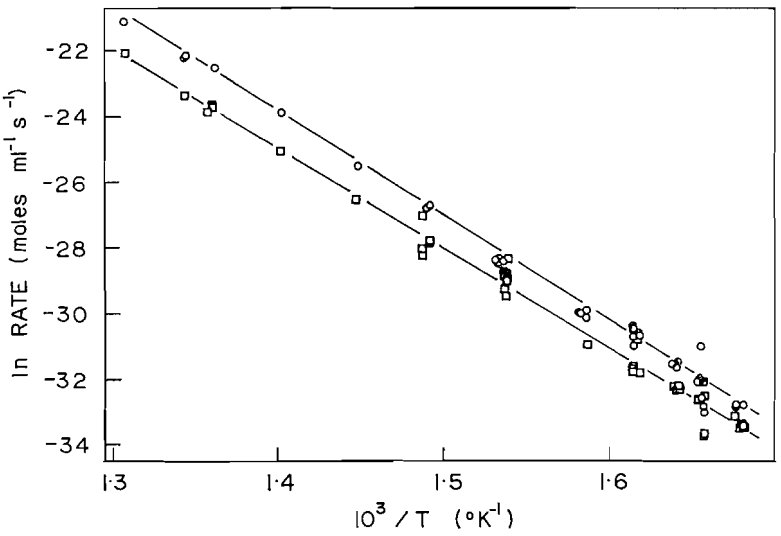

FIG. 6. Natural logarithm of reaction rate as a function of reciprocal temperature for unpacked reactor. Reaction pressure: ○, 200 mm Hg; □, 94 mm Hg.

[6][2] $C_2H_5\cdot + eC_4H_{10} \rightarrow C_2H_4 + H\cdot + eC_4H_{10}$

[7] $H\cdot + C_4H_{10} \rightarrow H_2 + s\text{- or } p\text{-}C_4H_9\cdot$

Termination

For the derivation of an expression for the overall order, all possible combination reactions were considered, including radical combination and cross-combination reactions. Of these the following are the possible radical combination reactions

[8] $2CH_3\cdot \rightarrow C_2H_6$

[9] $2C_2H_5\cdot \rightarrow C_4H_{10}$ (or $C_2H_4 + C_2H_6$)

[10] $2s\text{-}C_4H_9\cdot \rightarrow C_8H_{18}$ (or $C_4H_8 + C_4H_{10}$)

[11] $2p\text{-}C_4H_9\cdot \rightarrow C_8H_{18}$ (or $C_4H_8 + C_4H_{10}$)

[12] $2H\cdot \rightarrow H_2$

Table I lists the kinetic parameter ratios for elementary reactions involved in the above mechanism, with the exception of parameters for reactions [7] and [12].

Since most radical combination reactions have zero or very low activation energies, the values $E_i - \frac{1}{2}E_j$ in Table I are approximately equal to E_i.

In the following discussion it will be assumed that (*i*) the fundamental hypothesis of Bodenstein, that the intermediate products of the reaction are of almost stationary concentration, is valid and (*ii*) the chain lengths involved are large.

Based on the proposed mechanism, a relationship between reaction products and rates may be established

$$([C_2H_4]/[C_2H_6]) - 1 = r_6/r_4$$

where r_i denotes the rate of reaction [*i*]. Above approximately 420 °C, the yield of ethylene is higher than the yield of ethane, thus reaction [6] has an appreciable rate. It is apparent from Fig. 2 that at lower temperatures the yields of ethane and ethylene are practically equivalent, and thus the rate of reaction [6] is negligible relative to the rate of reaction [4]. The temperature dependence of the relative rates of reactions [4] and [6] is mainly due to the difference in their activation energies (approximately 27.6 kcal).

Reactions [3] and [5] and reactions [2] and [4] are consecutive. Either one of these reaction pairs can complete a chain cycle converting a molecule of butane to products. Due to the large chain length, the rates of reactions [3] and [5] are approximately equal. The relative steady-state concentration of methyl and secondary butyl radicals is then dependent on the value of $k_3/k_5[C_4H_{10}]$. Above approximately 400 °C, $k_3 \gg k_5[C_4H_{10}]$ and therefore $[CH_3\cdot] \gg [s\text{-}C_4H_9\cdot]$. Similarly, $k_2 \gg (k_4[C_4H_{10}]$ or $k_6[C_4H_{10}]^e)$ and therefore $[C_2H_5\cdot] \gg [p\text{-}C_4H_9\cdot]$.

The above relative radical concentrations are

[2]The second term is introduced to represent the pressure dependence of this reaction, "*e*" is a stoichiometric coefficient, where $0 < e < 1$.

TABLE I

Kinetic parameters for the ratios of elementary reactions

Reaction i	Reaction j	Frequency factor* $A_i/A_j^{1/2}$	Activation energy $E_i - \frac{1}{2}E_j$ (kcal/mole)	Reference
2	11	7.94×10^{6}	28.7	Morganroth and Calvert (6)
3	10	1.31×10^{8}	32.6	Lin and Laidler (7)
4	9	2.45×10^{4}	10.4	Boddy and Steacie (8)
5	8	1.56×10^{4}	8.3	Trotman-Dickenson, Birchard, and Steacie (9)
6	9	8.5×10^{6}†	38.0†	Lin and Back (10)

*In units of $cc^{1/2}$ $mole^{-1/2}$ $s^{-1/2}$ or $cc^{-1/2}$ $mole^{1/2}$ $s^{-1/2}$.
†First order region, at high pressures, extrapolated value.

pressure dependent. A higher pressure produces a higher butyl radical concentration relative to that of the methyl or ethyl radicals.

Since $E_3 > E_5$, then, as the temperature is lowered the value of $k_3/k_5[C_4H_{10}]$ decreases, resulting in an increased concentration of secondary butyl radicals relative to the concentration of the methyl radicals. A similar argument applies to the relationship between primary butyl and ethyl radicals. Thus, at lower temperatures and higher pressures butyl radicals become the main chain terminators.

The rates of reactions [4] and [5] are pressure dependent since *n*-butane is one of the reactants. The rates of reactions [2] and [3] are pressure independent. A higher pressure, therefore, produces a higher butyl radical concentration relative to that of the methyl or ethyl radicals.

In the previous recent publication already mentioned (3), an equation was developed to predict the reaction order for the pyrolysis of *n*-butane

$$[II] \quad \text{Order} = \frac{\sum_{m=8}^{m=12}\sum_{n=8}^{n=12}(F_m + F_n)(r_m r_n)^{1/2}}{\sum_{m=8}^{m=12}\sum_{n=8}^{n=12}(r_m r_n)^{1/2}}$$

where values of m, n, F_m, and F_n are as given below.

Radical	m or n	$2(F_{m \text{ or } n})$
Methyl	8	1.5
Ethyl	9	$0.5 + u$
s-Butyl	10	0.5
p-Butyl	11	0.5
Hydrogen	12	$1.5 + u - e$

and

$r_{m \text{ or } n}$ = rate of reaction m or n

$$u = \frac{k_4[C_4H_{10}] + ek_6[C_4H_{10}]^e}{k_4[C_4H_{10}] + k_6[C_4H_{10}]^e}$$

$$0 < e < 1 \text{ and } 0 < u < 1$$

It was also shown that equations such as [II] for the overall order may be expressed in terms of the kinetic parameters of the propagation reactions; in this case, they are the parameters listed in Table I, and eq. [I] represents the product distribution[3].

Such an equation involving the kinetic parameters of the propagation reactions has been used for the prediction of the pressure and temperature dependence of the overall order of the pyrolysis of *n*-butane.

Equation [II] indicates that when reactions [10] or [11] predominate, the overall order is 0.5. When reaction [8] predominates, the overall order is 1.5, and when reaction [9] predominates it is between 0.5 and 1.5 (approximately 1.35 (3)).

The solid curve in Fig. 5 is a calculated one, assuming the predominance of reaction [8] over reaction [9] (at higher temperatures). The apparent difference between the experimental results and the calculated curve is most likely due to the uncertainties in the values of the kinetic parameters used in the calculations. The same equation was also used for the calculation of the log (rate) vs. log (pressure) curve shown in Fig. 4 along with the experimental points.

Lin and Laidler (7) studied the methyl radical initiated decomposition of *n*-butane in the 260–340 °C temperature region. They analyzed for the octanes which would be expected to be formed by the recombination of butyl radicals. Since 3,4-dimethylhexane was identified and *n*-octane was absent, it was indicated that

[10] $\quad 2s\text{-}C_4H_9\cdot \rightarrow C_8H_{18}$

[3]Activation energies and frequency factors involved in the computation of $k_7/k_{12}^{1/2}$ are not listed in Table I and were not used in the calculation of the overall order, since reaction [12] is in its third-order region. The value of $k_7/k_{12}^{1/2}$ enters only into the calculation of r_{12} in eq. [II]. Since the rate of reaction [12] is much smaller than the rate of other chain-termination reactions, the value of r_{12} in eq. [II] may be assumed to be 0.

was the major chain-termination reaction. Calculations also indicate that the rate of reaction [10] is expected to be approximately 2 orders of magnitude larger than the rate of reaction [11].

Chain-termination Mechanisms

In the previous publication (3), it was pointed out that the nature of the chain-termination mechanism at temperatures above 400 °C is still subject to considerable controversy. Either reaction [8] or reaction [9] may predominate.

In Fig. 5 it may be observed that at approximately 340 °C and 150 mm Hg the overall order is 1.0. Under these conditions the rate of the radical cross-combination reaction

[13] $$CH_3\cdot + s\text{-}C_4H_9\cdot \rightarrow C_5H_{12}$$

or

[14] $$C_2H_5\cdot + s\text{-}C_4H_9\cdot \rightarrow C_6H_{14}$$

should become as important as the sum of the rates of the recombination reactions of the participating radicals.

The relative concentrations of C_5 and C_6 minor products of the sensitized decomposition of *n*-butane at 340 °C should reveal the relative concentrations of methyl and ethyl radicals, thereby providing useful information about the high temperature chain-termination mechanism.

Based on the results of this investigation, it may be concluded that reaction [10] predominates at temperatures below about 320 °C. At temperatures between 320 and 400 °C, both the high and the low temperature mechanism plus the cross-combination reaction of the 2 radicals involved is operative. Thus, assuming that reaction [8] is dominant at temperatures above 400 °C, the following chain-termination mechanism would apply to the 320–400 °C range

[8] $$2CH_3\cdot \rightarrow C_2H_6$$

[10] $$2s\text{-}C_4H_9\cdot \rightarrow C_8H_{18}$$

[13] $$CH_3\cdot + s\text{-}C_4H_9\cdot \rightarrow C_5H_{12}$$

Conclusions

Organic radical decomposition reactions such as reactions [2], [3], and [6] generally have a higher activation energy than radical exchange reactions like reactions [4] and [5]. At high temperatures, the small radicals are present at the highest concentrations and are thus the predominant chain terminators. As the temperature is lowered and the pressure increased, the larger radicals become more important as chain terminators. In a study of the pyrolysis of propane at 440 °C, Leathard and Purnell (11) observed an order change similar to the one described here. A likely reason for the apparent lack of other evidence is that order changes occur in a yet unexplored temperature region, where the reaction rate is extremely low. Extension of pyrolytic reaction studies to lower temperatures and moderately high pressures may reveal that many other organic, free-radical chain reactions can undergo a change in overall reaction order resulting from a change in the termination mechanism.

Direct photolysis of tetrafluoroethylene at 1849 Å

J. R. DACEY AND J. G. F. LITTLER[1]

Department of Chemistry and Chemical Engineering, Royal Military College of Canada, Kingston, Ontario

Received February 3, 1969

The photolysis of C_2F_4 at 1849 Å gives the following products, whose quantum yields are strongly dependent on substrate pressure: C_2F_6, C_2F_2, cyclo-C_4F_8, cyclo-C_3F_6, C_3F_6, C_3F_8, and polymer. The primary photochemical reactions are tentatively identified, and involve double bond fission and fluorine molecule and fluorine atom elimination.

Canadian Journal of Chemistry, 47, 3871 (1969)

Introduction

The mercury photosensitized decomposition of tetrafluoroethylene (TFE) has been studied by Atkinson (1) and Cohen and Heicklen (2), and the flash photolysis by Dalby (3).

Cohen and Heicklen, using a filter to eliminate wavelengths shorter than 2200 Å, found only perfluorocyclopropane at room temperature, plus small amounts of (tentatively identified) perfluoropropene at temperatures above 175 °C. However, Atkinson, using silica cells with an unfiltered lamp, found perfluorocyclopropane plus polymer. In view of the present work, it seems probable that some direct photolysis was occurring in Atkinson's work.

The flash photolysis results suggest only the formation of perfluoropropene in the direct photolysis.

The thermal decomposition of TFE has been studied by Atkinson and co-workers (4), Miller (5), and Lacher (6). At low temperatures (300–500 °C), the only product found is perfluorocyclobutane; but at higher temperatures, perfluoropropene and perfluoroisobutene are the major products, and are probably formed (4) via a mechanism involving difluoromethylene radicals in the following sequence

$$2C_2F_4 \rightarrow \text{cyclo-}C_4F_8$$

$$\text{cyclo-}C_4F_8 \rightarrow CF_3{-}CF{=}CF_2 + CF_2$$

$$CF_2 + CF_3{-}CH{=}CF_2 \rightarrow \begin{matrix} CF_3 \\ \diagdown \\ \quad C{=}CF_2 \\ \diagup \\ CF_3 \end{matrix}$$

It does not, however, seem probable that similar steps are involved in the formation of products found in the present work.

Experimental

Tetrafluoroethylene (TFE) from Peninsular Chemical Research Inc. was used without further purification except for degassing at −196 °C, and contained small amounts (¼%) of C_2F_6 as an impurity.

The photolysis cell was 35 cm by 16 cm in diameter, and contained an axial low pressure mercury lamp based on the design by Dacey and Hodgins (7). The lamp, made of suprasil (Englehard Industries Inc.), was surrounded by a vacuum jacket to reduce the temperature of the surface exposed to the TFE. (The internal temperature of the lamp was 95 °C; the external temperature was thus low enough to prevent appreciable thermal polymerization of the TFE.)

The TFE was circulated through the cell by an all glass pump. Photolyses were carried out at 25 °C, from 1–10% conversion without appreciable affect on the quantum yields.

The lamp output (ca. 5×10^{16} quanta s^{-1}) was measured using ammonia as an actinometer, before and after each TFE photolysis. The quantum yield for ammonia decomposition was taken to be 0.45 (8) at a pressure of 15 cm.

Analysis was carried out, using a Burrell Kromo Tog Model KD vapor phase chromatograph on a 10 foot silica gel column (9), operating between 50 and 275 °C, with thermal conductivity detectors. The instrument was calibrated with known quantities of each of the perfluorocarbons found in the photolysis (apart from difluoroacetylene, which is unstable even at low concentrations (10)).

Mass spectrometry was used to distinguish C_2F_3H and C_3F_8 which were scarcely separated on the silica gel column.

Methane was added to the photolysis system, and the relative retention times for various additional species which might be formed by the attack of difluoromethylene or fluorine atoms on methane were measured.

Photolyses and gas collection were carried out on a newly constructed mercury-free vacuum line, employing oil diffusion pumps, and regularly held at 10^{-5} Torr between runs.

Some polymer and very small amounts of carbon gradually built up on the cell walls which were periodically cleaned. There was also very slight etching of the glass.

The absorption spectrum of TFE at 1.16 Torr, using

a 10 cm path length, was recorded on a Beckman DK-1 spectrophotometer fitted with far ultraviolet optics.

Results

Quantum yields were calculated using the measured lamp output, the extinction coefficient of TFE, and the vapor phase chromatographic analysis results. Inherently this is a poor method for gathering yields, which are probably accurate to $\pm 15\%$. Of course, accuracy also depends upon the value used for the quantum efficiency of the decomposition of ammonia.

Table I gives the quantum yields for the formation of perfluoro-cyclopropane, propene, propane, ethane, and cyclobutane in terms of the number of product molecules formed. Owing to the difficulty in analyzing for difluoroacetylene, no quantum yields are given; however, difluoroacetylene was observed in all photolyses.

Other higher molecular weight compounds were formed but not identified, except to note that of all the possible perfluoro-C_4 compounds, cyclo-C_4F_8 was by far the most important.

In some experiments excess methane was added to the TFE in order to take up any fluorine atoms. The amount of fluorine atom formation was monitored by determining the ethane formed in the following reaction

$$CH_4 + F \rightarrow CH_3 + HF$$

$$2CH_3 \rightarrow C_2H_6$$

The product distribution in the mass spectral analysis indicates that other routes to the formation of CH_3 radicals are of minor importance. In Table II the ratios of various products are listed against methane pressure at a constant TFE pressure, and are discussed below.

Additional experiments in which difluorodiazirine was decomposed in the presence of TFE are summarized in Table III. In view of these results, further experiments were carried out at 2537 Å using various pressures of difluorodiazirine and TFE. The pressure dependence of the degree of isomerization of perfluorocyclopropane to perfluoropropene is presented in Fig. 1.

The absorption spectrum of TFE, Fig. 2, is in agreement with unpublished results previously obtained by Walsh[2].

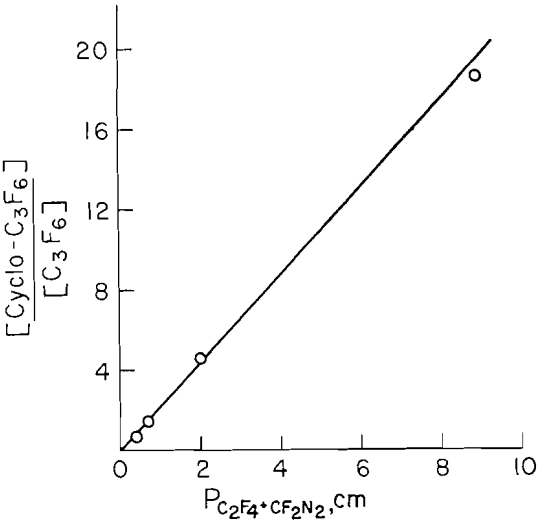

FIG. 1. Pressure dependence of the degree of isomerization of perfluorocyclopropane to perfluoropropene.

[2]In a personal communication, Professor A. D. Walsh suggests that the diffuse bands at 1940 and 1882 Å represent the symmetrical C—C stretching frequency appearing in the allowed lowest energy Rydberg transition, and that the continuous background arises from the allowed $^1(\pi^* \leftarrow n)$ transition.

Decomposition of difluorodiazirine in the presence of TFE

Method of decomposing CF_2N_2	Perfluorocyclopropane formed	Perfluoropropene formed
Thermally, 160 °C	Yes	No
Photolytically, 3650 Å	Yes	No
Photolytically, 3130 Å	Yes	No
Photolytically, 2537 Å	Yes	Yes

Discussion

The following reactions should be considered as possible primary processes in the direct photolysis of TFE

[1] $C_2F_4 \rightarrow C_2F_2 + F_2$

[2] $C_2F_4 \rightarrow C_2F_2 + 2F$

[3] $C_2F_4 \rightarrow 2CF_2$

[4] $C_2F_4 \rightarrow C_2F_3 + F$

[5] $C_2F_4 \rightarrow C_2F_4^*$

Reactions [1] and [2] are analogous to the primary processes in the direct photolysis of ethylene at 1849 Å (11), and reaction [3] has been found in the mercury sensitized decomposition of TFE at 2537 Å (1) and in the flash photolysis (3) of TFE. Reaction [5] is postulated to permit the formation of octafluorocyclobutane by collision of either a hot ground state TFE molecule or a collisionally deactivated TFE molecule in the first excited state with the substrate. Finally, process [4] (which does not occur in the direct (11) or mercury-sensitized (12, 13) photolyses of ethylene) is included to account for the formation of C_2F_3H when TFE is photolyzed in the presence of methane.

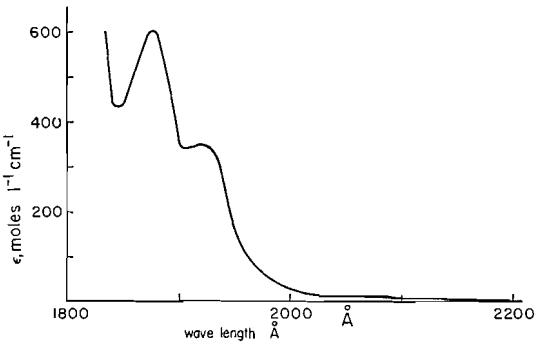

FIG. 2. Absorption spectrum of TFE.

Difluoromethylene Reactions

The heats of formation of TFE and C_3F_6 are −151.7 and −259 kcal/mole, respectively. Assuming that ΔH_f cyclo-C_3F_6 is also approximately −260 kcal/mole, then a reaction in which TFE is converted to cyclo-C_3F_6*, following light absorption at 1849 Å (154.8 kcal/mole), will form the cyclo-C_3F_6* at an energy of 110 kcal/mole above its ground state, providing that no energy is lost by collisions before reaction [6] is complete.

[6] $CF_2^* + C_2F_4 \rightarrow \text{cyclo-}C_3F_6^*$

It seems highly probable then that the hot (ground electronic state) perfluorocyclopropane can isomerize to perfluoropropene to an extent determined by the pressure in the system. Table I shows that the quantum yield for the perfluoropropene rises at low TFE pressures, whereas that for perfluorocyclopropane falls. However, the data in Table I also suggest that much of the perfluorocyclopropane in fact appears not as perfluoropropene, but as perfluoropropane, at low TFE pressures.

It is difficult to justify exclusively a mechanism for the formation of perfluoropropane. Reactions [7] to [9] indicate a probable pathway[3]

[7] $\text{cyclo-}C_3F_6^* \rightarrow C_3F_6^*$

[8] $C_3F_6^* + M \rightarrow C_3F_6$

[9] $C_3F_6^* \rightarrow CF_3 + CF{=}CF_2$

[3]The authors are grateful to a referee for suggesting this mechanism.

[10] $C_2F_4 + F \rightarrow C_2F_5$

[11] $C_2F_5 + CF_3 \rightarrow C_3F_8$

It is possible that C_3F_6 could acquire two fluorine atoms consecutively to form C_3F_8. However, since this mechanism does not appear to be followed in the formation of C_2F_6, and in view of the ratio of C_2F_4/C_3F_6 in the system, such a process appears unlikely.

Data concerning the isomerization of perfluorocyclopropane are shown in Table I, Column *A*, where the degree of isomerization displays the expected dependence on TFE pressure. A similar trend is found on the addition of methane, which is, however, far less efficient at quenching the hot perfluorocyclopropane.

Perfluorocyclopropane, made by decomposing difluorodiazirine thermally and photolytically in the presence of TFE, failed to isomerize unless the difluorodiazirine was decomposed at wavelengths shorter than 3130 Å (Table III). Since the heat of formation of difluorodiazirine is not available, it is difficult to use these experiments to bracket the energy required to isomerize perfluorocyclopropane. However, following the decomposition of difluorodiazirine at 2537 Å in the presence of TFE, a considerably higher pressure of TFE, as illustrated in Fig. 1, was required to prevent the isomerization to perfluoropropene than was the case in the direct photolysis of TFE (Table I), implying that the CF_2 fragment formed from CF_2N_2 at 2537 Å is more energetic than that formed from TFE at 1849 Å.

C_2F_6 and cyclo-C_4F_8 Production

Formation of C_2F_6 appears to proceed via the addition of F_2 from process [1] to the substrate. That the alternative pathway in which C_2F_4 successively acquires two fluorine atoms is not dominant is demonstrated by the continued formation of C_2F_6 in the presence of excess methane.

Comparison of Column *C*, Table I, and Column *B*, Table II, shows that excess methane suppresses cyclo-C_4F_8 formation, but rising C_2F_4 pressure augments substrate dimerization. Presumably those excited TFE molecules which do not undergo fission via steps [1]–[4] are collisionally deactivated in the presence of excess methane, whereas they may dimerize with undiluted TFE.

Energetics of the Primary Processes

The energy of the C=C bond in TFE is 77 ± 3 kcal/mole (14). In Table I, Column *B*, the *ratio* of the yields of products consequent upon primary process [3], namely the "C_3" compounds, over the yield of C_2F_6 from process [1] is listed against TFE pressure and shows that process [3] is favored at high pressures. Such behavior is in agreement with the greater energy required to effect process [1] (at least 100 kcal/mole).

According to the data available, primary process [1] is endothermic by 137 ± 15 kcal/mole, and in practice it is difficult to separate the probable products of reactions [2] and [4]. No C_4F_6 compounds were observed; however, C_2F_3H was found, presumably as a result of the following reaction

$$CH_4 + C_2F_3 \rightarrow C_2F_3H + CH_3$$

The fluorine atoms from primary processes [2] and [4] also react with methane to yield methyl radicals, and Table II, Column *A*, indicates that of the processes [1], [2], and [4],

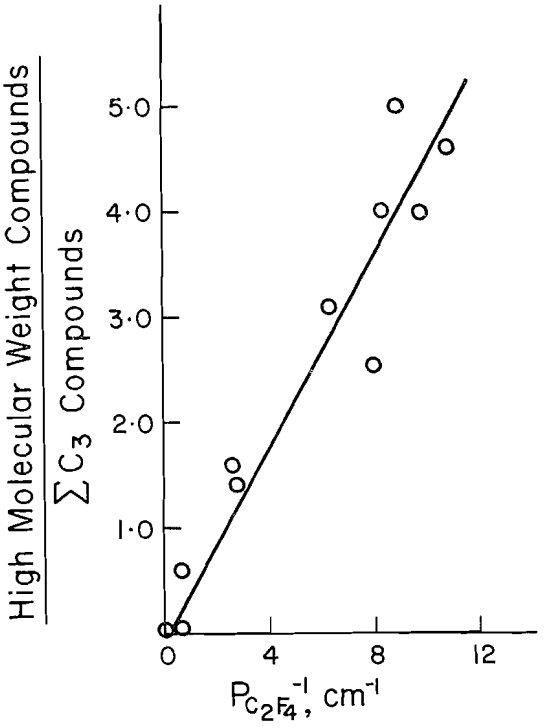

FIG. 3. Formation of higher molecular weight products with respect to TFE pressure.

[1] is the preferred path at high methane pressures, in agreement with the high C—F bond strength in C_2F_4.

Figure 3 shows that the higher molecular weight products formed increase in importance with respect, for instance, to the "C_3" compounds at low TFE pressures, implying that they are formed via a high energy primary step, which may support processes [2] and [4] as important reactions at low TFE pressures. Furthermore, the addition of a large excess of methane completely suppresses the production of these higher molecular weight compounds, but results in the appearance of C_2F_3H and C_2H_6. It seems probable that one important route to such polymers is via chain reactions with the substrate of the type

$$C_2F_3 + C_2F_4 \rightarrow C_4F_7 \xrightarrow{C_2F_4} C_6F_{11} \text{ etc.}$$

Infrared spectra and rotational isomerism of mono-, di-, and tri-ethylene glycol monoalkyl ethers[1]

T. K. K. Srinivasan, C. I. Jose, and A. B. Biswas[2]
National Chemical Laboratory, Poona-8, India

Received April 30, 1968

Infrared spectra have been recorded of the following mono-, di-, and tri-ethylene glycol monoalkyl ethers: $C_nH_{2n+1}OCH_2CH_2OH$ where $n = 17$ and 19; $C_nH_{2n+1}(OCH_2CH_2)_2OH$ where $n = 17$, 18, 19, and 22; and $C_{18}H_{37}(OCH_2CH_2)_3OH$. Spectra of the pure liquids, solutions in CCl_4, and the solids at room and liquid air temperatures have been studied. From a study of the CH_2 rocking modes at 927–934, 889, 900, and 862 cm^{-1} during the liquid–solid transformation and from solution studies, it has been shown that both the OCH_2CH_2O groups in diethylene glycol monoalkyl ethers exist predominantly in the *gauche* conformation in liquid and in solution. However, in the solid, while the end OCH_2CH_2O group takes both *trans* and *gauche* forms, the OCH_2CH_2O group adjacent to the polymethylene chain appears to take a *trans* configuration. The long polymethylene chain is found to pack in a triclinic subcell in the solid state, while in the quenched liquid state an orthorhombic or monoclinic packing is indicated. The present investigation has led to the conclusion that the difference in the conformations of end $CH_2CH_2CH_2OH$ groups found between the odd and even chain *n*-alcohols is removed in mono- and diethylene glycol monoalkyl ethers by the introduction of one or two OCH_2CH_2 groups.

Canadian Journal of Chemistry, 47, 3877 (1969)

Introduction

Previous infrared investigations of a series of long chain alkoxy ethanols ($C_nH_{2n+1}OCH_2CH_2OH$ where $n = 16$, 18, 20, and 22) have shown that the OCH_2CH_2O group in these compounds is present in both *gauche* and *trans* forms in the solid state and largely in the *gauche* form in the liquid or in solution (1). In the present work the study has been extended to compounds where *n* is odd (17 and 19) and compounds containing more than one OCH_2CH_2O group, namely some diethylene glycol monoalkyl ethers $C_nH_{2n+1}(OCH_2CH_2)_2OH$ where $n = 17$, 18, 19, and 22, and one triethylene glycol monoalkyl ether $C_{18}H_{37}(OCH_2CH_2)_3OH$.

The 4 important conformations of OCH_2CH_2O groups in a diethylene glycol monoalkyl ether ($R—OCH_2CH_2OCH_2CH_2OH$) molecule, namely *gauche–trans*, *trans–trans*, *trans–gauche*, and *gauche–gauche* are represented in Fig. 1.

An analysis of the hydroxyl stretching bands of $C_{18}H_{37}(OCH_2CH_2)_2OH$ has been made to obtain information on the association behavior of this compound in CCl_4 solution. The CH_2 group absorptions in compounds containing long polymethylene chains have been found to depend on the nature of chain packing (subcell) (2). In orthorhombic and monoclinic subcell packing, both symmetry considerations and interchain distance favor interaction leading to splitting of certain CH_2 fundamental modes. In the hexagonal subcell on the other hand, both symmetry considerations and interchain distance, which is practically the same as in the liquid, rule out splitting. In the triclinic subcell, there is only a single chain in the unit cell and, therefore, there is only a single component for every fundamental vibration. Using these arguments, an analysis of CH_2 group absorptions has enabled us to deduce the packing of the long polymethylene chains in terms of the possible subcells, for all the compounds studied in both solid and quenched liquid states.

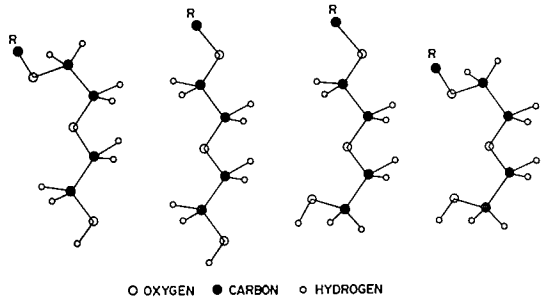

FIG. 1. Conformations of OCH_2CH_2O groups in a diethylene glycol monoalkyl ether: *gauche–trans*, *trans–trans*, *trans–gauche*, and *gauche–gauche*.

Experimental

Alkoxy ethanols, di- and tri-ethylene glycol monoalkyl ethers were synthesized from the respective alcohols and the corresponding ethylene glycols (3). The odd chain heptadecyl and nonadecyl alcohols were synthesized from cetyl and octadecyl alcohols, respectively. The latter were first converted to heptadecanoic and nonadecanoic acids according to the procedure of Levene and Taylor (4) and the corresponding esters were reduced with lithium aluminum hydride to give the alcohols. All the compounds investigated in this study were at least 99% pure except the C_{17} compounds which are 97% pure as checked by gas–liquid chromatography. The melting points of the compounds reported below are correct to half a degree.

Melting point of the glycols

Compound	Melting point (°C)
$C_{17}H_{35}(OCH_2CH_2)_2OH$	38.8
$C_{18}H_{37}(OCH_2CH_2)_2OH$	44.5
$C_{19}H_{39}(OCH_2CH_2)_2OH$	48.4
$C_{22}H_{45}(OCH_2CH_2)_2OH$	58.8
$C_{18}H_{37}(OCH_2CH_2)_3OH$	42.4
$C_{17}H_{35}OCH_2CH_2OH$	46.6
$C_{19}H_{39}OCH_2CH_2OH$	53.6

Spectral Studies

The spectra were obtained with a Perkin–Elmer model 221 infrared spectrophotometer equipped with a sodium chloride prism and grating interchanges. The instrument was kept in a constant temperature room at 25 °C. The spectral slit widths for the grating and prism interchanges were 5 cm^{-1} (at 3400 cm^{-1}) and 4 cm^{-1} (at 1500 cm^{-1}), respectively. The reported frequencies are accurate within ± 2 cm^{-1}.

The experimental methods were essentially the same as those described in the previous studies (1). A cell similar to that of Wagner and Hornig (5), with additional provision for heating the sample, was used for obtaining the spectra at liquid air temperatures. Association studies were carried out at 25 °C in carbon tetrachloride solution in the concentration range 0.005–0.5 *M*. Carbon tetrachloride (Merck proanalyse) was dried over P_2O_5 and distilled just before making up the solutions. Dilute solutions were made by successive dilution of the concentrated solution.

Results and Discussion

The frequencies of the principal maxima along with proposed assignments for di- and tri-ethylene glycol monoalkyl ethers in the solid state (−180 °C) are presented in Table I. Table II lists the observed frequencies with assignments for $C_{19}H_{39}(OCH_2CH_2)_2OH$ in the various states. The observed frequencies and assignments of the monoethylene glycol monoalkyl ethers (alkoxy ethanols) are presented in Table III. Some typical spectra are shown in Fig. 2.

All the compounds showed two strong bands at 2910 and 2840 cm^{-1} which arise from the CH asymmetric and symmetric stretching modes, respectively. The spectrum of solid $C_{19}H_{39}(OCH_2CH_2)_2OH$, recorded using the grating interchange, showed a series of bands at 2950 (ms), 2930 (sh), 2915 (vs), 2875 (sh), 2870 (w), and 2850 cm^{-1} (vs). A broad shoulder near 2940 cm^{-1} and bands at 2910 (vs) and 2840 cm^{-1} (vs) were observed in the liquid. The strong bands at 2915 and 2850 cm^{-1} are respectively ascribed to the asymmetric and symmetric stretching vibrations of the methylene group of the polymethylene chain, while the shoulders at 2930 and 2875 cm^{-1} are assigned to the stretching modes of the CH_2 groups adjacent to the oxygen. The methyl asymmetric and symmetric stretching modes occur at 2950 and 2870 cm^{-1}.

The methylene group deformation vibrations are classified as bending (scissoring), wagging, twisting, and rocking modes in order of decreasing frequency. In polymethylene chains there is some overlap among the different modes as well as with the skeletal modes. As mentioned in the introduction, splitting of certain fundamental modes occurs due to interaction between adjacent polymethylene chains in certain subcell packings (2). The doublets at 1472 and 1463 cm^{-1} in the spectra of alkoxy ethanols and the singlet at 1472 cm^{-1} in the di- and tri-ethylene glycol monoalkyl ether spectra (except $C_{22}H_{45}(OCH_2CH_2)_2OH$) are assigned to the methylene deformation of the chain in the orthorhombic or monoclinic and triclinic subcells, respectively. These assignments have been made by comparison with similar results reported for orthorhombic *n*-$C_{23}H_{48}$ and triclinic *n*-$C_{24}H_{50}$ (6). The methylene rocking modes also reflect the changes in the packing of the polymethylene chain, the triclinic giving rise to a singlet and the monoclinic or orthorhombic to a doublet near 720 cm^{-1}. However, $C_{22}H_{45}(OCH_2CH_2)_2OH$ shows splitting of the methylene bending and rocking modes indicating a monoclinic or orthorhombic packing, in contrast to the triclinic packing in the other diethylene glycol monoalkyl ethers. In the liquid state (see Fig. 3) all these compounds show a single band at 1466 cm^{-1}. The methyl asymmetric deformation mode in alkoxy ethanols appears to merge with the methylene deformation at 1463 cm^{-1}, while it is present as a weak band at 1453 cm^{-1} in di- and tri-ethylene glycol monoalkyl ethers. Similar assignments have been made for triclinic *n*-C_{24}-

A band at 1495 ± 5 cm^{-1} whose intensity increases with increasing number of OCH_2CH_2 groups is found in the solid state spectra of all compounds, although in the liquid state there is no band in this position. A methylene scissoring mode has not been generally found at such a high frequency. However, Matsuura and Miyazawa (8) have recently reported the presence of a band at 1484 cm^{-1} in the spectrum of diethylene glycol, although no specific assignment was made. A band at 864–871 cm^{-1} found in the spectra of the solid compounds and also absent in the spectra of

the liquids has been ascribed to the methylene rocking of the OCH_2CH_2O group in the *trans* form (see below). We have therefore assigned the band at 1495 $\pm$ 5 cm^{-1} to a methylene deformation of the *trans* OCH_2CH_2O group.

The quenched liquid alkoxy ethanols produced spectra which were the same as the spectra of the solids. However, di- and tri-ethylene glycol monoalkyl ethers (see Fig. 4) showed a splitting of the band at 1464 cm^{-1} (liquid) into two components at 1463 and 1472 cm^{-1} on quenching, (see Fig. 3). Similar splitting was also observed in the CH_2 rocking mode near 720 cm^{-1}. These splittings as mentioned earlier are characteristic of orthorhombic or monoclinic subcell packing of the polymethylene chain. The spectra of the quenched liquids differ from the solid spectra which show single bands in these regions (near 1460 and 720 cm^{-1}). The latter are characteristic of triclinic packing.

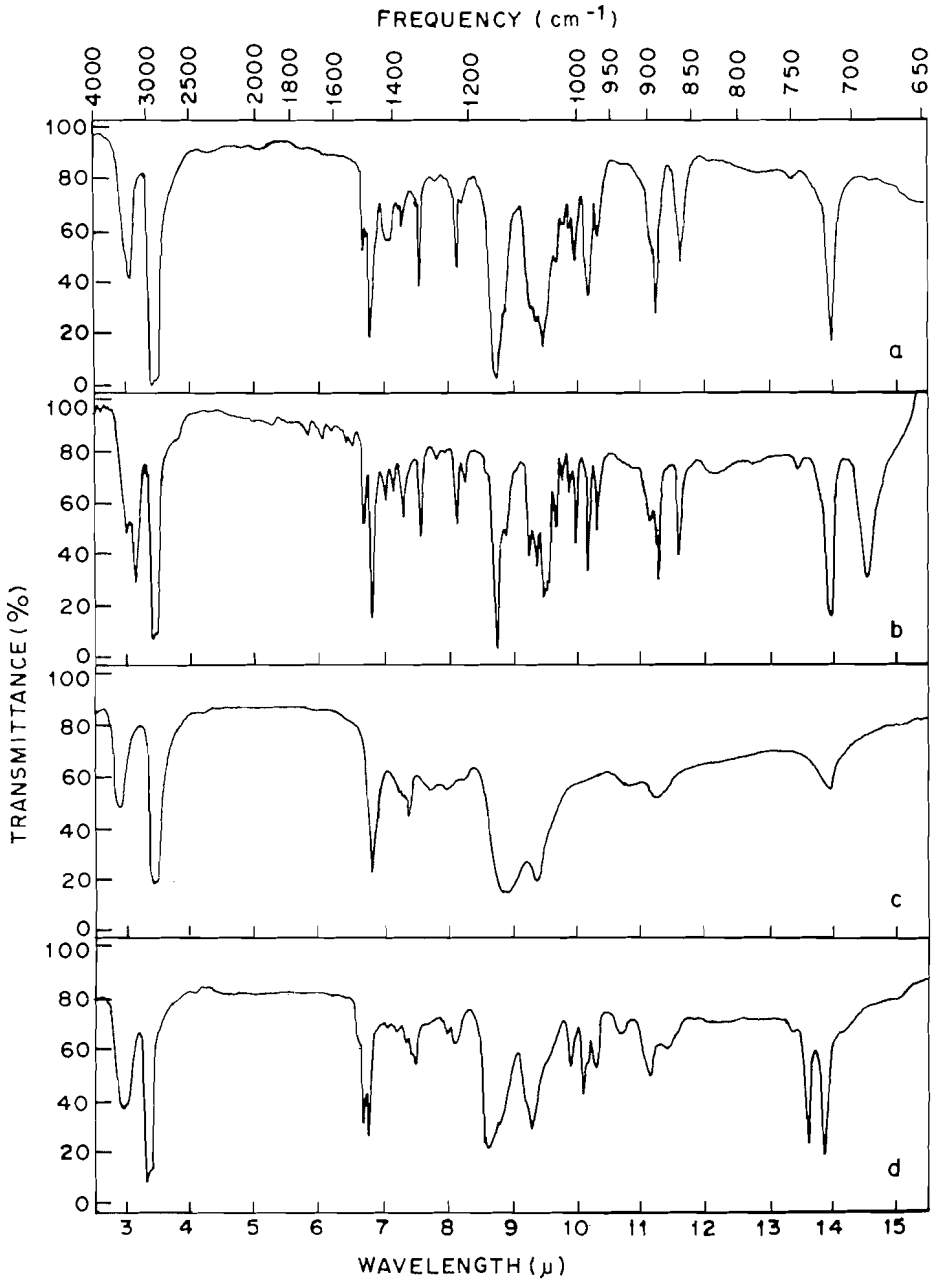

FIG. 3. Infrared spectra of $C_{19}H_{39}(OCH_2CH_2)_2OH$: (*a*) solid at 25 °C, (*b*) solid at −180 °C, (*c*) liquid, and (*d*) quenched liquid at −180 °C.

Liquid $C_{22}H_{45}(OCH_2CH_2)_2OH$ on quenching gives the same packing of the polymethylene chain as the solid, which as mentioned earlier was either orthorhombic or monoclinic. However, the bands at 1495, 862–871, and 964–969 cm^{-1} which are characteristic of the OCH_2CH_2O group in the *trans* form and were found in the spectra of the solids, are absent or very weak in the spectra of the quenched liquids. On warming the quenched liquids, the spectra revert to those

of the solid in all cases. These results can be explained on the basis that in the quenched state, while the long polymethylene chain packs in the orthorhombic or monoclinic subcell (in contrast to the triclinic subcell in the normal solid), the OCH_2CH_2O groups have been frozen into a disordered structure consisting mainly of the *gauche* conformations. Various polymorphic forms of monostearin obtained by different conditions of crystallization are found to give different packing of the polymethylene chain (9). In view of the transformation to the normal solid state structure on warming, it is unlikely that the OCH_2CH_2O groups are rotating. Rapidly frozen 1,1,2,2-tetrabromoethane has been shown (10) to have a *gauche* conformation, while the solid obtained by slow cooling crystallizes in the *trans* form (11).

The bands in the region 1380–1150 cm^{-1} have their origin in the wagging and twisting vibrations of the methylene groups. The bands at 1370, 1321 $\pm$ 5, 1225 $\pm$ 3, and 1212 $\pm$ 4 cm^{-1} in the spectra of di- and tri-ethylene glycol monoalkyl ethers, are stronger than those observed in the alkoxy ethanols at similar positions, and are ascribed to the CH_2 wagging and twisting modes of the OCH_2CH_2O groups. Miyake (12) and Buckley and Giguère (13) have also assigned bands at similar positions in the spectra of solid ethylene glycol to methylene wagging and twisting modes. However, Matsuura and Miyazawa (14) prefer to assign them to coupled modes of OH deformation and CH_2 wagging.

The bands in the region between 1150 and 1050 cm^{-1} are assigned to the C—O—C antisymmetric stretching vibrations ($\sim$ 1148, $\sim$ 1126 cm^{-1}), to the coupled C—O stretching and O—H deformation ($\sim$ 1080, $\sim$ 1075, $\sim$ 1055 cm^{-1}) (15), and C—C stretching modes (16). The bands between 1050 and 950 cm^{-1} arise from the various skeletal modes.

The spectra of mono-, di-, and tri-ethylene glycol monoalkyl ethers in the region 950–800 cm^{-1} are widely different in the liquid and solid states (see Fig. 3 for $C_{19}H_{39}(OCH_2CH_2)_2OH$ as an example). Changes in the absorption patterns for a typical liquid–solid transformation for the compound $C_{18}H_{37}(OCH_2CH_2)_2OH$ are represented in Fig. 5. In the case of certain alkoxy ethanols these changes have been explained as being due to different rocking modes of the 2 rotational isomeric configurations (RG and RT) of the OCH_2CH_2O group (1). In diethylene glycol monoalkyl ethers, as mentioned in the introduction, there are 4 such configurations for the two OCH_2CH_2O groups (see Fig. 1).

The bands at 889 cm^{-1} in the spectrum of the liquid and 891–897, 862–871, and 964–969 cm^{-1} in the solid spectra of di- and tri-ethylene glycol monoalkyl ethers are similar to those observed for the 2 alkoxy ethanols in the corresponding states studied in this work and earlier (1). They have thus been ascribed to the *gauche* (889–897 cm^{-1}) and *trans* (862–871 and 964–969 cm^{-1}) forms of the end OCH_2CH_2O group. The 927–934 cm^{-1} band in the liquid and 900 cm^{-1} in the solid spectra of di- and tri-ethylene glycol monoalkyl ethers are then ascribed to the *gauche* and *trans* configurations of the OCH_2CH_2O group adjacent to the polymethylene chain.

The band at 927–934 cm^{-1} in the liquid state of di- and tri-ethylene glycol monoalkyl ethers is similar to that found at 936–941 cm^{-1} in di-, tri-, and poly-ethylene glycols (17) and also to that at 934 cm^{-1} in mono alkylated polyethylene glycols (18). This band is not found in alkoxy ethanols. Further, in ethylene glycol dimethyl ether, 2 bands observed at 935 and 928 cm^{-1} are attributed to the *gauche* form by Miyake (17). This is in agreement with our assignment of the band at 927–934 cm^{-1} in the present compounds to the *gauche* OCH_2CH_2O group adjacent to the paraffin chain, which is different from the one containing the hydroxyl group. However, a band at 900 cm^{-1} observed in ethylene glycol ethers (19) and in $O_2NOCH_2CH_2ONO_2$ (20) has been ascribed to the methylene rocking in the *gauche* form. The absence of the 927–934 cm^{-1} band in the spectra of solid di- and tri-ethylene glycol monoalkyl ethers and the presence of a new band at 900 cm^{-1} shows the conversion of the RG- to RT-form during liquid–solid transformation.

The above results thus show that diethylene glycol monoalkyl ethers take the RGG conformation in the liquid and both RTG and RTT configurations in the solid state. The spectra of alkoxy ethanols (C_{17} and C_{19}) studied in the present work are similar to those of the even chain compounds studied earlier and have mainly RG configuration in the liquid and both RG and RT configurations in the solid. The triethylene glycol monoalkyl ether has probably RGGG configuration in the liquid and RTTG and RTTT configurations in the solid. The *trans* configuration of the OCH_2CH_2O group placed adjacent

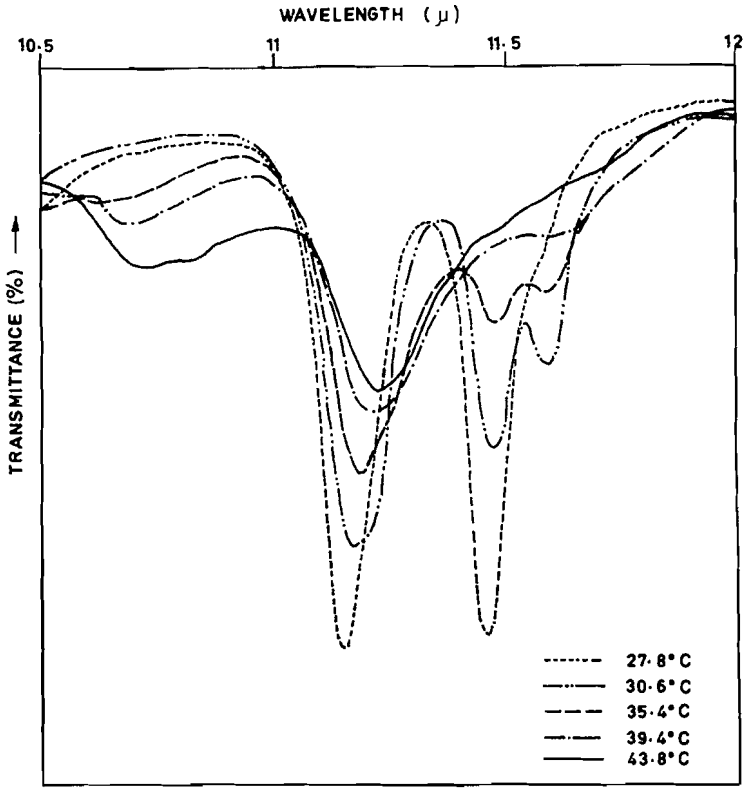

FIG. 5. Variation of intensity of the CH_2 rocking mode with temperature in $C_{18}H_{37}(OCH_2CH_2)_2OH$.

to the long methylene chain in the solid state of mono-, di-, and tri-ethylene glycol monoalkyl ethers is not unexpected in view of the known extended TTT . . . . T configuration (21) of the polymethylene chain itself. However, the occurrence of the end OCH_2CH_2O groups carrying a hydroxyl group in both *gauche* and *trans* configurations in all the present compounds is unexpected, since usually only one rotational isomer exists in the crystalline solid. Recently Tasumi *et al.* (22) have reported the odd (C_{17}–C_{29}) chain alcohols (β-form) to have equal numbers of *gauche* and *trans* configurations for the end $CH_2CH_2CH_2O$ group in the solid. The even (C_{18}–C_{34}) chain alcohols (γ-form) have, on the other hand, only the *trans* configuration for this group. The odd chain (hydrocarbon part) diethylene glycol monoalkyl ethers and even chain alkoxy ethanols may be compared to the odd chain alcohols if the ether oxygen is considered similar to a CH_2 group. However, our results show that even chain alcohols (γ-form), which have only the *trans* configuration for the end $CH_2CH_2CH_2O$ group, have no analogues either in the odd chain alkoxy ethanols or even chain diethylene glycol monoalkyl ethers. This leads to the conclusion that the effect of the number of carbon atoms (odd, even) on the end conformation, i.e. $CH_2CH_2CH_2O$ group found in alcohols, is destroyed by the presence of ether oxygen in the mono-, di-, and tri-ethylene glycol monoalkyl ethers.

Hydroxyl Absorptions

The liquid state spectra of all the di- and triethylene glycol monoalkyl ethers showed a broad band at 3450 ± 25 cm^{-1} attributable to an O—H stretching vibration. Solidification leads to a splitting into two peaks at 3335 ± 15 cm^{-1} and 3255 ± 15 cm^{-1} which occurs at 25 °C (see Fig. 6*a*). These two components are shifted down to 3280 and 3180 cm^{-1}, respectively, at −180 °C. However, the monoethylene glycol monoalkyl ethers showed a single O—H stretching band at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

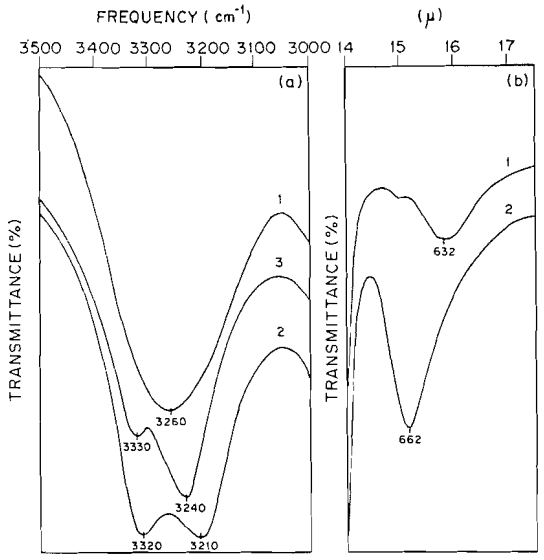

FIG. 6. (*a*) The OH stretching vibration region of the spectra of (*1*) $C_{18}H_{37}OCH_2CH_2OH$, (*2*) $C_{18}H_{37}(OCH_2CH_2)_2OH$, (*3*) $C_{19}H_{39}(OCH_2CH_2)_2OH$. (*b*) CsBr region (in part) of the spectra of (*1*) $C_{18}H_{37}OCH_2CH_2OH$, (*2*) $C_{18}H_{37}(OCH_2CH_2)_2OH$.

3270 cm^{-1} in the solid state. Two bands at 1427 $\pm$ 8 and 1406 $\pm$ 2 cm^{-1} are observed in the spectra of mono-, di-, and tri-ethylene glycol monoalkyl ethers. In previous work on alcohols (23), bands in this region have been assigned to the O—H in-plane deformation coupled with a C—O stretching mode. The O—H in-plane deformation modes in odd and even chain alcohols have been found at 1408 and 1427 cm^{-1}, respectively (20). Bands at 1414 and 1392 cm^{-1} in ethylene glycol have recently been assigned to the coupled vibration of the O—H in-plane deformation and a CH_2 wagging mode (12). A band at 1422 cm^{-1} in the spectrum of liquid di-ethylene glycol (8) which shifts to 1439 cm^{-1} in the solid, has been attributed to an O—H in-plane deformation. The O—H out-of-plane deformation for solid $C_{18}H_{37}(OCH_2CH_2)_2OH$ at 25 °C is observed at 660 cm^{-1}. This is higher than that observed (634 cm^{-1}) in the spectrum of the alkoxy ethanol $C_{18}H_{37}OCH_2CH_2OH$ (see Fig. 6 *b*). These peaks are shifted to higher frequencies at -180 °C. The O—H out-of-plane deformation modes in the odd and even chain alcohols at 25 °C are found at 687 and 612 cm^{-1}, respectively (20).

Hydrogen Bonding

In order to elucidate the association behavior of diethylene glycol monoalkyl ethers, the spectrum of $C_{18}H_{37}(OCH_2CH_2)_2OH$ was studied in detail in the hydroxyl stretching region. In dilute CCl_4 solution (0.005 *M*) 3 bands at 3645, 3615, and 3480 cm^{-1} have been observed. These are similar to those observed by Flett (24) for diethylene glycol monoethyl ether. These absorptions are assigned to a free OH (*trans* or non-bonded *gauche*) and intramolecularly bonded 5 and 8 membered ring monomers, respectively. The assignments have been made by comparison with the spectrum of octadecoxy ethanol, which exhibits the monomer bands at 3640 and 3610 cm^{-1} at this concentration. With increasing concentration up to 0.5 *M* no new band was observed, but the relative intensity of the band near 3480 cm^{-1} increased with respect to that at 3615 cm^{-1}. The intensity of the free OH band at 3640–3645 cm^{-1} of these 2 compounds is small and is estimated to be less than 10% of the band at 3480 cm^{-1} at these concentrations. In octadecoxy ethanol, a band attributable to a dimer was found at 3480 cm^{-1} at concentrations above 0.02 *M*. It is concluded that at higher concentrations, the band near 3480 cm^{-1} observed in the spectrum of $C_{18}H_{37}(OCH_2CH_2)_2OH$ may also include absorption due to the dimer. Since no bands below 3480 cm^{-1} were observed even at the highest concentration (0.5 *M*) and since the pure liquid shows a broad band close to this frequency ($\sim$ 3450 cm^{-1}), it is concluded that the liquid consists largely of dimers. The formation of dimers only by $C_{18}H_{37}(OCH_2CH_2)_2OH$ and $C_{18}H_{37}OCH_2CH_2OH$ in concentrated solutions (0.5 *M*) is in sharp contrast to the higher polymers formed by long chain alcohols under similar conditions.

Conclusions

The present study has shown that the OCH_2CH_2O groups in mono-, di-, and tri-ethylene glycol monoalkyl ethers exist largely in the *gauche* configuration in the liquid (RG, RGG, RGGG) and in both *trans* and *gauche* configurations in the solid state (RG and RT, RTG and RTT, and RTTG and RTTT). The existence of 2 different configurations of the end OCH_2CH_2O group containing the hydroxy group bears similarity to the β-form of long chain alcohols. The conversion of the OCH_2CH_2O group adjacent to the long polymethylene chain from a *gauche* to a *trans* configuration on solidification shows the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

influence of the extended TT . . . T configuration of the polymethylene chain. While the quenching of liquid di- and tri-ethylene glycol monoalkyl ethers brings about a change in the polymethylene chain packing (subcell) as compared to the solid state spectra, quenching of monoethylene glycol monoalkyl ethers produced normal solid state spectra. Further quenching did not bring about any appreciable change in the configuration of the OCH_2CH_2O groups in the case of di- and tri-ethylene glycol monoalkyl ethers. Solution studies on $C_{18}H_{37}OCH_2CH_2OH$ and $C_{18}H_{37}(OCH_2CH_2)_2OH$ have shown that these compounds form largely dimers in concentrated solutions (~ 0.5 M) in contrast to polymers formed by simple alcohols.

The critical constants and orthobaric densities of acetone, chloroform, benzene, and carbon tetrachloride[1]

A. N. CAMPBELL AND R. M. CHATTERJEE
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received April 18, 1969

The specific volumes and pressures in the saturated states of the pure liquids acetone, benzene, chloroform, and carbon tetrachloride have been determined from a temperature of 100 °C and a pressure of about 2 atm up to the highest temperatures and pressures at which liquid and vapor coexist. The critical temperatures have been determined by the method of disappearance of meniscus, critical densities from the law of the rectilinear diameter, and critical pressures by extrapolation of the log P vs. $1/T$ line to the critical temperature.

Introduction

Acetone, chloroform, benzene, and carbon tetrachloride were chosen for study as a preliminary to an investigation of critical phenomena in binary systems containing them. The literature data, even of well known liquids such as those of this research, are surprisingly limited. A survey of critical data, measured in different ways, shows not only a wide variation in the values reported by different investigators for a single liquid, but very frequently a considerable variation in the data of the same investigator.

Campbell, Kartzmark, and Chatterjee (1) have investigated the excess volumes and total and partial pressures of the binary systems acetone–chloroform, benzene–chloroform, acetone–benzene, and of the ternary system acetone–chloroform–benzene. From these data, the excess Gibbs free energies and excess entropies were calculated. Since the publication of this work, Abbott (2) has obtained second virial coefficients from measurements on a vapor density balance. The orthobaric densities and vapor pressures of acetone, chloroform, and benzene have previously been reported by us (3).

Experimental

The methods of purification, experimental technique, and results have already been reported for acetone, chloroform, and benzene (3). It remains only to report the purification of carbon tetrachloride. This was distilled through a vacuum jacketed column with glass helix packing. The temperature of distillation was found to be constant throughout (76.6 °C at 750 mm Hg). The middle third fraction was examined for purity by gas chromatography. A column of 6 ft length, containing dimethylformamide on chromosorb P as supporting material for the liquid stationary phase, was used. The carrier gas was helium. Only one main peak was observed. All liquids were transferred to the vacuum line (for removal of non-condensible gases) in a dry-box.

Experimental Results

The orthobaric densities and vapor pressures of acetone, benzene, and chloroform have been reported previously (3). Table I gives the saturated densities of carbon tetrachloride at approximately 40 temperatures, ranging from near the standard boiling point to the critical point. Critical phenomena were observed, at a constant temperature of 283.15 °C, at the following densities: 0.4953, 0.5095, 0.5424, 0.5578, 0.5829, and 0.6047 g/cc.

The vapor pressures of carbon tetrachloride are shown in Table II. The critical temperatures of all 4 liquids were observed visually with the following results: acetone, 235.0°; benzene, 288.95°; chloroform, 262.9°; carbon tetrachloride, 283.15°.

Discussion

Because of the difficulties discussed by Campbell and Chatterjee (3), we obtained the critical pressure by an extension of the log P vs. $1/T$ line to the critical temperature; the agreement with the latest published data is good. Our results are

Acetone	P_c = 46.96 atm
Benzene	P_c = 48.22 atm
Chloroform	P_c = 52.59 atm
Carbon tetrachloride	P_c = 44.98 atm

[1]An extensive bibliography and complete details of experimental procedure are to be found in the Ph.D. thesis of Chatterjee at University of Manitoba, Winnipeg, Manitoba, 1968.

*Values were calculated using eq. [1] and the constants given in Table III.

The critical density can only be obtained by extrapolation of results obtained at lower temperatures and it is the most difficult of the 3 constants to measure accurately. The most commonly used method is to extrapolate the mean of the orthobaric liquid and vapor densities to the critical temperature, that is, to employ the law of Cailletet and Mathias, expressed analytically as

$$\tfrac{1}{2}(\rho_l + \rho_v) = \rho_c + b(t_c - t)$$

We restricted the application to a range of 50° below the critical temperature and obtained the following results

Acetone	ρ_c = 0.269 g/cc
Benzene	ρ_c = 0.306 g/cc
Chloroform	ρ_c = 0.491 g/cc
Carbon tetrachloride	ρ_c = 0.557 g/cc

The method of the rectilinear diameter, whatever may be its theoretical basis, or lack of it, does in fact work rather well if the true values of the orthobaric densities are known.

It has been shown repeatedly (4) that the dependence of both orthobaric densities on temperature are represented by a leading term

proportional to $(T_c - T)^{1/3}$. When and if the $(T_c - T)^{1/3}$ relation is obeyed, the slope of the curve, e.g., of orthobaric density vs. T, will be very slight in the neighborhood of the critical temperature. The question then is, is the slope of the curve near T_c less than that predicted by the $(T_c - T)^{1/3}$ relation? If it is, the existence of a horizontal on the curve, with all this implies, might then be conceded. To settle the point experimentally, one requires materials of the highest purity and a temperature control of great accuracy, e.g., $\pm 0.001°$. Since our control was only good to $\pm 0.03°$, we can draw no conclusion. When our data are plotted in the form of orthobaric density vs. $(T_c - T)^{1/3}$, two straight lines are obtained for each substance, which, presumably, intersect at the critical density for $(T_c - T) = 0$. Since, however, our experimental measurements do not extend quite to the critical temperature, we are really not justified in assuming that the 1/3 power relation extends all the way and, even if it does, the possibility of a truly horizontal top still exists. There is no doubt that the top is "flat" in the ordinary sense of the word, but whether it is truly horizontal in the mathematical sense can never be decided. It is an old observation, recently reaffirmed by Lorentzen (5), that the disappearance of the meniscus in the body of the tube, and not by "moving out" (as Lorentzen calls it), is not confined to the critical volume, but this does not necessarily prove that the nose of the curve of orthobaric densities vs. temperature is horizontal.

In our previous paper (3), we obtained critical densities by extrapolation of ρ_l and ρ_v plots against $(T_c - T)^{1/3}$, with the result that our values for the critical density are much lower than those reported by other workers. The discrepancy is due, however, to the method of extrapolation, and not to experimental inaccuracy. The values for critical density which we now propose, based on the law of rectilinear diameter, agree very well with literature values[2].

Francis (6) has shown that the saturated density of the liquid phase (i.e. ρ_l under its own vapor pressure) as a function of t (temperature on the centigrade scale) can be expressed by the empirical equation

$$[1] \qquad \rho_l = A + Bt + C/(E - t)$$

In this equation, A is a constant, generally about 0.06 higher than the density at 20 °C; B is the slope coefficient, a little lower than the

[2]We are greatly indebted to Dr. D. Ambrose, of the Division of Chemical Standards, National Physical Laboratory, Teddington, England, who has processed our data for benzene. He says in a letter of July 25, 1968, "We have processed your values for benzene by our standard program to obtain the critical density from the law of rectilinear diameters, and to fit equations for the variation in $(\rho_l + \rho_v)$ and $(\rho_l - \rho_v)$ as power series in $(T_c - T)$ and $(T_c - T)^{1/3}$ respectively. From this we find your results give us a critical volume (*sic.* obviously density is intended) of 0.306 g/cc, in very close agreement with the values of Young and of Bender, Furukawa, and Hyndman. In fact, the agreement throughout the whole range of your experiments with those of Young is very good."

expansion coefficient at ordinary temperature; C is an integer, generally between 6 and 10; and E is a number generally 34° above the critical temperature. We evaluated the 4 constants, for all 4 liquids, with the aid of an IBM 360/65 computer, using a multiple regression method of analysis. The values of the constants, together with the multiple correlation coefficients, and the standard error of estimate, are given in Table III. Using these constants, we calculated the liquid densities for all our experimental points. The agreement is very good; the calculated liquid densities are within 0.0010 g/cc of the experimental values.

Waring (7) has suggested a criterion, which need not be dealt with here, for the suitability of the various vapor–pressure equations. Recently, Ambrose *et al.* (8) have chosen the equations of Cox (9), Cragoe (10), and Frost–Kalkwarf (11) as possibly the best. These are

[2] Cox $\log P = A(1 - (T_b/T))$

[3] Cragoe $\log P = A + BT + CT + DT^2$

[4] Frost–Kalkwarf
$$\log P = A + B/T + C \log T + DP/T^2$$

In addition to these equations, Ambrose *et al.* (8) have used a 7-constant equation to represent their vapor–pressure data, but they find that this equation is only slightly better than the Frost–Kalkwarf equation over the whole temperature range, except for the range $T_R = 0.95$ to 1.00 (T_R = reduced temperature), where the 7-constant equation gave a markedly better fit. We therefore chose to fit our data to the Frost–Kalkwarf equation. In this semi-theoretical equation, the slight reverse curvature in the plot of $\log P$ vs. $1/T$ is explained on the basis of the non-ideal behavior of the vapor, together with the change in the heat of vaporization with temperature. If it is assumed that ΔH is linear in T and that the van der Waals a/V^2 term is a first approximation to the deviation from ideality, the Frost–Kalkwarf equation is obtained by integration of the Clapeyron–Clausius equation. The constant D is related to the van der Waals "a" as follows

$$D = a/(2.303R^2)$$

According to Thodos (12)

$$a = 27R^2T_c^2/64P_c$$

so that

$$D = 27T_c^2/(64 \times 2.303P_c)$$

The remaining constants were obtained by multiple regression analysis. The statistical analysis of the coefficients is given in Table IV, which lists the values of the constants, the standard deviation in their estimation, the values of the multiple correlation coefficient, etc. We have calculated the vapor pressures corresponding to each experimental point. The agreement with the observed values is fairly good for benzene, acetone, and carbon tetrachloride. The chloroform results scatter, especially at high temperatures. This is probably due to decomposition of this compound near the critical temperature and, therefore, we have not attempted to fit the data for chloroform to either the Cox or Cragoe equations.

The constants[3] obtained are shown in Table V. As we stated in our previous communication (3), we used the van der Waals equation to obtain the equilibrium pressure in our air manometer. Thus, at a temperature 0.45° below the critical temperature of benzene, the van der Waals equation gave a pressure of 3636.7 cm Hg. Had we used the Beattie–Bridgman equation we should have obtained a value of 3651.2 cm Hg, while the experimental value of Bender, Furukawa, and Hyndman (14) is 3641.0. The discrepancy is about 0.3% and this is about the same as the discrepancies between the observed vapor pressures and those calculated by the Cox and by the Cragoe equations.

TABLE V

Constants obtained by fitting vapor pressure data for benzene and carbon tetrachloride to the Cox and the Cragoe equations

Constant	Benzene	Carbon tetrachloride
$\log A_c$*	0.6408	0.6475
E*	−0.2445	0.1719
T_b*	346.10	349.71

C†	+1.005633	−7.418258
D†	−6.508827	+5.463349

*Constant obtained for Cox equation (ref. 9).
†Constant obtained for Cragoe equation (ref. 10).

[3]We are indebted to Dr. J. F. Counsell (13) of the National Physical Laboratory, Teddington, for an analysis of our benzene and carbon tetrachloride data, using the equations of Cox and of Cragoe.

Chebyshev (15) has discussed the use of polynomials of an orthogonal system in the solution of the problem of the best approximation of continuous functions. Thus $T \log P$ can be fitted to an orthogonal series in T and the constants rearranged so that $T \log P$ is expressed as a Chebyshev series. It is then possible to write $T \log P$ as

$$T \log P = 1/2\, a_0 + a_1 c_1(x) + a_2 c_2(x) + \cdots$$

where a_0, a_1, a_2, $\cdots$ are constants and $c_1(x)$, $c_2(x), \cdots$ are Chebyshev polynomials. Truncation may occur wherever desired by the size of the residuals and smoothness of fit[4], and x is defined by

$$x = [2T - (T_{max} - T_{min})]/(T_{max} - T_{min})$$

We think, however, that these extensive tables are of no interest to the general reader; they can always be obtained directly from us. Klaus and Van Ness (16) have recently advocated the use of orthogonal polynomials for representing thermodynamic excess functions and, in view of this, we thought it worthwhile to mention their application to vapor pressure data, as suggested by Counsell, since vapor pressure is a property of pure liquids very often used to give other thermodynamic functions.

[4]Again, we are indebted to Dr. Counsell for carrying out the fits for the 4 compounds.

Semiconduction in charge-transfer complexes[1]

S. N. BHAT AND C. N. R. RAO[2]
Department of Chemistry, Indian Institute of Technology Kanpur, Kanpur, India

Received April 16, 1969

Electrical conductivities, electron spin resonance spectra, electronic spectra, and Seebeck coefficients of solid charge-transfer complexes of benzidine–iodine, *p*-phenylenediamine–iodine, and phenothiazine–iodine as well as two antimony chloride complexes of phenothiazine have been studied. The phenothiazine–I_2 system shows change in sign of the majority charge carriers with the donor–acceptor ratio. The effect of ambient gases on the conductivities of a few donors, acceptors, and their complexes in the solid state have been examined. Seebeck coefficient measurements show that the conduction in TCNQ salts takes place by a hopping mechanism.

Canadian Journal of Chemistry, 47, 3899 (1969)

Solid charge-transfer (c.t.) complexes, particularly those involving appreciable contribution from the dative structures, exhibit high conductivities and interesting magnetic properties (1). We have presently investigated semiconduction in the iodine complexes of *p*-phenylenediamine (PDA), benzidine (BZ), and phenothiazine (PTZ) as well as two antimony chloride complexes of phenothiazine. There is some evidence in the literature for the relatively high conductivities of these amine–iodine complexes (1) and for the formation of ion radicals in the antimony chloride complexes of PTZ (2). We were interested in comparing the activation energies for the conduction process in these complexes with the c.t. energies ($h\nu_{ct}$) from electronic absorption spectra and the spin activation energies (E_s) from temperature-dependent electron spin resonance (e.s.r.) spectra. Further, we were interested in finding whether the sign of the majority charge carriers varied with the donor–acceptor ratio. We have also examined the anisotropic conductivity and the sign of the majority carriers in single crystals of two salts of TCNQ.

Experimental

The organic compounds employed were of high purity and were further purified by crystallization and zone-refining. The conductivities of the complexes were measured as functions of temperature by employing a cell described earlier (3). The E_a ($= E_g/2$) values obtained from the relation

$$\sigma = \sigma_0 \exp(-E_a/kT)$$

were reproducible in the pressed pellets of charge-transfer complexes as well as in the single crystals of the TCNQ salts. The Seebeck coefficients, α, were measured employing a cell fabricated locally. E_s was obtained by measuring the spin concentration (from areas of e.s.r. signals) relative to DPPH at different temperatures. A Varian V-4502 e.s.r. spectrometer with 100 k.c. modulation was used for the purpose. Electronic absorption spectra were recorded employing a Cary 14 spectrophotometer by taking the samples as mulls (in Nujol) between quartz plates. Typical absorption spectra of a solid c.t. complex obtained in this manner are shown in Fig. 1.

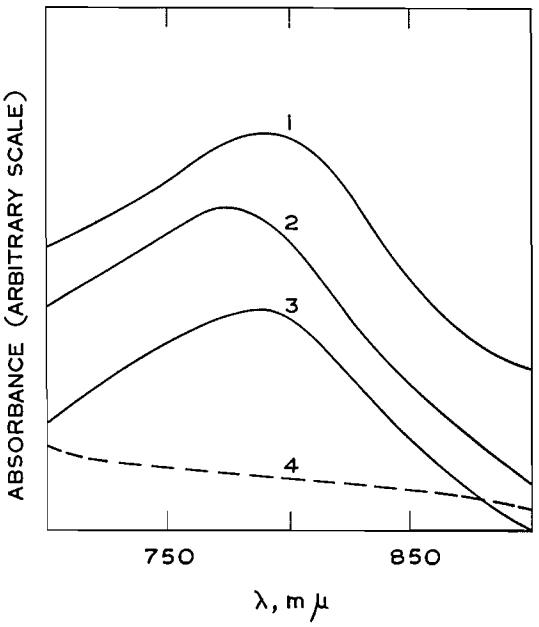

FIG. 1. Long wavelength absorption band of the PTZ–I_2 system in the solid state: curve 1, donor–acceptor ratio, 1.5:1; curve 2, 1:1; curve 3, 3:1; and curve 4, pure donor.

†Conductivity (a.c., 1 k.c.) and E_a values are nearly the same as expected of electronic semiconductors.
‡E_s may be taken as zero.
§These values are for absorption maxima and the values in parenthesis correspond to the absorption edges.

Results and Discussion

All the solid c.t. complexes showed e.s.r. signals. The signal intensities of PDA–I_2 (g = 2.0111), BZ–I_2 (g = 2.0123), and PTZ–$SbCl_4$ (g = 2.0054) increased with increase in temperature. This may be taken to indicate the presence of ground-singlet and excited-triplet states; the E_s values for these complexes are shown in Table I. PTZ–I_2 (g_{ave} = 2.005) and PTZ–$SbCl_5$ (g_{ave} = 2.005), however, showed Curie law behavior typical of two independent doublet states (Fig. 2); the interesting doublet structure (Fig. 2) could arise from g-factor anisotropy. Both these PTZ complexes had very high spin concentrations (of about 85% at 25 °C).

The conductivity data of the complexes are summarized in Table I. The data are in general agreement with some of the literature reports (1). Among the I_2 complexes, the highest conductivity and the lowest E_a values are found in PTZ–I_2, probably because of the formation of the radical cation with large polarizability. The E_a (as well as E_s) is generally lowest when the donor–acceptor ratio is close to 1:1, even though one would expect them to be lowest in the presence of neutral molecules. E_a is higher than E_s in all the systems including PTZ–$SbCl_5$ and PTZ–I_2 where e.s.r. and magnetic measurements (1, 2) show the concentration of the radical ion to be about 85%. This is because E_s reflects only the formation of the charge carriers while E_a mainly depends upon the mode of transport of charge carriers; ($E_a - E_s$) may be taken as the energy required for the separation of the charge carriers (4).

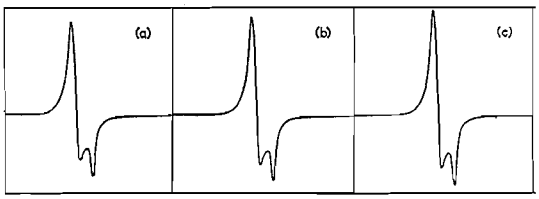

FIG. 2. Electron spin resonance spectra of a powder sample of PTZ–I_2 at different temperatures showing behavior of two independent doublet states: (*a*) 20 °C (*b*) 0 °C, and (*c*) −20 °C.

Thermoelectric power measurements indicate that the majority charge carriers in PDA–I_2 and BZ–I_2 are positive holes, independent of the donor–acceptor ratio. In PTZ–I_2, however, the sign of the majority carriers varies with the donor–acceptor ratio, a phenomenon which has been reported only in one other c.t. system (perylene–$FeCl_3$) hitherto (1). The variation of the sign of the majority carriers can be understood in terms of the proposal of Kearns (as quoted in ref. 1, pp. 470–471) according to which the positive charge moves through the crystal by electron transfer from adjacent neutral donor molecules, while the negative charges become mobile due to electron transfer from negative to neutral acceptors. The hole and electron mobilities calculated from the data on α and σ are in the range 6×10^{-5} to 7×10^{1} cm^2 V^{-1} s^{-1} and the

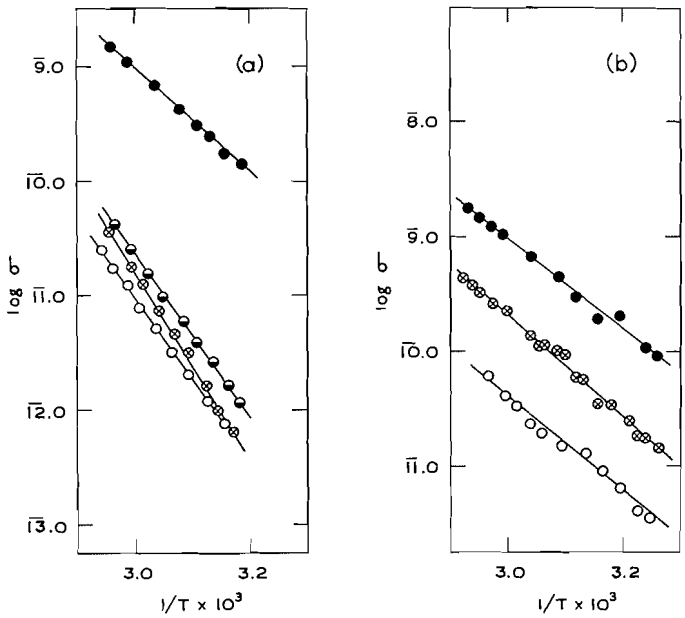

FIG. 3. Effect of ambient gases on the electrical conductivity of solid charge-transfer complexes: (*a*) anthracene–TCNE, (*b*) anthracene – tropylium bromide. Dry oxygen (open circles), moist oxygen, $p_{H_2O} \approx 18$ mm Hg (half-shaded circles), vacuum (crossed circles), ammonia (fully shaded circles).

carrier concentrations are in the range 10^{10} to 10^{18} cm^{-3}.

The energies corresponding to the absorption maxima as well as the edges of the lowest energy bands in the electronic absorption spectra (Table I) are appreciably higher than the E_a values. It appears that E_a for the conduction process is comparable to $h\nu_{ct}$ or E_s only in the case of the weak c.t. complexes (5, 6).

The conductivities of a few c.t. complexes as well as their component donors and acceptors were measured in vacuum and in ambient atmospheres of O_2 and NH_3. Compared to the data in vacuum, the conductivity of the donor, PDA, increases (from 4.0×10^{-13} to 8.7×10^{-13} Ω^{-1} cm^{-1} at 50 °C) in the presence of O_2 which is an acceptor; E_a decreases from 1.21 to 1.15 eV. Similarly, the conductivity of acceptors like tropylium bromide increases (from 4.0×10^{-9} to 9.0×10^{-8} Ω^{-1} cm^{-1} at 50 °C) and E_a decreases (from 1.19 to 1.10 eV) in the presence of NH_3 which acts as a donor. The effect of ambient gases on the conductivities of the c.t. complexes was significant only if the gas was a better donor or an acceptor than the corresponding component in the complex. Thus, the conductivity of anthracene–TCNE (3.0×10^{-12} Ω^{-1} cm^{-1} at 50 °C; E_a, 0.67 eV) or anthracene – tropylium bromide (9.0×10^{-11} Ω^{-1} cm^{-1} at 50 °C; E_a, 0.39 eV) is not affected much in the presence of oxygen, but increases in an atmosphere of NH_3 (3.6×10^{-10} Ω^{-1} cm^{-1} and 3.8×10^{-10} Ω^{-1} cm^{-1}, respectively, for the above systems) as shown in Fig. 3; the E_a values for these two systems were 0.55 and 0.36 eV, respectively, in an ammonia atmosphere.

We have measured the anisotropic conductivities and Seebeck coefficients in single crystals of two salts of TCNQ employing techniques similar to those reported earlier (7, 8). Triethylammonium $(TCNQ)_2$ showed anisotropic conduction with σ values of 3.0, 0.04, and 0.0008 Ω^{-1} cm^{-1} at 25 °C along the *a*, *b*, and *c* axes, respectively; the E_a values along the three axes were 0.15, 0.14, and 0.15 eV, respectively. The absence of anisotropy in the activation energy is indeed surprising, as noted by earlier workers (7). The quinolinium $(TCNQ)_2$ showed σ values of 10^2 and 10^{-2} Ω^{-1} cm^{-1} along two axes with E_a values of 0.02 and 0.04 eV, respectively; it is difficult to consider these observed changes in E_a as due to anisotropy since the

magnitudes are rather small. The α value of the triethylammonium salt was negative (−250 μv/deg) and remained constant with temperature (from −78 to 50 °C); this may indicate that the transport of charge carriers is by the hopping mechanism (9).

Spectral reflectance studies of some metal chelates in the adsorbed state[1]

R. W. FREI
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

AND

H. ZEITLIN
Department of Chemistry, University of Hawaii, Honolulu, Hawaii

Received February 5, 1969

Adsorption phenomena of a group of metal chelates of pyridine-2-aldehyde-2-quinolylhydrazone (PAQH) have been investigated. Formulas have been postulated for the chelates on the basis of ultraviolet and visible transmittance and reflectance spectra, ion exchange studies of charges, and chromatographic and temperature behavior. Shifts of spectra with varying adsorbents have been explained on the basis of the electronic polarization theory. Unusual behavior of the chelates has been observed on starch and cellulose and the existence of mixed ligand species due to interaction of adsorbents with the chelates has been suggested.

Canadian Journal of Chemistry, 47, 3902 (1969)

Pyridine - 2 - aldehyde - 2 - quinolylhydrazone (PAQH) has been used successfully for the colorimetric analysis of traces of various transition metals (1–4). PAQH has also shown considerable promise as a spraying reagent for cobalt, nickel, and copper following chromatographic separation of the cations (5, 6). The chromatographic properties of PAQH complexes have been investigated for use in trace metal analysis (7). In this paper, ultraviolet and visible reflectance spectroscopy is used to investigate the adsorption properties of these complexes on a group of important chromatographic adsorbents. Suggestions are made as to the possible composition of the compounds in the adsorbed state. The present study is not intended as an exhaustive structural investigation but it is hoped that it will enhance the applicability of the existing analytical methods which make use of PAQH.

[1]Presented at the 5th Caribbean Chemical Conference, Barbados, January 1969.

Experimental

The stock solutions of the cations (1 g/l) were prepared from reagent grade chemicals. PAQH was prepared as described previously (1) and dissolved in 95% ethanol (0.03% wt./vol). Doubly distilled water was used throughout. Thin layer chromatographic grades of alumina and silica gel (H. Merck) and cellulose (Macherey Nagel) were used. The starch, alkaline earth, and alkaline metal carbonates were reagent grade. Solvents used for chromatographic purification, ion exchange studies, and extraction were reagent grade. Amberlite ion exchange resins type IR–120, IRC–50, IR–45 were used for investigation of complex charges.

Transmittance and reflectance spectra were recorded with Beckman DK-2 and Spectronic 505 recording spectrophotometers equipped with standard reflectance attachments. For ultraviolet reflectance measurements

windowless cells (8) and, in the visible region, glass covered cells (9) were employed.

The complexes were prepared and extracted according to a previous communication. Chromatographic purification was carried out on a column packed with Woelm alumina, chromatography grade (neutral), with chloroform as the eluant, or directly on alumina or silica gel thin-plates. Transmittance measurements were made from ethanolic solutions of the metal chelates. The adsorbents were sieved through 200 mesh screens. Drying procedures, after application of samples on the adsorbent with micropipettes, were carried out at 110 °C for controlled time periods (usually 5 min). The samples, ranging from 20 to 60 mg and containing between 1–5 μg of metal ion, were mixed thoroughly in a small agate mortar, equilibriated in an air-conditioned room of controlled humidity and packed in the appropriate cells. For a study of the effect of temperature, the same samples were heated at 110 °C for various periods of time ranging from 5 min to 2 h and the spectra recorded immediately.

Results and Discussion

In an earlier paper (7) it was reported that chromatographic separation of these chelates occurred in the order of R_f-values on alumina layers

$$Co^{3+},0.00 < Fe^{2+},0.05 < Cu^{2+},0.07 < Ni^{2+},0.35 < Fe^{3+},0.82$$

Decomposition of the adsorbed chelates at high temperature follows a similar pattern, with the cobalt chelate showing the highest temperature stability and the iron(III) complex decomposing irreversibly at 180 °C after 1.5 h.

Since the chelates have been separated on regenerated alumina layers with chloroform as a single phase developing system, the separation mechanism is believed to be primarily based on adsorption chromatography. Accordingly, the degree of adsorption would be greatest in the case of the cobalt complex and least for the iron(III) chelate. It is believed that the variation in degree of chelate–adsorbent interaction of the compounds studied, based on current and previous observations on the nature of metal chelates, is a function of charge and relative polarities.

From previous work (10) and the present ion exchange studies, the following structures for the analytically important complexes can be postulated with some certainty: $[(Co(III)\text{-}(PAQH)_2)]^+$ Anion, $Ni(II)(PAQH)_2$, $Cu(II)(PAQH)_2$, and $Fe(II)(PAQH)_2$.

The strong retention and interaction of the cobalt species on the adsorbent (R_f-value of zero)

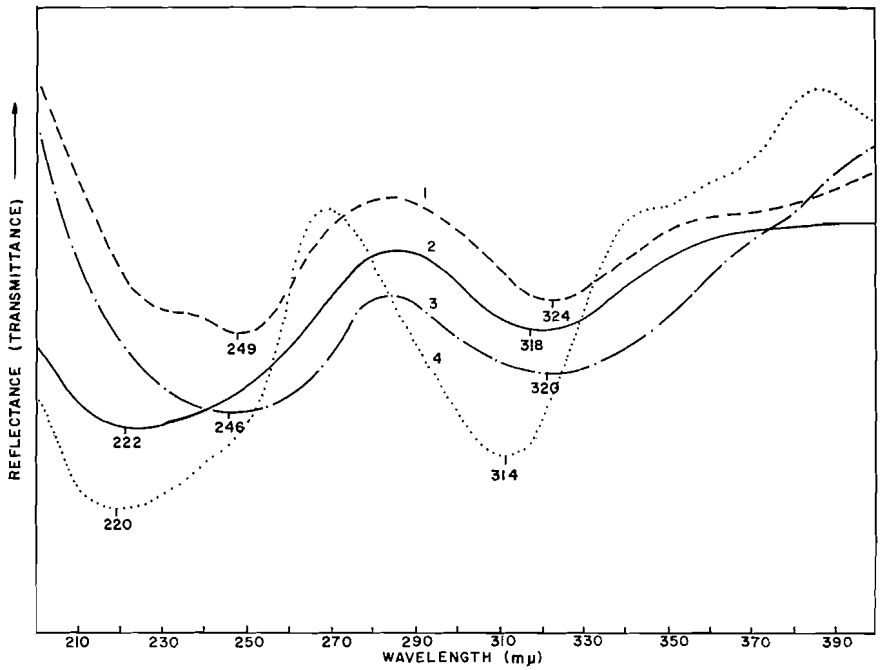

FIG. 2. Ultraviolet reflectance spectra of (1), Co chelate and (3), Ni chelate adsorbed on alumina; (2), Ni chelate adsorbed on silica gel; (4), transmittance spectrum of Ni chelate in ethanol.

in comparison to the other chelates (which were found to be neutral) can, therefore, be explained satisfactorily on the basis of its charge. It may well be possible that the anion for the above complex is provided by an active site on the adsorbent.

Both 1:1 and 2:1 (reagent-to-metal) complexes of nickel and copper were found in solution and adsorbed on silica gel, depending on ligand concentration and pH (5). Only the 2:1 species were investigated. The formation constants of these chelates as determined from Bjerrum plots were reported for copper chelate ($\log K_1 = 11.60$) and for nickel chelate ($\log K_1 = 10.46$) (1). The difference in complex stability may account for the apparent difference in polarity (as determined from chromatographic data) for the two compounds, which otherwise have similar magnetic and structural properties.

The green Fe(III) complex formed in basic solution was also investigated by ion exchange and found to be neutral. It is concluded that there is evidence for at least a 3:1 reagent-to-metal species. On the ultraviolet spectrum (Fig. 1) an absorption maximum can be seen at 390 mμ for the iron(III) chelate (Fig. 1). This is close to the maximum for the free reagent (Fig. 1) at 363 mμ and is unique to the iron complex, suggesting that at least one ligand is only loosely attached to the complex species. The additional maxima at 212 and 311 mμ occur in the vicinity of maxima of the other metal chelates and suggest some bonding between Fe(III) and PAQH to be similar to that with the other metals. The high R_f-value (higher than for the free reagent) and the low decomposition temperature (7), and hence stability, suggest an unusual complex formation.

Upon adsorption of the metal chelates on adsorbents of varying polarity or activity, regular shifts are observed (Fig. 2 and Table I).

The polarizing effects of various adsorbents was further investigated by adsorbing the chelates on several carbonates. Bathochromic shifts in the order

$$BaCO_3 > SrCO_3 > CaCO_3 > MgCO_3$$

and

$$K_2CO_3 > Na_2CO_3 > Li_2CO_3$$

were observed for all four chelates. Similar observations have been made for nitrophenols and nitroanilines adsorbed on alkaline metal carbonates (11, 12) and on alkaline earth oxides and

Cu complex	478	483	498	509	508
Co complex	494	500	522	530	530

carbonates (13, 14). The shifts can be interpreted partially in terms of the electronic polarization theory. When the alkaline earths or alkaline metals are arranged in the order of increasing cationic size, i.e. Mg to Ba, or Li to K, the effective nuclear charge decreases due to increased screening by additional electron levels. The cation in the crystal lattice of the adsorbent exerts a polarizing action on the chelate, followed by a chemisorptive process similar to a Lewis acid–base type interaction. The polarization on the π-bond system of the chelate should then increase in the order

$$Ba^{2+} < Sr^{2+} < Ca^{2+} < Mg^{2+}$$

or

$$K^{+} < Na^{+} < Li^{+}.$$

Partial freezing or localization of the electron cloud of the chelate would render electronic excitation more difficult and thereby account for the shift of absorption maxima toward the more energetic shorter wavelength.

The resolution in reflectance spectroscopy is poorer, both because larger slitwidths have to be used to get sufficient radiation energy and because of the light scattering effect. As an illustration, the double peak at 224/248 mμ observed in the cobalt chelate transmission spectrum (Fig. 1) is barely noticeable in the reflectance spectrum (Fig. 2).

In accordance with previous studies (5), a reversible bathochromic shift was observed upon heating of the adsorbent–adsorbate system at 110 °C for various periods of time. Partial or complete removal of co-adsorbed water, which competes for the adsorption sites, is believed to be the reason for this phenomenon. When water covers a large portion or all of the first monomolecular layer (zone of chemisorption), the chelate–adsorbent system comes closer to an aqueous solution. The attractive forces exerted on the chelate may consist primarily of van der Waals forces or bonding between the water layer and the complex, similar to conditions in solution. This would explain the shift of maxima to lower wavelengths upon increased saturation of the adsorbent with moist air.

Surprisingly large bathochromic shifts are observed on cellulose and starch (see Table I). At the equilibrium condition with air humidity, these two chromatographic adsorbents would be classified as relatively weak (11) and one would expect maxima to appear near or below those observed on silica gel. Previous studies (5) have shown that the nickel or copper species observed on cellulose are probably identical to the 1:1 chelates. If the brownish bis-chelates are applied to a cellulose or starch layer, their change to the red 1:1 configuration can be observed visually to occur within a few seconds. According to this observation the cellulose– or starch–water complex may be blocking some of the coordination sites of the metal and hence permitting only one PAQH ligand to react. The existance of a mixed ligand complex, for example of the formula

$$[Ni(PAQH)\text{–}Cellulose:(H_2O)_x]$$

with unknown charge is, therefore, suggested as a possibility.

Dual interaction of anisole with surface hydroxyls

M. J. D. LOW AND J. A. CUSUMANO
Department of Chemistry, New York University, New York, N.Y. 10453

Received March 31, 1969

Infrared spectra were recorded of anisole adsorbed on porous glass which had been dehydroxylated to various extents, on highly dehydroxylated silica, and on fully fluoridated porous glass. Spectra recorded at various surface coverages showed 2 broad bands near 3600 and 3400 cm^{-1} due to perturbed surface hydroxyls, indicating that the adsorbed anisole was weakly held to the surface in 2 ways. The surface structures and mechanism are discussed.

Canadian Journal of Chemistry, **47**, 3906 (1969)

The adsorption of molecules on hydroxylated surfaces generally leads to an easily observed perturbation of the stretching fundamental of the surface hydroxyl. The effects are small with simple, nonpolar adsorbates and may involve only a small shift to lower wavenumbers and a slight diminution, broadening, and "tailing" of the hydroxyl band. Interaction of the hydroxyls with the π systems of adsorbed aromatics brings about somewhat larger changes, and can cause a broad shoulder or a distinct band approximately 100–160 cm^{-1} below the position of the bank of "free" hydroxyls. The most pronounced changes of the spectrum, including the formation of a broad and frequently intense band approximately 300–500 cm^{-1} below the hydroxyl band, are caused by molecules capable of hydrogen-bonding to the hydroxyls through the lone electron pairs of atoms such as oxygen or nitrogen. The various aspects of such adsorbate–hydroxyl interactions have been extensively reviewed by Little and in supplementary chapters by Kiselev and Lygin (1).

Complex adsorbates have also been of interest. The adsorption of benzene derivatives such as aniline or phenol, which have an atom with a lone electron pair, led to the large changes caused by hydrogen bonding via the lone electron pairs; but the effects produced by nitrobenzene, which does not have a lone electron pair on its nitrogen atom, were smaller than those of the π-OH interaction. In general, the observations made so far indicate that the "strongest" mechanism predominated, so that a substituted benzene would interact with the hydroxyls in one of two ways. Dual binding does not seem to have been considered. We have found, however, that two clearly distinguishable perturbations were produced when anisole was adsorbed on hydroxylated surfaces.

Experimental

The adsorbents used were Cab-O-Sil silica[1], porous glass[2], and fully fluoridated porous glass (2). The porous glass was used for most of the work because of the ease of preparing and handling of the samples. Porous glass specimens were subjected to the following treatment: (*a*) a specimen was alternately degassed at 700° and hydrated, 7 or 8 times, (*b*) heated in 100 Torr oxygen at 600° for 4 h, (*c*) exposed to 4 Torr water vapor at 25° for 45 min, and (*d*) degassed at 250, 500, or 750° for 12 h. Samples hydroxylated to various extents could be prepared reproducibly by means of these steps. C.P. anisole was subjected to freeze–thaw cycles and was distilled in vacuo. Some minor experimental details are given elsewhere (2). Spectra were recorded with a Perkin–Elmer model 621 spectrometer.

Dual interaction of anisole with surface hydroxyls

M. J. D. LOW AND J. A. CUSUMANO
Department of Chemistry, New York University, New York, N.Y. 10453

Received March 31, 1969

Infrared spectra were recorded of anisole adsorbed on porous glass which had been dehydroxylated to various extents, on highly dehydroxylated silica, and on fully fluoridated porous glass. Spectra recorded at various surface coverages showed 2 broad bands near 3600 and 3400 cm^{-1} due to perturbed surface hydroxyls, indicating that the adsorbed anisole was weakly held to the surface in 2 ways. The surface structures and mechanism are discussed.

Canadian Journal of Chemistry, **47**, 3906 (1969)

The adsorption of molecules on hydroxylated surfaces generally leads to an easily observed perturbation of the stretching fundamental of the surface hydroxyl. The effects are small with simple, nonpolar adsorbates and may involve only a small shift to lower wavenumbers and a slight diminution, broadening, and "tailing" of the hydroxyl band. Interaction of the hydroxyls with the π systems of adsorbed aromatics brings about somewhat larger changes, and can cause a broad shoulder or a distinct band approximately 100–160 cm^{-1} below the position of the bank of "free" hydroxyls. The most pronounced changes of the spectrum, including the formation of a broad and frequently intense band approximately 300–500 cm^{-1} below the hydroxyl band, are caused by molecules capable of hydrogen-bonding to the hydroxyls through the lone electron pairs of atoms such as oxygen or nitrogen. The various aspects of such adsorbate–hydroxyl interactions have been extensively reviewed by Little and in supplementary chapters by Kiselev and Lygin (1).

Complex adsorbates have also been of interest. The adsorption of benzene derivatives such as aniline or phenol, which have an atom with a lone electron pair, led to the large changes caused by hydrogen bonding via the lone electron pairs; but the effects produced by nitrobenzene, which does not have a lone electron pair on its nitrogen atom, were smaller than those of the π-OH interaction. In general, the observations made so far indicate that the "strongest" mechanism predominated, so that a substituted benzene would interact with the hydroxyls in one of two ways. Dual binding does not seem to have been considered. We have found, however, that two clearly distinguishable perturbations were produced when anisole was adsorbed on hydroxylated surfaces.

Experimental

The adsorbents used were Cab-O-Sil silica[1], porous glass[2], and fully fluoridated porous glass (2). The porous glass was used for most of the work because of the ease of preparing and handling of the samples. Porous glass specimens were subjected to the following treatment: (*a*) a specimen was alternately degassed at 700° and hydrated, 7 or 8 times, (*b*) heated in 100 Torr oxygen at 600° for 4 h, (*c*) exposed to 4 Torr water vapor at 25° for 45 min, and (*d*) degassed at 250, 500, or 750° for 12 h. Samples hydroxylated to various extents could be prepared reproducibly by means of these steps. C.P. anisole was subjected to freeze–thaw cycles and was distilled in vacuo. Some minor experimental details are given elsewhere (2). Spectra were recorded with a Perkin–Elmer model 621 spectrometer.

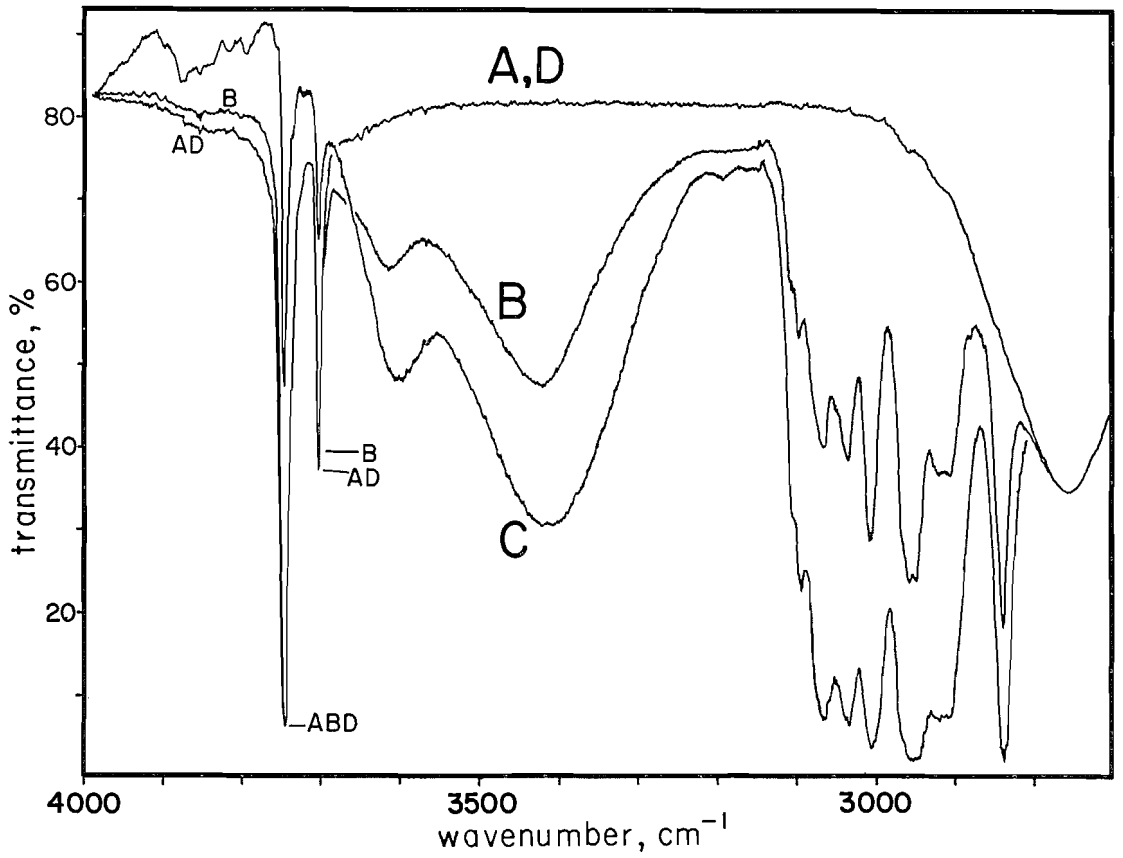

FIG. 1. Infrared spectra of anisole on porous glass. A, clean surface, after 750° degassing; B, 0.5 Torr anisole; C, 2 Torr anisole; D, after 25° degassing.

Results

Porous glass specimens prepared and finally degassed at 250, 500, or 750° were exposed to anisole vapor at 25° at relative pressures, p/p_0, ranging from 0.01 to 0.44. The various results, in part illustrated by Fig. 1, can be summarized as follows.

(*a*) When anisole became adsorbed, a group of 10 absorptions was observed in the C—H region, initially at positions $\sim$ 3 to 5 cm^{-1} higher than the corresponding absorptions of liquid anisole. The absorptions increased in concert with increasing anisole pressure and shifted by 2 to 3 cm^{-1} toward the positions of the bands of the liquid at 3102, 3094, 3063, 3033, 3004, 2957, 2947, 2925, 2907, and 2838 cm^{-1}. Some additional bands were observed near 2912, 2550, 2495, and 2283 cm^{-1} at the highest pressures.

(*b*) The 3747 cm^{-1} Si—OH and 3703 cm^{-1} B—OH bands (3) declined in intensity, retaining their intensity ratio, and shifted to 3746 and 3702 cm^{-1} with increasing anisole coverage.

(*c*) Two broad bands initially observed near 3625 and 3440 cm^{-1} at $p/p_0 \sim 0.01$ shifted to 3612 and 3422 cm^{-1} at $p/p_0 = 0.11$, and then shifted to near 3602 and 3407 cm^{-1} when p/p_0 was increased from 0.32 to 0.44. These will be termed the 3600 and 3400 cm^{-1} bands.

(*d*) Changes in the background transmittance in the O—H region make it difficult to assess precisely the changes in the intensities of all bands. However, measurements of the optical densities and integrated band intensities, I, made it clear that the ratio I_{3600}/I_{3400} of the two broad bands increased with increasing coverage. (I values were estimated using the base-line method, by drawing a tangent to the transmission curve for each band. The area of each segment was then measured with a planimeter.)

(*e*) Increasing the degassing temperature (and

For personal use only.

consequently increasing the degree of dehydroxylation) caused a decrease in the amount of anisole adsorbed at a particular p/p_0 value, a decline in I_{3600} and I_{3400}, but I_{3600}/I_{3400} was not changed. Conversely, the Si—OH and B—OH band intensities decreased to a greater extent with increasing p/p_0 with highly degassed than with poorly degassed samples. Prior to adsorption, the OH bands of the highly degassed 750° specimens were sharp, e.g., spectrum A of Fig. 1, but those of specimens degassed at lower temperatures exhibited the "tailing" on the low wave number side of the OH bands, which is characteristic of the presence of hydrogen-bonded hydroxyls.

(*f*) The adsorption and the effects produced by it were completely reversible.

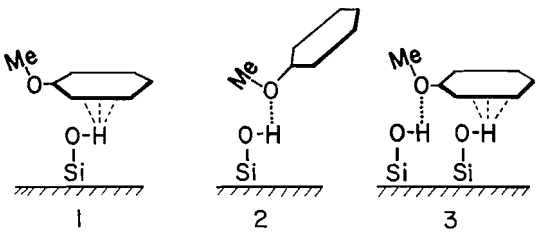
A small number of experiments were carried out with Cab-O-Sil, anisole adsorption also causing the 3600 and 3400 cm^{-1} bands to appear. In general, the effects observed with the pure silica were like those found with porous glass except, of course, that the B—OH band was not present. The interaction of anisole with fluoridated glass was only briefly studied because the amounts adsorbed were quite small. In distinct contrast to porous glass, e.g., spectrum B of Fig. 1, exposing a fluoridated porous glass specimen to anisole at 25° at $p/p_0 = 0.11$ caused the transmittance in the C—H region to decrease by only 3–4%.

Discussion

The observations on the small shift of the C—H bands, reversibility, perturbation of free OH bands, and the greatly decreased adsorption in the absence of hydroxyls plainly indicate that anisole was adsorbed in a molecular form and was weakly held to the surfaces by interactions with OH groups. The formation of two "perturbed hydroxyl bands" is of greater interest.

The 3600 and 3400 cm^{-1} bands, respectively shifted by approximately 150 and 350 cm^{-1} from the position of the band of free silanols, were observed with pure silica as well as with porous glass. Possible effects of B—OH groups can therefore be discounted. The behavior of the hydroxyl bands and of each of the broad bands (which are not found in the spectrum of liquid anisole) is like that found in many instances involving adsorbate–OH interactions. Also, the 150 cm^{-1} shift of the 3600 cm^{-1} band falls well within the range of shifts found with benzene and substituted benzenes not having an atom with a lone electron pair. The 350 cm^{-1} shift of the 3400 cm^{-1} band, while differing somewhat from the 450 cm^{-1} shift produced by diethyl ether, falls in the range found for substituted benzenes and other molecules having an atom with a free lone electron pair. In view of such similarities (1, and supplementary chapters), it is reasonable to assign the 3600 cm^{-1} band to hydroxyls perturbed by a π–OH interaction such as the one shown in structure **1**, and the 3400 cm^{-1} band to hydroxyls perturbed by hydrogen bonding as shown in structure **2**.

The larger increase of the 3600 cm^{-1} than the 3400 cm^{-1} band with increasing adsorption then implies the occurrence of a change in the structure of the adsorbed layer, the π–OH interaction becoming less important at higher coverages. Also, as the intensities of the sharp OH bands were diminished to a greater extent at higher degrees of dehydroxylation, it appears that both bonding modes occurred preferentially with OH groups which had already been perturbed by hydrogen bonding.



1 2 3

Although both broad bands were always observed even at the lowest coverages, it is not possible to use individual spectra to establish if both types of bonding occurred simultaneously as in structure **3**. However, the observed relations of increasing band shift with increasing differential heat of adsorption (1) indicate that the bonding of **1** would be weaker than that of **2**. The observed change in I_{3600}/I_{3400} indicates an increase in the relative number of structures **2** at higher pressures. If only structures **1** and **2** existed, this would imply an increase in the heat of adsorption with increasing coverage, in contrast to the *decrease* in the heat of adsorption reported for the adsorption of several substituted benzenes on hydroxylated surfaces (supplementary chapter in ref. 1). This apparent discrepancy, which rests on the reasonable assumption that the physical adsorption of anisole and

other similar molecules would show similar energetic trends, is removed by postulating that the doubly bound structure **3** would form preferentially to **1**.

These considerations suggest that the adsorbed layer consisted of a mixture of structures. At the lowest coverages a large fraction of the molecules would be "flat" on the surface; e.g., structure **3**. As the coverage was increased, additional adsorbed molecules would stand "on end", e.g., structure **2**, and some **3** would be converted to **2**.

The mechanism is of interest per se, but the steric and energetic changes implied by it would also be important to theoretical studies attempting to relate various adsorption parameters. Although two distinct bands were observed and the existence of two surface species is reasonably clear in the present case, severe overlapping of bands may not make it possible to recognize such effects with other adsorbates, so that changes in adsorption heats and shifts with increasing coverage should be approached with caution.

Investigations of copper(II) complexes of bispyridylglycol and 6,6′-dimethyl bispyridylglycol

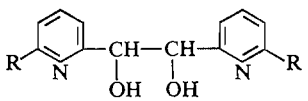
G. S. MANKU, R. D. GUPTA, A. N. BHAT, AND B. D. JAIN
Department of Chemistry, University of Delhi, Delhi-7, India

Received January 21, 1969

The formation of a greenish blue 1:1 metal:ligand chelate at pH 5–7 and a faint violet 1:1:1 metal:ligand:hydroxyl chelate at pH > 10 has been observed in Cu(II) complexes with bis-2-pyridylglycol and its 6,6′-dimethyl derivative using spectrophotometric, conductometric, and pH-metric methods.

Canadian Journal of Chemistry, **47**, 3909 (1969)

Bis-2-pyridylglycol (**1**) (BPG) has already been used as a gravimetric reagent (1) for aluminum(III), beryllium(II), and uranium(VI) and as a spectrophotometric reagent for iron(III) (2) and cobalt(II) (3). The present note deals with the studies of copper(II) complexes of BPG and its 6,6′-dimethyl derivative (**2**) (DMBPG) using spectrophotometric, conductometric, and pH-metric methods. With both these ligands, the formation of a greenish blue 1:1 metal:ligand complex at pH 5–7 and a faint violet 1:1:1 metal:ligand:hydroxyl complex at pH > 10 is indicated.



1 R = H
2 R = CH_3

Experimental

Chemicals and Instruments

BPG and DMBPG, obtained from F. Raschig, GmbH, Ludwigschafen, were used in aqueous solutions without further purification. Copper(II) solution, prepared from $CuSO_4 \cdot 5H_2O$ (Analar BDH), was standardized as sulfocyanide. Other chemicals used were of Analyzed Reagent grade. pH of the solutions was adjusted with sulfuric acid and sodium hydroxide. Carbonate-free sodium hydroxide used for pH-metric titrations was standardized with potassium hydrogen phthalate.

A Beckman pH meter Model H-2 with glass electrode, Unicam Spectrophotometer Model SP600 with 1 cm cells, and Leeds and Northrup drum-type conductometer were used for all the pH, absorbance, and conductance measurements, respectively.

Results and Discussion

absorption maximum at 600–620 and at 660–680 mμ, respectively, within the pH range 3.7–12.7. From Fig. 1, it is observed that the absorbance of the solutions containing a copper(II):ligand ratio of 1:5 remains constant in the pH ranges 4.0–6.3 and >9.3 for BPG and in the pH ranges 7.0–7.5 and >10.6 for DMBPG complexes. Furthermore, the color of the solution is greenish blue at lower pH and faint violet at higher pH for both ligands, thus indicating the formation of different complexes at different pH values.

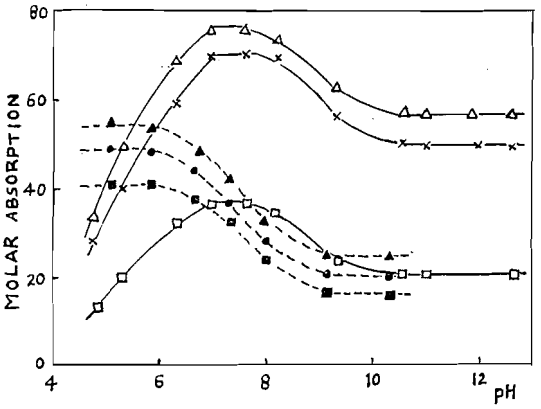

FIG. 1. Effect of pH on the absorbance of copper(II)–BPG (---) and copper(II)–DMBPG (—) complexes containing 2.5 m*M* copper(II) and 12.5 m*M* BPG/DMBPG. Wavelength (in mμ) for △, ▲, 620; ●, 700; ■, 725; ×, 750; and □, 900.

Molar Composition

The metal:ligand ratio in these complexes was determined spectrophotometrically by the modified method of continuous variations (4) as well as by the slope ratio method (5). Between 600–800 mμ, the formation of the 1:1 complex only was observed at pH 7.0 and 11.0 for BPG and 7.2 and 11.2 for DMBPG complexes. The precipitation of copper(II) during these studies was prevented by the addition of tartrate ions, as no mixed-ligand complexes could be detected spectrophotometrically in the ternary system copper(II)–tartrate–BPG or –DMBPG.

The metal:ligand ratio in the greenish blue complex, determined by the conductometric titrations of 20 ml of 2.5 m*M* copper(II) and 2 m*M* ligand solutions against ligand and copper(II), respectively, was also found to be 1:1, thus confirming the above results.

Determination of the Stability Constants

Table I shows the acid and base dissociation constants of these ligands ($R(OH)_2$ being the unionized and unprotonated reagent) which were determined pH-metrically (ref. 6. p. 158); both BPG and DMBPG contain two basic nitrogen atoms and two ionizable hydroxyl groups.

The pH-titration of the reagents against sodium hydroxide, in the absence as well as in the presence of copper(II) ions, showed that when copper (II) ions are present, the pH of the solution is lowered as a result of liberation of two protons per copper(II) ion. Thus chelation with both of the ionized hydroxyl groups of the ligands is indicated, since the metal:ligand ratio in these complexes is 1:1.

The stability constant of the greenish blue chelate (K_{11}) was determined spectrophotometrically using (*i*) Harvey and Manning's method of calculation of degree of complex formation (5), (*ii*) Foley and Anderson's method of preparing solutions having equal absorbance (7) and (*iii*) from Bjerrum's formation curves (8) (Fig. 2) from the intercepts of linear plots of log $[\bar{n}/(1-\bar{n})]$ against log [L] (ref. 6. p. 86) ($\bar{n}$ = average ligand number, [L] = equilibrium concentration of

TABLE II

The stability constants (K_{11}) of the copper(II) complexes with BPG and DMBPG in aqueous medium at 30 °C.

Method used	log K_{11} Cu–BPG	log K_{11} Cu–DMBPG
Degree of complex formation (5)	12.1±0.1	11.6±0.1
Solutions having equal absorbance (7)	12.0±0.1	11.6±0.1
Formation curves obtained spectrophotometrically (8)	12.0±0.1	11.5±0.1
Formation curves obtained by pH-metric titrations (6)	12.1±0.1	11.5±0.1

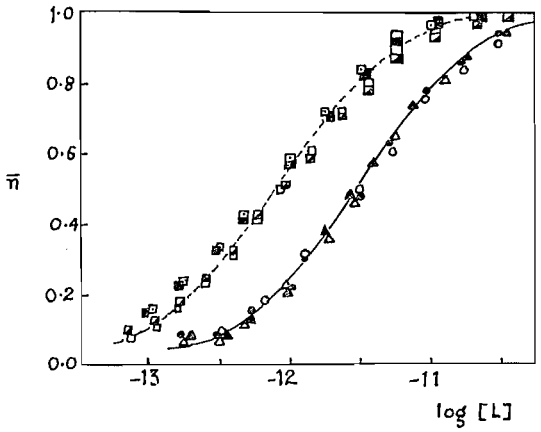

FIG. 2. Bjerrum's formation curves for copper(II)–BPG (---) and copper(II)–DMBPG (—) complexes. Points from spectrophotometric measurements are ⊡ and △ at 640 mμ, and □ and ▲ at 720 mμ (concentration: copper(II), 1.0 mM; reagent, 2 mM). For pH-metric titrations, concentration of reagents = 3 mM; copper, for ◪ and ○, 0.75 mM; for ◙ and ●, 1.5 mM.

ligand present as RO_2^{2-} anion) as well as from the formation curves obtained pH-metrically (9) using Calvin–Wilson's technique (10). The results obtained are given in Table II. The log K_{11} values as determined above were found to be constant (within ± 0.1 units) when copper(II) and the ligand concentrations were varied within 2–20 mM, indicating the absence of polynuclear complexes within the concentration ranges employed.

Since the metal:ligand ratio in the faint violet complex formed at high pH was 1:1, we only considered the formation of polynuclear as well as hydroxy complexes. The degree of formation of the faint violet complex, determined spectrophotometrically at different pH values using copper(II) and reagent of 2–20 mM concentration, was found to be independent of the concentration of ligand or metal at constant pH value, thus indicating the absence of a higher or polynuclear complex, but not excluding possible formation of hydroxy complexes (Fig. 3). Since both BPG as well as DMBPG are tetradentates, formation of only the mono- and the di-hydroxy species was considered. The following methods were used to study their formation.

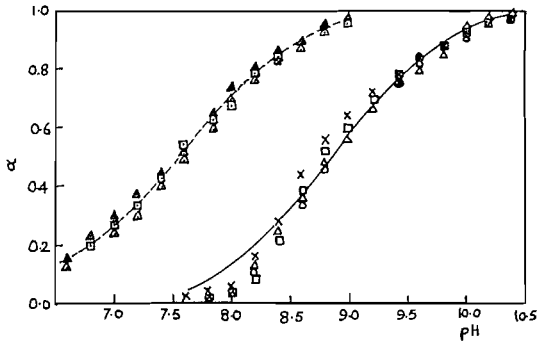

FIG. 3. Plots of degree of formation of the faint violet complexes (α) of BPG (---) and DMBPG (—), with copper(II). Wavelength (in mμ) for □, 640; △, 660; ▲, 680; ×, ⊡, 700; △, 725; and ○, 750.

Method 1

In the absence of any lower complexes, the formation of $CuL(OH)_n^{n-}$ from CuL can be written as

[1] $$CuL + nOH^- \rightarrow CuL(OH)_n^{n-}$$

with the corresponding equilibrium constant

[2] $$K_{11} = [CuL(OH)_n^{-n}]/[CuL][OH^-]^n$$

If, at equilibrium

$$a_0 = [CuL]/\{[CuL] + [CuL(OH)_n^{-n}]\}$$

$$K_w = [H^+][OH^-]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and

$$pH = -\log[H^+]$$

eq. [2] transforms into

$$[3] \quad \log \frac{1 - a_0}{a_0} = (\log K_{11n} + n \log K_w) + npH$$

From spectrophotometric measurements the plot of $\log (1 - a_0)/a_0$ against pH was found to be linear with unit slope, indicating $n = 1$ (Fig. 4); from the intercept of the above plots, K_{111} was found to be $(2.6 \pm 0.2) \times 10^6$ and $(1.0 \pm 0.1) \times 10^5$ for BPG and DMBPG complexes, respectively (at 30 °C).

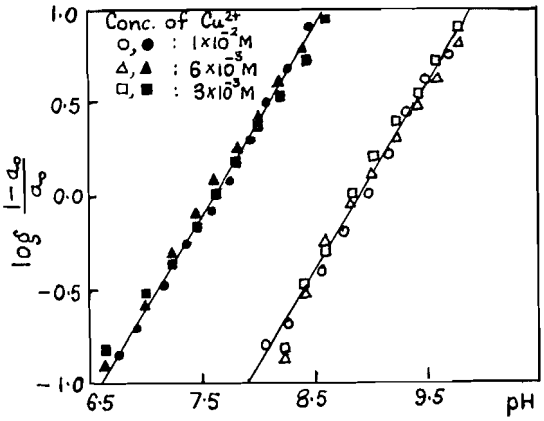

FIG. 4. Plots of $\log (1 - a_0)/a_0$ against pH for the faint violet copper(II) complexes with BPG (●, ▲, ■) and DMBPG (○, △, □).

Method 2

The formation of $CuL(OH)_2^{-2}$ from CuL is similar to the formation of 1:2 metal:ligand complex. The following relation must, therefore, hold between a_0 and $[OH^-]$ (ref. 6. p. 89)

$$[4] \quad \frac{1 - a_0}{a_0}[OH^-]^{-1} = K_{111} + K_{111} \cdot K_{112}[OH^-]$$

where K_{111} and K_{112} are the corresponding step stability constants for these complexes. From the plots of $(1 - a_0)/(a_0[OH^-])$ against $[OH^-]$, which were straight lines parallel to the $[OH^-]$ axis, the value of K_{111} was found to be $(2.65 \pm 0.2) \times 10^6$ and $(1.02 \pm 0.10) \times 10^5$ for BPG and DMBPG complexes, respectively, whereas K_{112} was zero for both these ligands, showing that under the experimental conditions, $CuL(OH)_2^{2-}$ is not formed.

Furthermore, during the pH-titrations, the conversion of the greenish blue chelate into faint violet chelate proceeds with the consumption of one mole of OH^- ions per mole of copper(II), thus confirming the above conclusions.

The anionic nature of the faint violet complexes was confirmed by their complete exchange by Amberlite ion exchanger IRA 400 (OH) as well as by IRA 410 (OH).

Absorption of β particles from tritium and rhenium 187 in helium and aluminum

S. N. NALDRETT
The Royal Military College of Canada, Kingston, Ontario
Received June 21, 1968

The absorption of the β particles from tritium and from ^{187}Re was found to obey an exponential law for a range of about 6 or 7 times the half-thicknesses. In helium the half-thicknesses of tritium and of ^{187}Re are found to be $0.046_0 \pm 0.000_7$ and $0.039_3 \pm 0.001_2$ mg/cm^2; in aluminum they are $0.036_7 \pm 0.000_9$ and $0.033_6 \pm 0.001_3$ mg/cm^2, respectively.

Introduction

Naturally occurring ^{187}Re decays by β emission to ^{187}Os. The ratio of rhenium to osmium offers promise as a means of determining ages in geochemistry and cosmology, provided that the rate of decay of rhenium to osmium can be determined with sufficient accuracy. Gas counting is generally the most accurate technique, but unfortunately all of the compounds of rhenium which are sufficiently volatile behave as "counter poisons" and attempts to measure the half-life of ^{187}Re in gas counters have not been very successful (1, 2). An accurate determination of the range of the β particles emitted in the decay is required in order to permit a calculation of the half-life of this isotope from the activity of solid samples. The particles are very feeble, apparently of about the same energy as those from tritium. Moreover, the activity is low, considerably less than 1 d/m per cm^2 of surface, so that measurement of absorption is difficult. It was thought that comparison with absorption of tritium which is available in high specific activity, through the same absorbers would provide the best data since the tritium would in effect be used to calibrate the very thin absorbers involved. Unfortunately it was found that there do not seem to be any data for tritium which are generally accepted or of sufficient precision. For example, Dorfman (3) estimated the half-thicknesses as 31, 61, and 80 μg/cm^2 in hydrogen, helium, and oxygen, respectively. Suttle and Libby (4) and Libby (5) gave an estimate of 50 μg/cm^2 in helium and argon. Rydberg (6) gave the half-thickness in *p*-aminosalicylic acid as 80 μg/cm^2. The data of Beltz (7) give a calculation of half-thickness of 12 μg/cm^2 in very thin samples of thymidine and 116 μg/cm^2 in thick samples. Determinations of the absorption of the β particles from tritium as well as from ^{187}Re in several materials were therefore made.

Experimental

Measurements were made using a screen-wall type counter (cylindrical geometry) with a solid sample area of about 400 cm^2. Details of this instrument and of the preparation of the rhenium samples have already been reported (1). Tritium was counted as tritiated succinic acid or lucite. With the screen-wall counter the distance between the sample and the active counter space was not variable, but the thickness of the gas absorber, helium, argon, etc., could be varied by using different pressures, and in addition, one or more thicknesses of aluminum film could be placed over the screen as additional absorbers.

Another series of measurements was made using a Beckman–Sharp Low Beta Counter with a solid sample area of about 20 cm^2 (sandwich geometry). This is a flow-type counter in which the pressure of the gas (helium 98.5, propane 1.5) is constant. The thickness of the gas absorber could be changed by raising or lowering the surface of the sample a few millimeters by means of spacing discs. It was determined that the count rate was affected by absorber thickness and not by geometry within the limits studied. One or more thicknesses of aluminum foil or other material could be placed directly over the top of the sample to observe the absorbing effects of solid materials.

Background count rates were minimized by mass shielding and by anticoincidence circuitry. Data were collected by automatic print-out of counts collected over intervals of 20 or 50 min so that periods in which irregular behavior occurred could be recognized. Evaluation was made by means of a computer which had been programmed to reject by Chauvenet's criterion, and to make a Pearson's χ^2 assessment. This was advantageous since a large amount of data was needed to reduce the statistical error, and moreover, on several occasions the rejection of data by the computer for non-randomness was the first evidence that an electronic fault was developing. The error estimates in what follows are the statistical standard deviations.

TABLE I

Absorption of β particles

β particle from	In helium		In aluminum	
	$t_{\frac{1}{2}}$, mg/cm^2	μ	$t_{\frac{1}{2}}$, mg/cm	μ
T	$0.046_0 \pm 0.000_7$	15.07 ± 0.22	$0.036_7 \pm 0.000_9$	18.90 ± 0.46
^{187}Re	$0.039_3 \pm 0.001_2$	17.65 ± 0.53	$0.033_6 \pm 0.001_3$	20.66 ± 0.80

Observations

Absorption of β Particles in Helium or Aluminum

No significant differences were observed between cylindrical and sandwich geometry and all data were therefore combined, weighted according to statistical error. The absorption of the β particles from T and from ^{187}Re in helium and in aluminum are shown in Fig. 1. Except towards the end of the range, the absorption of β particles from simple decay processes can be expressed by an equation of the form

$$[1] \qquad \ln \frac{I_0}{I} = \mu t$$

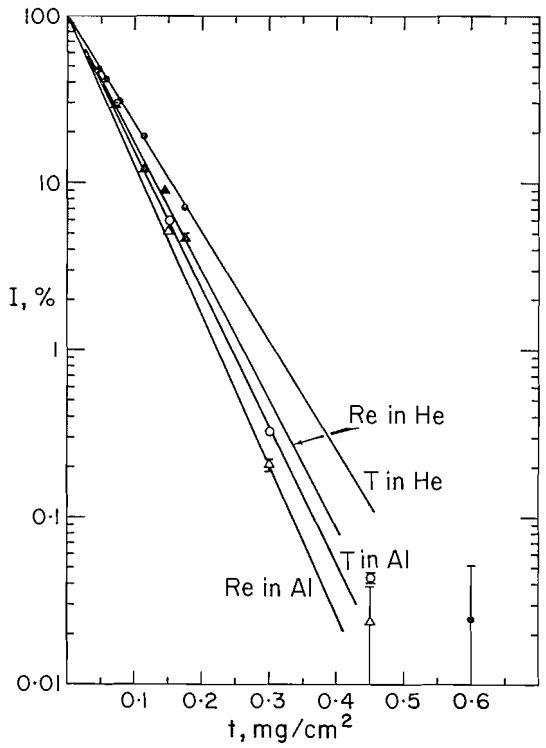

FIG. 1. The absorption of the β particles from T and from ^{187}Re in helium and in aluminum.

where I_0 is the original activity, I is the activity after passing through an absorber of thickness t and absorption coefficient μ. The "maximum range", although frequently quoted, is an arbitrary term since it depends upon the reduction which is significant for the problem in hand or on the sensitivity of the detection methods, and is not given here. For these low energy particles, exponential behavior persists up to about 6 or 7 times the half-thickness. This is a useful approximation of the "maximum range". For example, in Libby's equation, recommended for calculating saturation activities, I_∞,

$$[2] \qquad \frac{I}{I_\infty} = 1 - e^{-5t/t_\infty}$$

from measurements of layers which are less than "infinite thickness", or "maximum range", t_∞, the maximum range is taken as 7.2 times the half-thickness (8). Table I shows the thickness of helium or of aluminum which reduces the initial activity to ½. The absorption coefficients, μ, of eq. [1] are also given, from which one can calculate the thickness of absorber which will produce any other reduction.

In order to determine the disintegration rate of ^{187}Re from the activity of samples of Re_2S_7 it is necessary to know the range of the rhenium β particles in Re_2S_7. Empirical equations relating absorption coefficients of γ-free β particles to the average atomic weight of the absorber have been proposed, for example by Lerch (9). Direct observation of the range of the β particles from tritium in Re_2S_7 have also been made by us. The validity of using these data to estimate the range of rhenium β particles in Re_2S_7, and the disintegration rate of ^{187}Re calculated from these data, will be discussed in another communication.

Studies on metal hydroxy compounds. IX. Kinetics of thermal decomposition of twelve copper halide derivatives

P. Ramamurthy and E. A. Secco
Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia

Received May 30, 1969

The kinetics of the thermal decomposition of 12 halide (F, Cl, Br, I) derivatives of copper hydroxide are reported. The kinetic results and their interpretation in terms of activated complex theory are compared with the results and interpretation of the thermal decomposition of zinc and cadmium hydroxyhalides.

Canadian Journal of Chemistry, **47**, 3915 (1969)

Introduction

This report represents the second part of a systematic program of study on the solid-state decomposition kinetics of metal hydroxy compounds dealing with copper hydroxide and its halide (F, Cl, Br, I) derivatives. Details of these decomposition reactions and analyses have already been reported (1, 2).

Experimental

All compounds used in this study were prepared in this laboratory using procedures already described (1).

The decomposition kinetics were determined gravimetrically, i.e. weight loss vs. time, using a duPont TGA-950 plug-in module for the duPont DTA-900 thermal analyzer console, calibrated and programmed as already described in Part VI (3).

The recorded weight loss vs. time trace was translated into decomposition fraction, α, vs. time data. The kinetic data were subsequently computer processed and plotted to obtain the best straight line or linear fit with the known rate expressions. The kinetic data from a continuous recording of the progress of reaction can be evaluated in a more critical manner thus minimizing the inherent risk of fitting the data to a rate expression of questionable validity.

All decomposition experiments were done in nitrogen gas atmosphere as previously described (3).

Results and Discussion

The kinetic results for decomposition according to the written reaction equations are given in Table I. These results represent the best fit between the experimental data and the known rate expressions over the maximum reaction fraction $\alpha \geq 0.8$ and over the temperature ranges studied. In all cases excepting $CuF_2.2H_2O$, the fitting of the data to a particular rate expression was straightforward and clear-cut. In contrast, the $CuF_2.2H_2O$ data are fitted equally well to three rate equations; (*i*) Avrami–Erofeyev (A–E) type with $n = \frac{3}{2}$, (*ii*) the contracting sphere or Roginskii – Todes – Mampel (R–T–M) equation, and (*iii*) modified Prout–Tompkins (P–T) equation, in order of listing in Table I. The general kinetic features contained in the Table, that is, predominance of first order rate and the single instance of second order rate, along with the group of three rate equations for $CuF_2.2H_2O$, bear a striking parallel to the results observed for zinc and cadmium compounds (3).

The decomposition of CuOHF was also studied but the kinetic data could not be fitted to any known rate expression. This failure results

				$1-(1-\alpha)^{1/3} = kt$	29.0±0.5	12.8	
				$\log\left(\frac{\alpha}{1-\alpha}\right) = k \log t + C$	21.0±2.0		

*Listed in order of increasing pre-exponential factor A with an effort to retain the 4 structural forms of $Cu_2(OH)_3Cl$ together in one group.

from the interference of, and our inability to separate, two overlapping processes contributing to the weight loss, viz.

[1] $4CuOHF \rightarrow Cu_2(OH)F_3 + HF + H_2O$

and

[2] $Cu_2(OH)F_3 \rightarrow CuO + CuF_2 + HF$

The kinetic behavior of CuOHF is in contrast to $Cu_2(OH)_3Br$ and $Cu_2(OH)_3I$; the latter undergo simultaneous dehydroxylation and disproportionation according to a first order rate law.

In the $CuF_2.2H_2O$ case, the modified P–T rate equation is disregarded since the requirement $E_a \geq \Delta H$ for an endothermic reaction is not fulfilled. From their respective plots of the function of α vs. time for the rate laws

$$-\ln(1 - \alpha) = kt^{\frac{1}{2}}$$

and

$$1 - (1 - \alpha)^{\frac{1}{3}} = kt$$

which were unquestionably linear, we are unable to distinguish between these two rate expressions.

The rate equation

[3] $$-\ln(1 - \alpha) = kt^{\frac{3}{2}}$$

has been routinely disregarded (4) on the basis that this equation has no theoretical significance in solid phase kinetics. A theoretical basis for this equation, however, has been found in precipitation kinetics. Turnbull (5), in a review of the theory of phase change kinetics, has included a kinetic description of precipitation reactions as derived by Wert and Zener. In this derivation Wert and Zener assumed that the particle growth of the β phase was governed by the diffusion of its components in the bulk γ phase rather than processes at the γ–β interface for the simplest case of spherical particles, and showed that the kinetic law of precipitation is given by eq. [3]. This precipitation process can be translated into a decomposition process visualizing the initial decomposition to germinate at the center of the reactant bulk. The growth of the product particle or the extent of decomposition in the bulk is governed by diffusion of the volatile product-species through the reactant matrix. Such a decomposition mechanism parallels the precipitation process envisaged by Wert and Zener and would be expected to obey the rate eq. [3].

No dependence of E_a on ΔH is revealed in Table I nor is there any relationship discernible between the pre-exponential factor A of the Arrhenius equation and E_a. However, the E_a values of all hydroxyhalide compounds, excluding γ-$Cu_2(OH)_3Cl$, are noted to fall within the range 35–45 kcal/mole.

Ball and Coultard (6) have reported activation energies evaluated from the differential weight loss vs. temperature curves. All their activation energy values from thermogravimetric curves are appreciably higher than the E_a values reported herein from isothermal experiments. Their fitting of the CuOHCl thermogram to a "second order" equation also differs from our kinetic results. These discrepancies illustrate the lack of reliability of the present analytical procedures used to extract kinetic data from dynamic methods such as thermogravimetric analysis or differential thermal analysis.

The existence of 4 crystalline structures of $Cu_2(OH)_3Cl$ incorporating a variation in the crystalline lattice with no alteration in the molecular conformation could be a kinetically useful parameter especially if the reaction rate is controlled by the molecularity alone and not by the topochemistry of the solid. The relatively constant ΔH values and the different E_a values of these 4 structures suggest that the pertinent kinetic parameter resides in the activated complex configurations.

From the Arrhenius rate equation, in the form derived from activated complex theory

$$k_r = \left[10^{13} \cdot \frac{Q^*}{Q}\right] e^{-E_a/RT} = A\, e^{-E_a/RT}$$

A values of approximately 10^{13}, as for δ- and β-structures, imply a Q^*/Q ratio of unity with an equal number of active modes of freedom in both the activated complex and reactant configurations. On the other hand, α- and γ-$Cu_2(OH)_3Cl$ with A values of 10^{16}–10^{19} imply a Q^*/Q ratio greater than unity with more modes of freedom in the complex configuration relative to the reactant configuration. Cordes (7) has predicted A values of 10^{16} for a monomolecular reaction and 10^{18} for a bimolecular reaction in terms of an increased number of rotational modes in the complex, and assuming bulk decomposition, i.e. where any molecule is as likely to react as any other. We can assume therefore that α-$Cu_2(OH)_3Cl$ undergoes bulk

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

decomposition via a monomolecular process whereas γ-$Cu_2(OH)_3Cl$ occurs via a bimolecular one. These data illustrate that the crystal structure parameter does affect the active modes of freedom in the complex in its decomposition course but the analysis of this parameter in the absence of detailed torsional, rotational, and vibrational data can be at best an exercise in conjecture.

The excellent agreement between the observed A value of 10^{18} for $Cu_2(OH)_3Br$ with the prediction by Cordes lends strong support to the interpretation that $Cu_2(OH)_3Br$, along with γ-$Cu_2(OH)_3Cl$, undergoes bulk decomposition in a bimolecular manner. The exceedingly high A value of 10^{23} for $Cu_2(OH)_3I$ cannot be accommodated by increased rotational modes of freedom and therefore must involve translational modes as was suggested (3) for ZnOHCl and ZnOHF.

For the compounds $Cu(OH)_2$, $CuBr_2$, and $Cu_2(OH)F_3$ the pre-exponential values of 10^8–10^9 can be interpreted in terms of a complex highly restricted in its modes of rotation as discussed by Cordes.

Preparation of ferrimagnetic barium- and strontium-iron oxides, $BaFe_{12}O_{19}$ and $SrFe_{12}O_{19}$

R. J. Routil and D. Barham

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto 181, Ontario

Received August 21, 1969

Ferrimagnetic $BaFe_{12}O_{19}$ and $SrFe_{12}O_{19}$ were prepared from $BaSO_4$ and from $SrSO_4$ by heating the sulfates in mixtures with Fe_2O_3 and Na_2CO_3 to 900–1400 °C. The highest yields were obtained from mixtures containing 6 moles of Fe_2O_3 and 1 mole of Na_2CO_3 per mole of sulfate. Similar results were observed when Na_2CO_3 was substituted with compounds yielding oxides of sodium, potassium, or calcium but not with analogous lithium compounds.

Canadian Journal of Chemistry. 47, 3919 (1969)

Preparation of $SrFe_{12}O_{19}$ from mixtures of Fe_2O_3 and $SrCO_3$ containing Na_2SO_4 and other impurities, as reported by Cochardt (1) was basis to a hypothesis that $SrFe_{12}O_{19}$ should exist as a stable phase in certain regions of the $SrSO_4$–Fe_2O_3–Na_2O system. This was confirmed by an investigation of the system at high temperatures. Similarly, the occurrence of $BaFe_{12}O_{19}$ in the $BaSO_4$–Fe_2O_3–Na_2O system was anticipated and proved.

High temperature reactions of the $x\ MSO_4 + y\ Fe_2O_3 + z\ Na_2CO_3$ mixtures were studied first by keeping $x:z = 1$ and by changing $x:y$ within the limits which, according to refs. 2 to 5, yielded $MFe_{12}O_{19}$ as the main phase of the MO–Fe_2O_3 systems (M = Ba or Sr). Then the effects of $x:z \neq 1$ were investigated in ranges for which the lowest melting points were reported in refs. 6 to 8.

Ferrimagnetic phases isolated from the reacted mixtures were identified by X-ray diffraction analysis as being of the magnetoplumbite crystal structure. Chemical analyses verified the composition as $MFe_{12}O_{19}$.

The highest yield of $MFe_{12}O_{19}$ was found when $x = z = 1$ and $y = 6$. Omitting intermediate stages the following overall reaction was proposed

$$[1]\quad MSO_4 + 6\ Fe_2O_3 + Na_2CO_3 \rightarrow MFe_{12}O_{19} + Na_2SO_4 + CO_2$$

The reaction proceeded very slowly below 900 °C and, depending on the grain size of starting reagents, it was completed in less than 1 h at 1200 °C. Theoretical yields were approached within experimental errors. Heating above 1400 °C caused partial decomposition of $MFe_{12}O_{19}$ and lower yields.

The lowest melting point (about 1140 °C) was observed when $x = 1$, $y = 12$, and $z = 7$. The main overall reaction was formulated as

$$[2]\quad MSO_4 + 12\ Fe_2O_3 + 7\ NaCO_3 \rightarrow MFe_{12}O_{19} + 12\ NaFeO_2 + Na_2SO_4 + 7\ CO_2$$

The yields of $MFe_{12}O_{19}$ were more than 90% of the theory.

By similar reactions $MFe_{12}O_{19}$ was prepared from mixtures in which Na_2CO_3 was substituted with NaOH, $NaNO_3$, CH_3COONa, K_2CO_3, or with $CaCO_3$. (Initial heating of mixtures containing CH_3COONa had to be slow enough to prevent reduction of Fe_2O_3.)

$MFe_{12}O_{19}$ was not produced when Na_2CO_3 was substituted with Li_2CO_3. Ferrimagnetic phases isolated from these samples were of the spinel type.

Experimental

Reagent grade strontium sulfate from British Drug Houses Ltd. and "Certified" grade reagents from Fisher Scientific Co. were used.

The preparation procedure comprised following steps: (*a*) Mixing $BaSO_4$ or $SrSO_4$ with Fe_2O_3 and with a third component which was either dry Li_2CO_3, Na_2CO_3, K_2CO_3, $CaCO_3$, a solution of NaOH, $NaNO_3$, or CH_2COONa. (*b*) Heating the mixture in a platinum crucible to a temperature between 900 and 1400 °C in air atmosphere. Samples containing visible particles of unreacted $BaSO_4$ or $SrSO_4$ were homogenized by crushing and screening and the heating was repeated at a higher temperature. (*c*) Separation of the ferrimagnetic phase from other components of the reacted mixture. Leaching with water or with diluted nitric acid and

magnetic separation were employed. Samples which did not disintegrate by leaching were crushed to pass 100 mesh and the leaching was repeated.

Example to Reaction [1]

$BaSO_4$, Fe_2O_3, and Na_2CO_3 were mixed in the stoichiometric ratio of reaction [1]. The mixture was fired at 900 °C for 1 h and after cooling, it was ground to pass 100 mesh and then refired at 1200 °C for 1 h. The resulting cake was crushed to pass 100 mesh. The powder was leached with hot water which was changed frequently until the extract remained clear on addition of $BaCl_2$ solution.

Example to Reaction [2]

$SrSO_4$, Fe_2O_3, and Na_2CO_3 were mixed in the stoichiometric ratio of reaction [2] and the mixture was melted by heating to 1150 °C. On cooling the melt divided into a heavy black layer and a lighter white layer. The white layer containing mainly Na_2SO_4 was washed out with water and the remaining black layer was leached with hot 5% nitric acid. Loosening of ferrimagnetic particles from the $NaFeO_2$ matrix was facilitated by magnetic stirring and by occasional mechanical prying. Separated ferrimagnetic particles were washed with water and dried.

Quantitative investigation of the ozonolysis reaction. IX. On the mechanism of ozonide formation

SÁNDOR FLISZÁR AND JACQUES CARLES

Department of Chemistry, University of Montreal, Montreal, Quebec

Received January 14, 1969

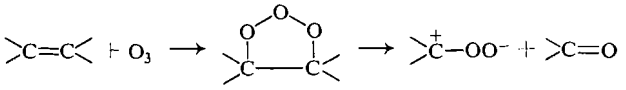
The ozonide *cis–trans* ratios, for both normal and cross-ozonides, have been examined, in a number of cases, in pentane and in benzene solutions. In benzene, at 25 °C, almost invariant *cis–trans* ratios are observed, regardless of the geometry and initial concentration of olefin. In pentane, these ratios have been found to depend, both at −78 and 25 °C, on the geometry and the initial concentration of the olefin when 1,2-disubstituted ethylenes with bulky substituents are ozonized. However, the cross-ozonide *cis–trans* ratios obtained from trisubstituted ethylenes do not depend on the initial olefin concentration. A tentative mechanistic proposal is suggested in terms of transitory zwitterion–olefin adducts.

Canadian Journal of Chemistry, 47, 3921 (1969)

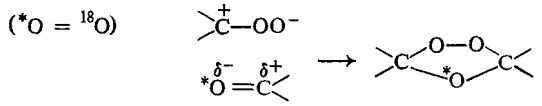
The mechanism of ozonolysis proposed by Criegee (1) (Scheme 1) has been the object of recent discussions (2–4), and has received considerable experimental support (5). This support includes (*i*) the reaction of the zwitterion with those solvents which participate in the ozonolysis, forming hydroperoxides, or the reaction with added aldehyde to form an ozonide other than that of the original olefin, and (*ii*) the formation of cross-ozonides from unsymmetrical olefins (3).

The primary ozonides **1** are unstable even at low temperatures, and this instability did not readily permit their detection. However, evidence for their existence has been obtained by Criegee and Schröder (6) for the primary ozonide of *trans*-di-*t*-butylethylene, and by Greenwood (7) for the primary ozonides of some *trans* alkenes. In the ozonolysis of *trans*-di-*t*-butylethylene at −78° in pentane, a crystalline product is formed, which, upon "heating" to −60°, decomposes explosively to give the normal products of ozonolysis (6). The 1,2,3-trioxolane structure **1** for the primary ozonide of *trans*-di-*t*-butylethylene was confirmed by Bailey (8) from low temperature (−110°) nuclear magnetic resonance (n.m.r.) experiments which indicated that both methine protons are equivalent.

The detection of primary ozonides from *cis* olefins has been even more difficult, apparently due to their greater instability at temperatures as low as −110°. Greenwood (9) has reported some evidence for the existence of the *cis* primary ozonides (at −130° in CF_2Cl_2 solutions) of butene-2, pentene-2, and hexene-3. While the

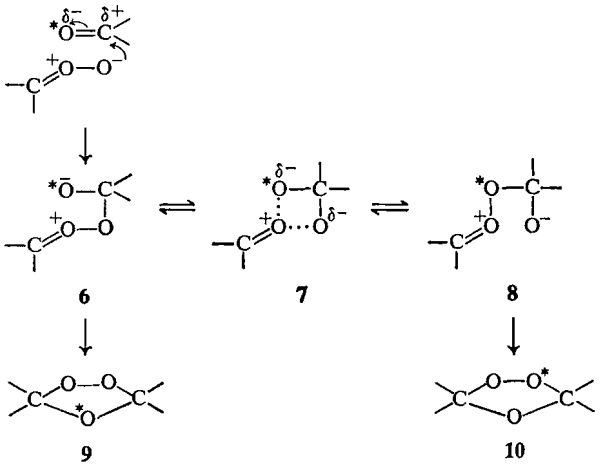


1 **2** **3**



($^*O = {}^{18}O$)

SCHEME 1



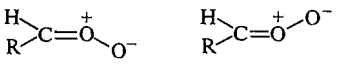
SCHEME 2

evidence for a 1,2,3-trioxolane structure is not unambiguous for the *cis* primary ozonides, an analogous structure to the *trans* primary ozonides is expected.

The participation of zwitterions in the formation of ozonides from phenylethylenes has been clearly established from the ozonolysis of *cis*- and *trans*-stilbene, styrene, β-methyl-styrene, and triphenylethylene in the presence of ^{18}O-labelled benzaldehyde (4, 10). The ^{18}O atoms are incorporated *exclusively* in the ether position of the ozonides formed, as predicted by Criegee's mechanism.

The original Criegee mechanism (Scheme 1) predicts that all the products arising from the ozonolysis of *cis* and *trans* olefins will be formed in the same proportions. It is found, however, that *cis* and *trans* olefins often give different ozonide *cis–trans* ratios (2, 11), both for the normal and the cross-ozonides. This indicates that the Criegee mechanism requires refinement or that an alternative mechanism is in operation. Possible alternative routes to ozonide formation are discussed in this paper.

Bailey (3) has suggested that the dependence of the *cis–trans* ozonide distribution on the geometry of the olefin may be accommodated within the Criegee mechanism if the zwitterions have *syn* and *anti* forms, and has discussed in detail the formation of *syn* and *anti* zwitterions from *cis* and *trans* primary ozonides.[1] These *syn* and *anti* forms, which were originally suggested by Criegee (12), may be considered analogous to the recently observed *syn* and *anti* forms of protonated aldehydes, ketones, and carboxylic acids at low temperature (13).



4 *syn* **5** *anti*

A consideration of the zwitterion–^{18}O–aldehyde reaction leads to a novel interpretation of the mechanism which accounts for the formation of ozonides in which the incorporation of the label is in the peroxide or the ether position.

The "oxonium" intermediate **6** can react to give the ozonide **9** (Criegee product). Alternatively, it may be reversibly transformed into the isomeric form **8**, via an intermediate species approaching structure **7**, which would give the ozonide **10**. Thus, the formation of an ozonide of type **10** in the ozonolysis (14) of *trans*-1,2-diisopropylethylene in the presence of acetaldehyde-^{18}O can be rationalized on the basis of the mechanism shown in Scheme 2. However the possible participation of this mechanism requires further investigation. It is justified, at present, by its ability to explain, within the frame of a refined Criegee mechanism, the incorporation of aldehyde-^{18}O in the peroxide position of the ozonide. From a consideration of **6** it would be expected that an electron-releasing group, such as the isopropyl group, would render the original zwitterionic carbo-cation less electrophilic, thus

[1]It results, from Bailey's (3) stereochemical analysis, that aldehydes preferentially interact with *anti* zwitterions so as to orient bulky substituents diequatorially (*cis*) and with *syn* zwitterions to orient bulky substituents into an equatorial, axial (*trans*) conformation.

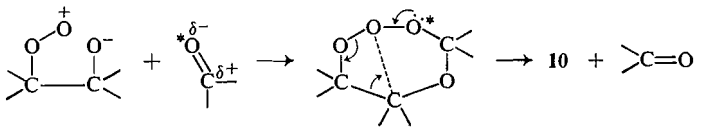

SCHEME 3

retarding the ozonide formation **6** → **9**, and, hence, promoting the equilibrium **6** ⇌ **8**. This would consequently increase the possibility for the formation of the ozonide corresponding to **10**. This is indicated by the ozonolysis (14) of *trans*-1,2-diisopropylethylene in the presence of acetaldehyde-^{18}O which led to a substantial ^{18}O incorporation in the peroxide position.[2] It should be considered, however, that electronic factors may not be solely responsible in directing the reaction paths, but in addition steric factors may influence the proportions of ozonides **9** and **10**.

The formation of an ozonide of type **10** can also be accounted for by the mechanism proposed by Story *et al.* (2), which has been used to explain the stereospecific dependence of the ozonide *cis–trans* distribution on olefin geometry (Scheme 3). It is considered that ^{18}O is perhaps incorporated in the peroxidic position only in the case of the *trans* olefin at a low temperature, where the Murray–Story–Youssefyeh mechanism could play a part due to excess aldehyde and the greater stability of the *trans* initial ozonide in comparison to the *cis* initial ozonide. Of course, this possibility would not be relevant if ^{18}O was incorporated into the peroxidic position in the case of the *cis* olefin. Further studies are in progress to clarify this question.

The incorporation of labelled oxygen in the peroxide position of the ozonide does not, in itself, support one mechanism in preference to the other. Additional parameters affecting the *cis–trans* ozonide distributions must be taken into consideration which would reconcile these data with the stereospecificity observed in ozonide formation from *cis* and *trans* olefins. These include temperature and olefin concentration.

Results and Discussion

It is found that, in general, the ozonide *cis–trans* ratios are affected when the temperature of ozonolysis is changed from −78 to 25° (Table 1). Significant differences are observed for the cross-ozonides from 1,2-disubstituted ethylenes and for the normal *cis–trans* ozonides of *cis*- and *trans*-2,2-dimethylhexene-3. The *cis–trans* ratios observed for the normal ozonides of *trans*-1,2-diisopropylethylene and of *cis*- and *trans*-4-methylpentene-2 appear, however, to be insensitive to the change in temperature of ozonolysis.

An examination of the results given in Table I indicates that the ozonide *cis–trans* ratios depend on the olefin geometry at −78°, more *cis* ozonide being obtained from the *cis* olefin than from the *trans* isomer. This remarkable structural effect, which has been widely observed (2, 11) at −78°, is now found to occur also at 25°. The *cis*- and *trans*-4-methylpentene-2 are, once again, an exceptional case, in that the observed *cis–trans* ratios for the *normal* ozonides do not appear to be related to the *cis* or *trans* configuration of the olefin. Similar exceptional behavior is also observed at −78°. It should be pointed out, however, that for these relatively unhindered

[2]A calculation (15) from the literature data (14) for the ozonolysis of *trans*-di-isopropylethylene in the presence of acetaldehyde-^{18}O indicates that ~43% of ozonide **10** and, hence, 57% of ozonide **9** are formed. From the reported results (14) of methyllithium reduction of the ozonide, ~39% of ozonide **10** and, hence, 61% of ozonide **9**, can be calculated.

olefins the cross-ozonide *cis–trans* ratios exhibit a significant stereochemical dependence on olefin geometry, both at −78 and at 25 °C.

A similar stereochemical dependence of the ozonide *cis–trans* ratio on olefin geometry is also observed in the ozonolysis of phenylethylenes in CCl_4 solution, at temperatures between −15 and 40° (Table II, Fig. 1).

The extreme instability of the primary ozonides (6–9) indicates that a reaction between such intermediates and aldehyde molecules, as depicted in Scheme 3, will be highly improbable at 25°. The results presented here thus favor the explanation for the dependence of the *cis–trans* distribution on the geometry of the olefin given in terms of *syn* and *anti* zwitterions (3), rather than Scheme 3, which is based on a reaction between primary ozonide and aldehyde.

However, it would be expected that, at 25°, the *syn* and *anti* zwitterions will rapidly equilibrate. Such an equilibration would affect the *cis–trans* distributions so that the same distribution would be observed with a *cis* and the corresponding *trans* olefin isomer. This is in variance with the experimental results.

A possible explanation for the non-equilibration of the *syn* and *anti* zwitterions can be drawn from a consideration that the ozonide *cis–trans* ratios are solvent dependent (3, 16). Pertinent examples are the results obtained (11g) in the ozonolysis of *trans*-hexene-3 (0.2 *M* at −30°) in pentane, CH_2Cl_2, and Et_2O, in addition to the normal and cross-ozonide *cis–trans* ratios observed (3) in the ozonolysis of *cis*- and *trans*-4-methylpentene-2 (1.0 *M* at −75°) in pentane, CH_2Cl_2, and AcOEt. Similar observations have also been made with *cis*- and *trans*-1,2-diisopropylethylene, when ozonized in different solvents (16). The results indicated in Table I also show a significant difference between the *cis–trans* ratios measured at 25° in pentane and in benzene. Moreover, in contrast with most of the results obtained in pentane, the *cis–trans* ratios observed in benzene appear to be independent of olefin concentration.

The results given in Table I indicate that, in pentane solution, there is a significant increase in the normal and cross-ozonide *cis–trans* ratios when the initial olefin concentration is changed from 0.1 to 1.0 *M*. This is found to occur both at −78 and at 25°. Similar results have been reported previously (16) for the ozonolysis of *cis*- and *trans*-1,2-diisopropylethylene in pentane at −70°. The present results indicate that the dependence of the ozonide *cis–trans* ratio on the olefin concentration is particularly pronounced in the low concentration region, whereas, at olefin concentrations above 1.0 *M*, the ozonide distribution appears to vary little and to tend to an asymptotic value, independent of olefin concentration. (Fig. 2).

It is also noteworthy that in the early stages of the reaction, the ozonide *cis–trans* ratios are higher than those measured when most of the olefin has reacted with ozone (Figs. 3, 4). This is in agreement with the observed effect of olefin concentration, owing to the fact that the olefin concentrations are higher at the beginning than toward the completion of the ozonolysis.

The observations on the effect of the solvent and of the olefin concentration on the ozonide *cis–trans* ratios may be rationalized by considering that the olefin itself, when dissolved in an inert solvent, such as pentane, may influence the course of the ozonolysis by a "solvent effect".

The effect of the olefin concentration, or of the solvent, cannot be readily interpreted in terms of interactions between olefin, or solvent and the primary ozonide **1**, or the seven membered ring depicted in Scheme 3. The participation of olefin

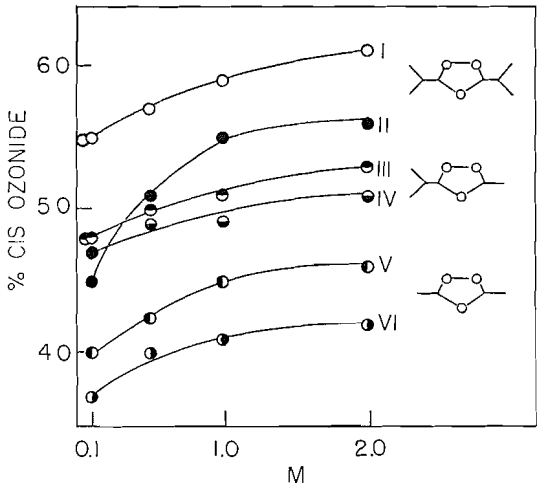

FIG. 2. A plot of % *cis* ozonide formed vs. olefin initial concentration (*M*), in pentane at 25 °C. Curves I, III, and V: from *cis*-4-methylpentene-2. II, IV, and VI: from *trans*-4-methylpentene-2. The ozonides formed are diisopropylethylene ozonide (I and II), 4-methylpentene-2 ozonide (III and IV) and butene ozonide (V and VI).

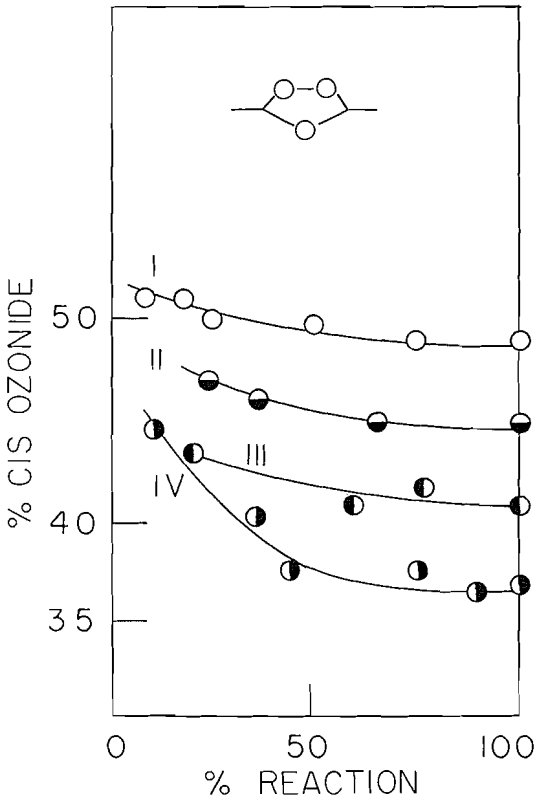

FIG. 3. A plot of % *cis*-butene ozonide formed vs. percentage of 4-methylpentene-2 reacted, in pentane, from *cis* olefin at −78° (I) and 25° (II), and from *trans* olefin at 25° (III) and −78° (IV).

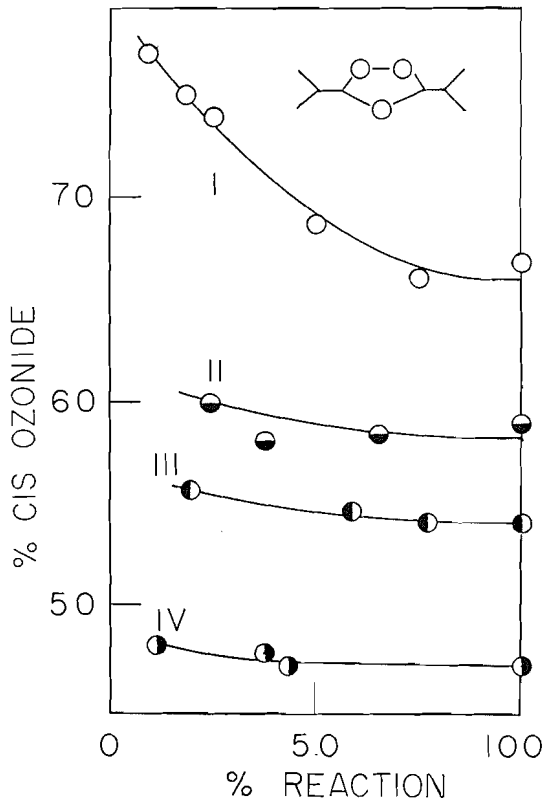

FIG. 4. A plot of % *cis*-diisopropylethylene ozonide formed vs. % of 4-methylpentene-2 reacted in pentane, from *cis* olefin at −78° (I) and 25° (II), and from *trans* olefin at 25° (III) and −78° (IV).

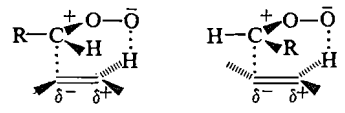
in directing the ozonide *cis–trans* distributions can, however, be interpreted by the postulation of a zwitterion–olefin interaction which could "stabilize" the zwitterion in a *syn* or *anti* configuration. Such transitory zwitterion–olefin adducts could approach the structures indicated in Scheme 4.

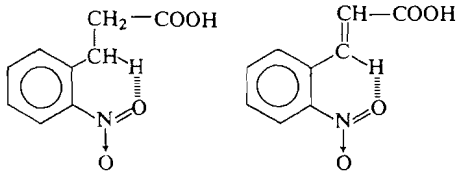


SCHEME 4

The mode of stabilization of the zwitterionic positive charge by the olefin is subject to some reservations owing to the difficulty of localizing the positive charge. It can be considered, however, that the negative charge of the zwitterion may interact with an olefinic hydrogen atom to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

form a hydrogen bond. Unfortunately there appears to be little information on whether the ethylenic hydrogen atoms are sufficiently acidic to cause the hydrogen bonding depicted in Scheme 4. However, self-consistent field (s.c.f.) calculations by Cook *et al.* (17) indicate a low but definite acidity of H atoms attached to sp^2 carbon atoms compared with the H atoms in paraffins. Hence, *in the presence of a strong proton acceptor*, such as the O^- of the zwitterion, the postulated hydrogen bond seems quite plausible. Similar interactions have already been considered by Sidgwick *et al.* (18), and by Dippy *et al.* (19) for the *o*-nitrophenylpropionic and *o*-nitrocinnamic acids. Such a zwitterion–olefin interaction



may explain the dependence of the ozonide *cis–trans* distribution on the olefin concentration and also provide a possible explanation for the non-equilibration of the *syn* and *anti* forms, which is observed at 25°. The stereochemical requirements necessary for the formation of zwitterion–olefin adducts may influence the direction of the ozonide *cis–trans* distributions. A consideration of the mutual interactions in such adducts between the substituents of the olefin and of the zwitterion seems to indicate that a *cis* olefin is capable of stabilizing an *anti* zwitterion rather than a *syn* zwitterion, and hence favoring the formation of *cis* ozonide.[1] As indicated by Scheme 4, if the group R of the zwitterion was in the *syn* configuration, strong interactions between this group and the two substituents of the *cis* olefin would occur. The *syn* zwitterion, which is expected to lead predominantly to a *trans* ozonide (3),[1] appears to be better stabilized by *trans* olefin, than by *cis* olefin. The *trans* olefin, however, would also be capable of stabilizing the *anti* zwitterion. It would be expected, therefore, that the increase in olefin concentration, both for the *cis* and the *trans* isomer, would favor the stabilization of *anti* zwitterions. This is, indeed, indicated by the results in Table I which show a definite increase of the ozonide *cis–trans* ratio accompanying the increase in *cis* or *trans* olefin concentration.

It is, however, not clear to what extent the stereoselective decomposition, suggested by Bailey (3), of the *cis* and *trans* primary ozonides to isomeric *syn* and *anti* zwitterions, is responsible for the stereospecificity in ozonide and cross-ozonide formation; and what contribution is due to the stabilization of the *syn* and *anti* forms by the olefin.

The observation that, in benzene solutions, the ozonide *cis–trans* ratios (Table I) are almost independent of olefin geometry and concentration can be interpreted by considering that this solvent, which is in great excess with respect to the olefin, can play a similar role in stabilizing the zwitterions (possibly by formation of π complexes) without favoring any particular zwitterion configuration.

From a consideration of the structures postulated for the zwitterion–olefin adducts, which are dependent upon the formation of a hydrogen bond as indicated in Scheme 4, it would be expected that with olefins which are not capable of forming such a hydrogen bond no such adducts should be formed. Consequently, in the case of the trisubstituted ethylenes, the cross-ozonide *cis–trans* distributions are expected to be independent of the olefin concentration inasmuch as the inductive effect of the substituents does not produce a charge δ^+ on the carbon atom bearing the H atom. This is the case with the substituents considered here. The results given in Table III confirm this prediction.

From an inspection of all the data presented, it is concluded that zwitterions are likely, in pentane solution, to form transitory adducts with 1,2-disubstituted olefins. The formation of such adducts participates in distributing the ozonide *cis–trans* ratios, as indicated by their dependence on olefin concentration. These observations, in addition to the observation that the stereochemical dependence of the ozonide *cis–trans* ratio on olefin geometry is significant at 25°, i.e. at a temperature at which a primary ozonide–aldehyde reaction is unlikely, strongly support a refined zwitterion–aldehyde mechanism for ozonolysis. Although there is no evidence to suggest that, at low temperature, the mechanism of ozonolysis is different in principle from that at room temperature, the possibility of a reaction at *very low temperature* between primary ozonide and aldehyde cannot, from the data presented, be ruled out.

TABLE III

Ozonide *cis–trans* ratios observed in pentane

		0.1	49/51	48/52
		1.0	47/53	48/52
		0.1	59/41	59/41
		1.0	60/40	59/41

Experimental

The ozonolyses were carried out using O_2–O_3 mixtures. The ozone output was 0.15–0.20 mmole O_3 per min and the ozonolyses were continued to 90–95% of the theoretical amount of ozone required.

The ozonide *cis–trans* ratios indicated in Tables I and III were measured by an F and M 5750 gas chromatograph, equipped with a 20 ft 10% Nitrilesilicone–Chromosorb P column, operated at temperatures not in excess of 60°. Each of the reported results were obtained from several independent experiments and have a maximum variation of ±1%. Retention times were checked with authentic samples of the ozonides and the reliability of the method used for the ozonide *cis–trans* determinations confirmed with ozonide mixtures of known proportions. In order to further verify the reliability of the gas chromatographic method used for determining the ozonide *cis–trans* ratios, n.m.r. measurements of these ratios were also performed in some cases. The ozonide *cis–trans* ratios, as determined by n.m.r. spectroscopy, were identical to those found by gas chromatographic analytical techniques. For example, the diisopropylethylene ozonide *cis–trans* ratios were determined by ozonizing a 1 *M* solution of *trans*-diisopropylethylene in pentane at −78°. After the ozonolysis was achieved with about 90% of the theoretical amount of ozone, the solvent was evaporated at room temperature and the residue dissolved in CCl_4 containing some tetramethylsilane. The n.m.r. methine proton signals of the *cis* ozonide (τ 5.23) and of the *trans* isomer (τ 5.25) were integrated and were found to correspond to a 52/48 ozonide *cis–trans* ratio, which is the value as determined by gas chromatography. Similarly, the 3-hexene ozonide *cis–trans* ratio, as obtained in the ozonolysis of a 1.0 *M* solution of *trans* 3-hexene in pentane at −78°, was determined by means of integrated n.m.r. spectra recorded on the 100 c.p.s. scale. The measurements were made on the methine proton triplets at τ 5.02 for the *cis* ozonide and at τ 5.04 for the *trans* ozonide. A 50/50 ozonide *cis–trans* ratio was observed, which is in complete agreement with the results obtained by gas chromatography.

The ozonide *cis–trans* ratios indicated in Table II were measured as follows. For each experiment, 5 mmoles of olefin, dissolved in 25 ml of CCl_4, were maintained at the appropriate temperature (±0.1 °C) until temperature equilibration was attained. In the 5–7 runs made for each olefin, the amounts of ozone used were varied between 30 and 80% of the theoretical amount. The stilbene ozonide *cis–trans* distributions were calculated from n.m.r. spectra recorded using a Varian A-60 and a Jeolco C-60 H spectrometer. On the 100 c.p.s. scale, the signals for the *cis* stilbene ozonide (τ 3.79) and the *trans* isomer (τ 3.83) can be integrated separately. Measurements made with known proportions of *cis–trans* mixtures, which were prepared from the pure isomers, confirmed the reliability of the method used. It was found that the *cis–trans* distributions did not depend on the extent of the reaction. The given proportions were calculated from 5–7 independent experiments in each case and they are expressed with a 95% confidence limit.

Synthesis of L-glucurone. Conversion of D-glucose into L-glucose

WALTER SOWA
Ontario Research Foundation, Sheridan Park, Ontario
Received May 5, 1969

L-Glucurone (**2**) was readily prepared on a small scale by treatment of D-*glycero*-D-*gulo*-heptonolactone (**1**) with a molar equivalent of periodic acid; thin-layer chromatography was used for its isolation. On a larger scale pure crystalline L-glucurone was obtained in over 80% yield from 3,5;6,7-di-*O*-isopropylidene-D-*glycero*-D-*gulo*-heptonolactone (**4**) in two steps consisting of concomitant hydrolysis and oxidation of **4** with periodic acid followed by treatment of the intermediate oxidation product with trifluoroacetic acid. L-Glucose was prepared from L-glucurone by borohydride reduction and hydrolysis of the 1,2-*O*-isopropylidene derivative. Since **1** was derived from D-glucose, the result of this series of reactions was the conversion of D-glucose into its enantiomer L-glucose.

The first chemical synthesis of a uronic acid was carried out in 1890 by Fischer who obtained D-glucuronic acid and its lactone by reduction of D-glucaro-1,4-lactone with sodium amalgam in acid solution (1). Niemann and Link in 1934 used the same procedure for the enantiomer L-glucuronic acid (2). The starting material, L-glucaro-1,4-lactone, was prepared via calcium L-glucarate from nitric acid oxidation of D-gulono-1,4-lactone. The yield of L-glucurone (**2**), the form in which the L-glucuronic acid was isolated, was about 1% based on calcium L-glucarate. L-Glucuronic acid is of interest because it has been reported to occur naturally, along with D-glucuronic acid, as a metabolic product of the action of rat kidney enzymes on inositol (3). Other workers, however, were unable to detect L-glucuronic acid and have found that inositol is converted into D-glucuronic and L-gulonic acids (4). This discrepancy has not been explained.

The biochemical and pharmacological importance of D-glucuronic acid (5) has led to a thorough investigation of methods for its synthesis, especially those based on oxidation of suitably protected D-glucose derivatives (6). Undoubtedly these procedures can be applied to the synthesis of L-glucuronic acid from L-glucose, but this is not attractive because L-glucose is not readily available. The present publication describes a facile synthesis of L-glucurone (**2**) from D-*glycero*-D-*gulo*-heptonolactone (**1**), a starting material easily prepared from ordinary D-glucose by the Kiliani synthesis (7). This work is an example of the application of a simple and general method for the preparation of uronic acids directly as their lactones, namely selective periodate cleavage of the exocyclic glycol system of an aldonolactone. The procedure has been used on two previous occasions. Woods and Neish treated 2-*C*-hydroxymethyl-D-glucono-1,4-lactone with an equimolar amount of periodate and obtained 4-*C*-hydroxymethyl-L-xyluronolactone, which crystallized as the acid (8). Similarly, Hulyalkar and Perry oxidized D-galactono-1,4-lactone to obtain L-lyxuronic acid, isolated as methyl L-lyxuronate (9). Essentially, oxidative removal of the primary alcohol of an aldonolactone results in inversion of the molecule with the penultimate carbon atom of the aldonolactone becoming C-1 of the uronic acid lactone.

Trial experiments followed by paper chromatography indicated that D-*glycero*-D-*gulo*-hepto nolactone (**1**) is oxidized by an equimolar quantity of periodic acid to yield approximately equal amounts of arabinose (**3**), glucurone (**2**), and unreacted starting material. The arabinose and glucurone arise from glycol cleavage of the heptonolactone at C_2—C_3 and C_6—C_7, respectively. Apparently, 2-*O*-glyoxylyl-D-arabinose, the initial product expected from oxidation at C_2—C_3, is unstable under the experimental conditions which were used. The products were identified as D-arabinose and L-glucurone by isolation as the crystalline derivatives D-arabinose diethyl dithioacetal and 2,4,5-tri-*O*-acetyl-L-glucurone diethyl dithioacetal.

Two procedures were developed for the preparation of L-glucurone. Small quantities (ca. 25 mg) were very simply obtained by treatment of D-*glycero*-D-*gulo*-heptonolactone with an equimolar amount of periodic acid followed by thin-layer chromatography (t.l.c.) of the oxidation mixture on cellulose. The L-glucurone was either crystallized directly or converted to the triacetate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

For larger scale work it was desirable to improve the yield of L-glucurone and avoid chromatographic isolation. It was therefore necessary to prevent cyclic glycol cleavage and ensure that oxidation of the exocyclic triol (C_5—C_6—C_7) was restricted to C_6—C_7. This was accomplished by using a suitably substituted starting material, the 3,5;6,7-di-*O*-isopropylidene derivative (**4**) of D-*glycero*-D-*gulo*-heptonolactone.

Isopropylidene acetals involving primary alcohol groups are often acid-labile as, for example, in the case of exocyclic acetal groups of di-*O*-isopropylidene hexofuranoses (11). A similar sensitivity to acid has been found with the C_6—C_7 isopropylidene group of **4** (12).[1] It was advantageous to effect both hydrolysis and oxidation of **4** in one step with periodic acid. The product, presumably 2,4-*O*-isopropylidene-*aldehydo*-L-glucurone (**5**), gave positive reactions with Fehling's solution and Schiff reagent. According to t.l.c. the oxidation product was a mixture of two compounds both of which gave a distinctive purple color with the *p*-anisidine hydrochloride spray reagent. The two compounds were probably **5** in the form of lactone and acid. Treatment of the syrupy mixture with 90% trifluoroacetic acid for hydrolysis of the isopropylidene group (13) afforded crude crystalline L-glucurone in almost theoretical yield based on **4**. The yield of pure recrystallized L-glucurone was over 80%.

L-Glucose was prepared from L-glucurone by procedures previously developed for the enantiomeric compound. This involved temporary blocking of the reducing group as the 1,2-*O*-isopropylidene acetal (14), followed by reduction of the lactone with sodium borohydride in the presence of boric acid (15). The crude 1,2-*O*-isopropylidene-L-glucose which was obtained was hydrolyzed with trifluoroacetic acid to L-glucose. Since D-glucose was the precursor of D-*glycero*-D-*gulo*-heptonolactone from which the L-glucurone was derived, this overall sequence of reactions constitutes the conversion of D-glucose into L-glucose.

[1]In two publications Brimacombe and co-workers discuss the acetonation of **1** to yield **4** and refer to an analogous case (25) stating "acid-catalyzed acetonation of D-glucurono-δ-lactone diethyl dithioacetal yields a 2,4-*O*-isopropylidene derivative, presumably with contraction in size of the lactone ring" (10), and "D-glucurono-6,2-lactone diethyl dithioacetal, which yields a 2,4-*O*-isopropylidene derivative, presumably with contraction in size of the lactone ring" (12). The assumption of ring contraction is erroneous and has apparently arisen from a typographical error in Gorin's paper in which compounds referred to as δ-lactones were actually γ-lactones. This is indicated by infrared (i.r.) data for the isopropylidene derivative of D-glucurone diethyl dithioacetal (absorption at 1780 cm^{-1}). Moreover the starting material "D-glucurono-δ-lactone diethyl dithioacetal prepared by the method of Zinner and Dassler" was in fact the γ-lactone (26).

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Paper chromatography was carried out by the descending method on Whatman No. 4 paper using ethyl acetate–pyridine–water (10:4:3 v/v) as developing solvent. Thin-layer chromatography was performed on silica gel G with development in ethyl acetate. Spray reagents for detection of compounds were *p*-anisidine hydrochloride (16) and alkaline silver nitrate (17); for t.l.c. 50% sulfuric acid was also used. Chromatograms sprayed with *p*-anisidine hydrochloride or sulfuric acid were heated at 120° for visualization. Solutions were concentrated under reduced pressure using a rotary evaporator and a water bath at a temperature of 50° or less.

L-*Glucurone (2) from Unsubstituted* D-*Glycero*-D-*gulo*-*heptonolactone (1)*

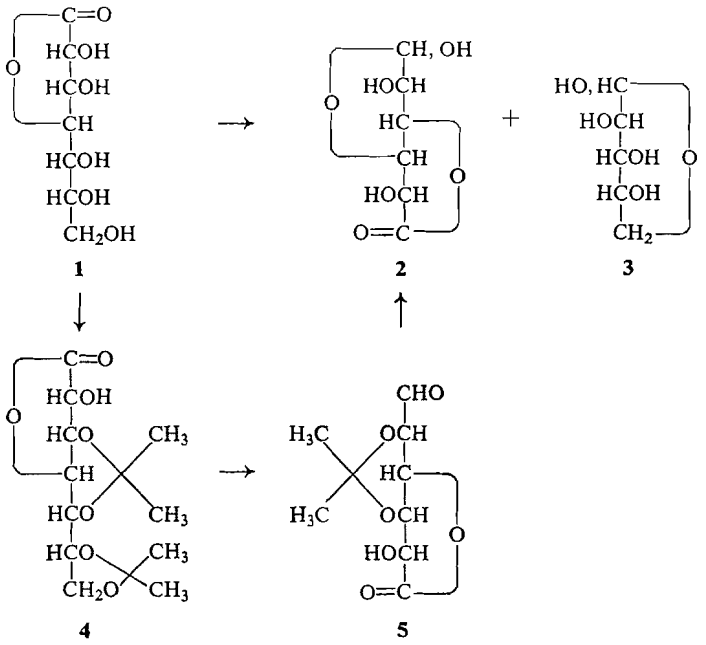
(a) Characterization of Products

In small scale (mmole) experiments followed by paper chromatography, solutions of **1** (7) were treated with an equimolar amount of periodic acid at 5° and at room temperature, and for periods ranging from a few min to 1 h. Under all conditions there appeared to be roughly equal amounts of arabinose (**3**), glucurone (**2**), and unreacted **1**. The products were characterized from an oxidation carried out on a larger scale.

Solutions of periodic acid (4.56 g) and **1** (4.16 g), each in 100 ml of water, were mixed and left for 1 h at room temperature. Barium acetate (2.8 g) in water (25 ml) was added to the mixture, the precipitate was removed by filtration and the filtrate was evaporated. The residue was treated with hydrochloric acid (5 ml) and ethanethiol (5 ml) for 1 h at 10°. Ice and water (15 ml) were added to the reaction and the mixture was extracted with ethyl acetate (5 × 50 ml). The aqueous layer was evaporated to dryness and the residue was crystallized from methanol–water to recover unoxidized heptonolactone (1.5 g, 36%), m.p. 152–154°. The combined ethyl acetate extracts were washed with saturated sodium bicarbonate solution (30 ml) and water (2 × 30 ml) and dried over anhydrous sodium sulfate. The solution was concentrated to about 30 ml and cooled to yield D-arabinose diethyl dithioacetal (0.9 g), m.p. 126–127° and $[\alpha]_D^{23}$ −11.2° (*c*, 3.67 in methanol). The reported values are m.p. 126° and $[\alpha]_D^{24}$ −11.0° (*c*, 3.69 in methanol) (18).

Anal. Calcd. for $C_9H_{20}O_4S_2$: C, 42.16; H, 7.89; S, 25.01. Found: C, 42.54; H, 7.60; S, 25.11.

The mother liquor from the D-arabinose diethyl dithioacetal was evaporated to a syrup which was dried over phosphorus pentoxide in a vacuum desiccator. The residue (2.3 g) was acetylated with acetic anhydride (10 ml) and pyridine (8 ml) for 5 h at 4°. The mixture was poured into ice and water containing sodium bicarbonate and extracted with ether. The combined ether



extracts were washed successively with cold dilute sulfuric acid, water, saturated sodium bicarbonate solution and water and then dried over anhydrous sodium sulfate. The ether solution was evaporated to a residue which was redissolved in ether–petroleum ether to crystallize 2,4,5-tri-*O*-acetyl-L-glucurone diethyl dithioacetal (1.0 g from 4 crops); m.p. 113–114° and $[\alpha]_D^{23}$ −53.3° (*c*, 4.30 in chloroform). Literature values for 2,4,5-tri-*O*-acetyl-D-glucurone diethyl dithioacetal are m.p. 113–114° and $[\alpha]_D^{25}$ +58° (*c*, 4.1 in chloroform) (19); and m.p. 110–112° and $[\alpha]_D^{16}$ +53.9° (*c*, 1.61 in methanol) (20).

Anal. Calcd. for $C_{16}H_{24}O_8S_2$: C, 47.04; H, 5.93; S, 15.69. Found: C, 46.83; H, 5.81; S, 15.59.

(b) L-Glucurone

L-Glucurone was conveniently prepared in small amounts directly from **1** by using t.l.c. for its isolation. A solution of periodic acid (H_5IO_6, 228 mg) in water (5 ml) was added to a solution of D-*glycero*-D-*gulo*-heptonolactone (208 mg) in water (5 ml). The reaction mixture was left for 15 min at room temperature and barium acetate (137 mg) was added. The precipitate was removed by filtration and the filtrate was evaporated to a syrup (*ca.* 210–220 mg). Preparative t.l.c. of the mixture on microcrystalline cellulose (21) (0.5 mm layers on 2 plates 20 × 20 cm) using double development in acetone–water (19:1 v/v) gave syrupy L-glucurone. Yields ranged from 40 to 52 mg. For crystallization the syrupy product (42 mg) was first dissolved in hot acetic acid. The solution was then evaporated and the residue was crystallized from methanol–ether to obtain L-glucurone (28 mg, 16% yield from **1**) with m.p. 174–176° and $[\alpha]_D^{23}$ −19° (*c*, 2.07 in water). The reported values for L-glucurone are m.p. 169–172° and $[\alpha]_D^{25}$ −18.5° (*c*, 0.6 in water) (2); for D-glucurone m.p. 180° and $[\alpha]_D^{23}$ +18.55° (*c*, 1.914 in water) (22).

Anal. Calcd. for $C_6H_8O_6$: C, 40.91; H, 4.59. Found: C, 41.22; H, 4.59.

Syrupy L-glucurone (52 mg) isolated by t.l.c. was acetylated by treatment for 1 h with acetic anhydride (0.5 ml) containing boron trifluoride etherate (0.05 ml). The mixture was poured into ice and water and the resulting precipitate was recrystallized from methanol to obtain 1,2,5-tri-*O*-acetyl-β-L-glucurone (53 mg) having m.p. 195–196° and $[\alpha]_D^{21}$ −85.4° (*c*, 2.58 in chloroform). Literature values for 1,2,5-tri-*O*-acetyl-β-D-glucurone are m.p. 193–194° and $[\alpha]_D^{20}$ +89.6° (*c*, 2.21 in chloroform) (23).

Anal. Calcd. for $C_{12}H_{14}O_9$: C, 47.68; H, 4.68. Found: C, 47.69; H, 4.66.

L-Glucurone (2) from 3,5;6,7-di-O-isopropylidene-D-glycero-D-gulo-heptonolactone (4)

A solution of periodic acid (H_5IO_6, 2.28 g) in water (25 ml) was added to **4** (10) (2.88 g) in an equal volume of water and the mixture was shaken for 1 h at room temperature. Barium carbonate (1.5 g) was added and shaking was continued for 15 min. The neutralized mixture was filtered and the filtrate was evaporated to dryness. The residue was extracted with acetone and the extract was concentrated to obtain a hygroscopic syrup (2.10 g) having $[\alpha]_D^{22}$ −83° (*c*, 1.9 in acetone). This product, which gave positive reactions with Fehling's solution and Schiff reagent, was a mixture of two compounds according to t.l.c. Both produced a distinctive purple color with the *p*-anisidine hydrochloride spray reagent. The major compound was mobile with a tendency to streak, while the minor compound remained on the starting line. The mixture (1.00 g) was hydrolyzed with 90% trifluoroacetic acid (13) (10 ml) for 10 min at room temperature. Evaporation of the hydrolyzate gave crude crystalline L-glucurone, m.p. 165–167°, (0.81 g,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

yield 97% from **4**). On recrystallization from acetic acid (10 ml) the product (0.69 g, yield 83% from **4**) had m.p. 180–181° and $[\alpha]_D^{22}$ −18° (*c*, 2.0 in water).

Anal. Calcd. for $C_6H_8O_6$: C, 40.91; H, 4.59. Found: C, 41.06; H, 4.52.

L-Glucose

1,2-*O*-Isopropylidene-L-glucurone, m.p. 122–123° and $[\alpha]_D^{22}$ −68° (*c*, 1.2 in water), was prepared from L-glucurone and acetone using sulfuric acid catalyst according to procedures described for the D-glucurone derivative (14) except that the calculated quantity of ammonium hydroxide instead of barium carbonate or sodium carbonate was used for neutralization of the sulfuric acid. The corresponding constants recorded for 1,2-*O*-isopropylidene-D-glucurone are m.p. 120° and $[\alpha]_D^{18}$ +70° (*c*, 1.0 in water) (14).

Anal. Calcd. for $C_9H_{12}O_6$: C, 49.99; H, 5.60. Found: C, 50.03; H, 5.56.

1,2-*O*-Isopropylidene-L-glucurone was reduced in boric acid solution with sodium borohydride (15). A stirred solution of the sugar (0.54 g) in 0.4 *M* boric acid (15 ml) was cooled in an ice-bath and treated with 0.3 *M* sodium borohydride (25 ml) added over 30 min. The reaction was stored at 4° for 22 h with a further addition of 0.3 *M* sodium borohydride (15 ml) after 4 h. The solution was neutralized with dilute acetic acid, passed through Rexyn 101 (H^+) (Fisher Scientific Co., Ltd.) and evaporated to dryness. Some of the borate was removed from the residue by adding methanol and evaporating to dryness several times. The mixture was then hydrolyzed with 90% trifluoroacetic acid (6 ml) for 15 min at room temperature. The hydrolyzate, after concentration to dryness, was repeatedly treated with methanol until the remaining borate was removed. The syrupy product was crystallized from ethanol–water to obtain 2 crops of L-glucose (390 mg) having m.p. and mixed m.p. 146–147° and $[\alpha]_D^{24}$ −53° (*c*, 3 0 in water). Reported values for α-L-glucose are m.p. 146–147° and $[\alpha]_D^{22}$ −53° (at equilibrium; *c*, 2.6 in water) (24).

Substitutions électrophiles en série naphtalènique. VI. Sur le diméthoxy-2,6 naphtalène[1]

JEAN-CLAUDE RICHER ET ARMAND ROSSI
Département de Chimie, Université de Montréal, B.P. 6128, Montréal, Québec

Reçu le 29 novembre 1968

Les réactions de chloration, bromation, iodation, et nitration du diméthoxy-2,6 naphtalène et de ses dérivés ont été étudiées. La nature des produits obtenus a été établie grâce à la résonance magnétique nucléaire. Les effets isotopiques qui affectent les réactions de chloration, bromation, iodation, et nitration du diméthoxy-2,6 naphthalène ont aussi été évalués.

Canadian Journal of Chemistry, 47, 3935 (1969)

Introduction

Il a été établi au cours de travaux précédents (1,2) sur les réactions de substitutions électrophiles des naphtalènes (**1***a* et **1***b*) disubstitués en position 2 et 6 que le groupe *tert*-butyle provoque un encombrement stérique tel qu'il modifie considérablement le cours de la réaction. Il s'avérait intéressant d'examiner les facteurs mésomériques sur cette réaction, et pour fins de comparaison, le groupe méthoxy qui est reconnu pour fournir des électrons par résonance a été choisi. Les résultats obtenus au cours de ces études font l'objet de la présente communication.

Resultats

La chloration par SO_2Cl_2, la bromation par le brome dans le chloroforme, l'iodation par ICl, et la nitration par l'acide nitrique du diméthoxy-2,6 naphtalène (**1***c*) conduisent aux dérivés monosubstitués en position 1 (**2***a–d*) et disubstitués en positions 1 et 5 (**3***a–d*). La chloration par SO_2Cl_2 et la bromation par le brome dans l'acide acétique du diméthoxy-2,6 iodo-1 naphtalène (**2***c*) conduit aux dérivés halogénés mixtes correspondants (**3***e* et *f*). La chloration, la bromation, et l'iodation (HIO_3; I_2) du diméthoxy-2,6 nitro-1 naphtalène (**2***d*) fournissent les dérivés nitrohalogénés en positions 1 et 5 (**3***g*, *h*, et *i*). La nitration du dinitro-1,5 diméthoxy-2,6 naphtalène (**3***d*) ou des dérivés nitrohalogénés **3***g* et *h* conduit aux dérivés correspondants **4***a*, *b*, et *c* possédant un groupe nitro supplémentaire; par ailleurs la nitration du diméthoxy-2,6 iodo-1 nitro-5 naphtalène (**3***i*) conduit à une substitution de l'iode par le groupe nitro menant au dinitro-1,5 diméthoxy-2,6 naphtalène (**3***d*). La nitration des dichloro-1,5 (**3***a*) et dibromo-1,5 (**3***b*) diméthoxy-2,6 naphtalène conduit aux dérivés nitrés correspondants **4***d* et *e* alors que la nitration du diiodo-1,5 diméthoxy-2,6 naphtalène (**3***c*) conduit à une substitution des deux iodes par deux groupes nitro et fournit ainsi le dérivé **3***d*.

La nitration des dichloro-1,5 (**4***d*) et dibromo-1,5 (**4***e*) diméthoxy-2,6 nitro-4 naphtalènes mène d'une part à une substitution de l'un des halogènes par le groupe nitro et fournit ainsi les chloro-1

[1]Les résultats rapportés dans cette communication sont extraits en partie du mémoire soumis par M. Armand Rossi à la Faculté des Sciences de l'Université de Montréal, Montréal, P.Q., en vue de l'obtention du grade de Maitre ès Sciences, Août, 1968.

(**4***b*) et bromo-1 (**4***c*) diméthoxy-2,6 dinitro-4,5 naphtalènes et d'autre part aux chloro-5 (**6***b*) et bromo-5 (**6***a*) méthoxy-6 nitro-8 naphtoquinones-1,2 caractérisées sous forme des quinoxalines **7** correspondantes; cette quinone se formerait par l'intermédiaire des produits d'addition **5** dont l'un (**5***a*) a pu être caractérisé. La nitration des quinones **6** dans des conditions plus poussées conduit à des mélanges de dinitro-3,8 et dinitro-4,8 méthoxy-6 halogéno-5 naphtoquinone-1,2 (**8** et **9**)

Utilisant du diméthoxy-2,6 naphtalène-*d*, (**2***e*) préparé par hydrolyse de l'organomagnésien du diméthoxy-2,6 iodo-1 naphtalène avec un mélange D_2O/DCl, les effets isotopiques des réactions de chloration par SO_2Cl_2, de bromation par le brome dans le chloroforme, de l'iodation par ICl, et de nitration très ménagées ont été évalués. Les résultats obtenus au cours de ces études sont consignées dans le tableau I qui montre que les effets isotopiques moyens varient de 1.07 pour la chloration à 6.2 pour la réaction d'iodation.

Discussion

D'une manière générale, la structure des produits obtenus a été établie en se basant sur les spectres infra-rouges (i.r.) (3), les spectres de masse, et les couplages des bandes dues aux protons aromatiques dans les spectres de résonance magnétiques nucléaire (r.m.n.). Les positions des bandes dûes à des protons sont résumées dans les tableaux II et III. Dans le cas des dérivés nitrés la méthode empirique proposée par Wells et Alcorn (4), et appliquée dans les cas précédents (1,2,5, et 6), a aussi été utilisée. Les positions des bandes déduites par l'application de cette méthode sont mises en regard des valeurs observées dans le tableau II.

L'utilisation d'une méthode semblable à celle utilisée pour les dérivés nitrés a permis d'élucider sans ambiguité la structure des dérivés halogénés dans la série du diméthoxy-2,6 naphtalène (**1***c*). Une observation a été faite concernant la possibilité de prévoir les positions de résonance de différents protons aromatiques des dérivés dihalogénés et nitrohalogénés obtenus. Cette méthode consiste à ajouter aux déplacements chimiques des protons de la molécule monosubstituée des incréments déterminés expérimentalement à partir des spectres de r.m.n. des dérivés halogénés en position 1 (**1***a*, *b*, et *c*) du diméthoxy-2,6 naphtalène. Le tableau III montre les déplacements chimiques dus à un halogène

entrant en position 1 dans le diméthoxy-2,6 naphtalène. L'application des incréments ainsi déterminés à des dérivés de structure non prouvée a été faite; les prédictions ainsi que les valeurs expérimentales observées pour quelques dérivés du diméthoxy-2,6 naphtalène sont résumées dans le tableau IV. La concordance entre les valeurs calculées et les valeurs expérimentales est assez bonne dans tous les cas considérés. Cette méthode ne peut toutefois pas être généralisée aux dérivés halogénés des diméthoxy-2,7 et diméthoxy-1,7 naphtalènes; elle permet cependant d'assigner sans ambiguité aux bandes de résonance des spectres des chloro-1 (**3***e*) et bromo-1 (**3***f*) diméthoxy-2,6 iodo-1 naphtalène et des dérivés nitrohalogénés en positions 1 et 5 (**3***g*, *h*, et *i*) les protons correspondants.

La structure des quinones préparées peut être attribuée elle aussi en se basant sur le couplage des bandes des protons. Les spectres de r.m.n. des naphtoquinones-1,2 (**6***a*, *b*) correspondent à la superposition d'un singulet (H_7) sur les éléments d'un système AB (H_3 et H_4). Il est possible d'attribuer à la paire de doublet (J = 11 c.p.s.) les protons correspondants, H_3 pour le doublet se trouvant vers les champs les plus hauts, et H_4 pour le doublet se trouvant vers les champs les plus bas; l'étude des spectres de r.m.n. des dérivés donnés dans le tableau V confirme cette hypothèse. Il s'avère plus difficile d'attribuer avec certitude les structures aux nitronaphtoquinones **8** et **9**; cependant Fieser et Ames (9) ayant démontré que la nitration d'une naphtoquinone-1,2 conduit principalement au dérivé nitré en position 3, il est possible de suggérer d'après l'intégration des groupes méthoxy ou des protons en position 3 et 4 que la nitronaphtoquinone **8***b* représente 64% du produit de nitration de la quinone **6***b*.

Les résultats obtenus au cours du présent travail montrent l'influence nette des effets mésomériques des groupes méthoxy en position 2 et 6 qui orientent essentiellement toutes les réactions

vers les positions α adjacentes à savoir les positions 1 et 5. Cette influence se manifeste de plus par la facilité avec laquelle des substituants déjà fixés à ces positions sont déplacés au cours de réactions de substitution subséquentes; la formation des quinones **6** par l'intermédiaire des produits d'additions **5** correspondants pourrait aussi être attribuée essentiellement à l'orientation d'une substitution vers une position adjacente à un groupe méthoxy. L'ensemble de ces résultats montre que, contrairement aux résultats obtenus lors des réactions de substitution sur le diméthyl-2,6 (**1***a*) et sur le di-*tert*-butyl-2,6 (**1***b*) naphtalènes, les facteurs influençant l'orientation des réactions de substitution, qui sont dans le cas présent des facteurs de nature électroniques, conduisent toujours à une orientation similaire des réactions de substitutions.

La formation des naphtoquinones-1,2 (**6**) doit être rapprochée du résultat rapporté par Bell (10) lors de la nitration du chloro-1 diméthoxy-2,7 nitro-8 naphtalène qui conduirait à une dinitro-3,8 méthoxy-7 naphtoquinone-1,2. Les conditions expérimentales utilisées étant plus douces que celles utilisées par Bell (température ambiante et acide nitrique densité 1.42) les différentes séquences de la nitration ont pu, dans notre étude, être mises en évidence.

Les réactions de chloration, de bromation, d'iodation, et de nitration de dérivés aromatiques procèdent vraisemblablement par stades multiples; les effets isotopiques mesurés pour ces réactions sont généralement faibles (11,12) ou quelque fois même inversés (11–14). Des effets isotopiques plus grands que l'unité ont toutefois été observés lors de substitutions au cours desquelles des effets stériques pouvaient intervenir (15–20). Les effets isotopiques déterminés pour les réactions de chloration, de bromation, et de nitration du diméthoxy-2,6 naphtalène, sont faibles. Bien que tous ces effets soient plus grands que l'unité, il est difficile considérant les conditions diverses sous lesquelles ces réactions ont été conduites, d'en tirer des conclusions concernant l'étape déterminante de la réaction. La réaction d'iodation de **1***c* qui peut-être rapprochée des résultats obtenus avec l'anisole (20) permet toutefois de préciser que l'étape déterminante de cette réaction est l'enlèvement de l'hydrogène. Ce résultat confirmerait l'importance des effets stériques sur la nature de l'étape déterminante dans les réactions de substitutions électrophiles en série aromatique. Il permettrait aussi d'envisager (voir schéma 1) que la nature des produits formés lors des réactions de substitutions électrophiles sur le di-*tert*-butyl-2,6 naphtalène **1***b* (2) est déterminée par la diminution de la vitesse (k_2) d'élimination de l'hydrogène en position 1 par rapport à la vitesse (k_2') d'élimination de l'hydro-

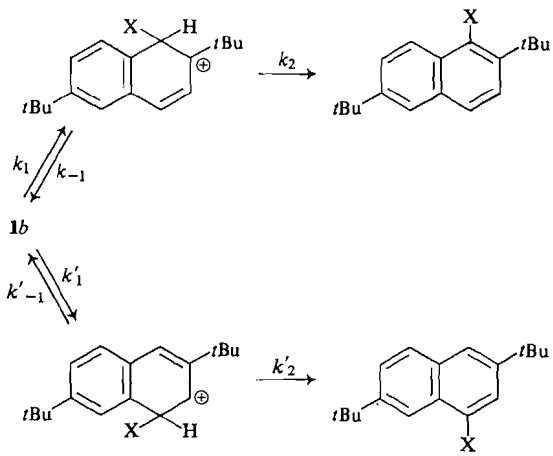

SCHÉMA 1

gène en position 4 au fur et à mesure de l'accroissement de la taille de 10. Un raisonnement semblable pourrait être développé pour expliquer les résultats obtenus lors des substitutions sur le di-*tert*-butyl-2,7 naphtalène (21).

Partie expérimentale

Les techniques expérimentales générales ont été décrites dans une publication précédente (21). Les spectres de masse sous forme de graphiques et la description des spectres ultra-violets (u.v.) et (i.r.) des produits décrits dans cette publication sont rapportés en détail dans le mémoire de Maitrise de M. Armand Rossi dont une copie a été déposée à la bibliothèque du Conseil National de Recherches.

Les caractéristiques des produits obtenus au cours du présent travail sont résumées dans le tableau VI. Les techniques de chloration, bromation, iodation, et nitration sont essentiellement celles qui ont déjà été rapportées.

Préparation de naphtoquinones-1,2 substituées

Bromo-5 méthoxy-6 nitro-8 naphtoquinone-1,2 (6a)

A 3 g (8.7 mmoles) de dibromo-1,5 diméthoxy-2,7 naphtalène (3*b*) dans 30 ml d'acide acétique, 5 ml d'acide nitrique (d = 1.42) sont ajoutés et le mélange agité à la température ambiante durant 1.5 h. Le produit solide (1.21 g) obtenu par filtration et chromatographié sur une colonne de gel de silice conduit à : 1.01 g (30% du rendement théorique) du dibromo-1,5 diméthoxy-2,6 nitro-4 naphtalène (4*e*), p.f. 228–230 °C (benzène/éthanol) et 50 mg (0.5% du rendement théorique) du bromo-1 diméthoxy-2,6 dinitro-4,5 naphtalène (4*c*) p.f. 268–269°. La dilution du filtrat avec 5 fois son volume d'eau conduit à un précipité qui est recueilli, lavé rapidement avec une faible quantité de méthanol puis d'éther de pétrole; on obtient ainsi 657 mg (18% du rendement théorique) de dibromo-1,5 dihydro-1,2 méthoxy-6 dinitro-1,8 oxo-2 naphtalène (5*a*) de p.f. 210° (décomposition).

Par dissolution dans 20 ml de tétrachlorure de carbone bouillant ce composé perd NOBr; après refroidissement de la solution et filtration, 407 mg d'un produit sont obtenus et chromatographiés sur 40 g de gel de silice utilisant comme éluant du benzène mélangé au chloroforme. On obtient ainsi 380 mg de bromo-5 méthoxy-6 nitro-8 naphtoquinone-1,2 (6*a*) de p.f. 235–236° (avec décomposition). Cette quinone est caractérisée sous forme de quinoxaline (7*a*).

Ce dérivé est obtenu en ajoutant une solution contenant 60 mg d'*o*-phénylènediamine dans 2 ml d'acide acétique à 45 mg de naphtoquinone (6*a*) dissoute dans 10 ml d'acide acétique glaciale, et en chauffant le mélange à reflux pendant 30 min. Ce dérivé fond à 293–294° et donne une coloration bleue foncé avec l'acide sulfurique concentré. Son spectre de masse montre un pic à *m/e* 383.

Bromo-5 méthoxy-6 dinitro-3,8 naphtoquinone-1,2 (8a)

A 190 mg de naphtoquinone 6*a* dissoute dans 4 ml d'acide acétique glaciale, 5 ml d'acide nitrique (d = 1.42) sont ajoutés et le mélange est chauffé à reflux pendant 40 min. Le solide obtenu par refroidissement est filtré et conduit à 161 mg d'un produit montrant un pic à 356 unités dans le spectre de masse et dont l'étude du spectre r.m.n. laisse supposer qu'il s'agit d'un mélange de composants qui serait les bromo-5 méthoxy-6 dinitro-3,8 (8*a*, 64%) et bromo-5 méthoxy-6 dinitro-4,8 (9*a*, 36%) naphtoquinone-1,2.

Effets isotopiques

Préparation du diméthoxy-2,6 naphtalène-d_1 (2e)

A une solution de 5 g (16 mmoles) de diméthoxy-2,6 iodo-1 naphtalène (**2c**) dans 60 ml de T.H.F. strictement anhydre, 450 mg de magnésium et une trace d'iode sont ajoutés. Le mélange est maintenu sous une atmosphère d'azote avec agitation et chauffé à reflux durant 4 h: après refroidissement, 5 ml de D_2O et 3 ml de DCl (38% dans D_2O) sont ajoutés. Les produits (1.72 g, 71% de rendement après recristallisation dans l'éthanol) sont extraits au chloroforme. Le p.f. de ce naphtalène est le même que celui du diméthoxy-2,6 naphtalène non deutérié.

Evaluation des effets isotopiques

Les effets isotopiques (E.I.) sont évalués à partir des pourcentages (A) de deutérium dans le naphtalène **2e** et (A') de deutérium présent dans les dérivés monosubstitués obtenus et à l'aide de l'équation:

$$\text{E.I.} = AA'/100A + AA' - 200A'.$$

Cette équation est strictement applicable dans les cas où la conversion en dérivé monosubstitué est faible: dans le cas actuel elle représente une approximation correcte de l'effet isotopique. Les pourcentages de deutérium présents sont mesurés par spectrométrie de masse utilisant un appareil Hilachi–Perkin-Elmer, modèle RMU-6D muni d'un mécanisme d'introduction à la source. Les échantillons de dérivés monosubstitués (accompagnés de **2e** qui n'a pas réagi) qui ont ainsi été analysés ont été obtenus en faisant réagir à la température ambiante des méthoxy-2,6 naphtalène-1, avec des quantités déficitaires (approximativement 0.5 mole de réactif/mole de naphtalène) de réactifs. Ces réactions ont été conduites pour des temps courts (15 min) afin de s'assurer que la conversion est faible (évalué à 25%) et que des réactions de disubstitution n'ont pas lieu (il a été établi par chromatographie en phase gaseuse (c.p.g.) que les échantillons analysés ne contenaient pas de produits disubstitués).

Remerciements

Les auteurs remercient vivement le Conseil National de Recherches du Canada et le Service de l'Aide Extérieure du Ministère de l'Education de la Province de Québec pour l'Aide financière apportée sous forme de subventions de recherches et bourse d'études.

L'un de nous (J. C. R.) tient à exprimer sa gratitude au Dr. Pierre Maroni et Mlle. Marthe Benoit de la Faculté des Sciences de Toulouse pour l'acceuil et l'aide apportés au cours de la préparation de ce manuscrit.

Branched-chain sugar nucleosides.[1] III. 9-(3-Deoxy-3-*C*-methyl-β-D-allofuranosyl and ribofuranosyl)adenine

ALEX ROSENTHAL AND MATEJ SPRINZL
Department of Chemistry, University of British Columbia, Vancouver, B.C.
Received May 20, 1969

Condensation of triphenylphosphinemethylene (Wittig reagent) with 5-*O*-benzyl-1,2-*O*-isopropylidene-α-D-*erythro*-pentafuranos-3-ulose and with 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (**1**) afforded 5-*O*-benzyl-1,2-*O*-isopropylidene-3-deoxy-3-*C*-methylene-α-D-ribofuranose in 36% yield and 1,2:5,6-di-*O*-isopropylidene-3-*C*-methylene-α-D-*ribo*-hexofuranose (**2**) in 55% yield, respectively. A detailed study of the affect of reaction conditions on the yield of the unsaturated sugar is described. Hydrogenation of **2** proceeded stereoselectively to yield **4** which was hydrolyzed selectively to the 1,2-*O*-monoisopropylidene derivative **5**. Benzoylation of the latter gave **6** which was converted by acetolysis to the 1,2-diacetate **7**. Condensation of this compound with 6-benzamidochloromercuripurine in the presence of titanium tetrachloride followed by deblocking with methanolic sodium methoxide, yielded 9-(3-deoxy-3-*C*-methyl-β-D-allofuranosyl)adenine (**10**) in 48% yield based on **7**. Sodium metaperiodate oxidation of **10**, followed by sodium borohydride reduction of the *aldehydo* derivative, afforded 9-(3-deoxy-3-*C*-methyl-β-D-ribofuranosyl)adenine (**11**) in 85% yield.

Canadian Journal of Chemistry, 47, 3941 (1969)

Interest in 3′-deoxyribofuranosyl nucleosides stems partly from the fact that 3′-deoxyadenosine (cordycepin, the first isolated nucleoside antibiotic) inhibits nucleic acid synthesis in Ehrlich ascites cells (1,2). The recent synthesis of 3′-*C*-methyladenosine (3) and the finding that it also exhibits biological activity, has further stimulated a concern in the nucleoside antibotics. Branched-chain sugar nucleosides have recently been prepared from 3-deoxy-3-*C*-hydroxymethyl-D-erythrofuranose (4). Our laboratory has been interested in developing a general method of synthesis of branched-chain sugar nucleosides (5), and in particular, the synthesis of 3′-deoxy and 2′-deoxy branched-chain sugar nucleosides having the ribofuranosyl skeleton in the sugar moiety. In this paper we wish to report the synthesis of several deoxy branched-chain sugar nucleosides and in particular, the synthesis of a structural analogue of cordycepin by application of a Wittig reaction to ketoses.

The readily available 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexafuranos-3-ulose (**1**) (6,7) is a useful intermediate for the synthesis of 3-deoxy-3-*C*-substituted branched-chain sugars. In a previous communication (8) we described the application of the modified Wittig reaction to **1** to afford a 3-hydroxyethyl substituted branched-chain sugar, and in this paper we report the application of the basic Wittig reaction to the ketose **1**. Condensation of triphenylphosphinemethylene with **1** in the ratio 3:1 using methyl sulfoxide as solvent (9,10) gave 1,2:5,6-di-*O*-isopropylidene-3-*C*-methylene-α-D-*ribo*-hexofuranose (**2**) in 55% yield, and in addition, a by-product **3** of unknown constitution. Compounds **2** and **3** were separated by column chromatography on silica gel. The yield of **2**, as shown in Table I, was dependent on the reaction conditions. In all cases the reaction was monitored by thin layer chromatography (t.l.c.) and stopped when all ketose (except in procedure 5) was consumed. When the temperature was increased from 22° to 60°, the yield of by-product was significantly increased and the yield of **2** decreased to 23%. On the other hand, use of an equimolar ratio of ketose and ylid (see procedure 4) led to a significant decrease in the yields of both products. When 1,2-dimethoxyethane (glyme) was used as a solvent, elevated temperature (60°) was required and the maximum yield of unsaturated sugar was 28%. From the results shown in procedures 2 and 3 it would appear that the yield of **2** is approximately the same when the ketose is added to the ylid as when all the reactants are mixed together at the beginning of the reaction.

Product **3** reacted slowly with bromine in carbon tetrachloride to give an unstable halide. It also reacted with potassium permanganate but absorbed less than 0.2 mole equivalent of hydrogen over palladium. Attempts to purify it by preparative t.l.c. on silica gel led to degradation as evidenced by the fact that **3** was converted into a mixture of three new substances. Compound **3** did not contain any phosphorus or sulfur. Based

TABLE I

Wittig reaction of triphenylphosphinemethylene with 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranose (**1**) to yield unsaturated sugar **2** and by-product **3**

Procedure	Ketose:Ylid ratio	Solvent	Temperature (°C)	Time (h)	Yield **2** %	Products **2** and **3** ratio
1*	1:3	DMSO	60	2	23	2:1
2*	1:3	DMSO	22	5	53	3:1
3†	1:3	DMSO	22	1	55	3:1
4†	1:1	DMSO	22	5	30	10:1
5*	1:3	Glyme	22	12	0	
6*	1:3	Glyme	70	10	28	1:0

*Ketose added directly to the mixture of methyltriphenylphosphonium bromide, sodium hydride, and methyl sulfoxide.
†Methyltriphenylphosphonium bromide converted into the ylid before addition of the ketose.

on the work of Walling and co-worker (11) and the molecular weight of **3** (determined from its mass spectrum), it might be inferred that side products from methyl sulfoxide might have added to the ketose to afford addition products. The great difficulty in isolating sufficient material of sufficient stability to do structural work led us to abandon this phase of the research.

Hydrogenation of **2** using palladium on charcoal proceeded stereoselectively to afford, after high vacuum distillation, compound **4** in 75% yield. The configuration of C-3 of **4** was readily ascertained from its nuclear magnetic resonance (n.m.r.) spectrum. The H-2 signal of **4** appears as a triplet (resolved into two doublets under magnification) showing that H-2 is coupled to H-3 and to H-1. On the other hand, in the glucofuranose series (12) there is no coupling between H-2 and H-3, thus leading to a doublet for H-2. Therefore, the only possible configuration for C-3 is the *allo*-configuration. This was further proved by spin–spin decoupling experiments. Irradiation of H-2 of **4** collapsed H-1 into a singlet and altered H-3. Therefore, **4** is undoubtedly 1,2:5,6-di-*O*-isopropylidene-3-deoxy-3-*C*-methyl-α-D-allofuranose.

Selective hydrolysis of the 5,6-*O*-isopropylidene group of **4** to yield **5** in 81% yield was accomplished using aqueous methanol containing sulfuric acid. Benzoylation of the latter gave the dibenzoate **6** in 94% yield which was purified by column chromatography on silica gel. Acetolysis of **6** with acetic acid, acetic anhydride, and sulfuric acid for 3 days gave mainly the β-anomer **7** in 82% yield. Condensation of the latter with 6-benzamidochloromercuripurine by the titanium tetrachloride method (13) afforded the blocked *allo*-nucleoside **9**. Deacylation of **9** using methanolic sodium methoxide afforded crystalline β-nucleoside **10** in 48% yield based on **7**. The assignment of structure and anomeric configuration to 9-(3-deoxy-3-*C*-methyl-β-D-allofuranosyl)-adenine (**10**) was based on the following: (*1*) ultraviolet (u.v.) absorption data of **10** substantiates the site of glycosylation (14) at N-9, (*2*) the trans rule (15) indicates that **10** has a β-configuration, and (*3*) the *allo*-nucleoside **10** exhibits a negative Cotton effect that is consistent with the proposals advanced (16,17) for assignment of structure to purine nucleosides. The mother liquor from **10** was carefully investigated by paper chromatography and also by column chromatography on Dowex 1 × 2 (OH^-) (18) using gradient elution but the presence of any α-anomer of **10** was not detected.

Sodium metaperiodate oxidation of the *allo*-nucleoside **10** yielded an *aldehydo*-nucleoside that was immediately reduced with sodium borohydride to yield the crystalline *ribo*-nucleoside **11** in 85% yield. Surveillance of the degradation reaction using a starch–iodine test was essential to minimize production of a by-product which was difficult to remove. Based on the fact that the *allo*-nucleoside **10** was degraded to the *ribo*-nucleoside **11** by steps which are known not to alter the configuration of sugars, therefore, **11** can be assigned the structure 9-(3-deoxy-3-*C*-methyl-β-D-ribofuranosyl)adenine. In the latter nucleoside, n.m.r. evidence (H-1′ gave a doublet having $J_{1',2'} = 1.5$ Hz) corroborates the β-anomeric configuration of **11**.

The general applicability of the Wittig reaction for preparing methyl analogues of cordycepin was demonstrated by condensing 5-*O*-benzyl-1,2-*O*-isopropylidene-α-D-*erythro*-pentafuranos-3-ulose (19) with triphenylphosphinemethylene to

yield, after column chromatography on silica gel, 5-*O*-benzyl-1,2-*O*-isopropylidene-3-deoxy-3-*C*-methylene-α-D-ribofuranose in 36% yield.

Experimental

General Considerations

Nuclear magnetic resonance (n.m.r.) spectra were obtained on deuteriochloroform solution (unless otherwise stated) with tetramethylsilane as the internal standard (set at τ 10) using a Jeolco 60, a Varian A-60, or Varian HA-100 spectrometers. Mass spectroscopy was obtained with an A.E.I. M.S.9 spectrometer. The ultraviolet (u.v.) spectral measurements were performed on a Cary 140 spectrophotometer. The optical rotary dispersion (o.r.d.) measurements were performed on a Jasco Model ORD/UV-5 Spectropolarimeter at room temperature on aqueous solutions. All melting points (micro hot stage) are corrected. Silica gel G was used in the thin layer chromatography (t.l.c.). For column chromatography Silica gel Woelm 100-200 mesh, activity grade II, was used. Elemental analyses were performed by the Microanalytical Laboratory, University of British Columbia.

Application of Wittig Reaction to 1,2:5,6-Di-O-isopropylidene-α-D-ribo-hexofuranos-3-ulose (1) to Yield 1,2:5,6-Di-O-isopropylidene-3-C-methylene-α-D-ribo-hexofuranose (2)

Sodium hydride (0.240 g, 0.01 mole) was suspended in 30 ml of anhydrous methyl sulfoxide and the mixture was heated at 75° for 45 min in a dry box in an anhydrous nitrogen atmosphere. After the solution was cooled to 20° methyltriphenylphosphonium bromide (3.95 g, 0.011 mole) was added and the mixture stirred for 30 min. To the resulting mixture was added dropwise with stirring (with external cooling at 20°) a solution of 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (0.84 g, 0.0033 mole) in 10 ml of anhydrous methyl sulfoxide. After the addition, the reaction mixture was stirred for an additional 2 h and then poured into 100 ml water. The aqueous solution was extracted with 5 separate portions of 30 ml ether. The combined ether extracts were washed with water (5 × 30 ml), dried over magnesium sulfate, filtered, and evaporated under reduced pressure to yield a syrup. This syrup was dissolved in petroleum ether (50 ml, b.p. 60–90°) and then left stand overnight at 0°. Triphenylphosphonium oxide was removed by filtration and washed with several small portions of cold petroleum ether. The combined filtrate and washings were evaporated under reduced pressure to yield a syrup (0.760 g). Thin layer chromatography on silica gel G using benzene–ethyl acetate (20:1) as developer and 2% potassium permanganate or sulfuric acid as detector revealed two spots having R_f's of 0.6 and 0.5. The syrup was separated by column chromatography (60 × 1.5 cm diam) on silica gel using 100 ml of benzene followed by 600 ml of benzene–ethyl acetate (9:1) as developer. Aliquots were collected on a fraction collector and analyzed by t.l.c. as described above. Evaporation of the eluents afforded compound **2** (0.458 g, 55% yield) and a second faster moving fraction **3** (0.140 g, 17% yield).

Compound **2** showed no carbonyl in its infrared (i.r.) spectrum. It showed the presence of a methylene group (1660 cm^{-1}); τ ($CDCl_3$), 4.2 (1-H, d, $J_{1,2}$ = 4.5 Hz due to H-1), 4.55 (1-H, m, due to H-3), 5.1 (1-H, d, $J_{2,1}$ = 4.5 Hz, due to H-2), 6.0 (m, due to H-4, H-5, and H-6), 8.5 (12-H, t, due to isopropylidene groups); the compound was homogeneous by vapor phase chromatography (v.p.c.) at 160°; t.l.c. R_f 0.5, $[\alpha]_D^{22}$ + 104° (*c*, 2, chloroform).

Anal. Calcd. for $C_{13}H_{20}O_5$: C, 60.90; H, 7.84. Found: C, 61.13; H, 8.00.

The faster moving component **3** (R_f 0.6) was recrystallized from petroleum ether (b.p. 35–60°), m.p. 35–37°, and sublimed at 50 °C (0.056 mm pressure), $[\alpha]_D^{22}$ −174° (*c*, 2, chloroform). Mass spectroscopy: 304, 289. The n.m.r. spectrum showed τ ($CDCl_3$), 3.7–4.1 (1-H, m), 4.4–4.9 (1-H, m), 5.7–6.0 (m), 8.5 (12-H, due to isopropylidene groups); i.r., 1660 cm^{-1}. The compound was unstable at room temperature or on rechromatography on silica gel G (gave three new compounds). Attempts to hydrogenate this substance were unsuccessful (less than 0.2 mole equivalent of hydrogen was absorbed).

1,2:5,6-Di-O-isopropylidene-3-deoxy-3-C-methyl-α-D-allofuranose (4)

Compound **2** (1.024 g) dissolved in methanol (30 ml), was allowed to react with hydrogen at room temperature and 1 atm pressure using 10% palladium on charcoal (0.2 g) as catalyst until the gas pressure remained constant (86 ml of hydrogen absorbed). Work-up of the product **4** in the usual way followed by distillation under high vacuum (b.p. 77–80° at 0.05 mm) gave an oil, yield 0.765 g (75%), which was homogeneous by v.p.c. (at 160°) and by t.l.c. (benzene–ethyl acetate, 20:1), R_f 0.5. The n.m.r. spectrum showed τ ($CDCl_3$), 4.25 (H-1, d, $J_{1,2}$ = 3.7 Hz), 5.50 (H-2, t, $J_{2,1}$ = 3.7 Hz and $J_{2,3}$ = 3.7 Hz), 5.9–6.4 (m, due to H-4, H-5, and H-6), 8.1 (m, due to H-3), 8.6 (t, due to isopropylidene groups), 8.4 (d, due to H-3′, $J_{3,3'}$ = 7 Hz). Irradiation of H-3 collapsed the doublet at 8.5 p.p.m. to a singlet; $[\alpha]_D^{22}$ +37° (*c*, 1, chloroform).

Anal. Calcd. for $C_{13}H_{22}O_5$: C, 60.40; H, 8.52. Found: C, 60.28; H, 8.52.

5-O-Benzyl-1,2-O-isopropylidene-3-deoxy-3-C-methylene-α-D-ribofuranose

Application of the Wittig reaction to 5-*O*-benzyl-1,2-*O*-isopropylidene-α-D-*erythro*-pentafuranos-3-ulose as described in the first part of the experimental gave after column chromatography of the product 5-*O*-benzyl-1,2-*O*-isopropylidene-3-deoxy-3-*C*-methylene-α-D-ribofuranose in 36% yield, τ ($CDCl_3$), 4.12 (d, H-1, $J_{1,2}$ = 4 Hz), 4.5–4.8 (m), 5.1 (d, due to =CH_2), 5.42 (s, due to O—$CH_2C_6H_5$), 6.04 (m, due to H-5), 8.55 (d, due to isopropylidene group), R_f = 0.55 (benzene–ethyl acetate 10:1), $[\alpha]_D^{22}$ +63° (*c*, 1, chloroform).

Anal. Calcd. for $C_{16}H_{20}O_4$: C, 69.60; H, 7.26. Found: C, 70.02; H, 7.15.

1,2-O-Isopropylidene-3-deoxy-3-C-methyl-α-D-allofuranose (5)

To a solution of 0.520 g of **4** in 4 ml of methanol was added 4 ml of 0.1 *N* sulfuric acid. After the reaction mixture was left standing at room temperature for 3.5 h it was neutralized with barium hydroxide (p*H* kept at 7), boiled, and filtered through Celite. The filtrate was evaporated to dryness and the residue dissolved in 20 ml water. The solution was extracted with 5 ml chloroform to remove a trace of **4**. After the water solution was again evaporated to dryness the residue was extracted with 3 × 20 ml of boiling chloroform. The combined chloroform extracts were dried over magnesium sulfate, filtered, and evaporated to dryness, yield 0.356 g (81%) of a syrup, R_f = 0.45 (benzene–methanol 3:1), $[\alpha]_D^{22}$ + 35° (*c*, 1, chloroform).

5,6-Di-O-benzoyl-1,2-O-isopropylidene-3-deoxy-3-C-methyl-α-D-allofuranose (6)

To a solution of **5** (0.870 g) in pyridine (10 ml) was added dropwise freshly distilled benzoyl chloride (1 ml). After the reaction mixture was kept at room temperature overnight it was poured into water, and the product extracted with chloroform in the usual way, yield 1.48 g (94%). Fractionation of the crude product on silica gel (80 × 2 cm diam) with 20:1 benzene–ethyl acetate gave 1.35 g of product which was dissolved in methanol to yield a glass, R_f = 0.6 (10:1 benzene–ethyl acetate), τ ($CDCl_3$), 1.9–2.5 (10-H due to phenyl), 4.15 (d, H-1, $J_{1,2}$ = 3.5 Hz), 8.0 (m, due to H-3), 8.8 (d, due to H-3′, $J_{3,3'}$ = 7 Hz), $[\alpha]_D^{22}$ +32° (*c*, 1, chloroform).

Anal. Calcd. for $C_{24}H_{26}O_6$: C, 70.3; H, 6.39. Found: C, 70.5; H, 6.72.

1,2-Di-O-acetyl-5,6-di-O-benzoyl-3-deoxy-3-C-methyl-α(β)-D-allofuranose (7)

To a well-stirred solution (kept at 0°) of **6** (1.230 g) in glacial acetic acid (15 ml) and acetic anhydride (1.5 ml) was added dropwise 0.82 ml of concentrated sulfuric acid. After storage at room temperature for 4 days the solution was poured into 50 ml of vigorously stirred mixture of ice and water. The resulting mixture was extracted with chloroform (2 × 20 ml), the chloroform extracts washed with 20 ml of water, aqueous sodium bicarbonate, water, dried over magnesium sulfate, filtered, and evaporated to dryness *in vacuo* to give 1.12 g (83%) of a syrup **7**; $[\alpha]_D^{22}$ 0° (*c*, 2, chloroform), τ ($CDCl_3$), 3.95 (s, due to H-1), 4.75 (d, H-2, $J_{2,3}$ = 5.2 Hz).

9-(3-Deoxy-3-C-methyl-β-D-allofuranosyl)-adenine (10)

A mixture of 1.35 g (0.003 mole) of sugar **7**, 1.60 g (0.0037 mole) of 6-benzamidochloromercuripurine (**8**), and 1 g of Celite and anhydrous xylene (20 ml) was dried by distilling off the xylene under reduced pressure. To the resulting residue was added 50 ml of anhydrous ethylene dichloride and 15 ml of the solvent was distilled. To the partially cooled mixture was added a solution of 0.338 ml of titanium tetrachloride in 4 ml of ethylene dichloride, and the reaction mixture was heated under reflux for 4 h. The cooled reaction mixture was then poured into 50 ml of saturated sodium bicarbonate and stirred vigorously for 30 min, and then filtered through Celite. The Celite cake was washed with chloroform, and the combined organic extracts washed with 15 ml of 30% aqueous potassium iodide and 15 ml of water. After evaporation of the solvent under reduced pressure the residue was dissolved in 30 ml methanol and the resulting solution decolorized with charcoal, filtered through a Celite column, and then evaporated to dryness under *vacuo* to give 0.98 g (52%) of the blocked nucleoside **9**, R_f = 0.32 using 1:2 benzene–ethyl acetate as developer. Compound **9** was deacylated by refluxing with 15 ml of 0.05 *N* methanolic sodium methoxide for 4 h. The cooled solution was neutralized with glacial acetic acid and left stand overnight at 0°. The unblocked nucleoside **10** was removed by filtration, yield 0.275 g. The mother liquor was evaporated under reduced pressure and the residue dissolved in 20 ml water. The aqueous solution was then extracted with 2 × 10 ml ether. Passage of the aqueous solution through a Dowex 1 × 2 (OH^-) column (15 × 1 cm diam) followed by elution with water (to remove inorganic ions), 30% methanol, and finally 60% methanol (total about 200 ml) afforded 0.090 g of **10** in the last fraction. No observable amount of the α-anomer of **10** was found in any fraction of the eluent. Recrystallization of combined **10** from 80% methanol-water afforded 0.35 g (79%) of crystalline **10**, m.p. 227–228°, $[\alpha]_D^{22}$ −25° (*c*, 1, water), $\lambda_{max}(H_2O)$ (mμ) 261 (ε 18,250), R_f (adenine) 0.96 on Whatman paper No. 1 using water as developer. The o.r.d. spectrum of **10** showed a negative Cotton effect, $[\phi]_{270}$ −780°, $[\phi]_{262}$ 0°, $[\phi]_{247}$ +975° (*c*, 1.0 × 10^{-4} in water), λ (D_2O, at 60°); 4.08 (d, H-1′, $J_{1,2}$ = 2.5 Hz), 7.45 (m, H-3′), 8.85 (d, CH_3, $J_{3,3'}$ = 6 Hz).

Anal. Calcd. for $C_{12}H_{17}O_5N_4$: C, 48.80; H, 5.80; N, 23.72. Found: C, 48.65; H, 5.77; N, 23.88.

*Sodium Metaperiodate Oxidation and Reduction of the Allo-nucleoside **10** to Yield 9-(3-Deoxy-3-C-methyl-β-D-ribofuranosyl)-adenine (11)*

To a solution of the allo nucleoside **10** (0.295 g, 0.001 mole) in 30 ml of water and 15 ml of ethanol was added with stirring a 5% aqueous solution of sodium metaperiodate (0.214 g, 0.001 mole). The progress of the reaction was monitored by the starch–iodine test (compared with a blank). It was essential to avoid use of excess oxidant as this caused a significant decrease in yield of **11**. The solution was kept at neutral p*H* with saturated sodium bicarbonate solution (about 0.5 ml). The reaction mixture was left standing at room temperature in the dark for 2 h. To the resulting solution was added with stirring sodium borohydride (0.300 g) and the mixture stirred for 3 h. Excess of sodium borohydride was decomposed by addition of glacial acetic acid. The reaction mixture was evaporated under reduced pressure and the residue treated with 3 × 5 ml of methanol followed by evaporation. The crystalline residue was dissolved in 2% acetic acid (5 ml) and applied onto a column of Dowex 50 (NH_4^+) resin (15 ml of 1 cm diam column). The inorganic ions were eluted with 300 ml water and the nucleoside was then eluted with 5% ammonium hydroxide. Evaporation of the solvent followed by recrystallization of **11** from 80% methanol–water gave 0.225 g of **11** (85%), m.p. 231–232°, $[\alpha]_D^{22}$ −36° (*c*, 1, water), $\lambda_{max}(H_2O)$ 261 (ε 13,400), $R_{adenine}$ 1.2; τ (deuteriomethylsulfoxide) 1.68 (s, H-2), 1.95 (s, H-8), 2.82 (s, NH_2), 4.15 (d, H-1′, $J_{1',2'}$ = 1.5 Hz), 4.4 (d), 5.0 (m), 5.75 (m), 6.4 (m), 8.4 (m near DMSO peak), 9.1 (d, CH_3, $J_{3,3'}$ = 7 Hz).

Anal. Calcd. for $C_{11}H_{15}O_3N_5$: C, 49.80; H, 5.70; N, 26.40. Found: C, 49.87; H, 5.74; N, 26.57.

Carbohydrates in alkaline systems. I. Kinetics of the transformation and degradation of D-glucose, D-fructose, and D-mannose in 1 *M* sodium hydroxide at 22 °C[1]

DONALD J. MACLAURIN[2] AND JOHN W. GREEN[3]
The Institute of Paper Chemistry, Appleton, Wis. 54911

Received November 18, 1968

Rates of isomerization, epimerization, and degradation reactions were measured for D-glucose (**1**), D-fructose (**2**), and D-mannose (**3**) at 0.002 *M* in 1 *M* NaOH under N_2 in the dark at 22 °C. Reaction system resolution was by column chromatography on anion resins in the borate form. Assay for **1**, **2**, and **3** was by continuous automated colorimetry of column effluent using orcinol/sulfuric acid as a reagent. D-Allose and D-altrose were not detected. Reaction rate constants (h^{-1}) found: k_{12} 0.038, k_{13} 0.0005, k_{15} 0.002, k_{21} 0.036, k_{23} 0.006, k_{24} 0.072, k_{31} 0.0005, k_{32} 0.011, k_{36} 0.002, where **4**, **5**, and **6** are products formed from **1**, **2**, or **3**, respectively.

Introduction

The isomerization, epimerization, and degradation of carbohydrates in alkaline systems have been extensively studied and reviewed (1–6). Interest in these reactions continues because of their important theoretical physiological and industrial implications. Previous work (e.g., 7–21) gives much insight into the mechanism of these reactions and provides some semiquantitative kinetic information. However, specific kinetic studies do not appear to be available. Apparently, this is due to the previous lack of facile methods of assay for reaction system components. This study shows that chromatographic separations on anion-exchange resin columns in the borate form, together with continuous automated colorimetry of the column effluent, offers an assay method of apparent potential for studies of these reactions. Kesler (22) has reviewed these assay techniques and has reported methods which were the basis of the procedures used in this work.

For this study, 1 ml (10 mg) of an aqueous solution of a carbohydrate was combined with 25 ml of 1 *M* NaOH in a capped pyrex tube. Solutions and the reaction vessel were essentially freed of oxygen and saturated with nitrogen. Light was excluded by wrapping the tube with aluminum foil. The reaction was quenched to p*H* 1–2 with 25 ml 1 *M* HCl. A 20 ml aliquot of the quenched system was combined with 10 ml of 0.36 *M* H_3BO_3 which had been adjusted to p*H* 9.0 with 12 *M* KOH. Samples (0.250–1.000 ml) from the borated system were applied to a 6 × 700 mm anion resin column (borate form) held at 30 °C. A carefully designed graded eluant (H_3BO_3–$K_2B_4O_7$) was pumped through the column at 500 psig and 3.5 ml/min/cm^2 resin bed cross section area. These conditions freed D-glucose, the slowest moving material of interest, from the column in 8 h and provided for good simultaneous resolution of the monosaccharides of present interest and certain disaccharides of interest in continuing studies. A column effluent sample was monitored continuously with a Technicon Auto-Analyzer using orcinol/sulfuric acid to give a colorimetric assay on a strip chart chromatogram. The chromatogram peaks were calibrated against weights of known material. Thus, concentrations of D-glucose, D-fructose, and D-mannose were measured at selected reaction times. The overall accuracy of individual measurements of these concentrations was about ±2–3%.

Derivation of Reaction Rate Constants

The analytical data showed qualitatively that when a reaction was begun with D-glucose, D-fructose, or D-mannose, the other two of these quickly appeared in the system. This was as expected and was in harmony with the generally accepted theory and observations of the Lobry de Bruyn–Alberda van Ekenstein transformations for these materials. Separate experiments with D-allose and D-altrose established that these

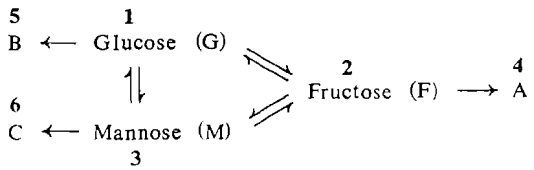
materials did not appear in detectable amounts (i.e., more than 0.25% of the starting material) in any of the various reaction mixtures that were chromatographed. Plots of the logarithm of the relative concentration of the starting material against time gave quite good straight lines in each case for the early stages of the reaction. From this observation and the experimental design which provided essentially no change in concentration of the base during the disappearance of at least half the starting material, it was concluded that the several reactions involving the starting material were pseudo first order. On the basis of these observations and conclusions, a simplified reaction scheme (Scheme 1) was postulated as a basis for calculation of reaction rate constants. In this scheme, A (**4**), B (**5**), and C (**6**) are reaction products (saccharinic acids, etc., which were not determined) other than fructose, glucose, and mannose, arising from each of these latter, respectively. Possible intermediates are omitted from the triangle; such intermediates will be discussed in more detail later.



SCHEME 1

For Scheme 1 with first order reactions, the following equations apply.

$$[1]\quad dG/dt = k_{21}F + k_{31}M - (k_{12} + k_{13} + k_{15})G$$

$$[2]\quad dF/dt = k_{12}G + k_{32}M - (k_{21} + k_{23} + k_{24})F$$

$$[3]\quad dM/dt = k_{13}G + k_{23}F - (k_{31} + k_{32} + k_{36})M$$

$$[4]\quad dA/dt = k_{24}F$$

$$[5]\quad dB/dt = k_{15}G$$

$$[6]\quad dC/dt = k_{36}M$$

The data from Table VIII were then substituted into these equations. It soon became apparent that direct calculation of final values of the several rate constants could not be done through algebraic manipulation of the rate equations. A best preliminary set of values of these constants was then obtained from estimation of initial rates and selected use of the rate equations. These preliminary values were then fed into a digital analog-simulator program (PACTOLUS) on a 1620 IBM computer to generate a set of curves preliminary to those of Fig. 1. The values of the various rate constants were then slowly adjusted until the generated curves gave an acceptable fit to the experimental data. The values of the several rate constants thus obtained are given in Table I. The precisions assigned to values in this table are liberal estimates based on observed effects during curve fitting. The computer-derived curves, using these rate constants and eqs. [1], [2], and [3], superimposed on the experimental data points for glucose, fructose, and mannose are given in Fig. 1. Computer plots for eqs. [4], [5], and [6] are given in Fig. 2. The fit between the curves and the experimental points in Fig. 1 for each of the three systems is considered to give support to the validity of the experimental methods, the data obtained, the reaction scheme, and the rate constants derived from the data. A paper on the computer program is planned (23).

Discussion and Results

In this paper the term "transformation" is used to describe, in a collective sense, epimerization and isomerization reactions of the Lobry de Bruyn–Alberda van Ekenstein type; the term "degradation" is used to describe other reactions undergone by carbohydrates in alkaline systems. Actually, the overall rate constants represent not only changes within an alkaline system but also conversion of the intermediates in the system to

final products by a process of acidification. The various reactions involved are so complex that it is difficult to draw definite conclusions from the kinetic data.

The present work has been confined to an analysis for D-glucose, D-mannose, and D-fructose. No attempt has been made to explore the "triangle" comprising D-altrose, D-allose, and D-psicose (D-*ribo*-hexulose). Control experiments were carried out involving D-allose and D-altrose. It was concluded that these two sugars did not occur in the present systems, at least to any extent greater than about 0.25% of the starting material; this percentage was the limiting sensitivity of the analytical procedures employed.

No attempt was made to look for D-psicose, because of the trace amounts at best, present of D-allose and D-altrose; epimerization at C-3 is

considered to be rather remote (2). This ketose has been reported in 0.6% yield from D-glucose (24) after 48 h treatment with 3 *N* ammonium hydroxide at 37 °C; it has also been prepared by the action of lime water on turanose (12), D-altrose (25), and sugar beet juice (26). The action of potassium aconitate at p*H* 8 on D-fructose gave small amounts of DL-*ribo*-hexose (as the phenylosazone), formed presumably by recombination of triose fragments (27).

The rate constants for the three reversible pathways (Table I) are interesting for two reasons: (*a*) the constants for each pathway, for the forward and for the reverse reactions, are almost the same (with the exception of the fructo–manno pathway); (*b*) the magnitude of these constants falls into three levels, a very low level for the gluco–manno system (0.0005), a higher level for the manno–fructo system (0.006 to 0.011), and a much higher value for the gluco–fructo pathway (0.036 to 0.038).

At present all that can be said of the kinetic data is that they show clearly, and for the first time, that the gluco–manno epimerization reaction is energetically very unfavorable compared with the observed isomerization reactions. Presumably there is some higher energy barrier in the formation of possible intermediates and along possible pathways to and from the mannose molecule. A greater amount of non-bonded interactions for the acyclic form of mannose may be a factor here; such interactions of course would be much less prevalent than in the cyclic form.

Isbell and co-worker (28) have recently suggested pseudo-acyclic intermediates, which have conformations similar to the parent sugars; these are converted into *cis*- and *trans*-enediols and various sugars produce different ratios of the two isomers. They have concluded that glucose, mannose, and fructose did not form the same enediol, as the rates of conversion of these several sugars into one another (at 5–7°) were not proportional to the rates of enolization. Hence, the difference in the rates must be attributed to two different types of 1,2-enediols.

They also studied the enolization (uptake of tritium in 0.5 *M* sodium carbonate in water-*t*) at 25° (29). The rate was very low; after 28 h the reaction for glucose was only 1.39% complete. The relative rates of enolization for glucose, mannose, and fructose were found to be 1.0, 0.5, and 10.7. These are in the same order as the relative rates of initial disappearance of glucose, mannose, and fructose in 1 *M* sodium hydroxide determined in the present work.[4] These latter rates are 1.0, 0.3, and 3.0 and are calculated before reverse reactions or indirect pathways become important. So undoubtedly the formation of enediols plays an important role in the transformation of the various sugars.

It should be pointed out that the relative rates of initial disappearance are for the overall disappearance of a given sugar and represent at least three pathways: i.e., the conversion of glucose to mannose, to fructose, and to other products. Similar pathways exist for the other two starting sugars. The enolization rates are, in contrast, measurements of all products containing tritium; they comprise the three pathways mentioned and also one other, the reconversion of the starting sugar, via the enediol, to itself again. This fourth pathway, an "equilibration", may account for the higher relative rate of enolization of fructose (10.7) in contrast to the relative rate of disappearance (3.0) of the same compound from the alkaline system. Part of this higher rate may also be attributed to a possibly easier attack on the two primary hydrogens at C-1, as well as that of the secondary hydrogen at C-3, in contrast to an attack on the single secondary hydrogen at C-2 of an aldose. Thus, the rate constant k_{24}, with a value of 0.072, would involve 2,3-enediols, β-eliminations, the formation of unsaturated sugars and cleavage products, and benzilic acid rearrangements, as well as reactions involving 1,2-enediols. The lower rate constants k_{15} and k_{36} would involve initially only the 1,2-enediols. Many factors are involved in these rate constants and it is difficult to ascribe the rate-determining steps to any particular one.

Isbell *et al.* (29) have also pointed out the higher rate of enolization of 2-deoxy-sugars (90–155 compared to 1.0 for glucose) and ascribed this to the higher proportions of acyclic intermediates. Penta-*O*-methyl-*aldehydo*-D-glucose, containing a free carbonyl group, is extremely reactive to alkali; Anet (30) found that it was readily rapidly converted by 0.02 *N* lime water into an unsaturated derivative. Since these open-chain compounds seem to react so readily, ring-opening could be a definite rate-determining factor in the enolization and subsequent transformations of sugars existing normally in the ring form.

[4]These relative rates were calculated by a comparison of the rate constants for identical concentrations of reactants at 22°; the constants are given in Table I.

It is interesting to note in connection with the gluco–manno isomerization that the finding in this study of equal values for the rate constants in each direction of this reaction is in harmony with the early work of Wolfrom and Lewis (31) and Greene and Lewis (32) on the observation of an "equilibrium" isomerization between 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,3,4,6-tetra-*O*-methyl-D-mannose. While they used quite different reaction conditions (1 *M* carbohydrate in 0.018 *M* calcium hydroxide and reaction run to exhaustion of the base, compared with the present 0.002 *M* carbohydrate in 1 *M* sodium hydroxide), they reported a 50/50 "equilibrium mixture" of the epimers. This finding is in harmony with the present finding of equal rate constants for each direction of this reversible reaction. However, it is probable that the equal rate constants observed here and the approximate equality observed for the constants of the gluco–fructo pathway are fortuitous.

Work with deuterium labeling on the formation of D-mannose from D-glucose in saturated lime water (33, 34) has shown that the former sugar can be formed both by a direct pathway and indirectly from D-fructose. An examination of the triangle in the present work will show that initially the rate of direct mannose formation will be appreciable, despite the low value of the rate constant ($k_{13} = 0.0005$), because of the high initial concentration of glucose. The rate of indirect formation, via the fructo–manno pathway, will be low, despite the higher rate constant ($k_{23} = 0.006$), as the initial concentration of fructose will be very low. With increasing reaction time the concentration of fructose formed directly from glucose will increase, and the rate of the fructo–manno pathway will also increase. Thus, analysis of deuterated products (specifically D-mannose), formed after appreciable reaction time, will show a combination of both direct and indirect pathways.

Similar reasoning can be applied to a study of pathways when D-fructose or D-mannose are the starting materials. The interpretation will necessarily become blurred as reverse reactions become appreciable; also degradation reactions, especially that for fructose, will be a factor.

Experimental

Materials

Carbohydrates

The carbohydrates were assessed for chromatographic purity and then further purified as necessary and possible. A chromatographically pure material was taken as one which gave a single symmetrical peak when assayed by the chromatographic procedure to be used in subsequent analytical work and by a procedure with a different column elution gradient. The criterion that purity be established by at least two different gradients was imposed to minimize overlooking the unlikely event that more than one material resulted in a single peak for a particular gradient. A carbohydrate producing a minor peak of less than 1% at a point on the chromatogram not occupied by any of the other carbohydrates of interest (or a very minor peak of a carbohydrate of interest) while not chromatographically pure was accepted in some cases.

In assessing the purity, an aqueous solution (boiled, N_2-saturated, distilled water) of the carbohydrate to be chromatographed was prepared so that it was 0.0100–0.01500 ± 0.00005 g/100.0 ml in the carbohydrate, 0.33 *M* in NaCl, and 0.12 *M* in H_3BO_3 at p*H* 7–8. Thus, this solution contained essentially the same concentrations of the several inorganic ions present in a reaction run sample as prepared for chromatography. A volume of this solution containing 500–1500 μg of the carbohydrate was then chromatographed. By these procedures, chromatographic purity can be assessed to within ±0.1%. The carbohydrates used were: D-glucose (Baker AR Dextrose, anhydrous powder, Lot 25814). Found to be ≮99.9% pure and dry as received. Used as received, D-fructose (Pfanstiehl C.P. Special Lot 3155). Found to be ≮99.9% pure. Used after drying over Drierite, D-mannose (Matheson, Coleman and Bell, and Pfanstiehl, Lot 6799-A). Both were found to be about 98% pure as received. MCB material was recrystallized from methanol–isopropanol (35), dried over Drierite, and used.

Nitrogen

This was Matheson Prepurified Grade, of 99.997% purity.

Solutions

H_3BO_3 (0.12 M) pH 8.50

30.00 ± 0.01 g H_3BO_3 (Mallinckrodt AR) dissolved in 4000 ± 1 ml. (72 °F) distilled water and nominal 12 *M* KOH added to p*H* 8.50 ± 0.02 at 72 °F, (about 10 ml KOH solution required). The solution was filtered through a Whatman GF/A, 5.5 cm glass filter paper supported on a Millipore sintered disk-and-funnel unit and stored in a clear glass bottle at 72 °F.

$K_2B_4O_7$ (0.15 M), pH 9.4

184 ± 0.05 g $K_2B_4O_7 \cdot 4H_2O$ (Mallinckrodt AR) was dissolved in 4000 ± 1 ml (72 °F) distilled water and filtered as above. It was stored in a clear glass bottle at 72 °F.

$K_2B_4O_7$ (0.50 M), pH 9.7

611.0 ± 0.5 g $K_2B_4O_7 \cdot 4H_2O$ (Mallinckrodt AR) was dissolved in 4000 ± 1 ml (72 °F) distilled water and filtered as above. It was stored in a clear glass bottle at 72 °F.

Orcinol/70% H_2SO_4

95.5–96.5% sp.gr. 1.84 H_2SO_4, was slowly added with cooling to 600.0 ± 1 ml (72 °F) distilled water in a 2 l volumetric flask. The addition of the final 1–2 ml of H_2SO_4 to the mark is done after the well-mixed H_2SO_4/H_2O solution has stood at least 12 h at 72 °F. The 2 l of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

70% H_2SO_4 is slowly poured onto 3.500 ± 0.001 g of near-white color orcinol monohydrate (K and K Laboratories) in a 2 1/2 l wide-mouth brown glass bottle. The orcinol/H_2SO_4 solution is stirred with a magnetic stirrer for about 1/2 h and then carefully examined, particularly at the scum line, for complete solution of the orcinol. The color of this solution deepens with time, and in this research a solution more than 24 h old was not used for quantitative work. It appears, though, that orcinol solutions even a week old are useful for qualitative work.

1 M NaOH

In a Teflon beaker, 500 g NaOH (Mallinckrodt AR) was dissolved in 500 ml boiled, N_2-saturated, distilled water. This "lye-oil" is let stand under N_2 in a thick-walled, 1 l, tightly capped polypropylene bottle at room temperature for no less than two weeks to allow Na_2CO_3 to settle out. Aliquots of the clear supernate were transferred by pipet to 2 l of boiled, distilled, N_2-saturated water in a polyethylene bottle in which the stock 1 *M* NaOH was stored. The 1 *M* NaOH solution was standardized against $KHC_3H_4O_4$ (Mallinckrodt Primary Standard) to the phenolphthalein end point. The carbonate content of the 1 *M* NaOH was determined by the carbon dioxide evolution method (TAPPI T 624 m-60) and found to be 0.002–0.003 molar.

Apparatus and Procedures

Constant-Temperature Bath

A 40-gallon tank of water was maintained at temperature with a precision of ±0.05 °C and an accuracy of ±0.05 °C.

Resin Column Chromatography and Automated Analytical Equipment

A schematic diagram showing the equipment and its arrangement as used for the chromatographic separation and quantitative analysis of the compounds of interest in reaction mixture samples is shown in Fig. 3. All components and accessories except the Haake Type FJ constant-temperature circulator were supplied by the Technicon Corporation, Research Park, Ardsley, New York 20502.

Reaction Run Chromatography Sample Preparation

A 25.00 ± 0.02 ml (72 °F) volume of about 1 *M* HCl of strength just sufficient to result in a mixture with p*H* 1–2 was delivered by pipet to the 26.0 ml reaction system. The stopping time of the reaction was defined as when the last of the HCl from the pipet entered the reaction system. The mixture was shaken and then cooled in the constant-temperature bath. A 20.00 ± 0.02 ml (72 °F) aliquot of this acidic mixture was combined in a capped 1 oz glass bottle with 10.00 ± 0.01 ml (72 °F) of 0.36 *M* H_3BO_3, p*H* 9.0. This gave a solution, p*H* 7–8, 0.12 *M* in H_3BO_3 and 0.33 *M* in NaCl. The H_3BO_3 concentration was thus the same as at the beginning of the subsequent elution.

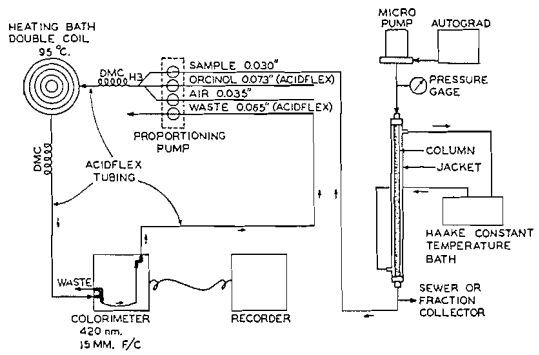

FIG. 3. Schematic diagram for equipment used for chromatographic separation and quantitative analysis.

Chromatography and Auto-Analyzer Conditions

The following conditions were established for column chromatography and Auto-Analyzer operation. Column: 6 mm i.d. × 750 mm water-jacketed glass tube column, resin bed length of 700 mm. Resin: Technicon 3/28/VI; spherical beads. Diameters: 11% > 30 μ, 5% < 10 μ; average diameter = 21 μ. Several resins were used successfully in this study. However, the resin used to obtain the bulk of the data (Technicon 3/28/VI) had a narrower range of particle size at an apparently better average particle diameter and more nearly spherical particles than other resins available. Presumably, these factors contributed significantly to its better performance, compared with say Bio-Rad AG1-X8, 325–400 mesh resin which is Dowex AG1, sized and prepared by the Bio-Rad Corporation of California. It is understood that the Technicon Corporation is actively pursuing the production of resin equivalent to the 3/28/VI resin which at present has an experimental status.

Column Temperature: 30.0 ± 0.1 °C, measured at the jacket outlet. Eluent flow rate: 1.00 ± 0.01 ml/min. This gave a maximum pressure drop of about 500 psig across the column, which occurred during column washing with 0.5 *M* $K_2B_4O_7$. Elution system: in the nine-chambered, rectangular, form Autograd - chambers 1–4, each 100 ml of 0.12 *M* H_3BO_3, p*H* 8.50; chambers 5–8, each 100 ml of 0.15 *M* $K_2B_4O_7$, p*H* 9.30; chamber 9, empty. Proportioning pump tubing: sample from column, color code, black, Tygon, 0.030 in. (i.d.); air supply, color code, orange, Tygon, 0.035 in. (i.d.); orcinol/H_2SO_4 reagent, color code, green, Acidflex, 0.073 in. (i.d.); from colorimeter cell, color code, blue, Acidflex, 0.065 in. (i.d.); Micropipet: Gilmont Micrometer Syringe, 2.0 ml capacity, Cat. No. 7844, Cole-Parmer, Chicago, Ill.

Chromatography Run Procedures

The chromatography and Auto-Analyzer units were operated essentially in accordance with manufacturer's instructions. Upon completion of a run, the column was immediately washed for 1 h with 0.50 *M* $K_2B_4O_7$ and then for 1 h with 0.12 *M* H_3BO_3, p*H* 8.50, by pumping through to the drain with the micro pump.

Experimental Data

Three series of reaction runs were made using in turn D-glucose, D-fructose, and D-mannose as starting material. The reaction conditions and chromatography data for these are given in Table II. A series of column runs was made for calibration purposes using solutions of known concentration of carbohydrates and the same concen-

trations of inorganic ions as present in column samples prepared from reaction systems. The chromatography data from this series of calibration runs are given in Table III.

The studies of Kesler (22) showed that for absorbance values below about 0.400 there is a straight line relationship between the height of a chromatogram peak and the quantity of that carbohydrate applied to the column. This finding was fully supported by separate experiments in the present study and was used in relating absorbance to weight rather than say area under a chromatogram peak. For a given carbohydrate, the slope of this straight line varies with the operating parameters of both the column and the Auto-Analyzer. In this work, the final choice of operating parameters was directed in part toward those which gave calibration lines of higher slopes, thus increasing the sensitivity of the detection and measurement. Large scale plots (500 × 500 mm) were made of chromatogram peak height *vs* weight of carbohydrate applied to the column from the calibration data of Table III. Visual best-fit straight lines were drawn through these data and the origin. The conversion factors given in Table IV were then derived from these plots. Then the chromatography data of Table II were converted, using these factors, to the relative molar data given in Tables V, VI, and VII. Visual best-fit curves were drawn through large scale plots of these relative molar data.

The slopes of these curves in regions where the data were considered to be the most reliable were then determined by graphical means as follows: 2 250 mm lengths of clear and uniform 10 mm diameter glass rod were tapered snugly together, in parallel arrangement with ends even, using a few wraps of clear Scotch Tape. A sharp, black ink ordinate line was drawn through the curves at the selected times. The pair of glass rods was laid across a curve at a point where the slope was to be measured. The curve line and the black ordinate line were viewed through the pair of glass rods from directly above the point of interest. Then the position of the glass rods was adjusted slowly until simultaneously (*1*) the curve appeared a continuous line, and (*2*) the two wavy, discontinuous segments of the black ordinate line were equidistant from the curve. When the rods were thus positioned, their long axis was parallel with the normal to the tangent to the curve at the point of intersection of the curve and the black

Carbohydrates in alkaline systems. II. Kinetics of the transformation and degradation reactions of cellobiose, cellobiulose, and 4-*O*-β-D-glucopyranosyl-D-mannose in 1 *M* sodium hydroxide at 22 °C[1]

DONALD J. MACLAURIN[2] AND JOHN W. GREEN[3]
The Institute of Paper Chemistry, Appleton, Wis. 54911

Received November 18, 1968

Rates of isomerization, epimerization, and degradation reactions were measured for cellobiose (**7**), cellobiulose (**8**), and 4-*O*-β-D-glucopyranosyl-D-mannose (**9**) at 0.001 *M* in 1 *M* NaOH under N_2 in the dark at 22 °C. Reaction system resolution was by column chromatography on anion resins in the borate form. Assay for D-glucose (**1**), D-fructose (**2**), D-mannose (**3**), and **7**, **8**, and **9** was by continuous automated colorimetry of column effluent with orcinol–sulfuric acid as reagent. Reaction rate constants (h^{-1}) found: k_{78} 0.078, k_{79} 0.0005, $k_{7,10}$ 0.002, k_{87} 0.022, k_{89} 0.003, k_{81} 0.065, $k_{8,12}$ 0.023, k_{97} 0.002, k_{98} 0.013, $k_{9,11}$ 0.006 where **10**, **11**, and **12** are other products than **1**, **2**, **3**, **7**, **8**, and **9**. Details for preparation of **8** and **9** are given.

Introduction

Previous work (1) on D-glucose, D-fructose, and D-mannose gave rate constants for the various interconversions and degradations in 1 *M* sodium hydroxide at 22 °C. These data were necessary and were utilized in studying the present work with cellobiose, cellobiulose, and 4-*O*-β-D-glucopyranosyl-D-mannose. This permits further investigation of the "peeling" and "stopping" reactions, studied by Kenner and associates (2–4) and reviewed by Whistler and BeMiller (5).

Derivation of Reaction Rate Constants

The analytical data showed qualitatively that when a reaction was begun with cellobiose, cellobiulose, or 4-*O*-β-D-glucopyranosyl-D-mannose, (glucosylmannose), each of the other two disaccharides and the three hexoses (D-glucose, D-fructose, and D-mannose) appeared in the system. On a similar basis as that previously described for the hexoses (1), the reaction scheme shown in Fig. 1 was postulated for calculation of reaction rate constants.

For this reaction scheme with first-order reactions, the following equations apply:

$$[1]\quad dG/dt = k_{81}GF + k_{21}F + k_{31}M - (k_{12} + k_{13} + k_{15})G$$

$$[2]\quad dF/dt = k_{12}G + k_{32}M - (k_{21} + k_{23} + k_{24})F$$

$$[3]\quad dM/dt = k_{13}G + k_{23}F - (k_{31} + k_{32} + k_{36})M$$

$$[4]\quad dA/dt = k_{24}F$$

$$[5]\quad dB/dt = k_{15}G$$

$$[6]\quad dC/dt = k_{36}M$$

$$[7]\quad dGG/dt = k_{87}GF + k_{97}GM - (k_{78} + k_{79} + k_{7,10})GG$$

$$[8]\quad dGF/dt = k_{78}GG + k_{98}GM - (k_{81} + k_{87} + k_{89} + k_{8,12})GF$$

$$[9]\quad dGM/dt = k_{79}GG + k_{89}GF - (k_{97} + k_{98} + k_{9,11})GM$$

$$[10]\quad dD/dt = k_{7,10}GG$$

$$[11]\quad dE/dt = k_{9,11}GM$$

$$[12]\quad dH/dt = k_{8,12}GF$$

where: GG = cellobiose; GF = cellobiulose; GM = glucosylmannose; G = glucose; F = fructose; M = mannose; A, B, C, D, E, H = other products; S = saccharinic acids.

A preliminary set of values for the rate constants of the reactions involving the disaccharides was obtained by estimation from plots of concentrations *vs.* time. These preliminary values and the reaction rate constants previously obtained (1) for the monosaccharide portion of the system were then refined on a computer as before (1). The final values of the rate constants

[1]A portion of a thesis submitted by D. J. M. in partial fulfillment of the requirements of The Institute of Paper Chemistry for the degree of Doctor of Philosophy from Lawrence University, Appleton, Wis., January, 1969.

[3]Senior Research Associate, The Institute of Paper Chemistry, Appleton, Wis. 54911.

obtained are shown in Fig. 1 and listed in Table I. The precisions assigned in the table are liberal estimates based on effects observed during curve fitting. The computer-derived curves, using these rate constants and equations [1], [2], [3], [8], and [9] are shown in Fig. 2 for the cellobiose, cellobiulose, and glucosylmannose systems.

Computer plots for other products (saccharinic acids etc. which were not determined analytically) are shown in Fig. 3. The computer plots for the disaccharides only in each of these systems, superimposed on the experimental data, are shown in Fig. 4, and those for the monosaccharides only in Fig. 5. The fit between the curves and the experimental points in Fig. 4 and 5 is considered to give support to the validity of the experimental methods, the data obtained, the reaction scheme, and the rate constants derived from the data.

strated qualitatively by Corbett and Kenner (6) for cellobiose; the base used was saturated lime water at 25 °C and the reaction was observed over a period of several weeks. These authors also showed qualitatively that cellobiulose was formed initially and that glucose and fructose were formed later in the reaction. The peeling reaction was found to be much faster for cellobiulose than for cellobiose. The quantitative studies were confined to the disappearance of total disaccharides and the appearance of total monosaccharides (7); these data suggested that the aldose is first converted to a ketose before the peeling reaction occurs.

In the present work, carried out in 1 *M* sodium hydroxide at 22 °C, the formation of cellobiulose from cellobiose and its faster conversion during peeling to give D-glucose (and then D-fructose) has been confirmed, and in addition the rates of these individual reactions have been determined quantitatively. Also, the reversible formations of 4-*O*-β-D-glucopyranosyl-D-mannose and of D-mannose have been demonstrated, and rate constants determined. As in the case for the monosaccharides (1), the disappearance of the disaccharides from the several systems seems to be mostly through the ketose, cellobiulose.

Thus, the greater role of the ketose, whether mono- or disaccharides, in alkaline systems, as demonstrated earlier by Kenner, *et al.*, is clearly shown in the present kinetic data.

In addition, it has been demonstrated that, while the interconversion of the several disaccharides is reversible, no equilibrium conditions exist when an excess of alkali is present, because degradation of the disaccharides, either directly or by a peeling reaction, proceeds indefinitely. The main loss of disaccharides seems to occur through cellobiulose as an intermediate, predominantly by peeling, but also by other undetermined pathways.

As in the preceding paper (1) the term "transformation" is used to describe, in a collective sense, reversible epimerization and isomerization reactions of the Lobry de Bruyn–Alberda van Ekenstein type which occur between carbohydrates. The term "degradation" is used to describe other, generally, more drastic irreversible reactions undergone by carbohydrates in alkaline systems. The overall rate constants obtained represent not only changes within the alkaline system but also the conversion of the intermediates in the system to final products by a process of acidification. The various reactions involved here are part of a complex system so that it is difficult to draw definite conclusions from the kinetic data.

In the present system (see Fig. 1) there are two triangles. Each is composed of reversible epimerization and isomerization reactions. Equilibrium conditions do not exist in the overall system, studied with an excess of alkali. The disaccharide triangle is connected to the monosaccharide triangle by an irreversible "peeling" reaction, proceeding through cellobiulose, and characterized by the rate constant k_{81}. Equilibrium conditions are also disturbed by other less specific degradation reactions, characterized by k_{15}, k_{24}, k_{36}, $k_{7,10}$, $k_{8,12}$, and $k_{9,11}$.

As reported for D-glucose, D-fructose, and D-mannose, reversible transformation reactions involving C-1 and C-2 are now reported for the first time between the three parallel disaccharides. Transformation reactions involving C-3, of these disaccharides, did not occur, at least to any greater extent than about 1% of the starting material.

The results obtained in this work clearly confirm the existence of the peeling reaction (5,8,9) and extend the findings of Kenner and associates (2–4,6) by showing that mannose and 4-*O*-β-D-glucopyranosyl-D-mannose appear as intermediate products in the alkaline degradation of cellobiose and cellobiulose under the conditions used. However, it is noted that under these conditions it appears, as shown in Fig. 3, that only about 80% of the starting cellobiose molecules proceed through cellobiulose (either directly or in very small amount via 4-*O*-β-D-glucopyranosyl-D-mannose), and on to the peeling reaction. About 10% of the cellobiose molecules are converted directly (GG to D in Fig. 1) to unknown products. A further 10% are converted on a nonpeeling reaction route via cellobiulose (GF to H in Fig. 1). About 1–2% of the cellobiose molecules are converted on a nonpeeling reaction route via 4-*O*-β-D-glucopyranosyl-D-mannose (GM to E).

In the monosaccharide triangle the constants for the forward and reverse reactions were almost the same. In the disaccharide triangle (Fig. 1) the three sets of rate constants are in ratios of roughly three or four to one instead, but are of the same order of magnitude as the monosaccharide analogs. Thus, the cellobiose to glucosylmannose conversion has the same rate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

constant as that observed for the glucose-to-mannose pathway. However, the reverse pathway is much faster for the disaccharides.

The situation is different for the cellobiulose to glucosylmannose pathway; here the rate constant is only half that observed for the monosaccharide system. In both of the pathways starting with glucosylmannose, however, the "equilibrium" is increasingly unfavorable, in contrast to that observed for mannose.

The "equilibrium" between cellobiose and cellobiulose has also been displaced in favor of the latter, whereas for the monosaccharide analogs the two opposing rate constants were almost equal. This increased rate constant favoring cellobiulose may be a steric effect of the bulky glucosyl group at C-4, which is eased by ketose formation at C-2.

The rate constant for the degradation of cellobiose is similar to that of glucose (0.002) but that for glucosylmannose is larger (0.006) than that for mannose (0.002). Thus, this second disaccharide shows less stability in both transformation and degradation reactions.

Comparison of the degradation reactions for cellobiulose and fructose shows that those for the disaccharide (defined by two rate constants) are much faster than those for the monosaccharide. The constant k_{81} defines the elimination of a glucosyloxy anion from C-4; the corresponding elimination of a hydroxyl group from C-4 of fructose is only one of many reactions involved in the rate constant k_{24}. One would expect the elimination of the glucosyloxy group to be easier than that of the hydroxyl group, based on the more acidic character of the former group. This leaving group tendency has been shown in the alkaline cleavage of methyl β-cellobioside (10), where the interior glycosidic linkage (removal of methyl D-glucoside) is broken more readily than the glycosidic linkage containing the methoxyl group.

Isbell and co-worker (11) have postulated the existence of *cis*- and *trans*-isomers of the 1,2-enediols to explain the transformation of various sugars; thus, the ratio of these two isomers, formed as intermediates, would be different for an aldose and for a ketose. While the principal enolization is between C-1 and C-2, they found that the rates of conversion of glucose, mannose, and fructose into one another were not proportional to the rates of enolization. The existence of the two types of enediols was then suggested, since the same 1,2-enediol cannot be formed from the several starting sugars.

While this work was confined mostly to monosaccharides, they did determine the rate of enolization (uptake of tritium in 0.5 *M* sodium carbonate in water-*t*) at 25° for several disaccharides (12). The relative rate of enolization was 2.6, compared to 1.0 for glucose. The relative rates for the initial disappearance of cellobiose, compared to that for glucose, are 2.2 and 1.0. (These rates were obtained by a comparison of the rate constants in the present work, Table I, for identical concentrations and 22°.)

The relative rates of initial disappearance for cellobiulose and glucosylmannose are 2.9 and 0.6. Isbell, *et al.* do not give any data for these compounds; however, the relative rates of lactose and the corresponding ketose, lactulose, are 2.0 and 37.0. Here again, as was noted for the monosaccharide system (1), the relative rate of enolization of the ketose is much greater than the relative rate of initial appearance of the ketose from the alkaline system. The reconversion of the ketodisaccharide, via an enediol, to the ketodisaccharide (tritiated) again, may be a factor here.

The relative rates of disappearance for the three disaccharides are 2.1, 0.55, and 3.0, whereas those for glucose, mannose, and fructose are 1.0, 0.36, and 2.9. The rates for the two aldodisaccharides are approximately twice those for the corresponding monosaccharides, presumably showing the crowding effect of the 4-glucosyloxy group. However, no such accelerating effect is shown for the ketodisaccharide. The relative rate is surprisingly low, and the relative rate of enolization found by Isbell, *et al.* for lactulose is surprisingly high. In all cases studied the disaccharides showed higher enolization rates than did the monosaccharides; the relative rate of initial disappearance for cellobiulose simply does not follow this trend.

As suggested for the monosaccharides (1), both enolization and ring-opening may be involved in the rate-determining process for the transformations of the several disaccharides. The relatively low rate of initial disappearance for cellobiulose, less than anticipated, suggests that different rate-determining processes may be operative here than for fructose.

No precise quantitative data were obtained in this study with respect to the postulated stopping reaction (elimination of a hydroxyl group at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

C-3). However, some semiquantitative chromatography data indicated the presence of a reaction product (appearing late on the chromatogram and thus suggestive of a molecule containing a carboxyl group) which on hydrolysis gave glucose. The amounts of glucose so produced were in approximate accord with what might arise from the sum of the molecules D and H arising from cellobiose and cellobiulose, respectively. There was an indication that a higher percentage of the starting material appeared as glucose from the spent system, when the starting material was cellobiulose. This indication agrees with the calculated findings and suggests that the route to the stopped molecule, D-glucosylmetasaccharinic acid, is preferentially via cellobiulose. On the basis that molecules D and H and possibly also E are largely stopped biose molecules, then perhaps as much as 10–15% of a given amount of cellobiose proceeds under the conditions used to the glucosylmetasaccharinic acid molecule, as hypothesized for the stopping reaction. This tentative conclusion is in fair agreement with the recent studies of Lindberg, Theander, and Uddegard (13), who report a 3% stopping reaction for cellobiose in 0.02% molar sodium hydroxide at 90 °C and an increase to 4.5% at 60 °C.

Corbett and Kenner (14) observed a time-lag in the decomposition of lactose and ascribed this to the "necessary genesis of the ketose." In the present work this time-lag is shown very plainly in Fig. 5 for the generation of glucose from both cellobiose and from glucosylmannose, where time is needed to build up an appreciable concentration of the intermediate cellobiulose, before the peeling reaction, i.e., elimination of glucose at C-4, can occur in detectable amounts. In the case of cellobiulose (Fig. 5) the formation of glucose is very rapid, with no time-lag observed.

In contrast, the formation of fructose shows a time-lag in the case of all three disaccharides (Fig. 5), demonstrating that this monosaccharide is a secondary product, and must be formed from glucose, the initial product of the peeling reaction. The amounts of mannose formed are too small to show a similar effect.

Experimental

Apparatus and Procedures

All apparatus and procedures used were as previously described (1). The nitrogen was Matheson Prepurified Grade, of 99.997% purity.

Carbohydrates

The carbohydrates used were assessed for chromatographic purity as previously described (1). Cellobiose (Pfanstiehl Lot 7236) was found to contain 1% glucose. It was slowly recrystallized from 2:3 v/v acetone–water (25 g. from 56 ml) to give a fraction containing about 0.15% glucose and no other impurity. This material was dried over Drierite before use. Slow crystallization from a methanol-water system was not successful.

Cellobiulose

This syrupy sugar was prepared from cellobiose by a modification of the method used by Corbett and Kenner (6). Cellobiose (50 g) was treated with 0.015 *M* $Ba(OH)_2$ (500 ml) for 6.5 h at 30 °C and the reaction then quenched with Amberlite IR-120-H resin (200 ml). The filtrate and washings (1000 ml) were concentrated *in vacuo*, and the residue taken up in methanol (250 ml). The precipitate (45 g of 99% cellobiose) was removed. Concentration of the filtrate and washings (400 ml) to 75 ml gave more precipitate (1.5 g 97% cellobiose); further concentration to dryness and treatment of the residue with methanol (75 ml) gave a third precipitate (0.3 g, 90% cellobiose). The final filtrate was concentrated to dryness, and dissolved in water (500 ml); the solution was shown by paper chromatography to contain 1% cellobiulose, 0.2% cellobiose, and 0.2% glucose.

The aldoses in this solution were oxidized by NaOI with the method of Kline and Acree (15). The resultant solution was treated with Amberlite IR-120-H resin to p*H* 1.7. The filtrate and washings were concentrated to 1000 ml and treated with Amberlite IRA-400-OH resin to p*H* 9. The mixture was quickly filtered and IR-120-H resin added to the filtrate to p*H* 6.8. The solution, concentrated to 600 ml, contained a trace of glucose. Repetition of the NaOI and resin treatments, on a suitably reduced scale, gave a cellobiulose solution that was not chromatographically pure; it was concentrated to 5 ml syrup. Treatment with methanol (40 ml) at 75 °C gave a green–yellow solution and a fine dusty precipitate formed on cooling. Addition of methanol (100 ml) and ethyl ether (200 ml) to the cooled solution gave quickly a copious white floc. It was filtered off and washed with acetone and anhydrous ether under dry nitrogen. The 5% yield was amorphous, pure white and very hygroscopic. Found $[\alpha]_D^{20} - 75°$ (*c* 10 [anhydrous basis], H_2O). Reported (6) $[\alpha]_D^{23} - 60.1°$ (*c* 2.40, H_2O).

A chromatogram of the hydrolyzate of this material (1 *M* sulfuric acid for 6 h at 100°) showed only glucose and fructose, and in about equal amounts.

This material was weighed up under dry nitrogen for preparation of kinetic solutions.

4-O-β-D-glucopyranosyl-D-mannose

This disaccharide was prepared from cellobiose octaacetate by a modification of the method of Brauns (16).

A 1000 ml heavy-walled polypropylene screw-cap bottle containing cellobiose octaacetate (70 g) was cooled to −50 °C. By means of a 1/4 in. polyethylene tube anhydrous HF gas (140 g) was slowly bled (3.5 h) from a cylinder and condensed on the carbohydrate material, which went into solution during the first 2 h. The capped bottle was maintained at room temperature for 6.5 h, then recooled, opened, and cold $CHCl_3$ (300 ml) cautiously added. The mixture, with $CHCl_3$ (100 ml) as a rinse, was

*$[GM]_0 = 0.00110$; $[OH^-]_0 = 0.9845$; $T\,°C = 22.20 \pm 0.02$.

transferred to a polyethylene vessel containing ice and water (800 ml each) and $CHCl_3$ (400 ml), and stirred with a polyethylene rod. After the ice had melted, the clear water layer was decanted and the organic layer repeatedly stirred with water (20 l in all) until neutral washings were obtained. The final water washing was treated with $NaHCO_3$ (25 g) to give p*H* 8. The $CHCl_3$ layer (1500 ml) was dried over Na_2SO_4, and concentrated to about 30 ml syrup.

The syrup was treated with Ac_2O (470 ml), giving a clear solution (green–gold) within 5 min. Perchloric acid (72%, 3 ml) was then added and the mahogany–red solution maintained 1 h at 35–40 °C with occasional shaking. It was then added (with a rinse of 50 ml Ac_2O) to crushed ice and water (1 l each) and the mixture stirred 2.5 h. The brown precipitate was washed with water (20 ml) and dissolved in boiling 97% EtOH (2 l). After 3 h cooling with stirring, the fibrous crystals were filtered on glass filter paper (Whatman GF/A) and washed with 95% EtOH. (No product could be isolated from the mother liquor.) The product was washed by stirring with water (2.5 l) and dried at 43 °C *in vacuo* to 24 g weight; m.p. 204° corrected, compared with literature values of 202–203° for glucosylmannose octaacetate and 229° for cellobiose octaacetate.

The product (24 g) was deacetylated in dry MeOH (250 ml) with NaOMe solution (0.015 g Na in 30 ml MeOH) for 45 min (clear brown solution). IR-120-H Resin (10 ml) was then added (p*H* change from 8 to 6) with stirring, and the solution concentrated to 15 ml syrup. This was dissolved in 98% EtOH (300 ml) and cooled overnight with stirring. The product was washed with 95% EtOH and Me_2CO to give 8.7 g, m.p. 177°. It was dissolved in water (150 ml), decolorized with 5 ml of a 1:1 v/v mixture of Darco G-60/Celite 545 for 5 min with stirring, and the mixture filtered through 3 sheets of GF/A glass paper. The filtrate was concentrated to 10 ml syrup which was dissolved in boiling 95% EtOH (175 ml). Cooling with stirring 12 h, gave 8.3 g product, m.p. 178.5–179.5 °C corrected. Drying 4.5 h at 100 °C *in vacuo* gave a weight loss of 5.6% but no change in m.p. Reported 174–175 °C (8) and 175–176 °C (17,18). $[\alpha]_D^{20}$ 6.3° (*c* 2.2, H_2O) initially, and 6.5° after 60 min; reported (19) 14.6° and 6.2°, respectively. The material had a chromatographic purity of 99.8% with 0.2% cellobiose as impurity. Its chromatographic behavior was identical with that for a known sample (20).

Kinetic runs

Three series of reaction runs were made, using cellobiose, cellobiulose, or 4-*O*-β-D-glucopyranosyl-D-mannose as starting material. The reaction conditions and chromatographic data for these are given in Table II. These chromatographic data were converted to the relative molar data given in Tables III, IV, and V by the same procedures as previously reported (1).

Pyrazolines IX. Chemistry of some 3-cyano-3-carbomethoxy-1-pyrazolines[1]

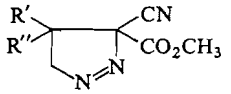
DONALD E. MCGREER AND Y. Y. WIGFIELD
Department of Chemistry, University of British Columbia, Vancouver, B.C.

Received June 5, 1969

Product and kinetic studies have been made on the pyrolysis of a series of 3-cyano-3-carbomethoxy-1-pyrazolines substituted at C-4 with a methyl and an aryl group (phenyl, *p*-methoxyphenyl, and *p*-nitrophenyl). Evidence is presented supporting a transition state structure in which little progress to bond breaking of the C-5 to N bond has taken place at the transition state. The product distribution is largely dependent on the stereochemistry of the initial pyrazoline and to a lesser degree on the nature of the aryl group at C-4. The *cis* pyrazolines gave products resulting primarily from aryl migration while the *trans* pyrazolines gave products predominantly from methyl migration.

Canadian Journal of Chemistry, 47, 3965 (1969)

As a continuation of our interest in the mechanism of the pyrolysis of pyrazolines we have extended our studies to a series of 3-cyano-3-carbomethoxy-1-pyrazolines (**1**) substituted with a variety of groups at C-4 having a known stereo-



1

chemical relation to the substituents on C-3. As the mechanism for the pyrolysis reaction evolves it becomes apparent that a spectrum of mechanisms may develop based on the nature of substituents attached to the ring carbons. Earlier studies on the kinetics (1) and stereochemistry (2) for the pyrolysis of **1** have indicated a change of mechanism occurs in going from pyrazolines substituted with one electron withdrawing group at C-3 to those with two electron withdrawing groups at C-3. It is our purpose in the present paper to evaluate this change in more detail. Recently Hamelin and Carrie (3–5) have reported results on a closely related series of compounds which differ primarily by the use of a carboethoxy group at C-3 rather than a carbomethoxy group. Because of this overlap we will emphasize that chemistry which we can add to their contributions.

Preparation of Pyrazolines

The pyrazolines for this study were all prepared by the addition of diazomethane to the appropriate methyl α-cyanoacrylate and are shown in Chart 1. Compounds **2–4** are isolated in the *trans*[2] form, from the condensation of benzaldehyde with methyl cyanoacetate. The *trans* form of compounds **8–10** is isolated as the only product from the pyrazolines **5–7** (herein, 6, and 7). The *cis* form of **8** and **10** are derived from *cis–trans* isomeric mixtures obtained by equilibration followed by separation and purification.

cis and *trans* **13** Ar = *p*-$NO_2C_6H_4$

CHART 1

A complication which continually appears in our work is the ease by which the *cis* and *trans* forms of the α-cyanoacrylates can be equilibrated. The sensitivity of **8** to base and heat can be illustrated by the following. After 2 h at room temperature a solution of 0.5 mmoles of *cis* **8** and 0.5 mmoles of pyridine in 0.6 ml of deuteriochloroform was found to be changed to a mixture of *trans* **8** and *cis* **8** in the ratio of 1:3 respectively.

After 30 min at 140° *trans* **8** is converted to the equilibrium mixture of *trans* **8** and *cis* **8** of 2:1. It has in fact been pointed out in the literature that similar olefins can be titrated reversibly as monobasic acids (8).

Base catalysis appears responsible for the following observations in the pyrazoline syntheses. Attempts to prepare *cis* **5**, as a mixture with *trans* **5**, from a mixture of *cis* and *trans* **2** gave only *trans* **5**; and examination of the reaction mixture after partial reaction showed that all of the *cis* **2** originally present had been converted to the more stable *trans* **2**. Synthesis of *trans* **13** from pure *trans* **10** gave yields of only 53% although *trans* **13** was easily isolated as it was only slightly soluble in the reaction medium. Examination of the remaining solution showed the presence of *cis* **13**. Reaction of *trans* **10** with less than one molar equivalent of diazomethane provided a reaction mixture containing *cis* and *trans* **10** and *cis* and *trans* **13**.

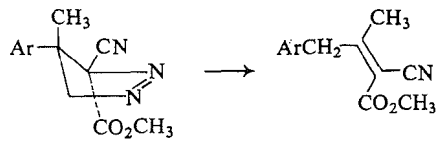
Our interpretation of these results is that the pyrazolines are sufficiently basic to induce equilibration of the α-cyanoacrylates and this is supported by some observations reported below. The degree to which isomerization occurs will depend on: (*1*) the rate of isomerization reactions, which is dependent on the olefin structure, (*2*) the concentration of the reactants, which is affected by the solubility of the pyrazolines, and (*3*) the time of contact between the pyrazoline and olefin, which is affected by the rate of pyrazoline formation and (see below) the rate of pyrazoline pyrolysis. We have not evaluated these three factors in detail in the present report.

The pyrazolines *trans* **11–13** and *cis* **13** were crystalline and as such were stable enough to be fully characterized. The pyrazolines *cis* **11** and **13** were readily distinguished from *trans* **11** and **13** in that the C-5 hydrogens gave a single broad peak for the *cis* series and an AB quartet for the *trans* series with $J \simeq 17$ Hz and $\Delta \simeq 0.5\,\tau$. Pyrazoline **7** on one occasion crystallized, indicating a definite occurrence of such a species, and gave an apparent m.p. of 45 °C. Recently the spectra of a number of such pyrazolines at low temperatures have been reported (*9*).

Pyrolysis of Pyrazolines

The only product formed in the reaction of **2–4** with diazomethane was the *trans* form of **8–10**. The formation of a single isomer has been noted earlier (6) and the *trans* stereochemistry is consistent with a mechanism involving concerted migration of hydrogen from C-4 to C-5 on the side *trans* to the leaving nitrogen (10,11).

The pyrazolines *cis* **11** and *cis* **13** on pyrolysis gave the olefin **14**, resulting from migration of the aryl group, as the major product (see runs 20–24 in Table I). The stereochemistry of this olefin was predominantly *cis* as predicted by the model reaction. The *trans* **14** is believed to be



cis **14** chief product

formed by isomerization of the initially formed *cis* **14**.

The reaction products from the *trans* isomers of pyrazolines **11–13** are much more complicated and are presented in runs 1–19 in Table I. In addition to aryl migration there is also methyl migration to give the methyl α-cyano-β-ethylcinnamates (**15**) and the formation of appreciable amounts of methyl 2-methyl-2-aryl-1-cyanocyclopropanecarboxylates (**16**). Not all of the products have been isolated pure due to complications resulting from the ease of *cis–trans* isomerization

in the olefin series. From *trans* **13** we have isolated *trans* **15**, *cis* **16**, *trans* **16**, a mixture of *cis* and *trans* **15**, and a mixture of *cis* and *trans* **14**. Hayashi (12) has reported the nuclear magnetic resonance (n.m.r.) spectra of related olefins and his data assists our stereochemical assignments. The stereochemistry of the cyclopropanes was readily determined since the *trans* **16** ring, when heated to 175° for 30 min, opened to a γ,δ-unsaturated ester (1,13) while *cis* **16** did not. Thus, characteristic n.m.r. peaks for all of the components in the product could be found so that product analysis on the crude mixtures could be made. In addition during the pyrolysis (for the *p*-nitrophenyl series only) some of the pyrazoline was isomerized to a 2-pyrazoline by tautomerization of a C-5 hydrogen.

Figures 1 and 2 show the n.m.r. analysis of runs 2 and 10 and clearly illustrate the presence of the indicated isomers due to changes in relative peak heights. Some of the *trans* cyclopropane **16** has rearranged as evidenced by the reduction of the τ 8.38 peak in Fig. 2. The data in Table I is reproducible to 2%.

Equilibration of the olefin products is achieved by the addition of a trace of pyridine (run 9) and heat (run 10) demonstrating the sensitivity of these compounds to base and heat. The product distribution in tetralin (runs 4, 12, 18) shows both olefins **14** and **15** close to equilibrium while in benzene (runs 2, 11, 16) shows mainly *trans* **14** and **15**. The pyrazolines are only slightly soluble in benzene. The greater solubility in tetralin maintains a higher concentration of pyrazoline to act as a base catalyst for the isomerization of these olefins. Nitrobenzene is intermediate in its effect.

*Runs used for the calculation of ΔH† and ΔS†.

Kinetics of the Pyrolysis Reaction

Further to the product studies we have carried out a kinetic study on the pyrolysis reaction for those pyrazolines which were crystalline. The apparatus and procedure for this study is described in a following paper (14). The weighed sample was added to 50 ml of solvent and the nitrogen evolved was measured in a gas burett. Runs were normally carried to over 80% completion. The V_∞ used was the calculated value and was shown to be within 2% of the observed value. A typical run is illustrated in Fig. 3. The results of this study are summarized in Table II. The solvents chosen were limited by the low solubility of the pyrazolines in benzene and hydrocarbon solvents. Standard error calculations showed that the limiting error is due to control of the temperature to ±0.1°.

Discussion

The value of the secondary α-deuterium kinetic isotope effect of $k_H/k_D = 1.01 \pm 0.07$ suggests that at the transition state there is little progress in the bond breaking of the C-5 to N bond. This is a major change in mechanistic detail from that found in 1-pyrazoline-α,α,α′,α′-d_4 ($k_H/k_D = 1.13$ per deuterium (15)), 3-methyl-3-carbomethoxy-5,5-d_2 ($k_H/k_D = 1.11$ per deuterium (14)), and the symmetric azo compound azobis-α-phenylethane-α,α′-d_2 ($k_H/k_D = 1.14$ per deuterium (16)). In the unsymmetric azo compound, α-phenylethylazomethane, with 3-deuteriums on the methyl, $k_H/k_D = 0.99$ per deuterium (16). The absence of an isotope effect in this case was attributed to a stepwise breaking of the two C—N bonds.

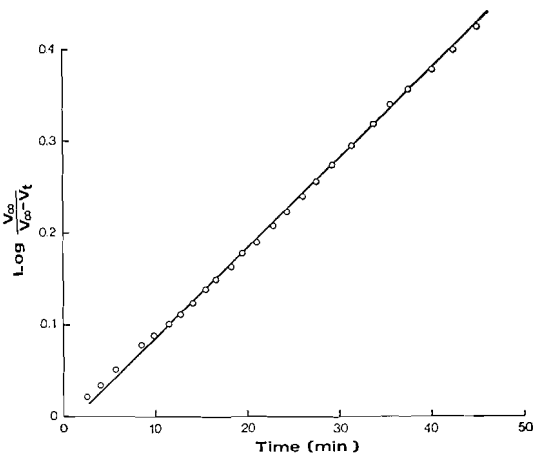

FIG. 3. Rate plot for *trans*-3-carbomethoxy-3-cyano-4-methyl-4-phenyl-1-pyrazoline (*trans* **11**) at 49.8 °C in nitrobenzene.

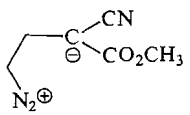
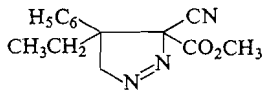
We also see from the kinetic results in Table II that there is negligible effect on the rate in going from *p*-methoxyphenyl to phenyl to *p*-nitrophenyl where the rate constants are 7.36, 6.41, and 6.57 respectively in nitrobenzene at 54.84°. This suggests that migration of the aryl group and the resulting effect of such participation has also progressed to a negligible degree in the transition state. Here again this is a major change from that observed in 3-methyl-3-carbomethoxy-1-pyrazoline-4,4-d_2 which showed an overall isotope effect of k_H/k_D of 1.36 attributable to considerable participation by the C-4 hydrogen in the transition state for that reaction (14).

The product analyses provide further information concerning the reaction mechanism. From this data we would like to be able to clearly determine whether after the transition state there is the opportunity for bond rotation as might be anticipated for an intermediate of the zwitterion type illustrated by **17**. The occurrence of olefin products of mixed stereochemistry suggests that



17

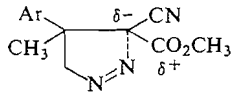


18

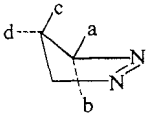
such is the case. However, the mixed stereochemistry in the olefin products can also be explained by isomerization after initial product formation. To clearly demonstrate this possibility, we pyrolized a pyrazoline **18** in the presence of a less than equimolar amount of *cis* **14**. Upon completion of the pyrolysis a mixture of *cis* **14** and *trans* **14** could clearly be shown to be present due to their n.m.r. peaks at τ 7.87 and 7.77 in the ratio of 54:46 respectively. It is significant that the benzyl olefins (**14**) are more readily isomerized than the aryl olefins (**15**) (see run 8 Table I) and it is the benzyl olefins in the product mixtures which are closest to equilibrium. The following additional observations also speak against **17** occurring as a distinct intermediate with sufficient lifetime for rotation of the C-3 to C-4 bond. The product distribution is largely controlled by the stereochemistry of the initial pyrazoline (compare runs 1–19 with runs 20–24 in Table I). If **17** were a distinct intermediate, it should be common to pyrazolines of both stereochemistries. Product formation from **17** would be expected to be markedly influenced by the ionic character of **17**. Aryl and particularly *p*-methoxyphenyl migration should be markedly favored over methyl or *p*-nitrophenyl. In fact for the *trans* pyrazolines, methyl migration is preferred to aryl migration by a ratio of 1.2:1.8:3 for *p*-methoxyphenyl, phenyl, and *p*-nitrophenyl respectively in benzene. This suggests that at the time the product is determined there is little positive charge at C-5 and there is still a stereochemical restriction controlling which groups migrate. Occurrence of **17** as an intermediate would imply that the transition state should also have a high degree of ionic character. Ionic character in the transition state can be evaluated by the solvent effect on the kinetics (17). The *p*-methoxyphenylpyrazolene (*trans* **12**) gave relative rate constants in tetralin, nitrobenzene, and formamide of $1:34:3.4 \times 10^3$. The change from tetralin to nitrobenzene is less than expected for a truly ionic transition state. However, the change in going to formamide may certainly be attributed to a normal ionic transition state and may imply that in formamide formation of a structure like **17** is fully realized. The negative value of the entropy is not consistent with earlier studies on the pyrazoline pyrolysis reaction where positive values have previously been found (14,18). The negative values of the entropy are consistent with additional constraint in the degrees of freedom of the transition state compared to the starting material. Such an effect is frequently observed in reactions occurring via ionic transition states, however, here again the magnitude of the effect is not as large as found in fully ionized systems.

Conclusions

The pyrazolines in the present study react by a mechanism for which the transition state can be described by **19** in which bond breaking of the C-3 to N bond is well advanced over bond breaking of the N to C-5 bond. This structure has a



19



20

polar character greater than the starting pyrazoline but less than expected for the zwitterion **17**. The product distribution is largely determined by the *cis* or *trans* geometry of the reacting pyrazoline presumably due to the steric requirements of the substituent groups and their influence on the conformational preference of the starting material and the transition state. This aspect has been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

discussed elegantly by Hamelin and Carrie (5). It can be concluded that the smaller group (CN) on C-3 preferentially adopts the pseudo equatorial position (a) of structure **20**. This is particularly evident from the product analysis when (c) and (d) are both phenyl (5) but less evident when (c) and (d) are both methyl (1). The larger group on C-4 appears to prefer the pseudo equatorial position (d). This is evident from the reaction of 3,3-dicyano-1-pyrazolines substituted with different alkyl groups at C-4 (19), from the kinetic evidence of Crawford and co-worker on the reaction of 4,4-dimethyl-1-pyrazoline (18), and from the n.m.r. evaluation of the preferred conformation of some 1-pyrazolines with a hydrogen and an alkyl group at C-4 (11,20).

We prefer to attribute the nonstereospecific olefin formation to isomerization after product formation rather than the alternative formation of a zwitterion intermediate capable of bond rotation before product formation. The stereochemistry of the cyclopropane products is solvent dependent and evidence to date has not permitted a rationalization of this part of the reaction.

Experimental

*Methyl trans-α-Cyano-β-methylcinnamate (trans **8**)*

Treatment of methyl *trans*-α-cyanocinnamate (**2**) (21) in benzene with excess diazomethane at 0 °C gave, on evaporation of the solvent at 0 °C, an unstable oil which decomposed to give nitrogen and methyl *trans*-α-cyano-β-methylcinnamate (*trans* **8**), b.p. 122° at 0.2 mm, m.p. 43–44 °C. The absence of *cis* **8** was revealed through a comparison of the n.m.r. spectrum with that recorded in the literature for the *cis–trans* mixture (12).

*Methyl trans-α-Cyano-β-methyl-p-methoxycinnamate (trans **9**)*

Reaction of methyl *trans*-α-cyano-*p*-methoxycinnamate (**3**) (12) by the manner described above gave methyl *trans*-α-cyano-β-methyl-*p*-methoxycinnamate (*trans* **9**), m.p. 90.5–92 °C (lit. (22), m.p. 73–74 °C for the *cis–trans* mixture); n.m.r. ($CDCl_3$) τ 2.48 and 3.02 (doublets with J = 8.8 Hz), 6.08, 6.10, and 7.30.

Anal. Calcd. for $C_{13}H_{13}NO$: C, 67.50; H, 5.67; N, 6.06. Found: C, 67.79; H, 5.81; N, 5.98.

*Methyl trans-α-Cyano-β-methyl-p-nitrocinnamate (trans **10**)*

Addition of diazomethane in ether to methyl *trans*-α-cyano-*p*-nitrocinnamate (**4**), m.p. 177–178 °C (lit. (12), 153–154 °C) in benzene gave after 1 h an unstable solid, m.p. 45° (d), which decomposed to give nitrogen and methyl *trans*-α-cyano-β-methyl-*p*-nitrocinnamate (*trans* **10**), m.p. 119–121 °C (lit. (12), m.p. 153–154 °C); n.m.r. ($CDCl_3$) τ 1.17 and 2.37 (doublets with J = 8.8 Hz), 6.07, and 7.25.

Anal. Calcd. for $C_{12}H_{10}N_2O_4$: C, 58.55; H, 4.09; N, 11.39. Found: C, 58.62; H, 4.29; N, 11.49.

*Methyl cis-α-Cyano-β-methylcinnamate (cis **8**)*

A solution of 8.0 g of distilled methyl *trans*-α-cyano-β-methylcinnamate in 70 ml of ether was irradiated in a silica tube in a Rayonet Photochemical Reactor using 75 W, 250 V, 2537 Å lamps for 2 days. Evaporation of the ether and filtration gave 3.0 g of methyl *cis*-α-cyano-β-methylcinnamate (*cis* **8**), m.p. 75–76 °C; n.m.r. (CCl_4) τ 2.60–3.05 (multiplet), 6.40, and 7.50.

Anal. Calcd. for $C_{12}H_{11}NO_2$: C, 71.64; H, 5.51; N, 6.96. Found: C, 71.78; H, 5.57; N, 7.08.

*Methyl cis-α-Cyano-β-methyl-p-nitrocinnamate (cis **10**)*

Methyl *trans*-α-cyano-β-methyl-*p*-nitrocinnamate (*trans* **10**) was heated at 150° for 2 h, cooled, and slurried with ether (3 × 70 ml). The remaining solid (0.4 g) was crystallized 3 times from methanol to give methyl *cis*-α-cyano-β-methyl-*p*-nitrocinnamate (*cis* **10**), m.p. 158–159 °C; n.m.r. ($CDCl_3$) τ 1.73 ar d 2.67 (doublets with J = 8.5 Hz), 6.30, and 7.43.

Anal. Calcd. for $C_{12}H_{10}N_2O_4$: C, 58.55; H, 4.09; N, 11.39. Found: C, 58.57; H, 4.17; N, 11.53.

*trans-3-Carbomethoxy-3-cyano-4-methyl-4-phenyl-1-pyrazoline (trans **11**)*

Reaction of *trans* **8** with diazomethane in ether gave in quantitative yield after standing overnight white crystals of *trans* **11**, m.p. 93–94 °C (d); n.m.r. ($CDCl_3$) τ 2.68 (multiplet), 4.70, and 5.22 (doublets with J = 18.0 Hz), 6.06, and 8.53.

Anal. Calcd. for $C_{13}H_{13}N_3O_2$: C, 64.16; H, 5.39; N, 17.27. Found: C, 63.95; H, 5.51; N, 17.16.

*trans-3-Carbomethoxy-3-cyano-4-methyl-4-p-methoxyphenyl-1-pyrazoline (trans **12**)*

By a procedure similar to the above *trans* **9** was converted in quantitative yield to *trans* **12**, m.p. 82–83 °C (d); n.m.r. ($CDCl_3$) τ 2.88, and 3.13 (doublets with J = 9.0 Hz), 4.70 and 5.25 (doublets with J = 17.7 Hz), 6.05, 6.20, and 8.52.

Anal. Calcd. for $C_{14}H_{15}N_3O_3$: C, 61.53; H, 5.53; N, 15.37. Found: C, 61.41; H, 5.71; N, 15.21.

*trans-3-Carbomethoxy-3-cyano-4-methyl-4-p-nitrophenyl-1-pyrazoline (trans **13**)*

By a procedure similar to the above *trans* **10** was converted in 50% yield to *trans* **13**, m.p. 101–102 °C (d); n.m.r. ($CDCl_3$) τ 1.80, and 2.63 (doublets with J = 9.0 Hz), 4.65, and 5.06 (doublets with J = 16.4 Hz), 5.95, and 8.46.

Anal. Calcd. for $C_{13}H_{12}N_4O_4$: C, 54.15; H, 4.20; N, 19.43. Found: C, 54.20; H, 4.30; N, 19.20.

The filtrate from the above preparation was evaporated and examined by n.m.r. and found to contain *trans* **13** (5%), *cis* **13** (35%); n.m.r. ($CDCl_3$) τ 1.78 and 2.58 (doublets with J = 8.5 Hz), 4.74, 6.48, and 8.50 and 4-methyl-4-*p*-nitrophenyl-5-carbomethoxy-5-cyano-2-pyrazoline (see below) (60%); n.m.r. ($CDCl_3$) τ 1.73, and 2.40 (doublets with J = 8.8 Hz), 3.19, 3.49, 6.00, and 8.33.

*cis-3-Carbomethoxy-3-cyano-4-methyl-4-phenyl-1-pyrazoline (cis **11**)*

The liquid pyrazoline *cis* **11** was obtained in quantitative yield from the reaction of *cis* **8** with one mole of diazomethane in ether followed by evaporation of the solvent at 0 °C; n.m.r. ($CDCl_3$) τ 2.55–3.0 (multiplet), 4.80, 6.65, and 8.56. No further data could be obtained due to the instability of this compound.

cis-3-Carbomethoxy-3-cyano-4-methyl-4-p-nitrophenyl-1-pyrazoline (cis **13***)*

Reaction of *cis* **10** with diazomethane gave on evaporation of the solvent at 0° a quantitative yield of *cis* **13**, m.p. 90–91 °C (d); n.m.r. ($CDCl_3$) τ 1.78 and 2.58 (doublets with J = 8.5 Hz), 4.74, 6.48, and 8.50.

Anal. Calcd. for $C_{13}H_{12}N_4O_4$: C, 54.15; H, 4.20; N, 19.43. Found: C, 54.08; H, 4.20; N, 19.41.

Pyrolysis of the Pyrazolines

The conditions for the pyrolyses and the analysis of the product mixtures are given in Table I. When benzene and decalin were used as solvents these solvents were evaporated under reduced pressure after complete pyrolysis and the product analyses were made from the n.m.r. spectrum of the residue in deuteriochloroform. When nitrobenzene and tetralin were used as decomposition solvents the product compositions were measured directly in the same solvents. When formamide was used, the products which were insoluble in these solvents were dissolved in deuteriochloroform to an equivalent volume to the formamide used and n.m.r. spectra were measured in both solvents under identical conditions.

A typical spectrum for the analysis of the product from *trans* **11** is given in Fig. 1. Peak positions characteristic of the individual products for the phenyl, *p*-methoxyphenyl, and *p*-nitrophenyl respectively in $CDCl_3$ in units of τ were: *trans* **14**: 7.77, 7.80, 7.70; *cis* **14**: 5.86, 5.97, 5.72 and 7.87, 7.90, 7.80; *trans* and *cis* **15**: 9.03, 9.00, 8.95 (triplets); *cis* **15**; 6.52, 6.43, 6.32; *trans* **16**: 8.50, 8.50, 8.38; *cis* **16**: 6.67, 6.58, 6.41. In addition the 2-pyrazoline from *trans* **13** was identified by peaks at τ 3.19 and 3.49. The following new compounds were characterized from the product mixtures.

Methyl α-Cyano-β-ethyl-p-nitrocinnamate

The decomposition products from *trans* **13** in benzene were separated by preparative thin layer chromatography (t.l.c.) on silica with carbon tetrachloride and ether (2:1) as solvent. Extraction of the component with R_f = 0.39 with chloroform and crystallization from methanol gave methyl *trans*-α-cyano-β-ethyl-*p*-nitrocinnamate, m.p. 100–101 °C; n.m.r. ($CDCl_3$) τ 1.68 and 2.46 (doublets with J = 8.5 Hz), 6.09, 6.85 (quartet with J = 7.5 Hz), and 8.95 (triplet with J = 7.5 Hz).

Anal. Calcd. for $C_{13}H_{12}N_2O_4$: C, 59.98; H, 4.65; N, 10.76. Found: C, 59.78; H, 4.63; N, 10.88.

A 1:1 mixture of methyl *cis* and *trans*-α-cyano-β-ethyl-*p*-nitrocinnamate was isolated from a thin layer chromatogram on alumina with chloroform. Analysis of the component with R_f = 0.8 provided the following n.m.r. assignments for the *cis* isomer ($CDCl_3$); τ 1.73 and 2.68 (doublets with J = 9.0 Hz), 6.32, 7.09 (quartet with J = 7.5 Hz), and 8.90 (triplet with J = 7.5 Hz).

Methyl trans-2-p-Nitrophenyl-2-methyl-1-cyano-1-cyclopropanecarboxylate

The fraction from the above separation on silica with an R_f of 0.29 was a mixture of the *trans* cyclopropane component and the *cis* and *trans* benzyl olefins (**14**). Recrystallization from methanol gave methyl *trans*-2-*p*-nitrophenyl-2-methyl-1-cyano-1-cyclopropanecarboxylate, m.p. 142–143 °C; n.m.r. ($CDCl_3$) τ 1.75 and 2.48 (doublets with J = 8.8 Hz), 6.10, 7.82, and 8.38.

Anal. Calcd. for $C_{13}H_{12}N_2O_4$: C, 59.98; H, 4.65; N, 10.76. Found: C, 59.70; H, 4.71; N, 10.91.

A sample of this cyclopropane was heated to 175° for 3 h and the residue purified by t.l.c. to give methyl 2-cyano-4-*p*-nitrophenylpent-4-enoate as an oil; n.m.r. ($CDCl_3$) τ 1.79 and 2.45 (doublets with J = 8.5 Hz), 4.41, 4.53, 6.26, 6.44 (quartet with J = 9.0 Hz and 5.8 Hz), 6.71 (quartet with J_{gem} = 14.2 Hz and J = 5.8 Hz), and 6.96 (J_{gem} = 14.2 Hz and J = 9.0 Hz). There was not sufficient sample for microanalysis.

Methyl cis-2-Methyl-2-p-nitrophenyl-1-cyano-1-cyclopropanecarboxylate

Pyrolysis of *cis* **13** in the absence of solvent gave on standing a small amount of crystalline material in addition to the major oily product. Filtration and crystallization from methanol gave the methyl *cis*-2-methyl-2-*p*-nitrophenyl-1-cyano-1-cyclopropanecarboxylate, m.p. 167.5–168.5 °C; n.m.r. ($CDCl_3$) τ 1.78 and 2.54 (doublets with J = 8.8 Hz), 6.41, 7.52, and 8.12 (doublets with J = 5.8 Hz), and 8.19.

Anal. Calcd. for $C_{13}H_{12}N_2O_4$: C, 59.98; H, 4.65; N, 10.76. Found: C, 59.78; H, 4.47; N, 10.67.

This sample was heated at 170° for 2 h with no change.

4-Methyl-4-p-nitrophenyl-5-cyano-5-carbomethoxy-2-pyrazoline

During pyrolysis of *trans* **13** in tetrachloroethylene a precipitate formed which was isolated and crystallized from chloroform to give the 2-pyrazoline (**18**), m.p. 171–172.5 °C; n.m.r. ($CDCl_3$) τ 1.73 and 2.40 (doublets with J = 8.8 Hz), 3.19, 3.49, 6.00, and 8.33. The peak at 3.49 disappeared on the addition of D_2O.

Anal. Calcd. for $C_{13}H_{12}N_4O_4$: C, 54.14; H, 4.20; N, 19.43. Found: C, 54.17; H, 4.35; N, 19.29.

Methyl cis-4-Phenyl-3-methyl-2-cyano-2-butenoate (cis **14***)*

The product from the pyrolysis of *cis* **11** in benzene was distilled to give a liquid which was 91% *cis* **14** in the presence of 5% of *trans* **14** and 4% of *cis* **16**. The n.m.r. spectrum ($CDCl_3$) showed peaks for *cis* **14** at τ 2.79, 5.86, 6.22, and 7.87.

Anal. Calcd. for $C_{13}H_{13}NO_2$: C, 72.54; H, 6.09; N, 6.50. Found: C, 72.74; H, 6.29; N, 6.30.

Equilibration of *cis* **14** with a trace of pyridine gave a ratio of *cis* **14** to *trans* **14** of 42:58 respectively. Peaks in the n.m.r. due to *trans* **14** appeared at τ 2.79, 6.16, 6.22, and 7.77.

trans-3-Carbomethoxy-3-cyano-4-methyl-4-phenyl-5,5-dideuterio-1-pyrazoline

Dideuteriodiazomethane was prepared from diazomethane in ether by exchange with D_2O catalyzed by potassium carbonate. The deuteriodiazomethane was reacted with *trans* **8** to give *trans* **11**-5,5-d_2 which contained 80% deuterium at C-5 as estimated by n.m.r. and mass spectral analysis.

Pyrazolines X. Kinetics for the pyrolysis of some deuterated 1-pyrazolines in solution[1]

DONALD E. MCGREER AND IAN M. E. MASTERS
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received June 5, 1969

The kinetics and product distribution have been measured for the pyrolysis of 3-methyl-3-carbomethoxy-1-pyrazoline (**1**) and its 4,4-d_2 and 5,5-d_2 analogues in tetralin, *n*-butyl phthalate, nitrobenzene, and formamide. The isotope effect k_H/k_D for **1**-5,5-d_2 of 1.22 and for **1**-4,4-d_2 of 1.36 is consistent with a mechanism involving migration of the C-4 hydrogen concerted with loss of nitrogen.

Canadian Journal of Chemistry, 47, 3975 (1969)

The use of deuterium isotope effects as a probe of mechanisms is well known. As a further evaluation of the mechanism of the pyrolysis of pyrazolines we have investigated the kinetics of this reaction for a series of pyrazolines and their deuterated analogues.

Experimental

Materials

3-Methyl-3-carbomethoxy-1-pyrazoline (**1**) and 3-methyl-3-cyano-1-pyrazoline (**2**) have been prepared previously (1,2). The 3-methyl-3-carbomethoxy-1-pyrazoline-5,5-d_2 was prepared using dideuterated diazomethane (prepared by exchange with D_2O using potassium carbonate) and analysis showed it to contain 80% deuterium at C-5. In a similar way 3-methyl-3-cyano-1-pyrazoline-5,5-d_2 was prepared and contained over 95% deuterium at C-5. Methyl methacrylate-3,3-d_2 was prepared by the Mannich reaction from methyl hydrogen methylmalonate and a 30% solution of formaldehyde-d_2 in water (Merck Sharp and Dohme of Canada, Ltd.). Yields of only 12% were obtained compared to 50% for trial runs in which methyl methacrylate was made from formalin solution. 3-Methyl-3-carbomethoxy-1-pyrazoline-4,4-d_2 was prepared from the methyl methacrylate-3,3-d_2 with diazomethane.

Kinetic Measurements

The rates of decomposition of the pyrazolines studied were determined by volumetric measurement of the rate of formation of nitrogen using an apparatus similar to that described by Peterson and co-workers (3). The reaction flask was heated in an oil bath (Dow Corning silicon fluid DC-550) and the reaction solution was stirred by a magnetic stirrer. The bath temperature was controlled to $\pm 0.05°$ and measured by a thermometer calibrated against an N.B.S. calibrated thermometer. The solvents used were all reagent grade and twice distilled at reduced pressure.

For the kinetic runs standard solutions of the pyrazolines were prepared in a 5 or 10 ml volumetric so that 1 ml of solution contained enough pyrazoline to yield 40–45 ml of nitrogen. Fifty ml of solvent was preheated in the reaction flask and purged with nitrogen for 30 min. The solution was stirred an additional 30 min to allow equilibration of the dissolved nitrogen with the surrounding gas. At this point 1 ml of the standard pyrazoline solution was added and the time recorded as 0 time. For most runs the reaction was followed to over 70% completion and in several to completion (ten half lives), permitting a comparison of the V_∞ observed with that calculated. This proved to be within 1% in *n*-butyl phthalate but greater in the more volatile solvents.

Product Analyses

Samples in solution or neat were heated in sealed ampoules in a constant temperature bath. The products were separated from the solvent or any unreacted pyrazoline by bulb to bulb distillation and analyzed by vapor chromatography. The instrument used was an Aerograph A-90P with thermal conductivity detectors and the peaks were recorded on an Electronic 15 recorder. The peak areas were determined by disc integration. For the data in Table II a 10′ × 1/4″ diisodecyl phthalate column at 100 °C with a helium flow rate of 50 ml/min was used.

Results and Discussion

Table I provides the kinetic results from this investigation. We were particularly concerned

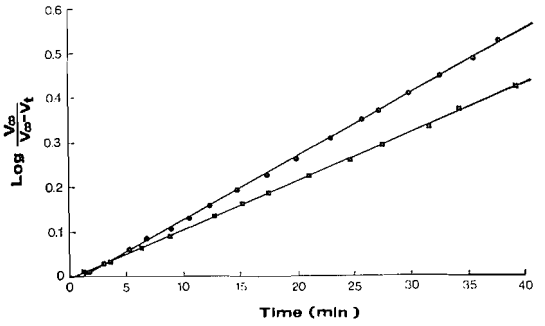

FIG. 1. Rate plots for 3-methyl-3-carbomethoxy-1-pyrazoline (**1**) (●) and its 4,4-dideuterio derivative (■) in *n*-butyl phthalate. (T = 127.0°).

[1]Taken in part from the Ph.D. thesis of I. M. Masters, University of British Columbia, Vancouver, B.C., February, 1969.

TABLE I

Rate constants and activation parameters for the pyrolysis of 1-pyrazolines

Compound	Solvent	Temperature (°C)	10^4k(sec^{-1})	$\Delta H\dagger$ (kcal mole^{-1})	$\Delta S\dagger$(e.u.)
 **1**	tetralin	109.4	1.28, 1.28		
		114.0	2.00		
		119.5	3.87		
		123.4	5.10	30.0	1.5
		126.0	6.82, 6.55

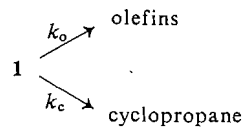
		127.0	4.62 (calcd. 100% d)		
 **2**	*n*-butyl phthalate	89.3	0.765		
		99.7	2.58	30.3	6.0
		109.4	7.34 ± 0.18		
2-5,5-d_2	*n*-butyl phthalate	109.4	5.95 ± 0.04		

for the reliability of the kinetics measured in this way using a magnetic stirrer. In view of the reproducibility of our results, the minimum scatter in the points as shown in Fig. 1 and the evidence provided by De Tar on this method (4), we feel the limiting factor is still in the control of the temperature. We estimate the temperatures reported to be reliable to better than ±0.1 °C corresponding to a maximum error of ±3% in the rate constants, ±5% in the enthalpies of activation ($\Delta H\dagger$) and ±3 e.u. in the entropies of activation ($\Delta S\dagger$).

The kinetic isotope effect k_H/k_D of 1.36 for **1**-4,4-*d* compared with **1** is considerably larger than the value of 1.07 found by Crawford and Mishra (5) for 4-methyl-1-pyrazoline-4-*d*, although their product distribution showed a larger isotope effect (1.80). The kinetic isotope effect observed by Crawford and Mishra can be attributed to a secondary effect due to hyperconjugation by the deuterium in a nitrogen free intermediate. We feel our value is too high for this interpretation and suggest that there must be some bond breaking of the C-4 to H bond at the transition state. An attractive approach to interpreting these results is to consider separate paths for the formation of the olefin and cyclopropane products. This possibility has been suggested earlier (6). Isotope effects for both paths can be calculated by making use of the product distributions given in Table II and the following equations.



$$k_H/k_D = (k_{oH} + k_{cH})/(k_{oD} + k_{cD}) = 1.36$$

but

$$k_{oH}/k_{cH} = 31.1/68.9 \text{ and } k_{oD}/k_{cD} = 21.8/78.2$$

this gives

$$k_{oH}/k_{oD} = 1.94 \text{ and } k_{cH}/k_{cD} = 1.20$$

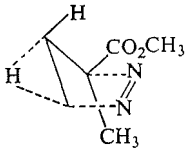
TABLE II

Product compositions for the pyrolysis of **1**, **1**-4,4-d_2, and **1**-5,5-d_2 at 127 °C

Reactant	Conditions	Product			
		Cyclopropane	*cis*-α,β	*trans*-α,β	β,γ
1	neat	66.8±0.9	12.2±0.7	16.4±1.2	4.6±0.4
	n-butylphthalate	68.9±0.8	14.7±0.6	12.3±0.6	4.1±0.5
	formamide	44.5±0.3	15.4±0.3	37.4±0.3	2.7±0.3
	tetralin	72.6	13.3	9.9	4.2
	nitrobenzene	72.5	13.0	10.1	4.4
1-4,4-d_2	neat	77.8±0.6	8.9±0.3	10.5±0.5	2.8±0.2
	n-butylphthalate	78.2±1.2	9.6±0.6	10.2±0.8	2.0±0.3
	formamide	61.0±0.7	11.3±0.8	26.2±0.6	1.5±0.2
1-5,5-d_2	neat	63.8±0.6	14.6±0.5	16.2±0.5	5.4±0.3

The isotope effect k_H/k_D for the olefin forming reaction thus becomes 1.94 and that for the cyclopropane forming reaction becomes 1.20.

We envisage the olefin forming reaction to involve an intermediate such as **3** (6). A primary isotope effect for the hydrogen on C-4 is expected with a magnitude of between 1.41 and 2.36 based



on studies by Rabinovitch and co-workers (7,8) and Blades (9) for the isomerization of cyclopropane to propylene. The isotope effect in the cyclopropane to propylene reaction has been attributed to a primary effect associated with breaking of the C—D bond as migration proceeds.

The isotope effect of 1.20 for the cyclopropane forming reaction is in line with that found by Al-Sader and Crawford (10) for conversion of trimethylene substituted by deuterium at the middle carbon to cyclopropane and amounting to 13% per deuterium. This affect was attributed to a secondary effect related to the hybridization change from sp^3 to sp^2 at that carbon.

The isotope effect of 1.22 and 1.23 for **1**-5,5-d_2 and **2**-5,5-d_2 is in excellent agreement with isotope effects found by Crawford and Cameron (11) for α-deuterated pyrazolines (10–14% per deuterium) and Seltzer and Mylonakis (12) for azobis-α-phenylethane-α,α-d_2 (14% per deuterium). This secondary isotope effect provides evidence for breaking of the C-5 to N bond at the transition state.

The presence of a carbomethoxy group at C-3 in the 1-pyrazoline system influences the reactivity of the pyrazoline to the extent that migration of the hydrogen from C-4 becomes concerted with loss of nitrogen. This is a subtle change in mechanism from that found for alkyl substituted pyrazolines in which loss of nitrogen clearly precedes migration (5,13). Although we might also expect the 3-carbomethoxy-1-pyrazoline to yield a polar transition state due to heterolytic cleavage of the C-3 to N bond this is not borne out by the solvent effects noted in Table I which instead suggest a reduction in the overall polarity of the transition state compared to the initial pyrazoline. The increase in olefin and particularly the *trans*-α,β-olefin in formamide suggests, however, that the olefin reaction is subject to a solvent effect and we attribute this change due to coordination of the solvent around the carbomethoxy group in the transition state resulting in an increased effective bulk of that group and thus an increased relative yield of the *trans* olefin.

Polarography of thioketones[1]

R. M. ELOFSON, F. F. GADALLAH, AND L. A. GADALLAH
Research Council of Alberta, Edmonton, Canada

Received March 26, 1969

Aliphatic and aromatic thiones are reduced at the dropping mercury electrode at potentials well below those of the corresponding ketones. The reductions take place by a mechanism whereby an electron is added to the molecule before protonation. The reducibility of camphorthione adds the isolated C=S group to the list of polarographically reducible functions. The half-wave potentials in acetonitrile correlate linearly with $n \rightarrow \pi^*$ transitions in the electronic spectra.

Canadian Journal of Chemistry, 47, 3979 (1969)

Sartori and Furlani (1) reported the polarographic reduction of a number of substituted thiobenzophenones. They found that the thioketones were reduced at somewhat less negative potentials than are the corresponding ketones. This behavior is indeed to be expected because the thioketones show electronic absorption bands at longer wavelengths than the ketones (2). The present paper presents the polarographic reduction of a wider structural range of thioketones including one aliphatic thioketone. Decidedly different behavior with change of p*H* was noted in this study than in that of Sartori and Furlani. The polarographic behavior in aprotic solvents has also been studied and the results correlated with the longest wavelength electronic absorption band which is an $n \rightarrow \pi^*$ transition (3).

Experimental

Polarograms were run with a Leeds and Northrup Electrochemograph Type E at 25°. With a mercury height of 48 cm the flow rate of mercury was 3.75 mgm/s and the drop rate was 2.55 s. Absorption spectra in isopropyl alcohol were measured with a Beckmann DK2 recording spectrophotometer. Acetonitrile was dried over phosphorus pentoxide and distilled. Buffers were prepared according to Clark and Lubs. No attempt was made to establish the true p*H* of the buffered isopropyl alcohol solutions.

Half-wave potentials have been corrected for small infrared (i.r.) drops. Consumption of electrons was measured by comparison with the well known behavior of 2-methylanthraquinone. No maximum suppression was used or needed at the concentrations used and with the electrode used in this investigation. At higher concentrations maxima did occur which could be partly suppressed with gelatin.

Camphorthione was prepared according to Sen (4). The resulting material contains some unchanged camphor and was further purified by chromatography on Florosil using hexane as eluant. The resulting material was pure as indicated by a single peak on gas–liquid chromatography (g.l.c.) using SE30 on chromosorb as packing. The m.p. was 115–117°.

Five grams of 3,3′-diaminobenzophenone was dissolved in 100 ml anhydrous hydrogen fluoride cooled to −20° and hydrogen sulfide was passed through it for 2 h. The resulting solution was poured into sodium bicarbonate solution and filtered. The mixture of sodium fluoride and 3,3′-diaminobenzothione was extracted with hot chloroform. Crystallization from chloroform produced 3.2 g of 3,3′-diaminobenzothione, m.p. 128°.

Anal. Calcd. for $C_{13}H_{12}N_2S$: S, 14.03. Found (mol. wt. (mass spectrometry) 228): S, 13.92.

Benzothione m.p. 52°, Michler's thione m.p. 209°, *p,p′*-dimethoxybenzothione m.p. 116–118°, and thiofluorenone m.p. 75–76° were prepared according to Elofson *et al.* (5). Xanthione was prepared according to Meyer (6) and had m.p. 158.0–158.5°; reported m.p. 155–156°.

Results

In Table I are presented the polarographic half-wave potentials of four thiones run in 77% isopropyl alcohol as a function of p*H* in buffered solutions. Contrary to Sartori and Furlani no adsorption currents were noted on any of the polarograms. In contrast to the results of Sartori and Furlani (1) little increase in half-wave potentials occurred above p*H* 5 for these thiones. Below p*H* 5 the half-wave potentials were dependent on p*H* as suggested by the former workers with approximate slopes of 0.70, 0.70, and 0.76 mV/p*H* unit for benzothione, xanthione, and Michler's thione respectively. At low p*H*, xanthione shows two one-electron reduction steps, the lower wave of which shows the linear relationship with p*H*. The total height of the waves corresponded to two electrons as measured against 2-methylanthraquinone. For camphorthione, measurements could not be made below p*H* 5 due to interference by hydrogen discharge. At p*H* 5 and above the half-wave potentials were

[1]Contribution No. 452, Research Council of Alberta.

TABLE I

Half-wave potentials of selected thiones in 77% isopropyl alcohol at various p*H*

	V vs. s.c.e.			
p*H*	Camphorthione	Benzothione	Michler's thione	Xanthione
1	—	−0.60	−0.66	−0.62 to −0.83
3	—	−0.70	−0.82	−0.77 to −0.98
5	−1.61	−0.88	−1.03	−0.90 to −1.01
6	−1.61	−0.88	−1.04	−0.89 to −0.97
7	−1.62	−0.95	—	−1.01
8	−1.66	−1.10	−1.18	—
9	−1.67	—	—	—
10	—	−1.08	−1.25	−1.10
13	−1.70	−1.06	−1.37	−1.07 to −1.49

essentially constant. At p*H* 7.0 and 9.0 single two-electron waves were obtained.

At p*H* 10 the wave for camphorthione was shortened and at p*H* 13.0 one-electron waves were obtained for all four compounds. Controlled potential electrolysis at −1.8 V at p*H* 7.0 for camphorthione produced only thioborneol as determined by g.l.c. At p*H* 13 small quantities of thioborneol but over 70% thioborneol disulfide, m.p. 168° (7), was obtained.

Xanthione showed additional reduction at higher potentials in neutral and alkaline media with a definite reduction wave at p*H* 13.0 at −1.49 V with a height corresponding to three electrons. Presumably the product of reduction was xanthene. Controlled potential electrolysis at −1.6 V vs. standard calomel electrode (s.c.e.) at p*H* 9 in an ammonia buffer produced xanthene. No evidence for other than one electron reductions at high p*H* even with quaternary ammonium salts as supporting electrolytes was apparent with the three thiones, camphorthione, benzothione, or Michler's thione. Controlled potential electrolyses produced no evidence of thiopinacols for any of these compounds under any conditions of p*H*. Detailed study of the behavior of the wave height of Michler's thione as a function of p*H* was made in the range of 10–13. For p*H* of 10.1, 10.4, 11.3, 12.2, 12.5, and 12.9 the respective wave heights corresponded to 2, 1.8, 1.7, 1.5, 1.2, and 1.1 electrons respectively.

In contrast to the results in aqueous media, all the thiones showed a more or less distinct pre-wave in anhydrous acetonitrile 0.1 *M* with respect to tetrabutylammonium bromide (Table II and Fig. 1). These pre-waves were shown to be due to adsorption of the reduced form of the thione by the fact that their heights depended directly on the height of the mercury in the reservoir. Addition of 20–40% of water destroyed the adsorption curve and lowered the half-wave potential of the diffusion-controlled wave. The overall reduction in acetonitrile and acetonitrile – water mixtures required two electrons in all cases.

When the energy of the longest wavelength absorption band, as measured, is plotted against the half-wave potential in acetonitrile a straight line, Fig. 2, results. The actual bands of the long-

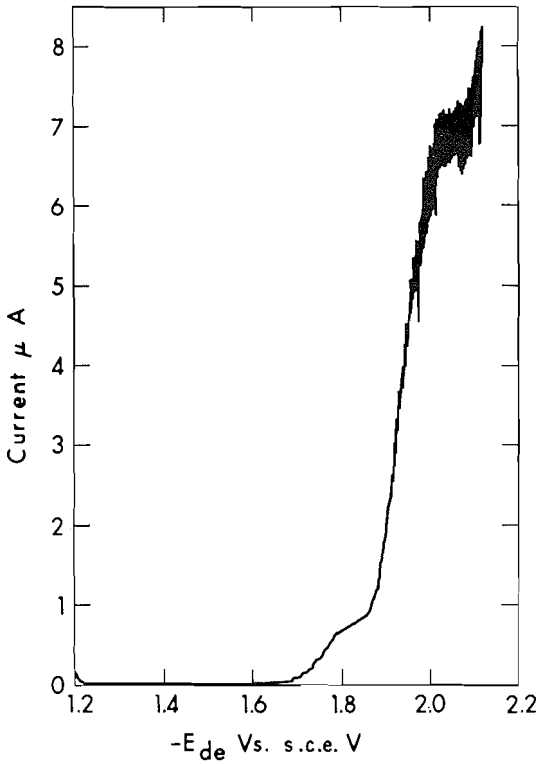

FIG. 1. Polarogram of 5.0×10^{-4} *M* camphorthione dissolved in 0.05 *M* tetrabutylammonium bromide in acetonitrile.

wavelength band frequently had fine structure (8) and the shorter wavelength maxima were chosen for the energy plot. The equation of the best fit line is

$$\bar{\nu} = -(0.592 \pm 0.037)\, E_{1/2} + 1.455 \pm 0.112 \text{ V}$$

Discussion

The two-electron reduction waves of the thiones in acetonitrile must arise from, first, the addition of a single electron followed rapidly by protonation and reduced further at the same potential since it has been shown by Hoijtink *et al.* (9) that the reduction potential of a radical RH must always be less negative than that of the hydrocarbon molecule R from which it is formed. Therefore, if it is assumed that the mechanism of protonation and the availability of protons are the same for all thiones, the half-wave potentials should be related to the energy required to put one electron into the lowest unoccupied molecular orbital. Since the energy of the n → π* absorption band has been shown to be linearly related to the calculated energy requirement of moving an electron from the highest occupied molecular orbital to the lowest empty molecular orbital (3), it seemed worthwhile to try to correlate the half-wave potentials with the absorption spectra. Bergmann (10) has already shown for alternate hydrocarbons that a straight line relationship exists for the plot of the absorption spectra of the π → π* band against the half-wave potentials. The slope of the plot of this transition energy of hydrocarbons vs. half-wave potentials is near the theoretical value of 2 (11). When n → π* transition of thiones vs. the half-wave potentials is plotted the slope is much lower at 0.60.

The reduction in aqueous alcohol solution corresponds to some extent to that observed of aryl alkyl ketones (12). Thus in acid solution the dependency of $E_{1/2}$ on p*H* suggests that reduction occurs simultaneously or following protonation.

$$\text{[1]}\quad \text{R'R''C=S} \xrightarrow{\text{H}^+} \text{R'R''C(H)—S}^+ \xrightarrow{+\,e,\ E_1} \text{RĊSH}^+$$

$$\text{RĊSH} \xrightarrow[+\,e,\ E_2]{-\,\text{H}^+} \text{RR'CSH} \rightarrow \text{RCHSH}$$

For xanthione the first wave is p*H* dependent corresponding to [1] whereas the second wave is p*H* independent so the waves merge above p*H* 6. For the remainder of the thiones $E_1 = E_2$ and the observed p*H* dependence results. The fate of the product of one-electron reduction of xanthione is not known. From the results of controlled potential electrolysis no evidence for thiopinacal formation could be obtained.

At intermediate and higher p*H* direct reduction of the thione occurs prior to protonation

$$\text{[2]}\quad \text{R'R'C=S} \xrightarrow[+\,e,\ E_3]{} \text{RR'C—S}\cdot^- \xrightarrow{\text{H}^+} \text{RR'CHS}\cdot$$

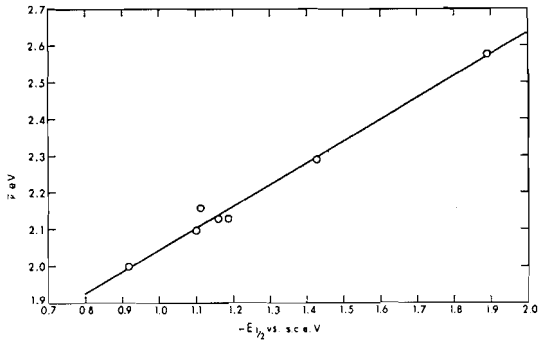

FIG. 2. Plot of absorption spectra of thiones in eV vs. $E_{1/2}$ in acetonitrile.

[3] 
In neutral solution further reduction occurs to produce the mercaptan. In strongly alkaline solution dimerization of the radicals occurs to produce the disulfide with no further reduction occurring except in the case of xanthione wherein reduction to the parent hydrocarbon occurs.

This ready availability of thiones toward direct reduction by electrons at low voltages correlates well with the ability of DPNH analogues to reduce thioketones but not ketones eq. [3] (13, 14).

It is a more satisfactory explanation of this phenomenon than that of Westheimer and coworkers who suggested the greater polarity of thioketones relative to ketones might be the explanation. This is manifestly not so since thioketones elute more quickly on adsorbents such as Florosil than ketones do. Our mechanism is further supported by the failure in this laboratory to isolate thiopinacols by electrolysis even with xanthione at low p*H* and at the potential of the first reduction wave. The independence of reaction [3] to p*H* changes further demonstrates the analogy between this reaction and reducibility at the electrode.

Oxidation with lead tetraacetate. IV. Cyclization of phenylhydrazones of levulinic acid, levulinanilide, 5-ketohexanoic acid, 4-keto-1-pentanol, and of levulinic acid oxime

GERTFRIED B. GUBELT AND JOHN WARKENTIN
Department of Chemistry, McMaster University, Hamilton, Ontario

Received June 23, 1969

The phenylhydrazones of levulinic acid (**3***a*) and 5-ketohexanoic acid (**4**) are cyclized by lead tetraacetate (LTA) to γ-phenylazo-γ-valerolactone (**9***a*) and δ-phenylazo-δ-caprolactone (**11**), respectively. Oxidation of levulinanilide phenylhydrazone (**3***b*) leads, by analogous oxygen-to-carbon ring closure, to γ-phenylazo-α-phenylimino-γ-valerolactone (**15**) which is hydrolyzed to **9***a*. Similarly, the phenylhydrazone of 4-keto-1-pentanol (**5**) is cyclized to 2-phenylazo-2-methyl tetrahydrofuran (**12**) and the oxime of levulinic acid (**7**) is converted to γ-nitroso-γ-valerolactone which is isolated as the dimer, *trans*-bis[γ-nitroso-γ-valerolactone] (**14**).

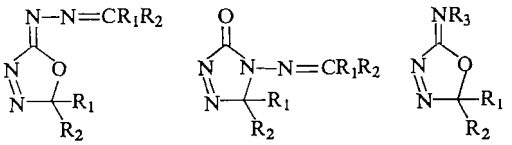
Introduction

Among the many organic compounds that have been oxidized with lead tetraacetate (LTA) are carbonyl derivatives such as oximes (1), hydrazones (2), carbohydrazones (3), and semicarbazones (4). Hydrazones and oximes react according to the generalized equation [1], forming azoacetates and nitrosoacetates, respectively (1,2).

[1] 
Y = NHR, OH Z = NR, O

Carbohydrazones, on the other hand, are cyclized by LTA and it is now established that the products are oxadiazolines (**1***a*) (3) rather than triazolinones (**1***b*) (5). Semicarbazones are cyclized to analogous oxadiazolines (**2**) (4).



1*a* **1***b* **2**

These cyclizations probably involve organolead intermediates which undergo ring closure to carbonyl oxygen through cationic transition states (6). Such a mechanistic picture led us to look for other heterocyclic systems, arising from attack of a nucleophilic center in R of 
on the erstwhile carbonyl carbon. The present work adds to the variety of heterocyclic compounds now available by oxidative cyclization with LTA.

Results and Discussion

The systems studied include aryl hydrazones of substituted ketones with the substituent so situated that cyclization would produce either a 5-membered or a 6-membered ring, eq.[2]. Cyclization was pitted against azoacetate formation (eqs. [1] and [2]) which is the major reaction in systems lacking the potential for cyclization.

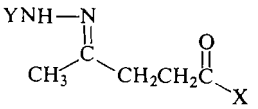
Aryl hydrazones of levulinic acid (**3***a*, **3***d*) gave mainly the corresponding γ-arylazo-γ-valerolactones, **9***a* and **9***b*, with small amounts of the azoacetates, **10***a* and **10***b*.[1] Similarly, **4** and **5** gave mainly **11** and **12**, respectively. The oxime **7** was also smoothly oxidized to form, presumably, γ-nitroso-γ-valerolactone which dimerized to **14**.[2] The dimer is stable for several days at room temperature, in contrast to the ready decomposition of bis-nitrosoacetates and nitrosoacetates (1). At its melting point, **14** decomposes to levulinic acid and other, unidentified products.

[1]The presence of azoacetate in the crude product, after acetic acid had been removed with bicarbonate, (see Experimental) was inferred from the proton magnetic resonance spectrum and from the infrared spectrum. Since our interest was primarily in the cyclic compounds no effort was made, in general, to isolate the azoacetates.

[2]The product does not show typical N=O absorption near 1555 cm^{-1} but absorbs instead at 1200 cm^{-1}. Nitroso dimers (1) are said to absorb in the region 1185–1195 cm^{-1}. The low value (Table II) obtained for the molecular weight (Rast) suggests that the dimer is partly dissociated at higher temperatures. The *trans* configuration is assigned by analogy (1).

[2] 
[3] 
The phenylhydrazone of levulinanilide (**3***b*) was oxidized by LTA to a crude product which absorbed at 1691 cm^{-1} and less strongly at 1750 and 1787 cm^{-1}. The 1787 cm^{-1} band was assigned to **9***a* which, together with aniline, was the product of hydrolysis during workup. An *N*-aryl-5-membered lactam is expected to resist hydrolysis and to show carbonyl absorption near 1715 cm^{-1}, well above the 1691 cm^{-1} band observed. On the basis of the infrared (i.r.), the ease of hydrolysis, and the hydrolysis products, it is likely that a major component of the crude product was the iminolactone **15**.

This preference for closure to oxygen rather than nitrogen in the case of **3***b* is readily rationalized in terms of a likely mechanism (eq. [3]) for the cyclization.[3] The organolead intermediate is formulated as having a nitrogen-to-lead bond (6)



3*a* X = OH; Y = C_6H_5
3*b* X = NHC_6H_5; Y = C_6H_5
3*c* X = OC_2H_5; Y = C_6H_5
3*d* X = OH; Y = $C_6H_3(NO_2)_2$-2,4

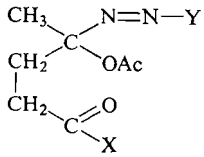
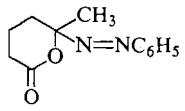
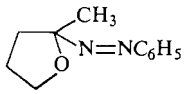
9*a* Y = C_6H_5
9*b* Y = $C_6H_3(NO_2)_2$-2,4



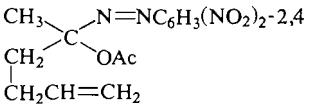
10*a* Y = C_6H_5; X = OH
10*b* Y = $C_6H_3(NO_2)_2$-2,4; X = OH
10*c* Y = C_6H_5; X = OC_2H_5



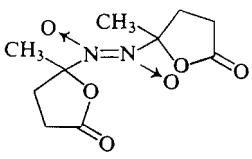
11



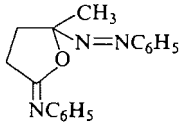
12



13



14



15

[3]The same rationale applies to oxadiazoline formation (3,4). Cyclization to sulfur rather than nitrogen is probably also preferred. The yield of a Δ^3-1,3,4-thiadiazoline prepared from acetone thiocarbohydrazone (3) was not high enough, however, to prove such a preference.

†Ether chromophore.
‡The nitrosodimer must be a mixture of diastereoisomers and therefore has more than one methyl signal.

although the allylic alternative has been suggested (7) and a π-bonded species is also conceivable. Whatever its structure, ready heterolysis is to be expected and the cationic precursor (eq. [3]) of **15** should be considerably more stable than that resulting from use of the amide nitrogen in cyclization.

Neither **3***c* nor **6** were cyclized by LTA; azoacetates **10***c* and **13** being formed instead.[1] The double bond is probably not sufficiently nucleophilic to allow cyclization to compete with azoacetate formation. Whether the ester (**3***c*) cyclizes in the sense of eq. [3], with subsequent ring opening faster than displacement on the ethyl group, is not known.

The carbonyl stretching frequencies (Table I) of the azo-substituted lactones are increased slightly by the arylazo substituents.[4] Carbonyl stretching frequencies of δ-valerolactone and of γ-lactones in $CHCl_3$ are 1732 and 1775–1777 cm^{-1}, respectively (8).

Experimental

Infrared spectra and proton magnetic resonance (p.m.r.) spectra were obtained with Perkin-Elmer, Model 337 and Varian Associates, A-60 instruments, respectively, unless otherwise indicated. Melting points were determined with a Thomas "Unimelt" capillary-melting-point apparatus. Analyses were by Alfred Bernhardt, Elbach, Germany and by A. B. Gygli, Toronto, Canada.

Chemicals

Methylene chloride was used as supplied by Matheson, Coleman and Bell (MCB). Lead tetraacetate (MCB), wet with acetic acid, was washed with petroleum ether (30–60°) before use. Levulinic acid, 4-keto-1-pentanol, 5-ketobutyric acid, 5-hexene-2-one, phenylhydrazine,2,4-dinitrophenylhydrazine, and aniline were obtained from the Aldrich Chemical Co., Milwaukee. Florisil (60–100 mesh), for column chromatography, was obtained from the Fisher Scientific Co., Toronto.

Levulinic Acid Phenylhydrazone (3a)

Levulinic acid (20 g, 0.17 mole) and phenylhydrazine (18.6 g, 0.19 mole) in 20 ml of ether gave 32 g (91%) of **3***a*, m.p. 108–109° (lit. (9) m.p. 109–110°).

Levulinic Acid-2,4-dinitrophenylhydrazone (3d)

Levulinic acid (11.6 g, 0.1 mole) was refluxed for 6 h in benzene with 2,4-dinitrophenylhydrazine (19.8 g, 0.1 mole). After cooling, the precipitate was filtered off and recrystallized from ethanol to give 21 g (71%) of yellow **3***d*, m.p. 204° (lit. (10) m.p. 206°).

5-Ketohexanoic Acid Phenylhydrazone(4)

5-Ketohexanoic acid (5 g, 0.038 mole) was mixed with phenylhydrazine (4.15 g, 0.038 mole) in 10 ml of ether. A yellow oil was obtained which crystallized after several days to yield 7.2 g (86%) of **4**, m.p. 48–51°; p.m.r. ($CDCl_3$) δ 1.71 (s, 3, CH_3), 1.72–2.55 (m, 6, CH_2),

[4]The direction of the effect is that expected from inductive electron withdrawal by the arylazo function. Its magnitude (ca. 5 cm^{-1}) is appreciable when compared with the effect of equatorial bromine and chlorine *alpha* to carbonyl of cyclohexanones (Δ vCO = 15 and 20 cm^{-1}, respectively).

6.59–7.41 (m, 5, C_6H_5), 8.32 (s, 2, *NH* and *OH*); i.r. (neat) 1780 cm^{-1} (C=O).

4-Keto-1-pentanol Phenylhydrazone (5)

Heating phenylhydrazine (10.8 g, 0.1 mole) with 4-keto-1-pentanol (10.2 g, 0.1 mole) for 0.5 h in 6 ml of acetic acid at 100° gave, after addition of NH_4OH and extraction with ether, 15 g (78%) of **5**, m.p. 64–65° (lit. (11) m.p. 60–66°).

Ethyllevulinate Phenylhydrazone (3c)

To a saturated solution of phenylhydrazine hydrochloride (43.2 g, 0.3 mole) in water was added ethyllevulinate (43.2 g, 0.3 mole). The mixture was shaken and after a few h the crystals which had separated were recovered and recrystallized from benzene. The yield of **3***c*, m.p. 108–109° (lit. (12) m.p. 103–104°), was 54 g (77%).

Levulinanilide Phenylhydrazone (3b)

Levulinic anilide (19.1 g, 0.1 mole) and phenylhydrazine (10.8 g, 0.1 mole) gave 22 g (78%) of **3***b*, m.p. 110–111°; p.m.r. ($CDCl_3$) δ 1.71 (s, 3, CH_3), 2.65 (s, 4, CH_2), 6.70–7.60 (m, 10, C_6H_5), 8.42 (s, 2, *NH*); i.r. (KBr) 1670 cm^{-1} (C=O).

5-Hexen-2-one-2,4-dinitrophenylhydrazone (6)

2,4-Dinitrophenylhydrazine (18.2 g, 0.1 mole) was refluxed briefly with 5-hexen-2-one (9.8 g, 0.1 mole) in 100 ml of ethanol. The mixture was cooled, 5 ml of conc. HCl was added, and the resulting mixture was heated again for 2 min. After cooling there was obtained 10.5 g (38%) of **6**, m.p. 104° (lit. (13) m.p. 104°).

Levulinic Acid Oxime (7)

Hydroxylamine hydrochloride (50 g, 0.72 mole) and levulinic acid (8.3 g, 0.07 mole) were dissolved in a little water and a hot, saturated solution of Na_2CO_3 (38 g) in H_2O was added. On cooling 6.7 g (76%) of **7** precipitated, m.p. 95–96° (lit. (14) m.p. 95–96°).

Oxidation of Phenylhydrazones

The general procedure involved gradual addition of 0.03 mole of the hydrazone in methylene chloride solution to a stirring solution of 20 g (0.045 mole) LTA in methylene chloride at 0–5°. The mixture was allowed to warm to room temperature and stirred another h after which time cold water was added. Filtration through a bed of Celite, separation of the organic layer, washing with cold water and with cold bicarbonate solution, drying with Na_2SO_4, and evaporation of the solvent gave the reaction product. Preliminary purification was done by chromatography on Florisil with methylene chloride as eluent. The first small fraction contained mainly azobenzene, the second fraction contained the desired reaction product while the azoacetates remained on the column.[5] Further purification was achieved by recrystallization or distillation. Analyses and physical constants of the oxidation products are in Table II.

Oxidation of Levulinic Acid Oxime

To 33.3 g (0.075 mole) of LTA in 150 ml of methylene chloride was added, gradually and with stirring, 9.82 g (0.075 mole) of the oxime at 0–5 °C. The reaction mixture was kept 2 h at room temperature, water was added, the organic layer was separated, washed with cold water and bicarbonate solution, dried, and the solvent evaporated. After recrystallization from methylene chloride–petroleum ether, 5.4 g (56%) of *trans*-bis[γ-nitroso-γ-valerolactone] (**14**) was obtained, m.p. 118–119 °C.

1,2:5,6-Di-*O*-isopropylidene-D-hexofuranoses and their 3-keto derivatives

K. N. SLESSOR AND A. S. TRACEY
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received May 12, 1969

The synthesis of the only unknown 1,2:5,6-di-*O*-isopropylidene-D-hexose, D-mannose, is reported. Its preparation involved the stereospecific borohydride reduction of the 3-keto intermediate prepared from D-altrose. An improved synthesis of the known D-talose derivative proceeded in an analogous manner from the parent ketone. The four 3-keto derivatives of the diacetone D-hexoses were prepared and their properties compared. In an attempt to explain the differences found in the ease of hydration of these materials, high resolution infrared hydrogen bonding studies were carried out on the eight hexose derivatives and the one hydrated ketone.

Canadian Journal of Chemistry, 47, 3989 (1969)

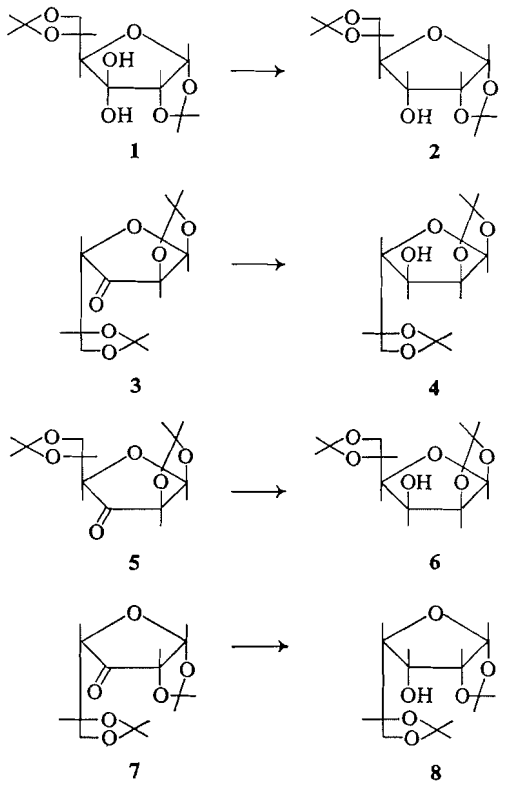
The synthetic utility of the isopropylidene blocking group has been well recognized for many years in the synthesis of specifically substituted carbohydrates (1, 2). Quite recently the application of oxidative methods to these derivatives has resulted in the facile synthesis of the rare hexoses, D-allose (3) and D-gulose (4). If some of the other isopropylidene hexoses were available, analogous reactions could be used, yielding other more difficultly obtained hexoses.

It should be pointed out that the hydrolysis of the isopropylidene group occurs under mildly acidic conditions probably involving cleavage of the C—O bond of the ketal (5). This is important when dealing with sugars which readily form 1,6-anhydro derivatives under acidic conditions as it allows hydrolysis to the free sugar, rather than a mixture of anhydride and the free sugar that one obtains upon hydrolysis of a glycoside. An example is the quantitative yield of D-gulose from the 1,2:5,6 ketal (4) whereas under more strongly acidic conditions, D-gulose gave 41% of the 1,6-anhydro-β-D-gulopyranose as well as the free sugar (6).

In order to study the conformational properties of the *cis* fused isopropylidene derivatives of furans, the synthesis of all the 1,2:5,6-di-*O*-isopropylidene-D-hexofuranoses was undertaken. Although seven of the eight were known, the synthetic procedures for several of them were poor in terms of yield. As noted below, the 3-keto derivatives are excellent synthetic intermediates as well as derivatives which provide an optically active chromophore for optical rotatory dispersion studies.

Theander's synthesis of D-allose (**2**) from the keto compound (**1**) clearly indicated the stereospecific nature of the hydride reduction of 3-keto-1,2-*O*-isopropylidene compounds (3). The presence of the *endo* methyl group of the isopropylidene acetal completely prevents reduction from this side, giving the alcohol *cis* to the 1,2-ring as in the D-allose derivative. With the appropriate ketones being available the 1,2:5,6-di-*O*-isopropylidene derivatives of D-talose (**4**), D-mannose (**6**), and D-gulose (**8**) are readily prepared.

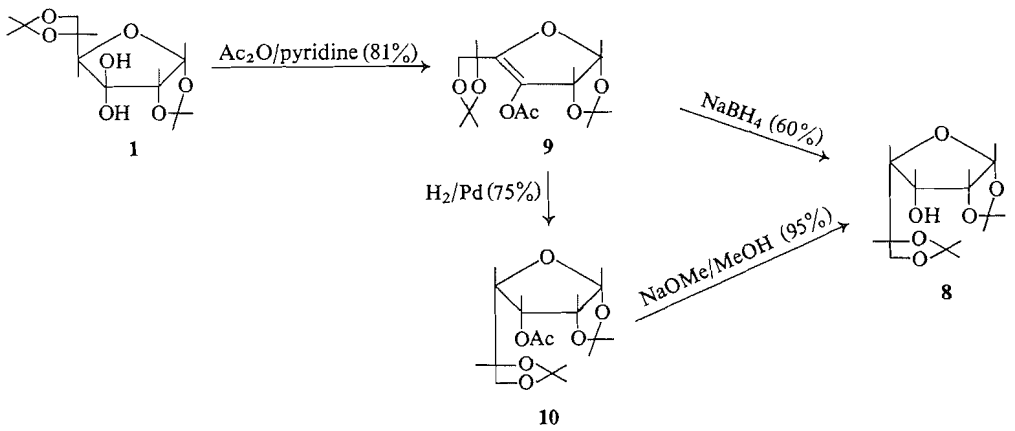
1,2:5,6-Di-*O*-isopropylidene-β-D-talofuranose (**4**) is known as a side product in the acetonation



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of D-talose (7). The D-gulose can be readily prepared by the borohydride reduction of 3-*O*-acetyl-1,2:5,6-di-*O*-isopropylidene-α-D-*erythro*hexofuran-3-enose (4) or as described below. The mannofuranose derivative has not previously been prepared as acetonation of D-mannose gives only 2,3:5,6-di-*O*-isopropylidene-D-mannofuranose (8).

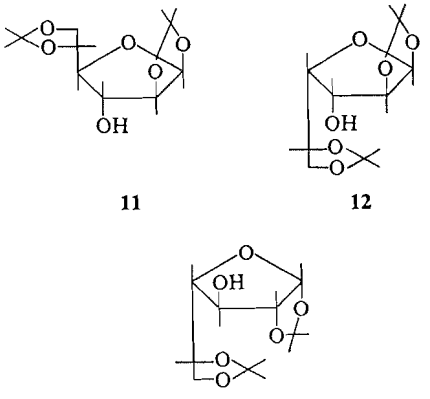
1,2:5,6-Di-*O*-isopropylidene-α-D-gulofuranose (**8**) has been synthesized by Meyer zu Reckendorf (4) by conversion of the hydrated 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*hexofuranos-3-ulose (**1**) into the enol acetate (**9**). Reduction of this material with sodium borohydride yields the diacetone gulose. The reaction is complicated by loss of the 5,6-*O*-isopropylidene acetal and the yield in the borohydride reduction is often low due to this. We have found catalytic hydrogenation of the enol acetate gives an excellent yield of the 3-*O*-acetate (**10**). Catalytic deacetylation with methoxide then gives the gulose derivative (**8**) in very high yield.



1 **9** **8** **10**

It is worth mentioning that the reduction is not a simple addition of hydrogen across the 3,4-ene but involves a rearrangement which is being investigated and will be reported later.

The preparation of the ketones was carried out in an analogous way to the known route for 3-keto diacetone glucose (**1**) (9). D-Altrose was prepared from methyl 4,6-benzylidene-α-D-glucoside and was converted into the known 1,2:5,6-di-*O*-isopropylidene-β-D-altrofuranose (**11**). Oxidation of this material by the very convenient IO_4^-/RuO_2 method of Parikh and Jones (9*b*) yielded the desired keto sugar as a syrup which crystallized after vacuum distillation. Borohydride reduction allowed isolation of the hitherto unknown 1,2:5,6-di-*O*-isopropylidene-β-D-mannofuranose (**6**). D-Idose was prepared from its penta-acetate (10) and condensed with acetone to give the known 1,2:5,6-acetonate (**12**) (11). Oxidation yielded a crystalline ketone which on borohydride reduction gave the known β-D-talofuranose derivative (**4**) (12). 1,2:5,6-Di-*O*-isopropylidene-α-D-galactofuranose (**13**) was readily prepared by hydroboration of 3-deoxy-1,2:5,6-di-*O*-isopropylidene-α-D-*erythro*hexofuran-3-enose (13).



11 **12** **13**

The reduction of the four ketones with borodeuteride gives excellent yields of the 3-deutero-D-allose, -D-talose, -D-mannose, and -D-gulose[1], which are valuable compounds for spectroscopic

[1]Unpublished results.

TABLE I

Proton magnetic resonance chemical shift data*

Sugar	H_1	$J_{1,2}$(Hz)	H_2	H_3	H_4	H_5	H_{6_1}	H_{6_2}	CH_3's

arabino Ketone (**5**)	3.99	4.3	5.53	5.60 to 6.08					8.48, 8.60(3)
xylo Ketone (**7**)	3.94	4.4	5.49	5.60 to 6.20					8.50, 8.56(3)
lyxo Ketone (**3**)	3.88	4.2	5.51	5.54 to 6.24					8.70, 8.58(3)

*Run on a Varian A 56–60 at room temperature using $CDCl_3$ as solvent and internal TMS as standard (10.0 τ).

analyses of the diacetone hexoses. In an attempt to introduce deuterium at the 4-position, the ketones were treated with pyridine–D_2O (2:1) (14) at temperatures ranging from 20–100° for periods of up to 1 h. No introduction of deuterium was observed at either the 2 or 4 positions nor did any epimerization of the 4 position take place. Under the conditions used the ketones decomposed at varying rates. Deuteration was checked by reisolation of the ketone, purification, and nuclear magnetic resonance (n.m.r.) spectroscopy (see Table I). We believe the resistance to enolization to be due to the hydration of the ketone in aqueous solution. This is born out by the absence of a ketone absorption at 325 mμ in aqueous solutions of all the ketones. The optical rotatory dispersion studies (15) show no anomalous dispersion in aqueous solution but strong Cotton effects when run in non-aqueous media. This phenomenon has already been reported for 3-keto diacetone glucose (4).

Not too surprising is the observation that the ketones hydrate with varying ease as is evident from Table II. On isolation, however, only one of the ketones is isolated as the hydrate, the others all existing in their keto modification as shown by the presence of a strong band at 1770–1780 cm^{-1} indicating C=O, and the absence of a band at 3300–3600 cm^{-1} indicating no OH in the infrared spectra of the samples in KBr discs. Crystalline 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*hexofuranos-3-ulose (**1**) has been shown to be hydrated and this was substantiated by the strong band at 3400 cm^{-1} and the complete absence of a ketone absorption.

In an attempt to explain the differential hydration of these substances, intramolecular hydrogen bonding studies were carried out by high resolution infrared spectroscopy on dilute carbon tetrachloride solutions. Spedding has reviewed the applicability of this technique to conformational assignments in carbohydrate chemistry (16). Spectra were run at 3 concentrations (0.005, 0.0025, and 0.0012 *M*) in carbon tetrachloride that had been dried over molecular sieve (Linde type 3A). In all nine compounds no observable peak change or shift occurred on changing concentration. The spectra are shown in Fig. 1.

Figures 1*A* and 1*B* represent compounds (*altro* and *galacto*) in which intramolecular hydrogen bonding of the 3-hydroxyl would not be expected because of its distance from any suitable oxygen. The similarity of these spectra and the position of the band at 3630 cm^{-1} indicate a free hydroxyl on a secondary center. Figures 1*C* and 1*D* are compounds (*allo* and *talo*) in which the stereochemistry only allows the hydroxyl to hydrogen bond to the 2-*O* in the 1,2-*O*-isopropylidene ring. This is in agreement with the position of the bands in 1*C* and 1*D* at

TABLE II

Extent of hydration (%) of the 1,2:5,6-di-*O*-isopropylidene-D-hexofuranos-3-uloses*

Ketone	0.5 h	1.5 h	3.5 h	8 h	18 h
Acetonitrile containing 4.25% water					
ribo† (**1***a*)	2	7	14	26	45
arabino (**5**)	1	3	4	6	10
xylo (**7**)	5	14	17	17	17
lyxo (**3**)	2	4	9	17	29
Acetonitrile containing 10% water					
ribo† (**1***a*)	34	69	82	83	84‡
arabino (**5**)	11	26	39	41	43
xylo (**7**)	25	34	38	39	39
lyxo (**3**)	23	46	60	61	61

*Measured on a Unicam SP200 at 320 mμ at a sugar concentration of 0.015–0.017 *M* in 1 cm cells. Beer's law was obeyed for the ketones in acetonitrile over this concentration range giving ε values of (1*a*) 23, (5) 31, (7) 28, (3) 30. All the ketones showed no absorption at 320 mμ after 5 min of being dissolved in water.

†The *ribo* ketone (1*a*) was prepared by vacuum distillation of the hydrated ketone (1*b*) (b.p. 112°/0.04 mm) to give a mobile syrup which crystallized, m.p. 38–39°.

‡After 18 h in acetonitrile containing 10% water the hydrated *ribo* ketone (1*b*) showed 85% hydration, confirming that equilibrium conditions had been reached.

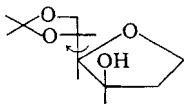
3570 cm^{-1} indicating a 5 membered hydrogen bond ring (17).

$$C_2—O_2\cdots H—O_3—C_3$$

The stereochemistry of compounds 1*E* and 1*F* (*gluco* and *ido*) restricts any hydrogen bonding of the 3-OH to the oxygen at C_5 involved in the 5,6-*O*-isopropylidene ring. Surprisingly, the spectra are quite different, the glucose derivative having 2 peaks, one at 3622 cm^{-1} (free OH) and the less intense band at 3485 cm^{-1}. The latter band indicates a larger $\Delta\nu$ as could be expected from the formation of a six membered ring (17)

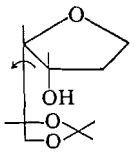
$$C_3—O—H\cdots O_5—C_5—C_4.$$

Hydrogen bonding of this type will prevent free rotation of the "tail" (C_5—C_6 and their substituents) about the C_4—C_5 bond. At room temperature it is unlikely that free rotation is completely hindered in the glucose derivative, and thus the band at 3622 cm^{-1} can be attributed to that fraction of the 3-OH in which the "tail" is in a rotamer that cannot be hydrogen bonded. The diacetone idose spectrum shows only one band at 3502 cm^{-1} indicating complete hydrogen bonding to the "tail". Careful examination of molecular models indicates that when the "tail" and the 3-OH are *cis*, then in the D-C_5:D-C_3 configuration (D-*gulo* and D-*ido*) rotation about the C_4—C_5 bond is more hindered than for the D-C_5:L-C_3 configuration (D-*gluco* and D-*manno*).



Rotation easier

D-C_5; L-C_3



Rotation more difficult

D-C_5; D-C_3

It would seem that the formation of a 3-OH···O_5 hydrogen bond as well as the hindered rotation effectively maintains the "tail" of 1,2:5,6-di-*O*-isopropylidene-β-D-idofuranose in one rotamer.

Figures 1*G* and 1*H* (*gulo* and *manno*) indicate the spectra in which the 3-OH is able to choose whether it bonds with the "tail" or the oxygen at the 2 position. We believe the peaks at 3532 and 3538 cm^{-1} respectively, indicate a preferential formation of the hydrogen bond to the "tail". The shoulder in the *manno* (1H) derivative at 3585 cm^{-1} we feel corroborates the evidence that the D-C_5:L-C_3 system (*gluco* and *manno*) has freer rotation about the C_4—C_5 bond. Such rotation would prevent complete hydrogen bonding to the "tail" and allow the 3-OH to form a hydrogen bond to the 2 oxygen of the 1,2-*O*-isopropylidene unit, thus giving rise to the 3585 cm^{-1} shoulder.

Figure 1*I* shows the spectrum of the hydrated 3-keto diacetone glucose (**1**). Both hydroxyl groups at the 3 position can hydrogen bond. The band at 3550 cm^{-1} we ascribe to the OH group hydrogen bonded to the C_2 oxygen and the bands at 3608 and 3423 cm^{-1} to the other OH. The 3423 cm^{-1} band is attributed to the one hydrogen bonded to the "tail" and the 3608 cm^{-1} band being due to free OH not being able to bond because of the "tail" being in another rotamer. The apparent strengthening (lowering of the frequency) of these bands is readily ascribed to the extra electronegative OH group at C_3.

Two di-*O*-isopropylidene compounds are capable of double hydrogen bonding in their hydrated keto form. The first is the keto glucose (**1**) that we have just discussed, the second the keto idose derivative (**3**).

3

In its crystalline state, the latter exists in the keto form. That this is not just a property of the crystalline material is obvious from the ease of extraction from aqueous solution and the inability to form an enol acetate under identical conditions to those for the hydrated keto glucose derivative. That is, in spite of the ability of 1,2:5,6-di-*O*-isopropylidene-β-D-idofuranose to form a strong hydrogen bond with its "tail", the hydrated keto

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

form of **3***b* is not stabilized by such formation. We believe the reason for this is that in the very rigid conformation that must be adopted to simultaneously form two hydrogen bonds, there is steric interaction of the "tail" with the furan ring. This does not seem to be the situation in the hydrated keto D-glucose derivative (**1***b*).

The hydrogen bonding results must be regarded with care as they pertain only to dilute, non-polar solutions and will not be applicable to aqueous systems. Nevertheless, the information one can derive from such results allows a much better appreciation for the forces acting within the molecule and thus a better understanding of the chemistry of these compounds.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Evaporations were carried out on Buchi rotary evaporators at bath temperatures not exceeding 45°. Optical rotations were measured on a Perkin Elmer Model P22 spectropolarimeter using thermostatted jacketed cells of varying path lengths at 20°. Hydrogen bonding studies were performed in matched cells of 1 cm path length on a Beckman IR 12. Thin layer chromatography (t.l.c.) was carried out on Silica gel G using 10% sulfuric acid and heat for development.

1,2:5,6-Di-O-isopropylidene-α-D-glucofuranose

It was prepared from D-glucose by the method of Schmidt (18), m.p. 110°, $[\alpha]_D$ −17.5° (*c*, 0.4, water). Lit. (18), m.p. 110–111°, $[\alpha]_D$ −18.5° (*c*, 5, water).

*1,2:5,6-Di-O-isopropylidene-α-D-ribohexofuranos-3-ulose (**1**)*

To 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (5.0 g) in carbon tetrachloride (50ml), sodium bicarbonate (0.4 g) in water (4 ml) was added. Ruthenium dioxide (40 mg) was added and 5% aqueous sodium metaperiodate was added dropwise[2] with stirring until the oxidation was complete, as indicated by t.l.c. The mixture was separated and the aqueous phase extracted twelve times with an equal volume of chloroform. The organic phases were combined, dried over calcium chloride, filtered, and evaporated to give a syrup which crystallized readily. Recrystallization from chloroform – petroleum ether (30–60°) (1:2) gave (**1**) 4.0 g, m.p. 109–111°, $[\alpha]_D$ 37.5° (*c*, 0.4, water). Lit. (3), m.p. 108–110°, $[\alpha]_D$ 40.2 (*c*, 0.5, water).

*1,2:5,6-Di-O-isopropylidene-α-D-allofuranose (**2**)*

It was prepared by the sodium borohydride reduction of (**1**) as described by Theander (3), m.p. 73–74°, $[\alpha]_D$ 34° (*c*, 0.4, water). Lit. (3), m.p. 76–77°, $[\alpha]_D$ 37.7° (*c*, 0.5, water).

[2]Periodate is added only if the black RuO_2 is reformed after each addition of periodate.

*3-O-Acetyl-1,2:5,6-di-O-isopropylidene-α-D-gulofuranose (**10**)*

Catalytic reduction of 3-*O*-acetyl-1,2:5,6-di-O-isopropylidene-α-D-*erythro*hexofuran-3-enose (**9**) (3 g) in ether (60 ml) at room temperature and atmospheric pressure with palladium black for 2 h gave upon filtration and evaporation of the solvent, crystalline 3-*O*-acetyl-1,2:5,6-di-*O*-isopropylidene-α-D-gulofuranose (2.3 g), m.p. 73–74°, recrystallized from ethanol, $[\alpha]_D$ 66.0° (*c*, 0.36, $CHCl_3$).

Anal. Calcd. for $C_{14}H_{22}O_7$: C, 55.62; H, 7.33. Found: C, 55.43; H, 7.16.

*1,2:5,6-Di-O-isopropylidene-α-D-gulofuranose (**8**)*

Deacetylation of the 3-*O*-acetate (1.55 g) with 0.01 *N* sodium methoxide (50 ml) for 2 h followed by neutralization of the base with solid carbon dioxide gave the known gulose derivative (1.25 g) m.p. 103°, $[\alpha]_D$ 10.0° (*c*, 0.4, $CHCl_3$). Lit. (4), m.p. 105–106°, $[\alpha]_D$ 7.5° (*c*, 1, $CHCl_3$).

*1,2:5,6-Di-O-isopropylidene-α-D-xylohexofuranos-3-ulose (**7**)*

1,2:5,6-Di-*O*-isopropylidene-α-D-gulofuranose (1.1 g) was oxidized by the IO_4^-/RuO_2 method described above. Only four extractions with chloroform were necessary to give the product (0.79 g) which crystallized readily. Recrystallization from petroleum ether (65–110°) gave the ketone m.p. 76–77°, $[\alpha]_D$ −58.5° (*c*, 0.4, water).

Anal. Calcd. for $C_{12}H_{18}O_6$: C, 55.80; H, 6.96. Found: C, 55.63; H, 6.89.

*1,2:5,6-Di-O-isopropylidene-α-D-galactofuranose (**13**)*

It was prepared by hydroboration of 3-deoxy-1,2:5,6-di-*O*-isopropylidene-α-D-*erythro*hexofuran-3-enose as described by Paulsen and Behre (13), m.p. 94–95°, $[\alpha]_D$ −20.5° (*c*, 0.4, $CHCl_3$). Lit. (13), m.p. 97.5–98°, $[\alpha]_D$ −35.3° (*c*, 0.8, methanol).

*1,2:5,6-Di-O-isopropylidene-β-D-altrofuranose (**11**)*

Syrupy D-altrose (19) (1.3 g) was dissolved in a mixture of dry acetone (100 ml) that contained zinc chloride (12 g) and 85% phosphoric acid (0.5 ml). The solution was stirred overnight at room temperature and then neutralized by careful addition of 50% aqueous sodium hydroxide. The mixture was then filtered, the precipitate washed thoroughly with acetone, and the filtrate and washings combined and evaporated. The resultant thin syrup was dissolved in chloroform (25 ml) and washed with 1% aqueous sodium bicarbonate (15 ml). The bicarbonate wash water was extracted once with chloroform (15 ml) and the extracts pooled, dried over calcium chloride, filtered, and evaporated. The resultant syrup crystallized readily and could be recrystallized from petroleum ether (65–110°) to yield the diacetone altrose (1.22 g), m.p. 87–88°, $[\alpha]_D$ 28.5° (*c*, 0.4, acetone). Lit. (20), m.p. 87–88°, $[\alpha]_D$ 28.7° (*c*, 1.04, acetone).

*1,2:5,6-Di-O-isopropylidene-β-D-arabinohexofuranos-3-ulose (**5**)*

1,2:5,6-Di-*O*-isopropylidene-β-D-altrofuranose (1.65 g) was oxidized in the same manner as was the glucofuranose. The oxidation yielded a non-crystalline material (1.28 g) after four extractions, which was free of impurities as judged by n.m.r. and t.l.c. (ethyl ether:toluene, 2:1). Vacuum distillation of the syrup (b.p. 87°/0.01 mm) gave a colorless liquid which crystallized spontaneously. Recrystallization from petroleum ether (65–110°) gave

material (1.11 g) melting at 31–32°, $[\alpha]_D$ 25.5° (*c*, 0.49, water).

Anal. Calcd. for $C_{12}H_{18}O_6$: C, 55.80; H, 6.96. Found: C, 55.59; H, 7.09.

1,2:5,6-Di-O-isopropylidene-β-D-mannofuranose (6)

1,2:5,6-Di-*O*-isopropylidene-β-D-arabinohexofuranos-3-ulose (440 mg) was dissolved in ethanol:water (5:1) (50 ml) and sodium borohydride (50 mg) was added. The reduction was carried out at room temperature for 30 min after which time the solution was neutralized with carbon dioxide. Extraction of this solution with chloroform (4 × 50 ml) gave a solution which was dried with calcium chloride, filtered, and evaporated to a syrup. The syrup was dissolved in chloroform (50 ml) and washed with 2% aqueous sodium bicarbonate (25 ml). The bicarbonate wash was extracted once with chloroform (50 ml), the chloroform layers combined, dried, filtered, and evaporated to a syrup which crystallized. Recrystallization from petroleum ether (65–110°) gave material (400 mg) melting at 52–53°, $[\alpha]_D$ 12.5° (*c*, 0.4, water).

Anal. Calcd. for $C_{12}H_{20}O_6$: C, 55.37; H, 7.75. Found: C, 55.27; H, 7.86.

2,3:5,6-Di-O-isopropylidene-D-mannofuranose

1,2:5,6-Di-*O*-isopropylidene-β-D-mannofuranose (**6**) (200 mg) was dissolved in a solution of acetone (12 ml) containing concentrated sulfuric acid (0.2 ml). After 1 h at room temperature, sodium carbonate (1 g) was added and the mixture was stirred for 6 h. The neutral acetone solution was then filtered and the filtrate evaporated. The solid residue was dissolved in a minimum of hot petroleum ether (65–110°) which upon cooling yielded crystalline material (180 mg) melting at 118–119°. Three recrystallizations from petroleum ether (65–110°) gave m.p. 118–119°, mixed melting point with the 2,3:5,6 ketal prepared from D-mannose, 118–119°. Freudenberg and Hixon (21) give the m.p. as 118°. The 2,3:5,6 ketal prepared from the 1,2:5,6 had an identical infrared spectrum to that of the material prepared in the standard way (22).

1,2:5,6-Di-O-isopropylidene-β-D-idofuranose (12)

Amorphous D-idose was prepared by the method of Paulsen *et al.* (10). The D-idose so produced (5 g) was converted into the known di-*O*-isopropylidene derivative using zinc chloride (12 g), 85% phosphoric acid (0.5 ml) in dry acetone (100 ml). On working up the product as described above for 1,2:5,6-di-*O*-isopropylidene-β-D-altrofuranose, a crystalline product was obtained by cooling a petroleum ether (65–110°) solution of the material. The mother liquor contained an isomeric di-*O*-isopropylidene derivative, presumably the 1,2:3,5 furanose derivative. This material could be retreated with the acetal forming reagents to produce further amounts of **12**. Recrystallization from petroleum ether (65–110°) gave 1,2:5,6-di-*O*-isopropylidene-β-D-idofuranose (3.5 g), m.p. 151–152°, $[\alpha]_D$ 33.5° (*c*, 0.4, acetone). Lit. (11), m.p. 151–152.5°, $[\alpha]_D$ 36.0° (acetone).

1,2:5,6-Di-O-isopropylidene-β-D-lyxohexofuranos-3-ulose (3)

1,2:5,6-Di-*O*-isopropylidene-β-D-idofuranose (1.3 g) was oxidized in the same manner as the glucofuranose. The oxidation yielded a crystalline material (1.1 g), m.p. 87.5–88° from petroleum ether (65–110°), $[\alpha]_D$ −21.0° (*c*, 0.4, water).

Anal. Calcd. for $C_{12}H_{18}O_6$: C, 55.80; H, 6.96. Found: C, 55.95; H, 6.79.

1,2:5,6-Di-O-isopropylidene-β-D-talofuranose (4)

Borohydride reduction of 1,2:5,6-di-*O*-isopropylidene-β-D-*lyxo*hexofuranos-3-ulose (400 mg) was carried out in the same way as described for the conversion of the *arabino* ketone (**5**) to the mannofuranose (**6**). The reduced product (350 mg) was recrystallized from petroleum ether (65–110°), m.p. 83–84°, $[\alpha]_D$ −25.0° (*c*, 0.40, $CHCl_3$). Lit. (7), m.p. 85–86°, $[\alpha]_D$ −25° (*c*, 0.47, $CHCl_3$).

Aliphatic diazo compounds. IX. The base-induced dimerization of α-diazo ketones[1,2]

PETER YATES, R. G. F. GILES, AND D. G. FARNUM

Department of Chemistry, University of Toronto, Toronto 5, Ontario, and Department of Chemistry, Harvard University, Cambridge, Massachusetts

Received June 2, 1969

Treatment of 2-diazoacetophenone (**1**) with potassium *t*-butoxide in *t*-butyl alcohol gives a colorless dimer, which is shown to be 5-benzoyl-2-phenacyltetrazole (**4**) by its independent synthesis by phenacylation of 5-benzoyltetrazole. The latter reaction also gives 5-benzoyl-1-phenacyltetrazole (**3**), which is distinguished from **4** by its reduction to di(2-hydroxy-2-phenylethyl)amine and by its cyclization on treatment with ammonium acetate. The assignment of the structure of the colorless dimer of **1** permits the postulation of related pathways for its formation and that of the red–brown dimer obtained on treatment of **1** with potassium hydroxide in dimethyl sulfoxide. 2-Phenacyltetrazole (**22**) and benzoic acid are formed in addition to **4** on treatment of **1** with potassium *t*-butoxide in *t*-butyl alcohol; these are considered to arise via cleavage of **4**, since prolonged treatment of **4** and **3** with potassium *t*-butoxide in *t*-butyl alcohol gives **22** and 1-phenacyltetrazole (**24**), respectively. Compounds **22** and **24** have been prepared independently by phenacylation of tetrazole.

Canadian Journal of Chemistry, 47, 3997 (1969)

α-Diazo ketones have been observed to give two types of dimer on reaction with bases. Treatment of 2-diazoacetophenone (**1**) with potassium hydroxide in dimethyl sulfoxide gives a red–brown dimer that has been shown to be 3,6-dibenzoyl-1,2(4)-dihydrotetrazine (**2**) by independent synthesis (3). Treatment of 2-diazoacetophenone with potassium *t*-butoxide in *t*-butyl alcohol gives a colorless dimer that was previously considered to be 5-benzoyl-1-phenacyltetrazole (**3**) (2), but is now shown to be 5-benzoyl-2-phenacyltetrazole (**4**). Both types of dimer have also been obtained from the α-diazo ketones **5** and **6** under various basic conditions (3, 4).

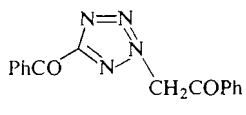
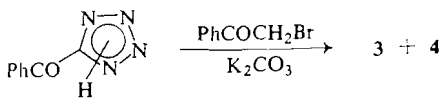
3



4

The colorless dimer, m.p. 114–114.5°, was obtained in 69% yield by reaction of 2-diazoacetophenone (**1**) with 1.2 molar equivalents of potassium *t*-butoxide in dilute solution in *t*-butyl alcohol at room temperature. Its infrared spectrum, which included bands at 5.85 and 5.95 μ, suggested that it contained two carbonyl groups; the absence of a band in the 2.75–3.2 μ region further indicated that the dimer possessed no N—H bond. These conclusions and the earlier observation of the formation of 5-benzoyltetrazole (**7**) in the reaction of **1** with methanolic sodium methoxide (1) led to the formulation of the dimer as either **3** or **4**. These structures were in accord with its proton magnetic resonance (p.m.r.) spectrum, which showed a two-proton singlet at δ 6.31 and a ten-proton multiplet at δ 7.5–8.5, assignable to the methylene and aromatic protons, respectively. Its formulation as a *C*-benzoyl nitrogen heterocycle was also in accord with the presence of a strong band at 10.82 μ in its infrared spectrum (5).

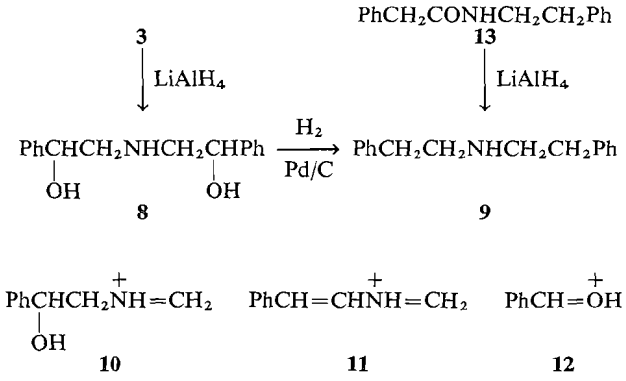
This structural assignment was confirmed by the independent synthesis of **3** and **4** by treatment of **7** with phenacyl bromide and potassium carbonate in acetone. The major product (65% yield) from this reaction was a compound shown



7

to be identical with the colorless dimer of **1**. A second, isomeric product, m.p. 126–127°, was obtained in 14% yield; its infrared spectrum, which included bands at 5.85, 5.97, and 10.80 μ,

[1]For Part VIII, see reference 1.
[2]Part of this work has been reported in a preliminary communication (2).



and its p.m.r. spectrum, with signals at δ 6.33 (2H, s) and 7.5–8.6 (10H, m), were very similar to the spectra of the major product. These compounds were clearly the two possible *N*-phenacylation products derivable from **7**; the unusually short wavelength (5.85 μ) of the carbony-stretching band attributable to the phenacyl carbonyl group can be interpreted in terms of the strong electron-withdrawing effect of the tetrazole ring.

It remained to assign individual structures to the two phenacylation products. The isomer, m.p. 126–127°, was shown to have structure **3** in the following way [cf. (6)]. Reduction with lithium aluminium hydride gave a compound, $C_{16}H_{19}NO_2$, which was shown to be di(2-hydroxy-2-phenylethyl)amine (**8**) by its spectral properties and its conversion on catalytic hydrogenolysis to di(2-phenylethyl)amine (**9**). The amine **8** showed bands at 2.77 and 3.0 μ in its infrared spectrum, but no band in the carbonyl-stretching region. Its p.m.r. spectrum showed a two-proton multiplet at δ 4.75 and a ten-proton signal at δ 7.36, assigned to the methine and aromatic protons, respectively. The remaining protons gave rise to a seven-proton multiplet at δ 2.75–3.0 that was replaced by a four-proton doublet (*J* 6 Hz) at δ 2.82, assigned to the methylene protons, after treatment of the sample with deuterium oxide. The mass spectrum of the product showed no molecular ion peak, but exhibited a fragmentation pattern in accord with the structural assignment [cf. (7)], with peaks at *m/e* 150, 132 (base peak), and 107, attributable, respectively, to the ions **10**, **11**, and **12**; a metastable peak at 116.1 corroborated the formation of **11** from **10** (calcd. 116.2). The structure of the hydrogenolysis product **9** was established by direct comparison of it and its hydrochloride with authentic samples prepared via reduction of *N*-(2-phenylethyl)phenylacetamide (**13**) with lithium aluminium hydride.

The formation of **8** on reductive cleavage of the tetrazole, m.p. 126–127°, establishes that this tetrazole has structure **3** rather than **4**, and leads to the assignment of the latter structure to the dimer, m.p. 114–114.5°, of 2-diazoacetophenone. Reduction of **4** with lithium aluminium hydride failed to cleave the tetrazole ring; the product obtained was the diol **14**.[3] This was converted by hydrogenolysis to 2-benzyl-5-(2-phenylethyl)-tetrazole (**15**), which was also obtained directly from **4** by hydrogenolysis under analogous conditions. The tetrazole ring of **15** was also resistant to cleavage by lithium aluminium hydride.

The individual assignments of structure **3** and **4** were confirmed by treatment of **3** with ammonium acetate in boiling acetic acid. There was thus obtained a product, $C_{16}H_{11}N_5$, in 78% yield, that is assigned structure **16**. Its infrared spectrum showed no bands in the N—H or C=O stretching regions, and its p.m.r. spectrum, which was confined to the δ 7.5–9.1 region, included a three-proton signal at δ 8.9–9.1 consisting of a singlet superimposed on a multiplet. Subjection of **4** to similar conditions failed to effect any analogous reaction. The difference between the ultraviolet spectra of **3** and **4** could also be interpreted in terms of these structural assignments. The spectrum of compound **3** showed a maximum at 252 mμ (ε 19 500) with a shoulder at 272 mμ (ε 15 500), while that of **4** showed a simple max-

[3]Although both diastereomers of the diols **14** and **8** are very probably formed during the reduction of **4** and **3**, respectively, the sharp-melting product isolated in each case may well have been a single diastereomer.

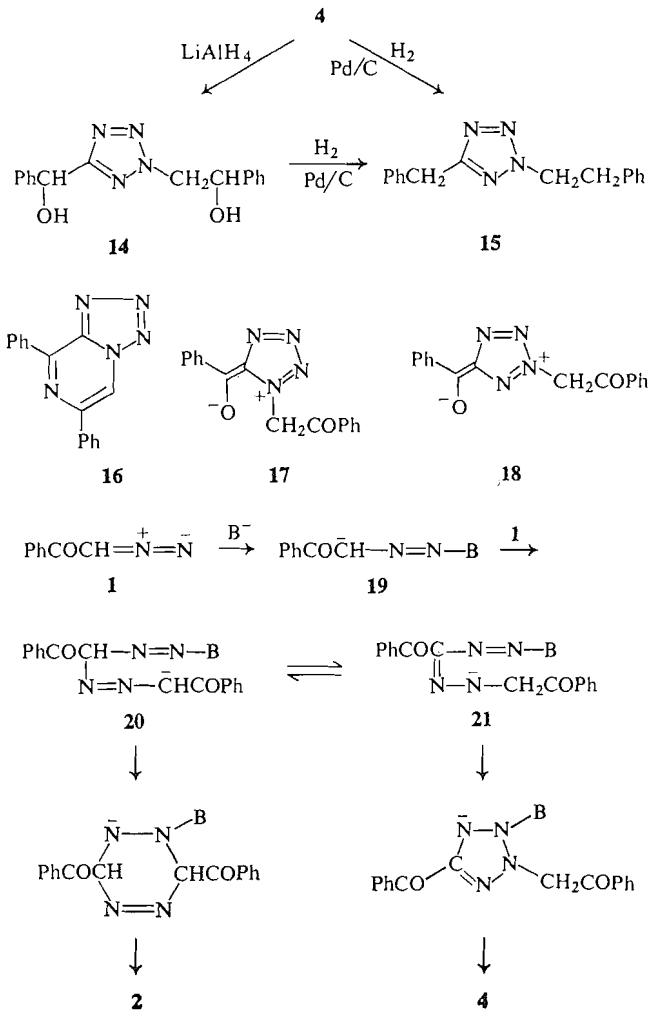
For personal use only.



imum at 250 mμ (ε 24 600). These spectra represent the superimposition of bands due to the $C_6H_5COCH_2X$ system [cf. acetophenone, λ_{max}(EtOH) 243 mμ (ε 12 600) (8)] and the *C*–benzoyltetrazole system [cf. 5-benzoyltetrazole, λ_{max}(EtOH) 261 mμ (ε 12 600) (9)]. The presence of the long wavelength shoulder in the case of **3**, but not of **4**, is compatible with the circumstance that the *C*–benzoyltetrazole system of the former is linearly conjugated, while that of the latter is cross-conjugated (cf. reduced charge separation in **17** vs. **18**).[4]

[4]A misinterpretation of the relationship between the ultraviolet spectra of **3** and **4** originally led to erroneous individual structural assignments (2).

The establishment of **4** as the structure of the dimer of 2-diazoacetophenone (**1**) formed on its treatment with potassium *t*-butoxide in *t*-butyl alcohol[5] reveals that it has a close relationship to the dimer **2** formed on treatment with potassium

[5]It is appropriate here to clarify several confusing aspects of the literature. In the paper by Yates and Farnum (2) there is a typographical error on p. 24, where 5-benzoyl-1-phenacylpyrazole(VII) should have read 5-benzoyl-1-phenacyltetrazole(VII). In the paper by Yates, Meresz, and Morrison (3) there is a typographical error in the first sentence, where 5-benzoyl-2-phenacyltetrazole(I) should have read 5-benzoyl-1-phenacyltetrazole(I). In a recent review (10) it is erroneously stated that Yates and Farnum (2) observed the formation of *both* **3** and **4** from **1** on treatment with potassium *t*-butoxide in *t*-butyl alcohol.

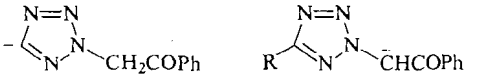
hydroxide in dimethyl sulfoxide. The formation of both can readily be rationalized in terms of the intermediacy of an anion of type **19**, formed via terminal attack (11) of base (B^-) on **1**. Addition of **19** to a second molecule of **1** could give **20** and **21**, which could serve as the source of **2** and **4**, respectively.[6] The manner in which the nature of the basic reagent controls the type of dimer found has not been established.

As previously mentioned, the yield of **4** on treatment of **1** with potassium *t*-butoxide in *t*-butyl alcohol is 69%; the remainder of the starting material is accounted for by two other products, benzoic acid and a compound, $C_9H_8N_4O$. The spectra of the latter suggested that it was 2-phenacyltetrazole (**22**), and this was established by its independent synthesis by phenacylation of tetrazole (**23**) and by cleavage of **4** with potassium *t*-butoxide in *t*-butyl alcohol. The major product in the phenacylation of **23** was 1-phenacyltetrazole (**24**), which was also obtained by the cleavage of **3** with potassium *t*-butoxide in *t*-butyl alcohol.

The cleavage of **4** with base was also carried out by treating it with potassium *t*-butoxide in commercial "anhydrous" ether. The solution momentarily assumed a red coloration, which changed to pale yellow with concomitant formation of a precipitate. Work-up with aqueous ammonium chloride gave **22** and benzoic acid. The possibility that reaction occurred by attack of *t*-butoxide ion at the 5-benzoyl group to give *t*-butyl benzoate and the anion **25**, was excluded by the demonstration that *t*-butyl benzoate was neither a reaction product nor was it converted in major extent to benzoic acid under the conditions of the reaction. It seemed probable that the cleavage of **4** had occurred as a result of the adventitious presence of water, and that the cleavage involved formation of the anion **25** by attack of hydroxide ion at the 5-benzoyl group and was of a type recently investigated by Gassman and co-workers (13). This view was corroborated by the observation that treatment of **4** with potassium *t*-butoxide in ether that had been distilled from lithium aluminium hydride immediately prior to use led to a red coloration that persisted in the anhydrous medium. Work-up



25 **26**, R = PhCO
28, R = D
30, R = H

with deuterium chloride in acetic acid-*d* led to the recovery of **4** with partial deuteration of the methylene group, indicating the formation of the anion **26** in the basic medium; no 2-phenacyltetrazole (**22**) was formed. When the anhydrous ether was treated with deuterium oxide (1.67 moles per mole of **4**) before use, the red coloration again rapidly gave way to a yellow coloration, and after work-up with aqueous ammonium chloride the deuterated cleavage product **27** was obtained. It seems likely that **27** is first formed in the reaction mixture by transfer of deuterium to the anion **25** from benzoic acid-*d* formed simultaneously in the cleavage reaction; subsequent reaction with *t*-butoxide ion could give the anion **28**, from which **27** would be regenerated in the aqueous work-up. Further, when **4** was cleaved with potassium *t*-butoxide in commercial "anhydrous" ether and the solid obtained from the reaction mixture was treated with methyl iodide, only the side-chain methylation product **29** was isolated, suggesting that the anion **25** is converted by reaction with benzoic acid to **22** which then reacts

[6]A related route involving initial proton abstraction (12) rather than terminal attack also leads to an anion that could serve as an intermediate in the formation of both **2** and **4**.

27 29

with *t*-butoxide ion to give the anion **30**. The isolation of the dimethylated product is ascribed to the presence of excess potassium *t*-butoxide in the solid product subjected to methylation.

The demonstration that the presence of water is required for the cleavage of **4** by potassium *t*-butoxide in ether suggests that the cleavage of both **3** and **4** with potassium *t*-butoxide in *t*-butyl alcohol may also have involved the intervention of adventitious water.

Experimental

Melting points, which were determined with a Thomas Hoover "Uni-melt" capillary melting point apparatus, are uncorrected. Solutions in organic solvents were dried over anhydrous magnesium sulfate. Unless otherwise stated, infrared spectra were recorded in solution in dichloromethane, ultraviolet spectra in 95% ethanol, and proton magnetic resonance (p.m.r.) spectra at 100 MHz in deuteriochloroform with tetramethylsilane as internal reference.

Reaction of 2-Diazoacetophenone (1) with Potassium t-Butoxide in t-Butyl Alcohol: Formation of 5-Benzoyl-2-phenacyltetrazole (4) and 2-Phenacyltetrazole (22)

2-Diazoacetophenone (1.00 g) was added to a solution of potassium *t*-butoxide (0.92 g) in *t*-butyl alcohol (55 ml) and the mixture was swirled to dissolve the diazo ketone. The solution immediately became red and after standing for 30 min at room temperature was poured into cold, dilute hydrochloride acid. The mixture was extracted with several portions of dichloromethane, and the extract was dried and stripped of solvent. The resulting solid was dissolved in benzene and chromatographed on a Florisil column (100 g, packed in benzene). Elution with dichloromethane – benzene (1:1) gave 2-phenacyltetrazole (**22**) (0.15 g, 23%), m.p. 104–104.5° after recrystallization from benzene – hexane (*vide infra*).

Elution of the column with 2% methanol – dichloromethane yielded 5-benzoyl-2-phenacyltetrazole (**4**) (0.69 g, 69%), m.p. 114–114.5° after recrystallization from 95% ethanol; λ_{max} 5.85, 5.95, 6.23, 6.30, 10.82 μ; λ_{max} 250 mμ (log ε 4.39); δ 6.31 (2H, s), δ 7.5–8.5 (10H, m).

Anal. Calcd. for $C_{16}H_{12}N_4O_2$: C, 65.75; H, 4.14; N, 19.17. Found: C, 65.58; H, 4.25; N, 18.80.

Elution of the column with 10% methanol – dichloromethane gave benzoic acid (0.17 g).

Phenacylation of 5-Benzoyltetrazole (7): Formation of 5-Benzoyl-1-phenacyltetrazole (3) and 5-Benzoyl-2-phenacyltetrazole (4)

5-Benzoyltetrazole[1] (0.87 g) was dissolved in dry acetone (20 ml) and potassium carbonate (0.35 g) was added. The mixture was swirled and warmed until most of the base had dissolved, and phenacyl bromide (1.00 g) was added. The reaction mixture was boiled gently under reflux for 30 min, diluted to the cloud point with water, and chilled to 0°. The crystalline deposit was recrystallized from 95% ethanol to give **4** (0.70 g, 47%), m.p. 113.5–114°, undepressed on admixture with the 5-benzoyl-2-phenacyltetrazole (**4**) obtained above; the infrared spectra of the two samples were identical.

The original filtrate was combined with the recrystallization mother liquors, diluted with water, and extracted with dichloromethane. The extract was dried and evaporated, and the residue (0.64 g) was chromatographed on a Florisil column packed in benzene. Elution of a pale yellow band with dichloromethane – benzene (1:1) afforded colorless needles of 5-benzoyl-1-phenacyltetrazole (**3**) (0.20 g, 14%), m.p. 126–127° after recrystallization from 95% ethanol; λ_{max} 5.85, 5.97, 6.23, 6.30, 10.80 μ; λ_{max} 252 mμ (log ε 4.29), 272 mμ (sh, log ε 4.19); δ 6.33 (2H, s), 7.5–8.6 (10H, m).

Anal. Calcd. for $C_{16}H_{12}N_4O_2$: C, 65.75; H, 4.14; N, 19.17. Found: C, 65.69; H, 4.23; N, 19.39.

Elution with 5% methanol – dichloromethane gave a further quantity of tetrazole **4** (0.25 g; total yield 65%).

Reduction of 3 with Lithium Aluminium Hydride: Formation of Di(2-hydroxy-2-phenylethyl)amine (8)

A solution of the tetrazole **3** (0.151 g) in tetrahydrofuran (15 ml) was added dropwise to a suspension of lithium aluminium hydride (0.240 g) in boiling tetrahydrofuran (20 ml) under reflux. The solution was boiled under reflux for 18 h, and the excess of the hydride was decomposed by the cautious addition of 0.2 *N* hydrochloric acid. The mixture was added to concentrated aqueous sodium hydroxide and extracted with ether. The extract was dried and stripped of solvent to give crude **8** in quantitative yield. Recrystallization from benzene afforded plates (0.075 g, 54%), m.p. 115–117°; λ_{max} 2.77, 3.0, 6.68 μ; δ 2.75–3.0 (7H, m) [2.82 (4H, d, *J* 6 Hz) after treatment with D_2O], 4.75 (2H, m; t, *J* 6 Hz, after treatment with D_2O), 7.36 (10H, m).

Anal. Calcd. for $C_{16}H_{19}NO_2$: C, 74.68; H, 7.44; N, 5.44. Found: C, 74.77; H, 7.46; N, 5.54.

Hydrogenolysis of 8: Formation of Di(2-phenylethyl)amine (9)

The amine **8** (0.245 g) in acetic acid (10 ml) was added to a stirred suspension of 10% palladium on charcoal (0.065 g) in acetic acid (10 ml) containing a catalytic amount of dilute hydrochloric acid. The solution was maintained at 80° under hydrogen for 12 h. After cooling, the hydrogen uptake was 45 ml at 27° and 753 mm (96% of the volume of hydrogen required for complete hydrogenolysis). The catalyst was removed by filtration, and the filtrate was cautiously added to cold, concentrated aqueous sodium hydroxide. The mixture was extracted with several portions of chloroform. The extract was dried and stripped of solvent to give di(2-phenylethyl)-amine (**9**) (0.170 g, 79%); $\lambda_{max}(CHCl_3)$ 3.13, 6.26, 6.76 μ. This was shown by infrared spectral comparison to be identical with an authentic sample (*vide infra*).

The amine (**9**) was dissolved in ether containing a little chloroform, and hydrogen chloride was bubbled through the solution. The solid deposited was recrystallized from

For personal use only.

ethanol – ether to give di(2-phenylethyl)amine hydrochloride, m.p. 265–266° [lit. (14) m.p. 267–268°], undepressed on admixture with an authentic sample (*vide infra*); its infrared spectrum was identical with that of the authentic sample.

*Reduction of N-(2-Phenylethyl)phenylacetamide (**13**) with Lithium Aluminium Hydride: Formation of Di(2-phenylethyl)amine (**9**)*

Phenylacetyl chloride (15.4 ml) was added dropwise to a solution of 2-phenylethylamine (24.2 ml) in benzene (40 ml). After standing for 1 h the reaction mixture was partitioned between dichloromethane and water. The organic layer was dried and stripped of solvent to give *N*-(2-phenylethyl)phenylacetamide (**13**) (16.5 g), m.p. 93.5–94° after recrystallization from benzene – ligroin [lit. (15) m.p. 94–95°]; λ_{max} 3.02, 6.04, 6.66 μ; δ 2.72 (2H, t), 3.3–3.7 (4H, s superimposed on m), 5.5 (1H, br s), 7.0–7.5 (10H, m).

A solution of **13** (0.98 g) in 1,2-dimethoxyethane (20 ml) was added dropwise to a suspension of lithium aluminium hydride (0.30 g) in boiling 1,2-dimethoxyethane (25 ml), and the mixture was boiled under reflux for 50 h. The excess of hydride was decomposed by the successive addition of anhydrous magnesium sulfate, Celite, and aqueous 1,2-dimethoxyethane. The solution was filtered, dried, and stripped of solvent to give **9** as an oil. This was converted to its hydrochloride as described above; m.p. 266–267°; λ_{max} 3.70, 3.95, 4.15, 6.3 μ; δ (CF_3CO_3H) 3.05 (4H, t, *J* 7 Hz), 3.3–3.7 (4H, m), 7.1–7.5 (10H, m).

*Reduction of **4** with Lithium Aluminium Hydride: Formation of **14***

A solution of the tetrazole **4** (0.28 g) in anhydrous ether (250 ml) was slowly added to a suspension of lithium aluminium hydride (0.64 g) in ether (30 ml). The mixture was boiled under reflux for 4 h and then cooled to room temperature. Celite and anhydrous magnesium sulfate were added, followed by moist ether. The mixture was filtered, and the filtrate was dried and stripped of solvent to give an oily residue; crystallization at 0° from benzene – ligroin gave **14** (0.16 g, 57%), which was recrystallized from benzene; m.p. 108–109.5°; λ_{max} 2.85, 2.95, 6.23, 6.71 μ; δ 3.50 (1H, br s; absent after D_2O treatment), 3.78 (1H, br s; absent after D_2O treatment), 4.6–4.9 (2H, m), 5.3 (1H, m), 6.14 (1H, d, *J* 4 Hz; s after treatment with D_2O), 7.4 (10H, m).

Anal. Calcd. for $C_{16}H_{16}N_4O_2$: C, 64.85; H, 5.44; N, 18.91. Found: C, 65.04; H, 5.67; N, 18.79.

*Hydrogenolysis of **14**: Formation of 5-Benzyl-2-(2-phenylethyl)-tetrazole (**15**)*

A solution of the diol **14** (0.100 g) in acetic acid (3 ml) was added to a stirred suspension of 10% palladium on charcoal (0.015 g) in acetic acid (10 ml) under hydrogen. The mixture was stirred for 20 h at room temperature, and hydrogen (6.1 ml at 27° and 754 mm, ca. 0.8 molar equiv.) was absorbed; it was then heated to 80–90° and maintained at this temperature for a further 7 h. The total hydrogen consumption was 19.1 ml at 27° and 745 mm (ca. 2.25 molar equiv.). The mixture was filtered, and the solvent was removed from the filtrate by freeze-drying to yield **15** (0.090 g, 100%) as an oil, b.p. 150–152° (0.02 mm); $\lambda_{max}(CCl_4)$ 6.23, 6.73 μ; δ 3.30 (2H, t, *J* 8 Hz), 4.16 (2H, s), 4.82 (2H, t, *J* 8 Hz), 7.0–7.5 (10H, m).

Anal. Calcd. for $C_{16}H_{16}N_4$: C, 72.70; H, 6.10; N, 21.20. Found: C, 72.45; H, 6.38; N, 21.35.

The tetrazole **4** was also converted directly to **15** under analogous conditions.

*Reaction of **3** with Ammonium Acetate in Acetic Acid: Formation of **16***

A solution of **3** (0.145 g) in acetic acid (15 ml) containing ammonium acetate (0.200 g) was boiled under reflux for 19 h. The solvent was removed by freeze-drying, the residue was dissolved in chloroform, and the solution was washed with aqueous sodium bicarbonate. The organic layer was dried and stripped of solvent to give **16**, (0.105 g, 78%), m.p. 160.5–161° after recrystallization from ethanol; λ_{max} 6.24, 6.33, 6.84 μ; δ 7.5–7.8 (6H, m), 8–8.3 (2H, m), 8.9–9.1 (3H, s superimposed on m).

Anal. Calcd. for $C_{16}H_{11}N_5$: C, 70.31; H, 4.06; N, 25.63. Found: C, 70.47; H, 4.35; N, 25.58.

Similar treatment of **4** failed to give an analogous product; thin layer chromatography of the crude reaction product showed that it consisted mainly of starting material.

*Phenacylation of Tetrazole (**23**): Formation of 2-Phenacyltetrazole (**22**) and 1-Phenacyltetrazole (**24**)*

A solution of tetrazole (**23**) (0.35 g) and phenacyl bromide (1.00 g) in hot acetone (50 ml) was treated with potassium carbonate (0.70 g), and the mixture was boiled gently under reflux for 30 min. The reaction mixture was poured into water, and the oil which separated was extracted with dichloromethane. The extract was dried and stripped of solvent to yield an oil, which crystallized from benzene to give 1-phenacyltetrazole (**24**) (0.53 g, 56%) as needles, m.p. 100–104°. Several recrystallizations of the crude product from benzene afforded pure material, m.p. 110.5–111.5°; λ_{max} 5.86, 6.26, 6.34, 8.51, 9.09 μ; δ 6.01 (2H, s), 7.5–8.2 (5H, m), 8.94 (1H, s).

Anal. Calcd. for $C_9H_8N_4O$: C, 57.44; H, 4.29; N, 29.77. Found: C, 57.56; H, 4.33; N, 29.94.

The semi-solid residue obtained upon evaporation of the mother liquors, after several recrystallizations from aqueous methanol with treatment with Norit, afforded faintly yellow needles of 2-phenacyltetrazole (**22**) (0.050 g, 5%), m.p. 104–104.5°, undepressed on admixture with material obtained from the reaction of 2-diazoacetophenone (**1**) and of 5-benzoyl-2-phenacyltetrazole (**4**) with potassium *t*-butoxide in *t*-butyl alcohol; the infrared spectra of these samples were identical.

*Cleavage of **4** with Potassium t-Butoxide in t-Butyl Alcohol: Formation of **22***

A solution of 5-benzoyl-2-phenacyltetrazole (**4**) (0.69 g) in hot *t*-butyl alcohol (5 ml) was poured into a solution of potassium *t*-butoxide prepared from potassium (0.29 g) and *t*-butyl alcohol (25 ml). The reaction mixture, which immediately became red, was stirred at room temperature for 84 h, during which time the intensity of the red color diminished. The resulting orange solution was added to an excess of 10% aqueous sodium bicarbonate, and the mixture was extracted with dichloromethane. The crude product obtained by drying and stripping the extract of solvent was chromatographed on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

a Florisil column (100 g, packed in benzene). 2-Phenacyltetrazole (**22**) (0.29 g, 70% based on unrecovered starting material) was eluted with dichloromethane – benzene (1:1) and after recrystallization from benzene – hexane had m.p. 104–104.5°; λ_{max} 5.85, 6.26, 6.32, 8.37, 8.42, 8.92 μ; δ 6.18 (2H, s), 7.5–8.2 (5H, m), 8.69 (1H, s).

Anal. Calcd. for $C_9H_8N_4O$: C, 57.44; H, 4.29; N, 29.77. Found: C, 57.76; H, 4.41; N, 29.87.

Starting material (**4**) (0.035 g) was isolated on elution of the column with 5% methanol – dichloromethane. Benzoic acid (0.091 g) was isolated from the sodium bicarbonate extract.

*Cleavage of **3** with Potassium t-Butoxide in t-Butyl Alcohol: Formation of **24***

5-Benzoyl-1-phenacyltetrazole (**3**) (0.69 g) was treated with potassium *t*-butoxide as in the case of **4** above, except that the reaction period was reduced to 66 h. Chromatography gave 1-phenacyltetrazole (**24**) (120 mg, 28%), which, after recrystallization from benzene with treatment with Norit, had m.p. 111–111.5°, undepressed on admixture with an authentic sample; its infrared spectrum was identical with that of the authentic sample.

*Reaction of 5-Benzoyl-2-Phenacyltetrazole (**4**) with Potassium t-Butoxide in Ether*

(a) In Commercial "Anhydrous" Ether

The tetrazole **4** (0.73 g) was dissolved in commercial "anhydrous" ether (350 ml) by heating. The solution was cooled to room temperature and poured into a stirred slurry of potassium *t*-butoxide (1.25 g) in ether (25 ml). The solution became red momentarily and then turned pale orange–yellow. It was stirred at room temperature for 10 min and then filtered, giving a whitish–yellow solid whose color deepened on exposure to air. Aqueous ammonium chloride was added to the filtrate, and the organic layer was separated, dried, and evaporated to give 2-phenacyltetrazole (**22**) (0.030 g), m.p. and mixed m.p. 103–104°. Its infrared spectrum was identical with that of authentic material. The whitish–yellow solid from above was added to the aqueous ammonium chloride solution and the mixture was extracted with ether. The extract was dried and stripped of solvent to give additional 2-phenacyltetrazole (0.40 g), identified as before. The total yield of **22** was 0.43 g (91%). Benzoic acid (0.30 g, 99%) was isolated from the aqueous layer after acidification.

(b) In Anhydrous Ether

Commercial "anhydrous" ether was boiled under reflux over lithium aluminium hydride and distilled therefrom immediately prior to use. A solution of **4** (1.00 g) in anhydrous ether (400 ml) was rapidly added to a suspension of potassium *t*-butoxide (1.54 g) in anhydrous ether (30 ml) whereupon the mixture turned red. This color persisted while the reaction mixture was stirred at room temperature for 10 min. The mixture was then added to a solution of deuterium chloride in acetic acid-*d*, prepared by mixture of acetyl chloride (12 ml) and deuterium oxide (4 ml). The ethereal solution became colorless (with concomitant salt precipitation) and was extracted with aqueous sodium bicarbonate. The organic phase was dried and stripped of solvent to give a residue which was recrystallized from ethanol. The infrared, n.m.r., and mass spectra of this product (0.59 g) indicated it to be 5-benzoyl-2-phenacyltetrazole partially deuterated at the methylene group. Its n.m.r. spectrum showed a relative intensity of the methylene to phenyl proton signals of ca. 1.5:10. Its mass spectrum showed a ratio of 1:1 in the abundances of the *m/e* 293 and 292 ions, as compared with a ratio of 1:5 in the spectrum of non-deuterated **4**.

A control experiment showed that in the absence of base no deuterium was incorporated into **4**.

(c) In Anhydrous Ether and Deuterium Oxide

The tetrazole **4** (0.61 g) was dissolved in anhydrous ether (rigorously dried as in (*b*), 300 ml) and deuterium oxide (0.7 ml) was well stirred into the solution. This mixture was then added to potassium *t*-butoxide (0.90 g) in ether (25 ml). A red color developed momentarily, rapidly turning to a pale yellow. The solution was stirred for 10 min and then added to aqueous ammonium chloride, whereupon the color was discharged. The ethereal layer was separated, and the aqueous layer was extracted with dichloromethane. The combined organic layers were dried and stripped of the solvent; the residue was crystallized from benzene – hexane affording 2-phenacyltetrazole-5-*d* (**27**) (0.25 g, 64%), m.p. 101.5–103°; δ 6.18 (2H, s), 7.5–8.2 (5H, m), 8.69 (0.3H, s). Its infrared spectrum differed in minor respects from that of 2-phenacyltetrazole (**22**). Its mass spectrum showed a ratio of 2:1 in the abundances of the *m/e* 189 and 188 ions, as compared with a ratio of 1:7 in the spectrum of **22**.

*2-(1,1-Dimethylphenacyl)tetrazole (**28**)*

A solution of **4** (0.73 g) in commercial "anhydrous" ether (not further dried, 350 ml), was added to a suspension of potassium *t*-butoxide (1.22 g) in ether (25 ml), and the mixture was stirred for 10 min. The precipitate was collected by filtration and rapidly transferred to a flask containing a solution of methyl iodide (10 ml) in dimethylformamide (50 ml) under nitrogen. The contents of the flask were stirred for 54 h under nitrogen at room temperature. The solution was added to aqueous ammonium chloride, and the mixture was extracted with dichloromethane. The extract was dried, and stripped of solvent to give an oily crystalline product which possessed the characteristic odor of methyl benzoate. Recrystallization from cyclohexane and sublimation gave **28** (0.23 g, 53%), m.p. 81.5–82°; λ_{max} 5.96, 6.28, 7.23, 7.33 μ; δ 2.11 (6H, s), 7.2–7.6 (5H, m), 8.56 (1H, s).

Anal. Calcd. for $C_{11}H_{12}N_4O$: C, 61.09; H, 5.59; N, 25.91. Found: C, 60.92; H, 5.68; N, 25.73.

Long-range spin–spin coupling constants between ring protons and aldehydic protons in some *para*-substituted benzaldehydes

S. S. DANYLUK, C. L. BELL[1,2] AND T. SCHAEFER[1,3]

Division of Biological and Medical Research, Argonne National Laboratory, Argonne, Illinois

Received June 16, 1969

The long-range proton–proton coupling constants between the ring protons and the aldehydic proton are reported for a series of *para*-substituted benzaldehyde derivatives. It was found that $J_o^{H,CHO} < 0$ and $J_m^{H,CHO} > 0$. Furthermore, $J_o^{H,CHO}$ increases in magnitude as the electron donating power of the substituent increases. A similar trend is observed for $J_m^{H,CHO}$ but the ratio of the increase to the magnitude of $J_m^{H,CHO}$ is much less than for $J_o^{H,CHO}$. A good correlation is obtained between $J_o^{H,CHO}$ and the substituent parameters of Swain and Lupton.

The coupling constant data are discussed in terms of σ and π coupling mechanisms and it is concluded that σ electron mechanisms are dominant for both $J_o^{H,CHO}$ and $J_m^{H,CHO}$.

Introduction

A number of nuclear magnetic resonance (n.m.r.) parameters correlate with Hammett sigma constants[4] (1). ^{19}F, ^{13}C, and ^{1}H chemical shifts are linearly related to σ_p, the sigma constant of a substituent in the *para* position of a benzene derivative. The linear relationships have been theoretically related to the modification of the π system by the substituent. The substituent contribution to the coupling between fluorine nuclei in *meta* difluorobenzene derivatives also depends on σ_p (2,3), suggesting the importance of π electron contributions to J_m^{FF}. The directly bonded C^{13}—H coupling constants of the methyl group in *para*-substituted toluenes are also related to σ_p of the substituent (4).

No strong correlation of couplings between ring protons and sigma constants has been reported for benzene derivatives. The available evidence indicates that $J_{o,m,p}^{HH}$ are affected via the σ electron system by a substituent and therefore such a correlation does not appear likely (5).

As part of a study of coupling mechanisms between aldehydic protons and ring protons in substituted benzaldehydes we have measured the long-range spin–spin coupling constants between the CHO proton and ring protons in a number of *para*-substituted benzaldehydes. In this communication we report a correlation of $J_o^{H,CHO}$ with the substituent constants of Swain and Lupton (28).

Experimental

The benzaldehyde derivatives were of commercial origin. Whenever solubility allowed, dilute solutions of these compounds were prepared in carbon disulfide together with about 10% tetramethylsilane (TMS) as internal reference. Other solvents were benzene-d_6 and acetone. Solutions were carefully degassed by the freeze-pump–thaw technique.

Proton magnetic resonance (p.m.r.) spectra were recorded on a DA60I spectrometer in the frequency sweep mode. Double resonance experiments were carried out in the usual manner (6). Calibration of peak positions involved the reading of sweep and manual oscillator frequencies together with an interpolation between pen positions on the recorder chart. Care was taken to achieve conditions whereby line broadening by saturation and radiation damping was minimized. In this way splittings of as little as 0.10 Hz were easily observable in the dilute, degassed solutions.

Solvent effects on the long-range couplings were evidently zero within experimental error. For example, solutions of *p*-methoxybenzaldehyde in carbon disulfide and in acetone displayed identical long-range couplings.

Results

Spectral Analysis

In Table I the measured long-range coupling constants are given for a series of benzaldehyde derivatives. Chemical shifts of the aldehyde protons are not included because earlier workers have discussed these at length (7) and because of varying solvent conditions in the present work. For most of the compounds the ring proton spectra were not analyzed completely. The magnitudes of the long-range couplings between the aldehyde proton and the ring protons could be

reliably obtained both from the aldehydic p.m.r. spectrum and from the small splittings in the ring proton spectra. Solvent effects were used in some cases to induce sufficiently large shifts (> 0.25 p.p.m.) between the ring protons to ensure the reliability of this procedure.

As a check of the latter we consider an extreme case where the chemical shift between the ring protons is 12 Hz, $J_o^{H,CHO} = -0.17$ Hz and $J_m^{H,CHO} = 0.43$ Hz. Then direct calculation shows that for an A_2B_2X system there arises an error of 0.02 Hz in $J_o^{H,CHO}$ and $J_m^{H,CHO}$ when these are extracted from the X spectrum by first order rules. None of the coupling constants in Table I were obtained under such extreme conditions.

Experiments in which the aldehydic proton was decoupled identified the splittings in the ring proton spectra caused by the aldehyde proton spin states. Other side-chain protons could also be decoupled from the ring protons.

As an example of the observed proton spectra, Fig. 1 illustrates the aldehydic p.m.r. spectra of *p*-isopropylbenzaldehyde and of *p*-cyanobenzaldehyde. The triplet, of triplets resulting from coupling to the two sets of two ring protons is clearly observable in *p*-isopropylbenzaldehyde. From the linewidths of the three peaks in the aldehyde spectrum of *p*-cyanobenzaldehyde and from its ring proton spectrum it is certain that $|J_o^{H,CHO}| < 0.06$ Hz.

Double Resonance Experiments

Sign of $J_o^{H,CHO}$

In Fig. 2(a) the aldehydic proton single resonance spectrum of *p*-N,N-dimethylaminobenzaldehyde is displayed. For this compound $|J_o^{H,CHO}| = \frac{1}{2}|J_m^{H,CHO}|$. Consequently, a spectrum of seven peaks is observed because two pairs of peaks (3,4 and 6,8) overlap. The net spin states of the *ortho* protons (H_A) are given in Fig. 2(a) with the convention that a positive sign beneath a low-field peak corresponds to positive coupling with the labelled protons. In Fig. 2(b) and (c), weak irradiation of *meta* ring proton (H_B) peaks corresponding to either *net* negative or "zero" spin states of the H_A protons (high field transitions in the H_B spectrum) results in a perturbation of a number of peaks in the aldehyde proton resonance. In (b) the weak irradiating field is of smaller amplitude than in (c). The important point is that 9 at high field is not perturbed under these conditions. Consequently, $J_o^{H,CHO}/J_o^{HH} < 0$. Because $J_o^{HH} > 0$, (8), it follows that $J_o^{H,CHO} < 0$. In Fig. 2(d), low-field peaks in the H_B region corresponding to net negative or "zero" spin states of the H_A protons are being irradiated by a second r.f. (radio frequency) field. Peak 1 is unaffected, confirming the above result. The negative sign of $J_o^{H,CHO}$ has previously been inferred from a computer analysis of the tightly coupled ring proton spectra in 2,4-dimethoxybenzaldehyde, 3-nitro-4-hydroxybenzaldehyde, and 2-chloro-4-*N*,*N*-dimethylaminobenzaldehyde (9).

That $J_m^{H,CHO} > 0$ has been established previously (10) by multiple resonance techniques. In benzaldehyde itself $J_o^{H,CHO} < 0$ and $J_m^{H,CHO} > 0$ (11).

Discussion

Conformation of the Aldehyde Group

The p.m.r. experiments show that the free energy of activation for rotation of the aldehyde

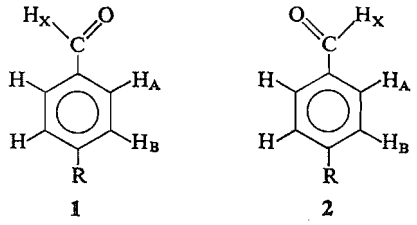
group in benzaldehyde is 7.9 kcal/mole at 150 °K but rises to 9.2 kcal/mole in *p*-methoxybenzaldehyde at 172 °K (12). Electron spin resonance (e.s.r.) data on the negative ion radical of *p*-nitrobenzaldehyde place an upper limit of about 10^6 s^{-1} on the rotational frequency of the aldehyde group at room temperature (13). The free energies of activation $\Delta F^{\ddagger}$, at temperature T, are derived from transition state theory via a relation of the type

$$[1] \qquad 1/\tau = h/kT \exp \Delta F^{\ddagger}/RT$$

where h, k, and R are the Planck, Boltzmann, and molar gas constants, respectively. τ is the mean time spent before rotation by the aldehyde group in a site coplanar with the aromatic ring. The n.m.r. and e.s.r. data agree in the conclusion that, even at room temperature, τ is some orders of magnitude larger than the time taken for a reorientation from one planar site to the other equivalent planar site. That is, the time spent by the aldehyde proton in planar conformations, **1** and **2**, is much larger than the time spent in nonplanar conformations. The planar conformation in an unhindered benzaldehyde arises from



the strong conjugation of the carbonyl group with the aromatic π electrons. This conclusion is supported by extensive molecular orbital calculations which also show that nonbonded interactions between the carbonyl group and neighbouring atoms in benzaldehyde affect the barrier to rotation by only about 1 kcal/mole (14).

A planar conformation of sterically unhindered

benzaldehydes was assumed in a previous discussion of $J_m^{H,CHO}$ (15).

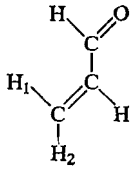
Sign and Magnitude of $J_o^{H,CHO}$

From the discussion above it follows that in the *para*-substituted benzaldehydes of Table I,

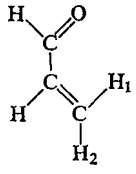
$$[2] \quad J_o^{H,CHO} = (J_1^{H_A,CHO} + J_2^{H_A,CHO})/2$$

It is not known whether $J_1^{H_A,CHO} > J_2^{H_A,CHO}$. The inequality is of interest when attempting to establish whether $J_o^{H,CHO}$ is a result of π or of σ contributions. If a σ–π mechanism is operative then a negative coupling is generally expected for out-of-plane arrangements of the two C—H bonds and a zero coupling for a coplanar arrangement (16–18). On the other hand, $J_4^{\sigma} > +1$ Hz when the H—C—C—C—H fragment takes on a planar zigzag arrangement (19). Nevertheless, in other conformations J_4^{σ} may evidently be small and negative, i.e., near -0.20 Hz (20,21).

The closest analogy to the present molecules is acrolein where the *S-trans* form, **3**, is more stable by 2 kcal/mole (22), than the *S-cis* form, **4**. Near room temperature the ratio of *S-trans* to *S-cis* molecules is therefore about 25 to 1.



3



4

In **3**, $J^{H_2,CHO} = -0.3$ Hz while $J^{H_1,CHO} = -0.15$ Hz (23). The latter is analogous to $J^{H_A,CHO}$ in **2** but unfortunately $J^{H_1,CHO}$ in **4**, analogous to $J^{H_A,CHO}$ in **1**, is unknown.

It is known, however, that when H_2 in **3** is replaced by CH_3 $J^{CH_3,CHO} = 0.0$ Hz (24). The "CH_3 replacement" technique (25) therefore suggests that in acrolein the small negative four-bond coupling is dominated by σ electron contributions. Similarly, in a series of acetophenone derivatives no coupling from the acetyl to the ring protons is observed (26,26*a*) again indicating a σ electron mechanism[5] for $J_o^{H,CHO}$.

This partial evidence for a σ electron dominated

[5]Steric hindrance by *ortho* substituents will twist the aldehyde group out of a planar conformation and lead to a measurable π contribution to $J_p^{H,CHO}$ (27).

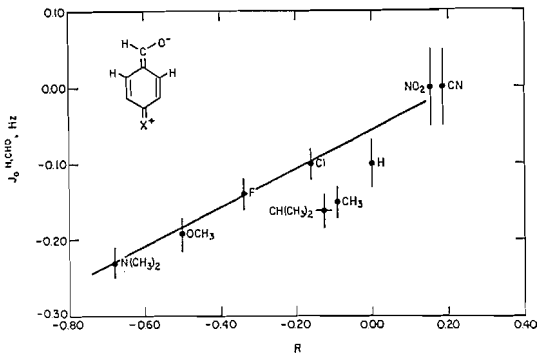


FIG. 3. A plot of $J_o^{H,CHO}$ in Hz versus the resonance substituent constant, R, of the substituent, X, in some *para*-X-benzaldehydes.

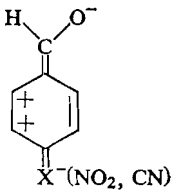
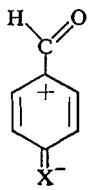
$J_o^{H,CHO}$ in planar benzaldehyde derivatives can be augmented in the following way. In Fig. 3 there is shown a plot of $J_o^{H,CHO}$ versus the resonance constant, R, of the *para*-substitutent (28). Note that $J_o^{H,CHO}$ is too small to measure for the cyano and nitro substituents and has been taken as zero. However, the linewidths of the aldehyde p.m.r. peaks in these instances are consistent with $J_o^{H,CHO}$ values falling exactly on the line in Fig. 3. The correlation between R, which is currently the best available measure of conjugation of a substituent with the aromatic ring, and $J_o^{H,CHO}$ is quite reasonable.

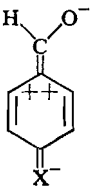
A plausible resonance structure illustrated in Fig. 3 can be drawn only for *para*-substituents which donate electrons by resonance, i.e., not for the nitro or cyano groups. For the latter, resonance structures **5** and **7** are intuitively expected to be less important than **6**, but **6** leads to a zero mobile bond order between the aldehyde carbon and the aromatic carbon atoms.



5



6



7

At first sight it is tempting to ascribe the observed correlation between $J_o^{H,CHO}$ and R to an increase in a π electron contribution to $J_o^{H,CHO}$. Molecular orbital calculations (29) do indeed substantiate the qualitative valence bond description above. The mobile bond order of the bond in question is 0.476, 0.400, 0.393 for X = NH_2, H,

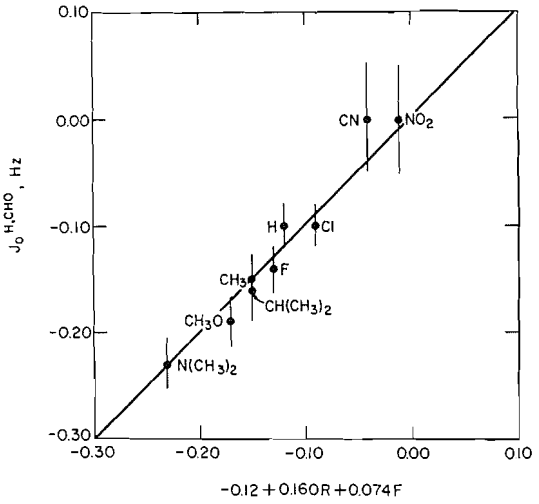


FIG. 4. A plot of $J_o^{H,CHO}$ in Hz versus the quantity $-0.12 + 0.160R + 0.074F$, as discussed in the text. The straight line is of unit slope.

NO_2, respectively. Yet a correlation of a coupling constant with a mobile bond order of an intervening bond does not prove the existence of a π contribution to the coupling (5). A good example is the vicinal proton coupling constant in a series of condensed aromatic molecules (30). In the present example it may well be that an increased mobile bond order shortens the bond, leads to a stronger correlation of the sigma electrons in that bond and therefore to a larger magnitude of the coupling constant.

Support for the latter argument comes from the negative deviation in Fig. 3 of the points for X = CH_3, $CH(CH_3)_2$. These are the only substituents in Fig. 3 which have negative field constants F, as well as negative R constants (28). Hence, both effects cause increased electron density in the distant bond and therefore, as it were, and excess magnitude of $J_o^{H,CHO}$ (the other substituents are all electron withdrawing by inductive effects). The negative inductive effect of the alkyl groups would lead, at the level of sophistication of the model, to an increase in σ electron density in the ring and hence would not increase $|J_o^{H,CHO}|$ if the latter were dominated by a π electron mechanism.[6]

On this basis a correlation of $J_o^{H,CHO}$ with the R and F substituent constants of the form $J = a + b\,R + c\,F$, where $b,c > 0$, should be found. This is indeed the case. Equation 3 reproduces the $J_o^{H,CHO}$ values in Table I with a mean deviation of just over 0.01 Hz, well within

$$[3]\quad J_o^{H,CHO} = -0.12 + 0.160R + 0.074F$$

experimental error. Figure 4 shows a graphical plot of the correlation. The straight line has the required unit slope (note that the coupling values for the nitro and cyano substituents *could* be placed precisely on the straight line).

Thus, although $J_o^{H,CHO} < 0$, a consideration of all the above evidence shows that a σ electron mechanism for $J_o^{H,CHO}$ is more favored than a π electron mechanism.[7]

It might be argued that the above discussion in terms of σ and π contributions is not really satisfactory in that recent molecular orbital formulations (32) do not make a rigid distinction between σ and π electrons. Nevertheless, the present discussion is in the spirit of most experimental papers and with some theoretical work (33) based on the valence bond method.

Magnitude of $J_m^{H,CHO}$

The "CH_3 replacement" technique indicates a dominant σ electron mechanism (26) for this coupling, as does the fact that $J_m^{H_B,CHO}$ is much larger in derivatives of **1** than of **2** (34). Stereospecificity of this kind in $J_m^{H,CHO}$ is difficult to account for by a π mechanism; although there may be a small contribution to $J_m^{H,CHO}$ from the latter.

The maximum magnitude of the increases in $J_m^{H,CHO}$ caused by the substituents in Table I is only 0.10 Hz and the cyano and nitro substituents cause the smallest increase, if any. Although a fair correlation with F and R constants may again be found (eq. [4]) it is preferable to simply note

$$[4]\quad J_m^{H,CHO} = 0.41 - 0.122R + 0.013F$$

that the increase in $J_m^{H,CHO}$ is, in general, largest for those substituents which increase most the electron density in the ring. As a final point, it may be of interest to mention a fairly good correlation of $J_m^{H,CHO}$ in the present compounds with $J_m^{H_2,H_4}$ in the corresponding phenyl compounds (35–37), i.e., the decrease of $J_m^{H_2,H_4}$ in

[6]A referee argues that the observed correlation between $J_o^{H,CHO}$ and R should be accepted as evidence for the π mechanism and suggests that the small deviations of the alkyl groups in Fig. 3 are insignificant. We feel, however, that these deviations are real and, together with the other evidence, that they indicate a σ mechanism.

[7]The apparent, small negative Q value for the aldehyde proton in certain paramagnetic γ-formyl nickel (II) aminotroponeimine derivatives (31) actually suggests a small positive π electron contribution to $J_o^{H,CHO}$.

the 1-X-benzenes roughly parallels the increase of $J_m^{H,CHO}$ in the *p*-X-benzaldehydes. At present there is no quantitative theory for the substituent effect on these coupling constants.

Kinetics of sulfonation of 4-hydroxyazobenzene[1]

W. M. J. STRACHAN AND E. BUNCEL
Department of Chemistry, Queen's University, Kingston, Ontario

Received June 18, 1969

Spectral changes exhibited by 4-hydroxyazobenzene in the 90–100% H_2SO_4 region are shown to be the result of a sulfonation process, superimposed (above 98% H_2SO_4) on a second equilibrium protonation. The reaction product is 4-hydroxyazobenzene-4′-sulfonic acid. The rate of this sulfonation reaction increases by a factor of 500 over 91.7–100.0% H_2SO_4. The increase in rate is more gradual in acid media in which diprotonation of reactant is effective.

In 100% H_2SO_4 and above, a second, much slower, rate process is discerned from the spectral changes in this system and is probably the result of a further sulfonation of 4-hydroxyazobenzene-4′-sulfonic acid. Kinetic data for this reaction are reported for 99.99–100.76% H_2SO_4.

The results are in agreement with previous qualitative reports on the formation of sulfonation products from 4-hydroxyazobenzene or from azoxybenzene, its precursor in the Wallach rearrangement. The mechanism of the consecutive sulfonation reactions is discussed.

Canadian Journal of Chemistry, 47, 4011 (1969)

In early studies of the Wallach rearrangement (1) of azoxybenzene in the 100% H_2SO_4 region, in addition to the formation of 4-hydroxyazobenzene, sulfonic acid derivatives were also noted to be present (2,3). In particular, Wilsing in 1882 (2) obtained mono-, di-, tri-, and even tetrasulfonic acid derivatives of 4-hydroxyazobenzene upon treatment of azoxybenzene with fuming sulfuric acid of unspecified concentration at temperatures in excess of 100°. Of these only the monosulfonic acid was fully identified (3) as 4-hydroxyazobenzene-4′-sulfonic acid, though it was shown (2) that the second and third sulfonic acid groups entered the ring containing the hydroxyl substituent. More recent work, by Gore and Hughes (4) and by Newbold and Akhtar (5), has confirmed the formation of sulfonic acid derivatives in the rearrangement of azoxybenzene and of substituted azoxybenzenes even under less vigorous conditions.

In order to evaluate quantitatively the importance of the sulfonation process in Wallach rearrangement reactions in the 100% H_2SO_4 region, we embarked on a systematic study with 4-hydroxyazobenzene under controlled conditions of temperature and acid concentration. In our previous kinetic study with azoxybenzene in acids up to 96% H_2SO_4, it was noted that in the upper acid region 4-hydroxyazobenzene undergoes a further, relatively slow, reaction whose nature was not identified (6).

[1]Part VII in series on the Wallach rearrangement.

Results

4-Hydroxyazobenzene in Acids Below 100% H_2SO_4

Examination of 4-hydroxyazobenzene in the present work was carried out spectrally (substrate concentration 10^{-5}–10^{-4} *M*), for 90–100% H_2SO_4, at 25°. The spectral changes in the lower acid region are illustrated by the following experiment using 94.73% H_2SO_4 (Fig. 1). The initial

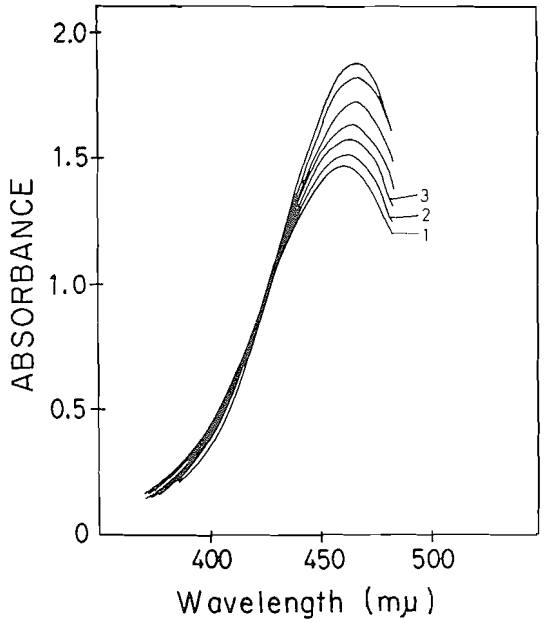

FIG. 1. 4-Hydroxyazobenzene in 94.73% H_2SO_4, 3.92×10^{-5} *M* substrate (25°, 1.00 cm cuvette). Scans noted are 1–0.1 h, 2–4 h, 3–9.5 h, last scan 120 h.

For personal use only.

spectrum of 4-hydroxyazobenzene in this medium shows absorption in the visible region at 460 mμ ($\varepsilon = 3.78 \times 10^4$), which can be ascribed to the azo-protonated substrate (7). This absorption slowly grows in intensity and simultaneously shifts to slightly longer wavelengths. After 10 h the absorbance has increased by about 8% with the peak shifted to 462 mμ, while after 50 h the increase is about 25% (λ_{max} 465 mμ), and beyond 120 h ($\varepsilon_{465} = 4.78 \times 10^4$) there is no further spectral change. The pseudo-first order rate constant for the growth of the absorption, calculated at 465 mμ by the log $(A_\infty - A_t)$ versus t plot where A_∞ is the final absorbance, is 1.16×10^{-5} s^{-1} ($T_{\frac{1}{2}} = 16.6$ h). Using the Guggenheim method and absorbance changes at 460 mμ, a rate constant of 1.18×10^{-5} s^{-1} is obtained. In an analogous manner, examination of 4-hydroxyazobenzene was extended to about 100% H_2SO_4. Over this range of acid concentration there is a gradation in the spectral changes, as illustrated by Figs. 1–3 and discussed below.

It is seen from Figs. 1–3 that the initial spectrum of 4-hydroxyazobenzene shifts to shorter wavelengths as the acid concentration is increased; this has been ascribed to a second equilibrium protonation of the substrate (7). The rate process

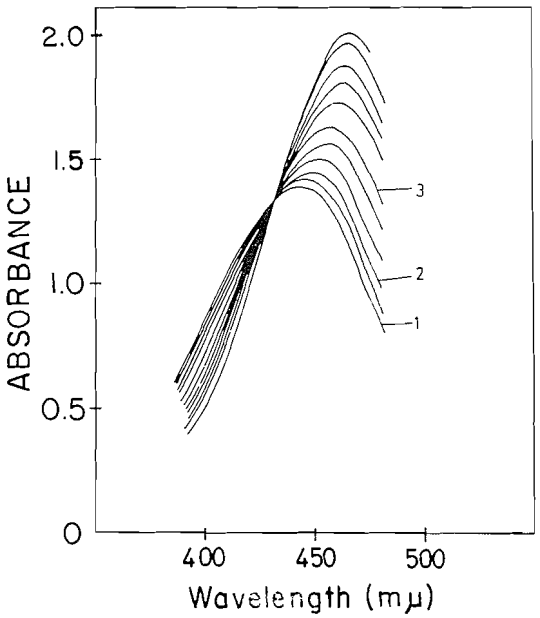

FIG. 2. 4-Hydroxyazobenzene in 99.72% H_2SO_4, 4.01×10^{-5} M substrate (25°, 1.00 cm cuvette). Scans noted are 1–1.5 min, 2–4 min, 3–12 min, last scan 60 min.

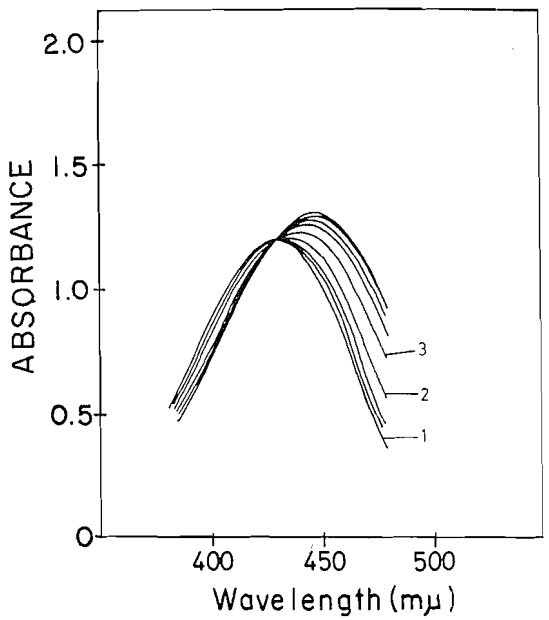

FIG. 3. 4-Hydroxyazobenzene in 99.96% H_2SO_4, 3.88×10^{-5} M substrate (25°, 1.00 cm cuvette). Scans noted are 1–1.5 min, 2–5 min, 3–9 min, last scan 55 min.

corresponding to the growth in absorbance, for which rate constants were obtained as previously (Table I), is characterized in each case by a sharp isosbestic point. The observed reaction is identified as sulfonation, to give 4-hydroxyazobenzene-4′-sulfonic acid; the shifts in λ_{max} of the product absorption with increasing acid concentration are ascribed to a second equilibrium protonation of this sulfonic acid (7).

4-Hydroxyazobenzene-4′-sulfonic acid has spectral absorption in concentrated sulfuric acid solutions which agrees quantitatively with the final "infinity" spectra of 4-hydroxyazobenzene following reaction in 94.5–98.9% H_2SO_4 (see Experimental). Near the 100% H_2SO_4 region, spectral comparison is made more difficult as a result of extensive diprotonation, with accompanying changes in absorption (7), and also due to the advent of a second sulfonation (*vide infra*).

The total rate data for this sulfonation process are given in Table I. The kinetic methods are described in detail in the Experimental section.

4-Hydroxyazobenzene and 4-Hydroxyazobenzene-4′-sulfonic Acid in the 100% H_2SO_4 Region

The spectral behaviour of 4-hydroxyazobenzene takes on distinctly different character close

*Reaction followed by periodic scanning. Rate constant calculated at wavelength indicated by Guggenheim method.

†Rate constant calculated using $A_\infty - A_t$ plot. Data obtained either as indicated under footnote * or as in footnote ‡. (When a rate constant was recalculated by the $A_\infty - A_t$ plot but using the raw data in a previous run, then the acid concentration is not re-stated in the first column.)

‡Reaction followed at constant wavelength shown. Rate constant calculated by Guggenheim method.

to 100% H_2SO_4 from that described hitherto. Figure 4 shows an illustrative run for 100.01% H_2SO_4. Two rate processes are reflected in Fig. 4, for which the corresponding spectra are drawn in dashed lines and in full lines for clarity. The two sets of curves correspond to different time scales, the former being taken minutes apart and representing an initial fast reaction and the latter taken hours apart and representing a subsequent slow reaction. The two processes were first observed on a scan of absorbance (460 mμ) versus time, as an initial rapid increase ($T_{\frac{1}{2}}$ = 4.5 min by the Guggenheim method) followed by a very slow increase ($T_{\frac{1}{2}}$ = 27.5 h) in absorbance. The fast reaction is identified as the sulfonation process discussed in the preceding section.

A further characteristic which differentiates the 4-hydroxyazobenzene runs near the 100% H_2SO_4 region is isosbestic point behaviour. Figure 4 shows that the initial dashed spectral curves do not pass through an isosbestic point but are nearly tangential on the short wavelength side of λ_{max} (426 mμ).[2] The isosbestic point that is observed (422 mμ) is common to the later full curves. It is shown below that the rate process corresponding to this isosbestic point is a second

[2]The absence of an isosbestic point with respect to the first sulfonation process represented by the dashed curves in Fig. 4 is explained by the very close wavelength maxima of the absorptions due to the largely diprotonated 4-hydroxyazobenzene reactant ($\lambda^{BH_2^{2+}}$ 426 mμ) and the partly diprotonated 4-hydroxyazobenzene-4′-sulfonic acid product ($\lambda^{BH_2^{2+}}$ 420 mμ) in 100.01% H_2SO_4.

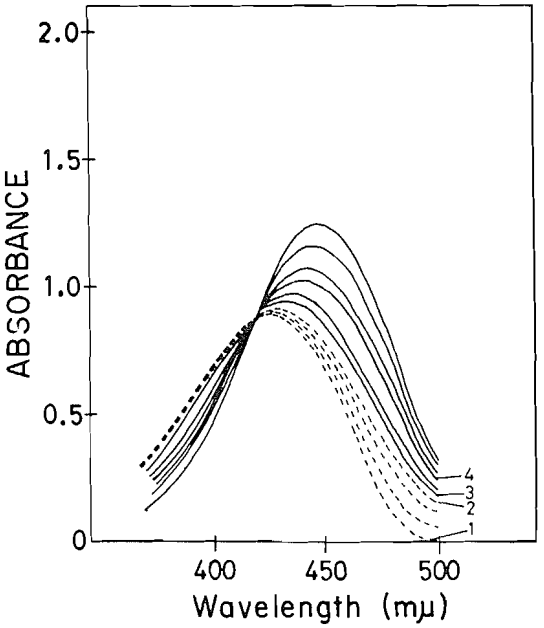

FIG. 4. 4-Hydroxyazobenzene (2.84×10^{-5} *M*) in 100.01% H_2SO_4 (25°, 1.00 cm cuvette). Scans noted are 1–1 min, 2–30 min, 3–4 h, 4–19 h, last scan 141 h.

sulfonation of 4-hydroxyazobenzene-4′-sulfonic acid. The positions of the maxima in Fig. 4 first need commenting on. The initial λ_{max} (426 mμ) corresponds to almost complete diprotonation in this medium of the reactant (pK_a^2 for 4-hydroxyazobenzene = −10.2 (7)). The first sulfonation is about complete with curve 2 (30 min, λ_{max} 429 mμ), which corresponds to about 50% diprotonation of the formed 4-hydroxyazobenzene-4′-sulfonic acid (pK_a^2 = −11.1). The final product spectrum (λ_{max} 449 mμ) is ascribed to a disulfonic acid derivative present essentially in monoprotonated form in this medium (see Experimental for an estimate of pK_a^2).

The reactivity of 4-hydroxyazobenzene-4′-sulfonic acid in the 100% H_2SO_4 region was confirmed by means of a kinetic run carried out with this substrate in 100.07% H_2SO_4, shown in Fig. 6. The spectral changes in Fig. 6 are typical of a rate process (isosbestic point at 422 mμ, $T_{\frac{1}{2}}$ = 15.0 h by the Guggenheim method). A kinetic run carried out with 4-hydroxyazobenzene in the same medium is shown in Fig. 5. The full curves in this 4-hydroxyazobenzene run show all the features (isosbestic point at 422 mμ, $T_{\frac{1}{2}}$ = 15.0 h) which characterized the reaction of 4-hydroxyazobenzene-4′-sulfonic acid (Fig. 6). However in addition Fig. 5 shows that 4-hydroxyazobenzene first undergoes a rapid rate process (dashed curves, $T_{\frac{1}{2}}$ = 4.5 min), which can clearly be ascribed to the first sulfonation reaction.

Rate data for the second reaction, as observed with 4-hydroxyazobenzene reactant, were obtained analogously over the region 99.99–100.76% H_2SO_4 and are given in Table II. Rate data for the first sulfonation process, which were obtained for part of this acid range from the initial fast increase in absorbance at 460/463 mμ, are included in Table I.

The product of the second process is tentatively identified as 4-hydroxyazobenzene-3,4′-disulfonic acid, though conclusive evidence is not available. The identification is made on the basis of the spectral absorptions in 100.79% H_2SO_4, 96% H_2SO_4, 0.2 *N* H_2SO_4, and 0.2 *N* KOH, in which media this product is expected to be present in several different ionization states (see Experimental). Also, this is the expected product on the basis of the directive effects of the substituents in 4-hydroxyazobenzene-4′-sulfonic acid toward electrophilic substitution (*vide infra*).

Independent evidence for the sulfonation pro-

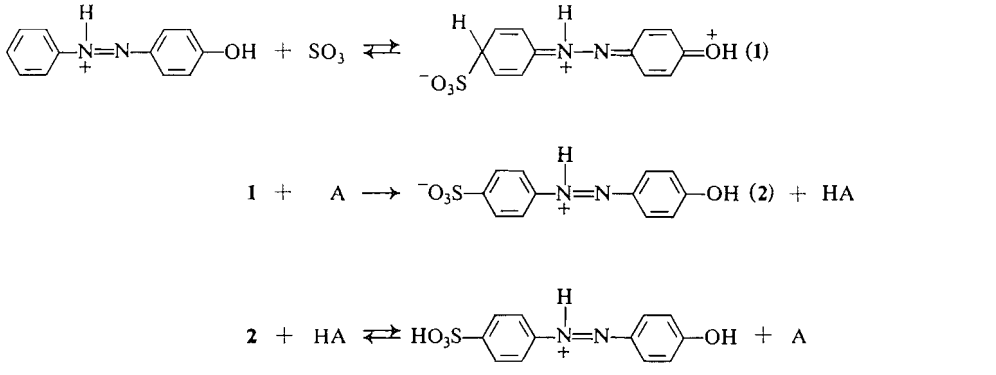
§Rate constant using 4-hydroxyazobenzene-4′-sulfonic acid as substrate.

cesses described above derives from cryoscopic and conductivity measurements obtained with 4-hydroxyazobenzene in 100% H_2SO_4 (8).

Discussion

The results of the quantitative study of the sulfonation of 4-hydroxyazobenzene described above are in accord with previous qualitative reports in the literature on the conversion of 4-hydroxyazobenzene (or of azoxybenzene, its precursor in the Wallach rearrangement) to 4-hydroxyazobenzene-4′-sulfonic acid and to higher sulfonation products (2–5).

The acidity dependence of the sulfonation of 4-hydroxyazobenzene is in many ways comparable to that in the sulfonation of benzene (9–11), *p*-nitrotoluene (12,13), benzenesulfonic acid (14*a*), and other aromatic derivatives, in concentrated sulfuric acid–dilute oleum media. Such sulfonation processes are recognized to belong to the class of electrophilic aromatic substitution reactions (15,16). However differences have been expressed concerning the detailed nature of the sulfonation mechanism (9–16), partly as a result of the uncertainty as to the identity of the sulfonating species (17): H_2SO_4, SO_3, $H_2S_2O_7$, S_2O_6, SO_3H^+, $H_3SO_4^+$, and others. The statement (15*a*) "that monomeric sulfur trioxide, or, possibly, a sulfuric acid solvate of it, is the active species contained in sulfonating media of this type" forms the basis of the mechanism proposed for the sulfonation of 4-hydroxyazobenzene:



In this mechanism the 4-hydroxyphenylazo group is taken as activating toward electrophilic substitution but its effect should be considerably reduced by the deactivating nature of the protonated azonium function. In accord with this consideration, the reactivity of 4-hydroxyazobenzene is greater than of benzene derivatives containing the trimethylammonio or nitro substituents (12,13), though less than of benzene itself (9–11).

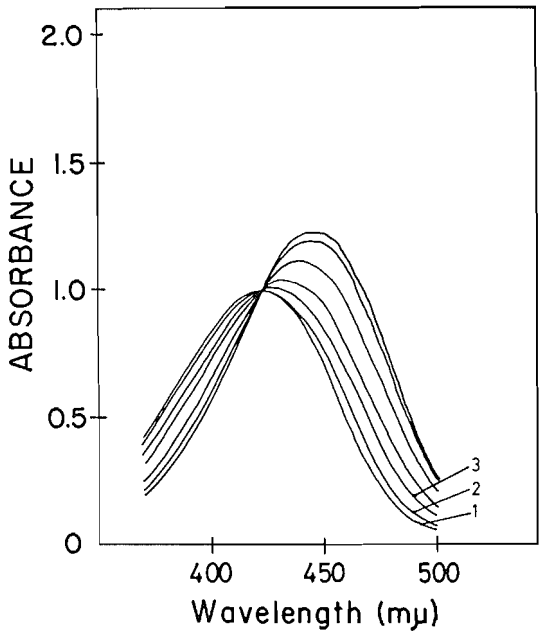

FIG. 6. 4-Hydroxyazobenzene-4′-sulfonic acid (2.97 × 10^{-5} M) in 100.07% H_2SO_4 (25°, 1.00 cm cuvette). Scans noted are 1–2.5 min, 2–2 h, 3–6 h, last scan 37 h.

The above scheme considers monoprotonated 4-hydroxyazobenzene to be the effective reactant on the ground that, with a pK_a^1 of −1.0 (reference 7 and others quoted therein) 4-hydroxyazobenzene is already 99.9% protonated in ca. 55% H_2SO_4. It is only in considerably more acidic media (ca. 90% H_2SO_4) that the sulfonating species reach effective concentration for reaction in this system.

It has been shown that above 98% H_2SO_4 a second equilibrium protonation of 4-hydroxyazobenzene becomes effective ($pK_a^2 = -10.2$ (7)) and that the site of the second protonation is the phenolic oxygen. The resulting diprotonated species should be very much less reactive toward sulfonation since *O*-protonation effectively negates the activating ability of the hydroxyphenylazo moiety. Some support for this view is given by the observation that the linearity range of the log k versus $-H_0$ plot is extended to higher acid concentrations when account is taken of the material present in diprotonated form by plotting log k − log $C_{SH^+}/(C_{SH^+} + C_{SH_2^{++}})^3$ versus H_0 (Fig. 7). The slope of the linear portion of this plot (1.50) is not readily interpretable but non-unit slopes appear to be general for reactions occurring in the concentrated sulfuric acid media (21,22).

The kinetic dependence of the second sulfonation is very similar to the first and requires little comment. The plot of log k − log $C_{SH^+}/(C_{SH^+} + C_{SH_2^{++}})$ versus H_0 is linear, which is analogously interpreted to mean that the reactive species is monoprotonated 4-hydroxyazobenzene-4′-sulfonic acid and that the diprotonated species is unreactive. It was shown previously (7) that for this substrate the second equilibrium protonation ($pK_a^2 = -11.1$) is also on phenolic oxygen. The above mentioned plot has a slope of 2.0

The observed orientation in these sulfonation reactions is of interest. The apparently exclusive first sulfonation in the 4′-position (rather than in the 3-position) is probably due in part to a steric factor, since it has been shown (15*b*) that *ortho* orientation is relatively disfavoured in aromatic sulfonation. However another factor (15*c*) influencing orientation in this system is the

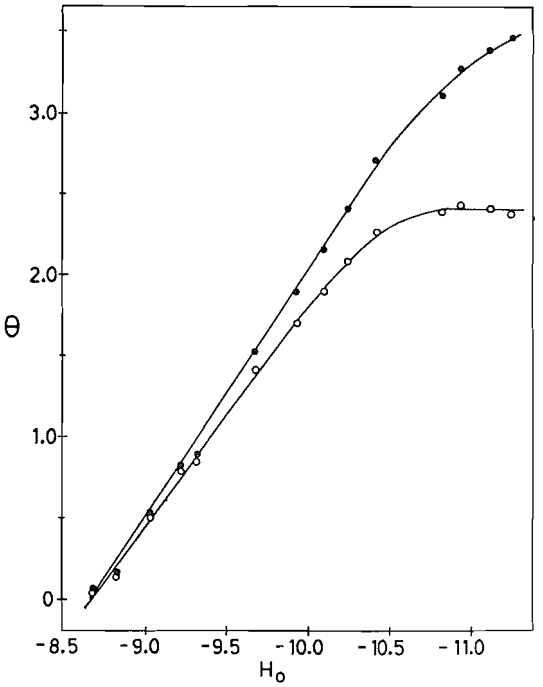

FIG. 7. Acidity function correlations for conversion of 4-hydroxyazobenzene to 4-hydroxyazobenzene-4′-sulfonic acid in sulfuric acid solutions at 25°.
O, Θ = 5 + log k_{obs}; ●, Θ = 5 + log k_{obs} − log $C_{SH^+}/(C_{SH^+} + C_{SH_2^{++}})$

[3]This term was evaluated by means of the expression log $C_{SH_2^{++}}/C_{SH^+} = pK_a^2 - H_0$ using the H_0 values (18) in Table I. The possible application of an H_+ function (19,20) in this system was considered previously (7).

increased through-conjugation in the reaction product (and in the reaction intermediates and transition states) which results when sulfonation occurs in the 4-position. The second sulfonation should then be directed in the position *ortho* to the hydroxyl group, which will be more activating than the azo-nitrogen bonded to the second proton-bearing nitrogen.

Experimental

Materials

4-Hydroxyazobenzene and 4-hydroxyazobenzene-4′-sulfonic acid had physical properties as described previously (7). Sulfuric acid solutions were prepared by addition of fuming acid (30% SO_3) to 96% acid and analyzed conductimetrically (23). Acid concentrations are given as weight per cent.

Kinetic Measurements

The bulk of the kinetic data were obtained by following the reactions (10^{-4} to 10^{-5} *M* in substrate) spectrally *in situ* in thermostated cells mounted in a constant temperature holder in the spectrophotometer (the "direct method"). The substrate (0.1–1.0 mg, weighed on a Cahn-M10 Electrobalance in glass boats of tare less than 5 mg) was added to a pre-thermostated, weighed quantity of sulfuric acid (25–100 ml) and transferred to the thermostated 1 cm cells (25.00 ± 0.03°). The spectrophotometers used were either a Unicam SP800B or a Bausch and Lomb Spectronic 600 Spectrophotometer, the latter in conjunction with a Sargent SRL recorder. In kinetic runs carried out on the former instrument spectral sweeps were taken at various times over the region of interest and rate constants calculated from absorbance values read off these sweeps. The latter instrument was generally used for following the reaction at constant wavelength. A small variation (2–4 mμ) in absorption characteristics (peak or isosbestic point wavelengths) was observed between runs, presumably as the result of small differences in acid concentration (particularly in the 100% H_2SO_4 region) and in instrumental settings over a period of time.

The wavelength at which absorbance changes were computed was usually in the region 460–465 mμ, being close to, though not necessarily at λ_{max} for the product of reaction. In acid media over 100% H_2SO_4 the first sulfonation was also followed on occasion at 480 mμ, which gave more optimum changes in absorbance than was afforded at 460–465 mμ (cf. Fig. 4); the rate of the second sulfonation was also computed on occasion for ca. 450 mμ.

Most of the rate constants were calculated by the Guggenheim method since this removed the uncertainty with respect to "infinity" absorbance values current with the small sized substrate samples employed, the slow rates in the lower acid range, and the two consecutive sulfonation processes above the 100.0% H_2SO_4. Where "infinity" absorbance values could be obtained, some of the rate constants were also evaluated by means of log $(A_\infty - A_t)$ versus t plots; in such cases experimental A_∞ values were used, which was deemed more accurate with the small sized samples.

Rate constants were calculated by means of a least square program using an IBM 360/–50 computer, with a Calcomp Digital Plotter 663 to plot the data. A correlation coefficient of 0.994 was taken as prepresentative of acceptable linearity. An illustrative plot is shown in Fig. 8.

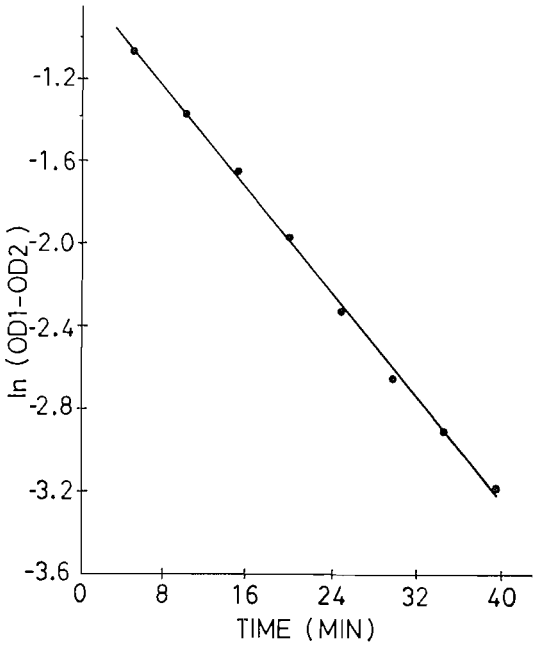

FIG. 8. Kinetic plot for sulfonation of 4-hydroxyazobenzene in 99.72% H_2SO_4. Data correspond to kinetic run illustrated in Fig. 2. Absorbance values at 460 mμ are plotted according to the Guggenheim method with Δt = 15 min and yield $k_{obs} = 102 \times 10^{-5}$ s^{-1}.

One kinetic run in this series was carried out by the base-quenching procedure ("the indirect method" (24)). The reaction solution was prepared by adding 2.49 mg of 4-hydroxyazobenzene in 20 ml (36.6 g) of 97.80% H_2SO_4 in a constant temperature bath (25.00 ± 03°). Aliquots (0.991 ml) were periodically quenched with cold 1 *N* aqueous KOH, diluted to 50 ml at 25°, and the spectra taken in 4.00 cm cells. The rate constant was calculated from the absorbance changes at 440 mμ, being λ_{max} for 4-hydroxyazobenzene-4′-sulfonic acid in basic medium. Using the log $(A_\infty - A_t)$ versus t plot, $k = 6.27 \times 10^{-5}$ s^{-1}.

Identification of Product of First Sulfonation

Spectral characteristics of "infinity" solutions (≥ 97% reaction) of 4-hydroxyazobenzene were compared with the spectrum of 4-hydroxyazobenzene-4′-sulfonic acid. For the range 94.52–98.92% H_2SO_4, the λ_{max} of the "infinity" solutions for 11 kinetic runs varied over 463–467 mμ, with molar extinctions taking the values 4.56×10^4–4.88×10^4. 4-Hydroxyazobenzene-4′-sulfonic acid in 89.3% H_2SO_4 showed λ_{max} 465 mμ ($\varepsilon = 4.61 \times 10^4$) and in 97.80% H_2SO_4, λ_{max} 463 mμ ($\varepsilon = 4.70 \times 10^4$). Below 94.5% H_2SO_4 "infinity" readings were not obtained due to the low reaction rate. Over 99% H_2SO_4, where the second equilibrium protonation of 4-hydroxyazobenzene-4′-sulfonic acid becomes important, the

‡Observed values in 100.02% H_2SO_4.

"infinity" extinctions of the product solutions from the 4-hydroxyazobenzene reaction were found to fit well along the pK_a^2 curve of this sulfonic acid (see reference 7, footnote 6).

Partial Identification of Product of Second Sulfonation

4-Hydroxyazobenzene and 4-hydroxyazobenzene-4′-sulfonic acid were allowed to react in 100.79% at 25° (separate runs, substrate concentrations ca. 3×10^{-4} *M*) for periods of 24 and 65 h (corresponding to 6 and 16 half-lives). The spectra were then examined in that medium as well as in 96% H_2SO_4, 0.2 *N* H_2SO_4, and 0.2 *N* KOH, obtained by dilution (1:50) of the original 100.79% reaction solution with 96% H_2SO_4, 0.6 *N* KOH and 1.0 *N* KOH, respectively. The reaction solutions derived from 4-hydroxyazobenzene and from 4-hydroxyazobenzene-4′-sulfonic acid showed virtually identical absorption, for both reaction times, as expected on the basis of product identity, and average ε values are considered below. The spectrum in 0.2 *N* KOH is identified with the azophenolate anion (ArO^-); the spectrum in 0.2 *N* H_2SO_4 with the neutral species (B) with respect to the azo linkage; in 96% H_2SO_4 with the azo-protonated species (BH^+); and the 100.79% H_2SO_4 spectrum is ascribed to partial diprotonation.

In Table III the λ and ε values for the various ionized forms of 4-hydroxyazobenzene and 4-hydroxyazobenzene-4′-sulfonic acid are compared with corresponding values for this reaction product, tentatively identified as 4-hydroxyazobenzene-3,4′-disulfonic acid. This identification rests largely on the close similarity in these λ,ε data, since it is known that the introduction of a sulfonic acid group in the azobenzene system does not significantly alter the spectral characteristics of the parent compound (7).

The site of the second equilibrium protonation in the disulfonic acid product is probably the phenolic oxygen (7) and a λ_{max} in the region of 420 mμ for this species can be assumed. Since λ_{max} shifts from 452 to 436 mμ between 96% H_2SO_4 and 100.79% H_2SO_4, the extent of this shift would roughly correspond to ~50% diprotonation, with a pK_a^2 of ca. −12.

p*H* Effects in trypsin catalysis

H. P. KASSERRA AND K. J. LAIDLER
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received December 12, 1968

A kinetic study has been made of the trypsin-catalyzed hydrolysis of *N*-benzoyl-L-alanine methyl ester, at p*H* values ranging from 6 to 10. The substrate concentrations varied from 1.7×10^{-3} to 4.3×10^{-2} *M*. From the rates were calculated, at each p*H*, values of $\tilde{k}_c$ (corresponding to $[S] \gg K_m$), $\tilde{k}_c/\tilde{K}_m$ (corresponding to $[S] \ll K_m$) and $\tilde{K}_m$. The specific levorotation of trypsin was measured and found to vary with p*H* in the p*H* region 5–11, the change in specific rotation following the ionization of a single group with p*K*(app) of 9.4. At p*H* 11 the specific rotation of trypsin, its zymogen, and its phosphorylated derivative were approximately the same, suggesting similar conformations for all three forms of the protein.

The kinetic results on the acid side were very similar to those obtained by other investigators for chymotrypsin; they imply that there is a group of $pK_b \approx 7$ in the free enzyme, presumably the imidazole function of a histidine residue, and that this group is involved in acylation and deacylation, which can only occur if it is unprotonated. The behavior on the basic side was found to be different from that with chymotrypsin revealing a decrease in $\tilde{k}_c$ at high p*H* corresponding to a value of $pK_a \approx 9.5$, whereas $\tilde{k}_c/\tilde{K}_m$ showed sigmoid p*H*-dependence. An interpretation of these results that is consistent with all available information is that a group of $pK \approx 9.5$ (presumably the $-NH_3^+$ function of the terminal isoleucine) controls the conformation and thereby the activity of the enzyme at different stages of complex formation. In contrast to chymotrypsin, the p*K* of this ionizing group appears to be generally lowered by covalent complex formation between trypsin and its substrates.

Canadian Journal of Chemistry, 47, 4021 (1969)

Introduction

Derivatives of lysine and arginine (1) appear to be the best substrates for bovine pancreatic trypsin (Enzyme Commission (E.C.) No. 3.4.4.4.). In recent years, it has been shown, however, that the enzyme is not absolutely specific with respect to the length (2–5) or type (6–8) of the substrate side-chain. This behavior, particularly that shown towards aromatic substrates, has been clearly established as being due to trypsin (6, 9) and not to contamination by small amounts of chymotrypsin (E.C. 3.4.4.5) which are usually found in commercial trypsin preparations.

Relatively few studies have been made of the influence of p*H* on the trypsin-catalyzed hydrolysis of esters (10–14) and all of these were done at substrate concentrations which are high relative to the apparent Michaelis constant; this constant, for the specific amino acid ester substrates, is of the order of 10^{-5} *M* or less. The kinetics of chymotrypsin action, however, have been investigated over a wider range of substrate concentrations, and have been interpreted in much greater detail (15, 16). On the basis of the striking similarities between trypsin and chymotrypsin (17), it has been generally concluded that in all important mechanistic aspects, catalyses by trypsin and α-chymotrypsin are similar. The present more detailed study of p*H* effects in trypsin kinetics indicates some significant differences between the two enzymes, a matter which is further considered in the following paper.

In the present investigation a study was made of the effect of p*H* on the hydrolysis of *N*-benzoyl-L-alanine methyl ester (BAME) by trypsin. This choice of substrate made it possible to cover low substrate concentrations relative to the apparent Michaelis–Menten constant (≈ 0.1 *M*) and to examine a wide range of p*H*.

Theory

The influence of p*H* on the kinetics of enzyme-catalyzed reactions involving two intermediates has been discussed in detail by Kaplan and Laidler (18). Most hydrolytic enzymes, such as trypsin and chymotrypsin, obey the modified Michaelis–Menten law

$$[1] \qquad v = \frac{\tilde{k}_c[E]_0[S]}{\tilde{K}_m + [S]}$$

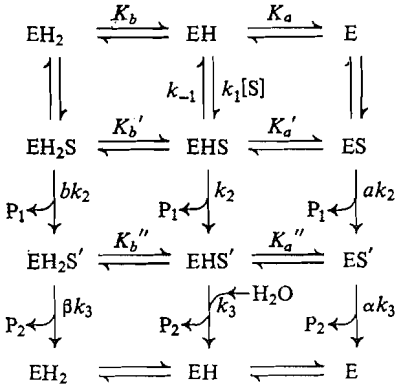
where $[E]_0$ and $[S]$ are the total enzyme and substrate concentrations and $\tilde{k}_c$ and $\tilde{K}_m$ are constants at a given p*H*; the symbol $\sim$ indicates that they are usually p*H*-dependent quantities. A general reaction mechanism involving two intermediates and two ionizing groups on the enzyme is shown in Scheme 1.

An approximate steady-state treatment leads to eqs. [2]–[4], expressions for the kinetic parameters.

$$[2]\qquad \tilde{k}_c = \frac{k_2}{\dfrac{1 + \dfrac{K_a'}{[H]} + \dfrac{[H]}{K_b'}}{1 + \dfrac{aK_a'}{[H]} + \dfrac{b[H]}{K_b'}} + \dfrac{k_2}{k_3}\dfrac{1 + \dfrac{K_a''}{[H]} + \dfrac{[H]}{K_b''}}{1 + \dfrac{\alpha K_a''}{[H]} + \dfrac{\beta[H]}{K_b''}}}$$

$$[3]\qquad \tilde{K}_m = \frac{\dfrac{k_{-1} + k_2}{k_1}\dfrac{1 + \dfrac{K_a}{[H]} + \dfrac{[H]}{K_b}}{1 + \dfrac{aK_a'}{[H]} + \dfrac{b[H]}{K_b'}}}{\dfrac{1 + \dfrac{K_a'}{[H]} + \dfrac{[H]}{K_b'}}{1 + \dfrac{aK_a'}{[H]} + \dfrac{b[H]}{K_b'}} + \dfrac{k_2}{k_3}\dfrac{1 + \dfrac{K_a''}{[H]} + \dfrac{[H]}{K_b''}}{1 + \dfrac{\alpha K_a''}{[H]} + \dfrac{\beta[H]}{K_b''}}}$$

$$[4]\qquad \frac{\tilde{k}_c}{\tilde{K}_m} = \frac{k_1 k_2}{k_{-1} + k_2}\frac{1 + \dfrac{aK_a'}{[H]} + \dfrac{b[H]}{K_b'}}{1 + \dfrac{K_a}{[H]} + \dfrac{[H]}{K_b}}$$



SCHEME 1

A general mechanism for p*H*-dependence. The symbols are defined in the same way as in the paper by Kaplan and Laidler (18).

The ratio $\tilde{k}_c/\tilde{K}_m$ is particularly significant in that it relates to the kinetic behavior at low substrate concentrations. It has been shown (18) that when one obtains K_a and K_b values from studies at low [S], one can conclude that the corresponding groups not only ionize in the free enzyme but are *essential to the subsequent reaction of the enzyme-substrate complex*. They may also be involved at a later stage, e.g. deacylation, but this must be investigated in other ways. Even if one is using a substrate for which deacylation is rate-limiting, one can still determine the ionizing groups involved in acylation by studying the p*H* dependence of $\tilde{k}_c/\tilde{K}_m$.

Experimental

Materials

N-Benzoyl-L-alanine methyl ester was prepared essentially according to the method used by Kaplan and Laidler (16). An improvement in yield and ease of purification was achieved by carrying out the reaction in an ice-water bath which caused the crude product to precipitate as a solid rather than a liquid. The yield after two recrystallizations was 66.4% of BAME, m.p. 57.5–58 °C, $[\alpha]_D^{22}$ +30.1° (*c*, 5 in *sym*-tetrachloroethane). This agrees well with previously reported results (16, 19).

Trypsin (twice crystallized, salt-free, Lot No. TRL 7EC) was obtained from Worthington Biochemical Corporation and used without further purification for most of the kinetic work. Enzyme concentrations, calculated on the basis of a molecular weight of 23 800 (20), ranged from 2 to 4 × 10^{-5} *M*. One gram of trypsin (same lot as above) was treated with L-(1-tosylamido-2-phenyl) ethylchloromethyl ketone (TPCK) according to the method described by Kostka and Carpenter (9). After dialysis and lyophilization, the yield of treated enzyme

was 84%. This enzyme in which all chymotrypsin activity is irreversibly inhibited was used as a control for some kinetic runs at pH 8.0. TPCK was purchased from Calbiochem (Lot No. 53227).

All proteins used for optical rotation studies were obtained from Worthington Biochemical Corporation; trypsin (twice crystallized, salt-free, Lot No. TRL 8CA), trypsin treated with diisopropyl fluorophosphate (DIP-trypsin, twice crystallized, Lot No. TDIP 7AA), and typsinogen (crystallized, Lot No. TG 7JH).

Water was doubly distilled, deionized, and free of carbon dioxide. The titrant used for pH-stat work was 0.02 N NaOH (0.05 N at pH 10.0) periodically restandardized with Fisher Certified hydrochloric acid.

Kinetic Procedure

Rates of hydrolysis were determined by the pH-stat method with a Radiometer automatic titrator (Model TTTlc) and titrigraph (Model SBR 2c). The reaction vessel was surrounded by a jacket through which water was circulated at 25.0 ± 0.05 °C. Inserted into the cell were a glass electrode (Radiometer G202B), a saturated calomel reference electrode, a stirrer, and leads for sodium hydroxide solution and nitrogen. The nitrogen was washed with acid and alkali and then with water before being passed in a slow stream over the surface of the reaction mixture. The titrant was delivered by a Radiometer syringe burette (Model SBUla) into the cell containing 15 ml of solution.

Stock solutions of trypsin were made up in 0.033 M $CaCl_2$(I = 0.10) and stored frozen for no longer than 3 days. A stock solution of BAME in water could be maintained indefinitely in the refrigerator. Substrate concentrations ranged from 0.167 to 4.33 × 10^{-2} M. In a typical run, substrate solution, water, and 1 ml of 1.4 M sodium chloride solution were mixed in the cell to make up 14 ml (I = 0.10). The pH was adjusted to the desired value with 1 N sodium hydroxide solution delivered by a micrometer screw gauge. The reaction was then started by the addition of 1.0 ml of enzyme solution and usually followed to 5–10% completion.

Methods of Computation

At higher pH values a correction had to be applied for the alkaline hydrolysis of BAME. The first-order rate constant ($k_{OH} = v/[S]$) was determined at various pH values and plotted against $1/[H^+]$ as in Fig. 1. The correction can then be directly calculated at all other pH values.

Throughout this work the v vs. [S] plots gave a non-zero intercept which (after correction for alkaline hydrolysis of BAME) could only be accounted for by an "enzyme-blank" reaction. This phenomenon has previously been observed and discussed (21, 22) and suitable corrections were made. In this study all experimental data have been analyzed and the kinetic constants computed on the IBM 360/65 computer using a slightly modified version of the program written by Hanson *et al.* (23). The program fits experimental data directly to the Michaelis–Menten equation according to the method described by Bliss and James (24). From an analysis of the standard errors in $\tilde{K}_m$ and $\tilde{k}_c$, the "enzyme-blank" correction could be deduced, assuming that the "enzyme-blank" rate was proportional to the total enzyme concentration. The correction amounts to 3–25% depending on rate, pH, and enzyme concentration.

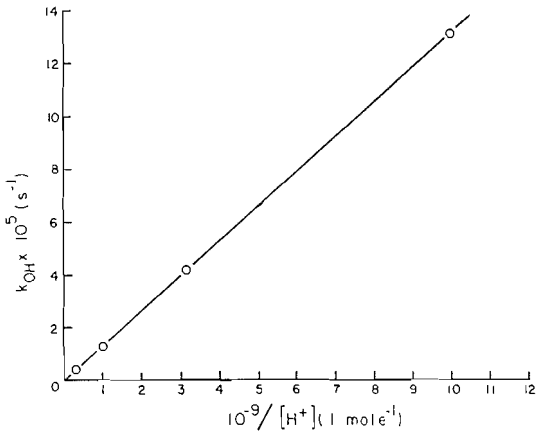

FIG. 1. Plot of first-order rate constant for the alkaline hydrolysis of BAME in water (0.1 M NaCl, 0.033 M $CaCl_2$) at 25.0 °C against the reciprocal of the hydrogen ion concentration.

Optical Rotation Measurements

Protein solutions of 1 mg per ml concentration were made up in 0.033 M $CaCl_2$ (I = 0.10). The solution of trypsinogen was centrifuged at 6000 r.p.m. in a Sorvall Superspeed RC2-B automatic refrigerated centrifuge to remove water-insoluble impurities. Protein concentrations were determined on a Perkin Elmer Model 350 spectrophotometer at 280 mμ with values of extinction $E_{1\,cm}$ (1%) = 14.4 for trypsin and DIP-trypsin and 13.9 for trypsinogen (25). Samples of each solution were adjusted to the desired pH with 1 N NaOH and placed in a 1-dm polarimeter tube with water jacket maintained at 23 °C. A Perkin Elmer Model 141 polarimeter was used to measure optical rotations at 365 and 436 mμ.

Results

pH Dependence of Kinetic Parameters

The values and standard errors of $\tilde{k}_c$, $\tilde{K}_m$, and $\tilde{k}_c/\tilde{K}_m$ for the hydrolysis of BAME by trypsin are given in Table I. The pH dependencies of these parameters are shown in Figs. 2–4.

The kinetic parameters are average values based on computed results from 3 to 5 runs covering the full range of substrate concentration from 0.167 to 4.33 × 10^{-2} M. The condition of low substrate concentration is strictly satisfied at pH 6 and 6.5 where a plot of rate against [S] is a straight line. At higher pH values, the plot becomes slightly curved as the order of the reaction becomes less than unity. Representative curves are shown in Fig. 5. Above pH 7.0 a slight extrapolation has therefore been made to obtain the second-order

TABLE I

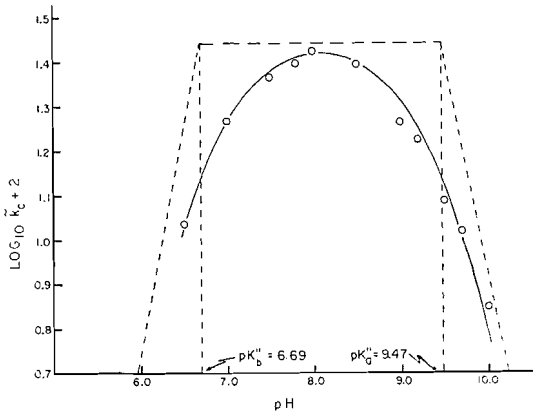

FIG. 2. Variation of $\log_{10} \tilde{k}_c$ with pH for the trypsin-catalyzed hydrolysis of BAME at 25.0 °C and $I = 0.10$ in $CaCl_2$ and NaCl.

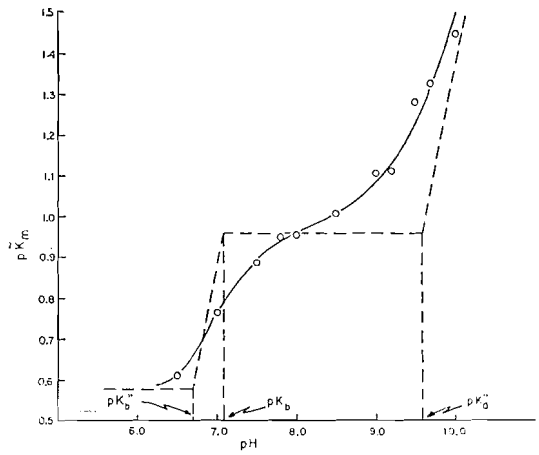

FIG. 3. Variation of $p\tilde{K}_m$ with pH for the trypsin-catalyzed hydrolysis of BAME at 25.0 °C and $I = 0.10$, in $CaCl_2$ and NaCl.

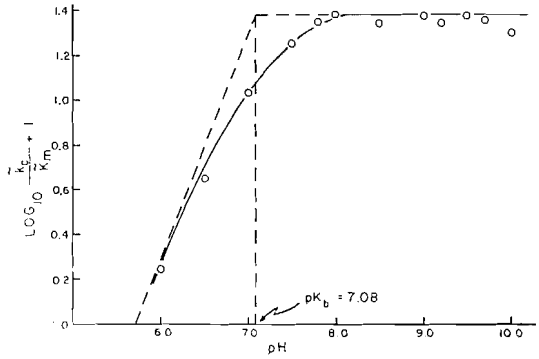

FIG. 4. Variation of $\log_{10} \tilde{k}_c/\tilde{K}_m$ with pH for the trypsin-catalyzed hydrolysis of BAME at 25.0 °C and $I = 0.10$ in $CaCl_2$ and NaCl.

rate constant $\tilde{k}_c/\tilde{K}_m$. The standard errors reported in Table I show that, with a few exceptions, the kinetic parameters can be considered reliable to ±5–10%.

Two control runs at pH 8.0 with TPCK-treated trypsin demonstrated within experimental error that the observed hydrolysis of BAME was indeed due to trypsin and not due to contaminating chymotrypsin. The results are shown in Table II.

The curves in Figs. 2 and 4 are the theoretical curves obtained by a reiterative process[1] which give the closest fit to the experimental points. The theoretical relationship between $p\tilde{K}_m$ and pH (eq. [3]) is too complex to permit such a fit and the curve in Fig. 3 is the best visual fit to the experimental data. The bell-shaped form of the $\log_{10} \tilde{k}_c$

[1]Knowledge of the pH-independent rate constants (see eqs. [2] and [4]) is not necessary. In the process of curve fitting, suitable values for these quantities can be found which give a best fit to the experimental points.

TPCK-treated trypsin	(*1*)	0.264	0.110	2.40
	(*2*)	0.261	0.114	2.29

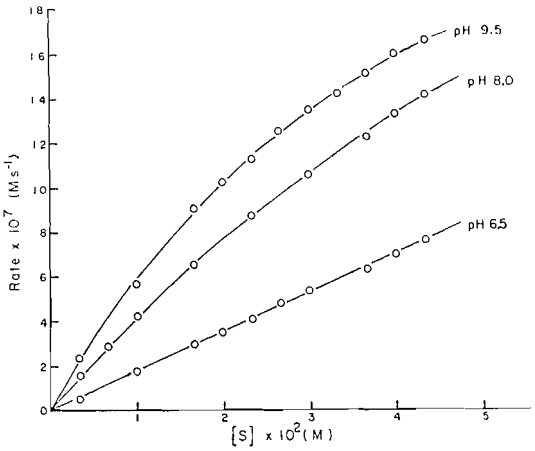

FIG. 5. Plots of rates against [S] for the trypsin-catalyzed hydrolysis of BAME at 25.0 °C and I = 0.10 in $CaCl_2$ and NaCl. The curves have been corrected for alkaline hydrolysis and "enzyme-blank" rate. At pH 8.0, $[E]_0 = 2 \times 10^{-5}$ M, at pH 9.5, $[E]_0 = 3 \times 10^{-5}$ M, and at pH 6.5, $[E]_0 = 4 \times 10^{-5}$ M.

– pH profile in Fig. 2 seems to suggest the participation of two groups in the catalytic reaction of the acylenzyme, $pK_b'' = 6.69$ and $pK_a'' = 9.47$. This implies that for the trypsin-catalyzed hydrolysis of BAME, deacylation is the rate-limiting step. It appears safe to make such an assumption in view of the extensive work done on α-chymotrypsin kinetics (26), as well as two studies on trypsin using *N-trans*-cinnamoyl imidazole (27) and *p*-nitrophenyl acetate (28).

As explained earlier, the pH profile of $\log_{10} \tilde{k}_c/\tilde{K}_m$ reveals the kinetically important groups on the free enzyme. In this case, the sigmoid-shaped curve in Fig. 4 shows that a basic group with $pK_b = 7.08$ is implicated in catalysis. It is believed that this is the first time that the trypsin-catalyzed hydrolysis of an ester has been studied at low substrate concentration over the full range of pH. The $p\tilde{K}_m$—pH profile in Fig. 3 provides an independent check for pK_a'' which is found to agree well with the value of 9.47 obtained from Fig. 2. The theoretical positions of pK_b and pK_b'' have also been indicated on Fig. 3.

The shape of the $\log_{10} \tilde{k}_c$—pH profile in Fig. 2 is essentially the same as that obtained by other investigators (11, 12, 29) for the trypsin-catalyzed hydrolysis of specific ester substrates. Similar bell-shaped behavior of the catalytic rate constant ($\tilde{k}_c$) has been reported by Chevallier and Yon (30) for the hydrolysis of benzoyl-L-arginin-amide at substrate concentrations larger than K_m and 35 °C. Their results qualitatively agree with those of Shukuya and Watanabe (31) and Wang and Carpenter (32). It must be remembered that, for amides, acylation is considered to be the rate-limiting step (33).

Effect of pH on Optical Rotation

The pH dependence of optical rotation at 365 mμ for trypsin, DIP-trypsin, and trypsinogen is shown in Fig. 6. Similar results were obtained for trypsin at 436 mμ involving smaller overall

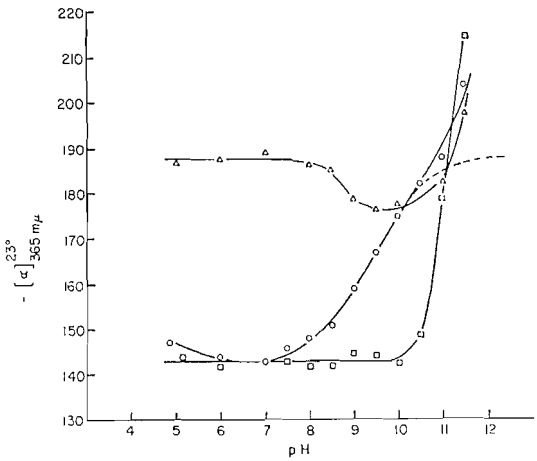

FIG. 6. Plots of specific rotation against pH at 365 mμ and 23 °C. Solutions contained 3.26 to 4.20 × 10^{-5} M protein in 0.033 M $CaCl_2$. Symbols: ○, trypsin; □, DIP-trypsin; △, trypsinogen.

changes in optical rotation. Samples at pH 11 were brought back to pH 8 and were found to exhibit complete reversibility in specific rotation within periods up to 20 min. Figure 6 shows that the specific rotation values for DIP-trypsin and trypsinogen are significantly different from each other. The optical rotation of DIP-trypsin is pH-independent between pH 5–10, and approximately 45° higher than that of trypsinogen which exhibits a small change in $[\alpha]$ above pH 8. The curve for trypsin has been extrapolated (dashed line) to a value of specific rotation equal to that of the inactive zymogen at neutral pH. Experimentally this value is not reached, owing to the ionization of titratable tyrosine residues which has been related by D'Albis and Béchet (34) to a decrease in the enzyme's rotary power. The specific levorotation of all three proteins decreases sharply above pH 11, presumably due to irreversible denaturation setting in. Similar results have been obtained by Neurath *et al.* (35) for trypsin and trypsinogen.

Using the same treatment as applied by Oppenheimer *et al.* (36) to acetylated δ-chymotrypsin, the pH-dependent change in specific levorotation of active trypsin can be related to the specific rotation of its precursor and its phosphorylated derivative as shown in Fig. 7. The equation used as basis for this plot is

$$[5] \qquad pH = pK + \log_{10} \frac{[E]}{[EH]}$$

where E and EH represent the different ionization states of the enzyme molecule. If $\Delta[\alpha]_{max}$ is defined as the total change in specific rotation between the value at pH 7 and the limiting value given by the dashed curve in Fig. 6, and $\Delta[\alpha]$ as the change in specific rotation between pH 7 and any pH, eq. [5] becomes

$$[6] \qquad pH = pK + \log_{10} \frac{\Delta[\alpha]}{\Delta[\alpha]_{max} - \Delta[\alpha]}$$

As can be seen from the plot in Fig. 7, eq. [6] is obeyed, indicating that the specific levorotation of trypsin follows the ionization of a single group. The pK(app) of the group controlling the change in specific rotation may be obtained from the abscissa of the plot in Fig. 7 at the point where $\log_{10} \Delta[\alpha](\Delta[\alpha]_{max} - \Delta[\alpha])^{-1} = 0$. A value of p$K$(app) = 9.4 was found.

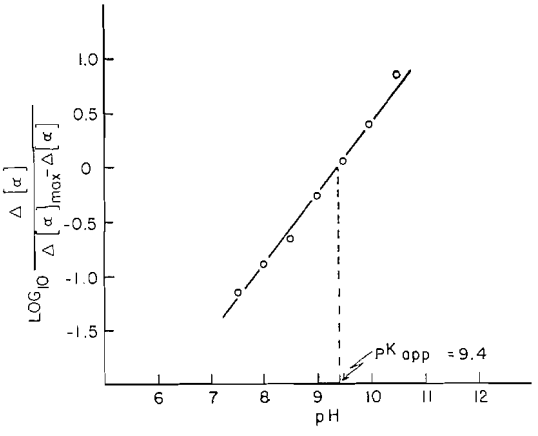

FIG. 7. Plot of $\log_{10} \Delta[\alpha](\Delta[\alpha]_{max} - \Delta[\alpha])^{-1}$ against pH for trypsin at 365 mμ.

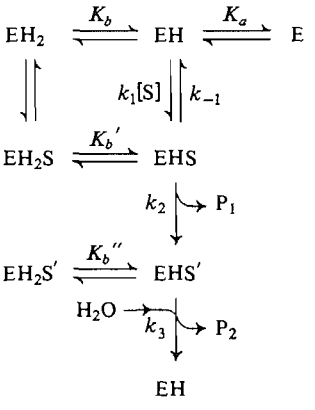
Discussion

The pH dependencies shown in Figs. 2–4 at first sight appear to suggest a different mechanism of catalysis by trypsin as opposed to that by chymotrypsin. Much evidence has been accumulated for chymotrypsin (16, 26, 37) which has been incorporated in a reaction mechanism as shown in Scheme 2. We propose that the same mechanism is in fact applicable to trypsin on the basis that the observed kinetic behavior of the enzyme is related to changes in conformation with pH. The relationship between the scheme and the catalytic action of trypsin is best discussed separately for the acid and basic sides.

Ionizations in Acidic Solution

The ionizations on the acid side are the same for trypsin and chymotrypsin, the entire pattern of kinetic behavior on the acid side being very similar. Figure 4, which relates to low substrate concentrations, shows that there is a decrease in rate on the acid side corresponding to a pK_b value of 7.08. This undoubtedly relates to the ionization of the imidazoyl side-chain of histidine-46[2]. The fact that this residue is revealed in the $\log_{10} (\tilde{k}_c/\tilde{K}_m)$ plot indicates not only that the group is free to ionize in the free enzyme, but also that it is involved in the acylation process; in other words, acylation requires the function to be in the unprotonated form and cannot occur if it is protonated. It is for this reason that (as with chy-

[2]Our numbering in trypsin is according to the linear sequence of amino acids in trypsinogen as given in ref. (38).



SCHEME 2

Reaction mechanism for trypsin and chymotrypsin catalysis.

motrypsin) the scheme shows no arrow between EH_2S and EH_2S'.

Figure 2, which relates to high substrate concentrations, provides information about the process of deacylation, which for esters is slower than that of acylation. The decrease in rate at low pH values corresponds to a pK_b'' value of 6.69. This undoubtedly can be attributed to the same imidazole group, and the fact that there is a falling-off in rate shows that this group is essential to deacylation, which can only occur if the function is unprotonated. The conclusion that the imidazole residue is essential to deacylation was first proposed by Gutfreund (10), who obtained pK_b'' = 6.25 with benzoyl-L-arginine ethyl ester. Béchet (12), on the other hand, found pK_b'' = 7.35 using tosyl-L-arginine methyl ester. Similar variations in pK values with different substrates are not uncommon.

Ionizations in Basic Solution

The situation on the basic side appears to be very different for trypsin from that with chymotrypsin. It is convenient to consider first the enzymatic behavior at high substrate concentrations, which relates to the rate-determining deacylation process. It is seen from Fig. 2 that (in contrast to chymotrypsin) there is a significant decrease in $\tilde{k}_c$ in basic solution, corresponding to the ionization of a group of pK_a'' equal to 9.47. In the case of chymotrypsin there seems to be no doubt (37) that one of the active residues in that enzyme is the $-NH_3^+$ group of the terminal isoleucine-16, and it is reasonable to suggest that in trypsin the observed pK relates to the corresponding $-NH_3^+$ group of the terminal isoleucine-7. Himoe *et al.* (37) propose, however, that this group is not *catalytically* active in chymotrypsin, but controls an equilibrium between two major conformations of the enzyme and thereby the enzymatic activity.

Similar evidence to ours has been obtained by Béchet (13) with tosyl-L-arginine methyl ester as substrate; he obtained pK_a'' = 10.1. It is significant in this connection that the reaction of nitrous acid with the α-amino group of the terminal isoleucine-7 causes inactivation of trypsin. Scrimger and Hofmann (39) have suggested that this is due to a complete destruction of the active site, and not to a change in the kinetic parameters, since the ability of the enzyme to react with diisopropyl fluorophosphate is lost at the same rate as the catalytic activity towards benzoyl-L-arginine ethyl ester. We suggest therefore on the basis of existing evidence that the observed fall-off in the rate of deacylation by trypsin in alkaline solution is the result of a conformational change in the acylenzyme and does not reflect the participation of an acidic group in the catalytic process. Ionization of the group with pK_a'' equal to 9.47 induces a catalytically inactive conformation of the acylenzyme and thereby controls the rate of deacylation.

Such an interpretation would also explain the observed shifts with pH in the bell-shaped deacylation curves of different trypsin substrates (Fig. 2, refs. 13, 29, 40) if it is assumed that different substrates stabilize the acylenzyme to a different extent and thus affect the pK of the conformation-controlling group. This is in contrast to most forms of acylchymotrypsin which do not exhibit a fall-off in $\tilde{k}_c$ up to pH 10 (16, 26). The specific rotation curve for DIP-trypsin (cf. Fig. 6) shows that even the irreversibly inhibited enzyme undergoes a conformational change at a lower pH (above pH 10) than does acetylated DIP-δ-chymotrypsin (above pH 11) (36). Similar variations in specific rotation relating to conformational stability have been observed by D'Albis and Béchet (34) and in this laboratory[3] for trypsin in the presence of reversible competitive inhibitors.

The work at low substrate concentrations (cf. Fig. 4) shows no significant decrease in the

[3]Unpublished experiments.

For personal use only.

second-order rate constant at high pH values. This result seems to suggest that the ionizing group, observed in deacylation, is free but not involved in complex formation (in contrast to the situation with chymotrypsin) or in the acylation process. We have summarized, in the paper following this one, the evidence leading to the conclusion that the terminal isoleucine residue does in fact play a less prominent role in trypsin than it does in chymotrypsin with regard to substrate binding. The interpretation of the optical rotation studies reported in Fig. 6 is that the conversion of catalytically inactive trypsinogen to active trypsin is accompanied by the appearance of a new ionizing group which controls the conformation of the enzyme. Evidence that a conformational change accompanies the activation of zymogen to enzyme has been previously published (35). We have shown that the specific levorotation of trypsin varies with pH and that the change in specific rotation follows the ionization of a single group with pK(app) of 9.4 (cf. Figs. 6 and 7). It can be seen in Fig. 6 that the specific rotation of trypsin is approximately the same as that of trypsinogen at pH 11 beyond which irreversible denaturation is known to set in.

The experimental results obtained in this work together with some facts presented below are consistent with the hypothesis that both kinetic and optical rotation studies in basic solution reveal the same group in the enzyme, namely the terminal isoleucine-7 residue. These facts are that (*a*) activation of trypsinogen to trypsin results in isoleucine-7 as the new NH_2-terminal residue (41), (*b*) reaction of nitrous acid with the isoleucine group causes inactivation of the enzyme (39), (*c*) acetylation of all lysyl ε-amino groups and exposed tyrosyl groups of trypsin does not cause reduced enzymatic activity (42). In contrast to chymotrypsin, however (16), conformational changes induced by ionization of the NH_2-terminal group do not become apparent in the kinetics of Michaelis complex formation between trypsin and the non-specific ester substrate BAME. The existence of inactive forms of the enzyme in subsequent stages of the catalytic process is revealed by a decrease in the kinetic constant (k_c) for both the amidase and esterase activity of trypsin. It is tempting to suggest that this difference in enzymatic behavior between chymotrypsin and trypsin in alkaline solution is related to their differences in specificity, i.e. to electrostatic interactions between substrate and enzyme which are present in trypsin but not in chymotrypsin. We have attempted in the following paper to elucidate this matter to some extent.

The present study has been carried out with a non-specific substrate, lacking a positive charge on the side chain. There is good reason to believe that the mechanisms are the same for both specific and non-specific substrates in view of the same pH dependence of the deacylation processes for the two classes of compounds (11, 29, 40).

Mechanisms of action of trypsin and chymotrypsin

H. P. KASSERRA AND K. J. LAIDLER
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received December 12, 1968

The mechanistic evidence for reactions catalyzed by chymotrypsin and trypsin is briefly reviewed and is considered with reference to the structure as determined by the X-ray studies. Conclusions are drawn about the detailed nature of the processes of complex formation, acylation, and deacylation. Although there are significant differences between the two enzymes as far as specificity and p*H* effects are concerned, it appears that the mechanisms of their action are very similar.

The preceding paper has presented evidence on trypsin which shows the kinetic behavior of this enzyme to be slightly different from that of chymotrypsin. The present paper is concerned with comparing and contrasting the two enzymes in some detail, and with drawing conclusions about the mechanisms of their action.

Structural Evidence

The three-dimensional structure of α-chymotrypsin has now been established by X-ray methods (1–4). Figure 1 has been constructed from Fig. 4 of reference 1 and Fig. 2 of reference 3, with the help of a model we have built. It shows in a purely schematic way the groups that appear to exist in the region of the active center, and their relative positions. The histidine-57 and serine-195 groups[1] are known from kinetic and other evidence to be catalytically important, whereas the $-NH_3^+$ group of *N*-terminal isoleucine-16 and the $-COO^-$ groups of aspartic acid-194 and aspartic acid-102[2] are believed to be more indirectly involved in the enzymatic process. Buried more deeply within the molecule are a number of non-polar groups, such as the side chains of isoleucine-16, leucine-163, and isoleucine-212. Some of these groups are probably concerned with forming hydrophobic bonds with the non-polar groups on the substrate.

The detailed X-ray structure of trypsin has not yet been established. However, there is very persuasive evidence that the general conformation of the enzyme is very similar to that of chymotrypsin. There is a very close correspondence between the amino acids along the chains, and there is a particularly strong homology as far as polar and non-polar groups are concerned (5). Further support for the similarity in conformation comes from the demonstration (2) that the two extra disulfide bridges that exist in trypsin can be built into the chymotrypsin model without distortion of the structure.

Figure 2 has been prepared for trypsin on the assumption that its general structure is the same as that of chymotrypsin. It is striking that so many of the groups near the active centers of the two enzymes are the same or very similar. The absence in trypsin of any group equivalent to leucine-13 of chymotrypsin is probably not significant, since this group is probably too far away in chymotrypsin to be actively involved. We are left with the result that the only significant difference between the two enzymes is that the neutral serine-189 in chymotrypsin has become the negatively-charged aspartic acid-177 in trypsin[3]. This strongly suggests that the different specificities of the two enzymes are largely due to the difference between these two groups; in particular, the fact that trypsin favors substrates having a positively-charged group in a suitable position (e.g. derivatives of arginine and lysine) seems to be related to the existence of the $-COO^-$ group at position 177 in trypsin.

Mechanistic Evidence

In Tables I–III we have summarized the most important mechanistic evidence for the two

[1]The present numbering of amino acids in chymotrypsin is the same as that in ref. 1.

[2]This group was originally identified as asparagine-102, but this has now been corrected (3).

[3]Our numbering for trypsin corresponds to consecutive numbering in trypsinogen, the order of amino acids (but not the numbering) being as in ref. 5, except for aspartic acid-177 which in the past has erroneously been reported as being asparagine-177 [B. S. Hartley, to be published; quoted in (4)].

TABLE I

Evidence relating to complex formation in chymotrypsin and trypsin

Kind of evidence	Chymotrypsin	Trypsin	Reference
p*H* Studies at low substrate concentrations	Bell-shaped curve; p*K* of ~7 and ~9	Sigmoid curve; p*K* of ~7; no falling-off up to p*H* ~10	6, 7
p*H* Studies in mixed solvents	Group of p*K* ~7 is a cationic acid; group of p*K* ~9 is a neutral or ion-pair acid	—	6
p*H* Studies at low p*H*	Carboxyl group (p*K* ~4) present	Carboxyl group (p*K* ~4) present	8, 9
Chemical and kinetic studies	Single histidine residue involved in reaction, but not in complex formation	Single histidine residue involved in reaction, but not in complex formation	6, 7, 10–12
Chemical and kinetic studies	*N*-terminal isoleucine-16 (p*K* ~9) indirectly participates in the binding process	—	13

TABLE II

Evidence relating to acylation of chymotrypsin and trypsin

Kind of evidence	Chymotrypsin	Trypsin	Reference
Chemical and kinetic studies	Acylation involves the hydroxyl group of serine-195	Acylation involves the hydroxyl group of serine-183	18–24
p*H* Studies with amides, for which acylation is rate-limiting	Rate falls off at p*H* < 7.5; no fall-off in alkaline solution up to p*H* 9.5	Rate falls off at p*H* < 7.5; no fall-off in alkaline solution up to p*H* 9.5	13, 16, 25–27
Substituent effects	Proton transfer is involved in acylation	—	28
Deuterium isotope effects	Proton transfer is involved in acylation	—	25
p*H* Studies at low concentrations of esters, for which deacylation is rate-limiting	Both ionizing groups are apparently involved in acylation	Single ionizing group (p*K* ≈ 7) participates in acylation	6, 7

TABLE III

Evidence relating to deacylation of chymotrypsin and trypsin

Kind of evidence	Chymotrypsin	Trypsin	Reference
p*H* Studies with *N*-α substituted esters, for which deacylation is rate limiting	Sigmoid curve; p*K* of ~7; no falling-off up to p*H* ~10	Bell-shaped curve; p*K* of ~7 and ~9.5. *Apparently* both groups involved in deacylation	6, 7, 15, 25, 31–34
p*H* Studies with esters on which the α-amino group is not substituted	Bell-shaped curve; p*H* optimum shifted from p*H* ~ 8 to p*H* ~ 6	Bell-shaped curve; p*H* optimum shifted from p*H* ~ 8 to p*H* ~ 6	35–37
Effect of added nucleophiles	Deacylation is first-order in nucleophile (e.g. methanol)	—	38
Kinetic studies	No intermediate detected in deacylation	—	15
Deuterium isotope effects	Proton transfer is involved in deacylation	Proton transfer is involved in deacylation	25, 39

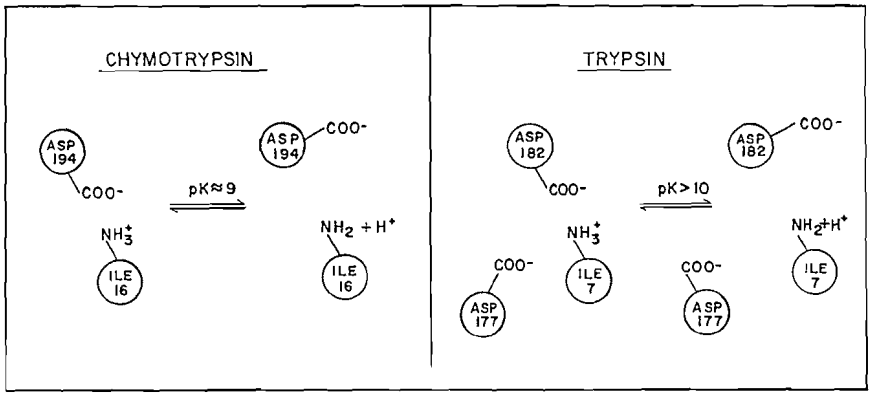

FIG. 3. Ionizations in chymotrypsin and trypsin.

enzymes, classifying it according to its relevance to (*1*) complex formation, (*2*) the acylation process, and (*3*) the deacylation process.

Complex Formation

Table I summarizes the evidence and conclusions regarding the process of complex formation. The main difference between the behavior of the two enzymes lies in their p*H* dependence at low substrate concentrations; with chymotrypsin there is evidence for a group of p$K \sim 9$, while with trypsin there is no falling-off in rate up to p$H \sim 10$.

There is no reason to doubt that the groups ionizing at pH ~ 7 are histidine-57 in the case of chymotrypsin and histidine-46 in the case of trypsin; support for this is provided by the work with chymotrypsin in mixed solvents (6). The mixed-solvent work also supports the conclusion that the group of p$H \sim 9$ in chymotrypsin is the $-NH_3^+$ group of isoleucine-16, existing in the charged state as an ion-pair with the $-COO^-$ group of aspartic acid-194 (1). When this $-NH_3^+$ group loses its proton it is postulated (2) that the $-COO^-$ group of aspartic acid-194 moves to a more polar environment. It appears likely that this causes a shift in the position of the reactive serine-195 residue which, as will be discussed, has an effect on subsequent processes.

A suggestion as to why the pK of the $-NH_3^+$ group in trypsin is higher than that in chymotrypsin is illustrated in Fig. 3. In trypsin the $-NH_3^+$ group is close to two $-COO^-$ groups, and it is therefore more difficult for the proton to leave.

The upper portions of Figs. 4 and 5 present more detailed mechanisms for the ionizations of chymotrypsin and trypsin, and for the way in which Michaelis-complex formation occurs. It is postulated, in agreement with other workers (13–17), that binding in the complexes does not directly involve the ionizing groups, but is primarily due to hydrophobic bonding between non-polar groups on the substrate and enzyme. In addition to this, the anionic site in trypsin (aspartate-177) forms an electrostatic bond with the positively-charged side chain of specific trypsin substrates. The state of ionization of the histidine residues has no effect on complex formation. However, ionization of the $-NH_3^+$ groups of the terminal isoleucines has an indirect effect on binding by bringing about a conformational change in the enzyme molecules; support for this in the case of chymotrypsin is provided by the work of Oppenheimer *et al.* (14), and is later discussed further with reference to trypsin.

Acylation

The evidence and conclusions relating to the acylation steps for the two enzymes are summarized in Table II. It has already been seen from the results relating to complex formation that the forms of the free enzyme in which the isoleucine $-NH_3^+$ group has lost its proton cannot bind substrate; expressed differently, the Michaelis complex cannot lose a proton from the $-NH_3^+$ group as readily as can the free enzyme, and the unprotonated form is of no significance within the range of pH that has been investigated.

The fact that with both enzymes the acylation rates fall off at pH values below about 7.5 implies that the imidazole ring of histidine-57 or histidine-42 must be unprotonated. The function of the unprotonated imidazole ring is no doubt to

aid in the removal of the proton from the serine hydroxyl group. At the same time a proton must be transferred to the alcoholic oxygen atom of the substrate. A way in which these processes can occur in a single stage is shown in Fig. 6. The

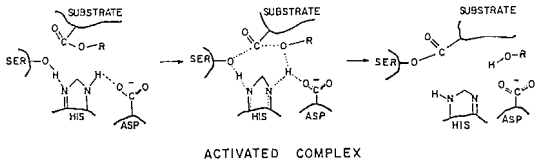

FIG. 6. Proton transfer processes during acylation.

suggested scheme makes use of the remarkable properties of the imidazole group as a proton-transfer agent. Eigen *et al.* (29, 30), who studied this as well as other acid–base catalysts, have shown that the effectiveness of this system is further increased by hydrogen bonds between the donor and acceptor molecules. In addition, the tautomeric character of the unprotonated imidazole ring makes it possible for this group to accept and donate a proton at the same time. These ideas are incorporated into the mechanisms shown in Figs. 4 and 5. As far as the behavior on the basic side is concerned it is suggested that, for both enzymes, the substrate has the effect of locking the enzyme into a conformation in which the $—COO^-$ group of aspartic acid-194 or -182 is held close to the $—NH_3^+$ group of the terminal isoleucine residue. This makes it more difficult for the α-amino group to lose a proton, a fact that explains why there is no decrease in the acylation rates up to high p*H* values. With trypsin this ionization is also difficult in the free enzyme, and we have suggested that this is due to the presence of the second $—COO^-$ group, i.e. aspartate-177. With chymotrypsin, however, the ionization is less difficult in the free enzyme, a p*K* of ~ 9 being observed.

Deacylation

Table III summarizes the evidence and conclusions relating to the deacylation step. It is seen that there is again a difference between the two enzymes in their p*H* dependence; with trypsin there is a falling-off above p*H* ~ 9, whereas with chymotrypsin there is no decrease in rate up to p*H* ~ 10; the results with chymotrypsin are consistent with a p*K* of 10.5 or greater.

In both enzymes the imidazole ring of histidine-57 or -46 must be in its unprotonated form in order for deacylation to occur. The function of the unprotonated imidazole group is to aid in the splitting of a water molecule acting as the nucleophile and to facilitate the transfer of a proton to the serine oxygen atom. This again involves a prototropic change in the imidazole ring, one of the nitrogen atoms accepting a proton from the water molecule and the other donating its proton to the serine oxygen atom. This process is the reverse of that shown in Fig. 6 with R = H. The lower portions of Figs. 4 and 5 show the conclusions arrived at for the deacylation process.

The behavior of trypsin on the alkaline side can be explained along the following lines. The $—NH_3^+$ group of isoleucine-7 splits off its proton with a p*K* of 9.5, and when this occurs there is a movement (probably to a more polar environment) of the $—COO^-$ group of aspartic acid-182; this movement affects the position of the neighboring serine residue and diminishes the ease with which the acyl portion of the substrate can be removed from the serine by the action of the imidazole group. The fact that this ionization occurs at p*H* 9.5, rather than at a higher value as in the free enzyme, is possibly the result of slightly different relative spatial arrangements of the $—NH_3^+$ and the two $—COO^-$ groups in the acyl enzyme compared with the free enzyme; the two $—COO^-$ groups may be a little further away from the $—NH_3^+$ group in the acyl enzyme and so allow the proton to leave more readily.

The different behavior of chymotrypsin is perhaps also to be explained in terms of slight conformational changes during complex formation and acylation. It is suggested that in acyl chymotrypsin the $—COO^-$ group of aspartic acid-194 has been brought a little closer to the $—NH_3^+$ group of isoleucine-16 than in the free enzyme; this could have the effect of raising the p*K* from the value of ~ 9.0 in the free enzyme to a value of 10.5 in the acyl enzyme.

The differences in kinetic behavior on the alkaline side between trypsin and chymotrypsin suggest the possibility that during the catalytic process the trypsin molecule is subjected to a general loosening of its three-dimensional structure, while chymotrypsin undergoes a tightening in conformation. The X-ray results for trypsin should prove to be of great interest.

General Discussion

The preceding discussion has led to the conclusion that, in spite of some differences in kinetic behavior, the mechanisms of chymotrypsin and trypsin action appear to be the same. We propose that the substrates fit into the two enzymes in a similar manner, the carbonyl carbon atom of the substrate forming roughly an equilateral triangle with the imidazole nitrogen atom and the alcoholic hydrogen atom of the serine residue. The alcoholic oxygen atom of the substrate also forms roughly an equilateral triangle with these two atoms on the enzyme. Both enzymes exhibit very low specificity as far as the alcoholic function of ester substrates is concerned, and this group almost certainly remains outside the enzyme. For chymotrypsin the X-ray evidence (4) indicates that the aromatic side chain of the substrate fits into a cavity which lies to the lower right of the histidine–serine pair (cf. Fig. 1); it is presumably held there largely by hydrophobic bonding. In trypsin the positively-charged side chain of the substrate, or the corresponding grouping in the case of a non-cationic substrate, is held in a similar position, there being electrostatic attraction to the aspartate-177 residue of the enzyme in the case of the cationic substrates. We suggest that this anionic binding site on trypsin makes an important contribution to the stereospecificity.

For α-chymotrypsin catalysis there have been proposed many mechanisms involving the imidazole and serine hydroxyl groups (10). Some of these mechanisms contained features which were later found to be inconsistent with experimental evidence, notably (*a*) the existence of a large deuterium-isotope effect in the acylation and deacylation steps, (*b*) the absence of an observable intermediate in the deacylation process, (*c*) the presence of a single histidine group in the active center, and (*d*) the conformation-controlling role attributed to the *N*-terminal residue. Specific mechanisms involving aspartic acid or arginine residues in the catalytic process can now be eliminated in view of the additional information derived from the three-dimensional structure of α-chymotrypsin (1–4). Recently Wang and Parker (40) have published a most interesting treatment applicable to the chymotrypsin-catalyzed hydrolysis of peptides, amides, and anilides which involves a pre-transition state protonation of the substrate. Unfortunately this hypothesis does not seem to be valid for substituted anilides or ester substrates. The mechanism of trypsin and chymotrypsin catalysis suggested in this paper is the product of as much kinetic, chemical, and crystallographic information as has been found to date, and can serve as a working hypothesis for the future.

Conformational Changes

A variety of evidence leads to suggestions of conformational changes during the action of these enzymes, and will be referred to briefly. The X-ray studies on chymotrypsin (1) have shown that there is an ion-pair between aspartic acid-194 and isoleucine-16. It has been suggested (2) that, as the latter group ionizes, the former moves away into a more polar environment, and this, we believe, indirectly affects the kinetic behavior. The resultant conformational change probably accounts for the decrease in catalytic properties at alkaline p*H*. In support of this suggestion, Oppenheimer *et al.* (14) find that acetylation of the α-amino group of isoleucine-16 inactivates δ-chymotrypsin, while all other amino groups can be acetylated without loss of activity. Furthermore Karibian *et al.* (41) have recently shown that the change in activity and structure of acetyl-δ-chymotrypsin in the alkaline p*H* range is not correlated with the ionizations of titratable tyrosine residues.

It seems likely that the terminal isoleucine-7 in trypsin performs a similar function to isoleucine-16 in chymotrypsin; this implies the existence of an ion-pair bond between this residue and aspartic acid-182. Support for this is provided by the work of Scrimger and Hofmann (42) who report that the reaction of nitrous acid with the *N*-terminal isoleucine group of trypsin causes inactivation of the enzyme. In the preceding paper (7) it was shown that the p*H*-dependent change in the specific levorotation of trypsin at 365 mμ can be associated with a single group having an apparent p*K* of 9.4. It is reasonable to suggest that this is the p*K* of isoleucine-7; its ionization probably causes a conformational change in the enzyme, but this does not become apparent in the kinetics of complex formation with the non-specific substrate benzoyl-L-alanine methyl ester. In this connection it should be noted that Wang and Carpenter (27) report a p*K* of 10.4 for the free enzyme using benzoyl-L-argininamide; this ionization can probably also be related to the *N*-terminal isoleucine residue.

The p*K* of this group appears to be strongly affected by the degree of conformational stability

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of the enzyme resulting from non-electrostatic, electrostatic, and even steric interactions between the substrate and various portions of the enzyme. Our results with diisopropylphosphoryl trypsin (7), showing that the specific rotation of the enzyme is p*H*-independent up to p*H* 10, are consistent with this suggestion.

The relatively high p*K* value of 9–10 observed for trypsin catalyses in alkaline solution has led previous investigators (32, 43) to suggest that this ionization relates to a tyrosine or lysine ε-amino group. Labouesse and Gervais (44) have recently shown, however, that at alkaline p*H* homogeneous *N*-ε-acetyltrypsin exhibits the same activity as native trypsin towards synthetic substrates. Furthermore, acetylation of the free tyrosines (4–5 out of 10) leads to an enzyme which, below p*H* 9, is even more active as an esterase than is native trypsin. As a result of the X-ray diffraction studies by Matthews *et al.* (1) on chymotrypsin, it is now likely that the existence of an ion-pair bond between isoleucine and aspartic acid contributes to the unusually high p*K* value of the isoleucine α-amino group in trypsin, compared to a p*K* of 8 or less in peptide terminal α-amino groups (45).

Mechanism of initiation in the thermal polymerization of styrene. Thermal decomposition of *cis*-3,6-diphenyl-3,4,5,6-tetrahydropyridazine[1,2,3]

KARL R. KOPECKY AND SYAMALARAO EVANI
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 12, 1969

Thermal decomposition of *cis*-3,6-diphenyl-3,4,5,6-tetrahydropyridazine, **1**, ($k = 5.6 \times 10^{-4}$ s^{-1} at 79.5°) results in the formation of about 60% styrene, 27% *cis*- and 13% *trans*-1,2-diphenylcyclobutane. The relative product yields vary little over the temperature range 64–133°. This indicates that **1** decomposes exclusively to the 1,4-diphenyl-1,4-butadiyl diradical, **2**, and nitrogen. The diradical, **2**, cannot be trapped by styrene and **1** is not an initiator of styrene polymerization. Therefore, **2** is not the radical intermediate responsible for the thermal initiation of styrene polymerization.

The thermal decomposition of 3,6-diphenyl-3,4,5,6-tetrahydropyridazine, **1**, was studied a number of years ago (1). A possible initial decomposition product, the 1,4-diphenyl-1,4-butadiyl diradical, **2**, has a structure identical to the classical Flory diradical whose formation by "tail to tail" dimerization of styrene, eq. [1], had been held to be responsible for the initiation of the

[1] $$2\ \mathrm{CH(C_6H_5)=CH_2} \longrightarrow \mathrm{\dot{C}H(C_6H_5)CH_2CH(C_6H_5)\dot{}}$$

2

thermal polymerization of this monomer (2). The only nitrogen-free decomposition product from **1** which was identified was styrene, as the dibromide, in 7% yield. There was no evidence to indicate whether the diradical, **2**, was actually formed as an intermediate in the decomposition of **1** or whether there occurred a concerted decomposition reaction to give styrene and nitrogen directly. It was found that **1** was a poor initiator of styrene polymerization. Previous reports also indicated that diradicals generated by thermal decomposition of cyclic peroxides (3, 4), by photolysis of a cyclic disulfide (5), and by thermal decomposition of a cyclic azo compound (6) are poor polymerization initiators. These experimental results had been anticipated by kinetic considerations (7, 8).

For these and other (9) reasons it had come to be considered unlikely that the thermal polymerization of styrene is initiated by formation of **2**. However, the report (9–11) that 1,2-diphenylcyclobutane, among other dimers, could be isolated from the thermal polymerization of styrene in dilute solution or in the presence of inhibitors maintained the question of the formation of **2** from dimerization of styrene.

In the present study the decomposition of **1** has been reinvestigated in order to determine the mode and products of the reaction, and to measure more accurately the efficiency of **1** as an initiator of styrene polymerization.

Results

Preparation and Stereochemistry of 1

Attempted preparation of **1** according to the published procedure (1) resulted in the isolation in low yield of material which did evolve gas upon melting but which always melted over a broad temperature range. This material was shown by ultraviolet (u.v.) and nuclear magnetic resonance (n.m.r.) spectroscopy to consist of **1** contaminated with appreciable amounts of the corresponding hydrazone, 3,6-diphenyl-2,3,4,5-tetrahydropyridazine, **9**. In this procedure saponification of *cis*-1,2-dicarbethoxy-3,6-diphenylhexahydropyridazine, **4**, with potassium hydroxide in methanol is followed by dilution of the reaction mixture with water and then ether extraction of the resulting basic solution. Decarboxylation of the dipotassium salt, **5**, was assumed to take place after the aqueous dilution. In the present study it was found the decarboxylation was slow and incomplete even in only slightly alkaline solution. The azo compound, **1**, could be obtained in a high state of purity in 75% yield, based on **4**, if

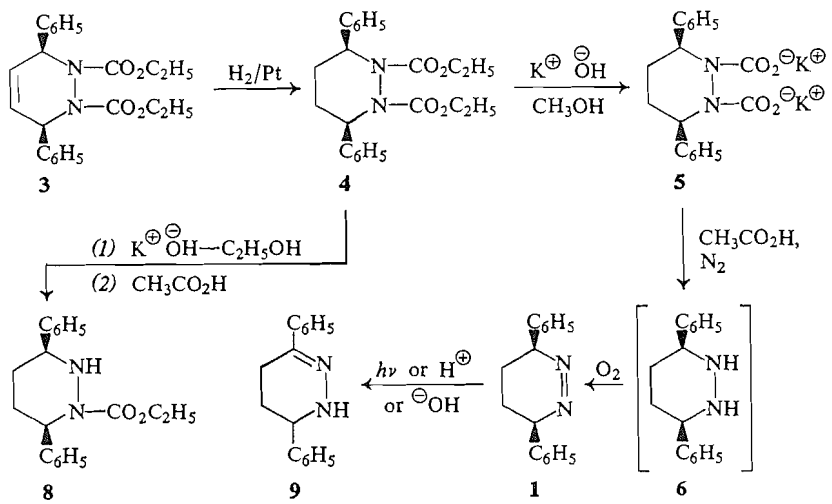

SCHEME 1

decarboxylation of **5** was carried out in acidic solution and all operations involving the hydrazine, *cis*-3,6-diphenylhexahydropyridazine, **6**, and its salts were carried out under nitrogen until **6** was oxidized by atmospheric oxygen in a dried ether solution free of inorganic acid or base (Scheme 1).

When a solution of **4** and potassium hydroxide in ethanol was heated under reflux for several hours, a water-soluble precipitate formed. This was shown to be mainly the half acid salt–half ester, **7**, by its conversion to the mono-ester, *cis*-3,6-diphenyl-1-carbethoxyhexahydropyridazine, **8**, in 53% overall yield upon addition of acid.

The presence of small amounts of acid resulted in the immediate isomerization of **1** to **9**. Attempts to take spectra of **1** even in purified carbon tetrachloride or chloroform resulted only in spectra corresponding to **9**. Stable solutions of **1** could be prepared in purified hydrocarbon solvents and in ether. The n.m.r. spectrum of **1** taken in benzene-d_6 confirms its structure and shows a complex multiplet centered at τ 3.2 for the phenyl protons, a multiplet centered at τ 7.2 for the benzylic protons, and a broad multiplet absorption from τ 8.9 to 9.8 for the methylene protons. The shifts given are relative to tetramethylsilane used as external standard. The stereochemistry of **1** cannot be determined with certainty from its n.m.r. spectrum, but can be deduced from the n.m.r. spectra of its precursors, **3** and **4**. It is now well established that **3** prepared by treatment of 1,4-diphenylbutadiene with diethyl azodicarboxylate has the *cis* configuration (12–17). Hydrogenation of **3** to **4** would not be expected to be accompanied by isomerization. That it was not, is shown by the n.m.r. spectrum of **4** taken in carbon tetrachloride which shows two broad one proton absorptions centered at τ 4.70 and at τ 5.16 for the benzylic protons. Only one signal would have been expected for these protons if **4** were the *trans* isomer. It is also unlikely that any isomerization occurred during saponification of **4** since **4** could be recovered unchanged after prolonged treatment with sodium ethoxide in boiling ethanol. It thus seems quite certain that **1** also has the *cis* configuration.

A number of attempts were made to prepare the corresponding *trans* azo compound, but these were unsuccessful.

Products from 1

The thermal decomposition of **1** was accompanied by only small amounts of isomerization to **9** if carried out in carefully cleaned apparatus and purified hydrocarbon solvents. In preliminary experiments the yield of nitrogen from the decomposition of **1** at 100° under these conditions was 90–100%. At lower temperatures somewhat less nitrogen was evolved. The presence of the hydrazone, **9**, could be detected in these reaction mixtures by u.v. spectroscopy. Control experiments showed that **9** did not rearrange or decompose under the experimental conditions used in this study.

Rates of decomposition of **1** were determined

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

by measuring the volume of nitrogen evolved as a function of time from solutions of **1** in ethylbenzene. The rate of decomposition of **1** at 79.5°, 5.6×10^{-4} s^{-1} (Table I) agrees well with the value of 6×10^{-4} s^{-1} at 80° estimated previously (1), but is about 10^2 as fast as that of the acyclic analogue, 1,1′-diphenylazoethane (18). A discussion of this difference is best deferred until data are available for the decomposition of the *trans* isomer of **1**.

TABLE I

Decomposition of **1** in ethylbenzene

Temperature, °C	$\%N_2$	$k^* \times 10^4$, s^{-1}
64.7	80	1.0
75.0	100	3.0
79.5	96	5.6

*At 79.5°, $\Delta H^* = 26.7$ kcal/mole, $\Delta S^* = 2.4$ eu.

Product analyses were made on a series of runs carried out with degassed solutions of **1** in benzene-d_6 in sealed n.m.r. tubes. The solutions were heated for 10 half-lives of decomposition and analyzed by n.m.r. spectroscopy and by gas chromatography (g.c.). Styrene and *cis*- and *trans*-1,2-diphenylcyclobutane, *cis*- and *trans*-**10**, were the only products detected by both methods. The presence of 10% hydrazone could have been detected in the n.m.r. spectrum. The composition of the products changes but little with temperature over the range 64–133°, Table II. In this range **1** decomposes to give 58–62% styrene, 25–29% *cis*-**10**, and 12–14% *trans*-**10**. The proportions of styrene and *trans*-**10** formed, increase somewhat with increasing temperature at the expense of *cis*-**10**. In each case the n.m.r. spectrum of the solution after decomposition of **1** was essentially superimposable upon that of a benzene-d_6 solution of styrene, *cis*- and *trans*-**10** present in the molar ratio 57.5:28.0:14.5 and in a concentration corresponding to 100% decomposition of **1**. The formation of diphenylcyclobutane in low yield from decomposition of **1** has previously been reported but the stereochemistry of the product was not determined (19).

Authentic samples of *cis*- and *trans*-**10** were prepared from 1,2-diphenylcyclobutene (20). Hydrogenation of this material gave *cis*-**10** which was isomerized to *trans*-**10** by potassium *t*-butoxide in dimethyl sulfoxide. The syntheses of *cis*- and *trans*-**10** by this route have since been reported (21). The properties of these compounds prepared in the present study agree with those reported except for the n.m.r. absorption of the phenyl protons of *cis*-**10**. These were reported to appear as a singlet whereas we find a multiplet similar to that reported for the absorptions of the phenyl protons of *cis*-1,2-diphenylcyclopropane (22).

A careful search was made for the presence of 1-phenyltetralin, **11**, among the products of decomposition of **1** but it could not be detected. Had **11** been formed in 0.1% yield it could have been found.

Attempts to decompose **1** photochemically resulted in the formation of only traces of styrene, *cis*- and *trans*-**10**. Irradiation of a benzene solution of **1** in Pyrex apparatus at 0° with light from a medium pressure mercury lamp gave the hydrazone, **9**, as the major product. Similar photoinduced rearrangements of azo compounds to hydrazones have been observed with 1-phenylazoalkanes (23).

1 as a Polymerization Initiator

The efficiency of **1** as an initiator in the polymerization of styrene was measured by determining the amount of diphenylcyclobutanes formed in the decomposition of **1** in pure styrene and by following the rate of polymerization of styrene containing **1**.

The yields of *cis*- and *trans*-**10** formed from decomposition of **1** at 98° in styrene and in an

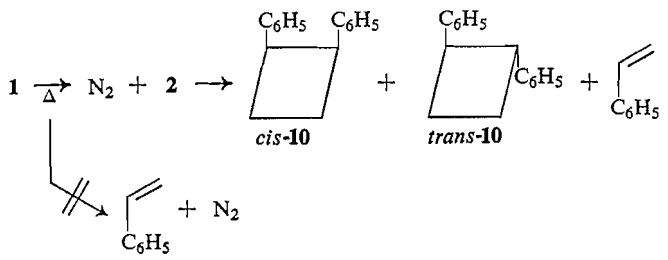
additional run in benzene are shown in Table III. Undetectable amounts of *cis*- and *trans*-**10** were formed when pure styrene was heated at 98° in the absence of **1** for the same length of time. There appears to be an error in the analysis as the total yield of **9**, *cis*-**10**, *trans*-**10**, and styrene formed from decomposition of **1** in benzene in this run is 105.1%. Also, upon correction of the product yields for isomerization of **1** to **9**, the yield of styrene seems to be ca. 4% too high by comparison with the results from the runs given in Table II. The corrected yields of *cis*- and *trans*-**10** are more in line. It appears that the quantitative g.c. analysis for styrene was in error and that the u.v. analysis for **9** was correct. This means that the corrected yields for *cis*- and *trans*-**10** given in Table III must be near the actual values, and the amounts of *cis*- and *trans*-**10** formed in styrene are only slightly smaller than the amounts formed in benzene. Very little, if any, of the diradical, **2**, is trapped under these conditions.

The rate of polymerization of styrene at 70° in the presence of **1** was followed by the dilatometric method. The data in Table IV indicate that the rate of polymerization of styrene in the presence of **1** is about 20% greater than the thermal rate, whereas the 2,2′-azobis-(2-methyl-propionitrile), ABN, initiated rate was 22 times faster. The rate of polymerization in the presence of **1** was slower than that in the presence of ABN at the same concentration in spite of the faster rate of decomposition of **1**. That **1** is a poor initiator is also seen by a comparison of the apparent kinetic chain lengths in the two cases. These were calculated using the relationship in eq. [2] where R_p is the rate of

$$[2] \quad \text{kinetic chain length} = R_p/R_i = R_p/k_d I$$

polymerization, R_i is the rate of initiation, k_d is the rate of decomposition of the initiator, and I is its concentration. The kinetic chain length, **8**, determined in this way for polymerization in the presence of **1** must be corrected for the contribution which the thermal rate makes to the overall rate of polymerization. When this is done it is seen that only 1.5 molecules of styrene are polymerized for each molecule of **1** which decomposes. This shows **1** to be about 0.4% as efficient as ABN in initiating the polymerization of styrene. By either

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



SCHEME 2

method of analysis it is seen that **1** is indeed a very inefficient initiator. This is in agreement with the earlier work (1) in which it was estimated from the increase in weight of polymer isolated from polymerization of styrene containing **1**, that about 8 molecules of styrene were polymerized per molecule of **1** decomposed at 80°.

Discussion

Decomposition of 1

There is good evidence that the thermal decomposition of symmetrical aliphatic azo compounds leads directly in a one step process to a pair of radicals in acyclic systems (18, 26), and to 1,3-diradicals in 5-membered ring systems (27, 28). But it does not follow that the 1,4-diradical, **2**, is formed from the thermal decomposition of **1**, for **1** has available to it a concerted, thermally allowed route (29) which leads directly to styrene and nitrogen. That **1** does not decompose exclusively by such a process is shown by the isolation of the 1,2-diphenylcyclobutanes, *cis*- and *trans*-**10**, in ca. 40% yield from the decomposition of **1**. In fact, although it is difficult to rule it out definitely, the concerted process does not appear to contribute to the thermal decomposition of **1** at all. The concerted route leading directly to styrene and the route leading to **2** would undoubtedly have different stereoelectronic requirements, and, therefore, probably different activation parameters. If both routes were operative this might result in a change in product distribution with temperature. In fact, there is a very small change in product distribution with temperature. This suggests that the products are formed exclusively from a common intermediate, the 1,4-diradical, **2**, via paths requiring small activation energies, Scheme 2.

Other 6-membered ring azo compounds also decompose to diradical intermediates, at least to a large extent, rather than by way of concerted processes (30, 31). These examples do not constitute violations of the Woodward–Hoffmann rules. It has already been pointed out (29) that these are not obligatory rules.

Reactions of the 1,4-Diradical, 2

The cyclization of **2**, obtained from **1**, is stereoselective and results predominantly in the formation of the thermodynamically less stable *cis*-**10** of retained configuration. This cyclization is less stereoselective than are the cyclizations of the diradicals obtained from both the thermal and photochemical decompositions of *meso*- and *dl*-3,6-diethyl-3,6-dimethyl-3,4,5,6-tetrahydropyridazine (31). The cyclobutanes obtained from these compounds are formed with virtual complete retention of configuration. Thus, while cyclization of **2** does compete well with internal rotation about the 1,2- and 3,4-carbon–carbon bonds of **2**, the competition is much less effective than is the case with either of the other diradicals. On the other hand the ratio of cleavage to cyclization of **2**, ca. 60:40, is only slightly greater than it is in the other systems, ca. 53:47. A meaningful evaluation of these differences must await information for the decomposition of the *trans* isomer of **1**.

In order for cyclization of **2** to compete effectively with internal rotation about the carbon–carbon bonds of **2** the rate constant for cyclization must be at least 10^{10} s^{-1} (32). This is equivalent to an intermolecular rate constant for the coupling of two monoradicals of at least 2×10^{10} M^{-1} s^{-1} (8) which corresponds well with the rate constant, 3×10^9, for the coupling of benzylic radicals (33) considering that the radical ends of **2** probably have no diffusive barrier to overcome. Such a rate is far too great for chain transfer with styrene or addition to styrene [for styrene at 60°, $k_{tr} \sim 10^{-2}$ (34) and $k_p \sim 10^2$ (35)] to compete with cyclization of **2**, unless, as has been pointed out (9), **2** is

very abnormally reactive compared to a polystyryl radical.

The results obtained from the decomposition of **1** in styrene provide further evidence on this point. Only 1.8 molecules of styrene are consumed for each diradical **2** produced, and little, if any, decrease in yield of *cis*- and *trans*-**10** is observed compared with yields from decompositions carried out in benzene. This indicates that most of the extra styrene consumed as a result of the presence of **1** is converted to high polymer. Assuming a molecular weight of ca. 10^6 for polystyrene produced at low conversions and under the conditions used (36), then only one of each 5000 to 10 000 of **2** produced will cause the formation of a molecule of high polymer. Approximately 40% of the diradicals produced cyclize. On this basis, if the diradical, **2**, were responsible for the initiation in the thermal polymerization of styrene, there should be roughly about 1/4 to 1/2 as much 1,2-diphenylcyclobutane formed, by weight, as of polystyrene in the thermal polymerization of pure styrene. This is not observed (9). The weight of dimers produced is only a small fraction of the weight of polymer formed. If some of the small amount of extra polymer formed in the presence of **1** is due to an impurity in **1** then the fraction of **2** diverted to polymer is even smaller than indicated. The present results provide direct experimental evidence for arguments made long ago (9) that **2** cannot be involved in the initiation of the thermal polymerization of styrene.

A recent report describes the study of the dimerization of styrene under a variety of conditions (37). The stereochemistry of the 1,2-diphenylcyclobutanes produced, varied considerably depending upon the experimental conditions. Thermal dimerization at 110° resulted in the formation of *cis*- and *trans*-**10** in a *cis*/*trans* ratio of 1/2. Thermal decomposition of **1** gives these materials with a *cis*/*trans* ratio of **2**. While the ratios are different the results are still compatible with the formulation in both cases that the 1,2-diphenylcyclobutanes are formed by way of the 1,4-diradical, **2**. Since in **2** cyclization competes with bond rotation, the stereochemistry of the products will be dependent upon the conformation of **2** when it is initially produced. The results suggest that **2** derived from **1** has a very different initial conformation from that of **2** obtained by thermal "tail to tail" dimerization of styrene, and it appears that both of these initial conformations are different from that of **2** formed by the photosenitized dimerization of styrene (37).

Experimental

Melting points and boiling points are uncorrected. Refractive indices were measured on a Bausch and Lomb Abbe-3L refractometer. Infrared spectra were recorded on a Beckman IR-7 recording spectrophotometer. The n.m.r. spectra were recorded on a Varian analytical spectrometer, Model A-60. Unless otherwise specified ca. 10% solutions in carbon tetrachloride containing tetramethylsilane as internal standard were used. Analyses by g.c. were carried out with an Aerograph-202 gas chromatograph using a 9.5 ft × 1.4 in. stainless steel column packed with 20% SF-96 on 60/80 Chromosorb P. Ultraviolet spectra were recorded on a Bausch and Lomb Spectronic 600 spectrophotometer. Elemental analyses were performed by Mrs. Darlene Mahlow.

cis-3,6-Diphenyl-1,2-dicarbethoxy-1,2,3,6-tetrahydropyridazine (3)

This material was prepared according to the method of Alder and Niklas (38) by the addition of diethyl azodicarboxylate to 1,4-diphenylbutadiene and had a m.p. 132–133°. Reported (38) m.p., 132°.

cis-3,6-Diphenyl-1,2-dicarbethoxyhexahydropyridazine (4)

The Diels–Alder adduct, **3**, was hydrogenated in ethanol using platinum oxide at 30 p.s.i. at room temperature. The syrupy liquid remaining after filtering the catalyst and removing the solvent was taken up in the minimum amount of methanol. Water was added until the solution just became turbid. The crystals which were deposited on allowing the solution to stand at 0° overnight were recrystallized in the same manner, m.p. 83–87°. Reported (38) m.p., 87°. Further recrystallization from methanol water did not improve the melting point. The n.m.r. spectrum ($CDCl_3$) showed absorption at τ 2.45–3.18 (multiplet with a strong, sharp absorption at τ 2.98, 9.96H) for the phenyl protons, at τ 4.60 (broad, 1/2 width = 17 c.p.s., 1.0H) and τ 5.03 (broad, 1/2 width = 10 c.p.s., 1.0H) for the benzylic protons, at τ 5.85 and 6.10 (a pair of overlapping quartets, J = 7.0 c.p.s., 4.0H) for the methylene protons of the carbethoxy groups, at τ 7.8–8.5 (broad multiplet, 4.0H) for the methylene protons of the ring and τ 8.76 (a pair of closely overlapping triplets, J = 7.0 c.p.s., 6.0H) for the protons of the methyl groups.

cis-3,6-Diphenyl-1-carbethoxyhexahydropyridazine (8)

A solution of 10 g (0.0254 mole) of **4** and 11.5 g (0.2 mole) of potassium hydroxide in 100 ml absolute ethanol was boiled under nitrogen for 6 h. A fine white precipitate had formed. The solvent was removed under vacuum and the remaining residue stirred in ether. The precipitate was filtered and dried, yield 11.0 g. The precipitate was taken up in water and the resulting solution acidified with acetic acid. There was effervescence and an oil separated which solidified on standing. The solid was taken up in ether, the ether solution dried over magnesium sulfate, and then pentane was added. On cooling 5.0 g (53%) of crystals were deposited, m.p. 59–60°.

For personal use only.

The infrared spectrum (KBr) showed N—H absorption at 3420 cm^{-1} and absorption at 1695 cm^{-1} for the carboethoxy group.

The n.m.r. spectrum showed absorption at τ 2.9 (multiplet, 10.0H) for the phenyl protons, at τ 4.65 (broad, 1.0H) for the benzylic hydrogen at C-6, at τ 5.20 (broad, exchanges with D_2O, 0.95H) for the amine proton, at τ 5.85 (quartet, $J = 7$ c.p.s., 2.0H) for the methylene protons of the carbethoxy group, at τ 6.22 (broad multiplet, 1.0H) for the benzylic proton at C-3, at τ 7.6–8.1 (broad multiplet, 2.0H) and at τ 8.15–8.41 (broad multiplet 2.0H) for the methylene protons of the ring, and τ 8.74 (triplet, $J = 7.0$ c.p.s., 3.0H) for the protons of the methyl group.

Anal. Calcd. for $C_{19}H_{22}O_2N_2$: C, 73.52; H, 7.14; N, 9.03. Found: C, 73.66; H, 6.88; N, 8.98.

*cis-3,6-Diphenyl-3,4,5,6-tetrahydropyridazine (**1**)*

A solution of 3.75 g (0.095 mole) of **4** and 7.5 g (0.13 mole) of potassium hydroxide in 17.5 ml methanol was boiled for 4 h and then cooled. Twenty-five ml of water were added to the reaction mixture and the resulting solution was acidified under nitrogen with acetic acid. There was effervescence and an oil separated. The mixture was stirred for 30 min and was then made alkaline to phenolphthalein with aqueous potassium hydroxide. Potassium carbonate was added to this mixture until the aqueous layer became saturated. The resulting mixture was extracted with ether and the ether layer was dried over potassium carbonate. All these operations were carried out under nitrogen. After drying, the loosely stoppered ether solution was allowed to stand overnight. Long flat crystals were formed. Concentration of the mother liquor yielded further crystals, total yield 1.9 g, m.p. 109–112° with decomposition. Recrystallization from benzene–octane yielded 1.75 g (75%) of plates, m.p. 112–113° with gas evolution. Reported (1) decomp. at 110° with gas evolution.

This material's facile isomerization to the hydrazone, **9**, made characterization difficult. It was stable in redistilled hydrocarbon solvents and methanol when the glassware containing its solutions had been carefully neutralized. The n.m.r. spectrum has been given in the text. The u.v. spectrum showed maximum absorption at 285 mμ, log ε 2.45 and at 385 mμ, log ε 2.56. Reported (1) λ_{max} (cyclohexane) 287 mμ, log ε 3.49 and 387 mμ, log ε 2.89. Material prepared in this way contained less than 2% of the hydrazone, **9**, on the basis of its absorbance at 285 mμ.

*3,6-Diphenyl-2,3,4,5-tetrahydropyirdazine (**9**)*

A small quantity of **1** was dissolved in carbon tetrachloride and in a few minutes, fine, needle-shaped crystals formed, m.p. 157–158°, λ_{max} (methanol) 285 mμ, log ε 4.14. Reported (1) m.p. 157–159°, λ_{max} (chloroform) 292 mμ, log ε 4.19. Solutions of this material in ethylbenzene did not evolve any gas upon prolonged heating at 100°, and it could be recovered quantitatively.

*cis-1,2-Diphenylcyclobutene (*cis*-**10**)*

cis-1,2-Diphenylcyclobutene (20) (250 mg), m.p. 53–54°, reported (20) m.p. 53–54°, was hydrogenated at atmospheric pressure in methanol solution with 5% palladium on charcoal. The hydrogenation was interrupted after one mole had been consumed. The catalyst was filtered and the solvent removed to give an oil which solidified at 0°. This was recrystallized twice from methanol at −20° to yield 180 mg (72%) crystals, m.p. 37–38°. Reported (21) m.p. 38–39°. The n.m.r. spectrum showed absorption at τ 2.8–3.3 (multiplet centered at τ 3.10, 10.0H) for the phenyl protons, at τ 6.06 (broad multiplet, 2.02H) for the benzylic protons, and at τ 7.57 (multiplet, 4.0H) for the methylene protons).

*trans-1,2-Diphenylcyclobutane (*trans*-**10**)*

A solution of 45 mg of *cis*-**10** and 100 mg potassium *t*-butoxide in 5 ml anhydrous dimethyl sulfoxide was heated on a steam bath for 15 min. The reaction mixture was diluted with water and the resulting mixture extracted with 10 ml carbon tetrachloride. The organic layer was dried and the solvent removed. The residue was distilled in a microdistillation apparatus to give 37 mg of an oil. Analysis by g.c. showed that no starting material (*cis*-**10**) or 1,4-diphenylbutane were present in the product. The n.m.r. spectrum showed absorption at τ 2.90 (singlet, 10.0H) for the phenyl proton, at τ 6.51 (multiplet, 1.9H) for the benzylic protons and at τ 7.25 (multiplet, 4.0H) for the methylene protons, in excellent agreement with the reported (21) n.m.r. spectrum.

Product Studies

All operations and reactions involving **1** were carried out using glassware which had been cleaned with a mixture (3:1) of concentrated sulfuric acid and nitric acid, rinsed several times with distilled water, soaked for several hours with dilute ammonium hydroxide solution, and finally dried at 130°.

Benzene-d_6 solutions 0.033 *M* in **1** were placed in n.m.r. sample tubes and degassed with 3 freeze–thaw cycles to 10^{-3} mm. The tubes were sealed and then heated at the appropriate temperature for 10 half-lives of decomposition. The n.m.r. spectra of the solutions were then taken and were found to be superimposable upon the spectrum of a benzene-d_6 solution of styrene, *cis*-**10** and *trans*-**10** present in the molar ratio 57.5:28.0:14.5 and in a concentration corresponding to 100% decomposition of **1**. No absorption attributable to the hydrazone, **9**, could be detected. Quantitative relative product yields were determined by analyzing the contents of the tubes by g.l.c. using temperature programming from 100 to 180° at 4°/min and a helium flow rate of 60 ml/min. The only products detected were styrene, *cis*-**10**, and *trans*-**10**. These were identified by comparison of their relative retention times with authentic samples. No trace of 1-phenyltetralin could be found at the time where authentic material was eluted. The product distributions, corrected using molar response factors, are given in Table II.

Determinations of the absolute product yields from the decomposition of **1** in benzene and in styrene were made on runs carried out as described above. After decomposition was complete a measured amount of chlorobenzene was added to each tube, the contents mixed, and analyzed by g.c. as above. The relative thermal response factors used are chlorobenzene, 100; styrene, 96; *cis*-**10**, 153; *trans*-**10**, 163. Solvent was then completely removed from the samples at reduced pressure and the residue was taken up in methanol. The amount

of hydrazone, **9**, present was estimated by measuring the absorbance of the methanol solutions at 285 mμ. The results are presented in Table III.

Kinetics of Decomposition of ***1***

The rates of nitrogen evolution from solutions of **1**, ca. 0.1 *M* in ethylbenzene, were measured using an apparatus and a procedure similar to that described by Petersen *et al.* (39). At 64.7° insufficient nitrogen was evolved and plots of log $(V_\infty - V_t)$ showed curvature after one half life. Rate constants were determined from the slopes of plots of log $(V_\infty - V_t)$ vs. time. For runs at 64.7° initial slopes and the theoretical values for V_∞ were used. The results are summarized in Table I.

Polymerization of Styrene in the Presence of ***1***

The rate of polymerization of styrene in the presence of **1** was measured by the dilatometric method described in the accompanying paper (24). The results are given in Table IV.

Control Experiments

A sample of *cis*-**10**, together with some diphenylmethane as an internal standard, was heated at 140° in a degassed benzene solution for 18 h. Analysis by g.c. of the solution after heating showed no change had taken place. No trace of styrene or of *trans*-**10** could be detected.

A sample of the hydrazone, **9**, was heated in benzene solution at 98° for 39 min. Analysis by g.c. after heating showed the presence of no materials other than the starting compound. Another sample of **9** was heated at 80° in ethylbenzene solution for 24 h in the apparatus used for measuring nitrogen evolution. No nitrogen was evolved.

Mechanism of initiation in the thermal polymerization of styrene. Kinetic deuterium isotope effects in the initiation step of the thermal polymerization of some deuterated styrenes[1,2,3]

KARL R. KOPECKY AND SYAMALARAO EVANI
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 12, 1969

A convenient synthesis of 2,6-dideuteriostyrene starts with *N*,*N*-dimethyl-(1-phenylethyl)-amine which is deuterated in the 2 and 6 positions by a series of exchanges using *n*-butyllithium followed by deuterium oxide. The deuterium isotope effects at 70° on the rates of the thermal polymerization, $\frac{R_{PH}}{R_{PD}}$, of 2,6-dideuterio-, α-deuterio-, and β,β-dideuteriostyrene are 1.29, 1.00, and 0.78, respectively. The deuterium isotope effects at 70° on the 2,2′-azobis-(2-methylpropionitrile) initiated rates of polymerization, $\frac{R'_{PH}}{R'_{PD}}$, are 0.96, 0.86, and 0.81, respectively. From these values the deuterium isotope effects on the rates of initiation of the thermal polymerization, k_{IH}/k_{ID}, are calculated to be 1.80, 1.31, and 0.92, respectively. At 147° the presence of 1.5% potassium *t*-butoxide decreases the rate of the thermal polymerization of neat styrene by a factor of 17, and results in the formation of 1-phenyltetralin as the greatly predominant dimer. The results support the suggestion that the thermal polymerization of styrene is initiated by hydrogen transfer from 1-phenyl-1,2,3,9-tetrahydronaphthalene, formed by a concerted dimerization of two molecules of styrene, to a third molecule of styrene.

Canadian Journal of Chemistry, 47, 4049 (1969)

Introduction

It has been known for a long time that pure styrene undergoes spontaneous polymerization at rates which are highly reproducible (1). This thermal polymerization can be inhibited by radical scavengers (2). An early proposal (3) that the polymerization was initiated by the formation of the 1,4-diphenyl-1,4-butadiyl diradical, eq. [1],

[1] $$2\ \underset{\displaystyle C_6H_5}{\overset{|}{CH}}{=}CH_2 \longrightarrow \dot{C}HCH_2CH_2\underset{\displaystyle C_6H_5}{\overset{|}{\dot{C}H}}$$

followed by the addition of monomer units to the diradical, was shown to be untenable by kinetic arguments (4) from which it was concluded that long chain polymer could result only from monoradical initiation. Also, it was shown (5, 6) that 3,6-diphenyl-3,4,5,6-tetrahydropyridazine, which decomposes thermally to give the 1,4-diphenyl-1,4-butadiyl diradical (6), is a very inefficient initiator of styrene polymerization as are other diradical sources (7). The thermal initiation step must be a reaction which involves only styrene molecules and which produces monoradicals. Several routes for the formation of monoradicals have been proposed. It has been shown that the radical forming reaction is third order in styrene (8, 9). This, coupled with the isolation of 1-phenyltetralin from the thermal polymerization of styrene in the presence of inhibitors (8, 10) led to the suggestion that the polymerization is initiated by monoradicals which are produced as shown in eqs. [2] and [3].

[2] 
[3] 
Another route for the formation of monoradicals which appears to be energetically feasible and consistent with the observed third order kinetics, provided that eq. [1] is reversible, is given by eq. [1] followed by eq. [4] (9). The reported lack of an isotope effect in the thermal

[4] $$\dot{C}HCH_2CH_2\underset{\displaystyle C_6H_5}{\overset{|}{\dot{C}H}} + \underset{\displaystyle C_6H_5}{\overset{|}{CH}}{=}CH_2 \rightarrow \dot{C}HCH_2CH{=}\underset{\displaystyle C_6H_5}{\overset{|}{CH}} + \dot{C}H\underset{\displaystyle C_6H_5}{\overset{|}{CH_3}}$$

polymerization of β,β-dideuteriostyrene (11) was taken as evidence against this mode of formation of monoradicals.

A bimolecular process, eq. [5], for the formation of monoradicals has also been proposed (12),

[5] $$2\ \underset{\underset{C_6H_5}{|}}{CH{=}CH_2} \rightarrow \underset{\underset{C_6H_5}{|}}{\dot{C}{=}CH_2} + \underset{\underset{C_6H_5}{|}}{\dot{C}HCH_3}$$

but this proposal was made before the kinetic order of the initiation reaction had become clarified (9).

All three proposals have in common the feature that a carbon–hydrogen bond is broken in the rate-determining step leading to monoradicals. The hydrogen atoms involved in the various proposals are those in the side chain and in the 2 and 6 positions of the ring. Intuitively, it would appear that these are the most likely hydrogen atoms to be involved in transfer processes. The purpose of the present study was to determine whether monoradicals are in fact produced by a process in which a carbon–hydrogen bond is broken in the rate-determining step and, if so, to identify the position(s) from which the transfer occurs. For this purpose β,β-dideuteriostyrene, α-deuteriostyrene, and 2,6-dideuteriostyrene were prepared and the kinetic deuterium isotope effect in the initiation step of the thermal polymerization of each of these monomers was determined.

When the experimental work described in this study had been largely completed two reports appeared describing the rates of the thermal polymerization of several ring deuterated and side chain deuterated styrenes (13). It was shown in one study (13*a*) that deuteration of the 2 and 6 positions of styrene resulted in a significantly decreased rate of thermal polymerization and that deuteration in the side chain slightly increased this rate. Similar results were obtained in the other study (13*b*) in the case of the side chain deuterated styrenes, but in contrast, the rate of the thermal polymerization of ring-d_5-styrene was found to be greater than that of normal styrene. The magnitude of the isotope effect in the initiation step of these polymerizations was not determined.

The Kinetic Method

Assuming a third order initiation step for the thermal polymerization of styrene the overall rate of thermal polymerization, R_P, is given by eq. [6] (3) in which $[M]$ is the monomer concentration

[6] $$R_P = k_p[M]^{5/2}(k_i/k_t)^{1/2}$$

and k_p, k_t, and k_i are the specific rate constants for the propagation, termination, and thermal initiation reactions, respectively. The kinetic deuterium isotope effect for the thermal initiation reaction, k_{iH}/k_{iD}, which is the quantity to be determined in this study, is given by eq. [7]. The

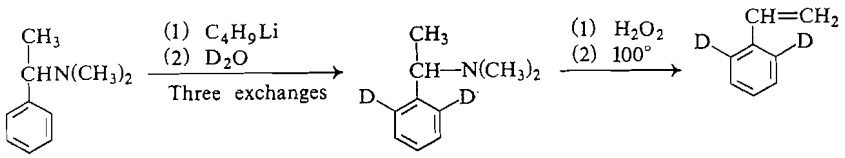
[7] $$k_{iH}/k_{iD} = \left(\frac{R_{PH}}{R_{PD}}\right)^2\left(\frac{k_{pD}k_{tH}^{1/2}}{k_{pH}k_{tD}^{1/2}}\right)^2\left(\frac{[M_D]}{[M_H]}\right)^5$$

kinetic parameters for the normal and deuterated styrenes are indicated by the subscripts H and D, respectively. The value of the middle term in eq. [7] can be determined from the ratio of the rates of the initiated polymerization of the deuterated and normal monomers, R'_{PD}/R'_{PH}, measured with identical initiator concentrations. This ratio, obtained from eq. [8] (14), is given in eq. [9], where

[8] $$R'_P = k_p[M]([I]fk_d/k_t)^{1/2}$$

[9] $$R'_{PD}/R'_{PH} = \left(\frac{k_{pD}k_{tH}^{1/2}}{k_{pH}k_{tD}^{1/2}}\right)\frac{[M_D]}{[M_H]} \times \frac{(k_d f[I])^{1/2}(\text{in deuterated styrene})}{(k_d f[I])^{1/2}(\text{in normal styrene})}$$

k_d is the specific rate constant for the decomposition of initiator, f is the fraction of radicals formed from the initiator which initiate polymer chains, and $[I]$ is the concentration of initiator. Since the rate of decomposition, k_d, of 2,2′-azobis-(2-methylpropionitrile), the initiator used in this study, is independent of solvent in similar solvents (15) the rates of its decomposition in deuterated and normal styrene would surely be equal. The rate of addition of 2-cyano-2-propyl radicals to normal styrene will probably differ from that to deuterated styrene (at least in the cases of the side chain deuterated styrenes). However, at low concentrations of initiator ($\sim 10^{-3}$ M) all radicals formed from the initiator which escape from the solvent cage will eventually add to monomer (16). Thus, under these conditions, the efficiency of initiation, f, will also be the same in deuterated as in normal styrene. If the rates of the initiated polymerizations of normal and deuterated styrene are measured under identical conditions of temperature and initiator concentrations eq. [10] can be obtained from eq. [9]. Equation [11], which results by combining eq. [7] with eq. [10], is an expression for the deuterium isotope effect of the



SCHEME 1

$$[10] \qquad \frac{k_{pD}k_{tH}^{1/2}}{k_{pH}k_{tD}^{1/2}} = \frac{[M_H]R'_{PD}}{[M_D]R'_{PH}}$$

$$[11] \qquad k_{iH}/k_{iD} = \left(\frac{R_{PH}R'_{PD}}{R_{PD}R'_{PH}}\right)^2\left(\frac{[M_D]}{[M_H]}\right)^3$$

initiation step of the thermal polymerization of styrene in terms of parameters which can be directly measured.

Deuteration will undoubtedly affect the rate of chain transfer, but this effect should be independent of any effect on the parameters in eq. [11].

Results

Preparation of Deuterated Styrenes

The side chain deuterated styrenes, α-deuteriostyrene and β,β-dideuteriostyrene, were prepared by pyrolysis of 1-deuterio-1-phenylethyl acetate and 1,1-dideuterio-2-phenylethyl acetate, respectively. Reduction of acetophenone and ethylphenylacetate by lithium aluminium deuteride provided the alcohols from which these esters were synthesized.

The preparation of 2,6-dideuteriostyrene, outlined in Scheme 1, is based upon the observation (17) that *N,N*-dimethylbenzylamine and related tertiary benzylic amines are readily metallated by *n*-butyllithium and that metallation occurs exclusively at the 2 position of the benzene ring. *N,N*-Dimethyl-(1-phenylethyl)-amine was treated in dry ether with *n*-butyllithium and deuterium oxide dispersed in benzene was added to the metallated amine. It was necessary to carry out the exchange three times in order to obtain product containing more than 90% dideuterioamine. Mass spectral analysis at low ionizing voltage (11 e.v.) shows that the product from the first exchange contains 5% undeuterated amine, 93% monodeuterio-, and 2% dideuterioamine, the product from the second exchange contains 2% undeuterated amine, 28% monodeuterio-, and 70% dideuterioamine, and the material from the third exchange consists of 0.6% undeuterated amine, 6.0% monodeuterio-, 91.4% dideuterio-, and 1.5% trideuterioamine. The nuclear magnetic resonance (n.m.r.) spectrum of the product of the third exchange shows that this material contains three aromatic protons. This shows, as was shown previously (17*a*), that essentially all the exchange took place in the benzene ring. The deuterium isotope effect for the metallation reaction is shown from these data to be 2.7.

The *N,N*-dimethyl-[1-(2,6-dideuteriophenyl)-ethyl]-amine obtained from the third exchange was converted to 2,6-dideuteriostyrene in 77% overall yield by conversion to and subsequent decomposition of its *N*-oxide (18). The mass spectrum taken at 12.5 e.v. shows that the product consists of 1.5% undeuterated styrene, 5% monodeuterio-, 92.7% dideuterio-, and 0.7% trideuteriostyrene. The n.m.r. spectrum of the product shows that it contains aromatic and vinyl protons in a 1:1 ratio, as required if the deuterium atoms are present in the benzene ring only. The aromatic protons of this material give a sharp singlet absorption peak in the n.m.r. spectrum, in contrast to those of normal and the other styrenes prepared which give a multiplet absorption peak.

Rates of Polymerization

The expression used to calculate the ratio, k_{iH}/k_{iD}, eq. [11], contains two terms of which the square of the product of four measured rates of polymerization will undoubtedly have the larger error. It is therefore necessary to measure these rates very accurately in order to keep the resulting uncertainty in k_{iH}/k_{iD} as small as possible. The rates of polymerization were followed by measuring the rate of decrease in the height of the meniscus of the degassed, pure monomer in a dilatometer of 6.7 ml capacity. This made possible the accurate measurement of rates with relatively small amounts of material per run and allowed recovery of unreacted monomer. In order to minimize errors further, all polymerization rates were measured using the same dilatometer. The rates of thermal polymerization were measured at 70° and were usually followed for about 12 h (ca. 2.5% polymerization). Runs for which plots

of the height of the meniscus versus time were not linear throughout were discarded. The initiated polymerizations, using 2,2′-azobis-(2-methylpropionitrile) as initiator, were also carried out at 70°. Details of the apparatus and rate measurements are given in the Experimental section.

The rates of thermal polymerization, Table I, of the synthetic styrenes prepared by the routes used to synthesize the various deuterated styrenes all fall within the range of rates obtained for the thermal polymerization of commercial styrene and show that no extraneous material which affects the rate of polymerization of styrene was formed in the syntheses. These rates of thermal polymerization of synthetic styrene were also used to obtain the overall average rate of the thermal polymerization of normal styrene. The results of Table I also show that reproducibility was maintained throughout the period during which the rate measurements were made since runs 5, 43, and 66, for example, which were carried out near the beginning, near the middle, and near the end of this period, respectively, agree very well. These rates are in reasonable agreement with the rate previously measured at 70° for the thermal polymerization of styrene, $R_P = 5.56 \times 10^{-6}\ M^{-1}\ s^{-1}$ (1*d*).

The rates of the thermal polymerization of the deuterated styrenes are also listed in Table I, together with the deuterium isotope effects on the overall rate of thermal polymerization, $\frac{R_{PH}}{R_{PD}}$, and with the deuterium isotope effects in the initiation step of the thermal polymerization, k_{iH}/k_{iD}. The latter ratio was obtained by combining the rates of the thermal polymerizations with the rates of the initiated polymerizations, Table II, according

to eq. [11]. The effects of deuteration on the rate of contraction of the polymerizing solutions are shown in Fig. 1 for the thermal polymerizations and in Fig. 2 for the initiated polymerizations. The results of the present study are compared in Table III with the results of previous studies on the rates of the thermal and initiated polymerizations of several deuterated styrenes.

As was observed previously (13*a*) styrene deuterated in the 2 and 6 positions undergoes thermal polymerization at a significantly slower rate than does normal styrene but the rate of the initiated polymerization is the same as that of normal styrene. On the other hand, deuteration in the β-position of styrene results in an increase in the rates of both the thermal and the initiated polymerizations. Deuteration in the α-position has little effect on the rate of the thermal polymerization but results in an increase in the rate of initiated polymerization. This last observation contrasts somewhat with previous work (13). However, the discrepancies which do exist in the data listed in Table III are very slight. In fact, the agreement between the various studies can be said to be remarkably good.

Discussion

The Radical Forming Step in the Thermal Initiation

Theoretical estimates of the maximum value of the secondary deuterium isotope effect range as high as 1.5 (20) and 1.74 (21). The deuterium isotope effect in the initiation step of the thermal polymerization of 2,6-dideuteriostyrene is calculated to be 1.80 ± 0.31. Taking into account the error this value falls within the realm of the theoretical maximum values for the secondary deuterium isotope effect. However, the maximum values observed experimentally for the secondary deuterium isotope effect (22–24) all lie below 1.3. On this latter basis it seems very improbable that the value of 1.80 ± 0.31 is a secondary deuterium isotope effect, and it is therefore quite likely that in the thermal polymerization of styrene the initiating monoradicals are formed in a process in which the carbon–hydrogen bond at the 2 or at the 6 position is broken in the rate determining step. This gives strong support to the suggestion (8) that the thermal initiation proceeds by way of eq. [2] and [3] where the transfer of the hydrogen atom at C-9 of the trienic styrene dimer, eq. [3], is rate determining. The magnitude of this isotope effect is rather small, although not unusually so (25), and can be accommodated on theoretical grounds (26).

The "true" isotope effect in the hydrogen transfer step, eq. [3], is probably different from that calculated on the basis of eq. [11]. Equation [11] gives a composite isotope effect made up of an isotope effect in the pre-equilibrium step, eq. [2], in addition to the isotope effect in the hydrogen transfer step, eq. [3]. In the case of 2,6-dideuteriostyrene, one would normally expect an inverse secondary deuterium isotope effect in the forward reaction of eq. [2] and a normal secondary deuterium isotope effect in the back reaction of eq. [2] (27). Experimental data which would test these predictions is very scanty. Small inverse secondary deuterium isotope effects of about 6% have been found in Diels–Alder reactions (28) and a small normal secondary deuterium isotope effect of about 7% has been found in a retro-Diels–Alder reaction (29). In each of these cases deuterium atoms were attached to the carbon atoms of the dienes which were undergoing a change of hybridization as is the case in eq. [2]. If secondary deuterium isotope effects of similar magnitude were operating in the reactions of eq. [2] then the "true" isotope effect in the hydrogen transfer step would be about 2.0 ($k_{iH}/k_{iD} \times k_{2D}/k_{2H} \times k_{-2H}/k_{-2D}$, where k_2 and k_{-2} are the specific rate constants for the forward and back reactions, respectively, of eq. [2]). If the magnitude of the secondary deuterium isotope effects in the reactions of eq. [2] were larger, then the "true" isotope effect in the hydrogen transfer step would be greater still.

However, not only is the magnitude of secondary deuterium isotope effects in cycloaddition reactions uncertain, recent evidence even puts into doubt predictions as to whether the effects will be normal or inverse. A relatively large *normal* secondary deuterium isotope effect of 1.23 was observed in the cycloaddition reaction between α-deuteriostyrene and diphenylketene (30). Therefore, a decision as to how much and in which direction the "true" isotope effect in the hydrogen transfer step, eq. [3], will differ from

the value of 1.80, calculated on the basis of eq. [11], cannot now be made.

The effect of deuteration in the side chain of styrene on the rate of thermal initiation is also interesting. During the reactions involved in the initiation step, eqs. [2] and [3], the hybridization of the β-C—H bonds changes from sp^2 to sp^3 in all three of the styrene molecules involved. It is surprising that no significant secondary deuterium isotope effect results. A larger inverse secondary deuterium isotope effect might be expected (27, 31). At any rate the results indicate that the β-hydrogens are not involved in the radical forming process. Such a change in hybridization occurs in the α-C—H bond of only one of the three styrene molecules involved in the initiation steps, and a significant normal secondary isotope effect results. As pointed out above, the reactions are complex and it is difficult to rationalize these secondary deuterium isotope effects.

Further Support for the Trienic Intermediate

If the monoradicals which initiate the thermal polymerization of styrene are formed by eqs. [2] and [3], it might be possible to convert the reversibly formed trienic dimer to 1-phenyltetralin with a strong base, such as potassium *t*-butoxide, eq. [12], and thereby reduce the rate of the thermal polymerization. Such an experiment has already been carried out (32). Stabilized styrene containing 1.5% potassium *t*-butoxide was heated under reflux for 24 h. Styrene was recovered in 46% yield and 5.5% of 1-phenyltetralin was isolated. We have repeated this experiment, primarily to determine whether any 1,2-diphenylcyclobutane (6) was present in the dimeric product, using styrene freed from stabilizer. Again, considerable, 55%, styrene was recovered and 1-phenyltetralin was obtained in 5% yield. Only trace amounts, less than 0.01%, of *cis*- and *trans*-1,2-diphenylcyclobutane, in about a 1:3 ratio, were formed.

[12] 
No more than 40% of the styrene polymerized in the presence of base under these conditions. This corresponds to a rate of polymerization of less than 1.7% per hour. At 127° pure styrene polymerizes at a rate of 14% per hour (33), and at the reflux temperature (~ 140°) this rate would be at least 30% per hour (1*c*). The presence of 1.5% potassium *t*-butoxide reduces the thermal rate of polymerization by a factor of at least 17. It is unlikely that *t*-butoxide would terminate a growing polymer radical once it was formed. An attractive mode for the retardation is that *t*-butoxide diverts an intermediate responsible for the formation of radicals, namely, the triene as shown in eq. [12].

Formation of the Triene

It now appears certain that the 1,4-diphenyl-1,4-butadiyl diradical, eq. [1], is not directly involved in the initiation of the thermal polymerization of styrene. It may, however, be indirectly involved, affording a route to the triene, eq. [13] (34). The thermal formation of diphenylcyclobutane from styrene has been reported a number of times (8, 10, 34, 35). This is unlikely to be a concerted reaction (36) and may be taken as evidence for the intermediate formation of the diradical.[4] It has been shown that the diradical, when formed from the corresponding cyclic azo compound, does give diphenylcyclobutane in appreciable yield (6). The conformation which would be required for the diradical in order for it to close to form the triene must be similar to that required in order for it to form the diphenylcyclobutane. This makes it unlikely that the diradical would be formed in a conformation which could form the triene without also forming a considerable amount of diphenylcyclobutane. Since a great majority of the triene molecules, once formed, must revert to styrene (8, 9), it follows that a considerable fraction, at least, of the dimeric material formed during the thermal polymerization of styrene would have to be diphenylcyclobutane if the triene were formed by

[13] [14] 
[4]There is good evidence that diradicals are intermediates in a number of other thermal cycloaddition reactions (37).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

way of the diradical, eq. [13]. This is not observed (8, 10, 34, 35). Even in neat styrene, where a minimum amount of the triene would be diverted by extraneous materials (8, 34) to 1-phenyltetralin, resulting in the most favorable diphenylcyclobutane:1-phenyltetralin ratio, this ratio is only about 1:5[5] (35). This supports the original suggestion (8, 10) that the triene and the diphenylcyclobutane are formed by different reactions, eqs. [13] and [14], respectively. A reasonable route to the triene is the thermally allowed Diels–Alder reaction between two styrene molecules.

Experimental

Boiling points and melting points are uncorrected. Refractive indices were measured on a Bausch and Lomb Abbe-3L Refractometer. Infrared spectra (i.r.) were recorded on a Beckman IR-7 Recording Spectrophotometer. The n.m.r. spectra were obtained with a Varian Analytical Spectrophotometer, Model A-60. Ca. 10% v/v solutions in carbon tetrachloride were used. Tetramethylsilane was used as the internal standard. Mass spectra were obtained with an A.E.I. MS-2-H mass spectrometer. Gas chromatography (g.c.) was carried out on an Aerograph-202 Gas Chromatograph. A 5 ft × 1/4 in. column packed with 20% SF-96 on 60/80 Chromosorb P was used.

Materials

Commercial styrene was shaken 3 times with cold 10% sodium hydroxide solution, with saturated aqueous sodium chloride until free from alkali, dried over magnesium sulfate, and then distilled. A middle cut was collected, b.p. 44–45° (20 mm), n_D^{27} 1.5435.

Commercial 2,2′-azobis-(2-methylpropionitrile) was recrystallized twice from acetone–Skelly B and stored in the dark over phosphorous pentoxide, m.p. 101–102° (decomposition).

α-Deuteriostyrene

The alcohol, 1-deuterio-1-phenylethanol, was prepared by the reduction of acetophenone with lithium aluminium deuteride (38) b.p. 63–65° (6 mm), n_D^{29} 1.5230; reported (38) b.p. 79° (23 mm), n_D^{24} 1.5267. This material was acetylated (39) to give 86% of 1-deuterio-1-phenylethyl acetate, b.p. 91–92° (8 mm). This acetate (57 g) was pyrolyzed (40) at 400° to α-deuteriostyrene (27 g, 77%), b.p. 55° (28 mm), n_D^{27} 1.5425; reported (38) b.p. 76° (82 mm), n_D^{24} 1.5435. The n.m.r. spectrum agrees very well with that reported (41) for this material and shows no extraneous peaks. Mass spectral analysis (42) using an ionizing voltage of 11 e.v. shows that the product consists of 1.2% undeuterated styrene, 98.5% monodeuterio-, and 0.2% dideuteriostyrene. It was stored in degassed, sealed ampoules at −20°.

β,β-Dideuteriostyrene

Ethyl phenylacetate (49.2 g) was reduced with a slight excess of lithium aluminium deuteride to 1,1-dideuterio-2-phenylethanol (33.5 g, 90%), b.p. 103° (12 mm), n_D^{29} 1.5279; reported (11) b.p. 91–93° (8 mm), n_D^{25} 1.5269. This product was acetylated (39) in 94% yield to 1,1-dideuterio-2-phenylethyl acetate, b.p. 93° (7 mm), n_D^{29} 1.4962; reported (11) b.p. 122–123° (26 mm). Pyrolysis (40, 11) of this acetate (36 g) gave β,β-dideuteriostyrene (11.3 g, 50%), b.p. 53–54° (30 mm), n_D^{25} 1.5438; reported (11) b.p. 54° (31 mm). Mass spectral analysis (42) using an ionizing voltage of 11.5 e.v. shows that the product consists of 1.1% undeuterated styrene, 1.6% of monodeuterio-, and 97.3% of dideuteriostyrene.

N,N-Dimethyl-[1-(2-deuteriophenyl)-ethyl]-amine

This procedure is a slight modification of that used for the deuteration of *N,N*-dimethylbenzylamine (17*a*).

N,N-Dimethyl-(1-phenylethyl)-amine (43) b.p. 84° (20 mm), n_D^{29} 1.4980; reported (43) b.p. 71° (11 mm), n_D^{25} 1.5000, 44.7 g (0.3 mole) in 40 ml anhydrous ether was treated with a 1.6 *M* solution of *n*-butyllithium in hexane, 360 ml (0.6 mole). The resulting solution was stirred for 36 h and then added to a suspension of 48 ml deuterium oxide in 250 ml dry benzene. The resulting mixture was stirred for 6 h and then allowed to settle. The clear top layer was decanted from the white sludge and the sludge washed 3 times with 50 ml ether. The combined organic solutions were dried over sodium sulfate, concentrated, and the residual oil distilled to give 42.3 g (94%) of a colorless liquid, b.p. 73° (13 mm), n_D^{29} 1.4986. The i.r. spectrum (neat) of the product shows a strong absorption band at 2270 cm^{-1}. The n.m.r. spectrum shows absorption at τ 2.82 (singlet 4.03H) for the phenyl protons, at τ 6.86 (quartet, J = 7 Hz, 1.03H), for the methine proton, at τ 7.87 (singlet, 5.93H) for the protons of the *N*-methyl groups and at τ 8.71 (doublet, J = 7 Hz, 2.9H) for the protons of the 1-methyl group. Mass spectral analysis (42) using an ionizing voltage of 11 e.v. shows that the product consists of 5% undeuterated amine, 93% monodeuterio-, and 2% dideuterioamine.

N,N-Dimethyl-[1-(2,6-dideuteriophenyl)-ethyl]-amine

Repetition of the exchange reaction described above using 40 g of the monodeuterated amine gave 37.5 g (94%) of product. Mass spectral analysis using an ionizing voltage of 11 e.v. indicates that this product consisted of 2% undeuterated amine, 28% monodeuterio-, and 70% dideuterioamine. This material was again subjected to the exchange reactions from which 34 g (92.5%) of product was obtained, b.p. 97° (50 mm), n_D^{29} 1.4975. The n.m.r. spectrum of this product shows absorption in exactly the same places as does that of the monodeuterioamine, above, but the ratio of the areas for these absorptions is now 2.98:1.0:6.0:3.1. Mass spectral analysis (42) using an ionizing voltage of 11 e.v. shows that the product consists of 0.6% undeuterated amine, 6.0% of monodeuterio-, 91.4% of dideuterio-, and 1.5% of trideuterioamine.

2,6-Dideuteriostyrene

The above dideuterioamine (30 g) was converted (18) to the amine oxide which was, in turn, decomposed at 100° (18) to give 16.3 g (76.8%) of the styrene, b.p. 63° (48 mm), n_D^{27} 1.5419. The n.m.r. spectrum shows that the ratio of the aromatic to the vinyl protons is 1.0:1.0.

[5]Diphenylcyclobutane is thermally stable at the temperature used in this experiment (6).

TABLE IV

Density, molarity, and C for some styrenes at 70°

Styrene	D, g/cc	$[M]$, moles/l	$C = \frac{2[M]\,AD\,\mathrm{d}X}{100\,\mathrm{d}D}$
Normal	0.860	8.26	0.728
α-d	0.866	8.23	0.730
β,β-d_2	0.871	8.20	0.732
2,6-d_2	0.872	8.21	0.733

The aromatic protons in this compound appear as a sharp singlet in the n.m.r. spectrum. Mass spectral analysis (42) using an ionizing voltage of 12.5 e.v. shows that the product consists of 1.6% undeuterated styrene, 5.0% monodeuterio-, 92.7% dideuterio-, and 0.7% trideuteriostyrene. The product was stored in degassed, sealed ampoules at −20°.

Polymerization Rate Measurements

The rates of polymerization were determined by measuring the rate of decrease in the height of the meniscus of the monomer in the capillary of a dilatometer. The dilatometer had capillaries 15 cm long made of precision bore tubing 1.0 mm in diameter and was similar in design to one described by Bartlett (44) except that the monomer reservoir was on the same side as the volume cell. The volume of the dilatometer, up to an arbitrary mark in the capillary, was 6.748 ml.

The procedure used for the measurement of the thermal rates of polymerization is as follows. Monomer was introduced into a storage reservoir on a high-vacuum line and degassed to 10^{-4} mm with 4 freeze-thaw cycles. From this reservoir the monomer was distilled into the reservoir of the dilatometer which had been sealed to the vacuum line.[6] The monomer was again degassed to 10^{-4} mm with two more freeze-thaw cycles. The dilatometer was then sealed off and tilted to allow the monomer to flow into the volume cell. The volume cell was filled to a mark chosen such that when the dilatometer was heated to 70° the meniscus would be near the arbitrary mark near the top of the capillary. The dilatometer was then completely immersed in a constant temperature bath which was maintained at 69.96 ± 0.02° throughout with the aid of two high-speed stirrers. The height of the meniscus in the capillary was measured with a precision cathetometer. Readings were taken at about 1/2 h intervals for about 12 h except for the runs using β,β-dideuteriostyrene, which were terminated after 8 h. After 12 h the rates of contraction of the solutions began to decrease noticeably. After completion of a run using a deuterated styrene the unreacted monomer was distilled and stored in degassed, sealed ampoules at −20°. After each run the dilatometer was drained, filled with distilled benzene, and placed in a warm bath for 1/2 h. This was repeated twice more. It was then rinsed 4 times with distilled acetone, several times with distilled water, and dried at 110°. After every second run the dilatometer was, after the above rinsings, filled with a warm 3:1 concentrated sulfuric acid:concentrated nitric acid solution, allowed to stand 1/2 h, drained, rinsed several times with water, and filled with dilute ammonium hydroxide solution. After standing for 2 h the dilatometer was drained, rinsed several times with water, and dried.

The procedure used in the case of the initiated runs was as follows: A weighed amount of the initiator, 2,2′-azobis-(2-methylpropionitrile), was added to a weighed amount of freshly distilled monomer. This solution was transferred into the dilatometer reservoir and degassed to 10^{-4} mm pressure with 4 freeze-thaw cycles. The solution was protected from the light. The remainder of the procedure is the same as that described for the thermal rates except that during the rate runs readings were taken about every 300 s for about 1.5 h.

The rate of polymerization, R_P, was calculated from the expression $R_P = \frac{C\,\mathrm{d}h}{V\,\mathrm{d}t}$ where C is a constant for each monomer and equal to $\frac{2[M]AD\,\mathrm{d}X}{100\,\mathrm{d}D}$. V is the volume of the polymerizing solution, $[M]$ is the monomer concentration, t is the time, h is the height of the meniscus in the capillary, A is the cross-sectional area of the capillary, X is the mole percent of polymer in the solution, and D is the density of the solution. A linear relationship exists between the density and the mole percent polymer for dilute solutions of polystyrene in styrene and $\mathrm{d}X/\mathrm{d}D$ at 70° has the numerical value 682 (1d). The same value of $\mathrm{d}X/\mathrm{d}D$ was used for the deuterated styrenes. The densities of the deuterated styrenes were measured with the dilatometer. The dilatometer, containing a known volume at 70° of the deuterated styrene, was carefully cleaned and weighed after a thermal kinetic run. The seal was broken carefully, the dilatometer drained, cleaned, dried, and weighed together with the broken seal. Table IV lists the values of the density, molarity, and the constant C determined for each of the monomers.

Potassium t-Butoxide Inhibited Polymerization of Styrene

A solution of 7.4 g of the potassium t-butoxide–t-butyl alcohol complex (32) in 208 g styrene was heated under reflux (140°) under an atmosphere of nitrogen for 24 h. The unreacted styrene, which was flash distilled under vacuum, weighed 119 g (55%). The thick residue was dissolved in benzene and the polymer precipitated from the resulting solution with methanol. The clear solvent was drained from the precipitated polymer which was then kneaded with several fresh portions of methanol. The combined solutions were concentrated to an oil which was then diluted with ether. The solid which

[6]Highly erratic rates were obtained if the dilatometer was attached to the vacuum line with a greased ground glass joint.

For personal use only.

precipitated was filtered and the filtrate was concentrated. The residual oil was distilled to give 10.5 g of product, b.p. 154–163° (8 mm). This was shown by g.c. to consist of 96% 1-phenyltetralin, traces (less than 0.1%) of *cis*- and *trans*-1,2-diphenylcyclobutane, in about a 1:3 ratio, and about 4% of several other unidentified materials which were eluted both before and after 1-phenyltetralin. Under the g.c. conditions used, column temperature 220°, gas flow 80 ml/min, the elution times for authentic *cis*- and *trans*-1,2-diphenylcyclobutane (6) and 1-phenyltetralin were 13.4 min, 15.2 min, and 16.6 min, respectively. The i.r. and n.m.r. spectra of the product were superimposable with those of authentic (32) 1-phenyltetralin. The *cis*- and *trans*-1,2-diphenylcyclobutanes were identified solely on the basis of their retention times.

Hydrogenolysis by $LiAlH_4$–$AlCl_3$ of an ether solution of norcamphor isobutylene ketal[1]

P. C. Loewen, W. W. Zajac, Jr.,[2] and R. K. Brown
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received March 14, 1969

An approximately 1:1 mixture of the two isomers (**3** and **4**) of norcamphor isobutylene ketal was hydrogenolyzed by AlH_2Cl in ether at room temperature. The slow reaction (62% complete in 20 h; ~96% complete in 168 h) produced only 1-(2-*endo*-norbornyloxy)-2-methyl-2-propanol (**7**), 2-(2-*exo*-norbornyloxy)-2-methyl-1-propanol (**6**), 2-*exo*-norborneol (**10**), and unchanged **3** and **4** in the proportion 64.5:26.5:4.5:4.5. Recovery of materials was at least 95%.

Compound **10** is believed to arise from slow hydrogenolysis of the product **6**. Since the unreacted ketal was still an approximately 1:1 mixture of the isomers **3** and **4**, and because it is known that in the hydrogenolysis of acetals and ketals, the reduction by hydride donation is much faster than is the isomerization of the ketals, it is inferred that the two isomers (**3** and **4**) of norcamphor isobutylene ketal hydrogenolyze at approximately the same rate.

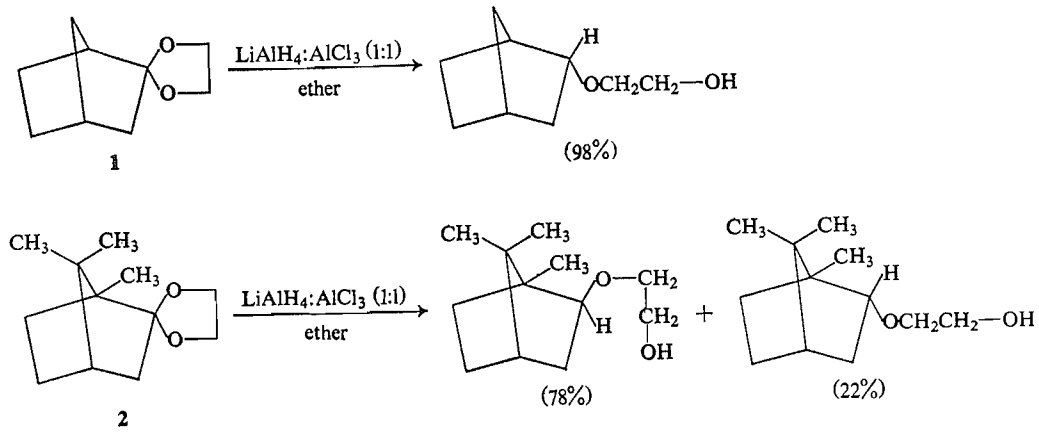
Arguments are presented to support the view that isomer **4** reacts with *two* molecules of AlH_2Cl, one as the Lewis acid and the other as the hydride donor, to provide product **7** and possibly some of product **6**, while isomer **3** reacts with *one* molecule of AlH_2Cl, which acts as the Lewis acid and the hydride donor, to provide most if not all of product **6** and some of product **7**.

Canadian Journal of Chemistry, 47, 4059 (1969)

Introduction

Recent work from this laboratory (1) has shown that lithium aluminum hydride–aluminum chloride reductive cleavage of norcamphor ethylene ketal (**1**) gave 2-(2-*endo*-norbornyloxy)-ethanol in 98% yield whereas similar reduction of camphor ethylene ketal (**2**) gave both 2-(2-isobornyloxy)ethanol and 2-(2-bornyloxy)-ethanol in 78% and 22% yield respectively (Scheme 1). These products were considered to be the result of steric approach control.

The question concerning the detail of the reductive cleavage, as to whether it took place via route *a* (Scheme 2) involving *both* Lewis acid attack of the reactive reducing species AlH_2Cl (2,3) *and* hydride donation by the same molecule,



Scheme 1

or via route *b* (Scheme 2) in which one molecule of AlH_2Cl played the part of the Lewis acid while a second molecule donated the hydride ion, could not be answered (1). However, considering the results of the hydrogenolysis of camphor

[1]Taken in part from the thesis of P. C. Loewen submitted to the Faculty of Graduate Studies, University of Alberta, Edmonton, Alberta, as part of the requirements for the degree of Doctor of Philosophy.

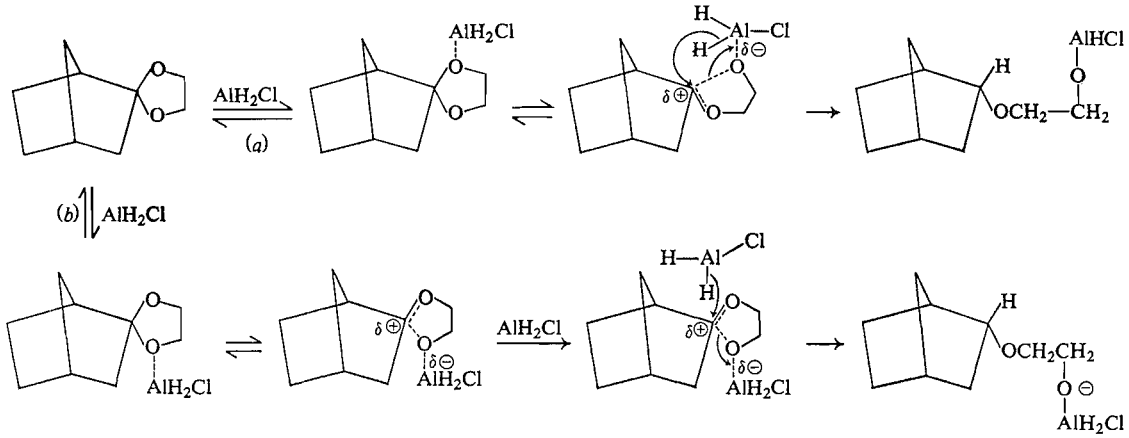
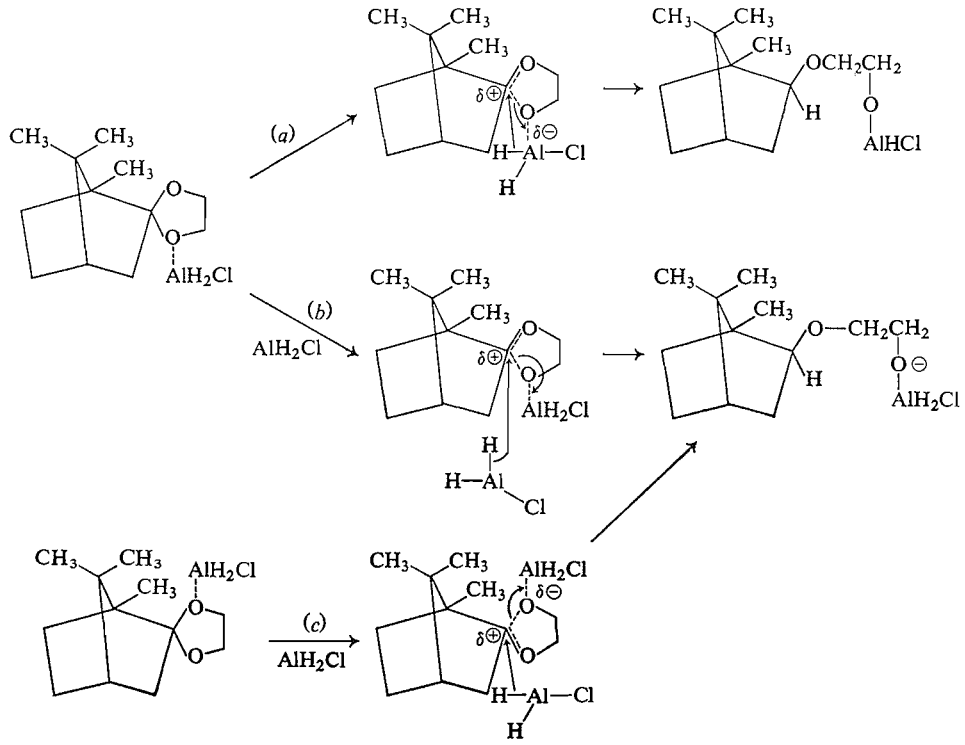


SCHEME 2



SCHEME 3

ethylene ketal, for the formation of the major product (78% yield), route *a* (Scheme 3) involving the dual function of the same molecule of AlH_2Cl would seem from a steric point of view to be more reasonable than routes *b* and/or *c* which involve two molecules of AlH_2Cl. As yet a suitable system for a kinetic study of this reaction has not been devised.

We have now examined the hydrogenolysis, by AlH_2Cl, of the isomeric norcamphor isobutylene ketals, **3** and **4**, in order to obtain more information concerning this question. The reason

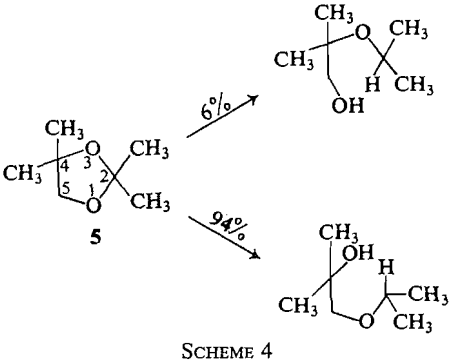
3 4

for the choice of this particular ketal stemmed from some previous work (4) in this laboratory in which it was found that hydrogenolysis of 2,2,4,4-tetramethyl-1,3-dioxolane (**5**) did not cleave the O_1—C_2 bond as expected on the basis of the inductive effects of the C-4 methyl groups (5), but instead gave nearly total cleavage (94%) of the O_3—C_2 bond of the ketal (Scheme 4).[3] This anomalous cleavage was interpreted as being due to a steric repression in the intermediate oxocarbonium ion resulting from O_1—C_2 bond cleavage, such steric repression being minimal or absent in the oxocarbonium ion which arises due to O_3—C_2 cleavage.



SCHEME 4

It is seen that both **3** and **4** possess the same structural feature as is found in 2,2,4,4-tetramethyl-1,3-dioxolane (Scheme 4). One would then expect, on the basis of the results of the hydrogenolysis of the tetramethyl-1,3-dioxolane, that both **3** and **4** would hydrogenolyze preferentially by cleavage of the C_2—$O_{3'}$ bond. However, the work on the norcamphor ethylene ketal (1) shows that the favored approach of the reducing agent is to the *exo* side. This would result in preferential cleavage of the C_2—$O_{3'}$ bond in **3** and the C_2—$O_{1'}$ bond in **4**, thus forming the *endo*-norbornyloxy compound. It was thus of interest to find out how these two directive systems behaved in the hydrogenolysis of **3** and **4**.

[3]E. L. Eliel *et al.* (14) have also reported that the mixed hydride hydrogenolysis of cyclohexanone isobutylene ketal produces exclusively that product which is the tertiary alcohol.

Results and Discussion

Preparation of Compounds

The norcamphor isobutylene ketals were prepared by the acid catalyzed reaction of norcamphor with isobutylene glycol. The product of this reaction was no doubt an equilibrium mixture of the isomers **3** and **4**. The elemental analysis agreed well with that expected for these isomers. The 60 MHz nuclear magnetic resonance (n.m.r.) spectrum in $CDCl_3$ (Fig. 1) shows the presence of two isomers. It is expected that for each isomer the methylene protons of the 1,3-dioxolane portion of the ketal should provide a simple AB quartet and these signals should appear in the portion of the spectrum, between τ 6.0 and 7.0 where protons attached to carbon atoms which are in turn attached to an ether oxygen are known to absorb. Since the multiplet lying between τ 6.2 and 6.6 is not a simple quartet, it is clear that more than one isomer must be present. From the 100 MHz n.m.r. spectrum, expanded to show these signals more clearly (see inset, Fig. 1), it is seen that the multiplet between τ 6.2 and 6.6 is due to two overlapping quartets. The areas under the two sets of peaks are in the approximate ratio of 45:55 (i.e. nearly 1:1).

The gas liquid chromatogram (g.l.c.) of this mixture of isomers gave a single peak which showed no evidence whatsoever of the presence of two isomers. All attempts to separate these, either by careful fractional distillation with a spinning band column, or by using a variety of g.l.c. columns, among which were those containing butanediol succinate, carbowax, silicone rubber, or Apiezon L on Gas-Chrom W, were quite ineffective. This was a serious handicap, since the solution of this problem would have been greatly facilitated had the two pure isomers been individually available. Accordingly, there was no way of determining which of the two isomers was in the greater abundance.

Of the four possible reduction products of **3** and **4** (Scheme 5), only the tertiary alcohols **7** and **8** were successfully prepared. These were made by the reaction of 2-*exo*- and 2-*endo*-norborneol with ethyl bromoacetate by the method of Leffler and Calkins (6), followed by treatment of the product with methymagnesium bromide. That both of these compounds, **7** and **8**, were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

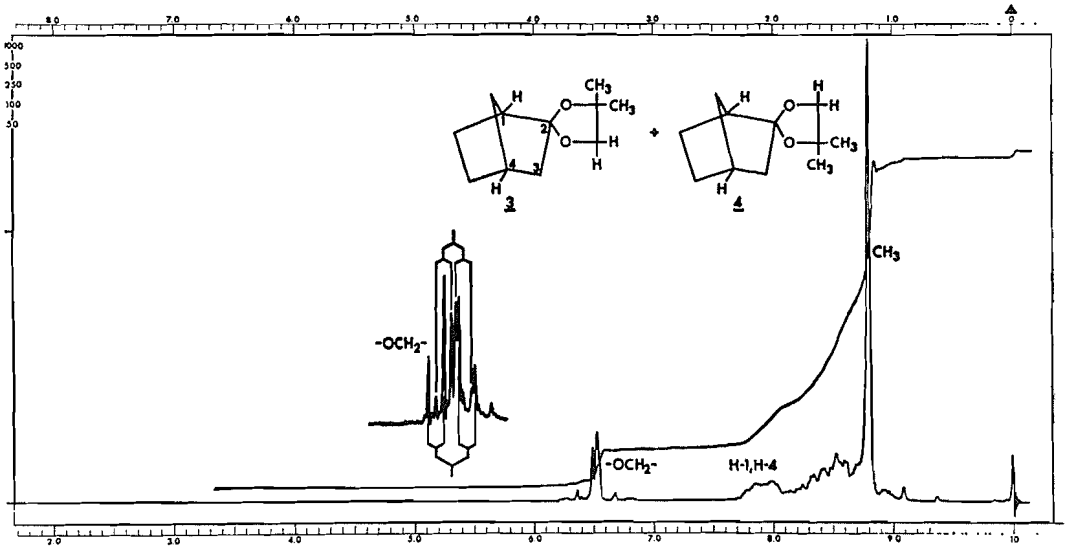

FIG. 1. The 60 MHz n.m.r. spectrum of the equilibrium mixture of the two isomeric norcamphor isobutylene ketals **3** and **4**; reference, tetramethylsilane. The inset is a partial 100 MHz n.m.r. spectrum, showing the two overlapping AB quartets of the two geminal protons of the methylene group in the dioxolane ring.

tertiary alcohols was verified by their infrared (i.r.) spectra, which showed a band for hydroxyl group absorption, and by their n.m.r. spectra in dimethyl sulfoxide-d_6 (DMSO-d_6) which showed the signal for the hydroxyl proton shifted downfield from τ 7.75 (in $CDCl_3$) to 5.85 as a sharp singlet (8). The *exo* and *endo* isomers could be distinguished by a characteristic feature indicated in our previous work (1). The signals for the bridgehead protons (C-1 and C-4) of the *endo* isomer, **7**, appear as *two* unresolved closely spaced multiplets ($W/2 \sim 10$ Hz and $W/2 \sim 12$ Hz) centred at τ 7.65 and 7.85 respectively in the spectrum in DMSO-d_6 (Fig. 2) whereas the spectrum of the *exo* isomer in the same solvent shows only *one* closely spaced unresolved multiplet at τ 7.8 ($W/2 \sim 10$ Hz)(Fig. 3).

All attempts to prepare the primary alcohols, **6** and **9**, met with failure. However, this did not interfere seriously with the identification of the products of hydrogenolysis of **3** and **4**.

Hydrogenolysis of 3 and 4

The hydrogenolysis of the mixture of the two isomers (**3** and **4**) of norcamphor isobutylene ketal was carried out according to published directions (7) using an equimolar mixture of $LiAlH_4$ and $AlCl_3$ in dry diethyl ether. The

results of the hydrogenolysis are assembled in Table I.

Each of the products of hydrogenolysis was collected by preparative g.l.c. and identified with the aid of elemental analysis, a g.l.c. retention time and n.m.r. spectrum, and by comparison with these characteristics of authentic specimens of compounds **10** and **7**. The structure of the primary alcohol **6** obtained from the hydrogenolysis was determined by its elemental analysis, i.r. spectrum and particularly the n.m.r. spectrum in DMSO-d_6 (Fig. 4). The latter spectrum showed the hydroxyl proton signal shifted downfield from a broad singlet in $CDCl_3$ at τ 7.85 to a triplet (J = 6 Hz) centred at τ 5.6 which is indicative of a primary alcohol (8). The spectrum also showed one closely spaced unresolved multiplet ($W/2 \sim 12$ Hz) centred at

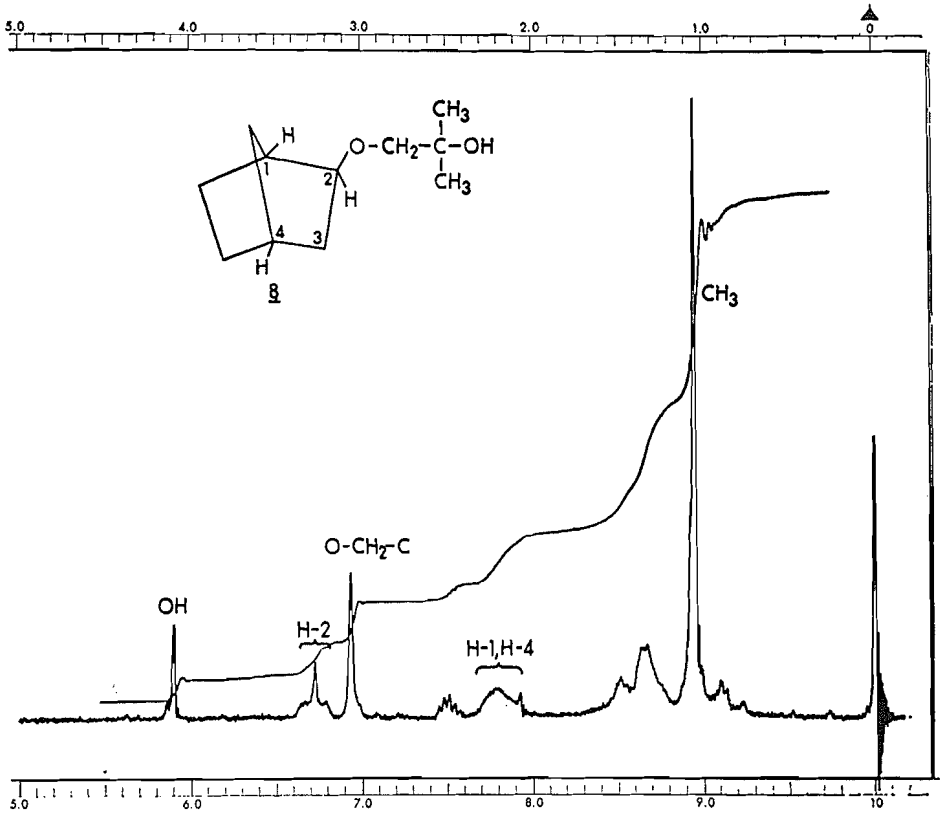

FIG. 3. The 60 MHz spectrum of synthetic 1-(2-*exo*-norbornyloxy)-2-methyl-2-propanol (8) in dimethylsulfoxide-d_6.

τ 7.92 indicative of the signals for the bridgehead protons when an *exo* substituent is present (1).

The n.m.r. spectrum of the recovered unreacted ketal mixture **3** and **4**, obtained after 20 h of reduction, was clearly identical to the n.m.r. spectrum of the starting isomeric mixture. This indicates that *either* the rate of hydrogenolysis of both isomers is practically the same, *or* that one isomer, **3** or **4**, might be reduced more rapidly, but the rate of isomerization of the unreduced material, under the reaction conditions, is sufficiently greater than the rate of reduction that maintenance of an equilibrium mixture of **3** and **4** is ensured. Work recently reported (9) has shown that when both *cis*- and *trans*-2,4-dimethyl-1,3-dioxolane were hydrogenolyzed separately and under identical conditions, but with sufficient $LiAlH_4$–$AlCl_3$ to reduce only half of the dioxolane, no significant isomerization of the unreacted *cis* or *trans* isomers had occurred. This supported the view that the slow, rate-determining step of the reaction was indeed the C_2—O bond breaking, leading to the formation (or incipient formation) of the intermediate oxocarbonium ion, and that subsequent (and nonreversible) reduction by hydride donation to this oxocarbonium ion was very much faster than was isomerization (Scheme 6).

Unfortunately, because we were unable to separate the isomers **3** and **4**, it was not possible to ascertain, by partial hydrogenolysis, whether isomerization of the starting isomer **3** or **4** did or did not occur. However it is not unreasonable to assume that, as in the case of the *cis*- and *trans*-2,4-dimethyl-1,3-dioxolanes, reduction by hydride donation here is also much faster than C—O bond cleavage to form the intermediate oxocarbonium ion. Accordingly, the following discussion is based on the acceptance of this view.

Several points are quite clear. (*i*) If indeed there is no significant isomerization of the unreacted isomers **3** or **4**, then from the knowledge

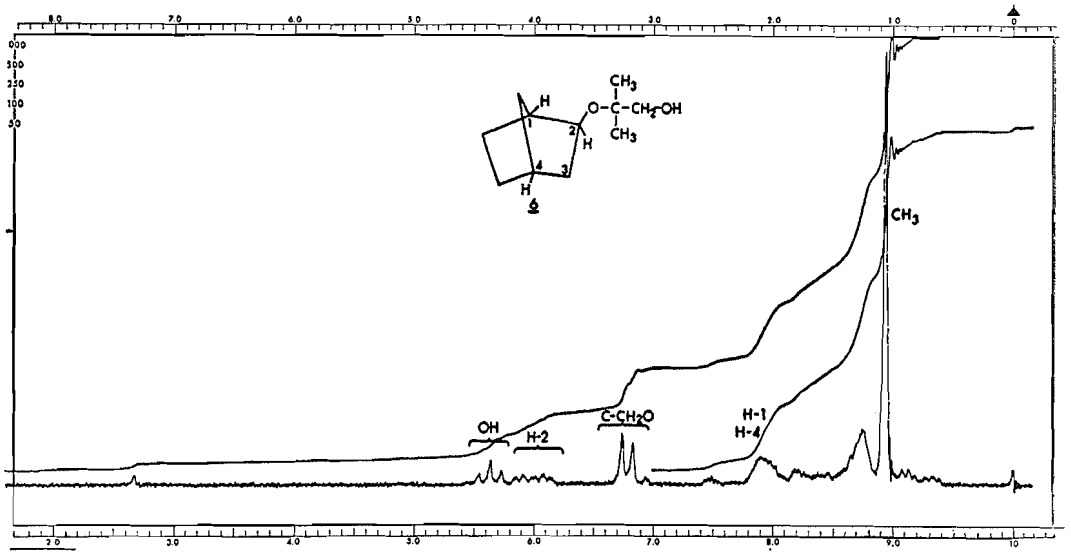

FIG. 4. The 60 MHz n.m.r. spectrum of one of the products from the AlH_2Cl hydrogenolysis of the equilibrium mixture of the two isomeric norcamphor isobutylene ketals **3** and **4**.

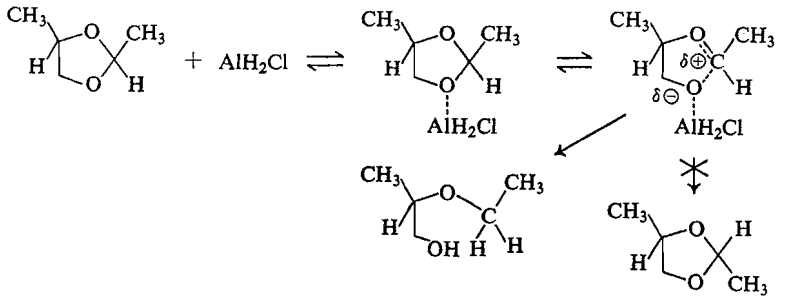

SCHEME 6

that the ratio of the products **7** to **6** is 64.5 to 26.5, it can be inferred that each of the two isomers **3** or **4** does not reduce specifically to one of the products. If this had been so, then the product ratio would also have been 55:45 (or 45:55), the same as that found for the original material. It is however quite possible that one isomer **3** (or **4**) could produce essentially the product **7**, while the other isomer **4** (or **3**) would then provide both **7** and **6**. (*ii*) Since a substantial amount (26.5%) of the product is the primary alcohol **6**, the steric restriction (4) which strongly retarded the C_2—O_1 bond breaking of **5** (Scheme 4) could not have been as important in retarding the C_2—O_1, bond cleavage in **3** and/or **4**. Some factor must then retard the alternate C_2—O_3, bond cleavage sufficiently to allow C_2—O_1, bond cleavage to become competitive to the extent of 26.5% (four times as much as was found for **5**). (*iii*) From the work on norcamphor ethylene ketal (1) it is also clear that approach of the reducing species to C-2 of structures **3** and **4**, from the *exo* side is preferred to approach from the *endo* side. However, if structural features are present which inhibit approach from the *exo* side, then *endo* attack by the reducing agent becomes competitive and important as shown by the hydrogenolysis of camphor ethylene ketal (1). (*iv*) It is also quite certain that for hydrogenolysis of the acetals or ketals to occur at all, the Lewis acid property of the reducing species, AlH_2Cl, must be involved, and the particular C—O bond which is broken is that in which the Lewis acid is associated with the oxygen atom.

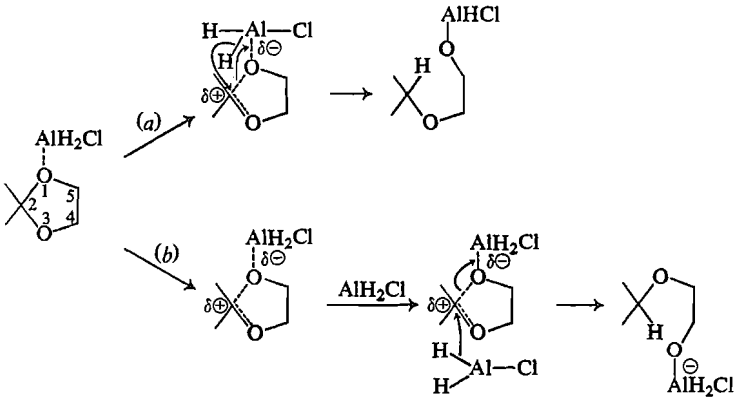

SCHEME 7

A point which has not been determined to date is whether the molecule which acts as the Lewis acid is also the one which donates the hydride ion (route *a*, Scheme 7). If this is so then the hydride ion will enter on the same side of the C-2 carbon atom of the 1,3-dioxolane as that from which the oxygen atom leaves, and thus the stereochemistry of the C-2 carbon is maintained. On the other hand, it is possible that one molecule of AlH_2Cl acts as the Lewis acid while a second molecule provides the hydride ion (route *b*, Scheme 7). If this is so, then the hydride ion will enter on the side of C-2 opposite to that from which the oxygen atom leaves, thus inverting the stereochemistry about the C-2 atom.

There are therefore, for each of the compounds **3** and **4**, two possible products if the stereochemistry about C-2 is maintained (Scheme 8). Compounds **7** and **6**, the products expected by hydrogenolysis of **3** by this route which maintains C-2 stereochemistry, are indeed those which are observed. Compounds **8** and **9**, the products expected from hydrogenolysis of **4** by the same route are *not* found among the products of hydrogenolysis. Hence, hydrogenolysis of **4** by such a route can be eliminated as a possibility.

Of the two courses of hydrogenolysis of compound **3** (Scheme 8), route *b* has two features militating against its easy accomplishment. The first is the cleavage of the C_2—$O_{1'}$ bond to produce an intermediate (or incipient) oxocarbonium ion which possesses the unfavorable steric factor (4) noted for the tetramethyl-1,3-dioxolane (**5**) (Scheme 4). As well, attack by the AlH_2Cl from the *endo* direction is also less favored (1). However, route *a* requires association of the AlH_2Cl with the oxygen atom in the *exo* position, an oxygen atom in a steric environment similar to that found for 2,2,5,5-tetramethyltetrahydrofuran. It is known that a bulky Lewis acid ($SnCl_4$) is associated to a lesser extent with 2,5-dimethyltetrahydrofuran than with 2-methyltetrahydrofuran or with tetrahydrofuran (10). This was considered to be due to steric factors rather than electronic factors. It is thus quite conceivable that such steric factors in compound **3** would retard association of the Lewis acid AlH_2Cl with the *exo* oxygen atom sufficiently so that the alternate route *b* becomes competitive.

Since isomer **4** does hydrogenolyze about as easily as does **3**, then it can do so by the route (route *b* in Scheme 7) involving *two* molecules of AlH_2Cl. This is shown in Scheme 9. It is seen that both of the compounds **6** and **7** actually found as hydrogenolysis products, can be obtained by this method. If one considers these two paths *a* and *b* (Scheme 9) in more detail, it is seen that the hydrogenolysis by route *a* which might provide compound **6** is less likely than the alternate route which provides **7** (route *b*). For route *a* to take place, there must be at least partial C_2—$O_{1'}$, bond breaking with a tendency for the remaining substituents at C-2 to become coplanar about C-2. Attack at C-2 by a second molecule of AlH_2Cl would require its approach via a path perpendicular to the plane in which C-2 lies. Models show that such an approach is strongly inhibited by the three *endo* hydrogen atoms of the norcamphor system. On the other hand, models show that the association of the Lewis acid with the *endo* oxygen atom (route *b*)

is possible. This would lead to incipient C_2—O_3, bond breaking. Subsequent attack at C-2 by the second molecule of AlH_2Cl is then quite easy (1). From these arguments, it is our view that compound **4** reacts practically completely via route *b* (Scheme 9) to provide the product **7**. We realize that this conclusion can be verified only by direct experimental evidence.

Reaction of compound **3** with two molecules of AlH_2Cl by the same sequence as is shown for compound **4** in Scheme 9, would provide the substances **8** and **9**. Since these were not observed as products of the hydrogenolysis, such a scheme of reaction for compound **3** can be dismissed.

If then practically all of **4** provides product **7**, then one must conclude that compound **3** provides all of the alternate product **6** along with some of **7**. The feasibility of such dual production from compound **3** has already been discussed above. Final proof as to whether this is in fact the case must await isolation or preparation of the individual isomers **3** and **4**. The necessity of this is quite apparent, but as yet this goal has not been realized.

Our view, based upon the above arguments, is that hydrogenolysis by AlH_2Cl can occur by two routes. One involves a single molecule of AlH_2Cl, and the other requires two molecules of AlH_2Cl. The proportion of hydrogenolysis taking place by these two methods depends upon the steric factors involved in the ketal under consideration.

A final point concerns the small amount of the third product, 2-*exo*-norborneol (**10**) isolated from the reduction. The source of this compound might be from Lewis acid catalyzed cleavage of the compound **6**, which is an ether containing an oxygen atom linked to a tertiary carbon. It is known that hydriodic acid cleaves ethers in such a way that the more stable carbonium ion is formed (11).

Experimental

All boiling points are uncorrected.

Infrared spectra were obtained with a Perkin–Elmer Model 337 grating spectrometer.

Nuclear magnetic resonance spectra were obtained with a Varian Associates A-60 instrument by Mr. Robert Swindlehurst, and an HR-100 spectrometer by Mr. Glen Bigham. All spectra were referred to tetramethylsilane.

Gas chromatographic analyses were carried out with either an F and M Model 700 instrument using 1/8″ × 12′ columns or an Aerograph Model A-700 equipped with 1/4″ × 12′ columns. The column packings employed were 20% butanediol succinate on Chromosorb W, 60–80 mesh (the most useful column packing); 25% Carbowax 6000 on Gas Chrom P, 60–80 mesh; 10% silicone rubber on Chromosorb W, 30–60 mesh and 10% Apiezon L on Chromosorb W. Helium was the carrier gas. The g.l.c. instruments were each equipped with an integrator and temperature programming unit. The temperature program was begun at ~50°.

2-Methyl-1,2-propanediol (Isobutylene Glycol)

This compound was prepared in 53% yield by $LiAlH_4$ reduction of methyl α-hydroxyisobutyrate(5).

Norcamphor Isobutylene Ketal (3 and 4)

This compound was prepared in 69% yield from norcamphor and isobutylene glycol according to the method of Salmi (12); b.p., 56–57° at 3.0 mm; η_D^{23}, 1.4603.

Anal. Calcd. for $C_{11}H_{18}O_2$: C, 72.49; H, 9.95. Found: C, 72.33; H, 9.82.

The i.r. spectrum (neat) showed no absorption attributable to hydroxyl or carbonyl groups. Significant features of the 60 MHz n.m.r. spectrum (Fig. 1) in $CDCl_3$ are described in the Discussion.

Ethyl(2-exo-norbornyloxy)acetate

This acetate was prepared in 30% yield by the reaction, in either benzene or 1,2-dimethoxyethane solution, of 2-*exo*-norborneol (Aldrich Chemical Co.) with ethyl bromoacetate in the presence of sodium hydride following the procedure of Leffler and Calkins (6); b.p., 83° at 2.5 mm; η_D^{23}, 1.4668 (lit. (1) b.p., 77° at 1 mm; η_D^{25}, 1.4162).

Ethyl(2-endo-norbornyloxy)acetate

This acetate was prepared in 25% yield by the reaction of 2-*endo*-norborneol (13) with ethyl bromoacetate in benzene or 1,2-dimethoxyethane, in the presence of sodium hydride (6); b.p., 77° at 0.8 mm; η_D^{22}, 1.4680 (lit. (1) b.p., 80° at 0.1 mm; η_D^{25}, 1.4160).

1-(2-exo-norbornyloxy)-2-methyl-2-propanol (8)

To a quantity (2.64 g, 0.11 mole) of magnesium turnings in 100 ml of dry ether kept at 0° to −5° by an ice bath, was added, with stirring, 15.4 g (0.11 mole) of methyl iodide dropwise. When all the methyl iodide had been added, the solution was stirred for 10 min at room temperature and then 10 g (0.05 mole) of ethyl (2-*exo*-norbornyloxy)acetate was added dropwise to the stirred solution at a rate which maintained the ether solution at gentle reflux. When the acetate had been added, the solution was stirred for 2 h at room temperature, whereupon 2 ml of water was cautiously added to decompose the complex. The ether layer was decanted and the residue diluted with sufficient 15% hydrochloric acid to dissolve the solids. An ether extract of this aqueous mixture, combined with the decanted ether, was dried ($MgSO_4$) and the drying agent then removed by filtration. Elimination of the solvent by rotary evaporator under vacuum gave an oil which was fractionally distilled to give 5 g (55%) of the alcohol **8**; b.p., 71° at 2.5 mm; η_D^{24}, 1.4640.

Anal. Calcd. for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94. Found: C, 71.92; H, 10.91.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The n.m.r. spectrum in CCl_4 (reference, tetramethylsilane) was consistent with the structure of **8** and showed a multiplet between τ 6.6 and 6.8 (1H), a singlet at τ 6.9 (2H), *one* closely spaced unresolved multiplet centred at τ 7.72 (2H, bridgehead protons of the *exo* isomer), a singlet at τ 7.9 (1H), a multiplet between τ 8.1–9.3 overlapping a singlet at τ 8.91 (8H + 6H). In dimethylsulfoxide-d_6 (DMSO-d_6) the spectrum (Fig. 3) had essentially the same features except that the singlet at τ 7.9 (in CCl_4) moved downfield to τ 5.88 and remained a singlet, indicating that this signal was due to the proton of a tertiary hydroxyl group (8).

The i.r. spectrum (neat) showed a strong broad absorption band between 3100 and 3600 cm^{-1} and strong broad absorption in the region 1200 to 1050 cm^{-1} (C—O stretching).

The g.l.c. (butanediol succinate column) showed one sharp symmetrical peak.

1-(2-endo-norbornyloxy)-2-methyl-2-propanol (7)

This compound was prepared according to the method described immediately above for the preparation of the *exo* isomer, **8**. Because of the small quantity of material, it could not be satisfactorily purified by fractional distillation. The g.l.c. of each fraction still showed several small peaks of the contaminants. Final purification was carried out by preparative g.l.c. on a column using butanediol succinate; b.p. (micro), 79–80° at 3.0 mm; η_D^{25}, 1.4642.

Anal. Calcd. for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94. Found: C, 71.44; H, 10.65.

The n.m.r. spectrum in CCl_4 agreed with the structure of **7**. The significant features were *two* narrowly spaced unresolved multiplets for the bridgehead protons centred at τ 7.65 and 7.86 indicative of the *endo* substitution (1) and a singlet at τ 7.57 in the n.m.r. spectrum in CCl_4 which shifted downfield to τ 5.93 and remained as a sharp singlet in the n.m.r. spectrum in DMSO-d_6 (Fig. 2), thus indicating that the proton was that of a tertiary hydroxyl group (8).

The i.r. spectrum (neat) showed strong broad absorption between 3600 and 3100 cm^{-1} (OH) and strong broad absorption between 1200 and 1050 cm^{-1} (C—O stretching).

2-(2-exo-norbornyloxy)-2-methyl-1-propanol (6)

This compound was isolated by g.l.c. on a column of 20% butanediol succinate on Chromosorb W, from the mixture of products obtained from the hydrogenolysis of the mixture of the two isomers of norcamphor isobutylene ketal, **3** and **4**; b.p. (micro), 77–79° at 1.5 mm; η_D^{23}, 1.4734.

Anal. Calcd. for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94. Found: C, 71.35; H, 10.37.

The n.m.r. spectrum in DMSO-d_6 is shown in Fig. 4. The position of the signals and their integrated areas agree with a structure such as **6**. The significant details are described in the Discussion.

Hydrogenolysis of Norcamphor Isobutylene Ketal (3 and 4)

The hydrogenolysis was carried out either as described for the reduction of acetals and ketals (7) or preferably by adding the ketal to a previously prepared solution of equimolar amounts of $LiAlH_4$ and $AlCl_3$ in anhydrous ether. Both procedures gave the same results. The reduction was allowed to proceed at room temperature for the appropriate length of time (20 h or 168 h), whereupon sufficient 15% aqueous KOH was added dropwise to decompose the complex and form a colorless precipitate which was readily removed by filtration. The ether was then removed by rotary evaporator. Recovery of material was 95% (2.8 g from 3.0 g of ketal mixture). The oil was then subjected to g.l.c. and the products obtained were those indicated in Table I along with unreacted starting material.

Pyrolytic rearrangement of norbornene oxide[1]

DAVID L. GARIN
Department of Chemistry, University of Missouri-St. Louis, St. Louis, Mo. 63121

Received May 26, 1969

Norbornene oxide (**4**), stable to pyrolysis at 500°, rearranges at 550° to give Δ^3-cyclohexenylcarboxaldehyde (**8**), norcamphor (**6**), and Δ^2-cyclopentenone (**7**).

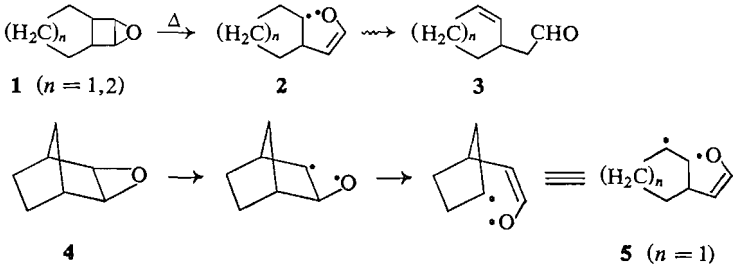
Canadian Journal of Chemistry, 47, 4071 (1969)

Introduction

The formation of cycloalkene acetaldehydes (**3**) from the pyrolysis of bridged cyclobutene epoxides (**1**) led to the consideration of a diradical intermediate **2** (1,2) (see Scheme 1). It appeared plausible that the pyrolysis of *exo*-2,3-epoxybicyclo[2.2.1]heptane (**4**, norbornene oxide) might give similar products via the closely related intermediate **5**. To examine this possibility, norbornene oxide was subjected to pyrolysis in a fashion similar to that reported for the pyrolysis of the cyclobutene epoxides (1).

Results

The solid epoxide (**4**) was added in small portions to a vertical pyrolysis column packed with glass helices under slow nitrogen flow. At temperatures up to 500°, the epoxide passed through the heated column unchanged but at 550° it was completely transformed into a large number of compounds. Analysis by vapor phase chromatography (v.p.c.) showed three major peaks whose ratios varied slightly from run to run. Samples of these three products were collected from the gas chromatograph and shown to be (in order of appearance) **7** (5–10%), **8** (62–67%), and **6** (5–10%) by spectral analysis and comparison with authentic samples. Percentage compositions refer to the relative areas observed for the different components in the chromatogram. A comparison of v.p.c. retention times showed that **3** ($n = 1$) was not present in the pyrolysate. These results are similar to those reported by Crandall for the acid catalyzed rearrangement of **4** which gives **6** and **8** (in approximately equal amounts) and nortricyclanol as primary products but no **7** (3). Norcamphor is not an intermediate in this reaction being stable to pyrolysis at 550°.



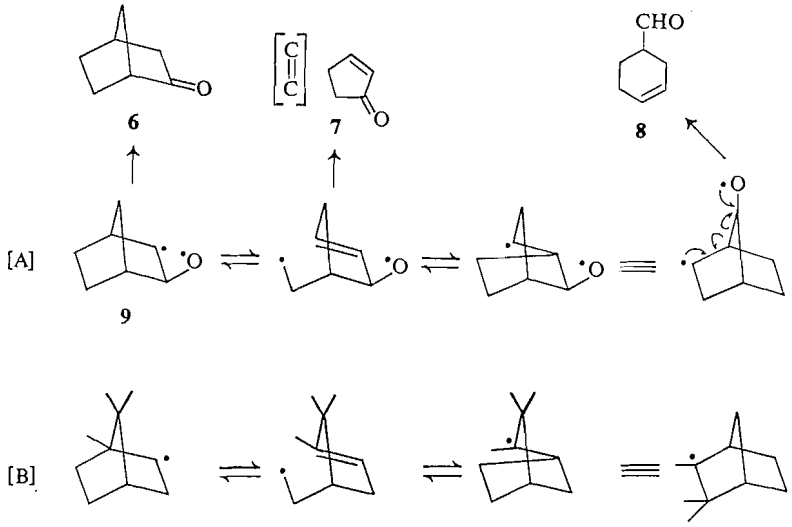
SCHEME 1

Discussion

Schematically, intermediate **9** could account for the observed products (equation A, Scheme 2) but various mechanisms can be considered depicting either homonuclear or heteronuclear

[1]Presented in part at the Midwest Regional American Chemical Society Meeting, Columbia, Missouri, November, 1967.

Portions of this manuscript were abstracted from the Ph.D. Thesis of D. L. Garin, Iowa State University, 1964.



SCHEME 2

cleavage. (A referee has suggested the formation of **7** via a retro Diels–Alder reaction of the enol of norcamphor derived directly from **9**.) This intermediate (**9**) is analogous to that reported (4) for the rearrangement of the camphane radical (equation B, Scheme 2).

Experimental

Melting points and boiling points are uncorrected.

Norbornene Oxide (4)

Following the epoxidation procedure of Korach, Nielsen, and Rideout, norbornene (8.0 g, 0.085 mole) was reacted with 18 g of a 40% peracetic acid solution (FMC Corp., 0.095 mole) over 0.5 h, maintaining the temperature at 20° (5). The crude product was sublimed at atmospheric pressure using an oil bath at 130° to give 7.0 g (75%) of a white crystalline material m.p. 120–122° [lit. m.p. 118–119° (6) and 125–127° (7)]; infrared (i.r.) (CCl_4): 848 cm^{-1}. The peracid preparation of **4** is reported to give an isomeric composition that is 94% *exo* and 6% *endo* (8).

Pyrolysis of 4

Norbornene oxide, in *ca.* 50 mg portions, was manually dropped onto a vertical column of glass helices in a temperature control oven kept under continual nitrogen flow occasionally broken for 2–3 seconds for addition of the epoxide. Products were separated and collected by v.p.c. using a Perkin–Elmer RX column (two meter, 1/4" diameter column utilizing Ucon oil LB-550-X on diatomaceous earth) at 125°. The retention times for the products (in min) were 7.0 (**7**), 10.1 (**8**), and 13.2 (**6**).

Δ^2-Cyclopentenone (7)

The nuclear magnetic resonance (n.m.r.) spectrum of the unsaturated ketone, collected by preparative v.p.c. from the pyrolysis of **4**, was consistent with that reported (9). The 2,4-dinitrophenylhydrazone was deep red and had m.p. 165–166°; lit. m.p. 165–166° (10).

Δ^3-Cyclohexenylcarboxaldehyde (8)

The n.m.r. and i.r. spectra of the aldehyde from the pyrolysis of **4** was identical to that of an authentic sample of Δ^3-cyclohexenylcarboxaldehyde (kindly supplied by Dr. H. E. Hennis, Dow Chemical Co., Midland, Michigan). The 2,4-dinitrophenylhydrazone had m.p. 176–177°; lit. m.p. 176–177° (11).

Norcamphor (6)

The i.r. spectrum of the solid ketone was superimposable with that of an authentic sample (Aldrich Chemical Co., Inc.). The 2,4-dinitrophenylhydrazone had m.p. 131–131.7°; lit. m.p. 130–131.5° (12).

New approach to the synthesis of optically active trityl systems

K. G. RUTHERFORD, J. L. H. BATISTE, AND J. M. PROKIPCAK
Department of Chemistry, University of Windsor, Windsor, Ontario

Received August 13, 1968

A new method for the resolution of potentially optically active trityl alcohols is reported. Three trityl alcohols as pilot compounds were converted to hydracrylic acid derivatives. Esterification with diazomethane was followed by degradation (reverse Michael reaction) to the original alcohols with sodium hydride. The resolution of phenyl-α-naphthyl-*p*-tolylcarbinol was effected conveniently by this route.

The fundamental procedure of preparative optical resolution is conversion of the racemic compound to diastereoisomeric salts of an optically active acid or base obtained from nature. Racemic primary and secondary alcohols are usually esterified with a dicarboxylic acid to provide racemic half esters for neutralization with the chiral base (alkaloid) and the enantiomers are isolated in good yield and with negligible racemization on hydrolysis of the separated salts (1). Racemic tertiary alcohols, however, because of their tendency for alkyl-oxy bond fission, readily lose structural integrity and hence, routes leading to optically active triaryl carbinols have been scarce in the literature since Wallis' first report on the resolution of phenylbiphenyl-α-naphthylcarbinol (2).

In 1962 Thaker and Dave (3) reported the synthesis of optically active phenyl-α-naphthyl-*p*-tolylcarbinol by the classical procedure which involved preparation of the hydrogen phthalate derivative of the alcohol. Resolution of this by brucine followed by hydrolysis of the ester reportedly yielded the optically active *d*-ROH. Several attempts to repeat Thaker's synthesis of the hydrogen phthalate derivative failed including the use of a method previously developed in this laboratory for the preparation of hydrogen phthalate esters of sterically hindered alcohols (4).

In 1963 Murr (5) reported on the resolution of phenylbiphenyl-α-naphthylcarbinol by an elegant procedure which involved conversion of the *dl*-ROH to the *dl*-glycolic acid derivative. Resolution of this with brucine followed by degradation yielded the *d*-ROH (Sequence I). Simultaneously our laboratory using triphenylcarbinol as a pilot system succeeded in degrading the glycolic acid derivative back to the ROH in good yield by the following procedure:

$$\mathrm{ROCH_2COOH} \xrightarrow[(3)\ \mathrm{Mg}\\(4)\ \mathrm{H_3O^+}]{(1)\ \mathrm{LAH}\\(2)\ \mathrm{SOCl_2}} \mathrm{ROH} + \mathrm{CH_2{=}CH_2}$$

Attempts to apply this to the preparation of optically active phenyl-*p*-chlorophenyl-*p*-bromophenyl-carbinol failed at the salt resolution stage, although this does not detract from the potential usefulness of this procedure for other compounds. Recently Murr and Feller (6) succeeded in effecting a spontaneous resolution of phenylbiphenyl-1-(8-methylnaphthyl) carbinol according to the method of Powell (7).

We wish to report the use of hydracrylic acid derivatives as useful intermediates for the resolution of triarylcarbinols. These derivatives can be readily prepared and degraded giving good yields in all steps with triphenylcarbinol and phenyl-α-naphthyl-*p*-tolylcarbinol as pilot compounds

$$\textit{dl}\text{-ROH} \xrightarrow{\mathrm{AcCl}} \textit{dl}\text{-RCl} \xrightarrow[\mathrm{HOCH_2COOCH_3}\\(2)\ \mathrm{KOH}]{(1)\ \text{pyridine, benzene,}} \textit{dl}\text{-}\mathrm{ROCH_2COOH}$$

$$\xrightarrow[(2)\ \mathrm{H_3O^+}]{(1)\ \textit{l}\text{-brucine}} \textit{l}\text{-}\mathrm{ROCH_2COOH} \xrightarrow[(3)\ t\text{-butyl-hypochlorite}\\(4)\ \mathrm{NaOCH_3},\ \text{benzene}]{(1)\ \mathrm{CH_2N_2}\\(2)\ \mathrm{NH_3}} \textit{d}\text{-ROH}$$

SEQUENCE I

$$ROH + CH_2 = CHCOOCH_3$$

SEQUENCE II

(Sequence II). The hydracrylic acid from phenyl-*p*-bromophenyl-*p*-chlorophenylcarbinol could be obtained directly in good yield by reacting the ROH with propiolactone in the presence of *p*-toluenesulfonic acid, thus saving the hydrolysis step. The diazomethane reactions proceeded smoothly and the reverse Michael reactions were carried out most conveniently and in excellent yields using either triphenylmethyl sodium or sodium hydride in anhydrous ether. The latter base is preferred because of its ready availability.

Attempts to completely resolve phenyl-α-naphthyl-*p*-tolylcarbinol (Thaker's alcohol) are still somewhat inconclusive. However, it is felt that a reasonable degree of resolution has been effected and that the low rotations indicated below are not due to some impurity because of the appreciable difference in melting points of the *dl*- and *d*-ROH as well as those of the *dl*- and *d*-RCOOH. The *dl*-ROH (m.p. 110–112°) was converted to methyl β-(phenyl-α-naphthyl-*p*-tolylmethoxy)-propionate by reaction with methyl β-hydroxypropionate in trifluoroacetic acid. Hydrolysis of this methyl ester afforded the *dl*-β-(phenyl-α-naphthyl-*p*-tolylmethoxy)-propionic acid (m.p. 151–152.5°). Conversion of the propionic acid to the optically active brucine salt, $[\alpha]_{436}^{25}$ −23.5° (c = 4.0524) proceeded in low yield (*ca.* 20%). It should be noted that brucine is levorotating in chloroform. The salt was decomposed by aqueous hydrochloric acid to optically active *d*-β-(phenyl-α-naphthyl-*p*-tolylmethoxy)-propionic acid, $[\alpha]_{436}^{25}$ +3.19° (c = 1.0176), m.p. 159–160.5°. The infrared (i.r.) spectrum of this acid was identical to that of the *dl*-acid. The optically active propionic acid was converted with diazomethane to the methyl ester which on subsequent treatment with sodium hydride in anhydrous ether yielded optically active phenyl-α-naphthyl-*p*-tolylcarbinol, $[\alpha]_{436}^{25}$ + 3.12 (c = 1.0092), m.p. 90–93°. The i.r. spectrum was identical to that of the *dl*-alcohol. The overall yield from the *d*-acid was *ca.* 85%. The optical purity of the *d*-acid was not determined. However, the brucine salt of the *d*-acid was crystallized until no significant change could be observed in optical rotation.

It would appear that the hydracrylic acid route to potentially optically active trityl alcohols could be a very useful procedure because of the ease of preparation and degradation which is less involved than the glycolic acid route. Hydracrylic acids should be no more difficult to resolve than corresponding glycolic acids although many variables are involved here.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Optical rotation measurements were determined in chloroform with a Rudolph Model 80 polarimeter equipped with a mercury vapor lamp (λ 4358 Å). Infrared spectra were recorded in chloroform with a Beckman IR-10 spectrophotometer equipped with potassium bromide cells. Microanalyses were performed by Midwest Microlab, Inc., 6000 East 46th Street, Indianapolis, Indiana, 46226.

Hydracrylic Acid Derivatives

β-*(Triphenylmethoxy)-propionic acid* was prepared by the two procedures outlined.

Procedure 1

A solution of triphenylcarbinol (1.032 g, 3.96 mmole) in 3 ml trifluoroacetic acid was added dropwise to 15 ml (0.159 mole) methyl β-hydroxypropionate which was cooled by means of an ice bath. The reaction mixture was poured onto cracked ice and neutralized with sodium bicarbonate. Methyl β-(triphenylmethoxy)-propionate was removed by filtration and air dried. Yields of 90–95% of quite pure product (m.p. 116–118°) were obtained consistently.

Anal. Calcd. for $C_{23}H_{22}O_3$: C, 79.74; H, 6.40. Found: C, 79.69; H, 6.40.

The ester (1.0 g, 2.89 mmole) was dissolved in 50 ml methanol. To this solution was added 10 ml 20% aqueous sodium hydroxide solution. After the solution was refluxed for 6 h, more water was added and the methanol was removed by distillation. Hydrochloric acid (3 *N*) was added to the cooled solution to p*H* 3. The product was filtered, air dried, and recrystallized from chloroform–petroleum ether (b.p. 30–60°), m.p. 164–166° (literature (8) 164–166°). Yields in this hydrolysis step ranged from 80–85% of recrystallized β-(triphenylmethoxy)-propionic acid.

Procedure 2

Triphenylcarbinol (2.01 g, 7.7 mmole) and 2 ml (0.032

mole) propiolactone were dissolved in 6 ml dry benzene. *p*-Toluenesulfonic acid (54 mg) was added and the solution was refluxed for 6 h. Aqueous potassium hydroxide solution (5%, 70 ml) was added and the solution was refluxed an additional 4 h. The addition of 30 ml ether to the cooled reaction mixture gave a good separation of layers. The aqueous layer was heated (50–60°) *in vacuo* to remove last traces of benzene and ether. Hydrochloric acid (6 *N*) was added to p*H* 3. The product was filtered and air dried. Recrystallization from chloroform–petroleum ether (b.p. 30–60°) yielded between 75–80% of pure β-(triphenylmethoxy)-propionic acid.

Methyl β-*(phenyl-α-naphthyl-p-tolylmethoxy)-propionate* was made in 80–85% yield by procedure 1 and was recrystallized from chloroform–heptane, m.p. 96–97°. The i.r. spectrum showed bands at 1735 cm^{-1} (C=O stretch), 1200–1170 cm^{-1} (ester C—O stretch) and 1065 cm^{-1} (R—O—R′ stretch).

Anal. Calcd. for $C_{28}H_{26}O_3$: C, 81.92; H, 6.39. Found: C, 81.74; H, 6.35.

β-*(Phenyl-α-naphthyl-p-tolylmethoxy)-propionic acid* was prepared in 95% yield from the methyl ester by hydrolysis using 5% aqueous sodium hydroxide. Recrystallization from chloroform–heptane gave m.p. 151–152.5°. The i.r. spectrum showed bands at 3600–2500 cm^{-1} (O—H stretch), 1715 cm^{-1} (C=O stretch), 1080–1060 cm^{-1} (R—O—R′ stretch).

Anal. Calcd. for $C_{27}H_{24}O_3$: C, 81.79; H, 6.10. Found: C, 81.66; H, 6.28.

β-*(Phenyl-p-bromophenyl-p-chlorophenyl)-propionic acid* was made from phenyl-*p*-bromophenyl-*p*-chlorophenyl-carbinol (prepared by the method of Stagner (9)) and propiolactone according to Procedure 2 in yields of 75–80%. Recrystallization from chloroform–petroleum ether (30–60°) gave m.p. 138–139°. The i.r. spectrum showed bands at 3600–2400 cm^{-1} (O—H stretch), 1715 cm^{-1} (C=O stretch) and 1090–1070 cm^{-1} (R—O—R′ stretch).

Anal. Calcd. for $C_{22}H_{18}O_3BrCl$: C, 59.30; H, 4.07. Found: C, 59.74; H, 3.84.

N.E. (Neutral Equivalent) Calcd.: 445.7. Found: 444.9.

Reactions of Hydracrylic Acids with Diazomethane

Methyl β-*(triphenylmethoxy)-propionate* was prepared in the following manner.

An ethereal solution of diazomethane (approx. 1.56 g, 0.0372 mole) was prepared by adding a solution of 8.0 g (0.0372 mole) *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide in 37 ml ether to a mixture of 3 ml water, 10 ml ethanol, and 2.0 g (0.0351 mole) potassium hydroxide heated to 65° (10). The liberated diazomethane was carefully distilled directly into a solution of 0.9 g (2.71 mmole) β-(triphenylmethoxy)-propionic acid in 10 ml ether cooled in an ice bath (11). After the reaction had ceased, the excess diazomethane was destroyed with 2.3 ml (*ca.* 0.0372 mole) glacial acetic acid. The ether layer was extracted with saturated sodium bicarbonate solution, dried over anhydrous magnesium sulfate, and evaporated *in vacuo*. The crude product was recrystallized from chloroform–petroleum ether (b.p. 30–60°), m.p. 114–116° (80–85% yield).

Methyl β-*(phenyl-p-bromophenyl-p-chlorophenylmethoxy)-propionate* was not isolated in crystalline form. The i.r. spectrum however showed bands at 1735 cm^{-1} (C=O stretch), 1170 cm^{-1} (ester C—OR stretch) and 1090–1065 cm^{-1} (R—O—R′ stretch). Hydrolysis to the acid proceeded cleanly with potassium hydroxide.

Resolution of β-*(Phenyl-α-naphthyl-p-tolylmethoxy)-propionic Acid*

All rotations were taken in chloroform in a 2 dm cell and deviations in specific rotations were not greater than ± 0.5°. The brucine salt was prepared in acetone by the standard method (1), $[\alpha]_{436}^{25}$ −30.9° (c = 4.0236). Several recrystallizations of this salt from toluene-methylcyclohexane gave a fraction (*ca.* 20% yield) with constant rotation $[\alpha]_{436}^{25}$ −23.5° (c = 4.0524). The salt was decomposed in an ether–water system with an excess of 0.25 *N* hydrochloric acid. The ether layer was dried with anhydrous magnesium sulfate, heptane was added and the *d*-acid slowly recrystallized, m.p. 159–160.5°, $[\alpha]_{436}^{25}$ +3.19° (c = 1.6176). The i.r. spectrum of the *d*-acid was identical to that of the *dl*-acid.

Reverse Michael Reactions

The reaction of methyl β-(triphenylmethoxy)-propionate with sodium hydride is given: sodium hydride (7g of a 50% dispersion in mineral oil, 0.146 mole NaH) was suspended in 75 ml dry ether in a 250 ml 3-necked flask which was equipped with a glass stopper, a pressure-equalizing addition funnel, and a reflux condenser. A solution of the ester (1.8 g, 5.2 mmole) in 100 ml dry ether was added rapidly with stirring to the flask. The mixture was stirred for 24–26 h, cooled to ice bath temperature, and 75 ml water was added slowly. The ether layer was separated from the water layer, dried over anhydrous magnesium sulfate, and evaporated *in vacuo*. The triphenylcarbinol was separated from the mineral oil by filtration and recrystallized from methanol–benzene, m.p. 163–164° (yield *ca.* 90%). Similarly, and with excellent yields, reverse Michael reactions were carried out with methyl β-(phenyl-*p*-bromophenyl-*p*-chlorophenyl-methoxy)-propionate and methyl β-(phenyl-α-naphthyl-*p*-tolylmethoxy)-propionate. The optically active methyl β-(phenyl-α-naphthyl-*p*-tolylmethoxy)-propionate was not isolated from the diazomethane reaction with the corresponding *d*-acid but was subjected directly to the reverse Michael reaction in ether solution. The *d*-alcohol was separated from the mineral oil by filtration and recrystallized several times from ether–heptane, $[\alpha]_{436}^{25}$ +3.12° (c = 1.0092), m.p. 90–93°. The i.r. spectrum of the *d*-alcohol was identical to that of the *dl*-alcohol. The yield of *d*-alcohol was *ca.* 85% from the *d*-acid.

Polarographic half-wave potentials and ultraviolet absorption spectra of some conjugated heteroenoid compounds

H. L. HOLMES AND D. J. CURRIE
Chemistry Section, Defence Research Establishment, Suffield, Ralston, Alberta

Received September 9, 1968

The half-wave potentials of phenyl substituted derivatives for each series of conjugated heteroenoid compounds studied follow a Hammett relationship. The effect of change in the functional groups and of increase in length of the conjugated system upon half-wave potentials and ultraviolet absorption maxima is briefly discussed. Terephthalylidene derivatives of active methylene compounds function like the cinnamylidene derivatives.

Canadian Journal of Chemistry, 47, 4076 (1969)

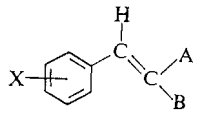
Equations already developed for calculating the stimulatory activities (1) and the bacterial growth inhibitory activities (2) of a number of conjugated heteroenoid compounds with the generalized formula **1**, required the determination of their polarographic half-wave potentials. This note discusses the effect of phenyl substituents,



1

(*a*) A = B = $COCH_3$; (*b*) AB =  ;

(*c*) A = $COCH_3$, B = $CO_2C_2H_5$; (*d*) A = $COCH_3$, B = COC_6H_5; (*e*) A = $CO_2C_2H_5$, B = COC_6H_5; (*f*) A = COC_6H_5, B = CN; (*g*) A = $CO_2C_2H_5$, B = CN; (*h*) A = B = CN; (*i*) A = $CONH_2$, B = CN; (*j*) A = $CONHC_6H_5$, B = CN; (*k*) A = B = $CONH_2$; (*l*) A = B = $CO_2C_2H_5$; (*m*) A = $CO_2C_2H_5$, B = $CONH_2$.

X, and functional groups, A and B, on the half-wave potentials of these compounds. The mechanism of the polarographic reduction in aqueous and non-aqueous media has been examined by Bargain *et al.* (3–5) and Marciszewski (6) has reduced methyl 1-methylbutylidenecyanoacetate.

In this work, the reduction of these compounds (7,8) was carried out under conditions similar to those used by Silver and Holmes (9). In all but a few cases single waves were obtained (Tables I and II). The second wave in the polarogram for the 2-benzal-1,3-indanediones (**1***b*) appears to be due to the hydrolysis product, 1,3-indanedione ($E_{\frac{1}{2}} = -1.182$ V) but not to the respective aldehyde (Table IV). The polarogram of the α-cyano-*trans*-benzalacetophenones (**1***f*) appears to be similarly complicated by reduction of benzoylacetonitrile. The ranges of diffusion currents for the various classes of compounds are listed in Table III.

For the reduction of these various classes of compounds, the relationship between half-wave potentials and Hammett's σ or Taft's σ* value is linear except for compounds containing strong electron-withdrawing X groups, e.g. NO_2, CN. The ρ values (Table V) fall into three groups: the *gem*-diketones, **1***a*, **1***b*, and **1***d*, all have a ρ value between 0.26 and 0.29; the keto-esters, **1***c* and **1***e*, and the benzalmalonamides, **1***k*, have a ρ value

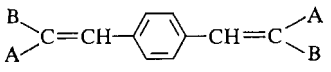
between 0.16 and 0.19; while the cyano-containing compounds, **1***g*, **1***h*, and **1***i*, comprise a third group with ρ values between 0.36 and 0.39.

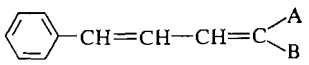
Half-wave potentials were obtained for the terephthalylidene derivatives of some active methylene compounds, **2** (Table VI). The tetracarbethoxy compound (**2**) has a half-wave



2

A = B = $CO_2C_2H_5$

potential much less negative than that of diethyl benzalmalonate (**1***l*) ($E_{\frac{1}{2}} \geqslant -1.4$ V) (9), and even less than that of diethyl cinnamylidenemalonate (**3**). This is not the case for the related *meta* isomer of **2** ($E_{\frac{1}{2}} \geqslant -1.4$ V). The alternating system of



3

A = B = $CO_2C_2H_5$

single and double bonds in these terephthalylidene compounds probably acts as one long conjugated system with reduced transmission of the mesomeric effect through the ring (10). The marked similarity in the long-wavelength absorption maxima and extinction coefficients of **2**

*A saturated solution was used in these cases.
†The corresponding *meta* isomer had a half-wave potential more negative than −1.4 V.

compounds with those of the analogous **3** derivatives (Table VII) indicate that this is the case. A method for calculating the long-wavelength absorption maxima of these terephthalylidene derivatives has already been described (11).

The half-wave potentials of diethyl benzalmalonate (**1***l*), ethyl benzalmalonamate (**1***m*), (⩾ −1.3 V), and ethyl benzalcyanoacetate (**1***g*) are all more negative than the analogous 3-substituted coumarins, **4** (Table VIII), indicating that the carbethoxyl group of ethyl benzalmalonamate probably is *trans* to the phenyl group.

A = $CO_2C_2H_5$; $CONH_2$; CN

Experimental

The preparations of the terephthalylidene, isophthalylidene, and cinnamylidene derivatives of some active methylene compounds are summarized in Tables IX and X. The absorption spectra of ethanolic solutions of the compounds were recorded in a model 15 Cary spectrophotometer.

The polarograms were recorded on a Sargent model XV polarograph. Stock solutions of the compounds were made up in ethanol and the determinations were made on 25 ml samples of a 75% v/v aqueous ethanolic solution, 8×10^{-4} *M* in the reducible substance, containing 0.1 *M* acetic acid and 0.1 *M* sodium acetate. The p*H* of the ethanolic buffer solution as measured with a glass electrode was 6.6 and methylene blue thiocyanate (0.01%) was used as a maximum suppressor. The half-wave potential was measured against a saturated calomel electrode. The cell resistance was ~6800 Ω; with no applied voltage and the mercury at a height of 84 cm the drop mass was 2.68 mg/s and the drop time was 3.27 s.

Before the polarogram was recorded at 25 °C the solution was deaerated by bubbling nitrogen through it for 20 min. A second polarogram was recorded on the same solution after a further 10 min sweep with nitrogen. The half-wave potentials recorded are the averages of the values obtained from the two determinations and are accurate to ±0.01 V. The hydrogen wave occurred at −1.4 V and half-wave potentials more negative than this could not be obtained.

Acknowledgments

The determination of the polarographic half-wave potentials by Messrs. F. K. McClusky and R. F. Silver and the recording of the absorption

Proton magnetic resonance and mass spectrometric studies on derivatives of sodium 2-*O*-α-D-mannopyranosyl-D-glycerate and related compounds

J. N. C. WHYTE

Fisheries Research Board of Canada, Vancouver Laboratory, 6640 N.W. Marine Drive, Vancouver 8, B.C.

Received April 11, 1969

The proton magnetic resonance (p.m.r.) and mass spectra of the methyl ester pentaacetate of sodium 2-*O*-α-D-mannopyranosyl-D-glycerate from the red alga *Rhodomela larix* are compared to those of related compounds to affirm the assigned structure.

Canadian Journal of Chemistry, **47**, 4083 (1969)

The observation that the water soluble components of an 80% aqueous methanol extract of *Rhodomela larix* inhibited the growth of *E. coli* (1) prompted an interest in the low molecular weight components of this alga. Extraction of the seaweed with a chloroform–methanol–water mixture yielded sodium 2-*O*-α-D-mannopyranosyl-D-glycerate (**1**) (2) as the major water soluble component. The corresponding free acid provided a poorly resolved p.m.r. spectra, but that of the

Proton magnetic resonance and mass spectrometric studies on derivatives of sodium 2-*O*-α-D-mannopyranosyl-D-glycerate and related compounds

J. N. C. WHYTE

Fisheries Research Board of Canada, Vancouver Laboratory, 6640 N.W. Marine Drive, Vancouver 8, B.C.

Received April 11, 1969

The proton magnetic resonance (p.m.r.) and mass spectra of the methyl ester pentaacetate of sodium 2-*O*-α-D-mannopyranosyl-D-glycerate from the red alga *Rhodomela larix* are compared to those of related compounds to affirm the assigned structure.

Canadian Journal of Chemistry, **47**, 4083 (1969)

The observation that the water soluble components of an 80% aqueous methanol extract of *Rhodomela larix* inhibited the growth of *E. coli* (1) prompted an interest in the low molecular weight components of this alga. Extraction of the seaweed with a chloroform–methanol–water mixture yielded sodium 2-*O*-α-D-mannopyranosyl-D-glycerate (**1**) (2) as the major water soluble component. The corresponding free acid provided a poorly resolved p.m.r. spectra, but that of the

*Values taken from the spectrum in pyridine-d_5.
†Overlapping signals.

methyl ester **3** in deuterium oxide displayed a doublet of intensity 1 at τ 4.57, $J_{1',2'} = 1.7$ Hz for the anomeric proton, which on irradiation, collapsed the quartet for H-2′ at τ 5.45 to a doublet, splitting 3.0 Hz. The protons of the glycerate moiety appeared as a simple AB_2 pattern with H-2 appearing as a triplet at τ 5.0 coupled to the doublet with a spacing of 3.8 Hz for the methylene protons (H-3_1 and H-3_2) at τ 5.6.

The corresponding acetate, methyl 3-*O*-acetyl-2-*O*-(2′,3′,4′,6′-tetra-*O*-acetyl-α-D-mannopyranosyl)-D-glycerate (**4**) furnished a p.m.r. spectrum in chloroform-d_1, in which the proton signals were assigned from double irradiation experiments, Tables I and II. The observation that the methine proton of the glycerate moiety resonated to higher field than that in the spectrum of methyl 2,3-di-*O*-acetyl-DL-glycerate (τ 4.71) where it is geminal to a deshielding acetoxyl group, together with the comparable chemical shifts for the methylene protons in both compounds, would substantiate the structure having the glycosidic linkage at C-2 of the glycerate moiety. Although the configuration at C-1 for mannose derivatives cannot be assessed by the spacing of the anomeric signal (3) the coalescence of the H-5′ with the H-6_2′ signal, together with the complex pattern to low field for H-2′, H-3′, and H-4′ signals, was consistent with an α-glycoside of mannopyranose tetraacetate. Of interest from Table I was the observed long range deshielding effect (0.1 p.p.m.) on the protons at C-3 and C-5 by the carbonyl function of the C-1 acetoxyl group in β-D-mannopyranose pentaacetate. The chemical shifts of the acetoxyl groups in the spectrum of **4**, indicate that the mannose ring must exist, predominantly in the C-1 (D) conformation with one acetoxyl group at C-2, axially oriented (4).

The mass spectra of methyl β-D-mannopyranoside and methyl α-D-mannopyranoside tetraacetates and the derivative **4** showed a corresponding increase in the A relative to the C and F series (5) of ion fragments where the percentage of the A_1 (*m/e* 331) to F_2 (*m/e* 115) peaks was 2.9, 8.9, and 80% respectively. This increase in the A series depends on the rate of elimination of the C-1 substituent favored by the α anomeric configuration, presumably a reversed anomeric effect caused by removal of an electron from the ring oxygen in the formation of the molecular ion, and by the anchimeric assistance of the *trans vicinal* acetoxyl group; a factor substantiated by the ratio of the A_1 peaks for the anomers of glucose and mannose pentaacetate (6) and by the relative exclusion of the A series of ions in the spectrum of 2-*O*-methyl-β-D-glucopyranose tetraacetate which are abundant in that of the corresponding 3-*O*-methyl isomer (7). Although the spectrum of **4** lacked a molecular ion, it exhibited peaks of low intensity at *m/e* 433 ($M - CO_2CH_3$) and *m/e* 419 ($M - CH_2OCOCH_3$). Apart from the characteristic base peak at mass 43 the most intense peak in the spectrum at mass 145 was attributed to the stable glycerate fragment formed by cleavage of the glycosidic bond. The contribution to the species at mass 145 by the triacetyloxonium ion was minimal as it is invariably less abundant than the diacetyloxonium ion at mass 103. The sodium salt **1** exhibited no antibacterial activity.

Experimental

Proton magnetic resonance spectra were obtained with

For personal use only.

a Varian HA 100 spectrometer, τ values are relative to tetramethylsilane as an internal or external standard in the solvent specified at 30°. The mass spectra were obtained with a Nuclide spectrometer.

The seaweed, 1750 g fresh weight, was exhaustively extracted with the solvent mixture, chloroform–methanol–water, to afford an aqueous methanol layer which was passed through a column of cation, then anion, exchange resins; the latter of which on elution with 0.2 *N* formic acid gave an eluate, neutralised with sodium bicarbonate and evaporated to a residue subsequently recrystallized from aqueous methanol to give sodium 2-*O*-(α-D-mannopyranosyl)-D-glycerate (**1**) (300 mg) m.p., mixed m.p. 265°, $[\alpha]_D$ + 106° (*c*, 1.4 in H_2O).

The free acid **2** as a syrup $[\alpha]_D$ + 93° (*c*,2.3 in H_2O) gave a p.m.r. spectrum in D_2O displaying a signal at τ 4.65 (1H) multiplets at τ 5.25 and 5.51 (each 1H) and a complex multiplet τ 5.60–6.00 (7H's). Treatment of **2** (150 mg) with diazomethane gave the methyl ester **3** (157 mg), $[\alpha]_D$ + 95° (*c*,2.1 in H_2O) which on acetylation of a portion (125 mg) gave the corresponding pentaacetate **4** (190 mg) recrystallized from ethyl acetate–*n*-pentane, m.p. 91°, $[\alpha]_D$ + 73.1° (*c*,1.2 in methanol).

Anal. Calcd. for $C_{20}H_{28}O_{14}$: C, 48.78; H, 5.73. Found: C, 49.06; H, 5.67.

Methyl 2,3-di-*O*-acetyl-DL-glycerate, b.p. 84° at 0.05 mm, prepared from the parent calcium salt as above, gave a p.m.r. spectrum in $CDCl_3$ showing a quartet signal at τ 4.71 (H-2), two overlapping quartets at τ 5.49 (H-3_1, $J_{2,3_1}$ = 3.7 Hz) and τ 5.71 (H-3_2, $J_{2,3_2}$ = 5.0 Hz) with $J_{3_1,3_2}$ = 11.5 Hz. The compounds cited in Tables I and II were prepared by well established procedures (8).

Bisglycosidylamines, a new class of amino sugars[1,2]

HANS H. BAER AND FAROUK RAJABALEE

Department of Chemistry, University of Ottawa, Ottawa, Canada

Received May 7, 1969

Nucleophilic addition of methyl 2-amino-4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-glucopyranoside (**2**) to methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-*erythro*-hex-2-enopyranoside (**1**) furnished bis(methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-glucopyranosid-2-yl)amine (**3**). The debenzylidenated product (**4**) gave a tetraacetate (**5**) and, on catalytic hydrogenation, it afforded bis(methyl 3-amino-2,3-dideoxy-α-D-glucopyranosid-2-yl)amine which crystallized as a trihydrochloride (**6**). Acetylation of **6** gave a di-*N*-acetyltetra-*O*-acetyl derivative (**7**); the secondary amino group remained free, presumably owing to steric hindrance.

Canadian Journal of Chemistry, **47**, 4086 (1969)

In continuation of our synthetic work on aminonitro sugars (1), branched-chain dinitro sugars (2), and nitro disaccharides (3), which made use of the facile addition of nucleophiles to carbohydrate nitroolefins (4), we wish to report another application of the same principle. Reaction between methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-*erythro*-hex-2-enopyranoside (**1**) and methyl 2-amino-4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-glucopyranoside (**2**) furnished in up to 75% yield a secondary amine representing a new type of carbohydrate structure, namely, a bisglycosidylamine. The product, bis(methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-glucopyranosid-2-yl)amine (**3**), was debenzylidenated with trifluoroacetic acid (5) to give bis(methyl 2,3-dideoxy-3-nitro-α-D-glucopyranosid-2-yl)amine (**4**) from which a tetraacetate (**5**) was obtained by boron trifluoride-catalyzed acetylation (6). The dinitroamine **4** was hydrogenated catalytically to the triamine, bis(methyl 3-amino-2,3-dideoxy-α-D-glucopyrano-

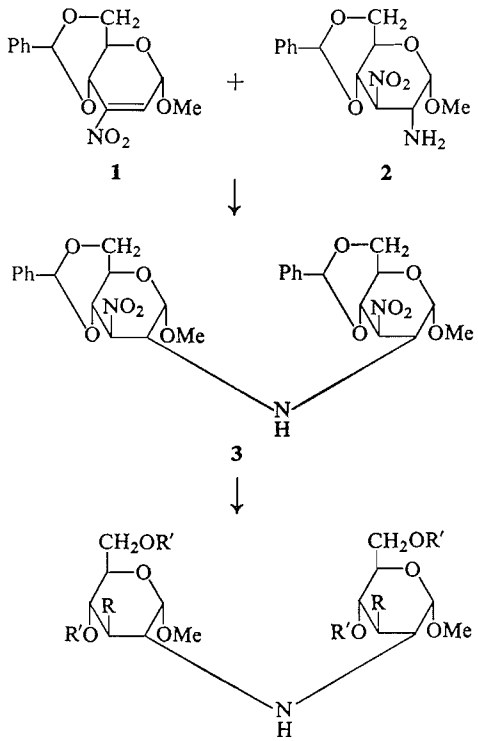
sid-2-yl)amine. In this compound the secondary amine nitrogen appears to be severely crowded in by the bulky glycosidyl substituents; for although the compound crystallized as a trihydrochloride (**6**), only two *N*-acetyl groups were introduced by its treatment with acetic anhydride in pyridine, the product being a di-*N*-acetyltetra-*O*-acetyl derivative (**7**).



The bis-α-D-*gluco* configuration of the new compounds was ascertained by nuclear magnetic resonance (n.m.r.) spectroscopy. The 100 MHz spectra of **3**, **5**, and **7** clearly indicated that the two glycosidyl moieties in each of the compounds were identical, since each compound gave only one set of substituent resonances. That is to say, one sharp methoxyl signal was given by **3**, **5**, and **7**, and one benzylidenic proton singlet was given by **3**; compound **5** showed two *O*-acetyl signals and compound **7**, one *N*-acetyl signal and two *O*-acetyl signals. Inspection of the ring proton resonances (to the extent that they were resolved well enough) likewise revealed equal chemical shifts and spin couplings of corresponding protons in the two glycosidyl moieties of each compound analyzed, proving the moieties to be identical. This fact alone already suggested the bis-α-D-*gluco* configuration since it was considered highly unlikely that the α-D-*gluco* reaction partner (**2**) should have suffered any stereochemical change during its addition to the α-D-*erythro* component (**1**). Direct proof was obtained most conveniently by a more detailed analysis of the spectrum of **5** (in chloroform-*d*) in which the ring proton signals were resolved best. Two symmetrical triplets, each of 2-proton intensity,[3] occurred at τ 4.66 and 5.37 and were assignable to the protons in the positions 3 and 4, respectively. Their large splittings of ca. 10 Hz not only confirmed the known axial orientation of the protons on C-5 and C-4, but also required axial orientation of those on C-3 and C-2, thus establishing the *gluco* configuration. The anomeric protons gave at τ 5.56 a 2-proton doublet which was split by 3 Hz in accord with 1,2-equatorial–axial interaction. The C-6 methylene groups produced two unsymmetrical quartets with an integrated intensity of four protons in the region τ 5.7–6.0, and the protons in position 5 gave a 2-proton octet (width, 18 Hz) centered at τ 6.18. The methoxyl peak (6H) occurred at τ 6.64. It partially overlapped a 2-proton multiplet which was centered slightly upfield and must belong to the protons on C-2. Despite this overlap a large splitting (by H-3) and a small splitting (by H-1) were recognizable in that signal which showed additional, weak coupling with the vicinal amine hydrogen.[4] The amine hydrogen gave a somewhat broadened signal (apparently a narrow triplet) at τ 8.33, upfield from the two *O*-acetyl singlets (τ 7.92, 7.99). The existence of vicinal coupling between the hydrogen atoms on C-2 and the amine hydrogen indicates a retardation of intermolecular exchange of the latter, and bespeaks the low reactivity at this site.

Experimental

Melting points were determined in capillaries in an electrically heated aluminum block equipped with a

[3]This intensity and all others recorded are relative to the strength of an upfield signal attributable to the secondary amine proton (the only proton not duplicated in the molecule).

[4]Similar multiplets, fortuitously unobscured by the methoxyl absorption, were found in the spectra of **3** and **7**.

calibrated thermometer. Thin-layer chromatography (t.l.c.) was performed on silica gel G plates with chloroform–ethyl acetate (1:1, v/v). Petroleum ether refers to the fraction of boiling range 30–60°. Infrared (i.r.) spectra were obtained from Nujol mulls on a Beckman IR-8 instrument; only the most characteristic bands are listed. Optical rotations were measured at about 23° in a Perkin-Elmer 141 automatic polarimeter. Nuclear magnetic resonances (n.m.r.) were recorded on a Varian Associates HA-100 instrument.

Bis(methyl 4,6-O-benzylidene-2,3-dideoxy-3-nitro-α-D-glucopyranosid-2-yl)amine (3)

Reagent grade benzene was refluxed for 15 h over sodium wire and distilled before use. The nitroolefin **1** (1*e*,7) (147 mg) and the amine **2** (1*f*) (155 mg) were refluxed in benzene (40 ml) in the presence of a pellet of potassium hydroxide and a few pieces of fresh Drierite. Thin-layer chromatography revealed a gradual appearance, after 2 h, of a product migrating faster than either reactant. In several runs the reaction required 1–3.5 days for completion, with time variations apparently being occasioned by the quality of the solvent and (or) inadvertent access of traces of moisture. The yellow solution was then treated with activated charcoal, filtered, and evaporated to give a white residue. By recrystallization from ethyl acetate–petroleum ether, **3** was obtained as beautiful, colorless needles (204–235 mg, 67–78%): m.p. 284–285° (decomposition); $[\alpha]_D$ +78.5° (*c*, 0.8, dimethylformamide); ν_{max} 3360 (w, NH), 1555 (s, NO_2) with shoulder at 1565 (NH bending?), 765 and 705 cm^{-1} (ms, phenyl); n.m.r. ($CDCl_3$): τ 2.65 (narrow multiplet, C_6H_5), τ 4.50 (singlet, $PhCHO_2$), τ 5.30 (triplet, H-3, $J_{2,3} = J_{3,4} = 10$ Hz), τ 5.56 (doublet, H-1, $J_{1,2} = 3.5$ Hz); τ 5.67–6.45 (overlapping signals ascribable to H-4, H-5, H-6, and H-6′), τ 6.61 (singlet, OCH_3), τ 6.74 (multiplet, H-2, width ca. 18 Hz), τ 8.2 (broad signal, NH).

Anal. Calcd. for $C_{28}H_{33}N_3O_{12}$ (603.6): C, 55.72; H, 5.51; N, 6.96. Found: C, 55.61; H, 5.38; N, 6.95.

Bis(methyl 2,3-dideoxy-3-nitro-α-D-glucopyranosid-2-yl)amine (4)

The benzylidene compound **3** (517 mg) was dissolved in 90% trifluoroacetic acid (6 ml). The slightly exothermic reaction was allowed to proceed at ambient temperature for 10 min. The mixture was then evaporated to give a yellow syrup from which two portions of added water and two portions of ethanol were consecutively evaporated. Trituration of the syrup with ether then produced a first crop (262 mg) of **4** as small colorless prisms which were washed with ether. The ethereal mother liquor was evaporated to dryness and the residue, which was not homogeneous on t.l.c., yielded a second crop (20 mg) of **4** upon repetition of the hydrolysis with trifluoroacetic acid. The combined crops were recrystallized from ethyl acetate–petroleum ether. The crystals thereafter exhibited a medium strong i.r. band at 1740 cm^{-1} which was not present in the initial, crude product and which evidently was due to retained solvent. Drying of the product for 50 h at 100° and 1 mm removed this band, and 218 mg (60%) of pure **4** was obtained: m.p. 212–213° (decomposition, gradual darkening from 205°); $[\alpha]_D$ +161.2° (*c*, 0.7, water); ν_{max} 3500–3100 (broad, OH, NH), 1557 cm^{-1} (NO_2).

Anal. Calcd. for $C_{14}H_{25}N_3O_{12}$ (427.4): C, 39.34; H, 5.89; N, 9.83. Found: C, 39.37; H, 5.75; N, 9.95.

Debenzylidenation of **3** could also be effected with 70% acetic acid (1 h on a steam bath). The recrystallized product was identical with **4** in every respect, but its yield was only 37%.

Bis(methyl 4,6-di-O-acetyl-2,3-dideoxy-3-nitro-α-D-glucopyranosid-2-yl)amine (5)

Compound **4** (100 mg) was suspended in acetic anhydride (3 ml), and 3 drops of boron trifluoride etherate were added. The dissolution of **4** was completed by gentle warming, and the reaction mixture was then allowed to stand at ambient temperature for 40 min and was thereafter poured into excess, cold ethanol. The solution was evaporated, and the residue was co-evaporated five times with added ethanol and then recrystallized from ethyl acetate–petroleum ether. The tetraacetate (**5**) was obtained as colorless, elongated platelets (85 mg, 61%): m.p. 208–209°; $[\alpha]_D$ +118.5° (*c*, 1.1, chloroform); ν_{max} 3440 (w, NH), 1740 with shoulder at 1755 (s, ester CO), 1565 (w, NH bending), 1552 cm^{-1} (s, NO_2). For the n.m.r. data, see the discussion section.

Anal. Calcd. for $C_{22}H_{33}N_3O_{16}$ (595.5): C, 44.36; H, 5.58; N, 7.05. Found: C, 44.35; H, 5.56; N, 7.15.

Bis(methyl 3-amino-2,3-dideoxy-α-D-glucopyranosid-2-yl)amine Trihydrochloride (6)

In some experiments the benzylidene compound **3** was debenzylidenated as described above and the crude, chromatographically inhomogeneous syrup that contained **4** was hydrogenated directly. In a typical run, the syrup obtained from 542 mg of **3** was dissolved in water (40 ml), *N* hydrochloric acid (2.5 ml) and platinum catalyst (200 mg PtO_2, prehydrogenated) were added, and the mixture was hydrogenated for 24 h at ordinary temperature and pressure. The filtered solution was evaporated to give a syrup which was twice co-evaporated with water. The product (**6**) then crystallized from absolute ethanol as white prisms, in a yield of 190 mg (44% based on **3**). It gave a single, ninhydrin-positive spot on paper chromatography, R_{GN} 1.11,[5] and it showed $[\alpha]_D$ +144.7 (*c*, 0.9, water) and decomposed at 245–250° with gradual darkening from 200°. The i.r. spectrum exhibited a sharp band at 3540 and broad absorption in the 3300 cm^{-1} region with ν_{max} 3340, 3300, and 3250 (OH, NH), a band at 3060 and broad absorption in the 2700–2400 region, as well as bands at 1640, 1612, 1598, and 1520 cm^{-1}.

Anal. Calcd. for $C_{14}H_{32}Cl_3N_3O_8$ (476.8): Cl, 22.31; N, 8.81. Found: Cl, 22.5; N, 8.90.

A similarly performed hydrogenation of crystalline **4** (300 mg) gave **6** in higher yield (230 mg, 69%). Inadvertently, an insufficient amount of hydrochloric acid had been added in this experiment; this circumstance precluded an even better yield of crystalline trihydrochloride. The product had R_{GN} 1.11 and $[\alpha]_D$ +142.9° (*c*, 0.7, water), decomposed slowly above 205° and extensively at 240–250°, and its i.r. spectrum was identical with that from a previous preparation.

[5]Speed relative to D-glucosamine hydrochloride in descending chromatography using the system pyridine–ethyl acetate–water–acetic acid (5:5:3:1, v/v) according to Fischer and Dörfel (8).

Bis(methyl 3-acetamido-4,6-di-O-acetyl-2,3-dideoxy-α-D-glucopyranosid-2-yl)amine (7)

The trihydrochloride **6** (121 mg), acetic anhydride (3.5 ml), and pyridine (7 ml) were magnetically stirred for 16 h at room temperature in a stoppered flask. Excess methanol was added and the mixture was evaporated. The residue was evaporated in succession with fresh methanol, several portions of toluene, and again with methanol. A solution of the resulting, brownish syrup in chloroform was washed with water to remove pyridine hydrochloride, dried over sodium sulfate, and evaporated with an ultimate addition of ethanol. Recrystallization of the semi-solid residue from absolute ethanol–petroleum ether gave **7** (68 mg, 40%) as colorless platelets: m.p. 328° (decomposition); $[\alpha]_D$ +123.5° (*c*, 0.8, chloroform); ν_{max} 3310 (NH), 1740 (ester CO), 1658 (amide I), and 1560 cm^{-1} (amide II); n.m.r. ($CDCl_3$): τ 3.27 (broadened doublet, amide NH), τ 5.15 (triplet, J = 9.5 Hz, H-4), τ 5.44 (doublet, J = 3 Hz, H-1), τ 5.6–6.3 (overlapping signals ascribable to H-3, H-5, H-6, and H-6′), τ 6.64 (singlet, OCH_3), τ 7.00 (multiplet, width ca. 18 Hz, H-2), τ 7.92, 7.95 (singlets, *O*-acetyl), τ 8.05 (singlet, *N*-acetyl), τ 8.27 (broadened signal of *sec.*-amine NH).

Anal. Calcd. for $C_{26}H_{41}N_3O_{14}$ (619.6): C, 50.40; H, 6.67; N, 6.78. Found: C, 50.26; H, 6.48; N, 6.79.

Absolute configurations of the (−)-*erythro* and (−)-*threo*-2,3-dihydroxybutyric acids

F. W. BACHELOR AND G. A. MIANA[1]

Department of Chemistry, University of Calgary, Calgary 44, Alberta, Canada

Received June 23, 1969

The absolute configurations of (−)-*erythro*-2,3-dihydroxybutyric acid and (−)-*threo*-2,3-dihydroxybutyric acid have been determined by optical rotatory dispersion and found to be 2(R), 3(R) for the *erythro* acid and 2(S), 3(R) for the *threo* acid.

Canadian Journal of Chemistry, **47**, 4089 (1969)

We recently found it necessary to determine the absolute configurations of the active *erythro*-2,3-dihydroxybutyric and *threo*-2,3-dihydroxybutyric acids for use in a stereospecific synthesis. Because of the inquiries which we have received regarding these compounds we felt it expedient to communicate this information prior to the completion of the synthetic problem.

The absolute configuration of (−)-*threo*-2,3-dihydroxybutyric acid has been indirectly determined by its production from L-threonine with nitrous acid (1). Since the stereochemistry of the deaminations of α-amino acids has been established to give unequivocably retention of configuration (2), this establishes the stereochemistry of the (−)-*threo*-dihydroxybutyric acid as being the same as L-threonine.

Erythro-2,3-dihydroxybutyric acid was prepared by hydroxylation of *trans*-crotonic acid with hydrogen peroxide and tungstic acid according to the method of Mugdan and Young (3). This acid was resolved through its quinine salt (4) to give (−)-*erythro*-2,3-dihydroxybutyric acid with a specific rotation of −9.5°.

The *threo*-isomer was prepared by a Milas oxidation of *trans*-crotonic acid with osmium tetroxide and hydrogen peroxide (5) and the dihydroxy acid resolved through its quinidine salt (6) to give (−)-*threo*-2,3-dihydroxybutyric acid with a specific rotation of −17.75°.

Because of the poor recovery of the resolved acids from their salts by previously reported procedures (4,6) the free acids were regenerated by their passage through a weak acid ion exchange column, a method recently communicated by us (7).

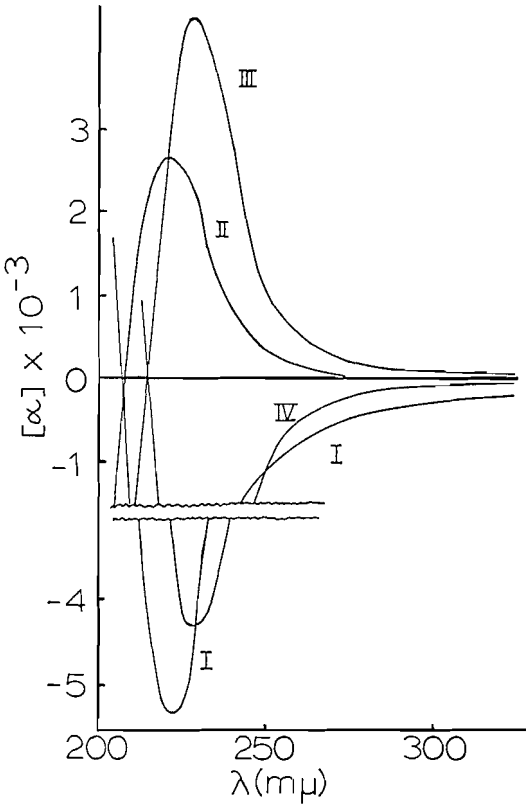

FIG. 1. Optical rotatory dispersion curves of: I, (−)-*erythro*-2,3-dihydroxybutyric acid; II, (−)-*threo*-2,3-dihydroxybutyric acid; III, (S)-(−)-tartaric acid; IV, (R)-(+)-tartaric acid.

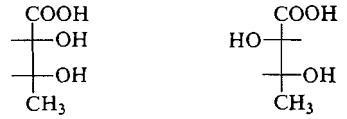
Since the observation by Dirkx and Sixma (8) that the 210 mμ absorption band of active α-substituted acids is optically active the Cotton effects of a number of acids of known absolute configuration have been measured (8, 9). These workers have shown that α-hydroxy acids having the S-configuration at the α-carbon atom exhibit a positive Cotton effect in the region 220–235 mμ, depending on the solvent and the p*H*.

We have measured the optical rotatory dispersion curves of our resolved acids and these are shown in Fig. 1. The curves for (R)-(+)- and (L)-(−)-tartaric acids are included for comparison. As can be seen, (−)-*threo*-2,3-dihydroxybutyric acid exhibits a positive Cotton effect with an absorption maximum at 221 mμ and a specific rotation of +2640°. This acid therefore has the S-configuration at the α-carbon atom. On the other hand, (−)-*erythro*-2,3-dihydroxybutyric acid shows a negative Cotton effect with a trough at 221 mμ and a specific rotation of −5380°, and therefore has the R-configuration at the α-carbon atom.

From the stereospecific methods of preparation it then follows that the complete configuration for (−)-*erythro*-2,3-dihydroxybutyric acid (**1**) is 2(R), 3(R) and that for (−)-*threo*-2,3-dihydroxybutyric acid (**2**) is 2(S), 3(R).



1 **2**

Experimental

All rotations and optical rotatory dispersion (o.r.d.) measurements were taken on a Jasco ORD/UV-5 spectropolarimeter.

(±)-Erythro-2,3-dihydroxybutyric Acid

86 g (1 mole) of *trans*-crotonic acid was dissolved in 500 ml of hot water and the solution stirred vigorously. A 30% hydrogen peroxide solution (106 ml, 0.95 mole) containing 540 mg of tungstic acid was added portionwise in about 10 min. The temperature of the reaction mixture was raised to 70° and maintained for 4 h. The reaction mixture was cooled to room temperature, extracted with chloroform, and the chloroform extract washed with distilled water. The combined aqueous extracts were filtered to remove inorganic material, and the filtrate concentrated *in vacuo* at 50° to give a syrup. The syrup was dissolved in one part of boiling anhydrous ethyl acetate and treated with charcoal. The filtered solution, when cooled to 0°, deposited colorless crystals of (±)-*erythro*-2,3-dihydroxybutyric acid. Yield, 67.2 g (70%); m.p. 80–83° (over P_2O_5).

(±)-Threo-2,3-dihydroxybutyric Acid

50 ml of a 0.5% solution of osmium tetroxide in *tert*-butanol was added slowly and cautiously to a cooled solution of 86.0 g (1 mole) of *trans*-crotonic acid in 125 ml of 30% hydrogen peroxide, made up to a volume of 600 ml. The solution, which becomes very hot after complete addition of the osmium tetroxide solution, was allowed to stand for 2 h at room temperature. The reaction mixture was extracted 3 times with 300 ml of benzene to remove the osmium tetroxide and was further extracted with chloroform. The aqueous layer was evaporated to dryness *in vacuo* to a syrup. The syrup was dissolved in anhydrous ethyl acetate, treated with charcoal and filtered. The filtrate on cooling deposited crystalline (±)-*threo*-2,3-dihydroxybutyric acid. Yield, 74 g (64%); m.p. 73–74° (over P_2O_5).

(−)-Erythro-2,3-dihydroxybutyric Acid (1)

20 g (0.165 mole) of (±)-*erythro*-2,3-dihydroxybutyric acid was dissolved in 250 ml of water. The solution was heated to 50 °C and neutralized with 60 g (0.185 mole) of

quinine. The cooled solution was filtered to remove undissolved quinine and cooled to 0°. After two days the crystals formed were collected and washed with ice water. The crystals (30 g) were recrystallized twice from water and dried *in vacuo* over H_2SO_4. Yield, 29.0 g; m.p. 195°; $[\alpha]_D^{20}$ −115° (*c*, 5.04, H_2O); [lit. (4), $[\alpha]_D^{20}$ −113° (*c*, 5.0, H_2O)].

Concentration of the original filtrate gave a further 6 g of crystalline material.

The free acid was regenerated by passing an aqueous solution of the resolved quinine salt through a Bio-Rex-70 (H^+) resin column (7) yielding (−)-*erythro*-2,3-dihydroxybutyric acid, $[\alpha]_D^{25}$ −9.5° (*c*, 1.0, H_2O); [lit. (4), $[\alpha]_D^{20}$ −9.30° (*c*, 0.5, H_2O)].

Rotatory dispersion (*c*, 0.5, H_2O): $[\alpha]_{589}$ −9.5°, $[\alpha]_{250}$ −1060°, $[\alpha]_{221}$ −5380° (trough), $[\alpha]_{210}$ −1790°.

(−)-Threo-2,3-dihydroxybutyric Acid (2)

To a hot solution of 20 g (0.165 mole) of (±)-*threo*-2,3-dihydroxybutyric acid in 500 ml of water 60 g (0.185 mole) of quinidine was added. The hot solution was filtered and cooled. The crystalline salt (37.3 g) was dried in a vacuum desiccator over H_2SO_4. Concentration of the filtrate gave a further 2.0 g of material. After several recrystallizations from water, a salt with constant rotation was obtained, m.p. 117°; $[\alpha]_D^{20}$ +145.5° (*c*, 3.3, H_2O); [lit. (6), m.p. 114°, $[\alpha]_D^{18}$ +142.2°, (*c*, 3.31, H_2O)].

Regeneration of the free acid was accomplished in the same manner as with the *erythro* acid yielding (−)-*threo*-2,3-dihydroxybutyric acid as a syrup, $[\alpha]_D^{25}$ −17.75° (*c*, 1.0 H_2O); [lit. (6), $[\alpha]_D^{16}$ −13.51° (*c*, 6.0, H_2O)].

Rotatory dispersion (*c*, 0.5, H_2O): $[\alpha]_{589}$ −17.75°, $[\alpha]_{250}$ +360°, $[\alpha]_{221}$ +2640° (peak), $[\alpha]_{210}$ +880°.

Chromatographic analysis of methyl ethers of 2-amino-2-deoxy-D-glucopyranose[1]

M. B. Perry and Ann C. Webb

The Biochemistry Laboratory, National Research Council of Canada, Ottawa, Canada

Received May 27, 1969

The mono-, di-, and tri-*O*-methyl ether derivatives of 2-amino-2-deoxy-D-glucopyranose have been analyzed by gas–liquid chromatography of their fully acetylated 2-acetamido-2-deoxy-D-glucitol derivatives which were prepared from the glycoses by reduction with sodium borohydride followed by acetylation with acetic anhydride. The methyl ethers of 2-amino-2-deoxy-D-glucopyranose were also characterized by degradation with ninhydrin to the corresponding methyl ether derivatives of D-arabinose which were identified by paper chromatography.

Canadian Journal of Chemistry, 47, 4091 (1969)

The identification of the methyl ether derivatives of 2-amino-2-deoxy-D-glucose from the hydrolyzates of methylated glycans containing 2-amino-2-deoxy-D-glucose units is usually a part of the procedure involved in the structural analysis of the original glycan. The paper chromatographic (1–6) method has been used for the identification of the methyl ethers of 2-amino-2-deoxy-D-glucose. However, in our experience, this method did not provide a satisfactory separation of the individual mono- and di-*O*-methyl derivatives. Gas–liquid chromatography (g.l.c.) has been used to identify some methyl ethers as their methyl 2-acetamido-2-deoxy-D-glucoside derivatives (7–9). A recent thin-layer chromatographic (t.l.c.) method for the separation of the methyl ethers of ethyl 2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranoside and of 2-deoxy-2-(2,4-dinitroanilino)-D-glucose (10) offers a practical procedure for the analysis of mixtures of the methyl ethers of 2-amino-2-deoxy-D-glucose. This note records a

quinine. The cooled solution was filtered to remove undissolved quinine and cooled to 0°. After two days the crystals formed were collected and washed with ice water. The crystals (30 g) were recrystallized twice from water and dried *in vacuo* over H_2SO_4. Yield, 29.0 g; m.p. 195°; $[\alpha]_D^{20}$ −115° (*c*, 5.04, H_2O); [lit. (4), $[\alpha]_D^{20}$ −113° (*c*, 5.0, H_2O)].

Concentration of the original filtrate gave a further 6 g of crystalline material.

The free acid was regenerated by passing an aqueous solution of the resolved quinine salt through a Bio-Rex-70 (H^+) resin column (7) yielding (−)-*erythro*-2,3-dihydroxybutyric acid, $[\alpha]_D^{25}$ −9.5° (*c*, 1.0, H_2O); [lit. (4), $[\alpha]_D^{20}$ −9.30° (*c*, 0.5, H_2O)].

Rotatory dispersion (*c*, 0.5, H_2O): $[\alpha]_{589}$ −9.5°, $[\alpha]_{250}$ −1060°, $[\alpha]_{221}$ −5380° (trough), $[\alpha]_{210}$ −1790°.

(−)-Threo-2,3-dihydroxybutyric Acid (2)

To a hot solution of 20 g (0.165 mole) of (±)-*threo*-2,3-dihydroxybutyric acid in 500 ml of water 60 g (0.185 mole) of quinidine was added. The hot solution was filtered and cooled. The crystalline salt (37.3 g) was dried in a vacuum desiccator over H_2SO_4. Concentration of the filtrate gave a further 2.0 g of material. After several recrystallizations from water, a salt with constant rotation was obtained, m.p. 117°; $[\alpha]_D^{20}$ +145.5° (*c*, 3.3, H_2O); [lit. (6), m.p. 114°, $[\alpha]_D^{18}$ +142.2°, (*c*, 3.31, H_2O)].

Regeneration of the free acid was accomplished in the same manner as with the *erythro* acid yielding (−)-*threo*-2,3-dihydroxybutyric acid as a syrup, $[\alpha]_D^{25}$ −17.75° (*c*, 1.0 H_2O); [lit. (6), $[\alpha]_D^{16}$ −13.51° (*c*, 6.0, H_2O)].

Rotatory dispersion (*c*, 0.5, H_2O): $[\alpha]_{589}$ −17.75°, $[\alpha]_{250}$ +360°, $[\alpha]_{221}$ +2640° (peak), $[\alpha]_{210}$ +880°.

Chromatographic analysis of methyl ethers of 2-amino-2-deoxy-D-glucopyranose[1]

M. B. Perry and Ann C. Webb

The Biochemistry Laboratory, National Research Council of Canada, Ottawa, Canada

Received May 27, 1969

The mono-, di-, and tri-*O*-methyl ether derivatives of 2-amino-2-deoxy-D-glucopyranose have been analyzed by gas–liquid chromatography of their fully acetylated 2-acetamido-2-deoxy-D-glucitol derivatives which were prepared from the glycoses by reduction with sodium borohydride followed by acetylation with acetic anhydride. The methyl ethers of 2-amino-2-deoxy-D-glucopyranose were also characterized by degradation with ninhydrin to the corresponding methyl ether derivatives of D-arabinose which were identified by paper chromatography.

Canadian Journal of Chemistry, **47**, 4091 (1969)

The identification of the methyl ether derivatives of 2-amino-2-deoxy-D-glucose from the hydrolyzates of methylated glycans containing 2-amino-2-deoxy-D-glucose units is usually a part of the procedure involved in the structural analysis of the original glycan. The paper chromatographic (1–6) method has been used for the identification of the methyl ethers of 2-amino-2-deoxy-D-glucose. However, in our experience, this method did not provide a satisfactory separation of the individual mono- and di-*O*-methyl derivatives. Gas–liquid chromatography (g.l.c.) has been used to identify some methyl ethers as their methyl 2-acetamido-2-deoxy-D-glucoside derivatives (7–9). A recent thin-layer chromatographic (t.l.c.) method for the separation of the methyl ethers of ethyl 2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranoside and of 2-deoxy-2-(2,4-dinitroanilino)-D-glucose (10) offers a practical procedure for the analysis of mixtures of the methyl ethers of 2-amino-2-deoxy-D-glucose. This note records a

g.l.c. and a paper chromatographic method for the identification of the methyl ethers of 2-amino-2-deoxy-D-glucopyranose.

Initial attempts to analyze mixtures of *O*-methyl derivatives of 2-amino-2-deoxy-D-glucopyranose by g.l.c. of either their trimethylsilylated 2-acetamido-2-deoxy-D-glucopyranoside or methyl 2-acetamido-2-deoxy-D-glucopyranoside derivatives gave complex chromatograms with peak overlaps. Simplified chromatograms were however achieved on g.l.c. of the fully acetylated methyl ether derivatives of 2-acetamido-2-deoxy-D-glucitol derived from the original methyl ethers of 2-amino-2-deoxy-D-glucopyranose.

Authentic mono-, di-, and tri-*O*-methyl derivatives of 2-acetamido-2-deoxy-D-glucopyranose were reduced to their corresponding D-glucitol derivatives with sodium borohydride and after acidification with acetic acid, the mixtures were concentrated to dryness and the boric acid was removed by repeated distillations with methanol. The residual D-glucitol derivatives and sodium acetate were treated with acetic anhydride and the resulting acetylated products were analyzed directly by g.l.c. The retention times of the derivatives, quoted relative to 1,3,4,5,6-penta-*O*-acetyl-2-acetamido-2-deoxy-D-glucitol, are recorded in Table I.

The use of the polyester liquid phase column gave a good separation of the individual derivatives one from another and since it was found that the derivatives gave equal molar response, determined by measurement of peak areas, the procedure can be extended to the quantitative analysis of the mixed methyl ethers of 2-amino-2-deoxy-D-glucopyranose with an accuracy of $\pm$ 4%.

A further characterization of the methyl ethers of 2-amino-2-deoxy-D-glucopyranose can be made by paper chromatographic analysis of the methyl ethers of D-arabinose produced by degradation of the aminoglycoses with ninhydrin (11) following the experimental procedure of Stoffyn and Jeanloz (12). The chromatographic mobilities of the D-arabinose derivatives are recorded in Table II. Of the possible methyl ether derivatives of D-arabinose derived from methyl ethers of 2-amino-2-deoxy-D-glucopyranose, only 2,5- and 3,5-di-*O*-methyl-D-arabinose (13), derived from 2-amino-2-deoxy-D-glucose 3,6- and 4,6-di-*O*-methyl derivatives respectively, failed to separate on paper chromatography. The identity of the above di-*O*-methyl-D-arabinose derivatives can be established by paper electrophoretic examination of this fraction using sodium borate buffer. The 2,5-di-*O*-methyl-D-arabinose has zero mobility whereas the 3,5-di-*O*-methyl-D-arabinose shows considerable migration (M_G 0.67).

When the above procedures are applied to the identification of 2-amino-2-deoxy-D-glucopyranose derivatives in the hydrolysates of methylated glycans containing neutral glycoses, the basic glycoses are best separated from the neutral compounds before analysis, by using cation-exchange resin (H^+ form) from which they can be subsequently eluted with dilute mineral acid (14,15).

Experimental

The 3-, 4-, 6-mono-*O*-, 3,4-, 3,6-, 4,6-di-*O*-, and 3,4,6-tri-*O*-methyl derivatives of 2-amino-2-deoxy-D-glucose hydrochloride and 2-acetamido-2-deoxy-D-glucose were prepared by the methods of Jeanloz (16) and they had physical and chemical properties in agreement with those recorded in the literature.

Gas-liquid chromatography was done using a Hewlett-Packard model 402 gas chromatograph with a hydrogen

TABLE II

Paper chromatographic mobilities of the methyl ethers of D-arabinose obtained by the degradation of the methyl ethers of 2-amino-2-deoxy-D-glucopyranose with ninhydrin

Methyl ether of 2-amino-2-deoxy-D-glucose	Methyl ether of D-arabinose obtained by ninhydrin degradation	Chromatographic mobility*
2-Amino-2-deoxy-3-*O*-methyl-D-glucose	2-*O*-Methyl-D-arabinose	0.18
2-Amino-2-deoxy-4-*O*-methyl-D-glucose	3-*O*-Methyl-D-arabinose	0.12
2-Amino-2-deoxy-6-*O*-methyl-D-glucose	5-*O*-Methyl-D-arabinose	0.37
2-Amino-2-deoxy-3,4-di-*O*-methyl-D-glucose	2,3-Di-*O*-methyl-D-arabinose	0.55
2-Amino-2-deoxy-3,6-di-*O*-methyl-D-glucose	2,5-Di-*O*-methyl-D-arabinose	0.75
2-Amino-2-deoxy-4,6-di-*O*-methyl-D-glucose	3,5-Di-*O*-methyl-D-arabinose	0.77
2-Amino-2-deoxy-3,4,6-tri-*O*-methyl-D-glucose	2,3,5-Tri-*O*-methyl-D-arabinose	1.00

*Mobilities are quoted relative to 2,3,5-tri-*O*-methyl-D-arabinose (= 1.00). Solvent system: butan-2-one saturated with 3% aqueous ammonium hydroxide (13).

flame detector, and fitted with glass U tubes (5 ft × 6 mm × 3 mm i.d.) packed to each end with 10% (w/w) neopentylglycol sebacate polyester (Chromatographic Specialities, Brockville, Ont.) on 80–100 mesh acid-washed Chromosorb W (Johns-Manville). Development was made with dry helium at a flow rate of 100 ml/min and column temperature of 245 °C, and the flash heating system was not used.

Paper chromatography was performed by the descending method on Whatman No. 1 filter paper using butan-2-one saturated with 3% aqueous ammonium hydroxide as the mobile phase. Paper electrophoresis was done on Whatman No. 1 filter paper in 0.1 *M* sodium tetraborate at 750 V (potential gradient 25V/cm) and 30–40 ma for 2 h. Glycoses were detected using the 3% *p*-anisidine hydrochloride in ethanol spray reagent (17).

Preparation of Acetylated Methyl Ethers of 2-Acetamido-2-deoxy-D-glucitol for Gas-liquid Chromatography

The methyl ethers of 2-acetamido-2-deoxy-D-glucitol (2–5 mg) in water (2 ml) were reduced with sodium borohydride (15 mg) for 40 h. The mixtures were acidified with acetic acid and after concentration to dryness under reduced pressure, the residues were taken down with methanol containing 3% acetic acid (5 × 20 ml). The final residues were treated with acetic anhydride (1.2 ml) and were kept at 130 °C for 3 h. Samples (1 µl) of the reaction mixtures were injected directly onto the gas chromatographic column packing.

Degradation of Methyl Ethers of 2-Amino-2-deoxy-D-glucopyranose with Ninhydrin

Samples of the methyl ethers of 2-amino-2-deoxy-D-glucopyranose hydrochloride (0.1 mg) were dissolved in a 2% (w/v) solution of ninhydrin in water containing 4% (v/v) pyridine (0.2 ml) and the mixtures, contained in sealed tubes, were kept at 100° C for 40 min. The reaction mixtures were dried in an air stream and the residues were mixed with 2 drops of water and the solutions were applied directly to paper chromatograms. In each case a single glycose spot was detected on the developed chromatograms which corresponded in mobility with that of the expected authentic methyl ether derivative of D-arabinose.

In analyses in which a spot corresponding to either 2,5- or 3,5-di-*O*-methyl-D-arabinose was present, a preparative paper chromatogram was made and the excised spot corresponding to the di-*O*-methyl glycose was eluted and examined by paper electrophoresis. 2,5-Di-*O*-methyl-D-arabinose had zero mobility and the 3,5-di-*O*-methyl-D-arabinose had a mobility relative to D-glucose of 0.67 (M_G). This analysis permits the identification of either one or both of the glycoses in the degradation mixture.

Acknowledgment

We thank Mrs. S. C. Williams for supplying us with authentic methyl ethers of arabinose.

4,6-*O*-Benzylidene-3-deoxy-3-*C*-(iodomethyl)-D-allal: precursor of a cyclopropylcarbinyl-oxo-carbonium ion

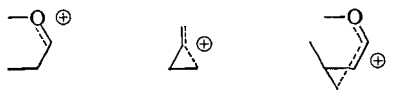
BERT FRASER-REID AND BRUNO RADATUS
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received May 16, 1969

Treatment of methyl 4,6-*O*-benzylidene-α-D-*erythro*-hex-2-enopyranoside (**5**) with the Simmons–Smith reagents gives 85% of the expected cyclopropane adduct **6** and about 10% of a second product **4**. When the cyclopropane derivative **6** is allowed to react further with the Simmons–Smith reagents, it is 40% converted to **4**. The structure of compound **4** is established to be 4,6-*O*-benzylidene-3-deoxy-3-*C*-(iodomethyl)-D-allal (4,6-*O*-benzylidene-1,2,3-trideoxy-3-*C*-iodomethyl-D-*ribo*-hex-1-enopyranose), and the unusually high solvolytic reactivity observed for it, as well as its formation from **6**, are rationalized as proceeding through the *cyclopropylcarbinyl-oxo-carbonium ion* **3**.

Canadian Journal of Chemistry, 47, 4095 (1969)

The stabilized carbonium ion **1** is frequently invoked as an intermediate in reactions occurring at the anomeric center of carbohydrate molecules (1). Another stabilized ion, **2**, has been demonstrated to be an intermediate in reactions where a cationic center is generated at a homoallylic site (2). Carbonium ion **3** is a combination of **1** and **2**. In this communication we describe a novel



1 **2** **3**

vinyl ether, **4**, whose unusually high solvolytic reactivity appears best rationalized by invoking the intervention of the cyclopropylcarbinyl-oxo-carbonium ion **3**.[1]

Cyclopropanation[2] of olefin **5** (4), as with most additions to this compound (3), proceeds with difficulty[3]; however, a procedure was established whereby **5** could be converted to the cyclopropane derivative **6** in greater than 80% yield based on unrecovered olefin. A minor component (**4**) was produced in about 10% yield and this was isolated in a fairly high state of purity by silica column chromatography.[4]

This component **4** gave: m.p. 130–132 °C; $[\alpha]_D^{23}$ + 129.0° (*c*, 2.8 in $CHCl_3$).

Anal. Calcd. for $C_{14}H_{15}IO_3$: C, 46.92; H, 4.22; I, 35.47. Found: C, 46.87; H, 4.22; I, 34.67.[5]

The nuclear magnetic resonance (n.m.r.) spectrum showed the absence of a methoxyl signal but retention of the benzylidene group. Infrared (i.r.) absorptions at 1645, 1235, and 1081 cm^{-1} suggested a vinyl ether (7), and n.m.r. support for this feature was provided by two quartets at τ 3.66 and 5.00 (ascribable to the α-(H-1) and β-(H-2) hydrogens) with a common coupling constant $J_{1,2}$ of 6.5 Hz, excellent diagnosis of a glycal (8). The iodine was located at a primary carbon since reduction with lithium aluminum hydride afforded a substance whose n.m.r. spectrum contained a methyl group. The latter

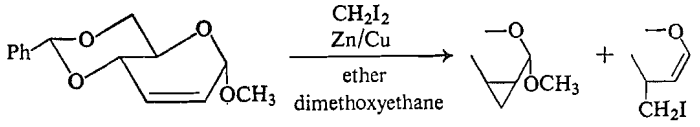
[1]The drawing of **3** is not intended to convey anything about the geometry of the species. This aspect of the ion will be discussed when appropriate data have accumulated.

[2]A well stirred mixture of methylene iodide (1.44 ml; 0.0179 mole), zinc–copper couple (5) (1.0 g; 0.0513 mole), and ether (6 ml; 0.0576 mole) was refluxed for 1 h. Olefin **5** (2.0 g; 0.008 mole) was then added along with ether (4 ml; 0.0384 mole) and dimethoxyethane (0.16 ml) (6). After (total) reaction periods of 0.5, 1, 3, and 4 h, further 0.16 ml portions of dimethoxyethane were added. After a total reaction time of 8 h, isolation in the usual way (5) afforded 2.255 g of material, 85% of which was judged (n.m.r.) to be **5** and **6** in ratio 1:2. Physical constants of **6** agree with those reported by Horton and co-workers (3).

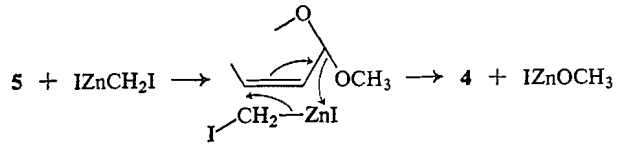
[3]After our work had commenced we learned of similar studies in progress at Ohio State University. We are grateful to Professor Horton for informing us of the progress of his work prior to publication (3).

[4]R_f on thin layer chromatography (silica) 0.8 in EtOAc–petroleum ether (1:4).

[5]Horton and co-workers (3) isolated a compound: C, 60.65; H, 5.28; I, 19.60; m.p. 81–83° with "no intense singlet for an OMe group" in the n.m.r.

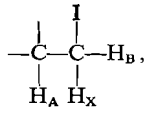


5 6 4



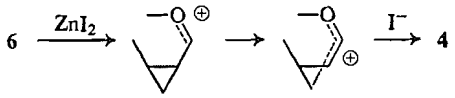
SCHEME 1

appeared as a doublet and was therefore adjacent to a methine proton (*vide infra*). The iodide evidently had structure **4**. The iodomethyl group is judged to be axially oriented since the coupling constant $J_{2,3}$ (6.0 Hz) is closer to that observed in allal and gulal derivatives (8*a*,*b*), in which H-3 is pseudo-equatorial (9), than is observed in glucal (8) and galactal (10) derivatives in which H-3 is pseudo-axial.[6] Detailed description of the n.m.r. spectrum will be presented elsewhere but it may be noted here that the asymmetry at carbon-3 renders the adjoining methylene protons non-equivalent (11). Thus for the moiety



H_B is a quartet at τ 7.00 with $J_{A,B}$ = 8.5 Hz and $J_{B,X}$ = 10.5 Hz, while H_X occurs 0.6 p.p.m. to lower field. H_A (i.e. H-3) whose coupling to H_B, H_X, and H-4 could be demonstrated by double irradiation experiments, is a complex multiplet centered at τ 7.20. In the lithium aluminum hydride-reduced material this signal is shifted to τ 7.43; the latter is simplified on irradiation of a methyl doublet at τ 8.86.

The formal accomplishment in the synthesis of **4** is addition of the iodomethyl anion to carbon-3 of **5** and expulsion of the methoxy substituent. The allylic rearrangement depicted in Scheme 1 is attractive in that it provides for *cis*-relationship between entering and leaving nucleophiles, in accordance with the observed stereochemical course for such rearrangements (12). However, although "forward" allylic rearrangements in which glycals are converted to hex-2-enopyranosides are well known (1*b*,9*a*), the "reverse" rearrangement such as that implied in Scheme 1 has not been reported (1*b*,3,9*a*). An alternative route to **4** (Scheme 2) originates with cleavage of the methoxyl of **6** to give ion **7**,[7] which undoubtedly goes to the more delocalized form represented by **3**, which then suffers iodinolysis at the methylene group to give



7 3

SCHEME 2

4. Such a route is indeed possible since **6** was 40% converted to **4**,[8] the reaction conditions[2] being maintained for 8 h. This conversion provides independent proof of the configuration assigned to **4**, since under the reaction conditions epimerization at carbon-3 is inconceivable.

Ion **3** would also be expected to intervene and facilitate nucleophilic displacement of the iodine atom of **4**. Indeed, *under conditions where methyl*

[6]The allylic coupling constant ($J_{1,3}$) observed is 1.5 Hz and could be compatible with either axial or equatorial orientation of the iodomethyl group. Data presented in Table I of ref. 8*b* indicate that these long range coupling constants are very sensitive to changes in electronegativity.

[7]Cleavage could conceivably be induced by zinc iodide produced in the Simmons–Smith reaction (6). However, surprisingly, compound **6** has so far not given **4** when treated with zinc iodide in ether!!

[8]This observation does not specifically preclude Scheme 1; it merely demonstrates that under the reaction conditions, **6** is convertible to **4**.

For personal use only.

6-deoxy-6-iodo-α-D-glucopyranoside triacetate (13) required more than 24 h to react appreciably with excess silver nitrate in 50% aqueous dioxan buffered with silver carbonate, the iodide 4 was solvolyzed completely in less than 1 min.

Investigation of the synthetic utility of **4** and of the chemistry of the cyclopropylcarbinyl-oxocarbonium ion **3** is underway and will be reported in due course.

Acknowledgments

The authors are grateful to the National Research Council of Canada and the University of Waterloo for providing generous financial support for this work. We express our deep appreciation to the Chemistry Department of McMaster University and in particular Mr. Brian Sayer, for the 100 MHz n.m.r. determinations.

Distribution of reaction products (theory). VII. $D^+ + H_2 \rightarrow DH + H^+$ using an *ab initio* potential-energy surface

I. G. CSIZMADIA, J. C. POLANYI, A. C. ROACH,[1] AND W. H. WONG[2]

Department of Chemistry, University of Toronto, Toronto, Ontario

Received September 10, 1969

A three-dimensional classical trajectory calculation has been made of the dynamics of the reaction $D^+ + H_2 \rightarrow DH + H^+$. In contrast to earlier trajectory studies the potential-energy surface was obtained *ab initio*, consequently the results have predictive interest.

Canadian Journal of Chemistry, 47, 4097 (1969)

In this Communication we give a preliminary report of a computer study of the dynamics of the reaction $D^+ + H_2 \rightarrow DH + H^+$. This is, to our knowledge, the first calculation of the dynamics of a chemical reaction using an *ab initio* potential-energy surface.

The variational treatment (for some recent treatments of H_3^+, see ref. 1) took the form of an l.c.a.o.–m.o.–s.c.f. (linear combination of atomic orbitals, molecular orbital, self-consistent field) calculation with configuration interaction (c.i.). A basis-set of 24 Gaussian-type functions (g.t.f.'s) were used (reasons for this choice are in ref. 2); 8 functions centered on each of the 3 nuclei (5 s-type;[3] 3 p-type, i.e. p_x, p_y, p_z).[4] The

c.i. was complete for the lowest 15 s.c.f.–m.o.'s. Approximately 15 min of IBM 7094 computer time were required for each of the 250 nuclear configurations. The calculated energies of the most stable equilateral, collinear, and reactant configurations were respectively 3, 4, and 5 kcal $mole^{-1}$ above the estimated true values, indicating that our surface ran closely parallel to the true one (4).

A potential curve, composed of three superimposed Morse-like functions, was "rotated" about a separated-atom configuration to produce a potential-energy surface for a given $(H—H—H)^+$ angle.[5] The curve parameters varied with both "rotational" and bending angles, yielding an expression for the full hypersurface with a standard deviation of 6.65 kcal $mole^{-1}$ from the *ab initio* points.

Classical trajectories (6) were run in three dimensions[6] for the mass-combination $D^+ + H_2$. Fixed center-of-mass (c.m.) collision energies of 3, 4.5, and (in a smaller sample) 6 eV were used. Other variables (including H_2 rotation and vibration) were chosen by Monte Carlo selection.[7]

The main results can be summarized as follows:

(*i*) As expected for an energy-surface with a very deep potential-well, reaction proceeded by way of a complex. At a collision-energy of 3 eV (i.e. 3 eV in excess of the energy required to dissociate the complex), the complex had a lifetime which was typically $\sim 1 \times 10^{-13}$ s. The great majority (> 90%) of trajectories took from $(0.4–3.0) \times 10^{-13}$ s; the low figure corresponded to approximately one rotation of the complex. The duration of the reactive trajectories increased markedly with increasing impact parameter, b.

(*ii*) Reaction occurred out to maximum impact parameters, b_{max}, significantly in excess of the Gioumousis and Stevenson polarization limit, $b_{max}{}^{p}$ (10). For the present reaction $b_{max} > 2.4$ Å, at both 3 and 4.5 eV,[8] whereas $b_{max}{}^{p}$ is 1.66 Å at 3 eV, and 1.5 Å at 4.5 eV (see eq. [12] of ref. 11). This discrepancy [9] can be explained qualitatively by the effect of the valence forces in the neighborhood of $b_{max}{}^{p}$ in increasing the *attraction* and hence decreasing the height of the rotational barrier on the effective potential. It does not follow that the polarization-model cross-sections will be smaller than the computed ones, since the trajectories led to a reaction probability of 0.2–0.3 for $b \leqslant 2.4$ Å (the polarization theory assumes unit probability).

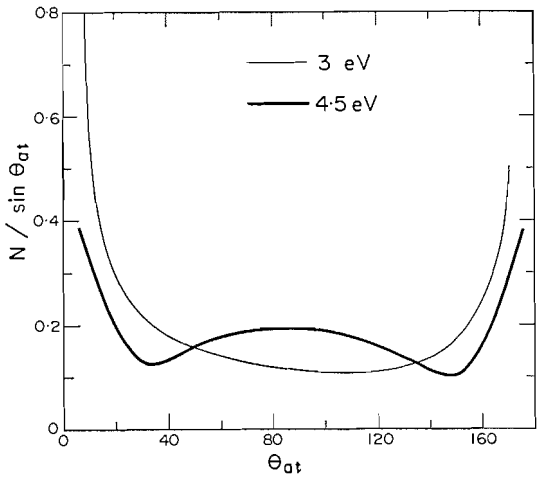

FIG. 1. Center-of-mass differential cross-section for the atomic product of $D^+ + H_2 \rightarrow DH + H^+$ at 3 eV (104 reactive trajectories) and 4.5 eV (83 reactive trajectories).

(*iii*) The c.m. differential cross-section (Fig. 1) showed forward and backward peaked scattering of the molecular product. At 3 eV collision energy the backward peak was slightly more prominent; at 4.5 eV the scattering was symmetrical (giving the appearance of purely statistical behavior).[10] Probably due to the large (positive) slope of the potential-energy surface along the coordinate of separation, the stripping threshold energy is very high (see Fig. 1 of ref. 13) (so high as to be inaccessible, see (*v*) below).

(*iv*) The product vibrational and rotational energy-distributions[10] at 3 eV were characterized

[5]F. T. Wall and R. N. Porter (5) originated this method in a simpler form suitable for collinear reaction.

[6]The coordinate system (see also footnote 7) and method for integrating the equations of motion is described in part V of this series (7).

[7]The Monte Carlo selection procedure is described in refs. 8 and 9.

[8]We do not yet have precise values for b_{max} or for the reactive cross-section, since a number of complex trajectories remain to be computed. The total reactive cross-section is $S_r > 2.7$ Å^2 at 3 eV, and > 2.2 Å^2 at 4.5 eV.

[9]Failure of the polarization theory at collision energies $\gtrsim$ 1 eV has been predicted: see refs. 10 and 12. The valence forces were presumed to be *repulsive*, hence $b_{max} < b_{max}{}^{p}$.

[10]Though the data are incomplete (see footnote 8), the results are unlikely to alter; partial histograms which included only the shorter trajectories closely resembled those for the more complex trajectories.

by a steadily descending curve of probability from zero energy up to the maximum[11] possible energy of 76 kcal mole^{-1}. The mean vibrational and rotational energies in the products were $\langle E_V' \rangle \simeq \langle E_R' \rangle \simeq 23$ kcal mole^{-1}. At 4.5 eV collision energy the N (E_V') curve, giving the distribution of product over vibrational energies, was double-peaked with a more prominent low-energy peak at 28 kcal mole^{-1} and a smaller high-energy peak at 88 kcal mole^{-1} (available energy 112 kcal mole^{-1}).[11] The N (E_R') curve at 4.5 eV descended steadily from $E_R' = 0$ to $E_R' \simeq$ 70 kcal mole^{-1}, with evidence of a secondary peak centered at approximately 84 kcal mole^{-1}. The tendency for DH to be formed with greatest probability in low states of rotation implied that the outcome of the reaction was not statistical, despite the complexity of the trajectories.[12]

The translational energy-distributions at 3 and 4.5 eV were roughly Boltzmann in shape; mean values were $\langle E_T' \rangle \simeq 30$ kcal mole^{-1} at 3 eV, and $\langle E_T' \rangle \simeq 38$ kcal mole^{-1} at 4.5 eV.

(*v*) Approximately 20% of the reactive trajectories at 4.5 eV led to fragmentation into 3 particles, despite the fact that the collision-energy was only 0.1 eV in excess of the dissociation energy, D_0. At 6 eV it appeared that over 90% of the reactive trajectories gave fragmentation. This very steep rise in percentage of fragmentation immediately above the dissociation energy may be connected with the complexity of the trajectories (arising from the existence of deep potential-well) which partitions the energy among all three atoms.[13]

[11]This figure is the c.m. collision energy, plus 6.3 kcal mole^{-1} of vibration, plus the mean rotational energy (0.6 kcal mole^{-1}).

[12]If the product states were populated in proportion to the available phase-space, there would be increasing population toward higher J levels (14). It is noteworthy that a statistical distribution over angles need not imply a statistical distribution over energy states (see results for 4.5 eV collision energy). The former merely requires that the particles shall have scrambled their momenta to the point that the initial direction of approach of D^+ has been "forgotten". The latter makes the more stringent requirement that there be no preferred paths through phase-space for the dissociation of $DH_2^+ \rightarrow DH + H^+$.

[13]Two studies of *direct* reaction (15) showed a more gradual increase in the proportion of fragmentation.

There is at the present time no experimental information concerning the dynamics of the $D^+ + H_2$ reaction, but beam studies are planned in several laboratories.

Structural aspects of the hydrolysis products of metal alkoxides and metal trialkylsilyloxides[1]

J. W. LORIMER AND D. E. G. JONES[2]

Department of Chemistry, University of Western Ontario, London, Ontario

Received April 30, 1969

The average degree of polymerization $\bar{n}_n$ depends on the average degree of hydrolysis $\bar{x}_n$ as $1/\bar{n}_n = a + b\bar{x}_n$ over a large range of $\bar{x}_n$ for all metal oxide alkoxides and oxide trialkylsilyloxides that have been formed by hydrolysis and examined in solution. A number of general theoretical models are developed which permit quantitative interpretation of the parameters a and b. Mixtures of linear or branched chains in proportions governed wholly or partly by the degree of polymerization of the unhydrolyzed alkoxide can explain all the data on oxide alkoxides in solution in their corresponding alcohol, and the model leads to a plausible mechanism for disproportionation. Similar models with more complex structure can be involved in the metal oxide trialkylsilyloxides. Heterogeneity in the composition of the repeating units or in the number of metal–oxygen–metal bridges between successive repeating units can also be significant for both oxide alkoxides and oxide trialkylsilyloxides. Models involving cyclic chains are possible, but steric effects make them improbable in many cases. Mixtures of chains with equal average degrees of hydrolysis for each type of chain have been assumed in previous analyses, but are shown to be special cases of the more general model.

Canadian Journal of Chemistry, 47, 4101 (1969)

Introduction

Bradley and co-workers have examined a large number of the polymeric hydrolysis products of metal alkoxides (1–7) and of metal trialkylsilyloxides (8–11). Hydrolysis of metal alkoxides gives metal oxide alkoxides, or polyalkylmetalloxanes, e.g.

$$[1a] \quad n\mathrm{Sn(OPr^i)_4} + nx\mathrm{H_2O} \rightarrow [\mathrm{SnO}_x(\mathrm{OPr^i})_{4-2x}]_n + 2nx\mathrm{Pr^iOH}$$

while hydrolysis of metal trialkylsilyloxides gives metal oxide trialkylsilyloxides, or polytrialkylsiloxanometalloxanes, e.g.

$$[1b] \quad n\mathrm{Ti(OSiMe_3)_4} + nx\mathrm{H_2O} \rightarrow [\mathrm{TiO}_x(\mathrm{OSiMe_3})_{4-2x}]_n + 2nx\mathrm{Me_3SiOH}$$

The number of metal atoms per polymer molecule, n, is called the degree of polymerization or molecular complexity, and the number of water molecules per metal atom, x, is called the degree of hydrolysis. In the case of the oxide alkoxides, the stoichiometry or analysis for the metal gives the value of x. For the oxide trialkylsilyloxides, condensation of trialkylsilanols can produce more water and enhance the degree of hydrolysis, so that analysis for the ratio of silicon to metal is required to find the value of x. In either case, combination of the number average molecular weight (obtained by ebullioscopy or cryoscopy, for example), with the value of x gives the value of n.

For almost all the soluble polymers examined, $1/n$ was a linear function of x over a large range of x, and neither n nor x were integral. This linear dependence has been explained by a general theory of "regular polymer series" (7). By combining this theory with the postulate that the polymers adopt the smallest possible structural unit consistent with attainment of the highest possible coordination number by all metal atoms (12), information about the structure of the polymers has also been derived. Conclusions concerning structure obtained in this

way have been criticized (13, 14) in the case of the titanium oxide ethoxides. X-Ray analysis of one crystalline hydrolysis product of titanium tetraethoxide (15) confirms the prediction (1) that titanium has a coordination number of 6, although the structures in the solid state and in solution (1) appear to be different. Recent investigations in this laboratory of light scattering, refractivity, specific volume, and viscosity in solutions of titanium oxide trimethylsilyloxide (16) lend support to the structural model proposed on the basis of the theory of regular polymer series (8). However, it became clear that the theory as originally formulated lacked sufficient generality. The object of this paper is to give a correct and complete theory of regular polymer series, to ascertain what information may or may not be obtained from the linear dependence of $1/n$ on x, and to apply the theory systematically to existing experimental data.

General Theory for Homogeneous Polymer Chains

(a) Single Linear or Branched Chains

A "regular polymer series" is defined as a set of hydrolysis products with structures that fulfill the following requirements (7). (*i*) Each member of the series is considered to be derived from an integral number r of repeating units linked together by an integral number q of metal–oxygen–metal bridges formed by condensation. The value of q will be called the "bridge multiplicity". (*ii*) The degree of polymerization p of the repeating units must retain the same integral values throughout the series. (*iii*) The bridge multiplicity must be constant throughout the series. Requirements (*ii*) and (*iii*) define the chains to be homogeneous. This definition of a regular polymer series will be expanded to include polydisperse, mixed, and heterogeneous polymers in subsequent sections.

The degree of polymerization of chain i is

$$[2] \qquad n_i = pr, \quad r = 1, 2, 3, \ldots$$

If there are l water molecules per metal atom in an isolated repeating unit ($r = 1$), the number of water molecules used to form the chain is

$$[3] \qquad n_i x_i = q(r - 1) + plr$$

Elimination of r from eqs. [2] and [3] and rearrangement gives

$$[4] \qquad 1/n_i = (l/q + 1/p) - x_i/q$$

Inspection of eqs. [1*a*] and [1*b*] indicates that the molecular weight of chain i will be of the form

$$[5] \qquad M_i = Ar + B$$

where A and B are constants to be determined from the chemical formula of the structural model. Substitution of eq. [2] in eq. [5] and use of eq. [4] gives

$$[6] \qquad 1/(M_i - B) = (pl/q + 1 - px_i/q)/A$$

Thus, x_i is more simply related to n_i than to M_i.

The equation deduced by Bradley and Holloway (7) is the same as eq. [4] without the term in l/q, which must be included if the repeating units are themselves hydrolysis products. This term has been introduced previously in only one specific case, that of the zirconium oxide trimethylsilyloxides (9). Several features of eq. [4] should be noted. First, a branched chain is always isomeric with a linear chain of the same degree of polymerization. Chain branching cannot, therefore, be detected by use of eq. [4]. Secondly, coordinated bridging oxygens are not included in the definition of q, but may account wholly for the value of p. Thus, eq. [4] offers incomplete evidence, at best, concerning the coordination number of the metal atom. Thirdly, the derivation of the equation implies that the molecular weights are the true values measured at infinite dilution. Hydrolysis experiments carried out at finite concentrations may show effects due to the changing activities of various species, and corrections for these effects may be necessary.

(b) Cyclic Chains

If a homogeneous chain closes upon itself, the term $q(r - 1)$ in eq. [3] becomes qr, and eq. [4] becomes

$$[7] \qquad 0 = l/q + 1/p - x_i/q$$

and x_i is a constant independent of n_i. This corresponds to the case of a non-cyclic chain with infinite degree of polymerization but finite degree of hydrolysis.

(c) Linear or Branched Chains Polydisperse in Number of Metal Atoms

(i) Number Average Quantities

In general, the observed degrees of polymerization and hydrolysis are not integral, and a distribution of these values must occur. If the

For personal use only.

mole fraction of chains with degree of polymerization n_i is N_i, rearrangement of eq. [4], multiplication by N_i, and summation over all species give

$$[8] \qquad 1/\bar{n}_n = (l/q + 1/p) - \bar{x}_n/q$$

where

$$\bar{n}_n = \sum_i N_i n_i$$

is the number average degree of polymerization, and

$$\bar{x}_n = \sum_i N_i x_i n_i/\bar{n}_n$$

is the number average degree of hydrolysis. From eqs. [2] and [5], the number average molecular weight is

$$[9] \qquad \bar{M}_n = \sum_i N_i M_i = A\bar{n}_n/p + B$$

and the average number of repeating units per chain is, from eq. [2]

$$[10] \qquad \bar{r}_n = \sum_i N_i n_i/p = \bar{n}_n/p$$

The values of $\bar{x}_n$ and $\bar{n}_n$ are those determined by ordinary chemical analysis and measurements of the number average molecular weight (by cryoscopy or ebullioscopy, for example). Equation [8] also holds for cyclic chains if the term in $\bar{n}_n$ is set equal to zero.

(ii) Weight Average Quantities

If w_i is the weight fraction of chains with molecular weight M_i, a series of equations analogous to eqs. [8] through [10] may be written, with weight average quantities replacing the number average quantities. The weight average molecular weight can be determined by light scattering measurements (16), but the weight average degree of hydrolysis cannot be obtained by direct experiment. The weight average molecular weight is thus an independent parameter of a particular distribution, unless the distribution happens to be known. The relation between the weight average molecular weight $\bar{M}_w$ and the weight average degree of polymerization $\bar{n}_w$ is readily found to be $p(\bar{M}_w - B) = A\bar{n}_w$.

(d) Mixtures of Homogeneous, Polydisperse Chains

(i) Linear or Branched Chains. Models I, II

Let a mole fraction α of metal atoms be in polymer series A, and a mole fraction $1 - \alpha$ be in series B. The two series are characterized by the parameters p_A, q_A, l_A and p_B, q_B, l_B. The number of molecules in series A and B per total number of metal atoms is $\alpha/\bar{n}_A$ and $(1 - \alpha)/\bar{n}_B$, respectively, where

$$[11] \qquad 1/\bar{n}_j = (l_j/q_j + 1/p_j) - \bar{x}_j/q_j \qquad j = A, B$$

Bradley and Holloway (7) assumed that the number average degree of hydrolysis was identical for each series. Consideration of two single chains with $n_A = n_B$, $p_A = p_B$, $l_A = l_B$, but $q_A \neq q_B$, shows at once that this assumption is not generally true. The observed number average degree of hydrolysis is

$$[12] \qquad \bar{x}_n = \alpha\bar{x}_A + (1 - \alpha)\bar{x}_B$$

and the total number of molecules per total number of metal atoms is

$$[13] \qquad 1/\bar{n}_n = \alpha/\bar{n}_A + (1 - \alpha)/\bar{n}_B$$

Hence

$$[14] \qquad \alpha q_A/\bar{n}_A + (1 - \alpha)q_B/\bar{n}_B = \bar{l} + \overline{(q/p)} - \bar{x}_n$$

where

$$\bar{l} = \alpha l_A + (1 - \alpha)l_B$$

and

$$\overline{(q/p)} = \alpha q_A/p_A + (1 - \alpha)q_B/p_B$$

If β is the mole fraction of A-type molecules, then by definition and eq. [13]

$$[15] \qquad \beta = \alpha\bar{n}_n/\bar{n}_A, \quad 1 - \beta = (1 - \alpha)\bar{n}_n/\bar{n}_B$$

Equation [14] then becomes

$$[16] \qquad 1/n_n = [\bar{l} + \overline{(q/p)}]/\bar{q} - \bar{x}_n/\bar{q} \qquad \text{(Model I)}$$

where

$$\bar{q} = \beta q_A + (1 - \beta)q_B$$

is the average bridge multiplicity. If α and β are constants, eq. [16] has the form observed experimentally. If $\alpha/\beta \gtrless 1$, then eqs. [15] and [16] show that, correspondingly, $\bar{n}_A \gtrless \bar{n}_B$. Equation [16] describes the properties of Model I for a regular polymer series, and includes eq. [8] as a special case.

In many cases, the value of $1/\bar{n}$ for the unhydrolyzed "monomer" in solution is equal to the intercept of the plot of $1/\bar{n}_n$ against $\bar{x}_n$; that is, α and β are the same for the monomer and the polymers, and the intercept must therefore be independent of $\bar{l}$, q_A, and q_B. If $\bar{n}_n$ for the monomer is non-integral, it is customary to assume that the monomer forms ideal self-associated solutions (13, 17–19). For such monomers, if N_A and N_B are the number of molecules of type A($p = p_A$) and type B($p = p_B$), respectively, then

$$\beta = N_A/(N_A + N_B)$$

$$\alpha = N_A p_A/(N_A p_A + N_B p_B)$$

from which

[17] $$(1 - \alpha)p_A/\alpha = (1 - \beta)p_B/\beta$$

Substitution of eq. [17] into the value of $1/\bar{n}_n$ at $\bar{x}_n = \bar{l}$ in eq. [16] gives

$$(\overline{q/p})/\bar{q} = \alpha/\beta p_A = (\overline{1/p})$$

where

$$(\overline{1/p}) = \alpha/p_A + (1 - \alpha)/p_B$$

Equation [16] may then be written as

[18] $$1/\bar{n}_n = (\overline{1/p})[1 - (\bar{x}_n - \bar{l})/(\overline{q/p})] \quad \text{(Model II)}$$

Values of α calculated from the slope and intercept should be the same in this case. Substitution of eq. [15] into eq. [10] and use of eq. [17] give

[19] $$\bar{r}_A/\bar{r}_B = \bar{n}_A p_B/\bar{n}_B p_A = 1$$

or, if the value of $1/\bar{n}$ at $\bar{x}_n = 0$ or $\bar{l}$ is independent of $\bar{q}$, the average degree of polymerization of type A and type B molecules must be equal. Note that eq. [16] and eq. [18] are identical if $1/\bar{n}_n$ at $\bar{x}_n = 0$ or $\bar{l}$ is independent of $\bar{q}$. From eqs. [11] and [19], it is found that

$$(\bar{x}_A - l_A)p_A/q_A = (\bar{x}_B - l_B)p_B/q_B$$

Thus, the average degrees of hydrolysis of chains A and B are simply related.

Model II (as defined by eq. [18]) may be extended to include mixtures containing mole fractions α_A, α_B, $1 - \alpha_A - \alpha_B$ of metal atoms in polymer series A, B, and C, respectively. Equation [18] is again obtained, with averages taken over the 3 series, with

$$\alpha_A/p_A\beta_A = \alpha_B/p_B\beta_B = (1 - \alpha_A - \alpha_B)/p_C(1 - \beta_A - \beta_B)$$

with $(\overline{q/p}) = \bar{q}(\overline{1/p})$ as before, with $\bar{r}_A = \bar{r}_B = \bar{r}_C$, and with

$$(\bar{x}_A - l_A)p_A/q_A = (\bar{x}_B - l_B)p_B/q_B = (\bar{x}_C - l_C)p_C/q_C$$

Values of α_A and α_B can be found from the slope and intercept.

If a plot of $1/\bar{n}_n$ against $\bar{x}_n$ is not linear over the whole range of $\bar{x}_n$, but extrapolates to the value of $(\overline{1/p})$ for the monomer at $\bar{x}_n = \bar{l}$, α and β must be considered to be functions of $\bar{x}_n$. In this case, it is no longer possible to obtain separate values of α and β from eqs. [16] or [18].

If it is assumed that $\bar{x}_A = \bar{x}_B$, eqs. [11] and [13] give

[20] $$1/\bar{n}_n = (\overline{1/p}) + (\overline{l/q}) - (\overline{1/q})\bar{x}_n$$

where

$$(\overline{1/q}) = \alpha/q_A + (1 - \alpha)/q_B$$

$$(\overline{l/q}) = \alpha l_A/q_A + (1 - \alpha)l_B/q_B$$

This equation has been deduced previously by Bradley and Holloway (7), who write $1/\bar{q}$ for $(\overline{1/q})$ and neglect the term $(\overline{l/q})$. In practice, eq. [20] cannot be distinguished from eq. [18]. For example, mixtures of equal proportions of metal atoms in a p_2q_3 series and a p_3q_4 series give a slope of -0.294 from eq. [18] and a slope of -0.292 from eq. [20]. Note that β does not appear in eq. [20], that the intercept is necessarily independent of $\bar{q}$ if $\bar{l} = 0$, and that $\bar{r}_A \neq \bar{r}_B$. This model thus lacks sufficient generality to be useful in all cases, and, in addition, no evidence is available to support the assumption that $\bar{x}_A = \bar{x}_B$. For these reasons, this model is considered to be simply a special case of Model II with $l_A = l_B = 0$ and $p_A/q_A = p_B/q_B$.

(ii). Cyclic Chains and Mixed Types. Model III

It follows readily from eqs. [7], [8], [11], [12], [13], and [16] that a mixture of two cyclic chains is described by

$$\bar{x}_n = \bar{l} + (\overline{q/p})$$

For a mixture of linear or branched chains (mole fraction α of metal atoms) and cyclic chains (mole fraction $1 - \alpha$ of metal atoms), eq. [11] holds for the linear or branched chains A. For the cyclic chains B

[21] $$0 = (q_B/q_A)(l_B/q_B + 1/p_B) - \bar{x}_B/q_A$$

Multiplication of eq. [11] by α and of eq. [21] by $1 - \alpha$ and addition give

[22] $$1/\bar{n}_n = \alpha/\bar{n}_A = \{\bar{l} + (\overline{q/p})\}/q_A - \bar{x}_n/q_A \quad \text{(Model III)}$$

If the value of $1/\bar{n}_n$ at $\bar{x}_n = 0$ or $\bar{l}$ is independent of $\bar{q}$ and equal to $(\overline{1/p})$, then it is found that $q_A = q_B$, with $\bar{x}_A \neq \bar{x}_B$.

General Theory for Heterogeneous Polymer Chains

(a) Single Linear, Branched, or Cyclic Chains

In this and the following sections, the restric-

For personal use only.

tions of fixed bridge multiplicity (q) and size of repeating unit (p) will be removed, giving rise to heterogeneous chains.

Let the relative numbers of bridges of multiplicity q_A be γ, and that of multiplicity q_B be $1 - \gamma$. Further, let the relative numbers of repeating units with $p = p_A$ be ε, and of repeating units with $p = p_B$ be $1 - \varepsilon$. Equations [2] and [3] become

$$n_i = \{\varepsilon p_A + (1 - \varepsilon)p_B\}r \equiv \bar{\bar{p}}r$$

$$n_i x_i = \{\gamma q_A + (1 - \gamma)q_B\}(r - 1) + \{\varepsilon p_A l_A + (1 - \varepsilon)p_B l_B\}r \equiv \bar{\bar{q}}(r - 1) + \overline{\overline{pl}}r$$

where the double bars indicate averages over a single heterogeneous chain. Thus

$$1/n_i = (\overline{\overline{pl}}/\bar{\bar{q}} + 1)/\bar{\bar{p}} - x_i/\bar{\bar{q}}$$

an equation that holds for heterogeneous cyclic chains, as well, if $1/n_i$ is set equal to zero.

(b) Polydisperse Linear, Branched, or Cyclic Heterogeneous Chains. Model IV

Application of the same procedure that led to eq. [8] gives

$$\sum_{i,\gamma,\varepsilon} \overline{\overline{pq}} N_i = \sum_{i,\gamma,\varepsilon} (\overline{\overline{pl}} + \bar{\bar{q}}) n_i N_i - \sum_{i,\gamma,\varepsilon} \bar{\bar{p}} n_i x_i N_i$$

where $N_i(\gamma, \varepsilon)$ is the mole fraction of chains with degree of polymerization i, distribution of bridge multiplicity γ, and distribution of repeating units ε. The sums are no longer related simply to $\bar{x}_n$ and $\bar{n}_n$ since $\bar{\bar{p}}$ and $\overline{\overline{pl}}$ are functions of ε and q is a function of γ. If it is assumed that each chain has the same distribution of bridge multiplicity and of repeating units, summation may be carried out to give

$$[23] \quad 1/\bar{n}_n = (\overline{\overline{pl}}/\bar{\bar{q}} + 1)/\bar{\bar{p}} - \bar{x}_n/\bar{\bar{q}} \qquad \text{(Model IV)}$$

This is probably a good assumption if the chains are sufficiently long and if the free energies of formation of bridges of different multiplicity and of repeating units of different size are not very different. Again, eq. [23] holds for cyclic chains if $1/\bar{n}_n$ is set equal to zero.

Two special cases of eq. [23] may be considered. If $\varepsilon = 1$, $\bar{\bar{p}} = p_A$, $\overline{\overline{pl}} = p_A l_A$, chains with 3 types of multiplicity, q_A, q_B, q_C, can be then treated. If $\gamma = 1$, analogous conclusions can be drawn. From the nature of the model, it is obvious that the intercept of eq. [23] is independent of q only if $l_A = l_B = 0$ and if $\varepsilon = 1$; i.e., the reciprocal intercept is integral.

(c) Mixtures of Heterogeneous and Homogeneous Polydisperse Chains

Even if constant distributions of bridge multiplicity and of repeating units are assumed, no mixture of this type can be analyzed completely. For example, a mixture of homogeneous chains with parameters α, β, p_A, q_A, $l_A = 0$ with heterogeneous chains with parameters $1 - \alpha$, $1 - \beta$, p_A, q_A, q_B, $l_A = l_B = 0$ gives the value of $\bar{q}$ in eq. [16] as

$$\bar{q} = q_B + (q_A - q_B)(\beta + \gamma - \beta\gamma)$$

a lineo-linear equation in β and γ which possesses no unique solution, but can be consistent with experiment in special cases. If $q_A = 2$, $q_B = 1$, $\bar{q} = 1 + \delta$, where $0 < \delta < 1$, for example, the equation is satisfied if β and γ are both less than δ.

Equations [16], [18], [22], and [23], corresponding to Models I–IV, are basic for the analysis of experimental data.

Discussion of Experimental Data

Table I contains an analysis of all published data on the metal oxide alkoxides (1–7) and the metal oxide trialkylsilyloxides (8–10), with the exception of the titanium oxide triethylsilyloxides (11), which will be discussed elsewhere along with new experimental data (20).

For each product, the simplest formula, initial molality (where reported) and reciprocal degree of polymerization ($y_0 = 1/\bar{n}_n$ at $\bar{x}_n = 0$) are given for the monomer. For the polymers, the range of $\bar{x}_n$ (excluding $\bar{x}_n = 0$) over which a plot of $y = 1/\bar{n}_n$ was observed, by inspection, to be linear in $\bar{x}_n$ and the number of points N in this range are tabulated. The remainder of Table I contains a least-squares analysis of the data, carried out by means of Fortran IV computer programs and standard statistical methods (21, 22).

In general, since the degree of hydrolysis is used to derive values of $\bar{n}_n$, the errors in $\bar{n}_n$ and $\bar{x}_n$ are correlated. However, errors in the molecular weight measurements are much greater than those from the chemical analyses, and unweighted least squares, assuming that only the

$y = 1/\bar{n}_n$ were in error, were used to derive estimates of the intercept a and the slope b in the general relation $y = a + bx$, where x is written for $\bar{x}_n$. The large absolute values of the correlation coefficient ρ_{xy} for the variables supports this assumption. The estimated standard deviation of the observed y-values from the calculated values is σ (with $N - 2$ degrees of freedom), the estimated standard deviations of the intercept and slope are given by

$$\sigma(a)^2 = \sigma(b)^2 \sum x^2/N$$

$$\sigma(b)^2 = \sigma^2 N/\{N\sum x^2 - (\sum x)^2\}$$

respectively, and the correlation coefficient for the parameters a and b is

$$\rho_{ab} = -\sum x/(N\sum x^2)^{\frac{1}{2}}$$

The standard error in the ratio $a/|b|$ is then given approximately by

$$\sigma(a/b)^2/(a/b)^2 = \sigma(a)^2/a^2 + \sigma(b)^2/b^2 - 2\rho_{ab}\sigma(a)\sigma(b)/a|b|$$

The value y_0 at $\bar{x}_n = 0$ is not included in these calculations, and its deviation from the intercept a is measured by the statistic

$$t = (a - y_0)/\{\sigma^2 + \sigma(a)^2\}^{\frac{1}{2}}$$

for $N - 2$ degrees of freedom. If t is greater than the theoretical value at a 95% confidence level (23), a and y_0 are considered to differ significantly. For three cases in Table I (entries 3, 22, 27), significant differences are not clearly indicated, and decisions are made to conform with similar cases.

It is convenient to discuss the results in terms of the four general models.

Model I

Table II lists the cases that conform to Model I, eq. [16]. The subscripts in the specification of the structural models refer to the values of the parameters, and α, β refer to the set of parameters listed first. Thus, the titanium oxide trimethylsilyloxides are described by a mixture of series A molecules with $l_A = 3/2$, $p_A = 8$, $q_A = 1$, $\alpha = 0.38$, $\beta = 0.34$ and series B molecules with $l_B = 3/2$, $p_B = 8$, $q_B = 2$, $1 - \alpha = 0.62$, $1 - \beta = 0.66$. The respective standard errors in α and β are

$$\sigma(\alpha) = \sigma(a/b)/(q_A/p_A - q_B/p_B + l_A - l_B)$$

and

$$\sigma(\beta) = \sigma(b)/b^2(q_A - q_B)$$

For all those products with $q_A = q_B$, t-tests for equality between the observed and theoretical values were significant within 95% confidence levels.

All the metal oxide alkoxides in Table II show curvature towards the value $1/\bar{n}_n$ for the monomer for values of $\bar{x}_n$ less than 0.1–0.2, and curvature beyond the maximum value of $\bar{x}_n$ listed in Table I is also apparent. Hence, these products can be considered to conform to Model II, with values of α and β that vary with $\bar{x}_n$ over part of the range of $\bar{x}_n$. Note that in each case the more complex series has the higher average degree of polymerization. The parameters listed agree with those assigned previously (3, 6) except

for the p_2q_2 series. This series may be considered to be a p_2q_3 type with one M—O → M and two M—O—M bridges between dimer units.

For the titanium oxide trimethylsilyloxides, previous analysis (8) did not reveal that the observed intercept is fortuitously close to unity, and is not directly related to the degree of polymerization of the monomer. The estimated value of $\bar{n}_n$ at $\bar{x}_n = \bar{l} = 3/2$ is 8.13, which differs from the theoretical value 8 by 1.6%. For the thermally disproportionated zirconium oxide trimethylsilyloxides, the parameters in Table I do not agree with previous values, because fewer points over a narrower range of $\bar{x}_n$ were used and presumably the assumption that $y_0 = 1$ was made (9). No valid reason could be found for excluding any of the observations, but the range of extrapolation is still large. The parameters for the tantalum oxide trimethylsilyloxides agree with those deduced previously (10).

Model II

Table III lists those cases for which the intercept is equal to the reciprocal degree of polymerization of the monomer, and which thus conform to Model II. The values α_a and α_b calculated from the intercept and slope have the respective standard errors

$$\sigma(\alpha_a) = \sigma(a)/(1/p_A - 1/p_B)$$

and

$$\sigma(\alpha_b) = \sigma(a/b)/(q_A/p_A - q_B/p_B)$$

The $Ti(OBu^s)_4$ and $Ti(OBu^i)_4$ products were evidently similar, and the few available data were combined.

For those cases in which only one series is present, the statistics

$$t_a = |a - 1/p_A|/\sigma_a$$

and

$$t_b = |b - 1/q_A|/\sigma b$$

show that the observed and theoretical parameters are equal within 95% confidence limits. For those cases with $q_A = q_B$, α_a only may be obtained, and appropriate t-tests for equality of the theoretical and experimental slopes are signifi-

cant at the 95% level except for one set of tantalum oxide ethoxides and one set of uranium oxide isopropoxides which require 3 series to account for the data. For the remaining cases, the values of α_a and α_b should be equal, but are highly susceptible to errors in the slope and intercept. Rather than guess at suitable parameters, a better procedure in this case is to equate the values of α_a and α_b to obtain, from eq. [18]

$$[24] \quad q_A(p_B - 1/a) + q_B(1/a - p_A) = (p_B - p_A)/|b|$$

The left side of this equation is denoted by L, and has a relative standard error

$$\sigma(L)/L = [\sigma(a)/a]/[1 + ap_Ap_B(q_A/p_A - q_B/p_B)/(q_B - q_A)]$$

while the right side R has a relative standard error $\sigma(R) = \sigma(b)/|b|$. These errors are roughly equal in magnitude. Equation [24] is a Diophantine equation in the four integral unknowns, p_A, p_B, q_A, and q_B, and may be solved systematically by assigning values of p_A and p_B, then choosing q_A and q_B so that the difference between the two sides of the equation is a minimum. The statistic

$$t' = |1 + R/L|/\{\sigma(L)^2/L^2 + \sigma(R)^2/R^2\}^{\frac{1}{2}}$$

is then a measure of deviations due to random errors between the two sides. The t'-values indicate that in all but two cases the equation is satisfied to within random error at the 95% confidence level, and a very slightly greater standard error would bring cases 17 and 31 into agreement as well.

A second method of testing Model II is to plot theoretical lines for various series along with the least-square lines. If the theoretical lines are suitably chosen, and the same value of α applies throughout, the lines will have a common point of intersection. This method is very sensitive to errors in the slope, and can be used to eliminate certain choices of the parameters and to detect a variable α. The zirconium oxide *n*-propoxides and oxide isobutoxides do not fit any reasonable model with constant α. Plots show that the oxide *n*-propoxides conform roughly to a $p_2q_3 + p_3q_4$ mixture, while the oxide isobutoxides conform roughly to a $p_1q_3 + p_3q_4$ mixture, and eq. [17] shows that the ratio $\beta/\alpha = (1 + p_A)/(\alpha + p_A)$ (for $p_B - p_A = 1$) is not very sensitive to the value of α. Hence, if the ratio β/α remains roughly constant, α can vary, and a reasonably linear relation between $1/\bar{n}_n$ and $\bar{x}_n$ will still be obtained. Significant variations in α with $\bar{x}_n$ can thus be masked by a linear plot. The same structural parameters and variation of α with $\bar{x}_n$ have been proposed previously for these two zirconium oxide alkoxides (3). In general, structural parameters assigned for the other products agree with those assigned by Bradley and co-workers with a few exceptions. For the tantalum oxide ethoxides, no sharp distinction can be drawn between the p_1q_2 and the p_1q_3 series. The mixture $p_1q_1 + p_2q_3$ fits the data on stannic and ceric oxide isopropoxides better than the mixture $p_1q_2 + p_2q_3$ (7). The p_2q_2 series provides a better fit than the p_2q_3 series for the titanium oxide *n*-propoxides (2) and the tantalum oxide ethoxides, entry number 23, which were examined in boiling benzene instead of boiling ethanol (4).

The condition $\bar{r}_A = \bar{r}_B$, under which Model II applies, implies that the free energy of formation from the monomer of chains with different parameters but with the same average number of repeating units must be close to zero. As an example, the formation of p_2q_3 molecules from titanium ethoxide is described by

$$n[Ti(OEt)_4]_2 + 3nH_2O \rightarrow [Ti_2O_3(OEt)_2]_n + 6n\text{EtOH}$$

while the formation of p_3q_4 molecules is described by

$$m[Ti(OEt)_4]_3 + 4mH_2O \rightarrow [Ti_3O_4(OEt)_4]_m + 8m\text{EtOH}$$

Here, $\bar{r}_A = \bar{r}_B$ gives $n = m$, and the free energy changes for these two processes differ by the free energy change for the process

$$n[Ti(OEt)_4]_3 + nH_2O + [Ti_2O_3(OEt)_2]_n \rightarrow n[Ti(OEt)_4]_2 + 2n\text{EtOH} + [Ti_3O_4(OEt)_4]_n$$

If the free energy change for this process is zero, the process must be an equilibrium, and provides a mechanism through which disproportionation processes (1) can occur readily. The general validity of Model II for all the oxide alkoxides examined in solution in their corresponding alcohols is thus seen to be a consequence of equilibria among various species. For products examined in non-polar solvents, variations in the type of model are to be expected, and are found with 3 of the 4 metal oxide trimethylsilyloxides. The initial hydrolysis products of zirconium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

trimethylsilyloxide, however, could be fitted best by a $p_2q_2 + p_2q_3$ mixture, but not by the series suggested previously (9). Another possibility is that the products contain monomers, and a $p_2q_0 + p_2q_3$ mixture gives $\alpha = 0.14$ for the p_2q_0 monomer, an assumption that is consistent with establishment of an equilibrium system on initial hydrolysis.

Model III

For a number of cases, the reciprocal slopes are integral, and a mixture of cyclic and linear (or branched) series can be used to describe the products. These cases include all those entries in Tables II and III for which there is only one series, or for which the two linear series have the same value of q.

The relevant cases in Table II (entries 26–29) can be described by the same parameters given in Table II if either of the two sets of parameters corresponds to a cyclic series, and the other set corresponds to a linear series. The relevant cases in Table III (entries 7, 8, 13–16, 21–23) have a value of $1/\bar{n}_n$ at $\bar{x}_n = 0$ equal to the reciprocal degree of polymerization of the unhydrolyzed alkoxide, and Model III requires that the cyclic and linear series have the same value of q. The parameters are then the same as those listed in Table III, where either of the two sets corresponds to a cyclic series. If the values of p and q are the same for both the cyclic and linear series, no difference can be detected between a single linear series and a mixture of linear and cyclic series (entries 7, 8, 13, 16).

Martin and Winter (13, 24) have given arguments in favor of cyclic polymers in the titanium oxide alkoxides. While we do not wish to revive the polemical discussion on this point (13, 14), it should be noted that, in practice, Model III is of much less general applicability than Model I and, especially, Model II in describing the experimental results. In addition, the only cyclic polymers that arise on application of Model III are of the types p_1q_2, p_1q_3, p_2q_2, and p_2q_3. The models proposed for these types (2, 5) indicate that bridge multiplicities of 2 or 3 would fix the orientation of successive repeating units such that formation of cyclic polymers would be difficult.

Model IV

Table IV lists those products that can be described by Model IV. These fall into two classes: (*i*) $a = y_0$, $\varepsilon = 1$, reciprocal intercept integral; (*ii*) $a \neq y_0$, neither reciprocal slope nor reciprocal intercept integral. For either class, the standard error in γ is

$$\sigma(\gamma) = \sigma(b)/b^2(q_A - q_B)$$

For class (*i*), *t*-tests for the equality of the theoretical and observed intercept are contained

*Entry numbers correspond to those in Table I.

in Table IV, and $\sigma(\varepsilon) = \sigma(a)/a^2$, while for class (*ii*), the standard error in ε is

$$\sigma(\varepsilon) = \sigma(a)/a^2(p_A - p_B)$$

except when $pl \neq 0$, when the expression for the standard error is complicated. The structural parameters listed first are those with fractions ε and γ. Thus, $p_1q_2 + p_2q_3$ signifies heterogeneous chains with fractions ε, $1 - \varepsilon$ of repeating units with $p = 1$, 2, respectively, and with fractions γ, $1 - \gamma$ of bridge multiplicities 2 and 3, respectively.

The titanium oxide *n*-butoxides and the titanium oxide trimethylsilyloxides are the only two cases that fulfil the requirements for class (*i*) but do not give acceptable values of γ. It is not difficult to propose mechanisms by which heterogeneity could arise. By introduction of more parameters (e.g., mixtures of homogeneous and heterogeneous chains), all cases in Table I could be described eventually, and it must be concluded that heterogeneity with respect to bridge multiplicity or size of repeating unit is an ever-present possibility.

The above analysis does not include discussion of departures from linearity beyond the range of $\bar{x}_n$ listed in Table I. Such departures occur for entries 2–6, 8, 13, 14, 16–22, 24–29, and 37. For discussion of these data and for more details about the structural types, reference is made to the original sources (1–11).

Acknowledgments

Metal oxide trialkylsilyloxide polymers. Part V. Further studies on titanium oxide triethylsilyloxide polymers[1]

D. C. BRADLEY[2], J. W. LORIMER, AND C. PREVEDOROU-DEMAS
Department of Chemistry, The University of Western Ontario, London, Ontario

Received June 4, 1969

Tetrakis(triethylsilyloxy)titanium, $Ti(OSiEt_3)_4$, was hydrolyzed under controlled conditions in dioxane at 60 °C. The soluble initial products $[TiO_x(OSiEt_3)_{4-2x}]_n$, with $x = 0.1$–0.5, underwent disproportionation when heated at 65 °C under high vacuum to give $Ti(OSiEt_3)_4$ and products with values of x in the range 0.4–1.4. Molecular weights were determined by cryoscopy in cyclohexane, and the linear dependence of $1/n$ on x was used as a basis for structural proposals. The results are compared with those obtained previously for the initial products of hydrolysis.

Canadian Journal of Chemistry, 47, 4113 (1969)

Introduction

In Part IV of this series (1), the hydrolysis of tetrakis(triethylsilyloxy)titanium(IV) was described, and some possible structures for the titanium oxide triethylsilyloxides were proposed by considering the variation of the number average degree of polymerization as a function of the number average degree of hydrolysis. Heating of the oxide triethylsilyloxides at 150–180 °C under vacuum caused disproportionation into $Ti(OSiEt_3)_4$ and a slightly soluble residue (1). This paper describes the removal of $Ti(OSiEt_3)_4$ from the initial hydrolysis products at a much lower temperature (65 °C), the examination of the residues, and some tentative structural and compositional parameters which may be obtained by application of the theory of regular polymer series (2, 3) to the experimental data.

Experimental

Tetrakis(triethylsilyloxy)titanium(IV) (titanium triethylsilyloxide, $Ti(OSiEt_3)_4$) was prepared and hydrolyzed for 2 h at 60 °C in dioxane containing h moles of water per mole of $Ti(OSiEt_3)_4$, as described previously (1). The solvent and volatile silanols were removed under vacuum.

The initial hydrolysis products were kept under high vacuum (oil diffusion pump, backing pressure 10^{-4} Torr) in a sublimation apparatus (path length 1 cm) overnight at room temperature to remove the last traces of solvent and silanols. The temperature was then raised to 65 °C, and a sublimate was collected on the water-cooled condensing surface of the sublimation apparatus. Quantitative recovery was difficult. Analysis of the residues and sublimates for Ti and Si (4) gave values of x and the formula weights in $[TiO_x(OSiEt_3)_{4-2x}]_n$, while molecular weight determinations (by cryoscopy in cyclohexane solution (5)) could be combined with the formula weights to obtain values of n. The values of n and x are in general not integral, and are written as number averages $\bar{n}_n$ and $\bar{x}_n$, respectively. No OH groups could be detected in any of the hydrolysis products by infrared spectroscopy in CS_2 solution.

Results and Discussion

Table I gives the percentages by weight of titanium and silicon, the number average molecular weight $\bar{M}_n$, and derived values of $\bar{n}_n$ and $\bar{x}_n$ for the residual hydrolysis products. Values of $\bar{x}_n$ are found from the ratio of silicon to titanium, and can be used in the formula $TiO_x(OSiEt_3)_{4-2x}$ to calculate the percentages of titanium and silicon. The good agreement between the observed and calculated values indicates that the formula is accurate and, for example, the polymers are not contaminated with solvent (6). The sublimates were pure $Ti(OSiEt_3)_4$ and accounted for 60–80% of the total mass of a sample.

Figure 1 shows that a plot of $1/\bar{n}_n$ against $\bar{x}_n$ is linear over the whole range of $\bar{n}_n$ given in Table I. For comparison, the data for the initial hydrolysis products (1) are also plotted in Fig. 1. Table II contains the results of a least squares analysis for the data in Table I and that for the initial hydrolysis products (1), assuming that errors in $\bar{x}_n$ were negligible compared to those in $1/\bar{n}_n$ (3). The slope, a, and intercept, b, in the general relation $y = 1/\bar{n}_n = a + b\bar{x}_n$ are given, together with the ratio $a/|b|$, the corresponding standard errors, the standard error $\sigma(y)$ in $1/\bar{n}_n$ and the correlation coefficients $\rho(xy)$ for the

variables and $\rho(ab)$ for the parameters. These values were computed by methods described elsewhere (3).

The theory of regular polymer series (3) gives rise to 4 general models for the structure of metal oxide trialkylsilyloxide polymers. For Model I, if the repeating units are not themselves hydrolysis products

$$[1] \qquad 1/\bar{n}_n = \overline{(q/p)}/\bar{q} - \bar{x}_n/\bar{q}$$

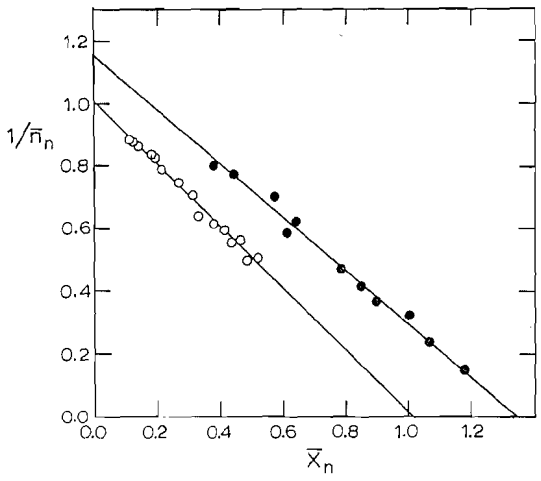

FIG. 1. Dependence of reciprocal degree of polymerization on degree of hydrolysis for titanium oxide triethylsilyloxides: ○, before thermal disproportionation; ●, after thermal disproportionation. The lines are the least-squares equations with parameters given in Table II.

where

$$\overline{(q/p)} = \alpha(q_A/p_A) + (1 - \alpha)(q_B/p_B)$$

$$\bar{q} = \beta q_A + (1 - \beta)q_B$$

describes a mixture of series A polymers containing a mole fraction α of metal atoms and a mole fraction β of molecules, with p_A metal atoms per repeating unit and with q_A metal–oxygen–metal bridges between repeating units, and series B polymers with corresponding parameters $1 - \alpha$, $1 - \beta$, p_B, q_B. The relation between α and β is

$$\alpha/\beta = \bar{n}_A/\bar{n}_n, (1 - \alpha)/(1 - \beta) = \bar{n}_B/\bar{n}_n$$

For Model II, the intercept of the plot of

$1/\bar{n}_n$ against $\bar{x}_n$ is equal to the reciprocal degree of polymerization of the unhydrolyzed trialkylsilyloxide, and

$$1/\bar{n}_n = (\overline{1/p})[1 - \bar{x}_n/(\overline{q/p})]$$

where

$$(\overline{1/p}) = \alpha/p_A + (1 - \alpha)/p_B$$

Clearly, the initial hydrolysis products satisfy Model II, since the unhydrolyzed $Ti(OSiEt_3)_4$ is truly monomeric (4), and since the intercept is unity to well within one standard deviation. Since the slope is also unity to well within one standard deviation, these products can be described as linear molecules with one metal atom per repeating unit and one metal–oxygen–metal bridge between adjacent repeating units; i.e., a p_1q_1 series. Since $q = 1$, there is no possibility for chain branching.

The final products satisfy Model I with $\alpha = 0.65$, $\beta = 0.83$, if $p_A = p_B = 1$, $q_A = 1$, $q_B = 2$. Hence the average degree of polymerization of the B-series molecules is greater than that of the A-series molecules. This mixture of p_1q_1 and p_1q_2 series can arise by thermal disproportionation. The general formula for series A molecules is $Ti_nO_{n-1}(OSiEt_3)_{2n+2}$, while that for series B molecules is $Ti_nO_{2n-2}(OSiEt_3)_4$, with $n = 1,2,\ldots$. The disproportionation reaction may occur by condensation of two series A molecules

$$2Ti_2O(OSiEt_3)_6 \rightarrow Ti_2O_2(OSiEt_3)_4 + 2Ti(OSiEt_3)_4$$

followed by successive end-to-end condensations of type B molecules

$$2Ti_2O_2(OSiEt_3)_4 \rightarrow Ti_3O_4(OSiEt_3)_4 + Ti(OSiEt_3)_4$$

$$2Ti_nO_{2n-2}(OSiEt_3)_4 \rightarrow Ti_{2n-1}O_{4n-4}(OSiEt_3)_4 + Ti(OSiEt_3)_4$$

or

$$Ti_nO_{2n-2}(OSiEt_3)_4 + Ti_{n-1}O_{2n-4}(OSiEt_3)_4 \rightarrow Ti_{2n-2}O_{4n-6}(OSiEt_3)_4 + Ti(OSiEt_3)_4$$

Similar disproportionations have been proposed for the trimethylsilyloxides of titanium (6) and zirconium (7). In solution, the p_1q_1 and p_1q_2 series may be regarded as consisting of 4 coordinate titanium atoms linked through 1 or 2 bridging oxygens. In the solid or in concentrated solutions, coordination between chains could result in an increase of the coordination number of titanium to 6, as observed in the titanium oxide ethoxides (8). The first hydrolyzed members of these series are $Ti_2O(OSiEt_3)_6$ (p_1q_1) and $Ti_2O_2(OSiEt_3)_4$ (p_1q_2). If only these were present, the minimum degree of polymerization would be 2. Since degrees of polymerization as low as 1.25 are observed, and since the monomer is the first member of each series, it must be concluded that the hydrolysis products still contain monomer. Presence of monomer is consistent with the disproportionation reactions postulated above, if these are equilibria. An equilibrium mechanism for disproportionation has been proposed previously (3). This mechanism also accounts readily for the observations that heating in vacuum at higher temperatures produces less soluble products, for removal of monomer will simply shift the equilibrium to favor products of higher degree of polymerization.

The final products can also be described by Model I with $\alpha = 0.53$, $\beta = 0.83$ if $p_A = 1$, $p_B = 8$, $q_A = 1$, $q_B = 2$, $l_B = 3/2$; i.e., by mixtures of p_1q_1 and $l_{3/2}p_8q_2$ chains. The chains with octameric repeating units and $l = 3/2$ molecules of water required to form a repeating unit have been postulated previously to describe the titanium and zirconium oxide trimethylsilyloxides (3, 6, 7). The minimum degree of polymerization for this mixture (even if monomer were present as the first member of the p_1q_1 series) would only be 1.7, and almost half the observed values are less than this value. The $l_{3/2}p_8q_2$ chains cannot be ruled out completely, since their formation at higher degrees of hydrolysis could occur in such proportions that the linearity of the plots of $1/\bar{n}_n$ against $\bar{x}_n$ would not be affected appreciably. It is clear, however, that octameric repeating units are formed with greater difficulty from $Ti(OSiEt_3)_4$ molecules than from $Ti(OSiMe_3)_4$ molecules, and molecular models suggest that this is due simply to steric effects of the bulkier ethyl groups.

Model III consists of a mixture of a linear series A, containing a mole fraction α of metal atoms, and a cyclic series B, containing the remaining fraction $1 - \alpha$ of metal atoms, and gives eq. [1] if $\bar{q}$ is replaced by q_A (3). The nonintegral reciprocal slope makes this model improbable for the final products. For the initial products, a mixture of linear chains with $p_A = q_A = 1$ and cyclic chains with $p_B = q_B = 1$ (general formula $Ti_{n+1}O_{n+1}(OSiEt_3)_{2n+2}$, $n =$

1, 2, ...) would give $1/\bar{n}_n = 1 - \bar{x}_n$, in agreement with experiment. Cyclic chains with $\bar{n}_n = 4$ make up parts of the octameric repeating units postulated for the titanium oxide trimethylsilyloxides (6). Their presence in the initial hydrolysis products of the triethylsilyloxide is thus a possibility that cannot be established with certainty by the present analysis.

Model IV consists of heterogeneous chains with the same distribution of repeating units and number of metal–oxygen–metal bridges in each chain. Heterogeneous chains with single and double bridges can be rejected as unnecessary for the initial products. For the final products, the non-integral reciprocal intercept would require repeating units with both $p = 1$ and 2, which appears to be unreasonable. A mixture of heterogeneous chains with $p = 1$ and 2, $q = 1$ and 2, and homogeneous p_1q_1 or p_1q_2 chains could describe the results, although the relative proportions in the mixture cannot be determined (3). Heterogeneous chains could arise by reaction between series A and series B molecules, for example

$$Ti_2O(OSiEt_3)_6 + Ti_2O_2(OSiEt_3)_4 \rightarrow Ti(OSiEt_3)_4 + (OSiEt_3)_3TiOTi(OSiEt_3)O_2Ti(OSiEt_3)_2$$

For the final products, another possibility which involves cyclic chains is a mixture of the Model I series described above ($p_A = p_B = 1$, $q_A = 1$, $q_B = 2$) with the cyclic molecule $Ti_3O_4(OSiEt_3)_4$. This molecule contains a 6-atom ring, 2 oxygen atoms in single bridges and 2 in double bridges. If η is the mole fraction of atoms in the Model I series, then this model gives the same slope as eq. [1], but an intercept $\eta(2 - \alpha) = 1.353$, from which acceptable values of α and η lie in the range $0 < \alpha \leqslant 0.65$ and $0.68 < \eta \leqslant 1$. The next member of the cyclic series $Ti_{2n-1}O_{4n-4}(OSiEt_3)_4$, $n = 2, 3, \ldots$, would contain a 10-atom ring whose formation would be less probable than a linear chain of the same number of atoms.

The lower solubility of the titanium oxide triethylsilyloxides compared to the titanium oxide trimethylsilyloxides for the same degree of hydrolysis is consistent with the occurrence of $p_1q_1 + p_1q_2$ chains for the former, and chains based on octameric repeating units (6) for the latter. The solubility process can be discussed conveniently in terms of an equivalent thermodynamic process involving melting of the polymer and mixing of the melt with solvent. The free energies of melting and the entropies of mixing are probably comparable for each polymer. However, the more compact octameric repeating units expose more trialkylsilyloxy groups per unit volume than do the extended p_1q_1 and p_2q_2 structures, resulting in a lower energy of mixing and a higher solubility for the oxide trimethylsilyloxides.

Vibrational spectra of halopentacarbonylmanganese(I) derivatives

I. S. BUTLER AND H. K. SPENDJIAN
Department of Chemistry, McGill University, Montreal, Quebec

Received April 21, 1969

The solid-state infrared (i.r.) and laser Raman spectra of the halopentacarbonylmanganese(I) derivatives, $Mn(CO)_5X$ (X = Cl, Br, and I), have been recorded in the C—O stretching and the low frequency (700–33 cm^{-1}) regions. The i.r. overtone and combination spectra recorded in the regions 2800–2250 and 1350–700 cm^{-1} have been used to help in the assignment of some of the low frequency fundamentals. The solid-state i.r. and laser Raman spectra of the dimeric halotetracarbonylmanganese(I) derivatives, $[Mn(CO)_4X]_2$ (X = Br and I), have been recorded in the C—O stretching and the low frequency regions for comparative purposes and shown to be consistent with the expected D_{2h} symmetry of the molecules.

Introduction

The recent interest in the low frequency infrared (i.r.) (1–5) and Raman (3, 4) spectra of the halopentacarbonylmanganese(I) derivatives, $Mn(CO)_5X$ (X = Cl, Br, and I), prompts us to report our results for the solid-state and carbon disulfide solution i.r. and solid-state laser Raman spectra of these compounds in the region 700–33 cm^{-1}. Our results are substantially in agreement with those published, although in some cases we observed a few additional frequencies and managed to resolve certain bands in the i.r. spectra previously reported as shoulders. In addition, we wish to report overtone and combination spectra in the regions 2800–2250 and 1350–700 cm^{-1} and their use in assigning some of the low frequency fundamentals. With a few exceptions (such as refs. 6–11), the overtones and combinations associated with the low frequency fundamentals of metal carbonyl derivatives have previously been ignored.

Although the solid-state laser Raman spectra of the $Mn(CO)_5X$ derivatives in the C—O stretching region have recently been reported (4, 12), we also wish to present our results for this region because we found that under high resolution certain of the lines reported for $Mn(CO)_5Cl$ and $Mn(CO)_5Br$ could be split into well defined doublets. The $Mn(CO)_5X$ derivatives are known to be readily decomposed thermally to form the dimeric $[Mn(CO)_4X]_2$ derivatives (13). In view of this, it was initially felt that the additional lines observed in the Raman spectra of $Mn(CO)_5Cl$ and $Mn(CO)_5Br$ might well have been the result of the presence of some of the dimers as impurities. These dimers could have been formed by thermal decomposition induced by the laser beam. In order to test this possibility, the solid-state laser Raman spectrum of $[Mn(CO)_4Br]_2$ was recorded and compared with that of $Mn(CO)_5Br$. From this comparison, the chance of any decomposition occurring while the spectrum of $Mn(CO)_5Br$ was being recorded was quickly ruled out. Since definite splittings were also observed in the C—O stretching region of the solid-state i.r. spectra of $Mn(CO)_5Cl$ and $Mn(CO)_5Br$, it appears most likely that the splittings in both the Raman and the i.r. spectra were the result of correlation effects. With this in mind, the solid-state spectra of the $Mn(CO)_5X$ derivatives are discussed here in terms of the recently determined[1] crystal structure of $Mn(CO)_5Cl$.

The solid-state i.r. spectrum of $[Mn(CO)_4Br]_2$ and the solid-state i.r. and Raman spectra of $[Mn(CO)_4I]_2$ were also recorded and the results are presented here. The i.r. and Raman data for these 2 compounds are in accord with the D_{2h} symmetry expected.

Experimental

Materials

The compounds studied, prepared by the methods described in the literature, were $Mn(CO)_5Cl$ and $Mn(CO)_5Br$ (13), $Mn(CO)_5I$ (14), and $[Mn(CO)_4Br]_2$ and $[Mn(CO)_4I]_2$ (13). The purity of the compounds was established by the absence of any impurity bands in their i.r. spectra in the C—O stretching region.

Spectra

All spectra were recorded using freshly prepared samples.

Infrared spectra below 300 cm^{-1} were recorded on a Beckman IR-11 spectrophotometer. In the other regions, spectra were recorded on a Perkin–Elmer Model 521 spectrophotometer. All measurements were carried out at room temperature with the samples in the form of Nujol mulls pressed between plates appropriate for the spectral region under investigation. The solution spectrum of $Mn(CO)_5I$ was studied using spectrograde CS_2 (Fisher Chemical Co.). The frequencies shown in the Tables are accurate to ± 1 cm^{-1}.

Raman spectra of the powdered solids were recorded on either a Spex Ramalog or a Jarrell–Ash Model 25-300 Raman spectrophotometer using helium–neon (6328 Å) excitation. The frequencies shown in the Tables are accurate to ± 1–2 cm^{-1}.

Results and Discussion

The crystal and molecular structure of $Mn(CO)_5Cl$ has recently been determined.[1] The space group is *Pnma* (D_{2h}^{16}) and there are 4 molecules per unit cell. The site symmetry of the molecules is C_s. The molecular symmetry is C_s, but the deviations from C_{4v} are within experimental error. $Mn(CO)_5Br$ is isomorphous[1] with $Mn(CO)_5Cl$, and so, presumably, is $Mn(CO)_5I$.

The vibrational representation for an isolated $Mn(CO)_5X$ molecule of C_{4v} symmetry reduces as follows

$$\Gamma_{vib}^{C_{4v}} = 7a_1 + 4b_1 + 8e + a_2 + 2b_2$$

The correlation between the C_{4v} symmetry of the free molecule, the C_s site symmetry, and the D_{2h}^{16} symmetry of the crystal is shown in Table I, together with the spectroscopic activity. The factor group D_{2h}^{16} is isomorphous with the corresponding point group D_{2h}. It is apparent from the correlation diagram that non-degenerate modes in the free $Mn(CO)_5X$ molecule could be split into 4 components in the crystal and doubly degenerate modes into 8. Furthermore, the irreducible representations for the internal and external optically active vibrational modes of crystalline $Mn(CO)_5X$ are given by

$$\Gamma_{vib}^{D_{2h}} = 19a_g + 19b_{2g} + 19b_{1u} + 19b_{3u} + 11b_{1g} + 11b_{3g} + 11b_{2u}$$

for the internal modes and

$$\Gamma_{vib}^{D_{2h}} = 3a_g + 3b_{2g} + 2b_{1u} + 2b_{3u} + 3b_{1g} + 3b_{3g} + 2b_{2u}$$

for the external modes.

In our treatment of the vibrational spectra of the $Mn(CO)_5X$ molecules, therefore, it is important to know whether or not any correlation splitting occurs in the solid-state spectra, and also whether or not any of the frequencies observed below 150 cm^{-1} result from external rather than internal modes.

The only compound whose i.r. spectrum was measured in CS_2 solution and in the solid-state was $Mn(CO)_5I$. The observed frequencies are given in Table II. There was no difference between the spectrum of the solution and that of the solid, apart from some frequency shifts. (The slight differences in the overtone and combination regions are excluded from this discussion.) The observed frequencies for the solid-state i.r. spectra of $Mn(CO)_5Cl$ and $Mn(CO)_5Br$ are also given in Table II. By comparison with the spectra in CCl_4 solution reported by El-Sayed and Kaesz (15), these solid-state spectra are very complex, owing to splittings in some of the bands. Other research groups have investigated the solution and solid-state i.r. spectra of $Mn(CO)_5Cl$ and $Mn(CO)_5Br$ throughout the various spectral regions and found that differences only occurred in the C—O stretching region (1, 4, 5).

Solution Raman spectra of the $Mn(CO)_5X$ compounds were not measured in the present study. Other workers have experienced considerable difficulty in measuring solution spectra of the compounds in the low frequency region (3, 4), but fortunately solution spectra in the C—O stretching region have proved more readily obtainable (16). Solid-state Raman data for the C—O stretching region have been published recently (4, 12), and we have also studied the solid-state spectra in this region. A comparison of our results with those already published is given in Table III. The spectrum of $Mn(CO)_5Br$ recorded in this work is shown in Fig. 1. For C_{4v} symmetry, four Raman active C—O modes ($2a_1 + b_1 + e$) are expected, and from i.r. studies involving force constant calculations (17, 18), these modes decrease in frequency in the order

$$a_1 \text{ (radial)} > b_1 > e > a_1 \text{ (axial)}$$

Reference to Table IV shows that Cotton *et al.* (16) observed 4 strong Raman lines for $Mn(CO)_5Br$ in CS_2 and in *n*-hexane solution, while Clark and Crosse (4) found 4 strong lines and 1 very weak line in the solid-state spectrum of the same compound. Our solid-state spectrum of $Mn(CO)_5Br$ was recorded under very high resolution (slit width ~ 1 cm^{-1}) and 6 strong

		a_u (inactive)
b_2 (Raman)		b_{2u} (i.r.)

lines and no weak ones were observed. (The very weak line observed by Clark and Crosse suggests the presence of a small amount of some impurity.) It is apparent that, in addition to some fairly large frequency shifts, there are 2 new lines in going from the solution spectrum of $Mn(CO)_5Br$ to that of the solid. These new lines resulted from small splittings in the a_1 (axial) and b_1 modes. The splittings may have been the result of correlation effects; the correlation diagram in Table I indicates that modes of a_1 or b_1 symmetry in the free molecule could be split into 2 Raman components ($a_g + b_{2g}$) in the crystal. The a_1 (axial) mode of $Mn(CO)_5Cl$ was also observed to be split in the solid-state spectrum, but no splittings at all could be detected in the spectrum of $Mn(CO)_5I$. The latter was unique in that only 3 lines were observed. Since the 2 outermost lines were readily assigned as a_1 modes, and the third line was in the region where the b_1 mode was expected, it seems that in this case either the b_1 and e modes were accidentally degenerate or that the e mode was too weak to be observed.

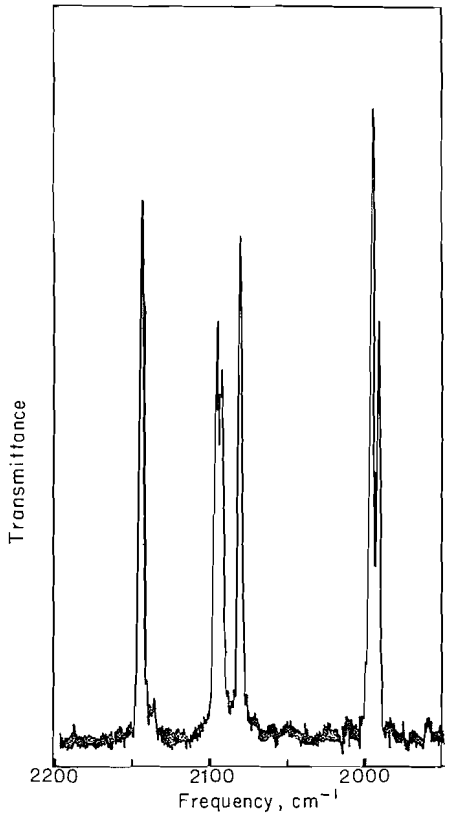

FIG. 1. Raman spectrum of $Mn(CO)_5Br$ in the C—O stretching region (powdered solid).

It was felt that before we could attribute the splittings in the solid-state Raman spectra of $Mn(CO)_5Cl$ and $Mn(CO)_5Br$ to correlation effects, there was one other possibility which should be considered. The $Mn(CO)_5X$ compounds are readily thermally decomposed to form the dimeric $[Mn(CO)_4X]_2$ compounds (13). It was possible that the laser beam could cause such decompositions to take place, resulting in the appearance of additional lines in the Raman spectra. In view of this, the solid-state laser Raman spectra of $[Mn(CO)_4Br]_2$ was recorded in both the C—O stretching and the low frequency regions. The solid-state Raman spectrum of

[d]Observed at 2072 cm^{-1} in cyclohexane solution (18).

$[Mn(CO)_4I]_2$ was studied in the same regions for comparative purposes. The spectrum of the dimeric chloro-compound was not investigated. Both $[Mn(CO)_4Br]_2$ and $[Mn(CO)_4I)_2$ proved to be extremely poor scatterers and only a few lines could be clearly discerned above the noise level. The observed frequencies are given in Table IV. A comparison of the C—O stretching frequencies of $Mn(CO)_5Br$ and $[Mn(CO)_4Br]_2$ immediately reveals that no detectable amount of the dimer was being formed while the spectrum of the pentacarbonyl was being recorded. Even without the obvious differences in the C—O frequencies, the vastly different scattering properties of the 2 compounds and the high intensity of all the lines in the $Mn(CO)_5Br$ spectrum would have been enough to rule out the possibility of any dimer formation.

From the above discussion, it appears that there was some correlation splitting in the solid-state spectra of the $Mn(CO)_5X$ derivatives but that it was restricted to the C—O stretching region. Owing to this, the low frequency vibrational spectra of the pentacarbonyls will be discussed in terms of the C_{4v} symmetry of an isolated $Mn(CO)_5X$ molecule.

Low Frequency Vibrations of the $Mn(CO)_5X$ Molecules

On the basis of C_{4v} symmetry, the fundamentals expected for the $Mn(CO)_5X$ molecules in the region below 700 cm^{-1} are: MnCO bending ($a_1 + a_2 + b_1 + b_2 + 3e$), Mn—C stretching ($2a_1 + b_1 + e$), Mn—X stretching ($a_1$), CMnC bending ($a_1 + b_1 + b_2 + 2e$), and CMnX bending ($e$). The a_1 and e modes are the only i.r. active ones, whereas all but the a_2 MnCO bending mode are Raman active. Most of our low frequency assignments shown in Table II are in agreement with those proposed by other research groups (1–5). Consequently, in the following discussion we will only consider those frequencies which have not been reported before and those for which we prefer alternative assignments to those already suggested. It should be mentioned that the assignments proposed for the frequencies below 150 cm^{-1} are particularly suspect, owing to the likelihood of external modes of the solids becoming active in this region. Some of the external modes might be coupled with each other, as well as with some of the very low frequency internal modes, rendering the interpretation of the region below 150 cm^{-1} even more speculative.

There is a weak band at 50 cm^{-1} in the i.r. spectrum of $Mn(CO)_5Br$ and a medium intensity Raman line at 54 cm^{-1}. Neither of these frequencies had been reported before and we have tentatively assigned them both to the CMnBr bending e mode, which is expected to occur below 70 cm^{-1} (4). This mode is almost certainly the lowest fundamental frequency of the

$Mn(CO)_5Br$ molecule and is expected to be extensively mixed with the 2 CMnC bending e modes.

There is a weak band at 64 cm^{-1} in the i.r. spectrum of $Mn(CO)_5Br$ which had previously only been observed by Edgell and Cengel (5). These workers assigned the band to the a_1 CMnC bending mode. We might have provided some support for their assignment if a strong Raman line had appeared at the same frequency, but unfortunately the presence of an intense laser line at 65 cm^{-1} prevented us from making any measurements in this region. The i.r. band can also be explained either by one of the 2 i.r. inactive CMnC bending modes (b_1 or b_2), becoming active because of site symmetry effects, or by one of the 6 i.r. active external modes of the $Mn(CO)_5Br$ lattice. Hyams *et al.* (6) have recently assigned a line at 57 cm^{-1} in the solid-state Raman spectrum of $Re(CO)_5I$ to the CReC bending b_1 mode, but this line, too, may have been derived from an external rather than an internal mode of the lattice.

The 4 Mn—C stretching modes ($2a_1 + b_1 + b_2$) are expected in the region 500–300 cm^{-1}, while the 7 MnCO bending modes ($a_1 + a_2 + b_1 + b_2 + 3e$) should lie in the region 700–450 cm^{-1} (19). Owing to the proximity of the 2 regions, extensive mixing of modes of the same symmetry type is anticipated. Since our assignments in the Mn—C stretching region differ somewhat from those given previously, we will discuss them in some detail.

The strongest i.r. active Mn—C stretching vibration of $Mn(CO)_5Br$ was at approximately 420 cm^{-1}. Under high resolution this band appeared as a doublet. The splitting could have been the result of (*i*), factor group effects on one of the a_1 modes or on the b_1 mode: both of these non-degenerate species would have given rise to 2 i.r. active modes ($b_{1u} + b_{3u}$) in the crystal, or (*ii*), site symmetry effects on the degenerate e mode which would have also led to 2 i.r. active modes ($a' + a''$) in the crystal. By analogy with the C—O stretching region, the most intense band in the Mn—C stretching region would be expected to result from the e mode and, as a consequence, the formation of the doublet is attributed to the second possibility above. The e mode should also be Raman active. A medium intensity line was found at 415 cm^{-1}, but no splitting could be detected in this case. It will be demonstrated later in this paper that the assignment proposed for the e mode can be verified from overtone and combination spectra. The strong i.r. bands at 418 and 427 cm^{-1} for $Mn(CO)_5Cl$ and $Mn(CO)_5I$, respectively, have been similarly designated as Mn—C stretching e modes. Our assignments for the e modes are in agreement with those proposed by other research groups (3–5).

Each pentacarbonyl derivative exhibited a strong Raman line in the neighborhood of 385 cm^{-1}, but only in the case of $Mn(CO)_5I$ was there a corresponding i.r. band, and even then it was extremely weak. These frequencies have been assigned to the a_1 (radial) Mn—C stretching modes, which, by analogy with the a_1 (radial) C—O stretching modes, would be expected to exhibit strong Raman lines and weak i.r. bands, in accord with our experimental observations. The same assignment has been proposed by Adams and Squire (3).

There was a fairly strong band near 410 cm^{-1} in the i.r. spectrum of each compound[2]. These bands have previously been reported as shoulders, but in our spectra they were quite well resolved, especially in the case of $Mn(CO)_5I$. There were weak Raman lines coincident with the i.r. bands. With the exception of the work of Clark and Crosse (4), these frequencies have been completely disregarded in all previous assignments of the Mn—C stretching modes. Clark and Crosse studied the i.r. spectra in tetrachloroethylene solution and indicated that the bands near 410 cm^{-1} most probably arose from a_1 Mn—C stretching modes, but they did not suggest which type. We have assigned the frequencies to the a_1 (axial) modes. If this designation is correct, then the Raman lines should be polarized. Unfortunately, the lines were too weak for polarization measurements. Our proposed assignment of the a_1 (axial) modes is contrary to that of Adams and Squire (3) and Edgell and Cengel (5), who assigned these modes to the frequencies observed near 470 cm^{-1}. However, we feel that the i.r. bands at 470 cm^{-1} were too weak,

[2]In the case of $Mn(CO)_5Cl$, the band at 409 cm^{-1} was in fact the strongest in the Mn—C stretching region. On the basis of its intensity, this band would normally have been assigned to the e mode, but it turned out that the overtone and combination spectra were better explained if it was assigned to the a_1 (axial) mode and the somewhat weaker band at 418 cm^{-1} was assigned to the e mode.

For personal use only.

compared with those at 410 cm^{-1}, to support their assignment. In the present study, the former have been assigned to the a_1 MnCO bending modes. This assignment is in harmony with the solution Raman work of Adams and Squire (3) who found that the lines at 470 cm^{-1} were polarized.

A weak Raman line was observed near 630 cm^{-1} for both $Mn(CO)_5Cl$ and $Mn(CO)_5Br$ but not for $Mn(CO)_5I$. These lines had previously been noted by Edgell and Cengel (5) and by Adams and Squire (3). These research groups assigned the frequencies to the a_1 and one of the e MnCO bending modes, respectively. However, both of these assignments would necessitate the appearance of one i.r. band for each compound in the region of 630 cm^{-1}, and, since these were not observed, we prefer to assign the frequencies to either the b_1 or the b_2 purely Raman active MnCO bending modes.

One unusual feature of the CS_2 solution i.r. spectrum of $Mn(CO)_5I$ was the appearance of a weak band at 608 cm^{-1}, which was *not* observed in the solid-state spectrum. Reference to the literature shows that a similar band appears in tetrachloroethane (4), cyclohexane, and carbon tetrachloride solutions (1*b*). We are unable to offer an explanation for this anomaly.

In conclusion, it should be re-emphasized that because modes of the same symmetry type are known to be extensively mixed in the low frequency region, none of the frequencies in this region will be comprised of the assigned motion alone. This caveat applies particularly to the a_1 and e modes in the Mn—C stretching and MnCO bending regions.

Overtone and Combination Spectra of the $Mn(CO)_5X$ Molecules in the 1350–700 and 2800–2250 cm^{-1} Regions

The selection rules for the binary combinations of the $Mn(CO)_5X$ molecules assuming C_{4v} symmetry are shown in Table V. It is evident that i.r. inactive modes must combine with e modes in order to produce i.r. allowed combinations. This point is important in some of the low frequency assignments to be discussed shortly. All first overtones are allowed, but are expected to be only weakly i.r. active. The frequencies observed in the 1350–700 and 2800–2250 cm^{-1} regions and the proposed assignments are given in Table II. In order to facilitate the interpretation of the assignments, a table containing frequency information for only the fundamentals is provided (Table VI). Typical spectra in the 1350–700 and 2800–2250 cm^{-1} regions are shown in Figs. 2 and 3, respectively.

In the discussion of the low frequency vibrations, the Mn—C stretching e modes were assigned to the frequencies observed near 420 cm^{-1}. The non-appearance of the first overtones, although these modes apparently combine with the other Mn—C stretching fundamentals to produce fairly strong combinations, provides some support for this assignment. A more important observation, however, is that the combination bands at 2500 cm^{-1} can only be satisfactorily explained by the combination of the bands at 420 cm^{-1} with the i.r. inactive

b_1 C—O stretching modes at approximately 2080 cm^{-1}. It could perhaps be argued that forbidden combination bands may have become active because of solid-state effects, but the intensity of these combination bands, as well as the appearance of a similar band for $Mn(CO)_5I$ in CS_2 solution, make this possibility somewhat remote. Consequently, in order for the combination bands at 2500 cm^{-1} to satisfy the selection rules, the i.r. bands at 420 cm^{-1} must be of *e* symmetry.

It is also possible to verify the assignment of some of the other low frequency *e* modes from studies of the combination spectra in the 2800–2250 cm^{-1} region and knowledge of the b_1 C—O stretching modes from Raman spectra. For example, all 3 compounds exhibit weak intensity combination bands at about 2720 cm^{-1}, which are best explained as arising from combinations of the b_1 C—O stretching modes with the MCO bending modes at about 640 cm^{-1}. The activity of the combination bands suggests the MnCO bending modes must be of *e* symmetry, in accord with the previous assignments (3–5).

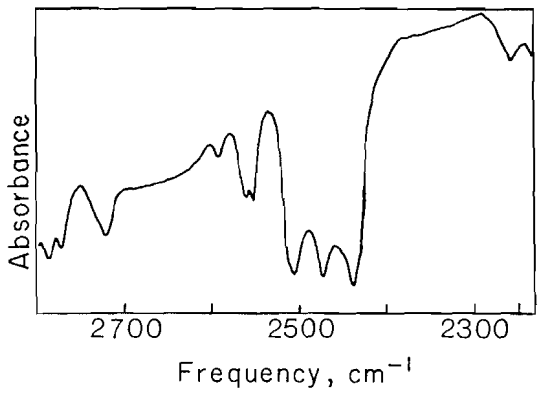

FIG. 3. Combination spectrum of $Mn(CO)_5Br$ in the 2800–2250 cm^{-1} region (Nujol mull).

A few of the bands in the combination spectra can only be explained by the combination of *e* fundamentals with low frequency fundamentals which were not observed in either the i.r. or Raman spectra. The predicted frequencies and suggested assignments for these unobserved fundamentals are given in footnotes *e* and *f* of Table II. The assignments cannot at present be substantiated further.

Vibrational Spectra of $[Mn(CO)_4Br]_2$ and $[Mn(CO)_4I]_2$

It has already been mentioned that, during the course of our studies on the $Mn(CO)_5X$ derivatives, we had occasion to record the solid-state

i.r. and laser Raman spectra of $[Mn(CO)_4Br]_2$ and $[Mn(CO)_4I]_2$ in the C—O stretching and low frequency regions. In this section we wish to comment briefly on the spectra.

The solution i.r. spectra of the three $[Mn(CO)_4X]_2$ derivatives have been thoroughly investigated in the C—O stretching region by El-Sayed and Kaesz (15) and Abel and Butler (20). The former research workers have also reported data for the solid-state i.r. spectrum of the iodo-compound in the region 700–250 cm^{-1}. However apart from these studies there have been the dimers were extremely poor scatterers, 4 sharp lines were easily observable in both cases, in agreement with the group theoretical prediction for D_{2h} symmetry. There were no splittings detected in any of the lines. Although it is not strictly valid to compare frequencies from different physical states, it is apparent that there are no coincidences between the CCl_4 solution i.r. and the solid-state Raman data. The complexity of the solid-state i.r. spectra in the C—O stretching region renders a similar comparison less meaningful However even though fewer Raman

Equilibrium constants for σ-complex formation between cyanide ion and 1,3,5-trinitrobenzene in alcoholic solvents

E. Buncel, A. R. Norris, W. Proudlock, and K. E. Russell
Department of Chemistry, Queen's University, Kingston, Ontario

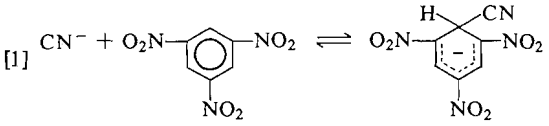
Received June 6, 1969

Equilibrium constants have been determined spectrophotometrically for the reaction of cyanide ion with 1,3,5-trinitrobenzene in methanol, ethanol, *n*- and iso-propanol, and *n*- and *t*-butanol. The equilibrium constants at 25 °C vary from 39 l mole^{-1} for the reaction in methanol to 500 000 l mole^{-1} with *t*-butanol as solvent. Enthalpy changes, determined from equilibrium measurements and by direct calorimetry, vary from 0 to −15.5 kcal mole^{-1} and the calculated entropy changes decrease from 7 to −26 cal deg^{-1} mole^{-1} as the solvent is changed from methanol to *t*-butanol. These results are interpreted on the basis that desolvation of the small cyanide ion is the primary factor influencing enthalpies and entropies of reaction. The equilibrium constant in *t*-butanol is comparable to the values observed for aprotic solvents such as chloroform and acetone.

Canadian Journal of Chemistry, 47, 4129 (1969)

Introduction

The reaction of cyanide ion with 1,3,5-trinitrobenzene in chloroform gives rise to a deep red solution which is fairly stable at low temperatures (1). Proton magnetic resonance (p.m.r.) studies (2, 3) establish the structure of the red product as the σ-complex **1** formed as in reaction [1]



[1]

1

The complex has absorption maxima in chloroform solution at 442 mμ ($\varepsilon = 3.98 \times 10^4$ l mole^{-1} cm^{-1}) and 558 mμ ($\varepsilon = 2.24 \times 10^4$ l mole^{-1} cm^{-1}). Red solutions with similar absorption characteristics are observed in a variety of other solvents and it is considered that the σ-complex **1** is formed in all cases (1, 4). The equilibrium constant in chloroform solution at 25 °C is 3.35×10^5 l mole^{-1} and in acetone solution 1.44×10^5 l mole^{-1} (1). In this study we have investigated the effect of alcoholic solvents on the equilibrium constant and on the enthalpy and entropy changes in reaction [1]. The equilibrium constant for the reaction in *t*-butanol is very large and it is not feasible to estimate the enthalpy change from the variation of equilibrium constant with temperature. Direct calorimetric measurements of enthalpy change have therefore been made, using a solution calorimeter.

Experimental

Materials

1,3,5-Trinitrobenzene was recrystallized twice from ethanol and dried in vacuo.

Tetraphenylarsonium cyanide was prepared by adding a concentrated solution of sodium cyanide to an aqueous solution of tetraphenylarsonium chloride. The resulting tetraphenylarsonium cyanide was recrystallized twice from water in the presence of sodium cyanide, care being taken that the solution temperature did not exceed 60 °C. The compound was dried in vacuo and stored over silica gel.

Methanol and ethanol were dried over Drierite and fractionally distilled in the absence of atmospheric moisture.

n-Propanol, iso-propanol, *n*-butanol, and *t*-butanol were dried over Drierite and passed through a column of neutral alumina. They were fractionally distilled from Linde 4A molecular sieves.

Procedure

Solutions of tetraphenylarsonium cyanide and 1,3,5-trinitrobenzene were made up in an atmosphere of dry nitrogen. All flasks were sealed with silicone rubber serum caps and wrapped in aluminum foil to protect the solutions from light. In a typical experiment, 5 ml of 1,3,5-trinitrobenzene solution was placed in a quartz cell of 2 cm path length and the cell stoppered with teflon stoppers. The solution was allowed to reach the temperature of the thermostated cell compartment in the spectrophotometer and 0.1–0.5 ml solution of tetraphenylarsonium cyanide added by means of a calibrated "Repette" syringe. Spectra were determined using a Unicam SP800 spectrophotometer or occasionally Beckman DKl or DU spectrophotometers. The cell temperature was controlled to better than ±0.5 °C in the temperature range 5–45 °C. Condensation on cell windows at temperatures below 25 °C was prevented by purging with dry air or nitrogen.

Calorimetric measurements were made using a Guild Corporation Solution Calorimeter (Model 400) equipped with a base line compensator. Solvent (215 ml) was placed in the Dewar flask (capacity 250 ml). Normally

0.1–0.5 g 1,3,5-trinitrobenzene was weighed into a tube whose base consisted of a thin-walled glass bulb, and the tube and breaker inserted through the teflon cover of the Dewar flask so that the glass bulb was immersed in the solvent. After a period of not less than 1 h, 2 electrical calibrations of the heat capacity of the system were made. The glass bulb was then broken and the heat of solution of 1,3,5-trinitrobenzene in the solvent determined. To the resulting solution was added 0.04–0.18 g tetraphenylarsonium cyanide using the same procedure. In some experiments the order of addition was reversed, the heat of solution of tetraphenylarsonium cyanide being determined in the first step. The molar ratio of 1,3,5-trinitrobenzene to tetraphenylarsonium cyanide was always greater than 4:1. The initial temperature of the solvent in the calorimetric studies was close to 25 °C with all solvents except *t*-butanol for which the initial temperature was about 26.5 °C.

Results

Preliminary spectroscopic studies were performed with ethanol as solvent. The concentration of 1,3,5-trinitrobenzene was low (about 10^{-5} *M*) and a large excess of tetraphenylarsonium cyanide was added to give solutions which were 10^{-3} to 10^{-2} *M* in cyanide ion. A red color developed but the color faded rapidly to pale yellow even in the dark and no meaningful absorption spectrum could be obtained.

Addition of a small amount of tetraphenylarsonium cyanide to a large excess of 1,3,5-trinitrobenzene in ethanol solution gave a red solution whose absorbance at 435 mμ reached a maximum after a few minutes. The absorbance did not change significantly over a period of 15–20 min. The visible spectrum showed maxima at 435 and 544 mμ, the absorbance at 435 mμ being nearly twice that at 544 mμ ($\varepsilon_{435}/\varepsilon_{544} = 1.76$ for ethanol). Similar results were obtained with other alcohols; the wavelengths of the absorption maxima are given in Table I. The spectrum in each solvent is almost identical with that of the red substance formed in chloroform or acetone solution which has been shown to be the σ-complex **1** (2, 3). The 1:1 stoichiometry has been confirmed in the case of *n*-propanol as solvent by the method of continuous variations.

TABLE I

Wavelengths of absorption maxima of σ-complex **1** in various alcohols at 25 °C

Solvent	λ_{max} (mμ)	λ_{max} (mμ)
Methanol	428	540
Ethanol	435	544
n-Propanol	435	542
iso-Propanol	436	546
n-Butanol	435	540
t-Butanol	437	549

Equilibrium constants were determined by analysis of absorbance measurements at the short wavelength maximum for solutions which were initially 2–7 × 10^{-5} *M* in tetraphenylarsonium cyanide and 10^{-4}–10^{-2} *M* in 1,3,5-trinitrobenzene (TNB). For the reaction

$$[2] \qquad TNB + CN^- \rightleftharpoons TNB{\cdot}CN^-$$

the equilibrium constant

$$K = \frac{[TNB{\cdot}CN^-]}{[TNB][CN^-]}$$

If the absorbance at equilibrium in the 2 cm cell is given by *A* and the extinction coefficient for this wavelength is ε, it follows that

$$\frac{1}{K} = \frac{A}{2\varepsilon} - [CN^-]_0 - [TNB]_0 + \frac{2[CN^-]_0[TNB]_0}{A}$$

where $[CN^-]_0$, $[TNB]_0$ are the initial concentrations of cyanide ion and 1,3,5-trinitrobenzene. Following the Rose–Drago method of analysis (5), plots were made of $1/K$ vs. assumed values of ε for each set of initial concentrations of cyanide ion and 1,3,5-trinitrobenzene (Fig. 1). Values of *K* and ε were obtained from the points of intersection of the lines and error limits were based on average deviations from the mean of individual estimates of *K* and ε. Equilibrium constants were in some cases also determined from absorbances

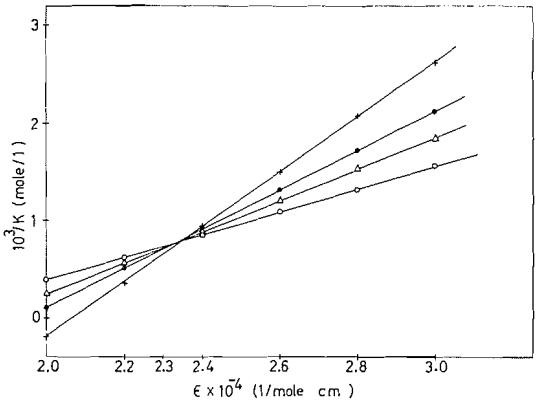

FIG. 1. Rose–Drago plot for the reaction of cyanide ion with 1,3,5-trinitrobenzene in ethanol at 25 °C. K = 1265 ± 20 l mole^{-1}; ε = 23 500 ± 300 l mole^{-1} cm^{-1}.

For personal use only.

at the long wavelength maximum and these agreed within experimental error with values of K obtained at the short wavelength maximum.

The equilibrium constants K of reaction [1] at 25 °C and the extinction coefficients of the σ-complex at the lower wavelength maxima for the solvents methanol, ethanol, *n*-propanol, iso-propanol, *n*-butanol, and *t*-butanol are given in Table II. With methanol as solvent the low equilibrium constant results in a relatively high concentration of free cyanide, with the consequence that at 25 °C the maximum absorbance begins to decrease significantly after a period of only 2 or 3 min. The rate of fading was lower at 6 and 15 °C; maximum absorbance values were constant for over 5 min at these temperatures. Rose–Drago plots at 25 °C gave reproducible values of K, but the value of 39 ± 2 l mole^{-1} is probably less than the true value because of the fade reaction. The maximum absorbances for reactions in ethanol, *n*-propanol, iso-propanol, and *n*-butanol are not subject to significant fading under the chosen experimental conditions and the equilibrium constants are hence assigned narrow limits of error. The equilibrium constant for the reaction in *t*-butanol is very large and its value is probably not known to better than ±20% because complexing occurs to a large extent over the whole range of 1,3,5-trinitrobenzene concentrations employed.

TABLE II

Equilibrium constants K for reaction [1] at 25 °C and extinction coefficients at lower wavelength maximum

Solvent	K (l mole^{-1})	$10^{-4}\,\varepsilon$ (l mole^{-1} cm^{-1})
Methanol	39 ± 2	2.37 ± 0.02
Ethanol	1 265 ± 20	2.35 ± 0.03
n-Propanol	1 470 ± 50	2.43 ± 0.02
iso-Propanol	10 000 ± 300	2.63 ± 0.02
n-Butanol	2 020 ± 50	2.40 ± 0.03
t-Butanol	5 ± 1 × 10^5	2.60 ± 0.03

Enthalpies of reaction have been obtained from the variation of equilibrium constants with temperature over the range 6–25 °C with methanol as solvent, 15–45 °C with ethanol, and 25–45 °C with *n*-propanol and *n*-butanol. The values are recorded as ΔH_{eq}^{0} in Table III. Enthalpies of reaction determined calorimetrically ΔH_{cal} are also given in Table III. The fraction of cyanide ion converted to complex varied from 83 to close to 100% dependent on solvent and reaction conditions and the calorimetric enthalpies of reaction are based on the amount of complex formed calculated from the equilibrium constants of Table II.

The maximum concentration of tetraphenylarsonium cyanide used in the calorimetric measurements was 2×10^{-3} M and the ratio of concentrations of 1,3,5-trinitrobenzene to cyanide ion was always at least 4:1; even so, some difficulties were experienced because of secondary reactions. With ethanol as solvent, for example, the temperature of the reaction system continued to rise slowly after equilibrium should have effectively been reached and the measured heat of reaction was dependent on the concentration of free cyanide ion in the final solution. The ΔH_{cal} for ethanol was obtained by extrapolating the experimental values of ΔH to zero concentration of free cyanide ion. The reproducibility of individual values of ΔH was better than ±2% and the larger limits of error are assigned in Table III because of the difficulties with secondary reactions.

No solubility problems were encountered with the first 5 alcohols listed in Table III. With *t*-butanol as solvent, however, the 1,3,5-trinitrobenzene dissolved slowly and precipitation of the

TABLE III

t-Butanol	7.78	—	15.5 ± 1.0	25.0 ± 3

*ΔH_{eq}^{0} in methanol was calculated using equilibrium constants determined at 6, 15, and 25 °C. All other ΔH_{eq}^{0} values were calculated using equilibrium constants determined at 25, 35, and 45 °C. The larger error associated with ΔH_{eq}^{0} in methanol reflects the greater uncertainty in the equilibrium constants in this solvent due to the presence of a slow secondary reaction.

red complex occurred when the initial cyanide concentration was greater than 1.5×10^{-3} M.

Free energy changes, ΔG^0, and entropy changes, ΔS^0, for reaction [1] in the various alcoholic solvents are also given in Table III. The standard state is 1 mole l^{-1}.

Discussion

Since the concentration of tetraphenylarsonium cyanide does not exceed 0.002 M, it is probable that ion pair formation between the bulky tetraphenylarsonium ion and the cyanide ion is small in the alcohols studied. The equilibrium measurements are therefore considered to apply to the reaction between free cyanide ion and 1,3,5-trinitrobenzene. Differences of solvation of reactants and products may vary considerably from one solvent to another. The cyanide ion is small with a relatively localized negative charge and it should be strongly solvated by polar protic solvents such as methanol and ethanol (6). The charge on the σ-complex is dispersed and hydrogen bonding between the complex and polar protic solvents is probably fairly weak. Formation of the σ-complex thus requires desolvation of cyanide ion to occur and this is likely to be a major factor in determining enthalpy and entropy changes for reaction [1] in methanol. At the other extreme, *t*-butanol solvates the cyanide ion only to a limited extent and solvation effects are likely to be of minor importance.

The highest equilibrium constant observed is 5×10^5 l mole^{-1} for reaction [1] in *t*-butanol; there is a large negative enthalpy change and the effect of the enthalpy term on the equilibrium constant is only partially compensated by the large entropy decrease. Differences in solvation of reactants and products are expected to be small with *t*-butanol as solvent. It might therefore be anticipated that the reaction of cyanide ion with 1,3,5-trinitrobenzene to give the σ-complex in a weakly interacting solvent would be characterized by a high equilibrium constant, a large enthalpy of reaction (~ -15 kcal mole^{-1}) and a large negative entropy change (~ -25 cal deg^{-1} mole^{-1}). Values of ΔH and ΔS of this order of magnitude are associated with σ-complex formation in chloroform and acetone[1].

The other alcoholic solvents possess OH groups which are considerably less shielded by methyl groups and solvation by these alcohols has a considerable effect on the equilibrium constant. The equilibrium constant in methanol at 25 °C is some 10 000 times smaller than in *t*-butanol; for the former, the enthalpy change is approximately zero and the entropy change is small and positive. The most important reason for the striking behavior of methanol as solvent is the solvation of the small cyanide ion. Apparently a large positive enthalpy change accompanies the reduction in solvation as the σ-complex is formed. There is a simultaneous decrease in order, and, although methanol has some structure, the overall result is a much more positive entropy change for the reaction in methanol than in *t*-butanol.

The equilibrium constants at 25 °C in ethanol, *n*-propanol, and *n*-butanol are all in the range 1000–2000 l mole^{-1} at 25 °C. The heats of reaction are -7 ± 1.5 kcal mole^{-1} and the entropy changes -9 ± 3 cal deg mole^{-1}. They thus show intermediate behavior between the 2 extremes of methanol and *t*-butanol. Desolvation of the cyanide ion appears to be the main factor causing a decrease in equilibrium constant from the value in *t*-butanol, but the effect is smaller than in methanol and there is a slight trend towards larger equilibrium constants as the size of the alkyl group is increased. As judged by the equilibrium constant, the solvating effect of iso-propanol is significantly weaker than that of the normal alcohols. It was anticipated that the equilibrium constant of 10 000 l mole^{-1} would be associated with a heat of reaction of about -9 kcal mole^{-1}. The lower observed value was reproducible in calorimetric studies but secondary reactions at higher temperatures prevented confirmation of this heat of reaction in equilibrium studies.

The enthalpy and entropy changes recorded here for the reaction of cyanide ion with 1,3,5-trinitrobenzene in ethanol may be compared with an enthalpy change of 0.3 kcal mole^{-1} and an entropy change of 16.3 cal deg^{-1} mole^{-1} for the formation of the σ-complex between ethoxide ion and 1,3,5-trinitrobenzene in ethanol (7). The larger entropy change in the latter case may imply that desolvation of ethoxide ion in the formation of its σ-complex with 1,3,5-trinitrobenzene is greater than with cyanide ion. Ethoxide ion attacks 2,4,6-trinitrotoluene under some conditions to form almost exclusively the trinitro-

For personal use only.

benzyl anion (8).

[4] 
The entropy change in this reaction is 27 cal deg mole^{-1}, and this large value has been interpreted by Caldin as being largely due to desolvation of ethoxide ion (7).

We have attempted to determine whether any relationship exists between the observed solvent effects on reaction [1] and the various empirical solvent polarity parameters (9). Figure 2 shows a plot of $-\Delta G^0$ for reaction [1] at 25 °C against E_T which measures the energy of the intramolecular charge transfer transition in a pyridinium N-phenol betaine (10). It appears that the results for σ-complex formation in the 6 alcohol solvents are correlated well by the parameter E_T. The closeness of the correlation may be in part due to the fact that these solvents are all of the same general type. The significance of such correlations and the extension to other systems are being investigated.

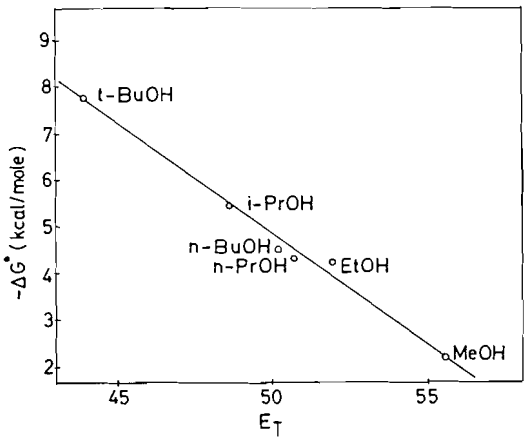

FIG. 2. Plot of $-\Delta G^0$ for reaction of cyanide ion with 1,3,5-trinitrobenzene in various alcohols at 25 °C vs. the solvent parameter E_T.

A study of the complexing of gold(I) with tertiary phosphine, arsine, and stibine

A. D. WESTLAND
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received April 29, 1969

The equilibrium

$$(Ph_3P)AuX + (n - 1)Ph_3P \leftrightarrows (Ph_3P)_nAu^+ + X^-$$

was studied in nitrobenzene solution and evidence for the occurrence of tricoordinate $(Ph_3P)_2AuX$ was obtained. The results indicate that π-bonding of phosphine to gold(I) is much stronger than that of phosphine to silver(I). Attempts to prepare tricoordinate complexes from di(tertiary)phosphine or arsine failed. Chloro- and bromo(triphenylstibine)gold(I) have been prepared. The dipole moments of Ph_3MAuX, where M = P or As, and X = Cl, Br, and I, or M = Sb and X = Br have been determined. Metal–ligand stretching frequencies are compared.

Triphenylphosphine and triphenylarsine form reasonably stable complexes with gold(I) but attempts to isolate a pure triphenylstibine complex have hitherto failed (1). We have now succeeded in preparing crystalline halo(triphenylstibine)gold(I) complexes containing either chlorine or bromine.

With the availability of these complexes, it became possible to examine dipole moments and bond stretching frequencies of the series of complexes containing P, As, and Sb as ligand donor atoms. The complexing ability of the ligands Ph_3P, Ph_3As, and Ph_3Sb falls off with increasing size of the donor atom. It was hoped that one could study the equilibria

$$LAuX + (n - 1)L \leftrightarrows L_nAu^+ + X^-$$

where L is one of the above ligands. However, the equilibria lay so far toward the left hand side of the equation that it was possible to obtain sufficiently accurate results only with triphenylphosphine.

These studies enable us to make some inferences about the nature of the bonding in these complexes, i.e., the relative importance of π-bonding with gold(I).

Experimental

Preparation of Complexes

Chloro(triphenylstibine)gold(I)

Chloroaurous acid trihydrate (3 g) was dissolved in ethanol (50 cc) and triphenylstibine (3.82 g, 1.05 equivalent) was added. The solution was heated on the steam bath until it became colorless. The solution was then allowed to cool and a white precipitate of crude $Ph_3SbAuCl$ was separated by filtration. The product was recrystallized from tetrahydrofuran by addition of petroleum ether (30–60°) and white needles decomposing at 90° were obtained in 28% yield. Colloidal gold appeared slowly in the dark and rapidly when the product was exposed to light. The compound was best preserved at low temperature.

Anal. Calcd. for $C_{18}H_{15}AuClSb$: C, 36.93; H, 2.58; Cl, 6.05. Found: C, 36.92; H, 2.66; Cl, 6.20.

Bromo(triphenylstibine)gold(I)

Crude chloro(triphenylstibine)gold(I) (0.5 g) was dissolved in benzene using no heat. Concentrated hydrobromic acid (1.1 cc) was added immediately[1] whereupon the solution began to turn dark blue. Thin layer chromatography was used to determine when all of the starting material had been converted (about 10 min). The aqueous layer was separated and the benzene solution washed twice with water. The benzene solution was dried with sodium sulfate and evaporated to dryness. The residue was recrystallized from tetrahydrofuran by the addition of petroleum ether. The product (white needles) was much more stable than the chloro compound. A yield of 43.5% was obtained.

Anal. Calcd. for $C_{18}H_{15}AuBrSb$: C, 34.32; H, 2.40; Br, 12.69. Found: C, 34.60; H, 2.17; Br, 12.82.

Halo Complexes of Triphenylphosphine and Triphenylarsine

Halo complexes containing triphenylphosphine and triphenylarsine were prepared by a method of which the following example is typical.

Bromo(triphenylphosphine)gold(I). Chloro(triphenylphosphine)gold(I) (1 g) was dissolved in warm acetone (50 cc) and concentrated hydrobromic acid (2.5 cc) added. Evaporation of the solvent under reduced pressure and cooling gave white crystals (m.p. 250–251°) in 92% yield.

Anal. Calcd. for $C_{18}H_{15}AuBrP$: C, 40.10; H, 2.80; Br, 14.82. Found: C, 40.32; H, 2.82; Br, 14.67.

The melting points and analytical data of the other compounds are as follows.

Ph_3PAuI: m.p. 230–231°. Anal. Calcd. for $C_{18}H_{15}AuIP$: C, 36.88; H, 2.58; I, 21.65. Found: C, 37.21; H, 2.65; I, 22.02.

$Ph_3AsAuCl$: m.p. 219–220°. Anal. Calcd. for $C_{18}H_{15}AsAuCl$: C, 40.14; H, 2.81; Cl, 6.58. Found: C, 41.03; H, 2.70; Cl, 6.66.

[1]Benzene solutions of the chloro complex are very unstable and rapidly turn brown.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$Ph_3AsAuBr$: m.p. 224–225°. Anal. Calcd. for $C_{18}H_{15}AsAuBr$: C, 37.08; H, 2.59; Br, 13.70. Found: C, 37.25; H, 2.42; Br, 13.56.

Ph_3AsAuI: m.p. 201–202°. Anal. Calcd. for $C_{18}H_{15}AsAuI$: C, 34.31; H, 2.40; I, 20.14. Found: C, 34.51; H, 1.81; I, 20.37.

Bis(triphenylphosphine)gold(I) Fluoroborate

Chloro(triphenylphosphine)gold (0.25 g) was dissolved in acetone (50 cc) and the solution cooled to 0 °C. Crystals of $AgBF_4$ (0.202 g) and Ph_3P(0.132 g) were added and a precipitate of AgCl separated by filtration. Evaporation of the filtrate gave an oil which crystallized upon adding MeOH. Recrystallization gave a white product (m.p. 234–236°) in 66% yield.

Anal. Calcd. for $C_{36}H_{30}AuBF_4P_2$: C, 53.49; H, 3.74. Found: C, 53.44; H, 3.70.

Dichloro-μ-1,2-bis(diphenylphosphino)ethanedigold(I)

Chloroauric acid trihydrate (1 g) in water (8 cc) was diluted with ethanol (50 cc) and the solution warmed on the steam bath. Excess ligand 1,2-bis(diphenylphosphino)-ethane (2 g) was added and the warming continued until the yellow color had disappeared and a white product (m.p. 276–279°) was collected in 83% yield. This was slightly soluble in warm chloroform and in warm acetone.

Anal. Calcd. for $C_{26}H_{24}Au_2Cl_2P_2$: C, 36.17; H, 2.80; Cl, 8.21. Found: C, 36.33; H, 2.94; Cl, 8.05.

Dichloro-μ-1,2-bis(diphenylarsino)ethanedigold(I)

This was prepared in the same way as the preceding compound in 84% yield (m.p. 221–224°) and it had similar properties.

Anal. Calcd. for $C_{26}H_{24}As_2Au_2Cl_2$: C, 32.83; H, 2.54. Found: C, 32.13; H, 2.53.

Dichloro-μ-1,2-bis(diphenylphosphino)acetylenedigold(I)

This was prepared in the same way as the preceding compounds in 95% yield (m.p. 262–265°). The C≡C stretch appeared in the infrared (i.r.) spectrum weakly at 2340 cm^{-1}.

Anal. Calcd. for $C_{26}H_{20}Au_2Cl_2P_2$: C, 36.35; H, 2.35. Found[2]: C, 36.35; H, 2.54.

The molar conductivity of 5×10^{-4} *M* solutions in nitrobenzene of each of the above compounds except $[(Ph_3P)_2Au]BF_4$ was less than 0.5 mho cm^2.

Conductivity Measurements

Measurements were carried out at 25 °C. using an Industrial Instruments, Inc., Model RC18 conductivity bridge. The solvent was redistilled nitrobenzene which had a specific conductivity of less than 0.1×10^{-6} mho. The equilibria were investigated over a range of total gold concentrations from 1×10^{-4} to 2×10^{-3} *M* and excess triphenylphosphine concentrations up to 0.1 *M*. Conductivities were corrected for a small contribution to the conductivity, probably due to an impurity, which was introduced by the triphenylphosphine. Conductivities reached a steady value in the time it took to prepare a sample solution for measurement.

Dipole Moment Measurements

A Wissenschaftlich–Technische Werkstätten Dipolmeter Model DM-01 was used for measuring dielectric constants of solutions at 25 °C. Measurements were made on benzene or dioxane solutions. Benzene was employed wherever possible, but solutions of $Ph_3SbAuBr$ and Ph_3AsAuI in this solvent were unstable. The dipole moments were calculated by the method of Smith (2). Refractive indices were measured at 25 °C with an Abbé refractometer, but the term involving refractive index in the equation for dipole moment was negligible in all cases.

Infrared Spectra

Infrared spectra in the range 600–200 cm^{-1} were carried out using a Beckman Instruments Model IR-12 spectrometer. The complexes were contained in cesium iodide pellets.

Results and Discussion

Examination of Solution Equilibria

The addition of triphenylphosphine to a solution of $(Ph_3P)AuX$ produced an electrolyte, and when the concentration of ligand was raised to about 0.1 *M*, the specific conductivity appeared to be close to reaching a limiting value corresponding, presumably, to the process

$$LAuCl + (n - 1)L \leftrightarrows L_nAu^+ + X^-$$

where $L = Ph_3P$.

The limiting value referred to was obtained for several concentrations of gold by a graphical extrapolation of the quantity κ^{-1} plotted against $\kappa/[L]^2$ which was found empirically to be satisfactory, as the plot was either linear or only slightly curved. The value of κ^{-1} reached its limiting value at $\kappa/[L]^2 = 0$. The values of κ so obtained were used to construct a plot of the molar conductivity of L_nAuX against $\sqrt{c}$ (c =

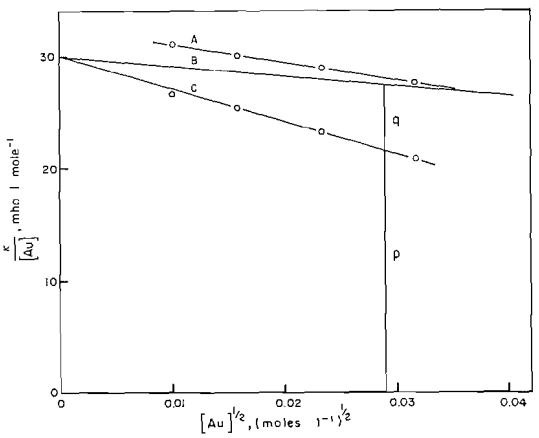

FIG. 1. Plots of molar conductivity against (concentration)$^{\frac{1}{2}}$. *A*, $[(Ph_3)_2Au]BF_4$; *B*, theoretical line (Robinson and Stokes equation); *C*, system: Ph_3PAuCl plus excess Ph_3P.

[2]Microanalyses were performed by the firm of A. Bernhardt, Elbach, West Germany.

For personal use only.

concentration of gold complex). This is shown in Fig. 1 as curve *C*.

It was assumed that the molar conductivity of L_nAuX, if completely ionized, would be given by the limiting law equation as modified by Robinson and Stokes (3). This is shown as curve *B* in Fig. 1. The fraction $p/(p + q)$ is then the degree of dissociation at concentration *c*. Curve *A* shows a plot for $[Ph_3P)_2Au]BF_4$ which is similar to the Robinson–Stokes line. The association may be due to outer sphere ion-pairing. Fuoss' treatment predicts for the chloride an equilibrium constant $K = \alpha^2 c/(1 - \alpha)$ of 0.045 mole l^{-1}. For $c = 5 \times 10^{-4}$ this gives a degree of dissociation, α, of 0.9, which is in good agreement with the observed value of 0.84.

The data shown in Fig. 1 enabled us to relate conductivities of samples to their ion and ion-pair concentrations. The expression

$$K_{n-1} = \frac{[L_nAu^+][X^-]}{\{[Au_t] - [L_nAu^+] - [L_nAuX]\}[L]^{n-1}}$$

may be rearranged to

$$\frac{[L_nAu^+]}{[L]^{n-1}} = K_{n-1}\left\{\frac{[Au_t] - [L_nAuX]}{[L_nAu^+]} - 1\right\}$$

where $[Au_t]$ represents the total gold concentration.

It follows that a plot of $[L_nAu^+]/[L]^{n-1}$ against $1/[L_nAu^+]$ will be very nearly a straight line if *n* is a unique constant and $[L_nAuX]$ is small relative to $[L_nAu^+]$. These conditions are met for the chloro compound when the concentrations of Ph_3P are relatively large and *n* is set equal to 3. A plot of the data is shown in Fig. 2. For small concentrations of excess ligand, *n* tends toward 2.

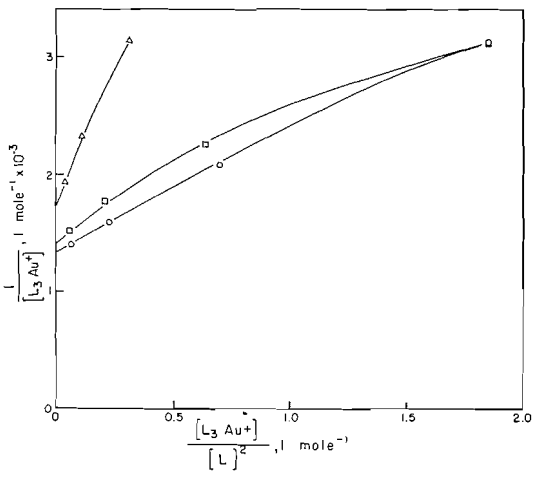

FIG. 2. Plots which illustrate second order dependence upon concentration of excess ligand. Total gold concentrations: 1×10^{-3} *M*. ○, Ph_3PAuCl; □, Ph_3PAuBr; Δ, Ph_3PAuI.

By substituting in the equilibrium expression, approximate values of K_{n-1} for $n = 3$ were obtained. These were not quite constant for the chloro compound and showed large variations for the bromo and iodo compounds. Limiting values were obtained by plots of the approximate *K* values against $[L_nAu^+]/[L]$ and extrapolating to infinite ligand concentration. The results are given in Table I.

TABLE I

Equilibrium constants for the addition of triphenylphosphine to $(Ph_3P)AuX$

Compound	$K_1 \times 10^{-2}$	K_2 (m/l)	$\frac{K_1}{K_2}$	$\frac{K_1^2}{K_2} \times 10^{-4}$
$(Ph_3P)AuCl$	7±1	1.5±0.1	480	33
$(Ph_3P)AuBr$	3.0±0.2	3.7±0.1	83	2.4
$(Ph_3P)AuI$	2.2±0.2	>35	<6.3	<0.14

The variation in apparent values of *K* is evidently due to the intermixing of the equilibrium with $n = 2$, resulting in the formation of some L_2Au^+ ions. Meyer and Allred have commented upon the existence of $[(Ph_3P)_2Au^+]Cl^-$ both in solution and in the crystalline state (4). Compounds in which univalent gold assumes a coordination number of 3 and 4 have been reported (5–10) even though 2 is the usual number. This equilibrium is of decreasing importance as $[L_nAu^+]/[Ph_3P]$ approaches zero.

An attempt was made to estimate K_1, i.e., *K* for $n = 2$. It was assumed that the ionic conductivity of L_2Au^+ was about the same as that of L_3Au^+ and hence the measured values of the concentration of ionic gold were in fact $[L_3Au^+] + [L_2Au^+]$. From the value of K_2, $[L_3Au^+]$ was calculated for each concentration of ligand. The limit of K_1 as $[Ph_3P]$ approached zero was then taken to be the best value. The assumption made is at best an approximation, so the values of K_1 have significance only in relation to one another. Values for the bromo and iodo compounds and a lower limit for the chloro compound appear in Table I.

The quotient K_1/K_2 is the equilibrium constant which refers to the addition of the third mole of

Ph_3P to the ion L_2Au^+ or to L_2AuX, i.e.

$$\frac{K_1}{K_2} = \frac{[L_2Au^+][L]}{[L_3Au^+]}$$

or

$$\frac{K_1}{K_2} = \frac{[L_2AuX][L]}{[L_3Au^+][X^-]}$$

If the first of these two expressions is valid, K_1/K_2 should be independent of the choice of halogen in the starting compound. The values shown in Table I show that this is not the case. We conclude that the undissociated complex, L_2AuCl, is present in appreciable concentrations. The values of K_1 for the bromo and iodo complexes are not greatly different, which indicates that for these systems, very little ionization occurs until the addition of the third molecule of Ph_3P.

Ahrland and Chatt have observed that only three monotertiary phosphine molecules can be added to Ag^+ ion even though it is normal for four monodentate groups to add (11). They attribute this difference to the important role of π-bonding in the phosphine complexes. Their theoretical arguments to support this have been discounted (12), but the empirical evidence that typical π-bonding ligands seem to prefer lower coordination numbers with d^{10} ions appears to be significant. The present stability studies of gold(I) phosphine complexes are of interest in view of the paucity of information available on π-bonding in gold(I) compounds.

For reasons referred to above, Ahrland and Chatt state that the value of the ratio of the equilibrium constants for the successive addition of ligand molecules to Ag^+ ion is an indication of the degree of π-bonding. They obtained a large ratio $K_1/K_2 = 160$ for the first and second additions, respectively.

In our experiments, the addition of the additional ligand molecules is accompanied by the breaking of a gold–halogen bond. For this reason we have defined K_2 for our gold complexes in a different way. Ahrland and Chatt's ratio now becomes $K_1/(K_2/K_1)$ or K_1^2/K_2. These values are given in Table I. They show a variation because of the increasing difficulty of breaking the gold–halogen bond in the order Cl < Br < I. The very large ratios of K_1^2/K_2 indicate that π-bonding is of great importance in bonding triphenylphosphine to gold.

Reaction of $Ph_2PC_2H_4PPh_2$ and the corresponding arsine with $HAuCl_4$ did not lead to tricoordinate complexes of the type (chel)AuCl. Instead, the stoichiometry of the products suggests that the ligand served as a bridge between two Au—Cl units. The properties of the complex formed from $Ph_2PC{\equiv}CPPh_2$, which cannot serve as chelating ligand, were almost identical with those of the more flexible ligands. Thus, gold(I) is asserting its tendency toward 2-coordination in these reactions.

Dipole Moments

Attempts to prepare iodo(triphenylstibine)gold were unsuccessful. Only the bromo complex was stable enough to permit a determination of the dipole moment. The dipole moments are given in Table II. Owing to their instability in benzene solution, some of the complexes had to be examined in dioxane. The solubility in this solvent was very low so that the values are probably not so precise as those obtained with benzene.

TABLE II

Dipole moments of the compounds Ph_3MAuX

Compound	Dipole moments (D) in Benzene	Dipole moments (D) in *p*-Dioxane
Ph_3PAuCl	9.0	
Ph_3PAuBr	8.6	
Ph_3PAuI	8.2	
$Ph_3AsAuCl$	8.9	9.9
$Ph_3AsAuBr$	8.5	9.1
Ph_3AsAuI		8.6
$Ph_3SbAuBr$		8.5

It can be seen that the dipole moment of LAuCl, LAuBr, and LAuI vary in the order Cl > Br > I which is the normal order for halogenated hydrocarbons for example. Jensen's values for *cis* complexes of platinum are: $(Et_3P)_2PtCl_2$, 10.7 D; $(Et_3P)_2PtBr_2$, 11.2 D; and $(Et_3P)_2PtI_2$, 8.2 D (13). For *trans*-$(Et_3P)_2PtRX$, where R is an alkyl group, the order is Cl < Br < I (14). In the series of platinum compounds there is uncertainty about the bond angles and hence about the distribution of charge, but it appears that chlorine is not decidedly more negative than the other halogen atoms. Parshall has suggested that the halogens may be π-donors toward platinum and his results indicate that chlorine should be a stronger donor than bromine (15).

Gold with an oxidation state of only 1 will be a much poorer acceptor of π-electron density and

$Ph_3SbAuBr$§	457 (vs),	309 (w),	274 (vs),	250 (sh),	230 (w),†	220 (sh)				

*s = strong, m = medium, w = weak, v = very, sh = shoulder.
†Tentative assignment of the M—Au stretching frequency.
‡Au—X stretching frequency.
§The expected intense Au—Br stretching band was not observed. The very weak shoulder at 250 cm^{-1} may be due to Au—Br stretching.

thus the Au—X bond should be of nearly pure σ-character. The very large values of dipole moment suggest, moreover, that the Au(I)—X bond is much more polar than the Pt(II)—X bond.

The moments of Ph_3PAuBr, $Ph_3AsAuBr$, and $Ph_3SbAuBr$ are interrelated in an almost identical way to those of the corresponding *cis*-platinum compounds. Chatt and Wilkins obtained the following values: $(Et_3P)_2PtCl_2$, 10.9 D; $(Et_3As)_2PtCl_2$, 10.9 D; and $(Et_3Sb)_2PtCl_2$, 10.45 D (16). These values would be expected to get progressively larger in the sequence $P \rightarrow As \rightarrow Sb$ if some counteracting influence were not present. If π-bonding in the M—Pt bond becomes progressively more important in this sequence a near constancy of the dipole moment values might well result. We have previously given independent evidence of such a trend (17). The present results with gold complexes indicate that very similar bonding influences are involved.

Infrared Spectra

The i.r. frequencies observed in the range 600–200 cm^{-1} are listed in Table III. The Au—X stretching frequencies were identified fairly easily by comparison of the corresponding chloro and bromo compounds. In the case of $Ph_3AsAuCl$, however, a band characteristic of triphenylarsine falls in the range expected for Au—Cl stretching. The band for this compound at 330 cm^{-1} with an indication of a shoulder at 338 cm^{-1} is probably therefore a composite band. The Au—X stretching frequencies for Ph_3PAuCl and Ph_3PAuBr have previously been reported (18).

The Au—X stretching frequencies show only a slight dependence on the nature of the other ligand. This is similar to the behavior of *cis*-$(R_3M)_2PtCl_2$ and *cis*-$(R_3M)_2PtBr_2$ (19).

The assignment of the Au—M stretching frequencies is less certain owing to the fact that their intensities are subject to wide variation. We note that these bands are weak for the chloro complexes but moderately strong for the bromo analogues.

Acknowledgments

Binuclear copper(II) complexes of the tetradentate ligand 1,4-di(2′-pyridyl)aminophthalazine: some novel five-coordinate derivatives

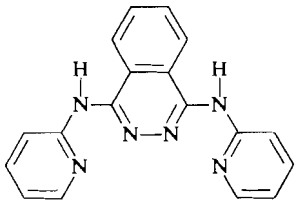
L. K. THOMPSON, V. T. CHACKO, J. A. ELVIDGE[1], A. B. P. LEVER, AND R. V. PARISH[2]
Department of Chemistry, York University, Downsview, Toronto, Ontario

Received May 7, 1969

Reaction of the title ligand (L) with copper salts leads to the formation of three principal series of compounds, $LCu_2X_3(OH)\cdot H_2O$ (X = Cl, Br), $LCu_2(RCO_2)_3$, and $LCu_2(RCO_2)_4$, where RCO_2 represents various aliphatic and aromatic carboxylate species. Magnetic data, electronic spectroscopic data both at room temperature and at −196 °C, infrared spectra, and microanalytical data are correlated to reveal that these complexes contain a binuclear copper–copper system in which the copper atoms are 5-coordinate and square pyramidal. Brief details are presented of an X-ray structural analysis of the chloride complex confirming the structure proposed. The ligand forms complexes both in its neutral form and in an anionic deprotonated form. The ultraviolet spectra of the complexes distinguish these modes of bonding. The electronic spectra are discussed in terms of the 5-coordinate square pyramidal copper chromophore deemed to be present. In the complex L_2Cu, the copper atom has a trigonally distorted 6-coordinate environment with tridentate anionic ligand.

Canadian Journal of Chemistry, **47**, 4141 (1969)

The ring expansion of 1,3-di(2′-pyridyl)-iminoisoindoline with hydrazine hydrate yields the novel ligand 1,4-di(2′-pyridyl)aminophthalazine L (**1**). This ligand has the unusual property



1

of preferentially combining with 2 metal atoms to yield binuclear derivatives of the general formula LM_2X_n, where X is a halogen or carboxylate group, *n* is commonly 3 or 4, and M is Co(II), Ni(II), or Cu(II). Of these the copper(II) complexes were most extensively studied, and form the content of this paper. Very recently a closely related ligand 1,4-di(hydrazinyl)phthalazine has been reported (1) to yield binuclear derivatives of nickel.

Experimental

Magnetic susceptibility measurements were obtained using a Newport Magnetic (Gouy) balance. Mercury tetrathiocyanatocobaltate(II) was used as calibrant. Infrared (i.r.) spectra were obtained with Perkin–Elmer 21, 257, and 125 spectrophotometers and electronic spectra with an "Optika" CF_4 double beam grating instrument and a Cary 14 instrument. Molecular weight data were obtained with a "Mechrolab" series 300 osmometer, and a Gallenkamp model 7665K semimicro-ebulliometer. In the latter case, measurements were made over the concentration range 0.02 to 0.14 *M* and the molecular weight estimated graphically. Conductivity measurements were made using a Cambridge instruments conductivity bridge or a Wayne Kerr B221A bridge. Copper was determined as $CuPy_2(NCS)_2$. C, H, and N analyses were carried out in part by the Microanalytical Laboratory of the University of Manchester Institute of Science and Technology under the direction of Mr. Manohin, and in part by Galbraith Laboratories, Knoxville, Tenn. (see Table I). L is 1,4-di(2′-pyridyl)-aminophthalazine.

Preparation and Characterization of the Ligand L

1,3-di(2′-pyridyl)-iminoisoindoline (2) (4 g) was refluxed in methanol (200 ml) for ½ h, and the solution then filtered from undissolved material. Some crystallization usually occurred and hence the filtrate was refluxed once more until a clear yellow solution was obtained (charcoal if necessary). A solution of hydrazine hydrate (10 ml, 64%) was added to the hot solution and the mixture allowed to stand at room temperature overnight. Yellow crystals, m.p. 205° (4 g, 96%) were obtained. Other solvents were investigated for the hydrazine reaction. Methanol gives the highest yield but ethanol gives a very much larger crystalline form. The product was sublimed at 190°/10^{-6} mm and the sublimate recrystallized from acetone, m.p. 210°.

Anal. Calcd. for $C_{18}H_{14}N_6$ (mol. wt. 314): C, 68.8; H, 4.5; N, 26.7. Found (mol. wt. 306): C, 68.45; H, 4.65; N, 27.1.

Nitrate Salt

The ligand, L, was recrystallized twice from 0.5 *N*

by addition of sodium dichromate, a purple precipitate was produced which could not be purified. This was probably $L \cdot CrO_5$).

Alternative Preparative Route

1,4-Diphenoxyphthalazine (3) (2.0 g) was refluxed under nitrogen in 2-aminopyridine (10 g, b.p. 204°) for 13 h. Phenol was soon observed on the sides of the tube, whilst on cooling, yellow crystals were obtained suspended in the solid 2-aminopyridine. The reaction mixture was crushed and washed with methanol. The 2-aminopyridine dissolved leaving a yellow crystalline mass, m.p. 205°, which was recrystallized from *n*-butanol and shown to be compound L, m.p. 209°, mixed m.p. 210°.

Hydrolysis of Ligand L

The compound (115 mg) was refluxed in concentrated hydrochloric acid (15 ml) for 6 h. The solvent was removed at the pump and the residue shaken with aqueous potassium hydroxide (10 ml). 1-2(2'-pyridyl)-aminophthalaz-4-one (80 mg, 0.98 equivalent), m.p. 305° was obtained as a white precipitate. This was recrystallized twice from dimethylformamide.

Anal. Calcd. for $C_{13}H_{10}N_4O$: C, 65.5; H, 4.2; N, 23.5. Found: C, 65.25; H, 4.2; N, 23.4.

The alkaline filtrate was just acidified (HCl) and excess picric acid was added. A yield of 75 mg, 1.15 moles of 2-aminopyridine picrate, m.p. 216° (lit. 216°) was obtained. (N.B. under similar conditions, 100 mg of 2-aminopyridine yielded 185 mg of picrate).

Preparation of 1-(2'-pyridyl)aminophthalaz-4-one

3-Oxo-1-(2'-pyridyl)iminoisoindoline (1.2 g) was dissolved in methanol (30 ml) and hydrazine hydrate (5 ml, 64%) added to the hot solution. After standing at 0° for 24 h, a white product was obtained, (0.6 g, 47%), m.p. 270°. This was recrystallized from dimethylformamide, m.p. 304°, mixed m.p. with sample from degradation, 305°.

$Cu_2L(acetate)_3$

Cupric acetate (2.8 g) was dissolved in ethanol (140 ml) and the solution filtered. The ligand (2.0 g) was added and the mixture refluxed for 15 min. The resulting khaki-green solution was filtered and placed in a refrigerator. A khaki-green crystalline product was obtained (3.6 g, 91%). This was filtered off, washed with ethanol and ether, and dried in air. The product was recrystallized from methanol and dried in air.

The other carboxylate complexes were prepared in a similar fashion (see Table I). The copper carboxylates, where not available commercially, were prepared by reaction of the appropriate acid with copper carbonate and extracting the product with a suitable solvent.

Acetonitrile was used for recrystallization in some cases, particularly those where a solvated species was obtained from methanol. The complexes were dried at 100°/15 mm prior to analysis and study.

$Cu_2LCl_3.(OH)H_2O$

The ligand (L) (1.4 g) was crushed and refluxed in an aqueous solution of cupric chloride (5 g in 100 ml) for 5 min. After cooling, the green crystalline product (2.1 g, 81%) was filtered and washed with water, methanol, and ether. The product was recrystallized from water and dried at 50°/15 mm. The bromide complex was prepared by a similar procedure.

The X-ray structure of the chloride complex (4) indicates the presence of an additional molecule of lattice water per 2 molecules of complex[3]. Our compounds, after drying under vacuum, gave analyses which suggested that this additional water was no longer present. The difference between the required analytical figures for the two formulations is, however, relatively small.

$Cu_2L(IO_3)_3.(OH)3H_2O$

$Cu_2LCl_3.(OH)H_2O$ (0.2 g) was dissolved in hot water (20 ml) and an aqueous solution of potassium iodate (0.5 g in 10 ml) was added. After maintaining the solution at 0 °C for some time, a green crystalline product was obtained which was recrystallized from water and dried at 100°/15 mm.

The complexes are all green in color; the alkanoate derivatives are very soluble in many organic solvents but almost insoluble in water. The dark green aquo-halide and iodate complexes are insoluble in most organic solvents but slightly soluble in water.

CuL_2

Aqueous ammonium hydroxide was added to an aqueous solution of $Cu_2LCl_3(OH)H_2O$. A precipitate was obtained, which, upon drying, analyzed approximately for $CuL_2(OH)_2$. This was dissolved in chloroform, boiled momentarily, then the solvent was removed at the pump. The residue was recrystallized twice from *n*-butanol to yield large black crystals of the product.

Variable Temperature Range Magnetic Study

The magnetic moment of the iodate complex, $Cu_2L(IO_3)_3OH.3H_2O$ was investigated over the temperature range 108–295 °K using the standard Gouy method. The system was calibrated with nickel chloride solution. The diamagnetic correction of the complex was taken from Pascal's constants to be 190×10^{-6} c.g.s.u. The data obtained are as follows

Variable temperature magnetic data

Temperature (°K)	χ_m^{corr}	μ_{eff} (B.M.)
295	758	1.34
275	731	1.28
243.5	701	1.17
213.5	651	1.06
191	607	0.97
159	523	0.82
136	440	0.69
117.5	370	0.59
108.5	315	0.52

Note: See text for the calculated parameters.

[3]The derivative investigated contained an extra molecule of water per 4 copper atoms, located in the lattice. It would be correctly formulated $2LCu_2(OH)Cl_3.3H_2O$.

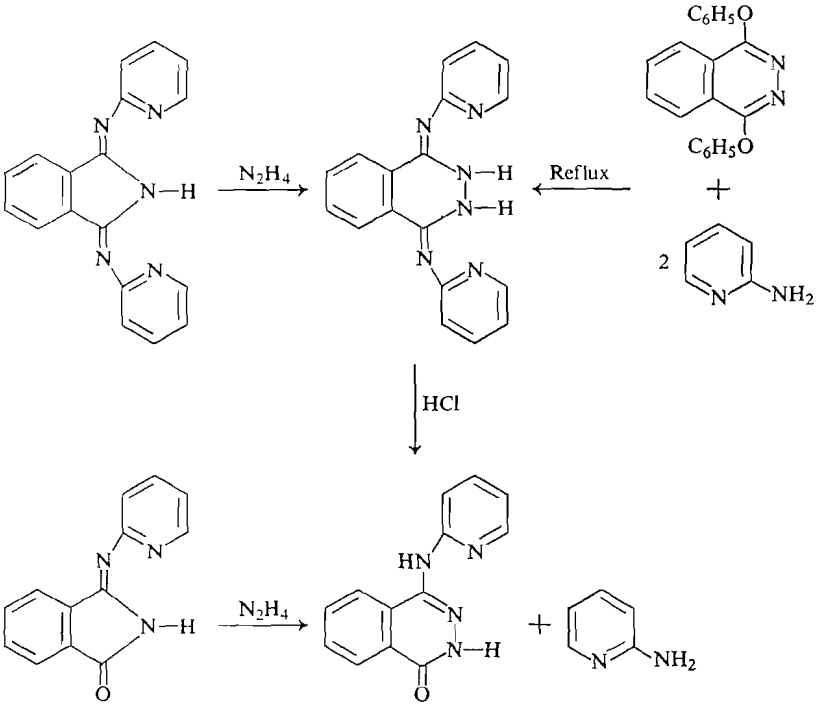

FIG. 1. The synthesis and degradation of 1,4-di(2′-pyridyl)aminophthalazine.

Results and Discussion

Synthesis and Characterization of the Ligand

The phthalazine ligand was prepared by the ring expansion of 1,3-di(2′-pyridyl)-iminoisoindoline (2) with hydrazine hydrate. The structure (**1**) of the new ligand was substantiated by an alternative synthesis and by degradation, as indicated in Fig. 1.

An unequivocal proof of the structure of the ligand was obtained by an X-ray structural investigation of the copper complex $LCu_2Cl_3(OH).H_2O$, full details of which will appear elsewhere (4).

The Complexed Ligand

Reaction of the ligand with copper halides yielded the derivatives $Cu_2LX_3(OH)H_2O$ where X = Cl and Br. Reaction of these complexes with potassium iodate gave $Cu_2L(IO_3)_3(OH).3H_2O$. Reaction with copper carboxylates generated 2 series of complexes, $Cu_2L(RCO_2)_3$ and $Cu_2L(RCO_2)_4$.

The mode of bonding of the ligand in these complexes was investigated by vibrational and electronic spectroscopy. The hydrated halide complexes and the tetracarboxylate series give rise to a rich spectrum in the N—H stretching region. These complexes are assumed to contain the neutral ligand. In the case of the chloride complex alluded to above, the X-ray study confirms that this complex contains the neutral ligand. The complexes $Cu_2L(RCO_2)_3$ would appear, on the basis of stoichiometry, to contain a monoanionic ligand derived from the ligand by loss of 1 hydrogen atom. In agreement with this supposition the N—H stretching region of the i.r. spectra of these derivatives is considerably weaker, relative to the aromatic ν_{CH} vibrations, than is the corresponding region of the tetracarboxylate series.

The ligand may be thought of as a 2-substituted pyridine derivative. In such complexes it is well documented (5–8) that the ring breathing mode of vibration near 990 cm^{-1} is a reliable guide to coordination of the pyridine residue. Upon coordination of the pyridine group this band increases in energy generally to above 1000 cm^{-1}. The ligand (**1**) exhibits a band at 989 cm^{-1} which may safely be assigned to this vibration since 1,4-diaminophthalazine is transparent from 950

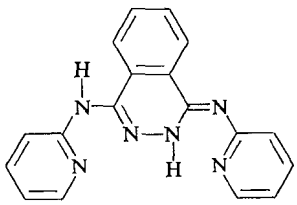
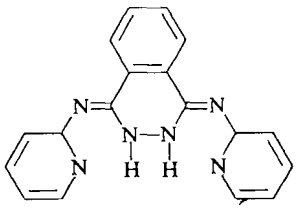
to 1010 cm^{-1}. None of the complexes has a band in this region but all exhibit an additional band between 1010 and 1022 cm^{-1} which we assign to coordinated pyridine. Thus in all cases *both* pyridine residues of the ligand are coordinated to the metal atoms (6). Whilst there are a number of other pyridine vibrations which have been used in the past (6–8) as a guide to coordination of the pyridine residue to a metal ion, these cannot reliably be picked out from the extremely complex spectra of the phthalazine derivatives.

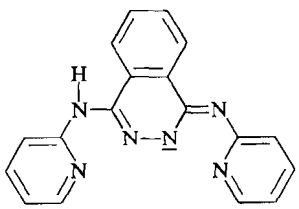
The X-ray structural determination (4) of the copper chloride derivative reveals that the ligand exists in the tautomeric form (**1**) with both hydrogen atoms on exocyclic nitrogen atoms, and not in the tautomeric forms (**2**) and (**3**). This conclusion is based on the angles at the nitrogen atoms, tetrahedral hybridization of the exocyclic nitrogen atoms being inferred therefrom. Because of the similarity of their N—H stretching frequencies and their ultraviolet (u.v.) spectra (see below) the aquo-halide and tetracarboxylate series of complexes are all believed to contain the neutral ligand in tautomeric form (**1**). The tricarboxylate series, with a monoanionic ligand are believed to involve tautomeric form (**4**) since (*a*) this form will surely be more stable than (**5**) when a metal is coordinated to the phthalazine nitrogen atoms, and (*b*) the N—H stretching frequency of the group —NH—M is likely to be lower (9) than 3280 cm^{-1}.



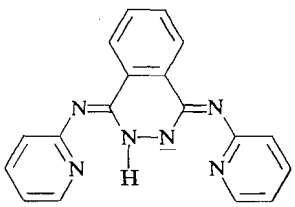
2



3



4



5

There is a clear distinction in the near-u.v. region between the complexes believed to contain a neutral ligand and those believed to contain an anionic ligand.

The lowest energy *peak* in the u.v. spectrum of the neutral ligand species is observed between 27 400 and 29 600 cm^{-1}, whilst in the anionic ligand complexes, the lowest energy peak (not shoulders) occurs between 24 000 and 25 600 cm^{-1} (Table II). This band, which also appears in the uncomplexed ligand (at 26 200 cm^{-1}), is assigned by virtue of its moderate intensity to a π–π^* transition. Its energy would be sensitive to the degree of conjugation in the molecule. Whilst nitrogen atoms are not very effective in extending a conjugated pathway, nevertheless it remains true that the tautomeric form (**4**) involves a longer conjugated pathway (phthalazine and one pyridine ring conjugated) than tautomeric form (**1**) (no conjugation across the exocyclic nitrogen atoms). This is in keeping with the movement of the band in question to lower energies on formation of the anion. The compound L_2Cu which must contain anionic ligand groups also has its first major absorption band in the anionic region at 24 500 cm^{-1}. Having established the nature of the phthalazine ligand bound to the metal atoms in these complexes, it is convenient to discuss the stereochemistry of the copper atoms by dividing the discussion into two parts, halide complexes and carboxylate complexes.

Halide Complexes

These green complexes are slightly soluble in

water but are insoluble in common organic solvents. The water molecule is difficult to remove, the complexes being stable in vacuo up to 150°. Aqueous solutions of the halides are conductors (Table III) and react with silver nitrate yielding 3 equivalents of halogen. The aqueous solution spectra of all 3 complexes are essentially identical with each other and with the solid state spectrum of the iodate complex. This latter complex is assumed to contain iodate ions and the cationic species $LCu_2(OH)(H_2O)_3^{3+}$, which is also assumed to be the predominant species in aqueous solution.

The basic structural unit presented in the chloride complex is depicted in Fig. 2. The X-ray study by Lingafelter and Marongiu (4) has shown the presence of two 5-coordinated copper atoms in square pyramidal environments. The square pyramids share a corner (hydroxy bridge) and the apex (bridging chloride). It is not unreasonable to suppose that the bromide complex has a similar structure. The presence of 3 different bridging groups (OH, Cl, —N—N—) is remarkable. It seems likely that the iodate complex and the aqueous solution species have essentially the same structure with the halogen atoms replaced by water molecules. The presence of a water bridge on the apices of the square

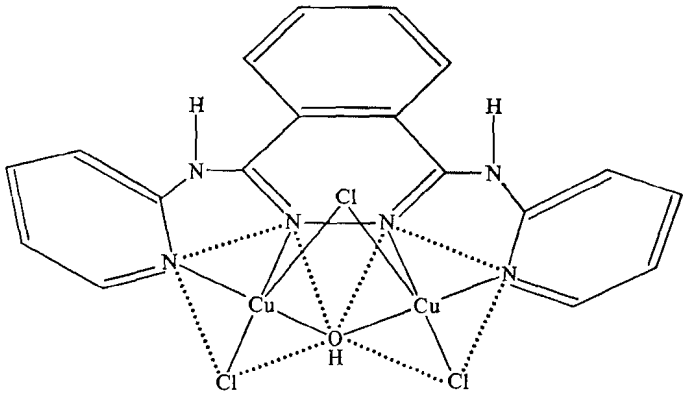

FIG. 2. The structure of $Cu_2LCl_3(OH)\cdot H_2O$ as indicated by X-ray crystallography (4). The water molecule is in the lattice uncoordinated to the copper atoms. The dotted lines indicate the planes of the square pyramids about each copper atom. These planes are canted towards one another. The apical copper–chlorine distance is some 0.3 Å longer than the in-plane copper chlorine distance. Complete details of this structure will be published shortly (4). The $LCu_2(RCO_2)_4$ series are presumed to have a similar structure in which the Cl^- and OH^- groups are replaced by RCO_2^-. Only one intramolecular bridge is presumed to be present in the $LCu_2(RCO_2)_3$ series (replacement of OH^- by RCO_2^-). The apical Cl is replaced by intermolecular bridging (—OCO—) and the ligand is in tautomeric form **4**.

R

pyramids is debatable since water does not readily act as a bridge between 2 metal atoms.

There is a regular increase in the energy of the principal d–d absorption band in the spectra of these complexes as one replaces chloride by bromide by water (Table II). However, the magnetic moment (Table III) of the iodate complex is much lower than those of the halides suggesting that the copper–copper distance has been decreased. A temperature range magnetic study (see Experimental) yields $2J = -335$ cm^{-1}, $g = 1.95$, and $N\alpha = 145 \times 10^{-6}$ c.g.s., using the conventional model for two interacting $S = \frac{1}{2}$ states (10).

Carboxylate Complexes

Reaction of copper carboxylates with the ligand in alcoholic or acetonitrile solution leads to the formation of 2 principal series of complexes, $LCu_2(RCO_2)_3$ and $LCu_2(RCO_2)_4$. The former series comprises those acids whose pK_a is greater than 3.8 whilst the latter series arises when the pK_a value of the acid is less than 3.8. The u.v. spectra of the complexes reveal that the tricarboxylic series contains anionic ligand, whilst the tetracarboxylic series contains neutral ligand. This suggests that the pK_a of the ligand is close to 3.8. In the case of formic acid with a pK_a of 3.75 placing the complex close to the crossover point, solution of the tetracarboxylate complex in the basic solvent pyridine, leads to the formation in solution of the tricarboxylate complex, as indicated by the u.v. spectrum (Table II). The methoxyl derivatives behave in a similar manner. With the exception of the formate complex, the magnetic moments of the complexes range from 1.66 to 1.90 B.M. suggesting little or no copper–copper interaction in either series. The tricarboxylic series shows ready solubility in many organic solvents including chloroform; the tetracarboxylic series, on the other hand, shows rather more limited solubility in organic solvents. Both series are insoluble in water.

$LCu_2(RCO_2)_3$

It is likely that the ligand is acting as a quadridentate donor in the carboxylate derivatives as well as the halides and we may assume that the i.r. absorption of the ligand will be similar in both series of complexes. Comparison of the spectra of the carboxylates with the halides allows us to isolate absorption bands arising from the $—CO_2$ groups. The i.r. spectra of carboxylate complexes have been adequately discussed in the past (11–17). Suffice to say that since the symmetry of the carboxylate group is unchanged upon coordination, no new bands will appear in its spectrum. Structural assignments generally rely on the positions of the symmetric and antisymmetric $—CO_2$ stretching vibrations.

The carboxylate complexes under discussion exhibit multiple symmetric stretching bands

†Only the principal NH stretching frequency is reported. In addition to this band the complexes generally show up to 4 additional and weaker bands between 3100 and 3285 cm^{-1}.

indicative of the presence of both bridging and terminal carboxylate groups.

Absorption bands are observed in the following regions in the mull spectra (Table IV): (*i*) 1578–1590 cm^{-1} assigned to the antisymmetric stretching vibration of a bridging carboxyl group, (*ii*) 1390–1410 cm^{-1} assigned to the symmetric stretching vibration in a bridging carboxyl group, and (*iii*) 1360–1370 cm^{-1} assigned to the symmetric stretching vibration in a carboxyl group apparently bound in a terminal manner to the copper atom.

The above assignments may be rationalized as follows. The antisymmetric vibrational frequencies observed in a series of alkanoate complexes (12), known unequivocally to contain carboxylate groups bridging between 2 copper atoms, lie in the range 1560–1603 cm^{-1}. The symmetric stretching vibrations in these same compounds lie between 1410–1430 cm^{-1}. Thus the assignments cited above for the bridging carboxylate groups are fully consistent with the earlier literature.

There is less information available concerning molecules which unequivocally contain terminally bound carboxylate groups. In such complexes (11) the symmetric frequency should be lower than 1400 cm^{-1} since the vibration will

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

have more single bond C—O stretching character. Similarly, the antisymmetric vibration will lie above 1600 cm^{-1}, since it will possess more double bond C=O character than the bridging ligand. In the complexes of picolinic acid N-oxide (12), bands attributable to the antisymmetric vibration of a terminally bound carboxyl group are observed between 1650–1700 cm^{-1}. However, when water is present in the molecule, hydrogen bonding of the "ketonic" oxygen atom can occur leading to a considerable reduction in the antisymmetric frequency.

The carboxylate complexes have a band around 1360 cm^{-1} which is absent in the halide spectra; such a band could be the symmetric frequency of a terminally bound $-CO_2$ group. The highest energy band observed in this region of the spectrum lies at about 1640 cm^{-1}. This band is also present in the free ligand and in the halide complexes and is probably a $\nu_{(C=N)}$ vibration. No evidence was found for the terminal asymmetric frequency in the mull spectra. Accepting the validity of the assignments so far, there are two reasons why the asymmetric frequency might not be observed. The "ketone" residue may be hydrogen bonded, presumably to the NH group on the ligand or it may be coordinated to a copper atom. It would be reduced in frequency and might be obscured by the multiple C=N absorption of the ligand. Hydrogen bonding would necessarily be intermolecular and should be absent in solution. In chloroform solution all the carboxylate complexes (which were sufficiently soluble for investigation) showed a strong band near 1700 cm^{-1} which is absent in the mull spectrum. There can be little doubt that this is the "missing" antisymmetric stretching frequency of the terminally bound carboxyl groups. The other $-CO_2$ bands were observed in the solution spectra at frequencies close to their mull spectra. Moreover, the $\nu_{(NH)}$ band appeared at precisely the same frequency as it does in the mull spectra. This is not consistent with the presence of a hydrogen bond which is broken in solution. It follows that the terminal carboxyl groups must be associated with copper atoms, and it is suggested that in the solid state there is a loose intermolecular association between neighboring binuclear units leading to a reduction in the antisymmetric frequency of the "terminal" carboxyl groups. A 5-coordinate configuration for the copper atoms is then inferred (Fig. 2, caption). The electronic spectra, discussed below in detail, suggest the presence of square pyramidal copper atoms.

In solution this association is destroyed. Molecular weight measurements (Table III) show that these complexes are monomeric (but binuclear) in chloroform solution. Since chloroform is unlikely to coordinate to the copper, the species must be 4-coordinate and square planar. In methanol the complexes behave as 1:1 electrolytes, and yield molecular weights approximately one-half their formula weights. Apparently methanolysis is occurring, probably at the intramolecular carboxylate bridge.

$LCu_2(RCO_2)_4$

The i.r. spectra of the tetracarboxylate series infer quadridentate coordination of the neutral ligand and the presence of 2 types of carboxylate group. Unfortunately, most members of this series are haloacetates where the i.r. criterion for the mode of bonding of the carboxylate group is uncertain (16, 17).

Comparison of the i.r. spectra of the complexes with the spectra of the aquo-halide derivative reveals at least 4 bands in the region 1300–1700 cm^{-1} assignable to the carboxyl group (Table IV). Utilizing some previous work by Kettle and Pioli (17) who studied the complexes (2-picoline)$_x$Cu$(RCO_2)_2$ ($x = 2$ or 4), a band near 1350 cm^{-1} in our complexes may be assigned to the antisymmetric stretching vibration of a terminally bound haloacetate carboxyl group. An additional band occurring between 1400 and 1475 cm^{-1}, which cannot always be positively identified, is assigned to the symmetric stretching frequency of a bridging haloacetate group. The intense absorption between 1650 and 1700 cm^{-1} contains one or more bands assignable to the antisymmetric stretching vibrations of haloacetate carboxyl groups. Absorption in this region does not distinguish bridging from terminal ligands (16).

The low solubility of these complexes in organic solvents precludes molecular weight determination. They are, however, soluble in pyridine in which most or all of them appear to be solvated.

The electronic spectra of these complexes do not differ appreciably from those of the tricarboxylate series, and therefore a 5-coordinate square pyramidal structure with 2 intramolecular

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

bridging acetate groups and 2 terminal acetate groups is proposed (Fig. 2, caption). The possibility that there are 2 intermolecular rather than intramolecular bridges cannot be excluded. However, the presence of intramolecular bridges in the halide complexes, and the inferred presence of such a bridge in the tricarboxylate series, leads us to prefer this formulation (**8**). Two tricarboxylate complexes also appear to belong to this neutral ligand series. They are LCu_2(*m*-Cl-benzoate)$_3$-OMe(MeOH) and LCu_2(benzoate)$_3$OMe(MeOH), and are formulated to contain a methoxy group, rather than to be solvated by 2 methanol residues since their principal low energy u.v. absorption implies that they contain the neutral ligand. It seems likely that the methoxyl group acts as a bridge between the 2 copper atoms. Their magnetic moments indicate the presence of an exchange interaction.

Electronic Spectra

Further support for the 5-coordinate square pyramidal model for these complexes stems from a more detailed consideration of the electronic spectra.

Recent studies (18–20) with 5-coordinate square pyramidal copper(II) complexes have revealed that at least 3 transitions may normally be observed. The lowest energy band assigned to the $z^2 \rightarrow x^2 - y^2$ transition (xy molecular plane, z is the four-fold axis) lies in the region 10 000 – 13 000 cm^{-1}. The $xy \rightarrow x^2 - y^2$ (10 Dq) transition lies next in the region 13 000 – 15 000 cm^{-1}, whilst the most intense band is the doubly degenerate transition, $xz,yz \rightarrow x^2 - y^2$ lying at 15 000 – 18 000 cm^{-1}. In symmetry lower than D_{4h} this last transition may split into 2. The actual band energies depend on the ligating atoms. In our case we do not have a regular square pyramid since there are several different ligating atoms. However, it does seem possible to make some tentative assignments based on this model.

The strong absorption band observed in the visible region in the mull transmittance spectra of these derivatives may be resolved at −196 °C. Whilst some of the tricarboxylates show 3 bands at low temperature, the tetracarboxylates in general only show 2, but not always the same 2. In the former series the 3 bands lie in the regions (*i*) 12 700 – 13 400 cm^{-1}, (*ii*) 14 100 – 14 900 cm^{-1}, and (*iii*) 15 900 – 17 100 cm^{-1}. The benzoate is atypical in band (*iii*). In the latter series band (*i*) falls in the range 11 000 – 13 000 cm^{-1}, band (*ii*) 14 300 cm^{-1}, and band (*iii*) 15 400 – 17 400 cm^{-1} (Table II). One of us has recently discussed the spectra of 5-coordinate square pyramidal copper complexes (18) which will therefore not be repeated here. The following band assignments may tentatively be made

$$\text{Band } (i) \qquad z^2 \rightarrow x^2 - y^2$$

$$\text{Band } (ii) \qquad xy \rightarrow x^2 - y^2$$

$$\text{Band } (iii) \quad xz, yz \rightarrow x^2 - y^2$$

Bands (*ii*) and (*iii*) might alternatively be assigned as $xz \rightarrow x^2 - y^2$ and $yz \rightarrow x^2 - y^2$, since the xz and yz levels will not be degenerate in this rather distorted system; however, this assignment is considered unlikely on the basis that the energy of band (*ii*) is almost independent of the complex under discussion. The invariance of band (*ii*) confirms its assignments to the 10 Dq transition since all the complexes have essentially the same in-plane CuN_2O_2 chromophore. It is known (20, 21) that 10 Dq for the CuO_4 chromophore in a square pyramidal CuO_4X system generally lies between 13 000 and 14 000 cm^{-1}. The value observed above, between 14 000 and 15 000 cm^{-1} for the CuO_2N_2 in-plane chromophore, is quite acceptable. Thus the electronic spectroscopic data are in complete agreement with the assignment of square pyramidal structures for these complexes. Unfortunately the spectra of the square pyramidal halide derivatives did not resolve well at low temperature.

In closing it is necessary to ensure that the above spectroscopic interpretation is not consistent with any other stereochemistry about the copper atom. Trigonal bipyramidal (22), octahedral, trigonal 6-coordinate (23), and tetrahedral (24) copper stereochemistries can be definitely eliminated since their absorption maxima for d–d transitions always lie below about 15 000 cm^{-1} for ligand atoms of the type under discussion. Square complexes frequently absorb at fairly high energies since the crystal field splitting for the square stereochemistry is large. Copper acetylacetonate, for example, with a CuO_4 chromophore absorbs (20) at 18 500 cm^{-1} with a lower energy band at 15 000 cm^{-1}. Other acetylacetonates absorb at a similarly high energy. Distortion will tend to decrease these

energies so that our results might be deemed consistent with a distorted square environment. However, we feel that this alternative interpretation can be discarded on the basis that in a square environment in which there is little distortion towards a tetrahedron there should be no low energy band. The $z^2 \rightarrow x^2 - y^2$ transition lies at a high energy since the z^2 orbital is not unduly perturbed by the ligand in a square environment (20). There cannot be appreciable distortion towards a tetrahedron in our case, since this would result in an overall shift of the entire spectrum to lower energies (25). Thus the presence of both low energy (band (*i*)) and high energy bands (band (*iii*)) in the spectrum is in itself an indication of the 5-coordinate square pyramidal environment.

Other Complexes

Reaction of the copper chloride complex with ammonium hydroxide leads to the formation of L_2Cu. The electronic spectrum of this complex in chloroform shows 3 main bands in the region 5 000 – 30 000 cm^{-1} at 8 700 (85), 16 680 (460), and 24 500 (3 050) cm^{-1}, with shoulders at 23 500, 26 000, and 27 200 cm^{-1}. The 24 500 cm^{-1} absorption is indicative of the anionic ligand as would be deduced from the stoichiometry whilst the d–d bands at 8 700 and 16 680 would strongly infer a trigonal 6-coordinate environment for the copper atom (cf. Cu(dipyridyl)$_3^{2+}$ with d–d bands (23) at 6 400 (28) and 14 400 (54)). The bands are assigned to the $^2A_1 \leftarrow {}^2E$ and $^2E \leftarrow {}^2E$ transitions in D_3 symmetry, respectively. The intensities are rather high when compared with the dipyridyl derivative and intensity stealing from the low lying ligand band is probably responsible for this. This structure requires the ligand to be tridentate. Molecular models show that this can be achieved without strain using the 2 pyridine residues and the tetrahedrally disposed phthalazine nitrogen atom of tautomer (**4**). The i.r. spectrum has a strong band at 1007 cm^{-1} (with a very weak absorption peak at 993 cm^{-1}) assigned to the ring breathing mode of the coordinated pyridine residues. The magnetic moment was observed to be 1.79 B.M. at room temperature.

Selenium tetrafluoride adducts. I. Trifluoroselenium fluorosulfate

R. J. GILLESPIE AND W. A. WHITLA
Department of Chemistry, McMaster University, Hamilton, Ontario

Received June 13, 1969

The structure of the adduct between selenium tetrafluoride and sulfur trioxide in the solid state, in the molten state, and in solution has been investigated using infrared, Raman, nuclear magnetic resonance spectroscopy, conductivity measurements in fluorosulfuric acid and nitrobenzene, and cryoscopic measurements in nitrobenzene. The data can be best interpreted in terms of a polymeric bridged fluorosulfate structure for the solid and the melt, which is broken down in solution to form mainly a dimeric species.

Canadian Journal of Chemistry, 47, 4153 (1969)

A large number of adducts of selenium tetrafluoride with acceptor molecules have been prepared. The first of these was made by Peacock (1). He isolated a white solid $SeF_4.SO_3$ which he suggested might have the ionic structure SeF_3^+-SO_3F^-. Bartlett and Robinson (2, 3) prepared adducts with boron trifluoride, arsenic pentafluoride, and antimony pentafluoride. Subsequently a number of other similar adducts have been prepared and it has been suggested that all these adducts contain the SeF_3^+ ion (4). Recently, the X-ray structure of trifluoroselenium(IV)fluorobis[pentafluoroniobate(V)] (5) has given the first direct evidence for the SeF_3^+ ion. Considerable interaction through fluorine bridging with the $Nb_2F_{11}^-$ ion was observed giving the selenium a pseudoseven coordinate environment. Still more recently Evans and Long (6) have interpreted the Raman spectra of the molten adducts $SeF_4.SbF_5$ and $SeF_4.AsF_5$ in terms of the ionic structures $SeF_3^+.SbF_6^-$ and $SeF_3^+.AsF_6^-$.

We have investigated a series of 1:1 adducts of selenium tetrafluoride using infrared, Raman, and nuclear magnetic resonance (n.m.r.) spectroscopy, and conductimetric and cryoscopic measurements. This paper reports the results of our investigation of the adduct with sulfur trioxide, $SeF_4.SO_3$.

Experimental

Selenium tetrafluoride was prepared by the fluorination of selenium (Analar) at 0 °C. The product was stored in liquid air in glass containers with break seals until used. Sulfur trioxide was obtained either by distillation from 65% oleum (Allied Chemicals) or from Sulfan-B (Allied Chemicals).

The adduct $SeF_4.SO_3$ was prepared by direct combination of selenium tetrafluoride and sulfur trioxide using an excess of selenium tetrafluoride as solvent (1). Excess selenium tetrafluoride was removed under vacuum, leaving a fine white powder. The product was used directly or, if it had been stored for some time in a sealed ampoule, was sublimed immediately before use.

Anal. Calcd. for SeF_4SO_3: Se, 33.60; F, 32.34; SO_3, 34.07. Found: Se, 34.1; F, 32.5; SO_3, 33.4.

Infrared spectra were obtained using a Perkin–Elmer model 521 grating infrared spectrometer with extended range interchange. A modified gas cell with silver chloride or polythene windows was used in which the sample was sublimed onto a silver chloride or polythene plate held by a copper cold finger in the center of the cell and cooled by filling the cold finger with liquid air.

A Hilger Watts E612 Raman spectrometer was used in conjunction with a water cooled Toronto-type mercury-arc lamp (7). Spectra of the solid were obtained from 1–2 cm of powder packed in the bottom of a cylindrical sample cell. Generally a fine powder gave better results than a crystalline sample. Spectra of the melt were obtained by passing a stream of heated air around the Raman tube to melt the sample. Temperatures up to 150 °C were readily obtained in this manner.

The ^{19}F n.m.r. spectra were recorded with a Varian DP-60 high resolution n.m.r. spectrometer operating at 56.4 Mc/s. The Varian variable temperature probe was used for both the low and high temperature studies. Referencing was performed by sample exchange with either fluorosulfuric acid or trifluoroacetic acid.

Conductivity measurements were made using methods and conductivity cells described previously (8). The cryoscopic measurements in nitrobenzene were made using the equilibrium technique and a cryoscope identical to that used for sulfuric acid (9). A platinum resistance thermometer was used to record the freezing point. The nitrobenzene was purified by fractional distillation at atmospheric pressure and stored over molecular sieve until used.

Results and Discussion

Vibrational Spectra

The observed vibrational frequencies for the solid adduct in the infrared and for the molten adducts in the Raman are given in Table I and Fig. 1. The Raman spectra of the solid were not satisfactory below 700 cm^{-1} because of an intense background. At higher frequencies sharp lines were obtained which agreed well with those observed for the melt (Table I). The spectrum of

both the solid and the melt can be reasonably satisfactorily interpreted in terms of the simple ionic formulation $SeF_3^+.SO_3F^-$. The infrared and Raman spectra of the fluorosulfate ion are well known and typical values for the vibrational frequencies are given in Table I. The frequencies for the SeF_3^+ ion would be expected to be close to those for the isoelectronic AsF_3, for which the vibrational frequencies are also listed in Table I. On this basis, appropriate frequencies are readily assigned to SeF_3^+ although we note that they are slightly higher than those for AsF_3. This is consistent with the formal charge on selenium, which would be expected to reduce the polarity of the Se—F bonds compared to the As—F bonds and hence increase their strength. We note that there are splittings of the degenerate vibrations ν_4, ν_5, and ν_6 of the fluorosulfate ion which could be attributed to lowered site symmetry in the crystal. However, as some of these splittings are also observed in the melt, there is presumably some strong specific association between the ions in the liquid state which would also lower the symmetry of the SO_3F^- ion. The splittings of ν_3 and ν_2 and the splitting of $\nu_4(E)$ into a triplet might be factor group splittings in the crystal, although this leaves unexplained the fact that the splittings of ν_2 and ν_4 are also observed in the melt. The frequency of the S—F stretch (ν_2) is rather higher than has been observed previously for an ionic fluorosulfate and, indeed, approaches the values observed for covalent fluorosulfates which lie in the range from 842 cm^{-1} for $SF_5.SO_3F$ (10) to 876 cm^{-1} for $S_3O_8F_2$ (11).

As an ionic structure $SeF_3^+.SO_3F^-$ does not seem completely compatible with the experimental data, and, as the compound SbF_4SO_3F has previously been shown to have a highly polymerized structure involving fluorosulfate bridges in the liquid state (12), it seems reasonable to postulate a similar structure for $SeF_3.SO_3F$ (**1**). If the bridge

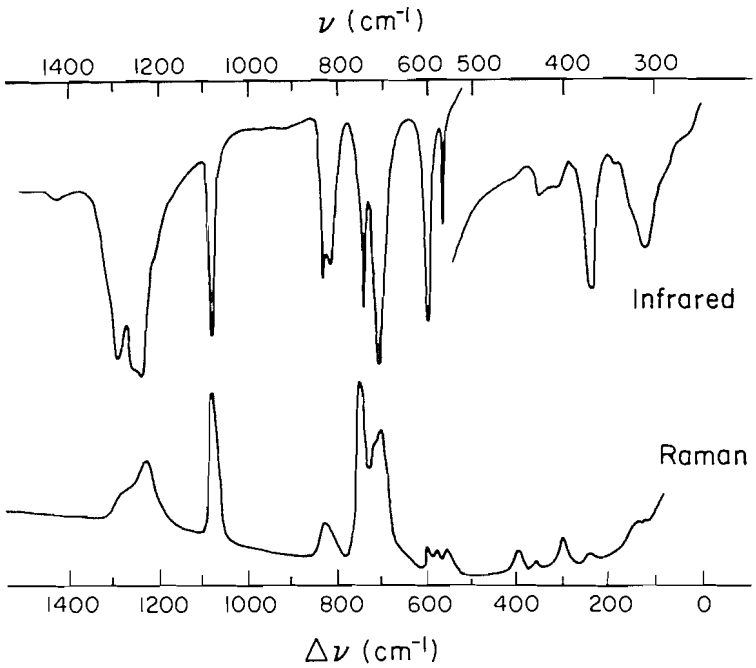

FIG. 1. Vibrational spectra for $SeF_4.SO_3$.

bonds have a certain amount of ionic character then this accounts for the S—F frequency being intermediate between that expected for an ionic and a covalent fluorosulfate. The reduced symmetry of the bridging fluorosulfate group could also account for at least part of the splitting of the S—O asymmetric stretching and bending vibrations ν_4 and ν_5. If the polymeric chains are not very long, the presence of fluorosulfate as both a bridging group and an end group could account for the splitting of ν_2 and the additional splitting of ν_4.

Our assignment for the SeF_3^+ ion agrees with that of Evans and Long except ν_4 to which they assign a frequency of 275 cm^{-1}, which is lower than would be expected on the basis of the relation of the other frequencies to those of AsF_3. This is further discussed in a following paper. The good agreement between the observed frequencies for both the solid and liquid states indicates that the structure of $SeF_3.SO_3F$ is essentially the same in both states.

Conductivity Measurements

The conductivities of solutions of $SeF_3.SO_3F$ in fluorosulfuric acid are shown in Fig. 2. It is clear that ionization is not complete as the conductivities are considerably less than those of a typical strong electrolyte such as KSO_3F. Assuming the simple equilibrium

$$SeF_3.SO_3F \rightleftarrows SeF_3^+ + SO_3F^-$$

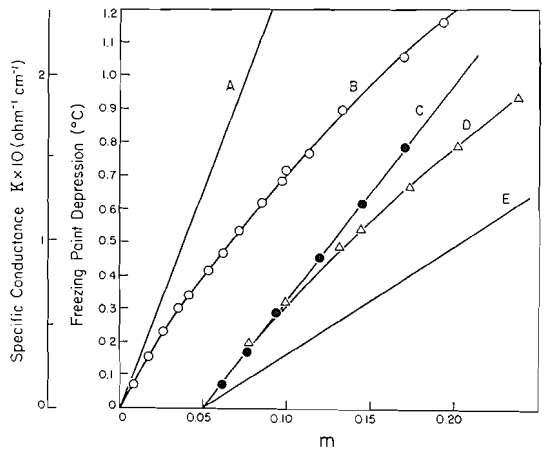

FIG. 2. *A*, conductivity of KSO_3F solution in HSO_3F; *B*, conductivity of $SeF_3.SO_3F$ solution in HSO_3F; *C*, freezing point depression for the non-electrolyte trinitrobenzene in nitrobenzene; *D*, freezing point depression for $SeF_3.SO_3F$ in nitrobenzene; *E*, freezing point depression for a dimeric non-electrolyte.

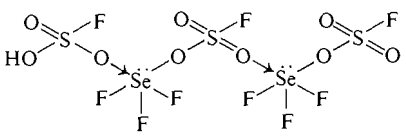
the degree of ionization can be obtained by comparison with the conductivity curve of the strong base KSO_3F. If the concentration of KSO_3F giving the same conductivity as a solution of $SeF_3.SO_3F$ of concentration $m_{SeF_3.SO_3F}$ is m_{KSO_3F}, then the degree of dissociation $\alpha = m_{KSO_3F}/m_{SeF_3.SO_3F}$ and the equilibrium constant for the above ionization is $K_b = \alpha^2/(1 - \alpha)$. Values of K_b calculated in this manner varied markedly with concentration and we conclude, therefore, that $SeF_3.SO_3F$ does not ionize as a simple base. This is perhaps not surprising in view of our previous conclusion that it is probably a polymeric material. If this is the case we might write the ionization in the following manner

$$(SeF_3.SO_3F)_n \rightarrow (SeF_3)_n(SO_3F)_{n-1}^+ + SO_3F^-$$

If it is assumed that this ionization is complete, then, if $[SeF_3.SO_3F]_s$ is the stoichiometric concentration of $SeF_3.SO_3F$, the degree of polymerization n of the cation in solution is given by

$$n = \frac{[SeF_3.SO_3F]_s}{[SO_3F^-]}$$

where the concentration of fluorosulfate ion is determined by comparison with the conductivity of a solution of the strong base KSO_3F. The values of n were found to be constant at about 1.6 at concentrations up to approximately 0.08 m and then to gradually increase to ~ 2.1 at 0.18 m. If there is also incomplete ionization then the results cannot be interpreted quantitatively, but one could say that probably $n \geq 2$, i.e., the dimer is probably the predominant species at low concentrations. If, as seems very likely, the selenium at one end of the chain is solvated with a solvent molecule, the species (**2**) is very similar to the polymeric chain postulated for the solid and molten states



2

Conductivity measurements were also made in nitrobenzene. This solvent was selected because it gave stable solutions and has a relatively high dielectric constant of 34.8 at 30°. Solutions of $SeF_3.SO_3F$ in nitrobenzene were, however, found to have conductivities that are lower than those of solutions of $AlCl_3$ over the same concentration range (13). As $AlCl_3$ appears to be a very weak electrolyte in nitrobenzene, we conclude that $SeF_3.SO_3F$ is only very slightly ionized in this medium.

The molten complex has a low conductivity at 70° of only 6×10^{-4} ohm^{-1} cm^{-1} which, taking any reasonable value for the ionic mobilities, indicates a degree of ionization of only 1% or less. This again provides supporting evidence for our suggestion that the melt consists largely of the polymeric chain **1** and contains very few free ions.

Nuclear Magnetic Resonance

The ^{19}F n.m.r. spectrum of a solution of $SeF_3.SO_3F$ in HSO_3F at room temperature consisted of one line at -86.6 p.p.m. from CF_3CO_2H which may be assigned to fluorine on selenium in addition to the solvent line at -119.4 p.p.m. from CF_3CO_2H. The spectrum remained essentially the same down to $-85°$ except for a slight down-field shift of the higher field peak from -86.6 to -83.8 p.p.m. and also a broadening of this peak. Clearly the SO_3F group is exchanging rapidly with the solvent, as would indeed be expected if it is partially ionized. The single resonance observed for fluorine on selenium is consistent with the presence of the symmetrical SeF_3^+ ion. However, this signal becomes quite broad at low temperatures and was observed to have a width of 48 Hz at $-85°$. This must be attributed presumably to the slowing down of some exchange process between non-equivalent fluorines on selenium and this is consistent with the proposed bridged polymeric structure in which all three fluorines on the pseudo six-coordinated selenium cannot all be equivalent. Signals from non-equivalent fluorines on antimony have been observed for the analogous polymeric compound $SbF_4.SO_3F$ (12). Intramolecular fluorine exchange could occur via breaking and reforming of the fluorosulfate bridge. However, we also found that the expected ^{77}Se—F satellites could only be observed at $-85°$ ($J_{Se-F} = 1088$ Hz) so at higher temperatures there must be some relatively rapid intermolecular exchange involving the breaking of the Se—F bonds. The simplest explanation for this is that there is exchange via a small equilibrium concentration of SeF_4 and SO_3 at temperatures above $-85°$. This observed down-field shift in the F-on-Se resonance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

from -83.8 to -86.8 p.p.m. from CF_3CO_2H on raising the temperature from $-85°$ to room temperature is also consistent with an increasing dissociation into SeF_4 and SO_3, as the chemical shift of SeF_4 is -141 p.p.m. from CF_3CO_2H. The Se—F coupling constant of 1088 Hz is of the same order of magnitude as the value of 837 Hz observed for $SeOF_2$ (14).

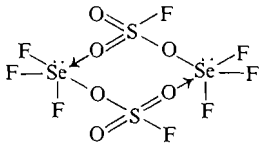
Molten $SeF_3.SO_3F$ also gave two resonances: one at -119 p.p.m. which may be attributed to the SO_3F group and one at -84.2 p.p.m. which may be attributed to the SeF_3 group. These resonances had the expected relative areas of 1:3.

Cryoscopy in Nitrobenzene

The freezing point depression of nitrobenzene produced by $SeF_3.SO_3F$ is compared with that produced by the non-electrolyte trinitrobenzene in Fig. 2. It may be seen that at very low concentrations $SeF_3.SO_3F$ apparently behaves like a non-electrolyte, and there cannot be more than a very small amount of ionization. As the concentration is increased, however, the slope of the freezing point curve for $SeF_3.SO_3F$ rapidly decreases until at 0.2 *M* it is scarcely more than half that for trinitrobenzene indicating essentially complete dimerization.

Conclusions

All our observations can be interpreted consistently in terms of a polymeric fluorosulfate bridged structure for the solid and molten states of the adduct $SeF_4.SO_3$. There is evidence that this polymeric structure persists in solution and that in dilute solution in nitrobenzene a dimer is probably the predominant species. This dimer could have the following cyclic structure



3

but a linear structure is equally probable particularly in a solvating solvent such as HSO_3F when one end of the chain could be stabilized by a solvent molecule (**2**). The spectroscopic evidence, in particular, shows that the bridge bonds in the polymer have appreciable ionic character, but there is no evidence in the solid or the melt for a free SeF_3^+ ion which is apparently a strong enough Lewis acid to form a bond of significant covalent character, even with the very weakly basic SO_3F^- ion. Only in the strongly ionizing fluorosulfuric acid does there appear to be any considerable amount of dissociation to free ions.

An investigation of the structures of the adducts of SF_4 with BF_3, PF_5, AsF_5, and SbF_5 in the solid state and in solution in HF

M. AZEEM[1], M. BROWNSTEIN, AND R. J. GILLESPIE
Department of Chemistry, McMaster University, Hamilton, Ontario

Received May 22, 1969

The structure of the solid adducts of SF_4 with several fluoride acceptors has been studied by investigations of the ^{18}F exchange between $S^{18}F_4$ and BF_3 and between SF_4 and $B^{18}F_4$, the infrared spectrum of $SF_4.BF_3$, and the Raman spectra of $SF_4.BF_3$, $SF_4.PF_5$, $SF_4.AsF_5$, and $SF_4.SbF_5$. The experimental observations are best accounted for in terms of an ionic structure $SF_3^+.MX_n^-$ in each case, but there is good evidence for relatively strong fluorine bridging between the ions.

In anhydrous hydrogen fluoride solution, SF_4 and the adducts $SF_4.BF_3$ and $SF_4.SbF_5$ were studied conductimetrically and by ^{19}F nuclear magnetic resonance. Both methods indicate complete ionization of the adducts to SF_3^+ and the complex fluoroanion. SF_4 is a weak base in hydrogen fluoride ionizing to SF_3^+ and HF_2^-.

Canadian Journal of Chemistry, 47, 4159 (1969)

Introduction

Bartlett and Robinson (1, 2) first reported that SF_4 forms a series of solid complexes with a number of inorganic fluorides that act as fluoride ion acceptors, e.g. $SF_4.BF_3$, $SF_4.AsF_5$, $SF_4.SbF_5$. These authors first postulated (1) that these compounds are simple donor–acceptor complexes, e.g., $F_4S{:}BF_3$. Since that time, there has been considerable discussion of the structures of these compounds. It has been generally supposed that they are either ionic, e.g., $SF_3^+.BF_4^-$, or fluorine-bridged (2–5), but convincing experimental evidence has been lacking. The great reactivity of the compounds towards moisture and solvents and their insolubility in all solvents except HF has made spectroscopic studies extremely difficult. Cotton and George (3) were unable to obtain an infrared (i.r.) spectrum, but later Seel and Detmer (4) observed a few bands in the i.r. spectrum of the solid. In particular, they found a band at 1050 cm^{-1} which they assigned to BF_4^- and bands at 908 and 940 cm^{-1} which, by comparison with the known spectrum of the isoelectronic PF_3, they assigned to SF_3^+.

We have attempted to obtain further information on the structures of these complexes by (*a*) studying the ^{18}F exchange when they are formed from the 2 components and then decomposed by a suitable donor molecule, (*b*) measuring the i.r. and Raman spectra of the solids, and (*c*) investigating solutions of the complexes in anhydrous hydrogen fluoride by means of electrical conductivity and nuclear magnetic resonance (n.m.r.) measurements. Since our work was completed, Evans and Long (6) have reported the Raman spectrum of the molten complex $SF_4.SbF_5$ at 250 °C and they have interpreted their results in terms of the ionic formulation $SF_3^+.SbF_6^-$.

Results and Discussion

^{18}F Exchange Studies

The adduct $SF_4.BF_3$ was prepared using BF_3 labelled with ^{18}F (7) by condensing equal volumes of the 2 gases into a trap cooled with liquid air. The trap was then allowed to warm up to some higher temperature in the range $-100°$ to room temperature and to remain at this temperature for some period of time between 5 and 60 min in order to allow the formation of the adduct. Any excess reactants were then pumped off and after again cooling the adduct to liquid air temperature, it was decomposed by the addition of tetrahydrofuran or diethyl ether (precooled to $\sim -80°$) and then warmed to $-20°$, or to the temperature at which the adduct had previously been formed if this was lower. The liberated SF_4

$$BF_3.SF_4 + R_2O \rightarrow BF_3.OR_2 + SF_4$$

was collected and its specific activity determined. The exchange was also studied using labelled SF_4. The results are given in Table I. The results obtained at room temperature show that, for reaction times of 20 min or more, the exchange was complete. Shorter reaction times were not

[1]Present Address: College of Engineering, P.O. Box 800, Riyadh, Saudi Arabia.

−100	10	18.7	

studied. The average values of 56% transfer of activity from $B^{18}F_3$ to SF_4 and of 43% transfer of activity from $S^{18}F_4$ to BF_3 agree well with the values of 57 and 43%, respectively, expected for complete exchange. At temperatures of −15° and below, exchange was incomplete even after 1 h and the amount of exchange after a fixed reaction time, e.g., 20 min, decreased and appeared to reach a constant limiting value, at −80°, which was independent of time (Table I).

At room temperature, the adduct is in equilibrium with its components in the vapor state and has a vapor pressure of approximately 100 mm. It seems reasonable to suppose, therefore, that rapid and complete exchange occurs by the rapid formation and dissociation of the adduct. If the adduct were a simple donor–acceptor complex, then there would be no obvious mechanism for exchange. However, if the adduct is a fluorine-bridged compound or an ionic compound, $SF_3^+BF_4^-$, then exchange can occur on the formation and dissociation of the adduct.

At low temperatures of −80° and below, a constant minimum amount of exchange occurs even after 5 min reaction time. Because this amount of exchange occurs so rapidly, and because the vapor pressure is extremely small at this temperature, it seems reasonable to suppose that exchange is not occurring via the vapor phase, but directly on the formation and decomposition of the adduct. On the formation of the ionic complex $SF_3^+BF_4^-$ with labelled BF_3, 1 of the 4 fluorines in BF_4^- would be labelled, and hence, on decomposing the adduct with ether or tetrahydrofuran, 25% of the activity would be transferred to the SF_4, assuming that BF_4^- is free to rotate in the solid or during the reaction with the ether. If labelled SF_4 is used to form the adduct, then we expect that 25% of the activity will be transferred to the BF_4^- and then 25% of this activity will be returned to SF_4 when the adduct is decomposed, i.e., we expect an overall transfer of 19% of the activity. In both types of experiment, less activity was transferred at −80° than predicted. We conclude, therefore, that either the adduct does not have a simple ionic structure, or, if it is ionic, the ions have their rotational motion restricted in the solid state and during the reaction with ether.

Hindrance to rotational motion could arise from fluorine bridging between the ions. We therefore now consider the expected results for a fluorine-bridged structure. If the bridging between molecules was relatively weak and unsymmetrical as in **1**, the weak component of the bridge would be expected to break on decomposition, and no fluorine transfer would be observed. However, if both fluorine bridge bonds are identical as in **2**–**4**, giving an essentially ionic compound, then fluorine exchange between SF_4 and BF_3 will be observed on formation and decomposition of the adduct. If BF_3 is labelled, then there is a 33% chance of forming a bridge bond containing ^{18}F, and on decomposition of the adduct, one of the two B—F bridge bonds must break, transferring one of the fluorines to SF_4. Thus, about 17% of the $B^{18}F_3$ activity is expected to be transferred to SF_4. The experimental results at −80 and −100° showed that between 15 and 19% of the activity was transferred. When labelled SF_4 is used to form the adduct, the

probability of forming an ^{18}F bridge will be 25%. Hence, when the adduct is decomposed, the fluorine in one of the two bridge bonds to each boron will be transferred to the boron and thus there will be a transfer of approximately 12.5% of the activity. The observed results that approximately 9–11% of the activity was transferred are in reasonable agreement with this prediction.

Thus the results of the fluorine exchange experiments are best interpreted in terms of fluorine-bridged ionic structures such as **2**–**4**. These structures differ only in the position of the fluorine in the bridge. Structure **2** corresponds to fluorine bridges between BF_4^- and SF_3^+, structure **4** to fluorine bridges between BF_2^+ and SF_5^- and structure **3** is intermediate with a symmetrical fluorine bridge.

Vibrational Spectra

$SF_4.SbF_5$

The Raman spectrum of the molten complex has been reported very recently by Evans and Long (6) and interpreted in terms of the ionic structure $SF_3^+SbF_6^-$. We have obtained the Raman spectrum of the solid. The results are given in Table II.

The hexafluoroantimonate ion belongs to the point group O_h and therefore has 6 normal modes of vibration: $\nu_1(A_{1g})$, $\nu_2(E_g)$, $\nu_3(T_{1u})$, $\nu_4(T_{1u})$, $\nu_5(T_{2g})$, $\nu_6(T_{2u})$; ν_1, ν_2, and ν_5 are Raman active and ν_3 and ν_4 are i.r. active. Previous assignments for SbF_6^- are given in Table III. We can assign the fundamental vibrations of the SbF_6^- ion observed in our spectra of the solid complex by comparison with these earlier assignments. Our assignments for SbF_6^- agree quite well with those of Evans and Long (6), except that we found ν_2 and ν_5 to be doublets, and we attribute the weak line at 680 cm^{-1} to ν_3, which is formally forbidden, instead of to the SF_3^+ ion. We assume that the splitting of ν_2 and ν_5 and the observation of ν_3 in the Raman spectrum arise from some lowering of the symmetry of the SbF_6^- in the crystal, probably as a result of fluorine bridging with SF_3^+.

The bands observed at 928, 943, 529, and 411

cm^{-1} are assigned by comparison with the spectrum of the isoelectronic molecule PF_3 (9) to ν_3, ν_1, ν_2, and ν_4, respectively, of the SF_3^+ ion (Table IV). A shoulder on the ν_3 band is apparent at 955 cm^{-1}. This is consistent with some reduction in symmetry as a consequence of fluorine bridging. This assignment differs from that proposed by Evans and Long (6) on two points: (*a*) We assign the weak band at 529 cm^{-1} rather than the band at 690 cm^{-1} to ν_2; this latter band, which we observed at 680 cm^{-1}, being assigned to ν_3 of SbF_6^-. Although ν_3 should be forbidden, it is reasonable to assume that it is weakly allowed in the melt as well as in the crystal because of fluorine bridging. This assignment is confirmed by the fact that no line at 680 cm^{-1} is found in the spectra of $SF_4.BF_3$ and $SF_4.PF_5$ although both contain the SF_3^+ ion. Evans and Long themselves regarded the assignment of the 690 cm^{-1} band to ν_2 as rather unsatisfactory; (*b*) We find the ν_4 band at 411 cm^{-1} rather than at 356 cm^{-1}. This is confirmed by the observation of bands having frequencies close to this value in all the other SF_3^+ compounds that we have studied (Table IV). Perhaps this difference is a consequence of passing from the liquid to the solid state.

$SF_4.BF_3$

The results of our measurements on the i.r. and Raman spectra of solid $SF_4.BF_3$ are given in Table V. The incomplete i.r. spectrum obtained previously by Seel and Detmer (4) was interpreted by them in terms of the ionic structure $SF_3^+BF_4^-$.

The tetrafluoroborate anion belongs to the point group T_d and therefore has 4 normal modes of vibration, all of which are active in the Raman ($\nu_1(A_1)$, $\nu_2(E)$, $\nu_3(T_2)$, and $\nu_4(T_2)$) and only ν_3 and ν_4 are active in the i.r. An assignment of the observed bands in the i.r. and Raman spectra can be made in terms of the ionic model SF_3^+-BF_4^- using the previous assignments for BF_4^- (Table VI) and PF_3 (Table IV). However, the forbidden i.r. frequencies ν_1 and ν_2 appear with reasonable intensity, and ν_2 appears as a doublet. In addition, ν_3 for SF_3^+ is also split. The occurrence of the forbidden bands and the additional splittings can be attributed to a lowering of the symmetry of both ions in the crystal, probably as a result of fluorine bridging.

$SF_4.PF_5$

The vibrational spectrum of this compound has not been previously studied. The Raman spectrum (Table VII) can again be assigned on the basis of the ionic structure $SF_3^+PF_6^-$ making use of previous assignments for PF_6^- and PF_3. The spectrum of PF_6^- is very similar to that of SbF_6^- and again indicates a lower symmetry than O_h. Thus, we see that ν_5 and ν_2 are split into doublets, and the forbidden ν_3 vibration appears weakly at 815 cm^{-1}. As in all the other compounds studied, ν_3 of SF_3^+ is split into a doublet. These observations are consistent with fluorine bridging between the ions SF_3^+ and PF_6^-.

$SF_4.AsF_5$

The vibrational spectrum of this compound has not been previously studied. As for $SF_3.PF_6$ and $SF_3.SbF_6$, a reasonable assignment can be made in terms of the ionic structure $SF_3^+.AsF_6^-$ (Table VIII). Again we note that ν_2 for AsF_6^- and ν_3 for SF_3^+ are split, indicating probable fluorine bridging. The frequencies assigned to SF_3^+ in all 4 compounds studied have been summarized in Table IV. The good agreement between the observed frequencies gives further confirmation of the correctness of the assignment.

Conductivity Measurements in HF Solution

The two adducts $SF_4.BF_3$ and $SF_4.SbF_5$ give solutions in anhydrous HF which have conductivities that are closely similar to, although slightly lower than, those of KBF_4 and $KSbF_6$ (14) (Table IX and Fig. 1). We conclude, therefore, that the 2 adducts are fully ionized in solution in HF, e.g.

$$SF_4.BF_3 \rightarrow SF_3^+ + BF_4^-$$

*Molalities of the KF solutions having the same conductivities as the SF_4 solutions, $[KF] = [SF_3^+]$.
†$K = [SF_3^+][HF_2^-]/[SF_4]$.

A solution of SF_4 also has a moderate conductivity, although this is considerably smaller than the fully ionized $SF_4.BF_3$ and $SF_4.SbF_5$. We conclude that SF_4 behaves as a partially ionized weak base in solution in anhydrous HF

$$SF_4 + HF \rightleftarrows SF_3^+ + HF_2^-$$

The results in Fig. 1 show that the mobility of the SF_3^+ ion must be similar to that of the K^+ ion. Hence, by comparing the observed conductivity of SF_4 with that of KF at any given temperature, one can obtain the degree of dissociation and hence the equilibrium constant for its ionization

$$K = [SF_3^+][HF_2^-]/[SF_4] = 4 \pm 2 \times 10^{-2}$$

at 0 °C

Nuclear Magnetic Resonance Spectra

Solutions of $SF_4.BF_3$ in anhydrous HF gave spectra consisting of a single broad line at room temperature which split into 2 lines at low temperatures. Similar behavior was observed for $SF_4.SbF_5$ and $SF_4.AsF_5$ solutions (Table X).

†The values may be compared with those for $CsSb_2F_{11}$ in SO_2 (89.4, 109.1, and 131.2 (p.p.m. from $CFCl_3$) (16)) and for $Sb_2F_{11}^-$ in HF ((ref. 15 and this work) 93.0, 120.1, and 141.8). We note that there is an appreciable solvent shift in going from HF to SO_2, probably because of some ion-pair formation in SO_2.

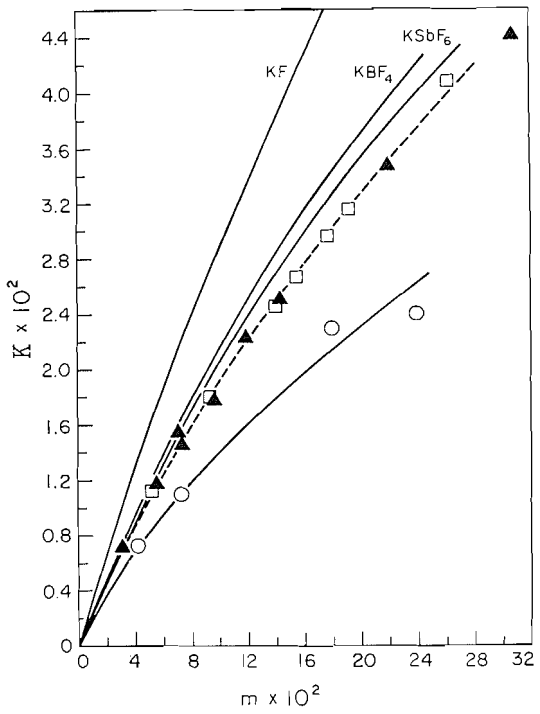

FIG. 1. Conductivities κ (ohm^{-1} cm^{-1}) of solutions in anhydrous HF. □, $SF_4.BF_3$; ▲, $SF_4.SbF_5$; ○, SF_4.

The low field line has very nearly the same chemical shift in each case (−25 to −30 p.p.m. from $CFCl_3$) and is in the fluorine-on-sulfur region of the spectrum. We attribute this peak to the SF_3^+ ion. The high field peak is due to the anion BF_4^-, SbF_6^-, or AsF_6^- exchanging with the solvent. Additions of a small amount of fluoride ion to solutions of $SF_4.BF_3$ resulted in the appearance of a new peak at 153.5 p.p.m. from $CFCl_3$ and the simultaneous disappearance of the peak assigned to SF_3^+, which could not then be observed even at low temperatures. The new peak is due to BF_4^- (cf. the shift of +153.6 p.p.m. observed for a solution of KBF_4 in HF). The addition of fluoride represses the exchange of fluoride between BF_4^- and the solvent

$$BF_4^- + HF \rightleftarrows BF_3 + HF_2^-$$

while at the same time promoting the exchange between SF_3^+ and the solvent

$$SF_3^+ + HF_2^- \rightleftarrows SF_4 + HF$$

Addition of a slight excess of AsF_5 to the $SF_4.AsF_5$ solution gave an SF_3^+ peak which was observable, although rather broad, even at room temperature. Addition of 1 mole of AsF_5 per

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

mole of $SF_4.AsF_5$ gave a sharp SF_3^+ peak even at room temperature. No AsF_6^- peak was observed in any of the spectra, presumably because of exchange of fluoride with the solvent and quadrupole relaxation of the ^{75}As nucleus. For the solutions of $SF_4.SbF_5$, a peak at -27.6 p.p.m. which may be attributed to SF_3^+ was obtained at low temperature in addition to a peak due to the solvent. No peak was observed from SbF_6^-, presumably because of partially relaxed coupling to $^{121}Sb(I = 5/2)$ and ^{127}Sb $(I = 7/2)$ and exchange with the solvent, giving a very broad spectrum which could not be detected above the base line noise. Addition of SbF_5 to this solution, however, gave signals which can be attributed to SbF_6^- and $Sb_2F_{11}^-$ (15, 16). The n.m.r. data thus provides strong support for the conclusion that all 3 adducts are completely ionized to SF_3^+ and the corresponding anion in solution in HF.

A solution of SF_4 in HF gave only a single resonance at all temperatures, showing that exchange occurs. This is consistent with the conductimetric evidence for incomplete ionization of SF_4 in HF.

Experimental

Fluorine Exchange Reactions

The labelled fluorides were prepared and their specific activity determined as described previously (7). The adduct $SF_4.B^{18}F_3$ was prepared by condensing equal volumes of the 2 gases into a trap cooled in liquid air. The trap was then allowed to warm up to some higher temperature in the range $-100°$ to room temperature and allowed to remain at this temperature for some time between 5 and 60 min in order to allow formation of the adduct. Any excess of the reactants was pumped off. After again cooling the adduct to liquid air temperature, it was decomposed by the addition of tetrahydrofuran or diethyl ether, precooled to $-80°$, and then warmed to $-20°$ or to the temperature at which the adduct had previously been formed if this was lower. The liberated SF_4 was collected in a trap cooled in liquid air. Sodium hydroxide solution was then added to the cold trap and the temperature allowed to rise gradually to room temperature to obtain complete hydrolysis of the SF_4. The solution was then made up to a standard volume for determination of the activity, and hence the % activity transferred from the $B^{18}F_3$ was determined. Portions of this solution were taken for the determination of the ^{18}F activity and for analysis. The remaining tetrahydrofuran solution was also analyzed and the ^{18}F activity determined. Sulfur was determined as barium sulfate and boron as boric acid. From the analytical and ^{18}F activity data, the percentage of activity transferred from BF_3 to SF_4 was calculated. The exchange between $S^{18}F_4$ and BF_3 was studied in the same manner.

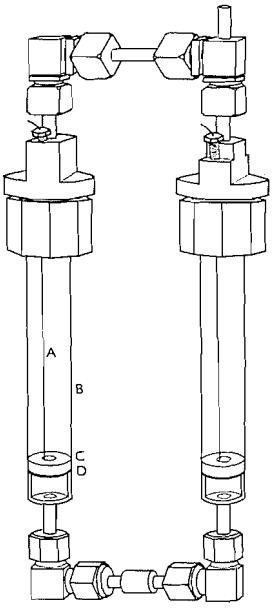

FIG. 2. Conductivity cell: A, platinum lead; B, Kel-F tube; C, teflon washer; D, platinum disk electrode supported on ledge at side of tube.

Conductivity Measurements

These were made as described previously (15). Solutions of the SF_4 adducts appeared to attack the platinum black coating used on the electrodes, which were, therefore, replaced by rhodium electrodes coated with a layer of rhodium black which appeared to be resistant to attack. Some measurements were made with the same type of cell as described previously, while some, particularly on dilute solutions, were made with the type of cell shown in Fig. 2, which was constructed entirely of Kel-F, Teflon and platinum (or rhodium). The larger volume of this cell enabled measurements to be made more easily on dilute solutions.

Nuclear Magnetic Resonance Spectra

Solutions were contained in thin-wall Kel-F tubes which were inserted into precision glass tubes. The reference liquid $CFCl_3$ was contained in the annular space. Spectra were obtained on either a Varian Associates HA-100 or a DA-60 spectrometer.

Raman Spectra

These were obtained using a Spex Industries double monochromator with a phototube detector and electronic amplifier and recorder. Spectra Physics Model 125 helium–neon and Model 145 argon-ion lasers were used as light sources.

Materials

Hydrogen fluoride was purified as previously described (15). Antimony pentafluoride (Ozark-Mahoning Co.) was distilled twice in an all glass apparatus immediately before use. Sulfur tetrafluoride (Matheson) was purified by bubbling through mercury to remove SCl_2 and then

distilled on a vacuum line. Boron trifluoride and phosphorus pentafluoride (Matheson) and arsenic pentafluoride (Ozark-Mahoning Co.) were purified by trap-to-trap distillation on a vacuum line. The purity of the SF_4, PF_5, and AsF_5 was checked by determining their i.r. spectra in a 10 cm Monel gas cell with silver chloride windows.

The adducts $SF_4.BF_3$, $SF_4.PF_5$, and $SF_4.AsF_5$ were prepared by direct combination of the gases in a glass vacuum line. Excess of either component was removed by pumping on the solid adduct. The adduct $SF_4.SbF_5$ was prepared in a similar manner, using an excess of SF_4. To ensure complete reaction, the product was heated to 200 °C under an atmosphere of SF_4 and then pumped, after cooling to room temperature. An X-ray powder photograph gave the space group and cell dimensions previously found by Bartlett and Robinson (3).

Infrared Spectra

The i.r. spectrum of $SF_4.BF_3$ was determined by condensing the adduct onto a window which was held in a brass frame mounted on a glass tube into which liquid air could be poured. The window was thus cooled and the $SF_4.BF_3$ was sublimed onto the cold window until a sufficient thickness was obtained. The spectrum was recorded between 2100 and 500 cm^{-1} using a silver chloride window, and between 600 and 250 cm^{-1} with a polythene window.

The photolyses of acetyl and ethyl isocyanates in the vapor phase: new examples of Type II photodissociation[1]

N. J. FRISWELL[2] AND R. A. BACK
Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received June 24, 1969

The photolyses of acetyl and ethyl isocyanate vapors have been studied at 25 °C, at pressures between about 2 and 30 Torr, using either monochromatic 2288 Å radiation or light from a medium-pressure mercury arc equipped with a Vycor filter. Molecular photodissociations were of major importance with both compounds, with formation of HNCO + CH_2CO and HNCO + C_2H_4 accounting for about 70 and 60% of the decomposition of the acetyl and ethyl esters, respectively. It is suggested that these products were formed through a 6-membered ring transition state analogous to that involved in the Norrish Type II process observed in other carbonyl compounds.

Minor free-radical processes also occurred with both isocyanates, with evidence for photodissociation of both R—NCO and RN—CO bonds. There was also apparently some collisional deactivation of excited precursors of both the molecular and free-radical photodissociations.

Vapor pressure data for the 2 isocyanates, and molar extinction coefficients between about 2200 and 3000 Å, are also reported.

Canadian Journal of Chemistry, 47, 4169 (1969)

Introduction

The photolysis of isocyanic acid vapor has been studied in some detail recently, in this laboratory (1) and elsewhere (2); the isocyanate esters are of obvious interest for comparison. Their photolyses are also of interest as possible sources of nitrenes or NCO radicals, and for comparison with other types of carbonyl compounds and with azides. Previous studies of isocyanate photolyses are very limited. The photolysis of CH_3NCO was investigated in some detail by Bamford and Bamford (3) in 1940. The flash photolysis of C_2H_5NCO has been used to study the spectrum of NCO (4), and the products of the flash photolysis of CH_3NCO have been examined briefly in this laboratory (5). Brief studies of the photolyses of *n*-butyl cyanate vapor and of several alkyl and aryl cyanates in the liquid phase have been described recently (6). One of our original objectives in the present work was to find a useful source of NCO radicals, and it was hoped that the photolysis of $CH_3CO.NCO$, by analogy with other acetyl compounds, might be suitable. The photolysis of C_2H_5NCO was studied for comparison after the somewhat unexpected behavior of the acetyl ester became apparent.

Experimental

Materials

$CH_3CO.NCO$ was prepared by reaction of CH_3COCl with AgNCO, and separated by distillation, collecting the fraction boiling at 80 °C at atmospheric pressure (7). Minor impurities (< 0.1%) were $CH_3CO.OCH_3$, CH_3CN, and CO_2, the latter forming in a slow dark reaction of the isocyanate at −78 °C. Pumping at −95 °C before each experiment removed all of the CO_2 and most of the acetate. The trace of CH_3CN, which is transparent down to ~1850 Å and which is also a reaction product, was not removed.

Ethyl isocyanate was obtained from Eastman Co., and gas chromatographic analysis showed no significant impurities after several trap-to-trap distillations. 2,3-Dimethyl butane was Phillip's Research grade, used after simple degassing. Azomethane was obtained from Merck, Sharp, and Dohme of Canada, Ltd., and used after degassing to remove traces of N_2, CH_4, and C_2H_6.

Vapor Pressures

Saturation vapor pressures of the 2 isocyanates, apparently not reported previously, were measured on a simple mercury manometer and are given by the equations

$$\log_{10} P_{CH_3CO.NCO} = 7.94 - 1813/T$$

and

$$\log_{10} P_{C_2H_5NCO} = 7.81 - 1620/T$$

(where P is in Torr and T in °K) based on data obtained from −33 to 10 °C and −52 to 5 °C for the acetyl and ethyl esters, respectively.

Absorption Spectra

Absorption spectra of the 2 isocyanates were measured on a Cary ultraviolet spectrophotometer at pressures of 29 and 40 Torr for the acetyl and ethyl esters, respectively, and are shown in Fig. 1. Woo and Liu (8) reported continuous absorption in ethyl isocyanate below a limit

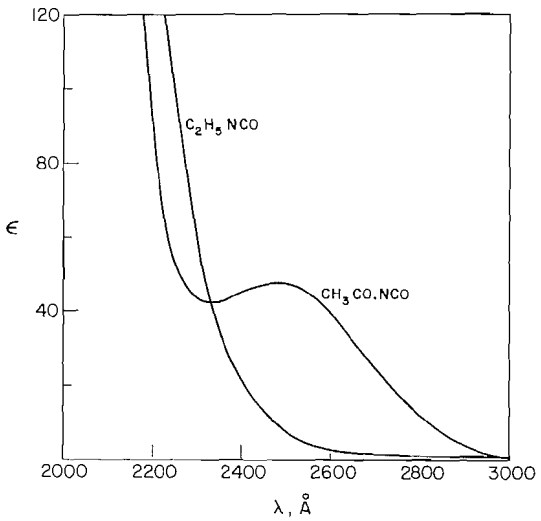

FIG. 1. Absorption spectra of acetyl and ethyl isocyanates. ε is the decadic molar extinction coefficient.

of 2480 Å. The spectrum of the acetyl ester had not been described before; the broad maximum at 2480 Å, which is absent in the alkyl isocyanates, may be ascribed to the acetyl carbonyl chromophore.

Apparatus

Photolyses were carried out in a conventional cylindrical quartz vessel, 5 cm in diameter, 10 cm long, and of about 200 cc volume, equipped with plane quartz windows. This was mounted in an air thermostat and attached to a vacuum line used for preparation and analysis, similar to those used previously in this laboratory (1). All photolyses were done at 25 °C.

Light Sources

Two light sources were employed, a Hanovia S-500 medium-pressure mercury arc, used with a Corning 7910 filter to cut off wavelengths below 2200 Å, and a flat-spiral cadmium resonance lamp operated at 271 °C with a current of 75 mA. The latter was used with a Hg-vapor – H_2-filter to remove traces of mercury resonance radiation, and with a gaseous Cl_2–$NiSO_4$–$CoSO_4$ combination of filters to remove the first Cd resonance line at 3261 Å and other light of longer wavelengths. The resulting light was examined with a grating spectrometer and found to be >99% monochromatic 2288 Å radiation. Quantum yield measurements were made with this light source, using azomethane as an actinometer (1), assuming $\Phi(N_2) = 1$. The relative transmitted light intensity was measured in these experiments by a suitably conditioned phototube with a platinum cathode (1).

Analysis

Products volatile at −196 °C (N_2, H_2, CO, CH_4) were removed by a Toepler pump, measured in a gas burette, and analyzed by gas chromatography on a 5A molecular sieve column at 28 °C. In the $CH_3CO.NCO$ photolysis, a fraction volatile at −160 °C (C_2H_4, C_2H_6) was removed and analyzed on a silica gel column at 28 °C. The remaining material, reagent and products (ketene, CH_3NCO, HCN, HNCO), was analyzed on a dinonyl phthalate column at 30 °C in an all-glass gas chromatograph, after partial fractionation at −120 or −95 °C to minimize complications arising from decomposition of the starting material, which occurred to some extent on every one of a number of columns that were tried.

In the C_2H_5NCO photolysis, C_4H_{10}, C_3H_8, C_2H_6, and C_2H_4 were removed at −120 °C and analyzed on a silica gel column at 50 °C, while the remaining reagents and products (HNCO, HCN, CH_3CN, CH_3NCO) were analyzed on a dinonyl phthalate column at 30 °C. All gas chromatogram peaks from both isocyanates were identified by retention times and by mass spectrometric analysis of effluent vapors, comparing with standard samples in all cases.

Results and Discussion

Photolysis of $CH_3CO.NCO$

Products from a typical experiment with the S-500 lamp (10 Torr isocyanate, 60 min irradiation), with approximate amounts in μmoles given in parentheses, were CH_2CO (31), CO (7), CO_2 (3), CH_3NCO (2), C_2H_4 (0.4), C_2H_6 (0.3), CH_4 (0.02), and N_2 (0.01). Rates of formation of the 3 hydrocarbons and CO showed a marked dependence on photolysis time, shown in Fig. 2; all other product yields were approximately proportional to time. All products increased roughly linearly with pressure of isocyanate from 2 to 23 Torr, presumably reflecting simply the increasing absorption of light.

The rather unexpected appearance of ketene as a major product of the photolysis would appear to be best explained by a molecular

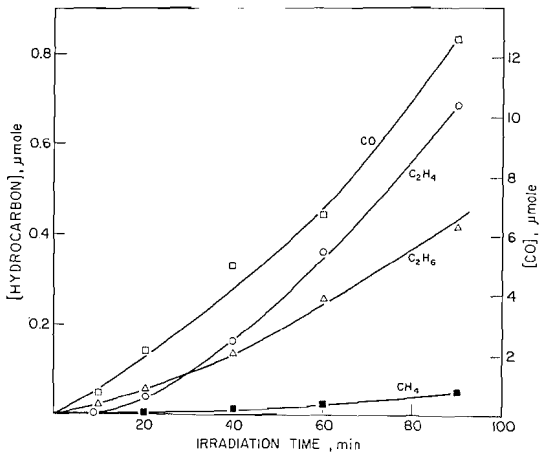

FIG. 2. Dependence of product yields on time of irradiation in the photolysis of $CH_3CO.NCO$. (Note different ordinate scale for CO on right-hand side.)

photodissociation

[1] $CH_3CO.NCO + h\nu \rightarrow CH_2CO + HNCO$

Isocyanic acid was not detected among the products, but tests showed that when it was added to $CH_3CO.NCO$, it could not be recovered, seeming to disappear in a reaction (probably co-polymerization) which yielded no volatile products. Certainly the elemental balance in the observed products demands the formation of HNCO or its stoichiometric equivalent. The radical-chain sequence

[2] $NCO + CH_3CO.NCO \rightarrow HNCO + CH_2CO.NCO$

[3] $CH_2CO.NCO \rightarrow CH_2CO + NCO$

could yield the same products as reaction [1], and to test this possibility, some photolyses were done with about 80 Torr of 2,3-dimethylbutane added. Production of C_2H_4 and C_2H_6 was completely suppressed, and that of CH_4 enhanced. All other products were reduced to about 2/3 of their original yields, but their ratios were unchanged. These observations appear to rule out the radical chain as a source of ketene, since NCO radicals should have reacted with the hydrocarbon, inhibiting the chain. The observed reduction in ketene and other products suggests quenching of an excited-molecule intermediate in reaction [1]. Further evidence against the radical chain is the quantum yield data obtained at 2288 Å, shown in Table I

Despite the considerable scatter in these data (which reflects the difficulty in the quantitative analysis of the small amounts of ketene formed at the low conversions ($\sim 1\%$) used in an attempt to minimize secondary photolysis), Φ(ketene) is clearly less than unity, and does not show the upward trend with increasing pressure of isocyanate that would be expected of a chain reaction. Yields of CO at 2288 Å were much higher, relative to those of ketene, than with the mercury arc. It is not certain whether this was a real change in the primary photolysis or whether secondary photolysis of ketene was more extensive at the shorter wavelength. Yields of other products at 2288 Å were too small to measure with any accuracy, and the photolysis at this wavelength was not pursued further.

TABLE I

Quantum yields of ketene and CO from the photolysis of $CH_3CO.NCO$ at 2288 Å

*Photolysis time was about 130 min and absorbed light intensity 3–9 × 10^{-10} einstein/l s.
†Not measured.

While it seems clear that reaction [1] describes the main course of the photolysis, there is evidence from the minor products observed that several other primary and secondary processes were also occurring. It is evident that ethylene is entirely a secondary product (see Fig. 2), and almost certainly comes from the photolysis of ketene and subsequent reaction of CH_2 radicals. The suppression of C_2H_4 production by 2,3-dimethylbutane supports this conclusion. Yields of CO, CH_4, and C_2H_6 also increased with increasing conversion, but to a lesser extent, and unlike C_2H_4, had appreciable initial values. The increase in CO is probably due to decomposition of ketene, while the source of the extra CH_4 and C_2H_6 is not clear. Other primary processes which must be considered are

[4] $CH_3CO.NCO + h\nu \rightarrow CH_3 + CO.NCO$

[5] $\rightarrow CH_3CO + NCO$

[6] $\rightarrow CH_3CO.N + CO$

[7] $\rightarrow CH_3NCO + CO$

[8] $\rightarrow CH_3CN + CO_2$

The production of CH_4 and C_2H_6, and the enhancement of the former and suppression of the latter by 2,3-dimethyl butane, provide good evidence for the presence of CH_3 radicals, presumably from reaction [4]. Evidence for NCO radicals in the system is less clear, since HNCO would be the product formed by hydrogen abstraction, and it could not be measured. If the combination of NCO radicals leads to N_2 and 2CO, as has been reasonably suggested in the past, then the very low yields of N_2 indicate a concentration of NCO much less than that of CH_3, assuming similar combination rates. It is possible that NCO could abstract H from $CH_3CO.NCO$ much faster than does CH_3, thus

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

reducing the NCO concentration. The CO.NCO radical formed in reaction [4] would probably decompose to CO and NCO, although nothing is known of its stability. If it abstracted H, the resulting HCO.NCO would probably decompose to HNCO and CO. Reaction [5] would yield NCO directly; there is no evidence for acetyl radicals in the system. It should be noted that the photon energy was probably sufficient to cause a primary dissociation to CH_3 + NCO + CO rather than reaction [4] or [5] (cf. acetone photolysis (9)).

Reaction [6] is suggested by analogy with the photolyses of HNCO and organic azides. The fate of the nitrene in the present system is not known. Similar nitrenes from the photolysis of azidoformates apparently do *not* rearrange to isocyanates (10), and for this reason reaction [7] is suggested as the probable source of the CH_3NCO observed in the present photolysis. Cross combination of CH_3 and NCO may be ruled out as an alternate source by the apparently low concentration of NCO noted earlier.

Finally, reaction [8] is postulated as the most likely source of the CO_2 observed. The same reaction also occurred slowly in the dark even with the isocyanate stored at −78 °C. For this reason, small amounts (<0.5%) of CH_3CN were usually present in the starting material, and it was impossible to say whether it was also produced in the photolysis. Small yields of CO_2 were undoubtedly formed in the photolysis, however.

The primary processes [4] to [8] were of very minor importance compared to reaction [1]. For photolysis with the S500 mercury arc, reactions [4], [7], and [8] may be estimated as about 2, 7, and 10% of reaction [1], based on yields of $CH_4 + 2C_2H_6$, CH_3NCO, and CO_2, respectively. The yield of CO might be thought to be a useful measure of the sum of reactions [4], [5], [6], and [8], but secondary photolysis of ketene became an important CO source at quite low conversions, and it is difficult to estimate. The quantum yields of reactions [5] and [6] are rather uncertain, but their sum is not more than 10% of reaction [1].

Photolysis of C_2H_5NCO

A series of experiments was done using the S-500 medium-pressure mercury arc with a 7910 Vycor filter, with pressures of isocyanate from about 4 to 30 Torr. Products from a typical experiment (13 Torr C_2H_5NCO, 60 min irradiation), with amounts in μmoles in parentheses, were C_2H_4 (2.16), CO (0.81), C_2H_6 (0.53), C_3H_8 (0.24), CH_4 (0.20), C_4H_{10} (0.07), and N_2 (0.001). Appreciable yields of HNCO were also observed, but quantitative analysis was not possible. All the products increased with increasing pressure, presumably due to increased absorption of light. The addition of 2,3-dimethyl butane reduced the yields of all products by roughly similar amounts, with a pressure of about 200 Torr causing a reduction of more than 50%. The addition of 1 Torr of oxygen reduced yields of C_2H_6, C_3H_8, and C_4H_{10} virtually to zero, and that of CH_4 by about 50%. Ethylene was approximately unaffected, while CO was about doubled. Addition of 3 Torr of nitric oxide also eliminated C_2H_6, C_3H_8, and C_4H_{10}, leaving CO and C_2H_4 almost unaffected.

All these observations point to a major primary process

[9] $$C_2H_5NCO + h\nu \rightarrow C_2H_4 + HNCO$$

which is analogous to reaction [1] in the $CH_3CO.NCO$ photolysis. The formation of CO seems best explained by another primary process

[10] $$C_2H_5NCO + h\nu \rightarrow CO + C_2H_5N$$

The alkane products and their suppression by NO and O_2 clearly indicate the presence of CH_3 and C_2H_5 radicals, and suggest a third primary process

[11] $$C_2H_5NCO + h\nu \rightarrow C_2H_5 + NCO$$

The source of CH_3 radicals, apparently in relatively large quantities, is not so obvious. Secondary reactions of ethylene with H or NCO from secondary photolysis of HNCO were considered, but were shown not to be a source of either CH_3 or C_2H_5 by experiments in which C_2D_4 was added to the photolysis system and no deuterium was found in the alkane products. The most probable source of CH_3 would seem to be decomposition of the nitrene formed in reaction [10]

[12] $$C_2H_5N \rightarrow CH_3 + H_2CN \text{ (or } H + HCN)$$

occurring as either a concerted part of reaction [10] or a subsequent decomposition. Such a reaction gains some support from the mechanism postulated for the reactions of N atoms with alkyl radicals (11). An alternative decomposition

[13] $$C_2H_5N \rightarrow CH_4 + HCN$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

might account for the incomplete suppression of CH_4 in the presence of O_2 and NO. There is some evidence that reactions analogous to [12] and [13] occur in the photolysis of CH_3NCO, yielding HCN and H_2 or 2H (5). In considering such decompositions, which are not a feature of liquid-phase nitrene chemistry, it should be noted that in the photolyses of isocyanates in the gas phase, the photon energies are probably much in excess of the RN—CO bond dissociation energy, and much of this excess energy will reside in the nitrene as electronic and vibrational excitation. It should also be noted that HCN was not observed as a product in the present system, but there seems to be great difficulty in detecting the relatively small amounts expected in the presence of the large excess of isocyanate and HNCO.

Reaction [11] generates equal numbers of C_2H_5 and NCO radicals, and one might expect that C_4H_{10} and N_2 should be about equal if the latter arose from combination of NCO radicals. As with the $CH_3CO.NCO$ photolysis, however, the much lower yield of N_2 suggests that NCO must disappear by abstracting H from the parent compound much faster than does C_2H_5; this is compatible with other evidence for a very strong H—NCO bond in isocyanic acid (1).

The photolysis of C_2H_5NCO with monochromatic 2288 Å radiation was studied briefly in order to obtain quantum yields. The quantum yield of ethylene is shown in Fig. 3, and is seen to decline steadily with increasing pressure from a low pressure limit of about 0.45. The other products showed a similar decline. The addition of 2,3-dimethyl butane also caused a considerable reduction in yields using the mercury arc, and it seems probable that collisional deactivation of an excited state, or states, of C_2H_5NCO is responsible for these pressure effects. The value of the quantum yield of ethylene and its decline with increasing pressure are strong evidence against a chain reaction analogous to reactions [2] and [3] as the source of HNCO and C_2H_4.

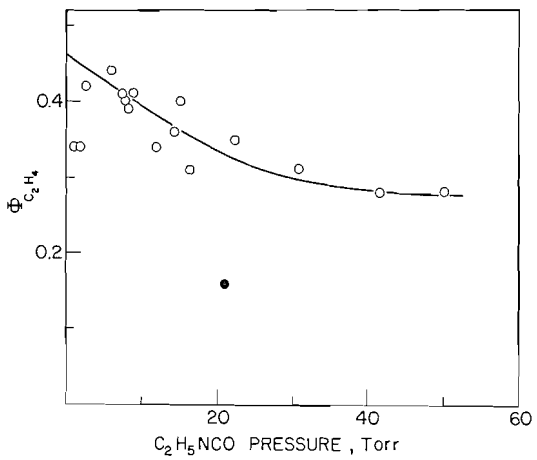

FIG. 3. Quantum yield of ethylene from the photolysis of C_2H_5NCO at 2288 Å ●; 180 Torr 2,3-dimethyl butane added.

Ethane and CO were also major products of the 2288 Å photolysis and were relatively more important than with the mercury arc. Accurate measurement of limiting low-pressure quantum yields were hampered by the relatively small amounts measured and, in the case of ethane, by an increase in yield with increasing conversion, perhaps due to photolysis of HNCO and subsequent secondary reactions. The initial limiting low-pressure quantum yield of CO was about 0.28, and that of C_2H_6 probably somewhat less. The minor products observed with the mercury arc were also formed at 2288 Å, but could not be measured with any accuracy.

It is clear that with both light sources, the molecular dissociation (reaction [9]) is the major primary process, but reactions [10] and [11] are relatively more important than their analogues in the photolysis of acetyl isocyanate. With the mercury arc, it may be estimated that reactions [10] and [11] each amounted to about 1/3 of reaction [9], while at 2288 Å they were somewhat more important.

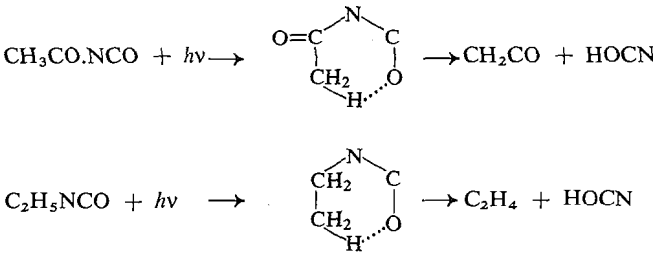
General Conclusions

The photolyses of four R—NCO compounds have now been studied in the gas phase, with R = H (1, 2), CH_3 (3, 5), C_2H_5, and CH_3CO, and some general features may be noted.

(*a*) In every case it appears that both R—NCO and RN—CO bonds are dissociated. This leads to complex secondary reactions and complicates the use of isocyanates as sources of NCO radicals or nitrenes for kinetic studies. Organic azides, by contrast, appear on photolysis to dissociate much more cleanly at the RN—NN bond, and the difference in behavior must be ascribed to the much greater stability of the NCO radical relative to N_3.

(*b*) In the photolysis of the 2 higher isocyanates studied in the present work, molecular dissociations apparently become predominant. By analogy with the higher ketones, it seems reasonable to suggest that these dissociations are

essentially Norrish Type II processes, involving 6-membered transition states



Cyanic acid, HOCN, is analogous to the enols formed in the Type II process in ketones and should rearrange rapidly at room temperature to the more stable HNCO isomer. It is interesting to note that formation of the postulated 6-membered rings requires bending of the NCO group in the excited state, presumably corresponding to an "opening" of the C=O double bond. There seems no reason to doubt that this Type II process is common to other isocyanate esters.

Oxidation of hydrocarbons in the liquid phase: *n*-dodecane in a borosilicate glass chamber at 200 °C

B. D. Boss and R. N. Hazlett
Fuels Branch, Chemistry Division, Naval Research Laboratory, Washington, D.C. 20390

Received February 17, 1969

The 5-h oxidation of *n*-dodecane at 200 °C by air at 1 atm is reported for experiments in a borosilicate glass reaction chamber equipped with a gas bubbler. The rate of reaction was limited by the rate of oxygen diffusion from the gas phase due to the rapid reaction of dissolved oxygen. The reaction products were analyzed in aliquots taken periodically from the reaction chamber. Chemical analyses, gas–liquid phase chromatography (g.l.p.c.), tandem g.l.p.c.-mass spectroscopy, infrared, and ultraviolet were used to identify products accounting for 98% of the oxygen reacted. The isomer distribution of the dodecenes, dodecanols, and dodecanones formed, as well as the distribution of carboxylic acids, were determined. Three classes of intramolecular reaction products, cyclic ethers, cyclic hydrocarbons, and lactones, were detected. Many volatile products were detected. A filterable precipitate obtained after 10 h of oxidation was studied using infrared attenuated total reflectance techniques. A reaction mechanism is discussed based on current knowledge of other systems, the products identified, and the stoichiometry of the reaction.

Canadian Journal of Chemistry, 47, 4175 (1969)

An understanding of oxidation of hydrocarbons in the liquid phase is important in several fields of technology as well as being of considerable theoretical interest. Consequently, many investigations have dealt with this subject. The detailed mechanism of the early stages (1–12) and the general mechanism of later stages have been examined (4, 10, 13–16). Often the materials used are complex mixtures of hydrocarbons (13, 17, 18). In some studies, the effect of pertinent variables, such as the solid surface, have not been considered. The solvent effect is not completely understood at this time (3, 6, 11, 19).

An appropriate mechanism for *n*-alkane oxidation can be extracted from the current theory (simplified) of the mechanism of initial stages of oxidation of saturated hydrocarbons as follows (1, 2, 10–13, 20–23)

Initiation

[1] $2RH + O_2 \rightarrow 2R\cdot + H_2O_2$

[2] $RH + O_2 \rightarrow R\cdot + HO_2\cdot$

Propagation

[3] $R\cdot + O_2 \rightarrow RO_2\cdot$

[4] $RO_2\cdot + RH \rightarrow ROOH + R\cdot$

Branching

[5] $2ROOH \rightarrow RO_2\cdot + H_2O + RO\cdot$

[6] $ROOH \rightarrow RO\cdot + \cdot OH$

Termination

[7] $RO_2\cdot + R'CHOOR'' \rightarrow ROH + R'COR'' + O_2$

[8] $RO_2\cdot + R\cdot \rightarrow ROOR$

[9] $R\cdot + R\cdot \rightarrow R{-}R$

At low temperatures where hydroperoxide, $ROOH$, is relatively stable, we expect the predominant product in the initial stages of reaction to be ROOH along with some alcohols and ketones from reaction [7] in equal amounts. Reactions [5] and [6] rapidly become more important than reactions [1] and [2] as the end of an induction period is approached. In addition, hydrogen peroxide and dialkyl peroxides (12) should participate in chain branching processes. Reactions of RO· similar to those delineated for cyclohexane lead to ketones, alcohols, aldehydes, acids, and primary alkyl radicals.

[10] $RO\cdot \xrightarrow{-H\cdot} RO$

[11] $RO\cdot \xrightarrow{+H\cdot} ROH$

[12] $RO\cdot \rightarrow R'CHO + R''$

[13] $R'CHO \xrightarrow{O_2} \text{Acids}$

In this case alcohols and ketones are the predominant products for periods up to several hours at temperatures below 180 °C (2). Clearly reactions [10] through [12] produce free radicals which can continue the chain.

The work reported here is the initial phase of a study aimed at investigating aspects of the oxidation of simple mixtures of hydrocarbons. *n*-Dodecane was selected as the major component of the mixtures because its boiling point (216.3 °C) permits liquid-phase experiments at high temperatures in an open system and it is relatively stable to oxidation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The oxidation of *n*-dodecane has been carried out in the liquid phase at 200 °C in a borosilicate glass chamber (24) at 1 atm of air. Initiation reactions ([1], [2]) were sufficiently rapid that enough air could not be supplied to simultaneously maintain an equilibrium oxygen concentration of 21% and maintain the *n*-dodecane as a bulk liquid (i.e., avoid the frothy state). Thus, the reaction was limited by the rate of oxygen diffusion from the gas phase. The gas exhaust contained 17.8% O_2. The reaction has been studied over a period of 5 h, and 98% of the absorbed oxygen has been accounted for in the products identified using gas–liquid phase chromatography (g.l.p.c.), g.l.p.c.-mass spectroscopy, infrared (i.r.), ultraviolet (u.v.), and chemical analyses. This thorough analysis allows us to suggest a macroscopic reaction mechanism based on the products identified, the stoichiometry of the reaction, and current knowledge of reaction mechanisms tested for similar systems.

Experimental

Reagents

n-Dodecane was obtained from Phillips Petroleum Co. as 99.7$^+$% pure grade. The material was passed through drierite, activated alumina, and silica gel to remove traces of polar impurities. The only major impurity identified by g.l.p.c. was *n*-hendecane (0.15%).

Apparatus

A diagram of the reaction vessel is presented in Fig. 1. The O-ring seal glands assure a tight fit. The chamber can be conveniently replaced with cylinders of various materials. The borosilicate glass chambers were prepared from different lots of glass stock and exposed to chromic acid cleaning solutions for 1 week followed by soaking and rinsing first in ammonia and then in distilled water. Collection tubes of drierite, of ascarite, and of borosilicate glass wool (cooled in dry ice – acetone) are connected to the chamber exhaust. The exhaust passes finally through a gas sampling valve in a Fisher Scientific Co. gas partitioner used to analyze the oxygen concentration. The reaction temperature was maintained by a heated, fluidized alumina bed.

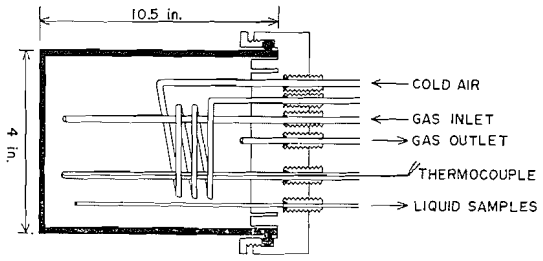

FIG. 1. Cylindrical reaction chamber with polytetrafluoroethylene cap and cooling coil; silicone rubber O-ring seals.

Reaction Conditions

The reaction chamber was maintained at 200.5 °C with oscillations of ±0.8 °C. The pressure was maintained at 10 mm above the generally prevailing 750 mm Hg atmospheric pressure. Dry air, with the CO_2 removed, was bubbled through the liquid at 260 cm^3 min^{-1}. Diffusion controlled kinetics (25) are expected (see discussion in introductory section).

The original charge of 325 ml of *n*-dodecane was sampled in seven 25-ml aliquots. Three runs were performed using air and one run was made with N_2 containing 160 ± 20 p.p.m. of O_2. In each case an analysis was made of all accessible products in the chamber and in the collection tubes.

A further experiment was performed at 200 °C using *n*-dodecane at air flow rates between 260 and 4500 cm^3 min^{-1}. In Fig. 2 the rate of accumulation of 4-, 5-, and 6-dodecanone is plotted as a function of flow rate. We conclude that to maintain the reaction in the kinetic region, at least 4000 cm^3 min^{-1} of air must be bubbled through the liquid with the configuration shown in Fig. 1. Thus it is not practical to perform experiments at 200 °C in the kinetic region and avoid a frothy state of the dodecane.

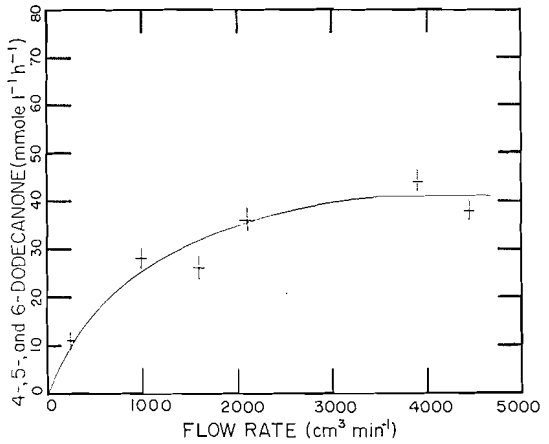

FIG. 2. Effect of air input flow rate on rate of formation of the combined ketones, 4-, 5-, and 6-dodecanone, at 200 °C. Measurements are made on randomly selected flow rates.

Chemical Tests

Hydroperoxide was determined by a minor variation of the colorimetric iodine method of Heaton and Uri (26). A spectrophotometric variation of Mair and Graupner's (27) method II was developed, but no dialkyl peroxide was detected in the product mix. No H_2O_2 was detected in a water extraction of the product mix. Carbonyl was determined by the very sensitive colorimetric method of Lappin and Clark (28). Acids and esters were determined according to American Society for Testing Materials test methods D974-58T (alcoholic KOH titration) and D94056T (saponification), respectively.

Chromatographic Analyses

Each liquid sample was analyzed by g.l.p.c. immediately after sampling (Fig. 3). In addition, chromatograms were

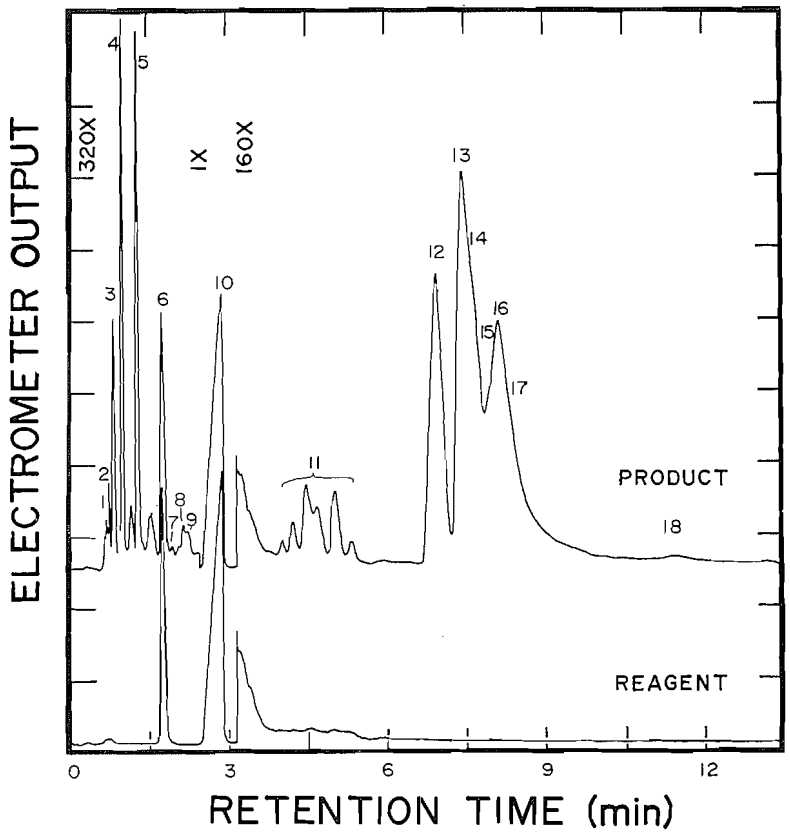

FIG. 3. Gas chromatograms of the *n*-dodecane starting material and of the reaction products after 5 h. Chromatographs obtained using a 100 ft × 0.020 in. i.d. DC-550 silicone oil support-coated open tubular column with a He carrier gas supplied at 35 p.s.i. (4 ml/min). The following temperatures were used: column, 126 °C; injector, 200 °C; flame ionization detector, 270 °C. The products were identified as follows: (1), *n*-hexane; (2), *n*-heptane; (3), *n*-octane; (4), *n*-nonane; (5), *n*-decane; (6), *n*-undecane; (7), decanone; (8), decanal; (9), C_{12} single ring alicyclics; (10), *n*-dodecane; (11), cyclic C_{12} ethers; (12), 6-, 5-, and 4-dodecanone; (13), 6- and 5-dodecanol; (14), 3-dodecanone; (15), 4-dodecanol; (16), 2-dodecanone; (17), 3-dodecanol; (18),2-dodecanol.

obtained on the liquid after reaction with benzoyl chloride (Fig. 4), and after reaction with hexamethyldisilazane (29) (Fig. 5). These derivative chromatograms were necessary to separate the dodecanol isomers from the dodecanone isomers by analyzing displacements of the alcohol peaks. Hydroperoxides do not interfere with the scheme presented here.

The distribution of the non-volatile carboxylic acids formed was determined by extraction of the reaction residue with 1 *N* KOH, neutralization with HCl, and formation of the methyl esters with a methanol–BF_3 reagent mixture (30). Chromatograms of this reaction mixture gave the distribution of the C_5 through C_{12} carboxylic acids. These acids were almost completely retained in the reaction chamber at 200 °C. Comparable treatment of a known acid mixture was used to verify the analysis.

Dodecenes were detected by bromination of the product mixture followed by g.l.p.c. under the conditions in Fig. 3 but with a column temperature of 150 °C. Peaks for monobromo-substituted dodecanes were detected and reaction with alcohols and ketones was observed. However, a set of dibromo dodecanes was eluted after a considerable time lag. Tests were made to identify, to measure quantitatively, and to establish any interference made by the alcohol and ketone products. No interferences were detected.

Mass Spectra

The mass spectra were obtained with a CH-4 Atlas mass spectrometer (with double ion source) fed by an F and M 810 gas chromatograph (31). The interface was a stainless steel capillary tube heated to 250 °C. The 200:1 exit split on the gas chromatograph effluent which was attained in this manner was effective for qualitative analysis purposes. Neither a polytetrafluoroethylene nor a sintered glass molecular separator (31) afforded adequate separation of the sample from the He carrier.

Absorption Spectra

Spectra of the product mixture in the i.r., u.v., and visible regions were obtained. A solid material which

precipitated after 10 h of oxidation was examined using i.r. attenuated total reflectance (a.t.r.) techniques on a Perkin–Elmer 457 dual grating spectrophotometer.

Results

The blank reaction using N_2 with 160 ± 20 p.p.m. O_2 contained 0.37 mmole l^{-1} of hydroperoxide as the only product detected after 5 h. Using air, numerous compounds were detected in a 5-h experiment as listed in Table I. The reaction consumed 9.4% of the *n*-dodecane starting material and at least 80% of the products have the same carbon backbone. The listed products account for consumption of 0.364 mole l^{-1} of oxygen. The exhaust contained 17.8% O_2. The oxygen uptake, as determined from the difference between the input and exhaust levels, was 0.370 mole l^{-1}. Thus 98% of the oxygen is accounted for. No induction period is observed for early products.

The starting material and reaction product mixture chromatograms are reproduced in Fig. 3. Intramolecular reaction products, cyclic C_{12} ethers, cyclic C_{12} hydrocarbons, and lactones (some of which are C_{12}) have been identified using combined information from mass spectra, g.l.p.c. and/or i.r. Some of the lactones appear

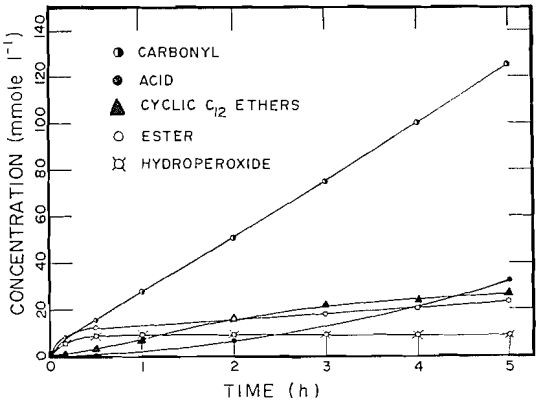

FIG. 6. Concentration of selected reaction products as a function of time under the conditions specified in the text.

from the i.r. absorption to be strained rings (i.e., less than 5-membered).

Concentrations of the major products determined by g.l.p.c. and chemical analysis are plotted in Figs. 6 and 7. The net carbonyl is the difference between the total carbonyl and the dodecanone concentration. Note that the net carbonyl concentration builds up at first and levels off rapidly. The peaks in the gas chromatograms which can

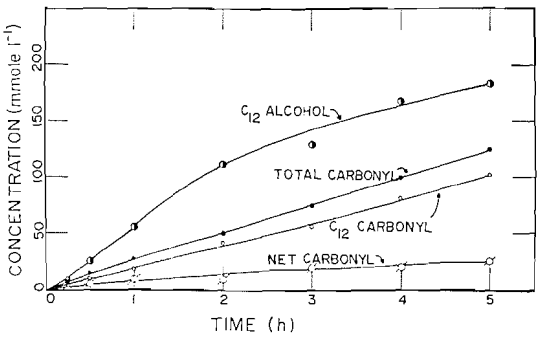

FIG. 7. Concentration of selected reaction products as a function of time under the conditions specified in the text.

be assigned to lower molecular weight aldehydes exhibit similar behavior.

It would be interesting to calculate the amount of water expected by accounting for all the hydrogen atoms in the product mixture. However, this would require a very accurate knowledge of all the volatile hydrocarbon products that escaped from the chamber. Thus, no such analysis was attempted.

Besides CO_2 and H_2O, insoluble products (gums) can form after considerable oxidation. No filterable material was detected after 5 h, but after 10 h a considerable amount was formed. This material was easily dissolved in acetone, coated on an a.t.r. plate, and dried for i.r. analysis. Significant absorption at 3460, 1790, 1650, 1180, 1050, and 1730 cm^{-1} indicate that this gum contains high concentrations of hydroxyl, acid, ester, and carbonyl groups. This information indicates that the gum contains highly polar molecules, some of which are capable of forming hydrogen bonds and possibly micelles (32).

Further details of the reaction were ascertained using g.l.p.c. The distributions of dodecanols, dodecanones, and carboxylic acids were examined. The distribution of C_5 to C_{12} straight chain monobasic acids relative to C_7 is as follows

Distribution of straight chain monobasic acids

No. of C	Relative amount	No. of C	Relative amount
5	5	9	7.5
6	9	10	4.5
7	10	11	0.9
8	9	12	0.4

Kudo *et al.* (15) have determined the isomer distributions for oxidation of *n*-decane under somewhat different conditions. Their observations are comparable to ours except that decanoic acid was relatively less plentiful than we observed for dodecanoic acid. Dawkins has noted the virtual absence of C_{11} acid among the oxidation products of *n*-dodecane (12).

The point of oxidative attack along the carbon chain is indicated by the data in Table II since the alcohols and ketones are abundant, relatively stable products. We conclude that the C-2 position is favored if the reasonable assumption is made that each of the 3 isomers determined in the combined C-4, -5, and -6 peak constitutes 1/3 of the total peak. Favored attack at C-2 was not observed in some studies performed in the kinetic reaction region by other workers (4, 8, 18, 23). Recent studies by Dawkins (13) tend to support preferential attack at C-2. Selectivity may be controlled by peroxy, alkoxy, and alkyl radical attacks on dodecane.

TABLE II

Isomers of dodecanol and dodecanone

Time*	Position of the functional group	% Isomer present	
		Dodecanones	Dodecanols
30 min	C-1	1.1±0.5†	—
	C-2	24.5±0.7	25.3±0.7
	C-3	19.0±0.7	18.2±0.7
	C-4, -5, -6	55.4±0.5	55.4±0.5
5 h	C-1	1.1±0.5	1.0±0.5
	C-2	25.5±0.7	25.4±0.7
	C-3	18.4±0.7	18.5±0.7
	C-4, -5, -6	55.0±0.5	55.1±0.5

*Under the conditions specified in the text.
†Dodecanal.

Dodecene was determined as 41 mmoles l^{-1}. The six isomers were distributed relative to the 4-dodecene isomer as follows

Relative distribution of dodecene isomers

Isomer	Relative amount	Isomer	Relative amount
1-C_{12}	2	4-C_{12}	10
2-C_{12}	5	5-C_{12}	6
3-C_{12}	12	6-C_{12}	2

This distribution is different from that found for the dodecanol and dodecanone isomers.

A close examination of the mass spectra of the eluted lighter-weight *n*-alkanes failed to detect

For personal use only.

olefins. These analyses indicate the absence of any one such olefin above about 0.2 mmole l^{-1}.

Discussion

The data should be considered in the light of the restrictions associated with a bubbler reaction chamber operating under diffusion limited kinetics: loss of volatile products, possible vapor phase reactions, surface catalysis, and oxygen concentration gradient. In addition, taking samples of finite size (25 ml) changes the surface-to-volume ratio from 0.64 cm^{-1} at the beginning to 0.85 cm^{-1} at the end (24) of the experiment.

The limited mechanism scheme presented above provides an adequate, but simplified (11, 12) framework for the major course of the reaction. The absence of an observed induction period is the result of the time scale for sampling and the deficiency of oxygen in the experiment. Oxygen was limited to a steady rate perhaps 20 times below the kinetic rate. The considerable quantities of dodecene formed might be the result of the infrequent collisions of dodecyl radicals with O_2 molecules. The smaller alkyl radicals apparently formed few peroxy radicals for the same reason, but instead abstracted a hydrogen atom from the abundant dodecane solvent. We note the early appearance of hydroperoxides and the accumulation of considerable quantities of dodecanols and dodecanones. Similar isomer distributions for the dodecanols and dodecanones indicate a common precursor (i.e., hydroperoxide or peroxy radical). Though neither H_2O_2 nor dialkyl peroxides was detected, they still are likely to participate in chain initiation.

A slight leveling off of the dodecanol concentration indicates further reaction to form the ketone (1, 10). The series of short chain *n*-alkanes (C_6–C_{10} in the liquid phase, and C_4–C_8 from the vapor trap) and the series of aldehydes (C_5–C_{11} seen by the g.l.p.c. and measured as the net carbonyl) are reaction products predicted by the mechanism scheme for an alkoxy radical undergoing chain scission (reaction [12]). This reaction has been observed in hydroperoxide decomposition (33). The quantity of C_1–C_{11} *n*-alkanes cannot be accounted for by chain scission during acid formation from the ketone and/or alcohol (13). We estimate that the net carbonyl plus the carboxylic acids can account for the *n*-alkanes (allowing for loss of volatile components) in support of the above mechanism. Some decarbonylation of aldehydes seems likely. Further evidence that acids are formed by a later reaction (i.e., from aldehydes and/or esters) is the absence of an induction period for the formation of hydrocarbons, but a considerable time lag for acid formation.

There are two others features of the reaction to be discussed: the early formation of esters and the formation of intramolecular compounds. Intramolecular reaction products, cyclic hydrocarbons, cyclic ethers, and lactones, may be the result of vapor-phase reactions. A cyclic C_{12} hydrocarbon may form by the cyclization of a dodecyl free radical with loss of a hydrogen atom, while loss of water from dodecylhydroperoxide through a 5- or 6-membered transition state may account for cyclic ethers. Berry *et al.* (34) have determined a plausible mechanism in the gas phase. Both of these products appear early in the reaction. The method of formation of lactones is not clear at this time. Dodecene is a possible source.

Esters are an early product of the oxidation. Determined by saponification, the ester content does not include hydroperoxides, which decomposed to alcohols and ketones in alcoholic KOH. Lactones are included as esters. Esters are not the product of esterification between accumulated acid and alcohol molecules, since acids form only after a considerable time lag. Indeed, as water accumulates, esters are a likely source of acids by hydrolysis. To account for ester formation, rearrangement from an α-hydroperoxyketone has been suggested (35). The presence of this intermediate can be inferred by the accumulation of α-hydroxyketones (18). Further, we have observed absorption at 310 mμ which might be attributed to vicinal diketones.

Dawkins suggests that esters are formed by reaction of an alkoxy free radical with a *gem*-hydroperoxyalkyl free radical R′ĊOOHR″ to form the 3° ether hydroperoxide which can decompose to an ester. This would presumably yield esters early in the oxidation as we have noted. The reaction of a peracid (from aldehyde oxidation) with a ketone (12) can also yield an ester by the Baeyer–Villiger reaction.

Kinetics of the acetone-photosensitized addition of HBr to ethylene

K. T. WONG[1] AND D. A. ARMSTRONG
Chemistry Department, The University of Calgary, Calgary, Alberta

Received May 26, 1969

The kinetics of the acetone-sensitized photoaddition of HBr to ethylene are consistent with the free radical chain mechanism of Vaughan, Rust, and Evans. In the presence of excess propane the combination of bromine atoms (reaction [4]) is the main termination step, and bromoethyl radicals formed by the addition of bromine atoms to ethylene (reaction [2]) are collisionally stabilized. They undergo thermal decomposition (reaction [−2]) or abstract a hydrogen atom from hydrogen bromide (reaction [3*a*]) to form the product, ethyl bromide. The rate constant ratio, k_{-2}/k_{3a}, increases from 5.6×10^{18} molecules cm^{-3} at 15.3 °C to 11.5×10^{18} molecules cm^{-3} at 45.0 °C. This corresponds to $E_{-2} - E_{3a} = 4.5 \pm 0.5$ kcal $mole^{-1}$, and is in accord with the thermochemical data. Within experimental error, k_2 and k_{-2} are independent of propane pressure in the range 260 to 390 Torr. Also, $(2k_4[M]/k_2)^{\frac{1}{2}}$ is equal to $5.5 \pm 0.3 \times 10^8$ $cm^{3/2}$ $molecule^{-1/2}$ $s^{-1/2}$, independent of temperature over the range 15.3 to 45.0 °C, and $E_2 = 0.0 \pm 0.5$ kcal $mole^{-1}$. In the absence of propane, and at ethylene pressures in excess of 400 Torr, the combination and disproportionation of bromoethyl radicals is the main termination process (reaction [7]). The value of $k_{3a}/(2k_7)^{\frac{1}{2}}$ is $8.9 \pm 0.1 \times 10^{-10}$ $cm^{3/2}$ $molecule^{-1/2}$ $s^{-1/2}$ at 35.1 °C, in agreement with kinetic data for related reactions.

Canadian Journal of Chemistry, 47, 4183 (1969)

Introduction

During the past 15 years, extensive studies of the photochlorination of ethylene and its derivatives have contributed much to our understanding of the reactions of chloroethyl radicals (1–5). In contrast, few investigations of the analogous bromination and hydrobromination reactions have been reported, and there is a noticeable lack of information on bromoethyl radicals (6, 7).

The only kinetic investigation of the photobromination of ethylene appears to be that of Schmitz, Schumacher, and Jager (8), who confirmed its free radical chain mechanism in 1942. The chain character of the gas phase hydrobromination was established in the same year by Vaughan, Rust, and Evans (9). The kinetics of the latter reaction were not studied in detail, but thermodynamic considerations (10) show unequivocally that bromine atoms and bromoethyl radicals are the chain carriers. Since the same situation holds for the photobromination, the mechanisms of the 2 additions differ only in reactions [3*a*] and [3*b*] in the following reaction sequence

[1] $\quad X + h\nu \xrightarrow{I_a} \phi Br$

where X = HBr, Br_2, or a sensitizer

[2]/[−2] $\quad Br + C_2H_4 \rightleftarrows C_2H_4Br$

[3*a*] $\quad HBr + C_2H_4Br \rightarrow Br + C_2H_5Br$

[3*b*] $\quad Br_2 + C_2H_4Br \rightarrow Br + C_2H_4Br_2$

[4] $\quad Br + Br + M \rightarrow Br_2 + M$

[5] $\quad Br \xrightarrow{k_d}$ (Br on wall) $\rightarrow \frac{1}{2}Br_2$

[6] $\quad C_2H_4Br + Br \rightarrow C_2H_4Br_2$ or $C_2H_4 + Br_2$

[7] $\quad 2C_2H_4Br \rightarrow C_2H_4Br_2 + C_2H_4$ or $C_4H_8Br_2$

Armstrong and Spinks (11) studied the hydrobromination in 1959. Since their prime objective was to demonstrate the catalysis of gas phase chain addition reactions by ionizing radiation, they used ^{60}Co γ-rays as the initiating source. At ethylene pressures below 100 Torr, the reaction bore a strong resemblance to the photobromination. Similarities were: linear termination, attributed to reaction [5]; a negative temperature coefficient, ascribed to the occurrence of reaction [−2]; and a value of about 6×10^{-14} cm^3 $mole^{-1}$ s^{-1} for k_2. The only apparent discrepancy between the 2 sets of data lay in the values of $E_{-2} - E_{3a}$ and $E_{-2} - E_{3b}$, which were estimated to be 14 ± 2 and 6 ± 1 kcal $mole^{-1}$, respectively. Since Anderson and Van Artsdalen (12) had observed $k_{3c}/k_{3d} = 0.6$,

[3*c*] $\quad C_2H_5 + HBr \rightarrow C_2H_6 + Br$

[3*d*] $\quad C_2H_5 + Br_2 \rightarrow C_2H_5Br + Br$

independent of temperature over the range 35 to 90 °C, the difference was much larger than

[1]Present address: Chemistry Department, Northern Alberta Institute of Technology, Edmonton, Alberta.

For personal use only.

expected, and the authors noted the need for more extensive studies to resolve this problem.

Kinetic and thermochemical data from related chemical systems now make it possible to reject the high value of $E_{-2} - E_{3a}$. From published heats of formation at 298 °K and 1 atm

$$\Delta H^0_f \text{ of } C_2H_5Br = -15.0 \pm 0.3 \quad \text{(ref. 13)}$$

$$\Delta H^0_f \text{ of } C_2H_4 = 12.5 \quad \text{(ref. 14)}$$

and

$$\Delta H^0_f \text{ of HBr} = -8.7 \text{ kcal mole}^{-1} \quad \text{(ref. 14)}$$

the heat of reaction [I]

[I] $$C_2H_4(g) + HBr(g) = C_2H_5Br(g)$$

is -18.8 ± 0.5 kcal mole^{-1}. The heat of reaction [3*a*] should not differ by more than 1 kcal mole^{-1} from that of reaction [3*c*], which is 10.5 kcal mole^{-1} (15). Thus, $\Delta H_2^0 = -8.3$[2] and $\Delta E_2^0 = -7.7$ kcal mole^{-1}. This was pointed out previously by Barker and Maccoll (16), whose value of

$$E_{-2} + E_{-3a} = 21.2 \text{ kcal mole}^{-1}$$

requires

$$E_{3a} \simeq 3.0 \text{ kcal mole}^{-1}$$

as shown on the energy level diagram in Fig. 1. By analogy with chlorine atom addition to ethylene (1, 2), E_2 is probably 0. In any case, it is most unlikely that E_2 exceeds E_{3a}, and, since

$$E_{-2} - E_{3a} = -\Delta E_2 + E_2 - E_{3a}$$

(see Fig. 1), values of $E_{-2} - E_{3a}$ larger than 8 kcal mole^{-1} can be excluded. Indeed, the high apparent value of

$$E_{-2} - E_{3a} = 14 \pm 2 \text{ kcal mole}^{-1}$$

implies that the radiation-induced addition cannot be explained purely on the basis of the foregoing free radical mechanism. Thus, there is an obvious need for further work on the kinetics of the hydrobromination reaction, and it was for this reason that the present study was undertaken. The main objectives were to provide kinetic verification of the Vaughan, Rust, and Evans mechanism (9), and to determine the conditions under which the various termination reactions occurred. A preliminary report of some of our results was published in 1966 (17).

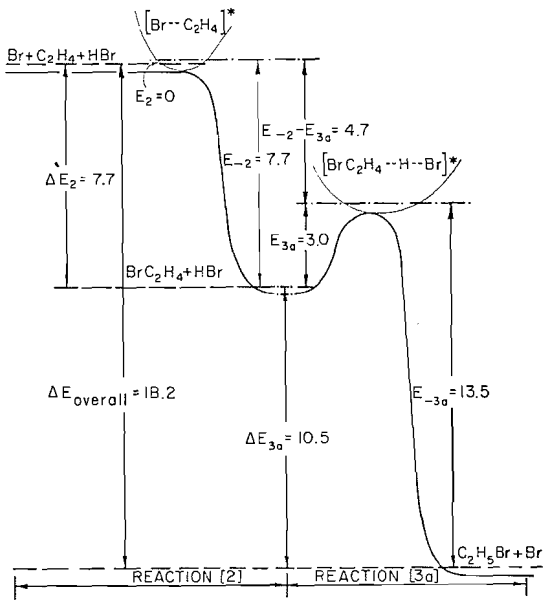

FIG. 1. Energy level diagram for reactions [2] and [3].

While this study was in progress, 3 other investigations of the hydrobromination were published. Abell's initial work (18*a*) was primarily concerned with the relative rates of addition of bromine atoms to different olefins and did not deal with the kinetics of the ethylene reaction per se. In a more recent publication with Field (18*b*), he has reported a study of the kinetics of the addition reaction at temperatures in the range 40–125 °C and pressures of 25–125 Torr. Their observations will be considered in the Results and Discussion sections below. Oldershaw and Cvetanović (19) showed that the hydrobromination of *cis*-1,2-dideuteroethylene was accompanied by a rapid isomerization. They interpreted this in terms of reactions [2*], [−2*], [8*], and [9*]

[2*]/[−2*] $$Br + C_2H_4 \rightleftarrows C_2H_4Br^*$$

[8*] $$C_2H_4Br^* + M \rightarrow C_2H_4 + Br + M$$

[9*] $$C_2H_4Br^* + M \rightarrow C_2H_4Br + M$$

The above presentation represents a slight generalization of their hypothesis, for they postu-

[2] Essentially the same result (-8.2 kcal mole^{-1}) is obtained from the data of ref. (14) by a similar treatment of reactions [II]

[II] $$Br_2(g) + C_2H_4(g) = C_2H_4Br_2(g)$$

and [3*b*]. We also note that Kerr and Lloyd (7) report $\Delta H_2^0 = -8.8$, based on thermodynamic data.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

lated reactions [8*] and [9*] for M = HBr only. However, this generalization is necessary (3) and it follows that k_2 is a complex rate constant equal to

$$\frac{k_2^* \sum_M k_9^* [M]}{\sum_M k_8^* [M] + \sum_M k_9^* [M] + k_{-2}^*}$$

in the first approximation (a more complete treatment of the pressure dependence of k_2 is to be found in ref. 20).

It is clear from Oldershaw and Cvetanović's work and from the related observations on chloroethyl radicals, that an efficient deactivator, M, must be added to the reaction bath if the bromoethyl radicals are to be stabilized and brought to thermal energies. For this reason, most of our experiments at low ethylene pressures were conducted in the presence of 260 to 400 Torr of propane, which would be expected to have a high efficiency for deactivating $C_2H_4Br^*$ radicals. By contrast, HBr, which resembles krypton in terms of size and mass, should be relatively inefficient. As an illustration, it may be noted that krypton removes only ~ 2 kcal mole^{-1} of excess energy in the average collision with activated alkyl radicals, while C_3 and C_4 hydrocarbons remove $\geqslant 9$ kcal mole^{-1} (21). The addition of propane has a second simplifying effect in eliminating reaction [5] (see below).

One further point deserves comment here. At 2537Å, ethyl bromide has an extinction coefficient about twice that of HBr (22). Because of this, it was decided that a sensitizer, which absorbed at wavelengths longer than either of these molecules, should be used. This procedure avoided changes in the absorbed light intensity and rate of initiation during the course of a run and also provided a far more uniform absorbed light intensity than would have been possible with HBr as the light absorbing species. After preliminary trials of a number of compounds, acetone was chosen as the sensitizer. Its photolysis in the presence of HBr had been investigated in 1955 by Ridge and Steacie (23). During the course of this work, a more comprehensive study was published by Larson and O'Neal (24). Their results will be reviewed in the Discussion section.

Experimental

Materials

Matheson Co. anhydrous HBr of 99.8% purity was irradiated with a ^{60}Co γ-ray source as previously described (25) to remove impurities which were reactive to Br atoms. It was then sublimed through copper turnings to remove bromine, and further purified by several distillations from a trap at -120 °C to a trap cooled by liquid nitrogen. Philips research grade ethylene was degassed by bulb-to-bulb distillation and pumping. Matheson sulfur hexafluoride and ethyl chloride were treated in the same way. Spectrograde acetone was purchased from the Eastman Kodak Co. and thoroughly degassed by freeze–pump–thaw cycles before use.

Apparatus

The cylindrical quartz reaction cell was 10 cm long and had optically plane end windows. Its internal diameter was nominally 4.0 cm, and its volume 111.41 cm^3. It was connected to a mercury-free vacuum line and immersed in a thermostat tank which was regulated to within ± 0.03 °C. The tank and cell were mounted on a rugged optical bench.

Light from the Osram 100 W/2 high pressure mercury light source passed through a series of collimating quartz lenses, 2 filter glasses (Corning 0–53 and 7–54), and a 3×10^{-4} M K_2CrO_4 solution of 3 cm path length. The wavelengths of the emerging beam extended from 3050 to 3250 Å, with a maximum at 3125 Å. The incident light intensity was measured by a photometer, which had been calibrated against the ferri-oxalate actinometer (26). The absorbed light intensity, I_a, was calculated from the incident light intensity, I_0, and the acetone concentration in the reaction cell. The usual corrections were made for light losses in the cell windows, etc. (27). The effective extinction coefficient of acetone for the incident light spectrum was calculated to be 2.4 l mole^{-1} cm^{-1}, which compares well with an experimentally determined value of 1.97 for a similar light source (24). In a typical run, only about 0.7% of the light was absorbed over the length of the cell and I_a was taken to be uniform, within experimental error.

The absorbed light intensity was varied by using lamps of different output intensity, by changing the acetone pressure, or by changing the focal length of the first collimating lens. Care was taken to ensure that the light beam through the cell was homogeneous and parallel. It was defined by an iris diaphragm with a diameter only about 1 mm less than that of the cell. This procedure reduced the unirradiated volume of the cell to a minimum and avoided uncertainties caused by reactions of bromine atoms which diffused out of the light zone.

The rate of the overall addition (i.e., of reaction [1]) was measured by the decrease in pressure. For experiments to determine the light intensity dependence, the pressure was monitored with a Pyrex diaphragm gauge (28). For most other experiments, a Pyrex spiral gauge (Kern Chemical Corporation) with an optical lever was used. Both gauges were calibrated against a mercury manometer in an auxiliary vacuum system.

Procedure

For each experiment, the desired pressure of acetone vapor was admitted to a calibrated volume. This was isolated while the acetone vapor was pumped from the remainder of the system. The contents of the calibrated volume were then admitted to the reaction cell and flushed through the connecting tubes with measured

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

amounts of ethylene and HBr. This procedure gave reproducible rates. It was adopted after initial experiments showed that acetone and HBr reacted when condensed together at liquid nitrogen temperature (cf. ref. 24). When required, propane was introduced along with the HBr and ethylene. After all gases had been expanded into the reaction cell, the system was allowed to stand for about 25 min before photolysis commenced.

More extensive details of the apparatus and experimental procedures are given in ref. 22.

Results

The experiments fall into 3 categories: experiments with excess ethylene, experiments at ethylene pressures below 100 Torr with only the reactants present, and experiments at ethylene pressures below 100 Torr with propane and other added gases. Before presenting them under these 3 headings in sections (*iii*), (*iv*), and (*v*), we shall first describe the general features of the reaction.

(i) Reaction–Time Curves

Figure 2 shows plots of pressure decrease vs. time for experiments both with and without added propane. In each case, data are given for 2 almost identical experiments. The curves are typical of those used to obtain reaction rates, and they illustrate the precision which was achieved. The inset of Fig. 2 shows pressure changes recorded with the Kern spiral gauge for photolysis over 1 min periods followed by equal dark periods. The initial pressure rise, and the pressure decrease occurring after illumination ceased, are due to the heat liberated in the reaction (i.e., to the Budde–Draper effect). The induction periods observed in the reaction–time curves for continuous photolysis (main Fig. 2) are due mainly to this effect. It cannot be entirely eliminated, but in kinetic runs reaction conditions which caused the average temperature of the cell contents to rise by more than 2 °C above the thermostat temperature were avoided. Reaction rates were determined from the slopes of the reaction–time curves after about 10% reaction or, when possible (see below), from first order log plots for ethylene consumption.

When photolysis was continued until reaction ceased, the pressure drop corresponded to the initial pressure of the reactant present in stoichiometric deficiency. Analysis of the reaction mixture with an AEI type MS2 mass spectrometer confirmed that ethyl bromide was the only major product in systems both with and without added propane. No peaks of mass greater than the parent peak of ethyl bromide were detectable. Thus, C_4H_9Br and $C_2H_4Br_2$ can, at most, only be formed in trace quantities; also, the bromination of propane cannot be of any importance. Detection of "termination" or "initiation" products was not expected, since their partial pressures would have been of the order of 0.04 Torr in a total pressure of ~ 400 Torr.

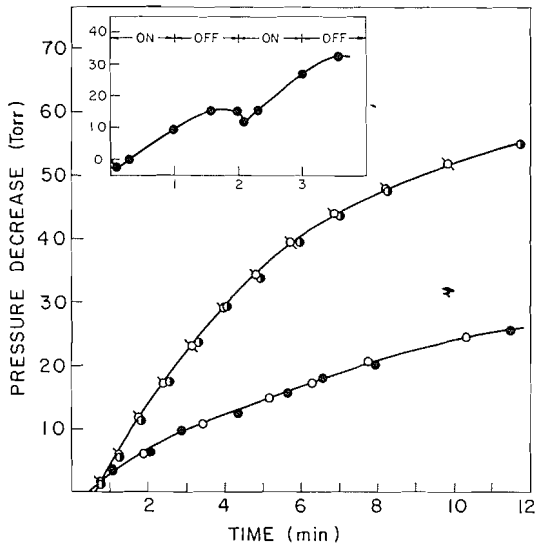

FIG. 2. Pressure decrease vs. time curves for reaction at 25.0 °C. Main figure: continuous illumination with points taken only after induction period. Inset: intermittent illumination; points taken to show the initial pressure increase and the pressure decrease after the light period. Both are caused by the Budde–Draper effect.

(ii) The Effect of Light Intensity on Reaction Rate

Table I summarizes the intensity exponents for experiments under the 3 different sets of conditions mentioned above. They were derived from the least-squares slopes of log–log plots. Those shown in Fig. 3*a* are for experiments with HBr in excess, and the intensity exponents lie between 0.5 and 1.0. For all other conditions, the intensity exponents were close to 0.5, indicating that mutual termination was almost exclusive.

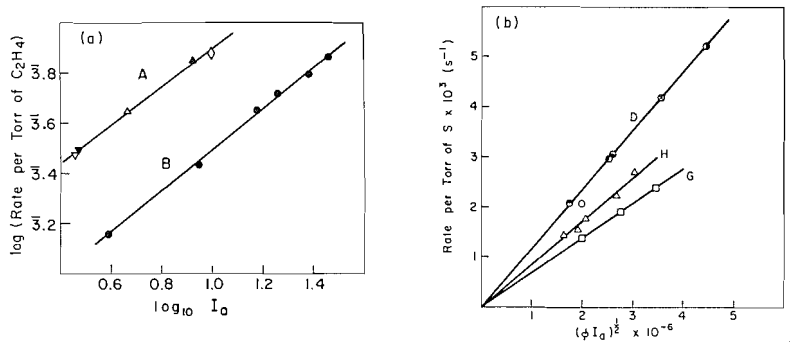

FIG. 3. Dependence of reaction rate on light intensity (*a*) $\log_{10}$ (reaction rate per Torr of C_2H_4) vs. $\log_{10}$ (absorbed light intensity) at 25 °C. Conditions for plots A and B are given in Table I, with more detailed data for plot A in Table II. (*b*) Reaction rate normalized with respect to *S* plotted as a function of $(\phi I_a)^{\frac{1}{2}}$. Conditions for plots D, H, and G are given in Table I, with more detailed data for plot D in Table II. S = C_2H_4 for plot D and S = HBr for plots H and G.

Figure 3*b* shows a graph of reaction rate vs. $(\phi I_a)^{\frac{1}{2}}$ for the experiments of code numbers D, G, and H in Table I. The linearity confirms the dependence of reaction rate on $(\phi I_a)^{\frac{1}{2}}$. The acetone pressures and incident light intensities, I_0, used in obtaining the data for plot D of this figure and plot A of Fig. 3*a* are given in Table II. The data illustrate the fact that the intensity dependence is the same whether I_a is altered by changing I_0 or the acetone pressure over a factor

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of 4. From this it may be concluded that acetone serves only as a photosensitizer and that it does not take part in the propagation or termination reactions. It may also be noted that in the absence of acetone, HBr–ethylene mixtures showed no measurable reaction after photolysis with our light system for periods of up to 1 h.

(iii) Experiments with Excess Ethylene

The reaction rate at 35.1 °C was studied as a function of ethylene pressure over the range 100 to 590 Torr with the HBr pressure held to 60 ± 6 Torr and the absorbed light intensity kept as close as possible to 2.9×10^{12} photons $cm^{-3}\ s^{-1}$. As shown in Fig. 4*a*, the reaction rate becomes independent of ethylene pressure above 380 Torr.

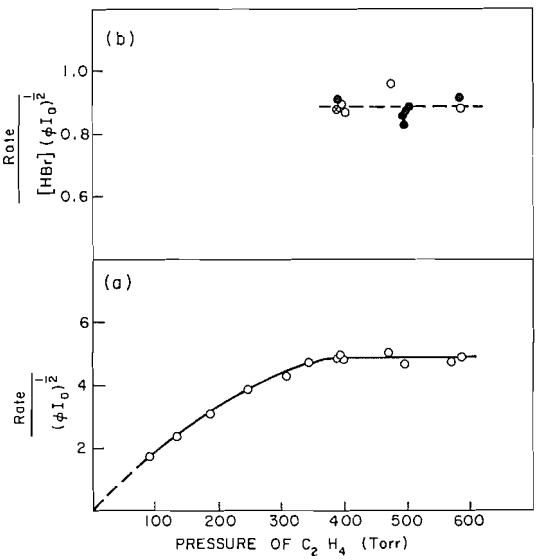

FIG. 4. Dependence of reaction rate on ethylene pressure at 35.1 °C; ethylene in excess. (*a*) Reaction rate $\times (\phi I_a)^{-\frac{1}{2}}$ for $I_a \simeq 2.9 \times 10^{12}$ photons $cm^{-3}\ s^{-1}$ and [HBr] = 60 ± 1 Torr, plotted against ethylene pressure. (*b*) Rate $\times (\phi I_a)^{-\frac{1}{2}} \times [HBr]^{-1}$ plotted vs. ethylene pressure. HBr pressure: 60 Torr, ○; 32 Torr, ⊗; 45 Torr (with I_a varied), ●.

From the linear plot of rate vs. HBr pressure in Fig. 5, the reaction is first order in HBr at high ethylene pressures. The empirical rate expression for experiments with ethylene in excess is therefore

$$[i] \qquad \frac{d[C_2H_5Br]}{dt} = k'[HBr]I_a^{\frac{1}{2}}$$

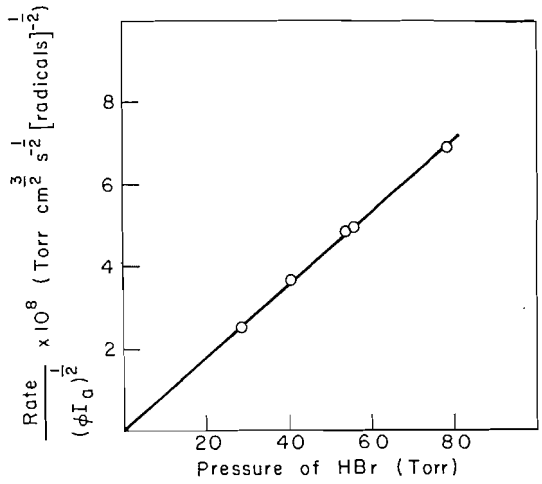

FIG. 5. Reaction rate $\times (\phi I_a)^{-\frac{1}{2}}$ plotted against HBr pressure. Temperature = 35.1 °C; ethylene pressure = 395 Torr.

(iv) Experiments at Ethylene Pressures Below 100 Torr with Only the Reactants Present

As the ethylene pressure is reduced below 400 Torr, the ethylene exponent increases (see Fig. 4*a*). Below 100 Torr it becomes unity. This was demonstrated by the fact that plots of initial reaction rate vs. ethylene pressure were linear. First order log plots showed that this dependence was maintained up to about 50% addition, beyond which there was a tendency for the rate to increase. A similar effect was observed by Field and Abell (18*b*) and attributed to the greater efficiency of ethyl bromide (than HBr and ethylene) as a deactivator of $C_2H_4Br^*$.

(v) Experiments at Ethylene Pressures Below 100 Torr with Propane and Other Added Gases

The effects of added gases on the reaction rate are illustrated in Table III, which summarizes the reaction rates observed in the presence of propane, sulfur hexafluoride, and ethyl chloride, each at 2 different pressures. The rate in their absence is shown for comparison. In each case, the reaction rate initially rises with added gas pressure and then falls as the added gas pressure is further increased.

In the presence of 260 to 400 Torr propane, the dependence on ethylene was again first order. The linearity of the first order log plots for these conditions was maintained up to at least 2 reaction half lives (see Fig. 6), showing that the effect of a growing concentration of ethyl bromide was

60.1	59.7	391(SF_6)	2.13

*$\phi I_a = 1.2 \times 10^{13}$ radicals cm^{-3} s^{-1}.

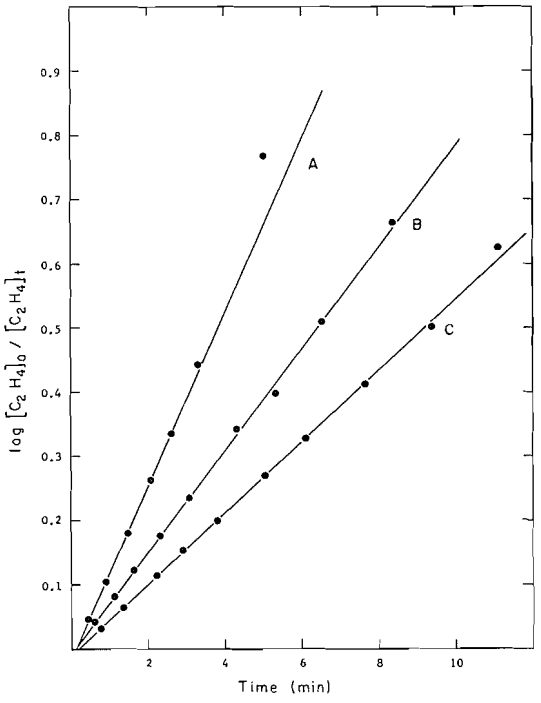

FIG. 6. First order plots for ethylene consumption at 25 °C in the presence of propane. HBr pressure, 300 Torr; C_2H_4 pressure, 61 Torr; C_3H_8 pressure, 257 Torr; ϕI_a, 20.2, 6.4_3, and $3.0_6 \times 10^{12}$ radicals cm^{-3} s^{-1} for A, B, and C, respectively.

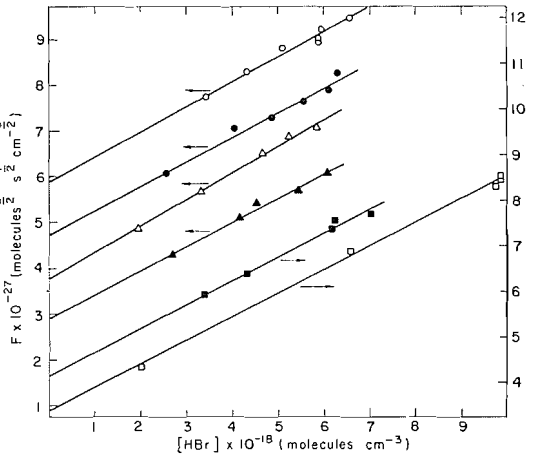

FIG. 7. Dependence of reaction rate on HBr concentration. Plot of $F = (\phi I_a)^{\frac{1}{2}}[C_2H_4][HBr]$/rate vs. [HBr]. Ethylene pressure ~60 Torr; C_3H_8 pressure (Torr) and temperature (°C) are, respectively: ○, 385 and 45.0; ●, 380 and 35.0; △, 390 and 25.0; ▲, 380 and 15.3; ■, 291 and 35.1; □, 259 and 25.0.

not as noticeable in the presence of propane. A similar behavior was observed at all of the temperatures used in this study, and as a general rule reaction rates were calculated from the slopes of such plots.

The dependence of reaction rate on HBr pressure, at fixed pressures of ethylene and propane, was investigated at 15.3, 25.0, 35.0, and 45.0 °C. The results are given in Fig. 7. The HBr dependence is complex, and the manner of presentation will be explained in the discussion.

The empirical rate expression for experiments in the presence of added propane is

$$[ii] \qquad \frac{d[C_2H_5Br]}{dt} = k''[C_2H_4]I_a^{\frac{1}{2}}f[HBr]$$

where $f[HBr]$ is a complex function of [HBr].

Discussion

A discussion of the photolysis of acetone in the present system is necessary before consideration of the chain reaction per se. The work of Larson and O'Neal (24) has shown that HBr is a highly efficient scavenger for triplet state

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

acetone molecules. The following reactions, in which A = acetone, were postulated to explain their results:

[A] $A + h\nu \xrightarrow{I_a} A_m^3$ (triplet, vibrationally active)

[B] $A_m^3 \rightarrow CH_3 + CH_3CO$

[C] $M + A_m^3 \rightarrow M + A_0^3$ (thermalized triplet)

[D] $HBr + A_0^3 \rightarrow CH_3C(OH)CH_3 + Br$

[E] $CH_3 + HBr \rightarrow CH_4 + Br$

[F] $CH_3CO + HBr \rightarrow CH_3CHO + Br$

[G] $CH_3C(OH)CH_3 + HBr \rightarrow CH_3CH(OH)CH_3 + Br$

[H] $Br +$ scavenger $\rightarrow$ Unreactive radical

Reactions [E] and [F] had previously been proposed by Ridge and Steacie (23). Like reaction [E], reaction [D] was estimated to have a rate constant equal to $6.6 \times 10^{-12} \times 10^{-1.1/\theta}$ cm^3 molecule^{-1} s^{-1}, and quenching of the acetone triplets by ethylene obviously could not compete with it, since the collision efficiency of the latter process is only $\simeq 2.6 \times 10^{-6}$ (29).

Larson and O'Neal also estimated

$$k_G \simeq 2 \times 10^{-12} \times 10^{-4.5/\theta} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1},$$

which gives a lifetime of about 10^{-4} s for the 2-hydroxyisopropyl radicals at the HBr pressures employed in this study. Rotating sector experiments (22, 30) and other considerations show that the lifetimes of the chain centers in our system are of the order of 0.03 s or longer. Hence, it follows that reactions [I] and [J]

[I] $CH_3C(OH)CH_3 + Br \rightarrow CH_3CBr(OH)CH_3$

[J] $CH_3C(OH)CH_3 + C_2H_4Br \rightarrow CH_3CBr(OH)CH_3 + C_2H_4$

cannot be of any importance under present conditions. The situation for reaction [K]

[K] $CH_3CO + Br \rightarrow CH_2CO + HBr$

is less clear, since k_F is likely to be smaller than k_G. However, ϕ_{CH_3CO} will only be 0.1, or less, and discrepancies arising from the neglect of reaction [K] should not be serious. The foregoing mechanism leads to a quantum yield, ϕ, for bromine atoms equal to

$$2\phi_{\text{Isopropanol}} + \phi_{CH_3} + \phi_{CH_3CO}$$

and ϕ approaches 2 in the presence of bromine atom scavengers (24). To allow for some uncertainty, notably in the reactions of CH_3CO, we have taken $\phi = 1.7 \pm 0.3$. We assume this to be independent of temperature in the range 15 to 45 °C.

Returning to the results of this investigation, we may note from expression [*i*] of section (*iii*), that the data at ethylene concentrations in excess of 380 Torr are the most clear cut. The intensity exponent of 0.5, the lack of dependence on ethylene pressure, and the first order dependence on HBr all conform to expression [*iii*]

$$[iii] \qquad \frac{d[C_2H_5Br]}{dt} = k_{3a}\left(\frac{\phi I_a}{2k_7}\right)^{\frac{1}{2}}[HBr]$$

which is obtained when reaction [7] is the only significant termination reaction (11). The slope of the line in Fig. 5 gives

$$k_{3a}/(2k_7)^{\frac{1}{2}} = 8.9 \pm 0.1 \times 10^{-10} \text{ cm}^{3/2} \text{ molecule}^{-1/2} \text{ s}^{-1/2}$$

at 35.1 °C. Rearrangement of [*iii*] leads to

$$[iv] \qquad \frac{k_{3a}}{(2k_7)^{\frac{1}{2}}} = \frac{\text{Rate}}{(\phi I_a)^{\frac{1}{2}}[HBr]}$$

Figure 4b is a plot of the right hand side of expression [*iv*] against ethylene pressure, over the range 380 to 590 Torr. The above value of $k_{3a}/(2k_7)^{\frac{1}{2}}$ is seen to hold for all of the conditions shown on the figure.

Rotating sector experiments (1, 2) have led to rate constants of 2×10^{-11} and 3×10^{-11} cm^3 molecule^{-1} s^{-1}, respectively, for the combination plus disproportionation of the chlorethyl radicals Cl—CH_2—CH_2 and Cl—CHCl—CHCl. Because of the weaker bonding and slightly larger size of bromine atoms, one would expect a faster rate of disproportionation and a somewhat enhanced value of k_7 for Br—CH_2—CH_2 radicals. Taking

$$k_7 = 5 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

leads to

$$k_{3a} = 0.9 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

at 35.1 °C, which is consistent with 2.0×10^{-14} calculated for reaction [3*c*] at 35.0 °C from the data of Fettis, Knox, and Trotman-Dickenson (31).

Attention can now be given to the results observed at ethylene pressures below 100 Torr. The first order dependence on ethylene shows that addition of bromine atoms to the C=C bond is the main rate controlling process. Termination

For personal use only.

must be by reactions [4] and [5] as was observed previously for the photobromination (8). The intensity exponents for code numbers A and B in Table I imply that both processes occur in the absence of propane, and that the proportion of termination by reaction [5] tends to decrease as the total pressure of reactants increases. This behavior is as expected, since the rate of reaction [5] is proportional to the diffusion coefficient of bromine atoms in the system and hence varies inversely with pressure. For the same reason, the addition of chemically inert gases to a system with constant light intensity and concentrations of the reactants should cause an increase in reaction rate until reaction [5] becomes negligible, and then a decrease, as the total concentration of third bodies (i.e., [M] in reaction [4]) is increased still further. This type of behavior is well documented for related systems (8, 32) and only a cursory investigation of the effects of C_2H_5Cl and SF_6 at $\sim$ 260 and $\sim$ 385 Torr was performed to establish that propane was not unique in its effect on this system. The results in Table III show the expected reduction in rate for high pressures of all 3 added gases. The initial enhancement in rate is in accord with the observations of Field and Abell (18*b*), and may be due, in fact, to the reduction in the rate of reaction [5]. However, in this system a large part of the enhancement is probably due to the greater efficiency of the added gases as moderators of $C_2H_4Br^*$ in reaction [9*], and the contributions of the 2 processes cannot be separated.

At 385 $\pm$ 5 Torr, propane gave a 50% lower rate than SF_6 or C_2H_5Cl. We attribute this to a better efficiency of propane as a third body in reaction [4], rather than to its failure as a deactivator of $C_2H_4Br^*$ or to the occurrence of the following reactions

$$[10]/[-10] \quad Br + C_3H_8 \rightleftarrows HBr + C_3H_7 \qquad \Delta H = 7.0 \text{ kcal mole}^{-1}$$

$$[11] \quad Br + C_3H_7 \rightarrow C_3H_7Br \text{ or } C_3H_6 + HBr$$

Reactions [10], [−10], and [11] lead to

$$[Br]_{ss} = \left(\frac{(\phi I_a)[HBr]}{2k_{11}K_{10}[C_3H_8]}\right)^{\frac{1}{2}}$$

and, if reaction [4] were unimportant, our apparent value of k_4 would in fact be $k_{11}K_{10}/(HBr)$. The data of refs. 14, 15, and 33 give

$$K_{10} = 6 \times 10^{-4} \text{ at } 298 \text{ °K}$$

and k_{11} should not exceed 6×10^{-11} cm^3 molecule^{-1} s^{-1}. Consequently, for our conditions of temperature and HBr concentration ($\sim 4 \times 10^{18}$ molecules ml^{-1}), $k_{11}K_{10}/[HBr]$ should be about 8×10^{-33} cm^6 molecule^{-2} s^{-1}, which is an order of magnitude smaller than would be expected for k_4, since Russell and Simons (34) observed

$$k_4 = 8 \times 10^{-32} \text{ cm}^6 \text{ molecule}^{-2} \text{ s}^{-1}$$

for iodine atoms combining in the presence of propane. The magnitude of $k_{11}K_{10}/[HBr]$ should also show a positive activation energy of 7 kcal mole^{-1} and vary inversely with [HBr]. The present data give no evidence for such trends in k_4. For these reasons, it is evident that reactions [10] and [11] do not contribute significantly to the termination reaction under the conditions of this study.

It can be shown (cf. ref. 1) that the intensity exponent of 0.77 for 440 Torr of HBr and 60 Torr of ethylene (See Table I*a*) corresponds to roughly equal proportions of mutual and linear termination. Comparison with the value of 0.52, which corresponds to over 90% termination by reaction [4], for a mixture containing 392 Torr of propane at a similar absorbed light intensity and total pressure, leads to the obvious conclusion that k_4 for M = HBr is at least a factor of 10 less than k_4 for M = C_3H_8. For this reason, the contribution of HBr as a third body in reaction [4] will be neglected in the subsequent analysis of the dependence of the reaction rate on HBr concentration.

The first order dependence on ethylene and mutual termination in the presence of propane (see expression [*ii*]) are both in accordance with expression [*v*]

$$[v] \quad \frac{d[C_2H_5Br]}{dt} = \left(\frac{\phi I_a}{2k_4[M]}\right)^{\frac{1}{2}} \frac{k_2[C_2H_4][HBr]}{[HBr] + k_{-2}/k_{3a}}$$

based on termination by reaction [4] (see ref. 11). It may be rearranged to

$$[vi] \quad \frac{(\phi I_a)^{\frac{1}{2}}[C_2H_4][HBr]}{\left(\frac{d[C_2H_5Br]}{dt}\right)} = \frac{(2k_4[M])^{\frac{1}{2}}}{k_2}\left(\frac{k_{-2}}{k_{3a}} + [HBr]\right)$$

TABLE IV

Rate constant ratios for experiments with propane present

Temperature (°C)	Pressure of $C_3H_8 + C_2H_4$ (Torr)	k_{-2}/k_{3a} (molecules $cm^{-3} \times 10^{-18}$)
15.3	440	5.6±0.6
25.0	445	6.5±0.3
35.0	445	8.7±0.8
45.0	445	11.5±1.0
25.0	320	6.5±0.3
35.1	350	8.2±0.7

Figure 7 shows values of F, the quantity on the left hand side of this expression, plotted against the HBr concentration for fixed pressures of propane and ethylene at temperatures of 15.3, 25.0, 35.0 and 45.0 °C. The magnitude of k_{-2}/k_{3a} calculated from the ratio of the slope to the intercept of each of the lines is given in Table IV. Since k_{3a} should not vary with pressure, any dependence of k_{-2} on pressure will be reflected in a pressure dependence of k_{-2}/k_{3a}. Analogy with other radical decompositions suggests that k_{-2} would be near its pressure dependent region under our conditions. For example, $P_{\frac{1}{2}}$ is estimated to be ~ 101 Torr for the acetyl radical at 235 °C (35), and ~ 110 Torr for C_2H_5CO at 42 °C (36). Due to practical limitations, the range of pressures shown in Table IV represents the maximum variation possible in this system with the present apparatus, and a meaningful estimate of $P_{\frac{1}{2}}$ for C_2H_5Br is impossible. However, the results for the 2 propane pressures at 25.0 and 35.0 °C imply that any pressure dependence of k_{-2} is minor, so that it is probably close to, if not equal to, its high pressure limiting value. Consistent with this is the fact that the Arrhenius plot for k_{-2}/k_{3a} in Fig. 8 gives

$$E_{-2} - E_{3a} = 4.5 \pm 0.5 \text{ kcal mole}^{-1}$$

which agrees within experimental error with the value predicted in Fig. 1. The above result is also in accord with

$$E_{-2} - E_{3b} = 6.1 \text{ kcal mole}^{-1}$$

obtained from the photobromination of ethylene in the presence of ~ 300 Torr of CF_2Cl_2 as moderating gas (8). Figure 8 also gives

$$A_{-2}/A_{3a} = 1.3 \times 10^{22} \text{ molecule cm}^{-3}$$

which is to be compared with

$$A_{-2}/A_{3b} = 0.8 \times 10^{22} \text{ molecule cm}^{-3}$$

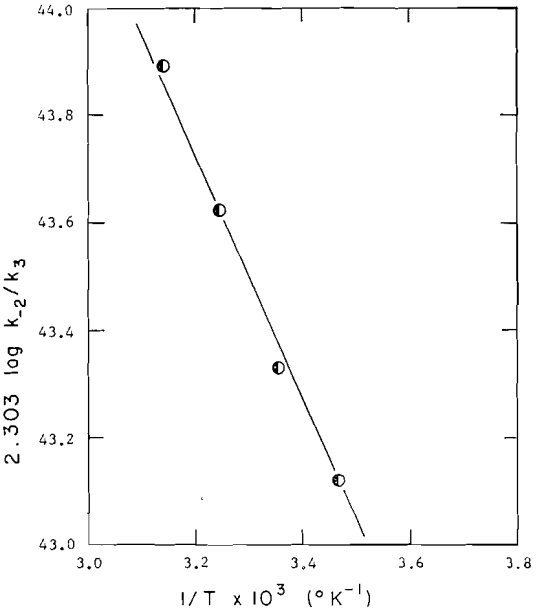

FIG. 8. Arrhenius plot of k_{-2}/k_{3a}.

The combined data for the bromination and hydrobromination lead to

$$k_{3a}/k_{3b} = 1.6 \exp(-1600/RT)$$

which has a value of 0.2 at 60 °C. The agreement of this value with the value of 0.6 for k_{3c}/k_{3d} at the same temperature from Anderson and Van Artsdalen (12) confirms the similarity of the mechanisms for the 2 chain reactions.

From expression [*vi*], it can be seen that the slopes of the lines in Fig. 7 correspond to the values of $(2k_4[M])^{\frac{1}{2}}/k_2$. For ethylene plus propane pressures of 440–445 Torr, there is some scatter, but all values of $(2k_4[M])^{\frac{1}{2}}/k_2$ for the temperature region 15.3 to 45.0 °C are accommodated within the range $5.5 \pm 0.3 \times 10^8$ $cm^{3/2}$ $molecule^{-1/2}$ $s^{-1/2}$. From the determined tem-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

perature dependence of k_4 (22, 30), we conclude that $E_2 = 0.0 \pm 0.5$ kcal mole^{-1}.

Because of its complex nature, the dependence of k_2 on propane pressure is clearly of interest. The values of $(2k_4[M])^{\frac{1}{2}}/k_2$ for $\sim$ 330 Torr of ethylene plus propane at 25.0 and 35.0 °C are both 5.1×10^8, which is about 10% lower than the mean of those observed for $\sim$ 440 Torr, and in the opposite direction to that expected for a decrease in k_2. The intercepts of the 2 sets of data at 25.0 and 35.0 °C show a similar trend. Both observations can be explained by the reduction in $[M]^{\ddagger}$, if it is assumed that ethylene and propane have similar values of k_4. There is, therefore, no evidence for any significant change in k_2 over the limited range of propane pressures employed. This implies that effectively all $C_2H_4Br^*$ are deactivated by propane at 260 Torr (i.e., that $k_2 = k_2^*$ for these conditions). Confirmation of this may be obtained from studies of the isomerization:addition ratio for *cis*-1,2-dideuteroethylene in the presence and absence of propane.

Results obtained in the absence of propane and at low ethylene pressures lead to the conclusion that HBr is much less effective in deactivating $C_2H_4Br^*$ (17), and are in accord with the conclusions of Field and Abell (18*b*) as well as the observations of Oldershaw and Cvetanović (19). They will be reported in detail elsewhere. However, 3 points deserve immediate clarification. (*a*) We have not determined overall temperature dependences, only values of $E_{-2} - E_{3a}$. (*b*) Apart from the experiments in section (*iii*) of Results above, our work has been confined to conditions such that $k_{-2} \simeq k_{3a}[HBr]$, while Field and Abell's studies (18) have been done at conditions where $k_{-2} \gg k_{3a}[HBr]$. This difference and our previous comment (*a*) may contribute to some of the anomalies noted by them. (*c*) The rate of the linear termination process does not enter into the calculation of $E_{-2} - E_{3a}$. Hence, contrary to the statement on p. 754 of ref. 18*b*, the high apparent value of

$$E_{-2} - E_{3a} = 14 \text{ kcal mole}^{-1}$$

reported by Armstrong and Spinks (11) cannot be explained by a high activation energy E_5. In addition to this discrepancy, the chain lengths in the radiation-induced reaction are significantly longer than those observed for the photoinitiated reaction under comparable conditions. This implies that there is an enhanced catalysis of the radiation-induced reaction, possibly due to the creation of ions which are not produced in the photolysis. More detailed studies will be required to confirm this, but it is now quite clear that the results of Armstrong and Spinks cannot be used as a source of kinetic data for the free radical reaction.

Acknowledgments

The authors are grateful to the National Research Council of Canada for its financial support. One of us (K.T.W.) was the recipient of a studentship. D.A.A. wishes to express his gratitude to the University of Calgary for a sabbatical leave and to Atomic Energy of Canada, Chalk River Nuclear Laboratories, for a Visiting Scientist Appointment, 1968–1969. The assistance of Dr. A. M. Hogg, who kindly carried out the mass spectral analyses, is also acknowledged.

Some thermodynamic properties of the sulfolane–benzene and sulfolane–dichloromethane systems

R. L. BENOIT AND J. CHARBONNEAU
Department of Chemistry, University of Montreal, Montreal, Quebec
Received April 9, 1969

Molar excess free energies of the systems sulfolane–benzene and sulfolane–dichloromethane have been calculated from static vapor pressure measurements at 30.00 °C. Refractive indices, excess partial molar volumes of mixing, and enthalpies of mixing at infinite dilution of benzene and dichloromethane were also determined.

Les énergies libres molaires d'excès des systèmes sulfolane–dichlorométhane et sulfolane–benzène ont été calculées à partir de mesures statiques de pressions de vapeur, à 30.00 °C. Les indices de réfraction, les volumes molaires partiels d'excès de mélange, et les enthalpies de mélange à dilution infinie de benzène ou de dichlorométhane, ont aussi été déterminés.

Canadian Journal of Chemistry, 47, 4195 (1969)

Introduction

As part of a continuing study of binary systems involving sulfolane (TMS) (1), vapor pressure equilibrium data were obtained at 30.00 °C for the two binary systems of sulfolane with benzene and dichloromethane. Benzene was taken as representative of aromatics, and dichloromethane as representative of hydrogen bond donors involving the C—H link. Although refractive indices and densities were determined primarily as potential analytical methods, the latter data were used to calculate partial molar volumes. Finally, the heats of solution of the solutes at infinite dilution in sulfolane were also determined by calorimetry.

Experimental

(i) Chemicals

Sulfolane, kindly supplied by Shell Canada Ltd., was oxidized by air for 12 h at 180 °C. The liquid was then treated with activated charcoal and filtered. A distillation at 70 °C under a 0.5 mm vacuum yielded an ultraviolet transparent product.

Baker dichloromethane was treated successively with concentrated sulfuric acid and dilute sodium hydroxide, and then washed to neutrality with water. The product was stirred overnight over Drierite, filtered, and then subjected to a distillation from calcium hydride, using a 1 m high column filled with glass helices. The portion boiling at 39.85 °C, at 760 mm Hg, was retained.

Fisher high purity benzene was stirred overnight over Drierite, then filtered. The product was used without further purification.

(ii) Apparatus and Procedure

Density

Densities were determined at 30.00 ± 0.02 °C using a 25 ml capped picnometer, previously calibrated with conductivity water. This procedure, checked against KCl solutions, gave densities known to within 0.0001 g per ml. The samples were prepared by weight in approximately 10% steps, using 50 ml glass-stoppered flasks. The samples were kept at least 8 h in a constant temperature bath before measurement.

Refractive Index

An Abbe-type refractometer was used to determine refractive indices to 0.0001 with the temperature controlled at 30.00 ± 0.02 °C.

Vapor Pressure

Vapor pressure data were obtained by a static method previously described (1). Mole fractions were determined by weighing the samples of known composition before and after vapor pressure measurement. Assuming that sulfolane is non-volatile, the loss of weight corresponds to the second component.

Calorimetry

The same microcalorimeter was used as in a previous study (1). The paraffin oil used to prevent diffusion of the volatile component was replaced here by a glass cap containing mercury and a 1 cm layer of mercury, to facilitate mixing of the liquids.

Results and Discussion

The refractive indices (n_{12}) of the mixtures and the pure components are summarized in Table I. Results of the density measurements (d_{12}) are given in Table II. Partial molar volumes ($\overline{V}_1$ and $\overline{V}_2$), believed to be accurate to 0.3% for CH_2Cl_2 and to 0.2% for C_6H_6 and TMS, were determined from molar volume plots (V_{12} vs. x_1) by the method of intercepts. Curves for the excess partial molar volumes ($V_1^E = \overline{V}_1 - V_1^0$) are illustrated in Fig. 1. There is a slight contraction over the whole concentration range, with maximum variation at low TMS concentrations.

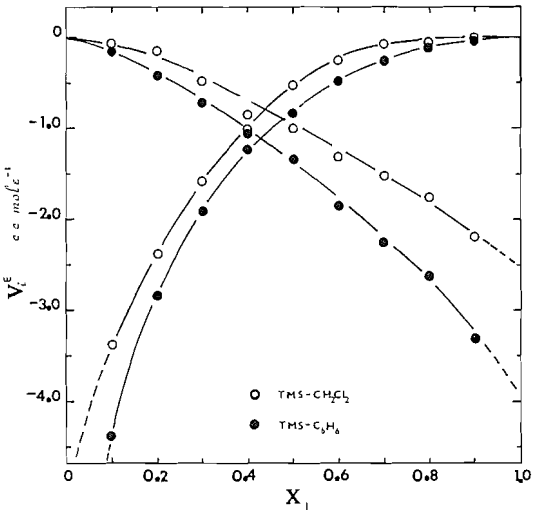

FIG. 1. Excess partial molar volumes of the components, for the TMS–C_6H_6 and TMS–CH_2Cl_2 mixtures at 30.00 °C.

Results for the liquid–vapor equilibrium of sulfolane–benzene and sulfolane–dichloromethane mixtures are presented in Table III. The partial vapor pressures (p_1 and p_2) were determined by the method of Boissonnas (2), and are given in Table IV, together with the activity coefficients (γ_1 and γ_2).

The Redlich–Kister procedure (3) was used to give smoothed curves of ΔG^E against x_1 (Fig. 2).

Approximate values of the parameters B, C, and D were first obtained for the equation

$$[1]\quad \Delta G^E = RT x_1 (1 - x_1) \times [B + C(2x_1 - 1) + D(2x_1 - 1)^2]$$

through a plot of $\ln \gamma_1/\gamma_2$ vs. x_1. More accurate values were then selected by means of a program which allowed each coefficient to be varied by steps of 0.01 for C_6H_6 and 0.001 for CH_2Cl_2 and gave the corresponding root-mean-square (r.m.s.) deviation. The smallest r.m.s. deviations were found to correspond to the following sets of coefficients.

	Parameter values			
System	B	C	D	σ (cal mole^{-1})
TMS–C_6H_6	1.10	−0.34	0.19	2.65
TMS–CH_2Cl_2	−0.208	0.100	−0.035	0.335

The assumption that the vapor phase was ideal was checked using Schiebel's nomograph (4) and the critical constants of C_6H_6 and CH_2Cl_2. The values of the correction factors were found to be smaller than 1.01 for C_6H_6 and 1.03 for CH_2Cl_2.

The results of the calorimetric measurements are the average of two (CH_2Cl_2) or three (C_6H_6) determinations. As the C_6H_6 or CH_2Cl_2 mole fractions used are about 0.01, the heats of mixing can be considered approximately equal to the heats of solution at infinite dilution: $\Delta H^\infty = 0.080$ (C_6H_6), and -0.52 kcal mole^{-1} (CH_2Cl_2).

The volume contraction observed on mixing C_6H_6 or CH_2Cl_2 with TMS can either be attributed to structural effects, or to complex-forming interactions between solvent and solute molecules. For the TMS–C_6H_6 system, the positive excess Gibbs free energy, and the slightly endothermic heat of solution of C_6H_6 at infinite dilution, tend to indicate that the contraction is mainly due to structural factors. Other binary systems of benzene with oxygen-containing compounds, such as acetone (5), dimethylsulfoxyde (6), dioxan and diethylformamide (7), show this

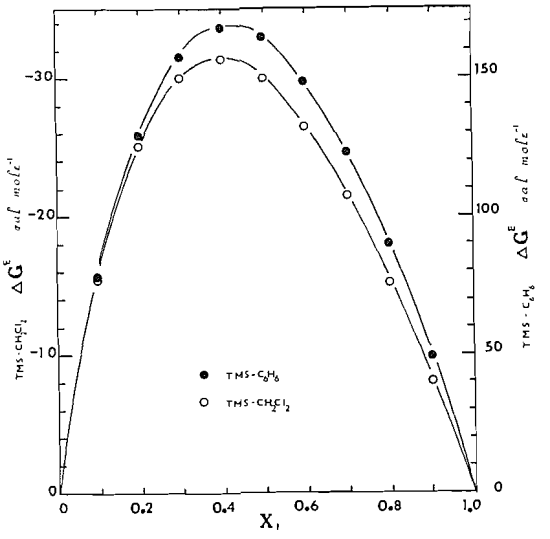

FIG. 2. Excess Gibbs free energy of the TMS–C_6H_6 and TMS–CH_2Cl_2 mixtures at 30.00 °C.

same tendency to a positive excess Gibbs free energy and an endothermic heat of mixing. The molar volumes of mixing have only been determined for the benzene–acetone system (5), where a volume contraction is also observed.

For the TMS–CH_2Cl_2 system, the excess Gibbs free energy is negative, and the heat of solution at infinite dilution of CH_2Cl_2 is exothermic. This suggests complex-forming interactions between solvent and solute molecules. Such complexes are known to exist in other binary systems of CH_2Cl_2 with a proton acceptor. Solid–liquid phase equilibria and infrared studies support the existence of complexes in the systems CH_2Cl_2–dioxan (8) and CH_2Cl_2–acetone (9). Although these complexes are weak, these systems exhibit somewhat larger heats of mixing at infinite dilution of CH_2Cl_2 than the CH_2Cl_2–TMS system (10).

Heat capacity of activation for the hydrolysis of methanesulfonyl chloride and benzenesulfonyl chloride in light and heavy water[1]

R. E. ROBERTSON[2], B. ROSSALL[3], S. E. SUGAMORI, AND L. TREINDL[4]
Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received June 2, 1969

Rates of solvolysis of methanesulfonyl chloride and benzenesulfonyl chloride have been determined in H_2O and D_2O. The free energy, enthalpy, entropy, and heat capacity of activation were calculated. The exceptional accuracy of the data permitted an estimation of $d\Delta C_p^{\ddagger}/dT$ from a four parameter temperature dependence of the kinetic rates.

From these data we conclude that both sulfonyl chlorides hydrolyse by the same mechanism (S_N2) The change in R from CH_3 to C_6H_5 in RSO_2Cl did not alter $\Delta C_p^{\ddagger}$ but $\Delta S^{\ddagger}$ (20°) was changed from -8.32 to -13.25 cal deg^{-1} mole^{-1}, respectively. The significance of this difference is attributed to the probability of bond formation rather than to differences in solvent reorganization.

This paper is the first of a series reporting detailed studies of the hydrolysis of sulfonyl chlorides[5]. The experimental approach is the same as that applied in preceding studies on the halides and sulfonates: a careful examination of the effect of temperature and of isotopic substitution in the solvent on the temperature dependence of the rate of hydrolysis.

In the halide series we found a remarkable similarity in the values of the heat capacity of activation, $\Delta C_p^{\ddagger}$ (10), and in the differences in $\Delta G^{\ddagger}$ for hydrolysis in H_2O and D_2O over a range of structures for which it was reasonable to expect different degrees of bond-making in the activation process (11). These observations led to the conclusion that the S_N2 transition state was reached when the charge on the halide being displaced created interaction with the solvent equal to water–water interaction; i.e. the transition state corresponded to that degree of charge development where exothermic solvation of the quasi-halide was about to begin. Consequently, it followed that for a given temperature, the charge level ($\delta-$) on the chlorine atom, for example, is the same whether the ion is being displaced from allyl, ethyl, or methyl chloride. This in turn implies that the charge level on the anion at the transition state of an S_N2 displacement is independent of the degree of nucleophilic interaction. The evidence in favor of this conclusion derived from the similarity in $\Delta C_p^{\ddagger}$ values and from the limited range of $\delta_I\Delta H^{\ddagger} = \Delta H_{D_2O}^{\ddagger} - \Delta H_{H_2O}^{\ddagger}$ for S_N2 displacement for the hydrolysis of alkyl halides, is weakened by the possibility that the difference in the degree of bond-making at the transition state for the hydrolysis of the available halides is small, a possibility suggested by the uniformity of our kinetic solvent isotope effect (k.s.i.e.) values (10). To fill this deficiency we were led to examine the hydrolysis of the sulfonyl chlorides, since in this series there are good indications that a greater degree of nucleophilic overlap is required at the transition state (10, 12). We assumed that the nature of the activation process in the latter series is sufficiently similar in mechanism to that for the hydrolysis of alkyl halides, where some degree of bond-making is required, to provide an insight into the question of charge development on the anion and the associated solvent reorganization at the transition state for both systems.

In this first paper we report the results of a kinetic study for the hydrolysis of the first members of two series, methanesulfonyl chloride and benzenesulfonyl chloride.

The enhanced value of the kinetic solvent isotope effect found for the hydrolysis of these two reactants (k.s.i.e.(methanesulfonyl chloride) $= 1.568 \pm 0.006$, k.s.i.e.(benzenesulfonyl chloride) $= 1.564 \pm 0.006$, at 20°) compared with the corresponding value characterizing the hydrolysis of halides (k.s.i.e. = 1.20–1.25) together with the much higher selectivity ratio $k_{OH^-}/k_{H_2O} > 10^5$ (12) leaves little doubt that bond-making is more advanced at the transition state for the displacement of Cl^- from RSO_2Cl than from RCl. This

does not exclude the possibility that certain sulfonyl chlorides may be found which react by an S_N1 mechanism (4, 13), but these appear to be exceptional. If changes in nucleophilic interaction at the transition state are accompanied by corresponding changes in the charge on the anion being displaced, then this should alter solvent reorganization about the quasi-anion. This fact should be reflected in the value of $\Delta C_p^{\ddagger}$, since this is the most sensitive indicator of solvent reorganization presently available. Further information reflecting relative degrees of solvent reorganization were expected from a comparison of $\Delta H^{\ddagger}$ and $\Delta C_p^{\ddagger}$ values for hydrolysis in H_2O and D_2O (11). While we recognize that $\Delta C_p^{\ddagger}$ is a sensitive indicator of the extent of solvent reorganization associated with ionogenic reactions in water, the interpretation of derived values is not simple and frequently the necessary data are lacking for any save the broadest conclusions. Not only must there be some basis for estimating probable initial state differences but in a comparison of $\Delta C_p^{\ddagger}$ values, either the rate data must be collected over the same temperature range or some allowance must be made for the fact that the structural stability of the initial state solvation shell decreases as the temperature increases. Further, the problem of deriving mechanistic information from a comparison of $\Delta C_p^{\ddagger}$ values is rendered more difficult by the complexity of the changes in water structure. Drost-Hansen (14) finds that the temperature dependence of the fluidity of water requires 5 terms in temperature to produce a good fit to the experimental points. The same complexities are likely to be found in the characterizing parameters for hydrolyses in water when rate data and initial state data can be determined with sufficient accuracy. However, as a balance for these potential difficulties, there is the operative fact that the effect of temperature on structural stability of the solvent in initial and transition states will be in the same direction leading to smaller differences.

The problem of initial state differences is inherent in any satisfactory interpretation of derived pseudo-thermodynamic parameters. Even if these data were available in the present instance, we should still face difficulties in application. Thus, only those solvation differences which relate directly to the solvent volume affected by the kinetic process are significant for the interpretation of $\Delta C_p^{\ddagger}$. As yet, the experimental problems associated with these questions have not been solved for the sulfonyl chlorides. These compounds range from being poorly soluble to practically insoluble in water. Therefore, we have assumed that the initial state differences are small compared with those arising between the initial and the transition state. The restriction imposed on interpretation by that area of ignorance was not considered sufficient to cancel out the advantage to be gained from comparing $\Delta C_p^{\ddagger}$ values.

Experimental

Methanesulfonyl chloride and benzenesulfonyl chloride were commercial samples. Methanesulfonyl chloride was redistilled (b.p. 161° at 730 mm Hg). Benzenesulfonyl chloride was vacuum distilled (b.p. 91° at 4 mm Hg) and zone refined. Excellent first order kinetics were found for both compounds.

D_2O was obtained either from Merck, Sharpe, and Dohme or from the A.E.C. of USA and was 99.8% D, as determined by density measurements. It was found necessary to subject the D_2O to a preliminary distillation from NaOD and thence through a Stuart–Wormwell still (15) having a quartz condenser. The cause of this difficulty was attributed to small amounts of impurities which were not identified.

Kinetic measurements on methanesulfonyl chloride were made by a conductance method using the traditional bridge system and rates were calculated by machine computation (10); benzenesulfonyl chloride hydrolyses were studied by the Auto-RAM system (16). Temperature control was better than ± 0.002°.

Hydrolysis of a sulfonyl chloride molecule in water produces 4 ions, 2 of which are protons

$$RSO_2Cl + H_2O \rightarrow RSO_3^- + 2H^+ + Cl^-$$

This is a particularly convenient system for a study dependent on accurate data and replicate determinations with a precision of ± 0.1% were usually found.

Results

The method of Clarke and Glew (17, 18) modified to treat kinetic data[6] was used to compute the pseudo-thermodynamic parameters. The temperature dependence of the rates was expressed by an equation of the general form.

$$[1] \quad \log_{10} k = A_1 + A_2/T + A_3 \log_{10} T + A_4 T + \cdots\cdots$$

Temperature–rate equations of the form of eq. [1] conveniently summarize these data within the limits of experimental error, permitting calculation of rates at any temperature with high accu-

	D_2O	10	3.98	17 829 ± 7	11.03 ± 0.02	57 ± 2
		20	11.93	17 258 ± 11	13.01 ± 0.04	57 ± 2

racy. The corresponding constants are given in Table I.

The pseudo-thermodynamic parameters, derived from the empirical constants listed in Table I on the basis of the familiar assumptions of the transition state theory and the further assumption that $d\Delta C_p{}^{\neq}/dT \neq 0$, are given in Table II. An indication of the possible effect of assuming that $d\Delta C_p{}^{\neq}/dT \neq 0$ but that $d^2\Delta C_p{}^{\neq}/dT^2 = 0$ is indicated by the change in the corresponding terms with temperature as shown in Table III. The assumption ($d\Delta C_p{}^{\neq}/dT = 0$) is clearly an approximation accepted protempore as a consequence of the inadequate accuracy of the rates. It should be noted, that the value of $\Delta C_p{}^{\neq}$ at the midpoint of the temperature range will be the same for both equations, hence the effect of this approximation is unimportant where comparisons of $\Delta C_p{}^{\neq}$ values are made taking this fact into consideration.

Discussion

We have proceeded on the assumption that the mechanism of hydrolysis for the methanesulfonyl chloride and benzenesulfonyl chlorides is analogous to that for S_N2 displacement of halides from alkyl-carbon, the major difference being the requirement for a greater degree of bond-making to sulfur than to carbon. Thus Swain and Scott (12) report what might be called a "selectivity ratio" of $k_{OH^-}/k_{H_2O} = 7 \times 10^5$ for benzenesulfonyl chloride compared to the range about 10^3 for the primary halides (4, 9, 19). The effect of para-substitution on the rate of hydrolysis of this series in water is consistent with the requirements of an S_N2 mechanism (though Hedlund appears to reach a different conclusion (2)). However, successive methylation of the ring in benzenesulfonyl chloride can lead to a loss of sensitivity to the presence of alkali. Thus at 30° hydrolysis of 2,4,6-trimethylbenzenesulfonyl chloride in water has a mean rate of 1.66×10^{-4} s^{-1}, but only 1.73×10^{-4} s^{-1} in the presence of 0.004 *M* KOH (13). Such a loss of selectivity between OH^- and H_2O does not in itself signify the shift to an S_N1 mechanism as Vizgert would appear to assume; it may be no more than a reduction in the bond-making requirement. Other evidence would be required to support a claim of a shift in mechanism. There is no question that such substitution

Benzenesulfonyl chloride	1.564 ± 0.006	261 ± 2	332 ± 20	−0.24 ± 0.07	1 ± 3

*The values for H_2O are subtracted from the corresponding values found in D_2O, $\delta_I\Delta X^{\ddagger} = \Delta X_{D_2O}^{\ddagger} - \Delta X_{H_2O}^{\ddagger}$.

would alter the mechanism in the sense of reducing the requirements for bond-making at the transition state. If the 2,6-dimethyl substitution introduces sufficient steric hindrance to bond-making to permit an alternative mechanism (13), the difference is in kind (20) rather than degree (19, 21, 22).

Hall (4) suggests as an alternative to the normal three-center nucleophilic displacement the possibility of formation of a sulfonyl chloride hydrate

$$RSO_2Cl + H_2O \rightleftharpoons R{-}\overset{\displaystyle O}{\overset{\|}{S}}(OH)_2\,{}_{Cl} \rightarrow R{-}\overset{\displaystyle O}{\overset{\|}{S}}(OH)_2^{+} + Cl^-$$

and finds some support for this suggestion from k vs. σ plots based on Hedlund's rate data. Some years later, Jenkins and Hambly (9) returned to this hypothesis. As an alternative to the S_N2 mechanism for the hydrolysis of the sulfonyl chlorides they suggest that the preliminary step may be the formation of an addition compound of the solvent and the reactant. Such a complex has been advanced to account for the larger kinetic solvent isotope effect found in the case of neutral hydrolysis of acetic anhydride (23, 24). It should be noted that the corresponding term for the hydrolysis of the sulfonyl chlorides is much less (k.s.i.e.(25°) = 2.90 vs. 1.55), although the latter value is significantly larger than that for the hydrolysis of the primary halides (k.s.i.e.(ca. 90°) = 1.25). The difference in k.s.i.e. between values for the sulfonyl chlorides and for the alkyl halides is partly due to the differences in the experimental temperatures and hence in the relative stability of water structures in H_2O and D_2O, and in part to differences in the requirement for nucleophilic interaction. Conclusions based on much comparison are necessarily speculative. We have no way of knowing a priori whether the hydration of the proposed sulfonyl chloride hydrate and the corresponding complex with acetic anhydride would necessarily lead to similar k.s.i.e. values. There is no unambiguous proof of hydrate in either case; just working hypotheses, useful for the design of experiment and testing of results. As evidence against the formation of the proposed intermediate in the case of the solvolysis of benzenesulfonyl chloride, we may cite the failure of Bunton to find evidence of any such intermediate from studies in water containing ^{18}O (25).

In so far as they go, the derived parameters in Tables II and IV tend to confirm the conclusion based on k_{OH^-}/k_{H_2O} and k.s.i.e. values cited above in two respects: (*a*) the nucleophilic interaction is greater than that required for the corresponding S_N2 hydrolysis of the alkyl halides and (*b*) that solvent reorganization is about the same for both sulfonyl chlorides.

The first conclusion is supported by the larger value of $\delta_I\Delta H^{\ddagger} = \Delta H^{\ddagger}(D_2O) - \Delta H^{\ddagger}(H_2O)$ and about the same value of $\delta_I\Delta S^{\ddagger}$ and $\delta_I\Delta C_p^{\ddagger}$ for the sulfonyl chlorides compared to the corresponding values for the primary alkyl halides (11). For a wide range of the latter which react by an S_N2 mechanism, values of $\delta_I\Delta G^{\ddagger}$ have been found to lie in the range 150–200 cal, while $\delta_I\Delta H^{\ddagger}$ covers a somewhat wider range, 200–300 cal, compensating changes in $T\Delta S^{\ddagger}$ accounting for the difference. A similar comparison of data from Table IV shows that the values of $\delta_I\Delta G^{\ddagger}$ and $\delta_I\Delta H^{\ddagger}$ for the sulfonyl chlorides are about 100 cal higher than the corresponding terms for the primary alkyl halides while $\delta_I\Delta S^{\ddagger}$ and $\delta_I\Delta C_p^{\ddagger}$ remain about the same.

The small values of $\delta_I\Delta S^{\ddagger}$ and $\delta_I\Delta C_p^{\ddagger}$ suggest that for these systems, the solvent reorganization attending activation in H_2O and D_2O is about the same. It seems anomalous that there is an obvious difference in the size of RSO_2Cl, where R = CH_3 and C_6H_5, but no corresponding difference

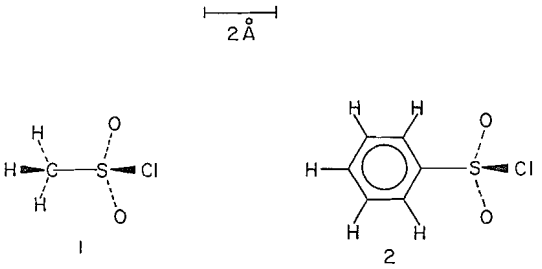
TABLE V

A comparison of derived kinetic parameters

Compound RX	Temperature (°C)	$\Delta H^{\ddagger}$ (cal mole^{-1})	$-\Delta S^{\ddagger}$ (cal deg^{-1} mole^{-1})	$-\Delta C_p^{\ddagger}$ (cal deg^{-1} mole^{-1})
$MeSO_2Cl$	20	20 034	8.32	53
$C_6H_5SO_2Cl$	20	16 926	13.25	56
MeCl	50	25 250	8.64	49
$C_6H_5CH_2Cl$	50	20 420	12.23	39
EtBr	50	24 370	5.95	49
CH_2=$CHCH_2Br$	50	20 560	9.15	62

appears in $\Delta C_p^{\ddagger}$. Granted the absence of some undetected compensating factor, the simplest conclusion is that the corresponding solvent reorganization about CH_3 and C_6H_5 is small, the changes occurring close to the seat of reaction.

It is worth noting, however, that in spite of a similarity in solvent reorganization judged by the above criteria, the entropies of activation for the two sulfonyl chlorides are quite different. At 20° in H_2O, $\Delta S^{\ddagger}$ for the hydrolysis of methanesulfonyl chloride is -8.32 cal deg^{-1} mole^{-1} while a value of -13.25 cal deg^{-1} mole^{-1} is calculated for benzenesulfonyl chloride (equivalent to an energy difference of 1445 cal mole^{-1}) (8). We recognize that differences in this term ($\Delta S^{\ddagger}$) are less specific for solvent reorganization than the corresponding changes in $\Delta C_p^{\ddagger}$, at least for solvolysis in water. Undefined factors other than solvent reorganization are important in determining $\Delta S^{\ddagger}$, and for this reason entropies of activation have, so far, proven of limited value in characterizing solvolytic reactions (26, 27). Granted that solvent reorganization is about the same for the hydrolysis of methanesulfonyl and benzenesulfonyl chlorides, it is reasonable to inquire as to which stereochemical or electronic differences between the methyl and phenyl groups might account for such a variation in $\Delta S^{\ddagger}$. One possibility may arise from the fact that the distance between adjacent hydrogen atoms and the sulfonyl oxygen atoms will be smaller in the benzenesulfonyl chloride, see structures **1** and **2**. Hence, an interaction between these atoms would be more likely in benzenesulfonyl chloride than in methanesulfonyl chloride. In the transition state these interactions will be modified and hence the effect on the rotational entropy of the respective groups will change. We estimate this difference is likely to make a small contribution to $\Delta S^{\ddagger}$. Similarly initial state interaction of the



sulfonyl oxygens with water though small would tend to make $\Delta C_p^{\ddagger}$ more positive than -45 cal deg^{-1} mole^{-1} rather than more negative as observed (compare with $\Delta C_p^{\ddagger}$ for the hydrolysis of sulfonic esters (10)).

A much more likely source of difference in $\Delta S^{\ddagger}$ than changes in internal rotation is related to the nature of nucleophilic displacement and restrictions governing the initiation of a partial covalent bond at the transition state. Whereas for those reactants which can react by an S_N1 mechanism, increasing the size of the R group from which displacement occurs frequently leads to a positive shift in $\Delta S^{\ddagger}$ (28), just the opposite effect may be found where the S_N2 mechanism is operative. Displacement from a bridgehead carbon forms a special case; the S_N2 mechanism is unavailable and $\Delta S^{\ddagger}$ is very negative (29). In attempting to account for the relationship between nucleophilic reactivity and structure, entropy differences have, in many cases, been neglected, either explicitly (30) or implicitly through correlation of activation energy. In the present example such an approximation is clearly unjustified; a large entropy difference is found equivalent to about one-half of the enthalpy difference.

The general trend apparent in the pairs-comparison in Table V is that the introduction of a more polarizable R group reduces the enthalpy

of activation ($\Delta H^{\ddagger}$) and at the same time results in a more negative entropy of activation ($\Delta S^{\ddagger}$), the former being the dominant factor. Since the $\Delta C_p^{\ddagger}$ values are about the same, we can discount differences in solvent reorganization as providing an alternative explanation. Since the k.s.i.e. values are similar, and larger than found for the displacement of halogen from a series of saturated carbon atoms, the degree of bond-making at the transition state is about the same, appreciable but incomplete. Hence we are led to conclude that the observed differences in the value of $\Delta S^{\ddagger}$ is related in some way to the probability of establishing the required degree of nucleophilic overlap. In the unspecific terminology of "hard" and "soft" acids and bases (30, 31) water would be a "hard" base and methanesulfonyl chloride would be less polarizable than benzenesulfonyl chloride. A similar distinction marks the two other pairs given in Table V. Schwarzenbach and Schellenberg (32) have shown that a large entropy difference is found favoring (h–h) combinations as opposed to (h–s) combinations in the formation of certain ligands. A somewhat smaller entropy difference characterizes the pairs-comparison given in Table V. Hence we can conclude that a major part of this characteristic entropy difference is related to some intimate condition pertaining to bond formation. Since the same kind of a change is found for bond formation of the "hard" water with the halide examples presented in Table V, we think it probable that this probability factor associated with bond-making is likely to have much wider application in accounting for some of the remarkable changes in $\Delta S^{\ddagger}$ for S_N2 displacements. It is not our intention to develop this point further here, but we may draw attention to one question raised by such a claim. The $\Delta C_p^{\ddagger}$ for the solvolysis of isopropyl bromide is -59 cal deg^{-1} mole^{-1}, about the same as that for the hydrolysis of allyl bromide (-62 cal deg^{-1} mole^{-1}). While $\Delta S^{\ddagger}$ for the former is -1.4 cal deg^{-1} mole^{-1} at 50°, the corresponding value for the latter is -9.15 cal deg^{-1} mole^{-1} at the same temperature. It is probable that the former hydrolyses in water by an S_N1 mechanism and it might seem reasonable to assume that allyl bromide also reacts by the same mechanism. However, if our speculation about the negative $\delta_I\Delta S^{\ddagger}$ for the hydrolysis of the sulfonyl chlorides can be applied to the hydrolysis of the halides, then in spite of having a value of $\Delta C_p^{\ddagger}$ about the same as a compound which probably reacts by an S_N1 mechanism, the large negative shift in $\Delta S^{\ddagger}$ noted above indicates some degree of nucleophilic interaction in the activation process for the hydrolysis of allyl bromide.

Because of the high degree of precision and (presumably) accuracy possible in rate determinations for these systems, analysis of the temperature dependence of the rate data gave values of $d\Delta C_p^{\ddagger}/dT$ (Table III). The four-parameter analysis is sufficiently close to that of the three-parameter calculations that the values of $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$ are unchanged. The values for $\Delta C_p^{\ddagger}$ at the midpoint of the temperature range are unaltered. The four-parameter analysis suggests that while the assumption $d\Delta C_p/dT = 0$ does not hold for these systems, the values obtained for $d\Delta C_p^{\ddagger}/dT$ are small.

We conclude by suggesting that the value of the results submitted here lies less in the indications that the hydrolysis of the two sulfonyl chlorides follow an S_N2 mechanism but rather in providing the experimental data to illustrate the kind of changes which characterize such a mechanism in the terms $\Delta C_p^{\ddagger}$, and the differential terms $\delta_I\Delta G^{\ddagger}$, $\delta_I\Delta H^{\ddagger}$, $\delta_I\Delta S^{\ddagger}$, and $\delta_I\Delta C_p^{\ddagger}$. The question of differences in $d\Delta C_p^{\ddagger}/dT$ is left in abeyance until we have further pertinent data for allied systems. In our view the most significant fact to emerge is an indication of the source of an important contribution to $\Delta S^{\ddagger}$ for nucleophilic displacement reactions.

Conductances, densities, and viscosities of concentrated solutions of lithium chlorate and of sodium chlorate in water–dioxane mixtures, at 25°

B. G. OLIVER[1] AND A. N. CAMPBELL
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received June 5, 1969

The conductances, densities, and viscosities of sodium chlorate and of lithium chlorate in the solvents 44.5% dioxane – 55.5% water and 64.5% dioxane – 35.5% water were determined, at 25 °C, almost up to saturation. The apparent molal volume of the electrolytes, calculated from the density data, was found to be greater in the dioxane–water solvents than it is in water, indicating a decrease in solvation in the mixed solvents. The relative viscosity increased as the dioxane content of the solvent increased, showing a larger ordering effect of the electrolytes as the solvent became less hydrogen bonded and less ordered. The equivalent conductance of both electrolytes was greatly reduced as the dioxane content of the solvent was increased, in accord with predictions based on solvent viscosity and dielectric properties. Also, sodium chlorate was found to be more associated than lithium chlorate in the mixed solvents.

We previously determined the conductances, densities, and viscosities of sodium chlorate at 25° and at 35° in 64.5% and 90% dioxane–water mixtures (1). To complete this work we have now extended our observations to include lithium chlorate in 64.5% dioxane and sodium and lithium chlorates in 44.5% dioxane. Very little work has been done on concentrated solutions of electrolytes in nonaqueous solvents, with one notable exception: Janz, Marcinkowski, and Ahmad (2) have studied concentrated solutions of silver nitrate in acetonitrile and benzonitrile.

Experimental

The experimental procedure and preparation of materials have been described previously (1). Because of the extremely hygroscopic nature of lithium chlorate, all solutions were prepared in a dry box.

We have used density determinations to obtain apparent molal volumes. This method is only permissible if the density determinations have a high degree of accuracy. We used Ostwald-type pyknometers, modified to our own design, of about 45 cc capacity. Two identical pyknometers were used, one serving as a counterpoise in the weighing procedure. The experimental pyknometer was kept, after removal from the thermostat, in the balance case for a fixed time before weighing. Only with such precautions can reproducible weighings be obtained. Our accuracy of density determination was ±0.0001 g/ml.

Results

Results are given in Tables I to IV.

TABLE I
Physical properties of water–dioxane solvents at 25 °C

Weight % dioxane	Density (g/ml)	Dielectric constant	Viscosity (cP)
0.0	0.99707	78.5	0.8903
44.5	1.0310	40.6	1.784
64.5	1.0366	23.4	1.923

Discussion

From the densities of the solutions given in Tables II and III, and those taken from refs. 1 and 5, the apparent molal volumes of the solutions were calculated, using the expression

$$\phi_v = \frac{1000}{cd_0}(d_0 - d) + \frac{M_2}{d_0}$$

where ϕ_v is the apparent molal volume, c is the concentration in mole per l, d_0 and d are the densities of the solvent and of the solution, respectively, and M_2 is the molecular weight of the solute. The ϕ_v values at rounded concentrations are given in Table IV.

The apparent molal volume is the result of 2 effects: the actual volume of the ions and the effect of the ions on the solvent. Ions with high surface charge tend to attract to themselves neighboring solvent dipoles and thus cause electrostriction of solvent molecules. This causes a decrease in the volume of the solvent in the immediate vicinity of the ion. It follows that the smaller lithium ion, with higher surface charge than the sodium ion, should have a smaller

apparent volume, and this is found to be the case. The increase in apparent molal volume with increasing concentration and with changing solvent (from water to water–dioxane) indicates a decrease in solvation in both cases.

The apparent molal volume of lithium chlorate, at a fixed concentration, increases in going from water to 44.5 % dioxane, passing through a maximum and then decreasing. The ϕ_v values for sodium chlorate also increase in the water–dioxane solvents and seem to be approaching a maximum in 64.5 % dioxane. Similar maxima were observed by Bateman for strontium chloride (6) and for barium chloride (7), in ethanol–water mixtures. Presumably, solvation decreases up to the maximum ϕ_v and then increases.

The change in apparent molal volume with solvent is much smaller for lithium chlorate than

for sodium chlorate, indicating a stronger interaction between solute and solvent in the former case. Such a conclusion is in agreement with the work of Campbell, Kartzmark, and Maryk (8) who isolated the compound $LiClO_3 \cdot C_4H_8O_2$ but failed to observe any such compound with $NaClO_3$ in the corresponding ternary system $H_2O - C_4H_8O_2 - NaClO_3$.

Recently, viscosity has become an important method of characterizing ion–solvent interactions (9–11). The influence of a strong electrolyte upon the viscosity of a solvent is given (up to a concentration of about 0.1 M) by the Jones–Dole equation (12)

$$\eta/\eta_0 = 1 + A\sqrt{c} + Bc$$

where η/η_0 is the relative viscosity, c is the concentration in mole per l, and A and B are constants characteristic of the electrolyte. The coefficient A represents the contribution due to interionic electrostatic forces (13). The B coefficient represents the ion–solvent interaction and measures the order and disorder caused by the introduction of the ions into the solvent structure. The lithium and sodium ions have positive B coefficients in water and are thus structure ordering, whereas the chlorate ion has a negative B coefficient and is therefore structure disordering. The terms positive and negative hydration have been applied to the above phenomena (14).

Little work has been done on the viscosity of electrolytes in nonaqueous solvents, but Golek, Oristschenko, and Artentschenko (15) have studied the behavior of potassium iodide (a structure breaker which decreases the viscosity of water) in monohydric alcohols, glycol, and glycerol. They found that an increase in the concentration of potassium iodide in monohydric alcohols led to a large increase in viscosity, in glycol to little change in viscosity, and in glycerol to a large decrease in viscosity (negative viscosity). In this sequence, the number of hydroxyl groups in the alcohol molecule increases, the bonding between the molecules becomes more complex, and, correspondingly, the close-range order of the liquid increases. It thus appears that electrolytes have a larger ordering effect on those liquids that have the least ordered structure and, conversely, the greatest disordering effect on liquids with highly ordered structures.

Our experimental results are not sufficiently extensive to test the Jones–Dole equation and thus derive the B coefficients for the mixed solvents, but it is possible to make some qualitative statements about the ordering effects of sodium and lithium chlorates in these solvents. It is evident from Fig. 1 that the curve of relative viscosity for lithium chlorate lies above that of sodium chlorate, in all solvents studied, in agreement with the belief that lithium chlorate has a higher ordering effect (larger B coefficient) than sodium chlorate.

Moreover, the relative viscosities of sodium and lithium chlorates increase as the solvent changes from water to 44.5% dioxane to 64.5% dioxane (Fig. 1). The dioxane–water solvent must be less hydrogen bonded and less ordered than water because of the low dipole moment of

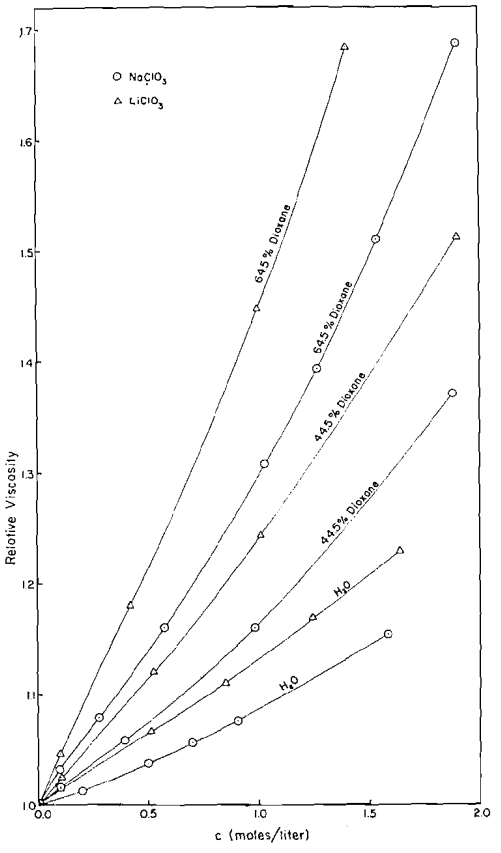

FIG. 1. Plot of relative viscosity of $NaClO_3$ and $LiClO_3$ in water, 44.5% dioxane, and 64.5% dioxane vs. c.

dioxane. Therefore, in agreement with Golek's results (15), the electrolytes should have a larger structure ordering effect and thus larger relative viscosities in the dioxane–water solvents.

The apparent molal volume results, viz., less solvation of the electrolytes in the dioxane–water mixtures, and the viscosity results (larger ordering effect of the electrolytes in the dioxane–water mixtures) are not incompatible. The apparent molal volume is affected by both short and long range interactions, while viscosity is affected by mainly short range effects.

The equivalent conductances of sodium and lithium chlorate in water, 44.5% dioxane, and 64.5% dioxane are plotted against the square root of concentration in Fig. 2. The data for the mixed solvents were taken from Tables II and III, and those for water from previous work (1, 5).

The equivalent conductances of sodium and lithium chlorates are greatly reduced in the dioxane–water solvents. Examination of Table I gives an obvious explanation. The mixed solvents are more than twice as viscous as water and their dielectric constants are much smaller.

Figure 2 also shows that the conductance curves of the 2 salts approach one another as the dioxane content of the solvent increases. In fact, the curve for lithium chlorate is well above that for sodium chlorate, in 90% dioxane (1). Since the apparent molal volume and viscosity results seem to indicate that the mobility of the lithium ion should be retarded more than that of the sodium ion, a possible explanation of this phenomenon may lie in higher ion association for sodium chlorate than for lithium chlorate, in the mixed solvents. This conclusion is supported by the work of Accascina, D'Aprano, and Triolo (4), who found sodium chlorate to be more highly associated than lithium chlorate in dilute solutions in water–dioxane.

The criteria for ion pair and triple ion aggregates, based on the Bjerrum and Fuoss–Kraus

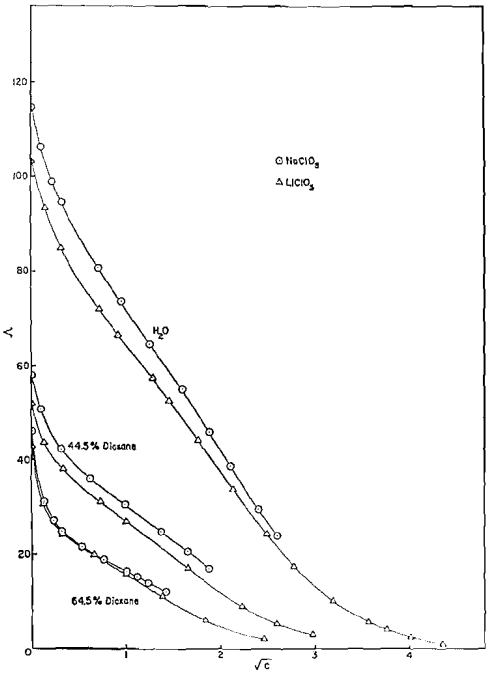

FIG. 2. Plot of equivalent conductance of $NaClO_3$ and $LiClO_3$ in water, 44.5% dioxane, and 64.5% dioxane vs. $\sqrt{c}$.

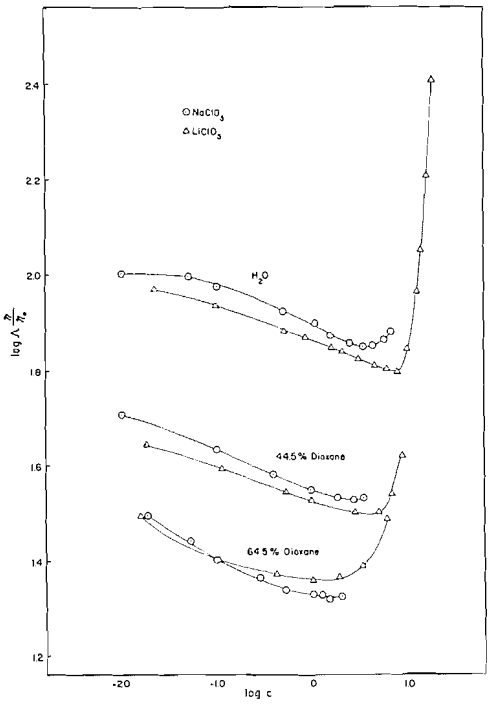

FIG. 3. Plot of log $\Lambda(\eta/\eta_0)$ of $NaClO_3$ and $LiClO_3$ in water, 44.5% dioxane, and 64.5% dioxane vs. log c.

scheme (16–18), which takes cognizance of the viscosity differences, are illustrated by the log $\Lambda(\eta/\eta_0)$ vs. log c graphs of Fig. 3. With increasing concentration, the log $\Lambda(\eta/\eta_0)$ curves show a minimum characteristic of triple-ion formation (19, 20). The minima in the log $\Lambda(\eta/\eta_0)$ curves shift to lower concentrations as the dielectric constant of the solvent decreases. This is in accord with the prediction for ionic interactions based on solvent dielectric properties.

Studies of rhenium–carboxylate complexes. I. Tris(μ-*i*-butyrato)di(chlororhenium(III)) perrhenate

C. CALVO, N. C. JAYADEVAN, AND C. J. L. LOCK[1]

Department of Chemistry and Institute for Materials Research, McMaster University, Hamilton, Ontario

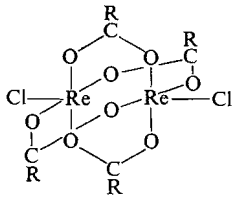
Received June 20, 1969

One of the compounds obtained by reacting rhenium(III) chloride with isobutyric acid while exposed to oxygen has been shown by single crystal X-ray diffraction to be tris(μ-*i*-butyrato)di(chlororhenium(III)) perrhenate. The crystals are monoclinic with lattice parameters $a = 8.980(5)$ Å, $b = 17.790(8)$ Å, $c = 15.361(8)$ Å, and $\beta = 114.4(1)°$. The space group is $P2_1/c$ and there are 4 formula units per cell. A total of 1729 independent reflections were examined and the structure was refined by full three dimensional least squares to an R value of 0.114. Two Re environments are found, one consisting of a dimer unit bridged by three carboxylate groups with a chlorine atom per rhenium and the other as a perrhenate group. This latter group, showing a mean Re—O distance of 1.74 Å, shares an oxygen atom with a Re in the dimer unit, and this Re—O bond length is 2.28 Å long. The structure consists of a packing of chains of alternate dimers and perrhenate groups running parallel to the *c* axis.

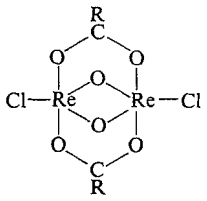
Canadian Journal of Chemistry 47, 4213 (1969)

Introduction

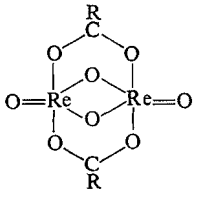
Taha and Wilkinson investigated the reaction of rhenium trichloride with carboxylic acids both in air and in oxygen-free (< 10 p.p.m.) nitrogen (1). The compound obtained in the absence of air



1



2



3

was postulated to be **1**, formally a compound of Re(III). The compounds obtained in the presence of air were postulated to be **2** and **3**, formally compounds of Re(IV) and Re(V), respectively. It has been shown (2, 3) that although the structure of **1** is basically correct, the compound has a very short Re—Re distance and this has been interpreted as indicating the presence of a very strong quadruple bond between the rhenium atoms in the dimer unit. It was of great interest to see whether strong metal–metal bonds were present in compounds **2** and **3**. In this paper we report our structural investigations of the μ-*i*-butyrato-complex supposedly of type **2**.

Experiments

Preparation

Rhenium(III) chloride[2] (2 g) was refluxed with isobutyric acid (25 ml) in a slow stream of oxygen which was dried by bubbling through concentrated sulfuric acid. After about 12 h, purple crystals formed and were filtered from the hot orange solution. The solid product was purified by repeated rapid crystallization from ethanol while under evacuation. Single crystals were prepared by recrystallization from chloroform. Attempts to crystallize the compound from acetone or ethanol solution in air always yielded a blue solid. The purple solid analyzed as C, 15.7%, H, 2.2%, O, 16.8%, and atoms Re:Cl, 1.4:1. $C_{12}H_{21}Cl_2O_{10}Re_3$ requires C, 15.1%, H, 2.2%, O, 16.8%, and atoms Re:Cl, 1.5:1. The suggested stoichiometry is confirmed by the successful structure analysis.

Analysis

C and H analyses were performed by the Galbraith Laboratories, Knoxville, Tennessee. Oxygen analyses were performed at the Microchemical Laboratories, Imperial College, London, by courtesy of Professor G. Wilkinson. The rhenium:chlorine atom ratio was determined by A. Guest using neutron activation analysis (4).

Infrared Spectra

The infrared absorption spectra were recorded on a Perkin–Elmer 337B spectrophotometer and are given in Table I. Powder samples dispersed as a mull in Nujol and mounted between potassium bromide plates, or dispersed in powdered potassium bromide and pressed in a disc, were used for recording spectra.

Crystallography

The density of a few single crystals were determined by flotation in a mixture of di-iodomethane and tetrachloromethane, whose density was subsequently determined with a pycnometer.

Accurate unit cell parameters were determined from precession photographs of the [100] and [001] zones which were calibrated with a diffraction pattern from a TiO_2 single crystal (a = 4.5929(5) Å and c = 2.9591(3) Å (5)). The monoclinic angle β was measured from the spindle settings at which these two precession photographs were taken. The crystal data are shown in Table II. It was observed that reflections of the type $0k0$ with k odd were absent as were $h0l$ reflections with l odd. Thus, the space group was determined uniquely as $P2_1/c\text{–}C_{2h}^5$. A single crystal (0.1 × 0.1 × 0.1 mm^3) was used in taking the X-ray photographs. The equi-inclination Weissenberg method was used to record layers hnl (n = 0 to 6), the photographs being taken with Cu-K_α radiation. The $hk0$ and nkl (n = 0, 1, 2) layers were photographed by the precession method, using Mo-K_α radiation.

*Systematic absences, $0k0$, k odd; $h0l$, l odd. Space group, $P2_1/c\text{–}C_{2h}^5$.

Each layer was photographed 3 times using exposures involving time intervals differing by a factor of 3. The intensities were estimated visually and then corrected for Lorentz and polarization effects. All data obtained using copper radiation were corrected for absorption since otherwise errors of about 15% would have been introduced into the structure factors [μR = 1.66 for Cu-K_α and 0.08 for Mo-K_α]. For Mo-K_α radiation the absorption corrections would be negligible. These corrections were made assuming the crystal was a sphere of radius 0.05 mm.

Standard errors, σ, were assigned to each intensity and weights $w = 1/\sigma^2$ were used throughout the refinement. Greater weights were given to reflections which could be measured on all 3 films than to those which could be measured only on 1 or 2 films[3]. For unobserved reflections weights, calculated from $\sigma = 0.5\,F_{min}$ were used only when the calculated structure factor $|F_c| > 0.8\,F_{min}$, where F_{min} was the local minimum of the observed intensity. Otherwise they were given zero weight.

Solution of the Structure

The density required 12 rhenium atoms per unit cell and, if the structure proposed were correct (1), the cell must contain 6 dimeric groups per unit cell. Since the space group, $P2_1/c$, will generate 4 symmetry-related groups, one of the dimers must possess an element of symmetry and one must be in a general position. Thus, one of the dimers must have an inversion center. The Patterson function must show a rhenium–rhenium distance of the order of 2.5 to 3.4 Å, attributable to a dimer unit located at a center of symmetry together with a similar peak of double weight arising from the dimer in a general position. Otherwise the cell cannot contain 6 dimers of the type postulated in (1). These estimated distances were derived from known ReO separations and a range of assumed ReORe angles.

The two-dimensional Patterson maps for the 3 zero layer projections were readily soluble for the Re atoms. This solution was inconsistent with a dimeric unit placed on a center of symmetry. In addition the smallest Re—Re vector was 2.2 Å in length and indicated that the dimer in the general position must differ from that proposed by Taha and Wilkinson (1). The trial solution was obtained for the rhenium atom positions, however, and these positions were confirmed by an examination of the generalized Patterson maps using $h1l$ and $h2l$ reflections.

Structure factor calculations with these atomic positions gave, after one cycle of least-square refinement, an isotropic temperature factor B = 2.0 and the x, y, z coordinates Re(1): 0.073, 0.083, 0.126; Re(2): 0.191, 0.181, 0.372; Re(3): 0.141, 0.250, −0.027, and the overall residual error

$$R_1 = \frac{\sum|F_o - F_c|}{\sum|F_o|}$$

of 0.30. The 3 rhenium atoms in the asymmetric zone

[3]Thus $\sigma = 0.1\,F_o$ if $60 < F_o < 300$, $\sigma = 0.15\,F_o$ if $300 < F_o < 500$ or $40 < F_o < 60$, and $\sigma = 0.25\,F_o$ if $500 < F_o$ or $F_o < 40$.

*Estimated standard deviations in parentheses.
†Anisotropic thermal parameters used for rhenium atoms (Å)^2 × 10^4.
‡These values were obtained from $\beta_{ij} = 2\pi^2 b_i b_j U_{ij}$ where β_{ij}'s appear as a temperature effect through exp $[-(\beta_{11}h^2 + 2\beta_{12}hk + \ldots)]$ in the structure factor expression and b_i are the reciprocal lattice vectors.

consisted of 2 at a distance of 2.2 Å from each other, thus forming a dimer, while the third was at 3.8 Å from the nearest rhenium atom in the dimer. The nearest symmetry related pair of non-dimer atoms was at 4.6 Å. Thus there were 2 types of rhenium environments present in this structure; a pair of rhenium atoms were strongly bonded to each other while the third was either independent of the dimer or, at best, weakly bonded to it.

Electron density and difference syntheses based upon the signs determined for the structure factor for the contributions of the 3 rhenium atoms showed only 2 peaks that were large enough to be attributable to chlorine atoms. Ten more peaks had approximately half the chlorine peak heights and were attributed to oxygen atoms. Repeated structure factor calculations followed by difference Fourier syntheses revealed all 12 carbon atom positions. The positional parameters, isotropic temperature factors of all non-rhenium atoms, and anisotropic temperature factors for the rhenium atoms were varied in a full matrix least-square refinement, using the program MACLS written by J. S. Stephens. The minimum value obtained was $R_1 = 0.126$ and $R_2 = 0.150$, where R_2 is defined as

$$\left[\frac{\sum\omega(|F_o|^2 - |F_c|^2)}{\sum\omega|F_o|^2}\right]^{1/2}$$

The anomalous dispersion effects, tabulated by Cromer (6), show a significantly different value for Mo-K_α from that for Cu-K_α data. In the final stages of the refinement, the molybdenum data were modified to obtain pseudo observed structure factors that would have been obtained if copper radiation were employed. The atomic scattering factors of C, Cl, and O were obtained from the International tables for X-ray crystallography (7) while that for Re was taken from Cromer and Waber (8).

The positional and thermal parameters were subsequently refined to a minimum value of $R_1 = 0.114$ and $R_2 = 0.118$. In the final cycle of refinement no parameter changed by more than 1/3 of its estimated standard deviation. A difference synthesis obtained had no peaks higher than 1.8 e/Å^3 or lower than −1.6 e/Å^3. The final positional and thermal parameters are presented in Table III. The observed and calculated structure factors

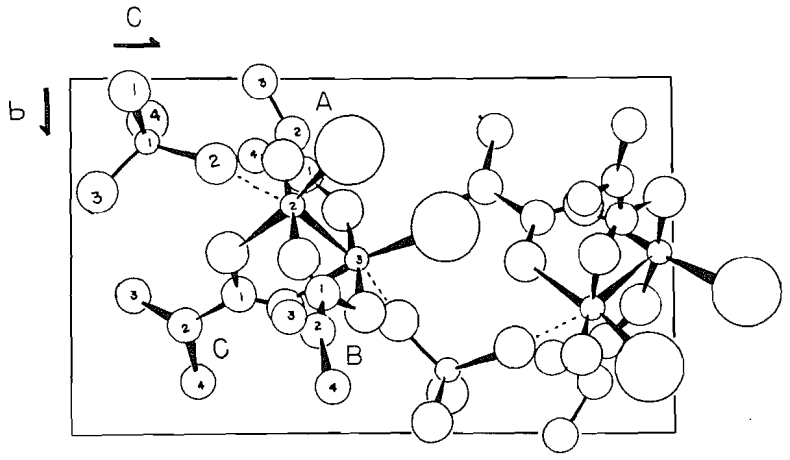

FIG. 1. The molecular packing of $[Re_2Cl_2(i\text{-}C_3H_7CO_2)_3](ReO_4)$ projected down the ***a*** axis. Atoms in order of decreasing size of circles are Cl, O, C, and Re. Full lines indicate bonds in the perrhenate group and dimer unit. Dotted lines indicate bonds between the perrhenate groups and the dimer units. A, B, C label the bridging carboxylate groups in the dimer unit. Of the small numbers 1 refers to the carboxylate carbon atom, 2 the α-carbon atom, and 3 and 4 the β-carbon atoms in each carboxylate group. The large numbers, 1–4, label the oxygen atoms in the perrhenate group.

are compared[4] in Table IV. Of the 1729 reflections examined, 1236 were observed. Each layer line was independently scaled and reflections observed on more than one film were averaged and assigned at random to one of the groups from which it originated.

Results and Discussion

The essential feature of the structure is the presence of a carboxylato-bridged rhenium dimer $[Re_2Cl_2(O_2CC_3H_7\text{-}i)_3]$ and a perrhenate group, ReO_4^-, per asymmetric unit of the unit cell, as shown in Fig. 1. Each dimeric unit has 3 bridging carboxylate groups and 1 chlorine atom on each rhenium atom. The other rhenium atom of the dimer and 1 oxygen atom of the perrhenate group completes a distorted octahedral arrangement of atoms around each rhenium atom. The dimeric unit is illustrated in Fig. 2. Two of the oxygen atoms of the ReO_4^- group are used to form a link between 2 otherwise independent dimer groups forming continuous chains. The compound is thus of interest, since it is the first of the series of compounds containing the strongly bonded Re_2 unit in addition to non-dimerized rhenium atoms. Since there are 2 ReO_4^- units

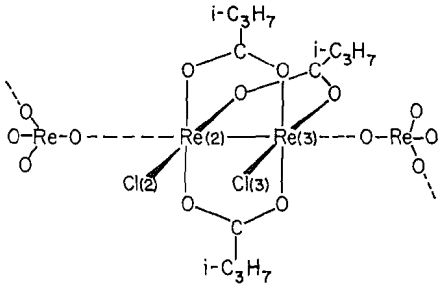

FIG. 2. The molecular geometry of the dimeric unit $[Re_2Cl_2(O_2CC_3H_7\text{-}i)_3]^+$.

associated with each dimer unit and 2 dimer groups associated with each ReO_4^-, the compound is properly called tris(μ-iso-butyrato)di-(chlororhenium(III)) perrhenate and the average formal oxidation number of rhenium is $4\frac{1}{3}$.

The bond distances and bond angles are listed in Table V. The numbering of atoms used refers to that in Fig. 1, which shows the packing of the molecule in the unit cell projected down the ***a*** axis. Within the dimer group the 2 rhenium atoms are separated by a distance of 2.259(3) Å. This distance is very similar to those observed in other dimeric Re(III) compounds where distances range from 2.20(2) to 2.241(7) Å (2, 3, 9–13), and lies well within the range 2.24 ± 0.10 Å predicted by Cotton (14) for a quadruple bond between the

2 rhenium atoms. The quadruple bond is postulated to consist of one σ, two π, and one δ bond. An eclipsed rotomeric configuration was shown to be necessary for the formation of the δ bond. The Re—Re distance obtained for the present compound and the eclipsed configuration in the dimer unit is consistent with Cotton's model for a quadruple bond between the 2 rhenium atoms.

The 2 independent Re–Cl distances are 2.29(1), and 2.22(2) Å. These values are within the range of distances observed in $[Re_2Cl_8]^{2-}$ (11), $Re_2Cl_6[P(C_2H_5)_3]_2$ (9), and $ReCl_2CH_3CO_2(H)\cdot H_2O$ (12), thereby suggesting a similar type of bonding. The bond distances and angles within the carboxylate groups are similar to those observed in other compounds where the carboxylate group is known to bridge 2 metal atoms (15). Thus the β-carbon atom and the 2 oxygen atoms attached to the α-carbon atom in the carboxylate group form a plane, and pairs of them subtend angles of approximately 120° at the α-carbon atom. The angles subtended by pairs of the 3 carbon atoms bonded to the β carbon atom are close to the tetrahedral angle. The 6 independent rhenium atom to carboxylic oxygen distances do not differ significantly.

All the relevant least-squares planes (16) in the dimeric unit were calculated using the program PALS written by P. Ashmore for the CDC 6400 computer. Individual atoms forming a plane were given weights

$$\left[\frac{1}{a.b.c.\sigma(x).\sigma(y).\sigma(z)}\right]^{2/3}$$

where a, b, c, are cell constants, and $\sigma(x)$, $\sigma(y)$, $\sigma(z)$ are standard deviations of the atomic coordinates. The equations of these planes are shown in Table VI. The calculations show that the 2 rhenium atoms and the bridging carboxylate groups form 3 planes, 2 of them being coplanar (planes 2 and 3) and orthogonal to the other (plane 1). The chlorine atoms on each rhenium are coplanar (plane 6) with plane 1 but are slightly out of the plane containing the rhenium atom and the 3 carboxylic oxygen atoms bonded to it (about 0.6 Å). The non-bonded distance between the 2 chlorine atoms is 3.40(3) Å, slightly shorter than the sum of the Van der Waals radii (3.6 Å), and each rhenium–chlorine bond makes an average angle of 104.8(5)° to the rhenium–rhenium axis. These values are very similar to those obtained in $[Re_2Cl_8]^{2-}$ (11) and the deviation is probably caused by steric repulsion.

As remarked earlier, there is an oxygen atom from a perrhenate group at each end of the dimeric unit, almost colinear with the Re—Re axis at a distance of 2.28(4) Å. The distance is probably somewhat longer than other Re—O lengths observed (average 2.10 Å) although the errors in the reported bond lengths are usually quite large. There has been a suggestion that the long Re—Cl distance for the chlorine atom bonded axially and *trans* to the Re—Re bond in $Re_2(RCO_2)_4Cl_2$ indicates a bond which is considerably weaker than normal and, by implication, that this is related to the strong Re—Re bonding (2). A similar interpretation may be made for the long Re—O distance in our compound, but we feel that in this case the long distance is caused at least partly by repulsive non-bonded interactions between the oxygen of the perrhenate group and the oxygen atoms of the carboxylate groups and the chlorine atom attached to the rhenium atom. The non-bonded distances of the axial oxygen atom with the chlorine atoms and the carboxylic oxygen atom "*trans*" to it are

$$O(12)\text{—}Cl(2) = 3.20(4)\ Å$$

$$O(13)\text{—}Cl(3) = 3.15(4)\ Å$$

$$O(12)\text{—}O(2C) = 2.72(5)\ Å$$

$$O(13)\text{—}O(3C) = 2.78(4)\ Å$$

These values are of the same order as the sum of the Van der Waals radii (O + Cl = 3.2 Å and O + O = 2.8 Å, using Pauling's values (17)). The O—Re—O angles in the ReO_4^- groups are close to the tetrahedral angle except for a small increase in the angle subtended by the 2 oxygen atoms (O(11) and O(14)) not coordinated to the dimer unit. Probably the increase is caused by the repulsion of the non-bonded electrons on the oxygen atoms although the Re—O bond lengths involving these oxygen atoms are not significantly shorter than the others, and are comparable to those observed in $KReO_4$ (18).

The 2 oxygen atoms coordinated to the dimeric rhenium atoms help to form a chain of alternate dimer and ReO_4^- units running parallel to the *c* axis as shown in Fig. 1. These chains form a hexagonally closest packed arrangement when viewed in a cross section containing the *a* and *b*

axes. The packing of adjacent chains seems to be determined by the Van der Waals separation of the pair of ReO_4 tetrahedra related by the center of symmetries at 0, 0, 0, and 0, 1/2, 1/2.

The compound whose structure is described above is probably different from that obtained by Taha and Wilkinson for which they proposed the structure in **1**. We have duplicated the reaction conditions as far as possible, but failed to obtain the purple compound in any isolable amounts if the reaction is continued for more than 1 day. After this time, the major product is identical in composition to the orange compound they obtained (Part III of this series, to be published). The rhenium(III) chloride used in the original preparations was obtained by the thermal decomposition of rhenium pentachloride. We have used rhenium(III) chloride obtained by the same method as well as that bought from the Shattuck Company, Denver, Colorado, and obtained identical products. Stoichiometrically the difference is an additional oxygen atom in our compound at the expense of a chlorine atom. Analyses of the compound reported here were performed on single crystals, so differences in analysis might have been caused either by impurities in Taha and Wilkinson's compounds or by the compounds being different.

Data from the infrared spectra of $[Re_2(i\text{-}C_4H_7O_2)_3Cl_2]ReO_4$ recorded using single crystals, powdered and dispersed in Nujol, are presented in Table I, together with data reported by Taha and Wilkinson (1) for $Re_2(i\text{-}C_4H_7O_2)_2O_2Cl_2$. It will be noticed that the spectra are very similar except in the region 750–1100 K, where Re—O stretches are normally found (19, 20). If Taha and Wilkinson's sample was identical to ours, but impure, we would expect to find that the spectra were identical except for possible extra bands in the spectrum for their sample. This does not appear to be the case and suggests that the compounds are different. An unambiguous decision cannot be made since many of the bands in the region 750–1100 K can be correlated if it is assumed that there is a zero shift of ~ 15–20 K in this region, although the good correlation above and below this region suggest such a shift is unlikely. No attempt has been made to assign the bands or to say which bands arise from the Re=O stretch, as bands from the complexed isobutyrate ion also occur in this region (1).

Conclusions

We conclude that our compound is another in

Cryoscopic studies with molten fluorides. I. Depression of the freezing point of calcium fluoride by alkaline-earth fluorides and oxides and calcium silicates[1]

H. KOJIMA[2] AND C. R. MASSON

Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received July 11, 1969

The depression of the freezing point of CaF_2 by BaF_2 and MgF_2 is ideal in the limit of low concentrations, and excess partial free energies of CaF_2 at finite concentrations are in accord with data for other systems. Limiting depressions due to SrF_2, CaO, and SrO are each approximately $\frac{1}{4}$, and due to BaO and MgO, $\frac{1}{2}$, of the ideal values. Calcium orthosilicate behaves ideally on the basis of 1 SiO_4^{4-} ion per molecule. For calcium metasilicate, the results are interpreted in terms of a distribution of fluorosilicate ions of general formula $(SiO_3)_nF^{(2n+1)-}$ in the melts. For Ca_3SiO_5, the depressions are complicated by the non-ideal behavior of oxygen ions. From the phase diagrams at low concentrations, CaO behaves ideally in $CaCl_2$, and MgO is ideal in MgF_2. The results are discussed in terms of possible formation of solid solutions in some of these systems.

Canadian Journal of Chemistry, 47, 4221 (1969)

Introduction

The depression of the freezing point (f.p.) of inorganic salts by substances such as silicates, phosphates, and borates which yield polymeric anions in solution, and structural conclusions derived from such studies, have been discussed by Førland (1). The object of the present work, which is part of a wider investigation of the constitution of polyionic melts, was to study the depression of the f.p. of CaF_2 by calcium silicates of varying CaO/SiO_2 ratios. Unexpected results with CaO alone as solute prompted a more detailed study, and depressions due to other alkaline earth oxides and the corresponding fluorides were also investigated.

Calcium fluoride was chosen as solvent because its heat of fusion has been determined calorimetrically (2), reliable data are available for the heat capacities of solid and liquid (2), and many phase diagrams (3) with CaF_2 as the main component, show the pure crystalline fluoride as primary phase.

Experimental

Materials

Calcium fluoride (B.D.H. "Extra Pure"), MgF_2 (Koch Light), SrF_2 and BaF_2 (B.D.H.) were purified by passing anhydrous HF through the melts in the apparatus described previously (4). The f.p.'s were 1423, 1261, 1473, and 1354 °C.

Calcium silicates with molar ratios CaO/SiO_2 of 1/1, 2/1, and 3/1 were prepared from $CaCO_3$ (B.D.H., AR) and SiO_2 (Mallinckrodt, AR) by repeated sintering at 1400–1410 °C and grinding. X-Ray diffraction of powdered specimens showed that the $CaSiO_3$ was pseudowollastonite and that the orthosilicate was γ-Ca_2SiO_4. No unreacted CaO or SiO_2 was detected in either product.

Strontium oxide was prepared from $SrCO_3$ (Hopkins and Williams) by heating in a stream of mixed H_2 (40%) and Ar (60%) at 1100 °C for 18 h (5). Barium oxide was prepared from $BaCO_3$ (Anachemia, Reagent) by heating at 1100 °C under high vacuum in a Pt container (5). Magnesium oxide (Mallinckrodt) was of reported purity 99.9%.

Apparatus and Procedure

Freezing points were determined by the method of thermal arrests with the apparatus described previously (6). Melts were held in graphite crucibles, 1 in. in diameter and 1.5 in. deep, equipped with a re-entrant well which housed the junction of the thermocouple. Crucibles were degassed at 1400–1450 °C in a separate apparatus before use. Approximately 11 g CaF_2 was used in each determination.

Temperatures were measured with a Pt/87% Pt - 13% Rh thermocouple calibrated periodically against copper, f.p. 1083.3 °C, supplied by the U.S. National Bureau of Standards. A Westronics potentiometric recorder with a full chart range of 2 mV was used to measure the electromotive force (e.m.f.). The recorder was calibrated after each series of measurements by a Leeds and Northrup potentiometer.

The temperature of the furnace was controlled by a Honeywell program controller, actuated by a second thermocouple located close to the winding. Linear cooling rates ranged from 1 to 3 °C per min. Too slow cooling often yielded indeterminate arrests at high concentrations of solute. Too rapid cooling occasionally resulted in supercooling. Each measurement reported is the mean of at least 3 determinations at a suitable rate. Melting points were reproducible to ±1.5 °C.

Results

The exact expression (7) for the temperature T

[1]NRCC No. 10 937.

[2]NRCC Postdoctorate Fellow, 1964–1966. Present address: Faculty of Engineering, Yamanashi University, Kofu-Shi, Japan.

at which pure solid component *1* crystallizes from a solution on cooling may be written

$$[1] \quad -R \ln a_{1(T)} = \frac{(T_0 - T)}{T} \times \left\{ \frac{\Delta H_f^0}{T_0} - A - \frac{B(T_0 - T)}{2} \right\} + A \ln \frac{T_0}{T}$$

where $a_{1(T)}$ is the activity of component *1*, at temperature T, relative to the supercooled liquid at the same temperature, ΔH_f^0 is the molar heat of fusion of pure component *1* at its melting point T_0, and A and B are constants in the equation

$$[2] \quad \Delta C_p = A + BT$$

where ΔC_p is the heat capacity of pure liquid component *1* less that of the crystalline solid at temperature T.

Various approximate forms of eq. [1] are found in the literature. As $T \rightarrow T_0$, the terms in A and B may be ignored and, for CaF_2 as solvent

$$[3] \quad \frac{1}{T} \simeq \frac{1}{T_0} - \frac{R}{\Delta H_f^0} \ln a_{CaF_2}$$

If the solute dissociates into ν foreign ions per molecule, and if the activity of CaF_2 can be replaced by its mole fraction N, eq. [3] becomes, in the limit (see also Appendix)

$$[4] \quad \frac{1}{T} \simeq \frac{1}{T_0} - \frac{\nu R}{\Delta H_f^0} \ln N_{CaF_2}$$

Alkaline-Earth Fluorides

Figure 1 shows the temperatures at which the first thermal arrests appeared on cooling. The solid lines correspond to ν = 1 and 1/4 in eq. [4]. Naylor's (2) value, 7100 cal/mole, was used for ΔH_f^0.

In the limit of low concentrations, the depressions due to MgF_2 and BaF_2 in Fig. 1 each correspond to 1 foreign ion, and that due to SrF_2, to 0.25 foreign ion per molecule of solute.

Activities of CaF_2 in its binary solutions with MgF_2 and BaF_2 were calculated by eqs. [1] and [2]. For CaF_2 in the range of temperatures under consideration, ΔC_p was obtained from the data of Naylor (2)

$$[5] \quad \Delta C_p = -1.93 - 0.0025T$$

Activities and activity coefficients calculated in this way are presented in Table I. For both systems, deviations from ideality are small over the range investigated.

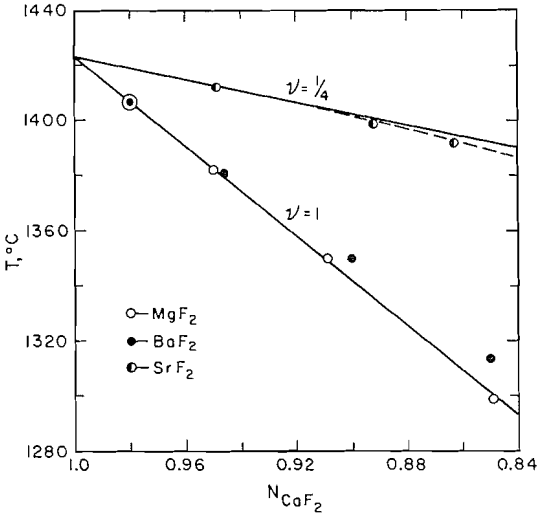

FIG. 1. Depression of the freezing point of CaF_2 by MgF_2, BaF_2, and SrF_2. The broken line corresponds to eq. [4′] in the Appendix, based on $n = 1/4$.

TABLE I

Activities of CaF_2 in its binaries with BaF_2 and MgF_2 at various temperatures

Mole fraction of CaF_2	Freezing point (°C)	a_{CaF_2}	γ_{CaF_2}
	(a) CaF_2–BaF_2		
1.000	1423		
0.980	1407	0.980	1.000
0.946	1381	0.947	1.001
0.900	1350	0.907	1.008
0.850	1313	0.858	1.010
	(b) CaF_2–MgF_2		
1.000	1423		
0.980	1407	0.980	1.000
0.950	1382	0.948	0.998
0.909	1350	0.907	0.997
0.849	1299	0.839	0.989

Alkaline-Earth Oxides

Figure 2 shows the results for MgO, CaO, SrO, and BaO as solutes. None of these systems approach ideal behavior in the accepted sense. At low concentrations, the depressions due to MgO and BaO each correspond to 1, rather than 2, foreign ion per molecule; that due to CaO corresponds approximately to ν = 1/4, while SrO shows intermediate behavior, with ν ≃ 1/2. The results for MgO show a minimum in the freezing curve near $T = 1370$ °C, $N_{CaF_2} = 0.93$.

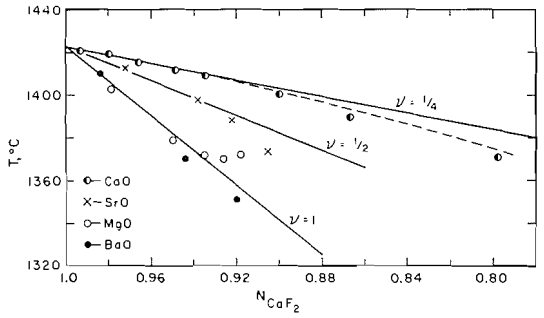

FIG. 2. Depression of the freezing point of CaF_2 by MgO, CaO, SrO, and BaO. Broken line corresponds to eq. [4′], based on $n = 1/4$.

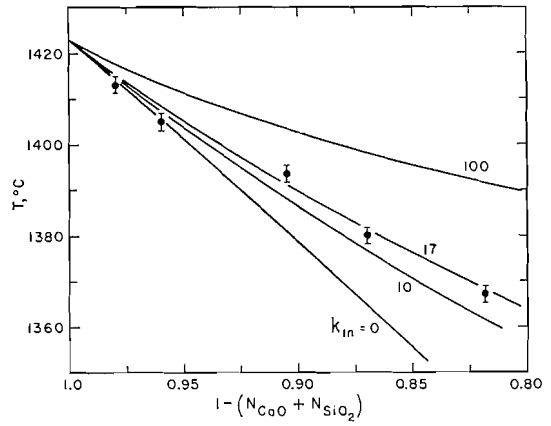

FIG. 3. Depression of the freezing point of CaF_2 by pseudowollastonite. The lines are calculated from eqs. [13] and [15] for various values of k_{1n}.

Calcium Silicates

The results for calcium silicates with molar ratio CaO/SiO_2 of 1/1 are shown in Fig. 3, and ratios of 2/1 and 3/1 in Fig. 4. Mole fractions of CaF_2 are expressed on the basis that CaF_2, CaO, and SiO_2 are components.

Discussion

Fluorides

The depressions due to MgF_2, SrF_2, and BaF_2 (Fig. 1) are in good agreement with values reported elsewhere (8, 9), although the absolute f.p. values are higher than those in previous studies, due to the higher purity of the materials in the present work.

Excess partial free energies of solution of CaF_2 in its binary solutions with MgF_2 and BaF_2, as calculated from the data in Table I, are plotted in Fig. 5 against the square of the mole fraction of solute. The slight negative departures from ideality associated with the smaller Mg^{2+} ion and the positive departures for the larger Ba^{2+} are in line with similar trends for the alkaline-earth fluorides in sodium fluoride, reported by Cantor (7), and for mixtures of the alkali fluorides themselves. Thus, LiF shows slightly negative, and KF slightly positive, deviations from ideality in NaF solutions (10).

The lower depressions for SrF_2 in CaF_2 (Fig. 1) are due to formation of solid solutions as concluded also by Delbove (9). This is supported by the work of Chernevskaya (11) and Chernevskaya and Anan'eva (12), who reported a complete series of solid solutions in this system. In line with this, it was noted in the present study that melts with SrF_2 as solute cooled to transparent solids,

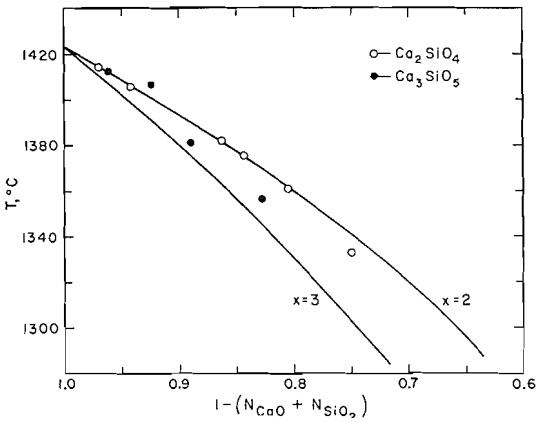

FIG. 4. Depression of the freezing point of CaF_2 by Ca_2SiO_4 and Ca_3SiO_5. The lines are calculated from eqs. [15] and [21] with $x = 2$ and 3.

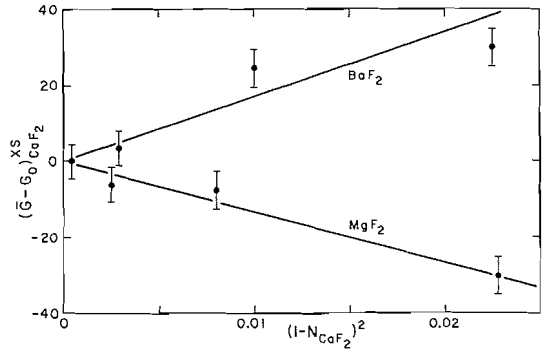

FIG. 5. Excess partial free energies of CaF_2 in its melts with BaF_2 and MgF_2 in the range 1299–1423 °C. The vertical lines correspond to an uncertainty of ± 1 °C in the freezing points.

in contrast to those with BaF_2 or MgF_2 which were milky or white.

Our results for the system CaF_2–SrF_2 indicate a value of 0.75 for the distribution coefficient ρ, the ratio of the concentration of solute in the solid to that in the liquid solution. This value, which does not vary with composition in the region investigated, is in reasonable agreement with the value of 0.705 reported by Delbove (9).

Oxides

The depressions due to CaO (Fig. 2) agree with those reported by Delbove (9) and Delbove *et al.* (13) and with the phase diagram as established by Mukerji (14), although our values of the f.p. are 4–10 °C higher. No evidence was found for the two-phase region of liquid immiscibility reported by Baak (15).

It has been shown recently (16) that solid solutions crystallize in the system CaF_2–CaO, and the relatively small depressions due to CaO must be attributed to this cause. The limiting value of 0.75 found for the distribution coefficient is in reasonable agreement with the value of 0.80 by Delbove *et al.* (13). This high value indicates that oxide ions readily substitute for fluoride ions in the CaF_2 lattice; two F^- ions are presumably replaced by one O^{2-} ion and a vacant anion site. A similar conclusion was reached by Baak (17) from studies of electrical conductivity and density.

All the oxides of Fig. 2 crystallize with the sodium chloride structure and might reasonably be expected to form solid solutions with CaF_2. The results are qualitatively in line with this expectation, the limiting depressions becoming greater as the cation becomes larger ($Ba^{2+} > Sr^{2+} > Ca^{2+}$) or smaller ($Mg^{2+} < Ca^{2+}$) than the Ca^{2+} ion.

An alternative, though less likely, interpretation is that the oxides MgO and BaO, for which $\nu \simeq 1$ in the limit, remain largely associated as ion pairs in the melt. Such an interpretation was used successfully by Lumsden (18) to predict the cryoscopic behavior of certain halides in fused nitrate media. In the present case, this would require a large increase in free energy when either BaO or MgO reacts with CaF_2. Available data do not allow these free energies to be estimated with sufficient accuracy to test this interpretation.

If the low depressions caused by the oxides in Fig. 2 were due to solid solutions, limiting depressions closer to ideality might be expected for CaO in $CaCl_2$ and MgO in MgF_2, as these solvents crystallize in the rutile structure and would not be expected to yield solid solutions with either CaO or MgO. This is borne out for MgO in MgF_2 by the data of Tomlinson and Welch (19) and of Delbove *et al.* (13), and for CaO in $CaCl_2$ by the data of Threadgill (20). The latter are shown in Fig. 6, where the line for $\nu = 1$ is based on Moore's (21) value of 6780 cal/mole for the heat of fusion of $CaCl_2$.

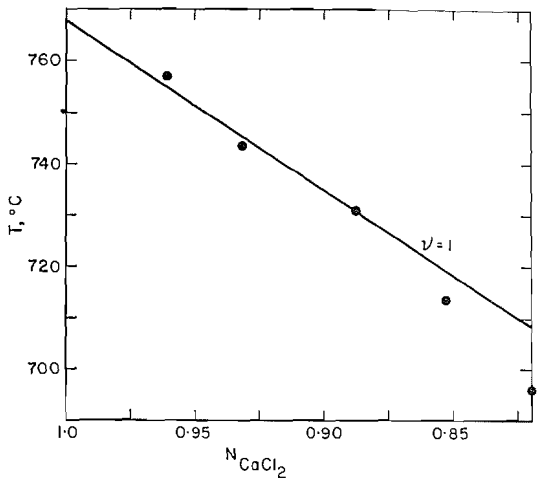

FIG. 6. Depression of the freezing point of $CaCl_2$ by CaO from the data of Threadgill (20).

Silicates

(a) The System CaF_2–$CaSiO_3$

Our results differ considerably from those of Baak and Olander (22) which correspond to $\nu = 1/3$ and were interpreted by them as evidence for cyclic $Si_3O_9^{6-}$ ions in the melt. Their results were in line with X-ray crystallographic data for pseudowollastonite, believed to have a ring structure (23). The discrepancy between our results and those of Baak and Olander is well beyond experimental error and amounts to 20 °C at the highest concentrations of solute. The reason for this discrepancy is at present unknown.

The results in Fig. 3 correspond, in the limit, to 1 foreign ion per molecule of $CaSiO_3$. The simplest anion which satisfies the tetrahedral coordination requirement of silicon and yields 1 foreign ion per molecule is SiO_3F^{3-} and the results are discussed below on the basis that such ions condense to yield linear chains of general formula $(SiO_3)_nF^{(2n+1)-}$ as the concentration of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

silicate increases. Evidence for the presence of chains rather than rings in this system has been given by Mitchell (24). Buehler and Bues (25) showed the presence of PO_3F^{2-} ions in fluorophosphate melts by Raman spectroscopy, and concluded that anions with more than 1 fluorine atom were not formed.

Consider the self-condensation of SiO_3F^{3-} anions in a fluoride melt. Polyanions, each terminated by 1 fluorine atom, can be formed in the following steps

$$[1,1]\quad SiO_3F^{3-} + SiO_3F^{3-} = Si_2O_6F^{5-} + F^- \qquad k_{11}$$

$$[1,2]\quad SiO_3F^{3-} + Si_2O_6F^{5-} = Si_3O_9F^{7-} + F^- \qquad k_{12}$$

$$[1,3]\quad SiO_3F^{3-} + Si_3O_9F^{7-} = Si_4O_{12}F^{9-} + F^- \qquad k_{13}$$

etc.

It has been shown previously (26, 27) that polycondensation reactions of this nature can be treated by assuming that, as a first approximation, the equilibrium constants $k_{11}, k_{12}, k_{13}, \cdots k_{1n}$ are identical. The treatment is similar to that developed by Tobolsky and Eisenberg (28). The same assumption is made here. Strictly speaking, this assumption is valid only for linear polymers in the limit of high values of n. Refinement to include variation of k_{1n} with n for nonlinear polymers is possible on the basis of theoretical considerations developed elsewhere (29), but as the above model is tentative and the degree of branching unknown, this refinement is not considered to be warranted at present.

From eqs. [1,1], [1,2], [1,3], $\cdots$ and the above assumption, it follows that

$$[6]\quad N_{(SiO_3)_nF} = \left(\frac{k_{1n}N_{SiO_3F}}{N_{F'}}\right)^{n-1} N_{SiO_3F}$$

where N is the ion fraction of the species indicated. (In this and subsequent equations, the charge associated with each silicate ion is, for simplicity, omitted in expressions for ion fractions; fluoride and oxygen ions are denoted by F′ and O″.)

Hence, for the sum of the ion fractions of fluorosilicate ions

$$[7]\quad \sum_{n=1}^{\infty} N_{(SiO_3)_nF} = N_{SiO_3F}\sum_{n=1}^{\infty}\left(\frac{k_{1n}N_{SiO_3F}}{N_{F'}}\right)^{n-1} = N_{SiO_3F}\left(\frac{1}{1 - k_{1n}N_{SiO_3F}/N_{F'}}\right)$$

As fluoride and fluorosilicate are the only species of anion in the melt, their sum, in the Temkin formulation (30), equals unity.

$$[8]\quad \sum_{n=1}^{\infty} N_{(SiO_3)_nF} + N_{F'} = 1$$

From eqs. [7] and [8]

$$[9]\quad N_{SiO_3F} = \frac{1 - N_{F'}}{1 + k_{1n}\left(\frac{1}{N_{F'}} - 1\right)}$$

To use this expression, we must relate the mole fraction of CaF_2 to the ion fractions of the proposed constituents of the melt. The necessary relationship is

$$[10]\quad N_{CaF_2} = \frac{\text{moles } CaF_2 \text{ from fluoride} + \text{moles } CaF_2 \text{ from fluorosilicate}}{\text{moles } CaF_2 \text{ from fluoride} + \text{moles } CaF_2 \text{ from fluorosilicate} + \text{moles } SiO_2 \text{ from fluorosilicate} + \text{moles CaO from fluorosilicate}}$$

$$= \frac{\frac{1}{2}N_{F'} + \sum_{n=1}^{\infty}\frac{1}{2}N_{(SiO_3)_nF}}{\frac{1}{2}N_{F'} + \sum_{n=1}^{\infty}\frac{1}{2}N_{(SiO_3)_nF} + \sum_{n=1}^{\infty} nN_{(SiO_3)_nF} + \sum_{n=1}^{\infty} nN_{(SiO_3)_nF}}$$

From eqs. [8] and [10]

$$[11]\quad N_{CaF_2} = \tfrac{1}{2}/\left(\tfrac{1}{2} + 2\sum_{n=1}^{\infty} nN_{(SiO_3)_nF}\right)$$

From eq. [6] and the identity

$$\sum_{n=1}^{\infty} nx^{n-1} = (1 - x)^{-2}$$

we have, for the summation in the denominator of eq. [11]

$$[12]\quad \sum_{n=1}^{\infty} nN_{(SiO_3)_nF} = \frac{N_{SiO_3F}}{(1 - k_{1n}N_{SiO_3F}/N_{F'})^2}$$

Substituting for N_{SiO_3F} from eq. [9] and combining the result with eq. [11], we obtain

$$[13]\quad 1/N_{CaF_2} = 5 - 4N_{F'} + 4k_{1n}(1 - N_{F'})^2/N_{F'}$$

which yields $N_{F'}$ as a function of composition if k_{1n} is known.

By Temkin's law

$$[14]\quad a_{CaF_2} = N_{Ca^{2+}}N_{F'}^2$$

As Ca^{2+} is the only species of cation in the melt,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$N_{Ca^{2+}}$ is unity and eq. [3] for the depression of the f.p. becomes

$$[15] \qquad \ln N_{F'}^{\,2} = -\frac{\Delta H_f^{\,0}}{R}\left(\frac{1}{T} - \frac{1}{T_0}\right)$$

Values of $N_{F'}$ corresponding to arbitrary values of N_{CaF_2} were calculated by eq. [13] for various values of k_{1n}. These were substituted in eq. [15] to yield theoretical plots of f.p. against composition. Calculated curves for various values of k_{1n} are shown in Fig. 3. A value of $k_{1n} = 17 \pm 5$ fits the data within experimental error.

From this value of k_{1n}, the average chain length of the fluorosilicate ions may be calculated as a function of the composition of the melt. These details and the effect of other cations on the mean chain length will be given in a subsequent communication.

(b) The System CaF_2–Ca_2SiO_4

Our data agree with those of Mukerji (14) and of Gutt and Osborne (31).

For Ca_2SiO_4 and silicates with higher ratios of CaO/SiO_2, sufficient oxygen is available to satisfy the coordination requirement of silicon at all concentrations. Condensation of SiO_4^{4-} anions can occur in the following steps

$$[16,1] \qquad SiO_4^{4-} + SiO_4^{4-} = Si_2O_7^{6-} + O^{2-}$$

$$[16,2] \qquad SiO_4^{4-} + Si_2O_7^{6-} = Si_3O_{10}^{8-} + O^{2-}$$

$$[16,3] \qquad SiO_4^{4-} + Si_3O_{10}^{8-} = Si_4O_{13}^{10-} + O^{2-}$$

etc.

As before, it is assumed that the equilibrium constants k are identical. By a procedure analogous to that outlined above, it may be shown that

$$[17] \qquad \frac{1}{N_{SiO_2}} = 3 + \frac{N_{O''} + N_{F'}/2}{1 - N_{O''} - N_{F'}} - \frac{1}{2k}\left[\frac{2 - N_{F'}}{N_{O''}\left(\frac{1}{k} - 1\right) + 1 - N_{F'}}\right]$$

$$[18] \qquad \frac{1}{N_{CaF_2}} = 1 + \frac{2}{N_{F'}}\left\{2N_{O''}(k-1) + (1 - N_{F'})\left[2k\left(\frac{1 - N_{F'}}{N_{O''}} - 2\right) + 3\right]\right\}$$

and

$$[19] \qquad \frac{1}{N_{CaO}} = \frac{N_{O''}(3 - 2N_{O''} - 5N_{F'}/2) + 2k(1 - N_{O''} - N_{F'})^2}{(1 - N_{F'})^2 + (k-1)(1 - N_{O''} - N_{F'})^2}$$

Combination of eqs. [17] and [19] yields

$$[20] \qquad \frac{N_{CaO}}{N_{SiO_2}} = 2 - k + \frac{N_{O''}}{1 - N_{O''} - N_{F'}} + \frac{k(k-1)}{\left(k + \frac{N_{O''}}{1 - N_{O''} - N_{F'}}\right)}$$

From eqs. [18] and [20]

$$[21] \qquad N_{F'} = \frac{2(x+1)N_{CaF_2}}{(x-1) + (x+3)N_{CaF_2}}$$

where

$$[22] \qquad x = N_{CaO}/N_{SiO_2}$$

Equation [21] shows that the ion fraction of fluoride ion, and hence the depression of the f.p., is independent of k and depends only on the mole fraction of CaF_2 and the molar ratio CaO/SiO_2, a result which is self-evident if fluoride ions do not participate in the polymerization. In this case, no information can be obtained regarding the mean chain length of the polyions from measurements of the depression of the f.p. alone. The reason is, of course, that as polymerization proceeds and the number of silicate ions decreases, there is a corresponding increase in the number of free oxygen ions so that the number of foreign ions remains constant.

Substitution of $x = 2$ in eq. [21] gives, for melts which contain Ca_2SiO_4

$$[23] \qquad N_{CaF_2} = N_{F'}/(6 - 5N_{F'})$$

and combination of this result with eq. [15] yields the theoretical curve for the depression of the f.p. for all degrees of polymerization. As shown in Fig. 4, it is in good agreement with the experimental data.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Equation [23] was derived on the basis that oxygen and silicate ions behave ideally in CaF_2. As shown by the results for CaO, however, oxygen ions yield less than the ideal depression in this solvent. The good agreement of eq. [23] with the data suggests that oxygen ions are absent and the depression by Ca_2SiO_4 is due to SiO_4^{4-} ions alone. This is substantiated by the results for Ca_3SiO_5, as indicated below. It is also in line with previous conclusions (26) that Ca^{2+} ions cause almost complete depolymerization of silicate ions in melts near the orthosilicate composition.

(c) The System CaF_2–Ca_3SiO_5

Substitution of $x = 3$ in eq. [21] gives

$$[24] \qquad N_{CaF_2} = N_{F'}/(4 - 3N_{F'})$$

and combination with eq. [15] yields the theoretical curve in Fig. 4. In this case, the experimental depressions are less than predicted. As this system must contain excess oxygen ions, the result is undoubtedly due to the nonideal behavior of these ions discussed above.

Appendix

Dissociation of Solute

The term ν in eq. [4] represents the number of foreign ions per molecule of solute in the limit of low concentrations. Deviations from eq. [4] may be due to (*a*) neglect of heat capacity terms, (*b*) use of mole fractions in place of activities, and (*c*) apparent changes in ν with concentration.

The purpose of this note is to point out that deviations due to (*c*) may be larger than to either (*a*) or (*b*) and that, even when the number of foreign ions remains constant, ν as defined by eq. [4] may change appreciably with concentration.

Let S denote the number of moles of solute. Then

$$N_{CaF_2} = \frac{\text{moles } CaF_2}{\text{moles } CaF_2 + S}$$

If we assume that the solute dissociates into n foreign ions per molecule we may define

$$N'_{CaF_2} = \frac{\text{moles } CaF_2}{\text{moles } CaF_2 + nS}$$

The quantity N'_{CaF_2}, rather than N_{CaF_2}, is the correct quantity to be used in eq. [3] if the activity of CaF_2 is replaced by its mole fraction and dissociation of the solute is allowed. Thus, eq. [4] should be written

$$[4'] \qquad \frac{1}{T} \simeq \frac{1}{T_0} - \frac{R}{\Delta H_f^0} \ln N'_{CaF_2}$$

Comparison of eqs. [4] and [4′] shows that

$$\nu \ln N_{CaF_2} = \ln N'_{CaF_2}$$

This expression may also be derived from the equations of Haase (32).

Table II lists values of ν corresponding to various values of n and N_{CaF_2}. It is obvious that ν is only approximately the number of foreign ions per molecule of solute at finite concentrations. It tends to be too large when less than unity and too small when greater than unity.

The broken lines in Figs. 1 and 2 were calculated by eq. [4′] with $n = 1/4$. It is obvious that the solid lines corresponding to $\nu = 1/4$ in eq. [4] hold only in the limit of low concentrations and that deviations are due mainly to variations in ν with concentration.

TABLE II

Hydrogen bonding in lidocaine salts. I. The $\overset{+}{N}H$ stretching band and its dependence on the associated anion[1]

GEORGE A. NEVILLE AND ZEPHYR R. REGNIER

Research Laboratories, Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Canada

Received April 29, 1969

By means of deuterium exchange, the ν^{+}_{NH} band was identified in a series of lidocaine salts with varying anionic size. A value for the free $\overset{+}{N}$—H stretching frequency was obtained which permitted $\Delta\nu^{+}_{NH}$ to be related to anionic radius. Similar relationships were found for triethylamine and pyridinium salts using frequency data available in the literature. Four new lidocaine salts (HI, CF_3CO_2H, $HAsF_6$, and $HSbCl_6$) are reported.

Canadian Journal of Chemistry, 47, 4229 (1969)

Introduction

No critical analysis of the infrared spectra of salts of lidocaine (a tertiary aliphatic amine) has appeared in the literature. In publishing the infrared spectra of the hydrochloride monohydrate, styphnate, reineckate, tetraphenylborate, chloroplatinate, and methiodide salts of lidocaine, Rich and Chatten (1) commented briefly on the spectra in the context of their utility in the identification and differentiation of organic medicinal agents. Sandorfy and coworkers (2, 3) have conducted extensive infrared studies on the salts of various amines including triethylamine but limited the anions to the hydrohalides. Ebsworth and Sheppard have examined the di-, tri-, and tetra-methylammonium iodide salts (4), Nakanishi, Goto, and Ohashi have studied various amine hydrochloride salts (5), Nuttall, Sharp, and Waddington included trimethylammonium and pyridinium salts in their study of alkyl- and aryl-ammonium salts with a wide range of anions (6), and, most recently, Cook has made a detailed study of the infrared spectra of pyridinium salts having a wide range of anionic size (7).

In this paper we will limit our discussion to the variation in $\overset{+}{N}$—H stretching frequency (ν^{+}_{NH}) with eight different anions of varying size in the anhydrous series of lidocaine salts. By associating different anions with the same amine we can introduce a gradual change in hydrogen bond energy.

[1]Presented in part at the 51st Conference of the Chemical Institute of Canada, Vancouver, British Columbia, June 4, 1968.

Experimental

Spectra

Infrared spectra were obtained from a Perkin–Elmer Model 621 spectrometer whose calibration was periodically checked against indene. The spectra were produced from fluorolube mulls in NaCl windows over the range 4000–1350 cm^{-1} and from Nujol mulls in CsI windows over the range 1350–200 cm^{-1}. The enhanced band detail shown in Fig. 1 was achieved through the use of thicker mulls (approximately 5 times the quantity of solid usually employed for mull preparation) in conjunction with the variable expansion control of the spectrometer.

The mulls of hygroscopic salts and deuterio-salts were prepared under dry-box conditions (P_2O_5 and dry N_2).

Preparation of Salts

Lidocaine (m.p. 66–67°, Astra Pharmaceuticals Ltd.) was used without further purification for the preparation of all salts except the hydrochlorides.

Lidocaine hydrochloride monohydrate (m.p. 73–74.5°, Astra Pharmaceuticals Ltd.) was used without further treatment. The anhydrous hydrochloride was prepared from the monohydrate by drying over P_2O_5 at 55° in a mechanical pumping vacuum until constant melting at 123.5–125° was obtained. Literature melting values for the anhydrous hydrochloride are 128–129° (8) and 127–132° (9).

Lidocaine hydrobromide proved to be extremely hygroscopic. It was prepared by adding a slight molar excess of 47% aqueous hydrobromic acid to a lidocaine solution in a minimum volume of acetone. The mixture was reduced to a dry cake under water pump vacuum; then it was pulverized and dried over P_2O_5 at 55° in a mechanical pumping vacuum to obtain the constant melting range, 73.5–76.5°. The literature melting range for the anhydrous hydrobromide (127–132°) (9) appears to be erroneous since the same melting range was reported for the anhydrous hydrochloride.

Lidocaine hydrobromide monohydrate was prepared from the anhydrous salt by exposure to humid air. The gummy hygroscopic substance that quickly formed was kept over silica gel for several days during which it was progressively pulverized to a fine dry powder (m.p. 68–71°). The literature melting range for the hydrobromide monohydrate is 94–103° (9).

Anal. Calcd. for $C_{14}H_{25}O_2N_2Br$: C, 50.46; H, 7.56; N, 8.41. Found: C, 50.55, 50.58; H, 7.58, 7.60; N, 8.51, 8.51.

Lidocaine hydroiodide was prepared by addition of a slight molar excess of 49% aqueous hydrogen iodide to a concentrated aqueous solution of lidocaine. The pale yellow solid obtained by slow evaporation was recrystallized as a fluffy white solid from hot methyl ethyl ketone to which sufficient hexane was added to produce turbidity. The solid was dried as above in a pumping vacuum until a constant melting range (145.5–146.5°) was obtained.

Anal. Calcd. for $C_{14}H_{23}ON_2I$: C, 46.42; H, 6.40; N, 7.75. Found: C, 46.10, 45.90; H, 6.45, 6.44; N, 7.89, 7.66.

In contrast to the above halide salts, the hydroiodide does not form a hydrate.

Lidocaine hydrotrifluoroacetate was obtained by addition of a slight molar excess of trifluoroacetic acid to a concentrated aqueous solution of lidocaine. The crystals obtained by slow evaporation were recrystallized from mixed petroleum ether (boiling range 30–60°) – diethyl ether (1:1) and dried in a pumping vacuum to give solid, m.p. 138–139.5°.

Anal. Calcd. for $C_{16}H_{23}O_3N_2F_3$: C, 55.17; H, 6.66; N, 8.04. Found: C, 55.11, 54.84; H, 6.82, 6.52; N, 7.96, 7.91.

The infrared spectrum of the trifluoroacetate shows a strong band at 1685 cm^{-1} (asymmetric $\nu_{CO_2^-}$) and strong bands at 1200, 1170, 1160, 1130, and 1125 (sh) characteristic of the strong CF_3 stretching absorption reported for the range 1350–1120 cm^{-1} (10). The sharp, strong (s) to medium (m) peaks at 826 (s), 812 (m), 800 (s), 785 (m), and 767 (s) represent another band reported to involve the CF_3 group over the range 780–680 cm^{-1} (10).

Lidocaine hydronitrate was prepared by treating a concentrated aqueous solution of lidocaine with a slight molar excess of 1 *N* nitric acid. The solid which formed on slow evaporation was recrystallized from absolute ethanol and subjected to the usual pumping–drying until constant melting point (128–130°, decomp.) was observed. Literature melting data for the nitrate are 133–134°, decomp. (8) and 131–133° (9). The infrared spectrum shows strong bands at 1365 and 1340 cm^{-1} (asymmetric NO_3^- stretch).

Lidocaine hydrobisulfate was prepared by adding an equivalent amount of 1 *N* sulfuric acid for hydrobisulfate formation to a weighed sample of lidocaine dissolved in a minimum volume of water. The mixture was left under the hood to evaporate slowly, then it was subjected to the usual pumping vacuum until a constant melting range (196–200°) was obtained. The literature melting range for the hydrobisulfate is 210–212° (9). The infrared spectrum shows broad, medium intensity bands at 2877 and 2782 cm^{-1} (SO—H stretching) and strong bands at 1175 (asymmetric S—O stretching of $HOSO_3^-$), 1066 (symmetrical S—O stretching of $HOSO_3^-$), and 848 cm^{-1} (S—O(H) stretching).

Lidocaine hydrohexafluoroarsenate was prepared by treating lidocaine (0.64 g) dissolved in water (100 ml) in a polyethylene beaker with hexafluoroarsenic acid (0.75 g, $d_{25°}$ 1.902, Ozark-Mahoning Co.). After the mixture was heated on a steam bath, the salt was taken into solution by adding acetone (10 ml). The crystals which formed on cooling were collected and washed with water. The dry solid melted at 260–260.5°.

Anal. Calcd. for $C_{14}H_{23}ON_2AsF_6$: C, 39.63; H, 5.46; N, 6.60. Found: C, 39.93, 40.06; H, 5.66, 5.50; N, 6.57, 6.32.

Lidocaine hydrohexachloroantimonate was prepared by treating lidocaine.$HCl.H_2O$ (0.520 g) dissolved in chloroform (2 ml) with an equivalent quantity of antimony pentachloride (0.538 g, specific gravity 2.39). The yellow solid, which precipitated instantly, was collected and washed with chloroform after which it was subjected to the usual pumping–drying procedures until a constant melting range (177–180°) was obtained.

Anal. Calcd. for $C_{14}H_{23}ON_2SbCl_6$: C, 29.51; H, 4.07; N, 4.92. Found: C, 29.24, 29.12; H, 4.12, 4.13; N, 5.17, 5.17.

Deuterium exchange of amide and ammonium hydrogen was effected in most of the salts by dissolving each salt (50–100 mg) in D_2O (1.0 ml) – DOAc (0.25 ml) and recovering the exchanged salt by mechanical pumping on a high-vacuum line. The deuteriotrifluoroacetate salt was prepared by treating lidocaine (free base) with D_2O and trifluoroacetic acid-*d*; the deuteriohexachloroantimonate salt was prepared by exchange in dimethyl sulfoxide with D_2O or in DOAc/D_2O with comparable results, and the deuterio-hexafluoroarsenate salt was prepared by exchange in acetone with D_2O. After initial heating to aid dissolution, each mixture was subjected to the pumping vacuum for 2–3 h while being heated at 100°. Infrared analysis showed that practically complete deuterium exchange was achieved under these conditions.

All melting points are reported as uncorrected and were obtained in sealed capillary tubes on a Thomas Hoover melting apparatus. The capillary tubes used for hygroscopic salts were prepared under dry-box conditions.

Carbon, hydrogen, and nitrogen analyses on the $HBr.H_2O$, HI, and $HSbCl_6$ salts were performed using an F & M Model 185 CHN analyzer. All other analyses reported were obtained from the Schwarzkopf Microanalytical Laboratory, 56-19 37th Ave., Woodside, N.Y. 11377.

*Frequency for center of gravity of band.
†Frequency for free $\overset{+}{N}H$ stretching taken as 3366 cm^{-1}.

Outline of the Work

The spectra of the following salts of lidocaine were measured: hydrochloride, hydrochloride monohydrate, hydrobromide, hydrobromide monohydrate, hydroiodide, hydrotrifluoroacetate, hydronitrate, hydrobisulfate, hydrohexafluoroarsenate, and the hydrohexachloroantimonate. Spectra were also measured from the deuterio-analogs (amide ND and $\overset{+}{N}D$) of these salts. The frequency data for the ν^{+}_{NH} and ν^{+}_{ND} vibrations along with the frequency ratios are given in Table I. The spectral range, 3100–2700 cm^{-1}, of the normal salts has been reproduced in Fig. 1 to show the wealth and complexity of spectral detail.

The change in frequency ($\Delta\nu$) from that assumed for an $\overset{+}{N}H$ stretching vibration free of hydrogen bonding has been related to the ionic radius of the anion for each of the lidocaine salts (Table II and Fig. 2). The crystallographic data used for calculation of the ionic radii are given in Table III. Similar relationships were found for series of pyridinium and triethylamine salts using data obtained from the literature (Tables IV and V, Fig. 2). Upper limiting frequencies of 3366, 3300, and 3400 cm^{-1} were assumed for the free $\overset{+}{N}H$ stretching vibration in lidocaine, pyridinium, and triethylammonium salts, respectively.

Interpretation of the Spectra

The pronounced difference in the optimum quality of the spectra from lidocaine salts[2] (Fig. 1), as judged by band detail, between those of the hydrochloride and

[2]A referee has observed that some of the spectra appear to contain scattered light. This feature can be recognized from the gradual increase of apparent absorption toward higher frequencies and is dependent upon the particle size in the mull. The referee noted that the condition cannot always be helped by grinding in agreement with our experience, and did not wish to take exception to the quality of the spectra.

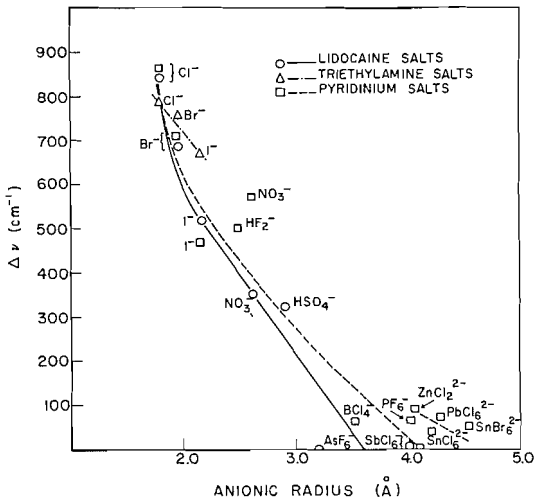

FIG. 2. Dependence of ν^{+}_{NH} on anionic radius in various salts.

hydrochloride monohydrate and between the hexachloroantimonate and the hexafluoroarsenate led us to suspect that the hydrochloride and hydrohexachloroantimonate salts were amorphous. Microscopic examination of these salts supported this hypothesis, the hydrochloride salt appearing as fragments of broken glass. X-Ray powder diffraction patterns, however, showed all four salts to be crystalline and confirmed the anhydrous nature of the hydrochloride relative to the monohydrated hydrochloride.

No attempt was made to disentangle and assign the generally poorly resolved C—H stretching bands near 3000 cm^{-1} arising from the N-ethyl substituents and the methyl substituents of the phenyl ring in these substituted ammonium salts. In this region overlapping occurs among ν_{CH_3} (asym) near 2960 ± 10 cm^{-1} (11), ν_{CH_3} (sym) near 2870 ± 10 cm^{-1} (11), ν_{CH_2} (asym) near 2930 cm^{-1} (11, 12) and those from the methyl groups of aromatic rings which usually give prominent bands near 2925 and 2865 cm^{-1} as well as variable intensity bands near 2975 and 2945 cm^{-1} (13). Although ν_{CH_2} (sym) for the CH_2 group next to nitrogen in tertiary amines is lowered from its value in hydrocarbons near 2850 cm^{-1} (11, 12) and appears near 2800 cm^{-1} (14), this effect is completely eliminated when the nitrogen acquires a positive charge in amine salts. In spite of the complexity of this region, the center of gravity of the ν^{+}_{NH} band could be located within it for the hydroiodide, hydrotrifluoroacetate, hydrobisulfate, and hydronitrate salts of lidocaine by careful comparison of the spectra from the normal salts and their deuterio-analogs. The frequency data for the ν^{+}_{NH} and ν^{+}_{ND} vibrations together with the frequency ratios are given in Table I.

The ν^{+}_{NH} band from the hydrochloride and hydrobromide of lidocaine is very broad and the center of gravity of the band shifts to higher frequency in the order Cl → Br → I. Both of these features were observed by Brissette and Sandorfy (3) from the spectra of the

†Frequency for free pyridinium $\overset{+}{N}H$ stretching taken as 3300 cm^{-1}.

hydrohalides of triethylamine, the frequency shift being in the reverse direction to that of the sharp bands between 2800 and 2400 cm^{-1} in primary and secondary amine salts. With increasing size of the anion from iodide to hexafluoroarsenate in the lidocaine salt series, the ν^{+}_{NH} frequency increases in the order $I^- \rightarrow CF_3CO_2^- \rightarrow NO_3^- \rightarrow HSO_4^- \rightarrow SbCl_6^- \approx AsF_6^-$ (Table I). While this shift to higher frequency with increasing size of anions is generally known and has been documented for salts of pyridine (6, 7), no demonstration of dependence of the ν^{+}_{NH} frequency on anionic size larger than the halides has been made for tertiary amines other than for salts of trimethylamine (6) as far as we know. Doubtless, other factors such as electronegativity, polarizability, crystal packing, and HY acid-strength are involved in the X—H...Y hydrogen bonding interaction, but this simple approach appears to offer a useful correlative procedure for an otherwise extremely complex bonding interaction.

The presence of multiple combination bands in the vicinity of the $\overset{+}{N}$—H stretching band is well displayed in the spectra from the monohydrated hydrochloride and hydrobromide salts and can also be seen on the low frequency side of the ν^{+}_{NH} band of the hydroiodide near 2500 cm^{-1}. Similar but weaker bands persist in the 2500 cm^{-1} region for the remaining salts of the series

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

with the exception of the hexafluoroarsenate and hexachloroantimonate salts where these bands appear to be absent. The presence of such multiple bands has been a controversial aspect of hydrogen bonding in amine salts. Sheppard (15) has reviewed the various explanations advanced in the literature for the low frequencies, and the broad and (sometimes) smooth contours observed for these bands under conditions of strong hydrogen bonding. More recently, from an analysis of band shifts, Brissette and Sandorfy (3) attributed the multiple band character seen in the ν^{+}_{NH} region in their study of tertiary amine hydrohalides to combination bands involving $\overset{+}{N}H$ deformation bands. Their interpretation is consistent with that arrived at by Bratož and Hadži (16) who demonstrated theoretically that anharmonicity in the stretching motion of a strongly bonded group (e.g. anion) gives rise to intense combination bands. For weak hydrogen bonding, they were also able to demonstrate theoretically that the combination effects could be reduced and that the ν^{+}_{NH} bands should be sharper and devoid of structure (16).

Discussion and Conclusions

The ν^{+}_{NH} band of the lidocaine salts varies in frequency from 2500 cm^{-1} in the hydrochloride to 3367 cm^{-1} in the hydrohexafluoroarsenate. The band is broad at low frequencies and becomes markedly sharper at the higher frequencies, culminating in a half width of 15 cm^{-1} for the hydrohexafluoroarsenate salt. Similar behavior has been observed and discussed by Sandorfy (hydrohalides of various amine salts) (2, 3), Nakanishi *et al.* (various amine hydrohalide salts) (5), Nuttall *et al.* (various trimethylammonium and pyridinium salts) (6), and recently by Cook (pyridinium salts) (7). Unfortunately only limited comparisons can be made since little ν^{+}_{NH} frequency data are available for salts of tertiary aliphatic amines with anions other than the halides (6). Nakanishi *et al.* (5) considered that the tetraphenylborate anion represented a case of free $\overset{+}{N}$—H stretching (near 3100 cm^{-1}); Nuttall *et al.* (6) regarded any trimethylammonium salt giving a strong ν^{+}_{NH} band near 3200 cm^{-1} to be free of hydrogen bonding; Mathieu and Poulet (17) questioned the degree of hydrogen bonding in the tetraphenylborates in particular and cited still higher frequencies (up to 3335 cm^{-1} with PF_6^-) from their study of unsubstitufed ammonium salts. For salts of pyridine, an aromatic tertiary amine, Nuttall *et al.* (6) considered those anions ($PbCl_6^{2-}$, ClO_4^-, BPh_4^-, BF_4^-, BCl_4^-, and PF_6^-) which gave ν^{+}_{NH} frequencies in the range 3230–3255 cm^{-1} to be free of hydrogen bonding[3] while Cook (7) has shown that both the reineckate and hexachloroantimonate salts of pyridine have a higher ν^{+}_{NH} frequency at 3300 cm^{-1}. In the lidocaine series, the $HSbCl_6$ and $HAsF_6$ salts give still higher ν^{+}_{NH} frequencies at 3357 and 3366 cm^{-1}, respectively, indicating weaker interionic interaction and a closer approximation to the condition of free $\overset{+}{N}$—H stretching. By comparing chemical shift values for the methylene protons from the series of lidocaine salts with those from the free base and the methiodide quaternary salt in DMSO-d_6 solution, we conclude that the tertiary amino nitrogen is strongly protonated and that $LidH^+...X^-$ is the correct model for all lidocaine salts (20).

The strong interaction between the nitrogen hydrogen and a small anion associated with an intense force field, appears to be responsible for the breadth, intensity, and low frequency that characterizes the ν^{+}_{NH} band. As the anion increases in size in the series Cl^-, Br^-, I^-, the force field weakens as the charge density decreases. For compounds containing polyatomic anions associated with weak peripheral force fields, the frequency increases until it appears that free $\overset{+}{N}$—H stretching is obtained as in the $HAsF_6$ salt. Lord and Merrifield, noting the striking breadth of X—H...Y bands in crystals, even at low temperatures, the near constancy of the band center[4] in tertiary amine hydrohalides, the structure of the bands, and the marked anharmonicity, considered such characterization to be incompatible with a simple electrostatic model of the hydrogen bond (21). Nevertheless, Lord and Merrifield showed a linear relationship between $\Delta\nu$ in stretching frequency vs. X—H...Y distance in various O—H...O strongly hydrogen bonded compounds. Similarly, Nakamoto, Margoshes, and Rundle (22) found approximately linear correlations between the N—H...Y distances and the N—H stretching frequencies in

[3]Recent crystallographic work has shown that no hydrogen bonding is found in any of the pyridinium (PyH^+) salts of PF_6^-, AsF_6^-, and SbF_6^- (18), whereas the interaction in pyridinium nitrate appears to be more correctly represented by the $PyH...NO_3^-$ model than by the $C_5H_5N...H—O—NO_2$ model (19).

[4]In succeeding years, it has been recognized that variations in the band center in tertiary amine hydrohalides are actually rather appreciable, e.g. see Tables II, IV, and V.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

the systems N—H...F, N—H...O, N—H...Cl, and N—H...N.

Lacking crystallographic data for the series of lidocaine salts, we have correlated the difference in $\overset{+}{N}$—H stretching frequency ($\Delta\nu$) with the ionic radius of the respective anion (Fig. 2). The hydrohexafluoroarsenate salt was assumed to have free $\overset{+}{N}H$ stretching, and $\Delta\nu$ for the other salts was calculated on this basis. The ionic radii used for the halide anions are the crystal radii calculated by Pauling (ref. 23, p. 521) while those used for the polyatomic anions were derived by summation of crystallographically measured interatomic distances (Table III) and Van der Waals radii (ref. 23, p. 260) for the appropriate peripheral atoms of the anions. A very pleasing correlation is seen (Fig. 2) for the lidocaine salt series which suggests that the changes in ν^{+}_{NH} frequency are largely dependent on ionic size for constant anionic charge. Similar correlations were carried out for triethylamine and pyridinium salts (Fig. 2) using frequency data available in the literature (Tables IV and V). It is readily apparent from the data for the pyridinium salts that the doubly negatively charged anions constitute a class by themselves and that $\Delta\nu$ can be correlated with isoelectronic anions only. A similar correlation for a series of trimethylamine salts using the frequency data of Nuttall *et al.* (6) proved unsuccessful due to great scattering of points.

Acknowledgments

The authors wish to thank Dr. M. Przybylska and Mrs. H. M. Sheppard of the National Research Council of Canada, Ottawa, for the X-ray powder diffraction spectra and for helpful discussions concerning crystallographic data; Dr. R. N. Jones of the National Research Council of Canada, Ottawa, for his encouragement and suggestions for this work; Dr. H. S. Chang for preparing some of the salts (HBr, HI, HNO_3, $H(HSO_4)$, and CF_3CO_2H); Dr. Denys Cook for his interest in this work and for suggesting the preparation of the $HSbCl_6$ and $HAsF_6$ salts, and Mrs. Ruth Lane and Mr. Bruce Flann for the carbon, hydrogen, and nitrogen analyses on the F & M analyzer.

The gift of research samples of lidocaine and lidocaine hydrochloride monohydrate by Astra Pharmaceuticals (Canada) Ltd. is gratefully acknowledged.

Electronic spectra of carbonato and oxalato ammine complexes of cobalt(III); average field model for singlet, triplet, and charge transfer bands[1]

V. S. SASTRI AND C. H. LANGFORD[2]
Department of Chemistry, Carleton University, Ottawa 1, Canada

Received May 22, 1969

The electronic spectra in ligand field (singlet and triplet) and charge transfer regions have been determined for a series of mixed carbonato and oxalato ammine complexes of Co(III). An average field model is shown to be quite adequate to complete interpretation of the spectra. The values of Δ appear to be dominated by σ bonding interactions. Full analysis of triplet bands reveals an abnormal C/B ratio which emphasizes the limitations to be placed on the interpretation of the values of parameters derived from first order perturbation theory parameterization of experimental spectra.

Canadian Journal of Chemistry, 47, 4237 (1969)

In the course of some kinetic studies[3], one of us had occasion to prepare a full series of carbonato and oxalato ammine complexes of Co(III) (1). The spectra of these complexes were recorded in singlet, triplet, and charge transfer regions. To our knowledge, the average field model (ref. 2, and earlier references cited therein), which treats the spectra of mixed nearly octahedral complexes in terms of the average of spectral parameters of the unmixed species, has not yet been subjected to test against such complete spectral data. Triplet bands have been recorded only comparatively rarely.

The first consequence of the analysis of the carbonato and oxalato ammine mixed systems was that the average field model proved successful to the usual degree. However, two dividends accrued. First, it emerged that the charge transfer bands in carbonato ammine complexes were readily interpretable. Second, the close analysis of triplet bands led to modification of the value of Δ (10 Dq) assigned to Co(III) and, in consequence, some modification of analysis of the evolution of Δ across the first transition series.

Experimental

Complexes were prepared by adaptation of standard procedures which have been described (1). Spectra in solution were recorded on a Cary 15 spectrophotometer. All measurements were made at room temperature. Spectral data for the spin forbidden bands were obtained with solutions nearly saturated with the complex. A sample spectrum is given in Fig. 1.

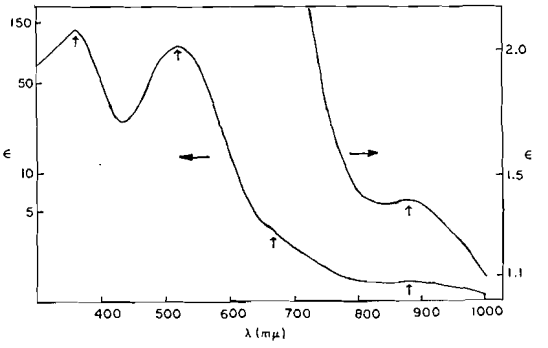

FIG. 1. Spectrum of $Co(NH_3)_4CO_3^+$ ion.

Results

Aqueous solution electronic spectral bands are recorded in Table I; assignments are indicated and calculated band maxima are given. The calculations are based on a best fit of the parameters Δ, B, and C to the spectra of $Co(NH_3)_6^{3+}$, $Co(CO_3)_3^{3-}$, and $Co(C_2O_4)_3^{3-}$, where Δ is the orbital energy difference between t_{2g} and e_g levels, B and C are the Racah interelectronic repulsion parameters[4]. For mixed complexes, weighted averages of the best fit values for $Co(NH_3)_6^{3+}$, $Co(CO_3)_3^{3-}$, or $Co(C_2O_4)_3^{3-}$ were used in the calculations. The energies of the levels of the d^6 system are taken to be (with respect to the free ion energy)

$$^1A_{1g}: \quad -2.4\Delta + 5B + 8C$$
$$^3T_{1g}: \quad -1.4\Delta + 5B + 5C$$
$$^3T_{2g}: \quad -1.4\Delta + 13B + 5C$$
$$^1T_{1g}: \quad -1.4\Delta + 5B + 7C$$
$$^1T_{2g}: \quad -1.4\Delta + 21B + 7C$$

	$^1A_{1g} \rightarrow {}^1T_{2g}$	25 800	26 300
	$^1A_{1g} \rightarrow {}^3T_{1g}$	10 300	10 400
	$^1A_{1g} \rightarrow {}^3T_{2g}$	14 000	14 000
$[Co(C_2O_4)_3]^{3-}$	$^1A_{1g} \rightarrow {}^1T_{1g}$	16 800	16 600
	$^1A_{1g} \rightarrow {}^1T_{2g}$	23 900	23 600
	$^1A_{1g} \rightarrow {}^3T_{1g}$	8 500	8 300
	$^1A_{1g} \rightarrow {}^3T_{2g}$	12 100	12 700

These formulas neglect off diagonal elements as is customary. Table II lists the relevant values of Δ, B, and C.

Discussion

Average Field Model

Note the modest but normal success of fit of calculated spectra to experimental spectra indicated in Table I. This indicates the reasonable success of an average field model when both singlet and triplet excitations are considered. Other examples indicate that this works only for *cis* complexes (4).

The Charge Transfer Bands

There is a linear relationship (Fig. 2) between the carbonato complex charge transfer (c.t.) energy and the ligand field (l.f.) bands with positive slope. This suggests assignment of the c.t. bands as ligand-to-metal. If the likely analogy between halide and oxygen donor ligands holds, this band is ligand $\pi \rightarrow$ metal e_g. It is noteworthy

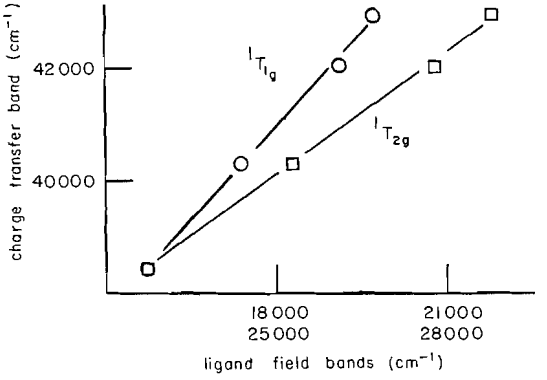

FIG. 2. Plot showing the linear relationship between charge transfer and ligand field energies.

that the slope of the correlation is almost unity between the $^1A_{1g} \rightarrow {}^1T_{1g}$ ligand field band and the c.t. band. The correlation slope is only 0.7 between $^1A_{1g} \rightarrow {}^1T_{2g}$ and c.t. bands but it is known (5) that the $^1T_{2g}$ state of $O_h d^6$ Co(III) has the configuration $t_{2g}{}^5e$ mixed significantly with $t_{2g}{}^4e^2$. We shall return to this point in the next section. At present, it seems fair to conclude that the linear relationship between the $\pi \rightarrow e_g$ c.t. transition energy and the $t_{2g} \rightarrow e_g$ ligand field transition energy strongly implies that *movement of the e_g levels dominates changes in both.* The e_g levels are σ^* and it would appear that changes from N to O donor ligands predominately change σ *bonding levels.* Δ appears to be determined by Δ_σ *not* Δ_π effects in the language of Wentworth and Piper (2).

The constancy implied for ligand π levels is an instance of the applicability of the independent ligand model (3).

The C/B Ratio and the Significance of Δ

It is usually assumed that the C/B ratio is approximately 4 as in the case of free ion spectra (3). When only the two singlet bands of Co(III) are measured, B is the only Racah parameter determinable and C is taken to equal $4B$. Since C is the parameter used to find Δ, this has led to Δ values lower by nearly 2000 cm^{-1} than those given here for $Co(NH_3)_6{}^{3+}$ and $Co(C_2O_4)_3{}^{3-}$. The discrepancy emerges when it is recognized that C/B ratios from the present analysis lie close to 8. The value of B usually obtained in a first order perturbation model may certainly be criticized. Usually, one calculates a B value from the $^1T_{1g}$–$^1T_{2g}$ splitting. This splitting is also influenced by $t_{2g}{}^5e_g$ mixing with $t_{2g}{}^4e_g{}^2$ in the $^1T_{2g}$ term. When only singlet bands are measured, the calculated B is low. Consequently, the estimated C is lower than the value given here and the value of Δ is also low. Such Δ values must be cautiously compared with those obtained where no estimate of B is required to get Δ. For example, a recent paper (6) compares Δ for Cr(III) and Co(III). It concludes that ligands with filled π levels which raise the π^* t_{2g} of the complex lead to decreasing Δ with increasing atomic number (or d″), that ligands without π symmetry orbitals are associated with constant Δ, and that ligands with empty π orbitals (acceptors) lead to increasing Δ. These results were taken to emphasize the importance of π interactions in a molecular orbital interpretation of Δ. In that paper, different parametrization schemes were used for different Co(III) complexes. Our results *do not* confirm the trends (Table III) which emphasize π interactions.

We do not wish to suggest that it is desirable to parameterize spectra of complexes in more elaborate terms or to make regular use of off diagonal elements. Other weaknesses in the approximation schemes of ligand field theory probably render additional sophistication nearly

Electrochemical generation of hydridopentamminerhodium(III) and its reaction with molecular oxygen

LESLIE E. JOHNSTON[1] AND JOHN A. PAGE
Department of Chemistry, Queen's University, Kingston, Ontario
Received July 8, 1969

The electrochemistry of $Rh(NH_3)_5OH^{2+}$ has been studied in a buffered ammoniacal solution. The polarographic reduction wave at the dropping mercury electrode had $E_{1/2}^0$ equal to -1.10 V (vs. saturated calomel electrode) in a 0.10 *M* NH_3 – 0.10 *M* NH_4ClO_4 electrolyte, and gross Hg cathode electrolysis at -1.19 V produced a stable $Rh(NH_3)_5H^{2+}$ hydride species. Both reductions were found to take place through a Rh(I) intermediate.

The reaction of the $Rh(NH_3)_5H^{2+}$ with molecular O_2 in the ammoniacal electrolyte was also studied. The product was demonstrated to be a stable $Rh(NH_3)_4(OH)(O_2H)^+$ hydroperoxo species.

Canadian Journal of Chemistry, 47, 4241 (1969)

Introduction

In a previous study (1), the electrochemical reduction of $RhPy_4Cl_2^+$ in aqueous pyridine was examined. The inability to demonstrate the formation of a Rh(III) hydride species paralleled the failure of the Wilkinson group (2–5) to chemically prepare a stable Rh(III) hydride in a similar medium. However, they were successful (6) in preparing $[Rh(NH_3)_5H]SO_4$ and this hydride was found to be stable in aqueous solution (7); this in turn prompted this electrochemical study of the rhodium(III) ammine system.

Gillard *et al.* (2) discussed the work done on the electrolytic reduction of $Rh(NH_3)_5Cl^{2+}$ and indicated that a 2 faradays per mole process at the dropping mercury electrode (d.m.e.) was consistent with diffusion data, although the coulometric studies by others indicated a 3 faradays per mole reduction. However, in the work reported here, the $Rh(NH_3)_5OH^{2+}$ complex and a buffered NH_3–NH_4ClO_4 electrolyte were used on account of the stability of the solution (8) and the absence of the pre-wave or maximum that was observed in polarography of solutions containing even minute amounts of chloride. A 2 faradays per mole reduction of $Rh(NH_3)_5OH^{2+}$ to stable $Rh(NH_3)_5H^{2+}$ has been characterized by coulometry, half-wave potential measurements, hydrogen ion consumption on gross electrolysis, and an identification of the reduced solution species.

The in situ generation of $Rh(NH_3)_5H^{2+}$ afforded an opportunity to study the reaction of the hydridic species with molecular O_2. Wilkinson (6, 7) has referred to a blue complex that results from the reaction of $Rh(NH_3)_5H^{2+}$ and O_2. More recently (9), Wilkinson has stated that the blue complex is likely aquotetramminerhodium (III)-μ-superoxoaquotetramminerhodium(III) formed from the initial product of the reaction, hydroperoxopentamminerhodium(III). This study, by a quantitative determination of the reaction stoichiometry and by examination of the product of the controlled potential reduction of the oxygen complex, shows that the initial reaction gives a stable hydroperoxo species.

Experimental

All potentials reported are in volts relative to a mercury calomel electrode used in conjunction with a 2.0 *M* $NaNO_3$ salt bridge. The reference electrode used throughout was a Metrohm EA-402 saturated KCl calomel electrode.

A three electrode system was used to record polarograms and to determine $E_{1/2}^0$ (1, 10) values and wave form parameters. This employed a Wenking Model 61 RS potentiostat to control the potential of the d.m.e. relative to a reference electrode in the working compartment of the cell. A Philbrick/Nexus Q3-A1P Stabilized Amplifier functioning as a current-to-voltage transducer (R = 100 kohm) was used to convert the polarographic current to a voltage suitable for display on a Hewlett–Packard Model 7100 B recorder (response time = 0.5 s). For normal polarography the potential was scanned manually; for $E_{1/2}^0$ and wave form parameter determination, the current was recorded as a function of time over a series of mercury drops at various fixed potentials on the rising part of the wave.

A conventional jacketed H-cell, thermostated at 25.0 °C and employing a frit/$NaClO_4$ agar gel to separate the working and counter compartments, was used. The d.m.e. had a flow rate of 1.401 mg s^{-1} with a drop time of 4.23 s at -1.20 V in a solution that was 0.851 m*M* in $Rh(NH_3)_5OH^{2+}$ and 0.1 *M* in each of NH_3 and

[1]Present address: Department of Chemistry, Erindale College, University of Toronto, Toronto 16, Ontario.

For personal use only.

NH_4ClO_4, and with the ionic strength (μ) adjusted to 1.00 *M* with added $NaClO_4$.

Controlled potential coulometry was carried out as previously described (1). The electrolyte volume in the working electrode compartment of the cell varied between 75 and 100 ml, and the Hg cathode had an area of 19 cm^2. For the measurement of pH a Beckman Research pH meter was used with a Fisher 13-639-250 glass electrode and the calomel reference electrode used in conjunction with a 2.0 *M* $NaNO_3$ bridge. The meter was standardized against a borax solution, prepared according to the directions of the National Bureau of Standards from their sample 187*a* (pH = 9.180 at 25.0 °C).

All solutions for polarography and coulometry were deaerated with nitrogen gas. Before use, the N_2 (Matheson, purified) was passed through an acid vanadium(II) solution (10), scrubbed with water, then equilibrated with ammonia by passage through 3 successive towers filled with the appropriate supporting electrolyte.

All chemicals used were reagent grade. The starting material for preparation of rhodium salts was $[Rh(NH_3)_5Cl]Cl_2$ supplied by Johnson, Matthey Chemicals Limited (Lot B/6). The aquopentammine salt $[Rh(NH_3)_5H_2O](ClO_4)_3$ was prepared according to Bushnell, Lalor, and Moelwyn-Hughes (11) and a stock $Rh(NH_3)_5OH^{2+}$ solution was prepared by dissolution of this salt in NH_3–NH_4ClO_4 electrolyte (each 0.1 *M*). This stock solution was standardized coulometrically after perchloric acid fuming (1) (vanadium catalyst was not required in destroying the ammine complex). Typical analyses gave rhodium concentrations of 8.60 ± 0.03 m*M*. Solutions for polarography and electrolysis were prepared by volumetric dilution of this stock solution using standard NH_3 and NH_4ClO_4 solutions to provide the various concentrations and pH values desired; in all cases $NaClO_4$ solution was also added to give a total ionic strength of 1.00 *M*.

A sample of $[Rh(NH_3)_5H](ClO_4)_2$ was prepared according to Thomas, Osborn, Powell, and Wilkinson (7). The compound's infrared spectrum matched the ones reported. The method of Lebedinski (12) was used to prepare $[trans\text{-}Rh(NH_3)_4Cl_2]Cl$; this salt was then hydrolyzed in a 0.1 *M* NaOH electrolyte whereby complete conversion to $trans\text{-}Rh(NH_3)_4(OH)_2^+$ is affected according to Johnson, Basolo, and Pearson (13).

The ultraviolet and visible spectra were obtained on a Bausch and Lomb 505 Spectrophotometer using matched 10.0 or 1.0 cm quartz cells. During the controlled potential reduction, spectra were obtained by means of a flow connection to the electrolysis vessel. Solution from the vessel was circulated through 1.0 cm flow cells in the spectrophotometer by a peristaltic pump (LKB-Produkter Ab., Type 4912A, full speed flow ca. 8 ml/min) using neoprene tubing. The spectrum of the air-sensitive $Rh(NH_3)_5H^{2+}$ species was obtained by adding the perchlorate salt to deaerated supporting electrolyte in the electrolysis vessel (used as a dissolution vessel only) and circulating the resultant solution through the flow cell. This same flow cell arrangement was also used to follow the uptake of oxygen by the electrochemically generated $Rh(NH_3)_5H^{2+}$ species.

For the determination of the stoichiometry of the reaction between $Rh(NH_3)_5H^{2+}$ and O_2, the consumption of dissolved O_2 was followed polarographically. The $Rh(NH_3)_5H^{2+}$ was prepared by the reduction of $Rh(NH_3)_5OH^{2+}$ (> 1 m*M*) in a small, known volume of concentrated NH_3–NH_4ClO_4 electrolyte (each > 1 *M*). The electrolyses were carried out under N_2 using a Hg cathode controlled at −1.19 V; the cell was a 200 ml round-bottom flask with a Hg inlet at the bottom and ground glass fittings for the counter electrode compartment, reference probe, and N_2 dispersion tube. Stirring was by a magnetic stirring bar. When the reduction was judged complete, the Hg was withdrawn, then the N_2 inlet was removed and the electrolyzed solution diluted with O_2 saturated distilled water. The cell was completely filled so that no gas pockets remained over the solution, then it was completely sealed ($[NH_3] = [NH_4ClO_4] = 0.2\ M$ on dilution).

The solution was stirred for 4 h, the cell was then opened and the electrolyte immediately polarographed, yielding a reduction current due to excess O_2 ($E_{1/2}$ −0.05 and −1.1 V) and the Rh–O_2 complex ($E_{1/2}$ −0.33 and −1.03 V). The solution was then deaerated and again polarographed to determine the reduction current due to the Rh–O_2 complex. The decrease in current at −0.54 V was then proportional to the original concentration of unreacted O_2. The proportionality factor was determined by polarography of a solution prepared by diluting concentrated O_2-free supporting electrolyte with O_2-saturated distilled water. The O_2 content of the saturated distilled water was obtained from the solution temperature and solubility data (1.23 m*M* O_2 at 25 °C). A blank run performed in the absence of rhodium indicated that a 6% loss of oxygen was experienced in the course of the reaction.

Results

Polarographic Reduction of $Rh(NH_3)_5OH^{2+}$

A well defined cathodic wave was obtained in the NH_3–NH_4ClO_4 electrolyte. While it showed a limiting current plateau only over a small range of potential before the discharge of the supporting electrolyte, the measurements showed a linear relation between the limiting current and concentration of the $Rh(NH_3)_5OH^{2+}$. Diffusion control was demonstrated through the constancy of $i_l/h_{corr}^{1/2}$ (10) and a temperature coefficient for i_l of +1.4% $°C^{-1}$ over the range 5 to 30 °C.

The effect of ammonia concentration and pH on the half-wave parameter $E_{1/2}{}^0$ (1, 10) was

studied. At constant pH and variable ammonia concentration the $E_{1/2}{}^0$ values were relatively constant (Table I). A similar study at constant ammonia concentration showed a pH dependence of $E_{1/2}{}^0$ (Table II). For pH > 9.4 the variation of αn precluded analysis of the data. However, for pH < 9.4, αn was reasonably constant and a plot of $E_{1/2}{}^0$ vs. pH had a slope of −77.6 mV per pH unit (Fig. 1). For an average αn of 0.748, this gives a value of p equal to 0.98

$$\frac{d(E_{1/2}{}^0)}{d(pH)} = -\frac{0.05915}{\alpha n} p$$

and indicates that a fast reaction involving the uptake of one proton occurs prior to the electron transfer step.

Controlled Potential Reduction of $Rh(NH_3)_5OH^{2+}$

Gross electrolysis of the $Rh(NH_3)_5OH^{2+}$ complex was carried out on a mercury pool cathode controlled at −1.19 V in the NH_3–NH_4ClO_4 electrolyte (each 0.1 M). The electrolysis current decayed only to about 5% of the initial value and similar behavior was noted in reductions at −1.09 and −1.14 V. The net quantity of electricity used in the reductions was determined by extrapolation of the final linear portion of the coulogram back to zero time and a 2 faradays per mole reduction was indicated (Table III). It would appear that the relatively high background is due to a cyclic process involving the reduced rhodium species, for the supporting electrolyte by itself gave no such discharge. Presumably the reduced rhodium was oxidized in a slow reaction with the solvent, and this, in turn, reduced at the cathode. The small steady-state concentration of oxidized rhodium would result in the observed background current.

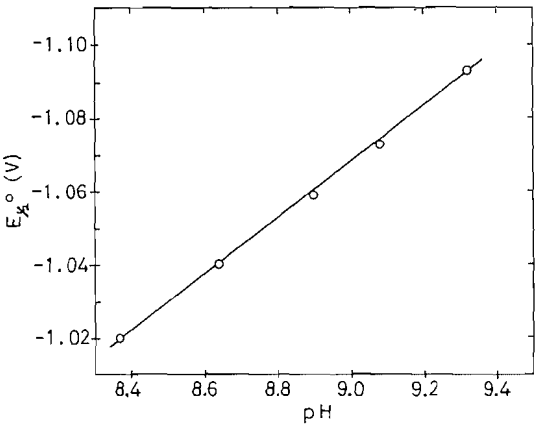

FIG. 1. Variation of $E_{1/2}{}^0$ with pH, $[Rh(NH_3)_5OH^{2+}]$ = 0.427 mM, $[NH_3]$ = 0.10, NH_4ClO_4 varied to control pH, μ = 1.00 M ($NaClO_4$); 25.0 °C.

Hydrogen ion consumption in the gross electrolysis was also studied by a titration technique. A series of reductions was carried out in which the pH of the electrolyte was maintained at its initial value by the addition of standard acid as necessary to replace the hydrogen ion consumed in the reduction. The pH was controlled within ±0.001 pH unit and titrations of about 5 ml of 0.02 M $HClO_4$ solution with a discrimination of 0.1 ml were typical.

To enhance the discrimination, these electrolyses were carried out in a relatively dilute NH_3–NH_4ClO_4 electrolyte at pH values somewhat removed from that of the optimum buffer capacity of the system. Three electrolyses were carried out at pH 8.45 and three at pH 8.60.

TABLE III

Coulometric reduction of $Rh(NH_3)_5OH^{2+}$*

Initial $Rh(NH_3)_5OH^{2+}$ (mM)	Electrolysis† (C)	n (faradays/mole Rh)
0.543	8.30	2.11
0.543	8.17	2.08
0.432	6.56	2.10
0.432	6.40	2.05
0.259	3.88	2.08
0.259	3.70	1.99

*Hg cathode at −1.19 V, T = 25 °C, 74.93 ml solution, $[NH_3]$ = $[NH_4{}^+]$ = 0.10, pH = 9.3, μ = 1.00 M ($NaClO_4$).
†Corrected for background.

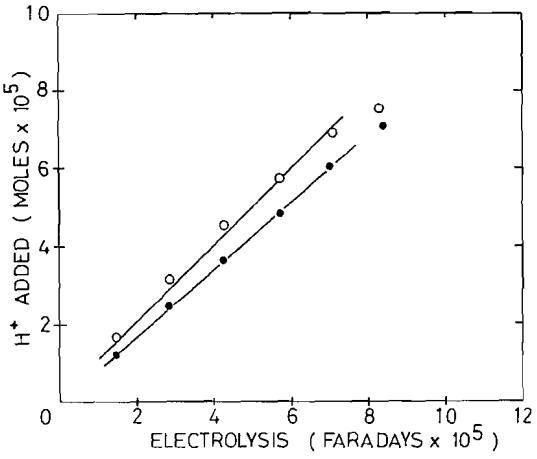

FIG. 2. Consumption of H^+ in reduction of $Rh(NH_3)_5OH^{2+}$. Initial $[Rh(NH_3)_5OH^{2+}] = 0.517$ mM, Hg cathode at -1.19 V, room temperature, 90.0 ml solution; ○, pH 8.45, $[NH_4^+] = 0.100$; ●, pH 8.60, $[NH_4^+] = 0.050$, varying $[NH_3]$ to give desired pH, $\mu = 0.100\ M$ ($NaClO_4$).

For each run, the moles of acid added were plotted against the quantity of electricity passed and typical plots are shown (Fig. 2). Good linearity was observed in each plot, except towards the end of the reductions. In the initial part of the reduction the background is negligible with respect to the total quantity of electricity passed, but at the end of the run the background effect would be the sole consumer of electricity. For the 6 runs, the observed slopes were 0.93 ± 0.09 moles H^+ consumed per faraday of electricity passed, corresponding to 1.8_6 moles H^+ consumed per mole of rhodium(III) reduced. This result is very close to the integral 2 expected for the formation of a $Rh(NH_3)_5H^{2+}$ product.

Characterization of the Reduced Species

The spectrum of the prepared $[Rh(NH_3)_5H](ClO_4)_2$ was obtained in the NH_3–NH_4ClO_4 electrolyte (both 0.4 M). Under the anaerobic conditions employed, 2 peaks were observed at 300 mμ ($\varepsilon = 300$) and 257 mμ ($\varepsilon = 400$).

The spectral changes during controlled potential reduction of a 2.36 mM $Rh(NH_3)_5H^{2+}$ solution in the same electrolyte were also followed. The final reduced solution had two absorption maxima at 300 mμ ($\varepsilon = 293$) and 257 mμ ($\varepsilon = 370$). However, the behavior during reduction depended upon the rate of mechanical stirring at the Hg cathode solution interface. With slow, steady stirring, spectra taken at intervals of time showed a clear-cut isobestic point at 326 mμ ($\varepsilon = 136$) throughout the reduction. Typically, in such cases the plot of ln i vs. t had a slope of -3×10^{-4} s^{-1} ($t_{1/2} = 2 \times 10^3$ s).

In contrast, with stirring that was much more vigorous than that normally employed, the isobestic point was not observed. The plots of ln i vs. t were only approximately linear but the initial slope was of the order of -3×10^{-3} s^{-1}. Typically, it was observed that the absorbance at 326 mμ increased from 0.32 to 0.38 over about the first 10 min of the reduction, then rapidly fell back to the original value. This behavior indicates that appreciable concentrations of some intermediate are present in the rapid electrolysis; this intermediate is presumably the first product of the electrode reaction, but does not build up to a detectable concentration in the slow reduction.

Nature of Product in $Rh(NH_3)_5H^{2+}$–O_2 Reaction

The reduction product of the gross electrolysis was observed to react readily with O_2. A peak grew at 237 mμ and an isobestic point was observed at 287 mμ as O_2 was introduced into the solution. The extinction coefficient at 237 mμ was 3800 l mole^{-1} cm^{-1} assigned on the basis of a clean complete reaction of the rhodium.

A polarographic reduction of the complex formed was observed after the excess O_2 was removed with N_2. The two polarographic steps found were of equal height, with $E_{1/2}$ values -0.33 and -1.03 V, respectively. The constancy of $i_l/h_{corr}^{1/2}$ indicated a diffusion controlled reduction.

This clean-cut behavior was important in that it permitted the polarographic determination of the stoichiometry of the $Rh(NH_3)_5H^{2+}$–O_2 reaction. The consumption of O_2 from a solution containing known concentrations of O_2 and $Rh(NH_3)_5H^{2+}$ was determined by the differential current measurement (vide supra) at -0.54 V, a potential where both O_2 and the Rh–O_2 complex are reduced under diffusion control. After applying the blank correction, the average found was 0.99 ± 0.07 mole of O_2 consumed per mole of $Rh(NH_3)_5H^{2+}$ (Table IV).

Gross reduction of this Rh–O_2 complex on a mercury cathode controlled at -0.70 V was carried out in the NH_3–NH_4ClO_4 electrolyte (each 1.0 M). The electrolysis proceeded smoothly to a negligible residual current (20–40 μA) and the quantity of electricity when corrected for background effects corresponded closely to 2

faradays per mole of rhodium (Table V). The spectrum of the product showed peaks at 302 mμ (ε = 123) and 345 mμ (ε = 93) and these match the spectrum of the prepared *trans*-$Rh(NH_3)_4(OH)_2^+$. After the reduction at −0.70 V was complete, a shift of the cathode potential to −1.20 V produced further reduction characterized by a high background current. The final solution had the same ultraviolet spectrum as $Rh(NH_3)_5H^{2+}$.

TABLE V

Coulometric reduction of rhodium–oxygen complex*

Initial [Rh] (mM)	Electrolysis† (C)	n (faradays/mole Rh)
0.591	10.18	1.98
0.591	10.23	1.99
0.469	8.13	2.00

*Hg cathode at −0.70 V, room temperature, 90.0 ml solution $[NH_3] = [NH_4^+] = 1.00$, pH = 9.3.
†Corrected for background.

The formation of the $Rh–O_2$ complex was also studied in an electrolyte of lower NH_3 concentration ($[NH_3] = [NH_4ClO_4] = 0.20$) and the rate was observed to be somewhat slower.

The $Rh–O_2$ complex was found to give an oxidation wave at a rotating platinum micro electrode with $E_{1/2} \approx +0.5$ V in the NH_3–NH_4ClO_4 electrolyte (each 1.0 M). Gross electrolysis at a platinum gauze anode controlled at +0.75 V showed an oxidation of approximately 1 faraday per mole of rhodium. During the electrolysis the solution became pink, but the color did not persist and had virtually disappeared at the end of the electrolysis (60 min).

In another reaction, the addition of 72% aqueous perchloric acid to the $Rh–O_2$ complex solution caused the solution to turn blue (absorption maximum, 556 mμ). As the acid concentration was increased from 1 to 40% (v/v), the extinction coefficient increased from 36 to 145 l $mole^{-1}$ cm^{-1}; at 40% $HClO_4$ the extinction coefficient was still increasing.

Discussion

This study shows that the electrochemical reduction of $Rh(NH_3)_5OH^{2+}$ proceeds to the hydridic species $Rh(NH_3)_5H^{2+}$. The reaction does not proceed directly to a Rh(III)–H species, for the shift of $E_{1/2}{}^0$ with pH indicates a unit involvement of hydrogen ion in the electrode process at the d.m.e. This may be accounted for by an equilibrium of the type

[1] $Rh(NH_3)_5OH^{2+} + H^+ \rightleftharpoons Rh(NH_3)_5H_2O^{3+}$

preceding the electron transfer step. Another valid interpretation of the pre-electrolysis equilibrium would be

[2] $Rh(NH_3)_5OH^{2+} \rightleftharpoons Rh(NH_3)_5{}^{3+} + OH^-$

but in both cases the initial product of the two-electron charge transfer would be a Rh(I) species

[3] $Rh(NH_3)_5H_2O^{3+} + 2e \rightarrow Rh(NH_3)_5H_2O^+$

or

$$Rh(NH_3)_5{}^{3+} + 2e \rightarrow Rh(NH_3)_5{}^+$$

and is the same result as was found in the electrochemical reduction of $RhPy_4Cl_2^+$ (1). The fate of this transient Rh(I) species was defined by the overall consumption of 2 moles of H^+ per mole of rhodium on gross electrolysis. This implies a bulk solution reaction of the sort

[4] $Rh(NH_3)_5H_2O^+ + H^+ \rightarrow Rh(NH_3)_5H^{2+} + H_2O$

or

$$Rh(NH_3)_5{}^+ + H^+ \rightarrow Rh(NH_3)_5H^{2+}$$

following the electrode reaction. This was substantiated by spectral studies that identified the Rh(III)–H as the final stable electrolysis product. The disappearance of the isobestic point upon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

rapid electrolysis is also evidence for these steps, since under conditions of rapid electrolysis, reaction [4] is apparently too slow to consume the Rh(I) species as it is formed, so that the absorbance at 326 mμ is due to three complexes, not just two.

The stoichiometry of the Rh(III)H–O_2 reaction was important in establishing the nature of the product. Two obvious possibilities (9) are the simple hydroperoxo product that would require an exact 1:1 stoichiometry, and the dimerized μ-superoxo complex which would show (unfortunately) a near 1:1 combining ratio

[5] $Rh(III)H^{2+} + O_2 \rightarrow Rh(III)—O—O—H^{2+}$

[6] $8Rh(III)H^{2+} + 7O_2 + 4H^+ \rightarrow 4\{Rh(III)—\dot{O}—O—Rh(III)^{5+}\} + 6H_2O$

However, the choice between the two can be made unequivocally from the electrochemical behavior of the product which undergoes a clean 2 faradays per mole reduction at −0.70 V. The only reaction consistent with this would be the reduction of the hydroperoxo species

[7] $Rh(III)—O—O—H^+ + H^+ + 2e \rightarrow Rh(III)OH^{2+} + OH^-$

The reduction of the dimerized μ-superoxo complex would (fortunately) give a quite different relation. Wilkinson (9) has suggested that under some conditions the hydroperoxo complex may dimerize to give a blue superoxo complex and this may be the reaction that takes place upon acidification with $HClO_4$. The pink species formed on electrolysis of the hydroperoxo complex at +0.5 V may be a superoxo complex as well, since the oxidation required 1 faraday per mole of rhodium

[8] $Rh(III)—O—O—H^{2+} \rightarrow Rh(III)—\dot{O}—O—H^{3+} + e$

but in the alkaline medium the complex evidently decomposes.

The remaining ligands on the hydroperoxo complex are of interest. Since the reduction product was demonstrated to be *trans*-$Rh(NH_3)_4(OH)_2^+$, it is likely the hydroperoxo complex exists as *trans*-$Rh(NH_3)_4(OH)(O_2H)^+$. This is not surprising, for Wilkinson (6, 7) has demonstrated the *trans* labilizing power of the hydridic ligand

[9] $Rh(NH_3)_5H^{2+} + H_2O \rightleftharpoons Rh(NH_3)_4(H_2O)H^{2+} + NH_3$

and the hydroperoxo group probably has a stronger effect.

A ^{14}N nuclear magnetic resonance study on nitrogen–oxygen–halogen compounds

A. M. QURESHI, J. A. RIPMEESTER, AND F. AUBKE[1]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received July 7, 1969

^{14}N nuclear magnetic resonance spectra of nitrogen oxides, fluorides, and oxyhalides have been recorded using direct measurement with a broad line nuclear magnetic resonance spectrometer. Also investigated are some nitrogen-containing fluoro- and oxo-cations in protonic solvents. Using the side band technique, fine structure due to ^{14}N–^{19}F spin–spin interaction could be resolved for nitrogen trifluoride, nitrogenoxide trifluoride, and nitrylfluoride.

Introduction

Due to an extremely poor natural sensitivity and quadrupole line broadening effects, ^{14}N nuclear magnetic resonance (n.m.r.) has found only limited use in spite of the high natural abundance of the ^{14}N isotope (99.635%). Whereas a fairly large number of spectra of organic compounds (1) have been recorded, only a very few studies are concerned with inorganic compounds (1, 2–5). For many inorganic nitrogen compounds, handling and corrosion problems exist. This has added to the fact that information is limited and agreement between different studies often poor.

The present study is concerned mainly with oxides, fluorides, and oxyhalides of nitrogen. The bonding in these compounds is subject to much discussion (6). Also included are nitrogen-containing heterocations in solution of strong protonic acids and dinitrogen tetroxide in solution of non-polar-oxygen-and-π-donor solvents. It was hoped to obtain a consistent series of ^{14}N chemical shifts of good accuracy to permit π-electron density calculations, currently in progress, using the molecular orbital method.

Of all published methods to record ^{14}N spectra (7), the method of Acrivos (8) seemingly promised the best resolution in order to resolve fine structure due to ^{14}N–^{19}F spin–spin interaction. Previous attempts (5) to observe fine structure had failed. Compared to the internuclear double resonance (INDOR) (9, 10) technique, a direct measuring method could be extended also to compounds without fluorine or protons attached to nitrogen.

[1]To whom correspondence should be addressed.

Experimental

Method

^{14}N resonances were recorded using a Varian DP60 spectrometer. A Varian 12 in. magnet provided the resonance field of about 13 000 G. The magnetic field was stabilized using a V-K 3506 flux stabilizer and swept using a V-K 3507 slow sweep unit. The frequency used was 4.000 MHz, provided by a V 4210 variable frequency r.f. unit stabilized by a crystal oscillator.

Two methods were used for recording the spectra. To resolve fine structure, the method of Acrivos was used with the modulation frequency and amplitude greater than the resonance line width. The modulation frequency generally used was 432 c.p.s. The ratio of the modulation amplitude to the modulation frequency $\beta = \gamma H \text{ mod}/\omega$ mod was equal to 1.54.

As can be seen in Fig. 1 it was not possible to phase out the centerband completely under this condition. The centerband, however, was of lesser intensity and also of opposite phase, so that reasonably well resolved absorption mode spectra could be obtained. This method has been found to give a higher resolution, because there is no line broadening arising from the finite modulation amplitude in the derivative method.

Chemical shifts were obtained by the sample replacement method, using the NO_3^- as a reference in a 4.5 *M* solution of NH_4NO_3 in 3 *M* aqueous HCl. The confidence limit is ±5 p.p.m. or better for most of the values obtained.

Samples were placed in 15 mm o.d. tubes for room temperature studies. For low temperature studies samples contained in ~10 mm o.d. tubes were placed in a Dewar containing slush baths as cooling agents. The sample tubes were made from Pyrex, quartz, or fluorocarbon resin depending on the system studied. The tubes were flame sealed or closed by teflon stem Fisher-Porter greaseless stopcocks and aluminum valves. Temperatures were monitored by placing a copper–constantan thermocouple next to the sample during the measurement. The accuracy of the temperature measurements was judged to be ±2.0 °C.

Materials and Preparative Methods

Nitrylfluoride and nitrogen trifluoride (Penninsular Chem. Research), nitrogendioxide (Matheson of Canada Ltd.), nitrosyl hydrogensulfate (Columbia Organic Chemicals), and tetrafluorohydrazine (Air Product Chemicals)

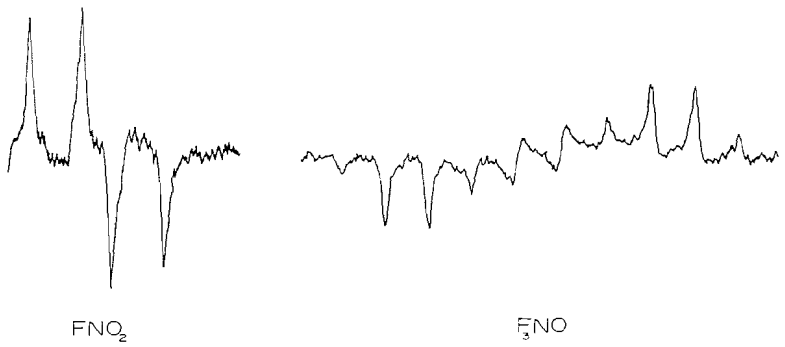

FIG. 1. ^{14}N–^{19}F fine structures.

were purchased, generally of research grade purity and further purified by vacuum distillation. Nitrosylchloride (ref. 11, p. 511), nitrosylbromide (ref. 11, p. 513), dinitrogenpentoxide (ref. 12, p. 83), chlorine(I) nitrate (ref. 12, p. 127), nitryl fluoride (13), nitrylchloride (14) and Cl_2O (15) (used in making chlorine nitrate) were all prepared using the literature methods. Nitrogen oxide trifluoride ONF_3 was obtained from Dr. J. M. Shreeve of the University of Idaho.

Nitronium- and nitrosonium-fluorosulfate, used as solutes to obtain the cations NO^+ and NO_2^+, were prepared by the interaction of nitric oxide (Matheson of Canada Ltd.) and nitrogendioxide with peroxydisulfuryl difluoride, $S_2O_6F_2$ (16). Details of this method together with solution studies in HSO_3F will be published later (17). The solutes ONF_2AsF_6 (18) and $N_2F_3AsF_6$ (19) were prepared from ONF_3 and N_2F_4, respectively, interacting with stoichiometric amounts of arsenic pentafluoride (Penninsular Chem. Research) as described. The products were characterized by their infrared spectra. Technical grade fluorosulfuric acid (Allied Chemical Corp.) was purified by double distillation in a nitrogen atmosphere. Solutions in anhydrous hydrogen fluoride (Matheson of Canada Ltd.) were prepared in Kel-F sample tubes using a monel metal vacuum line.

Where possible the purity was checked by infrared spectroscopy using a monel metal cell with silver chloride windows for gaseous samples. All solvents were of reagent grade purity and dried over molecular sieves.

Results and Discussion

The obtained ^{14}N chemical shifts together with previously reported values are listed in Table I. They now allow a more general discussion on trends of ^{14}N chemical shifts because the majority of the simple fluorides, oxides, and oxyhalides are listed together with a number of nitrogen containing ions. The chemical shifts of the two isomers of difluorodiazine are calculated on the basis of our value for nitrogen trifluoride. They had been determined originally by the double resonance technique (2) and were reported with NF_3 as a reference.

The agreement with previously reported chemical shifts is generally fair and often well within the reported confidence limits. Smaller discrepancies found for the oxyfluorides, FNO and FNO_2, are possibly caused by the extreme reactivity of the compounds. We have tried to eliminate the possible contamination due to wall reactions by using metal storage vessels and transfer systems and measuring the compounds in quartz tubes.

A large discrepancy is found for the chemical shift of the nitronium cation NO_2^+, apparently caused by the different ways in which the cation is produced. Kent and Wagner, who reported a chemical shift of 46 p.p.m., have used a 2:1 mixture of concentrated sulfuric acid and concentrated nitric acid, a mixture frequently used in preparative chemistry in aromatic substitution reactions. It must be regarded as very doubtful whether this procedure will lead to a quantitative formation of the NO_2^+ cation. An equilibrium of the following type is more likely

$$HNO_3 + 2H_2SO_4 \rightleftarrows NO_2^+ + 2HSO_4^- + H_3O$$

The reported ^{14}N chemical shift for 100% nitric acid is $+50 \pm 10$ p.p.m. upfield from NO_3^- in the ammonium nitrate reference and is relatively close to the above value.

Addition of sulfur trioxide to the sulfuric and nitric acid mixture will be expected to remove the H_3O^+ from the equilibrium and shift it gradually to the right side. This has been confirmed by us and was previously observed by Ogg and Ray in H_2SO_4 (21). The observed resonance signal is in

all cases a single line, the position depends on the SO_3 concentration. The value of +125 p.p.m. by Ogg and Ray for a mixture of nitric acid in oleum is in good agreement with our reported chemical shift of +129 p.p.m.

The conclusion that Kent and Wagner's value is in error and the high field value of 125 p.p.m. is more probable had been reached previously by Witanowski (22). On the other hand, NO_2SO_3F has found to be highly soluble in fluorosulfuric acid and to behave as strong electrolyte, comparable to KSO_3F. Evidence for extensive ionic dissociation has been obtained even for concentrated solutions (16).

A similar exchange equilibrium is probably responsible for the chemical shift of +89 p.p.m., obtained when N_2O_4 is dissolved in HSO_3F. It is surprising that only one ^{14}N signal is observed, since the nitrosonium cation NO^+ should be a very likely reaction product in the solvolysis of the tetroxide and has indeed been found when H_2SO_4 is used as a solvent (20). However, all attempts to detect this species by ^{14}N n.m.r. have failed using $NOSO_3F$ in fluorosulfuric acid or $NOSO_4H$ in sulfuric acid even at concentrations up to 70–80% nitrosyl hydrogen sulfate. We conclude that the resonance signal is broadened by quadrupole effects beyond detectibility limits. No previous reports on this cation could be found.

Similarly, no signal due to the F_2NO^+ cation was found, using ONF_2AsF_6 as the solute and HSO_3F and HF as solvents. Here additional difficulties arise from the limited solubility at lower temperatures and from unresolved ^{14}N–^{19}F spin–spin interaction.

For the $N_2F_3^+$ cation in HF only a single signal was obtained. Both cations have been detected previously via ^{19}F n.m.r. (19, 23), suggesting that the greater natural sensitivity of the fluorine nucleus presents a great advantage for solution studies. The limits of ^{14}N n.m.r. in this respect are evident.

Attempts to observe solvent–solute interaction when N_2O_4 is dissolved in a variety of solvents (24) at various temperatures and concentrations

are also reported in Table I. All changes in chemical shifts with temperature and also with concentration are rather insignificant and within limits of error. It appears that ^{14}N n.m.r. is not a sensitive enough method to detect this interaction in O- and-π-donor solvents, even though sufficient evidence for this interaction exists.

Some emphasis was placed on the direct detection of fine structure due to ^{14}N–^{19}F spin–spin interaction. A previous report (5) fails to observe multiplets when employing the derivative method to record the spectrum. Such a fine structure will be detectable only where molecules are highly symmetrical, the electric field gradient sufficiently small, and the quadrupole broadening largely reduced. So, when applying the more sensitive side band technique (8), fine structure could be resolved for three molecules: nitrogen oxide trifluoride ONF_3, nitrogen trifluoride NF_3, both having C_{3v} symmetry, and nitrylfluoride FNO_2, with C_{2v} symmetry. The first two compounds show quartets of roughly 1:3:3:1 intensity; the last one shows a 1:1 doublet. The spectra of F_3NO and FNO_2 are shown in Fig. 1, the coupling constants are listed in Table II together with the corresponding constants obtained via ^{19}F n.m.r. In all cases, good agreement is found. Double resonance for NF_3 led to a value of 155 c.p.s., again comparable to our value of 158 c.p.s. The temperatures where fine structure could be found are listed for the three compounds in Table I.

TABLE II

^{14}N–^{19}F spin–spin interaction

Compound	$J(^{14}N$–$^{19}F)$ (c.p.s.)		Reference
	^{14}N n.m.r.	^{19}F n.m.r.	
ONF_3	134 ± 2	135.5	37
O_2NF	109 ± 5	112.5	38
NF_3	158 ± 5	160	39

Attempts to observe fine structure for FNO failed. This is not very surprising since the ^{19}F spectrum (25) is also found to show only one broad line.

The observed ^{14}N chemical shifts reveal a fairly wide spread (from −329 p.p.m. for BrNO to +35 p.p.m. for N_2F_4) for those compounds where a lone pair on nitrogen is found, whereas the remaining compounds give rise to chemical shifts in a much smaller range (from 0 p.p.m. for NO_3^- to +131 p.p.m. for ONF_3).

Interpretation of ^{14}N chemical shifts (1, 4, 5) have stressed the dominant role played by the paramagnetic contribution to the chemical shift. This contribution σ_p is directly proportional to $1/\Delta E$, where ΔE is the excitation energy from the electronic ground state to excited states (26, 27). The most accessible excited states for the first group of compounds arise from $n_N \rightarrow \pi^*$ and $n_N \rightarrow \sigma^*$ transitions. The observed order of chemical shifts $BrNO < O_2NNO < ONO^- < ClNO < FNO <$ *trans*-$N_2F_2 <$ *cis*-$N_2F_2 < N_2F_4$ indicates an increase of ΔE, explained by an increasing stabilization of the nitrogen lone pair with increasing electronegativity of the substituents around nitrogen as pointed out by Mason and van Bronswijk (5).

A more accurate correlation of observed $n_N \rightarrow \pi^*$ and $n_N \rightarrow \sigma^*$ transitions, however, seems not possible because these electronic transitions are often very weak, the maximum difficult to determine, and unambiguous assignments often not available (28). This holds true for the nitrosyl halides where the deep brown color of the chloride (29) and bromide indicates low energy transitions in contrast to the fluoride (30) where the lowest absorption is found at 3110 Å.

In this connection it is interesting to note that the ^{14}N chemical shift for FNO is not unusually low as predicted by Holmes *et al.* (25) when commenting on the unusually large downfield shift in the ^{19}F n.m.r. spectrum. (−479 p.p.m. from $CFCl_3$) of this compound. The explanation forwarded involved the combination of a low-lying repulsive state for FNO, detected in the emission spectrum (30), about 2.4 eV above the ground state, which should affect the ^{14}N chemical shift likewise. The ^{14}N chemical shift of −116 p.p.m. is in fact the highest of all XNO compounds.

When substituting the lone pair by an oxygen atom the ^{14}N chemical shifts are moved upfield. The range for XNO_2 compounds is very narrow, e.g. FNO_2 and $ClNO_2$ exhibiting shifts separated by only 13.6 p.p.m. The separation between the corresponding XNO compounds has been 108 p.p.m. The general trend whereby the resonance moves upfield with increasing electronegativity of X has been observed for alkyl and aryl derivatives previously (31–33) and is apparently found

for inorganic derivatives too, even though the differences are quite small. An empirical rationalization of this observation by Witanowski (22) may be extended to the values reported. The highest chemical shift value is found for ONF_3 in agreement with previous work (5) where also an interpretation can be found. A more detailed discussion of the significance of the ^{14}N chemical shifts for the compounds studied here will be made when our molecular orbital calculations are completed.

Acknowledgments

We wish to thank the National Research Council of Canada for financial support, and for a post-graduate scholarship to one of us (J.A.R.). One of the authors (A.M.Q.) wishes to thank the Government of Pakistan and the Canadian External Aid Office for a Colombo Plan Scholarship. We are also indebted to Dr. Joan Mason for helpful discussion and for making some of her unpublished results available to us for comparison. We are also very grateful to Professor J. M. Shreeve of the University of Idaho for a sample of F_3NO used in this study.

Anodic behavior of silver in alkaline solutions

M. J. DIGNAM, H. M. BARRETT, AND G. D. NAGY[1]
Department of Chemistry, University of Toronto, Toronto 181, Ontario
Received August 28, 1968

Data, covering a range of pH and temperature, were obtained for the anodic oxidation of electropolished silver and the results compared with electrodes which had undergone repeated oxidation and reduction cycles. The behavior of the electrode is, in the main, complex, showing, for example, autopotential cycling under certain galvanostatic conditions (~3 μA/cm², 25 °C, 0.7 *N* NaOH), the period of oscillation being about ½ h. Several other hitherto unreported phenomena were also observed. The main conclusions reached are (*i*) that 2 different mechanisms are involved in the anodic formation of Ag_2O on silver electrodes in basic electrolytes resulting in 2 types of film, 1 mechanism involves a dissolution–precipitation process, the other possibly a direct interfacial reaction; (*ii*) that the reduction of anodically formed Ag_2O films either electrochemically or in hydrogen at 800 °C leaves behind a highly porous layer of silver metal; and (*iii*) that the limiting Ag_2O film thickness is probably determined by a diffusion process occurring within the film.

Introduction

To date, a considerable effort has been devoted to the study of the anodic behavior of silver (for reviews see refs. 1–5). Recent studies have been stimulated in large measure by applications of the Ag/AgO electrode in batteries of high energy-to-mass ratio (6–9). In addition, however, the system has intrinsic interest, as evidenced by the numerous theories which have been advanced to explain various features of the oxidation and reduction kinetics.

In relation to galvanostatic oxidation and reduction curves, the main processes occurring have been well established. Briefly, during oxidation from bare metal, Ag_2O is first formed on the electrode to a considerable thickness at a potential slightly above the reversible potential for the reaction, followed by conversion of the Ag_2O to AgO. Upon conversion of all the Ag_2O to AgO, oxygen is evolved. During reduction, AgO is first reduced to Ag_2O, which is subsequently reduced to metal.

The present paper is concerned principally with the growth of the Ag_2O film and its termination with the formation of AgO, the data being obtained for two types of electrodes. One type was first etched in nitric acid followed by cyclic anodic oxidation and cathodic reduction. This treatment was chosen for preliminary work primarily because most published data relate to this surface treatment. Most of the data reported here were obtained for electrodes prepared by electropolishing followed by reduction in hydrogen, and for conditions covering a range of pH and temperature.

Experimental

Apparatus

Two types of cells were used. For the cyclic oxidation and reduction experiments, the cell was of a standard two-compartment design, one compartment containing the test electrode and reference electrode with Luggin capillary (situated less than 0.5 mm from the electrode), the other a large area silver electrode with anodic oxide film. The cell was thermostated to within 0.1 °C and was grease free, employing KOH-lubricated standard tapered joints for connections. The electrolyte used was prepared from conductivity water of specific conductance approaching 7×10^{-7} ohm^{-1} cm^{-1} and reagent grade KOH. The stock solution was found to be 0.986 *N* in KOH and 0.077 *N* in K_2CO_3.

Galvanostatic runs were made employing a high voltage d.c. supply connected across the cell in series with a large resistor. Potential vs. time curves were measured using a strip chart recorder and cathode follower, or an oscilloscope (rise time < 0.1 μs) and camera.

Electropolished electrodes were investigated in the cell shown in Fig. 1. The Pyrex reaction cell was double walled in construction to permit easy temperature control. The electrodes, thermometer, and gas bubbling tube were mounted in a Lucite lid held by springs to the ground upper edge of the cell. A mercury – mercuric oxide reference electrode was immersed in a small compartment within the main cell compartment. The inner compartment and main cell compartment contained electrolyte of the same composition, and a capillary arm extended from the inner compartment terminating at a position close to the surface of the silver anode. The working cathode consisted of silver foil formed in the shape of an elliptical cylinder and coated electrochemically with silver oxide.

The electrolyte used in all cases was carbonate-free

[1]Present Address: Defence Research Board, Defence Research Establishment Ottawa, Ottawa 4, Canada.

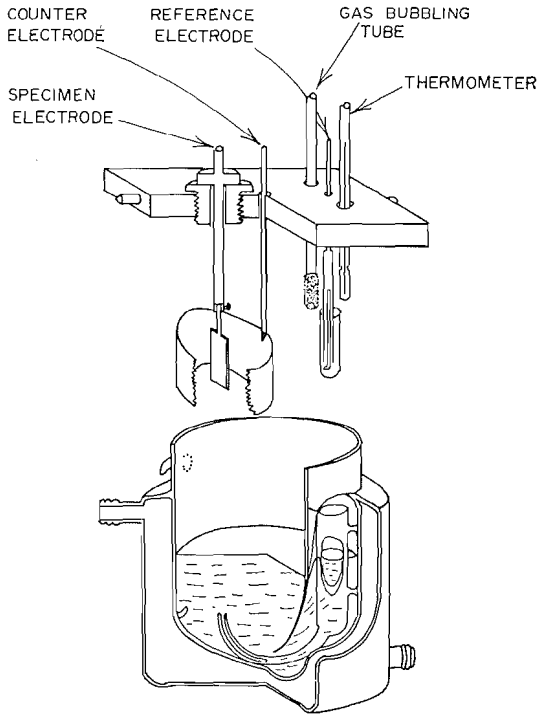

FIG. 1. Cell assembly.

sodium hydroxide. Care was taken to exclude CO_2 from the electrolyte, and to saturate freshly prepared electrolyte with Ag_2O.

The galvanostat used for the electropolished electrodes was constructed from operational amplifiers using conventional analogue computer circuits. Potentials were recorded either on a strip chart recorder or by employing an oscilloscope and polaroid camera, the recording systems being isolated by means of cathode followers.

Electrode Preparation

The test electrodes for the cyclic oxidation and reduction studies, were of dimensions 1.5 in. × 5/8 in. × 0.032 in., and were cut from a single piece of high purity silver (99.99%) obtained from Johnson, Matthey, and Mallory, Ltd. A length of 25 gauge silver wire was fused to a small tab at the top of the electrode. The electrodes were polished with numbers 1, 3/0, and 4/0 emery paper, etched in 1:1 aqueous nitric acid for 20 s, then rinsed well in conductivity water. This treatment left the surface of the electrode cream colored. The Ag/Ag_2O reference electrode and cathode were prepared in a similar manner and coated electrochemically with silver oxide.

The paddle-shaped, electropolished silver anodes, of dimensions 1/4 in. × 1 in. × 0.04 in., were punched from silver sheet stock from Johnson, Matthey, and Mallory (99.99% purity). The stem of each paddle was marked to create a level for immersion, then electropolished in a cyanide bath (35 g AgCN, 37 g KCN, and 38 g K_2CO_3 per l of water) (10) for 10 min. Following electropolishing, the majority of the electrodes were annealed in a stream of purified hydrogen for about 1 h at a temperature of 800 °C, cooled in hydrogen, then transferred to a CO_2-free desiccator. This procedure, which resulted in a bright, mirrorlike surface, gave the most reproducible kinetic results. Replacement of the hydrogen with nitrogen, annealing at lower temperatures, annealing for different times, mechanical buffing of the surface, and reduction in a furnace of a previously anodically oxidized electrode without intermediate acid washing or electropolishing were unable to surpass this preparation.

Other electrode preparations which were examined in some detail and which will be referred to in subsequent sections are summarized below, along with the main treatment outlined above, which will be referred to as Type I. (Type I, electropolished and annealed in hydrogen; Type II, electropolished only; Type III, electropolished, then anodically oxidized to completion of the Ag_2O film followed by reduction in hydrogen; Type IV, electropolished, anodically oxidized to completion of the Ag_2O film, then reduced electrochemically.)

The gases used for bubbling into the electrolysis chamber were at different times, carbon dioxide-free and water vapor-saturated nitrogen, oxygen, and air, with the choice having little or no effect on the results.

Typical Procedures for Electropolished Electrodes

To commence a run, the position of the silver electrode which was mounted in the cell holder was adjusted until the electrolyte–vapor interface coincided with the immersion mark. A box painted flat black was then lowered over the cell to exclude light, and the oxidation process initiated. On completion of a run, the specimen electrode was removed from the cell, rinsed, then dried (or rinsed and dipped in 1% nitric acid to remove the oxide, then rinsed and dried), placed in a desiccator and a new electrode mounted.

All potentials were measured against an Hg/HgO reference electrode in the same solution, but before recording, a potential of 0.244 V was added so that the zero of potential would correspond to the reversible potential for an unilluminated Ag/Ag_2O electrode. Insofar as formation of Ag_2O is concerned, therefore, the recorded potentials correspond to overpotentials.

A. Cycled Electrodes

General Features of Galvanostatic Polarization Studies

Figure 2 shows a typical galvanostatic polarization curve. This curve shows the regions of Ag_2O formation (*A* to *D*), AgO formation (*E–F*), and oxygen evolution (*G–H*). The dip, *B*, and arrest, *C*, were most prominent at low apparent current densities and at higher temperatures. At low temperatures, the maximum at *A* was broader. For very high current densities, no dip or arrest could be detected. For a freshly etched electrode (one that had not been subjected to oxidation and reduction cycles), the potentials along the portion

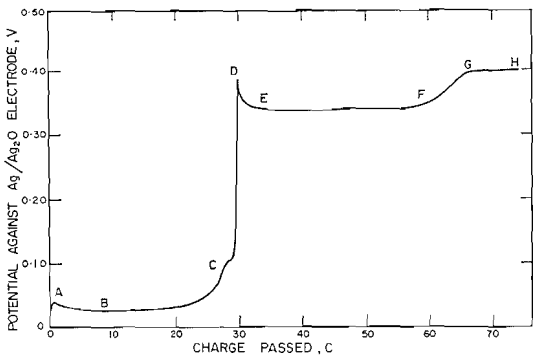

FIG. 2. Anodic polarization of Ag in *N* KOH at 25 °C. (Geometrical area of electrode, 12.6 cm²; apparent current density, 0.4 mA/cm².)

of the curve *AC* were substantially higher than those for a cycled electrode, the increase being as much as a factor of 2.

Charge Required to Complete Ag_2O Layer

Table I summarizes the data obtained for a succession of oxidation and reduction runs carried out on the same electrode at 25 °C. The oxidations were stopped when the potential reached 0.250 V, which is about 10 mV below the reversible potential for the Ag_2O/AgO couple. In all cases the reduction was carried out at an apparent current density of 0.4 mA/cm². The surface of the reduced electrode was observed to be darker than that for a freshly etched electrode, and remained so even after prolonged periods of hydrogen evolution. Because the charge passed for oxidation and reduction are in good agreement, it is reasonable to conclude that film formation and reduction took place with 100% current efficiency.

Examination of the Properties of Electrodes with Fully-Formed Ag_2O Films

Some properties of electrodes with fully-formed Ag_2O films (i.e., films formed under galvanostatic conditions to a potential of 0.250 V) were investigated in the course of obtaining the data in Table I. Two types of measurement were performed. In the first type, following completion of the Ag_2O layer as defined above, the cell was left on open circuit for a time period ranging from 3 min to 1000 h, then the same apparent current density as used to form the film was reapplied, the time being determined to charge the electrode once again to 0.250 V. The data for these experiments are summarized in Table II, insofar as the additional charge passed is concerned. The polarization curves on recharging the electrode gave rise to a hump similar to *C* of Fig. 2.

A second type of experiment was done in which, following formation of the Ag_2O layer at a high

Charge required to recharge "fully-formed" electrodes to 0.250 V at various apparent current densities. Formation current density was 0.77 mA/cm^2 for all 3 runs

Apparent current density (mA/cm^2)	Charge passed (C)		
	Run No. 27	Run No. 28	Run No. 29
0.77	14.36	11.91	10.18
0.40	0.053	0.065	—
0.08	0.085	0.044	—
0.04	0.061	0.038	0.22

current density (0.77 mA/cm^2) to a potential of 0.250 V, the cell was left on open circuit for 3 min, then repolarized to 0.250 V at a lower current density, allowed to decay on open circuit for 3 min once again, and so on. Table III summarizes the results for 3 such experiments, insofar as the charge passed is concerned.

Variation of Overpotential with Current Density for Successive Galvanostatic Conditions

Because of the large scatter in the measured potentials observed from run to run (see Table I) and the relatively small range of apparent current density used, it was not possible to determine the nature of the functional dependence of overpotential on current density from the data in Table I. The dependence was therefore determined during the course of a single oxidation run by increasing the current in 3 steps from 0.04 mA/cm^2 to 0.77 mA/cm^2, allowing only sufficient time for a steady potential to be established between steps. The process was repeated for various stages during the growth of the Ag_2O film. In order to make a correction for the slow rate of change of overpotential with charge passed, the overpotentials for each sequence of readings were extrapolated to a value for the charge passed lying at the midpoint of the particular sequence. The results of such measurements are summarized in Table IV.

Potential Decay Measurements

Open circuit potential decay measurements were obtained at various intervals during the formation of the Ag_2O film. Figure 3 illustrates a potential decay curve typical of those obtained for the region *B–C* of Fig. 2. The data are plotted in the manner of Morley and Wetmore (11), that is, in the form overpotential vs. $\log(t + \phi)$, where t is the elapsed time and ϕ is a constant chosen to linearize the initial portion of the decay. The decay of the final 20–30 mV was found invariably to give rise to an excellent linear plot on a potential vs. $\log(t)$ basis. For the particular run shown in Fig. 3, it appears probable that there is a change in the functional form of the decay at about 24 mV. This appears to be a general feature of all the decays, the position of the change varying somewhat in the range 20–30 mV.

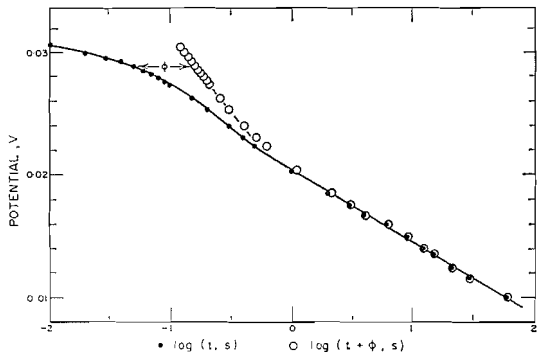

FIG. 3. Potential decay measurement for runs in which the current was interrupted near B of Fig. 2 (ϕ = 0.11 s).

The results of the measurements for the initial decay process in the region B–C are summarized in Fig. 4, in which the values for the potential decay slope (slope of potential vs. log (t)) and ϕ are plotted against the normalized charge passed. The potential decay slope for the second and slower portion of the decay was found to vary randomly from run to run between 0.004 and 0.0095 V, a period of from 4 to 8 h being required for the potential to reach essentially 0.

In order to elucidate the nature of the slow decay process, potential decay curves in the region B–C of Fig. 2 were obtained under conditions which were similar in all respects except for the resistance in parallel with the cell. For one run, a 50 kohm resistor was placed in parallel with the cell, whereas for another, the parallel resistance was that of the electrometer (about 10^{14} ohms). The potential decay slopes for the slow decay process were 0.00339 and 0.00405 V, respectively, for the 2 runs. Apparently a resistance of as low as 50 kohms across the cell has little or no effect on the rate of the slow potential decay, implying an effective electrode capacitance during the decay of about 2×10^4 μF, or more.

Potential decay measurements in the region C–D of Fig. 2 appear to give rise to 3 linear regions when plotted in the form potential vs. log ($t + \phi$). Figure 5 illustrates open circuit decays commencing from 150, 200, and 250 mV, respectively. The initial linear region appears to extend down to about 100 mV. From somewhat below 100 mV to approximately 20–25 mV, a second linear range is found with slope ranging from 0.019 to 0.023 V. The final decay took place with a slope in the range 0.007 to 0.009.

Effect of Stirring

Some experiments were carried out on cycled electrodes using a cell which permitted the effect of stirring on the electrode behavior to be examined. No significant dependence on either electrode potential or current efficiency for film

formation on stirring could be detected, provided that the electrolyte was saturated with respect to Ag_2O.

B. Electropolished Electrodes

General Features of Galvanostatic Polarization Studies

In Fig. 6, three typical anodic polarization curves in 0.7 *N* NaOH are illustrated for 4 different types of electrode preparation. Curve (*a*) represents the usual behavior for Type I and Type II electrodes, curve (*b*), that for Type III electrodes, and (*c*), that for Type IV electrodes.

During runs designed to determine the variation of electrode potential with current density at low current densities, abrupt changes in potential

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

were observed. As the oxidizing current was increased in steps, a critical level would be reached at which a further increase in current led to an abrupt drop in the overpotential. The effect was reversible, so that on decreasing the current density once again the electrode potential resumed its initial higher value. This behavior is presented in greater detail in the section dealing with Tafel slopes.

A number of electrodes were observed to oscillate spontaneously between the above two potential levels under galvanostatic conditions. In extreme cases this oscillating occurred for the greater part of the galvanostatic run, as illustrated in Fig. 7. More frequently, however, only 1 to 3 of these cycles appeared just preceding the rise in potential to the Ag_2O/AgO level. It was found that stirring resulted in a reduction of the potential in the plateau regions, but had no effect in the valley regions.

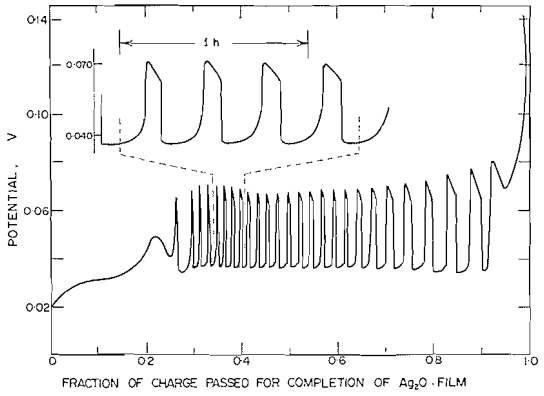

FIG. 7. Example of galvanostatic oxidation run exhibiting auto-oscillating of potential (0.7 *N* NaOH, 27 °C, 2.9 μA/cm²).

For measurements at low current densities, upon changing the current density, a period of about 1 h or more was required before the electrode potential achieved a constant value. The transition period was observed to increase with decreasing electrolyte concentration in the range 0.03 to 0.7 *N* NaOH, with Type I electrodes giving rise to the longest periods (3 or more h for 0.03 *N* NaOH). Type II electrodes gave rise to transition times lower by about a factor of 4. Type II electrodes were therefore used exclusively for the measurements at low concentrations, with Type I and Type II electrodes otherwise being used interchangeably.

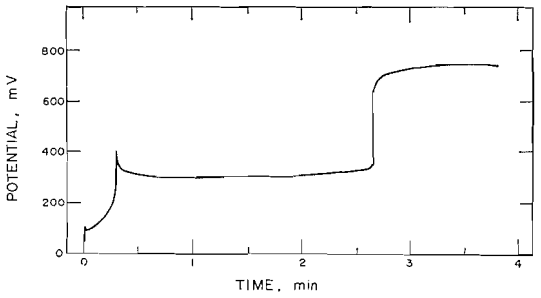

FIG. 8. Galvanostatic polarization curve for Type I electrode (0.7 *N* NaOH, 27 °C, 2.5 mA/cm²).

Charge Required to Complete Ag_2O Film

Figure 8 illustrates a typical galvanostatic polarization curve obtained for a Type I electrode at a relatively high current density (2.5 mA/cm²). The total charge passed for formation of Ag_2O is substantially less than that associated with the AgO plateau, a result found in general. At sufficiently high current density, no evidence of an Ag_2O plateau can be found. In order to determine the film thickness corresponding to completion of the Ag_2O plateau, galvanostatic polarization runs similar to that depicted in Fig. 8 were carried out on Type I, Type II, and Type III electrodes, the current being stopped, however, when the potential reached the peak between the Ag/Ag_2O and Ag_2O/AgO plateaus. The film was then reduced at 0.25 mA/cm² current density, the termination of the reduction process being signalled by an abrupt drop in electrode potential towards that for hydrogen evolution. The data collected in this manner for Type I and Type II electrodes are presented in Fig. 9. At low current

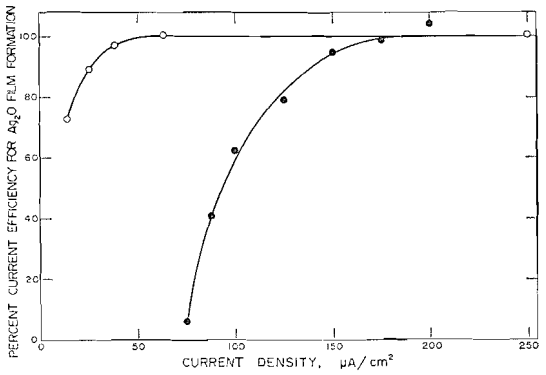

FIG. 9. Current efficiency for formation of Ag_2O films on Type I electrodes (0.7 *N* NaOH, 27 °C; ● and ○, in the presence and absence of electrolyte stirring, respectively).

densities, the current efficiency is less than 100%, increasing to 100% for currents of 0.062 mA/cm^2 or greater. For currents well above this value, film thicknesses were calculated from the charge passed during oxidation.

Film thicknesses were calculated using the bulk density (12) for Ag_2O (7.14 g/cm^3) and assuming unit roughness factor. The results for Type I electrodes are presented in Fig. 10.

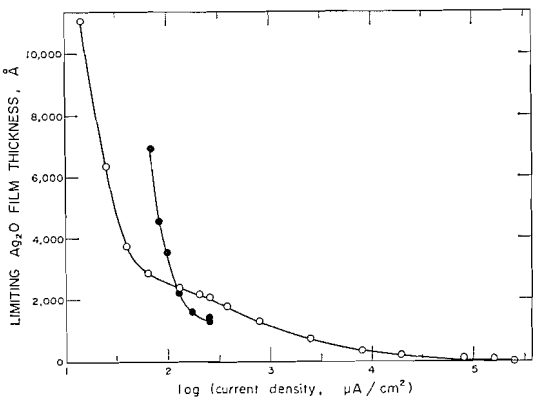

FIG. 10. Limiting thickness of Ag_2O film as a function of the formation current density for Types I and II electrodes (0.7 *N* NaOH, 27 °C; ● and ○, in the presence and absence of electrolyte stirring, respectively).

Ag_2O was found to form at 100% current efficiency on Type III electrodes at all current densities investigated. In other respects these electrodes gave irreproducible results which, in addition, were quite different from those for Type I and Type II electrodes.

Variation of Electrode Potential with Current Density, Film Thickness, and Electrolyte Concentration

Galvanostatic polarization curves for Type I electrodes polarized in 0.7 *N* NaOH at 27 °C are shown in Fig. 11. There is a pronounced dependence of overpotential on film thickness at high current densities, which decreases to essentially 0 at low current densities. At low current densities, it was therefore possible to determine the variation of overpotential with current density using the following procedure. A Type I or II electrode was anodically oxidized at 12 μA/cm^2 for a few hours. A succession of measurements were then made at different current densities as illustrated in Fig. 12. The behavior referred to earlier, in which, upon increasing the current density, the

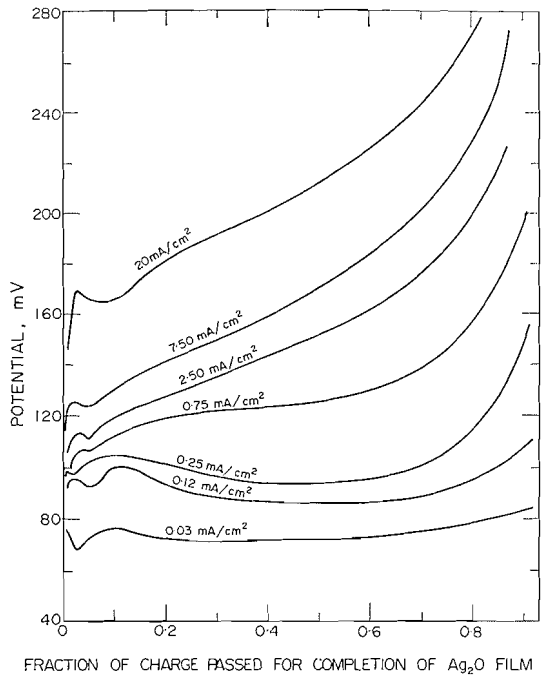

FIG. 11. Variation of galvanostatic polarization curve with current density (0.7 *N* NaOH, 27 °C).

potential first increases then decays to a value lying below the initial value, can be seen.

The results obtained from such runs are plotted in Tafel form in Fig. 13. The reproducibility of the data, both in connection with measurements made on a single Type I or II electrode and on comparing results for different electrodes, is evident.

In more dilute electrolytes a different behavior was observed. In the first instance it was noted that stirring the electrolyte caused a change in the steady-state potential. In Fig. 14, the variation of overpotential with electrolyte concentration and current density is illustrated, both in the absence and presence of stirring effected by agitation of the specimen electrode. The results for 0.7 *N* NaOH are taken from Fig. 13. At the lower concentrations, it is seen that a linear Tafel relationship is obtained only under conditions of stirring.

Influence of Stirring on Current Efficiency and Charge required to Complete Ag_2O Film

A few runs were carried out in a cell in which the electrolyte was stirred with a magnetic stirrer and, in addition, the electrode agitated through a

mechanical coupling to an electromagnetic vibrator. Data obtained in this manner are presented in Figs. 9 and 10, and in Table V. It is believed that all these data were obtained under conditions such that increasing the stirring rate would have only a small effect on the results. This opinion, however, is based solely on observing the variation in overpotential with the stirring rate. It

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

cannot be said with certainty, therefore, that the limit corresponding to high stirring rates was in fact achieved.

A further observation made during the course of these measurements was that films formed in the absence of stirring were dark brown or black in color and had a matt or semi-gloss appearance, whereas the films formed while stirring were light amber in color and transparent, even for films as thick as 7000 Å.

Discussion of Results

It is apparent from a number of different observations that at least 2 different mechanisms are operative during the anodic oxidation of silver in aqueous hydroxide solutions. We shall review the factors leading to this conclusion.

The most dramatic evidence is probably provided by the data of Fig. 7 in which, under galvanostatic conditions, the overpotential is seen to oscillate between 2 different levels differing from one another by about 40 mV. Again, from the data of Fig. 12, on increasing the current density above a certain critical value, the overpotential is seen to decrease abruptly, again by about 40 mV. Finally, from Fig. 9 it is apparent that the current efficiency for formation of Ag_2O in the current density range 60 to 200 $\mu A/cm^2$ is decreased by electrolyte stirring. This observation implies a mechanism which involves a dissolution–precipitation process similar to that proposed by Dirkse *et al.* (13), the solution species most likely being $Ag(OH)_2^-$ (solubility limit of $Ag(OH)_2^-$ in 1 *N* KOH solution is 1.9×10^{-4} g equiv./l (14)). The fact that current efficiencies do not go to 0 for conditions of rapid stirring, and furthermore that the films so produced have visual properties distinctly different from those formed in the absence of stirring, implies a parallel mechanism of film formation which does not involve dissolution–precipitation but rather formation of a compact film as a result of a direct interfacial reaction. The existence of a dual layer type of oxide film has also been reported previously by Briggs *et al.* (15).

In the following sections the electrode behavior is discussed on the premise that 2 mechanisms of the kind outlined above are indeed operative.

Charge Required to Complete Ag_2O Film

From Fig. 10, it can be seen that the effect of stirring on the limiting film thickness is to reduce

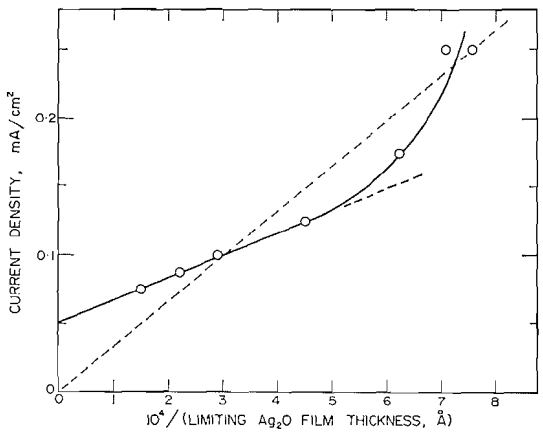

FIG. 15. Formation current density vs. reciprocal limiting film thickness for Type I electrodes under conditions of rapid electrolyte stirring (0.7 *N* NaOH, 27 °C).

it somewhat for current densities above about 12.5 $\mu A/cm^2$, while increasing it substantially for current densities below this value. Thus suppression of the precipitation process for Ag_2O formation has a very dramatic effect on the current dependence of the limiting film thickness only at very low current densities. It would seem therefore, that transport through the postulated "compact film", formed by the direct interface reaction, plays the major role in determining the limiting film thickness at high current densities, with the precipitated oxide assuming this role for very low current densities. Assuming, therefore, that in the presence of stirring the limiting film thickness is controlled by diffusion of some species (V centers, for example) through the compact oxide film, then the formation current density, i, should be a linear function of the reciprocal of the limiting film thickness, X. Referring to Fig. 15, it can be seen that the data do not conform well to such a relationship. A very much improved linear relationship is obtained by plotting i against $(X - A)^{-1}$ where A is a constant of the order of 600 Å. Some distortion, however, is not unexpected, because it is entirely possible that the stirring rate was insufficient to eliminate formation of oxide film by precipitation. The suggestion that the growth of the compact film is limited by diffusion remains, therefore, a reasonable one. The only immediate alternative explanations for the cessation of growth of the compact film are inapplicable to films which may be grown to a mean thickness of 7000 Å or more. Thus, a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

mechanism such as proposed by Dirkse and Werkema (16), involving nucleation and 2-dimensional growth but leaving bare silver, is untenable for films of this thickness. Again, any mechanism based on a sudden change in one or more of the intrinsic film properties, such as its resistance, at best begs the question, as a credible mechanism for bringing about this change in a film 7000 Å thick must also be provided. Finally, rate control, by ion or electron transport through the film, of itself cannot account for the abrupt cessation of the growth of Ag_2O under galvanostatic conditions and at a potential below that for AgO formation. Under such conditions the potential should increase linearly with time, at least until the Ag_2O/AgO potential is reached. The growth of anodic oxide films on Al, Nb, and Ta behaves in this manner, film growth continuing in these instances far beyond the potential for oxygen evolution (17).

In the absence of stirring and at low current densities the limiting film thickness appears to be controlled by transport through the film formed by precipitation, as previously noted. Assuming diffusion of some species through the precipitated film to be the rate controlling process, i should be a linear funtion of X^{-1}. We may attempt to correct for the compact film by subtracting from X the thickness of the compact film, e.g. A. An excellent linear relationship is achieved on this basis for $A = 1810$ Å (cf. Fig. 16).

Tafel Slope Determinations

The 3 lines in Fig. 13 all have a slope of approximately 22 mV per decade which agrees closely both with the upper limit value found for cycled electrodes (7 to 22 mV, cf. Table IV) and with the potential decay slope (see Fig. 4) made in the same potential range[2].

For more dilute electrolyte concentrations, linear Tafel plots are not obtained in the absence of stirring (see Fig. 14), but only when measurements are made while stirring. The Tafel slope values lie in the range 20–30 mV per decade.

Because the Tafel slopes for electropolished electrodes were determined at low current densities and with stirring, they presumably apply to the electrochemical dissolution of silver as

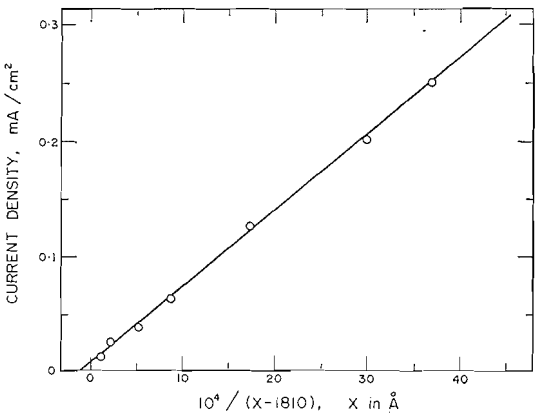

FIG. 16. Formation current density vs. $[X - 1810$ Å$]^{-1}$ for Type I electrodes in the absence of stirring (current densities < 0.25 mA/cm², 0.7 N NaOH, 27 °C).

$Ag(OH)_2^-$, the reaction occurring at the compact film–electrolyte interface. This account is consistent with the results obtained for the cycled electrodes in which the value of the potential-decay-slope/ϕ, which will be proportional to the reciprocal of the electrode capacitance for an electrode covered by a thick film (11), was found to vary approximately linearly with film thickness.

The high effective electrode capacitance associated with the slow decay (about 2×10^4 μF, or more) when combined with the assumption that it is determined by an interfacial or double layer capacitance of about 20 μF/cm² (which could only be the case if the oxide film were behaving as a good conductor during the decay) leads to an effective electrode area of about $2 \times 10^4/20 = 10^3$ cm², or more, and a roughness factor of about 10^2, or more. Surprisingly, a similar conclusion is reached in the section "Effect of electrode treatment". The high effective capacitance might, however, have a thermodynamic, rather than kinetic, origin.

Apparent Film "Resistivity"

At high current densities, the overpotential shows a definite upward rise with increasing film thickness, the rate of rise being approximately constant over a reasonable portion of the polarization curve. In Table VI, the slope of this nearly linear region in V/cm is recorded as a function of formation current density, and the ratio calculated in ohm cm. Apart from the very highest current densities, the ratio is approximately constant at 8×10^6 ohm cm (which is of

[2]For the relationship between the potential decay slope and the Tafel parameter, and also between the potential-decay-slope/ϕ and the electrode capacitance, see refs. 11 and 18–21.

TABLE VI

Calculation of apparent specific resistivity of film

Formation current density, i (mA/cm^2)	Rate of change of potential with film thickness, dV/dx (V/cm) $\times 10^{-5}$	Apparent specific resistivity of film, $(dV/dx)/i$ (ohm cm) $\times 10^{-6}$
162	2.83	1.75
19.7	0.580	2.95
7.61	0.502	6.67
2.47	0.227	9.19
0.75	0 038	5.07

0.250	0 0246	9.84
0.200	0.0168	8.40

the same order as the electronic conductivity for Ag_2O reported by Le Blanc and Sachse (22), namely, 10^8 ohm cm).

The values at high current density may be brought into accord with the others if it is assumed that the conduction equation giving rise to the resistance term deviates from Ohm's law at high field strengths according to the equation

$$[1] \qquad i = \alpha|\exp \beta E - \exp(-\beta E)|$$

where α and β are temperature dependent constants and E, the field strength. Equation [1] is of the form normally assumed for high field ionic transport (17), in which case $\beta = \mu^*/kT$ where μ^* is the activation dipole or charge-activation distance product for ion migration. The required value of μ^* is about 35 eÅ, which is close to those obtained for the anodic oxidation of the valve metals (23). Thus it appears likely that at high current densities an ionic or electronic resistive term, associated with the film, makes an important contribution to the overpotential. This term might arise either in the "compact film" or in that formed by the precipitation reaction. Thus the resistive term might be associated with hydroxyl ion transport through the open pore structure of the precipitated oxide film.

Effect of Electrode Treatment

It is apparent that surface preparation plays a major role in the subsequent anodic behavior of silver electrodes (see Fig. 6). One might suppose that the large difference in overpotential observed for a freshly electropolished electrode, as compared with one which has been once oxidized and then electrochemically reduced, might be in some way related to the oscillating behavior exhibited in Fig. 7, or to the anomalous drop in potential on increasing the current, illustrated in Fig. 12. This appears very likely, however, as the surface treatment effect persists at current densities very much higher than those for which the other phenomena are observed. We examine, therefore, the possibility that the surface treatment effect arises solely as a result of a change in electrode surface area. Using the Tafel data of Fig. 13 in order to reconcile curves *a* and *c* of Fig. 6, a roughness factor of approximately 200 must be assumed for an electrode which is reduced electrochemically. For comparison purposes, polarization curves for electrodes etched in 1:1 nitric acid were similarly analyzed, and led to roughness factors of 15 to 20, in good agreement with those reported by Cahan *et al.* (24) for silver treated in this manner. There seems to be no reason, therefore, to reject the roughness factor value of 200 for electrochemically reduced electrodes. Such a high value could only be achieved through a porous structure for the metal surface, as observed by Burbank (25).

The effect of the reduction current density on the subsequent oxidation process can be seen in Table I. Runs 17 to 24 show that when the electrode is reoxidized at a current less than the reduction current, the charge passed to complete the Ag_2O film increases with successive oxidation cycles. When the electrode is reoxidized at a current greater than the reduction current, however, the converse is true. This is consistent with Wales' and Burbank's (4) observation concerning the dependence of the crystal size for the reduced metal upon current density.

On reoxidizing the electrochemically reduced metal to Ag_2O under current conditions, the porous metal will be oxidized first and at a very low current density, leading to a low overpotential. When the porous metal is completely converted to Ag_2O, some of the underlying "virgin" metal may oxidize, at a current density roughly 200 times that for the porous metal and hence at a higher overpotential. The potential plateau occurring just before the potential rises toward that for AgO formation (see Fig. 2 and Fig. 6, curve *c'*) has therefore a natural explanation in the above model. It explains the observation that, although formation at a lower current density results in an appreciable increase in the total amount of Ag_2O which may be formed, once a film is fully formed (i.e. an overpotential of 0.250 V is reached), attempts to increase the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

film thickness by reducing the current density meet with remarkably little success (cf. Tables II and III).

Thus the termination of growth of Ag_2O on cycled electrodes is closely related to the filling in of a porous structure. The structure which is porous, however, is the metal substrate, not the forming oxide. In the absence of this porous structure, the film thickness appears to be limited by diffusion, the situation being complicated by the presence of more than 1 type of film material.

In the light of the above, the behavior of Type III electrodes (which are prepared by reduction in hydrogen for 1 h at 800 °C electrodes previously oxidized to completion of the Ag_2O film) is of interest. From Fig. 6 curve *b*, it can be seen that the electrode behaves initially in a similar manner to a freshly electropolished electrode (curve *a*) in that the overpotential is initially high. The potential soon drops, however, and subsequently matches fairly closely the behavior of electrochemically reduced electrodes. It would appear, therefore, that annealing at 800 °C leads to sintering of the porous metal only in a thin layer at the metal–hydrogen interface.

Clearly, the low current efficiency for formation of Ag_2O on electropolished electrodes (Types I and II) arises as a consequence of the silver dissolution mechanism. The postulate that Types III and IV and also cycled electrodes possess a highly porous surface layer of metal therefore provides an explanation for the fact that Ag_2O may be formed on these electrodes at close to 100% current efficiency, even at very low current densities and with electrolyte stirring, because the solution species will be formed within the cavities of the porous structure and will accordingly have little opportunity to escape into the bulk electrolyte before precipitating as oxide.

Summary

1. At least 2 different mechanisms are involved in the anodic formation of Ag_2O in basic electrolytes. One of these mechanisms involves a dissolution–precipitation process for the growth of the Ag_2O film, while another probably involves a direct interfacial reaction, leading to a compact film.

2. The reduction of anodically formed Ag_2O films, either electrochemically or in hydrogen at 800 °C, leaves behind a highly porous layer of silver metal.

3. Below 0.25 mA/cm^2, the anodic formation of Ag_2O on a smooth silver electrode (0.7 *N* aqueous NaOH) appears to be limited by the diffusion of some species (possibly OH^-, H^+, or H_2O) through the film formed by the dissolution–precipitation process. For these current densities, stirring greatly reduces the current efficiency for film formation, while at the same time greatly increasing the attainable limiting Ag_2O film thickness. The Tafel slope for the electrochemical dissolution process lies in the range 20 to 30 mV per decade of current.

4. Above 0.25 mA/cm^2, the anodic formation of Ag_2O on a smooth silver electrode appears to be limited by diffusion (and/or migration) of some species (possibly V centers and/or cation vacancies) through the underlying compact film. In this case, stirring reduces the limiting film thickness, presumably by suppressing the formation of the precipitated film. At these current densities, an overpotential, apparently resistive in nature, appears which corresponds to a mean film resistivity of the order of 10^7 ohm cm.

5. At low current densities, suppression of the precipitation mechanism for film formation leads to the growth of a film which is essentially transparent even for thickness as great as 7000 Å.

Infrared studies of the 1,3,5-trinitrobenzene – cyanide ion complex

A. R. NORRIS[1] AND H. F. SHURVELL
Department of Chemistry, Queen's University, Kingston, Ontario

Received June 16, 1969

Quantitative infrared studies have been made of the interactions of 1,3,5-trinitrobenzene and 1,3,5-trinitrobenzene-d_3 with cyanide ion in chloroform, deuterochloroform, and acetonitrile. Absorption bands assignable to the 1:1 complex have been characterized and attempts made to assign the absorptions to fundamental modes of the complex.

Canadian Journal of Chemistry, 47, 4267 (1969)

Introduction

Infrared studies have been reported on a wide variety of solid adducts precipitated from concentrated solutions containing an aromatic nitro compound and a suitable base (1–8). Although the infrared spectra are in accord with the formulation of these adducts as σ-complexes, this formulation receives much stronger support from proton nuclear magnetic resonance (n.m.r.) measurements (7, 9–11).

No attempt has so far been made to utilize infrared measurements to establish the stoichiometries of σ-complexes in solution or to analyze the spectra of the complexes in terms of their fundamental absorptions. We report here the results of our infrared investigations of the cyanide ion σ-complexes of 1,3,5-trinitrobenzene and 1,3,5-trinitrobenzene-d_3.

Experimental

Eastman 1,3,5-trinitrobenzene (TNB) was recrystallized several times from ethanol–water and dried to constant weight in vacuo over silica gel (m.p. 122 °C). 1,3,5-Trinitrobenzene-d_3 was prepared as described by Buncel and Symons (12), recrystallized from ethanol–water and dried in vacuo to constant weight (m.p. 120.5–121.5 °C). The deuterium content of the compound determined as described by Symons (13) was 91 ± 2% D.

Tetraphenylarsonium cyanide (TPAC) was prepared as described by Bosnich (14) and dried to constant weight in vacuo over phosphorous pentoxide.

Spectrograde chloroform and acetonitrile and Stohler Isotope Chemicals deuterochloroform (99.8%D) were used without further purification, but were stored over Linde Molecular Sieve once the bottles had been opened.

Spectra were run on a Beckman IR-10 grating instrument, a Perkin–Elmer Model 21 spectrophotometer equipped with a NaCl prism, and a Perkin–Elmer Eberr grating instrument. The latter two instruments were used primarily to check the accuracy of the peak positions as determined on the IR-10 and to resolve the fine structure associated with certain absorption bands near 3000, 1200, and 1050 cm^{-1}. Most of the quantitative data relates to work carried out on the IR-10.

Low-temperature spectra were recorded using a variable low-temperature cell unit (VLT-2 from Research and Industrial Instruments Co., London). The cell temperature was maintained at −31 ± 2 °C by adding sufficient finely-divided dry ice to the well of the low-temperature cell to keep the 50/50 (v/v) ethylene glycol – water mixture contained therein at its freezing point. The cell temperature was measured with a thermocouple (copper–constantan) inserted into one of the cell windows. Variable path length solution cells (FH-01) equipped with Teflon spacers were used in all the low-temperature work. Path lengths were determined both by the interference–fringe method (15) and the standard absorber method using benzene as the standard (16). Cell windows were of AgCl, CaF_2, and KRS-5, with AgCl being used most frequently. Since AgCl tends to deform under pressure, frequent checks on the path lengths were required when windows of this material were used.

Apparent molar extinction coefficients (ε_a) were calculated from the equation $\varepsilon_a = 1/Cl \log (I_0/I)$, where C is the concentration in moles l^{-1} and l is the path length in cm. Values of ε_a for 1,3,5-trinitrobenzene and tetraphenylarsonium cyanide were measured for solutions 10^{-1} to 10^{-2} M in cells of 0.005 to 0.020 cm path length. The molar extinction coefficients are dependent on the mode of operation of the spectrophotometer and the values quoted refer to measurements made at the normal setting of the IR-10 (nominal resolution ~4 cm^{-1}) and slow scan.

Solutions containing the complex were prepared by adding a known volume of pre-cooled solvent to weighed amounts of the two components contained in a test tube at −45 °C. When solution was complete a portion of the liquid was withdrawn using a cooled syringe and injected into the previously cooled cell. Indications are that in the transfer operation the temperature of the solution does not go above −20 °C. Recording of the spectrum was begun after the cell and contents had reached a constant temperature (~20 min). Spectra recorded on the Beckman IR-10 and the Perkin–Elmer 21 instruments were obtained using solvent alone in the reference beam.

Results

When solutions containing 1,3,5-trinitrobenzene (TNB) and tetraphenylarsonium cyanide

(TPAC) at the concentrations required for infrared studies are prepared at room temperature, deep red solutions result which slowly turn brownish-red, and finally become deep brown in color. In typical experiments carried out at room temperature the first reaction is complete on mixing the two solutions while the secondary reaction has a half-life of from 10 to 20 min. As a result, the secondary reaction seriously interferes with attempts to obtain good infrared spectra of the deep red solutions.

While the rate of formation of the red color seems to be very rapid at all temperatures between 25 and -45 °C, the rate of the secondary reaction is dramatically reduced at lower temperatures. At 0 °C, for instance, with both reactants $\sim 0.07\ M$, $t_{\frac{1}{2}}$ for the decay reaction is approximately 9 h while at -30 °C, the solutions can be kept for up to 8 h with no evidence of a secondary reaction. The infrared spectra of these red solutions consist of many bands which, in the absence of the decomposition product, can be satisfactorily accounted for in terms of uncomplexed TNB and cyanide ion, a cyanide ion – TNB complex and tetraphenylarsonium ion. All the infrared evidence collected to date suggests that no changes occur in the absorptions characteristic of the tetraphenylarsonium ion as a result of complex formation[2]. The analysis which follows is, therefore, concerned with those absorptions which are characteristic of uncomplexed TNB, the cyanide ion – TNB complex and uncomplexed cyanide ion. We expect absorptions assigned to the cyanide ion – TNB complex to grow as the concentration of complex in solution is increased and to disappear as the solution is warmed and the secondary reaction begins.

For convenience of discussion, the changes which occur as a result of complex formation are discussed in terms of the fundamental vibrations of 1,3,5-trinitrobenzene as reported by Shurvell and co-workers (17, 18).

NO_2 vibrations

The infrared spectrum of 1,3,5-trinitrobenzene (TNB) is characterized by antisymmetric and symmetric stretching vibrations of the NO_2 group at 1550 and 1345 cm^{-1}, respectively, a symmetric NO_2 deformation vibration at 825 cm^{-1}, an out-of-plane bending vibration at 518 cm^{-1}, and an in-plane rocking vibration at 360 cm^{-1}. At -30 °C, the apparent molar extinction coefficients of the first two bands in $CHCl_3$ solution are 1740 and 1400 $M^{-1}\,cm^{-1}$, respectively.

As cyanide ion is added to a $CHCl_3$ solution containing a fixed concentration of TNB, the absorbances of the bands at 1550 and 1345 cm^{-1} decrease linearly and at a [cyanide]-to-[TNB] ratio of 1.8:1, the bands are completely absent (Fig. 1). The pronounced breaks in the two plots at a [cyanide]-to-[TNB] ratio near 1 suggests a one-to-one stoichiometry for the complex and a large equilibrium constant for the formation reaction (19).

Although a number of new bands appear in the 4000 to 300 cm^{-1} region as the bands at 1550 and 1345 cm^{-1} disappear, only the new bands at 1235 and 1190 cm^{-1}, having apparent molar extinction coefficients of 2200 and 1800 $M^{-1}\,cm^{-1}$, respectively, approach the intensities of the original NO_2 stretching vibrations. Though not shown in Fig. 1, the intensities of both the 1235

[2]Nuclear magnetic resonance studies of this complex formation reaction indicate little change in the positions of resonance absorption of the protons in the tetraphenylarsonium ion as a result of complex formation (11, 21).

and the 1190 cm^{-1} bands reach a maximum at a [cyanide]-to-[TNB] ratio slightly greater than 1.

The positions and intensities of the bands at 1235 and 1190 cm^{-1} do not change when TNB-d_3 is substituted for TNB; nor are the positions and intensities markedly affected by changing from $CHCl_3$ to $CDCl_3$ or CH_3CN as solvent.

Possible changes in the symmetric deformation vibration at 825 cm^{-1} could not be observed in $CHCl_3$, $CDCl_3$, or CH_3CN solution due to strong solvent absorption in this region.

On decomposition of the complex, bands reappear near 1550 and 1345 cm^{-1} as the bands at 1235 and 1190 cm^{-1} disappear (Fig. 2). In the final reaction mixture the band near 1550 cm^{-1} is usually split, and the band at 1345 cm^{-1} broadened (compared to TNB). Similar results are observed when TNB-d_3 is substituted for TNB. The split band near 1550 cm^{-1} and the broadened 1345 cm^{-1} band may indicate that the nitro groups in the product are not equivalent; or that different nitro-containing aromatic compounds are present in the system. Separation of the product(s) of the reaction has not yet been accomplished.

CH Vibrations

The infrared spectrum of 1,3,5-trinitrobenzene is characterized by an antisymmetric stretching mode at 3108 cm^{-1} and a C—H in-plane bending mode at 1075 cm^{-1}. The apparent molar extinction coefficients of these two bands in $CHCl_3$ solution are 220 and 210 M^{-1} cm^{-1}, respectively, at −30 °C.

As cyanide ion is added to a $CHCl_3$ solution of fixed TNB concentration, the absorbance of the band at 3100 cm^{-1} decreases and at a [cyanide]-to-[TNB] ratio of 1.14:1, the band has virtually disappeared.

Studies in $CDCl_3$ solution at high ratios of [cyanide]-to-[TNB] indicate that in addition to the Φ_4As^+ absorptions at 3083, 3067, 3020, and 2990 cm^{-1} with apparent molar extinction coefficients of approximately 20 M^{-1} cm^{-1}, there is a new band at 3094 cm^{-1} with an apparent molar extinction coefficient of 30 M^{-1} cm^{-1}.

Because of strong new absorption bands which grow in at 1063 and 1050 cm^{-1} and which reach a maximum absorbance at a [cyanide]-to-[TNB] ratio slightly greater than 1 (Fig. 1), it is not possible to follow the disappearance of the C—H in-plane mode as increasing amounts of cyanide ion are added to the system. It seems clear, however, that the new bands at 1063 and 1050 cm^{-1} ($\varepsilon_a \sim 800$ M^{-1} cm^{-1}) are not the result of a shift in the 1075 cm^{-1} band to lower frequency, because a band near 1050 cm^{-1} is also generated when the cyanide ion complex is formed with TNB-d_3. The intensity of absorption of the 1050 cm^{-1} band in the TNB-d_3 complex with CN^- is, however, less than in the case of absorption by the TNB–CN^- complex. The C—D in-plane vibration occurs at 806 cm^{-1} in TNB-d_3, but we have been unable to locate this peak in the TNB-d_3 – cyanide ion complex because of strong solvent absorption by $CHCl_3$ and $CDCl_3$ in this region.

On decomposition of the complex, the bands at 1063 and 1050 cm^{-1} disappear completely (Fig. 2) and a band of reduced intensity (compared to TNB at the concentration of TNB initially present in the system) reappears at 3108 cm^{-1}.

C—C Vibrations

The C—C stretching vibrations of the benzene ring in TNB have been assigned to the peaks at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

1625 and 1443 cm^{-1}, while the out-of-plane deformation, Φ-CCC, has been assigned to the band at 620 cm^{-1}. In chloroform solution the apparent molar extinction coefficients of the bands at 1625 and 1443 cm^{-1} are 330 and 60 M^{-1} cm^{-1}, respectively. The band at 620 cm^{-1} is masked by strong solvent absorption in all the solvents studied.

As a result of complete conversion of TNB to the TNB – cyanide ion complex, the band at 1625 cm^{-1} is replaced by a new band at 1615 cm^{-1}. The absorption of the 1615 cm^{-1} band at high $[CN^-]$-to-[TNB] ratios is almost twice as great as the absorption of the original 1625 cm^{-1} band. Much the same behavior is observed when the TNB-d_3 – cyanide ion complex is studied in $CHCl_3$; the shift in this case is from 1610 to 1600 cm^{-1}.

It has not been possible to study the changes in the absorption band at 1443 cm^{-1} as the [cyanide]/[TNB] ratio is increased, because the Φ_4As^+ ion absorbs much more strongly at 1445 cm^{-1} than does TNB at 1443 cm^{-1}. No new absorption bands were noted in the 1430–1470 cm^{-1} region, but at the concentrations of reactants employed in studying this region of the spectrum, new absorption bands with molar extinction coefficients of 20–40 M^{-1} cm^{-1} would not have been detected.

A broader, less intense band reappears at 1625 cm^{-1} when the complex decomposes.

CN Vibrations

The C—N stretching mode in TNB is found at 918 cm^{-1}, and in $CHCl_3$ solution has an apparent molar extinction coefficient of 200 M^{-1} cm^{-1}.

As a result of the complete conversion of TNB to the TNB – cyanide ion complex in $CHCl_3$ a broader, slightly more intense band with a maximum at 928 cm^{-1} replaces the original 918 cm^{-1} band. There is some indication that the new band is split, but the band was never completely resolved on the IR-10. The effect of solvent on the position and intensity of the 928 cm^{-1} band could not be ascertained due to strong absorption by both $CDCl_3$ and CH_3CN in this region.

Absorption in the 920–930 cm^{-1} region persists in the spectra of the solutions after decomposition has occurred, suggesting that ring-bonded nitro groups are present in the final product(s).

The CN stretching mode for cyanide ion is found at 2060 cm^{-1} in a KBr disk and in solutions of $CHCl_3$ or $CDCl_3$. The apparent molar extinction coefficient of this band in $CDCl_3$ is 30 M^{-1} cm^{-1}.

We earlier reported (20) that conversion of cyanide ion to the TNB – cyanide ion complex was accompanied by the disappearance of the band at 2060 cm^{-1} and the growth of a band at 2320 cm^{-1}. We have been unable, however, to obtain good quantitative data from either of these bands. This is due in part to the low molar extinction coefficient of the cyanide ion band at 2060 cm^{-1}, and to interference by carbon dioxide absorption in the band at 2320 cm^{-1}. We therefore regard the previous assignment of the band at 2320 cm^{-1} as suspect.

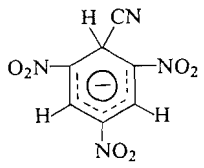
As a result of the decomposition reaction, the band at 2320 cm^{-1} disappears and is replaced by a broad absorption band with a maximum at 2210 cm^{-1}. At a constant TNB concentration the absorbance at 2210 cm^{-1} is proportional to the amount of TPAC added to the system, and the estimated ε_a at 2210 cm^{-1} is 75–95 M^{-1} cm^{-1}.

We have included in the above discussion all the new bands accompanying complex formation except for bands of medium intensity at 1410 cm^{-1} ($\varepsilon_a \sim 300$ M^{-1} cm^{-1}) and 1495–1505 cm^{-1} ($\varepsilon_a \sim 800$ M^{-1} cm^{-1}) and a very weak band at 1385 cm^{-1}. All three bands are unaffected in position or intensity by a change in solvent or by a change from TNB to TNB-d_3. Only the 1410 cm^{-1} band lies close to an absorption band of uncomplexed TNB (1443 cm^{-1}), but the complex band has an apparent molar extinction coefficient some 5 times greater. All three bands disappear completely when the TNB – cyanide ion complex decomposes (Fig. 2) and consequently are considered to be characteristic of the 1:1 complex.

Discussion

Proton n.m.r. studies (11, 21, 22) indicate that in deuterochloroform, acetone-d_6, acetonitrile-d_3, and dimethylsulfoxide-d_6, the predominant species formed by the interaction of 1,3,5-trinitrobenzene and cyanide ion is the σ-complex **1** The present infrared studies confirm the existence of a 1:1 complex in solution and this complex is postulated to be the same as that identified by proton n.m.r. studies (23).

The outstanding features of the infrared spectrum of this complex in chloroform, deuterochloroform, and acetonitrile are the absence of



1

absorptions at 1540 and 1345 cm^{-1} and the presence of two very strong bands at 1230 and 1190 cm^{-1}. In addition, the complex shows moderately strong absorption bands at 1615, 1495–1505, 1063, and 1050 cm^{-1} and weak absorption bands at 3094, 1410, 1385, ~1150, and 928 cm^{-1}. Uncomplexed TNB shows two strong absorptions at 1540 and 1345 cm^{-1}, four very weak absorptions in the 1100–1300 cm^{-1} region, and no absorptions at 1495–1505, 1063, or 1050 cm^{-1}. The absorptions at 1495–1505, 1230, 1190, and 1050 cm^{-1} remain when TNB-d_3 is substituted for TNB in the complex.

One can attempt to rationalize the spectrum observed for the complex on the basis of two effects. One, associated with the changes in electron distribution within the molecule on going from TNB to the complex, will result in changes in force constants and give rise to changes in the normal vibration frequencies associated with the NO_2 groups and other normal modes. On this basis, one might expect to find the same number of bands (plus vibrations due to the CN group) in the infrared spectrum of the complex as in the infrared spectrum of TNB, though, in many cases, at different frequencies. The second effect is associated with the lowering of the symmetry from D_{3h} in TNB to approximately C_{2v} or C_s in the complex. This would be expected to effect a splitting of degenerate fundamentals and to make "allowed" the infrared inactive modes of TNB as illustrated in Table I. In the limit of C_s symmetry, one might expect to see 54 infrared and 54 Raman bands for the complex. The deviation from the D_{3h} selection rules and removal of degeneracy will depend, however, on how far the molecule deviates from D_{3h} symmetry. In the case of the nitro groups and the ring carbon atoms for instance, the symmetry is not completely removed in the complex, since these groups (atoms) are still arranged symmetrically with respect to each other. As a result, fewer than 54 infrared active modes may be observed.

A consideration of the infrared spectrum of the complex in the 4000–300 cm^{-1} region indicates that there are far too few infrared bands to accommodate a complex whose essential symmetry is either C_{2v} or C_s. For this reason we will consider the complex in terms of D_{3h} symmetry, taking into account the probable effects of added electron density which accompanies formation of the complex.

Since the increased electron density is primarily delocalized in the NO_2 groups of the complex (24), we expect the nitro group vibrations to be most affected as a result of complex formation. Transfer of negative charge to the nitro group will lead to a decreased N—O bond order and thus to a lowering of the symmetric and antisymmetric N—O stretching frequencies. Foster and Hammick (1) assigned bands at 1492 and 1291 cm^{-1} in potassium ethyl 1-methoxypicrate to N—O antisymmetric and symmetric stretches, respectively. The corresponding frequencies of the parent nitro compound were 1552 and 1343 cm^{-1}. Dyall and co-workers (4–6), in studies of Meisenheimer adducts of a series of picryl ethers, seem to concur with these assignments. They suggest further that the covalent structure **1** should show the characteristic bands of a ketal (25) at 1195–1158, 1143–1124, 1098–1063, and 1058–1038 cm^{-1} and consequently assign the strong bands of the adducts in the region 1300–1000 cm^{-1} to this source. Although the TNB–CN^- complex does possess a band in the 1495–1505 cm^{-1} region, its apparent molar extinction coefficient is smaller than those associated with the nitro group vibrations in TNB, and we prefer to assign the far more intense bands at 1235 and 1190 cm^{-1} to the antisymmetric and symmetric N—O stretching modes in the complex. In this connection we note that the apparent molar extinction coefficients of the 1235 and 1190 cm^{-1} bands are an order of magnitude greater than the apparent molar extinction coefficients of the bands characteristic of ketals (25) and that only the 1063 and 1050 cm^{-1} bands have apparent molar extinction coefficients in the range of those expected for a ketal.

The bands at 1163–1152 and 1063–1053 cm^{-1} in the Meisenheimer adducts of the picryl ethers have been assigned to out-of-plane and in-phase in-plane C—H deformations (4). In our system the new band at 1050 cm^{-1} is present in both the

TNB–CN^- complex and the TNB-d_3 – CN^- complex and consequently cannot be assigned to a C—H mode. As in the picryl ether adducts, the C—H stretching mode (3094 cm^{-1}) is extremely weak.

The ring stretching frequency of TNB at 1625 cm^{-1} shifts to lower frequency and increases slightly in intensity as a result of complex formation. In accord with the assignment of the band in this region as a ring stretching frequency, the TNB-d_3 – CN^- complex absorbs at slightly lower frequency than the TNB – CN^- complex.

Although some progress can be made in assigning the frequencies of the complex to various fundamental modes, none of the assignments is proved by the present information. The Raman spectrum of the complex would be particularly valuable in this context. Thus the Raman spectrum of TNB has very strong bands assigned to A_1' modes at 1365, 1184, 1002, and 825 cm^{-1} (Raman-active only), which appear not to have been made "allowed" in the complex. These bands should be present, however, in the Raman spectrum of the complex. On the other hand, E' modes appear in both the infrared and Raman spectrum of TNB, and shifts in frequencies of these bands on complex formation should be similar in both the Raman and infrared. Consequently the Raman spectrum of the complex might give support to our suggestion that the symmetry of the complex can be considered to remain approximately that of TNB and aid us in the assignment of frequencies. Raman studies in these systems are anticipated.

Electrical conductivity studies of fluorosulfuric acid and tetramethylammonium fluorosulfate in nitrobenzene

W. Reed, D. W. Secret, R. C. Thompson, and P. A. Yeats
Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia
Received July 17, 1969

Electrical conductivity data for solutions of tetramethylammonium fluorosulfate and fluorosulfuric acid in nitrobenzene are reported. The dissociation constant of the tetramethylammonium salt is 2.0×10^{-2} and the mobility of the fluorosulfate ion is 21.4. Although the conductivity data for solutions of fluorosulfuric acid could not be treated rigorously, it is shown that in dilute solutions, fluorosulfuric acid undergoes rather weak dissociation with a dissociation constant estimated to be less than 6×10^{-6}. This result is contrasted with earlier work which showed that nitrobenzene is fully protonated and dissociation into ions is complete when fluorosulfuric acid forms the bulk solvent.

Introduction

As a nonaqueous solvent, fluorosulfuric acid has proven extremely useful for the study of the protonation of very weak bases and in the study of cationic species which are unstable in more basic media (1, 2). In bulk, it provides the most strongly acidic medium of any simple liquid. Relatively little work has been devoted to the study of the acid strength of fluorosulfuric acid under the condition that it is present as a dilute solution in another solvent where, as was suggested previously (3), the acid strength may differ considerably from that of bulk fluorosulfuric acid. Under these conditions a measure of its acid strength is the extent to which it dissociates a proton. Previous work of this nature has involved studies of solutions of fluorosulfuric acid in protonic solvents. It has been reported to be fully dissociated in water (4), and in acetic acid, although no dissociation constant was measured, it has been shown to dissociate to a greater extent than perchloric acid (5). Even in the highly acidic medium, sulfuric acid, fluorosulfuric acid undergoes weak dissociation (3). The present work was undertaken in an effort to determine the acid strength of fluorosulfuric acid in a nonprotonic medium. Nitrobenzene was chosen as it has a reasonably high dielectric constant for an organic liquid and, moreover, previous work (6) has shown that it has a high enough proton affinity so that it is completely protonated when present as a dilute solution in fluorosulfuric acid.

For comparison, we have also used electrical conductivity measurements to determine the degree of dissociation of an ionic fluorosulfate, namely, tetramethylammonium fluorosulfate, in nitrobenzene.

Experimental

Preparation and Purification of Materials

Reagent grade nitrobenzene was washed successively with 1 *N* sulfuric acid and saturated sodium carbonate solution followed by continuous washing with water until the aqueous layer was colorless. The nitrobenzene was then stored over molecular sieve and finally doubly distilled under vacuum at 30 °C. Fluorosulfuric acid was purified by double distillation at atmospheric pressure as described previously (6). Tetramethylammonium fluorosulfate was prepared by reacting dry tetramethylammonium chloride with fluorosulfuric acid in a manner analogous to that used previously in the preparation of the alkali metal fluorosulfates (6). The product was recrystallized from water. Microanalyses were obtained in the microanalytical laboratory of the University of British Columbia.

Anal. Calcd. for $(CH_3)_4NFSO_3$: C, 27.74; H, 8.09; N, 6.97. Found: C, 27.71; H, 8.01; N, 7.02.

Electrical Conductivity Measurements

Cell resistances were measured at 25 ± 0.01° and 2000 cycles using a precision a.c. bridge described previously (7). The cell consisted essentially of 2 flasks of approximately 200 ml capacity, fitted with ground glass caps and joined by an electrode chamber containing 2 platinum electrodes which were coated with platinum black as described by Jones and Bollinger (8). The cell constant, determined using aqueous potassium chloride solution (9), was approximately 0.6 cm^{-1}. Electrode polarization effects were apparently not serious as periodic checks of solution resistances at 4000 cycles were found to be in satisfactory agreement with those obtained at 2000 cycles.

The nitrobenzene used in this work had a specific conductivity of $1–4 \times 10^{-8}$ ohm^{-1} cm^{-1} and was less than 1% of the conductivity observed for the most dilute solutions studied. The solution conductivities were corrected by subtracting the solvent conductivity from those of the solutions.

Preliminary studies on solutions of fluorosulfuric acid in nitrobenzene showed that the solutions are not stable indefinitely, particularly in regions of high concentration. Experiments in which fluorosulfuric acid, in the form of concentrated solutions in nitrobenzene (approximately 0.2 g per g nitrobenzene) which had been allowed to

stand for several hours, was added to pure nitrobenzene in the conductivity cell did not give reproducible results. The procedure used in obtaining the results presented in Table I for solutions of fluorosulfuric acid over the concentration range 0.004 to 0.15 *M* avoided high concentrations and allowed for fairly rapid determinations of solution resistances.

The data given in Table I are presented in the order in which they were obtained. In experiment 1, approximately 15 ml of nitrobenzene were distilled directly into the conductivity cell. A dilute solution of fluorosulfuric acid in nitrobenzene (approximately 0.03 g acid per g nitrobenzene) was prepared in a weight dropper and the first 2 data points were obtained by making additions to the cell from this dropper. The next 3 points were obtained by making additions of pure nitrobenzene to the cell from a second weight dropper. The remaining points were obtained by adding pure fluorosulfuric acid to the cell from a third weight dropper. Resistance measurements were made 15 to 20 min after each addition to the cell, allowing time for mixing and the attainment of temperature equilibrium. Experiment 2 was performed in an analogous manner. A possible source of error in these experiments arises from the fact that, while every effort was made to minimize exposure of the contents of the cell to the atmosphere, the contents were exposed briefly during each addition and traces of atmospheric water entering the cell could affect the conductivity. The procedure employed allowed us to determine whether such errors are serious. The dilute region which was covered by the two experiments yields, apart from a single point corresponding to the first addition in experiment 1, a smooth conductivity vs. concentration curve with relatively small experimental scatter. If water impurities entering the cell during each addition were contributing significantly to the conductivity of the solution then data points obtained after 5 or 6 additions to the cell would not be expected to agree with those obtained on the first or second addition.

Fluorosulfuric acid and nitrobenzene are miscible in all proportions. To obtain conductivities of mixtures of the two over the entire range of composition the following procedure was used. The range 15 to 100 mole % nitrobenzene was covered by adding fluorosulfuric acid from a weight dropper to nitrobenzene in the cell. The range 0 to 45 mole % nitrobenzene was covered by adding nitrobenzene from a weight dropper to fluorosulfuric acid in the cell.

While visible–ultraviolet spectra of the solutions were not studied in this work, it was noted that the dilute solutions of fluorosulfuric acid in nitrobenzene were a very pale yellow, with the intensity increasing considerably in the higher concentration regions.

Solutions of tetramethylammonium fluorosulfate in nitrobenzene are stable and show no drift in conductivity with time. The solutions were obtained by making several additions from a weight dropper of a solution of the salt in nitrobenzene to nitrobenzene in the cell.

All solutions were made up by weight and where molarities are quoted these were calculated assuming a solution density of 1.1986 g/cc (10).

Molecular Weight Measurements

The molecular weight of fluorosulfuric acid in nitrobenzene was determined by the freezing-point depression method employing the conventional Beckmann technique. The cryoscope, which could be sealed to the atmosphere, was charged with a weighed amount of nitrobenzene in a drybox and opened to the atmosphere only momentarily during the addition of the solute. The solute, fluorosulfuric acid, was added in the form of a solution in nitrobenzene. Solutions in the cryoscope were stirred magnetically and temperatures were measured by a Leeds and Northrup capsule platinum resistance thermometer, calibrated by the National Research Council, Ottawa. Resistances were determined on a Guideline Potentiometer (Leeds and Northrup, Type 4363 A) with a standard 10 ohm resistance. The amount of supercooling was 0.5 to 0.9° and corrections were made for the amount of solvent frozen out. To test the accuracy of the apparatus and general procedure, the freezing points of solutions of benzil in nitrobenzene were determined. For freezing-point depressions over the range 0.05 to 1.3°, a plot of freezing-point depression vs. molality of benzil was linear

and corresponded to a molal freezing-point depression constant of 7.00, in good agreement with published values (11). This value of 7.00 was used in the subsequent calculation of the molecular weight of fluorosulfuric acid in nitrobenzene.

Results and Discussion

It is convenient to discuss first our results on solutions of tetramethylammonium fluorosulfate. Values of equivalent conductivity are tabulated in Table I. Electrical conductivity measurements have been reported on a number of alkylammonium salts in nitrobenzene (10, 12), where the authors used the method of Fuoss (13) to obtain values of Λ_0, the equivalent conductivity at infinite dilution, and K, the dissociation constant. Our data on tetramethylammonium fluorosulfate, treated in the same manner, yield values of 38.7 ohm^{-1} cm^2 equiv.$^{-1}$ for Λ_0 and 2.0×10^{-2} for K. The dissociation constant is comparable in magnitude to those reported for a number of tetraalkylammonium salts (10, 12). Employing the value 17.3 for the mobility (meaning here the equivalent conductivity at infinite dilution) of the tetramethylammonium cation (10) the mobility of the fluorosulfate ion is 21.4, agreeing favorably with the value 20.9 reported previously for the isoelectronic perchlorate ion (12). Woolf has estimated the mobility of the fluorosulfate ion in water to be 71, in close agreement with the value of 69 for the perchlorate ion in that solvent (4). In fluorosulfuric acid the fluorosulfate ion has an abnormally high mobility of 135, presumably due to its participation in a proton-transfer mechanism of conduction in fluorosulfuric acid (6).

We consider now the nature of solutions of fluorosulfuric acid in nitrobenzene. Since it is known that fluorosulfuric acid is extensively associated in the liquid state, freezing-point depression measurements on dilute solutions of the acid in nitrobenzene were made in order to determine whether any extensive association remains in solution. Results on 6 different concentrations in the range 7 to 32 g acid per kg nitrobenzene gave an average molecular weight of 103 ± 5 compared to the calculated value of 100, thus showing that the acid is essentially monomeric in solution.

Values of equivalent conductivity for dilute solutions of fluorosulfuric acid in nitrobenzene are given in Table I and plotted against the square root of the molarity, c, in Fig. 1. Although the simplest possible mode of dissociation of

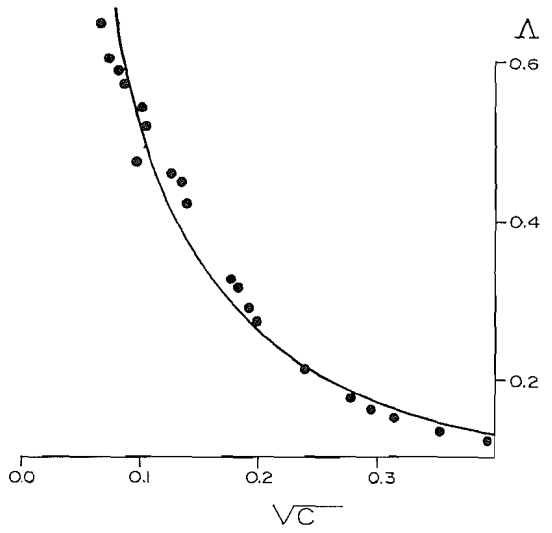

FIG. 1. Equivalent conductance (ohm^{-1} cm^2 equiv.$^{-1}$) vs. square root of molarity curve for fluorosulfuric acid in nitrobenzene. The solid line is calculated (see text).

fluorosulfuric acid in nitrobenzene is

[1] $$HSO_3F = H^+ + SO_3F^-$$

the possibility of the formation of triple ions according to

[2] $$SO_3F^- + HSO_3F = H(SO_3F)_2^-$$

cannot be neglected. Using a number of approximations, French and Roe (14) were able to account for the variation of the conductance of picric acid with concentration in a number of organic solvents by assuming processes analogous to those given in reactions [1] and [2]. Our data for dilute solutions of fluorosulfuric acid in nitrobenzene do not fit the expression developed by French and Roe. Ignoring reaction [2], the French and Roe equation becomes simply

[3] $$\Lambda = \Lambda_0 K_1^{1/2} c^{-1/2}$$

where K_1 is the dissociation constant for reaction [1] and Λ_0 is the equivalent conductivity at infinite dilution. Our data are in approximate agreement with a relationship of this form. In Fig. 1 the solid line was calculated using eq. [3] with $\Lambda_0 K_1^{1/2}$ equal to 0.052 ohm^{-1} cm$^{1/2}$ equiv.$^{-1/2}$. It would appear, then, that up to concentrations of 0.15 mole of fluorosulfuric acid per l of solution there is no significant amount of triple ion formation. Assuming that the dissociation of fluorosulfuric acid in nitro-

For personal use only.

benzene is correctly given by reaction [1], it should be possible to determine the equilibrium constant from the conductivity data. Attempts to determine K_1 accurately are, however, hampered by the low equivalent conductivities observed, by the scatter in the experimental points, and by the fact that it is impossible to extrapolate the data to obtain Λ_0. It is possible, however, to estimate an upper limit for K_1. The minimum possible value that Λ_0 can have is 21.4 ohm^{-1} cm^2 equiv., the equivalent conductivity of the fluorosulfate ion at infinite dilution, and using this value for Λ_0 and the value 0.052 ohm^{-1} $cm^{1/2}$ $equiv.^{-1/2}$ for Λ_0 $K_1^{1/2}$, the maximum possible value for K_1 is 6×10^{-6}. This is qualitatively consistent with the observation that the equivalent conductivity values of solutions of fluorosulfuric acid in nitrobenzene are lower than those obtained by other workers for the weak electrolyte trimethylhydroxyammonium picrate, which has a dissociation constant of 1.7×10^{-5} (12).

In acid–base reactions of the type under consideration here the extent to which dissociation into free ions takes place depends not only on the relative acid–base strengths of the reactants but also on the properties of the bulk solvent, such as its dielectric constant and its ability to solvate the ions produced. As mentioned in the introduction, when fluorosulfuric acid forms the bulk medium, dissociation into free ions is complete, whereas when nitrobenzene forms the bulk solvent, only very weak dissociation takes place. The difference in the bulk dielectric constants of nitrobenzene and fluorosulfuric acid will account for only a part of this difference and may be estimated on a purely electrostatic basis as described by Bell (15). For 2 ions of opposite charge separated by a distance of 2 Å the dissociation constant will decrease by a factor of approximately 3×10^2 on going from a solvent of dielectric constant 120 (fluorosulfuric acid) to a solvent of dielectric constant 34.5 (nitrobenzene). It appears then that an important factor in accounting for the very weak dissociation of fluorosulfuric acid in nitrobenzene is that the ions produced, particularly the fluorosulfate ion, are relatively weakly solvated by the solvent. Conversely, the relatively high acidity of fluorosulfuric acid in bulk, and presumably also in solution in other protonic solvents, is due to a large extent to extensive solvation of the fluorosulfate ion through hydrogen-bonding to solvent molecules. The effect is also seen, but to a lesser degree, in the case of the dissociation of ionic fluorosulfates. Ionic fluorosulfates are fully dissociated in fluorosulfuric acid solutions (6), whereas, as shown in the present work, tetramethylammonium fluorosulfate is incompletely dissociated in nitrobenzene solution.

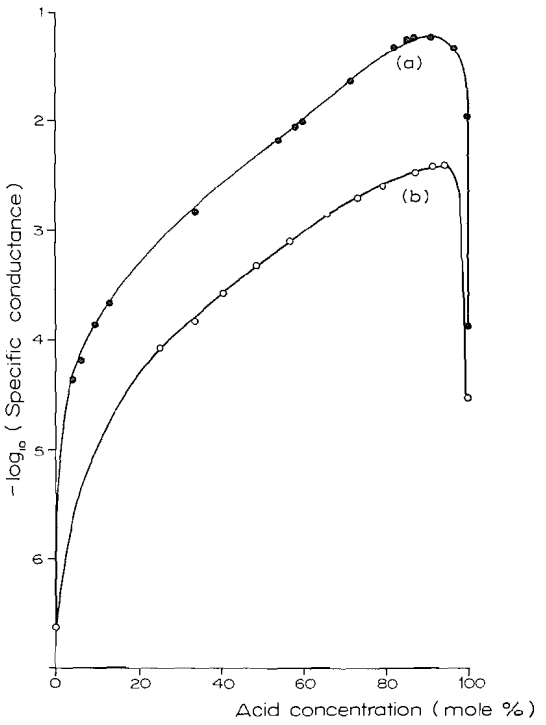

FIG. 2. Specific conductance (ohm^{-1} cm^{-1}) vs. mol % acid curves for: (*a*) HSO_3F–nitrobenzene mixtures, (*b*) HF–nitrobenzene mixtures (data taken from ref. 16).

Finally, specific conductivities of mixtures of fluorosulfuric acid and nitrobenzene over the entire range of compositions were measured and are presented graphically in Fig. 2, where they are compared with the findings of other workers (16) on the hydrogen fluoride–nitrobenzene system. Theoretical treatment of such results is difficult. It is interesting to note, however, that the general shape of the two curves, including the position of maximum conductance, is very similar. Over the entire range of compositions the fluorosulfuric acid – nitrobenzene mixtures give higher specific conductivities, reflecting a greater degree of dissociation of fluorosulfuric acid compared to hydrogen fluoride.

Isomers of bis(trifluoromethyl)phosphinomethylhydrazine, $(CF_3)_2PNHNHMe$ and $(CF_3)_2PN(Me)NH_2$

L. K. PETERSON AND G. L. WILSON
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received May 20, 1969

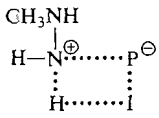
The synthesis of isomers of bis(trifluoromethyl)phosphinomethylhydrazine, $(CF_3)_2PNHNHMe$, **1**, and $(CF_3)_2PN(Me)NH_2$, **2**, and their characterization by infrared, nuclear magnetic resonance, and mass spectra, and by vapor phase molecular weight measurements are described. The significance of the formation of both isomers is discussed in terms of steric and electronic effects.

Canadian Journal of Chemistry, 47, 4281 (1969)

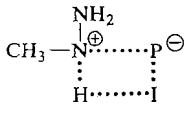
Discussion

The stepwise alkylation of methylhydrazine, which proceeds at the more alkylated of the 2 nitrogen atoms, has been rationalized in terms of the enhanced basicity of the methyl-nitrogen site (1). Substitution reactions of hydrazines with bis(trifluoromethyl)chloroarsine (2), however, give products indicative of reaction at the least alkylated site, a feature attributed to steric factors (2). In general, the reactions of trialkylsilylhydrazine, $R_3SiNHNH_2$, with chlorosilanes give mixtures of isomers, N,N- and N,N′-bis(trialkylsilyl)hydrazine (3); the presence of a bulky R group on silicon, such as *t*-butyl, results in exclusive formation of N,N′-isomers (3). A mixture of isomers was reported for the reaction of diphenylchlorophosphine with methylhydrazine, but separation was not achieved (4).

We have found that bis(trifluoromethyl)iodophosphine, $(CF_3)_2PI$, reacts at both nitrogen atoms of methylhydrazine, with equal preference, giving 2 isomeric compounds, N-methyl, N′-bis(trifluoromethyl)phosphinohydrazine, $MeNHNHP(CF_3)_2$, **1**, and N-methyl,N-bis(trifluoromethyl)phosphinohydrazine, $(CF_3)_2PN(Me)NH_2$, **2**. It appears that the enhanced basicity of the methyl nitrogen is compensated by steric interactions[1]. Alternatively, $(CF_3)_2PI$ may be insensitive to the differing basicities of the 2 nitrogen atoms, in the sense that the activation energies for the 2 possible 4-center intermediate complexes (**3**, **4**) may be quite similar.



3



4

Compounds **1** and **2** were separated by vacuum fractionation, and were identified on the basis of infrared, nuclear magnetic resonance (n.m.r.), and mass spectra (parent peaks, M_{obs}, 214; M_{calcd}, 214; major fragments, MeNHNH and $CF_3PNHNHMe$), and by vapor phase molecular weight measurements. In addition, the overall reaction was essentially quantitative

$$(CF_3)_2PI + 2\ MeNHNH_2 \rightarrow \tfrac{1}{2}MeNHNHP(CF_3)_2 + \tfrac{1}{2}(CF_3)_2PN(Me)NH_2 + MeNHNH_2HI$$

Compound **1**, which could be obtained pure, has the higher melting point (35.5 ± 0.1 °C), in line with its more symmetrical molecular structure. The proton n.m.r. spectrum corresponded to the resonance absorptions of the N—CH_3 (at τ 7.37, $SiMe_4$ internal reference), MeN—H (τ 6.39) and PN—H protons (τ 5.70), the integrated intensity ratios being 3:1:1 (NCH_3:NH:NH). The N—H assignments were made by comparison with other members of a series of phosphinohydrazines (see Table I); on the basis of its electronegative character, the $(CF_3)_2P$ group must be linked with the nitrogen atoms bearing the least shielded proton.

The proton n.m.r. spectrum of compound **2** consisted of a doublet, indicative of the N—CH_3 absorption split by the spin $+\frac{1}{2}$, ^{31}P nucleus (τ, midpoint, 6.93; *J*(PNCH), 8.5 c.p.s.); and a

N—H stretching modes, corresponding to the distinct PN—H and MeN—H groupings, at 3340 and 3428 cm^{-1}, respectively. Only one band at 3410 is found in compound **2**, in which the primary amino (NH_2) group is present.

Experimental

The experimental procedure has been described elsewhere (5).

Reaction of $(CF_3)_2PI$ with $MeNHNH_2$

Using a glass reaction vessel fitted with in situ filtration facilities, methylhydrazine (0.4550 g) was condensed onto a frozen solution of $(CF_3)_2PI$ (1.1952 g) in ether (5.1805 g); upon melting, a white precipitate was formed. After 1 h at room temperature, the products were filtered and separated by vacuum fractionation into $MeNHNHP(CF_3)_2$, **1** (0.3707 g, held at −33°), $(CF_3)_2PNMeNH_2$, **2** (0.43262 g, −63°), and ether (mainly held at −210°). A white residue of $MeNHNH_2HI$ (0.7796 g) remained. The overall yield of product was 91%. By repeated fractional condensation in vacuo, compound **1** was obtained pure (m.p. 35.5 ± 0.1°; b.p., 23.4°/6.60 mm). Compound **2** could not be freed from all traces of its isomer (b.p., ~23.2°/13.4 mm). Both compounds were identified by vapor phase molecular weight (*M*, calcd., 214; *M*, obsd., 215–219), by mass spectra (parent peak, obsd., 214; calcd., 214), by infrared (Tables II and III), and by n.m.r. measurements.

Adducts of oxovanadium(IV) dithiocarbamates

B. Jack McCormick

Department of Chemistry, West Virginia University, Morgantown, W.Va. 26506

Received May 12, 1969

Pyridine and 4-methylpyridine adducts of oxovanadium(IV) dithiocarbamates have been isolated and characterized as solids. It has been shown that the addenda can be removed under mild conditions with concomitant regeneration of the parent dithiocarbamate (DTC) complexes. Attempts to isolate dimethylsulfoxide adducts have not been successful, although spectral evidence suggests that adducts are formed in solution. A qualitative rationalization of the molecular orbital ordering and electronic spectral properties of the adducts is presented.

Canadian Journal of Chemistry, 47, 4283 (1969)

Introduction and Discussion

In a previous paper dealing with the isolation and characterization of several oxovanadium(IV) dithiocarbamate complexes, it was reported that rather significant spectral shifts occur in both the infrared and visible regions when the complexes

‡Carbon analyses on the methyl derivatives were consistently high.

are dissolved in pyridine or dimethylsulfoxide (1). These shifts were interpreted in terms of the addition of a solvent molecule to the sixth coordination position *trans* to the oxygen atom. The pyridine adduct of bis(N,N-dimethyldithiocarbamato)oxovanadium(IV) was isolated as a solid, but was not studied in detail. In view of the fact that very few of the adducts of oxovanadium(IV) complexes that have been so extensively studied in solution (2) have been prepared as solids, it seemed worthwhile to investigate solid adducts of oxovanadium(IV) dithiocarbamates more thoroughly.

Adducts of bis(N,N-dimethyldithiocarbamato)oxovanadium(IV) and bis(pyrrolidine-N-carbodithioato)oxovanadium(IV) with pyridine and 4-methylpyridine have been prepared as solids by straightforward synthetic procedures. Similar adducts of these and other oxovanadium(IV) dithiocarbamates with a variety of nitrogenous bases undoubtedly can be prepared by analogous techniques. The analytical data presented in Table I indicate that the adducts have the general formula $[VO(DTC)_2(base)]$.

It was shown previously that rather significant shifts in the C···N and V=O stretching frequencies result when the bis-dithiocarbamates are mulled with Nujol containing pyridine, and these shifts were interpreted in terms of the addition of pyridine to the sixth coordination position on the vanadium atom (1). The C···N and V=O stretching frequencies reported in Table II for the solid pyridine adducts are virtually identical to those reported earlier and the corresponding data for the 4-methylpyridine adducts is very similar to that obtained with pyridine. The infrared spectra clearly show bands attributable to coordinated pyridine and 4-methylpyridine (3). Of particular value are the strong bands near 1600 and 700 cm^{-1} in the pyridine complexes and near 1600, 800, and 715 cm^{-1} in the 4-methylpyridine complexes. Since the parent bis-dithiocarbamate complexes do not exhibit absorptions near these frequencies, the observance of these bands can be taken as good evidence for the presence of the addenda.

That addenda are rather weakly attached to the sixth coordination position of the bis-dithiocarbamates is shown by the ease with which coordinated pyridine and 4-methylpyridine can be removed. Removal can be effected by washing with a suitable solvent such as diethyl ether or by heating to 65–75° in vacuo for a period of ½ to 2 h. The gray compounds remaining after removal of the sixth ligand were shown to have infrared spectra which were *identical* to those of the parent bis-dithiocarbamates. A quantitative study was made of the weight loss that occurs when the pyridine adduct of bis(N,N-dimethyldithiocarbamato)oxovanadium(IV) is heated in vacuo (65° for 1.5 h). The weight loss corresponded to 1 mole of pyridine per mole of compound.

Since solutions of bis(dithiocarbamato)oxovanadium(IV) complexes in dimethylsulfoxide have optical spectra which are virtually identical to those measured in pyridine and 4-methylpyridine, and since pyridine and dimethylsulfoxide cause similar shifts in the C···N and V=O stretching frequencies (1), it is clear that dimethylsulfoxide forms adducts similar to those of pyridine and 4-methylpyridine. However, attempts to isolate such adducts have not been successful. The adducts are very soluble in dimethylsulfoxide and attempts to precipitate the desired compounds with reagents such as tetrahydrofuran have led to decomposition. Furthermore, it appears that the complexes slowly decompose in dimethylsulfoxide alone, and attempts to remove excess solvent by pumping have resulted in

decomposition. Decomposition does not take place immediately, as indicated by the fact that addition of water to freshly prepared dimethylsulfoxide solutions results in the precipitation of the parent bis-dithiocarbamates.

Figure 1 shows the diffuse reflectance spectra obtained for the solid adducts. These spectra are very similar to the corresponding pyridine and dimethylsulfoxide solution spectra reported earlier (1), except for the shoulder at ca. 25 000 kK. This shoulder was not observed in the solutions.

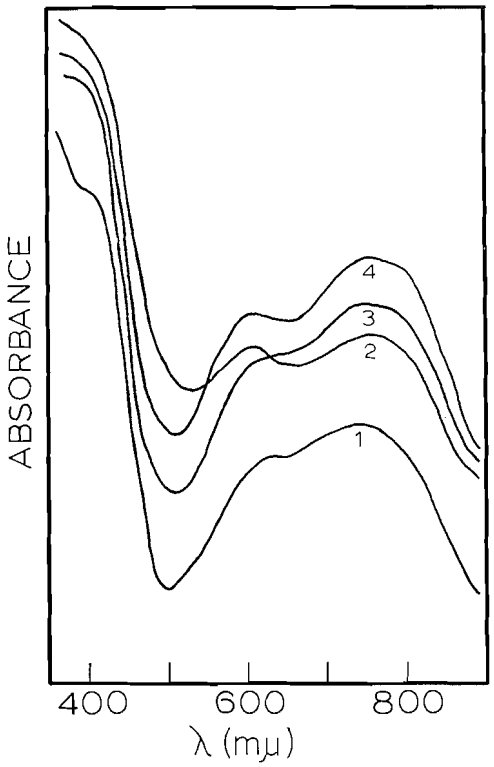

FIG. 1. Diffuse reflectance spectra of: **1**, VOL'_2A; **2**, VOL_2A; **3**, VOL'_2A'; **4**, VOL_2A'.

Our previous assignments of the optical bands of bis-dithiocarbamates were based on an inverted level scheme (4) in which the b_1* level lies below the e_π* level. It was suggested that such an inversion might result from π interactions between the vanadium atom and the equatorial sulfur ligands. Additional information bearing on the relative energies of the b_1* and e_π* levels is now available from the results of some recent molecular orbital calculations on $VO(H_2O)_5^{2+}$ by Vanquickenborne and McGlynn (5). It was shown that as the angle between the V—O axis and the 4 equatorial V—H_2O axes is increased from 90 to 105°, the b_1* and e_π* levels increase and decrease in stability, respectively, relative to the b_2 level. It is quite reasonable to expect that the O—V—S angles in the bis-dithiocarbamates are greater than 90°, since it has been shown that in other 5-coordinate dithiocarbamate complexes the metal atom is above the basal plane of the equatorial ligands (6–8). It should also be pointed out that O=V—O angles in VO(acetylacetonate)$_2$ are 106° (9). In view of these observations it is not difficult to understand the applicability of the inverted level scheme to the bis-dithiocarbamates, although it is difficult to assess the relative roles of π-bonding and O—V—S angle distortions from 90°.

Coordination of a sixth ligand to the bis-dithiocarbamates apparently displaces the sulfur atoms toward the oxygen atom with concomitant reduction of the O—V—S angles. This reduction results in the destabilization of the b_1* level relative to the e_π* level and renders the Ballhausen–Gray (10) scheme applicable to the adducts, as discussed previously (1).

The shoulder at ~25 000 kK in the adduct spectra is poorly defined, and further study will be necessary before the assignment of this band can be discussed.

Experimental

Bis (pyrrolidine - N - carbodithioato) oxovanadium (IV) and bis(N,N-dimethyldithiocarbamato)oxovanadium(IV) were prepared as described previously (1). Before use, all solvents and liquid reagents were deaerated with nitrogen, and all syntheses were carried out under an atmosphere of nitrogen.

In a typical preparation, 3 g of bis(pyrrolidine-N-carbodithioato)oxovanadium(IV) was treated with 20 ml of pyridine. The green precipitate which formed was separated by filtration and washed with five 30 ml portions of 1:1 pyridine–pentane mixtures. The adduct was dried first in a stream of dry nitrogen and then in vacuo for 10 h. Other adducts of nitrogenous bases were prepared similarly. The compounds were stored under dry nitrogen even though the air sensitivity of the adducts appears to be less than that of the parent compounds. Elemental analyses are given in Table I.

Reflectance spectra were measured with a Cary Model 14 spectrophotometer equipped with a Model 1411 reflectance attachment and a high intensity source (Cary Model 1471200) operating at 100 V. Infrared spectra were measured on Nujol mulls with a Beckman IR-8 spectrometer, and the reported frequencies are thought to be accurate to ± 2 cm^{-1}. Some pertinent spectral data are given in Table II.

Ionization of liquid argon by X-rays: $\overline{W}$-value[1]

N. V. Klassen
Division of Applied Physics, National Research Council, Ottawa, Canada

AND

Werner F. Schmidt
Chemistry Department, Brookhaven National Laboratory, Upton, N.Y. 11973

Received August 18, 1969

Liquid argon at 87 °K was irradiated with 1.5 MeV X-rays. Saturation currents were achieved at low dose rates. The energy required to produce an ion pair ($\overline{W}_x$) was found to be 22.5 ± 3 eV, which is similar to the gas phase value.

Canadian Journal of Chemistry, 47, 4286 (1969)

A necessary quantity for the understanding of a radiolized system is the value of $\overline{W}$, the average energy required for the production of an ion pair in the system. In the gas phase, $\overline{W}$ can be determined by the saturation current method. In most liquids, field strengths exceeding the breakdown strength would be required to achieve saturation currents. Therefore, most investigators have tried to determine $\overline{W}$ by extrapolating ionization current measurements to infinite field strengths (1–3). The $\overline{W}$-values obtained in this way were substantially higher than the gas phase values.

In several liquified rare gases, Ar, Kr, Xe, the mobilities of excess electrons are high (4). Ionization currents in liquid argon have been investigated extensively using α particles. Because of the high linear energy transfer (l.e.t.) of α radiation it was impossible to obtain saturation currents.

Canadian Journal of Chemistry, 47, 4286 (1969)

A necessary quantity for the understanding of a radiolized system is the value of $\overline{W}$, the average energy required for the production of an ion pair in the system. In the gas phase, $\overline{W}$ can be determined by the saturation current method. In most liquids, field strengths exceeding the breakdown strength would be required to achieve saturation currents. Therefore, most investigators have tried to determine $\overline{W}$ by extrapolating ionization current measurements to infinite field strengths (1–3). The $\overline{W}$-values obtained in this way were substantially higher than the gas phase values.

In several liquified rare gases, Ar, Kr, Xe, the mobilities of excess electrons are high (4). Ionization currents in liquid argon have been investigated extensively using α particles. Because of the high linear energy transfer (l.e.t.) of α radiation it was impossible to obtain saturation currents.

Swan (5) extrapolated to infinite field strength and estimated $\overline{W}_\alpha$ in liquid argon to be 26 eV, similar to the gas phase value. Hutchinson (6) felt that $\overline{W}$ for liquid argon irradiated by γ rays was also similar to the gas phase value. Ullmaier (7) irradiated liquid argon with low energy X-rays and obtained $\overline{W}_x = 25.7 \pm 3$ eV. He found a definite l.e.t. effect of the X-ray energy on the ionization current. Furthermore, the liquid argon in his experiments appears to have been in contact with the atmosphere which would have allowed oxygen to dissolve in the liquid. In view of the importance of comparing $\overline{W}$-values in gases and liquids it seemed appropriate to investigate the ionization currents in liquid argon at low dose rates and low l.e.t. using energetic X-rays and excluding oxygen.

Experimental

X-Rays were obtained from a Van de Graaff by a beam of 1.5 MeV electrons impinging on a gold target. Two conductivity cells were used. Cell No. 1 was the metal cell of Hummel and Allen (8). It was slightly modified by filling the dead space around the collector electrode with ceresin wax. It had an electrode distance of 5.1 mm and an effective volume of 0.48 cm^3. Cell No. 2 was made of Pyrex. It had aluminum electrodes, 1.14 cm apart, and an effective volume of 3.6 cm^3. Both cells had guard rings which defined the effective cell volume. Commerical argon (Liquid Carbonic) was used without purification. The cells were evacuated to 10^{-2} Torr and filled with liquid argon. The assembly was held at 87 °K in a bath of liquid argon. A pressure of 1.4 atm of argon in the cell prevented bubble formation. Dosimetry was accomplished with an air ionization chamber (Electronic Instruments Limited, Model 37A) mounted in the radiation field in a fixed position relative to the cell. The ratio of the dose rates between the two positions was determined with the air chamber. The attenuation of the X-ray beam by the cell No. 2 assembly was determined by placing the air chamber inside a dummy cell. Attenuation by cell No. 1 was determined by irradiating a Fricke solution inside the cell. The absorbed dose rate in argon was calculated using mass energy absorption coefficients (9).

Results and Discussion

Figure 1 shows the ionization currents in liquid argon at various dose rates. The currents were independent of the polarity of the applied voltage. The current in the absence of radiation was negligible. At the lower dose rates, saturation currents were obtained at about 10 kV/cm. At the higher dose rates, saturation was not achieved at the highest voltage applied, demonstrating the effect of volume recombination. Corrections for

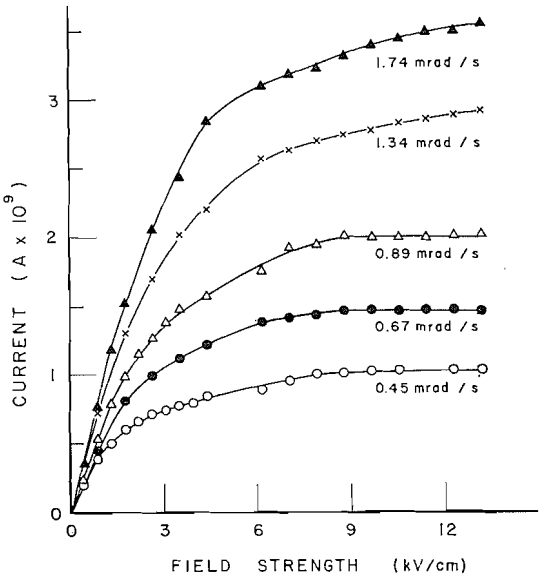

FIG. 1. Ionization current vs. electric field strength for liquid argon at several dose rates. The cell was Pyrex with 3.14 cm^2 aluminum electrodes spaced 1.14 cm apart.

current losses due to volume recombination can be made by plotting 1/current vs. 1/voltage^2. This plot yields a straight line which, on extrapolation to infinite voltage, gives the saturation current (10). The saturation current per unit dose rate obtained with this extrapolation agreed with the values determined at the lower dose rates.

The mean values of $\overline{W}_x$ were 22.3 eV with cell No. 1 and 22.7 eV with cell No. 2, determined with an estimated precision of ± 10%. This corresponds to G(total ionization) = 4.4 ± 0.4. Gas phase values for $\overline{W}$ range from 23.7 ± 1.4 to 27.9 ± 1.5 eV using X-ray and electron radiation (11).

The trapping of electrons by impurities, notably oxygen, should not have been a problem in this work since the results of Swan (12) suggest a mean capture distance of 1.4 cm at 10 kV/cm for electrons in liquid argon containing 1 p.p.m. oxygen. This conclusion was verified in the present work by observing the fast transient current generated by electrons when the X-ray beam was pulsed. This fast transient was partially removed by the addition of 100 p.p.m. oxygen and completely eliminated by 10 000 p.p.m. oxygen.

The fact that a saturation current can be achieved in liquid argon at relatively low electric

field strengths means that essentially all electrons escape geminate recombination. This is in contrast to liquid hydrocarbons in which most electrons are thermalized close to the parent positive ion and, therefore, undergo geminate recombination.

A low temperature phase of $(NH_4)_2TeBr_6$[1]

A. K. DAS[2] AND I. D. BROWN[3]

Department of Physics, Hamilton College, McMaster University, Hamilton, Ontario

Received June 20, 1969

X-Ray diffraction has shown the existence of a low temperature tetragonal phase of $(NH_4)_2TeBr_6$ having space group $P4/mnc(D_{4h}^6)$ with $a = 7.501$, $c = 10.765$ Å.

Canadian Journal of Chemistry, 47, 4288 (1969)

Our previous X-ray diffraction study of ammonium hexabromotellurate(IV), $(NH_4)_2TeBr_6$ (1), confirmed that at room temperature the compound has the cubic K_2PtCl_6 structure first observed by Manojlević (2). Nakamura, Ito, and Kubo (3) using nuclear quadrupole resonance (n.q.r.) have observed that at -52 °C, $(NH_4)_2TeBr_6$ undergoes a phase transition to a structure with lower symmetry in which the bromine atoms are no longer all equivalent. We have observed that under the polarizing microscope, crystals of $(NH_4)_2TeBr_6$, cooled to below the phase transition, exhibit the extinction pattern characteristic of a non-cubic crystal. On warming above the transition temperature, the crystals revert to the cubic form in a manner which indicates that the transformation is rapid and reversible in nature. Many of the crystals are observed to be twinned in the low temperature phase, suggesting that the transformation in this case is probably "displacive" in the sense described by Buerger (4).

In order to study the symmetry and cell constants of $(NH_4)_2TeBr_6$ below the transition temperature, double exposure Weissenberg photographs were taken with CuKα radiation. One exposure was taken below the phase transition, the other at room temperature. In this way it was possible to make accurate measurements of the differences between the high and low temperature forms. Two separate crystals were examined, one oriented along the cubic [110] direction and the other along [100]. From these photographs, it was possible to measure the cell constants of the low temperature phase and assign its space group (see Table I).

The atomic positions in the low temperature structure can be inferred from the space group, from the splitting of the n.q.r. signal into two, and from the obvious general similarity with the cubic structure. Values of the atomic coordinates were not found, since the photographs were not suitable for making intensity measurements.

The proposed structure of the low temperature form of $(NH_4)_2TeBr_6$ lies somewhere between

that of monoclinic K_2TeBr_6 (6) and the cubic form of $(NH_4)_2TeBr_6$. The principal change that occurs during the transformation is the rotation of the $TeBr_6^{2-}$ ion by a few degrees about the [001] direction. Although the anion is only required by the space group to have the symmetry D_{4h}, it is likely, by analogy with K_2TeBr_6, to retain the octahedral structure to a close approximation.

The sign of the long-range spin–spin coupling constant between ^{19}F and the aldehydic ^1H in *p*-fluorobenzaldehyde: evidence for a negative Q_{CCHO}

T. Schaefer[1] and S. S. Danyluk
Division of Biological and Medical Research, Argonne National Laboratory, Argonne, Ill. 60439

Received June 16, 1969

The spin–spin coupling constant of -0.50 ± 0.03 Hz between the ^{19}F nucleus and the aldehydic proton in *p*-fluorobenzaldehyde contrasts with a positive coupling between ^{19}F and methyl protons in *p*-fluorotoluene derivatives. If the former coupling is dominated by a π electron mechanism, it implies a negative hyperfine interaction constant between the aldehydic proton and the aromatic π system.

Canadian Journal of Chemistry, 47, 4289 (1969)

Negative spin–spin coupling constants between methyl protons and ring protons in the para position, J_p^{H,CH_3}, in toluene derivatives (1) are consistent with a σ–π exchange mechanism (2, 3) in which

$$[1] \qquad J_p^{H,CH_3} \propto Q_{CH}\, Q_{CCH}$$

In eq. [1], $Q_{CH} < 0$ represents a hyperfine interaction between the proton in the C—H bond and an electron in a p_π orbital on the carbon atom. $Q_{CCH} > 0$ is the corresponding interaction

between the proton in the methyl group and the p_π electron on the bonded ring carbon atom. $Q_{CCH} \propto \cos^2 \theta$, where θ is the angle between the axis of the p_π orbital and the C—H bond, both projected on a plane perpendicular to the C—C bond.

Similarly, $|J_p^{H,CH_3}| < |J_p^{F,CH_3}|$ and $J_p^{F,CH_3} > 0$ in *p*-fluorotoluene derivatives (4) is consistent with a dominant π coupling mechanism for which

$$[2] \qquad J_p^{F,CH_3} \propto Q_{CF}\, Q_{CCH}$$

In eq. [2], $Q_{CF} > 0$ but is a composite term (5) which may vary considerably in magnitude (6).

Now *p*-fluorobenzaldehyde is almost certainly a planar molecule (7–9) with a barrier to reorientation of the formyl group sufficiently large (> 6 kcal/mole) so as to give a $Q_{CCHO} \approx 0$ ($\theta \approx 90°$) for a spin delocalization mechanism (9). Recent valence bond calculations (10) suggest the possibility of a spin polarization mechanism giving rise to $Q_{CCH} < 0$ when $\theta = 90°$, at least in aliphatic π electron radicals. Perhaps more to the point, an apparent negative Q value is found for the formyl proton in certain paramagnetic γ-formyl nickel(II) aminotroponeimine derivatives (11). In this case, $|Q_{CCHO}| \approx 1/6|Q_{CCH}|$, where Q_{CCH} is an average over θ for almost free rotation in toluene radical anions (12).

These considerations imply that for *p*-fluorobenzaldehyde, eq. [3] may be roughly applicable

$$[3] \qquad J_p^{F,CHO} \propto Q_{CF}\, Q_{CCHO}$$

From eq. [3], it would be predicted that $J_p^{F,CHO} < 0$ and is probably smaller in magnitude than J_p^{F,CH_3} in *p*-fluorotoluene derivatives. We find, indeed, that $J_p^{F,CHO} = -0.50$ Hz (see Experimental section), compared to $J_p^{F,CH_3} = 1.3$ Hz in 4-fluoro-2-iodotoluene (4).

The σ–π mechanism also depends on excitation energies to triplet states as well as on long-range mobile bond orders (3), so that a more detailed discussion of the relative magnitudes of J_p^{F,CH_3} and $J_p^{F,CHO}$ is probably not warranted at this time. A test of the proposed coupling mechanism may be devised by measuring $J_p^{F,CHO}$ in *p*-fluorobenzaldehyde derivatives in which bulky ortho substituents force the formyl group into a nonplanar configuration. $J_p^{F,CHO}$ should then increase algebraically and, if the degree of nonplanarity is sufficiently large, a spin delocalization (hyperconjugative overlap) mechanism will result in a positive $J_p^{F,CHO}$. The synthesis of the appropriate compounds is being attempted.

Experimental

A solution consisting of equal volumes of *p*-fluorobenzaldehyde, carbon disulfide, and tetramethylsilane was degassed by the freeze–pump–thaw technique. Proton magnetic resonance spectra were taken in the frequency sweep mode on a DA-60I Varian spectrometer. Double resonance experiments under conditions of weak irradiation were performed in the normal way (13, 14).

In Fig. 1*a*, the formyl proton resonance of *p*-fluorobenzaldehyde shows the expected pattern under conditions where $|J_p^{F,CHO}|$ is almost the same as $|J_m^{H,CHO}|$ (the stick diagram is intended to clarify this situation). The triplets arising from the small $J_o^{H,CHO}$ are clearly visible. The magnitudes of $J_m^{H,CHO}$ and $J_o^{H,CHO}$ could also be obtained from the ring proton spectrum in which the internal shift approaches 1 p.p.m.

In Fig. 1*b*, the low-field peaks of the meta ring protons (H_B) corresponding to net positive or zero spin states of the H_A protons, and to positive spin states of the fluorine nucleus, are being weakly irradiated. In Fig. 1*c*, the amplitude of the irradiating field is larger than in *b*. The high-field formyl proton peaks are affected. Note the unperturbed shape of the low-field triplet. Consequently,

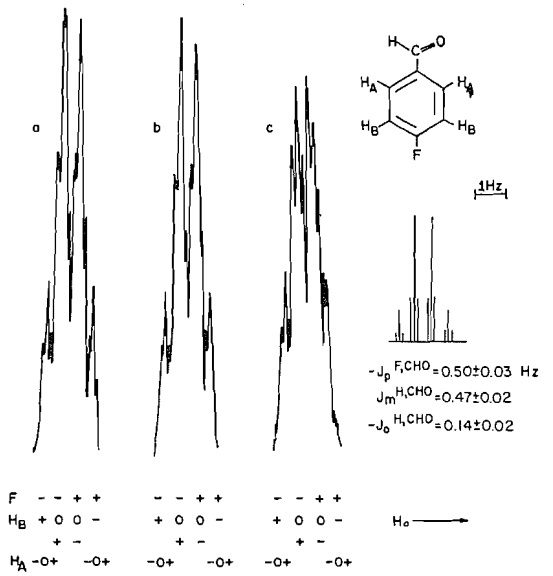

FIG. 1. The single proton resonance spectrum of the aldehydic proton in *p*-fluorobenzaldehyde is shown in *a*. Because the magnitudes of the spin–spin couplings to the 2 H_B protons and to the ^{19}F nucleus are very nearly equal, the aldehyde proton resonance appears as a basic 1:3:3:1 quartet, each of whose components are further split into a 1:2:1 triplet by the much smaller coupling of the 2 H_A protons. In *b* and *c* are shown double resonance spectra of the aldehydic proton under conditions described in the text (see experimental section). The spin states of the other nuclei are given with the convention that a positive sign under a low-field peak indicates a positive coupling to the aldehydic proton.

$J_o^{HF}/J_p^{F,CHO} < 0$. Because $J_o^{HF} > 0$ (15), it follows that $J_p^{F,CHO} < 0$. Other experiments indicate $J_o^{H,CHO} < 0$ in this molecule. In *p*-N,N-dimethylaminobenzaldehyde (16), as well as in a number of disubstituted benzaldehydes (17), it is known that $J_o^{H,CHO} < 0$.

Effect of temperature on the spectrum of sulfur dioxide[1]

J. BROWN AND GEORGE BURNS

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received March 26, 1969

The effect of temperature on the ultraviolet spectrum of sulfur dioxide has been studied over the temperature range 20 to 1000 °C. The equilibrium constant for the reaction

$$SO_2 \rightleftharpoons (SO_2)$$

where (SO_2) is an isomeric form or an excited state of sulfur dioxide, has been obtained at several temperatures. The enthalpy change for the transition was found to be 4.1 ± 0.4 kcal mole^{-1}.

Canadian Journal of Chemistry, **47**, 4291 (1969)

The spectrum of sulfur dioxide in the region accessible to quartz optics shows 2 main regions of absorption, the first approximately between 3100 and 2500 Å and the second extending from about 2500 Å into the vacuum ultraviolet (u.v.). It is known (e.g. refs. 1–3) that as the temperature is raised the absorption bands are considerably weakened (being replaced by a continuous absorption in the far u.v.) but return to their original intensity when the gas is cooled. A thermal equilibrium has been postulated (2), viz.

$$SO_2 \rightleftharpoons (SO_2)$$

where (SO_2) is an isomeric form (2) or an electronically excited state (4) of sulfur dioxide. Recently, however, Hays and Pfeiffer (5) have postulated that non-ionic AB_2-type molecules with 14–18 valence electrons may have double minima in their ground state potential energy surfaces. They suggest, on the basis of molecular orbital calculations, that the "high temperature isomer of sulfur dioxide" may be a symmetrical form of SO_2 with a somewhat extended S—O bond distance and a bond angle of about 72°. In the present note, measurements of equilibrium constant have been obtained for the transition at a series of temperatures and the corresponding enthalpy change has been calculated.

Experimental

The apparatus employed for this investigation was originally intended for study of reactions by the technique of flash photolysis and kinetic spectroscopy and has been described many times previously (e.g. ref. 6). The reaction vessel was contained in a furnace which could obtain a maximum temperature of 1250 °C. The detector was a Hilger medium quartz spectrograph and exposures were made on Kodak Type No. 3 spectrographic analysis plates. Band intensities were measured on a Joyce Loebl microphotometer Model MKIIIC. Sulfur dioxide was supplied by the Matheson Company and was reported

$J_o^{HF}/J_p^{F,CHO} < 0$. Because $J_o^{HF} > 0$ (15), it follows that $J_p^{F,CHO} < 0$. Other experiments indicate $J_o^{H,CHO} < 0$ in this molecule. In *p*-N,N-dimethylaminobenzaldehyde (16), as well as in a number of disubstituted benzaldehydes (17), it is known that $J_o^{H,CHO} < 0$.

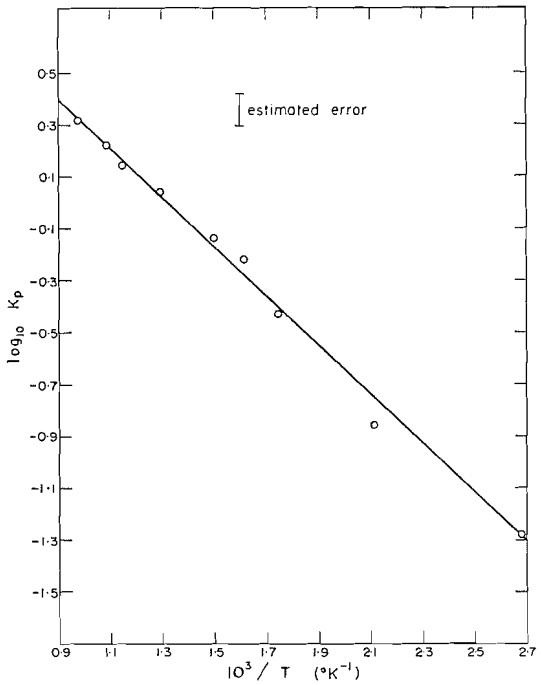

FIG. 2. Plot of logarithm of the equilibrium constant (K_P) against $1/T$. (Error estimated by comparing results obtained from all 4 calibration graphs and calculated by use of root-mean-square deviation formula.)

to have a purity of at least 99.98%. Pressures of the gas used throughout the experiment were of the order of mm and were measured on a glass Bourdon spoon gauge.

The effect of temperature on the absorption spectrum is shown on Fig. 1. It is readily observable that as the absorption bands of the system at 3000 Å become weakened with increasing temperature, there is a marked increase of continuous absorption at shorter wavelengths.

In order to calculate the enthalpy change accompanying the transition a plate was calibrated using known pressures of sulfur dioxide in the reaction vessel, at room temperature. The intensities of the absorption bands at 3131, 3088, 3043, and 3001 Å were measured on the microphotometer and graphs of $\log_{10}$ intensity (intensity being proportional to peak height) against concentration were drawn. Using the same plate, the absorption spectrum of sulfur dioxide (initial pressure 5 Torr) was photographed at a variety of temperatures up to 750 °C. The concentration of sulfur dioxide at each temperature was read from the calibration graphs. No significant change in the shape of the microphotometer trace was noted as the temperature was increased. The number of molecules in the ground vibrational state was calculated at each temperature, using the Boltzmann factor correction (exp $(-\Delta E/RT)$). The amount of sulfur dioxide present as isomer or in an electronically excited state (SO_2) was evaluated by difference. It was assumed that the amount of (SO_2) present at room temperature was zero. Since the rotational contour of a band changes with temperature the data were recalculated using the microdensitometer trace peak area rather than peak height. However, due probably to the low resolution of the spectrograph, no significant changes in the results obtained were noted. The equilibrium constant for the transition was calculated at each temperature, and a plot of $\log_{10} K_P$ (equilibrium constant) against $1/T$ was made (Fig. 2). The graph had a slope of $-0.9 \pm 0.1 \times 10^3$ (deg) which gave ΔH for the transition as 4.1 ± 0.4 kcal mole^{-1}. This result allows no conclusions to be drawn about the nature of (SO_2).

Professor N. Basco brought to our attention that, in general, in plate photometry it is difficult to separate unequivocally the continuum, which constitutes a base line, and peaks, which were used here to estimate SO_2 concentrations. For these reasons, plate photometric measurements of the type conducted here might be in error, especially if there is an appreciable overlap between various vibrational bands. However, in the present work, the vibrational bands seem to be well separated (Fig. 1), the continuum in the region in question (3000–3131 Å) is fairly weak (Fig. 1), and the calibration curves at wavelengths studied, as well as the plot in Fig. 2, produced good straight lines. For these reasons, we doubt that we can improve our results. However, we recognize that with superior equipment, it might be possible to do so.

An error in ref. 19 has led to some incorrect values of $\Delta G_{CON}{}^{0}/z$ in LiCl–KCl in Table I. The correct values are: V^{3+}, 452.447; Cr^{3+}, 467.736; Fe^{3+}, 463.174. The points for these ions in Fig. 5 should be raised by the difference between the values just given and those in Table I. The paper is not otherwise affected.

Photocycloaddition of 1,1-diphenylethylene to 2,3-dihydropyran

PAUL SERVÉ
The Department of Chemistry, Wright State University, Dayton, Ohio 45431

AND

HERBERT M. ROSENBERG AND R. RONDEAU
Air Force Materials Laboratory, Wright-Patterson Air Force Base, Ohio 45433

Received May 27, 1969

1,1-Diphenylethylene reacts with 2,3-dihydropyran on photolysis to yield two allylic addition products as well as cycloaddition product. The triplet state of 1,1-diphenylethylene is implicated in these reactions. The cycloaddition reaction is stereoselective and is thought to result from bond polarization of the reactants.

Canadian Journal of Chemistry, **47**, 4295 (1969)

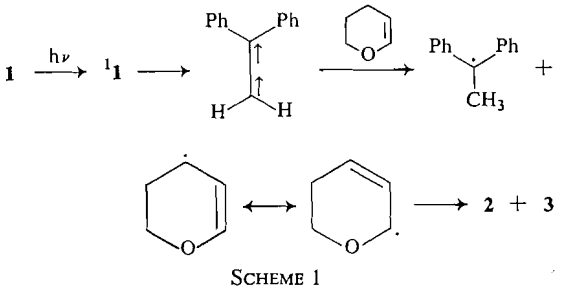
In two previous papers (1,2) we reported the photocycloaddition of diphenylacetylene and stilbene to 2,3-dihydropyran. The symmetry properties of the reactants precluded observation of orientational preference in these cycloaddition reactions. We now report the photochemical reaction of 1,1-diphenylethylene (**1**) with 2,3-dihydropyran at 2537 and 3000 Å.

A solution of **1** in 2,3-dihydropyran was irradiated in a quartz vessel at 2537 or 3000 Å for 150 h. At the end of this period gas-liquid phase chromatography (g.l.p.c.) analysis showed no trace of **1**. Three major products accounting for 55% of the reaction were isolated and characterized as: 2-(1,1-diphenylethyl)-2*H*,5,6-dihydropyran (**2**), 20%; 4-(1,1-diphenylethyl)-4*H*,5,6-dihydropyran (**3**), 25%; and 7,7-diphenyl-2-oxabicyclo[4.2.0]octane (**4**), 55%. It is noteworthy that irradiation at 2537 or 3000 Å caused no deviation in the type products formed or the product distribution.

Mass spectral parent peaks established that the three major products were 1:1 adducts. Infrared (i.r.) and proton magnetic resonance (p.m.r.) spectral data shown in the Experimental section are consistent with the assigned structures. The coupling constant $J_{1,6} = 8.0$ c.p.s. for **4** provides evidence for *cis* ring fusion (3).

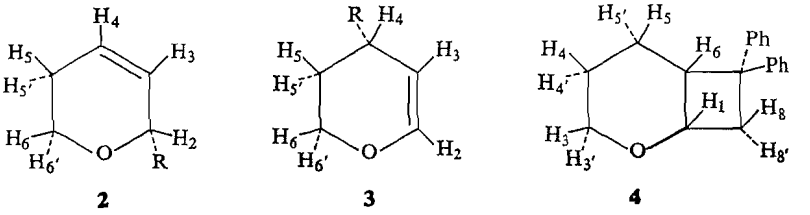
We note the apparent preference for *cis* ring fusion in photocycloaddition reactions to dihydropyran (1,2) in contrast to the frequent tendency toward *trans* ring fusion in cyclohexene adducts (4).

In order to obtain information concerning the reaction mechanism, sensitization experiments were performed. We found that the reaction was sensitized by benzophenone ($E_T = 69$ kcal) and the product distribution was not affected. The reaction could also be quenched by the addition of piperylene ($E_T = 58$ kcal). This demonstrated the involvement of the excited triplet state of **1** in the formation of the three major products.

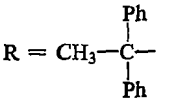


SCHEME 1

Formation of **2** and **3** is most readily accommodated by the reaction sequence (Scheme 1) in which allylic hydrogen abstraction by the



2 **3** **4**



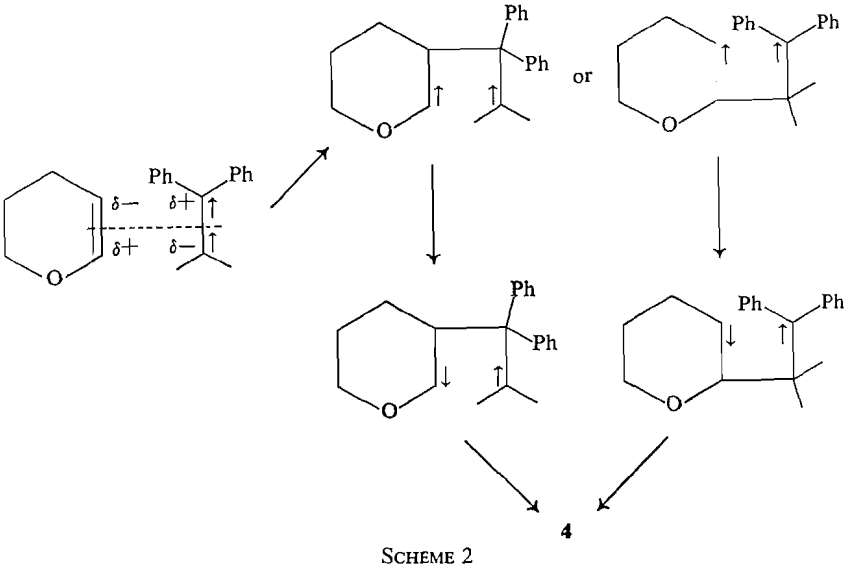
excited triplet (^{3}1) is followed by free radical combination.[1] Compound **4** is probably formed in a non-concerted cycloaddition reaction. There is no apparent steric basis for the orientational preference in the cycloaddition reaction which is contrary to the course that would be predicted for the initial formation of the more stable biradical. We postulate that bond polarization of the reacting species (Scheme 2) directs the initial attack, possibly via the formation of an excited state acceptor–donor complex (5), followed by intersystem crossing and ring closure to give the observed product. This hypothesis is speculative since we have no information regarding the charge distribution of the triplet olefin.

Experimental

Melting points are uncorrected. Photolyses were conducted in a Rayonet photochemical reactor at 2537, 3000, or 3500 Å. The i.r. spectra were obtained in a Perkin-Elmer Model 621 spectrophotometer. Mass spectra were obtained on a CEC-21-110 instrument. The g.l.p.c. was performed on a Varian Aerograph 1200 on 5 ft column packed with 3% SE30. The p.m.r. spectra were taken on a Varian DP-60-IL instrument.

Reaction of 1,1-Diphenylethylene with 2,3-Dihydropyran

A solution containing **1**, 3.6 g (0.02 mole) in 2,3-dihydropyran, 97 g (1.2 moles) was irradiated in a quartz vessel at 35° for 150 h at 3000 Å. At the end of the time no trace of **1** was observed by g.l.p.c. Three products were isolated by column chromatography on alumina (80–200 mesh). The following products in their order of elution were obtained with petroleum ether (b.p. 30–60°): **2**



SCHEME 2

($CDCl_3$) τ 2.80 (10H, multiplet, aromatic protons), 3.75 (1H, doublet of doublets, H_2), 5.30 (1H, multiplet, H_3), 6.25 (2H, multiplet, H_6 and $H_{6'}$), 8.20 (1H, multiplet, H_4), 8.50 (2H, multiplet, H_5 and $H_{5'}$), 8.20 (3H, singlet, methyl protons) $J_{1,2}$ = 6Hz, $J_{1,3}$ = 2 Hz]; **4** [1.2 g (30%); m.p. 46–8°; *m/e*, 264; i.r. (thin film) 3090, 3060, 3010, 2930, 1600, 1110, 730, and 690 cm^{-1}; p.m.r. ($CDCl_3$) τ 2.90 (10H, multiplet, aromatic protons), 5.8 (1H, quartet, H_1), 6.4 (2H, multiplet, H_3 and $H_{3'}$), 6.8 (2H, multiplet, H_8 and $H_{8'}$), 7.3 (1H, multiplet, H_6), 8.4 (4H, multiplet, H_5 and $H_{5'}$, H_4 and $H_{4'}$), $J_{1,6}$ = 8 Hz; $J_{1,8'} = J_{1,8'}$ = 8.5 Hz; spin decoupling experiments demonstrated the following couplings (H_6–$H_{5'}$,H_6–$H_{5'}$,$J_{6,5} = J_{6,5'}$ = 7.5 Hz).

Attempted Sensitization of 1,1-Diphenylethylene with 2,3-Dihydropyran with Benzophenone

A solution containing 1,1-diphenylethylene, 1.8 g (0.01 mole) in 100 ml of 2,3-dihydropyran was divided into 2 equal portions. Benzophenone, 3.6 g (0.02 mole) was added to one portion. Both solutions were then irradiated at 3500 Å for 48 h. The reactions were monitored using g.l.p.c. The reaction in the vessel containing the added benzophenone was shown to have progressed to about 30% completion, while the unsensitized reaction showed no product formation.

Attempting Quenching of the Reaction of 1,1-Diphenylethylene with 2,3-Dihydropyran with Piperylene

A solution containing 1,1-diphenylethylene, 1.8 g (0.01 mole) in 100 ml of 2,3-dihydropyran was divided into 2 portions of 50 ml each. Piperylene, 3.2 g (0.05 mole) was added to one portion. The two solutions were irradiated in quartz vessels at 3000 Å for 48 h. The reaction was monitored by g.l.p.c. The unquenched reaction was 3.5 times as rapid as the quenched reaction.

Total synthesis, stereochemistry, and lithium–ammonia reduction of (±)-4-demethylaristolone and (±)-5-epi-4-demethylaristolone

EDWARD PIERS, WILLIAM DE WAAL, AND RONALD W. BRITTON
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received June 2, 1969

The total synthesis of (±)-4-demethylaristolone (**14**) and its epimer, (±)-5-epi-4-demethylaristolone (**15**) is described. The key step of this synthesis involves the intramolecular cyclization of the olefinic diazoketone **12**, which produces the two epimers, **14** and **15**, in a ratio of approximately 2:1, respectively. The stereochemistry of the two epimers is unambiguously determined. It is observed that the lithium–ammonia reduction of **14** gives a dihydro derivative **16** containing *trans*-fused six-membered rings, while, interestingly, a similar reduction of **15** affords the corresponding *cis*-fused decalone system **26**.

Canadian Journal of Chemistry, 47, 4299 (1969)

Very recently, we reported (1) the total synthesis of the racemic form of the sesquiterpenoid aristolone (**1**) (2–4). This synthesis, in which the key step involved the cupric sulfate catalyzed intramolecular cyclization of the diazoketone **2**, was based on a model study involving the preparation of (±)-4-demethylaristolone. The model study, which has already been reported in preliminary form (5), was undertaken primarily with the aim of determining whether or not the crucial cyclization of the type **2** → **1** would take place. That is, in order to initially avoid some of the stereochemical problems involved in the synthesis of aristolone itself, we first decided to prepare a diazoketone of the type **3**. Successful intramolecular cyclization of the latter would then eventually lead to aristolone-type compounds lacking the C-4 secondary methyl group. We report here the details of this model study which, in addition to demonstrating the feasibility of the proposed synthetic approach, also produced some interesting results regarding the lithium–ammonia reduction of the final products, (±)-4-demethylaristolone and (±)-5-epi-4-demethylaristolone.

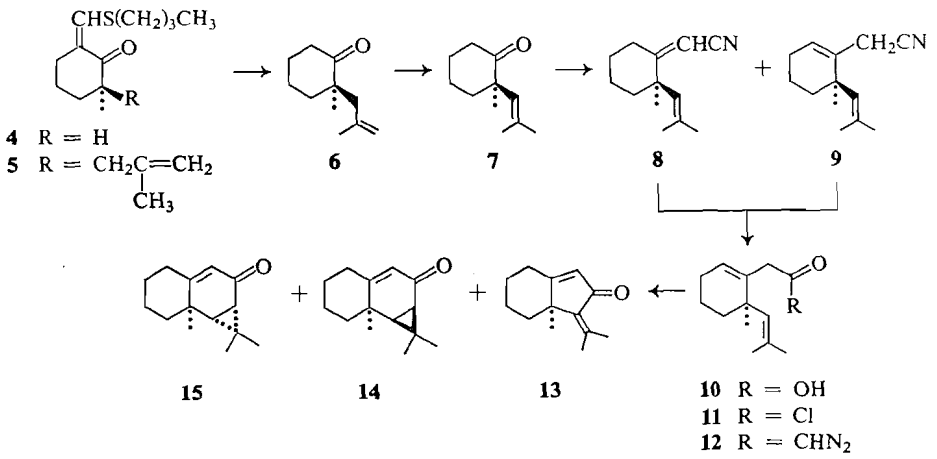
3

Alkylation of 2-methyl-6-*n*-butylthiomethylenecyclohexanone (**4**) (6) with methallyl chloride in *t*-butyl alcohol in the presence of potassium *t*-butoxide gave, after removal (6) of the *n*-butylthiomethylene blocking group from the product **5**, a 56% overall yield of 2-methyl-2-methallylcyclohexanone (**6**). Conversion of the latter into the desired 2-methyl-2-methylpropenylcyclohexanone (**7**) required isomerization of the olefinic double bond from the terminal position to the more highly substituted internal position. Although a number of different methods were attempted in order to carry out this transformation, it was eventually found that simple acid catalyzed isomerization was the most convenient. Thus, treatment of the methallyl compound **6** with *p*-toluenesulfonic acid in refluxing benzene for 3 days produced, in 77% yield, a mixture of compounds which, by gas–liquid chromatographic analysis, was shown to consist of approximately 80% of the desired isomerized ketone **7**, 17% of the starting material **6**, and 3% of an unidentified component. Careful fractionation of this mixture through a spinning band column allowed the isolation of nearly pure desired ketone **7**. The fact that simple double bond isomerization had taken place was shown clearly by the nuclear magnetic resonance (n.m.r.) spectra of compounds **6** and **7**. Thus, although the starting material **6** exhibited signals for two olefinic protons (τ 5.18 and 5.33) and one vinyl methyl group (τ 8.33), the product **7** showed signals for one olefinic proton (τ 4.74) and two vinyl methyl groups (τ 8.31 and 8.57).

In order to obtain, from ketone **7**, the diazoketone required to test the feasibility of the proposed intramolecular cyclization, the reaction of **7** with the modified Wittig reagent, triethyl phosphonoacetate (7), was attempted. This reaction proved very sluggish and even when high



reaction temperatures were used, none of the desired product could be isolated. However, use of the sterically less demanding reagent, diethyl cyanomethylphosphonate (7), proved successful. Thus, reaction of the cyclohexanone **7** with this reagent in the presence of methylsulfinyl carbanion in dimethyl sulfoxide (8) at 100° for 15 h gave, in 95% yield, a mixture of the α,β-unsaturated nitrile **8** and the β,γ-unsaturated nitrile **9**, in a ratio of approximately 4:1, respectively. An analytical sample of the major compound (**8**) was obtained by preparative gas–liquid chromatography (g.l.c.) and gave spectral data in complete accord with the assigned structure. Furthermore, the n.m.r. spectrum of the mixture clearly showed that the other component of the mixture was indeed the β,γ-unsaturated isomer **9**.

Hydrolysis of the mixture of nitriles with potassium hydroxide in ethanol produced, in good yield, the β,γ-unsaturated carboxylic acid **10**. The fact that the double bond had now completely isomerized into the β,γ-position was clearly shown by the spectral data. The acid **10** exhibited no strong absorption in the ultraviolet (u.v.) spectrum and, in the n.m.r. spectrum, exhibited, in addition to the expected signals due to the angular methyl group and the methylpropenyl side chain, a two-proton multiplet at τ 7.09 (—CH_2COOH) and a one-proton triplet at τ 4.38 due to the γ-vinyl hydrogen. Although it is well known that equilibration of α,β- and β,γ-unsaturated carboxylic acids occurs in the presence of base (9), it is of interest to note that in the present case the equilibrium lies completely on the side of the β,γ-unsaturated isomer. One of the major factors contributing to this phenomenon may well be the $A^{(1,3)}$ strain (10) which would be associated with the exocyclic double bond in the α,β-unsaturated isomer. Presumably this is more severe than the $A^{(1,2)}$ strain (10) which is inherently present in the β,γ-unsaturated compound.

Treatment of the sodium salt of the carboxylic acid **10** with oxalyl chloride in benzene at room temperature gave the acid chloride **11**. The latter was quite unstable and readily cyclized to the cross-conjugated dienone **13**. In fact, when the acid chloride was allowed to stand at room temperature, or if it was gently warmed, a nearly quantitative yield of the dienone **13** was obtained. Therefore, even though special precautions were taken during the isolation of the crude acid chloride and even though the latter was reacted immediately with excess diazomethane, the resulting crude diazoketone **12** contained a considerable quantity of the bicyclic dienone **13**. Since no separation was affected at this stage, compound **13** was eventually isolated along with the demethylaristolones (*vide infra*). It is important to note that the n.m.r. spectrum of the crude diazoketone clearly showed that the olefinic double bond of this compound had remained in the β,γ-position with respect to the carbonyl group.

When the crude diazoketone **12** was heated with cupric sulfate in refluxing cyclohexane (11) for 2 h, a mixture of products was obtained. Analysis of the mixture by g.l.c. showed that it contained, in addition to a number of minor components, three major products, the cross-

For personal use only.

conjugated dienone **13**, (±)-4-demethylaristolone (**14**), and (±)-5-epi-4-demethylaristolone (**15**), in a ratio of approximately 2:2:1, respectively. Treatment of this mixture with sodium hydroxide in hot aqueous ethanol for 10 min removed the minor components and gave a neutral product containing only the three compounds **13**, **14**, and **15**. Purification of this latter mixture by means of successive column chromatography on alumina and preparative g.l.c. allowed the isolation of all three components. The fact that the crucial cyclization had indeed taken place was clearly shown by the spectral data of the two cyclization products **14** and **15**. The major cyclization product, (±)-4-demethylaristolone (**14**), gave an u.v. maximum at 235 mμ and a strong carbonyl absorption at 6.10 μ in the infrared (i.r.). The n.m.r. spectrum, which was particularly instructive, exhibited a broad singlet at τ 4.32, due to the olefinic proton, and three sharp singlets at τ 8.70, 8.77, and 8.83 due to the three tertiary methyl groups. The minor cyclization product (±)-5-epi-4-demethylaristolone (**15**) was shown to be isomeric with **14** by means of a high resolution mass spectrometric measurement and gave spectral data very similar to that of compound **14**.

Having clearly shown that the initially proposed intramolecular cyclization of a diazoketone of the type **3** was a feasible process, we wished to unequivocally determine the stereochemistry of the two cyclization products, **14** and **15**. In order to accomplish this objective, we planned to convert the demethylaristolones into relatively simple decalone derivatives which, hopefully, could then be synthesized unambiguously.

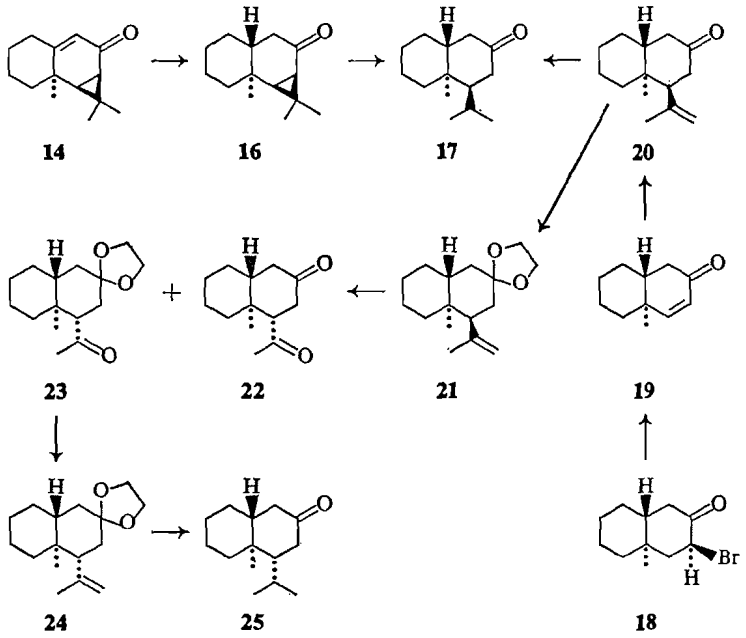
Lithium–ammonia reduction of (±)-4-demethylaristolone (**14**) gave, in quantitative yield, (±)-9,10-dihydro-4-demethylaristolone (**16**). The fact that only the olefinic double bond had reduced and that the *gem* dimethylcyclopropyl moiety had been retained was clearly shown by the spectral data of the product **16**. The latter gave an u.v. absorption maximum at 212.5 mμ (see reference 12) and, in the n.m.r. spectrum, showed three sharp singlets due to the tertiary methyl groups, but gave no signal due to a vinyl proton. When compound **16** was again subjected to reduction with lithium in ammonia, the expected (13) substituted decalone **17** was obtained, again in virtually quantitative yield.

An unambiguous synthesis of the decalone **17** and subsequent correlation with the above reduction product would, of course, provide unequivocal proof for the stereochemistry of (±)-4-demethylaristolone (**14**). This synthesis was carried out as follows. Dehydrobromination of the known bromo ketone **18** (14) with a mixture of lithium bromide and lithium carbonate in hot dimethylformamide (15) afforded, in 90% yield, the octalone **19** (16). When the latter was reacted with isopropenylmagnesium bromide in the presence of cuprous chloride in tetrahydrofuran (17, 18), a mixture of products was obtained. Column chromatography of this mixture gave, in addition to a number of minor uncharacterized non-ketonic materials (presumably resulting from 1,2-addition of the Grignard reagent to the carbonyl of **19**), a 50% yield of the conjugate addition product **20**. It is noteworthy that the conjugate addition reaction was completely stereoselective, since a careful examination of the crude product of the reaction revealed that only one of the two possible epimeric 1,4-addition products was formed. Hydrogenation of the olefinic ketone **20** over Adams catalyst produced the decalone **17**, which was shown to be identical (m.p., mixed m.p., i.r.) with the decalone **17** obtained from the lithium–ammonia reduction of (±)-9,10-dihydro-4-demethylaristolone (**16**).

The stereochemical outcome of the above conjugate addition reaction requires comment. It has been proposed (19) that the conjugate introduction of a Grignard reagent to octalones of the type **19** must, for stereoelectronic reasons, take place via one (or both) of the two transition states **A** and **B**. Molecular models show that if stereoelectronic control is to be maintained in the boat-like transition state **B**, then the incoming Grignard reagent must approach the molecule in such a way that it is nearly eclipsed with the angular methyl group. The resulting torsional strain (20, 21) should override the steric hindrance (between the incoming isopropenyl group and the *syn*-axial hydrogens) present in transition state **A** and should ensure that the latter is favored over transition state **B**. Therefore, we fully expected that the cuprous chloride catalyzed 1,4-addition of isopropenylmagnesium bromide to octalone **19** would be highly stereoselective and, furthermore, predicted that the product should possess the stereochemistry depicted in **20**.

That the above prediction regarding the stereochemistry of **20** was correct was shown unambiguously as follows. Ketalization of **20** with

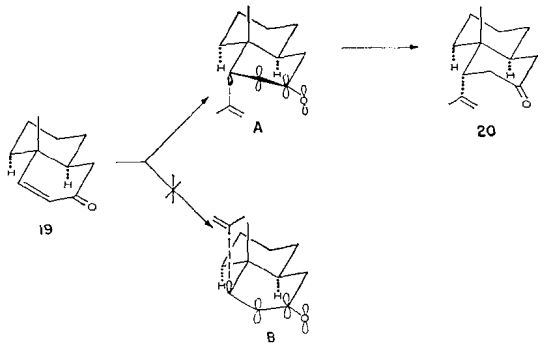
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.



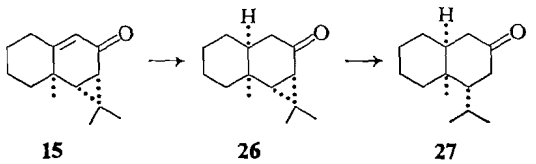
ethylene glycol afforded the crystalline ketal **21**, in 88% yield. Ozonolysis of this material, followed by column chromatography of the crude product, gave, in addition to the diketone **22**, the desired keto ketal **23**. The latter, upon reaction with methylenetriphenylphosphorane in dimethyl sulfoxide (8), gave a high yield of the olefinic ketal **24** which, on the basis of m.p., gas–liquid chromatographic retention time, and spectral data, was clearly different from, and therefore epimeric with, the olefinic ketal **21**. Successive hydrolysis and hydrogenation of compound **24** produced the decalone **25** which again was different from the decalone **17** obtained previously.

Obviously, the overall epimerization involved in the conversion of **21** into **24** required that the isopropenyl group was axial in the starting material **21**, and equatorial in the product **24**. The above stereochemical prediction was therefore correct and the stereochemistry of **20** was completely defined. This, in turn, unambiguously established the stereochemistry of (±)-4-demethylaristolone (**14**).

The lithium–ammonia reduction of (±)-5-epi-4-demethylaristolone (**15**) was also carried out. As in the case of the epimeric (±)-4-demethylaristolone (**14**), reduction of **15** was completely stereoselective and cleanly produced, in high yield, only one dihydro derivative (**26**). Lithium–



ammonia reduction of the latter afforded the substituted decalone **27**. Somewhat surprisingly, this decalone proved to be different from decalone **25**, the structure of which was unambiguously defined. This observation could only lead to the interesting conclusion that the lithium–ammonia reduction of (±)-5-epi-4-demethylaristolone (**15**) had produced a dihydro derivative with *cis*-fused six-membered rings. In contrast to the normal stereochemical outcome of reductions of this type (10, 22, 23) this is, to our knowledge, the



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

first recorded example of a lithium–ammonia reduction of a substituted $\Delta^{1(9)}$-octal-2-one which stereoselectively gave the corresponding *cis*-fused decalone derivative.

Experimental

General[1]

Melting points, which were determined on a Kofler block, and boiling points are uncorrected. Ultraviolet spectra were measured in methanol solution on either a Cary, model 14, or a Unicam, model SP.800, spectrophotometer. Routine i.r. spectra were recorded on a Perkin-Elmer Infracord model 137 spectrophotometer, while all comparison spectra were recorded on a Perkin-Elmer model 421 spectrophotometer. Nuclear magnetic resonance spectra were taken in deuterochloroform solution on Varian Associates spectrometers, model A-60 and/or model HA-100. Signal positions are given in the Tiers τ scale, with tetramethylsilane as an internal standard; the multiplicity, integrated peak areas, and proton assignments are indicated in parentheses. High resolution mass spectra were recorded on an AEI, type MS9, mass spectrometer. Gas–liquid chromatography was carried out on an Aerograph Autoprep, model 700. The following columns (10 ft × 1/4 in., unless otherwise stated) were employed, with the inert, supporting material being 60/80 mesh Chromosorb W in each case: Column A, 20% FFAP; Column B, 15% QF-1; Column C, 20% Apiezon J., Column D, 10% Apiezon J; Column E (10 ft × 3/8 in.), 30% FFAP; Column F (10 ft × 3/8 in.), 30% Carbowax 20 M; Column G (10 ft × 3/8 in.), 30% SE 30; Column H, 20% SE-30; Column I (10 ft × 3/8 in.), 30% Apiezon J. The specific column used, along with the column temperature and carrier gas (helium) flow-rate (in ml/min), are indicated in parentheses. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver.

The procedure employed for isolation of reaction products consisted of thorough extraction with the specified solvent, washing the combined extracts first with water, then with saturated brine, and drying over either anhydrous magnesium sulfate or sodium sulfate. The solvent was removed from the filtered extracts by means of a rotary evaporator, under reduced pressure.

2-Methyl-2-methallyl-6-n-butylthiomethylene-cyclohexanone (5)

To a stirred solution of potassium-*t*-butoxide (140 g, 1.23 moles) in 1200 ml of dry *t*-butyl alcohol was added 77 g (0.363 mole) of 2-methyl-6-*n*-butylthiomethylenecyclohexanone (**4**) (6) and the resulting solution was stirred at room temperature for 10 min and then cooled to 0°. Freshly distilled methallyl chloride (174 g, 1.92 moles) was added and the reaction mixture was refluxed under an atmosphere of dry nitrogen for 2 h. After most of the solvent had been removed under reduced pressure, the residue was diluted with water and the product was isolated with ether. Distillation under reduced pressure afforded 78 g (70%) of the alkylated ketone **5**, b.p. 101–103° at 0.08 mm; n_D^{20} 1.4965; u.v. λ_{max} 280 mμ (ε = 12 100); i.r. (film), λ_{max} 5.98, 6.31, 10.92 μ.

Anal. Calcd. for $C_{16}H_{22}OS$: C, 72.12; H, 9.84; S, 12.03. Found: C, 72.07; H, 9.77; S, 11.94.

2-Methyl-2-methallylcyclohexanone (6)

A stirred solution of compound **5** (65.8 g, 0.25 mole) in 150 ml of 25% aqueous potassium hydroxide and 150 ml of ethylene glycol was refluxed, under an atmosphere of nitrogen, for 18 h. The reaction mixture was steam distilled until the distillate was clear. The distillate was saturated with salt and the product was extracted with ether. Distillation of the crude oil gave 33.3 g (80%) of the desired ketone **6**, b.p. 54–58° at 0.6 mm; n_D^{20} 1.4772; i.r. (film), λ_{max} 5.86, 6.10, 11.16 μ; n.m.r., τ 5.18, 5.33 (two multiplets, 2H, $=CH_2$), 8.33 (broad singlet, 3H, vinyl methyl), 8.92 (singlet, 3H, tertiary methyl).

Anal. Calcd. for $C_{11}H_{18}O$: C, 79.47; H, 10.91. Found: C, 79.67; H, 10.79.

2-Methyl-2-methylpropenylcyclohexanone (7)

A solution of the ketone **6** (36 g) and *p*-toluenesulfonic acid (460 mg) in 700 ml of dry benzene was refluxed under nitrogen for 3 days. The solution was cooled, washed with saturated aqueous sodium bicarbonate, washed with saturated brine, and the product was isolated in the normal manner. Distillation of the crude product gave 27.7 g (77%) of a clear oil, b.p. 59–62° at 0.8 mm. Gas–liquid chromatographic analysis (column A, 170°, 75) of this material indicated that it was a mixture, consisting of approximately 80% of the desired ketone **7**, 17% starting material **6**, and 3% of an unidentified compound. This mixture was subjected to fractional distillation through a spinning band column (stainless steel, 8 mm × 24 in.). The distillation was carried out at a pressure of 28 mm, and each fraction was submitted to gas–liquid chromatographic analysis (column A, 170°, 75). The initial, small fractions (1 and 2), b.p. 105–112°, consisted mainly of the unidentified impurity. Fractions 3, 4, and 5 (15.1 g, b.p. 112–116°) contained the desired ketone **7**, greater than 97% pure. Fraction 6 (3.3 g, b.p. 116–118°) contained approximately 80% of the desired product **7**, and 20% starting material **6**. The still-pot residue (6.4 g) consisted of a mixture of compounds **6** (85%) and **7** (15%). An analytical sample of 2-methyl-2-methylpropenylcyclohexanone (**7**) was collected by preparative g.l.c. (column A, 170°, 75) and exhibited n_D^{20} 1.4767; i.r. (film), 5.88 μ; n.m.r., τ 4.74 (multiplet, 1H, vinyl H), 8.31, 8.57 (doublets, 6H, vinyl methyls, J = 1.5, 1.2 Hz, respectively), 8.91 (singlet, 3H, tertiary methyl).

Anal. Calcd. for $C_{11}H_{18}O$: C, 79.47; H, 10.91. Found: C, 79.56; H, 11.10.

Reaction of Ketone 7 with Diethyl Cyanomethylphosphonate

A stirred suspension of sodium hydride (10.9 g, 0.454 mole) in dry dimethyl sulfoxide (220 ml) was slowly heated, under an atmosphere of nitrogen, to 75° and kept at this temperature until frothing had ceased (approximately 45 min). The solution was cooled to room temperature and a solution of diethyl cyanomethylphosphonate (80.5 g, 0.455 mole) in 150 ml of dimethyl sulfoxide was added. After stirring the reaction mixture for 10 min, a solution of ketone **7** (15.1 g, 0.091 mole) in 40 ml of dimethyl sulfoxide was added. The reaction was heated at 100° overnight, cooled, diluted with water,

For personal use only.

and the product was isolated with petroleum ether (b.p. 30–60°). Distillation of the crude product gave 16.3 g (95%) of a clear oil, b.p. 84–87° at 0.15 mm. Analysis by g.l.c. (column B, 200°, 100) showed that this material was a mixture, containing approximately 80% of the α,β-unsaturated nitrile **8** and 20% of the β,γ-unsaturated nitrile **9**. An analytical sample of the major product was obtained by preparative g.l.c. (column B, 170°, 100) and exhibited n_D^{20} 1.5069; u.v., λ_{max} 219 mμ (ε = 10 900); i.r, (film), 4.55, 6.20 μ; n.m.r. τ 4.75 (singlet, 1H, =CHCN), 4.81 (multiplet, 1H, vinyl H), 8.28, 8.49 (doublets, 6H, vinyl methyls, J = 1.4, 1.3 Hz, respectively), 8.80 (singlet, 3H, tertiary methyl).

Mol. Wt. Calcd. for $C_{13}H_{19}N$: 189.152. Found (high resolution mass spectrometry): 189.150.

Although the minor product **9** was not isolated in pure form, the n.m.r. spectrum of the mixture of **8** and **9** clearly showed that the minor constituent was indeed the β,γ-unsaturated nitrile **9**. The mixture also gave satisfactory analytical data.

Dienone ***13****, (±)-4-Demethylaristolone (****14****), and (±)-5-Epi-4-demethylaristolone (****15****)*

The β,γ-unsaturated carboxylic acid **10** (4.0 g, 20.6 mmoles) was dissolved in 0.1 *N* aqueous sodium hydroxide (22.6 mmoles), the water was removed under reduced pressure, and the residue was dried in a vacuum oven at 70°. To a stirred suspension of the resulting acid salt in 80 ml of cold (0°), dry benzene was added 6 drops of pyridine, followed by 28 ml of oxalyl chloride. The solution was stirred at room temperature for 30 min, filtered, and concentrated, under reduced pressure, at 40°. The crude acid chloride **11** [i.r. (film), λ_{max} 5.60 μ] thus obtained was immediately dissolved in 40 ml of dry ether and an excess of dry, alcohol-free ethereal diazomethane was added. After 30 min the solvent was removed under reduced pressure, affording the crude diazoketone **12**. The i.r. (film) spectrum showed λ_{max} 4.80, 6.16 μ. The n.m.r. spectrum of this crude material indicated that the olefinic double bond had remained in the β,γ-position relative to the carbonyl group. Furthermore, it was clear from the spectrum that the crude material contained a significant amount of the cross-conjugated dienone **13**.

The crude diazoketone was dissolved in 400 ml of cyclohexane and 8 g of anhydrous cupric sulfate was added. The resulting suspension was stirred vigorously and refluxed under an atmosphere of nitrogen for 2 h, at which time the i.r. absorption at 4.80 μ had disappeared. The suspension was cooled, filtered, washed with saturated aqueous sodium bicarbonate and with saturated brine, dried, and concentrated. Gas–liquid chromatographic analysis (column C, 200°, 85) of the resulting crude product (3.77 g) showed that it contained, in addition to a number of minor components of short retention time, three major components, **13**, **14**, and **15**, in a ratio of 2:2:1, respectively. The crude product was refluxed for 10 min in a mixture of ethanol (280 ml) and water (25 ml) containing 10 g of sodium hydroxide. The solution was concentrated under reduced pressure, the residue was diluted with water, and the neutral product was isolated with ether. Analysis of this crude product (2.32 g) by g.l.c. showed that all the minor components had been removed by this treatment, leaving only a mixture of the three major components **13**, **14**, and **15**. After partial separation of these compounds had been effected by column chromatography on Woelm neutral alumina, activity 1, an analytical sample of each compound was obtained by preparative g.l.c. (column C, 200°, 85).

The cross-conjugated dienone **13**, an oil, exhibited n_D^{20} 1.5408; u.v. λ_{max} 255 mμ (ε = 17 200); i.r. ($CHCl_3$), λ_{max} 5.98, 6.18 μ; n.m.r., τ 4.13 (broad singlet, 1H, vinyl H, width at half-height = 2 Hz), 7.68, 8.06 (singlets, 6H, vinyl methyls), 8.66 (singlet, 3H, tertiary methyl).

Anal. Calcd. for $C_{13}H_{18}O$: C, 82.05; H, 9.54. Found: C, 81.94; H, 9.72.

This compound could also be prepared by allowing the acid chloride **11** to stand at room temperature for 24 h, followed by distillation, b.p. 75° (bath temperature) at 0.2 mm. This product was identical with **13**, described above.

(±)-4-Demethylaristolone (**14**), an oil, exhibited the following spectral properties: u.v., λ_{max} 235 mμ (ε = 11 600); i.r. ($CHCl_3$), λ_{max} 6.10 μ; n.m.r., τ 4.32 (broad singlet, 1H, vinyl H), 8.70, 8.77, 8.83 (singlets, 9H, tertiary methyls).

Mol. Wt. Calcd. for $C_{14}H_{20}O$: 204.151. Found (high resolution mass spectrometry): 204.151.

The crystalline (±)-5-epi-4-demethylaristolone (**15**) was recrystallized from petroleum ether (b.p. 60–80°) and exhibited m.p. 86.5–87.5°; u.v. λ_{max} 232 mμ (ε = 11 700); i.r. ($CHCl_3$), λ_{max} 6.11 μ; n.m.r. τ 4.28 (singlet, 1H, vinyl H), 8.62, 8.65, 8.70 (singlets, 9H, tertiary methyls).

Mol. Wt. Calcd. for $C_{14}H_{20}O$: 204.151. Found (high resolution mass spectrometry): 204.150.

Preparation of Octalone ***19***

A stirred suspension of lithium bromide (1.1 g) and lithium carbonate (1.6 g) in 30 ml of dry dimethylformamide was heated, under an atmosphere of nitrogen, to 120°. A solution of the bromo ketone **18** (14) (1.5 g, 6.1 mmoles) in 30 ml of dry dimethylformamide was added and the mixture was heated at 120° for 1.75 h. The reaction mixture was cooled, filtered, diluted with water, and the product was isolated with *n*-heptane. Distillation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

of the crude product gave 0.91 g (90%) of octalone **19** as a clear, colorless oil, b.p. 100° at 0.35 mm; n_D^{20} 1.5088 (lit. b.p. 69° at 0.1 mm; n_D^{26} 1.5006 (16)). Gas–liquid chromatographic analysis (column D, 200°, 85) of this material showed that it consisted of only one component; u.v. λ_{max} 229 mμ (ε = 9200); i.r. (film), λ_{max} 5.95, 6.16 μ; n.m.r., τ 3.33, 4.24 (pair of doublets, 2H, (O=C)CH=C*H* and (O=C)C*H*=CH, respectively, J = 9.8 Hz), 8.96 (singlet, 3H, tertiary methyl).

Preparation of Decalone ***20***

To a stirred, ice-cold 1 *M* solution (120 ml) of isopropenylmagnesium bromide in tetrahydrofuran was added 0.65 g of anhydrous cuprous chloride. A solution of octalone **19** (10.0 g, 0.061 mole) in 40 ml of tetrahydrofuran was added dropwise, over a period of 20 min. The reaction mixture was stirred for 2 h at 0° and then poured into 350 ml of aqueous ammonium chloride–ammonium hydroxide buffer (p*H* ≃ 8). The product was isolated by extraction with ether. Analysis by g.l.c. (column D, 180°, 80) revealed that the crude product (10.7 g, b.p. 99–103° at 0.5 mm) contained, in addition to a number of minor components, one major product (approximately 60% of the mixture). Chromatography of this mixture on Woelm neutral alumina (300 g) afforded, in the fractions eluted with 4:1 benzene–ether, 5.2 g (50%) of decalone **20**, as pale yellow crystals. A careful examination of the various chromatography fractions showed that **20** was the only carbonyl-containing compound present in the product. Recrystallization of **20** from hexane–ether afforded clear, colorless plates, m.p. 83–84°; i.r. (KBr), λ_{max} 5.88, 6.14, 11.25 μ; n.m.r., τ 5.08, 5.45 (multiplets, 2H, =CH_2), 8.23 (multiplet, 3H, vinyl methyl), 8.84 (singlet, 3H, tertiary methyl).

Anal. Calcd. for $C_{14}H_{22}O$: C, 81.49; H, 10.75. Found: C, 81.33; H, 10.69.

Lithium–ammonia Reduction of
*(±)-4-Demethylaristolone (**14**)*

To 50 ml of ammonia, which had been distilled from sodium metal, was added 70 mg of lithium metal, and the resulting blue solution was stirred, under an atmosphere of dry nitrogen, for 15 min. A solution of (±)-4-demethylaristolone (**14**) (100 mg) in 8 ml of anhydrous ether was added dropwise and the resulting solution was stirred for 1 h. After the reaction had been quenched with ammonium chloride, the ammonia was allowed to evaporate and the residual material was diluted with water. Isolation of the product with ether gave 90 mg (90%) of a clear, colorless oil. Gas–liquid chromatographic analysis (column C, 200°, 85) showed that this material consisted of nearly pure (±)-9,10-dihydro-4-demethylaristolone (**16**), the only impurity being a small amount of starting material (**14**). An analytical sample of compound **16**, an oil, was obtained by preparative g.l.c. (column C, 200°, 85); u.v., λ_{max} 212.5 mμ (ε = 5200); i.r. ($CHCl_3$), λ_{max} 6.00 μ; n.m.r., τ 8.35, 8.94 (pair of doublets, 2H, cyclopropyl protons, J = 8.0 Hz), 8.59, 8.87, 8.97 (singlets, 9H, tertiary methyls).

Mol. Wt. Calcd. for $C_{14}H_{22}O$: 206.167. Found (high resolution mass spectrometry): 206.166.

Preparation of Decalone ***17***

(a) By Hydrogenation of Decalone ***20***

Hydrogenation (platinum oxide, ethanol) of compound **20** was carried out at atmospheric pressure and room temperature. From 200 mg of **20**, there was obtained 182 mg (91%) of the crystalline decalone **17**. Recrystallization from *n*-hexane gave an analytical sample, m.p. 49–50°; i.r. ($CHCl_3$), λ_{max} 5.85 μ; n.m.r., τ 8.89 (singlet, 3H, tertiary methyl), 9.08, 9.17 (doublets, 6H, secondary methyls, J = 6.8 Hz).

Anal. Calcd. for $C_{14}H_{24}O$: C, 80.70; H, 11.61. Found: C, 80.95; H, 11.51.

(b) By Lithium–ammonia Reduction of
*(±)-9,10-Dihydro-4-demethylaristolone (**16**)*

The lithium–ammonia reduction of compound **16** was carried out by a procedure identical with that used for the reduction of (±)-4-demethylaristolone (**14**) (see above). From 60 mg of **16** there was obtained 58 mg of the crude crystalline decalone **17**. Recrystallization from *n*-hexane gave an analytical sample, m.p. 49–50°. This material was shown to be identical (m.p., mixed m.p., g.l.c. retention time, i.r. spectrum) with compound **17** obtained as described above.

Preparation of Ketal ***21***

A solution of the decalone **20** (3.1 g, 15 mmoles), ethylene glycol (3.72 g, 60 mmoles), and *p*-toluenesulfonic acid (50 mg) in 50 ml of dry benzene was refluxed under a Dean–Stark water separator for 20 h. The cooled solution was diluted with 50 ml of ether and washed with 50 ml of aqueous sodium bicarbonate. The organic layer was dried and concentrated, affording 3.93 g of colorless crystals. Recrystallization from *n*-hexane gave 3.31 g (88%) of the ketal **21** as colorless plates, m.p. 80–81°; i.r. ($CHCl_3$), λ_{max} 6.15, 9.07, 9.28, 11.18 μ; n.m.r., τ 5.01, 5.20 (multiplets, 2H, =CH_2), 6.10 (multiplet, 4H, —OCH_2CH_2O—), 8.13 (multiplet, 3H, vinyl methyl), 9.02 (singlet, 3H, tertiary methyl).

Anal. Calcd. for $C_{16}H_{26}O_2$: C, 76.75; H, 10.46. Found: C, 76.69; H, 10.39.

Ozonolysis of Ketal ***21***

A solution of 3.0 g (12 mmoles) of ketal **21** was dissolved in 150 ml of ethyl acetate and the solution was cooled in a dry ice–acetone bath. Ozone was bubbled through the solution until a blue color began to appear (approximately 15 min) and continued for a further 15 min. Platinum oxide (400 mg) was added and the reaction mixture was subjected to hydrogenation at room temperature and atmospheric pressure. After hydrogen uptake had ceased, the mixture was filtered and the filtrate was concentrated under reduced pressure. Gas–liquid chromatographic analysis (column B, 200°, 85) showed that the residual oil (2.63 g) consisted of three components. This material was subjected to column chromatography on Woelm neutral alumina (120 g). The first fraction (500 mg) showed no carbonyl absorption in its i.r. spectrum, and was not investigated further. The fractions eluted with 9:1 to 4:1 benzene–ether gave a total of 620 mg (21%) of the crystalline keto ketal **23** which, upon recrystallization from *n*-hexane, exhibited m.p. 74–74.5°; i.r. ($CHCl_3$), λ_{max} 5.88, 9.08, 9.28 μ; n.m.r., τ 6.06 (singlet, 4H, —OCH_2CH_2O—), 7.84 (singlet, 3H, —$COCH_3$), 9.09 (singlet, 3H, tertiary methyl).

Anal. Calcd. for $C_{15}H_{24}O_3$: C, 71.38; H, 9.59. Found: C, 71.15; H, 9.47.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

The fractions from the above chromatography which were eluted with 4:1 to 7:3 benzene–ether afforded 1.0 g of oily crystals which were recrystallized from *n*-hexane to afford 840 mg (33%) of the diketone **22**, m.p. 95–95.5°; i.r. ($CHCl_3$), λ_{max} 5.85 μ; n.m.r., τ 7.80 (singlet, 3H, $-COCH_3$), 8.83 (singlet, 3H, tertiary methyl).

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 74.95; H, 9.67. Found: C, 74.98; H, 9.89.

Preparation of Ketal ***24***

To a solution of methylenetriphenylphosphorane (1.27 g, 4.5 mmoles) in 6 ml of dimethyl sulfoxide was added a solution of the keto ketal **23** (225 mg, 0.9 mmole) in 10 ml of dimethyl sulfoxide. The resulting solution was heated at 100° for 6 h, cooled, and poured into 25 ml of cold water. Isolation of the product with pentane gave 203 mg (91%) of the crystalline ketal **24** which, upon recrystallization from *n*-hexane, exhibited m.p. 76–77°; i.r. ($CHCl_3$), λ_{max} 6.14, 9.08, 9.28, 11.18 μ; n.m.r., τ 5.05, 5.34 (multiplets, 2H, $=CH_2$), 6.04 (singlet, 4H, $-OCH_2-CH_2O-$), 8.26 (multiplet, 3H, vinyl methyl), 9.17 (singlet, 3H, tertiary methyl).

Anal. Calcd. for $C_{16}H_{26}O_2$: C, 76.75; H, 10.46. Found: C, 77.00; H, 10.45.

Preparation of Decalone ***25***

A solution of the ketal **24** (186 mg, 0.75 mmole) in a mixture of acetone (5 ml) and 10% hydrochloric acid (5 ml) was heated on a steam bath until most of the acetone had distilled. The product was isolated from the cooled reaction mixture by extraction with ether. The crude product [156 mg; i.r. (film), λ_{max} 5.85, 6.14, 11.20 μ] thus obtained was not purified further, but was subjected directly to hydrogenation (platinum oxide, ethanol) at atmospheric pressure and room temperature. Distillation of the crude hydrogenation product gave 110 mg of pure decalone **25** as a clear, colorless oil, b.p. 95° at 0.1 mm; n_D^{20} 1.4965; i.r. (film), λ_{max} 5.85 μ; n.m.r., τ 9.01 (singlet, 3H, tertiary methyl), 9.12, 9.18 (doublets, 6H, secondary methyls, $J = 6.5$ Hz).

Anal. Calcd. for $C_{14}H_{24}O$: C, 80.70; H, 11.61. Found: C, 80.63; H, 11.49.

*Lithium–ammonia Reduction of (±)-5-Epi-4-demethylaristolone (**15**)*

The lithium–ammonia reduction of **15** was carried out in a manner identical with that described previously for the reduction of (±)-4-demethylaristolone (**14**). From 100 mg of compound **15** there was obtained 90 mg of crude product, consisting nearly entirely of the dihydro derivative **26**. An analytical sample of the latter, an oil, was obtained by preparative g.l.c. (column C, 200°, 85); u.v., λ_{max} 210 mμ (ε = 4800); i.r. ($CHCl_3$), λ_{max} 5.99 μ; n.m.r., τ 8.43, 9.04 (pair of doublets, 2H, cyclopropyl protons, $J = 8$ Hz), 8.71, 8.74, 8.87 (singlets, 9H, tertiary methyls).

Mol. Wt. Calcd. for $C_{14}H_{22}O$: 206.167. Found (high resolution mass spectrometry): 206.167.

Lithium–ammonia Reduction of Compound ***26***

Reduction of 60 mg of compound **26**, *via* a procedure identical with that described previously for the reduction of **14**, gave 55 mg of crude crystalline material. Recrystallization from *n*-hexane afforded an analytical sample of the decalone **27**, m.p. 50.5–51°; i.r. ($CHCl_3$), λ_{max} 5.88 μ; n.m.r., τ 8.87 (singlet, 3H, tertiary methyl), 9.08, 9.16 (doublets, 6H, secondary methyls, $J = 6.5$ Hz).

Mol. Wt. Calcd. for $C_{14}H_{24}O$: 208.183. Found (high resolution mass spectrometry): 208.182.

Annelation of 2,3-dimethylcyclohexanone. Synthetic proof for the stereochemistry of the sesquiterpene aristolone

EDWARD PIERS, RONALD W. BRITTON, AND WILLIAM DE WAAL
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

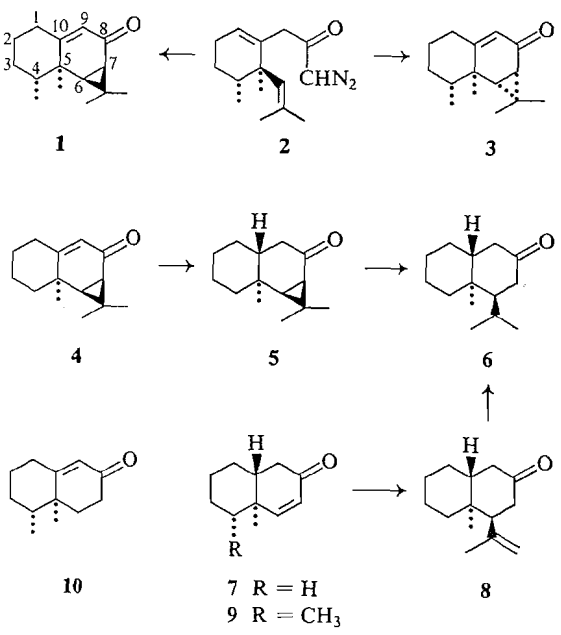
Received June 2, 1969

An efficient annelation of 2,3-dimethylcyclohexanone is described. The key step of this process involves the reaction of the enol lactone **16** with methyllithium, under carefully controlled conditions. The completely stereoselective conversion of the sesquiterpene (−)-aristolone (**1**) into the levorotatory decalone **22***b* is described. Comparison of the latter with the unambiguously synthesized racemic decalone **22***a* conclusively establishes the relative stereochemistry of aristolone (**1**).

Canadian Journal of Chemistry, 47, 4307 (1969)

The relative and absolute stereochemistry of the sesquiterpene aristolone (1,2) has been proposed (3) as shown in formula **1**. However, even though two independent and entirely different total syntheses of the racemic form of this interesting natural product have recently been reported (4,5), the stereochemical proposal (3) has not as yet received synthetic verification, since both of the syntheses were stereochemically ambiguous. For example, in the synthesis reported by the present authors (5), the key step involved the cupric sulfate catalyzed intramolecular cyclization of the olefinic diazoketone **2**. This reaction was not completely stereoselective, since it produced not only (±)-aristolone (**1**), but also the isomeric (±)-6,7-epi-aristolone (**3**). Therefore, although the stereochemistry of the crucial synthetic intermediate **2** was clearly and unambiguously determined (5), the above synthesis did not unequivocally establish the total relative stereochemistry of aristolone (**1**). We have therefore obtained direct independent synthetic evidence which fully corroborates the stereochemical assignment (3) of this sesquiterpene.

Previously, in a model study (6,7) we had shown that (±)-4-demethylaristolone (**4**) gave, upon reduction with lithium in ammonia, a near quantitative yield of (±)-9,10-dihydro-4-demethylaristolone (**5**). The latter, when again subjected to lithium–ammonia reduction, afforded the substituted decalone **6**. Furthermore, we had also shown (6,7) that the cuprous chloride catalyzed conjugate addition of isopropenylmagnesium bromide to the octalone **7** gave, completely stereoselectively, the decalone **8** which, upon hydrogenation, produced compound **6**, identical with that obtained from the lithium–ammonia reduction of **5**.



1 **2** **3**
4 **5** **6**
10 **7** R = H, R = CH_3 **8**

From the foregoing, it was clearly apparent that a similar series of reactions involving aristolone (**1**) and the octalone **9** would provide unambiguous synthetic proof for the relative stereochemistry of the natural product. It appeared highly unlikely that the presence of an extra (equatorial) methyl group (**1** and **9** as compared with **4** and **7**, respectively) would alter the stereochemical outcome of either the lithium–ammonia reduction (of **1**) or the conjugate addition of isopropenylmagnesium bromide (to **9**).

The first synthetic objective, then, was the octalone **10**, which presumably could be readily converted by standard reactions into the required isomeric compound **9**. One obvious way

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

to prepare **10** would be to carry out the Robinson annelation (8) of 2,3-dimethylcyclohexanone with methyl vinyl ketone or its equivalent. In fact, Ourisson and co-workers (4) had already reported this reaction, although no yield was given by these workers. We attempted the Robinson annelation of 2,3-dimethylcyclohexanone with both methyl vinyl ketone and 4-diethylamino-2-butanone methiodide under a variety of experimental conditions, but were unable to obtain the annelated material in yields exceeding approximately 15%. Furthermore, the octalone which was obtained consisted, in each case, of a mixture of two epimers in a ratio of approximately 3:2, making it extremely difficult to obtain a reasonable quantity of the desired octalone **10** in a pure state. Therefore, since the Robinson annelation did not appear to be a particularly efficient method for the preparation of **10**, we considered alternative routes to this compound.

During our work on the total synthesis of (±)-aristolone (5) we had observed that alkylation of 2,3-dimethyl-6-*n*-butylthiomethylenecyclohexanone (**11**) with methallyl chloride produced, in high yield, a mixture of *cis*- (**12**) and *trans* - 2,3 - dimethyl - 2 - methallyl - 6 - *n* - butylthiomethylenecyclohexanone (**13**), in a ratio of approximately 4:1, respectively. The fairly high stereoselectivity of this process encouraged us to consider a preparation of **10** which was based upon alkylation of **11**. This approach proved to be very satisfactory.

Alkylation of compound **11** with ethyl 3-bromopropionate in the presence of potassium-*t*-butoxide in *t*-butyl alcohol (9) proved to be a very facile reaction and produced, in 86% yield, a mixture of the keto esters **14**. Removal of the *n*-butylthiomethylene blocking group from the latter was accomplished in the normal way (9) (potassium hydroxide in hot aqueous diethylene glycol) and was accompanied by hydrolysis of the ester group. The product, a mixture of keto acids **15**, was obtained in 90% yield.

When the mixture of keto acids **15** was refluxed in acetic anhydride containing sodium acetate (see ref. 10), there was produced, in 85% yield, a crystalline material which consisted of a mixture of the two epimeric enol lactones **16** and **17**. The ratio of the two epimers, as judged by the nuclear magnetic resonance (n.m.r.) spectrum of the mixture, was approximately 9:1, respectively. The major, desired epimer **16** could readily be obtained in 80% yield from the mixture by careful recrystallization of the latter from *n*-hexane. An analytical sample of **17** was obtained from the mother liquors of recrystallization by means of preparative gas–liquid chromatography (g.l.c.). Both **16** and **17** exhibited spectral data which was in complete accord with the assigned structures.

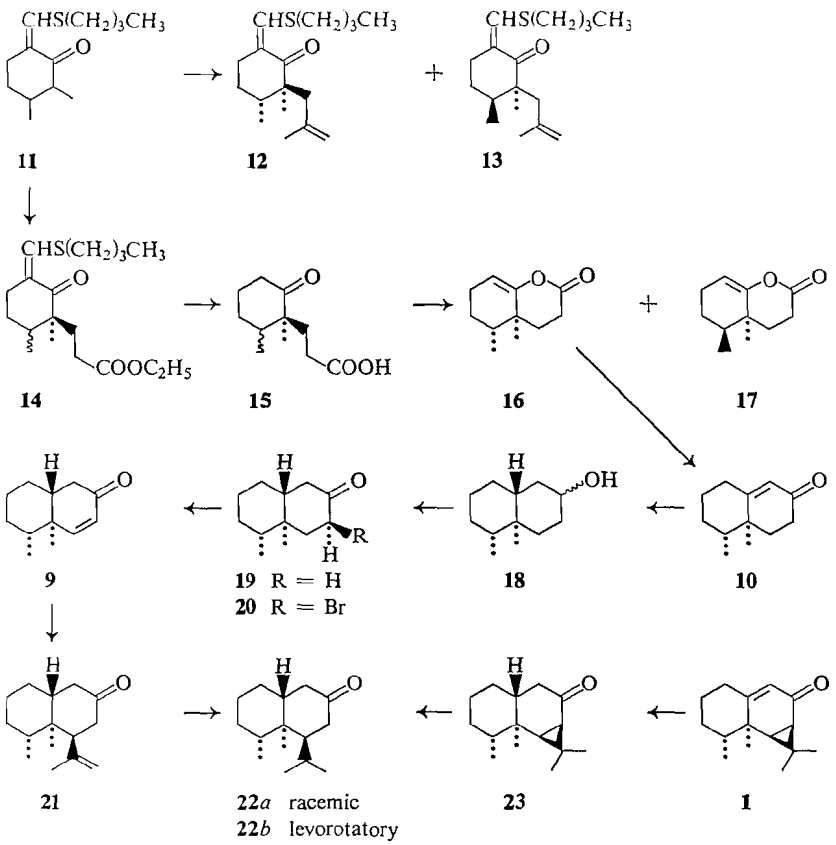
Although, in order to convert the enol lactone **16** into the required octalone **10**, we investigated the use of a number of different reagents,[1] it was eventually found that methyllithium was the most convenient and gave the most consistent results. Thus, reaction of **16** with methyllithium in dry ether at −25° for 1.75 h, followed by successive acidic hydrolysis and base-catalyzed aldol cyclization afforded, in addition to a small amount (10%) of starting material (in the form of the keto acid **15**, *cis* epimer) a 70% yield of the desired octalone. The overall yield of pure octalone **10**, based on 2,3-dimethylcyclohexanone, was, therefore, approximately 30%, obviously a considerable improvement over the Robinson annelation method.

It should be noted that the success of the reaction of the enol lactone **16** with methyllithium depended, to a large extent, upon a judicious choice of the reaction temperature and reaction time. That is, use of reaction temperatures greater than −25°, or use of longer reaction times, resulted in the formation of a considerable amount of alcohol-containing product, presumably due to "di-addition" of methyllithium to the enol lactone. On the other hand, milder reaction conditions (lower temperatures, shorter reaction times) resulted in the recovery of fairly copious amounts of starting material, in the form of the corresponding keto acid (**15**, *cis* epimer).

Reduction of the octalone **10** with lithium in ammonia in the presence of ethanol (see ref. 16) gave, in 75% yield, the decalol **18** which, upon oxidation with Jones reagent (17) gave the decalone **19**. The latter exhibited infrared (i.r.) spectrum and gas–liquid chromatographic retention times identical with those of the (+)-antipode of **19**, which had previously been prepared, via a lengthy synthetic sequence, by Djerassi and coworkers (18).[2] This comparison conclusively showed that the initial alkylation of compound

[1]For previous examples of annelation via enol lactones, see refs. 11–15, inclusive.

[2]We are very grateful to Professor Djerassi for a small sample of this compound.



11 with β-bromopropionate had been stereoselective in the desired sense and that, therefore, our synthetic intermediates indeed possessed a *cis* stereochemistry with respect to the two methyl groups.

Bromination of the decalone **19** with bromine in acetic acid (19) afforded the known (4) bromo ketone **20**. Dehydrobromination of the latter with a mixture of lithium bromide and lithium carbonate in hot dimethylformamide (20) gave, in 86% yield, a mixture of compounds which contained, in addition to a number of minor components, the desired octalone **9** as the major (80%) constituent. This material was isolated from the mixture by means of preparative g.l.c., and showed the expected spectral properties. Of particular pertinence was the ultraviolet (u.v.) spectrum, which exhibited a maximum at 230 mμ, and the n.m.r. spectrum, which showed the vinyl protons as an AB pair of doublets (J = 10 Hz) at τ 2.88 and 4.11.

When the octalone **9** was reacted with isopropenylmagnesium bromide in the presence of cuprous chloride in tetrahydrofuran (7), the decalone **21** was produced as the only conjugate addition product.[3] Hydrogenation of **21** over Adams catalyst afforded the racemic decalone **22*a***.

Lithium–ammonia reduction of (−)-aristolone (**1**)[4] gave, in high yield, (+)-9,10-dihydroaristolone (**23**). The latter gave an u.v. absorption maximum at 213 mμ (see ref. 21) and, in the n.m.r. spectrum, showed no signal due to a vinyl proton, thus clearly demonstrating that only the olefinic double bond had reduced. When compound **23** was again reduced with lithium in ammonia, the expected (22) levorotatory decalone **22*b*** was obtained in virtually quantitative yield. This compound gave spectra (i.r., n.m.r.)

[3]For a discussion regarding the stereochemical outcome of the conversion of **9** into **21**, see ref. 7.

[4]We are very grateful to Professor A. Marsili and to Professor F. Sorm for generous samples of authentic (−)-aristolone.

and gas–liquid chromatographic retention times identical with those of the racemic decalone **22***a* obtained as outlined above. Since, by analogy with previous work (7), the stereochemistry of **22***a* was completely defined, this comparison provided unambiguous synthetic evidence for the stereochemistry of aristolone (**1**).

Experimental[5]

*Alkylation of 2,3-Dimethyl-6-n-butylthiomethylene-cyclohexanone (**11**) with Ethyl 3-Bromopropionate*
