The *n*-butylthiomethylene derivative **11** (5) (100 g, 0.44 mole) was added to 1800 ml of dry *t*-butyl alcohol containing 144 g (1.4 moles) of potassium *t*-butoxide and the resulting solution was stirred at room temperature for 10 min. Ethyl 3-bromopropionate (250 g, 1.38 mole) was added slowly from a dropping funnel. The alkylation was exothermic and, after the addition was complete, the reaction mixture was stirred for an additional 15 min. Most of the solvent was removed under reduced pressure and the residue was diluted with water. Isolation of the product with ether gave an oil which, upon distillation under reduced pressure, afforded 124 g (86%) of the keto ester **14** (mixture of epimers); b.p. 190–195° at 0.2 mm; n_D^{20} 1.5261; u.v., λ_{max} 311 mμ (ε = 14 900); i.r. (film), λ_{max} 5.79, 6.03, 6.52 μ.

Anal. Calcd. for $C_{18}H_{30}O_3S$: C, 66.22; H, 9.26. Found: C, 66.14; H, 9.33.

*Preparation of Keto Acid **15***

To a solution of the above alkylated material (**14**) (124 g, 0.38 mole) in 600 ml of diethylene glycol was added 600 ml of 25% aqueous potassium hydroxide, and the resulting solution was refluxed, under an atmosphere of nitrogen, for 18 h. The solution was cooled, diluted with water, and extracted twice with ether. The ether extracts were discarded. The aqueous layer was acidified with 6 *N* hydrochloric acid, and the product was extracted with ether. Distillation of the crude material afforded 67.5 g (90%) of the keto acid **15** (mixture of epimers) as a clear viscous oil; b.p. 142–147° at 0.15 mm; n_D^{20} 1.4868; i.r. (film), λ_{max} 2.7–4.2 (very broad), 5.78, 5.85 μ.

Anal. Calcd. for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15. Found: C, 66.83; H, 9.07.

*Preparation of Enol Lactones **16** and **17***

A solution of the mixture of keto acids **15** (64 g, 0.32 mole) in 1400 ml of acetic anhydride containing 14 g of anhydrous sodium acetate was refluxed under an atmosphere of nitrogen for 2 h. The acetic anhydride was removed under reduced pressure, and the residual material was diluted with water. Isolation of the product with ether, followed by distillation, gave 49 g (85%) of crystalline material; b.p. 90–94° at 0.15 mm. This material, as judged by its n.m.r. spectrum, consisted of a mixture of the enol lactones **16** and **17**, in a ratio of approximately 9:1, respectively. Recrystallization of this mixture from *n*-hexane produced pure **16** (40 g). An analytical sample of **16** was obtained by vacuum sublimation and exhibited m.p. 51–51.5°; i.r. (CS_2), λ_{max} 5.72, 5.98 μ; n.m.r., τ 4.72 (triplet, 1H, vinyl H, J = 3.5 Hz), 8.97 (singlet, 3H, tertiary methyl), 9.04 (doublet, 3H, secondary methyl, J = 6.0 Hz).

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95. Found: C, 73.60; H, 8.93.

An analytical sample of the minor epimer **17**, an oil, was obtained from the mother liquors of the above recrystallization by means of preparative g.l.c. (column E, 225°, 200) and exhibited n_D^{20} 1.4910; i.r. (film) λ_{max} 5.71, 5.98 μ; n.m.r., τ 4.68 (triplet, 1H, vinyl H, J = 4.0 Hz), 8.79 (singlet, 3H, tertiary methyl), 9.04 (doublet, 3H, secondary methyl, J = 6.5 Hz).

Mol. Wt. Calcd. for $C_{11}H_{16}O_2$: 180.115. Found (high resolution mass spectrometry): 180.113.

*Preparation of Octalone **10***

A solution of the crystalline enol lactone **16** (19.6 g, 0.11 mole) in 200 ml of dry ether was cooled to −25° by means of an external carbon tetrachloride–dry ice slush bath. An ethereal solution of methyllithium (75 ml, 2.35 M) was added over a period of 3 min, and the resulting solution was stirred at −25°, under an atmosphere of dry nitrogen, for 1.75 h. The reaction mixture was poured into dilute hydrochloric acid and the product was extracted with ether. To the crude, oily product thus obtained was added a solution of potassium hydroxide (16 g) in 120 ml of water and 1000 ml of methanol, and the solution was refluxed under an atmosphere of nitrogen for 2 h. The methanol was removed under reduced pressure, the residue was diluted with water, and the neutral product was isolated by extraction with ether. Distillation of the crude yellow oil thus obtained gave 13.5 g (70%) of the octalone **10**; b.p. 96–99° at 0.2 mm; n_D^{20} 1.5155; u.v., λ_{max} 240 mμ (ε = 12 100); i.r. (film), λ_{max} 5.98, 6.19 μ; n.m.r., τ 4.33 (broad singlet, 1H, vinyl H), 8.90 (singlet, 3H, tertiary methyl), 9.09 (unresolved multiplet,[6] 3H, secondary methyl).

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.85; H, 10.18. Found: C, 80.96; H, 10.29.

The basic aqueous layer from the above extraction was acidified with concentrated hydrochloric acid and the acidic product was isolated by extraction with ether. Distillation of the crude product provided 2.1 g (10%) of a carboxylic acid (**15**, *cis* epimer) which, upon treatment with sodium acetate in refluxing acetic anhydride, as described above, gave the enol lactone **16**.

*Preparation of Decalol **18***

To a solution of 6 g of lithium metal in 1500 ml of liquid ammonia was slowly added, from a dropping funnel, a solution of the octalone **10** (15 g, 0.084 mole) in 100 ml of anhydrous ether. After 1 h, 16 ml of anhydrous ethanol was added and the reaction mixture was allowed to stir for an additional 1.5 h. The reaction was then quenched by careful addition of excess ethanol, and the ammonia was allowed to evaporate. The residual

[5]For general information, see preceding paper (ref. 7).

[6]In the n.m.r. spectrum of each of the compounds **9**, **10**, **18**, **19**, and **20**, the signal due to the secondary methyl group appeared as a broad band, with very little resolution. Presumably, this was due to virtual coupling (see ref. 23).

For personal use only.

material was diluted with saturated brine and the product was isolated by extraction of the mixture with ether. Distillation of the crude product afforded 11.5 g (75%) of the decalol **18**, b.p. 86–90° at 0.2 mm, as a clear, viscous oil which resisted crystallization. An analytical sample, collected by preparative g.l.c. (column F, 250°, 200), exhibited n_D^{20} 1.4944; i.r. (film), λ_{max} 3.01, 9.54 μ; n.m.r., τ 6.40 (broad signal, 1H, —C*H*OH), 9.24 (unresolved multiplet, 3H, secondary methyl), 9.29 (singlet, 3H, tertiary methyl).

Anal. Calcd. for $C_{12}H_{22}O$: C, 79.06; H, 12.16. Found: C, 79.03; H, 11.97.

Preparation of Decalone ***19***

Standard chromic acid solution (17) was added to a solution of the decalol **18** (8.7 g, 0.048 mole) in acetone (200 ml) at 0° until the orange color persisted. Isopropyl alcohol was added to destroy the excess oxidizing reagent, and the solution was evaporated under reduced pressure. The residual material was diluted with water and the product was extracted with ether. Distillation of the crude oil gave 7 g (81%) of the decalone **19**; b.p. 83–86° at 1.0 mm; n_D^{20} 1.4943; i.r. (film), λ_{max} 5.84 μ; n.m.r., τ 9.08 (singlet, 3H, tertiary methyl), 9.13 (unresolved multiplet, 3H, secondary methyl).

Anal. Calcd. for $C_{12}H_{20}O$: C, 79.94; H, 11.18. Found: C, 80.21; H, 11.24.

This compound exhibited i.r. spectrum and gas–liquid chromatographic retention time (column G, 245°, 190) identical with those of the (+)-antipode of **19**, which had been previously prepared by Djerassi and co-workers (18).

Preparation of the Bromo Ketone ***20***

A solution of bromine (4.7 g, 29.5 mmoles) in glacial acetic acid (40 ml) was added slowly, at room temperature, to a stirred glacial acetic acid (40 ml) solution of the decalone **19** (5.3 g, 29.5 mmoles). After the addition was complete, the solution was stirred for an additional 30 min and then poured into ice-cold water. The resultant mixture was extracted with ether. The combined ether extracts were washed twice with water, then with saturated aqueous sodium bicarbonate until free of acid, and finally with saturated brine. Recrystallization of the crude crystalline product from ether afforded 5.6 g (72%) of the bromo ketone **20**. An analytical sample was obtained by vacuum sublimation and exhibited m.p. 132–133° [lit. m.p. 132–133° (4)]; i.r. ($CHCl_3$), λ_{max} 5.80 μ; n.m.r., τ 5.22 (pair of doublets, 1H, —CHBr, J = 6.5 Hz and 13.5 Hz), 8.98 (singlet, 3H, tertiary methyl), 9.10 (unresolved multiplet, 3H, secondary methyl).

Anal. Calcd. for $C_{12}H_{19}OBr$: C, 55.61; H, 7.37; Br, 30.83. Found: C, 55.68; H, 7.48; Br, 31.02.

Preparation of Octalone ***9***

A stirred suspension of lithium bromide (0.3 g) and lithium carbonate (0.4 g) in 6 ml of dry dimethylformamide was heated to 120°, under an atmosphere of nitrogen. The bromo ketone **20** (0.57 g, 2.2 mmoles) was added and the reaction mixture was stirred at 120° for 75 min. The suspension was cooled and filtered. The filtrate was diluted with water and the product was isolated with *n*-heptane. Distillation of the crude oil gave 0.34 g (86%) of a clear, colorless oil, b.p. 100° (bath temperature) at 0.4 mm. Analysis of this material by g.l.c. (column F, 250°, 240) showed that it was a mixture consisting of approximately 80% of the desired octalone **9**, 5% of the isomeric octalone **10** (on the basis of g.l.c. retention time only), and some minor unidentified components. The desired compound **9** was isolated by preparative g.l.c. (column F, 250°, 240) and exhibited n_D^{20} 1.5122; u.v., λ_{max} 230 mμ (ε ≈ 9400); i.r. (film), λ_{max} 5.97, 6.15 μ; n.m.r., τ 2.88 (doublet, 1H, β-vinyl H, J = 10 Hz), 4.11 (doublet, 1H, α-vinyl H, J = 10 Hz), 9.03 (unresolved multiplet, 3H, secondary methyl), 9.07 (singlet, 3H, tertiary methyl).

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.85; H, 10.18. Found: C, 80.83; H, 10.16.

Preparation of Decalone ***21***

To a stirred solution of isopropenylmagnesium bromide (0.29 g, 2 mmoles) in 2 ml of dry tetrahydrofuran was added approximately 6 mg of anhydrous cuprous chloride and the resulting mixture was cooled to 0°. A solution of the octalone **9** (0.1 g, 0.56 mmoles) in tetrahydrofuran (4 ml) was added by means of a syringe, and the reaction mixture was stirred, under an atmosphere of nitrogen, at 0° for 15 min and then refluxed for 1 h. The cooled reaction mixture was poured slowly into rapidly stirred, ice-cold dilute hydrochloric acid, and the product was isolated by extraction with ether. Distillation of the crude product gave 110 mg (89%) of a clear oil, b.p. 100° (bath temperature) at 0.4 mm. Gas–liquid chromatographic analysis (column G, 245°, 190) of this material showed that it contained, in addition to a number of minor components, approximately 80–85% of the desired decalone **21**. The latter was isolated by preparative g.l.c. (column G, 245°, 190) and showed n_D^{20} 1.5147; i.r. (film), λ_{max} 5.87, 6.15, 11.22 μ; n.m.r., τ 5.10, 5.36 (unresolved multiplets, 2H, $=CH_2$, width at half-height ≃ 4.5 and 3.5 Hz, respectively), 8.24 (unresolved multiplet, 3H, vinyl methyl, width at half-height ≃ 3 Hz), 9.00 (singlet, 3H, tertiary methyl), 9.12 (poorly resolved doublet, 3H, secondary methyl).

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98. Found: C, 81.99; H, 11.08.

Preparation of Decalone ***22a***

Hydrogenation of the decalone **21** was carried out in ethanol, at atmospheric pressure and room temperature, over Adams catalyst. From 50 mg of **21** there was obtained a quantitative yield of decalone ***22a*** as a crystalline solid. Recrystallization from *n*-hexane afforded an analytical sample; m.p. 49–51°; i.r. (CS_2), λ_{max} 5.87 μ; n.m.r., τ 9.02 (singlet, 3H, tertiary methyl), 9.06, 9.17 (doublets, 3H and 6H, respectively, secondary methyls, J = 6.8 Hz).

Mol. Wt. Calcd. for $C_{15}H_{26}O$: 222.198. Found (high resolution mass spectrometry): 222.198.

*(+)-9,10-Dihydroaristolone (****23****)*

Small pieces of freshly cut lithium metal (210 mg) were added to 150 ml of liquid ammonia which had been distilled from sodium metal. The resulting solution was stirred for 30 min. A solution of (−)-aristolone (**1**) (300 mg) in 25 ml of dry ether was added and the reaction mixture was stirred for 45 min. After the reaction had been quenched by careful addition of excess dry ammonium chloride, the ammonia was allowed to evaporate under a stream of nitrogen. The residual material was

diluted with saturated brine and the product was isolated by extraction with ether. Distillation of the crude product gave 275 mg (92%) of (+)-9,10-dihydroaristolone (**23**) as a clear colorless oil; b.p. 100° (bath temperature) at 0.1 mm; $[\alpha]_D^{24}$ + 7° (*c*, 0.76 in methanol); u.v., λ_{max} 213 mμ (ε = 4300); i.r. (film), λ_{max} 5.98 μ; n.m.r., τ 8.36 (doublet, 1H, —C^7H, *J* = 8 Hz), 8.70 (doublet, 1H, —C^6H, *J* = 8 Hz), 8.59, 8.83, 9.08 (singlet, 9H, tertiary methyls), 8.99 (doublet, 3H, secondary methyl, *J* = 6 Hz).

Mol. Wt. Calcd. for $C_{15}H_{24}O$: 220.183. Found (high resolution mass spectrometry): 220.182.

Preparation of (−)-Decalone 22b

The lithium–ammonia reduction of (+)-9,10-dihydroaristolone (**23**) was carried out by a procedure identical with that described above for the reduction of (−)-aristolone. From 120 mg of **23**, there was obtained 110 mg (91%) of the crystalline (−)-decalone **22***b*. Recrystallization from *n*-hexane provided an analytical sample; m.p. 80–82°; $[\alpha]_D^{24}$ −30° (*c*, 0.59 in methanol). This material gave spectra (i.r., n.m.r.) and gas–liquid chromatographic retention times (column H, 210°, 90; column I, 260°, 200) identical with those of the racemic decalone **22***a*, prepared as described previously.

Mol. Wt. Calcd. for $C_{15}H_{26}O$: 222.198. Found (high resolution mass spectrometry): 222.197.

ortho-Diquaternary aromatic compounds. II. Synthesis and spectral properties of β,β′-dihydroxy-2,3-di-*t*-butylnaphthalene and related crowded aromatics

L. R. C. BARCLAY, G. R. NIXON,[1] H. M. FOOTE,[1] AND S. L. BARCLAY
Department of Chemistry, Mount Allison University, Sackville, New Brunswick

Received June 20, 1969

Cyclialkylation of naphthalene with 2,2,5,5-tetramethyltetrahydrofuranone yielded 2-keto-1,1,4,4-tetramethyl-1,2,3,4-tetrahydroanthracene (**1**). Selenium dioxide oxidation of **1** yielded the corresponding diketone (**3**) and periodate cleavage of **3** yielded 2,3-naphthalene-diisobutyric acid (**4**). Hydride reduction of the dimethyl ester (**6**) of **4** yielded the diol, β,β′-dihydroxy-2,3-di-*t*-butylnaphthalene (**7**). The relative chemical shifts of aromatic protons of 1,2,4,5-tetraalkylbenzenes containing *gem* dimethyls are rationalized in terms of compression effects exerted by the bulky *ortho* groups. Nuclear magnetic resonance and ultraviolet spectral results for the *ortho* di-*t*-butyl aromatic derivatives **4**, **6**, and **7** are compared to the model cyclic compounds **1** and anhydride (**5**) of **4** in terms of the strain caused by bond angle deformations in the side chains.

Introduction

There have been several syntheses and interesting studies of the chemistry and properties of *ortho*-di-*t*-butylbenzenes (1). The chemical and physical properties of naphthalene are also modified by crowding of substituents. For example, there is ample evidence of such steric effects by substituents at the 1- and 8-positions due to *peri* interactions (2). Compression effects (*peri*) in 1,4-di-*t*-butylnaphthalene are reflected in nuclear magnetic resonance (n.m.r.) spectra by deshielding of the *peri* hydrogens (3) and increased rate of hydrogenation of the substituted ring (4). A recent communication (5) reported significant ultraviolet (u.v.) spectral perturbations in the 1,8-di-*t*-butylnaphthalenes.

The first synthesis of a condensed aromatic system containing adjacent *t*-butyl groups was the synthesis of the crowded heteroaromatic compound, 2,3-di-*t*-butylquinoxaline, by de-Groot and Wynberg (6). X-Ray analysis of this compound (7) indicated some bond stretching and significant bond angle deformation (10°) between the *t*-butyl groups. 1,2,4,5-Tetra-*t*-butylbenzene also exhibited bond angle deformation (10°) due to repulsion of the *t*-butyl groups but the *planarity* of the benzene ring was not affected (8).

A synthesis of naphthalene containing adjacent *t*-butyl groups has not yet been reported. The continuing interest in strained aromatic systems prompted us to investigate methods of synthesizing naphthalenes containing adjacent *t*-butyl groups. The Friedel–Crafts cyclialkylation method (9) using 2,2,5,5-tetramethyltetrahydrofuranone does not lead directly to hydrocarbons. Nevertheless, this method produces suitable model compounds containing functional groups in the side chains. Cyclization at these groups permit a comparison between the crowded *ortho* diquaternary aromatic compounds and the cyclic analogues.

Discussion of Results

Cyclialkylation of naphthalene with 2,2,5,5-tetramethyltetrahydrofuranone yielded 2-keto-1,1,4,4-tetramethyl-1,2,3,4-tetrahydroanthracene (**1**). The structure of **1** was confirmed by its n.m.r. spectrum (Table I). Any possibility of **1** being the 1,2-isomer, 3-keto-1,1,4,4-tetramethyl-1,2,3,4-tetrahydrophenanthrene[2] (**2**), was ruled out by comparison of the n.m.r. spectra of the two compounds. The ketone (**1**) and the various products derived from it showed the typical AA′BB′ symmetrical multiplet in the aromatic proton region expected of 2,3-disubstitution (Table I). On the other hand, the 1,2-isomer (**2**) showed distinctly different absorption in the aromatic proton region. The absorption of H-5 in isomer **2** was shifted down field by approximately 0.9 τ compared to the multiplet for **1**. The effect is attributed to strong *peri* interaction or compression effect on H-5 by the *gem* dimethyl

[1]Recipient of National Research Council of Canada Scholarships.

[2]This isomer (m.p. 113–114°) was synthesized by an unambiguous route from α-(1-naphthyl)isobutyric acid. Details on this will be published separately.

group on carbon-4. Comparable shifts were observed for *peri* protons in 1,4-di-*t*-butylnaphthalene (3).

Selenium dioxide oxidation of the ketone **1** yielded the yellow diketone (**3**) which gave the expected n.m.r. spectrum (Table I). Periodic acid oxidation of the diketone (**3**) yielded an acid which was readily converted into the cyclic anhydride (**5**) or, by diazomethane, into the dimethyl ester (**6**). Lithium aluminum hydride reduction of **6** afforded the diol (**7**).

The n.m.r. spectra of **5**, **6**, and **7** were consistent with these structures (Table I). These spectra were normal in the aromatic region and comparable to that of the starting ketone (**1**). This indicates that the aromatic rings of the compounds are not significantly distorted from the preferred planar configuration. The n.m.r. spectra showed no evidence for enhanced double bond fixation in these compounds. Such bond fixation is known to shift the n.m.r. absorption of the naphthalene hydrogens towards the olefinic hydrogen region (10, 11). In contrast, the hydrogens of the substituted ring in **5**, **6**, and **7** showed a slight shift (approximately 0.1 p.p.m.) *downfield* relative to **1**. There has been considerable discussion on the effect of crowding on the n.m.r. spectra of crowded aromatics (1). It is of interest

1 3 5 6 7

to our present study to attempt an empirical rationalization of the chemical shifts of aromatic protons in various crowded aromatic systems in terms of compression forces (3).

In the initial part of the n.m.r. study, the chemical shifts of aromatic protons in a series of 1,2,4,5-symmetrically substituted aromatic hydrocarbons bearing *gem* dimethyl groups are compared to those of the crowded but planar (8) hydrocarbon 1,2,4,5-tetra-*t*-butylbenzene (**12**) (see Table II). The variation in chemical shifts can reasonably be accounted for in terms of comparative van der Waals or compression forces exerted on the aromatic hydrogens by the bulky *ortho* substituents. The downfield shift (approximately 0.3 to 0.4 p.p.m.) of the aromatic proton resonances in octamethyloctahydroanthracene (**11**) compared to octamethyl- and decamethylhydrindacene (**8** and **9**) can be attributed to more compression interaction exerted by the *gem* dimethyls of a six membered ring (**11**) than by those of a five membered ring in **8** and **9**. 1,2,4,5-Tetra-*t*-butylbenzene exhibits the largest shift; 0.58 p.p.m. relative to tetraisopropylbenzene (**10**) and 0.51 p.p.m. relative to the model compound (**11**). Presumably this is a reflection of the increased compression exerted by the crowded *ortho*-*t*-butyls in **12** on the aromatic protons.[3]

Variations in the compression forces can similarly account for chemical shift differences of compressed aromatic hydrogens (1 and 4) in the substituted aromatic ring of the naphthalene derivatives, **1**, **3**, **5**, **6**, and **7**. In Table III the downfield shifts of the compressed hydrogens (1 and 4) relative to the hydrogens of the unsubstituted ring are compared for the series. The diol **7** shows the maximum downfield shift for hydrogens 1 and 4 (24.6 c.p.s.). This compound probably has the maximum compression of these hydrogens as a result of maximum crowding between the substituted *t*-butyl groups. The compression effect is progressively less in the

[3]B. V. Cheney (17) has shown that magnetic deshielding of aromatic protons by steric interactions is not only dependent upon the separation of the interacting hydrogens. The steric shift observed for various structural types was much better correlated to the component of the hydrogen–hydrogen repulsive force along the H—C bond axis. Nevertheless, in the present series of aromatic compounds of closely related structures, there is some justification for qualitatively relating the deshielding of aromatic protons to the expected compression forces.

12		2.27

*Measurements were determined in $CDCl_3$ containing TMS; concentrations were 0.4 molar.

ester (**6**) and the cyclic anhydride (**5**). The result in the latter case indicates that crowding and the resulting repulsion between the groups can be partially relieved by cyclization.

Electronic spectra of *o*-di-*t*-butylbenzene systems are characterized by loss of the usual vibrational fine structure typical of benzenoid hydrocarbons in the 240–280 mμ region. This effect has been observed for certain highly substituted naphthanoid hydrocarbons such as 1,2,3,4-tetramethylnaphthalene (12) but not in 1,4-di-*t*-butylnaphthalene (3) or even in 2,3-di-*t*-butylquinoxaline (6). On the other hand, *peri* di-*t*-butyl groups cause a very significant alteration in the naphthalene spectrum through bathochromic shifts and loss of fine structure (5). The geometry of naphthalene brings substituents at the 1,8-positions in close proximity to each other in space even when compared to *ortho* substituents.

TABLE III

Chemical shift differences* between aromatic hydrogens 1 and 4, and 5, 6, 7, and 8 of 2,3-di-*t*-butylnaphthalene derivatives

Compound	Δ c.p.s.
1	12.3
3	11.0
5	15.9
6	18.4
7	24.6

*The differences were estimated by measuring the downfield shift of the singlet due to H-1 and H-4 relative to the centre of the symmetrical multiplet for H's 5,6,7, and 8. The results were for $CDCl_3$ solutions (Table I). The same trend was shown in CCl_4 solution but compound 7 was not sufficiently soluble in CCl_4 to complete the series.

This could result in more crowding in 1,8-di-*t*-butylnaphthalene than in compounds bearing adjacent *tertiary* butyl groups.

The u.v. spectra of the anhydride (**5**), dimethylester (**6**), diol (**7**), and starting ketone (**1**), the model for comparison, are compared in Fig. 1. Only minor differences were noticed in the strong band near 230 mμ. The dimethylester (**6**) and diol (**7**) exhibited a similar loss of fine structure in the regions near 320 and 280 mμ. This provides an interesting comparison with the same effect observed in the benzene series (9) which has been the subject of considerable speculation. As pointed out before (1, 9), the alteration in the spectra due to two adjacent *t*-butyl groups is only slight compared to that for a seriously distorted aromatic system. The

loss of fine structure in 2,3-di-*t*-butylnaphthalene derivatives (**6** and **7**) is not attributed to out-of-plane warping of the aromatic rings in the ground state because this is not consistent with the n.m.r. evidence (Table III). Qualitatively the perturbations of the aromatic fine structure in the u.v. spectra follows the same trend as observed in the comparison of aromatic hydrogens 1 and 4 in the n.m.r. spectra. The small spectral changes are undoubtedly to be associated with the angle deformations due to repulsions between *t*-butyl groups and not to a warped or puckered aromatic ring. Angle deformations probably provide the driving force for cyclizations of various derivatives of *o*-di-*t*-butylbenzene (13). It is of interest to find that the anhydride (**5**) exhibits fine structure in the u.v. (especially in the 280 mμ region, Fig. 1). This is to be expected if the angle deformation is at least partially relieved on cyclization.

Experimental

Ultraviolet spectra were recorded in cyclohexane on a Perkin–Elmer Model 202 Spectrophotometer. Nuclear magnetic resonance spectra were recorded on a Varian A-60 spectrometer in deuterochloroform containing tetramethylsilane as internal standard. Infrared (i.r.) spectra were recorded on a Perkin–Elmer Infracord Model 137 in potassium bromide pellets. Melting points were determined by the capillary method on a Thomas Hoover apparatus and are uncorrected. Elemental analyses were determined by Dr. C. Daessle, Montreal. Samples of aromatic hydrocarbons **8**, **9**, **10**, and **11** were available from earlier syntheses (14).

2-Keto-1,1,4,4-tetramethyl-1,2,3,4-tetrahydroanthracene (1)

Naphthalene (45 g, 0.35 mole) and 2,2,5,5-tetramethyltetrahydrofuranone (15) (50 g, 0.35 mole) were dissolved in 375 ml of carbon disulfide in a 1 l flask equipped with a stirrer, thermometer, reflux condenser, and gas trap. Commercial anhydrous aluminum chloride (94 g, 0.71 mole) was added to the above solution over a 5 min period while the temperature of the reaction mixture was maintained below 45°. The resulting reaction mixture was stirred at room temperature for 8 h. By the end of this time, the reaction mixture had separated into 2 layers, a carbon disulfide layer which contained unreacted naphthalene (21 g) and a lower thick complex layer. The complex layer was poured into ice water, the organic material extracted with ethyl ether, and the extract dried over anhydrous sodium sulfate. Distillation of the solvent left a dark amorphous residue. This product was heated at 200°/1 mm in a Späth tube and 25.6 g (29%) of crude crystalline material distilled. Recrystallization of this from petroleum ether gave 13 g of colorless crystals; m.p. 84–85°. Sublimation raised the melting point to 88–89°. The i.r. spectrum showed carbonyl absorption at 1710 cm^{-1}. The n.m.r. and u.v. spectral results are given in the Discussion.

Anal. Calcd. for $C_{18}H_{20}O$: C, 85.71; H, 7.94. Found (mass spectrum, 252): C, 85.68, 85.88; H, 8.02, 8.18.

The above synthesis of **1** was accompanied by the formation of rearrangement byproducts analogous to those reported in the benzene series (16). Details on such rearrangements will be published separately. In subsequent runs to prepare **1**, the progress of the cyclialkylation was followed by working up aliquots and analyzing for **1** by vapor phase chromatography (v.p.c.) using an F and M Model 500 instrument. Suitable separations were obtained on a 6 ft × ¼ in. column containing 5% apiezon on Chromosorb W and programming from 100 to 275°.

2,3-Dioxo-1,1,4,4-tetramethyl-1,2,3,4-tetrahydroanthracone (3)

2-Ketotetramethyltetrahydroanthracene (**1**) (12.8 g, 0.0508 mole) was dissolved in 110 ml of dioxane, selenium dioxide (5.99 g, 0.0532 mole) added, and the reaction mixture stirred while heating under reflux for 43 h. The precipitated selenium was filtered, the solvent distilled under reduced pressure, and the residue crystallized from petroleum ether to yield yellow crystals (10.8 g, 80%). Sublimation gave yellow crystals; m.p. 120–121°. The (i.r.) spectrum showed carbonyl absorption at 1725 cm^{-1}. The u.v. spectrum had maxima at 225 mμ (ε 87 393), 275 mμ (ε 4829), 286.6 mμ (ε 4132), 307 mμ (ε 1348), 323 mμ (ε 556). The n.m.r. spectral results are shown in Table I.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.20; H, 6.77. Found: C, 81.31, 81.13; H, 6.91, 6.77.

2,3-Naphthalenediisobutyric Acid, Anhydride (5), and Dimethyl Ester (6)

The above diketone (**3**) (10.0 g, 0.0396 mole) was dissolved in a solution containing 69 ml of dioxane and 36 ml of water. Periodic acid dihydrate (12.96 g, 0.0480 mole) was added and the reaction mixture was heated in a constant temperature bath at 60° ± 0.5° for 10 h. The solvent was distilled at 80° under reduced pressure. The residue was dissolved in ethyl ether and the ether solution extracted with 8% sodium hydroxide. The alkaline extract was boiled with decolorizing charcoal, filtered, and the solution acidified with hydrochloric acid to yield the crude acid (11.4 g, 96%). Recrystallization from 1:1 acetone–methanol yielded colorless prisms, m.p. 198° (decomposition). The i.r. spectrum exhibited carbonyl absorption at 1710 cm^{-1}. The u.v. spectrum (CH_3OH solution) had maxima at 230 mμ (ε 74 100) and 273.5 mμ (ε 3740).

A sample of the dicarboxylic acid (0.50 g) was heated under reflux in 5 ml of acetic anhydride for 3 h. The acetic anhydride was distilled under reduced pressure to give a quantitative yield of brown crystalline solid. Sublimation gave colorless crystals; m.p. 161–162°. The i.r. spectrum exhibited carbonyl bands at 1780 and 1740 cm^{-1} attributed to the anhydride (**5**). The u.v. and n.m.r. results are given in the Discussion.

Anal. Calcd. for $C_{18}H_{18}O_3$: C, 76.54; H, 6.45. Found: C, 76.33, 76.51; H, 6.54, 6.47.

The dicarboxylic acid (8.00 g, 0.027 mole) was dissolved in 400 ml of ethyl ether and to this solution was added a freshly prepared ethereal solution of diazomethane until the yellow color of diazomethane persisted.

The reaction mixture was stored in the refrigerator overnight, then extracted with 5% sodium hydroxide to recover unreacted acid. The ether solution was dried, the solvent distilled, and the residue recrystallized from petroleum ether to give 6.64 g (76%) of product; m.p. 123–124°. Sublimation yielded colorless crystals, m.p. 123.5–124°. The i.r. spectrum exhibited ester carbonyl absorption at 1725 cm^{-1}. The u.v. and n.m.r. spectral results are given in the Discussion.

Anal. Calcd. for $C_{20}H_{24}O_4$: C, 73.14; H, 7.37; O, 19.49. Found: C, 73.07, 72.85; H, 7.36, 7.16; O, 19.57, 19.99.

β,β′-*Dihydroxy-2,3-di-t-butylnaphthalene (7)*

A solution of the above dimethyl ester (**6**) (5.00 g, 0.0153 mole) in 200 ml of ethyl ether was added dropwise to an ethereal solution containing 2.3 g of lithium aluminum hydride and the mixture was heated under reflux in a nitrogen atmosphere for 24 h. The reaction mixture was slowly added to crushed ice and made acidic with hydrochloric acid. The residue obtained from working up the ether solution was recrystallized from petroleum ether to yield 3.22 g (78%) colorless crystals; m.p. 100.5–101.5°. The i.r. spectrum showed hydroxyl absorption at 3450 cm^{-1}. Carbonyl absorption was absent. The u.v. and n.m.r. spectral results are given in the Discussion.

Anal. Calcd. for $C_{18}H_{24}O_2$: C, 79.37; H, 8.90; O, 11.75. Found: C, 79.16, 79.39; H, 8.59, 8.60; O, 12.25, 12.01.

Influence of Lewis acids on the Diels–Alder reaction. II. Rearrangement of 1- and 1,4-substituted diethyl 7-oxabicyclo[2·2·1]2,5-heptadiene-2,3-dicarboxylate adducts to 4- and 4,6-substituted diethyl 3-hydroxyphthalates[1]

A. W. McCulloch,[2] B. Stanovnik,[3] D. G. Smith, and A. G. McInnes
Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received June 25, 1969

Direct formation of 4- or 4,6-alkyl and aryl substituted diethyl 3-hydroxyphthalates from the correspondingly substituted Diels–Alder adducts of 2- or 2,5-substituted furans and diethyl acetylenedicarboxylate is promoted by $AlCl_3$ in CH_2Cl_2 at room temperature. The first adduct of 2,5-diphenylfuran to be isolated has been obtained from the same reaction at −20°. The aromatic compounds can be obtained alternatively by treating the adducts with BF_3 or H_2SO_4: where the adducts can be prepared by conventional means this two-step procedure has resulted in greatly improved yields. Adducts of furan and furfuryl alcohol are similarly converted to substituted phenols. HCl effected conversion only in the case of adducts carrying a bridgehead aryl substituent; in all other cases HCl added to the substituted double bond. The mechanism of the adduct rearrangement is discussed.

Canadian Journal of Chemistry, 47, 4319 (1969)

Introduction

Suitably substituted Diels–Alder adducts provide the most versatile route by which a benzene ring may be formed while simultaneously introducing substituents (1). The adducts usually possess a six-membered carbocyclic ring containing one or two double bonds and may have in addition a 1,4-bridge consisting of one or two carbon atoms or a heteroatom. Aromatization is induced by dehydrogenation (2), dehydrohalogenation (3), deamination (4), pyrolytic elimination of substituents (5), or a 1,4-bridge (6), or fission of a 1,4-oxygen bridge followed by loss of H_2O (7). Less general procedures for the annelation of readily available molecules to benzene rings include the catalytic trimerization of acetylenes (8), the reaction of pyrylium salts with nitromethane (9), or triphenylphosphinemethylene (10), the condensation of pyrones with Grignard reagents (11), the ketovinylation of β-dicarbonyl compounds followed by intramolecular cyclization or further reaction with β-chlorovinyl ketones (12), and the reaction of enamines with esters of acetylenedicarboxylic acid (13).

In preliminary communications (14,15) we reported that Lewis acids produced an enormous increase in the rate of formation of 1- and 1,4-substituted diethyl 7-oxabicyclo[2·2·1]2,5-heptadiene-2,3-dicarboxylates (**1**) from suitably substituted furans and diethyl acetylenedicarboxylate (DEAD), and also promoted the rearrangement of these adducts to 4- and 4,6-substituted derivatives of diethyl 3-hydroxyphthalate (**2**). Reactions using ethyl propiolate behaved similarly (15). Subsequently, other workers have reported that the dimethyl ester corresponding to **1** (R_1 = 4-methoxyphenyl; R_2 = H) rearranged to the analogue of **2** (R_1 = 4-methoxyphenyl; R_2 = H) in the presence of warm acetic acid (16).[4]

This paper discusses in full the mechanism and experimental conditions for the conversion of **1** to **2**. The derivatives **2** prepared in this way, with one exception **2***a*, contain *three different types* of substituents, one of which is a phenolic hydroxyl group. Diels–Alder reactions using dienes such as 2-acetoxyfuran (17), 1,4-diacetoxybutadiene (5), and substituted 4-hydroxy-α-pyrones (18) have been used previously to introduce a phenolic hydroxyl substituent, but these methods seem to be of limited scope as compared to our method. The substituent migrations which occur in the transformation of **1** to **2**, although not particularly new from a chemical standpoint, are nevertheless the first to be reported in the direct formation of benzene derivatives from Diels–Alder adducts. High yields of **2** and the possibility of increasing the number of types of substituents

[4]During the final stages of preparation of this manuscript Vogel and co-workers published (30) an account of work closely related to that previously reported by us (14,15) and by Ayres and Smith (16). Their work involved acid-catalyzed rearrangement of a variety of methyl or methoxyl-substituted oxanorbornadienes. The spectral data reported for compounds analogous to **2***b* and **2***e* are in full agreement with our own data.

*Reactions were carried out in CH_2Cl_2 and were 0.1 *M* in addends and $AlCl_3$.
†Reactions were carried out in CH_2Cl_2 and were 0.3 *M* in **1**: the solutions were treated with excess BF_3 or H_2SO_4.
‡**1***f* could only be isolated in 40% yield but was converted to **2***f* quantitatively. Overall yield is therefore 40%.

suggests that our procedure should prove generally useful for the synthesis of a large number of benzene derivatives which would be difficult by more conventional routes.

Our studies on the formation of **1** in the presence of Lewis acids are not relevant to the present work and will therefore be published separately.

Results and Discussion

The proton magnetic resonance (p.m.r.) spectral evidence used in the structural elucidation of the compounds discussed below is detailed in Table I.

Preparation and Structures of 1

Thermal condensation of the addends (19) enabled the adducts **1***a–e* to be isolated in excellent yield. However, attempts to prepare **1***f* by heating the addends at temperatures up to 180° in a sealed tube were unsuccessful. Indeed no adducts of 2,5-diphenylfuran have been reported previously, and this can undoubtedly be attributed to a reduction in diene character as a result of extensive π-delocalization due to coplanarity of the aromatic and furan rings. Conversion of the addends to crystalline **1***f* was, however, promoted by $AlCl_3$ (see Experimental).

The structures of **1***a–f* were established from their p.m.r. spectra although their identity was quite clear from their mode of formation. Compounds **1***a*, *e*, and *f* belong to the symmetry group C_s and consequently gave characteristic p.m.r. signals for two chemically equivalent olefinic hydrogens, bridgehead substituents, and carbethoxy groups. The aromatic hydrogens in **1***f* gave a complex multiplet (ABCDE system? - due to asymmetry at C_1 and C_4), and the olefinic and bridgehead hydrogens of **1***a* an AXX'A' spectrum. The unsymmetrical adducts **1***b*, *c*, and *d*, on the other hand, gave characteristic ABX systems for the two olefinic and bridgehead hydrogens as well as signals for the bridgehead substituents and two chemically non-equivalent carbethoxy groups. An interesting example of long-range spin–spin coupling across five bonds (20) (J_{H_5,CH_3} = 0.4 Hz) was observed in **1***b*.

Preparation and Structures of 2

Adducts **1***a–f* rearranged in the presence of BF_3 or H_2SO_4 in CH_2Cl_2 to compounds of type **2** or to compound **3** (see Table II).

The p.m.r. and infrared (i.r.) spectra of **2***a* and the observation that it gave 3-hydroxyphthalic acid on saponification establishes the structure as diethyl 3-hydroxyphthalate.

The unsymmetrical tetra-substituted benzene derivatives gave p.m.r. signals with chemical shifts, multiplicities, and intensities consistent with the numbers and types of hydrogens shown in structures **2***b*, **2***d*, and **3**. Each compound gave a characteristic AB pattern for two *ortho* coupled aromatic hydrogens. In two compounds, the proton giving rise to the low-field half of the AB pattern was long-range coupled (21) to the benzylic methyl (**2***b*) or methylene (**3**) hydrogens, while in all three, the proton giving rise to the high-field part of the AB system had a chemical shift consistent with the presence of an *ortho* phenolic hydroxyl group (22). A proton *ortho* to

SCHEME 1

a carbonyl function would give a signal at lower field (ca. τ 2.0) (22). This evidence together with the known structures of **1***b*, *c*, and *d* and the fact that **1***a* gave diethyl 3-hydroxyphthalate (**2***a*), requires that the compounds be diethyl 6-methyl-3-hydroxyphthalate (**2***b*), diethyl 6-phenyl-3-hydroxyphthalate (**2***d*), and 7-carbethoxy-6-hydroxyphthalide (**3**). The i.r. spectra were consistent with these structures. The structure of **3** was confirmed by its saponification to the known 7-carboxy-6-hydroxyphthalide (23).

The structure of **2***e* was established from the following evidence: (*a*) it could be converted to isodurenol (**7**) via Scheme 1; (*b*) i.r. studies on a 0.005 *M* solution of **2***e* in CCl_4 indicated intramolecular hydrogen bonded hydroxyl and ester carbonyl groups as well as a free ester carbonyl group; (*c*) it could be converted to an anhydride (**4***g*) and the phenolic hydroxyl group of this compound could be methylated (**4***h*); and (*d*) the p.m.r. spectra of **2***e*, **4***g*, **4***h*, and **7** contained signals with characteristic chemical shifts, multiplicities, and intensities for each proton type. From (*b*), (*c*), and (*d*) it can be deduced that the phenolic hydroxyl and two carbethoxy groups in **2***e* have the same relative orientation as in diethyl 3-hydroxyphthalate (**2***a*). This structural feature together with (*a*) establishes that the two methyl substituents on C_2 and C_3 of isodurenol (**7**) must have been derived from the two carbethoxy groups of **2***e*. It follows that the two remaining methyl substituents at C_4 and C_6 of isodurenol must have been the original methyl substituents which were observed in (*d*) for **2***e*. We can, therefore, state unambiguously that **2***e* is diethyl 4,6-dimethyl-3-hydroxyphthalate and **4***g* and **4***h* are 4,6-dimethyl-3-hydroxy- and 3-methoxyphthalic anhydride. Compound **6** must be 2,3-dihydroxymethyl-4,6-dimethylphenol.

The single aromatic hydrogen in **2***e*, **4***g*, and **4***h* is long-range coupled to about the same extent with both methyl substituents (21) but is not similarly coupled to the methoxyl hydrogens (24) in **4***h*. These observations provide strong evidence that the aromatic hydrogen is *ortho* to both methyl substituents in all these compounds and confirms their structures by an alternative procedure.

The structure of the *m*-terphenyl derivative (**2***f*) was established in a similar manner to that of **2***e* [see (*b*), (*c*), and (*d*) above]. The 11 aromatic hydrogens in **2***f* covered the range from τ 2.3 to 2.7 and no characteristic signal was observed for a single aromatic hydrogen deshielded by an *ortho* carbonyl function (ca. τ 2.0) (22). This evidence, together with the structure of the adduct (**1***f*) from which **2***f* is produced, requires that the latter be diethyl 4,6-diphenyl-3-hydroxyphthalate and **4***i* be 4,6-diphenyl-3-hydroxyphthalic anhydride.

Optimum Conditions for the Formation of 2a, b, d, e, and f and 3

Table II lists the yields of benzene derivatives (**2** or **3**) formed either directly by a one-step synthesis from the addends in the presence of $AlCl_3$ or indirectly via Diels–Alder adducts (**1**) through the action of BF_3 or H_2SO_4.

When alkyl-substituted furans or 2-phenylfuran were used as the diene component in the one-step synthesis, yields of **2** were only about 50%; no aromatic compound was formed in the case of furan or furfuryl alcohol. The lack of reaction or low yields could be attributed to extensive diene polymerization caused by $AlCl_3$ and/or precipitation of insoluble diene-$AlCl_3$ complexes. One or other of these side reactions became more dominant if the $AlCl_3$ concentration was increased. Attempts to replace $AlCl_3$ with excess BF_3 or BCl_3 also led to lower yields of product indicating that these Lewis acids also promote the side reactions. The latter were less important in the case of 2,5-diphenylfuran where yields of **2***f* as high as 75% were obtained when the addends and $AlCl_3$ were equimolar.

The side reactions could be reduced or eliminated, and the scope of the synthetic procedure increased, by first converting the addends to the

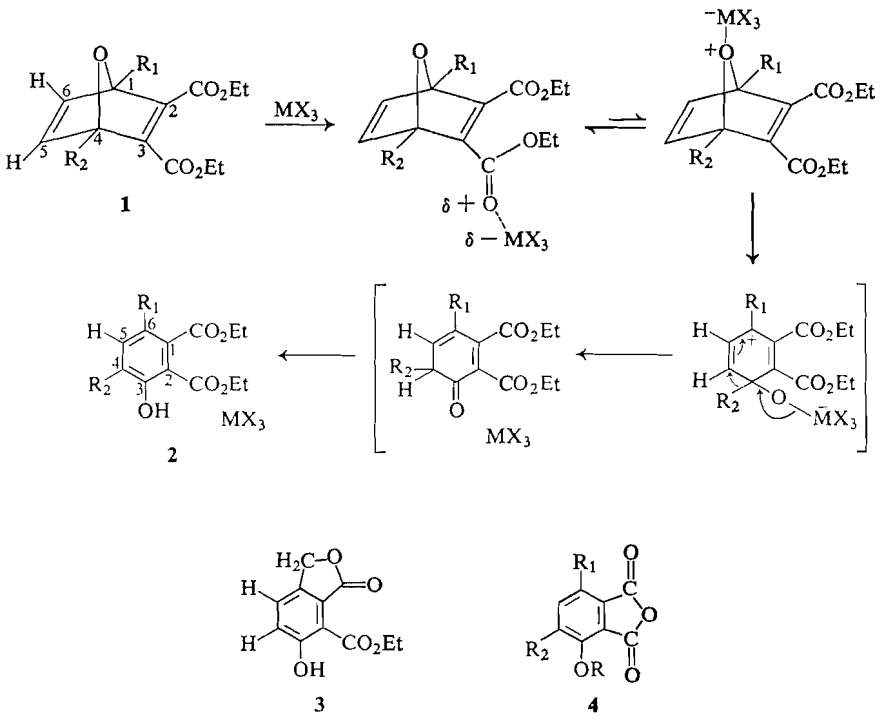
For personal use only.



a) $R_1 = R_2 = H$ *d*) $R_1 = C_6H_5$; $R_2 = H$ *g*) $R_1 = R_2 = CH_3$; $R = H$
b) $R_1 = CH_3$; $R_2 = H$ *e*) $R_1 = R_2 = CH_3$ *h*) $R_1 = R_2 = R = CH_3$
c) $R_1 = CH_2OH$; $R_2 = H$ *f*) $R_1 = R_2 = C_6H_5$ *i*) $R_1 = R_2 = C_6H_5$; $R = H$

Scheme 2

corresponding Diels–Alder adduct (**1**) in the absence of Lewis acid. The adducts (**1***a–e*) could be obtained in about 95% yield and rearranged in the presence of excess BF_3 or H_2SO_4 to the corresponding benzene derivatives (**2***a*, *b*, *d*, *e* and **3**). Essentially quantitative yields (>90%) of **2***b*, *d*, and *e* could be obtained, while **2***a* and **3** were isolated in about 40% yield. Since the adduct (**1***f*) can only be isolated in about 40% yield in the presence of $AlCl_3$ the two-step procedure for forming **2***f* is inferior to the direct method although acid promotes quantitative conversion to the aromatic compound.

In the one-step procedure, rates of conversion to alkyl-substituted derivatives of **2** were slower by a factor of about 70 than for the aryl-substituted derivatives.

Boron trichloride could be used in place of BF_3 or H_2SO_4 in the two-step method, but reaction times were increased by a factor of 20 if $SnCl_4$ was used. Aluminium chloride does, of course, catalyze the rearrangement of **1** to **2** but is much less soluble in the CH_2Cl_2 solution of the adduct and in some cases precipitation of adduct-$AlCl_3$ complexes occurs.

While H_2SO_4 is generally effective as a catalyst for the rearrangement of **1** to **2** or **3**, halogen acids are not. Although anhydrous HCl effects quantitative conversion of **1***d* and **1***f* to **2***d* and **2***f*, it adds (*cis* and *trans*) to the 2,3-double bond of **1***a*, *b*, *c*, and *e*. The structures of the products and mechanisms of the addition reactions of some of these adducts (**1**) will be reported in full elsewhere.

The structures of the aromatic compounds (**2**) formed from the adducts (**1**) suggest the mechanism of rearrangement outlined in Scheme 2. Coordination or protonation of the bridge oxygen in the adduct will induce bridge cleavage which is followed by migration of the unsubstituted double bond and substituent geminal to the complexed or protonated oxygen atom. Enolization then yields **2**. Where $R_2 = H$, bridge cleavage may be followed by elimination of this proton and double bond migration.

Substituents at the bridgehead, e.g. methyl or phenyl, will facilitate reaction by inductive and resonance stabilization of the carbonium ion formed on bridge cleavage. Consequently, excellent yields of **2** were obtained from adducts carrying these substituents at the bridgehead. Moreover, the rates of conversion of phenyl-substituted adducts to the corresponding derivatives of diethyl 3-hydroxyphthalate were greater than those for alkyl-substituted adducts (see Table II). This indicates that resonance stabilization of the transition state is more significant than inductive stabilization, as would be expected. In the case of the aryl-substituted compounds the rate of HCl-promoted bridge cleavage must be greater than that of HCl addition to the double bond while the reverse is true of the alkyl-substituted derivatives.

Rearrangement of the adducts of furan (**1***a*) and furfuryl alcohol (**1***c*), which lack substituents at the bridgehead, to **2***a* and **3** occurs more slowly and lower yields are obtained. The adduct of dimethyl acetylenedicarboxylate and 2,2′-bifuryl has been reported to be stable to acid (25). In view of our results, it seems probable that cleavage of the oxygen bridge of this compound might be induced by BF_3 or H_2SO_4.

Experimental

The p.m.r. spectra were obtained on a Varian A-60A spectrometer equipped with a V-6058A spin-decoupler using $CDCl_3$ as solvent (unless stated otherwise) and tetramethylsilane as internal standard. The i.r. spectra were recorded on either a Perkin–Elmer model 521 or 237 spectrometer.

Chromatographic separations were carried out on Mallinckrodt silicic acid (100–150 mesh) using $CHCl_3$ as eluant.

Preparation of ***1****a–e in the Absence of Lewis Acid*

The following adducts were prepared in the absence of solvent from the appropriate furan and diethyl acetylenedicarboxylate at 100° by the method of Alder *et al.* (19). Essentially quantitative conversion (>95%) of addends to adduct occurred in 4 h and the adducts were obtained in a pure state by chromatography.

1*a* ($\eta_d^{23} = 1.4795$), **1***b* ($\eta_d^{19} = 1.4749$), **1***c* ($\eta_d^{23} = 1.4971$), **1***d* ($\eta_d^{19} = 1.5240$) and **1***e* ($\eta_d^{19} = 1.4680$) were obtained as yellow oils.

Preparation of ***1****f in the Presence of Lewis Acid*

Two solutions containing 2,5-diphenylfuran (0.2 *M*) and DEAD (0.2 *M*) plus $AlCl_3$ (0.28 *M*) in CH_2Cl_2 were prepared separately, cooled to −20° and mixed. After 1 h at this temperature the reaction was stopped by washing the dark red reaction solution with water to remove the Lewis acid. After drying and removing the solvent the residue was triturated with petroleum ether to remove starting materials and leave the adduct as an insoluble residue.

1*f* was obtained as needles from ether–petroleum ether in 40% yield, m.p. 103–104°.

Direct Formation of 2b, d, e, and f from Furans and DEAD in the Presence of $AlCl_3$

The experimental procedure was the same as given above for the preparation of **1***f* except that all 3 reagents were equimolar, and the solutions were allowed to stand at room temperature until no further reaction occurred.

The reaction products were purified by chromatography or crystallization. Yields of **2** prepared in this way are given in Table II. This procedure can not be used with furan or furfuryl alcohol because of side reactions.

Using excess BF_3 or BCl_3 in place of $AlCl_3$ caused extensive diene polymerization which reduced the yields of **2**.

2*b* was obtained as a yellow oil, $\eta_d^{19} = 1.5083$. Characteristic i.r. absorptions (liquid film): hydrogen bonded (1675 cm^{-1}) and free (1735 cm^{-1}) carbonyl functions, and hydrogen bonded hydroxyl group (broad band with maximum at 3100 cm^{-1}).

2*d* was obtained as a yellow–orange oil, $\eta_d^{19} = 1.5630$. Characteristic i.r. absorptions (liquid film): hydrogen bonded (1675 cm^{-1}) and free (1730 cm^{-1}) carbonyl functions.

2*e* was obtained as a yellow oil, $\eta_d^{19} = 1.5186$. Characteristic i.r. absorptions (0.005 *M* in CCl_4): hydrogen bonded (1673 cm^{-1}) and free (1731 cm^{-1}) carbonyl functions, and hydrogen bonded hydroxyl group (measured after deuteration, at 2340 cm^{-1}).

Saponification of **2***e* with 1 *N* KOH followed by acidification gave an acid which was sublimed at 140–145° and 0.01 mm pressure to yield **4***g* in virtually quantitative yield, m.p. 178–179°. Characteristic i.r. absorptions (KBr disc): anhydride carbonyls (1760 and 1830 cm^{-1}) and phenolic hydroxyl (3450 cm^{-1}).

4*g* was converted to **4***h* with diazomethane in ether and the latter crystallized as colorless prisms from this solvent, m.p. 151–152°. Characteristic i.r. absorptions (KBr disc): anhydride carbonyls (1770 and 1845 cm^{-1}).

2*f* was obtained from methanol as colorless plates, m.p. 128–129°.

Anal. Calcd. for $C_{24}H_{22}O_5$ (mol. wt. 386): C, 73.83; H, 5.68; O, 20.49. Found (390 (osmometer)): C, 73.83; H, 5.76; O, 20.37. In ethanol $\lambda\lambda_{max}$ 232 (ε 33 500), 330 (ε 6 500) mμ; 0.025 *N* NaOH in 96% ethanol 254 (ε 22 900), 287 (ε 10 700), 365 (ε 9 900) mμ. Characteristic i.r. absorptions (0.005 *M* in CCl_4): hydrogen bonded (1665 cm^{-1}) and free (1732 cm^{-1}) carbonyl functions, and hydrogen bonded hydroxyl group (measured after deuteration at 2320 cm^{-1}).

2*f* was converted to diethyl 3-methoxy-4,6-diphenylphthalate with diazomethane in ether and crystallized from ethanol as needles, m.p. 96°.

Anal. Calcd. for $C_{25}H_{24}O_5$ (mol. wt. 404): C, 74.24; H, 5.98; O, 19.78. Found (399 (osmometer)): C, 74.13; H, 5.89; O, 19.74. In ethanol $\lambda\lambda_{max}$ 245 (ε 29 600), 294 (ε 4 150) mμ. Characteristic i.r. absorption (KBr disc): ester carbonyl (1730 cm^{-1}).

2*f* was converted to **4***i* by heating it with acetic acid saturated with HBr in a sealed tube at 110–125° for 7 h. **4***i* crystallized from the acetic acid solution on cooling

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and was recrystallized from CCl_4 as needles, m.p. 190–191°.

Anal. Calcd. for $C_{20}H_{22}O_4$ (mol. wt. 316): C, 75.94; H, 3.82; O, 20.83. Found (317 (osmometer)): C, 75.24; H, 3.97; O, 20.68. In ethanol $\lambda\lambda_{max}$ 237 (ε 26 200), 300 (ε 6 370), and 355 (ε 6 300) mμ. Characteristic i.r. absorptions (KBr disc): anhydride carbonyls (1750 and 1830 cm^{-1}) and phenolic hydroxyl (3450 cm^{-1}).

Preparation of 2a, b, d, e, and f and of 3 from the Corresponding Adducts 1

(a) In the Presence of BF_3

Solutions of the adducts in CH_2Cl_2 (0.33 *M*) were cooled in ice while saturating with BF_3 and then allowed to stand at room temperature. The reactions were stopped by removing the Lewis acid with water and the reaction products purified by chromatography or crystallization.

(b) In the Presence of H_2SO_4

Solutions of the adducts in CH_2Cl_2 were cooled in ice and a slight molar excess of concentrated H_2SO_4 added dropwise with stirring. After standing at room temperature the reactions were worked up as in (*a*).

The yields of **2** prepared in (*a*) and (*b*) are given in Table II.

2*a* was obtained as a yellow oil.

Saponification of **2***a* gave 3-hydroxyphthalic acid. Recrystallization from water gave colorless needles which on slow heating had m.p. 195–196° [reported m.p. for 3-hydroxyphthalic anhydride is 198–199° (29)]. The p.m.r. and i.r. spectra of this material were identical to those of an authentic sample of 3-hydroxyphthalic acid prepared by diazotization of 3-aminophthalic acid.

3 was obtained as colorless prisms from benzene–petroleum ether, m.p. 179–179.5°. Characteristic i.r. absorptions (KBr disc): α,β-unsaturated γ-lactone (1750 cm^{-1}) and ester (1728 cm^{-1}) carbonyls, and phenolic hydroxyl (broad band with maximum at 3200 cm^{-1}).

Saponification of **3** gave the free acid (90%), crystallized from acetone as colorless prisms, m.p. 216–217° [lit. (23) m.p. 212–213°].

Action of Hydrogen Chloride on 1d and 1f

When solutions of **1***d* or **1***f* (0.1 *M*) in CH_2Cl_2 were saturated with hydrogen chloride and left standing for 10 min at room temperature they were quantitatively (>95%) converted to **2***d* and **2***f*.

Conversion of 2e to Isodurenol

2*e* (8.38 g) was acetylated in 15 min at 100° with acetic anhydride (5.5 ml) in pyridine (10 ml). After working up in usual manner, **5** was obtained as a viscous oil (9.22 g, 95% yield). Characteristic i.r. absorption (liquid film): ester (1730 cm^{-1}) and phenolic acetate (1770 cm^{-1}) carbonyls.

Without further purification **5** (7.3 g) was reduced with $LiAlH_4$ (3 g) in ether (260 ml) in a nitrogen atmosphere. After standing for 1 h at room temperature and at reflux for a further 2 h the excess $LiAlH_4$ was destroyed by adding ethyl acetate (45 ml). The reaction solution was then worked up in the usual manner to yield a residue of **6** which crystallized from petroleum ether–ethyl acetate as cream colored needles (2.12 g, 50% yield), m.p. 125–128°. Characteristic i.r. absorption (KBr disc): hydroxyl (broad band, with maxima at 3350 and 3100 cm^{-1}).

6 (500 mg) was dissolved in 5% NaOH (135 ml) and Raney alloy (6 g) added in small portions with mechanical agitation. After standing for 1 h at room temperature, the mixture was heated for a further 1 h on a steam bath. The solution was then cooled, filtered, and acidified with concentrated hydrochloric acid. A colorless precipitate was collected by filtration and subsequently crystallized from petroleum ether to give **7** as colorless needles (298 mg, 72%), m.p. 79.5–81.5°. No depression in m.p. was observed on admixing with authentic isodurenol (**7**), and the i.r. and p.m.r. spectra of the synthetic material were identical to those of an authentic sample of isodurenol.

Dibenzo[*a*,*d*]cycloheptene and related compounds. II.[1] The synthesis of some 11-substituted dibenzo[*b*,*e*]azepin-6-one, 5-substituted dibenzo[*a*,*d*]cycloheptene, and 12-substituted dibenzo[*a*,*d*]cyclooctene derivatives

K. Ackermann, J. Chapuis, D. E. Horning, G. Lacasse, and J. M. Muchowski[2]
Bristol Laboratories of Canada, Candiac, Quebec

Received July 16, 1969

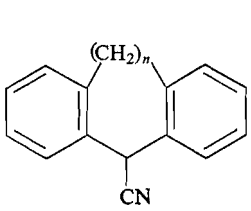
The synthesis of several 11-substituted-5,6-dihydro-11*H*-dibenzo[*b*,*e*]azepin-6-ones, and an improved method of preparing 5-cyano-10,11-dihydro-5*H*-dibenzo[*a*,*d*]cycloheptene and 12-cyano-5,6,7,12-tetrahydrodibenzo[*a*,*d*]cyclooctene are described.

A description of the synthesis of epoxides from diaryl ketones and dimethylsulfonium methylide by a modified technique is given.

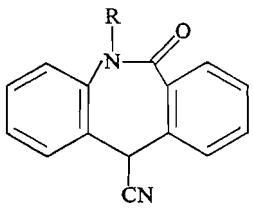
The nuclear magnetic resonance spectra of several of the 11-substituted dibenzo[*b*,*e*]azepin-6-ones are interpreted on the basis of a slow interconversion between diastereomeric boat conformers in which the C-11 substituent is quasi axial or quasi equatorial.

Canadian Journal of Chemistry, 47, 4327 (1969)

In connection with the synthesis of some compounds of potential pharmacological utility, we recently found it necessary to have available large amounts of the nitriles **1** (n = 2, 3) and **2**. The 7-membered nitrile **1** (n = 2) is well known, and has been prepared from the corresponding chloride and silver cyanide (2) or cuprous cyanide (3). The 8-membered nitrile (n = 3) has



1



2

apparently been prepared in the same way with silver cyanide, but it was not characterized (4). When these methods were applied to the synthesis of derivatives of **2**, mixtures which contained only moderate amounts of the desired materials were obtained. The solution to this problem was based on the observation that the epoxide **4** (n = 2) could be prepared in variable yield from dibenzosuberone (**3**, n = 2) and dimethylsulfonium methylide at 30–50°. This was doubly surprising in view of the known instability (5) of this ylid, and also because of a recently reported (6) failure to observe the formation of **4** (n = 2) from **3** (n = 2) and dimethylsulfonium methylide or dimethyloxosulfonium methylide. A careful study of the conditions for the reaction of dimethylsulfonium methylide with **3** (n = 2) in dimethyl sulfoxide (DMSO), showed that at 30–50°, the yields of **4** were not reproducible, and that at temperatures of ca. 15° no trace of product was ever observed. With these observations as a basis, it was found that **4** (n = 2) could be best produced by the addition of an excess (50%) of trimethylsulfonium iodide, in one or two portions at room temperature, to a slurry of sodium hydride in DMSO containing the dissolved ketone. There was no necessity to generate the dimethylsulfinyl carbanion as an ylid forming reagent; this observation was to be expected on the basis of work published several years ago by Franzen and Driesen (7). By this method, excellent yields of **4** (n = 2, 3) and the dibenzo[*b*,*e*]azepine derivatives **5** could be prepared in a matter of a few hours (see Table I). The epoxides were then converted to the nitriles by a classical sequence involving rearrangement of the epoxides to the aldehydes **6**, followed by dehydration (with hot acetic anhydride) of the oximes **7** obtained therefrom, to the nitriles **2** (see Table III). Dehydration of the oxime **7** (R = H) was exceptional in that the primary product was the imide **2** (R = CH_3CO; infrared (i.r.) absorptions at 1710 and 1687 cm^{-1}); hydrolysis to the nitrile **2** (R = H) was easily accomplished in refluxing aqueous acetonitrile.

*The synthesis of other epoxides has been examined in a cursory way; e.g. benzophenone and benzaldehyde gave 85% 1,1-diphenyl oxirane and 55% phenyl oxirane respectively. Enolizable aldehydes and ketones have not been investigated.
†Unless specified otherwise, the yields refer to those of the purified products, here and in tables following.
‡This compound decomposed after a few days at room temperature or after ca. one month at 0°.
§We have not yet succeeded in obtaining this compound in crystalline form. Attempts to effect its purification by molecular distillation resulted in partial or complete rearrangement to the aldehyde. The epoxide was, therefore, not characterized.
‖An extra equivalent of sodium hydride was added to convert the lactam to its sodium salt.

5

6 X = CHO
7 X = CHNOH
8 X = COOH

An analogous series of transformations beginning with the epoxides **4** (n = 2 and 3) gave 5-cyano-10,11-dihydro-5*H*-dibenzo[*a*,*d*]cycloheptene (**1**, n = 2; see Table II) and 12-cyano-5,6,7,12-tetrahydrodibenzo[*a*,*d*]cyclooctene (**1**, n = 3) respectively. When the sequence **3** to **1** was effected without purification of the intermediates, the overall yields of the nitriles **1** (n = 2) and **1** (n = 3) were 55 and 70% respectively, based on the ketones **3** (n = 2 and 3). This represents the most efficient and convenient synthesis of these compounds which has been published to date.

The oxidation of the aldehydes **6** to the carboxylic acids **8** was only moderately successful (see Table III). Nevertheless, this was found to be the most reliable method of preparing these compounds.

The i.r. and nuclear magnetic resonance (n.m.r.) spectra of the dibenzo[*b*,*e*]azepine derivatives[3] described above, are listed in Tables IV and V respectively. The i.r. spectral data were unexceptional and therefore require no comment. The n.m.r. spectra, on the other hand, were especially interesting since several of the *N*-substituted dibenzo[*b*,*e*]azepine derivatives showed two well separated resonances for the C-11 proton (in most, but not all cases, the *N*-substituent showed two closely spaced absorptions). The data presented in Table VI ("B" series) showed that the relative intensity of these absorptions was markedly dependent on

[3]The n.m.r. spectra of the dibenzo[*a*,*d*]cycloheptene and cyclooctene derivatives will be discussed in a forthcoming publication.

§A solution consisting of 6 ml of methanol and 0.09 ml of concentrated sulfuric acid for each gram of the carboxylic acid, was heated under reflux for the indicated period.

the solvent polarity and the C-11 substituent. These phenomena are interpreted as another case of slow (on the n.m.r. time scale) interconversion of diastereomeric boat conformers in which the C-11 substituent is quasi axial or quasi equatorial, like that described recently by Lansbury *et al.* (8) and others (9, 10) for similar systems. A particularly informative spectrum was observed for the 5-methyl-11-methoxy dibenzazepinone (**9**). In DMSO-d_6 the methine

protons showed two singlets at δ 5.31 and 5.67, while the methoxyl groups appeared as two singlets at δ 3.16 and 3.56. The integrated intensities of the two high field resonances, i.e. δ 5.31 and 3.16, for the methine and methoxyl protons respectively, indicated that these absorptions were due to the same and least abundant isomer. This isomer was assigned the quasi axial configuration **9***b*, on the expectation that an axially oriented methoxyl group would lie in the positive shielding region above the plane of the aromatic rings (11). Identical conclusions have been reached by Lansbury *et al.* (8) for 7-methoxy-7,12-dihydropleiadene and by Childs and Winstein (10) for the epimeric dibenzohomotropyl methyl ethers, and these results give much weight to our assignment. On the basis of the above information, for those compounds listed in Table VI ("B" series) which showed two signals for the C-11 proton, the axial configuration was assigned to that isomer having the C-11 proton resonance at higher field (i.e. H equatorial).

There were several interesting observations to be made from the data given in Tables V and VI ("B" series). Firstly, for those compounds which showed restricted inversion, the quasi axial isomer represented an appreciable fraction of the mixture. Indeed, when the 11-substituent was chlorine, the axial configuration was actually the

§§One singlet due to the *N*-methyl and the other due to the *O*-methyl hydrogens.

preferred one. This was not especially surprising, since Lansbury *et al.* have shown (8) that the axial configuration is favored over the equatorial in the dihydropleiadene series. Secondly, all the *N*-unsubstituted compounds in the "B" series (Tables V and VI) had only one sharp resonance for the C-11 proton. In those cases where a comparison was made, the position of this absorption was about halfway between the corresponding peaks in the *N*-methyl compounds. This would seem to indicate that these *N*-unsubstituted compounds are undergoing rapid inversion at the temperature of the measurement (37°). However, such a conclusion is unjustified in the absence of variable temperature studies. Whatever the explanation, it is indeed curious that the nitrogen substituent should have such a profound effect on the n.m.r. spectra of these compounds. Lastly, two of the *N*-methyl dibenzazepinones (Table V, "B" series), e.g. X = CHO and CO_2CH_3, also showed only a sharp singlet for the C-11 proton. Once again, without variable temperature spectra, a choice between fast inversion and configurational homogeneity cannot be made, but the high field position of the methine resonance may well be an implication of the latter.

The n.m.r. spectra of both epoxides (Tables V and VI, "A" series) showed evidence of restricted inversion. In as much as spiro fusion, such as is present in these epoxides, might, like a double bond, slow down the rate of inversion (e.g. compare refs. 9 and 12), this would also tend to implicate rapid inversion of the *N*-unsubstituted compounds discussed above.

Experimental

The melting points were determined in a Gallenkamp melting point apparatus and are not corrected. The i.r. spectra were measured in chloroform (unless specified otherwise) on a Perkin–Elmer 237-B grating spectrophotometer. The n.m.r. spectra were recorded at 60 Mc.p.s. on a Varian A-60A spectrometer at ca. 37°

(probe temperature). The chemical shifts are recorded as p.p.m. (δ) from internal tetramethylsilane, with tetramethylsilane taken as zero.

Dibenzosuberone was purchased from the Aldrich Chemical Company. 5,6,7,12-Tetrahydrodibenzo[*a*,*d*]cycloocten-12-one was prepared according to the method of Winthrop *et al.* (14). 5,6-Dihydro-11*H*-dibenzo[*b*,*e*]azepine-6,11-dione was prepared by the method of Caronna and Palazzo (15) in 85–90% yield.

5-Methyl-5,6-dihydro-11H-dibenzo[b,e]azepine-6,11-dione

This compound has previously been prepared by the alkylation of the sodium salt of the dioxo compound with methyl iodide. The anion was generated with sodamide in refluxing toluene (16). We have found that the sodium salt is more conveniently generated with sodium hydride in dimethyl formamide at room temperature. The addition of an excess of methyl iodide to this salt produced the *N*-methyl compound in yields of 85–90%.

Preparation of the Epoxides

A 250 ml three-necked flask containing a magnetic stirring bar, and fitted with a thermometer, a gas inlet, and a calcium chloride drying tube, was flame dried. A flow of purified dry nitrogen was initiated through the apparatus and 1.28 g of a 56% dispersion of sodium hydride in mineral oil (29.9 mmoles)[4] were placed in the flask. The sodium hydride was twice washed with petroleum ether (b.p. 35–60°) to remove the mineral oil, and then 75 ml of dry dimethyl sulfoxide and 19.3 mmoles of the ketone were added. The mixture was stirred to effect solution of the ketone, and then 6.0 g of trimethylsulfonium iodide were added all at once (for larger scale reactions the salt was sometimes added in two equal

[4]When the ketone was 5,6-dihydro-11*H*-dibenzo[*b*,*e*]azepine-6,11-dione, an extra equivalent of sodium hydride was added to convert the lactam to its sodium salt.

portions because of excess frothing). After stirring for the specified time (see Table I) at room temperature, the solution was poured into a large excess of cold water containing a little sodium chloride. The mixture was extracted with benzene (or the product was collected by filtration if it crystallized), the extract was washed well with water, dried over sodium sulfate, and then evaporated *in vacuo*. The residue was then crystallized from the solvent indicated in Table I.

Rearrangement of the Epoxides

To a solution of the epoxide (27 mmoles) in 150 ml of anhydrous dichloromethane or tetrahydrofuran, were added 1.6 ml of boron trifluoride etherate. The solution was stirred at room temperature for the specified time (see Tables II and III), then washed with sodium carbonate solution (10%), with water, and then it was dried over sodium sulfate. The solvent was removed *in vacuo*, and the residue was crystallized from the solvent indicated in the Tables.

Preparation of the Nitriles

The aldehyde (42.2 mmoles), hydroxylamine hydrochloride (3.57 g, 51.5 mmoles), dry pyridine (40 ml), and dry ethanol (160 ml) were heated under reflux for the times indicated in Tables II and III and then the solvent was removed *in vacuo*. The residue was taken up in dichloromethane, washed with 10% hydrochloric acid, then with water, and finally dried over sodium sulfate. The solvent was removed *in vacuo* and the residue was crystallized from a suitable solvent.

For the preparation of the nitriles, the oximes were not purified, but used directly in the manner indicated below.

Oxime (30.3 mmoles) and 150 ml of acetic anhydride were heated at reflux temperature for the times indicated in Tables II and III. The acetic anhydride was then removed *in vacuo*, and the residue was taken up in dichloromethane, extracted with 5% sodium carbonate solution, and then with water. The dichloromethane was dried over sodium sulfate, evaporated *in vacuo*, and the residue was crystallized from a suitable solvent.

In the preparation of 11-cyano-5,6-dihydro-11*H*-dibenzo[*b*,*e*]azepin-6-one the primary product was the 5-acetyl derivative (see text). Deacetylation was effected by heating a solution of the imide in 1:1 aqueous acetonitrile (20 ml/g) at reflux for 28 h. The major portion of the product crystallized when the solution had cooled to room temperature; the remainder was recovered by evaporation of the mother liquor and crystallization of the residue.

In the case of 5-cyano-10,11-dihydro-5*H*-dibenzo[*a*,*d*]-cycloheptene, the crude cyanide was taken up in the minimum amount of benzene and placed on a dry packed column of Fluka neutral alumina (act. II, 30–50 g of alumina/g of crude nitrile). The product was eluted with benzene and appeared in the first few fractions of the eluant. This chromatography was necessary to remove an orange-colored impurity.

Oxidation of the Aldehydes to the Carboxylic Acids

The aldehyde was dissolved in glacial acetic acid (10 ml/g for **6** (R = CH_3), or 120 ml/g for **6** (R = H) and titrated with 0.649 *M* sodium dichromate in 2.5 *M* sulfuric acid at a rate such that the reaction temperature did not exceed 30°. A 10% excess of the oxidant was used for **6** (R = CH_3) and a 2% excess for **6** (R = H). When the addition was completed, the mixture was stirred at room temperature for ½ h, and then poured into a large volume of cold water. The product was extracted into dichloromethane, the extract was washed well with water, dried over sodium sulfate, and then evaporated *in vacuo*. The residue was crystallized from a suitable solvent (see Table III).

Thermal [2 + 3] cycloaddition of imino compounds to 3-aroylaziridines. Synthesis of imidazolidines

J. W. LOWN, J. P. MOSER, AND R. WESTWOOD[1]
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received July 31, 1969

3-Aroylaziridines react with a variety of imines and aryl-*N*-sulfonylimines in refluxing benzene to give imidazolidines in excellent yield. The orientation of the [2 + 3] cycloaddition of the intermediate azomethine ylids to the C=N double bond was proven by synthesis of specifically 5-deuterated imidazolidines. The reactions provide a convenient new general synthesis of imidazolidines.

Canadian Journal of Chemistry, 47, 4335 (1969)

Many substituted aziridines will undergo thermal cleavage of the 2-3 bond to an azomethine ylid intermediate, and subsequent [2 + 3] cycloaddition can take place to the acetylenic bond and to activated alkenes, in many and stereospecifically (1–14).

We have reported the analogous thermally induced additions of 3-aroylaziridines to the polarized carbonyl bond of diphenylcyclopropenone with the formation of 4-aroyl-4-oxazolines (15) and to the C=S double bond of aryl isothiocyanates to form 4-aroyl-5-arylimino-4-thiazolines (16). In a continuing study of these additions to heteromultiple bonds, we report the [2 + 3] cycloaddition of 3-aroylaziridines to activated imino compounds which provides a new synthesis of imidazolidines.

Treatment of 3-benzoyl-1-isopropyl-2-phenylaziridine with an equimolar quantity of benzalaniline in refluxing toluene for 16 h, followed by chromatographic separation on alumina afforded the imidazolidine **1** as a white crystalline solid in 24% yield, m.p. 182°. The nuclear magnetic resonance (n.m.r.) spectrum of **1** shows the isopropyl methyl groups are non-equivalent, indicating proximity to an asymmetric center in accordance with the proposed structure. While the initial product consisted of an isomeric mixture corresponding to *cis* and *trans* arrangement of protons at the 4 and 5 positions as shown by the n.m.r. spectrum, only the isomer described above could be obtained in solid form. This was assigned the *cis* geometry at the 4,5 positions on the basis of an 8 Hz coupling constant for the AB

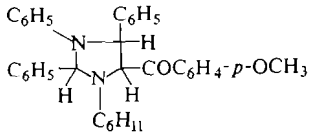
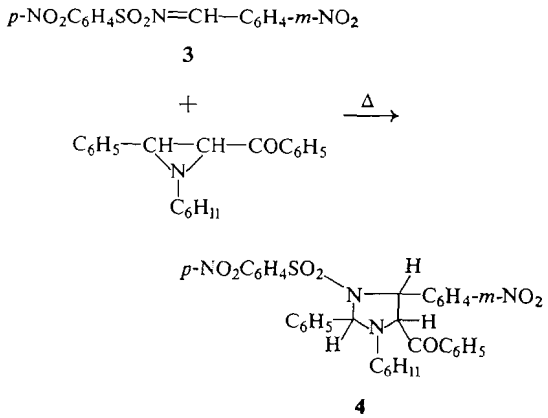
quartet due to these protons in the n.m.r. spectrum (8). This configuration of **1** is evidently quite stable since no epimerization occurred, and no deuterium was incorporated at the 5 position upon refluxing **1** with deuterium oxide containing potassium carbonate. Specifically 5-deuterated imidazolidines could however be synthesized by a different method (*vide infra*).

Similarly, benzalaniline reacted with 3-*p*-anisoyl-1-cyclohexyl-2-phenylaziridine to give imidazolidine **2**



2

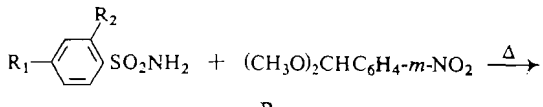
Addition of the more reactive *N*-(*m*-nitrobenzal)-*p*-nitrobenzenesulfonamide (**3**) to 3-benzoyl-1-cyclohexyl-2-phenylaziridine in refluxing benzene proceeded smoothly to give the imidazolidine **4** m.p. 160–161° in 94% yield.



4

The scope of this new synthesis of imidazolidines was then explored. Several *N*-sulfonylimines were prepared by condensation of arylsulfonamides with the methyl acetal of *m*-nitrobenzaldehyde, following a method previously used by Kresze *et al.* (17, 18).

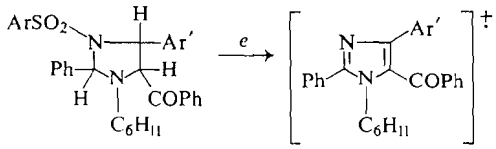
Excellent yields of imidazolidines were obtained by reaction of these sulfonylimines with a variety of aziridines containing different 2 and 3 substituents and with *N*-substituents of cyclohexyl, isopropyl, methyl, and benzyl. The sulfonylimines **3** and **5** gave excellent yields; **6** and **7** gave good to excellent yields, while **8**, containing



3 $R_1 = NO_2$, $R_2 = H$
5 $R_1 = -C{\equiv}N$, $R_2 = H$
6 $R_1 = Cl$, $R_2 = NO_2$
7 $R_1 = Cl$, $R_2 = H$
8 $R_1 = CH_3$, $R_2 = H$

an electron releasing substituent in the arylsulfonyl group, was an exception and gave only poor yields. The analytical and spectral data on the product imidazolidines are summarized in Tables I–IV. Table V contains the analytical data on the new aryl-*N*-sulfonylimines.

The molecular ion cannot be observed in the high resolution mass spectrum of these imidazolidines. Fragmentation to the ion of the 5-aroylimidazole, although in low abundance relative to the aroyl ion, was highly characteristic of these compounds (see Tables I and III).



Three distinct structural and spectral problems connected with this synthesis of imidazolidines, required solution, namely, (*i*) orientation of addition, (*ii*) dependence of product configuration on the stereochemistry of the aziridine, i.e., possible stereospecificity of the reaction, and (*iii*) unambiguous assignment of the imidazolidine ring proton magnetic resonances, which consisted of one sharp singlet in the region of 6.0 δ and two weakly coupled broad singlets at higher field in the region of 5.5 and 5.1 δ.

The question of orientation of addition, i.e., whether the products are of type **9** or **10** is not a trivial one, since Huisgen has pointed out that in 1,3-dipole addition reactions, one may not safely

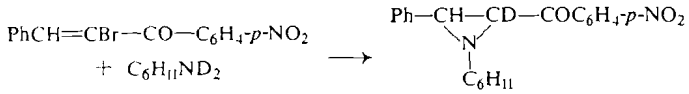
*From benzene/hexane.
†From ethyl acetate.

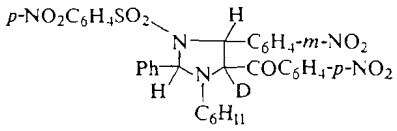


11

predict the orientation of addition on the basis of assignment of nucleophilic and electrophilic centers in the 1,3-dipole (19).

1-Cyclohexyl-3-deutero-2-phenyl-3-*p*-nitrobenzoylaziridine (**11**) was prepared by the reaction of 2-bromo-2-*p*-nitrobenzoyl-1-phenylethylene with cyclohexylamine-ND_2 in anhydrous ether. Examination of the integral of the aziridine ring protons in the n.m.r. spectrum showed, by comparison with the protium compound, about 50–60% deuterium incorporation at the 3-position.

Reaction of **11** with the sulfonylimine **3** gave an imidazolidine corresponding to **12** in structure.

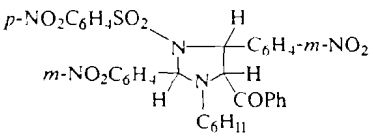


12

The n.m.r. spectrum of **12** showed a sharp singlet at 6.0 δ (1H), now assignable to the 2 proton; and two broad and weakly coupled singlets at 5.43 (0.75H) and 5.22(1H) δ now assigned unambiguously to the 5 and 4 imidazolidine ring protons respectively in **12**. An examination of several integrals showed an average of 24% deuterium incorporation in **12**.

The possible dependence of the course of the [2 + 3] cycloaddition on the stereochemistry of the aziridine was examined by reacting the *N*-sulfonylimine **3** in separate experiments with stereoisomerically pure samples of *cis*- and *trans*-3-benzoyl-1-cyclohexyl-2-*m*-nitrophenylaziridine.

In both cases the only product isolated in good yield was the imidazolidine **13**.

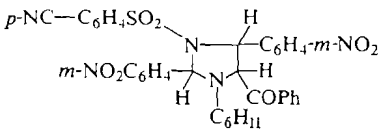


13

The n.m.r. spectrum showed a sharp singlet for the 2-imidazolidine proton at 6.04 δ and two broadened and weakly coupled singlets for the 4 and 5 protons at 5.01 and 5.35 δ respectively, and was therefore assigned the *trans* arrangement for the 4,5 protons because the small coupling constant is characteristic of *trans* coupling in a five membered ring (8).

Similarly reaction of *N*-(*m*-nitrobenzal)-*p*-cyanobenzenesulfonamide **5** with either *cis*- or *trans*-3-benzoyl-1-cyclohexyl-2-*m*-nitrophenylaziridine gave only the *trans* imidazolidine **14**.

5



14

It seems probable that in these reactions, the [2 + 3] cycloaddition is stereospecific, but in the case of *cis*-imidazolidines is usually followed by post isomerization to the more stable *trans*-imidazolidine, as has been observed in other [2 + 3] cycloadditions with aziridines (1).

All the imidazolidines listed in Tables I and III which show small or zero 4,5 proton coupling have accordingly been assigned the *trans* configuration. The n.m.r. spectra of the imidazolidines obtained from *N*-benzyl and *N*-methylaziridines were different from the majority of the compounds listed in Tables I–IV, consisting of singlet at about 5.1 δ flanked by a strongly coupled AB quartet centered at ca. 4.9 and 5.8 δ with a coupling constant ($J \approx 8$ Hz) characteristic of *cis* vicinal proton coupling. An opposite orientation of addition of the azomethine ylids derived from these aziridines to the sulfonylimines was possible. Therefore 1-benzyl-3-deutero-2-phenyl-3-toluoylaziridine (**15**) was prepared as shown. Integration of the n.m.r. spectrum of **15** confirmed 71% deuterium incorporation in the 3-position of **15**. Reaction of **15** with the *N*-sulfonylimine **3** afforded an imidazolidine to which structure **16** was assigned unambiguously.

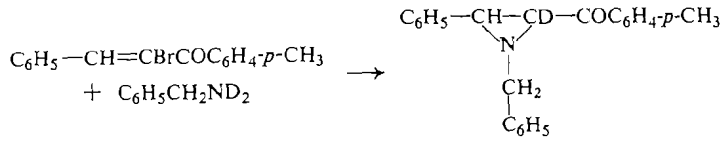
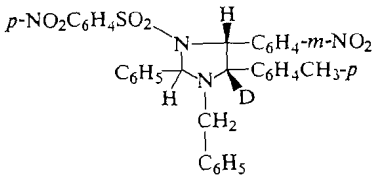
For personal use only.

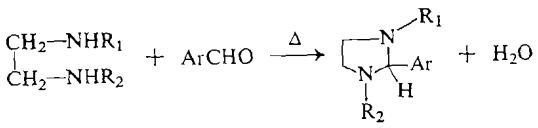




16

The n.m.r. spectrum of **16** showed a singlet at 5.13 (1H) δ and an AB quartet centered at 4.86(0.7H) and 5.84(1H) δ, $J = 8$ Hz, and integration confirmed 29% deuterium incorporation in the 5-position of **16**. Therefore the orientation of addition of all the *N*-sulfonylimines to the 3-aroylaziridines is the same. The exceptional line positions for the heterocycle **16** and similar compounds derived from *N*-methylaziridine is attributed to screening factors operating in *cis* 4,5 configuration of the imidazolidine ring.

Imidazolidines are rare in the chemical literature and very few general syntheses exist (20–23). The principal method of synthesis consists of reaction of aldehydes with 1,2 diamines.



The [2 + 3] cycloaddition reactions described in this paper provide a convenient and versatile general synthesis of imidazolidines which nicely complements the existing routes in allowing for a wide variety of substituents in the imidazolidine ring.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer model 421 spectrophotometer, and only the principal, sharply defined peaks are reported. Nuclear magnetic resonance spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in $CDCl_3$, with tetramethylsilane as a standard. Line positions are reported in p.p.m. from the reference. Absorption spectra were recorded in 'spectro'-grade solvents on a Beckman DB recording spectrophotometer. Mass spectra were determined on an Associated Electrical Industries MS-9 double focussing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15 000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for thin layer chromatography. Microanalyses were carried out by Dr. D. Daesslé, Organic Microanalysis Ltd., Montreal, Quebec and by Mrs. D. Mahlow of this department.

Reaction of 3-Benzoyl-1-isopropyl-2-phenylaziridine with Benzalaniline

A solution of 2.65 g (0.01 mole) of 3-benzoyl-1-isopropyl-2-phenylaziridine (16) and 1.81 g (0.01 mole) of benzalaniline in 15 ml of dry benzene was heated under reflux for 16 h when a deep orange color developed. The solution was passed down a column of Fisher alumina. Elution with benzene afforded one main fraction which upon evaporation of the solvent *in vacuo* gave a yellow gum, from which crystallized as a white powder, 5-benzoyl-1-isopropyl-2,3,4-triphenyl-(*cis*-4,5)-imidazolidine, 1.05 g (24% yield), m.p. 182°.

Anal. Calcd. for $C_{31}H_{30}N_2O$ (mol. wt. 446.2358): N, 6.27. Found (mol. wt. (mass spectrum) 446.2356): N, 6.20.

Infrared spectrum: ν_{max} (film): 1680 cm^{-1} (C=O). Nuclear magnetic resonance spectrum $\delta_{TMS}(CDCl_3)$: 0.85 and 1.15 (3H each, doublets $J = 6.5$ Hz, $(CH_3)_2CH$); 2.81–3.35 (1H, septet, $J = 6.5$ Hz, $(CH_3)_2CH$); AB quartet centered at 4.76 and 5.33 (2H, $J = 8$ Hz, 4 and 5 protons) 5.82 (1H, singlet, 2 proton); 6.60–8.40 (multiplet, 20H, aromatic protons).

A solution of 0.350 g (0.0008 moles) of 5-benzoyl-1-isopropyl-2,3,4-triphenylimidazolidine and 46 mg of potassium carbonate in a mixture of 10 ml of dry tetrahydrofuran and 3 ml of deuterium oxide was heated under reflux for 24 h, allowed to cool, and the organic material extracted with benzene. The combined extract was evaporated and the exchange process repeated with fresh deuterium oxide. Finally the recovered imidazolidine was purified by recrystallization from methanol m.p. 182°. An examination of the n.m.r. spectrum confirmed there had been no epimerization or deuterium incorporation.

Reaction of 3-p-Anisoyl-1-cyclohexyl-2-phenylaziridine with Benzalaniline

A solution of 3.35 g (0.01 mole) of 3-*p*-anisoyl-1-cyclohexyl-2-phenylaziridine (24) and 1.81 g (0.01 mole) of benzalaniline in 15 ml of dry benzene was heated under reflux for 48 h. The white solid which had precipitated 0.100 g (11% yield on the basis of unrecovered benzalaniline) was collected and purified by recrystallization from a large volume of benzene m.p. 182–184°, representing 5-*p*-anisoyl-1-cyclohexyl-2,3,4-triphenylimidazolidine.

Anal. Calcd. for $C_{35}H_{36}N_2O_2$ (mol. wt. 516.2777): C,

81.36; H, 7.03; N, 5.42. Found (mol. wt. (mass spectrum) 516.2773): C, 81.24; H, 6.96; N, 5.62.

Infrared spectrum ν_{max} ($CHCl_3$): 1677 cm^{-1} (C=O). Nuclear magnetic resonance spectrum $\delta_{TMS}(CDCl_3)$: 0.74–2.17 (10H, multiplet, cyclohexyl protons); 2.54–3.10 (1H, multiplet CH—N<); 3.73 (3H, singlet, —OCH_3); 5.51 (2H, singlet, 4,5 protons); 6.34 (1H, singlet, 2 proton); 6.38–7.80 (19H, multiplet, aromatic protons).

Preparation of Aryl-N-sulfonylimines

(i) m-Nitrobenzaldehyde Methyl Acetal

It was prepared in 85% yield by the method of Claisen (25), b.p. 139°/5 mm (lit. b.p. 145–146°/9 mm).

(ii) Preparation of N-(m-Nitrobenzal)-p-nitrobenzenesulfonamide

The following general method of preparation of this and similar aryl-*N*-sulfonylimines listed in Table V is due to Kresze *et al.* (18).

A mixture of 7.6 g (0.038 mole) of *p*-nitrobenzenesulfonamide and 8.2 g (0.042 mole) of *m*-nitrobenzaldehyde methyl acetal was heated to 150° until no more methanol was evolved. About 5 ml of 1:1 benzene/nitrobenzene mixture was added and the solution concentrated to ca. 20 ml and allowed to cool when the residue crystallized. The pure aryl-*N*-sulfonylimine was obtained by recrystallization from a 1:1 mixture of *o*-xylene and dimethylformamide in 84% yield, m.p. 212–214° (lit. 210–212° (18)).

General Method of Preparation of 1-Alkyl-2,4-diaryl-5-aroyl-3-(N-arylsulfonyl)-imidazolidines

The following experimental procedure is typical and was used to prepare all 22 imidazolidines listed in Tables I and III.

5-Benzoyl-1-cyclohexyl-3-(N-p-nitrobenzenesulfonyl)-4-m-nitrophenyl-2-phenylimidazolidine

A suspension of 1.53 g (0.005 mole) of 3-benzoyl-1-cyclohexyl-2-phenylaziridine and 1.68 g (0.005 mole) of *N*-(*m*-nitrobenzal)-*p*-nitrobenzenesulfonamide in 100 ml of dry benzene was stirred and heated under reflux for 24 h during which time the aryl-*N*-sulfonylimine gradually went into solution. The solvent was removed *in vacuo* and the residual yellow oil induced to crystallize as a pale yellow crystalline solid, 3.01 g (94% yield), m.p. 161–162°. The product was decolorised by treatment with charcoal in benzene and then purified by recrystallization from 3:2 hexane/benzene giving a white solid, m.p. 160–161°.

Anal. Calcd. for $C_{34}H_{32}N_4O_7S$: C, 63.74; H, 5.04; N, 8.74; S, 5.10. Found: C, 63.73; H, 5.09; N, 8.53; S, 5.40.

Mass spectrum calcd. for $C_{28}H_{25}N_3O_3$ (imidazole fragment ion): 451.1896. Found: 451.1898. Infrared spectrum ν_{max} ($CHCl_3$): 1681 cm^{-1} (C=O). Nuclear magnetic resonance spectrum δ_{TMS} ($(CD_3)_2SO$): 0.37–1.87 (10H, multiplet, cyclohexyl protons); 5.13 (1H, singlet, 4 proton); 5.39 (1H, singlet, 5 proton); 6.09 (1H, singlet, 2 proton); 7.1–8.7 (18H, multiplet, aromatic protons).

Preparation of 1-Cyclohexyl-2-phenyl-3-deutero-3-p-nitrobenzoylaziridine

(a) 2-Bromo-2-p-nitrobenzoyl-1-phenylethylene

A slurry of 4.13 g (0.01 mole) of 1,2-dibromo-1-phenyl-2-*p*-nitrobenzoylethane and 1.410 g (0.011 mole) of potassium acetate in 500 ml of 95% ethanol was heated under reflux for 12 h. The resulting pale yellow solution was evaporated to ca. 30 ml poured into 500 g of ice water and the organic material extracted with ether. The combined ether extract was dried ($MgSO_4$) and evaporated to give a pale yellow oil which readily solidified on cooling. Crystallization from benzene/heptane gave 2-bromo-2-*p*-nitrobenzoyl-1-phenylethylene, 2.1 g (63% yield), m.p. 108°.

Infrared spectrum ν_{max} ($CHCl_3$): 1670 (α,β unsaturated ketone) 1600 (C=C stretching); 1540 and 1350 cm^{-1} (aromatic —NO_2). Nuclear magnetic resonance spectrum $\delta_{TMS}(CDCl_3)$: 7.15 (singlet, 1H, —CH); 7.3–8.5 (multiplet, 9H, aromatic protons). Mass spectrum showed molecular ion at 331.

This material had previously been reported by Weygand as a pale yellow oil (26).

(b) Reaction of 2-Bromo-2-p-nitrobenzoyl-1-phenylethylene with Cyclohexylamine-ND_2

A solution of 2.495 g (0.05 mole) of redistilled dry cyclohexylamine (27) in 25 ml of anhydrous ether was shaken vigorously with 3 ml of deuterium oxide (99.97%), separated, and the ethereal layer washed with further quantities of deuterium oxide (5 × 1 ml), then removed and dried ($MgSO_4$). The ether solution was filtered directly into a dried ($MgSO_4$) solution of 1.66 g (0.005 mole) of 2-bromo-2-*p*-nitrobenzoyl-1-phenylethylene in 100 ml of ether. The mixture was stirred at room temperature for 24 h before being filtered to remove the precipitated cyclohexylamine hydrobromide 0.7 g; (78% of theoretical). The filtrate was washed with water and dried ($MgSO_4$). Evaporation of the ether gave a pale yellow oil which after trituration with hexane gave the solid aziridine 1.26 g (72% yield) pure enough for further use.

Mass spectrum: *m/e* 349 (3%); (undeuterated material $M-1$); *m/e* 350 (44%) (undeuterated material M); *m/e* 351 (40%) (deuterated material M'); *m/e* 352 (9%) (deuterated material, $M'+1$).

Nuclear magnetic resonance spectrum $\delta_{TMS}(CDCl_3)$: 1.0–2.0 (multiplet, 10H, cyclohexyl protons); 2.5 (multiplet, 1H, $C_5H_{10}CHN$); 3.2 and 3.55 (2 broad singlets 1.35 H; aziridine ring protons); 7.0–8.5 (multiplet, 9H, aromatic protons). The integral indicates about 60% deuterium incorporation of the 3 position.

Reaction between 1-Cyclohexyl-2-phenyl-3-deutero-3-p-nitrobenzoylaziridine and N-(m-Nitrobenzal)-p-nitrobenzenesulfonamide

Reaction of 0.329 g (0.93 mmole) of 1-cyclohexyl-2-phenyl-3-deutero-3-*p*-nitrobenzoylaziridine (containing about 60% deuterium incorporation) and 0.314 g (0.93 mmole) of *N*-(*m*-nitrobenzal)-*p*-nitrobenzenesulfonamide in the manner described in the general procedure above gave 1-cyclohexyl-5-deutero-3-(*N*-*p*-nitrobenzenesulfonyl)-4-*m*-nitrophenyl-5-*p*-nitrobenzoylimidazolidine in 41.3% yield, m.p. 160–161°. Examination of the n.m.r. spectrum showed the position and extent of deuterium incorporation. The product was identical in all other respects to the protium analogue listed in Table I.

Nuclear magnetic resonance spectrum: $\delta_{TMS}(CDCl_3)$: 0.30–1.90 (10H, multiplet, cyclohexyl protons); 2.9–3.3 (1H, multiplet, CH—N); 5.22 (1H broad singlet, 4-ring proton); 5.43 (0.7H, broad singlet, 5 ring proton); 6.02

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(1H, sharp singlet, 2-ring proton); 7.2–8.3 (17H, multiplet, aromatic proton).

Averaging of 6 integrals confirmed 24–25% deuterium incorporation at position 5.

cis- and trans-3-Benzoyl-1-cyclohexyl-2-m-nitrophenylaziridines

A solution of 50 g (0.121 mole) of 3-*m*-nitrophenyl-2,3-dibromopropiophenone (28) in 500 ml of benzene at 0° was treated dropwise with stirring with a solution of 35.9 g (0.363 mole) of cyclohexylamine in 100 ml of benzene. The mixture was stirred at room temperature for 24 h, the precipitated cyclohexylamine hydrobromide was collected, and the filtrate washed with water (3 × 100 ml) and dried ($MgSO_4$). The solvent was evaporated and the residual oil treated with 50 ml of benzene and 100 ml of heptane and chilled when 6.5 g of *cis*-3-benzoyl-1-cyclohexyl-2-*m*-nitrophenylaziridine, m.p. 124–126° (17% yield), precipitated.

Anal. Calcd. for $C_{21}H_{22}N_2O_3$ (mol. wt. 350.1630): C, 72.00; H, 6.29; N, 8.00. Found (mol. wt. (mass spectrum) 350.1630): C, 71.70; H, 6.17; N, 8.02.

Infrared spectrum ν_{max} ($CHCl_3$): 1680 cm^{-1} (C=O of *cis* isomer). Nuclear magnetic resonance spectrum $\delta_{TMS}(CDCl_3)$: 1.00–2.05 (10H, multiplet, cyclohexyl); AB quartet centered at 3.44 and 3.24, $J = 7$ Hz (2H, *cis* 2,3 protons (30)); 7.2–8.3 (9H, multiplet, aromatic protons).

The filtrate from the above separation was treated with a further 100 ml of heptane and kept at 0° for 4 weeks when 17.5 g (41.4% yield) of *trans*-3-benzoyl-1-cyclohexyl-2-*m*-nitrophenylaziridine, m.p. 82–84°, was obtained.

Mol. wt. Calcd. for $C_{21}H_{22}N_2O_3$: 350.1630. Found (mass spectrum): 350.1630. Infrared spectrum ν_{max} ($CHCl_3$): 1663 cm^{-1} (C=O of *trans* isomer). Nuclear magnetic resonance spectrum $\delta_{TMS}(CDCl_3)$: 0.89–2.02 (10H, multiplet, cyclohexyl protons); 2.30–2.87 (1H, multiplet, CH—N); 3.64 (2H, singlet, *trans* 2,3 protons (30)); 7.3–8.3 (9H, multiplet, aromatic protons).

Reaction of N-(m-Nitrobenzal)-p-nitrobenzenesulfonamide with Stereoisomerically pure cis- and trans-3-Benzoyl-1-cyclohexyl-2-m-nitrophenylaziridines

(*a*) Reaction of 1.68 g (0.005 mole) of *N*-(*m*-nitrobenzal)-*p*-nitrobenzenesulfonamide and 1.75 (0.005 mole) of *cis*-3-benzoyl-1-cyclohexyl-2-*m*-nitrophenylaziridine in the manner described in the general procedure above gave 2.73 g (80% yield) of 5-benzoyl-1-cyclohexyl-2,4-di(*m*-nitrophenyl)-3(-*N*-*p*-nitrobenzenesulfonyl)-imidazolidine, m.p. 112–113°.

(*b*) A similar reaction of 1.68 g (0.005 mole) of *N*-(*m*-nitrobenzal)-*p*-nitrobenzenesulfonamide and 1.75 g (0.005 mole) of *trans*-3-benzoyl-1-cyclohexyl-2-*m*-nitrophenylaziridine gave the identical imidazolidine, 2.61 g (76.5% yield), m.p. 111–112°.

Reaction of N-(-m-Nitrobenzal)-p-cyanobenzenesulfonamide with Stereoisomerically pure cis- and trans-3-Benzoyl-1-cyclohexyl-2-m-nitrophenylaziridine

(*a*) Reaction of 1.662 g (0.0053 mole) of *N*-(*m*-nitrobenzal)-*p*-cyanobenzene sulfonamide and 1.846 g (0.0053 mole) of *cis*-3-benzoyl-1-cyclohexyl-2-*m*-nitrophenylaziridine in the manner described in the general procedure above gave 3.25 g (93% yield) of 5-benzoyl-3-(*N*-*p*-cyanobenzenesulfonyl)-1-cyclohexyl-2,4-di(*m*-nitrophenyl)-imidazolidine, m.p. 180–182°.

(*b*) A similar reaction of 0.784 g (0.0025 mole) of *N*-(*m*-nitrobenzal)-*p*-cyanobenzenesulfonamide and 0.871 g (0.0025 mole) of *trans*-3-benzoyl-1-cyclohexyl-2-*m*-nitrophenylaziridine gave the identical imidazolidine 1.257 g (68% yield), m.p. 180–182°.

Preparation of 1-Benzyl-3-deutero-3-p-toluoyl-2-phenylaziridine

A solution of 7.64 g (0.070 mole) of redistilled dry benzylamine in 70 ml of anhydrous ether was shaken vigorously with 9 ml of deuterium oxide (99.97%), separated, and the organic layer washed with further quantities of deuterium oxide (4 × 3 ml), then removed and dried ($MgSO_4$). The ether solution was filtered directly into a dried ($MgSO_4$) solution of 4.30 g (0.014 mole) of 2-bromo-2-*p*-toluoyl-1-phenylethylene (26) in 200 ml of ether. The mixture was stirred at room temperature for 24 h before being filtered to remove the precipitated benzylamine hydrobromide ca. 1 g. The filtrate was washed with water and dried ($MgSO_4$). Evaporation of the ether gave a yellow oil which upon trituration with 2:1 heptane/benzene gave 1-benzyl-3-deutero-3-*p*-toluoyl-2-phenylaziridine 2.105 g (45% yield), m.p. 108–110° (lit. (29) m.p. 113–114°). Examination of the n.m.r. spectrum showed the position and extent of deuterium incorporation. The aziridine was identical in all other respects to the protium compound.

Nuclear magnetic resonance spectrum $\delta_{TMS}(CDCl_3)$: 2.30 (3H, singlet, aryl CH_3); 3.30 (1.3H, multiplet, aziridine ring protons). AB quartet centered at 3.73 and 4.05, $J = 14$ Hz (2H, $PhCH_2$); 7.0–8.0 (14H, multiplet, aromatic protons). Averaging of integrations confirmed 71% deuterium incorporation in position 3.

Reaction between 1-Benzyl-3-deutero-3-p-toluoyl-2-phenylaziridine and N-(m-Nitrobenzal)-p-nitrobenzenesulfonamide

Reaction of 0.290 g (0.89 mmole) of 1-benzyl-3-deutero-3-*p*-toluoyl-2-phenylaziridine (71% deuterium incorporation) and 0.300 g (0.89 mmole) of *N*-(*m*-nitrobenzal)-*p*-nitrobenzene sulfonamide in the manner described in the general procedure above gave 1-benzyl-5-deutero-3-(*N*-*p*-nitrobenzenesulfonyl)-4-*m*-nitrophenyl-5-*p*-toluoylimidazolidine, 0.231 g (39.3% yield), m.p. 160°. Examination of the n.m.r. spectrum showed the position and extent of deuterium incorporation. The product was identical in all other respects to the protium analogue listed in Table I.

Nuclear magnetic resonance spectrum: δ_{TMS} ($(CD_3)_2SO$): 2.36 (3H, singlet, aryl CH_3); 3.48–4.10 (2H, quartet, $J = 15$ Hz, $PhCH_2$); AB quartet centered at 4.86 (0.7H) and 5.84 (1H), $J = 8$ Hz, (now assigned unambiguously to the 5 and 4 imidazolidine ring protons respectively); 5.13 (1H, singlet, 2 proton); 6.7–8.3 (22H, multiplet, aromatic protons). Averaging of the integrations confirmed 29% deuterium incorporation in position 5.

Alkoxycarbenes from the thermolysis of silyl ketals

A. G. Brook and P. J. Dillon
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received June 13, 1969

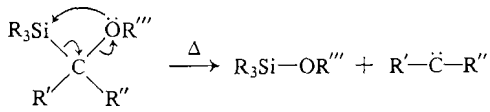
It is shown that α,α-dimethoxybenzylsilanes thermally rearrange to give methoxysilanes and phenylmethoxycarbene; the latter species has been trapped by a variety of reagents. The rearrangement involves retention of configuration at an asymmetric silicon center. While α,α-dimethoxyethylsilanes eliminate methanol when heated, methoxybenzhydrylsilanes rearrange to methoxysilane and diphenylcarbene but monomethoxybenzylsilanes or 2-silyldioxolanes do not thermally rearrange up to 250°.

Canadian Journal of Chemistry, 47, 4347 (1969)

The thermolysis of methoxypolysilanes has been reported to produce divalent organosilicon (silylene) species (1,2). It seemed possible that

$$MeOSiMe_2—(SiMe_2)_n—SiMe_2OMe \xrightarrow{\Delta} MeOSiMe_2—(SiMe_2)_n—OMe + :SiMe_2$$

α-alkoxyalkylmonosilanes might similarly undergo this sort of reaction to produce carbenes, and indeed, since this work was completed, Atwell *et al.* have reported such behavior on thermolysis of (dimethoxymethyl)trimethoxysilane (3).



α-Alkoxyalkylsilanes are generally difficult to synthesize, but a convenient source was found to be the ketals **1** of acylsilanes, which could be prepared either from the dithiane precursors (4,5) of the acylsilanes by reaction in methanol over several days with a mixture of mercuric

b R_3Si = Ph_3Si; R′ = Me

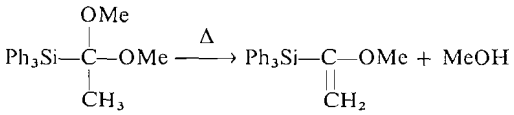
prepared from the acylsilanes and ethylene glycol in hot chloroform containing boron trifluoride etherate.

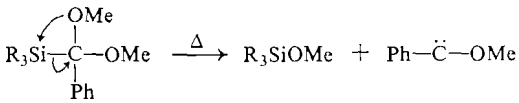
Attempts to prepare simple ketals using boron trifluoride etherate and alcohols were not successful. Details of the compounds prepared will be found in the Experimental section.

While the dioxolanes of acetyl and benzoyltriphenylsilane were thermally stable to at least 250°, it was found that the dimethoxy ketals, when pyrolyzed at 150–200°, readily decomposed in one of two ways. Where there was hydrogen α to the carbon bearing the alkoxy groups, e.g. **1***b*, methanol was thermally eliminated and an enol ether was formed. This type of reaction has been



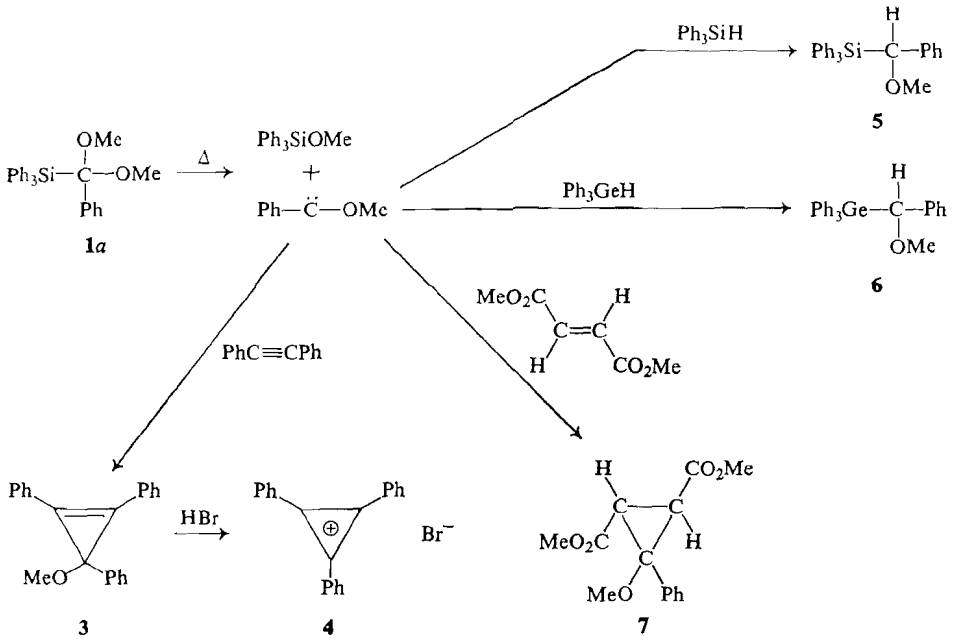
1*b*

observed previously (6). However, with α,α-dimethoxybenzylsilanes, which lack α-hydrogen, the thermolysis gave high yields of alkoxysilane, consistent with the elimination of an alkoxycarbene. Subsequent studies were devoted to



demonstrating the formation of the carbene by carrying out the thermolysis in the presence of suitable carbene traps.

When α,α-dimethoxybenzyltriphenylsilane (**1***a*) was heated at 170° in the presence of diphenylacetylene, 1-methoxy-1,2,3-triphenylcyclopropene (**3**) was evidently formed since the reaction product, when treated with gaseous



hydrogen bromide, gave triphenylcyclopropenium bromide (**4**) (7). The relatively low yield of **4** is probably due to a competitive thermal decomposition since no **4** was obtained when the thermolysis was carried out at 190°.

When the dimethoxy compound **1***a* was heated to 190° in the presence of about two equivalents of triphenylsilane, a 61% yield of α-methoxybenzyltriphenylsilane (**5**) was obtained; similarly, when heated in the presence of triphenylgermane, α-methoxybenzyltriphenylgermane (**6**) was isolated in 75% yield.

Finally, when **1***a* was heated in dimethyl fumarate, triphenylmethoxysilane and a compound believed to be the substituted cyclopropane **7** were obtained, the latter in 55% yield. The nuclear magnetic resonance (n.m.r.) spectrum of this compound showed two 1-proton doublets ($J = 3$ c.p.s.) at δ 2.88 and 2.90 p.p.m. attributable to the diastereotopic *trans* hydrogens, and three 3-proton singlets at δ 3.01, 3.40, and 3.70 p.p.m., corresponding to the methoxy group and the two diastereotopic methyl ester functions. There was no evidence for the formation of the *cis*-cyclopropane derivative.

These results are consistent with a thermal rearrangement of the α,α-dimethoxybenzylsilane resulting in the formation of triphenylmethoxysilane and phenylmethoxycarbene, which subsequently inserts either into a multiple bond or into an Si—H or Ge—H bond. Studies by Seyferth *et al.* have demonstrated the susceptibility of Si—H and Ge—H bonds toward insertion by dihalocarbenes (8) and the insertion of electronegatively-substituted carbenes into multiple bonds is also well-documented (9). The rearrangement closely parallels the known thermal rearrangements of silanecarboxylate and germanecarboxylate esters in which an alkoxysilane or -germane and carbon monoxide are formed (10,11).

$$R_3M{-}\overset{\overset{O}{\|}}{C}{-}OMe \xrightarrow{\Delta} R_3MOMe + :CO \qquad M = Si, Ge$$

It appeared to be of interest to establish the stereochemistry of the rearrangement at an asymmetric silicon atom. When optically active (+)-α,α-dimethoxybenzyl-1-naphthylphenylmethylsilane of known absolute configuration[1] and assumed 100% optical purity was thermally rearranged, the (−)-1-naphthylphenylmethyl-

[1]The absolute configuration of the dithiane precursor and hence of the α,α-dimethoxy compound is known both from its method of formation from (−)-R_3Si^*—Cl with 2-lithio-2-phenyl-1,3-dithiane (inversion) and also from the known configuration of its hydrolysis product (+)-benzoyl-1-naphthylphenylmethylsilane, established previously (12,13).

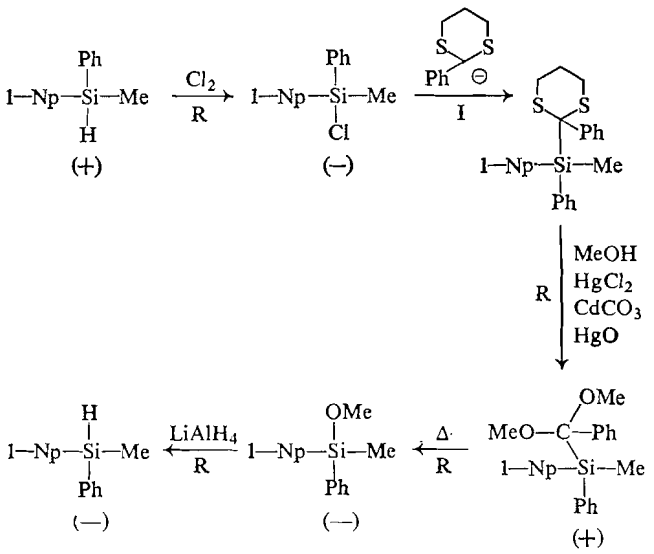
For personal use only.



R = retention; I = inversion

methoxysilane of known configuration (14), obtained in 87% yield, was 95% optically pure indicating that the reaction had occurred with high stereospecificity and involved retention of configuration at silicon as anticipated for a 1,2-rearrangement of this type.

Compared to dimethoxyalkylsilanes, monomethoxy compounds appear to rearrange much less readily. Thus α-methoxybenzyltriphenylsilane was formed at 190° from the reaction of phenylmethoxycarbene with triphenylsilane with little evidence of further reaction, and even when heated at 250° for 4 days, while some decomposition occurred, there was no evidence of triphenylmethoxysilane formation. Similarly, after being heated at 315° for 45 min, starting material was recovered in good yield. However, when α-methoxybenzhydrylmethyldiphenylsilane, prepared by refluxing a solution of the corresponding bromide in methanol–carbon tetrachloride, was heated to 250° in the presence of air, methyldiphenylmethoxysilane and benzophenone were formed, suggesting rearrangement of the compound to methoxysilane and diphenylcarbene; the reaction of diphenylcarbene with oxygen to form benzophenone is well known (15).

$$Ph_2MeSi—CPh_2OMe \xrightarrow{\Delta} Ph_2MeSiOMe + Ph_2C: \xrightarrow{O_2} Ph_2CO$$

This rearrangement is not likely to prove a very useful route to carbenes because of the relatively high temperatures involved but we are investigating its utility for substituted cyclopropane synthesis. However, it is another interesting example of a now common type of rearrangement like the silylcarbinol to silyl ether rearrangement (16) or the acylsilane to siloxycarbene photochemical interconversion (17) which involves, with retention stereochemistry, the formation of a silicon–oxygen bond and the cleavage of a silicon–carbon bond.

The fact that dimethoxyalkylsilanes rearrange much more readily than the monoalkoxysilane may be explained, at least in part, by the anticipated extra stability of methoxyphenylcarbene relative to phenylcarbene because of the possibility of sharing lone pair electrons on oxygen with the carbenoid carbon (18).

$$Ph—\ddot{C}—\ddot{O}—Me \longleftrightarrow Ph—\overset{-}{\ddot{C}}=\overset{+}{O}—Me$$

Experimental

Preparation of α,α-Dimethoxybenzyltriphenylsilane (1a)

In a typical experiment, 3.4 g (7.5 mmoles) of 2-triphenylsilyl-2-phenyl-1,3-dithiane, 8.1 g (37.5 mmoles) of mercuric oxide, 4.05 g (15 mmoles) of mercuric chloride, 3.9 g (22.5 mmoles) of anhydrous cadmium carbonate, and 175 ml of methanol were refluxed under an atmosphere of dry nitrogen for 84 h. Filtration, evaporation, and recrystallization from hexane gave 2.53 g (83%) of a white solid, m.p. 163–163.5 °C, with the following spectral data: n.m.r. (CCl_4) δ 3.23 (6H singlet), 7–8 p.p.m.

(20H multiplet); infrared (i.r.) (CCl_4) 3.52 (—OMe), 6.90 (C—Ph), 7.00, 9.05 μ(Si—Ph).

Anal. Calcd. for $C_{27}H_{26}O_2Si$: C, 78.98; H, 6.38. Found: C, 79.42; H, 6.46.

Preparation of (+)-α,α-Dimethoxybenzyl-1-naphthylphenylmethylsilane (1c)

This compound was prepared in an analogous manner to the above. The product was recrystallized several times from hexane to give a colorless solid, m.p. 135.5–136.5°, $[\alpha]_D^{25} = 46.1°$ (*c* 6.83, chloroform); n.m.r. (CCl_4) δ 0.73 (3H singlet), 3.22 (3H singlet), 3.27 (3H singlet), 6.8–8.0 p.p.m. (17H multiplet); i.r. (CCl_4) 3.52 (—OMe), 6.92 (C—Ph), 7.00, 9.05 μ (Si—Ph).

Anal. Calcd. for $C_{26}H_{26}O_2Si$: C, 78.35; H, 6.58. Found: C, 78.50; H, 6.59.

Preparation of α,α-Dimethoxyethyltriphenylsilane (1b)

This compound was prepared at room temperature but in an otherwise identical manner. Work-up gave a compound, m.p. 113–114°, that was very susceptible to hydrolysis and thermolysis. The n.m.r. (CCl_4) δ 1.41 (3H singlet), 3.19 (6H singlet), 7–8 p.p.m. (15H multiplet); i.r., 3.50 (—OMe), 7.00, 9.05 μ (Si—Ph). Since recrystallization led to partial decomposition, an accurate analysis could not be obtained.

Preparation of 2-Triphenylsilyl-2-phenyl-1,3-dioxolane (2a)

Benzoyltriphenylsilane (1.25 g, 3.42 mmoles) and 10 ml of ethylene glycol were added in 25 ml of chloroform to a refluxing solution of 5 ml of boron trifluoride etherate in 50 ml of chloroform. After 1 h, the mixture was extracted with 5% hydrochloric acid, dried over anhydrous magnesium sulfate, filtered, evaporated under reduced pressure, and the resulting solid was recrystallized from hexane to give 1.20 g (86%) of product, m.p. 212–213°; n.m.r. (CCl_4) δ 3.5–4.0 (4H multiplet), δ 7.1–7.7 p.p.m. (20H multiplet); i.r. (CCl_4) 6.90 (C—Ph), 7.00, 9.05 μ (Si—Ph).

Anal. Calcd. for $C_{27}H_{24}O_2Si$: C, 79.37; H, 5.93. Found: C, 79.06; H, 5.91.

Preparation of 2-Triphenylsilyl-2-methyl-1,3-dioxolane (2b)

This compound was prepared analogously to the 2-phenyl compound, using acetyltriphenylsilane in place of benzoyltriphenylsilane: m.p. 138–139.5°; n.m.r. (CCl_4) δ 1.35 (3H singlet), 3.4–4.0 (4H multiplet), 7.1–7.8 p.p.m. (15H multiplet).

Anal. Calcd. for $C_{22}H_{22}O_2Si$: C, 76.26; H, 6.40. Found: C, 76.00; H, 6.41.

Thermolysis of α,α-Dimethoxybenzyltriphenylsilane with Triphenylsilane

In a typical experiment, 0.494 g (1.2 mmoles) of **1***a* was heated at 190° with 0.59 g (2.3 mmoles) of triphenylsilane for 27 min. Chromatography of the reaction mixture on silica gel and elution with carbon tetrachloride gave triphenylmethoxysilane (91%), identified by spectrum and mixture melting point while benzene elution yielded α-methoxybenzyltriphenylsilane (**5**). Recrystallization from methanol gave a 61% yield of product, m.p. 148.5–149.5°. The mixture melting point with an authentic sample (19) was not depressed; n.m.r. (CCl_4) δ 3.30 (3H singlet), 4.65 (1H singlet), 7–8 p.p.m. (20H multiplet).

Anal. Calcd. for $C_{26}H_{24}OSi$: C, 82.06; H, 6.36. Found: C, 81.79; H, 6.46.

Thermolysis of α,α-Dimethoxybenzyltriphenylsilane in Triphenylgermane

Thermolysis of 0.37 g (0.9 mmole) of α,α-dimethoxybenzyltriphenylsilane in 0.27 g (0.9 mmole) of triphenylgermane gave 0.23 g (86%) of triphenylmethoxysilane and 0.29 g (75%) of α-methoxybenzyltriphenylgermane (**6**), m.p. 144–145°; n.m.r. (CCl_4) δ 3.30 (3H singlet), 4.85 (1H singlet), 7–8 p.p.m. (20H multiplet).

Anal. Calcd. for $C_{26}H_{24}OGe$: C, 73.47; H, 5.69. Found: C, 73.33; H, 5.72.

Thermolysis of α,α-Dimethoxybenzyltriphenylsilane with Diphenylacetylene

A mixture of 0.34 g (0.8 mmole) of **1***a* and 0.15 g (0.8 mmole) of diphenylacetylene was heated under nitrogen at 170° for 25 min. The crude melt, whose n.m.r. spectrum showed strong signals at δ 3.58 p.p.m. (Ph_3SiOMe) and 3.31 p.p.m. (methoxytriphenylcyclopropene?) was then dissolved in diethyl ether and HBr gas was bubbled into the solution. The white precipitate was collected to give 0.08 g (29%) of triphenylcyclopropenium bromide, **4**, m.p. 269.5–272°, (lit. (6) 269–271°), whose ultraviolet (u.v.) spectrum was very similar to that previously reported: u.v. (95% EtOH) λ_{max} 317 (ε 24 600), 302 (30 400), 287 (24 200), 230 (32 800), and 223 mμ (36 400). Triphenylmethoxysilane (0.18 g, 75%) was recovered by chromatography of the filtrate. Attempts to isolate the proposed cyclopropene intermediate were unsuccessful.

Thermolysis of α,α-Dimethoxybenzyltriphenylsilane with Dimethyl Fumarate

A mixture of 1.25 g (3.0 mmoles) of **1***a* and 0.44 g (3.0 mmoles) of dimethyl fumarate was heated at 185° for 30 min. Separation of the triphenylmethoxysilane (0.78 g, 89%), unreacted fumarate, and cyclopropyl product was accomplished by column chromatography (silica gel column, and elution with carbon tetrachloride, then benzene, and finally chloroform–benzene, 1:1), followed by fractional distillation. The carbene-trapped product was then recrystallized from carbon tetrachloride–hexane to give 0.44 g (55%) of a white solid, m.p. 76–77°; n.m.r. (CCl_4) δ 2.88, 2.90, $J = 3$ c.p.s. (two doublets for the two *trans* hydrogens) 3.01 (3H singlet), 3.40 (3H singlet), 3.70 (3H singlet), 7.32 (5H multiplet); i.r. (CCl_4) 3.51 (—OMe), 5.76 (ester carbonyl), 6.90 μ (C—Ph).

Anal. Calcd. for $C_{14}H_{16}O_5$: C, 63.63; H, 6.10. Found: C, 63.26; H, 6.15.

Thermolysis of α,α-Dimethoxyethyltriphenylsilane

A 0.20 g sample of **1***b* (0.58 mmole) was heated at 140° for 7 min. After pumping to dryness, a white solid, 1-triphenylsilyl-1-methoxyethene, m.p. 118–121° was obtained quantitatively; n.m.r. (CCl_4) δ 3.56 (3H singlet), 4.40 (1H doublet, $J = 2$ c.p.s.), 4.89 (1H doublet, $J = 2$ c.p.s.) 7.1–8 p.p.m. (15H multiplet); i.r. (CCl_4) 3.50 (—OMe), 7.00, 9.03 (Si—Ph), 11.20 μ (C=C).

Anal. Calcd. for $C_{21}H_{20}OSi$: C, 79.70; H, 6.37. Found: C, 79.65; H, 6.28.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Thermolysis of (+)-α,α-Dimethoxybenzyl-1-naphthylphenylmethylsilane

Thermolysis of 0.55 g (1.4 mmoles) of **1***c* ($[\alpha]_D^{25}$ = 46.1° (*c* 6.83, $CHCl_3$)) at 200° for 90 min gave a reaction mixture that was chromatographed on silica gel to give 0.34 g (89%) of pure (−)-1-naphthylphenylmethylmethoxysilane, $[\alpha]_D^{25} = -16.4°$ (*c* 4.70, pentane), [lit. (14) $[\alpha]_D^{25} = -17.2°$ (pentane)]. No attempt was made to isolate other products.

Thermolysis of α-Methoxybenzyltriphenylsilane

A small sample (0.05 g, 0.13 mmole) of α-methoxybenzyltriphenylsilane was heated at 240° for 65 h. An n.m.r. spectrum showed that starting material remained as well as some decomposition products; there was no evidence of formation of triphenylmethoxysilane. A similar experiment at 315° for 45 min showed that very little of the starting material had decomposed, and that again, no triphenylmethoxysilane was formed.

Preparation of α-Methoxybenzhydrylmethyldiphenylsilane

A solution of 2.0 g (4.5 mmoles) of bromobenzhydrylmethyldiphenylsilane in 40 ml of methanol and 60 ml of carbon tetrachloride was refluxed for 2 h. Partial evaporation and cooling gave 1.3 g (72%) of white solid, m.p. 149°; n.m.r. ($CDCl_3$) δ 0.35 p.p.m. (3H singlet), 3.05 p.p.m. (3H singlet), 7–8 p.p.m. (20H multiplet); i.r. ($CHCl_3$), 3.51 μ (—OMe).

Anal. Calcd. for $C_{27}H_{26}OSi$: C, 82.23; H, 6.59. Found: C, 82.10; H, 6.24.

Thermal Rearrangement of α-Methoxybenzhydrylmethyldiphenylsilane

A 2.0 g sample of compound was heated in a sealed tube containing air at 250° for 18 h. The crude brown liquid product showed the following spectral data: n.m.r. ($CDCl_3$) δ 0.55 p.p.m., 3.45 p.p.m. (ratio 1:1) 7–8 p.p.m. (multiplets); i.r. ($CHCl_3$) 3.53 (—OMe), 6.01 μ (C=O).

When the experiment was repeated in an open tube while oxygen was bubbled into the molten material, the i.r. band at 6.01 μ was stronger. Treatment of 1 g of the reaction product with 0.5 g of 2,4-dinitrophenylhydrazine in 15 ml of DMSO gave after 2 h 0.2 g of crude phenylhydrazone which after recrystallization gave 0.1 g of benzophenone-2,4-dinitrophenylhydrazone, m.p. and mixture m.p. 242–244°.

Methyldiphenylmethoxysilane (20)

To 5.8 g (25 mmoles) of methyldiphenylchlorosilane in 30 ml dry ether were added 1.5 g of methanol and 2.8 g of pyridine. After 1 h stirring, and filtration of the insoluble pyridine hydrochloride, the solution was distilled to yield 4.4 g (76%) of methyldiphenylmethoxysilane, b.p. 80° at 5 mm; n.m.r. ($CDCl_3$) δ 0.55 p.p.m. (3H, singlet), 3.45 p.p.m. (3H, singlet), 7–8 p.p.m. (10H, multiplet); i.r. (CCl_4) 3.53 μ.

The synthesis of silyl- and germyldiazoalkanes via tosylhydrazones

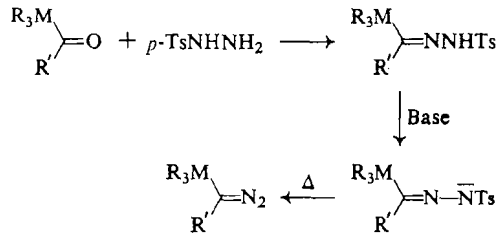
A. G. Brook and Peter F. Jones
Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario, Canada

Received December 27, 1968

Tosylhydrazones have been prepared from acylsilanes and -germanes. These may be converted in excellent yield by *n*-butyllithium to the metalloidal diazoalkanes under milder conditions than are required for the analogous carbon compounds. The diazoalkanes are far more stable than their carbon counterparts. These results, together with spectral shifts noted for the silyl and germyl compounds, are interpreted in terms of $d\pi$–$p\pi$ bonding between the diazo group and the metalloid atom.

Canadian Journal of Chemistry, 47, 4353 (1969)

The recent appearance in the literature (1–6) of a number of short communications on the preparation of silyldiazoalkanes reflects the interest currently being shown in these compounds. However, all these methods are somewhat restricted in scope due to the non-availability of suitable starting materials. It seemed to us that the best (and only general) route to silyl- and germyldiazoalkanes was, with the wide spectrum of acylmetalloids available in this laboratory (7), via the use of tosylhydrazones (eg. [1]).

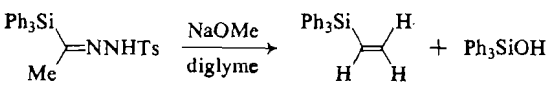


[1]

Prior to this work, few studies had been made on the synthesis of the "classical" ketone derivatives from acylmetalloids. Benzoyltriphenylsilane, the first acylsilane, was found (8) to give a phenylhydrazone, while 2,4-dinitrophenylhydrazones were prepared (9) from some low molecular weight acylmetalloids. We have found that tosylhydrazones may be prepared in good yield in the case of alkyl ketones ($R_3MCOAlk$) simply by heating the ketone and *p*-tosylhydrazine together under reflux in alcohol. However, on the attempted extension of this method to the aryl ketone benzoyltriphenylsilane, only a low yield of the desired tosylhydrazone was obtained, accompanied by extensive formation of silanol and benzaldehyde. In this case, attack of the hydroxylic solvent at silicon appears to be competitive with tosylhydrazone formation due to the lower reactivity of the carbonyl group in aryl ketones. A similar decomposition has been noted (8) in the attempted preparation of an oxime of this ketone. This difficulty has now been easily circumvented by heating the aryl ketone and *p*-tosylhydrazine together in a minimal volume of glacial acetic acid. Table III of the Experimental section lists the tosylhydrazones prepared in this study.

A preferred method for the generation of carbenes in carbon chemistry is the pyrolysis (10) of tosylhydrazone anions. The diazoalkanes obtained *in situ* decompose smoothly to carbenes in aprotic media at the elevated (ca. 150°) temperature employed, thus avoiding the necessity of isolating these explosive compounds. However, the use of this technique for the generation of silylcarbenes has been found to suffer from competing attack of the base employed (methoxide ion) at silicon, resulting in reduced yields of products derived from silylcarbenes. Thus the decomposition of acetyltriphenylsilane tosylhydrazone anion in refluxing diglyme gave vinyltriphenylsilane, the carbene rearrangement product and, in addition, considerable triphenylsilanol, arising from hydrolysis of triphenylmethoxysilane during workup (eq. [2]). Similarly,

[2]



in the pyrolysis of benzoyltriphenylsilane tosylhydrazone in dimethyl sulphoxide, none of the desired (11) benzoylsilane was isolated, and only its decomposition products, triphenylsilanol and benzaldehyde, were observed (eq. [3]). Benzoyltriphenylsilane was found to completely decompose under similar conditions.

TABLE I

The conversion of tosylhydrazones to diazoalkanes via their sodium salts*

R_3M	R′	Conditions	% Recovered tosylhydrazone	% Yield of diazoalkane†
Ph_3Si	Me	70°; 90 min	45	31
Ph_3Si	Ph	70°; 120 min	19	25
Ph_3Si	C_6H_4-*p*-Cl	75°; 90 min	—	31
Ph_3Si	C_6H_4-*p*-F	80°; 150 min	13	29
Me_3C	Ph	70°; 150 min	65	77‡

*The general reaction was: $R_3M(R')C{=}NNHTs \xrightarrow[\text{pyridine}]{\text{NaOMe}} R_3M(R')C{=}N_2$.

†Yield of crystallized, purified diazoalkane (based on the tosylhydrazone consumed).
‡Yield of crude red oil obtained after removal of tosylhydrazone.

[3] $Ph_3Si(Ph)C{=}NNHTs \xrightarrow[\text{DMSO}]{\text{NaOMe}} Ph_3SiCOPh + Ph_3SiOH + PhCHO$

To avoid these problems the direct isolation of silyldiazoalkanes and their decomposition under base-free conditions has been sought. Initial work was centered on the decomposition of the sodium salts of the tosylhydrazones. In their pioneering study Bamford and Stevens (12) showed that under mild conditions in ethanolic sodium ethoxide, the stabilized aryldiazoalkanes could be produced. Farnum (13) reported an improvement in the synthesis with the use of pyridine as solvent. However, non-stabilized alkyldiazoalkanes could not be prepared, since the parent tosylhydrazone salts showed no decomposition under the mild conditions employed. Using Farnum's conditions, it was found, in complete contrast to the carbon compounds, that this method can be used for the preparation of *both* alkyl- and arylsilyldiazoalkanes. Unfortunately the method suffers from incomplete conversion to silyldiazoalkanes, up to 50% recovered tosylhydrazone being obtained with the silyl–alkyl compounds, as shown in Table I. However, the extent of conversion does indicate an unexpected stability of the silyldiazoalkanes.

Excellent conversions of tosylhydrazones to diazoalkanes have been obtained using the decomposition of the lithium salts. Kaufman and co-workers have reported (14) that lithium salts of tosylhydrazones decompose at a lower temperature than the corresponding sodium salts. The metalloid compounds behave similarly, since treatment at room temperature of the tosylhydrazones in tetrahydrofuran with *n*-butyllithium gives complete conversion to the corresponding diazoalkane. Details are given in Table V in the experimental section. These results again reflect an unusual stability of silyl- and germyldiazoalkanes, since it is reported (14) that temperatures of 80–120° are required to effect decomposition of the solid lithium salts in carbon compounds.

As indicated above by their ease of formation, the metalloidal diazoalkanes do in fact possess striking stability. These compounds, which are yellow-orange in color in contrast to the characteristic red carbon compounds, may be readily purified by recrystallization and appear to be indefinitely stable on storage at room temperature. This behaviour may be contrasted to the notorious instability of carbon diazoalkanes such as 2-diazopropane, Me_2CN_2, which is reported (15) to have a half-life of 3 h at 0°.

Diazoalkanes are considered (16) to be a hybrid of 2 major resonance forms (I and II).

$$R_2C{=}\overset{+}{N}{=}\overset{-}{N} \leftrightarrow R_2\overset{-}{C}{-}\overset{+}{N}{\equiv}N$$
I II

Diazoketones and -esters are said to owe their increased stability to delocalization of charge by the carbonyl group (16).

$$R'{-}\underset{\underset{O}{\|}}{C}{-}\overset{-}{C}R{-}\overset{+}{N}{\equiv}N \leftrightarrow R'{-}\underset{\underset{-O}{|}}{C}{=}CR{-}\overset{+}{N}{\equiv}N$$

The aryl group of aryldiazoalkanes plays a similar stabilizing role. The increased stability of diazoalkanes on replacement of carbon by silicon is therefore surprising at first thought, since it is in apparent contradiction to the expected destabilization of contributors of type II due to the greater

inductive release arising from the lower electronegativity of silicon. However, silicon in addition to acting as a sigma-donor can act as a pi-acceptor since, unlike carbon, it possesses energetically available empty d orbitals capable of interaction with, and stabilization of, the adjacent carbanion centre. Similar arguments have

$$R_3Si{-}CR{=}\overset{+}{N}{=}\overset{-}{N} \leftrightarrow R_3Si{-}\overset{-}{C}R{-}\overset{+}{N}{\equiv}N \leftrightarrow R_3\overset{-}{Si}{=}CR{-}\overset{+}{N}{\equiv}N$$

I IIa IIb

been advanced (17) to explain the unexpected stability of carbanions adjacent to silicon. This $d\pi$–$p\pi$ ground state interaction, which alters so noticeably the stability of these compounds, is also reflected by changes in their spectral properties. In the ultraviolet (u.v.) region, the lower ground-state energy leads to an increased energy requirement for promotion to the excited state. The low energy transition responsible for the characteristic red color of diazoalkanes undergoes a hypsochromic shift, shown visually by the color change to yellow–orange, on replacement of carbon by a metalloid atom. The u.v. spectral data are given in Table II for representative compounds of the two general classes studied. Model carbon compounds containing the trityl group could not be prepared, due to the failure of both acetyltriphenylmethane and benzoyltriphenylmethane (β-benzopinacolone) to give tosylhydrazone derivatives, even under conditions more vigorous than those used successfully for the conversion of the analogous acylmetalloids. This inertness is presumably a result of steric factors. It was decided that diazoalkanes containing the *t*-butyl group would provide the best alternative, since the parent carbonyl compounds are known (14, 18) to give tosylhydrazones which may be readily converted to the diazo compounds.

TABLE II

Ph_3Si	Me	426	4.89
Me_3C	Me*	490	4.90

*Prepared by the pyrolysis of the dry lithium salt of the tosylhydrazone (reference 14).

The suggested increased contribution of resonance form II to the hybrid would be predicted to lead to an increase in the triple bond character of the N—N bond. Such an effect should be, and is, observable in the infrared (i.r.) spectrum by a shift of the diazo stretching band to higher energy. Significant data are given in Table II. The above results are very similar to those found (19) in the isoelectronic azide system, where substitution of adjacent carbon by silicon or germanium results in increased N—N i.r. stretching frequency and a hypsochromic shift of the low energy u.v. band.

Extensive work has been carried out on the 1,3-cycloaddition reactions of these compounds, together with their decomposition to carbenes and diazonium ions. This will be reported in a future paper.

Experimental

All reactions were carried out under an atmosphere of nitrogen. The nuclear magnetic resonance (n.m.r.) spectra were measured on a Varian A60 instrument, the i.r. spectra on a Perkin–Elmer 237B, and the u.v. spectra on a Perkin–Elmer Model 350.

Preparation of Acetyltriphenylsilane Toluene-p-sulphonylhydrazone

A mixture of 5.0 g (0.0166 mole) of acetyltriphenylsilane and 3.10 g (0.0166 mole) of toluene-*p*-sulphonylhydrazine was heated under reflux for 2 h in 100 ml of ethanol acidified by 20 drops of glacial acetic acid. During the course of the reaction an initial clear solution was obtained, which later deposited a white precipitate. This was filtered off to give 6.08 g (78%) of tosylhydrazone, m.p. 188–190° with decomposition.

Preparation of Benzoyltriphenylsilane Toluene-p-sulphonylhydrazone

Separate solutions of 2.2 g (0.0061 mole) of benzoyltriphenylsilane and 1.1 g (0.0059 mole) of toluene-*p*-sulphonylhydrazine, each dissolved in the minimal volume of hot glacial acetic acid, were mixed, and heated to boiling. Cooling precipitated a white solid, which was filtered off, washed with aqueous acetic acid and water, and then oven-dried to give 3.15 g (98%) of the crude tosylhydrazone, m.p. 170–180°. Recrystallization from methanol–benzene gave 2.35 g (73%) of product, m.p. 187–191° with decomposition.

The remainder of the tosylhydrazones were similarly prepared by one of the two methods given. Details are shown in Table III. The n.m.r. spectral data are given in Table IV.

Attempted Preparations of β-Benzopinacolone Toluene-p-sulphonylhydrazone

An equimolar mixture of β-benzopinacolone and

‖Boiling point (pressure).

zone and 0.041 g (0.00078 mole) of sodium methoxide was heated under reflux for 30 min in 15 ml of diglyme. The mixture was poured into water and extracted with hexane. After drying over magnesium sulphate, evaporation of the organic layer gave an oil, which was chromatographed on silica gel. Elution with carbon tetrachloride gave 0.075 g (30%) of vinyltriphenylsilane, m.p. 50–58°. Recrystallization from ethanol raised the m.p. to 67–68°. A mixed m.p. with an authentic sample was undepressed. Further elution with benzene gave 0.10 g (46%) of triphenylsilanol, m.p. 152–155°.

The Pyrolysis of the Sodium Salt of Benzoyltriphenylsilane Toluene-p-sulphonylhydrazone in Dimethyl Sulphoxide

A mixture of 0.20 g (0.00038 mole) of the tosylhydrazone and 0.024 g (0.00044 mole) of sodium methoxide was heated under nitrogen in 5 ml of dimethyl sulphoxide (dried over calcium hydride) at up to 145° for 15 min. The mixture was poured into water and extracted with ether. An oil was obtained upon workup of the organic layer, which smelled strongly of benzaldehyde. An i.r. spectrum confirmed the presence of benzaldehyde and also triphenylsilanol. None of the expected benzoyltriphenylsilane could be detected.

In a separate experiment, 0.20 g of benzoyltriphenylsilane was heated to 150° with 0.010 g of sodium methoxide in 5 ml of dimethyl sulphoxide for 15 min. The mixture was poured into water and extracted with ether. The colorless oil obtained from evaporation of the organic layer was shown by its i.r. spectrum to be a mixture of benzaldehyde and hexaphenyldisiloxane. None of the starting ketone could be observed.

In contrast to the above, when 0.15 g of benzoyltriphenylsilane was heated in 5 ml of dimethyl sulphoxide at up to 150° for 15 min in the absence of base, the ketone was recovered in 87% yield.

The Preparation of Triphenylsilylphenyldiazomethane using Sodium Methoxide in Pyridine

A mixture of 2.0 g (0.00376 mole) of benzoyltriphenylsilane toluene-*p*-sulphonylhydrazone and 0.20 g (0.00370 mole) of sodium methoxide in 50 ml of dry pyridine was heated by means of an oil bath at up to 70° for 2 h. The resulting orange mixture was poured into water and extracted with pentane. A white solid which precipitated from the organic layer was removed to give 0.38 g (19%) of crude recovered tosylhydrazone, m.p. 155–170°. Recrystallization from methanol raised the m.p. to 186–190°. The orange pentane filtrate was dried over magnesium sulphate and the solvent was evaporated. The resulting solid was recrystallized from pentane–benzene to give 0.30 g (25% based on tosylhydrazone consumed) of orange diazoalkane, m.p. 146–150°. A further recrystallization from pentane–benzene raised the m.p. to 150–152°.

Details are given in Table I of the other tosylhydrazones converted to diazoalkanes by this method.

The Preparation of 1-Triphenylsilyl-1-diazoethane using n-Butyllithium

To a solution of 9.40 g (0.02 mole) of acetyltriphenylsilane toluene-*p*-sulphonylhydrazone in 300 ml of anhydrous tetrahydrofuran, cooled to 0°, was added 12.5 ml (0.02 mole) of *n*-butyllithium solution. The mixture was stirred in the dark at room temperature for 46 h and then was filtered. Ether was added to the filtrate, which was then washed with water, dried over sodium sulphate, and evaporated to give a yellow solid. Recrystallization from a minimal volume of pentane gave 5.12 g (82%) of yellow diazoalkane, m.p. 82–84°.

Results of the other reactions of this class are given in Table V. Details of the u.v. and i.r. spectra of these compounds are given in Table VI. Table VII gives the n.m.r. data for the diazoalkanes.

Studies related to Bute Inlet wax[1]. The identity of norphytane, pristane, and bute hydrocarbon

TIKAM C. JAIN AND ROBERT J. STRIHA[2]
Department of Chemistry, University of Victoria, Victoria, British Columbia
Received June 20, 1969

Spectral and gas–liquid chromatographic evidence is presented to confirm the identity of pristane with norphytane and bute hydrocarbon.

Canadian Journal of Chemistry, 47, 4359 (1969)

Bute Inlet wax is a dark colored semi-solid which appears mysteriously during extremely cold winters on the water of Bute Inlet situated on the west coast of British Columbia. Recently we reported (1) on the isolation of a hydrocarbon, $C_{19}H_{40}$, from this source which was proven to be 2,6,10,14-tetramethylpentadecane (pristane) (**1**). Sörensen (2,3) established the identity of pristane with norphytane **1** on the basis of their physical constants and infrared (i.r.) spectra.[3] In view of the significance of pristane in organic geochemical work (4,5), coupled with our own work on bute hydrocarbon (1), it was desirable to execute a more rigorous comparison of pristane[4] with an authentic specimen of norphytane and bute hydrocarbon.

Norphytane required for this work was prepared[5] in the manner described in Scheme 1. The mass spectrum of norphytane (Table I) was identical with the corresponding spectra of pristane and bute hydrocarbon. Finally, gas–liquid chromatographic behavior of these three hydrocarbons (Table II) conclusively established their structural identity.

Experimental

All melting points and boiling points are uncorrected; melting points were determined on a Kofler hot stage. Infrared spectra were recorded with a Perkin–Elmer Infracord Model 337, calibrated with polystyrene film.

TABLE I

Important peaks (in order of decreasing mass) in the mass spectra of $C_{19}H_{40}$

	$\%\Sigma_{27}$		
m/e	Bute hydrocarbon	Pristane	Norphytane
268	1.10	1.27	1.19
183	4.65	4.79	4.58
113	4.46	4.54	4.46
85	5.14	5.28	5 30
71	12.33	12.12	12.14
57	14.70	12.56	12.78
43	10.12	10.19	10 40
41	4.53	4.48	4.65

Nuclear magnetic resonance (n.m.r.) spectra were obtained with Varian Associates Model HA-60 spectrometer. The mass spectra were measured with Hitachi–Perkin–Elmer RMU-6E single-focus mass spectrometer using an ionizing energy of 70 eV and a source temperature of 250°. Gas–liquid chromatographic analyses were carried out on a Perkin–Elmer Gas Chromatograph Model 810 (with flame ionization detector) equipped with 6 ft × 0.25 in. columns with helium as a carrier gas. Thin-layer chromatographic determinations were carried out on alumina and silica plates; the spots were developed by exposure to I_2 vapor. The microanalyses were performed by Schwarzkopf Microanalytical Laboratory, New York.

Phytol (2)

Commercially available phytol, 75% pure by gas–liquid chromatography (g.l.c.), was purified by column chromatography on silica gel followed by fractional distillation. The fraction boiling at 170–185° (bath)/0.25 mm was g.l.c. pure (> 99%) phytol (**2**) obtained as a colorless liquid; ν_{max} (film): 3340, 1670, 1375, 1365, and 1000 cm^{-1}; τ ($CDCl_3$): 9.14 (12H, doublet, J = 5.6 Hz), 8.35 (3H, singlet), 8.07 (2H, broad multiplet), 7.59 (1H, singlet), 5.91 (2H, doublet, J = 7.0 Hz), 4.62 (1H, broad multiplet); mass spectrum: *m/e* ($\%\Sigma_{29}$): 296 (1.09, M^+), 278 (0.47, M—H_2O).

Anal. Calcd. for $C_{20}H_{40}O$: C, 81.00; H, 13.60. Found: C, 80.49; H, 13.61.

Phytyl Acetate (3)

Freshly distilled phytol (**2**) turns light yellow on

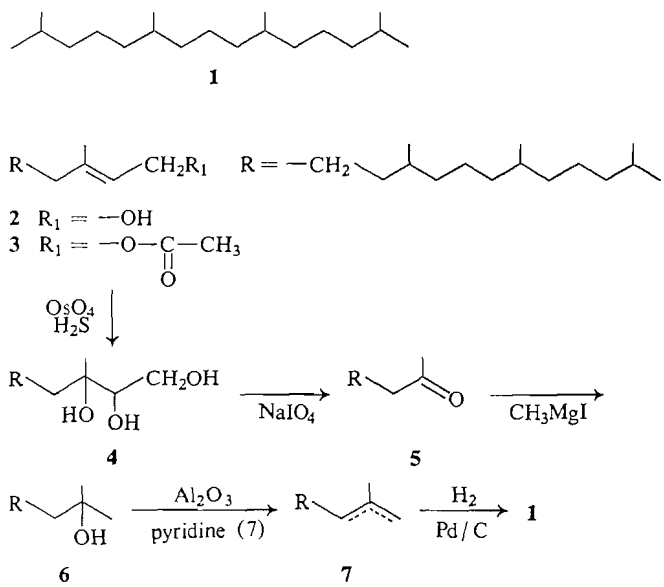
[2]N.R.C.C. Postgraduate Scholar, 1968–present.
[3]Besides these two publications (2,3), we are unaware of any other report concerning this aspect.
[4]From K & K Laboratories, Inc., U.S.A.
[5]Because of the lack of precise experimental details in the literature (2), a full account of our modified procedures is given in the experimental part of this paper. However, a different procedure for synthesis of pristane from phytol has been recently reported by Kates (6).



SCHEME 1

standing due to aerial oxidation. It was converted into its relatively more stable acetoxy derivative (Ac_2O–pyridine method). Phytyl acetate (**3**) was distilled[6] at 145–146°/0.25 mm as a clear liquid;[7] ν_{max} (film): 1740 (acetoxy carbonyl), 1670 (>C=C<), 1375, and 1360 cm^{-1} (*gem*-dimethyl); τ ($CDCl_3$): 9.14 (12H, doublet, J = 5.5 Hz), 8.79 (broad singlet), 8.33 (3H, broad singlet), 8.03 (3H, singlet), 5.45 (2H, broad doublet, J = 7.2 Hz), 4.5–4.8 (1H, broad multiplet).

Anal.[8] Calcd. for $C_{22}H_{42}O_2$: C, 78.04; H, 12.50. Found: C, 79.44; H, 12.95.

Phytane-1,2,3-triol (4)

A solution of OsO_4 (1 g) in 1:1 ether–petroleum ether (60 ml) was slowly added in two portions to a magnetically stirred solution of phytyl acetate (**3**) (1.3 g) dissolved in ether–petroleum ether (1:1, 40 ml) containing anhydrous pyridine (3 ml), and the reaction mixture was stirred at room temperature for 4 days in the dark. The bulk of the solution was concentrated to ca. 25 ml and the solid osmic ester was collected, dissolved in benzene–methanol (1:1, 120 ml), and the solution saturated with H_2S with cooling. The brownish–black precipitate was filtered off and washed with benzene (10 ml). The solvent was removed *in vacuo* and the residual gum [1.25 g; ν_{max} (film): 3450 (hydroxyl), 1745 cm^{-1} (acetate)] was hydrolyzed by refluxing in aqueous methanolic KOH. The reaction mixture was worked up in the usual manner yielding phytane-1,2,3-triol [**4**], crystallised from acetone–acetonitrile to give white crystals, m.p. 56–57°; ν_{max} ($CHCl_3$): 3445, 1210, 1086 cm^{-1} (hydroxyl); τ ($CDCl_3$): 9.13 (12H, doublet, J = 5.6 Hz), 8.85 (singlet), 5.8–6.7 (broad, 6-proton band reduced to a 3-proton multiplet after exchange with D_2O).

Anal. Calcd. for $C_{20}H_{42}O_3$: C, 72.67; H, 12.81. Found: C, 72.70; H, 12.68.

$NaIO_4$ Oxidation of Phytane-1,2,3-triol (4)

A solution of $NaIO_4$ (360 mg dissolved in 1 ml H_2O and diluted with 9 ml MeOH) was slowly added to the triol **4** (233 mg) dissolved in MeOH (9 ml) and the reaction mixture was set aside for 24 h at room temperature in the dark. The solvent was removed *in vacuo* and the residue diluted with water (30 ml) and extracted with Et_2O (3 × 20 ml). The combined extract was washed with brine solution (2 × 15 ml), dried over Na_2SO_4, and the solvent removed under suction, to yield a yellow oil (208 mg). Filtration through a column of silica gel (4.2 g) in petroleum ether (50 ml) afforded a clear mobile liquid (188 mg), b.p. 194–197° (bath)/8.5 mm; ν_{max} (film): 1717 cm^{-1} (acyclic ketone); τ ($CDCl_3$): 9.13 (12H, doublet, J = 5.7 Hz), 7.89 (3H, singlet), 7.61 (2H, broad triplet).

Anal. Calcd. for $C_{18}H_{36}O$: C, 80.52; H, 13.52. Found: C, 79.65; H, 13.05.

The ketone **5** was further characterized by its semicarbazone, m.p. 65–67° (lit. (8) m.p. 66–67°).

Grignard Addition to the Ketone 5

A solution of ketone **5** (219 mg) in dry ether (15 ml) was added in N_2 atmosphere to 5 equivalents of MeMgI (prepared from 125 mg Mg and 740 mg MeI) and the

[6]Attempted purification by column chromatography on alumina invariably led to its hydrolysis.

[7]The homogeneity of each liquid intermediate was rigorously checked by t.l.c. and g.l.c. [cf. experimental details given in reference (2)].

[8]A better analysis on this g.l.c. pure specimen could not be obtained presumably due to its tendency towards partial hydrolysis on standing. However, its mass spectrum displayed a weak molecular ion peak at *m/e* 338 with an intense peak at *m/e* 278 due to M—CH_3COOH fragment.

TABLE II

Retention times relative to nonadecane

Sample	DEGS*	MPS oil†	APL‡	MPS gum§
Nonadecane	1.00	1.00	1.00	1.00
Pristane	0.52	0.42	0.43	0.58
Norphytane	0.52	0.42	0.44	0.58
Bute hydrocarbon	0.52	0.42	0.44	0.58

*Diethyleneglycolsuccinate (DEGS) at 188° with 35 ml of helium/min.
†Methylphenylsilicone oil (MPS oil) at 189° with 23.5 ml of helium/min.
‡Apiezon L (APL) at 227° with 22 ml of helium/min.
§Methylphenylsilicone gum (MPS gum) at 237° with 30 ml of helium/min.

mixture was stirred at room temperature for 1 h. Ether was removed with a swift current of nitrogen and replaced with anhydrous benzene (40 ml) and the reaction mixture was refluxed for 24 h. The mixture was then cooled and rapidly acidified with saturated aqueous NH_4Cl. The product was extracted with ether (3 × 30 ml) and the combined ether extract was washed with brine (15 ml), dried, and evaporated to yield the alcohol **6** (245 mg); ν_{max} (film): 3390 cm^{-1} (hydroxyl). There was apparently some dehydration during the work up, evidenced by a band at 910 cm^{-1} in its i.r. spectrum. Consequently, the product was used as such without any further purification for subsequent reaction.

Dehydration of the Alcohol 6

The crude alcohol **6** (245 mg) was mixed with pyridine-treated alumina (2%) and heated in an atmosphere of nitrogen at 150–170° for 1 h (7). The reaction mixture was slurried with ether, filtered, and dried over Na_2SO_4. Removal of solvent *in vacuo* furnished a mobile liquid (200 mg) which was filtered through a column of silica gel and then distilled at 175° (bath)/7.0 mm to give a mixture[9] of hydrocarbons **7** (158 mg); ν_{max} (film): 1652, 1380, 1365, 1173, 1154, and 886 cm^{-1}.

Anal. Calcd. for $C_{19}H_{38}$: C, 85.63; H, 14.37. Found: C, 85.51; H, 14.42.

Norphytane (1)

A solution of hydrocarbons **7** (80 mg) in absolute ethanol (20 ml) containing 10% Pd/C (20 mg) was stirred at room temperature under H_2 until absorption ceased. The catalyst was removed by filtration and the filtrate was evaporated under reduced pressure to give norphytane **1** in quantitative yield; no coloration with tetranitromethane; distilled over sodium at 165–170° (bath)/7.0 mm as a clear liquid; ν_{max} (film): 1385, 1365, 1170, and 1155 cm^{-1}; τ ($CDCl_3$): 9.14 (18H, doublet, J = 5.8 Hz), 8.78 (22H, singlet); overall yield: 85% based on triol **4**.

Anal. Calcd. for $C_{19}H_{40}$: C, 84.98; H, 15.02. Found: C, 85.09; H, 14.70.

[9]Careful integration of the olefinic signals in the n.m.r. spectrum revealed the presence of norphytene-1 and norphytene-2 in the ratio of 3:7.

threo- and *erythro*-β-Hydroxy-DL-aspartic acids

CLIFTON W. JONES, III,[1] DONALD E. LEYDEN, AND CHARLES H. STAMMER[2]
Department of Chemistry, University of Georgia, Athens, Georgia 30601

Received May 1, 1969

An improved procedure for the synthesis of *threo*- and *erythro*-β-hydroxy-DL-aspartic acids is described. An nuclear magnetic resonance study of both diastereomers indicated that the *threo* isomer exists primarily as the conformer having *anti* carboxyl groups while the *erythro* compound prefers a conformation with *gauche* carboxyl functions. Possible reasons for this anomaly are presented.

Canadian Journal of Chemistry, 47, 4363 (1969)

During the pursuit of intermediates useful in the synthesis of cycloserine analogs, we became interested in the diastereomers of racemic β-hydroxyaspartic acid (HAA). The synthesis of these isomers was carried out using a reaction path described by Miller (*1*); i.e., the treatment of *cis*- and *trans*-epoxysuccinic acids with ammonia, with some considerable modification of the actual procedure. The sodium salt of *cis*-epoxysuccinic acid, which was obtained directly from the oxidation of maleic acid, was treated with concentrated ammonium hydroxide without the troublesome prior conversion to the free acid as was done by the early workers. This resulted in a considerable saving of time and an increased yield of the *threo* amino acids. The *erythro* isomer was also prepared by this modified procedure, and, even though the product had the expected physical properties, we found that it was impure. The melting points of these highly polar amino acids are very poor indices of purity since partial decomposition always occurs during heating. Dimethyl sulfite esterification of the recrystallized *erythro* amino acid gave a dimethyl ester which consistently contained excess nitrogen by elemental analysis. Apparently, an ammonium salt was coprecipitated with the acid when it was isolated from the amination reaction mixture by acidification. Since recrystallization failed to remove this, the amino acid was placed on a strongly basic anion exchange resin (Amberlite IRA-400) and eluted with acetic acid. Pure erythro-DL-HAA was obtained which gave derivatives having the correct nitrogen content.[3]

Having the pure diastereomers in hand, we investigated their nuclear magnetic resonance (n.m.r.) spectra in D_2O where only the H_α, H_β protons were detectable. Previous investigations of amino acid n.m.r. spectra (*3*) indicated that the size of the vicinal coupling constant, $J_{\alpha,\beta}$, might allow us to estimate which rotational conformation of HAA is preferred. Both cysteine and histidine (*3d*) had $J_{\alpha,\beta}$ values consistent with the Karplus relationship (*4*), but those for β-hydroxy amino acids, threonine, and *allo*-threonine are somewhat anomalous (*3f*); i.e., assuming that the preferred rotomer will have the carboxyl and β-substituents *anti*, the *threo* isomer should show $J_{\alpha,\beta} \sim 3$ and *erythro* isomer should have $J_{\alpha,\beta} \sim 11$ c.p.s., whereas the observed values are 3.8 and 3.6 c.p.s., respectively. A similar "anomaly" was reported in connection with the *N*,β-dimethylleucines and *N*-methylisoleucine (*5*). Reports by Pachler (*3a,b*) on aspartic acid and by Alberty and co-workers (*6a*), Gawron and co-worker (*6b*), and Pachler (*3a*) on malic acid indicated, however, that these dicarboxylic acids do indeed exist preferably with the carboxyl groups in the *anti* conformation. We were led, therefore, to expect that *threo*-HAA might have a small $J_{\alpha,\beta}$ (see TA, Chart 1) while that of the *erythro* isomer would be large (see EA, Chart 1). Tables I and II show that *erythro*-HAA does not conform to these expectations, but *threo*-HAA does.

When the staggered conformations for these amino acids (T = *threo*, E = *erythro*, R = H) are examined (Chart 1), the small $J_{\alpha,\beta}$ of the *threo* acid suggests that conformers TA and TB having H_α and H_β *gauche* are very largely preferred over TC. It follows from the conformer populations (Table II), that the equilibrium constant for the formation of TA + TB from TC is approximately 99, which corresponds

[1]Abstracted from the Master of Science thesis presented to the University of Georgia Graduate School by C. W. Jones, III, in June, 1968.

[2]To whom inquiries should be addressed.

[3]Early workers who obtained *erythro*-DL-HAA by acidification of its ammoniacal solutions undoubtedly had an impure product; cf. (*2*).

TABLE I

$J_{\alpha,\beta}$, ν_α, ν_β, and conformer populations at various pH's for *erythro*-β-hydroxy-DL-aspartic acid

†100 Hz values.

(7) to a ΔG of -2.72 kcal/mole. In order to calculate the enthalpy change for this equilibrium, we must take into account the fact that *two* of the possible conformers have a small $J_{\alpha,\beta}$ while only one has a large $J_{\alpha,\beta}$. The rotamers having the small coupling are favored probability-wise and ΔS for the equilibrium can be equated (7) to R ln 2. Using similar arguments for the *erythro* isomer, the thermodynamic parameters (see Table III) for the equilibrium formation of EB + EC (conformations with gauche protons) from EA were also calculated. These results show that the EB + EC mixture is strongly favored even though both of these conformations have *gauche* carboxyl groups. The overwhelmingly favored conformation (TA) of the *threo* isomer[4] has *anti* carboxyl functions and the question as to why the *anti* conformation is favored in one isomer and disfavored in the other is complex and cannot be completely explained at this time. As the pH of the solutions is increased, increasing electrostatic repulsion between the negatively charged carboxyl groups will cause the anti-conformers (EA and TA) to be favored. Since $J_{\alpha,\beta}$ of the *threo* isomer underwent essentially no change with pH, it most probably exists in both acid and base as the *anti* conformer, TA. The *erythro* compound should show a considerable increase in $J_{\alpha,\beta}$ as the pH rises since conformer EA should become more prevalent. The small change from 2.8 to only 4.3 c.p.s. concurrent with a pH increase of approximately 12 units shows that the concentration of EA does increase, but not to a predominant level. An n.m.r. study of both *threo*- and *erythro*-HAA in basic D_2O solution at temperatures between 30 and 90° showed essentially no change in $J_{\alpha,\beta}$ consistent

[4]TA is doubly favored because it allows a hydroxyl–amine hydrogen bond but lacks the carboxyl–carboxyl *gauche* interaction of TB.

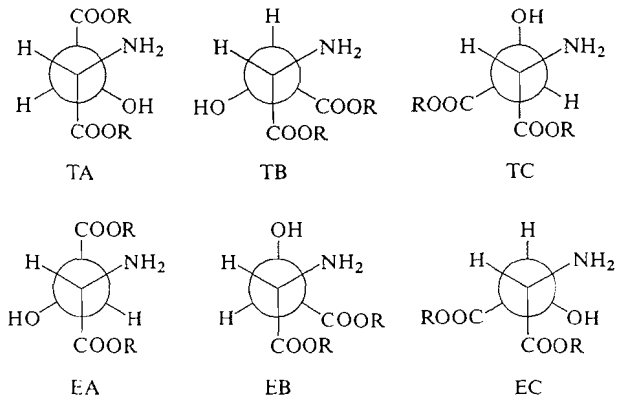

CHART 1

TABLE III
Thermodynamic parameters

	p*H*	*K*	Δ*G*(kcal/mole)	Δ*H*(kcal/mole)
threo-HAA TC ⇌ TA + TB	1.00 and 13.20	99	−2.72	−2.31
erythro-HAA	2.96	24	−1.88	−1.46
EA ⇌ EB + EC	13.30	5.75	−1.03	−0.62

with the small Δ*H* associated with these equilibria. The addition of Cd^{++} and Zn^{++} to solutions of these isomers also caused no change in $J_{\alpha,\beta}$ but did cause some shift in ν_α and ν_β.

In the course of the work on *erythro*-HAA, we determined pK_{a_1} (4.05) and pK_{a_2} (9.75) for the equilibria shown in Scheme 1. A plot of ν_α and ν_β vs. p*H* as shown in Fig. 1 allowed assignment of the more downfield doublet to H_β since this absorption underwent the larger diamagnetic shift (22 vs. 15 c.p.s.) during the first ionization, while H_α shifted more (44 vs. 17 c.p.s.) during the second. None of this information could be obtained for *threo*-HAA due to its very low solubility in water at ambient temperature.

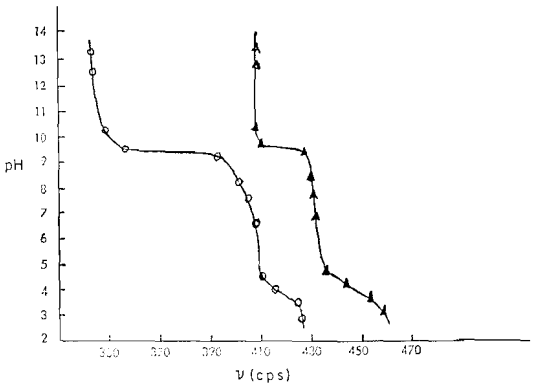

FIG. 1. Plot of p*H* versus ν(c.p.s., 100 Hz values) for *erythro*-HAA. ○—○, H_α values; ▲—▲, H_β values.

Experimental

Spectral Measurements

The proton magnetic resonance spectra were recorded using a Varian HA-100 high resolution n.m.r. spectrometer. Chemical shift measurements were made by the usual side band technique. Sodium-3-(trimethylsilyl)-propanesulfonate (tms*) was the internal reference compound. The ambient temperature of the sample compartment was 29 ± 2 °C. The precision of the chemical shift measurement was estimated to be better than ±0.01 p.p.m.

Measurement of pK_a Values

Measurements of p*H* were made at room temperature using a Leeds and Northrup Model No. 7403-A1 line operated expanded scale p*H* meter equipped with Model 124 138 miniature electrode assembly and standardized

using National Bureau of Standard buffers. No corrections were made for glass electrode errors at either p*H* extreme. The pK_a values of the compounds in D_2O were determined by potentiometric titration, using a semi-automatic recording device previously described. The titrant used was standard 6 *M* CO_2-free potassium deuteroxide solution. The KOD solution was prepared by reacting reagent grade potassium metal with CO_2-free D_2O (99.8%) in a nitrogen atmosphere. A layer of ether covered the D_2O to slow the reaction rate. The ether was removed by warming the KOD solution with hot water while passing a stream of nitrogen over the surface.

Infrared (i.r.) spectra were recorded on either a Perkin–Elmer Infracord Model 137 or Model 237-B. Melting points were taken on a Nalge–Axelrod apparatus and are corrected. Radial paper chromatography was carried out on 31-cm Whatman No. 1 circles having a 1 cm center hole. Compounds were visualized using ninhydrin (N). A substance having an R_f of 0.5 in the MPW system and located with ninhydrin is reported as R_f^{MPW} 0.5 (N). The solvent systems were as follows: MPW was methyl ethyl ketone:pyridine:water, 20:5:8; BAW was butanol:-acetic acid:water, 4:1:5 (upper phase); MAW was methyl ethyl ketone:acetic acid:water, 20:5:8.

erythro-β-*Hydroxy*-DL-*aspartic Acid*

A solution of 79.0 g (0.60 mole) *trans*-epoxysuccinic acid (8) in 2 l of concentrated ammonium hydroxide was heated to 40–50° for 25 h. The solution was evaporated to dryness on a rotary evaporator to remove residual ammonia and the residue was dissolved in sufficient water to make a 3% solution (w/v). The solution was placed on a column (6.5 × 65.0 cm) containing 2 pounds of Amberlite IRA-400 anion exchange resin (OH^- cycle) and eluted with 10% acetic acid. The combined acidic eluate was evaporated to dryness using a rotary evaporator and the resulting amino acid was crystallized from a 1:1 water:ethanol mixture giving 41.0 g (46%); i.r. (KBr) 3436 (O—H), 1710, and 1690 cm^{-1} (C=O); R_f^{MPW} 0.20 (N), R_f^{MAW} 0.64 (N).

threo-β-*Hydroxy*-DL-*aspartic Acid*

The disodium salt of *cis*-epoxysuccinic acid was prepared from 116 g (1 mole) maleic acid by the method of Payne and Williams (8). The crude salt was dissolved in 3.5 l conc. ammonium hydroxide and the solution was heated to 40–50° for 10 h. The reaction mixture was concentrated *in vacuo* to a heavy syrup and 700 ml of water was added. The solution was acidified to p*H* 3 with concentrated hydrochloric acid and kept at 5° for 12 h. The first crop, weighing 113.4 g, was filtered, washed with cold water, and dried *in vacuo*, over phosphorous pentoxide. The second crop, weighing 18.8 g, was obtained from the concentrated filtrate after cooling. The combined crude product was recrystallized from water giving a total of 66.0 g (44%) of *threo*-HAA; i.r. (nujol) 2.95 (O—H), 5.2, and 6.0 μ (C=O); R_f^{MPW} 0.21 (N), R_f^{BAW} 0.20 (N), R_f^{MAW} 0.42 (N).

Anal. Calcd. for $C_4H_7NO_2$: C, 32.23; H, 4.73; N, 9.38. Found: C, 32.19; H, 4.89; N, 9.35.

erythro-β-*Hydroxy*-DL-*aspartic Acid Dimethyl Ester Hydrochloride*

A solution of dimethylsulfite in methanol was prepared by the addition of 34 ml (0.48 mole) thionyl chloride to 230 ml of ice-cold methanol stirred magnetically. To this solution was added 23.0 g (0.15 mole) *erythro*-HAA and the mixture was refluxed 6 h. The solution was evaporated on a rotary evaporator, and the residue was redissolved in ca. 100 ml of methanol and the solution again evaporated to dryness. This process was repeated twice to remove excess hydrogen chloride. The resulting solid was pumped mechanically for 2 h and dissolved in a minimum amount of hot methanol. The solution was cooled and diluted with ether until crystals appeared. Slow dilution with ether as crystallization proceeded gave 25.0 g (76%) of crude *erythro*-β-hydroxy-DL-aspartic acid dimethyl ester hydrochloride; m.p. 148–151°; i.r. (KBr) 3240 ($\overset{+}{N}H_3$), 1750 cm^{-1} (C=O); n.m.r. (D_2O) δ 4.85 and 4.75 (d, 2, J = 2.8 Hz, H_β, H_α), and 3.83 p.p.m. (s, 6, —OCH_3); R_f^{MPW} 0.90 (N). A sample recrystallized three times from methanol–ether for analysis melted at 152–153°.

Anal. Calcd. for $C_6H_{12}ClNO_5$: C, 33.73; H, 5.66; N, 6.56. Found: C, 33.49; H, 5.78; N, 6.71.

threo-β-*Hydroxy*-DL-*aspartic Acid Dimethyl Ester Hydrochloride*

The procedure for synthesis of the *threo* ester hydrochloride was the same as that described for the *erythro* isomer; yield 31.7 g (96%); m.p. 134–136°; i.r. (nujol) 3.05 (O—H), 3.20 ($\overset{+}{N}H_3$), 5.70, and 5.75 μ (C=O); n.m.r. (D_2O) δ 4.91 and 4.48 (d, 2, J = 3.0 Hz, H_α, H_β) 3.88 (s, 3, —OCH_3), and 3.84 p.p.m. (s, 3, —OCH_3); R_f^{MPW} 0.91 (N), R_f^{MAW} 0.78 (N). Recrystallization of the crude product from methanol–ether gave an analytical sample.

Anal. Calcd. for $C_6H_{12}ClNO_5$: C, 33.73; H, 5.66; N, 6.56; Cl, 16.60. Found: C, 33.95; H, 5.69; N, 6.85; Cl, 16.53.

Reaction of methyl azidoformate with norbornene[1]

A. C. OEHLSCHLAGER, R. S. MCDANIEL, A. THAKORE, P. TILLMAN, AND L. H. ZALKOW[2]
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia
AND
Department of Chemistry, Oklahoma State University, Stillwater, Oklahoma

Received July 11, 1969

The thermal reaction of methyl azidoformate and norbornene has been found to proceed via 1,3-dipolar-cycloaddition yielding *exo* triazoline adduct, **15***a*. Thermal decomposition of the triazoline results in the loss of nitrogen and the formation of at least 5 products. The major products of the thermal decomposition in decalin were 3-carbomethoxy-3-azatricyclo(3.2.1.$0^{2,4}$ ^{exo})octane, **18***a*, and *N*-carbomethoxy-2-norbornimine, **20**. In addition, *syn*-2-norbornene-7-methyl carbamate, **21**, and 3-carbomethoxy-3-azatricyclo(3.2.1.$0^{2,3}$ ^{endo})octane, **19***a*, were isolated. The thermal decomposition of the triazoline adduct is considered to proceed by a multi-step mechanism. The first step is considered to involve heterolytic cleavage of the N_3—N_4 bond to give a zwitterion which may lead to products or rearrange *via* carbon–carbon bond cleavage to give a diazoalkyl imine.

Canadian Journal of Chemistry, 47, 4367 (1969)

Introduction

The thermal and photochemical reaction of ethyl azidoformate (**1**) with several acyclic and monocyclic alkenes has been investigated in detail by Lwowskii and co-workers (2). Thus, both the thermal and photolytic reaction of **1** with cyclohexene (**2**) gave approximately the same distribution of products consisting of aziridine, (**3**), urethanes (**4**–**7**), and 3,3′-biscyclohexenyl (**8**). Nearly the same product distribution was also observed from the base catalyzed decomposition of *N*-*p*-nitrobenzenesulfonoxyurethan (**9**) in cyclohexene. These observations, coupled with the observation that the rate of thermal decomposition of **1** in cyclohexene and cyclohexane was identical, led these workers to formulate the

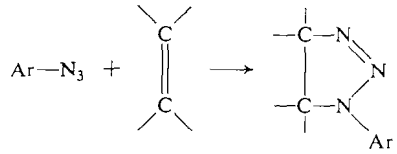
reaction of **1**, with cyclohexene as proceeding to carboethoxynitrene (**10**) prior to reaction with the carbon–carbon double bond. A further test of this mechanism would be to determine the molecular order to azide decomposition with respect to alkene.[3]

An observation that the reaction was zero order in alkene and first order in azidoformate would support the nitrene mechanism. If however the reaction was found to be first order in alkene and azidoformate, initial reaction between the azido group and alkene would be indicated.

The latter has been found to be the case in the reactions of aryl azides (**11**) and alkenes. In all cases reported thus far the thermal reaction proceeds by initial 1,3-dipolar cycloaddition of the azido group to the alkene to produce 1,2,3-Δ^2-triazolines (**12**), which may thermally decompose under the conditions of the reaction to give aziridines, imines, and products of molecular rearrangement (4, 5).

For the relatively thermally stable aryl azides, the 1,3-dipolar cycloaddition reaction with alkenes has a lower activation energy than nitrene generation (6). Conjugation, angle strain, and the presence of α heteroatoms have all been found to increase the reactivity of alkenes toward the 1,3-dipolar cycloaddition by aryl azides (7). The rate of azide–alkene addition is also increased by electron-withdrawing substituents on the azido group (8).



11 **12**

The apparent intervention of carboalkoxynitrenes in the reactions of azidoformates with unstrained alkenes prompted our investigation of methyl azidoformate (**13***a*) with an angle strained alkene, norbornene (**14**). Both the angle strain present in the alkene and the electron-withdrawing effect of the carbomethoxy group of the azide could be expected to facilitate a reaction via 1,3-dipolar cycloaddition. Since this mode of reaction was indeed observed we have

[3]Breslow and co-workers (3) have shown that the thermal decomposition of octadecylazidoformate in olefinic solvents obeys first order kinetics but the molecularity of the azide decomposition with respect to olefin was not determined.

TABLE I

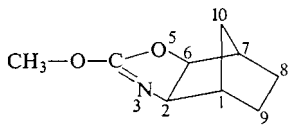
Rates and activation parameters for the addition of methylazidoformate to norbornene in 1,4-dioxane

Temperature (°C)	$k \times 10^5$ (l mole^{-1} s^{-1})	$\Delta H^{\ddagger}$ (kcal/mole)	$\Delta S^{\ddagger}$ (cal/mole deg)
39.65±0.02	3.93±0.01		
40.80±0.02	4.30±0.03	15.0	−30.0
49.75±0.1	8.41±0.03		
59.30±0.01	17.20±0.01		
71.40±0.05	39.9 ±0.5		

been able to study in some detail the thermal decomposition of the 1,2,3-Δ^2-triazoline adduct initially formed. The thermal decomposition of this triazoline is compared with the thermolysis of the triazoline adducts obtained from the reaction of phenyl azide (**13***b*) with norbornene (9*a*) and *cis-exo*-norbornene-5,6-dicarboxylic anhydride (**16**) (9*b*).

Methyl azidoformate and norbornene react slowly at 40–50 °C in hydrocarbon solvent. A typical reaction at this temperature took several days and gave good yields (70%) of a low-melting solid. The nuclear magnetic resonance (n.m.r.) spectrum of this solid revealed a methoxyl resonance (δ 3.80) and a two hydrogen AB quartet with doublets (J = 8.5 Hz) centered at δ 3.53 and 4.43.

A two hydrogen AB quartet would be expected for the C-2 and C-6 hydrogens of either the triazoline, **15***a*, or the oxazoline, **17**, both of which are reasonable on mechanistic grounds. The n.m.r. spectrum of the known triazoline, **15***b*, contains a two proton AB quartet due to the C-2 and C-6 hydrogens with doublets (J = 9.3 Hz) centered at δ 3.65 and 4.51 (10).



17

The observation that the solid product isolated evolves nitrogen when heated in an inert solvent indicates the triazoline structure **15***a* is correct. That a 1,3-dipolar cycloaddition of methyl azidoformate (**13***a*) and norbornene (**14**) had occurred was further substantiated by a kinetic study of the reaction.

The rates of addition of **13***a* to **14** were determined at different concentrations of norbornene and at different temperatures by infrared (i.r.) spectroscopy. The reaction was found to be first order in both azidoformate and norbornene. Thus graphs of second order plots of $1/C$ (azide) vs. time were linear over at least two half lives. The rate constants reported were determined graphically and are average values of two or more determinations. The enthalpy and entropy of activation were determined by least squares treatment of log k/T vs. $1/T$ using values in Table I. The standard deviation was found to be 0.013.

The relatively small enthalpy of the activation and strongly negative entropy of activation observed in the present addition are indicative of a 1,3-dipolar cycloaddition. The addition of phenyl azide to norbornene has been found (10) to have similar activation parameters ($\Delta H^{\ddagger}$ = 15.2 kcal/mole and $\Delta S^{\ddagger}$ = −29 cal/mole deg).

The triazoline ring in **15***a* is assumed to be fused *exo*. There is ample precedent for the addition of organic azides to norbornene from the least hindered *exo* side (11). Indeed no *endo* addition of organic azides to norbornenes has yet been detected. There is no reason to suspect a different course of addition in the present reaction. Furthermore, photolytic elimination of nitrogen from **15***a* gives exclusively one product which is assigned the *exo* aziridine structure, **18***a* (12).

Thermal decomposition of the *exo* triazoline **15***a* in dry decalin at 113.5° for 3 days gave a mixture that n.m.r., thin-layer chromatography (t.l.c.), and gas–liquid phase chromatography (g.l.p.c.) analyses showed to have 5 components (see Table II). The principle components, **18***a*, **19***a*, **20**, and **21** were isolated by a combination of g.l.p.c. and column chromatography. Compound **22** could not be isolated in a pure state but

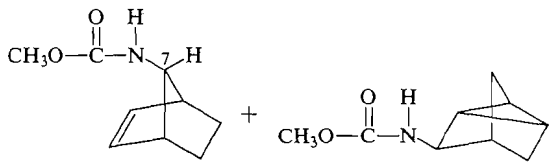
15*a* → **18***a* + **19***a*, R = $CH_3O-\overset{O}{\overset{\|}{C}}$ **20**
b, R = C_6H_5-



21 **22**

TABLE II

Products from decomposition of **15***a* in decalin

Component	%
exo Aziridine **18***a*	51.7
Imine **20**	36.1
endo Aziridine **19***a*	6.7
Unsaturated carbamate **21**	4.7
Unknown **22**	0.8

is probably the cyclopropyl isomer of **21** (9*a*). Analysis of the pyrolysate by g.l.p.c. after prolonged (24 h) heating showed there was no change in the product composition. Therefore the interconversion of products is not appreciable at the reaction temperature.

The i.r. spectrum of **18***a* was devoid of N—H absorptions and also of C=N absorption. Comparison of the n.m.r. spectra of **18***a* with the bicyclic *exo* aziridine (**18***b*) which was obtained from the photolysis of triazoline, **15***b*, (9*a*) showed basic similarities. A low field singlet was present in both cases and was attributed to the hydrogens attached to carbons bearing nitrogen. In **18***a* this occurred at δ 2.46 and in **18***b* at δ 2.10. A high field doublet (J = 9.5 Hz) at δ 0.73 in the n.m.r. of **18***a* is attributable to the *anti*-C_8-hydrogen, and a doublet of triplets (J = 9.5 and 1.8 Hz) at δ 1.51 is attributable to the *syn*-C_8-hydrogen. These signals are characteristic of 3-azatricyclo(3,2,1,$0^{2,4\text{-}exo}$)octanes (13).

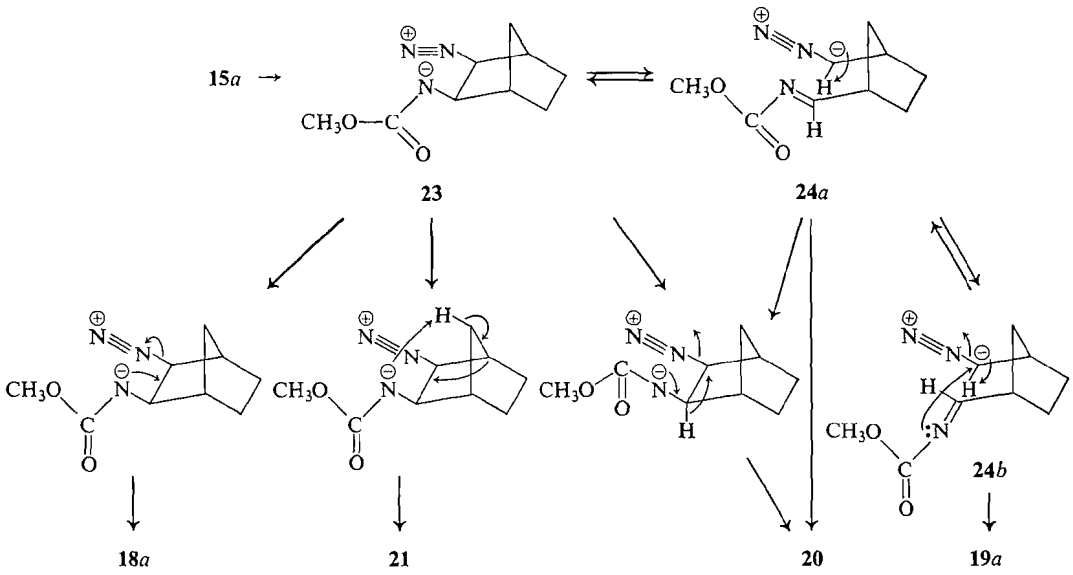
Since we obtained the corresponding *endo* aziridine **19***a* (see below) in the thermal decomposition of **15***a*, we were able to establish its absence in the photolytic decomposition. If any *endo* triazoline were present in **15***a*, its photolysis should have given the *endo* aziridine **19***a*.

The *endo* aziridine (**19***a*) was isolated from the pyrolysate by preparative gas chromatography. The n.m.r. spectrum of **19***a* exhibited 4 distinct signals in the ratio of 3:2:2:6 in the direction of stronger field. Specifically, the signals appeared as follows: a singlet centered at δ 3.58 assigned to the methoxyl hydrogens; a triplet (J = 2.0 Hz) at δ 3.0 assigned to the hydrogens attached to carbon bearing nitrogen at C-2 and C-4; a broad symmetrical peak at δ 2.37 assigned to the two bridgehead hydrogens, and a complex pattern at δ 0.96–1.82 corresponding to the three methylene groups of the norbornyl ring system. The spectrum was very similar to that of the known (9*a*) *endo* aziridine (**19***b*). The absence of N—H stretching bands and of bands due to C=N stretching in the i.r. spectrum of **19***a* supports the proposed structure.

The imine, **20**, was identified by its hydrolysis to 2-norbornanone and methyl carbamate. The 2-norbornanone was characterized by the mixture melting point of its 2,4-dinitrophenylhydrazone with that of an authentic derivative.

The unsaturated carbamate **21** was isolated by gas chromatography and characterized by its n.m.r. and i.r. spectra. The i.r. spectrum of **21** showed an absorption at 3300 cm^{-1} (N—H). The n.m.r. spectrum of **21** contained signals in the ratio 2:3:1:1:2:4 in the direction of stronger field. Two olefinic hydrogens appeared as a symmetrical triplet (J = 2.9 Hz) centered at δ

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



5.85. The hydrogen attached to nitrogen (exchanged with D_2O) gave a broad peak at δ 5.06. The hydrogen attached to carbon (C-7) bearing nitrogen appeared at δ 3.58 as a singlet.

The unsaturated carbamate, **21**, was reduced with H_2 over PtO_2 to give norbornane-7-methylcarbamate which was in turn hydrolyzed to 7-norbornamine, which when treated with acetic anhydride gave the 7-acetamidonorbornane. The 7-acetamidonorbornane prepared in this manner was identical to an authentic sample (14) and different from both 2-*exo*- and 2-*endo*-acetamidonorbornanes by g.l.p.c.

The pyrolysis of azide adducts of norbornene gives principally *exo* aziridines and imines. Recent investigations (9) have shown that, in addition to these products, varying amounts of Wagner–Meerwein rearranged and *endo* aziridine products were also formed. The production of the primary and minor products of pyrolysis of azide–norbornene adducts such as **15***a* is satisfactorily explained by the mechanism advanced below.

We consider the thermal decomposition of **15***a* to proceed *via* initial heterolytic cleavage of the N_3—N_4 bond of **15***a* (**15***a* → **23**) followed by carbon–carbon bond cleavage to give **24**. Each of these intermediates may lead to products as shown. The proposal for initial N_3—N_4 bond cleavage is based on the observation that the thermal decomposition of **15***a* is accelerated in more polar solvents (see Table III). This parallels the behavior noted in the decomposition of **15***b* (9*a*) and several related triazolines (5, 15, 16). The direction of N_3—N_4 heterolysis is considered by others (15, 16*a–d*) and ourselves (9) to involve formation of a negative charge on N-3 of the triazoline since electron withdrawing substituents at this position aid the pyrolysis reaction in analogous systems.

TABLE III

Relative rates of decomposition of triazoline **15***a* in different solvents

Solvent	Temperature (°C)	$t_{\frac{1}{2}}$ (min)
$(C_6H_5)_2C_2H_4$	71.40±0.05	4.68×10^4
Triglyme	71.40±0.05	3.98×10^2
DMSO	71.40±0.05	6.54×10
Decalin	113.5 ±0.2	9.09×10^2

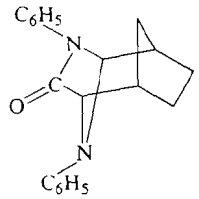
These data lead to the formulation of the initial species generated during the decomposition of **15***a* as **23**. Once formed, **23** may lose nitrogen to form the *exo* aziridine, **18***a*, the imine, **20**, and Wagner–Meerwein rearrangement products of which the carbamate, **21**, has been identified.

Alternatively, carbon–carbon bond cleavage may occur in **23** to produce **24**. Reformation of the carbon–carbon bond in **24** could produce **23** or an isomeric structure in which the vicinal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

nitrogen groups are *cis–endo*.[4] Any reclosure which produces an *endo*-carbomethoxy substituted nitrogen at C-2 could give rise to the *endo* aziridine **19***a* by loss of nitrogen.

Baldwin has put forward a scheme involving species analogous to **23** and **24** to account for the formation of **25** from the decomposition of **15***b* in the presence of phenyl isocyanate (17).



25

Furthermore, in our studies of the pyrolysis of **15***b*, which also produces a small amount of *endo* aziridine (**19***b*), we noted the appearance of an i.r. absorption at 2175 cm^{-1} during the pyrolysis (160°). This absorption is clearly in the region expected for intermediates such as **23** and **24**. It was observed to appear early in the reaction and decrease in intensity as the reaction proceeded (9*a*). Similar measurements during the decomposition of **15***a* were inconclusive.

The determination of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for the thermal decomposition of **15***a* was not attempted since the rate of nitrogen evolution was not strictly first order. During the later stages of the reaction, nitrogen evolution showed a positive deviation from first order kinetics. This type of deviation could mean that the generation of **23** and/or **24***a* is faster than their conversion to nitrogen and products (9*a*, 16*c*). Since there are other interpretations which may be placed on this result and since we were unsuccessful in detecting i.r. absorptions in the 2000–2500 cm^{-1} region for **23** or **24***a* during the pyrolysis in an i.r. hot cell, the evidence for these as stable intermediates is at present only circumstantial.

Comparison of the *exo-endo* aziridine ratio resulting from the thermal decomposition of triazolines **15***a* (15.7:6.7), **15***b* (49:9) (9*a*), and **16** (24:76) (9*b*) reveals that in norbornene triazolines **15***a* and **15***b*, the substituent on N-3 has only a small effect. The rather pronounced increase in *endo* aziridine formation in the case of **16** may be attributed to the enhancement of carbon–carbon bond cleavage during the pyrolysis of this triazoline, because of the stabilization of the incipient negative charge at C-6 by the electron-withdrawing anhydride groups (9*b*). Since Baldwin *et al.* (17) obtained a 60% yield of **25** in the pyrolysis of **15***b* in phenyl isocyanate and only 9% of *endo* aziridine **19***b* was isolated from pyrolysis of **15***b* in decalin, it is clear that the amount of *endo* aziridine formation may not be an accurate measure of the amount of C—C bond cleavage which is involved in the thermolysis of these triazolines. Assuming that a greater amount of carbon–carbon bond cleavage does occur in **16** than in **15***a* and **15***b*, it is still rather difficult to explain the *predominance* of *endo* aziridine from the pyrolysis of **16**.

The pathway from **15***a* to the *endo* aziridine **19***a* is not clear at present; it may involve conversion of **24***b* to the *endo–cis* analogue of **23** followed by loss of nitrogen and aziridine ring closure. Alternatively the *endo* triazoline might be formed from **24***b* by intramolecular 1,3-dipolar cycloaddition of the diazoalkane and imine groups. This could then undergo decomposition to **19***a* in a manner similar to the **15***a* → **23** → **18***a* conversion. Since diazoalkanes and imines combine in 1,3-dipolar cycloadditions only at moderate rates (18) and the triazoline products would be unstable at the reaction temperature, it seems reasonable that if the *endo* triazoline were involved in the production of the *endo* aziridine **19***a*, it would be difficult to detect. It is also not clear if the **23** → **24** reaction is reversible and if the imine **20** is formed via **23** as shown or also via **24**.

Experimental

Carbon and hydrogen analysis was performed by Midwest Microlabs, Inc., Indianapolis, Indiana. All thin layer chromatograms were developed in iodine vapor. Melting points were determined by a Fisher-Johns melting point apparatus and are uncorrected. Infrared spectra were recorded with a Unicam S.P. 200 i.r. spectrophotometer or a Beckman IR-5A spectrophotometer. Nuclear magnetic resonance spectra were recorded on Varian A-60 n.m.r. spectrometers with TMS as an internal standard. Analysis by g.l.p.c. was done using an Aerograph HiFi chromatograph and preparative work was done using an Aerograph autoprep 700 chromatograph. Gas–liquid phase chromatographic columns used were a 5 ft × 1/8 in. column with 20% XF-1150 on 60–80 Mesh Chrom

[4]It is of course possible for reformation of the carbon–carbon bond of **24** to occur in such a way that the vicinal nitrogen groups are *trans* in two possible orientations. There is no way *a priori* to determine if this is a significant process since the zwitterions thus formed would also be expected to lead to the products observed.

W for analysis, a 10 ft × 1/4 in. Craig's polyester column, and a 5 ft × 1/2 in. column with 20 in. XF-1150 on 60–80 Mesh Chrom W for preparative work.

*Preparation of 3-Carbomethoxy-3,4,5-triazatricyclo-(5.2.1.0^{2,6})dec-4-ene (**15a**)*

Methyl azidoformate (19, 20) (0.11 moles, 11 g) was added to 0.12 moles (14.2 g) of norbornene (Aldrich) dissolved in 80 ml of 30–60° petroleum ether. The solution was refluxed (45°) for several days until the azide peak in the i.r. spectrum had disappeared. A white solid (**15**a) was obtained in 70% yield which after recrystallization from *n*-hexane melted at 35.0–35.5 °C. Nuclear magnetic resonance data: δ 0.93–1.73 (m, 6, C-8, C-9, C-10); 2.55 (m, 1, C-1); 2.68 (m, 1, C-7); 3.80 (s, 3, OCH_3); 3.53 (d, 1, J = 8.5 Hz, C-2); 4.43 (d, 1, J = 8.5 Hz, C-6).

Pyrolysis of **15**a at 71.4 °C in diphenylethane, triglyme, and dimethyl sulfoxide gave 93–98% of the theoretical amount of nitrogen.

*Thermal Decomposition of 3-Carbomethoxy-3,4,5-triazotricyclo(5.2.1.0^{2,6})-4-decene (**15a**) in Decalin*

A 1 g sample of the triazoline, **15**a, was thermally decomposed at 113.5 °C in 10 ml of freshly distilled decalin under anhydrous conditions. After 72 h, a sample of the pyrolysate was injected onto the 1/8 in. XF 1150 column.

After 120 h, a second sample was analyzed by g.l.p.c. and found to be unchanged. Water was mixed with the remaining pyrolysate and the mixture was left for 24 h at room temperature. The appearance of norcamphor and methyl carbamate as well as the marked decrease in the amount of imine was shown by g.l.p.c.

Separation of the Products of Thermal Decomposition

The decalin was removed by distillation under vacuum and a portion of the remaining fraction was chromatographed on neutral alumina. The fractions collected were analyzed by g.l.p.c. and those showing the greatest enrichment in a particular component were used in isolating the pure components by preparative g.l.p.c.

*3-Carbomethoxy-3-azatricyclo(3.2.1.0$^{2,3\ endo}$)octane (**19a**)*

The *endo* aziridine, **19***a*, was isolated by g.l.p.c. and had a retention time of 4.8 min. Nuclear magnetic resonance (CCl_4): δ 0.96–1.82 (m, 6, C-6, C-7, C-8); 2.37 (s, 2, C-1, C-5); 3.0 (t, 2, J = 2.0 Hz, C-2, C-4) (9*a*); 3.58 (s, 3, OCH_3). Infrared (film): no peaks due to N—H or C=N. Mass Spectrum Calcd.: M, 167; M/M + 1, 13.6. Found: M, 167; M/M + 1, 14.0.

*syn-2-Norbornene-7-methyl Carbamate (**21**)*

Column chromatography of 3.11 g of the pyrolysate on 50 g of Woehm neutral alumina gave 0.78 g of **18***a* upon elution with 0.5 l of 95:5 petroleum ether – diethyl ether. Elution with 0.5 l of 9:1 petroleum ether – diethyl ether gave 0.24 g of a mixture of **21** and **18***a*. Elution with 0.5 l of 6:4 petroleum ether – diethyl ether gave 0.18 g of **21**. After distillation of the last fraction (b.p. 0.5 mm/70–75 °C) under vacuum, **21** showed by i.r.: ν_{max}(film) 3300 (N—H), 1725 (amide I), and 1520 (amide II) cm^{-1}; n.m.r. (CCl_4): δ 5.85 (t, 2, J = 2.0 Hz, C-2, C-3); 2.78 (s, 2, C-1, C-4); 3.72 (s, 3, OCH_3); 5.06 (s, 1, N—H); 3.58 (s, 1, C-7); 0.8–1.9 (m, 4, C-5, C-6).

Anal. Calcd. for $C_9H_{13}NO_2$: C, 64.65; H, 7.87. Found: C, 64.70; H, 7.81.

Conversion of syn-2-Norbornene-7-methyl Carbamate to 7-Acetamidonorbornane

A solution of 0.70 g of **21** in 2 cc of methyl acetate was stirred under an H_2 atmosphere with 0.30 g of PtO_2. After hydrogen uptake (≈ 10 cc) ceased, the solution was filtered and the catalyst washed with 5 cc of methyl acetate. Evaporation of the solvent *in vacuo* gave 0.66 g of norbornane-7-methyl carbamate, m.p. 79–80.5 °C after recrystallization from petroleum ether in the cold; ν_{max}(KBr) 3260 (NH), 1725, 1690 (amide I), 1540 (amide II), and 1265 (C—O) cm^{-1}; n.m.r. (CCl_4): δ 5.15 (s, 1, N—H); 3.57 (s, 3, OCH_3); 3.45 (s, 1, C-7); 1.0–2.2 (m, 10, C-1 to C-6).

A 2 cc aqueous solution of sodium hydroxide (6 *N*) containing 50 mg of dihydro-**21** was refluxed for 4 h. The solution was cooled and extracted with two 10 cc portions of petroleum ether. The petroleum ether extract was stirred with 0.6 g of acetic anhydride for 0.5 h, then sufficient aqueous sodium bicarbonate was added to destroy the excess acetic anhydride. The petroleum ether portion was separated from the aqueous layer and dried over anhydrous magnesium sulfate. Evaporation of the petroleum ether gave 35 mg of an oil. Gas chromatographic analysis of this oil on a 10 ft × 0.25 in. Craig's polyester column at 180 °C using a flow rate of 90 ml/min revealed two peaks in the ratio of 8:2 eluted at 12.5 and 23.5 min respectively. The larger peak was identical to dihydro-**21** upon mixed injection. The smaller peak was identical to 7-acetamido norbornane (14) upon mixed injection and different from both 2-*exo*- and 2-*endo*-acetamidonorbornanes (14), whose retention times under these conditions were 27.3 and 26.0 min respectively.

*3-Carbomethoxy-3-azatricyclo(3.2.1.0$^{2,3\ exo}$)octane (**18a**)*

The *exo* aziridine, **18***a*, was isolated by g.l.p.c. The sample was identical in all respects with a sample prepared by photolysis of **15***a*. A solution of 1.2 g of **15***a* in 125 cc of spectral grade cyclohexane was irradiated for 2 h with a Hanovia 200 W. mercury vapor lamp through a Pyrex filter. Evaporation of the solvent gave an oil which after distillation (b.p. 10 mm, 78–80 °C) under vacuum gave 0.58 g of aziridine **18***a*, n.m.r. (CCl_4): δ 0.73 (d, 1, $J_{8a,8s}$ = 9.5 Hz, C-8s); 2.40 (s, 2, C-1, C-5); 2.46 (s, 2, C-2, C-4); 3.51 (s, 3, OCH_3).

*N-Carbomethoxy-2-norbornimine (**20**)*

The imine, **20**, was isolated from the pyrolysis mixture by g.l.p.c. Nuclear magnetic resonance (CCl_4): δ 1.9 (m, 6, C-6, C-7); 2.05 (quartet, 2, C-3); 2.50 (s, 1, C-4); 2.72 (s, 1, C-1); 3.60 (s, 3, OCH_3). Infrared (film) data showed the absence of any N—H bonds.

A 0.330 g sample of the pyrolysis mixture was shaken with D_2O. The n.m.r. spectrum of the organic layer showed the disappearance of the signal at δ 3.60. The sample was dissolved in 50 cc of methanol containing 500 mg of 2,4-dinitrophenylhydrazine. The methanol was evaporated *in vacuo* and the mixture chromatographed on acid washed alumina using benzene as the eluent.

Evaporation of the solvent gave 0.317 g of the 2,4-dinitrophenylhydrazone of norbornanone, m.p. 128–129 °C. After recrystallization from ethanol, the derivatives melted at 130–131 °C, (lit. (21) m.p. 129.5–130.5 °C). The mixed m.p. (130–131°) with an authentic sample (m.p. 130–131°) prepared from norbornanone (Aldrich) was undepressed.

Kinetic Method for Rates of Addition of Azides to ***14***

The 2100–2200 cm^{-1} region of the i.r. was chosen for following the addition reactions. In this region the maximum difference in the magnitude of the extinction of azides and the olefin and products occurred. The i.r. measurements were taken using matched fixed thickness solution cells. The transmittance of 0.05 and 0.250 mm fixed thickness solution cells containing 0.2 *M* norbornene, 0.2 *M* products, and solvent, differed by less than 0.009 transmittance unit in this region. The transmittances of a solution of known azide concentration were measured and plots of azide concentration vs. log transmittance were linear. The transmittance of each sample from the kinetic experiments was measured and the concentration of azide was determined by graphical interpolation on a log transmittance vs. concentration plot. A plot of log transmittance vs. azide concentration was made for each solvent used.

Determination of Rates of Addition of Methyl Azidoformate to Norbornene

Separate solutions 0.2 *M* in norbornene and 0.2 *M* in azide in the appropriate solvent were made up just before use. Equal volumes (1.0 cc) of each solution were pipetted into precooled (in dry ice) ampules which were immediately sealed and stored at dry ice – acetone bath temperatures until they were immersed in a thermostatted bath. Duplicate ampules were periodically removed from the bath and placed in a dry ice – acetone bath to quench the reaction. After all ampules for a given experiment had been frozen, each ampule was thawed and immediately (within 5 min) analyzed by i.r.

Reactions were followed to at least 85% completion. Runs lasted from 8 to 100 h and usually involved a transmittance change of 0.5 transmittance unit.

*Kinetic Determination of the Pyrolysis of Triazoline (****15****a)*

A solution of 0.997 g of triazoline, **15***a*, in 50 ml of freshly distilled solvent was made while passing pure dry nitrogen through the liquid for 1 h at room temperature. The solution was kept in a sealed bottle.

The reaction was carried out in a glass reaction vessel immersed in an oil bath maintained at constant temperature (±0.15 °C). The measurements of gas evolution were made with the aid of a thermostatted 100 ml gas burette attached to the reaction vessel by a glass capillary. The results were reproducible to within ± 2% as shown by graphic and computer analysis.

A typical run was carried out by placing 20 ml of solvent into the reaction vessel and allowing it to come to equilibrium while flushing the system with dry nitrogen. To start a run, 10 ml of the triazoline solution was injected with a syringe into the reaction vessel. The system was sealed after 1 min and the volume of nitrogen evolved was recorded as a function of time. Plots of log $(V_\infty/V_\infty - V_t)$ vs. t, and log V_t vs. t gave smooth curves which exhibited divergence from linearity (9*a*). The $t_{\frac{1}{2}}$ values are recorded in Table III for various solvents.

Preparation and properties of the hydroxyindole-3-carboxylic acids[1]

ROSANGELA MARCHELLI,[2] O. HUTZINGER, AND R. A. HEACOCK
Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received June 5, 1969

A procedure for the synthesis of the 4-, 5-, 6-, and 7-hydroxyindole-3-carboxylic acids starting from the corresponding 4-, 5-, 6-, and 7-benzyloxyindoles respectively has been devised. The benzyloxyindoles are converted to mixtures of their 1- and 3-carbethoxy derivatives by the action of ethyl chloroformate on their Grignard reagents. The hydroxyindole-3-carboxylic acids are then obtained by the alkaline hydrolysis and debenzylation of the benzyloxy-3-carbethoxyindoles.

In view of their importance in biology and medicine [cf. review by Cerletti (1)], the metabolism of indole compounds in plants and animals has been the subject of extensive studies in the past. In recent years the importance of the hydroxyindoles (cf. 2, 3), has also been recognized.

Whilst a considerable amount of research has been carried out on the metabolism of 3-indolylacetic acid (cf. 4, 5), very little has been reported on the metabolism of indole-3-carboxylic acid. Acheson and King reported that the urine of rats which had been fed or injected intraperitoneally with indole-3-carboxylic acid, contained the original acid (ca. 20%), the corresponding glucuronide, and 6-hydroxyindole-3-carboxylic acid (6). These authors further reported that oxidation of indole-3-carboxylic acid with a model hydroxylating system (Fe^{2+}, ascorbic acid, EDTA, oxygen) (cf. 7, 8) gave 5- and 6-hydroxyindole-3-carboxylic acid, indole, anthranilic acid, *N*-formylanthranilic acid, and a number of unidentified products. In other instances the oxidation of indole compounds with this system [i.e. indole (9), tryptophan (9) and skatole (10)], has resulted in the formation of all 4 hydroxyindole derivatives, hydroxylated in the benzene moiety of the indole ring, together with other products produced by oxidation of the pyrrole ring.

Before reinvestigating the hydroxylation of indole-3-carboxylic acid, it was desirable to have available authentic samples of the 4-, 5-, 6-, and 7-hydroxyindole-3-carboxylic acids. The synthesis of these 4 compounds is described in this paper.

R_f Values have been reported for both 5- and 6-hydroxyindole-3-carboxylic acids (6, 11, 12), but as far as the authors are aware the unambiguous syntheses of neither these two acids nor the 4- and 7-hydroxyindole-3-carboxylic acids have been reported.

The syntheses of these 4 acids have now been achieved, starting from the corresponding authentic benzyloxyindoles, which are available commercially. Since the reactions of the indole Grignard reagent with both ethyl chloroformate and carbon dioxide [i.e. methods which introduce a COOR group into the 3-position of the indole ring system where R = C_2H_5 or H respectively (cf. 13)] have recently been the subject of extensive studies in these laboratories (14, 15), it was decided to apply one of these methods to the syntheses of the 4-, 5-, 6-, and 7-hydroxyindole-3-carboxylic acids. Preliminary experiments suggested that the route via the ester was the more promising. The benzyloxyindoles were converted into their Grignard reagents and the subsequent reactions with ethyl chloroformate carried out at low temperatures and for relatively short periods of time.

Preliminary thin-layer chromatographic (t.l.c.) analysis of the reaction mixtures indicated that they invariably consisted of mixtures of 3 major components: the benzyloxy-1-carbethoxyindole, the benzyloxy-3-carbethoxyindole, and unchanged starting material. Their presence was confirmed by gas–liquid chromatography (g.l.c.). It was not possible to separate efficiently the reaction mixtures into their individual components by fractional crystallization, but satisfactory separations could be achieved using preparative scale t.l.c.

The reaction between the indole Grignard reagent and ethyl chloroformate proceeded satisfactorily at 0° with the 4-, 5-, and 6-isomers, but was carried out at 20° in the case of the 7-isomer

---

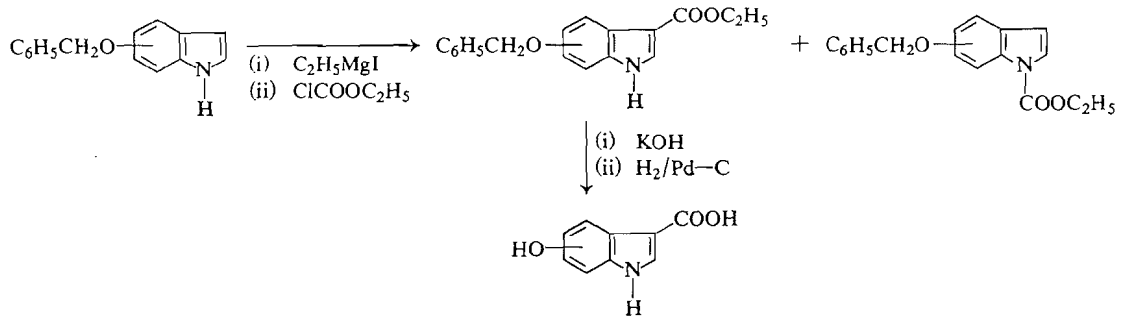
[2]NRCC Postdoctoral Fellow 1967–1969.



in view of the apparent insolubility of the 7-benzyloxyindole Grignard reagent in the reaction mixture at the lower temperature.

The position of the carbethoxy group in each of the major products was established by their infrared (i.r.) spectra. The carbonyl stretching peak of the 3-esters consistently occurred at lower frequencies (ca. 1670 cm^{-1}) than those of the 1-esters (ca. 1740 cm^{-1}) (cf. 14, 16). The typical N—H stretching peak at 3300–3200 cm^{-1} was also absent in the spectra of the 1-esters. Restricted rotation probably accounts for the fact that two peaks (at 1760 and 1730 cm^{-1}) are observed in the carbonyl region of the i.r. spectrum of 7-benzyloxy-1-carbethoxyindole. The 3-carbethoxy derivatives react slowly with Ehrlich's reagent on heating, whereas the 1-carbethoxy derivatives do not react with this reagent [cf. analogous behavior of 1- and 3-carbethoxyindole with Ehrlich's reagent (14)].

The benzyl group was easily removed from the 4 isomeric benzyloxy-3-carbethoxyindoles hydrogenolytically to give the corresponding 3-carbethoxyhydroxyindoles. The proton magnetic resonance (p.m.r.) spectra of these compounds confirmed that they were in fact substituted in the 3-position. The signals due to the indole 2-protons were observed as singlets (after exchange of the N—H protons with D_2O) at low field, in DMSO-d_6 [cf. Jardine and Brown (17)]. The chemical shifts of these signals and the fact that no significant secondary couplings were observed with any of the protons in the six-membered ring, confirmed that it was the indole 2-proton and not the indole 3-proton that was being observed.

The benzyloxyindole-3-carboxylic acids were readily obtained by hydrolysis of the corresponding benzyloxy-3-carbethoxyindoles with alcoholic potassium hydroxide. However, in the case of the 4-isomer it was impossible to prevent the formation of some decarboxylated product at the same time. In this case the decarboxylation reaction was presumably aided by steric assistance of the 4-benzyloxy group.

The benzyloxyindole-3-carboxylic acids were smoothly debenzylated by catalytic hydrogenation to give the desired hydroxyindole-3-carboxylic acids in high yield. The hydroxyindole-3-carboxylic acids are all high melting colorless crystalline solids, stable in the solid state; 7-hydroxyindole-3-carboxylic acid however, appears to be unstable in solution and is difficult to recrystallize without loss.

Experimental

The melting points were determined on a Thomas–Hoover capillary melting point apparatus and are uncorrected. Infrared, ultraviolet (u.v.), and p.m.r. spectra were recorded on Perkin–Elmer model 237, Beckman DK-2, and Varian A-60-A instruments respectively. The mass spectral data were obtained on a Consolidated Electrodynamics Corp. 21-110B mass spectrometer. A controlled temperature probe was used for introduction of the sample directly into the source.

Benzyloxy-1- and -3-Carbethoxyindoles

Preparation

A solution of the benzyloxyindole[3] (2.2 g, 0.01 moles) in anhydrous ether (50–75 ml) was added dropwise at 5°,[4] during 15–20 min, to the Grignard reagent, prepared from magnesium turnings (0.48 g, 0.02 moles) and ethyl iodide (3.2 g, 0.02 moles) in anhydrous ether (10 ml) (cf. ref. 18). The solution was boiled under reflux for 45 min to complete the formation of the indole Grignard reagent. The solution was cooled to 10°,[5] and ethyl chloroformate (1.2 g, 0.011 moles) added dropwise, with stirring, during 10 min. The resulting reaction mixture was cooled to 0°

[3]5-Benzyloxyindole was obtained from the Aldrich Chemical Co. and 4-, 6-, and 7-benzyloxyindoles were obtained from the Regis Chemical Co.

[4]Room temperature in the case of 7-benzyloxyindole.

[5]0° in the case of 6-benzyloxyindole.

TABLE II

Retention times of compounds present in the Grignard reaction mixtures

Compounds in the reaction mixture	Retention times (min) for isomers			
	4-	5-	6-	7-
Benzyloxyindole	1.58	2.50	2.00	0.42
Benzyloxy-1-carbethoxyindole	3.17	4.67	3.15	0.62
Benzyloxy-3-carbethoxyindole	8.12	14.25	2.48*	4.33

*Isothermal determination at 275°.

and the stirring continued for a further 15 min. The reaction mixture was poured into ice-water and extracted with ether (3 × 50 ml). The combined ether extracts were washed with saturated aqueous sodium bicarbonate, dried (Na_2SO_4), and concentrated to dryness *in vacuo*. The reaction products (which contained some unchanged starting material) were separated by preparative t.l.c. Glass plates (100 × 20 cm), coated with silica gel HF-254 (Merck; thickness, 0.9 mm) were used. In the case of the 7-benzyloxy isomer the developing solvent used was benzene – carbon tetrachloride (13:7). In all other cases the plates were developed twice in the same direction with cyclohexane – diisopropyl ether mixtures (a 1:1 mixture was used for the first development and a 4:1 mixture was used for the second run). Under these conditions each plate could initially be loaded with up to ca. 0.5 g of the solid mixture of reaction products. A total of 4 plates was used for each reaction mixture. The separated products were located on the developed chromatoplates by observing them in u.v. light. The bands of silica containing the individual components were scraped from the plates and the products obtained by extraction of the silica with ethanol (300 ml) at room temperature. The filtered ethanol extracts were concentrated to dryness *in vacuo* and the crude products recrystallized from suitable solvents, usually benzene – light petroleum or benzene for the 3-carbethoxy and 1-carbethoxy derivatives respectively. Details of the yields of the products obtained and their physical properties are given in Table I.

Gas–liquid Chromatography

A Varian Aerograph model 204, dual column instrument, fitted with two hydrogen-flame ionization detectors; a 6 ft × 1/8 in. stainless-steel column (5% SE-30 on 60–80 Chromosorb W) was used; the injector and detector temperatures were maintained at 275 and 300° respectively; the nitrogen carrier gas flow rate was 30 ml/min and the hydrogen flow rate was 27 ml/min. The column was maintained at 225° during the determination of the relative retention times of the compounds obtained from the reaction mixture. The values are reported in Table II.

3-Carbethoxyhydroxyindoles

The benzyloxy-3-carbethoxyindole (0.5 g) in methanol (100 ml) was shaken with palladium-on-charcoal (5%; 0.25 g) in a hydrogen atmosphere at room temperature for 1 h. The hydrogenation mixture was filtered through Celite 545 (Fisher) and the filtrate evaporated to dryness *in vacuo*. The crude 3-carbethoxyhydroxyindole so obtained was recrystallized from water containing a small amount of ethanol. The properties of the products are reported in Table III.

Benzyloxyindole-3-carboxylic Acids

A solution of the benzyloxy-3-carbethoxyindole (0.2 g) in a mixture of 1-propanol (30 ml), ethanol (3 ml), and 2 *N* aqueous potassium hydroxide[6] (14 ml) was heated at the temperatures and for the periods specified in Table IV. The solution was then evaporated to small bulk *in vacuo*, diluted with water, extracted with ether (3 × 20 ml), and the ether extracts discarded. The p*H* of the aqueous solution was adjusted to 3 with hydrochloric acid and extracted with ether (3 × 30 ml). The combined, dried (Na_2SO_4) ether extracts were evaporated to dryness *in vacuo* to give the benzyloxyindolecarboxylic acid, which, when recrystallized from aqueous ethanol, had the properties listed in Table IV.

Hydroxyindole-3-carboxylic Acids

A solution of the benzyloxyindole-3-carboxylic acid (0.25 g) in methanol[7] (50 ml) containing a palladium-on-charcoal catalyst (5%; 0.125 g)[8] was shaken in a hydrogen atmosphere at room temperature and under atmospheric pressure for 1 h. The reaction mixture was filtered through Celite 545 (Fisher) and concentrated to dryness *in vacuo*. The crude products were purified by recrystallization from a suitable solvent. The physical properties of the pure compounds and solvent of crystallization are given in Table V.

Thin-layer Chromatography

Glass plates (20 × 20 cm), precoated with silica gel F_{254} (Merck; thickness, 0.25 mm), were used throughout this investigation. The solvent systems used in the separations of the various groups of products and the R_f values of the individual compounds are given in Table VI. The colors given by the compounds with Ehrlich's reagent (after the sprayed plates had been heated at 125° for 10 min) are also reported in Table VI.

Acknowledgments

The authors wish to express their thanks to

[6]The same quantity of 1 *N* sodium hydroxide solution was used in the case of 4-benzyloxy-3-carbethoxyindole.

[7]A mixture of methanol and ethyl acetate was used to dissolve the 4-isomer.

[8]The catalyst was moistened with water before it was added to the solution to minimize the potential fire hazard.

Lanthanum ion catalysis of nucleophilic displacement reactions of monoesters of methyl phosphonic acid

R. J. WITHEY[1]

Chemical Defence Experimental Establishment, Porton Down, Nr. Salisbury, Wilts., England

Received February 24, 1969

The catalytic effects of lanthanum ion on the rate of hydrolysis of *p*-nitrophenyl hydrogen methylphosphonate in aqueous solution at p*H* >7.0 are reported. Increases in rate by a factor of about 3.6×10^4 have been observed. No such catalysis was found for diesters of methylphosphonic acid.

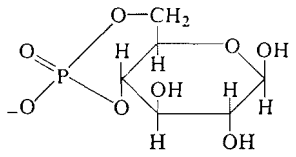
Canadian Journal of Chemistry, 47, 4383 (1969)

Introduction

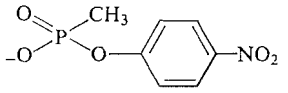
As long ago as 1938, Bamann and his collaborators investigated the catalysis of the hydrolysis of monoesters of phosphonic acid by metal ions (1). Since then many papers have been published on this subject by this group (2–14) and some conclusions about the mechanisms for the catalytic effects were described. Most of this work was carried out in heterogeneous conditions and, for mechanistic purposes, any interpretation of the experimental data is extremely complicated because of the two phases which are present. The catalytic effect of metal ions on the hydrolysis of various phosphorus esters has been reviewed recently (15) and suggests that the available data on heterogeneous metal ion catalysis does not allow any meaningful conclusions about the reaction mechanism.

Butcher and Westheimer (16) have also investigated the catalytic cleavage of phosphate esters in the presence of lanthanum hydroxide gel but their mechanistic interpretations demand the involvement of β-substituents in the ester group and cannot therefore be extrapolated to include phosphorus esters with less complicated structures.

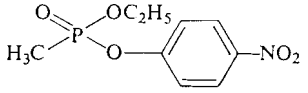
Szabo (17) has described some investigations of the catalytic cleavage of cyclic 5′,6′ glucose phosphates (**1**) by Ba^{++} and La^{+++}. Increases in the rate of hydrolysis of (**1**) of the order of ×35 to $\times 10^3$ at p*H* 8.0 were observed (18). The 1000 fold increase in rate which was observed in the case of La^{+++} by Szabo is in agreement with the values previously reported by Bamann and Westheimer.



1



2



3

In this paper the hydrolysis of *p*-nitrophenyl hydrogen methylphosphonate, which is analogous to **1**, was examined in aqueous solution at 70° and at p*H*'s between 7.3 and 9.0 in the presence and absence of added lanthanum ions. The diester, ethyl *p*-nitrophenyl methylphosphonate **3**, was also examined to ascertain whether the catalysis by lanthanum ion was specific for substrates having P—O^- functions.

Experimental

The kinetic experiments which were carried out were as follows:

(*a*) Hydrolysis rates for *p*-nitrophenyl hydrogen methylphosphonate in water at 70.0 ± 0.1° and p*H*'s 7.19, 7.88, 8.51 (obtained by diluting 0.1 *M* tris buffer and adding NaCl to maintain an ionic strength of 0.1.) Measurement of the uncatalyzed hydrolysis rate was essential in order to estimate the catalytic activity of lanthanum. Since exploratory investigations revealed that these rates were extremely slow (half-lives of the order of

[1]Present address: Research Laboratories, Food and Drug Directorate, Department of National Health & Welfare, Ottawa, Canada.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

two to three months) reactions were followed for a period of not less than six months.

(*b*) Hydrolysis rates for *p*-nitrophenyl hydrogen methylphosphonate in water at 50.0 ± 0.05° with 0.5 to 1.0 *M* NaOH in the presence and absence of lanthanum. It was hoped that at more basic p*H*'s the faster hydrolysis rates would allow greater facility in assessing the lanthanum catalytic effect.

(*c*) The lanthanum ion catalysed hydrolysis of *p*-nitrophenyl hydrogen methylphosphonate was studied at 79, 70, and 37° in the p*H* range 7.19 to 8.51 and with from 0.5 to 10 molar equivalents of lanthanum relative to an ester concentration of 5×10^{-4} *M*.

(*d*) The effect of lanthanum ion on the rate of nucleophilic attack by hydroxide ion and pyridine-2-aldoxime methyl methanesulphonate (P2S) at p*H* 7.5 on ethyl *p*-nitrophenyl methylphosphonate was measured. The object of this study was, first, to see if lanthanum ion catalyzed the hydrolysis of neutral phosphate esters and secondly to see if lanthanum formed a complex with the nucleophile so as to reduce the effective concentration of the nucleophilic anion. The nucleophile P2S was chosen because of its high activity towards phosphorus compounds.

Materials and Methods

p-Nitrophenyl hydrogen methylphosphonate (28), ethyl *p*-nitrophenyl methylphosphonate (27), and P2S (24) were prepared by the standard procedures and purified by distillation or recrystallization before use. *p*-Nitrophenyl hydrogen methylphosphonate was recrystallized and had m.p. 90 to 91°.

Anal. Calcd. for $C_7H_8NO_5P$: C, 38.73; H, 3.71; N, 6.45; P, 14.27. Found: C, 38.68; H, 3.79; N, 6.43; P, 14.20.

Ethyl *p*-nitrophenyl methylphosphonate was distilled at 0.1 mm and the fraction boiling at 125–126° was collected.

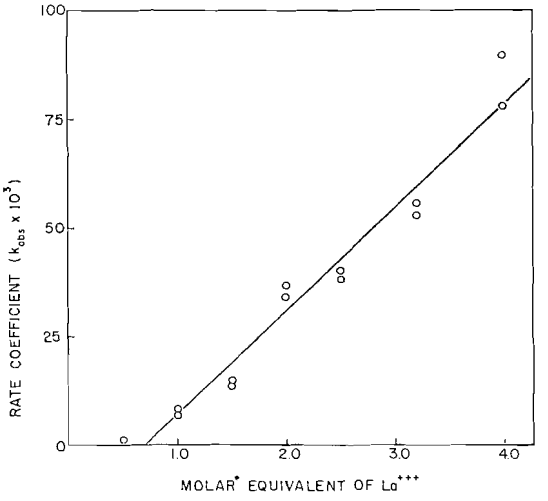


FIG. 1. First order rate coefficient plotted against $[La^{+++}]$ for the hydrolysis of *p*-nitrophenyl methylphosphonate at 70.0° and p*H* 7.60. *One molar equivalent $\equiv 5 \times 10^{-4}$ moles.

Anal. Calcd. for $C_9H_{12}NO_5P$: C, 44.09; H, 4.93; N, 5.71; P, 12.63. Found: C, 44.12; H, 5.01; N, 5.68; P, 12.71.

Pyridine-2-aldoxime methyl methanesulphonate was recrystallized and had m.p. 154–155°.

Anal. Calcd. for $C_8H_{12}N_2O_4S$: C, 41.37; H, 5.21; N, 12.06. Found: C, 41.42; H, 5.15; N, 12.11.

For the measurement of hydrolysis rates the concentration of ester substrate was usually about 5×10^{-4} *M*. Lanthanum ion solutions were prepared by dissolving lanthanum nitrate, $La(NO_3)_3 \cdot 6H_2O$, laboratory reagent grade purchased from B.D.H., in water and the solution was brought to the required p*H* before use.

Cleavage of the *p*-nitrophenyl group was followed at 400 millimicrons with a Unicam S.P.600 spectrophotometer. It was ascertained that, in the concentration range used throughout, Beer–Lamberts law was obeyed. In each hydrolysis reaction which was studied the stoichiometric release of one mole of *p*-nitrophenol per mole of substrate was observed.

Solutions of the reactants were prepared and aliquots pipetted into glass ampoules which were sealed under nitrogen and then placed in a thermostat bath at the required temperature. Tris buffer was used to maintain p*H*. Since this buffer has a relatively large p*H*-temperature coefficient, p*H* measurements of the reactant solutions at the operating temperature were carried out with a Radiometer type TTTIc in conjunction with the recommended special high temperature electrodes G.202BH and K4016.

Results

Rate data is presented in Tables I to V. A plot of the first order rate coefficient against the molar concentrations of lanthanum ion for the catalyzed hydrolysis of *p*-nitrophenyl hydrogen methylphosphonate at 70 °C and p*H* 7.6 is presented in Fig. 1.

Discussion

An anionic charge near a reaction center precludes facile interaction with nucleophiles so that the reactivity of *p*-nitrophenyl hydrogen methylphosphonate **2** towards hydroxide ion is predictably poor at alkaline pH on electrostatic grounds. No kinetic data are available for the alkaline hydrolysis of monoesters of methylphosphonic acid although Larsen (19) claims that the hydrolysis of dialkyl methyl phosphonofluoridates, in strongly alkaline conditions, results only in the release of one mole of acid per mole of substrate.

More information on the analogous dialkyl phosphate ester hydrolysis has been reported and Westheimer and his co-workers (20–22) found that the monoanion substrate species was relatively unreactive. In the case of dimethyl phosphate (see Table VI) the hydrolysis rate in alkaline solution was observed to be slow and first order in hydroxide ion which is consistent with the generalization (23) that alkaline lability in dialkyl hydrogen phosphates occurs only when the molecule contains an hydroxyl group in proximity to the phosphonyl function.

TABLE VI

Alkaline hydrolysis rates for dialkyl phosphate esters

Substrate	Temperature	pH	First order rate coefficient min^{-1}	Reference
Dibenzyl phosphate	75.6	5.85	0.25×10^{-5}	20
Dimethyl phosphate	124.9	>13	5×10^{-6}	22
Di-*p*-nitrophenyl-phosphate	25	>13	6×10^{-6}	27

The results for the hydrolysis of *p*-nitrophenyl hydrogen methylphosphonate, which are given in Table I, indicate a very slow cleavage of the ester group. The values of the observed first order rate coefficient are of the same order of magnitude as those previously reported for the electrostatically analogous dialkyl phosphate esters (see Table VI).

Excellent linear first order plots were obtained for these reactions but in a plot of the logarithm of the observed first order rate coefficient against pH, the points did not fall on a straight line.

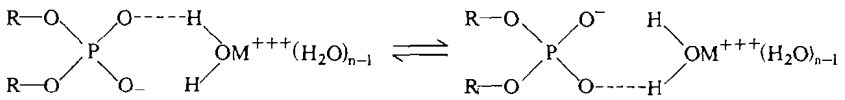

FIG. 2. Resonance structures involving hydrogen bonding.

However, the line of maximum slope that could be drawn through these points had a slope of only 0.15. In contrast, for runs carried out at pH > 13 (see Table II), the slope for a similar plot was found to be 1.29 ± 0.15. While the latter data does not allow the conclusion that the kinetic mechanism at pH > 13 is first order in hydroxide ion it, nevertheless, suggests a change in the mechanism of nucleophilic cleavage of the ester group as the pH increases.

The results in Table II indicate clearly that no enhancement of the hydrolysis rate for *p*-nitrophenyl hydrogen methylphosphonate, at pH > 13 and 50° in the presence of lanthanum ion, could be detected. According to Vickery (25), lanthanum ions exist in solution in at least three different forms depending on the pH:

$$La^{+++} \rightleftharpoons La(OH)^{++} \rightleftharpoons La(OH)_2^{+} \xrightarrow[\text{Increasing pH}]{}$$

In addition to the above species Lewis (26) has suggested that hydrolysis equilibria may involve polynuclear forms like $La[La(OH)_3]^{+++}$. Unfortunately, no evidence is available which allows an unambiguous assignment of the ionic state of lanthanum ion at alkaline pH. Certainly each of the complex forms, described above, would be hydrated in aqueous solution and the actual charge on the cation would be modified by hydration sheath field effects. A reduction in the net charge per mole of lanthanum, which occurs as the pH increases, would be expected to reduce the catalytic activity if any of the proposed mechanisms for lanthanum ion catalysis (*vide infra*) are valid.

The results for the lanthanum ion catalysis of the hydrolysis of *p*-nitrophenyl hydrogen methylphosphonate, which are presented in Table III, show the remarkably high catalytic activity for this cation. The highest concentration of lanthanum ion that we were able to obtain, which appeared to be a homogeneous solution at pH 7.8, was about 5×10^{-3} M.

At this concentration observed rates were too fast at 70° to allow good kinetic analysis without radical changes in the experimental method, but from extrapolation of the line of best fit through the points in Fig. 1 the rate should be about 0.221 min^{-1}. If this is compared with the uncatalyzed rate of 3.72×10^{-4} h^{-1}, at the same temperature and pH, it can be deduced that lanthanum at a concentration of 5×10^{-3} M would increase the hydrolysis rate by a factor of 35,600.

Westheimer (16) and Bamann (14) have shown that lanthanum hydroxide gel can increase the hydrolysis rate of the anionic species of diesters of phosphonic acid by a factor of one thousand. Westheimer suggests a mechanism which involves the catalytic species $La(OH)^{++}$ and its interaction with β-substituents on the ester group. Bamann also suggests that the catalytic species is $La(OH)^{++}$ although he implies that it behaves as a general acid catalyst.

The explanation by Szabo (17) for the metal ion catalytic hydrolysis of 5′6′ glucose phosphate **1** involves the hydrogen bonding of hydrated metal ions (Ba^{++} or La^{+++}) to give resonance structures like those in Fig. 2. If the catalytic mechanism does involve the formation of such complexes it would appear that two effects can operate which increase the nucleophilic susceptibility of the phosphorus atom, viz:

(*i*) The resonance structures lead to a delocalization of the integral charge on P—O^-;

(*ii*) The proximity of the positive charge on the metal ion to the phosphorus atom would polarize the substrate and make the phosphorus atom more electrophilic. Thus cleavage of the P—O-alkyl group by nucleophilic displacement is then feasible.

Whether the suggestion that one of the water molecules in the hydration sheath of the catalytic lanthanum ion can act as a "carrier" of lanthanum and its cationic charge to the substrate or whether lanthanum acts as a general acid catalyst cannot be decided until further examination of the reaction system.

The study of the reactivity of ethyl-*p*-nitrophenyl methylphosphonate toward hydroxide ion and pyridine-2-aldoxime methyl methanesulphonate, in the pH range 7 to 9 and in the presence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and absence of lanthanum ion was of importance for two reasons. First it was necessary to determine whether catalysis by the lanthanum ion was operative only with phosphorus esters having an anionic charge and secondly to see if, in the reaction of the substrate with a nucleophile other than hydroxide ion, lanthanum ions were capable of co-ordinating or complexing oximate anions so as to reduce the concentration of active nucleophile in the reaction system.

The results, presented in Table IV and V, show clearly that neither the rate of attack by $OH^{\ominus}$ nor oximate ions is altered in the presence of lanthanum ion. Spectrophotometric investigations showed no change for the ultraviolet absorption of P2S in the absence and presence of equimolar lanthanum ions.[2]

Norditerpene alcohols in the bark of *Thuja plicata* Donn

H. H. QUON[1] AND ERIC P. SWAN[2]

Canada Department of Fisheries and Forestry, Forest Products Laboratory, Vancouver 8, B.C.

Received May 6, 1969

The neutral extractives from the bark of western red cedar (*Thuja plicata* Donn) contained, among other components, three alcohols. One was the known diterpene alcohol, isopimarinol, the other two were the new $\Delta^{8(14),15}$-4α- and $\Delta^{8(14),15}$-4β-hydroxy-18-norisopimaradienes. The syntheses of these two alcohols are described. The greater amount of the 4α compound found in nature, and its relative ease of synthesis compared to the 4β isomer, showed it to be formed preferentially.

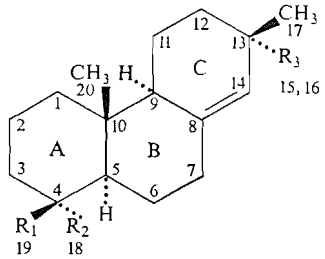
Canadian Journal of Chemistry, 47, 4389 (1969)

Introduction

The extraction of the outer bark of western red cedar (*Thuja plicata* Donn) with petroleum ether yielded 2.6% (1) of an oil. This has been fractionated and the neutral portion examined chromatographically. This paper describes the characterization and syntheses of three components of the neutral fraction.

Discussion

The neutral fraction of the petroleum ether solubles contained seven components as shown by thin-layer chromatography (t.l.c.). Three of these were new compounds (one ketone and two alcohols), two were known compounds, and the remainder were a hydrocarbon mixture and a fat mixture. One of the known compounds was isopimarinol[3] (**1**), a compound previously isolated from *Cryptomeria japonica* (3), and the other known compound was the ubiquitous β-sitosterol. The identity of **1** was the key to the structures of the two new alcohols. Compound **1** had an infrared (i.r.) spectrum identical with one from the material previously isolated from sugi (3). Comparison with a synthetic sample prepared by reduction of methyl isopimarate (**2**) showed identical nuclear magnetic resonance (n.m.r.) and undepressed mixture melting point. Compound **3** and **4** had spectra similar to **1**, except for the absence of the signals from the methylene carrying the hydroxyl group. The evidence supporting the formulation of compound **3** as $\Delta^{8(14),15}$-4α-hydroxy-18-norisopimaradiene and compound **4** as $\Delta^{8(14),15}$-4β-hydroxy-18-norisopimaradiene is now presented.



R_3 = vinyl
1 $R_1 = CH_3$; $R_2 = CH_2OH$
2 $R_1 = CH_3$; $R_2 = COOCH_3$
3 $R_1 = CH_3$; $R_2 = OH$
4 $R_1 = OH$; $R_2 = CH_3$

R_3 = ethyl
5 $R_1 = CH_3$; $R_2 = OH$
6 $R_1 = OH$; $R_2 = CH_3$
7 $R_1 + R_2 = CH_2$
8 $R_1 = CH_3$; $R_2 = CH_2OH$

The ultraviolet (u.v.) spectra of **1**, **3**, and **4** showed a single maximum at 209 mμ as expected from the unconjugated double bonds. The i.r. spectra showed bands at about 3080, 1640, 1410, 1000, and 906 cm^{-1}, attributed to a vinyl group and about 1660 and 820 cm^{-1} from a trisubstituted double bond. Hydroxyl group absorption in the near i.r. spectra of **1** was at 3642 cm^{-1}. Compounds **5** and **6**, which were the dihydroderivatives of **3** and **4**, absorbed at 3612 cm^{-1} and 3615 cm^{-1}. These data showed that **1** contained a primary hydroxyl group, and that **5** and **6** contained a tertiary hydroxyl group. Extinction coefficients calculated were 61, 30, and 41, respectively, and Bellamy (4) stated that primary alcohols absorbed at 3642 cm^{-1} and tertiary alcohols at 3618 cm^{-1} with extinction coefficients of 70 and 45.

[2]To whom enquiries should be addressed at the laboratory.

[3]We are following the nomenclature of Edwards and Rosich (2) who gave the names isopimarane and derivatives to compounds formerly called sandaracopimarane and derivatives.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The n.m.r. spectra of **1**, **3**, and **4** showed an ABX signal centered at 4.8 and 5.7 δ from the three protons of a monosubstituted double bond. The position of these signals suggested the $\Delta^{8(14),15}$ isopimaradiene configuration (2,5). However, Edwards and Rosich have shown similar vinyl absorption patterns from $\Delta^{8(9),15}$ pimaradiene and its 18- or 19-derivatives (2). These compounds also showed a broad singlet at about 5.2 δ arising from the proton on a trisubstituted double bond. The spectrum of compound **1** had a quartet from the C-18 methylene centered at 3.2 δ, and this indicated the equatorial configuration (6). Compounds **1**, **3**, and **4** each had three sharp singlets attributed to methyl groups. Since these were not coupled, the methyl groups were therefore all tertiary and the hydroxyl groups of **3** and **4** were probably on position 4. The absence of a signal from a proton on a carbinol in the spectra of **3** and **4** downfield from the methylene protons, showed that the hydroxyl groups were not secondary in these compounds.

The axial methyl groups at C-10 were at about 0.77 δ in the spectra of **1** and **3**. The signal shifted downfield to about 0.95 δ in **4**, showing an interesting effect with changes in structure. Table I shows the positions of the signals from the other two (C-17 and C-19) methyl groups in these compounds. These data indicated that compounds **3** and **4** were norditerpenes with the isopimaradiene configuration.

TABLE I

Chemical shifts of methyl groups in δ

Compound	C-20	C-19	C-17
1	0.79	0.86	1.02
3	0.75	1.08	1.02
4	0.91	1.13	1.01

Parent ion peaks in the low-resolution mass spectra of **1** and **3** to **6** were all visible at the calculated molecular weight. Empirical formulae were confirmed by high-resolution spectra of **1**, **5**, and **6**. The initial fragmentation mode appeared similar in all compounds; *i.e.* an initial loss of a methyl group (perhaps C-17), and loss of water in **3** and **4**. Table II summarizes the spectral data.

It was decided to synthesize the dihydroderivatives (compounds **5** and **6**) of compounds **3** and **4**. The synthesis of **5** was similar to the synthesis of $\Delta^{8(14)}$-4α-hydroxy-18-norpimarene by Grant *et al.* (7). Dihydroisopimaric acid was decarboxylated with lead tetraacetate (6) to a mixture of olefins and an acetoxy substituted compound. The desired product, the $\Delta^{4(19),8(14)}$ olefin **7** was separated by column chromatography on silver nitrate–alumina. Compound **7** was epoxidized (8) and then reduced with lithium aluminium hydride to give $\Delta^{8(14)}$-4α-hydroxy-18-norisopimarene (**5**). Compound **5** was identical (t.l.c. on silver nitrate–silica gel, mixture melting point, n.m.r. spectra) with the product from the hydrogenation of **3**.

The above mixture of hydrocarbons (from the decarboxylation of dihydroisopimaric acid) were examined on the gas chromatograph. They had the same retention times, on two different columns, as the mixture of hydrocarbons obtained from the dehydration of **5** and **6**. These data showed that the location of the hydroxyl group in **5** and **6**, and thus **3** and **4**, was on C-4.

Compound **6**, the dihydro derivative of **4**, was synthesized by the same method as used for the preparation of 4α- and 4β-hydroxy-18-norhibaene from erythroxylol A by Martin and Murray

(9). Partial hydrogenation of **1** gave **8** which was reacted with chromium trioxide in acetic acid. The major product was the putative aldehyde. The t.l.c. in two solvent systems showed both **5** and **6** as minor products. The latter was isolated in 1% yield. Other evidence supporting structure **4** was the similarities for it (and **3**) with the spectral data reported (7) for the 4α- and 4β-hydroxy-18-norhibaenes. Thus the methyl group resonance reported in Table I for **4** agreed within 0.06 δ with the data for 4α-hydroxy-18-norhibaene, and within 0.05 δ for **3** and the 4β-isomer.

Experimental

Melting points were uncorrected. Infrared spectra were taken of carbon tetrachloride solutions with Perkin–Elmer 421 and Beckman DK-2 spectrophotometers. Nuclear magnetic resonance spectra were taken in deuteriochloroform solutions containing tetramethylsilane (δ = 0) with Varian A-60 or HA-100 instruments. Low-resolution mass spectra were taken on an Atlas CH-4 and high-resolution mass spectra on an AEI-MS9 double-focusing spectrometer. Thin-layer chromatography was on Merck silica gel G with dichloromethane developing solvent and nitric–sulphuric acid detecting reagent unless otherwise noted. Petroleum ether was the 65–100° fraction.

Isolation of Compounds

Petroleum ether solubles (3.60 g) from the extraction of western red cedar bark (1) were placed on a column (5 × 40 cm) of Woelm alumina (activity III). The column was eluted with petroleum ether for the first 400 ml, followed by mixtures of petroleum ether containing increasing amounts of benzene (10% more every 200 ml); fractions were collected every 50 ml and examined by t.l.c. Fractions 1–4, 498 mg, contained a straight-chain hydrocarbon mixture which was not examined further. Fractions 5–6, 71 mg, contained a fat also not examined. Fractions 11–12, 33 mg, contained an unknown ketone (m.p. 50°, λ_{max} 267 mμ) whose structure has not yet been determined. Fraction 13–16, 43 mg, contained compound **4**. Fractions 17–20, 54 mg, contained compound **1**. Fractions 21–24, 62 mg, contained compound **3**. Fractions 25–28, 85 mg, contained β-sitosterol, m.p. 137°, mixture m.p. undepressed with an authentic sample, also identical t.l.c. R_f values. Yields quoted above were those obtained after the compound had been purified via preparative-layer chromatography. Compounds **1**, **3**, **4**, in ethanol absorbed at 209 mμ in the ultraviolet (u.v.) region. They all had a vinyl signal in their n.m.r. spectra, with the AB portion centered at 4.80 δ and the X at 5.70 δ, with $J_{AB} = 2$, $J_{AX} = 10$, and $J_{BX} = 18.5$ Hz: also a broad singlet at 5.15 δ (W 1/2, 3.5 Hz) from the proton on C-14. Other spectral data are summarized in Tables I and II.

Isopimarinol (1)

Compound **1** $[\alpha]_D$ − 1.5° (*c*, 0.2 ethanol) had identical i.r. and n.m.r. spectra with isopimarinol, m.p. 43–45°, mixture m.p. undepressed with a sample synthesized by reduction of methyl isopimarate $[\alpha]_D$ − 7.9° (*c*, 1 ethanol); both had R_f 0.26.

Calcd. (mass spectrum) for $C_{20}H_{32}O$: 288.245303. Found: 288.243135.

$\Delta^{8(14),15}$-4α-Hydroxy-18-norisopimaradiene (3) and $\Delta^{8(14)}$-4α-Hydroxy-18-norisopimarene (5)

Compound **3** had R_f 0.20, spectra very similar to **1** (except methylene components) and crystallized from ethanol–water to needles, m.p. 100–101°. Compound **3** (20 mg) in ethanol (5 ml) plus platinum oxide (5 mg) was treated with hydrogen at 2 atm and room temperature for 10 min. After isolation, the product **5** crystallized as needles from acetone–water, m.p. 93–95°. Both **3** and **5** had similar R_f values and colour reactions (purple) on the chromatoplate. On silver nitrate–silica gel G plates, however, **3** hardly moved from the origin whilst **5** had R_f 0.2.

Calcd. (mass spectrum) for $C_{19}H_{32}O$ (**5**): 276.245303. Found: 276.244319.

$\Delta^{8(14),15}$-4β-Hydroxy-18-norisopimaradiene (4) and $\Delta^{8(14)}$-4β-Hydroxy-18-norisopimarene (6)

Compound **4** had R_f 0.31, spectra similar to **3**, and did not crystallize. It was hydrogenated to **6**, as above, which crystallized from ethanol–water as plates, m.p. 82–84°. R_f values were again similar; on the argentous plate, **6** had R_f 0.5 and **4** had 0.1.

Calcd. (mass spectrum) for $C_{19}H_{32}O$ (**6**): 276.245303. Found: 276.243768.

Synthesis of $\Delta^{8(14)}$-4α-Hydroxy-18-norisopimarene (5)

Dihydroisopimaric acid (1.5 g) in dry benzene (45 ml) and pyridine (3 ml) under nitrogen was treated with lead tetraacetate (3.26 g) with stirring at room temperature for 1 h and refluxing for 3 h. The mixture was filtered, the filtrate was washed with water, and the solvent was evaporated to yield a yellow oil (1.20 g) which was placed on a column of silver nitrate–silica gel (40 g, 10%). The column was first eluted with 1 l of petroleum ether to yield a fraction (330 mg) of an oil believed to be a mixture of $\Delta^{3,8(14)}$- and $\Delta^{4(5),8(14)}$-18-norisopimaradienes. Elution of the column with 1 l of ether–petroleum ether (1:9) gave the desired crude **7** (345 mg), recognized from the *exo*-methylene signals in its i.r. (890 cm^{-1}) and n.m.r. (4.40, 4.68 δ broad singlets) spectra. Further elution of the column with ether–petroleum ether (2:8) gave an unknown product containing an acetoxy group. The crude **7** was purified on a similar column to give pure $\Delta^{4(19),8(14)}$-18-norisopimaradiene (245 mg), R_f = 0.75 on argentous plates (petroleum ether developed) vs. R_f 0.95 for the first fraction eluted from the column.

Compound **7** (113 mg) in chloroform (8 ml) was treated with *m*-chloroperbenzoic acid (86 mg) at about 0° for 1 day. Removal of the acid left the crude epoxide (86 mg) which was dissolved in ether (5 ml) and added to a stirred solution of lithium aluminium hydride (120 mg) in ether (10 ml). The mixture was refluxed under nitrogen for 2 h and worked up in the usual manner. The product, 71 mg recrystallized from ethanol–water, had m.p. 91–94°, undepressed on admixture with **5**; i.r. and n.m.r. spectra and chromatographic behaviour all identical to **5**. Its mass spectrum is given in Table II.

Syntheses of $\Delta^{8(14)}$*-4β-Hydroxy-18-norisopimarene (6)*

Compound **8** (650 mg), chromium trioxide (200 mg), acetic acid (15 ml), and water (0.50 ml) were stirred 2 h at room temperature. The reaction mixture was taken up in ether and washed with sodium bicarbonate. After ether evaporation, the product (0.475 g) was fractionated chromatographically on a small column of silica gel (10 g) with petroleum ether going to ether as the eluant. Concentration of the fractions and further chromatographic purification of the appropriate ones on preparative layer plates of silica gel G (dichloromethane eluant) gave crude **6** (7 mg), m.p. 83–85°, mixture m.p. undepressed. The identity was confirmed by R_f values in two t.l.c. systems, and the position of the methyl groups signals in the n.m.r. spectrum of the synthesized **6**.

Dehydration of ***5*** *and* ***6*** *and Gas-liquid Chromatography*

Compound **5** (14 mg) and compound **6** were each treated with phosphoryl chloride (0.5 ml) and pyridine (1.5 ml) in sealed tubes at 125° for 3.5 h. The products were isolated in the usual manner and examined with the aid of the gas chromatograph. Compounds **5** and **6** both gave the same mixture of three hydrocarbons, believed to be the $\Delta^{3,8(14)}$-, $\Delta^{4,8(14)}$-, and $\Delta^{4(18),8(14)}$-18-norisopimaradienes. The same 3 were isolated from the decarboxylation of dihydroisopimaric acid by lead tetraacetate above. Gas chromatographic columns used were 5′ × 1/8″ 25% SE-30 on Gas Chrom. Q (4.3, 4.8, 5.2) at 225°, and 5′ × 1/8″ 3% OV-1 on Gas Chrom. Q (4.8, 5.9, 6.5) at 175°, retention time in min for the 3 hydrocarbons are given in parentheses. Nitrogen carrier gas at 25 ml/min was used and the flame ionization detector was at 300°. The 3 olefins from each experiment also had the same R_f values on silver nitrate impregnated thin-layer plates.

Acknowledgments

Absolute configuration of conhydrine[1]

G. FODOR[2] AND E. BAUERSCHMIDT[3]
Department of Chemistry, Laval University, Quebec 10, Quebec

AND

J. CYMERMAN CRAIG

Received June 16, 1969

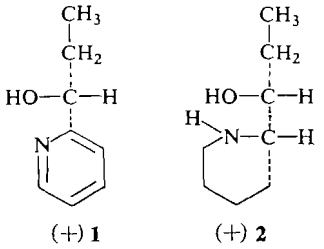
Catalytic hydrogenation of optically active 2-pyridyl ethylcarbinol (**1**) formed the alkaloid conhydrine (**2**) stereospecifically. Application of the von Braun reaction gave conversion of (+)-conhydrine into *R*-(−)-3-octyl benzoate and of (−)-conhydrine into the *S*-(+)-antimer. Both the relative and absolute configuration of the two asymmetric centers in natural (+)-conhydrine have been determined by the combined use of optical rotatory dispersion (o.r.d.) and circular dichroism (c.d.). The results are in agreement with other physical and chemical evidence.

Canadian Journal of Chemistry, 47, 4393 (1969)

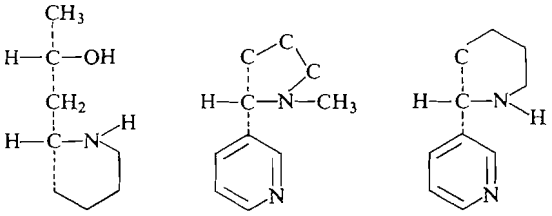
The alkaloid conhydrine was isolated from *Conium maculatum* and natural (+)-conhydrine was oxidized to L-(−)-pipecolic acid (1). The relative configuration of the two asymmetric centres in conhydrine is regarded as *erythro* on the basis of chemical evidence (2, 3) identifying the octan-3,4-diol obtained from (±)-conhydrine by Hofmann degradation and hydrogenation of the methine base (4) with racemic *erythro*-octan-3,4-diol.

Since this work was done on the racemic alkaloid, and the conclusions are based on assumptions regarding the stereochemistry of the intermediate steps, it was desirable to obtain further evidence concerning the configuration of the carbinol carbon. This has now been achieved both by chemical means and by the o.r.d.–c.d. method previously applied (5) to the configuration of the sedridine and allosedridine alkaloids.

The catalytic hydrogenation of optically active (+)-2-pyridyl ethylcarbinol (**1**) under conditions identical to those used (6*a*) for the reaction forming sedridine gave, by asymmetric induction, (+)-conhydrine (**2**) as the major product (6*b*).



(+) **1** (+) **2**



(+) **3** (−) **4** (−) **5**

N,*O*-Dibenzoyl-(+)-conhydrine (**6**) was subjected to the von Braun reaction (7, 8) with phosphorus pentabromide, giving levorotatory 4,8-dibromo-3-octyl benzoate[4] (**7**). Hydrogenolysis led to (−)-3-octyl benzoate (**8**), the infrared (i.r.) and nuclear magnetic resonance (n.m.r.) spectra of which were superimposable to those of the benzoate from natural (9*a*)

[1]Supported by research grant HE-5881 from the National Institutes of Health, U.S. Public Health Service to one of us (J.C.C.) and by Grant No. A-2839 of the National Research Council of Canada to the other (G.F.). This joint paper forms part XV of the series "Optical rotatory dispersion and absolute configuration" and it also belongs to the series on the "Applications and mechanism of the von Braun reaction."

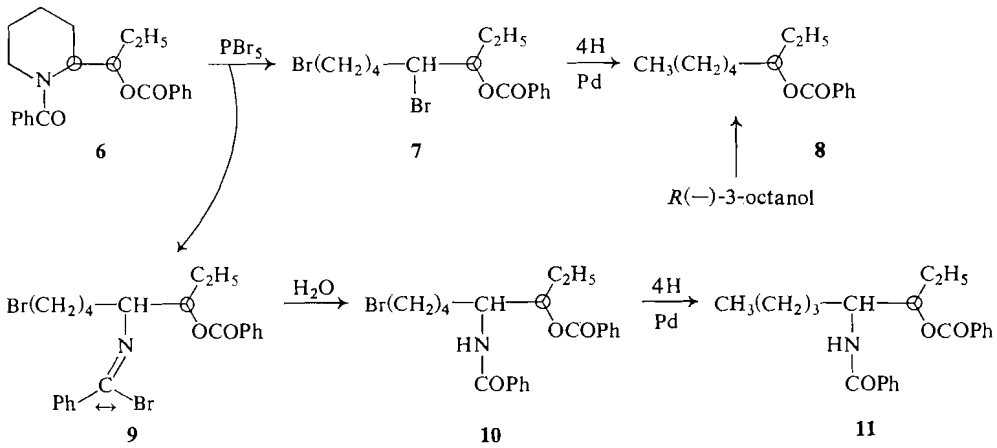
[3]Present address: Department of Chemistry, University of Virginia, Charlottesville, Va. 22903.

[4]*N*-4-(3-benzoxy-8-bromooctyl)-benzimidoyl bromide (**9**), was, however, the main product of the von Braun reaction unlike in the case of sedridine. Hydrolysis led to 3-benzoxy-4-benzamido-8-bromo-octane (**10**) as proven by n.m.r. and analytical data. Hydrogenolysis of this latter afforded 3-benzoxy-4-benzamido octane (**11**). Detailed study of the mechanism and steric course of the von Braun reaction will be presented in forthcoming papers.



(+)-3-octanol of *S*-configuration (9*b*) while the sense of optical rotation was the opposite.

Since the absolute configuration of the latter is known (9*b*), natural (+)-conhydrine has the *R*-configuration at the carbinol carbon of the side-chain. This direct method of chemical correlation has been applied formerly to the degradation of *N*,*O*-dibenzoyl sedridine to *S*-(+)-2-octanol (8).

The o.r.d. curve for (+)-conhydrine (Fig. 1) showed a positive Cotton effect centred around 200 mμ (confirmed by a positive c.d. maximum at

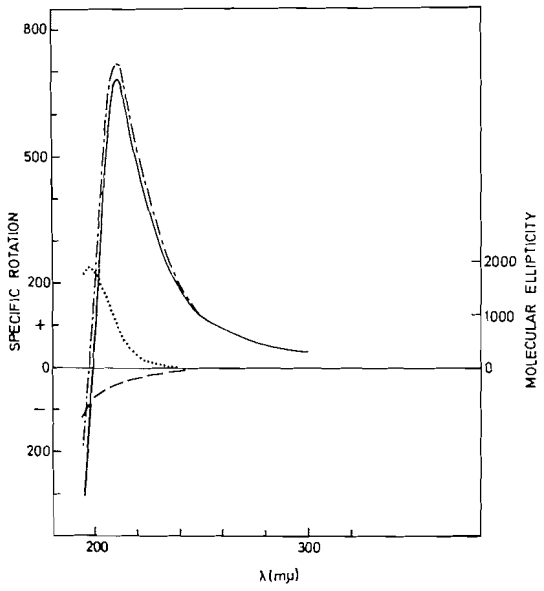


FIG. 1. (+)-Conhydrine, o.r.d. curves of base (—), hydrochloride (- - -), base–hydrochloride (—. —. —. —.); c.d. curve of base (. . . .).

that wavelength), which is due to the n → σ* transition of the non-bonding electrons of nitrogen and oxygen. Below 210 mμ, the curve descends steeply. However, the hydrochloride of (+)-conhydrine gave a plain negative curve (Fig. 1) while its c.d. was zero down to 195 mμ. Since protonation of the nitrogen is known (10) to remove the n → σ* transitions, shifting it into the low wavelength region of the σ → σ* transition, the curve of the hydrochloride is due to the n → σ* transition of the oxygen (11) and indicates the asymmetric centre in the side-chain to have the L-configuration, as found (12) for L-(−)-heptan-3-ol.

Subtraction of the curve for the hydrochloride from that of the base gives a curve very similar to, and slightly more intense than, that of the base, descending steeply below 210 mμ, (Fig. 1) and showing the same positive Cotton effect.

This indicates the absolute configuration of the asymmetric centre in the piperidine ring to be L, and is confirmed by the positive c.d. shown by (+)-conhydrine, identical in sign with that given by (+)-sedridine (5) and by *R*-(−)-coniine (13) both of which are known to give *S*-(−)pipecolic acid on oxidation (1) and thus to be members of the L-series for the asymmetric centre in the piperidine ring.

The absolute configuration of (+)-conhydrine is thus correctly given as **1** from o.r.d. and c.d. evidence, in complete agreement with the direct chemical evidence presented in this paper and in earlier work. As required by this conclusion, the o.r.d. and c.d. curves of (+)-conhydrine are the mirror images of those obtained (5) from (+)-allosedridine (**3**).

TABLE I
Ultraviolet spectra (in ethanol)

Compound	λ_{max}mμ (log ε)		
2-Pyridyl ethylcarbinol (**1**)	257 (3.30)	262 (3.33)	269 (3.24)
2-Picoline (15)	256 (3.4)	262 (3.5)	269 (3.3)
3-Picoline (15)	257 (3.3)	263 (3.4)	270 (3.3)
Nicotine (**4**)		262 (3.46)	
Nornicotine (16)		262 (3.47)	
Anabasine (17)		261 (3.46)	

The chromophore in (+)-2-pyridyl ethylcarbinol (**1**) is very similar to that in nicotine (3), being made up of the intense $\pi \rightarrow \pi^*$ transitions of the pyridine ring together with the (very much less intense) $n \rightarrow \sigma^*$ transitions of the non-bonding electrons of oxygen or nitrogen. This similarity is reflected in the almost identical ultraviolet (u.v.) absorption spectra (14) of 2-pyridyl ethylcarbinol (**1**), nicotine (**4**), 2-picoline, and 3-picoline (15), anabasine (**5**), and nor-nicotine (16) (Table I). It is significant that (−)-2-pyridyl ethylcarbinol gives an o.r.d. and c.d. spectrum which is almost the same as that given (17) by natural (−)-nicotine (**4**) and (−)-anabasine (**5**). Since (−)-nicotine has been assigned the *S*-configuration with reference to both L-proline (18*a*) and L-serine (18*b*) and (−)-anabasine has been related to L-pipecolic acid (19), it follows that (+)-2-pyridyl ethylcarbinol (**1**) has the *R*-configuration as shown.

This is in agreement with the fact that the conversion (+)**1** → (+)**2** does not alter the configuration of the carbinol carbon in the side-chain, known to be *R* in (+) **2** from the evidence reported above.

Experimental

The o.r.d. and c.d. curves were measured at 25° in 95% ethanol on a JASCO or Jouan spectropolarimeter. Rotations are given below only for (*1*) the highest and lowest wavelengths measured, and (*2*) peaks and troughs. The c.d. is recorded (20) in molecular ellipticity units, θ.

(+)-Conhydrine

The following values were obtained: α_D +9.3° (*c*, 3 in ethanol); o.r.d. (*c*, 0.492) α_{300} + 40.7°, α_{212} + 681°, α_{195} − 305°; c.d. $[\theta]_{240}$ 0, $[\theta]_{198}$ + 1917, $[\theta]_{195}$ + 1772.

Hydrochloride of (+)-Conhydrine

The following values were obtained: o.r.d. (*c*, 0.618 in 95% ethanolic 0.1 *N* HCl) α_{300} 0, α_{195} − 121.5°.

O,N-Dibenzoylconhydrine (6)

Dextrorotatory conhydrine (**2**) (1.43 g, 0.01 mole) was dissolved in dry pyridine (20 ml) and benzoyl chloride (3.51 g, 0.0255 mole) added after cooling with ice and stirring. The mixture was allowed to reach room temperature within 2 h and then was kept for another 24 h at 25°. This mixture was poured on ice cold 20% H_2SO_4 (100 ml), the precipitated yellowish dibenzoate taken up in chloroform (50 ml), and the acidic solution extracted five times with a total of 200 ml chloroform. The combined extracts were washed with a saturated sodium chloride solution, then 3 times with a total of 50 ml 5% sodium hydrogen carbonate solution, finally dried ($MgSO_4$) and evaporated to give 3.1 g (88%) of crude dibenzoylconhydrine. Recrystallization from 80% aqueous methanol (50 ml) afforded a pure product (2.6 g, 74%) m.p. 133–134%. The following data was obtained – i.r.: 2900, 1720 (benzoic ester); 1625 (N—CO), 1440, 1275 (ester C—O stretch) 710, 690 (aromatic); n.m.r.: multiplet δ, 7.45 (10H), 0.95 C—Me (triplet); α_D − 13° (*c*, 3 in chloroform).

Anal. Calcd. for $C_{22}H_{25}NO_3$: C, 75.18 H, 7.17 O, 13.66 N, 3.99. Found: C, 75.51 H, 6.81 O, 13.13 N, 4.52.

Treatment of (−)-Dibenzoylconhydrine with Phosphorus Pentabromide

Procedure A

(−)-Dibenzoylconhydrine (**6**) (2.6 g, 0.074 mole) and phosphorus tribromide (1.99 g, 0.07 mole) were dissolved in tetrachloromethane (10 ml) and a few drops of chloroform. Bromine (1.18 g, 0.074 mole) in CCl_4 (5 ml) was then added and the reddish colored solution evaporated on a Rotavapor at 25° to dryness. Distillation was begun under 20 mm pressure until the oil bath reached 100°, to give a fraction consisting mainly of phosphorus oxybromide and benzonitrile, as indicated by the i.r. bands at 1780 and 2100 cm^{-1}, respectively. Water decomposes the former to afford benzoic acid which was collected by filtration and identified, while the latter was taken up in ether (20 ml), and redistilled. An oil pump was used to collect the higher boiling products, under 1 mm pressure from 100–160°, a bromine-containing oil (1 g) distilled. The i.r. indicated the presence of some benzonitrile (2000 cm^{-1}) together with an ester (1720 and 1273 cm^{-1}) and a weak amide band appeared around 1620 cm^{-1}. It was levorotatory ($\alpha_D^{20} \sim 9.7°$) in chloroform; the concentration is uncertain because of benzonitrile as contamination. The n.m.r. spectrum resembles one obtained by similar treatment of dibenzoylsedridine (8).

Redistillation under 10^{-2} mm from a Späth tube gave a nearly colorless oil, dibromoester (**7**) (700 mg), (i.r.: 1725 and 1275 cm^{-1}), free of benzonitrile (which was collected in the liquid nitrogen trap). This fraction was

For personal use only.

subjected to catalytic hydrogenation in ethanol (50 ml) at atmospheric pressure and 25° over Pd/charcoal (0.5 g) and barium hydroxide octahydrate (1 g). The consumption of hydrogen amounted to 2 moles within 2 h. The solution was then filtered and evaporated to dryness, the residual oil taken up in chloroform (15 ml), washed with 0.1 *N* HCl (2 ml) and water (10 ml), dried ($MgSO_4$), and evaporated again leaving behind a colorless oil (500 mg) free of bromine. The n.m.r. showed the presence of 5 protons (7.8 δ), a deshielded H around 4.2 δ, and the terminal methyl at 1.1 δ. The i.r. showed an ester CO at 1720 cm^{-1}. The spectra were superimposable with those of authentic 3-octyl benzoate. The latter was prepared from natural (9*a*) (+)-3-octanol (240 mg, 0.002 mole) dissolved in dry pyridine (2 ml) and stirred with benzoyl chloride (300 mg, 0.0021 mole) at 25° for 24 h. Pyridine was removed on a Rotavapor and the product was extracted with chloroform (20 ml), washed with 0.1 *N* H_2SO_4 (5 ml), water (5 × 2 ml), 20% potassium hydrogen carbonate (5 ml), dried ($MgSO_4$), and finally the solvent removed; α_D^{20} + 6.8° (*c*, 2 in chloroform) (9*c*). The product of degradation showed α_D^{20} − 6.2° (*c*, 2 in chloroform).

Hydrolysis of the benzoate (**8**) was carried out by refluxing for 6 h with 10% methanolic (10 ml) potassium hydroxide. Evaporation of the solvent gave potassium benzoate together with 3-octanol. The salt was precipitated by adding dry ether (20 ml) and removing the solvent again. The residual colorless oil gave an i.r. spectra: 3390 (OH), 2950, 2880 (CH), 1470 (deformation), and 1270 cm^{-1} (C—O stretch) and n.m.r. spectra superimposable to those of an authentic specimen of *S*-(+)-3-octanol we obtained by courtesy of Professor Y. R. Naves (University of Lausanne); α_D^{20} − 8.9° (*c*, 2 in chloroform). An authentic specimen (9*a*) showed α_D^{20} + 8.97° ($CHCl_3$). The allophanate has m.p. 185°, as recorded by Dr. Naves in a previous publication for 3-octyl allophanate.

Procedure B

(+)-Dibenzoylconhydrine (5.6 g, 0.0169 mole, α_D^{20} + 12.8° (*c*, 3 in dimethyl formamide)) prepared from (−)-conhydrine in the same way as was its antimer from natural conhydrine was mixed in a 20 ml flask with phosphorus tribromide (3.32 g, 0.015 g mole) and bromine (2.55 g, 0.016 mole) was added. The reddish colored mixture was distilled *in vacuo* from the same flask essentially as described for Procedure A. After a first fraction (800 mg) consisting mainly of phosphorus oxybromide (b.p. below 80°, 20 mm) was obtained, distillation gave (+) **7**, together with benzonitrile (b.p. below 120°, 30–50 μ) and a viscous liquid (2.48 g, b.p. 120–170°). The lower boiling fraction when worked up as in Procedure A yielded some dextrorotatory octyl benzoate (**8**). The solution of the higher boiling fraction in ether (50 ml) was washed with ice-cold 10% potassium hydrogen carbonate solution (20 ml), dried ($MgSO_4$) and the solvent removed. The product was then purified by thin-layer chromatography (Silicagel/HF, 0.8 mm) using benzene and ethyl acetate (3:1). The main fraction of crystals, m.p. 107–108°, obtained after recrystallization from hexane proved to be 8-bromo-4-benzamido-3-octyl benzoate.

Anal. Calcd. for $C_{22}H_{26}BrNO_3$: C, 61.25; H, 6.63; Br, 17.56. Found: C, 61.78; H, 6.72; Br, 17.33.

The i.r. spectrum showed peaks at: 3380 (NH); 3010, 2290 (C—H); 1720 (CO ester); 1660 (CO amide); 1580 (amide II); 1270 (C—O stretch); 710 cm^{-1} (aromatic). The n.m.r. spectrum (on δ scale) showed: multiplet, 8.2–7.3 (10H) (aromatic); multiplet, 5.2 (1H) probably H-3; multiplet, 4.4 (2H) assigned to CH_2Br; multiplet, 2.1–1.6 (various methylenes); and a triplet at 1.0 δ (CH_3). The pseudotriplet at 3.32 δ corresponding to 2H disappears after catalytic hydrogenolysis over Pd/C in ethanol (20 ml) so the bromine was terminal, hence the benzamido group was attached to C-4 in the bromoamide. The methyl region increased from 3H to 6H after hydrogenolysis which is consistent with the structure of 4-benzamido-3-octyl benzoate; α_D^{20} + 32.6° (*c*, 3 in chloroform).

Anal. Calcd. for $C_{22}H_{27}NO_3$: C, 74.75; H, 7.70; N, 3.96. Found: C, 74.35; H, 6.65; N, 4.11.

(−)-2-Pyridyl Ethylcarbinol

This carbinol was obtained in crystalline form for the first time by Y. K. Wang, m.p. 25°. α_D − 72.9° (*c*, 2.0 in ethanol). The c.d. showed: *c*, 0.08 in 95% ethanol)$[\theta]_{280}$ 0, $[\theta]_{272}$ − 230, $[\theta]_{264}$ − 530, $[\theta]_{258}$ − 530, $[\theta]_{238}$ − 3000, $[\theta]_{220}$ − 1060 (sh), $[\theta]_{207}$ + 2100. α_D − 65° was reported earlier (6*b*) for this carbinol. However, checking its optical purity by integration of the diastereotopic n.m.r. signal of its acetyl mandelic ester, indicated an 93% optical purity. The product prepared for the present work α_D − 72.9 is therefore optically pure.

Acknowledgments

The authors wish to express their gratitude to Mr. Y. K. Wang, M.Sc., Laval University, who repeated some of Dr. Bauerschmidt's experiments and who is continuing the preparative work with conhydrine.

Synthèse et propriétés de la *tert*-butyl-5 diméthyl-3,3 cycloheptanone

JEAN-CLAUDE RICHER ET ROBERT BISSON[1]
Département de Chimie, Université de Montréal, Montréal, P.Q.

Reçu le 5 mai 1969

La *tert*-butyl-5 diméthyl-3,3 cycloheptanone a été synthétisée à partir de la *tert*-butyl-4 diméthyl-2,2 cyclohexanone; la stéréochimie de sa réduction par divers agents a été déterminée. Pour fins de comparaison, la *tert*-butyl-5 diméthyl-2,2 cycloheptanone a aussi été préparée en utilisant la *tert*-butyl-4 cyclohexanone comme produit de départ.

Introduction

Alors que la réduction des alkylcyclohexanones a fait l'objet de nombreuses communications (1) peu de travaux sur les cycloheptanones correspondantes ont été effectués (2–7). Il apparaissait intéressant, dans le cadre de nos travaux sur la stéréochimie des additions sur des systèmes cycliques (8), de déterminer si l'introduction sur la *tert*-butyl-5 cycloheptanone d'un groupe *gem*-diméthyle en position 3 provoquerait lors de la réduction de cette molécule (**1***a*) une stéréosélectivité plus élevée que celle observée lors de la réduction (6, 7) de la *tert*-butyl-4 cycloheptanone non substituée (**1***b*). Les résultats obtenus lors de la synthèse et de la réduction de **1***a* font l'objet du présent travail.

Résultats et discussion

Synthèse des tert-butyl-5 diméthyl-2,2 cycloheptanone (4a) et diméthyl-3,3 cycloheptanone (1a)

La réaction directe de la *tert*-butyl-4 diméthyl-2,2 cyclohexanone (**2***a*) avec le diazométhane pour conduire à la *tert*-butyl-5 diméthyl-3,3 cycloheptanone (**1***a*) a été tentée; cette réaction comme celle rapportée par Mousseron et Manon (9) sur la diméthyl-2,2 cyclohexanone **2***b* ne conduit qu'à peu d'agrandissement de cycle et le produit obtenu avec un faible rendement n'a pu être purifié. Les cyanohydrines **3***a* sont facilement obtenues à partir de la cétone **2***a*, suivant la technique de Bélanger (10); la présence dans le spectre de résonance magnétique nucléaire (r.m.n.) du mélange réactionnel de quatre pics dus à des groupes méthyles permet d'une part de réaliser que les deux cyanohydrines isomères se sont formées et d'autre part de préciser que l'une forme 83% du total. Par analogie avec les résultats de Gravel (11), il est permis de supposer que le produit prépondérant de la réaction correspond à une entrée axiale du réactif sur la cétone. La réduction des cyanohydrines brutes (**3***a*) par $LiAlH_4$ conduit aux aminoalcools **3***b* correspondants isolés sous forme de chlorhydrates **3***c*; l'existence des deux isomères attendus pour ces aminoalcools est mise en évidence par la présence dans leur spectre r.m.n. de deux pics dus aux groupements *tert*-butyles. La désamination nitreuse de ces aminoalcools fournit un mélange réactionnel qui d'après la chromatographie en

[1]Les résultats rapportés dans cette communication sont extraits du mémoire soumis par M. BISSON, en vue de l'obtention du grade de Maître ès-Sciences, Faculté des Sciences, Université de Montréal.

Les récherches qui font l'objet de la présente étude ont été appuyées en partie par le Conseil de Récherches pour la Défense du Canada, subvention numéro 9530-61.

For personal use only.

phase gazeuse (c.p.g.) contiendrait sept produits; la cétone **1***a* formerait 55% du total. La formation de **1***a* en prépondérance pouvait être prévue, quelle que soit la stéréochimie de l'aminoalcool **3***b* utilisé, par un simple examen des conformations privilégiés. La cétone **1***a* est isolée à l'état pur par l'intermédiaire de sa semicarbazone et sa structure est confirmée par le fait que quatre atomes de deutérium peuvent être introduits lors de sa deutération (12) par l'intermédiaire de son énamine **5**.

Pour fins de comparaison, la *tert*-butyl-5 diméthyl-2,2 cycloheptanone (**4***a*) a été préparée à partir de la *tert*-butyl-4 cyclohexanone (**2***c*) en mettant à profit les méthodes d'extension de cycles préconisées par Julia et Guereny (13) et Johnson *et al.* (14). La condensation de **2***c* avec le bromure d'*iso*propénylmagnésium conduit aux alcools tertiaires **3***d* qui seraient présents d'après la c.p.g. dans le rapport 60/40; le traitement de ces alcools par l'hypobromite de *tert*-butyle (14) fournit un mélange réactionnel duquel les cétones bromées **4***b* peuvent être isolées. Leur hydrogénolyse selon les indications de Julia et Guereny (13) mène quantitativement à la cétone désirée **4***a* dont la structure est confirmée par la fixation de deux atomes de deutérium lors de sa deutération (12).

Sur la réduction de la tert-butyl-5 diméthyl-3,3 cycloheptanone (1a)

La réduction de la cétone **1***a* par le sodium dans l'éthanol conduit à un mélange des deux alcools **6***a* et **7***a* qui peuvent être obtenus à l'état pur par recristallisations de leurs *p*-interbenzoates **6***b* et **7***b*. La c.p.g. appliquée aux alcools **6***a* et **7***a* n'a donné dans nos mains aucun résultat satisfaisant; les éthers triméthylsilanés **6***c* et **7***c* préparés d'après la méthode de Sweeley *et al.* (15) peuvent toutefois être très bien séparés et des expériences connexes ont permis de montrer que la transformation en éther est quantitative.

La cétone **1***a* a été réduite par divers agents réducteurs et les produits obtenus analysés par la méthode décrite plus haut; les résultats sont consignés dans le tableau I. Ces résultats montrent d'une part que la réduction par le sodium et l'éthanol conduit normalement au produit le plus stable **7***a*; d'autre part les résultats obtenus lors de la réduction par les hydrures complexes permettent de mettre en évidence qu'en passant à un hydrure plus volumineux la quantité de l'alcool le moins stable **6***a*, provenant d'une réduction de la cétone par sa face la plus dégagée (8) est formé en quantités croissantes. Les temps relatifs de rétention en c.p.g. des produits **6***c* et **7***c* de même que les résultats obtenus lors des réductions permettent après un examen attentif des modèles moléculaires, de suggérer les structures des alcools épimères; si l'on admet pour la cétone **1***a* la conformation "chaise tordue" (16) qui permet de fixer le groupe *tert*-butyle dans une position équatoriale tout en minimisant les intéractions du groupe *gem*-diméthyle d'une part avec le cycle et d'autre part avec le group carbonyle, l'alcool cis, **6***a*, aurait un groupement hydroxyle en position pseudo axiale alors que dans l'alcool *trans* **7***a*, ce groupe serait en position pseudo équatoriale.

TABLEAU I

Stéréochimie de la réduction de la cétone **1***a*

Agent réducteur	Références	Pourcentage alcool **6***a*/**7***a**
$Al(OiPr)_3$†	(20)	38/62
$Al(OiPr)_3$‡	(21)	57/43
H_2/Pt	(22)	46/54
Na/EtOH		45/55
$NaBH_4/iPrOH$	(23)	55/45
$LiAlH_4/Et_2O$	(24)	60/40
$LiAl(OtBu)_3H/THF$	(25)	70/30

*Les pourcentages indiqués sont les moyennes d'au moin trois essais.

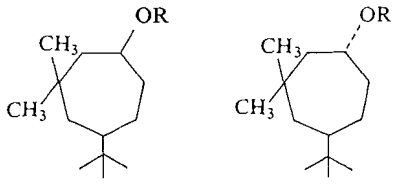
4 **5**

a R = CH_3
b R = CH_2Br



6 **7**

a R = H *b* R = CO—C_6H_4—NO_2—*p* *c* R = $Si(CH_3)_3$

Les résultats obtenus au cours du présent

travail permettent donc de noter que l'introduction du groupement *gem*-diméthyle en position 3 semble conférer à la molécule une rigidité conformationnelle que la cétone **1***b* ne possède pas, ce qui permet dans certains cas d'effectuer des réductions plus sélectives.

Partie expérimentale

Les spectres infrarouges (i.r.) ont été pris à l'aide d'un appareil Beckman, Modèle IR 8, à double faisceau pour des solutions chloroformiques, dans des cellules de chlorure de sodium de 0.1 mm d'épaisseur. Les spectres de r.m.n. ont été pris sur un spectromètre modèle JNM-C-60 H (Jeolco); les déplacements chimiques, δ, sont exprimés en partie par millions et se réfèrent au tétraméthylsilane utilisé comme référence interne. Les spectres de masse ont été pris sur un spectromètre modèle RMU-6D (Hitachi) à température ambiante; l'énergie du faisceau ionisant est de 70 e*V*. Les points de fusion ont été mesurés à l'aide d'un appareil "Hot Stage Apparatus" (Reichert); ils ne sont pas corrigés. Les indices de réfraction ont été mesurés à l'aide d'un réfractomètre Abbe (Carl Zeiss). Les analyses en c.p.g. ont été effectuées avec des chromatographes F et M, modèle 852 et 700 à ionisation de flamme. Les conditions d'analyse sont suivant la colonne utilisée : colonne de polyester de Craig à 15% sur chromosorb W 30–60 mesh, de 10 p, maintenue à 170° et utilisant un courant d'hélium de 80 ml par min; une colonne de Zonyl E-7 à 10% sur chromosorb W, 80–100 mesh, de 10 p, maintenue à 160° et utilisant un courant d'hélium de 60 ml par min ou une colonne de SE-30 à 9% sur Chromport XXX, 80–90 mesh, de 12 p maintenue à 160° et utilisant un courant d'hélium de 55 ml par min.

1. Synthèse de la tert-butyl-5 diméthyl-3,3 cycloheptanone (1a)

1.1 Les cyanohydrines 3a

Utilisant le protocole expérimental décrit par Belanger (10), une solution de bisulfite de sodium dans 55 ml l'eau distillée est ajoutée, sous bonne agitation et à un rythme tel que la température ne dépasse par 5°, à un mélange de 11.3 g de cyanure de sodium dans 55 ml d'eau distillée et de 28.8 g de *tert*-butyl-4 diméthyl-2,2 cyclohexanone (**2***a*). L'addition terminée, le mélange est agité à la température ambiante pendant 2 h et extrait à l'éther à la manière habituelle pour fournir 33 g (100% du rendement théorique) de produits bruts. Les cyanohydrines **3***a* montrent dans leur spectre i.r., la présence de bandes hydroxyle à 3410 et —C≡N à 2210 cm^{-1}. Le spectre r.m.n. de ce mélange déterminé dans le benzène, montre la présence du groupe *tert*-butyle à 0.74 p.p.m., de 4 singulets à 0.81, 0.96, 1.06, et 1.16 p.p.m. correspondants aux groupements méthyles en position 2 et les 2 groupes hydroxyles des alcools tertiaires apparaissent à 2.53 et 2.78 p.p.m.

1.2 Les aminoalcools 3b

Suivant les indications de Gravel (11) une solution de 24.9 g de cyanohydrines **3***a* dans 135 ml d'éther est ajoutée goutte à goutte à 0° à une suspension de 9.2 g d'hydrure de lithium et d'aluminium en suspension dans 200 ml d'éther. Le mélange réactionnel est agité à reflux pendant 21 h et le complexe décomposé par addition successivè à 0° de 12 ml d'eau, 9 ml d'une solution de soude 6 *N*, et de 30 ml d'eau. L'extraction des produits à la manière habituelle permet d'isoler 22.8 g (76% du rendement théorique) de chlorhydrate (**3***c*) d'aminoalcools fondant entre 235–242 °C et présentant dans le spectre i.r. déterminé dans la Nujol des bandes à 3300, 3070, 1625, 1585, 1510, 1368, et 1040 cm^{-1}.

Le spectre r.m.n. de ces dérivés, déterminé dans l'acide trifluoroacétique, montre la présence de pics à 0.89 et 1.02 p.p.m. (*tert*-butyles) et à 1.04 et 1.16 p.p.m. (*gem*-diméthyles). Les aminoalcools **3***b* régénérés de leur chlorhydrate fondent, après recristallisation de l'éther de pétrole, entre 102 et 112 °C et montrent dans l'i.r. des bandes à 3435, 1370, 1040, et 1005 cm^{-1} ; leur spectre r.m.n. présente des bandes à 0.82 et 0.84 p.p.m. (*tert*-butyles) et 0.87 et 1.07 p.p.m. (*gem*-diméthyles).

1.3 Désamination nitreuse

S'inspirant de la méthode décrite par Gravel (11), 34.2 g de chlorhydrate **3***e* sont dissous dans 575 ml d'eau distillée. A cette solution, 1.43 ml d'une solution *N* de soude sont d'abord ajoutés pour libérer l'aminoalcool, puis 247 ml d'acide acétique glaciale pour obtenir une solution d'aminoalcool dans l'acide acétique à 25%. A ce mélange 28 g de nitrite de sodium dissous dans 115 ml d'eau sont ajoutés lentement à 0°. L'addition terminée le mélange réactionnel est agité à 0° pendant 3 h, puis alcalinisé par addition à 0° d'une solution de soude 6 *N* puis légèrement acidifié par addition d'acide acétique glaciale et extrait à l'éther à la manière habituelle pour obtenir 25.4 g d'un liquide qui, après distillation sous pression réduite, est transformé en semicarbazone selon la méthode de Durocher (17). Après deux recristallisations fractionnées d'un mélange méthanol–éthanol, 8.5 g de prismes blancs fondant à 198° (décomposition) sont isolés. L'entraînement à la vapeur de la semicarbazone pure, mise en suspension dans une solution aqueuse contenant 14.5 g d'acide oxalique, conduit après les extractions habituelles à 6.3 g (95% de rendement) de produit cétonique. La distillation de ce produit brut utilisant une colonne Vigreux de 8 cm donne comme fraction de coeur 5.5 g d'un liquide incolore possédant les caractéristiques suivantes : n_D^{26}, 1.4631; p.c. : 134 °C/20 mm Hg ; i.r., bandes à 1692 (carbonyle) et 1368 cm^{-1} (*tert*-butyle) ; r.m.n. (solution benzénique), bandes à 0.72 p.p.m. (*tert*-butyle), à 0.81 et 0.84 p.p.m. (*gem*-diméthyle); spectre de masse, pic parent à *m/e* de 196. La dinitrophénylhydrazone, préparée à la manière habituelle, fond à 153–154 °C (éthanol) ; i.r. bandes à 3040, 1618, 1592, 1368, et 1335 cm^{-1} ; r.m.n. ($CDCl_3$), pics à 0.85 (*tert*-butyle), 0.87 et 1.06 p.p.m. (*gem*-diméthyle) et à 7.74, 8.06, et 8.85 (protons aromatiques); spectre de masse, pic parent à *m/e* de 376. La deutération selon les indications de Fuchs (12) à l'aide de 0.4 g de cétone **1***a*, de 0.16 g de pyrollidine, et 15 ml de benzène traités 8 fois par 0.5 ml d'oxyde de deuterium contenant des traces d'anhydride acétique conduit, après extraction à la méthode habituelle, à la cétone **1***a* deutériée contenant dans son spectre i.r. des bandes dans la région de 2220 à 2200 cm^{-1} et dans son spectre de masse des pics à 196 (100%), 197 (166%), 198 (248%), 199 (292%), et 200 (258%).

2. Synthèse de la tert-butyl-5 diméthyl-2,2 cycloheptanone (4a)

2.1 Tert-butyl-4 isopropenyl-1 cyclohexanol (3c)

Au réactif de Grignard préparé selon les indications de Normant (18) dans le tétrahydrofuranne et à partir de 3.6 g de magnésium et 18.2 g de bromo-2 propène, une solution de 17.9 g de *tert*-butyl-4 cyclohexanone (**2***c*) est ajoutée tout en maintenant la température à 0°. Le mélange est ensuite chauffé à reflux pendant 2 h, puis hydrolysé par addition goutte à goutte à 0° d'une solution de chlorure d'ammonium et extrait à l'éther à la manière habituelle pour fournir 23 g d'une huile montrant dans son spectre i.r. des vibrations caractéristiques à 3400 (hydroxyle) et 1710 cm^{-1} (cétone qui n'a pas réagie). Une analyse en c.p.g. (Zonyl E-7) du produit brut de la réaction révèle la présence de 3 produits principaux soit 52 et 35% respectivement, des 2 isomères de l'alcool **3***d* et 4% de cétone (**2***e*) qui n'a pas réagi.

2.2 Bromométhyl-2 tert-butyl-5 méthyl-2 cycloheptanone (4b)

Selon une technique expérimentale modifiée inspirée de Johnson *et al.* (14) 8.6 g d'alcool **3***d* sont mis en solution dans 205 ml de chloroforme débarassé de toute trace d'alcool et 10 g d'hypobromite de *tert*-butyle à 90% (d'après un dosage iodomidrique) préparé selon la méthode de Geneste et Kergomard (19) sont ajoutés ; le mélange est agité à 50–55° à l'abri de la lumière pendant 38 h puis filtré sur 80 g d'alumine neutre (colonne de 50 mm de diamètre) pour isoler, après évaporation du chloroforme, 10 g d'un liquide qui est chromatographié sur 900 g de gel de silice. L'élution de la colonne avec un mélange d'éther de pétrole contenant 3% d'éther anhydre permet d'isoler 2.2 g des bromocétones **4***b* pures à au moins 90% d'après la c.p.g. Ces composés p.e. 82–84°/0.04 mm Hg ; n_D^{25} 1.4988 ; test de Beilstein positif ; i.r.: bandes à 1695 (carbonyle) et à 1368 cm^{-1} (*tert*-butyle); r.m.n. (benzène) pics à 0.66 et 0.67 p.p.m. (*tert*-butyle), 0.94 et 1.02 (méthyle en position 2), et entre 2.86 et 3.72 (bromométhyle).

2.3 Hydrogénolyse des bromocétones 4b

Selon la procédure décrite par Julia et Guereny (13), 0.75 g de bromocétone **4***b*, 2.2 g de zinc en poudre, 10 ml d'acide acétique glaciale, et 2 ml d'acide bromhydrique à 48% sont chauffés à reflux pendant 3 h. Le mélange réactionnel est filtré, versé dans un excès d'ammoniaque à 50% et extrait à l'éther. Les fractions éthérées, lavées à la manière habituelle fournissent 0.55 g (100% de rendement) d'un liquide brun montrant dans son spectre i.r. une forte vibration à 1700 cm^{-1}. La distillation fractionnée permet d'isoler comme fraction de coeur un liquide montrant dans la c.p.g. (polyester de Craig) un seul pic (dans les conditions utilisées il a été démontré que la cétone isomère **1***a* peut être détectée). La cétone **4***a* : p.e., 130–131°/16 mm Hg ; n_D^{25} 1.4631; i.r., bandes à 1695 (vibration C=O) et 1368 cm^{-1} (*tert*-butyle) ; spectre r.m.n., pics à 0.71 p.p.m. (*tert*-butyle), à 0.89 et 1.08 p.p.m. (*gem*-diméthyle) et entre 1.90 et 2.55 p.p.m. massif intégrant pour les deux protons en position 7 ; spectre de masse, pic parent à *m/e* de 196. La dinitrophénylhydrazone de cette cétone fond à 147–149° (éthanol); i.r., bandes à 3300, 1618, 1592, 1368, et 1335 cm^{-1} ; spectre r.m.n. ($CDCl_3$), pics à 0.83 p.p.m. (*tert*-butyle), à 1.13 et 1.25 p.p.m. (*gem*-diméthyle), et à 7.73, 8.06, et 8.86 p.p.m. (protons aromatiques) ; spectre de masse, pic parent à *m/e* de 376. La deutériation (12) effectuée sur 200 mg de cétone en présence de 100 mg de pyrollidine dans 25 ml de benzène anhydre après 6 échanges à l'aide de 0.5 ml d'eau lourde fournit une cétone contenant dans son spectre i.r. une bande à 2170 cm^{-1} et une diminution sensible de l'intégration dans la région de 1.90 et 2.50 p.p.m. du spectre r.m.n. Le spectre de masse de cette cétone deutériée montre des pics à *m/e* de 196 (100%), 197 (50%), et 198 (23%).

3. Tert-butyl-5 diméthyl-3,3 cycloheptanols (6a et 7a)

3.1 Préparation

La réduction de 5 g de cétone **1***a* par 13 g de sodium et 28 ml d'éthanol absolu conduit, après extraction et distillation à 142°/16 mm de mercure, à 4.41 g (87% du rendement théorique) d'un liquide visqueux incolore dont le spectre i.r. montre une forte absorption à 3350 cm^{-1} et dont le spectre r.m.n. montre 4 singulets dans la région des méthyles. La réaction de 7.7 g de chlorure de *p*-nitrobenzoyle dans 37 ml de pyridine avec 3.7 g des alcools **6***a* et **7***a* conduit après extractions à la manière habituelle à 6.3 g de solide. Plusieurs recristallisations fractionnées dans l'éthanol permettent de recueillir deux types de produits cristallins ; le *p*-nitrobenzoate **6***b* sous forme de paillettes : p.f., 119–120° ; i.r., bandes à 1710, 1525, 1350, 1280, 1105, et 1100 cm^{-1} ; r.m.n., bandes à 0.87 p.p.m. (*tert*-butyle), à 0.95 et 1.11 p.p.m. (*gem*-diméthyle), entre 4.80 et 5.24 p.p.m. (proton carbinolique), et à 8.25 p.p.m. protons aromatiques ; le *p*-nitrobenzoate *trans* (**7***b*) : p.f., 111–112 °C (p.f. mixte avec le précédent 100°) ; i.r., bandes à 1710, 1538, 1320, 1280, 1112, et 1095 cm^{-1} ; r.m.n., bandes à 0.86 p.p.m. (*tert*-butyle), à 1.06 p.p.m. (*gem*-diméthyle), entre 4.85 et 5.24 p.p.m. (proton carbinolique), et à 8.25 p.p.m. (protons aromatiques) ; spectre de masse, pic parent à *m/e* de 347. La saponification de 0.80 g du *p*-nitrobenzoate **6***b* à l'aide de 0.2 g d'hydroxyde de potassium dans 8 ml de méthanol et 2 ml d'eau, conduit à 0.3 g d'un liquide **6***a*, p.e., 70°/0.06 mm Hg ; n_D^{25}, 1,4713 ; i.r., bandes à 3625, 3450, 1368, 1020, et 980 cm^{-1} ; r.m.n. ($CDCl_3$) bandes à 0.81 p.p.m. (*tert*-butyle), à 0.92 et 0.95 p.p.m. (*gem*-diméthyle), à 1.45 p.p.m. (proton hydroxylique), et entre 3.55 et 4.00 p.p.m. (proton carbinolique); spectre de masse, pic parent à *m/e* de 198. De la même manière la saponification de 0.80 g de *p*-nitrobenzoate *trans* **7***b* fournit 0.3 g de l'alcool **7***a*, p.e., 69°/0.96 mm Hg ; n_D^{25}, 1.4708 ; i.r., bandes à 3650, 3625, 1368, 1006, et 1007 cm^{-1} ; r.m.n., pics à 0.80 p.p.m. (*tert*-butyle), à 0.87 et 0.98 p.p.m. (*gem*-diméthyle), à 1.47 p.p.m. (hydroxyle), et entre 3.40 et 3.90 p.p.m. (proton carbinolique); spectre de masse, pic à *m/e* de 198. Lorsque le mélange des deux alcools **6***a* et **7***a* est traité selon la méthode Sweeley *et al.* (15) avec l'hexaméthyldisilazane et le triméthylchlorosilane en milieu pyridine anhydre, les dérivés **6***c* et **7***c* ainsi obtenus peuvent être séparés sur la colonne de SE 30. Ces dérivés triméthylsilyl **6***c* et **7***c* semblent être stables si gardés à l'abri de l'humidité puisque l'analyse en c.p.g. à différents intervalles de temps d'un même mélange a toujours donné des résultats constants. Afin de vérifier que la formation des dérivés triméthylsilanés est quantitative pour chacun des iso-

mères, 2 mélanges d'alcool **6***a* et **7***a* de compositions connues ont été préparés par pesée, traités avec les réactifs de silylation et analysés en c.p.g. (SE 30) ; des mélanges contenant respectivement 60.7% **6***a*/39.3% **7***a* et 33.8% **6***a*/65.2% **7***a* montraient par analyse en c.p.g. de leurs dérivés silanés des compositions de 61.3/38.7 et 35.6/64.4.

3.2 Réduction de la cétone ***1****a*

Les méthodes de réduction utilisées correspondent aux méthodes standards et les références appropriées sont indiquées dans le tableau I.

Remerciements

Les auteurs remercient vivement le Conseil National de Récherches du Canada pour l'aide financière apportée. Ils remercient aussi la compagnie Dow Chemicals du Canada pour un généreux échantillon de *tert*-butyl-4 cyclohexanone.

L'un de nous (J.C.R.) tient à exprimer sa profonde gratitude au Dr. Pierre Maroni et à Mlle Marthe Benoit de la Faculté des Sciences de Toulouse pour l'accueil et l'aide qui lui ont été accordés durant la préparation de ce manuscrit.

Decomposition of lauroyl, decanoyl, and octanoyl peroxides in solution

J. E. GUILLET
Department of Chemistry, University of Toronto, Toronto, Ontario

AND

J. C. GILMER
Research Laboratories, Tennessee Eastman Company, Kingsport, Tennessee

Received April 17, 1969

The thermal decomposition from 50 to 250° of lauroyl, decanoyl, and octanoyl peroxides in solution in a high molecular weight hydrocarbon was studied. These peroxides are convenient sources of C-11, C-9, and C-7 straight-chain aliphatic free radicals, whose reactions may be considered as models for the higher molecular weight radicals formed during thermal cracking of polyolefins.

The ratio of disproportionation to combination for these radicals is about 0.2, which is very similar to the values obtained for lower alkyl radicals in the gas phase. This ratio appears to be relatively independent of temperature. Intramolecular chain transfer, which results in the isomerization of the radical, occurs at the higher temperatures, and the process has an apparent activation energy of about 2 kcal per mole.

The product distribution indicates that at reaction temperatures up to 250° a statistically random distribution of alkyl radicals is never achieved in solution. Since the radicals are formed in pairs, they tend to react with each other rather than with radicals formed from other peroxide molecules. This is demonstrated by the near absence of cross-combination products when two different peroxides are decomposed in the same solution simultaneously at 70°. At 250°, some cross-product is formed but less than one-fifth of the amount expected if the radicals were uniformly distributed in the solution. The activation energy for the formation of cross-product is of the same order as that for diffusion. The significance of these results in terms of the classical picture of "cage reactions" is discussed.

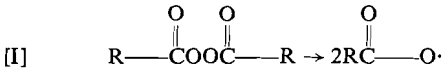
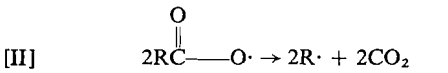
Introduction

Diacyl peroxides have been used for many years as sources of free radicals for the initiation of various radical reactions, such as vinyl polymerization. Early studies of the decomposition of such peroxides indicated a relatively straightforward mechanism by which the diacyl peroxide broke down by scission of the oxygen–oxygen bond to give acyloxy radicals



[I] $$R{-}\overset{O}{\overset{\|}{C}}{-}O{-}O{-}\overset{O}{\overset{\|}{C}}{-}R \rightarrow 2R\overset{O}{\overset{\|}{C}}{-}O\cdot$$

The acyloxy radicals were assumed to be unstable and to break down to give two alkyl radicals and two molecules of carbon dioxide



[II] $$2R\overset{O}{\overset{\|}{C}}{-}O\cdot \rightarrow 2R\cdot + 2CO_2$$

There was some evidence that the splitting out of carbon dioxide might take place simultaneously with the initial scission. On the basis of such a mechanism, Szwarc (1) used the decomposition of acetyl peroxide as a convenient source of free methyl radicals to study relative reactivities in solution. Propionyl and heptanoyl peroxides were used as sources of free ethyl (2) and hexyl (3) radicals in similar studies.

In the present work, studies of the decomposition of the higher diacyl peroxides were made to obtain a better understanding of the reactions of linear C-7, C-9, and C-11 alkyl radicals in solution. Of particular interest was the question of whether these species could be used as models for longer chain hydrocarbon radicals, such as those formed in the polymerization of ethylene and other olefins, and in the thermal and oxidative degradation of long-chain hydrocarbons.

Theory

The scheme of diacyl peroxide decomposition exemplified by eqs. [I] and [II] is now known to be a considerable oversimplification. Based on the very thorough studies of De Tar and coworkers, (4–6) it is now known that the major reactions occurring can best be explained by the following kinetic scheme:

[1] $$(RCOO)_2 \rightarrow [2RCOO\cdot]$$
[2] $$\rightarrow [RCOO\cdot + R\cdot] + CO_2$$
[3] $$\rightarrow [2R\cdot] + 2CO_2$$
[4] $$[2R\cdot] \rightarrow 2R\cdot$$
[5] $$\rightarrow R{-}R$$

[6] $\rightarrow R'CH_3 + R''CH{=}CH_2$

[7] $[RCOO\cdot + R\cdot] \rightarrow R\cdot + RCOO\cdot$

[8] $\rightarrow RCOOR$

[9] $\rightarrow RCOOH + R'CH{=}CH_2$

[10] $[2RCOO\cdot] \rightarrow 2RCOO\cdot$

[11] $\rightarrow (RCOO)_2$

[12] $RCOO\cdot \rightarrow R\cdot + CO_2$

[13] $R\cdot + SH \rightarrow RH + S\cdot$

[14] $RCOO\cdot + SH \rightarrow RCOOH + S\cdot$

[15] $2S\cdot \rightarrow S{-}S$

[16] $\rightarrow S'CH_3 + S''CH{=}CH_2$

where S = solvent molecule, R′ = R minus 1 methylene, R″ = R minus 2 methylenes, S′ = S minus 1 methylene, S″ = S minus 2 methylenes. In the above scheme, the terms in brackets denote components or reactions occurring within the solvent "cage", within the broad meaning of the term as defined by Noyes (7–10). It was shown by De Tar and co-workers (4–6) that these so-called "geminate cage" reactions represent at least 50% of the total decomposition products. The present study confirms that over half the total reaction may be considered to take place within a solvent "cage" which is a modification of the type envisaged by Frank and Rabinowitch (11) even at temperatures as high as 250°.

In addition to the reactions listed above, secondary reactions occur, such as the addition of a free radical to the olefins formed in reactions [6], [9], and [16], and radical attack on the peroxide molecule to give induced decomposition. De Tar and Weis (5) showed that the latter reaction represents only a small fraction of the total, even at quite high peroxide concentrations, and the analytical results of the present study confirm this.

Experimental

In the present work the objective was to study these reactions in hydrocarbon media at temperatures up to 250°. This necessitated the use of a high boiling hydrocarbon solvent, and heavyweight mineral oil (Primol D) was selected. At temperatures above 100° the rate of decomposition of the peroxides became very rapid and special techniques were necessary to make sure that most of the reaction was taking place at the desired temperature. Three methods were tried: (*1*) the peroxide solution was dropped into a stirred reactor containing mineral oil, (*2*) the mineral oil solution of the peroxide was dropped onto the surface of an aluminum block at a controlled temperature, and (*3*) the mineral oil solution was pumped through a heated capillary tube. Method (*3*) proved to be the most convenient and reliable and was used for most of the work.

Lauroyl, decanoyl, and octanoyl peroxides were obtained from Lucidol Corporation. Lauroyl and decanoyl peroxides were purified by recrystallizing them twice from pentane and drying them under high vacuum at 25°. Peroxide assay combined with infrared (i.r.) and gas chromatography measurements on the decomposition products indicated that the purity of the compounds was greater than 99%. Octanoyl peroxide was received as a 50% solution in mineral oil and was used without further purification.

Primol D is a completely saturated, branched hydrocarbon, which boils above 300° and has a viscosity of 125 cp at 25° and 3 cp at 250°. It was shown to contain no oxygen or unsaturation by i.r. analysis. For these experiments it was purified by heating it at 250° under 1 mm pressure for 3 h and then cooling under a blanket of nitrogen.

Thermal decomposition rates for the three peroxides were determined using 0.5% w/v solutions in mineral oil. Studies of product distribution were made by decomposing 10% w/v solutions of the peroxides in mineral oil. Thermal decompositions at temperatures below 100° were carried out in glass vials sealed under nitrogen after thorough degassing of the peroxide solutions. The vials were heated in thermostatted aluminum blocks. Decompositions above 100° were carried out using the procedure described by Guillet *et al.* (12). The degassed solution was pumped through a stainless steel capillary 20 in. long and 0.016 in. internal diameter. The volume of the heated part of the capillary was 0.0640 cc. A syringe pump (50 ml capacity) driven by a synchronous motor was used to pump the solution through the capillary. The rate of pumping could be varied widely by changing the frequency of the a.c. voltage applied to the motor. After passing through the heated zone, the solution was chilled in a water condenser and collected in sample vials.

Analyses of the decomposition products were carried out by gas chromatography using a thermal conductivity detector. In most of the work a Micro-Tek model GC-2500 PT programmed-temperature unit was used with a 4 ft × 1/4 in. column packed with 5% Silicone SE30 on Chromosorb W. A linear program rate from 50 to 300° was used for analysis of the decomposition products. At 300° the mineral oil solvent came off the column in about 10 min. Analyses for saturated and unsaturated hydrocarbons were performed on a 4 ft × 1/4 in. column packed with 20% Carbowax 20M on Chromosorb W. After several analyses the mineral oil was removed from the column by backflushing. The analyses were made on the basis of area percentage, using known hydrocarbons for calibration.

Lauric, decanoic, and octanoic acids were determined by titration in alcohol solutions with 0.025 *N* alcoholic sodium hydroxide using phenolphthalein indicator.

Results

Rate of Thermal Decomposition

The first-order rate constants for the thermal decomposition of the three peroxides were fitted to the Arrhenius equation by regression analysis. The frequency factors and activation energies obtained are listed in Table I.

It is apparent that the peroxides decompose at

*95% Confidence limits (2σ) based on regression equation.

nearly identical rates. A modified Arrhenius plot of the experimental data and the regression lines is given in Fig. 1 using the half life, $\tau = (0.6932/k)$, in place of the first-order rate constant, k. The activation energies are believed to be quite reliable because of the wide temperature range over which the rates were studied. With 5-phenylvaleryl peroxide De Tar and Weis (5) showed that the first-order rate constants were unchanged over a 600-fold variation in peroxide concentration. The three peroxides studied in this work appear to behave in the same manner, at least over the range of concentrations used. The values of the rate constants and activation energies obtained are almost identical to those reported previously by Ray (13) and Doehnert and Mageli (14).

Thermal Decomposition Products

The results of the study of the product distribution obtained by thermally decomposing solutions of lauroyl peroxide at temperatures from 50 to 257° are summarized in Table II. The most surprising aspect of these results is that the amount of docosane, usually considered to be formed exclusively in the solvent "cage", increases with temperature, whereas the amount of "noncage" product, undecane, decreases. The amount of ester produced is almost independent of temperature, whereas the amount of lauric acid produced appears to decrease as the temperature increases. The concentration of a sixth

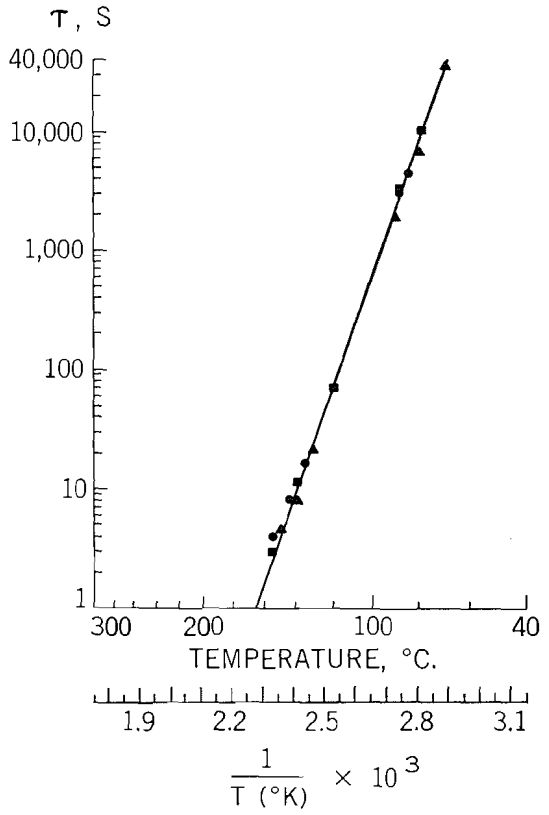

FIG. 1, Half-life τ of diacyl peroxides as function of reciprocal temperature measured in 1% solutions in Primol D; ▲ lauroyal peroxide; ● decanoyl peroxide; ■ octanoyl peroxide.

product, which appears in only very small amounts at low temperatures, increases significantly as the temperature is raised. Its retention time is slightly less than that of docosane. A similar product is formed in the decomposition of decanoyl peroxide or octanoyl peroxide and, in the latter case, has been isolated by gas chromatography and identified by i.r. studies as a

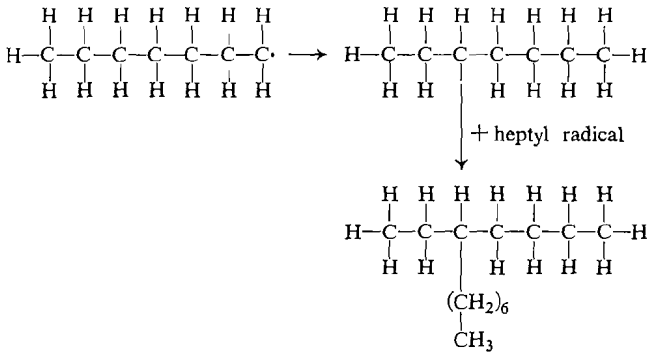

SCHEME 1

branched isomer of tetradecane, formed presumably by the reaction shown in Scheme 1. This intramolecular hydrogen abstraction reaction has been generally accepted as the basis for the formation of short-chain branches in polyethylene. This then represents an interesting experimental verification of the actual occurrence of such reactions. The same features are shown in the product distributions for the thermal decomposition of decanoyl and octanoyl peroxides, listed in Tables III and IV.

The amount of the combination products octadecane and tetradecane increases with temperature, whereas the amount of the "noncage" products nonane and heptane decreases. The theory of "cage" dissociation processes as formulated by Noyes (7) suggests that the probability of escape from the solvent "cage" should increase with temperature because of the decrease in density and viscosity of the medium. The increased yield of the combination products as the temperature is raised is in apparent contradiction to this theory, if it is true that all of the combination takes place as a "geminate cage" reaction.

It occurred to us that, since lauroyl and decanoyl peroxides decompose thermally at nearly identical rates, a study of the amount of cross-combination product formed when mixtures of the two are heated would give an indication of the number of radicals combining outside the "cage". Accordingly, 25 mmoles of each peroxide was dissolved in 19.0 ml of Primol D and heated at various temperatures until reaction was complete. The results are summarized in Table V.

The data in column 5, Table V, express the

TABLE III

Decomposition products of decanoyl peroxide (moles product/mole peroxide × 100)

TABLE V

Thermal decomposition of equimolar mixtures of lauroyl and decanoyl peroxide

Temperature, °C	Relative peak areas			Amount of "noncage" combination, %
	C-18	C-20	C-22	
76.5	9.7	0.50	10.0	4.9
96.5	17.5	0.92	16.0	5.4
152	20.7	1.82	21.5	8.3
183	12.8	1.95	16.7	12.4
262	19.9	3.60	21.20	16.1

results in terms of the amount of cross-product formed as a percentage of the amount expected if all the radicals formed in the decomposition were randomly distributed throughout the solution. The relatively small value (16.1%) at 262° indicates how poorly the system approximates this random distribution, even at temperatures where the peroxide is decomposing in about 10 ms. This value will be equivalent to the actual percentage of radicals combining outside the "cage". The data from Table V can be used to estimate the actual amount of "cage" recombination occurring at various temperatures. When this is done, the results shown in Tables VI and VII are obtained

TABLE VI

"Cage" recombination of C-11 radicals

Decomposition temperature °C	Moles docosane/mole peroxide	
	Measured	Corrected for "random" recombination
50.0	25.6	25.6
75.2	30.8	29.3
96.5	34.7	32.8
148	43.1	39.5
184	48.1	42.1
222	50.0	43.0
257	50.0	42.0

TABLE VII

"Cage" recombination of C-9 radicals

Decomposition temperature °C	Moles octadecane/mole peroxide	
	Measured	Corrected for "random" recombination
151	41.9	38.4
183	46.5	40.7
221	48.5	41.5
255	52.3	43.9

for lauroyl and decanoyl peroxides, respectively. It is apparent that the amount of "cage" recombination increases with temperature up to about 150°, after which only a slight increase is observed which may not be outside the experimental error. Similarly, the total amount of "noncage" products decreases with temperature up to 150° and then remains constant at about 35%.

A similar increase in "cage" recombination of methyl radicals from acetyl peroxide with temperatures increasing from 40 to 100° was observed by Braun *et al.* (15). This increase was attributed to a mechanism involving the separation of acetoxy radicals followed by decarboxylation to give methyl radicals which undergo "geminate diffusive recombination." The increase in combination with temperature is due to an activation energy of about 6.6 kcal/mole for the decarboxylation reaction, which becomes, in a sense, the rate controlling step. This mechanism appears to give a satisfactory explanation of the product distribution for acetyl peroxide. However, it has been well established (16–19) that the ester formed in the decomposition, if formed from an optically active diacyl peroxide, will retain configuration in both the alcohol and acyloxy groups. This would appear to preclude the formation of the ester by diffusive recombination of an alkyl and an acyl radical as proposed by Braun and co-workers (15), since the free alkyl group would be expected to lose configuration if it had any appreciable lifetime as a free radical. It would appear, therefore, that the ester must be formed either in a single step during the initial decomposition or by a reaction involving geminate diffusive recombination of two acyloxy radicals by the following kinetic scheme:

[17] $$\left[\begin{matrix}\text{O}\\ \|\\ 2\text{RC}\text{—O}\cdot\end{matrix}\right] \longrightarrow \begin{matrix}\text{O}\\ \|\\ \text{RCOR}\end{matrix} + \text{CO}_2$$

This reaction would require an appreciable activation energy in order to explain the fact that, with the higher diacyl peroxides, the yield of ester is much less than that for the combination of the two alkyl radicals. Recent studies on the decomposition of acetyl peroxide by isotopic tracer methods (20) confirm the intramolecular nature of the processes leading to both the ester and the recombination product of the primary alkyl radical.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

An Arrhenius plot of the amount of "random" combination taking place (from Table V) indicates an apparent activation energy of 2.6 kcal/mole. However, this probably does not represent the actual temperature coefficient for escape from the solvent "cage" since the probability of one free radical meeting another before chain transfer to solvent occurs is included in this.

Intramolecular Chain Transfer

A similar activation energy (2.0 kcal) is shown for the process involving intramolecular chain transfer (Scheme 1) to give a branched-chain combination product. This indicates that no intramolecular chain transfer takes place within the time interval (10^{-9} s) for "geminate cage" recombination; once the radical escapes from the immediate vicinity of the "cage", it has an appreciable lifetime during which intramolecular chain transfer will compete with chain transfer to solvent and reaction with another free radical.

Disproportionation/Combination Ratio

Estimates of the amount of disproportionation of alkyl radicals (reaction [6]) is complicated by the fact that alkenes can be formed both by reaction [6] and by the disproportionation of an alkyl radical with an acyloxy radical (reaction [9]) which is presumably a primary "cage" reaction. At low temperatures the amount of acid formed is greater than the amount of alkene, indicating that it is formed by another process, possibly by hydrolysis with traces of moisture. (The original peroxides and solutions contained less than 0.2% acid based on the peroxide.) The amount of acid reported in this work is higher than that shown by De Tar and Weis (4). In view of the uncertainty regarding the mechanism of formation of acid, the disproportionation/combination ratio can be reported only as maximum and minimum limits, assuming either absence or occurrence of reaction [9]. However, we feel that the maximum values are probably the more significant.

These limits are given in Table VIII for temperatures ranging from 50 to 260°. At temperatures of 180° and above, the values range from 0.2 to 0.3, which is of the order of magnitude expected from gas phase studies.

Role of the Solvent

In this work it has been assumed that most of the reactions with the solvent will be described by reactions [13] and [15]. That there is little combination of alkyl radicals with solvent is indicated by the material balances, which indicate that, in most cases, greater than 95% of all the alkyl radicals can be accounted for by the products listed in Tables II–IV.

TABLE VIII

Disproportionation/combination ratio for alkyl radicals

Temperature, °C	C-11 Radicals		C-9 Radicals		C-7 Radicals	
	Max.	Min.	Max.	Min.	Max.	Min.

257	0.34	0.19	0.25	0.11	0.33	0

Conclusion

We conclude from the present study that the thermal decomposition of the higher diacyl peroxides can be explained on the basis of a modified "cage" process in which ester and possibly acid are formed in a concerted or one-step process, probably within the original solvent "cage". About 10% of all the molecules decomposing give ester or acid by this mechanism. The acyloxy radicals, if formed in the initial decomposition of the peroxide, decarboxylate rapidly to give alkyl radicals which recombine exclusively by a "geminate cage" process at relatively low temperatures (50°). At higher temperatures, up to 16% of the radicals recombine after escape from the immediate vicinity of the "cage". The apparent activation energy for this process is 2.6 kcal/mole, which is of the same order as that for diffusion. The amount of "geminate cage" combination varies from about 46% at low temperatures to 65% at 260°; the remaining 35–54% of the radicals escape the immediate vicinity of the "cage". At low temperatures these react exclusively with solvent. At higher temperatures they may isomerize by intramolecular chain transfer or react with other alkyl radicals. When two alkyl radicals react, they may either disproportionate or combine, the ratio of the rate constants for these two reactions being 0.2–0.3.

The relatively high proportion of geminate cage processes (46–65%) in the higher diacyl peroxides relative to those observed in diacetyl peroxide (20–40%) is to be expected from the

larger size of the radicals produced. Since the enthalpy of decomposition is very similar for all diacyl peroxides, the separation velocity of the larger radical fragments will be much lower, and hence the probability of their escape from the "cage" will be significantly reduced.

Anomeric deoxy and unsaturated methyl pentofuranosides and pentopyranosides[1]

R. U. LEMIEUX, K. A. WATANABE[2], AND A. A. PAVIA[3]
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received May 5, 1969

Both the anomers for methyl 2,3-dideoxy-D-*glycero*-pent-2-enofuranoside were characterized and hydrogenated to the corresponding methyl 2,3-dideoxy-D-*glycero*-pentofuranosides. The similar compounds were prepared in the pyranoside ring form but in the L-*glycero* configuration. The anomeric forms for methyl 3-deoxy-L-*erythro*-pentopyranoside are reported together with a number of their derivatives of interest for the study of solvation effects on conformational equilibria (21). The molar rotations of the deoxy and unsaturated glycosides are discussed as are the conformational properties of the various compounds.

In a previous communication (1), the preparation of the four stereoisomeric methyl 4,6-*O*-benzylidene-2,3-dideoxy-D-hex-2-enopyranosides was accomplished, in each case, by opening of the epoxide ring of a parent 2,3-anhydro derivative to the corresponding iodohydrin which was treated with either *p*-toluenesulfonyl (tosyl) or methanesulfonyl (mesyl) chloride in pyridine. We wish to report a modified procedure which allowed the preparation of the anomeric forms both for methyl 2,3-dideoxy-D-*glycero*-pent-2-enofuranoside (**4***c* and **9***c*) and for methyl 2,3-dideoxy-L-*glycero*-pent-2-enopyranoside (**17***c* and **18***c*).

Methyl 5-*O*-benzoyl-2,3-dideoxy-β-D-*glycero*-pent-2-enofuranoside (**9***a*) was first prepared by reaction of 3,5-di-*O*-benzoyl-D-*erythro*-pent-1-enofuranose with methanol (2). The β-D-configuration was later assigned by an alternative synthesis (3,4) involving reduction of methyl 5-*O*-benzoyl-2,3-di-*O*-tosyl-β-D-ribofuranoside by the method of Tipson and Cohen (5). The physical constants and nuclear magnetic resonance (n.m.r.) spectrum reported for **9***a* indicate that this compound was not pure. Also, the n.m.r. signal for H_2 was erroneously assigned to H_1. It is of interest to note that several 2′,3′-unsaturated nucleosides have been prepared (6–10).

The 5-*O*-benzoyl derivative (**1***a*) of the readily available methyl 2,3-anhydro-α-D-lyxofuranoside (11) was treated with sodium iodide in acetone in the presence of acetic acid and sodium acetate as described previously (1). The spectrum of the sirupy product (**2***a*) required high purity. That the epoxide opening followed the normal course (attack at the 3-position) for a 2,3-anhydrofuranoside (12,13) was established by benzoylation of the iodohydrin **2***a* to **2***c* followed by hydrogenolysis to yield crystalline methyl 2,5-di-*O*-benzoyl-3-deoxy-α-D-*threo* pentofuranoside (**3**). This 3-deoxy structure was required since the anomeric proton (singlet at τ 4.85) was not appreciably coupled to either of the methylene protons at τ 7.35 and 8.05. The quartet at τ 5.35 was assigned to H_2 and the spacings indicated 6.5 Hz coupling with the methylene proton (H_3) at τ 7.35, and 1.6 Hz coupling with that (H_3) at τ 8.05. Spin decoupling also showed the methylenic protons to be coupled with a signal forming part of a multiplet (H_4, H_5, and $H_{5'}$) centered at τ 5.5 and assigned to H_4.

Following the previously reported procedure for the reduction of iodohydrins to olefins (1), namely, treatment of the iodohydrin **2***a* with tosyl chloride in boiling pyridine gave only furfuryl benzoate. However, when the *O*-tosyl derivative was treated with tetraethylammonium chloride in pyridine in the presence of zinc dust, an 82% yield of pure crystalline 2,3-unsaturated furanoside **4***a* was readily obtained.

Essentially the same sequence of reactions was carried out in the β-series starting with methyl 2,3-anhydro-β-D-lyxofuranoside (**5***c*) (11). The n.m.r. examination of the product obtained upon treatment of the sirupy 5-*O*-benzoyl derivative (**5***a*) with sodium iodide in the usual manner showed that the nucleophilic attack had occurred at the 2-position as readily as at the 3-position to

form compounds **6***a* and **7***a*. This was evident from the presence of two signals of about equal intensity for methoxy groups in the n.m.r. spectrum of the product and from the fact the product gave an over 71% yield of the olefin **9***a*.

The acetyl derivative **5***b* also gave an about equimolar mixture of the iodohydrins (**6***b* and **7***b*). On treatment of this mixture with tosyl chloride in pyridine, a crystalline product was obtained in 31% yield together with furfuryl acetate. The structure of this crystalline compound (**8**) was assigned as methyl 5-*O*-acetyl-2-deoxy-2-iodo-3-*O*-tosyl-β-D-xylofuranoside on the basis of n.m.r. analysis. The signal for the anomeric proton (pyridine-d_5 at 100 MHz) was a sharp singlet at τ 5.30, that for H_2 a doublet at τ 5.12 (spacing 4.3 Hz), and that for H_3 a quartet τ 4.81 ($J_{2,3}$ = 4.3 and $J_{3,4}$ = 9.3 Hz). The small

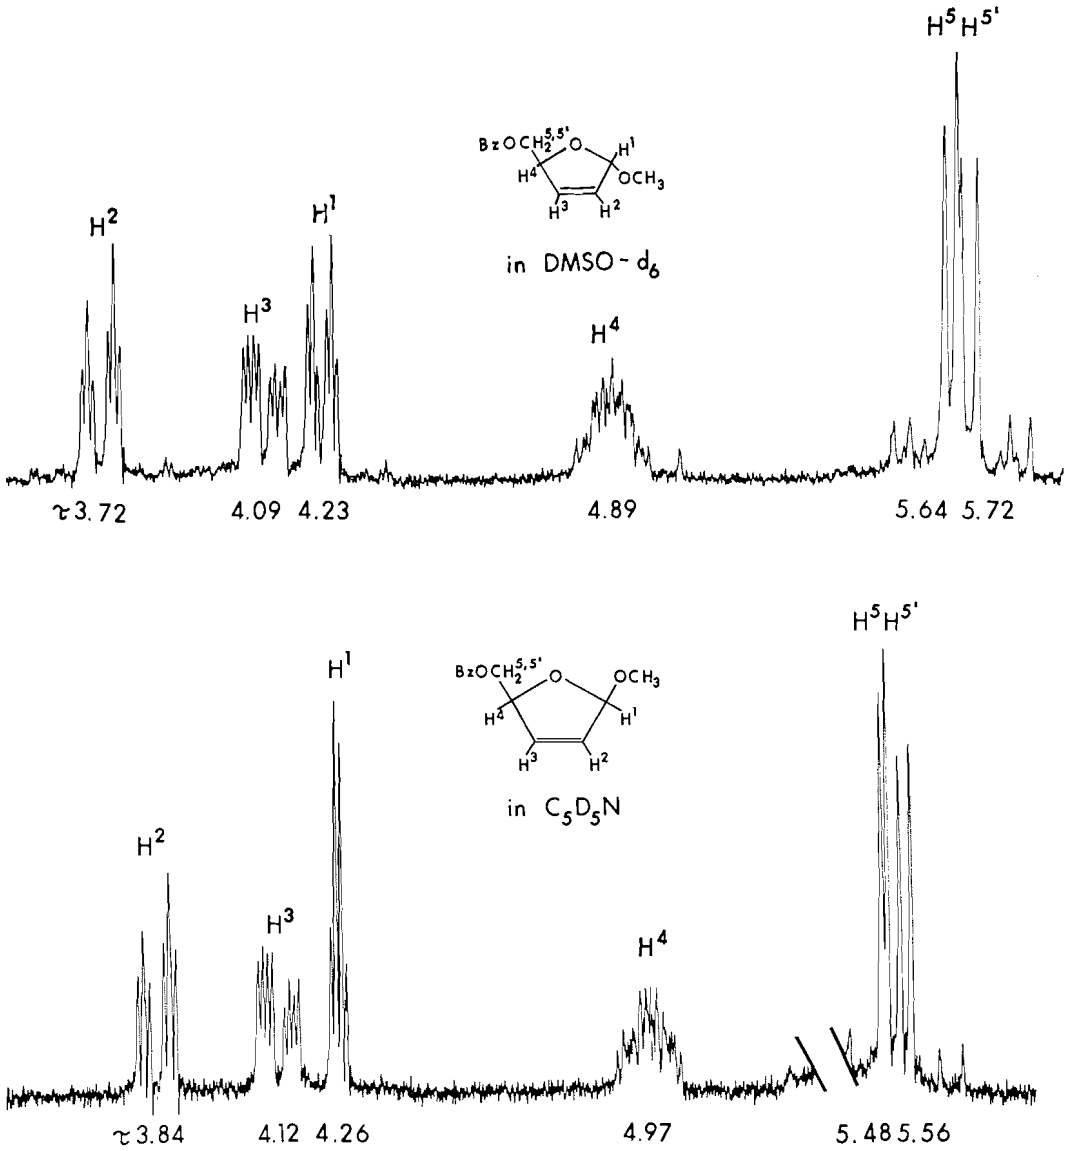

FIG. 1. The n.m.r. spectra at 100 MHz of methyl 5-*O*-benzoyl-2,3-dideoxy-α-D-*glycero*-pent-2-enofuranoside (**4***a*) and its β-anomer (**9***a*).

coupling constant (<0.5 Hz) for $J_{1,2}$ requires a *trans*-relationship for these two hydrogens. Therefore, as expected and as was confirmed by the quartet signal for H_3, C_2 was inverted in the formation of this iodohydrin. The large coupling of 9.3 Hz for H_3 and H_4 which are in *cis*-relationship on the furanoside ring is noteworthy. Extensive opening of the epoxide ring at C_2 as well as C_3 is rare (12,13). However, a result similar to that presented above was obtained on treating **5***b* with benzyl mercaptide ion (14,15). Dick and Jones (16) have recently concluded from a study of the epoxide ring opening of methyl 2,3-anhydro-4-azido-4-deoxypentopyranosides that the direction of opening could not, in some cases, be accounted for by consideration of only steric and inductive effects. A proper appreciation of these phenomena requires a consideration of the

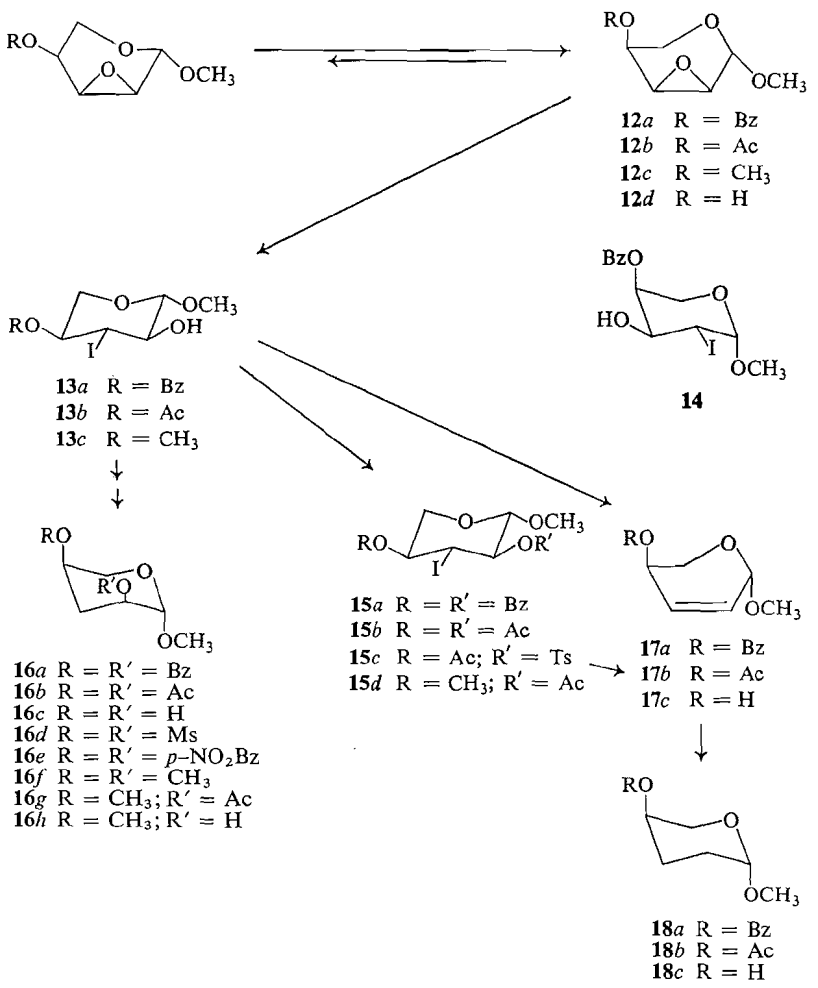
*The signs given to these coupling constants are assumed.



nucleophile as well as the epoxide and it is apparent that strongly nucleophilic reagents are either not as sensitive to differences in the electronegativities of the carbons of the epoxide group or actually prefer the more electronegative center. Methyl 5-*O*-acetyl-β-D-*glycero*-pent-2-enofuranoside (**9***b*) was readily obtained from **8** as a colorless liquid.

The mixture of iodohydrins (**6***a* and **7***a*) on tosylation followed by reduction as described above for the formation of **4***a* gave crystalline methyl 5-*O*-benzoyl-2,3-dideoxy-β-D-*glycero*-pent-2-enofuranoside (**9***a*); 71% yield; m.p. 62–63° (sharp); $[\alpha]_D^{25}$ −102° (chloroform), −104° (dichloromethane). The literature values (2,3) are m.p. 40–46°; $[\alpha]_D$ −98° [in chloroform (4) or in dichloromethane (2)]. The physical constants of the α-anomer (**4***a*) are remarkably similar; m.p. 61–62°; $[\alpha]_D^{25}$ −100° (in chloroform), −102° (in dichloromethane). That these compounds are in fact different and anomeric is clear from the n.m.r. spectra shown in Fig. 1. For the α-anomer (**4***a*), of the seven solvents used, only dimethylsulfoxide-d_6 brought about a complete separation of the signals for H_1 and H_3. The n.m.r. parameters for **4***a* and its β-anomer (**9***a*) are given in Table I. The assignments of the signals for H_2 and H_3 are based on the assumption that, as always found in glycosidic structures, the anomeric proton is more weakly coupled with a vicinal proton (because of the electron withdrawing effect of two oxygen atoms at C_1) than are the other ring protons in a similar geometric relationship. For both anomers, as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

seen in Table I, $J_{1,3}$ and $J_{2,4}$ are equal at -1.2 Hz. This result indicates that the dihedral angles defined by H_1 and H_2 and by H_3 and H_4 in each case are near equal and in the range 50 to 55° using the relationship shown in eq. [1] provided

$$[1] \quad J = 3.9\cos^2\phi - 2.6 \quad (0° \leq \phi \leq 90°)$$

by Garbisch (17) for the coupling of allylic protons. On this basis, the dihydrofuran rings in these compounds must be near planar as is indicated by molecular models. For both anomers, one of the vicinal coupling constants ($J_{1,2}$ or $J_{3,4}$) is 1.2 Hz and the other is 2.2–2.3 Hz. For the reason stated above, the smaller value is assigned to $J_{1,2}$. Thus, for both anomers the signal at lowest field is assigned to H_2. This procedure is supported by the fact that both $J_{1,3}$ and $J_{2,4}$ are also -1.2 Hz for methyl 4-*O*-acetyl-2,3-dideoxy-α-L-*glycero*-pent-2-enopyranoside (**23***b*) and for this compound $J_{1,2} = 1.5$ Hz and $J_{3,4} = 2.3$ Hz as established unequivocally by spin-decoupling. It may be noted that, for 2,3-unsaturated pyranosides, the signal for H_2 is to higher field than that for H_3 (see below and reference 1). It is of interest to note that the long range couplings $J_{1,4}$ for the 1,4-*trans*-α-anomers (**4**) are much larger, 4.4 Hz, than those, 1.2 Hz for the 1,4-*cis*-β-anomers (**9**).

The 4-*O*-acetyl derivatives of both the known α (19) and β (18,19) anomers for methyl 2,3-anhydro-L-ribopyranoside were treated with sodium iodide in the usual manner (1) to provide the iodohydrins. Assuming diaxial opening of the oxide ring from the compounds in half-chair conformation, the ground-state for attack in 3-position would be that depicted in **12***b* for the β-compound. High yields (>90%) of the 3-iodocompound were obtained from both the acetate (**12***b*) and the benzoate (**12***a*). The yield of the 2-iodobenzoate (**14**) was only 5%. The n.m.r. spectrum of **12***b* required $J_{4,5} = J_{4,5'} \simeq 4$ Hz and indicates that the compound is largely in the half-chair conformation wherein H_4 is in near gauche relationship with both the hydrogens at C_5. $J_{3,4}$ was about 2.5 Hz and $J_{5,5'}$ about -13 Hz. This latter coupling is in the range expected for the compound in this conformation (1).

In the case of α-anhydride, the conformation appears to be close to that depicted in formula **19***b* with the 4-acetoxy group in *quasi*-equatorial orientation. This was indicated by the fact that the rough quartet observed for H_4 collapsed to a clean quartet (τ 4.87) with spacings of 8.5 and 3.3 Hz when the signals for H_2 and H_3, both at about τ 6.50, were spin-decoupled. Therefore, diaxial opening of the epoxide ring with attack by iodide at the 3-position would require a change in conformation. Although a high yield of the 3-iodo compound was obtained from the acetate (**19***b*), about equal amounts of the 2- and 3-iodo derivatives were obtained from the benzoate **19***a*. This may result from a greater resistance by the benzoyloxy group to accept the *quasi*-axial orientation of the alternate half-chair conformation which can lead to diaxial opening. It should be noted that here, as for the analogous furanoside compounds considered earlier, extensive attack at the 2-position was observed only when the methoxyl group was *cis* to the oxygen of the anhydro ring so that a 1,2-*trans*-product was obtained. The n.m.r. spectra of the benzoates (**12***a* and **19***a*) gave almost identical patterns for the ring protons as did the corresponding acetates (**12***b* and **19***b*). It is of interest to note that for

both anomeric pairs of the anhydrides, the anomeric effect plays a significant role in determining conformation. This was especially surprising in the case of the β-anomers since, by the methoxy group becoming *quasi*-axial, the acetoxy group must approach closely the oxygen of the anhydride ring.

The iodohydrins (**13***b* and **20***b*) were tosylated and these treated with tetraethylammonium chloride in pyridine in the presence of zinc dust to provide the olefins (**17***b* and **23***b*) in excellent yield. Deacetylation provided the anomeric methyl 2,3-dideoxy-L-*glycero*-pent-2-enopyranosides (**17***c* and **23***c*). The n.m.r. parameters for these compounds are reported in Table I together with those for the 4-*O*-benzoates (**17***a* and **23***a*). The coupling constants which are apparent from the spacings observed clearly require a large predominance of the conformations shown for the compounds with R = Ac or Bz. This follows especially from a consideration of the magnitudes of $J_{2,4'}$ $J_{5,5'}$ and $J_{4,5'}$. According to the Garbisch relationship (17), the values for $J_{1,3}$ suggest that the anomeric protons of the β-anomers are more in the *quasi*-axial orientation than are those of the α-anomers. It is evident that, as found for the corresponding 2,3-anhydro compounds which are also expected to be in half-chair conformations, the anomeric effect controls the conformations of these olefins.

The alcohols of both the 2-enofuranosides (**4***c* and **9***c*) and the 2-enopyranosides (**23***c* and **17***c*) were readily hydrogenated to provide the anomeric forms for methyl 2,3-dideoxy-D-*glycero*-pentofuranoside (**10***c* and **11***c*) and methyl 2,3-dideoxy-L-*glycero*-pentopyranoside (**24***c* and **18***c*) respectively. From the n.m.r. parameters given in Table II, it is evident that for the 2,3-dideoxypyranosides the anomeric effect controls the conformational equilibria.

It is of interest to note (Table II) that neither acetylation nor benzoylation of a given anomer for a 2,3-dideoxyfuranoside changed the molar rotation appreciably. Therefore, following the line of interpretation presented by Brewster (20) to account for optical rotation, it is apparent that the contributions to rotation by the hydroxymethyl group is not affected by acylation. Application of Brewster's rules as elaborated for pyranoside structures to these furanosides yields molar rotations of 230 for the α-anomer and −180 for the β-anomer, values that are in excellent agreement with those observed, 194 and −169, respectively, if it is assumed that the furanose rings favor conformations for both anomers that have the methoxy group in *quasi*-axial orientation in accordance with expectations based on the anomeric effect.

According to Brewster (20), it can be expected that the conformational units defined by the

substituents at C_1 and C_4 with the endocyclic double bonds of the 2,3-unsaturated furanosides (**4***c* and **9***c*) make important contributions to rotation. For the α-D-anomer (**4***c*), following Brewster, two such contributions can be assigned each of about −130°. Also, a strong contribution of +105° from the conformational unit defined by the methoxy group and C_1 to ring-oxygen group can be expected. On this basis only, a molar rotation of −155° is indicated. The observed rotation was −102°. In the case of the β-anomer (**9***c*) (observed molar rotation = −202), the contributions arising from the conformational units defined by the C_1 and C_4 substituents with double bond should nearly cancel. Thus, a rotation of −105° would be indicated disregarding all contributions other than that arising from the methoxy group. Since other contributions to rotation can be expected to be *relatively* small, these considerations provide a basis for appreciating why both anomers are levorotatory. It should be noted, however, that the nature of the substituent at C_5 has, for these unsaturated compounds, a considerable influence on rotation. Indeed, for the 5-*O*-benzoyl derivatives, the anomers **4***a* and **9***a* differ little in rotation.

The molar rotations of the 2-enopyranosides, as seen in Table III, are very dependent on the nature of the substituent at C_4. The strong levorotations for all the compounds listed likely arise mainly for reasons similar to those noted above for the 2-enofuranosides.

TABLE III

Rotations in chloroform of 2,3-unsaturated methyl pentosides and their *O*-acyl derivatives

	$[\alpha]_D^{25}$	$[M]_D^{25}$
α-D-Furanoside		
4*a*	−100°	−234

β-L-Pyranoside		
17*a*	−187	−438
17*b*	−135	−232
17*c*	−108	−141

The main reason for undertaking these syntheses was to obtain the anomeric methyl 3-deoxy-L-*erythro*-pentopyranosides **16***c* and **22***b* by way of hydrogenolyses of the iodohydrins **13** and **20**. The effect of solvent on the conformational equilibria for the β-L-pentoside (**16***c*) has already been reported (21). An accompanying paper (22) reports the relative effects on conformational equilibria observed in changing the substituents at the 2 and 4 positions. These compounds are reported herein and include the dibenzoate, diacetate, dimesylate, di-*p*-nitrobenzoate, di-*O*-methyl, 4-*O*-methyl, and 2-*O*-acetyl-4-*O*-methyl derivatives of methyl 3-deoxy-β-L-*erythro*-pentopyranoside (**16***c*). The diacetate (**22***a*) of methyl 3-deoxy-α-L-*erythro*-pentopyranoside (**22***b*) is also reported.

The methyl 2,3-dideoxypentopyranosides **18***c* and **24***c* were desired for an extension of these studies and a discussion of the effect of solvent on their rotations is reserved for a communication related to solvent effects on the conformational equilibria of methyl 2,3,4-trideoxy-β-L-pentopyranoside (*dextro*-2-methoxypyran).

Experimental

*Methyl 2,3-Anhydro-α-D-lyxofuranoside (**1***c*)*

Methyl 2-*O*-methanesulfonyl-α-D-xylofuranoside (11) (70 g, 0.29 mole; obtained from 58.5 g of methyl 3,5-*O*-isopropylidene-α-D-xylofuranoside) was dissolved in absolute methanol (140 ml) and cooled to 0°. To the stirred solution was added freshly prepared 2 *M* methanolic sodium methoxide (158 ml, 0.316 mole) at such a rate that the temperature was maintained at 0°. After 3 days at this temperature the reaction mixture was filtered through Celite. The filtrate was neutralized with acetic acid (8 ml) then evaporated to dryness under reduced pressure. The residue was dissolved in water (50 ml) and extracted with chloroform (3 × 100 ml). The extracts were dried over magnesium sulfate and evaporated to dryness under reduced pressure. Crystallization occurred during evaporation of the chloroform. The residue was recrystallized from benzene (about 100 ml). A first crop was obtained (31.0 g) as colorless, long needles, m.p. 82–83°. A second crop (6.6 g), m.p. 75–79°, was obtained from the mother liquor, giving a total yield of 92.0%.

*Methyl 2,3-Anhydro-5-O-benzoyl-α-D-lyxofuranoside (**1a**)*

Compound **1***c* (29.2 g, 0.2 mole) was dissolved in pyridine (100 ml) and treated with benzoyl chloride (30 ml). After 3 h at room temperature, the mixture was poured onto an ice-water mixture (ca 1000 ml). The solid was collected and recrystallized from ethanol as colorless needles, (48.0 g, 96%); m.p. 88–90°, $[\alpha]_D^{25}$ + 42.6° (*c*, 2.32 in chloroform).

Anal. Calcd. for $C_{13}H_{14}O_5$: C, 62.40; H, 5.60. Found: C, 62.58; H, 5.66.

Methyl 5-O-Benzoyl-3-deoxy-3-iodo-α-D-arabino-furanoside (2a)

1*a* (25 g, 0.1 mole) was treated with sodium iodide (75 g, 0.5 mole), sodium acetate (4.1 g, 0.05 mole) and acetic acid (120 ml) in acetone (500 ml) at reflux temperature for 20 h. The orange solution was evaporated to dryness and the residue was partitioned between water (500 ml) and chloroform (500 ml). The aqueous layer was again washed with chloroform (500 ml). The combined organic extracts were washed with 0.1 *M* sodium thiosulfate and with water (each 500 ml), dried over sodium sulfate, and evaporated to a sirup under reduced pressure. The sirup (38 g, quantitative yield), $[\alpha]_D^{25}$ + 73.1° (*c*, 1.58 in chloroform), could not be crystallized, but examination by thin layer chromatography (t.l.c.) and n.m.r. spectroscopy showed it to be homogeneous.

Methyl 2,5-Di-O-benzoyl-3-deoxy-α-D-threo-pentofuranoside (3)

2*a* (1.56 g) was treated with benzoyl chloride (0.53 ml) in pyridine (2 ml) at room temperature overnight. The reaction mixture was worked up in the usual way, giving the sirupy dibenzoate of the iodohydrin (**2***c*).

The dibenzoate (**2***c*) (1.47 g, 0.003 mole) was dissolved in methanol (25 ml) and hydrogenated with 5% palladium on charcoal (0.22 g) in the presence of triethylamine (0.65 g). After 75 min, the mixture was filtered through Celite and the filtrate was evaporated to dryness. The residue was taken up in chloroform and washed with water. The organic layer was dried over magnesium sulfate and evaporated to dryness. The crystalline residue was recrystallized from ether–Skellysolve B. The yield (first crop) was 0.756 g (70%); m.p. 89–89.5°, $[\alpha]_D^{25}$ + 36.7° (*c*, 1.05 in chloroform).

Anal. Calcd. for $C_{20}H_{20}O_6$: C, 67.40; H, 5.67. Found: C, 67.10; H, 5.63.

Methyl 5-O-Benzoyl-α-D-glycero-pent-2-enofuranoside (4a)

2*a* (38 g, 0.1 mole) was treated with *p*-toluenesulfonyl chloride (21 g, 0.11 mole) in pyridine (100 ml) at 0° for 3 days. The reaction mixture was diluted with an ice-water mixture (600 ml) and extracted with chloroform (2 × 200 ml). The extracts were washed with saturated sodium bicarbonate solution and water then dried over sodium sulfate. Evaporation of the chloroform left a sirup (53.5 g, quantitative yield) which could not be crystallized, but examination by t.l.c. and n.m.r. showed that the sirup was practically pure.

The above compound (53.5 g, 0.1 mole) was dissolved in pyridine (150 ml). Tetraethylammonium chloride (1.66 g, 0.01 mole) and zinc dust (16 g, 0.25 mole) were added and the mixture was refluxed for 20 min. Residual zinc was collected and washed with a small amount of pyridine. The combined pyridine solutions were evaporated to dryness. The residue was suspended in water (200 ml) and extracted with ether (4 × 100 ml), and the extracts were dried over sodium sulfate and evaporated to dryness. The crystalline residue was recrystallized from a small amount of ether. The yield of colorless needles after two recrystallizations was 16.5 g (70.5%); m.p. 61–62°, $[\alpha]_D^{25}$ −100° (*c*, 1.25 in chloroform), −102° (*c*, 1.24 in methylene chloride).

Anal. Calcd. for $C_{13}H_{14}O_4$: C, 66.67; H, 5.98. Found: C, 66.38; H, 5.97.

The mother liquors from the two recrystallizations were evaporated to a dry brown solid. The solid was suspended in ether (20 ml) and filtered through an alumina column (1.7 × 4 cm). The column was washed with ether (20 ml), and the filtrate and washings were combined and evaporated. Colorless needles remained and were recrystallized from ether–Skellysolve B to yield 2.6 g (11.1%) of needles; m.p. 59.5–60°, alone or admixed with the first crop.

Methyl 5-O-Benzoyl-β-D-glycero-pent-2-enofuranoside (9a)

The epoxide (**5***c*) (11) (1.46 g, 0.01 mole) was quantitatively benzoylated in the usual way, giving **5***a* as a sirup; $[\alpha]_D^{25}$ −48.9° (*c*, 1.88 in chloroform). This (2.5 g) was refluxed for 6 h in acetone (50 ml) with sodium iodide (7.5 g), sodium acetate (0.41 g), and acetic acid (12 ml), then worked up as usual. The n.m.r. spectrum of the sirupy product showed two signals for methoxyl groups at $\tau \sim 5.5$, indicating that the product consisted of two compounds.

The mixture, without further purification, was treated with *p*-toluenesulfonyl chloride (2.1 g) in pyridine (15 ml) for 3 days at 0°. The dark sirup obtained (4.8 g) was triturated well with Skellysolve B (10 ml). The solvent was decanted and the residue was dissolved in pyridine (30 ml) and refluxed for 20 min with tetraethylammonium chloride 1.65 g) and zinc dust (16 g). Zinc was removed and washed with a small amount of pyridine and the combined filtrate and washings were evaporated to dryness to a dark sirup which was covered with Skellysolve B (10 ml) and stored overnight at 0°. Crystals separated which were gathered and redissolved in ether (20 ml). The ether solution was filtered through a bed of alumina (1.7 × 4 cm) and the alumina was washed with ether (20 ml). The filtrate and washings were combined and evaporated to dryness, whereupon colorless needles were obtained. After one recrystallization from ether–Skellysolve B, the yield of **9***a* was 1.67 g (71.4%); m.p. 62–63°, $[\alpha]_D^{25}$ = −102° (*c*, 1.1 in chloroform), −104° (*c*, 1.23 in methylene chloride; lit. m.p. 40–46° (2,3), $[\alpha]_D^{20}$ −98° both in chloroform (4) and in methylene chloride (2). The mixed m.p. with **4***a* was 37–44°.

Anal. Calcd. for $C_{13}H_{14}O_4$: C, 66.67; H, 5.98. Found: C, 66.25; H, 5.74.

Methyl 5-O-Acetyl-2,3-anhydro-α-D-lyxofuranoside (1b)

1*c* (2.92 g, 0.02 mole) (11) was acetylated in pyridine (5.5 ml) with acetic anhydride (3 ml) at room temperature overnight. The reaction mixture was poured onto an ice-water mixture (50 ml) and extracted with chloroform (5 × 10 ml). After being dried over magnesium sulfate, the extracts were evaporated to dryness under reduced pressure. The residual long, colorless needles were recrystallized from a small amount of ethanol. Yield, 3.70 g (98.4%); m.p. 73–75°, $[\alpha]_D^{25}$ + 64.2° (*c*, 1.84 in chloroform).

Anal. Calcd. for $C_8H_{12}O_5$: C, 51.06; H, 6.38. Found: C, 51.00; H, 6.45.

Methyl 5-O-Acetyl-α-D-glycero-pent-2-enofuranoside (4b)

1*b* (2.66 g, 0.014 mole) was treated with sodium iodide (10.5 g), sodium acetate (0.57 g), and acetic acid (17 ml) in acetone (70 ml) at reflux temperature for 20 h, then the mixture was worked up as usual. The iodohydrin **2***b* was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

obtained as a slightly yellowish sirup; 4.21 g (95.2%), $[\alpha]_D^{25}$ +78.3° (*c*, 4.1 in chloroform). The n.m.r. spectroscopy and examination by t.l.c. showed it to be homogeneous.

This sirup was treated with *p*-toluenesulfonyl chloride (3.46 g, 0.018 mole) in pyridine for 3 days at 4°. The product (7.30 g) isolated as a sirup was, without purification, dissolved in pyridine (15 ml) and refluxed for 20 min with tetraethylammonium chloride (0.23 g, 0.0014 mole) and zinc dust (2.3 g). The zinc was gathered and washed with a small amount of pyridine. The combined filtrate and washings were worked up as usual and purified by distillation; 1.92 g (79.8%); b.p. 47–47.5° (0.1 mm Hg), m.p. 0–2°, $[\alpha]_D^{25}$ −91° (*c*, 4.9 in chloroform), n_D^{23} = 1.4502.

Anal. Calcd. for $C_8H_{12}O_4$: C, 55.81; H, 7.03. Found: C, 56.25; H, 6.94.

*Methyl 5-O-Acetyl-2-deoxy-2-iodo-3-O-(p-toluenesulfonyl)-β-D-xylofuranoside (**8**)*

Acetylation of **5***c* (11) (1.50 g, 0.0104 mole) afforded **5***b* (1.88 g, 96.2%) as a sirup, which was, without further purification, refluxed in acetone (50 ml) with sodium idiode (7.5 g), sodium acetate (0.41 g), and acetic acid (12 ml) for 6 h. The product, 2.12 g (67%), isolated in the usual manner, was a mixture of two isomers (**6***b* and **7***b*) (n.m.r.). The mixture was dissolved in pyridine (15 ml) and treated with *p*-toluenesulfonyl chloride (1.6 g, 0.008 mole) for 3 days at 4°. The reaction mixture was poured onto an ice-water mixture (70 ml) and extracted with chloroform (3 × 30 ml). The extracts were dried over sodium sulfate then evaporated to dryness under reduced pressure. Pyridine was removed from the residue by repeated azeotropic distillation with ethanol. The semi-crystalline residue, 2.5 g (79%), was covered with a small amount of ethanol and kept at −7° for 3 h. Crystalline cubes deposited and were washed with a small amount of cold ethanol, 0.99 g (31.4%); m.p. 117–118°.

For analyses, a small amount of the compound was recrystallized from ethanol; m.p. 118–119°, $[\alpha]_D^{25}$ −80.7° (*c*, 3.4 in chloroform).

Anal. Calcd. for $C_{15}H_{19}O_7SI$: C, 38.31; H, 4.08; I, 26.98. Found: C, 38.27; H, 3.94; I, 26.95.

*Methyl 5-O-Acetyl-β-D-glycero-pent-2-enofuranoside (**9***b*)*

A mixture of **8** (4.70 g, 0.01 mole), tetraethylammonium chloride (0.17 g, 0.001 mole), and zinc dust (1.66 g) in pyridine (20 ml) was refluxed for 20 min. The product was isolated in the usual manner, purified by distillation to provide a colorless liquid, 1.21 g (70.3%); b.p. 49° (0.4 mm Hg), $[\alpha]_D^{25}$ −103° (*c*, 1.99 in chloroform), n_D^{23} = 1.4473.

Anal. Calcd. for $C_8H_{12}O_4$: C, 55. 81; H, 6.98. Found: C, 56.12; H, 7.06.

*Methyl 2,3-Anhydro-4-O-benzoyl-β-L-ribopyranoside (**12***a*)*

Benzoylation of **12***d* (18,19) and recrystallization from ethanol gave an analytical sample as colorless needles; m.p. 108–108.5°, $[\alpha]_D^{25}$ −22.4° (*c*, 2.78 in chloroform).

Anal. Calcd. for $C_{13}H_{14}O_5$: C, 62.40; H, 5.60. Found: C, 62.23; H, 5.31.

*Methyl 4-O-Benzoyl-3-deoxy-3-iodo-β-L-xylopyranoside (**13***a*) and Methyl 4-O-Benzoyl-2-deoxy-2-iodo-β-L-arabinopyranoside (**14**)*

12*a* (5.0 g, 0.02 mole) was mixed with sodium iodide (15 g, 0.1 mole), sodium acetate (0.84 g, 0.01 mole), acetic acid (24 ml), and acetone (100 ml) and refluxed for 20 h. The reaction mixture was worked up as usual and the semi-solid residue (7.6 g, quantitative yield) was recrystallized from ethanol (60 ml) to give **13***a* as colorless needles, 6.27 g (82.9%); m.p. 158–159°, $[\alpha]_D^{25}$ +113° (*c*, 1.44 in chloroform).

Anal. Calcd. for $C_{13}H_{15}O_5I$: C, 41.29; H, 3.99; I, 33.56. Found: C, 41.42; H, 3.95; I, 33.34.

The mother liquor of the above recrystallization was evaporated to dryness. Upon triturating the sirupy residue with cold ethanol (5 ml), crystals (m.p. 84–86°) separated, which were recrystallized from a small amount of ethanol (2.5 ml). Colorless needles of methyl 4-*O*-benzoyl-2-deoxy-2-iodo-β-L-arabinopyranoside (**14**) were obtained, 377 mg (5%); m.p .96–97°, $[\alpha]_D^{25}$ +144° (*c*, 2.32 in chloroform). Mixed m.p. with **13***a*, 68–76°.

Anal. Calcd. for $C_{13}H_{15}O_5I$: C, 41.29; H, 3.99. Found: C, 41.40; H, 4.01.

*Methyl 4-O-Benzoyl-β-L-glycero-pent-2-enopyranoside (**17***a*)*

13*a* (1.89 g, 0.005 mole) was treated with *p*-toluenesulfonyl chloride (1.29 g, 0.0063 mole) in pyridine (5 ml) for 3 days at room temperature. The mixture was poured onto an ice-water mixture (50 ml) and was extracted with chloroform (3 × 25 ml). The combined extracts were dried over sodium sulfate and evaporated.

The residue was mixed with pyridine (20 ml) containing tetraethylammonium chloride (0.083 g, 0.0005 mole) and zinc dust (0.83 g). The mixture was heated to reflux for 20 min, cooled, and filtered. The filtrate was evaporated to dryness and the residue was suspended in water (25 ml); then extracted with ether (3 × 25 ml). The combined ether extracts were dried over sodium sulfate and evaporated. A small amount of pyridine was removed from the residue by repeated azeotropic distillation with ethanol until fine needles were obtained. The crystalline residue was dissolved in ether (3 ml) and decolorized by filtration through an alumina column (2 × 2 cm) and the column was washed with ether (10 ml). Upon evaporation of the combined ethereal solutions and recrystallization of the residual colorless needles from ethanol, the product 0.86 g (75%) had the following properties, m.p. 58–59.5°, $[\alpha]_D^{25}$ −187° (*c*, 2.03 in chloroform).

Anal. Calcd. for $C_{13}H_{14}O_4$: C, 66.67; H, 5.98. Found: C, 66.56; H, 6.12.

*Methyl 2,4-Di-O-benzoyl-3-deoxy-3-iodo-β-L-ribopyranoside (**15***a*)*

Benzoylation of **13***a* in the usual manner and recrystallization of the product from ethanol gave colorless leaflets; m.p. 143–144°, $[\alpha]_D^{25}$ +55.0° (*c*, 1.64 in chloroform).

Anal. Calcd. for $C_{20}H_{19}O_6I$: C, 49.80; H, 3.98; I, 26.31. Found: C, 49.67; H, 4.04; I, 26.34.

*Methyl 2,4-Di-O-benzoyl-3-deoxy-β-L-erythropentopyranoside (**16***a*)*

15*a* (723 mg, 0.0015 mole) was hydrogenated in ethyl acetate (20 ml) with 5% palladium on charcoal (200 mg) in the presence of diethylamine (0.1 ml). After the consumption of hydrogen had ceased, the mixture was filtered the filtrate was evaporated to dryness to a sirup, which then was dissolved in chloroform (25 ml). The chloroform solution was, after being washed with water (3 × 25 ml) and dried over sodium sulfate, evaporated to dryness to a sirup. The sirup was dissolved in benzene (1 ml) and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solution was absorbed on an alumina column(1.2 × 4 cm) then eluted with benzene (50 ml). The eluate was evaporated to a colorless sirup to a constant weight (452 mg, 84.6%); $[\alpha]_D^{25}$ +100° (*c*, 1.70 in chloroform). The n.m.r. spectrum of this sirup was identical with that of the product formed on benzoylation of methyl 3-deoxy-β-L-*erythro*-pentopyranoside (**16***c*) as described below.

Anal. Calcd. for $C_{20}H_{20}O_6$: C, 67.40; H, 5.67. Found: C, 67.54; H, 6.08.

*Methyl 4-O-Acetyl-3-deoxy-3-iodo-*β*-L-xylopyranoside (13b)*

12*b* (18,19) (1.88 g, 0.01 mole) was treated with sodium iodide (7.5 g, 0.05 mole), sodium acetate (0.41 g, 0.005 mole) and acetic acid (12 ml) in acetone (50 ml) at reflux temperature for 6 h. The mixture was worked up in the usual manner. The product was recrystallized from a small amount of ethanol to yield 3.01 g (95.3%); m.p. 145–145.5°, $[\alpha]_D^{25}$ +10.7° (*c*, 3.28 in chloroform).

Anal. Calcd. for $C_8H_{13}O_5I$: C, 30.38; H, 4.11. Found: C, 30.44; H, 4.05.

Acetylation of **13***b* with acetic anhydride in pyridine gave methyl 2,4-di-*O*-acetyl-3-deoxy-3-iodo-β-L-xylopyranoside (**15***b*) as colorless leaflets; m.p. 141–141.5°, $[\alpha]_D^{25}$ +39.4° (*c*, 3.2 in chloroform).

Anal. Calcd. for $C_{10}H_{15}O_6I$: C, 33.54; H, 4.22. Found: C, 33.70; H, 4.04.

*Methyl 3-Deoxy-*β*-L-erythro-pentopyranoside (16c)*

15*b* (10.4 g, 0.029 mole) was dissolved in hot methanol (300 ml) containing triethylamine (3.6 g), and hydrogenated with 5% palladium on charcoal catalyst (1.25 g). After the theoretical amount of hydrogen was consumed, the catalyst was removed by filtration. The filtrate was evaporated to dryness. The residue was dissolved in ether. Insoluble triethylammonium iodide was filtered off and the filtrate was evaporated to yield 4.2 g (69.7%) of a colorless sirup. Examination by t.l.c. showed that deacetylation had occurred during hydrogenolysis.

The above sirup (450 mg) was dissolved in absolute methanol (6 ml). Sodium methoxide in methanol (3 ml), prepared by dissolving sodium (0.5 g) in methanol (100 ml), was added and the mixture was set aside for 1 h. The reaction mixture was neutralized with Dowex 50 (H^+), filtered and evaporated to a sirup. The residue was purified by chromatography on a Celite column (23), then by distillation (70–80° bath temperature at 0.05 mm Hg). The product had $[\alpha]_D^{25}$ +94.5° (*c*, 10.5 in water). The examination by t.l.c. and n.m.r. spectroscopy showed it to be homogeneous. The same product was obtained on deacylation of the crystalline *p*-nitrobenzoyl derivative (**16***e*).

Anal. Calcd. for $C_6H_{10}O_4$: C, 48.65; H, 8.16. Found: C, 48.72; H, 8.22.

*Methyl 2,4-Di-O-acetyl-3-deoxy-*β*-L-erythro-pentopyranoside(16b)*

Prepared by acetylation of the pure **16***c* obtained from **16***e* and isolated as a distilled sirup; $[\alpha]_D^{25}$ +117° (*c*, 1.78 in chloroform).

Anal. Calcd. for $C_{10}H_{16}O_6$: C, 51.72; H, 6.93. Found: C, 51.93; H, 7.12.

*Methyl 3-Deoxy-2,4-di-O-methanesulfonyl-*β*-L-erythro-pentopyranoside (16d)*

Prepared from **16***c* in the usual manner and recrystallized from ethanol; m.p. 101.5–102°, $[\alpha]_D^{25}$ +73.1° (*c*, 1.04 in chloroform).

Anal. Calcd. for $C_8H_{16}O_8S_2$: C, 31.58; H, 5.29. Found: C, 31.54; H, 5.16.

*Methyl 3-Deoxy-2,4-di-O-(p-nitrobenzoyl)-*β*-L-erythro-pentopyranoside (16e)*

Treatment of **16***c* with recrystallized *p*-nitrobenzoyl chloride in pyridine gave a crystalline product which was recrystallized from ether; m.p. 123.5–124.5°, $[\alpha]_D^{25}$ +51.2° (*c*, 1.30 in chloroform).

Anal. Calcd. for $C_{20}H_{18}O_{10}N_2$: C, 53.82; H, 4.06. Found: C, 53.63; H, 4.23.

*Methyl 3-Deoxy-2,4-di-O-methyl-*β*-L-erythro-pentopyranoside (16f)*

Methyl 3-deoxy-β-L-*erythro*-pentopyranoside (**16***c*, 200 mg) was dissolved in 6 ml of freshly distilled methyl iodide and gently refluxed for 6 h. Freshly prepared silver oxide (1.39 g) was added in 10 equal portions at 0.5 h intervals to the continuously stirred solution. The heating was continued for 1 h after the final addition, then the silver oxide was removed by filtration and washed with 15 ml of diethyl ether. After solvent removal, the slightly yellow liquid residue was twice distilled under vacuum to give a colorless liquid b.p. (25 mm), 80–85° (180 mg, yield 75%) with the n.m.r. parameters consistent with the assigned structure (22). The three methyl groups gave singlets at τ 4.7, 4.75, and 4.81 in $CDCl_3$. The specific rotations, $[\alpha]_D^{25}$, were +86.2° (*c*, 0.9 in chloroform) and +94.0° (*c*, 1 in water).

Anal. Calcd. for $C_8H_{16}O_4$: C, 54.54; H, 9.14. Found: C, 54.51; H, 9.05.

*Methyl 2,3-Anhydro-4-O-methyl-*β*-L-ribopyranoside (12c)*

Methyl 2,3-anhydro-β-L-ribopyranoside (10 g) was *O*-methylated using 30 ml of freshly distilled methyl iodide as described above. On solvent removal, crystalline material was obtained and recrystallized from ethanol to give 7.50 g (68%); m.p. 74–75°, $[\alpha]_D^{25}$ +3.6 (*c*, 1.2 in chloroform) and −10.6 (*c*, 1.3 in water). The n.m.r. spectrum (60 MHz in $CDCl_3$) showed two sharp methoxy signals at τ 6.50 and 6.53 and the anomeric singlet at τ 5.18.

*Methyl 3-Deoxy-3-iodo-4-O-methyl-*β*-L-xylopyranoside (13c)*

A solution of 7.5 g of **12***c*, 27.2 g of sodium iodide, 2 g of sodium acetate, and 50 ml of acetic acid in 50 ml of acetone was refluxed overnight. A crystalline product was isolated in the usual manner (1). After recrystallization from ethanol, the yield was 12.6 g, m.p. 94.5–95.5°. The signals for the two methyl groups in the n.m.r. spectrum (in $CDCl_3$ at 60 MHz) were at τ 6.45 and 6.49. The anomeric proton produced a doublet at τ 5.83 with a spacing of ~ 6.5 Hz.

*Methyl 2-O-Acetyl-3-deoxy-3-iodo-4-O-methyl-*β*-L-xylopyranoside (15d)*

Compound **13***c* 7.5 g was acetylated using pyridine and acetic anhydride in the usual manner to afford a crystalline product. After recrystallization from ethanol, the yield was 7.6 g; m.p. 125.5–126.5°. The n.m.r. spectrum (in $CDCl_3$ at 60 MHz) showed the presence of the two methoxy groups, τ 6.54 and 6.61 and the acetoxy group signal at τ 6.91. The anomeric proton produced a doublet at τ 5.89 with a spacing of 7 Hz.

For personal use only.

Methyl 2-O-Acetyl-3-deoxy-4-O-methyl-β-L-erythro-pentopyranoside (16g)

The above iodo-compound (**15***d*) (7.5 g) was dissolved in 100 ml of methanol containing 4 ml of triethylamine and shaken in an hydrogen atmosphere with 1 g of 5% palladium on charcoal. After the uptake of hydrogen ceased, the catalyst was removed by filtration and the filtrate evaporated to dryness. The residue was extracted with benzene, the benzene solution was washed with water, then with sodium thiosulfate, and finally with water. After drying with sodium sulfate, the solvent was removed to give a colorless syrup. The n.m.r. spectrum (22) required a high state of purity. The specific rotations, $[\alpha]_D^{25}$, were +94.8° (*c*, 1.3 in water) and +81.1° (*c*, 1.4 in CCl_4).

Methyl 3-Deoxy-4-O-methyl-β-L-erythro-pentopyranoside (16h)

Deacetylation of the foregoing methyl 2-*O*-acetyl-3-deoxy-4-*O*-methyl-β-L-*erythro*-pentopyranoside with 0.5% sodium methoxide solution at room temperature gave the desired methyl 3-deoxy-4-*O*-methyl-β-L-*erythro*-pentopyranoside in 95% yield. After short-path distillation (at about 0.5 mm with a bath temp. 50°) the specific rotations, $[\alpha]_D^{25}$, were +131° (*c*, 1.6 in chloroform), +144° (*c*, 1.4 in dichloroethane), and +83.5° (*c*, 1.4 in dimethylsulfoxide). The n.m.r. spectrum is discussed in the accompanying publication (22).

Anal. Calcd. for $C_7H_{14}O_4$: C, 51.85; H, 8.69. Found: C, 51.85; H, 8.72.

Methyl 4-O-Acetyl-3-deoxy-3-iodo-2-O-(p-toluenesulfonyl)β-L-xylopyranoside (15c)

The iodohydrin (**13***b*) (3.16 g, 0.01 mole) was treated with *p*-toluenesulfonyl chloride (2.10 g, 0.011 mole) in pyridine (20 ml) for 44 h at room temperature. The reaction mixture was worked up as usual whereupon a crystalline product was obtained (4.70 g, quantitative yield). A small amount was recrystallized from ethanol; m.p. 131–132.5°, $[\alpha]_D^{25}$ −60° (*c*, 2.51 in chloroform) and found to possess an n.m.r. spectrum consistent with the assigned structure.

Methyl 4-O-Acetyl-β-L-glycero-pent-2-enopyranoside (17b)

The foregoing crude **15***c* (4.5 g) was dissolved in pyridine (20 ml) and refluxed for 20 min with tetraethylammonium chloride (0.16 g) and zinc dust (1.6 g). The product was a colorless liquid, 1.28 g (78%); $b.p._{0.5}$ 56°, n_D^{22} 1.4582, $[\alpha]_D^{25}$ −135° (*c*, 1.56 in chloroform).

Anal. Calcd. for $C_8H_{12}O_4$: C, 55.81; H, 7.03. Found: C, 56.33; H, 7.26.

Methyl 2,3-Anhydro-4-O-benzoyl-α-L-ribopyranoside (19a)

Benzoylation of methyl 2,3-anhydro-α-L-ribopyranoside, m.p. 83–84.5°, $[\alpha]_D^{25}$ −160° (*c*, 2.1 in chloroform) (19), provided colorless needles; m.p. 80–81°, $[\alpha]_D^{25}$ −172° (*c*, 2.53 in chloroform).

Anal. Calcd. for $C_{13}H_{14}O_5$: C, 62.40; H, 5.60. Found: C, 62.66; H, 5.40.

Methyl 4-O-Benzoyl-α-L-glycero-pent-2-enopyranoside (23a)

The foregoing benzoate **19***a* (2.50 g, 0.01 mole) was treated with sodium iodide (7.5 g) in acetone (50 ml) with sodium acetate (0.41 g) and acetic acid (12 ml) for 6 h. A mixture containing **20***a* and **21** in approximately equal amounts was obtained as a sirup in quantitative yield.

The mixture, without purification, was dissolved in pyridine (30 ml) and treated with *p*-toluenesulfonyl chloride (2.1 g, 0.011 mole) at room temperature for 3 days. The dark product obtained was refluxed in pyridine (20 ml) containing tetraethylammonium chloride (0.166 g) and zinc dust (1.66 g) for 20 min. The product, 1.66 g (71%), was isolated in the usual manner, and after distillation, $b.p._{0.05}$ 95°, was found to have m.p. 14–15°, $[\alpha]_D^{25}$ −180° (*c*, 1.71 in chloroform).

Anal. Calcd. for $C_{13}H_{14}O_4$: C, 66.67; H, 5.98. Found: C, 66.82; H, 5.91.

Methyl 4-O-Acetyl-3-deoxy-3-iodo-α-L-xylopyranoside (20b)

Methyl 2,3-anhydro-α-L-ribopyranoside (2.92 g, 0.02 mole) (18), m.p. 83–84.5°, $[\alpha]_D^{25}$ −160° (*c*, 2.1 in chloroform), was acetylated in the usual way, giving **19***b* in quantitative yield. This product was treated with sodium iodide in acetone in the presence of sodium acetate and acetic acid as usual. A colorless, crystalline product which appeared to be homogeneous by t.l.c. and n.m.r. examinations, was obtained in quantitative yield. For analysis a small amount was recrystallized from ethanol; m.p. 125–126°, $[\alpha]_D^{25}$ −109° (*c*, 2.2 in chloroform).

Anal. Calcd. for $C_8H_{13}O_5I$: C, 30.40; H, 4.14. Found: C, 30.73; H, 4.47.

The n.m.r. spectrum in $CDCl_3$ showed two sharp singlets for the methoxy and acetoxy groups at τ 6.58 and 7.80, respectively. The anomeric proton gave a doublet (spacing 3.0 Hz) at τ 5.40 and H_3 a triplet (spacings 10.3 Hz) at τ 5.88.

Methyl 2,4-Di-O-acetyl-3-deoxy-3-iodo-α-L-xylopyranoside (20c)

Acetylation of **20***b* in pyridine–acetic anhydride provided a crystalline product; m.p. 89.5–90.5°. The n.m.r. spectrum in $CDCl_3$ showed singlets at τ 6.60 (methoxy) and τ 7.82 and 7.87 (acetoxy). The signal for the anomeric proton was a doublet (spacing 3.2 Hz) at τ 5.30 and H_3 was a triplet (spacings 10.6 Hz) at τ 5.72.

Methyl 3-Deoxy-α-L-erythro-pentopyranoside (22b)

The above diacetate (**20***c*) was hydrogenolized as described above for the preparation of its β-anomer. The product was a sirup which, on deacetylation using sodium methoxide in methanol provided the title compound; m.p. 95.5–96° with $[\alpha]_D^{25}$ −157° (*c*, 0.9 in water), −120° (*c*, 0.9 in chloroform).

The n.m.r. spectrum in D_2O at 100 MHz (TMS external) showed a doublet for H_1 (τ 4.90, spacing 3.5 Hz), a triplet for the axial-H_5 (τ 6.16, spacings 10.2 Hz), the equatorial-H_3 was a multiplet centered at τ 7.41, and the axial-H_3 appeared as a sextet centered at τ 7.89. The following approximate coupling constants were established by double irradiation, $J_{3a,3e} = 11.4$, $J_{3e,4} = J_{3e,2} = 4.5$, $J_{3a,4} = J_{3a,2} = 10.5$, and $J_{3e,5e} = 1.7$ Hz. The methoxy signal was at τ 6.10.

Methyl 4-O-Acetyl-3-deoxy-3-iodo-2-O-(p-toluenesulfonyl)-α-L-xylopyranoside (20d)

Treatment of **20***b* (3.16 g, 0.01 mole) with *p*-toluene-

For personal use only.

sulfonyl chloride (2.10 g, 0.011 mole) in pyridine (20 ml) for 44 h at room temperature gave a crystalline product in quantitative yield. A small quantity was recrystallized from ethanol; m.p. 116–117°, $[\alpha]_D^{25}$ −60° (*c*, 2.5 in chloroform).

Anal. Calcd. for $C_{15}H_{19}O_7SI$: C, 38.31; H, 4.08. Found: C, 38.02; H, 3.78.

Methyl 4-O-Acetyl-α-L-glycero-pent-2-enopyranoside (23b)

The crude product obtained in the above experiment was dissolved in pyridine and treated with tetraethylammonium chloride (0.16 g) and zinc dust (1.6 g) for 20 min at reflux temperature. The product was a colorless liquid, 1.19 g (69.2%); b.p.$_{0.5}$ 52.0°, $[\alpha]_D^{25}$ −148° (*c*, 1.32 in chloroform) n_D^{22} 1.4560.

Anal. Calcd. for $C_8H_{12}O_4$: C, 55.81; H, 7.03. Found: C, 55.68; H, 7.15.

Methyl 2,3-Dideoxy-β-L-glycero-pent-2-enopyranoside (17c)

The acetate (**17***b*) (5.0 g, 0.0287 mole) dissolved in absolute methanol (75 ml) was treated with 2 *M* sodium methoxide in methanol (5 ml) for 1 h at room temperature. The alkaline solution was neutralized to p*H* 6.8 with acetic acid and the solvent evaporated under reduced pressure. The residue was extracted with ethyl acetate. The ethyl acetate was removed and upon distillation of the colorless residue, there was obtained a colorless liquid (b.p. $_{0.07}$ 38.5°; 3.53 g, 93.3%) which crystallized to long needles; m.p. 44° $[\alpha]_D^{25}$ −108° (*c*, 1.5 in chloroform).

Anal. Calcd. for $C_6H_{10}O_3$: C, 55.38; H, 7.96. Found: C, 55.28; H, 7.66.

Methyl 2,3-Dideoxy-β-L-glycero-pentopyranoside (18c) and Derivatives

The foregoing olefin (**17***c*) (2.87 g, 0.022 mole) was dissolved in absolute methanol (30 ml) and hydrogenated in the presence of 5% palladium on charcoal catalyst (280 mg). The hydrogen uptake ceased within 2 h. The catalyst was filtered and washed with small amount of methanol. The combined filtrate and washings were evaporated and the residue was distillated. A colorless liquid was obtained; b.p.$_{0.1}$ 51.0°, 2.44 g (84%), $[\alpha]_D^{30}$ +168° (*c*, 1.5 in chloroform), n_D^{22} 1.4529.

Anal. Calcd. for $C_6H_{12}O_3$: C, 54.55; H, 9.09. Found: C, 54.31; H, 9.11.

Derivatives: Methyl 4-O-benzoyl-2,3-dideoxy-β-L-*glycero*-pento-pyranoside (**18***a*); b.p.$_{0.07}$ 92.0°, $[\alpha]_D^{25}$ +115° (*c*, 1.7 in chloroform), n_D^{22} 1.5173.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83. Found: C, 66.08; H, 6.84.

Methyl 4-O-acetyl-2,3-dideoxy-β-L-*glycero*-pentopyranoside (**18***b*); b.p.$_{0.07}$ 50.0°, $[\alpha]_D^{25}$ +141° (*c*, 1.8 in chloroform), n_D^{22} 1.4418.

Methyl 2,3-Dideoxy-α-L-glycero-pent-2-enopyranoside (23c) and Derivatives

The title compound b.p.$_{0.07}$ 40°, $[\alpha]_D^{25}$ −129° (chloroform), was obtained by deacetylation of **23***b* in the manner described above for the preparation of **17***c* from **17***b*.

Anal. Calcd. for $C_6H_{10}O_3$: C, 55.38; H, 7.96. Found: C, 55.18; H, 8.02.

Hydrogenation of **23***c* as described for the preparation of **18***c* provided methyl 2,3-dideoxy-α-L-*glycero*-pentopyranoside (**24***c*); b.p.$_{0.1}$ 48°, $[\alpha]_D^{25}$ −131° (*c*, 1.3 in chloroform), n_D^{22} 1.4550.

Anal. Calcd. for $C_6H_{12}O_3$: C, 54.55; H, 9.09. Found: C, 54.27; H, 8.99.

Benzoylation of **24***c* gave methyl 4-*O*-benzoyl-2,3-dideoxy-α-L-*glycero*-pentopyranoside (**24***a*); b.p. $_{0.07}$ 90°, $[\alpha]_D^{25}$ −85° (*c*, 2.0 in chloroform), n_D^{22} 1.5193.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83. Found: C, 66.04; H, 6.93.

Acetylation of **24***c* gave methyl 4-*O*-acetyl-2,3-dideoxy-α-L-*glycero*-pentopyranoside (**24***b*); b.p.$_{0.5}$ 52°, $[\alpha]_D^{25}$ −105° (*c*, 1.8 in chloroform), n_D^{22} 1.4429.

Anal. Calcd. for $C_8H_{14}O_4$: C, 55.17; H, 8.05. Found: C, 54.98; H, 8.18.

Methyl 2,3-Dideoxy-α-D-glycero-pent-2-enofuranoside (4c) and Derivatives

Deacetylation of **4***b* provided the title compound **4***c*; b.p.$_{0.07}$ 38°, $[\alpha]_D^{25}$ −78° (*c*, 2.5 in chloroform), n_D^{21} 1.4656.

Anal. Calcd. for $C_6H_{10}O_3$: C, 55.38; H, 7.96. Found: C, 55.19; H, 8.04.

Hydrogenation of **4***c* as described for the preparation of **18***c* gave methyl 2,3-dideoxy-α-D-*glycero*-pentofuranoside (**10***c*); b.p.$_{0.07}$ 40°, $[\alpha]_D^{25}$ +147° (*c*, 1.5 in chloroform), n_D^{22} 1.4460.

Anal. Calcd. for $C_6H_{12}O_3$: C, 54.55; H, 9.09. Found: C, 55.68; H, 8.95.

Benzoylation of **10***c* gave methyl 5-*O*-benzoyl-2,3-dideoxy-α-D-*glycero*-pentofuranoside (**10***a*); b.p.$_{0.07}$ 95°, $[\alpha]_D^{25}$ +88° (*c*, 1.5 in chloroform), n_D^{22} 1.5108.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83. Found: C, 66.17; H, 6.87.

Acetylation of **10***c* gave methyl 5-*O*-acetyl-2,3-dideoxy-α-D-*glycero*-pentofuranoside (**10***b*); b.p.$_{0.07}$ 41.5°, $[\alpha]_D^{25}$ +119° (*c*, 1.5 in chloroform), n_D^{22} 1.4368.

Anal. Calcd. for $C_8H_{14}O_4$: C, 55.17; H, 8.05. Found: C, 55.38; H, 8.23.

Methyl 2,3-Dideoxy-β-D-glycero-pento-2-enofuranoside (9c) and Derivatives

Deacetylation of **9***b* provided the title compound **9***c*; b.p.$_{0.07}$ 36°, $[\alpha]_D^{25}$ −155° (*c*, 2.4 in chloroform), n_D^{23} 1.4667.

Anal. Calcd. for $C_6H_{10}O_3$: C, 55.38; H, 7.96. Found: C, 55.22; H, 7.91.

Hydrogenation of **9***c* as described for the preparation of **18***c* gave methyl 2,3-dideoxy-β-D-*glycero*-pentofuranoside (**11***c*); b.p.$_{0.07}$ 38°, $[\alpha]_D^{25}$ −128° (*c*, 1.5 in chloroform), n_D^{22} 1.4446.

Anal. Calcd. for $C_6H_{12}O_3$: C, 54.55; H, 9.09. Found: C, 54.29; H, 9.03.

Benzoylation of **11***c* gave methyl 5-*O*-benzoyl-2,3-dideoxy-β-D-*glycero*-pentofuranoside (**11***a*); b.p.$_{0.07}$ 94°, $[\alpha]_D^{25}$ −73° (*c*, 1.8 in chloroform), n_D^{22} 1.5098.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83. Found: C, 66.01; H, 6.87.

Acetylation of **11***c* gave methyl 5-*O*-acetyl-2,3-dideoxy-β-D-*glycero*-pentofuranoside (**11***b*); b.p.$_{0.07}$ 41°, $[\alpha]_D^{25}$ −99° (*c*, 1.5 in chloroform), n_D^{22} 1.4340.

Anal. Calcd. for $C_8H_{14}O_4$: C, 55.17; H, 8.05. Found: C, 54.99; H, 8.18.

Solvation effects on conformational equilibria. Studies related to the conformational properties of 2-methoxytetrahydropyran and related methyl glycopyranosides[1]

R. U. LEMIEUX, A. A. PAVIA,[2] J. C. MARTIN,[3] AND K. A. WATANABE[4]
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received May 5, 1969

Further evidence is presented (8) that changes in optical rotation at the D-line of sodium which occur with changes in solvent largely reflect changes in conformational equilibria.

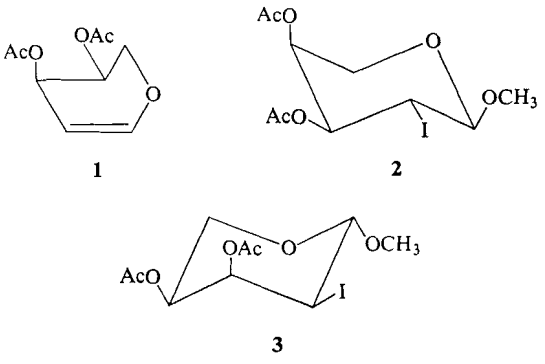
Changes in the nuclear magnetic resonance spectrum of 4,4,5,5-tetradeuterio-2-methoxytetrahydropyran and in the rotation of s(+)-2-methoxytetrahydropyran with changes in solvent are interpreted to show that solvents capable of donating a hydrogen to a hydrogen bond have an effect on the magnitude of the anomeric effect which is greater than that resulting from the change in the dielectric constant of the solvent. In the case of methyl 2-deoxypyranosides with the methoxy group in axial orientation, water appears to have an especially profound influence in stabilizing that orientation of the methyl group which brings it into *gauche* relationship with both the C_2-grouping and the anomeric hydrogen; that is, counter to the anomeric effect.

The methyl 2-deoxy-β-L-*erythro*-pentopyranoside was synthesized from di-*O*-acetyl-L-arabinal by way of an iodomethoxylation. Deuterolysis of the resulting 1,2-*trans*-acetylated methyl 2-deoxy-2-iodopentosides is shown to proceed in one case with extensive inversion of configuration and with extensive retention in the other case and offers a route to the preparation of 2-deoxy-2-deuterio-*erythro*-pentose with a high proportion (>75%) of the diastereoisomer with the *arabino*-configuration.

Canadian Journal of Chemistry, 47, 4427 (1969)

We wish to report synthetic routes to the α- and β-anomers of methyl 2-deoxy-2-deuterio-L-*arabino*-pentopyranoside and s-*dextro*-2-methoxytetrahydropyran(methyl 2,3,4-trideoxy-β-L-pentopyranoside).

Di-*O*-acetyl-L-arabinal (**1**) on treatment with iodine in methanol solution containing silver acetate following the directions of Lemieux and Fraser-Reid (1) yields approximately 1:1 mixture of methyl di-*O*-acetyl-2-deoxy-2-iodo-α-L-*arabino*-pyranoside (**2**) and methyl di-*O*-acetyl-2-deoxy-2-iodo-β-L-*ribo*-pyranoside (**3**). The *arabino*-isomer was isolated by crystallization. The *ribo*-isomer (**3**) was obtained only as a syrup of about 90% purity. However, catalytic hydrogenolysis of this compound followed by deacetylation gave a crystalline methyl 2-deoxy-β-L-*erythro*-pentopyranoside (**4***a*). Similar hydrogenolysis of the α-L-*arabino*-iodo compound (**2**) provided crystalline methyl di-*O*-acetyl-2-deoxy-α-L-*erythro*-pentopyranoside (**5***a*).



1 **2** **3**

Lemieux and Levine (2) showed that deuterolysis using palladium on charcoal as catalyst went with very high degree of retention of configuration from methyl 2-deoxy-2-iodo-β-D-glucopyranoside, whereas extensive inversion occurred with methyl 2-deoxy-2-iodo-α-D-mannopyranoside. The iodo compounds **2** and **3** were subjected to deuteriolysis in methanol. Replacement of the equatorial iodine of the *arabino* compound **2** proceeded with a high degree of retention, whereas the equatorial iodine of the isomeric *ribo* compound **3** was replaced with extensive inversion of the configuration. That is, both compounds **2** and **3** provided the 2-deoxy-2-deuterioglycoside with the *arabino* configuration (>75% yield). Evidently this procedure can

be used to provide 2-deoxy-D-ribose with either deuterium or tritium at the 2-position mainly in the *arabino*-configuration.

The configurations of the deuterated deoxypentopyranosides were established by nuclear magnetic resonance (n.m.r.) spectroscopy in deuterium oxide. The signal for the anomeric proton both for compounds **4***e* and **4***f* is in the form of a doublet with spacings of 8.5 and 7.3 Hz, respectively, indicating a *trans*-relationship between the hydrogens at positions 1 and 2. In the case of compound **5***c*, the spacings of the doublet for the anomeric proton was 3.0 Hz, both in deuterium oxide and deuteriochloroform. The optical purity seemed as great as that for compound **4***f* and probably better than 80%. The configuration for compound **5***c* was established by hydrolysis to provide the 2-deoxy-2-deuterio-L-arabinose. The n.m.r. spectrum of the compound in deuterium oxide showed the presence of the two pyranose and two furanose forms identified by Lemieux and Anderson (3). Thus, the quartet centered at τ 4.78, with spacings of 8.2 and 3.0 Hz, assigned to the anomeric proton of the α-pyranose form for 2-deoxy-D-ribose(2-deoxy-D-*erythro*-pentose) was now present in the spectrum for the 2-deoxy-2-deuteriopentose (**8**) as a doublet with a spacing of 9.0 Hz. This requires the hydrogens at positions 1 and 2 in **8** to be in *trans* relationship. Therefore, the hydrogens at positions 2 and 3 in compound **5***c* are in *trans* relationship and the compound has the *arabino*-configuration shown. It is planned to extend these studies and to establish the stereochemical routes of the deuteriolysis more precisely by use of mass spectroscopy.

The above routes for the preparation of the methyl 2-deoxy-α- and β-L-*erythro*-pentopyranosides were examined primarily to provide these compounds for studies on the effect of solvents on their conformations (4). Also, the use of these compounds to prepare optically active 2-methoxy-tetrahydropyran was of interest. Tosylation of the impure methyl 2-deoxy-β-L-*erythro*-pentopyranoside (**5***b*) provided the crystalline ditosylate (**5***d*) which was readily converted to the 6-methoxy-5,6-dihydro[2*H*]pyran (**6**). This compound was not characterized but converted directly to S-*dextro*-2-methoxytetrahydropyran (**7**), $[\alpha]_D$ + 157°(carbon tetrachloride), which had an infrared (i.r.) spectrum identical to the well-known racemic mixture (5).

In order to gain a better appreciation of the effects of solvent change on the optical rotation of the above 2-methoxytetrahydropyran and its 5-hydroxy derivative [namely, methyl 2,3-dideoxy-β-L-*glycero*-pentopyranoside (6)], the 4,6-ethylidene derivatives of both the α (**11***a*) and β (**11***b*) anomers for methyl 2,3-dideoxy-D-*erythro*-hexopyranoside were prepared. These compounds were prepared by hydrogenation of the α (**10***a*) and β (**10***b*) forms, respectively, of methyl 4,6-ethylidene-2,3-dideoxy-D-*erythro*-hex-2-enopyranoside. The latter compounds were synthesized from the known anomers for methyl

4,6-ethylidene-D-glucopyranoside (compounds **9***a* and **9***b*) respectively following the recently published (7) procedures for the corresponding 4,6-benzylidene derivatives of the methyl glucopyranosides. In order to provide further evidence in support of our contention (8) that changes in rotation which occur on changing solvent are largely related to changes in conformation, compounds of fixed conformation were prepared, namely, the 4,6-*O*-ethylidene derivatives of 1,2-dideoxy-D-*arabino*-hexopyranose (**16**) and 1,2,3-trideoxy-D-*erythro*-hexopyranose (**15**). These compounds were synthesized by hydrogenation of tri-*O*-acetyl-D-glucal (**12**) followed by deacetylation of the products **13***a* and **14***a* as described by Gray and Barker (9). As described in the experimental, in our hands, the course of the hydrogenation in the presence of diethylamine did not provide **14***a* as the major product. As expected, as seen in Table III, the rotations of compounds **15** and **16** are virtually insensitive to change in solvent.

A main purpose of this research was to investigate the possible effect of solvation phenomena on the apparent magnitude of the anomeric effect. For example, if the origin of the anomeric effect is indeed the result of dipole interactions between lone pairs of electrons on the oxygen atoms of the acetal linkage of glycosides or between those of the oxygen and halogen atoms of α-haloethers (10), then changes in the dielectric constant should tend to favor the more polar conformer (11,12). However, as suggested by Lemieux and Morgan (13), in view of the apparent occurrence of the "reverse anomeric effect", the engagement of the lone pair electrons of an acetal linkage in hydrogen bonds can be

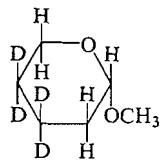
expected to lead to a change in the dipoles about these atoms and thereby influence the magnitude of the anomeric effect. For example, Lemieux and Saluja (14) have found that N-protonation of *N*-(tetra-*O*-acetyl-α-D-glycopyranosyl) imidazole with trifluoroacetic acid or N-methylation to the quaternary salt provides an important driving force for the imidazole residue to adopt the equatorial orientation. Certainly, the demonstration that specific solvation effects can substantially alter conformational equilibria is of basic importance for the appreciation of the interactions involved in enzyme–substrate complexing phenomena which may lead to stereoelectronic situations more favorable for reaction than are provided in the absence of such interactions. It was, therefore, desired to compare changes in conformation for 2-methoxytetrahydropyran with change in solvent both by n.m.r. and optical rotation. The n.m.r. data could be expected to provide information on chair–chair conformational change whereas the optical rotatory data would, following Brewster's rules for the anticipation of optical rotation (15), provide information on the effect of solvent on the orientation of the methoxy grouping relative to the pyranose ring.

$$HOCH_2—C\equiv C—CH_2—CH(OCH_3)_2$$

17

D_2 ↓ Pd/C

CH_3OH ↓ H^+



18

In order to obtain n.m.r. data on 2-methoxytetrahydropyran which was useful for the assessment of the coupling constants of H_2 with the geminal hydrogens at the 3-position, it was required to eliminate the virtual coupling of H_2 with the hydrogens at the 4-position which are only weakly chemically shifted from those at the 3-position. This was accomplished by replacement of the two C_4-hydrogens by deuterium atoms. Thus, 3-pentyn-5-ol-l-al-dimethyl-acetal (**17**) (16) was deuterated with deuterium over palladium on charcoal. The resulting 3,3,4,4-tetradeuteriopentane-5-ol-l-al-dimethyl-acetal was cyclized in methanolic hydrogen chloride to the desired 4,4,5,5-tetradeuterio-2-methoxytetrahydropyran (**18**). As expected, sharp signals were obtained for the hydrogens at the 2-, 3-, and 6-positions. The n.m.r. parameters for the product (**18**) in a variety of solvents are reported in Table I.

In order to attach a significance in terms of the populations of the two chair conformations for 2-methoxytetrahydropyran of the coupling constants of H_2 with H_3 and $H_{3\varepsilon'}$, it is necessary to evaluate the coupling constants $J_{aa} + J_{ae}$ and $J_{ee} + J_{ea}$ in order to apply the relationship $n(J_{aa} + J_{ae}) + (1 - n)(J_{ea} + J_{ee}) =$ observed sum of coupling constants where n is the fraction of the compound with the methoxy group in equatorial orientation. The individual coupling constants are known for the anomeric pair of the methyl 2-deoxy-D-*arabino*-hexopyranosides as a result of the preparation of three of the 2-deuterio-derivatives (2). The values found for these compounds in deuterium oxide wherein a high degree of conformational purity is expected, were $J_{aa} = 9.9, J_{ae} = 1.9, J_{ea} = 3.9$, and $J_{ee} = 1.4$ Hz, respectively. These values are expected to represent closely those existing for 2-methoxytetrahydropyran in view of the close structural similarities between these compounds. On this basis and assuming that only chair forms are present, the effects of solvent on the population of the conformer with the methoxy group in equatorial orientation are given in Table II. It is seen that there is not a simple relationship between dielectric constant and the equilibrium constant for this conformational change. Although the results show an increase in the presumably more polar equatorial form with increasing solvent polarity, the marked effect of chloroform as compared to the much more polar dimethylsulfoxide is noteworthy especially since chloroform like methanol and water is capable of donating its hydrogen to a hydrogen bond (17). Chloroform molecules can be expected to form weak hydrogen bonds with the oxygens of acetal linkage and, perhaps, thereby stabilize the less stable form of 2-methoxytetrahydropyran which has the methoxy group in equatorial orientation. This effect by chloroform has also been noted in the case of a number of glycosides (4).

The conclusion that hydrogen bonding can influence the strength of the anomeric effect is

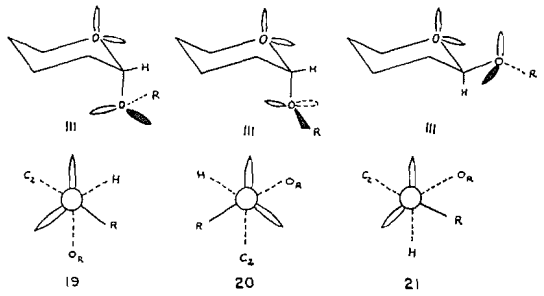
†In non-deuterated solvent, the molar rotations found are reported in Table III.

supported by the following studies of the effect of solvent on the rotations of 2-methoxytetrahydropyran derivatives with the methoxy group in axial orientation. Examination of the rotations given in Table III for a variety of compounds with an axial methoxy group at the anomeric center of fixed chair conformation shows that change in solvent has relatively little effect *except* for water and it is therefore concluded that water has a particularly strong ability to affect the orientation of the methoxy group.



19 20 21

It was pointed out several years ago that both for reasons of steric effects and of the anomeric effect, an aglycon (10,18) should tend to adopt the conformation shown in **19** when in axial orientation and that depicted by **21** when in equatorial orientation. Indeed, X-ray crystallographic studies (19–21) in a number of glycosidic structures have found the aglycons in these orientations which are those to which Brewster (15) assigned the value of $\pm 105°$ as their contribution to molar rotation for methyl glycosides in water. As is seen in the projections, the C—O_r bond is in *gauche*-relationship with an orbital for an unshared pair of electrons of the OR group in both the anomers. However, it can be seen from the conformational formulas that the equatorial OR group has an orbital parallel and opposing an orbital of the ring oxygen[5] and that such a dipole interaction is avoided in the axially oriented anomer.

There is to date no accurate way to establish, in solution, the relative importance of other staggered orientations for the aglycon about the anomeric center. However, the dipole moment of each conformer may be calculated by the bond moment (26) and are estimated to be 0.0, 1.84, 1.84, 1.84, 1.84, and 2.60 Debye (D) units for conformers **22**, **23**, **24**, **25**, **26**, and **27**, respectively. For the axial conformer, that (**24**) which has the methyl group oriented under the ring, can be expected to have a negligible existence. As seen in Table II, we estimate the mole fractions of the two chairs to be $n_{22} + n_{23} = 0.82$ and $n_{25} + n_{27} = 0.18$ with benzene as solvent. For the present purposes, it can be assumed that the equilibrium constant for the chair–chair equilibrium also applies to the equilibria which separate the various conformers of a given chair. On this basis, the concentration of **27** relative to these

[5]Hutchins, Kopp, and Eliel (22) have recently suggested that this interaction be termed the "rabbit ear effect." We consider the term "anomeric effect" first introduced in 1961 with reference to the establishment of the phenomenon through n.m.r. studies of conformation and studies of anomerization equilibria (10,23) to be of historical interest and recommend that it be maintained. The possibility that the effect may arise at least in part from such dipole interactions was clearly envisaged by Edward (24) and discussed by Kabayama and Patterson (25); Lemieux (10) designated the interaction by the term *e*//*e*.

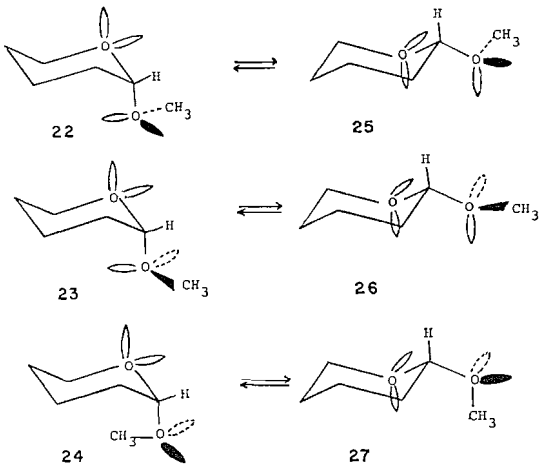
15 16 10

11*a* 28 (6) 7

†Δ[*M*] refers to the difference between the rotation in the solvent indicated to the left and that in chloroform.



22 25

23 26

24 27

of **23**, **25**, and **24** must be small. Therefore, we expect the square of the moment of 2-methoxytetrahydropyran in benzene to be approximately $0.82 \times 0.82 \times 0 + 0.82 \times 0.18 \times 1.84^2 + 0.18 \times 1.84^2 = 1.09$. The dipole moment, 1.06 D, thus estimated is in good agreement with that found, 1.16 D (27).

The changes in rotation noted above for compounds **11***a* and methyl 2,3-dideoxy-α-D-*glycero*-pentopyranoside are (Table III) taken as evidence that for these 2-deoxy-α-pyranosides, there exists a substantial abundance of at least another conformer. Since that conformer which would have the methyl group *gauche* to both the O_r and C_2 must be highly strained, the conformation (**20**) which has the methyl group in *gauche* orientation with C_2 and H_1 must be expected to be that which is most stable next to conformation **19**. The fact that the conformer **20** has an *e*//*e* interaction, whereas **19** has none, may provide the clue to apparent stabilization of **20** by water. Thus, by virtue of its dihydric structure, water may form a bridge between the two parallel and opposing orbitals and thereby cause an effective cancelling of what may be termed the *exo*-anomeric effect. Such considerations are of obvious interest to the eventual understanding of α-glucosidase action.

The effect of hydration on aglycon orientation was also evident from the changes in rotation given in Table III for s-*dextro*-2-methoxytetrahydropyran (**7**) and related compounds. The α- and β-anomers of 2,3-dideoxy-4,6-*O*-ethylidene-D-*erythro*-hexopyranoside **11***a* and **11***b*, respectively, and the 1,2,3-trideoxy-4,6-*O*-ethylidene-D-*erythro*-pyranoside (**15**) were prepared to

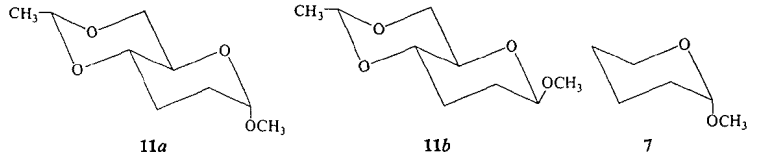
*The compounds have the following structures:



11*a* **11***b* **7**

†Calculated by extrapolation of values of methanol–water mixtures.

provide a basis for a rationalization of the optical rotatory change of **7** with changes in solvent. As expected (15), the rotation of **15** was near zero. The rotation of **11***b* could not be determined in water. However, it was found for several compounds that the rotation in water could be found by extrapolation of values found in mixtures of methanol and water. The rotations of **11***a*, **11***b*, and **7** in a variety of solvents are given in Table IV. Using the rotation of **11***a* for **7** in the 2-axial conformation and that for **11***b* for that of **7** in the other chair form, the calculated rotations for **7** using the chair–chair equilibria determined by n.m.r. and reported in Table II are listed in Table IV. It is seen that in all cases, there exists a difference of $57 \pm 3°$ between the calculated rotation and that observed. Although this discrepancy cannot be explained at this time, it seems most probable that it arose from a 15% racemization of **7** in the course of its preparation.

Assuming that changes in conformation are the most important factor causing changes in rotation and considering the general variation of rotation rather than particular experimental values, the proportions of conformers of **7** may be estimated. It can be anticipated (15,28) that the s-*dextro*-2-methoxytetrahydropyran (**7**) in conformation **22** will have a molar rotation of +205 and +105° in conformation **25**. If we assume that only these conformations prevail, the proportions of conformer **25** in the variety of solvents shown in Table II are obtained using the rotations listed in Table III. As it appears in Table II, the discrepancy between the proportions of conformers estimated by n.m.r. and by optical rotation may be explained by the partial racemization of **7** and the presence, mainly in water, of amounts of conformers involving rotation about CH_3O—C bond. It can be pointed out that change in solvent does not appreciably affect the molar rotation of the methyl 2,3-dideoxy-4,6-*O*-ethylidene-β-D-*erythro* hexopyranoside (**11***b*) (see Table IV).

The special effect of water on the rotation of compounds with the methoxy group in axial orientation is therefore readily apparent in both s-*dextro*-2-methoxytetrahydropyran and the bicyclic compound (**11***a*). These results confirm our general contention that specific solvation effects can play an important role in determining conformational equilibria. Clearly these conclusions have an important bearing on the conformational properties in water of important α-glucopyranoside structures as represented by starch, glycogen, several antibiotics, etc. In view of the marked changes in rotation which can occur for an α-D-hexopyranoside on changing solvent and which occur as a result of changes in the relative populations of conformers involving the aglycon, the proposal (29) that the rotation of ethyl 2,3,6-trideoxy-α-D-*threo*-hexopyranoside in water requires the compound to exist largely in the 1C-conformation is without basis.

Experimental

Methyl 3,4-Di-O-Acetyl-2-deoxy-2-iodo-α-L-arabinopyranoside (2)

Di-*O*-acetyl-L-arabinal (di-*O*-acetyl-1,2-dideoxy-L-*erythro*-pent-1-enopyranose (**1**) (30), 4.3 g, was dissolved in 200 ml of dry methanol containing 5.5 g of silver acetate. The mixture was maintained at 0° and 5.0 g of iodine were added over a period of 10 min with continuous stirring. After an additional h, the silver salts were removed by filtration, washed with methanol and the filtrate evaporated *in vacuo*. The residue was dissolved in chloroform, washed successively with water, saturated sodium bicarbonate solution, thiosulfate solution, water, and dried over sodium sulfate. Evaporation gave a semi-solid residue, 7.2 g, whose n.m.r. spectrum showed it to be a 1:1 mixture of the α and β iodo-compounds **2** and **3**, respectively. Successive recrystallizations from ether–petroleum ether provided the title compound, m.p. 100–101.5°. The n.m.r. spectrum in $CDCl_3$ showed singlets at τ 7.89 and 7.95 (acetyls) and τ 6.46 (methoxy). The signal for the anomeric proton (H_1) was a doublet at τ 5.50 with a spacing of 8.2 Hz. The signals for H_3 and H_4 were superimposed at τ 4.90.

Methyl 3,4-Di-O-acetyl-2-deoxy-α-L-erythro-pentopyranoside (4a)

Compound **2**, 11 g, was dissolved in 120 ml of methanol containing 4 g of triethylamine and hydrogenated at normal pressure using 1.8 g of 5% palladium on charcoal. After the hydrogen uptake had ceased the catalyst and the methanol were removed. The solid residue was dissolved in benzene and the solution was washed successively with water, sodium thiosulfate, water, and dried over sodium sulfate. Evaporation gave a crystalline product which was recrystallized from ether–petroleum ether to give 4.5 g of the title compound, m.p. 73.5–74°, $[\alpha]_D^{25}$ −22.7° (*c*, 0.9 in chloroform) and +4.3° (*c*, 0.9 in water).

Anal. Calcd. for $C_{10}H_{16}O_6$: C, 51.72; H, 6.89. Found: C, 52.00; H, 6.96.

The n.m.r. parameters are given in Table V.

Methyl 2-Deoxy-α-L-erythro-pentopyranoside (4b)

Deacetylation of **4***a* with 0.5% sodium methoxide solution at room temperature gave a theoretical yield, m.p. 101–102° (sublimes), $[\alpha]_D^{25}$ −169° (*c*, 1.03 chloroform) and −50° (*c*, 1.15 water).

Anal. Calcd. for $C_6H_{12}O_4$: C, 48.64; H, 8.10. Found: C, 48.68; H, 8.15.

The n.m.r. parameters are given in Table V.

Methyl 2-Deoxy-β-L-erythro-pentopyranoside (5b)

The sirupy residue from the isolation of the iodo-compound **2** was found by n.m.r. to be an approximately 9:1 mixture of compounds **3** and **2**, respectively. This mixture was hydrogenated in the same manner as described above for the preparation of **4***a* and the product was deacetylated as described for the preparation of **4***b*. Chromatography on a dry-packed silica gel column and using a 1:4 mixture of acetone and chloroform provided the title compound (**5***b*) after **4***b* had been eluted. Purification was achieved by recrystallization from ether–petroleum ether, m.p. 85.5–86.5°, $[\alpha]_D^{25}$ +197° (*c*, 1.25 in water), +201° (*c*, 1.36 in chloroform), +192° (*c*, 0.96 in dimethylsulfoxide).

The 100 MHz spectrum in deuterium oxide (TMS external) showed a triplet at τ 4.69 (spacings 3.0 Hz) for H_1, the methoxy signal at τ 6.22 and the multiplet for H_2 and H_3 centered at τ 7.16.

Methyl 2-Deoxy-3,4-di-O-mesyl-α-L-erythro-pentopyranoside (4c)

To a solution of 450 mg (0.003 ml) of **4***b* in 4 ml of pyridine chilled to 0°, 1 g (0.007 mole) of methanesulfonyl chloride. The reaction mixture was worked up as usual after 30 min to give, after recrystallization from ethanol, 700 mg of the title compound, m.p. 99–100°.

Anal. Calcd. for $C_8H_{14}O_8S$: C, 31.57; H, 5.25. Found: C, 31.32; H, 5.37.

The n.m.r. parameters are given in Table V.

Methyl 2-Deoxy-3,4-di-O-methyl-α-L-erythro-pentopyranoside (4d)

Compound **4***b*, 550 mg, was dissolved in 10 ml of pure anhydrous methyl iodide and, to stirred refluxing solution, 1.9 g of freshly prepared silver oxide was added in 10 equal portions over 30 min intervals. After refluxing an additional h, the product was isolated in the usual manner. Thin-layer chromatography revealed three components and purification required preparative gas chromatography on a 20% Carbowax column with a column temperature of 120° using an F&M Prepmaster Model 776. The main component, which also had the longest retention time, was assigned the structure **4***d* on the basis of its n.m.r. spectrum (see Table V).

It is noteworthy that both the 2-deoxy and 3-deoxy methyl *erythro*-pentopyranosides prepared in the course of this research exhibited pronounced instability in acid media. The by-products formed in the above methylation are believed to be isomers of **4***d* and their formation could not be avoided.

Methyl 2-Deoxy-2-deuterio-α-L-arabino pentopyranoside (4f)

The pure methyl di-O-acetyl-2-deoxy-2-iodo-α-L-arabinopyranoside (**2**) was deuterolyzed under the same conditions as used for the hydrogenolysis of **2** to provide **4***a* except that the deuterium gas was employed. The crystalline product (**4***e*) melted at 73–74.5° closely similar to that of compound **4***a*. The n.m.r. spectrum in dimethylsulfoxide-d_6 showed an intense doublet for the anomeric proton with a spacing of 8.5 Hz. As seen in Table V, the undeuterated compound (**4***a*) showed a quartet for this signal with coupling constants (calculated) of 8.5 and 2.6 Hz. The compound was evidently contaminated to an extent of 20 to 25% of the *ribo*-isomer in view of the presence of a low intensity doublet (spacing 2.6 Hz) centered at the same position as the above more intense doublet.

Deacetylation of **4***e* as described for the deacetylation of **4***a* provided the title compound (**4***f*), contaminated 20 to 25% by the *ribo*-isomer. The n.m.r. spectrum in deuterium oxide showed the main anomeric doublet with a spacing of 7.3 Hz. On changing the solvent to deuteriochloroform, the spacing diminished to 2.7 Hz.

Compound **4***f*, 120 mg, in 2 ml of 0.1 *N* aqueous sulfuric acid was maintained at 50° for 4.5 h in which time

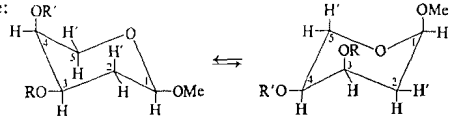
*The compounds have the following general structure:



†The chemical shifts are expressed in τ values from TMS as internal standard unless otherwise specified.

‡These values (±0.2 Hz) were calculated from the X part of an AB (2,2′) X(1) system. It is noteworthy that the shape of the H_1 signal was very dependent of the chemical shift of 2 and 2′. In some cases, although the H_1 axial was a triplet, the real coupling constant differed from the spacing by 2 to 3 Hz. In some of the compounds, the calculated $J_{1,2'}$ values agreed well with those derived from the 2-deuterated derivative.

§Assumed to be negative.

‖Pyrazine as internal standard (τ 1.65 versus TMS as external standard).

¶As previously reported (8), the coupling constants, $J_{1,2}$ and $J_{1,2'}$, of the β-anomer are 2.9 Hz, both in $CDCl_3$ and in D_2O.

**TMS as external standard.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the observed rotation increased from −2.8° to a constant value of +2.27°. Thin-layer chromatographic examination (silica gel, 3:7 methanol–benzene) showed the presence of a compound with R_f about half that of the starting material which was present in trace amount. The solution was neutralized with barium carbonate and the product isolated in the usual manner. The sirup was twice exchanged with deuterium oxide before the determination of its n.m.r. spectrum in this solvent at 100 MHz (TMS external). The spectrum showed signals at τ 4.45 (multiplet), 4.76 (doublet, spacing 3.2 Hz), and 5.22 (doublet, spacing 9.0 Hz). In the spectrum of 2-deoxy-D-ribose under the same conditions, these signals were present but the 2 higher-field signals were in the form of a triplet (spacing 3.6 Hz) and a quartet (spacings 8.2 and 3.0 Hz). The signal at τ 5.22 was assigned to the α-pyranose form (30) and the 9.0 Hz spacing for **4***f* requires the *arabino*-configuration for the main component (75–80%).

Methyl 2-Deoxy-2-deuterio-β-L-arabino-pentopyranoside (5c)

The impure **3**, as mentioned above for the preparation of **5***b*, was deuterolyzed as described for the preparation of **4***e* and **5***c* was obtained from this product as described in the preparation of **5***b*. The melting points of **5***b* and the title compound (**5***c*) were the same. The spacing of the doublet for the anomeric hydrogen at τ 4.69 was 3.0 Hz. Hydrolysis of this glycoside as described above for α-anomer (**4***f*) gave a product with an n.m.r. spectrum in deuterium oxide virtually identical to that of 2-deoxy-2-deuterio-L-*arabino*-pentose obtained from **4***f*. The sugar possessed less of the *ribo*-isomer as evidenced by a much lower intensity of signal corresponding to the anomeric proton of this compound. Thus, the stereoselectivity in the deuterolysis of **3** with inversion of the reacting center was greater than that for **2** which proceeded mainly (75–80%) with retention.

Methyl 2-Deoxy-di-O-(p-toluenesulfonyl)-β-L-erythro-pentopyranoside (5d)

Methyl 2-deoxy-β-L-*erythro*-pentopyranoside containing a small amount of its α-anomer (5.6 g, 0.038 mole) was dissolved in pyridine (25 ml) and treated with *p*-toluenesulfonyl chloride (15.3 g, 0.08 mole) for 2 h at room temperature. The reaction mixture was poured into an ice-water mixture (250 ml) and extracted with 2 × 200 ml of chloroform. The chloroform layer was washed with sodium carbonate solution (2 × 30 ml) then with water, dried over sodium sulfate, and evaporated to dryness. The solid residue was recrystallized 3 times from ethanol. Colorless, fine needles, m.p. 110–111°, $[\alpha]_D^{25}$ 117° (*c*, 1.8 in chloroform) were obtained. These constants were not changed by further recrystallization. The n.m.r. signal ($CDCl_3$ as solvent) showed the presence of the two *p*-toluenesulfonyl groups (singlet with relative intensity 6 at τ 7.55), the methoxy group (singlet of relative intensity 3 at τ 6.72).

dextro-2-Methoxytetrahydropyran (7) (Methyl 2,3,4-Trideoxy-β-L-pentopyranoside)

A mixture of the ditosylate (**5***d*), 6.84 g, sodium iodide, 113 g, zinc dust, 53 g, and *N,N*-dimethylformamide, 190 ml, was refluxed for 2 h without stirring. Fractional distillation at atmospheric pressure using a spinning-band column provided a 25 ml first fraction which contained over 95% of the optical activity. This fraction was diluted with 25 ml of water. The resulting solution and two 25 ml volumes of water were successively extracted with Skellysolve B (20 ml) until the three aqueous solutions were devoid of optical activity. Six extractions were required. The combined extracts were dried and hydrogenated within 1 h at atmospheric pressure in the presence of 5% palladium on charcoal. The catalyst was removed and the solution was concentrated to about 2.5 ml using a spinning-band column for fractional distillation. The distillate boiled in the range 66–67° and was optically inactive. The undistilled fraction was applied to a 20% butanediol succinate column at 65° for preparative gas chromatography using an F&M Prepmaster Model 776. In this way, the title compound (**7**) was purified to the extent that its i.r. spectrum in carbon tetrachloride was superimposable on that of an authentic sample of the racemic 2-methoxytetrahydropyran under the same conditions for measurement. The rotations of the compound in a variety of solvents is given in Table III.

The 6-methoxy-5,6-dihydro[2*H*]pyran intermediate **6** was not isolated for characterization.

Methyl 2,3-Dideoxy-4,6-O-ethylidene-α-D-erythro-hexopyranoside (11a)

Methyl 2,3-anhydro-4,6-*O*-ethylidene-α-D-allopyranoside was converted to methyl 2-deoxy-4,6-*O*-ethylidene-2-iodo-α-D-altropyranoside and this compound tosylated following the procedures described by Lemieux, Fraga, and Watanabe (7) for the sample reactions starting with methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside. Neither of the compounds crystallized. The tosylated iodohydrin appeared pure but some of the 2,3-unsaturated compound (**10***a*) was present in the product isolated from the tosylation. In order to complete the reduction, this product, 17.5 g, was heated with 0.64 g of tetraethylammonium chloride, 6.4 g of zinc dust, and 100 ml of pyridine at the reflux temperature for 40 min. The product (**10***a*) isolated in the usual manner, was not purified but hydrogenated in the presence of 5% palladium on charcoal in methanol (30 ml) which contained 6 ml of triethylamine. Although **10***a* was not highly pure, the n.m.r. parameters were consistent with the assigned structure as was ascertained by comparison with those of the corresponding 4,6-*O*-benzylidene compound (7). After the hydrogenation, the solvents were removed *in vacuo* and the residue dissolved in water for extraction with benzene. The benzene was removed by distillation at atmospheric pressure and the product purified by distillation at about 15 mm (bath temperature 60°). The yield was 3.0 g of a colorless liquid which gave an n.m.r. spectrum in $CDCl_3$ in complete accord with the assigned structure (**11***a*). The signal for H_1 (unresolved triplet) at τ 5.37 was partly overlapped by the quartet (spacing 5.0 Hz) for the acetal hydrogen of the ethylidene group centered at τ 5.23. The relative intensity of the group of signals in the range τ 5.9 to 6.8 (which includes a sharp signal of relative intensity three for the methoxy group at τ 6.67) was that expected for seven hydrogens (H_4, H_5, $2H_6$, and OCH_3). A multiplet in the range τ 8.08 to τ 8.30 had the relative intensity (4) required for the ethylene group. The methyl signal of the ethylidene group was a doublet (spacing 5.0 Hz) at τ 8.69. The optical rotations in a number of solvents are given in Table IV.

*Methyl 2,3-Dideoxy-4,6-O-ethylidene-β-D-erythro-hexopyranoside (**11b**)*

As was previously observed for the reaction of methyl 2,3-anhydro-4,6-*O*-benzylidene-β-D-allopyranoside (7), the reaction of methyl 2,3-anhydro-4,6-*O*-ethylidene-β-D-allopyranoside with sodium iodide proceeded with attack at both the 2 and 3 positions. The mixture of these iodohydrins was tosylated as described above and the product was hydrogenated directly under conditions described for the preparation of the α-anomer (**11a**). The product, isolated in the usual manner, was purified by chromatography on silica gel using 3% acetone in chloroform as eluant. After recrystallization from Skellysolve B, the compound (**11b**) melted at 65.5–66.5° and provided an n.m.r. spectrum in $CDCl_3$ in complete accord with the assigned structure. Thus, the ethylidene group provided a quartet (spacing 5.0 Hz) at τ 5.25 and a doublet (spacing 5.0 Hz) at τ 8.66. The methoxy group gave its signal at τ 6.50. In accordance with the axial orientation for H_1 and the strong virtual coupling to be expected between H_1 and the hydrogens at C_3, the signal for H_1 was broad multiplet centered at about τ 5.52. Also, the ethylene group produced a broad multiplet (as compared to the α-anomer) in the range τ 7.8 to 8.6.

The molar rotations of this compound in various solvents are listed in Table IV.

4,4,5,5-Tetradeuterio-2-methoxytetrahydropyran

Freshly distilled 1-methoxy-2-butene-3-yne was converted to pent-3-yne-5-ol-1-al dimethyl acetal following the directions prescribed by Weygand and Leube (16). The latter compound (14 g, 0.1 mole) was reacted with deuterium over 5% palladium on charcoal in 50 ml of ethyl acetate for 7 h at 50 p.s.i. Removal of the catalyst and solvent left a residue which was distilled under reduced pressure [b.p. 70° (1.2 mm)], n_D^{25} = 1.4325. Gas chromatography indicated a high state of purity as did the n.m.r. spectrum which was in general agreement with that expected for 3,3,4,4-tetradeuteriopentane-5-ol-1-al dimethylacetal.

The foregoing compound (0.5 g) was dissolved in dry methanol, 5 ml, containing a small amount (1%) of hydrogen chloride. After 3 h, the reaction was complete as evidenced by the appearance of peak in the gas chromatogram with a retention time equal to that of 2-methoxytetrahydropyran. After neutralization with sodium methoxide, the product (b.p. 124°, n_D^{25} 1.4234) was obtained by distillation at atmospheric pressure. High purity was evident from the gas chromatogram on a 15 ft, 1/4 in. (o.d.) column of diethyleneglycol succinate polyester on Chromosorb at 85°. Also, the n.m.r. spectrum (see Table I) were in good agreement (allowing for the deuteration) with that provided with an authentic sample of 2-methoxytetrahydropyran. The mass spectrum gave the required parent peak at *m/e* 120 and the most important fragments were at *m/e* 90, 89, 61, and 58 in accordance with the fragmentation pattern described by Isser and coworkers (32).

*Tri-O-acetyl-1,2-dideoxy-D-arabino-hexopyranose (**13a**) and Di-O-acetyl-1,2,3-trideoxy-D-erythro-hexopyranose (**14a**)*

These compounds were prepared from 3,4,6-tri-*O*-acetyl-D-glucal (**12**) following the directions reported by Gray and Barker (9). In our experience, based on a gas chromatographic investigation of the product using silicone rubber on Chromosorb at 175°, the dideoxy compound was the main product regardless of the catalyst solvent or presence of diethylamine. The maximum yields of the trideoxy compound was about 20% and were achieved using either platinum or palladium catalysts in ethyl acetate containing diethylamine. In absence of the amine, the yields of this product were less than 5%. Gray and Baker reported yields in order of 85%. The compounds were separated by fractional distillation at 0.7 mm pressure. Compound **13a**, $[\alpha]_D^{25}$ = 33° (*c*, 0.8 in carbon tetrachloride) distilled at 129–130° and **14a**, $[\alpha]_D^{25}$ = 23° (*c*, 0.9 in carbon tetrachloride), at 89–90°.

The structures of the products were confirmed by the following n.m.r. parameters obtained at 100 MHz in hexadeuteriobenzene.

For the dideoxy compound **13a**, the chemical shifts (τ values) were 7.10, 6.48, 8.2–8.6, 8.2–8.6, 5.06, 4.91, 6.81, 5.73, 5.93, 8.27, 8.31, and 8.25 for H_1, H_1', H_2, H_2', H_3 (axial), H_4, H_5, H_6, and H_6', and three acetoxy groups, respectively. First-order coupling constants could be established employing spin decoupling; namely, 11.5, 11.5, 3.6, 4.9, 2.0, 9.5, 9.5, 4.9, 2.5, and 12.0 for $J_{1,1'}$, $J_{1,2}$, $J_{1,2'}$, $J_{1',2'}$, $J_{3,4}$, $J_{4,5}$, $J_{5,6}$, $J_{5,6'}$, and $J_{6,6'}$, respectively.

For the trideoxy compound **14a**, the chemical shifts were 6.93, 6.28, 5.27, 6.66, 5.74, 5.85, 8.22, and 8.19 for H_1, H_1', H_4, H_5, H_6, H_6', and two acetoxy groups, respectively. The first-order coupling constants that could be determined were 11.0, 10, 3.7, 4.3, 2.0, 1.4, 10.0, 5.0, 2.7, and 12, for $J_{1,1'}$, $J_{1,2}$, $J_{1,2'}$, $J_{1',2}$, $J_{1',2'}$, $J_{1',3'}$, $J_{4,5}$, $J_{5,6}$, $J_{5,6'}$, and $J_{6,6'}$, respectively.

Compound **13a** was deacetylated to provide a crystalline product (**13b**) m.p. 79–80° (lit. (9), 76–77°), $[\alpha]_D$ = 14.0° (*c*, 1 in water). Deacetylation of **14a** gave a sirup (**14b**) b.p. 62–63° (0.7 mm), $[\alpha]_D^{25}$ = 40° (*c*, 0.6 in water). The n.m.r. spectra in deuterium oxide were in complete agreement with the assigned structures. In the case of **13b**, the signals of H_6 and $H_{6'}$ were at τ 5.96 and 5.78 and $J_{6,6'}$ = 12.0, $J_{5,6}$ = 5.7, $J_{5,6'}$ = 2.4 Hz were estimated. For **16b**, the signals for H_6 and $H_{6'}$ were at τ 6.02 and 5.80; $J_{6,6'}$ = − 12.0, $J_{5,6}$ = 6.0, and $J_{5,6'}$ = 2.7 Hz were estimated.

The 4,6-*O*-ethylidene derivatives of **13b** and **14b** were prepared in the usual manner using 1,1-dimethoxyethane in the presence of *p*-toluenesulfonic acid. The product (**15**), obtained from **13b**, was purified by preparative gas chromatography using a silicone rubber on Chromosorb column (15 ft × 1/4 in. diam.) at 175°. The n.m.r. spectrum required high purity and the assigned structure. Its optical rotations in the variety of solvents are presented in Table III.

The product **16**, obtained from **14b**, was crystallized in ethyl acetate–petroleum ether and has m.p. 55–56°. The n.m.r. spectrum required the assigned structure and its optical rotation in a variety of solvents are listed in Table III.

Acknowledgments

The authors are indebted to the National Research Council of Canada for generous support

of this research through Grant T-172 to R.U.L. and to the Corn Products Research Foundation for additional financial assistance. The n.m.r. spectra were provided by this Department of Chemistry under the supervision of G. Bigam. Mrs. E. Fraga provided valuable technical assistance.

Substitutional and solvation effects on conformational equilibria. Effects on the interaction between opposing axial oxygen atoms[1]

R. U. LEMIEUX AND A. A. PAVIA[2]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received May 5, 1969

Evidence based both on nuclear magnetic resonance and rotation data primarily obtained from methyl 3-deoxy-β-L-*erythro*-pentopyranoside and a number of its derivatives is interpreted to show that the electrostatic repulsion between the oxygen atoms at the 2 and 4 positions is substantially less when these oxygens are linked to acyl groups than when in the form of either methyl ethers or as hydroxyl groups hydrogen bonded to solvent. Also, experimental evidence is presented which requires the hydrogen bridge between two axially disposed hydroxyl groups to be substantially strengthened by hydrogen bonding of the free hydroxyl by solvent.

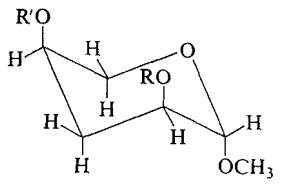
The purpose of this communication is to report on substitutional and solvation effects on chair–chair conformational equilibria which involve in one conformation an interaction between two oxygen atoms in opposing axial orientation. Profound effects are noted which have an important bearing on the notion that so-called non-bonded interaction free energies can be assigned to such interactions without reference to the kind of compound or to the conditions of the experiment.

As seen in Table I, the coupling constants estimated for the di-*O*-acyl derivatives (**1***b*, **1***c*, and **1***d*) of methyl 3-deoxy-β-L-*erythro*-pentopyranoside (**1***a*) require these compounds to exist largely in the C-1 conformation which has both the acyloxy groups in axial and opposing orientation. That this situation is maintained for solvents of such diverse polarity and chemical nature as carbon tetrachloride, chloroform, acetonitrile, and water in the case of the diacetate is particularly interesting. In all cases, appreciable (0.5–1.7 Hz) long range coupling was observed for the equatorial $H_{5'}$ and related by spin-decoupling to a hydrogen at the 3-position and expected to be the equatorial $H_{3'}$. This coupling together with the small chemical shift between H_3 and $H_{3'}$ [deshielding of H_3 by the methoxy group (1)] supports the evidence provided by the coupling constants that the compounds are in the chair conformation indicated.



1

a R = R′ = H
b R = R′ = CH_3CO
c R = R′ = *p*-$O_2NC_6H_4CO$
d R = R′ = CH_3SO_2
e R = R′ = CH_3
f R = Ac; R′ = CH_3
g R = H; R′ = CH_3

The main driving force for the compounds **1***b* to **1***d* to adopt the C-1 conformation must be the anomeric effect (2) which favors the axial orientation for the methoxy group. The *gauche* interaction between the C-1 and C-2 substituents in the alternate (1-C) conformation must also be important (3) in this regard, especially for the dimesylate **1***d*. Since the compounds **1***c* and **1***d* maintain the C-1 conformation in dimethylsulfoxide as well as in chloroform and this is also the case for the diacetate **1***b* when dissolved either in deuterium oxide or deuteriochloroform; it is abundantly clear that the preference for the C-1 conformation is not appreciably affected by the dielectric constant of the solvent. An electrostatic attraction between the acyloxy groups could be invoked to explain these results. However, a consideration of molecular models indicates this to be a highly improbable event for 1,3-diaxially disposed acyloxy groups. Most likely, the C-1 conformation is largely adopted because of a weak repulsion which does not effectively oppose

the non-bonded interactions in the alternate chair. The main interaction between the oxygen atoms in opposing axial orientation must be coulombic repulsion between the unshared pairs of electrons. As will be seen below, these repulsions appear minimized by the presence of strongly electron attracting substituents such as are the acyl groups in compounds **1***b* to **1***d*.

Examination of the nuclear magnetic resonance (n.m.r.) data reported in Table I reveals that, in all solvents studied, the repulsion between the two methoxy groups in compound **1***e* is sufficiently large to effectively overcome the non-bonded interactions in the 1-C conformation. This follows from the magnitudes of the coupling constants of hydrogens in *trans*-relationship on the pyranose ring ($J_{1,2}$, $J_{2,3'}$, and $J_{3',4}$). Thus a substantial increase in the repulsion between the oxygen atoms in axial orientation exists for this compound as compared to those of the di-*O*-acyl analogs unless this change substantially reduces the anomeric effect and the repulsion between the 1- and 2-substituents in *gauche* relationship. This latter possibility is not likely in view of the results obtained for compound **1***f* wherein the 2-substituent is acetoxy and the 4-substituent is methoxy. As for compound **1***e*, the conformational equilibrium favors the 2,4-diequatorial conformer in carbon tetrachloride, a solvent of low dielectric constant. However, in water, the 2,4-diaxial conformer is preferred for **1***f* as is clearly evident from the magnitudes of the coupling constants $J_{1,2}$, $J_{4,5}$, and $J_{4,5'}$. It is known that water has a special ability to weaken the anomeric effect (2). Nevertheless, these results appear best explained by a more *evident* stabilization of a weak coulombic repulsion between an axial acetoxy and an opposing axial methoxy group than when both groups are methoxy and the repulsion is greater. We, therefore, contend that the more electron-rich oxygen atoms of the methyl ether groupings exert a stronger repulsion than that between the relatively much more electron deficient ether oxygens of the acyloxy group when these oxygens are in opposing axial orientation. This conclusion found strong support in the following observations on the solvent effects on the conformational equilibria for the compounds listed in Table II.

The n.m.r. data in Table II require that the diol **1***a* favors the C-1 conformation in solvents which do not form strong hydrogen bonds with the hydrogens of the hydroxyl groups. However, the engagement of these hydroxyl groups in hydrogen bonds with strong proton-accepting solvents such as pyridine, dimethylsulfoxide, and water leads to predominance of the 1-C conformation. This is evident both from the changes in the magnitudes of the coupling of H_1 with H_2 and of the rotations of the solutions (Table III).

It is not possible to arrive at precise knowledge of the equilibria for this conformational change

in the various solvents. Nevertheless, for purposes of discussion, it is of interest to compare the n.m.r. and rotation data on the assumption that the compound is totally in the C-1 conformation in D_2O. On this basis, the fraction of the compound in the 1-C conformation in each of the solvents is calculated as shown in Table III. The excellent agreement between the estimates based on the n.m.r. and rotation data (4) requires the interpretation attached to these data. Furthermore, following Brewster's rules for the calculation of rotations for methyl glycopyranosides (5), the rotation of **1***a* in the C-1 conformation is expected to be 205° and that in the 1-C conformation, 155° and these values are in close correspondence to the molar rotations found in $CDCl_3$ (210°) and in D_2O (140°). It is known (2) that changes in solvent can affect the magnitude of the contributions made by the methoxy group through changes in the relative contributions of the asymmetric conformation units that arise from rotation about the C_1 to OCH_3 bond. These changes, however, are not so large as to obscure the present conclusions that, in contrast to the acylation of the hydroxyl groups of **1***a*, the engagement of both the hydroxyl groups in strong intermolecular hydrogen bonds depletes the C-1 conformation which has the two oxygen atoms in axial orientation.

It is not reasonable to expect the ability of a proton-accepting solvent to destabilize the C-1 conformation to be related to space demand by the solvent molecules hydrogen bonded to opposing axial hydroxyl groups since the resulting complex should not be more space demanding than, for example, the mesyl group. Instead, we propose that the hydrogen bonding of both hydroxyls with solvent (ROH- -S) increases the negative charge on the oxygen atoms through polarization of the O—H bond (RO←H←S) to such an extent that the repulsion of the C—O bond dipoles in opposing axial orientation becomes adequately large to force the compound from the 1-C to the C-1 conformation. It is, of course, not possible to know what the effect of two non-hydrogen bonded hydroxyl groups would be. Clearly in non-basic solvents such as chloroform, the C-1 conformation is stabilized by an intramolecular hydrogen bridge (6) and this intramolecular hydrogen bond will undoubtedly form in the absence of conditions (such as in dimethylsulfoxide and water) which compel intermolecular hydrogen bonding. The following studies of the effect of adding dimethylsulfoxide to solutions of **1***a* in ethylene chloride on the conformational equilibria require that the repulsion between two opposing axial hydroxyl groups be greater because of their external hydrogen bonding than that hypothetical situation wherein both such external solvation and intramolecular hydrogen bonding are absent.

The n.m.r. data in Table II for **1***g* in carbon tetrachloride require the compound to be largely in the C-1 conformation which has the 2- and 4-substituents in axial orientation. This conformation must also be preferred in ethylene chloride. The 1-C conformation is required for **1***g* in dimethyl sulfoxide in view of $J_{1,2} = 6.0$ Hz.

The breaking of the intramolecular hydrogen bond between the C_2—OH and the C_4—OCH_3 groups in methyl 3-deoxy-4-*O*-methyl-β-L-*erythro*-pentopyranoside (**1***g*), which helps maintain the compound in the C-1 conformation when dissolved in dry ethylene chloride, by addition of dimethylsulfoxide, leads to a decrease in specific rotation as seen in Fig. 1. This decrease in rotation is in good agreement with that expected from Brewster's rules for a change in the conformational equilibrium favoring the C-1 conformation in ethylene chloride to that favoring the 1-C

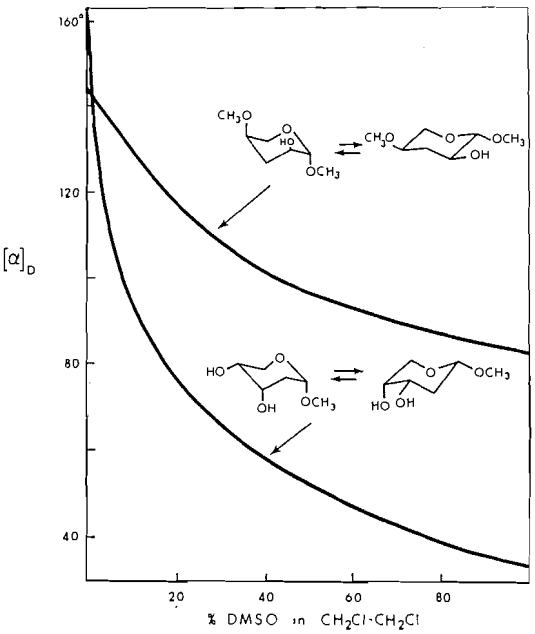

FIG. 1. Effect of increasing concentration of dimethylsulfoxide on the specific rotations at 25° of solutions (about 1%) of methyl 4-*O*-methyl-3-deoxy-β-L-*erythro*-pentopyranoside and of methyl 2-deoxy-α-D-*erythro*-pentopyranoside in ethylene chloride.

conformation in dimethylsulfoxide, the conclusion reached through the n.m.r. studies. It is therefore evident that the repulsion between the C_4—OCH_3 group in axial orientation with the C_2-hydroxyl hydrogen bonded to dimethylsulfoxide is sufficiently strong to require the 1-C conformation as was the case for the di-*O*-methyl derivative (**1***e*). Methyl 2-deoxy-α-D-*erythro*-pentopyranoside behaved in a similar manner and the shapes of these curves are as expected for such phenomena. It may be noted at this point that the pronounced initial changes in rotation on adding dimethylsulfoxide to a solution of the latter compound render this compound interesting as a probe for the study of hydrogen bonding phenomena. It is envisaged, for example, that competition of this compound with other alcohols for dimethylsulfoxide in the range of 2 to 5% in ethylene chloride as measured by the changes in rotation will yield a new approach to the establishment of relative strengths of hydrogen bonds with dimethylsulfoxide or other proton acceptor. These possibilities are under investigation.

The plots shown in Fig. 2 for the effect on rotation of adding dimethylsulfoxide to solutions of the diols shown in ethylene chloride are of extreme importance to this investigation. For the reasons already outlined, the initial numerical increases in rotation are assigned to an increase of that conformation which has the two hydroxyl groups in axial and opposing orientations. This type of plot was also observed in this laboratory for methyl 3-*O*-methyl-β-L-xylopyranoside and for 1,2,3-trideoxy-D-*erythro*-hexopyranoside and seems general for β-diol structures for which intramolecular hydrogen bonding is effective in solvents like ethylene chloride or carbon tetrachloride but which assume an alternate conformation in dimethylsulfoxide wherein both hydroxyls are bonded to solvent.[3] A detailed discussion of this phenomena is reserved for a forthcoming publication (7) where the relative effects of *para* substitution on pyridines used as bases will be described together with thermodynamic analyses of temperature effects. The general conclusions reached confirm the conclusion that at low (~7 moles of dimethylsulfoxide per mole of diol at 1% concentrations of diol) concentrations of dimethylsulfoxide the intramolecularly hydrogen bonded form is at higher concentrations than in pure ethylene chloride. We conclude this behavior to arise from a strengthening of the hydrogen bridge through hydrogen bonding of the remaining free hydroxyl. This result is in line with the above-made contention that the engagement of the hydrogen of an hydroxyl group in a hydrogen bond with a base results in a polarization of the H—O bond in the direction of the oxygen atom. Thus, the oxygen atom becomes a relatively better hydrogen acceptor in hydrogen bond formation. Also, it is at once apparent why the dipole interaction between two opposing axial hydroxyl groups both bonded to solvent is substantially greater than when both the hydroxyl groups are acylated by electron withdrawing acyl groups. These observations likely have a

[3]The data presented in Figure 2 for 1,2-*O*-isopropylidene-β-D-sorbopyranose was the first observation of this phenomenon in experiments by D. Detert in collaboration with R. U. Lemieux and J. A. Mills. A further point of interest was the observation that, for the diol the coupling constant for H_3 and OH_3 was 7.6, 6.5, and 5.0 Hz in 10% v/v, 40% v/v dimethylsulfoxide-d_6-benzene-d_6 mixtures and in dimethylsulfoxide-d_6, respectively. In contrast, H_5 and OH_5 were coupled by 5.0, 5.5, and 6.0 Hz, respectively. The high coupling of H_3 with OH_3 at the lowest concentrations of dimethylsulfoxide indicates that it is the OH_3 proton which is involved in the hydrogen bridge between O_3 and O_5 in the C-1 conformation where the 3-hydroxyl hydrogen defines a dihedral angle of 180° with H_3.

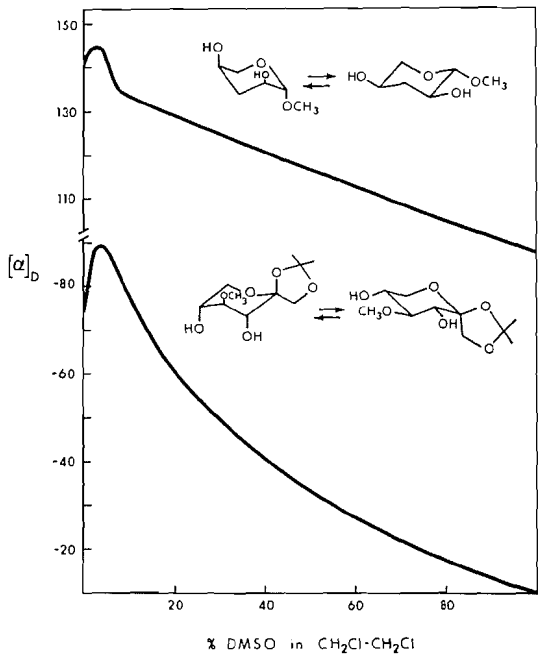

FIG. 2. Effect of increasing concentration of dimethylsulfoxide on the specific rotations at 25° of solutions (about 1%) of methyl 3-deoxy-β-L-*erythro*-pentopyranoside and of 1,2-*O*-isopropylidene 4-*O*-methyl-β-D-sorbopyranoside in ethylene chloride.

bearing on such facts as the A-value of the hydroxyl group being larger in deuterium oxide (1.25 kcal/mole) than in carbon tetrachloride (1.0 kcal/mole) and greater in both cases to the A-value of the acetoxy group (0.66 kcal/mole) (8). Also, the repulsion between the hydroxyl groups in *trans*-1,2-cyclohexanediol appeared to increase when the solvent was changed from deuteriochloroform to deuterium oxide (3). The greater preference for the anomeric hydroxyl group of aldopyranoses to occupy the equatorial rather than the axial orientation on changing the solvent from pyridine to water is probably at least in part a result of changes in the dipoles about the anomeric center as a result of the hydrogen bonding of the hydroxyl group with the solvent. As seen in Table III, such equilibria are more sensitive to the chemical nature of the solvent than on the dielectric constant. Similar specific solvation effects were demonstrated to influence the magnitude of the anomeric effect (2).

As a result of these studies, we conclude that meaningful conformational analyses involving non-bonded interactions between atoms which have unshared pairs of electrons will require a consideration of the substituents on these atoms either as chemically bonded groups or as solvates whether or not these substituents are sterically disposed for appreciable interaction. Furthermore, we contend to have gained evidence that the polarizations which occur as a result of an hydroxyl group becoming hydrogen bonded to a proton acceptor render the oxygen atom a better proton acceptor for hydrogen-bond formation. Such *hydrogen-bond conjugation* can conceivably be of importance as a force which originates in an anionic center for the organization of macromolecules into specific conformations as are known to exist for proteins and nucleic acids. Certainly, the results require the proton-accepting power of a solute in aqueous solution to be extended by this *hydrogen-bond conjugation* to influence the structure of the water beyond its immediate environment.

Experimental

The optical rotations were measured with an automatic Perkin Elmer 141 polarimeter using a thermostatted 10 cm tube. The solvents were purified by distillation and stored over Linde 4A molecular sieve. All solutions were made up and handled using syringes under strictly anhydrous conditions. The experimental points from which the curves in Figs. 1 and 2 were drawn did not deviate from the values provided by the width of line presented and were highly reproducible.

The preparations and further characterizations of the compounds **1***a* to **1***g* are reported in a separate communication (9). The 1,2-*O*-isopropylidene-4-*O*-methyl-β-D-sorbopyranose (Fig. 2) was prepared as described by Ohle and Just (10). The pure material melted at 118–119°, $[\alpha]_D$ −74° (*c*, 1 in ethylene chloride).

Received April 3, 1969

Tetrakis-(*p*-dimethylaminophenyl)-ethylene (**1**) dissolved in benzene and a small amount of acetic acid is oxidized by air and in time sets to a gel. The reaction products are formaldehyde, formylated and demethylated substances, peroxides, and there is evidence for the formation of polymeric peroxides. The latter are believed to bring about the gelation. The oxidation of **1** is autocatalyzed by a complex between oxygen and **1** in the presence of acetic acid.

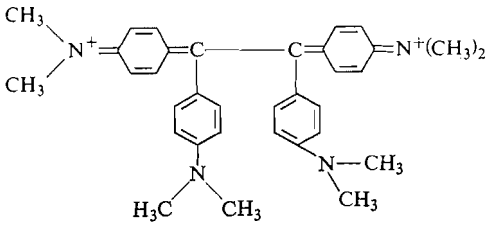
Canadian Journal of Chemistry, 47, 4447 (1969)

Introduction

Tetrakis - (*p* - dimethylaminophenyl) - ethylene (**1**) can be oxidized by two one-electron transfers by a variety of reagents such as chlorine, silver nitrate, ferric chloride, and lead tetraacetate to the dication (**2**). Buckles and Meinhardt (1) have made a careful study of the halogen arylated ethylene complexes and have established the ionic character of these complexes. In non-aqueous solvents, **1** and iodine undergo a reversible one-electron transfer to produce a cation radical (2,3). In aqueous solvents, **1** and iodine afford the diiodide.

$$[(CH_3)_2NC_6H_4]_2C = C[C_6H_4N(CH_3)_2]_2$$

1



2

The air oxidation of **1** has been examined by the present authors, using a variety of chemical and physical techniques, and with consistent results. It is felt that the results are pertinent to the work of Conant and Bigelow (4) in which they have shown that the associated free radicals (the ethane) from *sym-p,p'*-tetramethyldiaminohexaphenylethane and *p,p,p',p'*-octomethyltetraminohexaphenylethane on exposure to oxygen decompose with the evolution of formaldehyde. It is also felt that the present results are pertinent to the extensive work carried out by Horner and co-workers (5). The latter work has been discussed by Walling (6). Again it may be that the air oxidation of **1** is relevant to what has been shown for the oxidation of the electron rich *N,N,N',N'*-octamethyltetraminoethylene (**3**), (7).

Experimental

Tetrakis-(p-dimethylaminophenyl)-ethylene (1)

This material was prepared according to Willstätter and Goldman (8) and was purified by three recrystallizations from benzene.

Oxidation of 1

A solution of 4.0 g of **1** in 200 ml of benzene and 20 drops of acetic acid was allowed to stand in air at room temperature and in the absence of light for 48 h. At the end of this time the reaction mixture had become a green gel which was broken up with a stirring rod, washed with benzene, filtered, and air-dried to give 3.0 g of solid material A. On standing the solid became black and evolved formaldehyde which was collected in water and characterized as the dimedon derivative, m.p. 193–194°. A mixture melting point with an authentic sample of the dimedon formaldehyde derivative showed no depression. No satisfactory solvent was found for the purification of A. The black product A has been known to evolve formaldehyde for long periods of time (up to 2 mos).

Anal. Found for sample A: C, 76.20; H, 6.64; N, 9.48; O, 7.60.[1]

A second preparation gave a sample, B, which was air-dried for 1 week, was green in color, and evolved formaldehyde, in air, dried over phosphorous pentoxide.

Anal. Found for sample B: C, 74.90; H, 6.57; N, 11.03; O, 8.09.[1]

Many oxidation experiments were carried out and attempts to perform the experiment in the absence of air or acetic acid, and in the presence of octyl alcohol instead of acetic acid, afforded no gel and no change in color of the solution. Also, no gelation occurred when ionol, an inhibitor of free radical chain reactions, was added to the system benzene, acetic acid, and olefin **1**. However, ionol did not inhibit the air oxidation of **1**, in glacial acetic acid, to the dication. Addition of potassium bromide to the glacial acetic acid oxidation mixture afforded a good yield of $\mathbf{1}^{++}\ 2Br^-$. Oxidation in glacial acetic acid was relatively slow, compared with oxidation in the system benzene–acetic acid.

Hydrolysis and Infrared Spectroscopy of Product B

Sample B showed strong infrared (i.r.) absorption at 1670 cm^{-1}. Sample B (5 g) was refluxed with 150 ml of 10% sulfuric acid for 16 h to afford 0.0067 mole of formic acid, identified by a Duclaux distillation and recovered from the first 50 ml of distillate. The peak at 1670 cm^{-1} in the i.r. had decreased to approximately 26% of the original and further refluxing decreased the peak slightly.

Reaction with Raney Nickel

Product B and its hydrolysis derivative from the above experiment were insoluble in the common organic solvents. However, both materials dissolved and no significant change occurred in the i.r. absorption spectra, when they were suspended in isopropyl alcohol and refluxed with Raney Nickel W-2 catalyst (9).

Mass Spectra

A sample of B was examined with a mass spectrometer (A.E.I. type MS9) with a source temperature of 270° and ionizing voltage of 70 eV. Sharp peaks were found at *m/e* 448, 462, 476, 490, 504, 518, 532, 546, and 560. Examination of the 476 and 532 peaks with high resolution indicated the formulas, $C_{31}H_{32}N_4O$ and $C_{33}H_{32}N_4O_3$, respectively. The original olefin had a single strong peak at *m/e* of 504 and a weak peak at *m/e* of 490.

Optical Spectra

Compound **1** (0.8 g) was dissolved in benzene (100 ml) and acetic acid (10 drops) was added. The solution was kept in the dark and exposed to air. Examination of the aliquots taken at various time intervals showed no change in the intensities of the main absorption bands at 300 mμ ($\varepsilon = 48\,750$) and 375 mμ ($\varepsilon = 25\,000$) over a period of 31 h. However, a hypsochromic shift in the absorption became discernable after 23 h and became definite after 31 h, at which time the absorption occurred at 295 mμ and 365 mμ. After 47 h gelation occurred and the supernatant liquid showed maxima at 293 mμ and 360 mμ.

The above experiments were repeated with dilute solutions of **1** and under conditions of controlled oxidation. The olefin (50 mg) was dissolved in benzene (10 ml) and the solution was swept with purified nitrogen. Acetic acid (3 drops) was added and the spectrum shown in Fig. 1, curve *1* was obtained. The solution was now saturated with oxygen for 0.5 h and curve *2* resulted. Curve *3* was obtained by flushing the cell with oxygen for 1.5 h. At this point the cell was sealed and after 35 min curve *4* resulted. Curve *5* was obtained after 17 h and resaturation of the solution with oxygen restored the spectrum of curve *3*. Curve *6* is the spectrum of a solution of the diiodide of **1** in benzene and acetic acid. Pentane was added to the solution corresponding to curve *5* and this afforded a solid which showed formanilide structure in the i.r. spectra. Omission of acetic acid in the above experiment gave a very wide band from 525 mμ to 650 mμ, and of very low intensity, and which we believe is an olefin, oxygen charge transfer band.

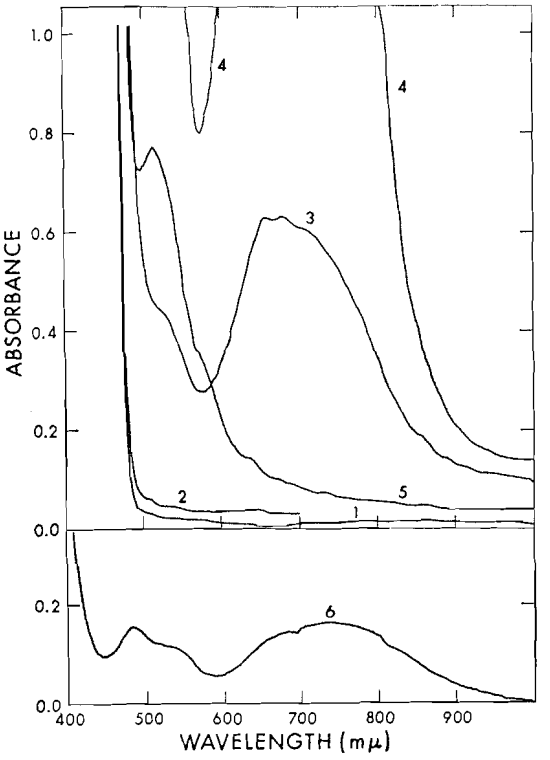

FIG. 1. Absorption spectra: (*1*) compound **1** (50 mg) in benzene (10 ml) and acetic acid (3 drops) and under nitrogen; (*2*) solution swept with oxygen for 0.5 h; (*3*) solution saturated with oxygen (after 1.5 h flushing) and sealed; (*4*) absorption spectrum 35 min after sealing the cell; (*5*) absorption spectrum 17 h after sealing; (*6*) diiodide of **1** (1.38 mg) in benzene (20 ml) and acetic acid (0.5 ml).

Polarographic Studies

In acetonitrile the olefin **1** produced a well-defined anodic wave at +0.25 V vs. saturated calomel electrode (s.c.e.). One gram of **1** was dissolved in 50 ml of benzene containing 5 drops of acetic acid. A 2 ml aliquot taken at zero time when mixed with 15 ml of 0.1 *M* tetrabutylammonium perchlorate, produced no other wave than the anodic wave. After oxidation for 375 min a 2 ml aliquot produced as well as the anodic wave, a mixed anodic cathodic wave at −0.12 V and a much larger cathodic wave at −0.8 to −0.9 V vs. s.c.e. (Fig. 2).

Pyrolysis Experiments

A sample of B was heated to 200° in a sealed tube. Aliquots were chromatographed on a molecular sieve

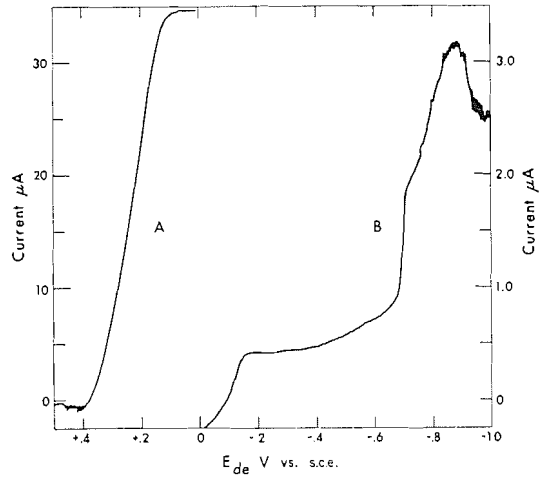

FIG. 2. Polarogram of **1** in 0.1 *M* $(C_4H_9)_4NClO_4$ in acetonitrile and oxidized for 375 min. (*A*) Anodic wave of **1**. (*B*) Waves of peroxides.

(13 × Linde) column. Hydrogen was detected but no other gases.

One gram of **1** was dissolved in 100 ml of benzene and 10 drops of acetic acid added. After standing in the air for 24 h a 5 ml aliquot was withdrawn and mixed with 10 ml of pentane. An i.r. spectrum on the resulting precipitate showed the presence of the formyl group at 1670 cm^{-1}. When the precipitate was heated between 150–200° for 5 min the intensity of the formyl peak increased. Sample B heated on a spatula in a flame burned with a mild explosion.

Oxygen Uptake Experiments

Oxygen uptake was followed manometrically using a Warburg apparatus, Model #66691, made by Precision Scientific Co., Chicago, Illinois. Reaction vessels No. 66703 and manometers No. 66693 were used throughout. A variable induction time was followed by an accelerating rate of oxygen uptake. Furthermore, the oxygen uptake rates were the same for pure oxygen and air, and remained so until near exhaustion of the oxygen in the sealed air reaction vessel. At this point the rate in air fell behind the rate of uptake in the pure oxygen containing vessel (Fig. 3). It is to be noted that in the pure oxygen, over 200 μmoles of oxygen have reacted with only 118 μmoles of **1**, implying secondary reactions (see Discussion). When catechol was added to the system no oxygen uptake occurred. When the acetic acid was reduced to a 1:5 mole ratio, the oxygen uptake was very slow. In pure acetic acid, slow absorption of oxygen occurred at a rate corresponding to that of the induction period (see Fig. 4). It was also found that in the latter case oxidation to the dication (**2**) had occurred and the oxidation corresponded quantitatively to the uptake of oxygen. Also, no evidence of the oxidation of methyl groups could be detected by i.r. analysis. At concentrations of acetic acid comparable to that of the olefin (**1**), the rates of oxygen uptake were roughly independent of acid concentration.

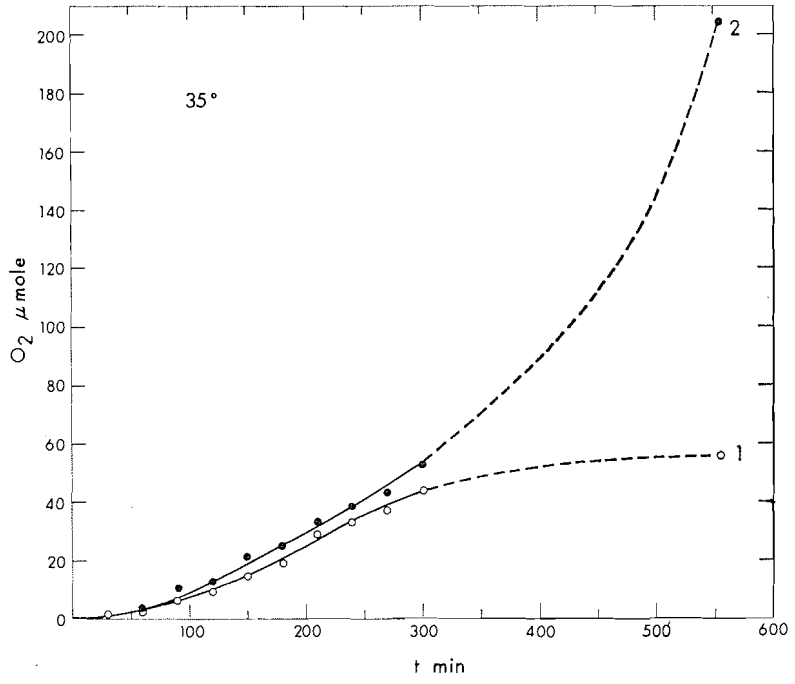

FIG. 3. Oxygen uptake rate: (*1*) olefin **1** (119 μmole) and acetic acid (64 μmole) in 2.8 cm^3 benzene and in air; (*2*) olefin **1** (199 μmole) and acetic acid (64 μmole) in 2.8 cm^3 benzene and in oxygen. All temperatures at 25°.

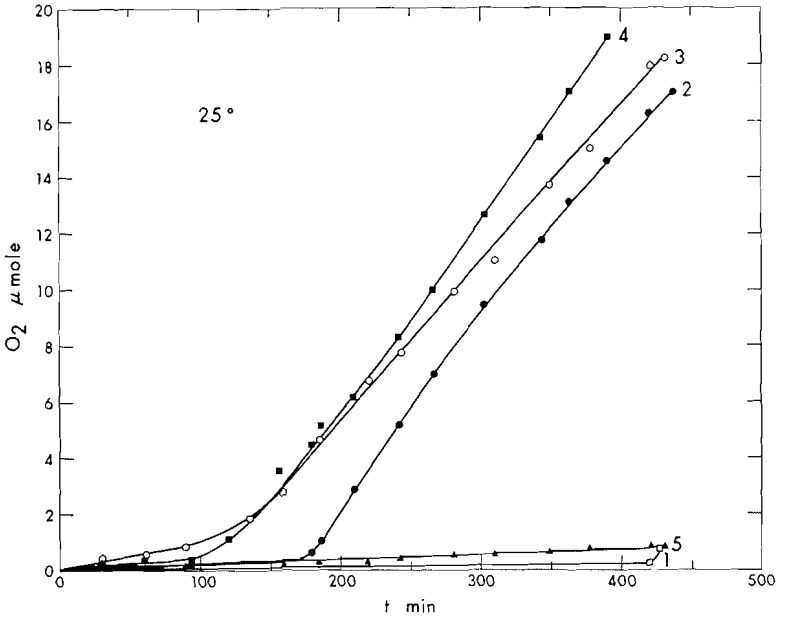

FIG. 4. Oxygen uptake rate: olefin **1** in different amounts of acetic acid and in 2.8 cm³ benzene: (*1*) acetic acid (24 μmole) in air; (*2*) acetic acid (94 μmole) in air; (*3*) acetic acid (140 μmole) in air; (*4*) acetic acid (94 μmole) in oxygen; (*5*) pure acetic acid (44 mmole) in air. All temperatures at 25°.

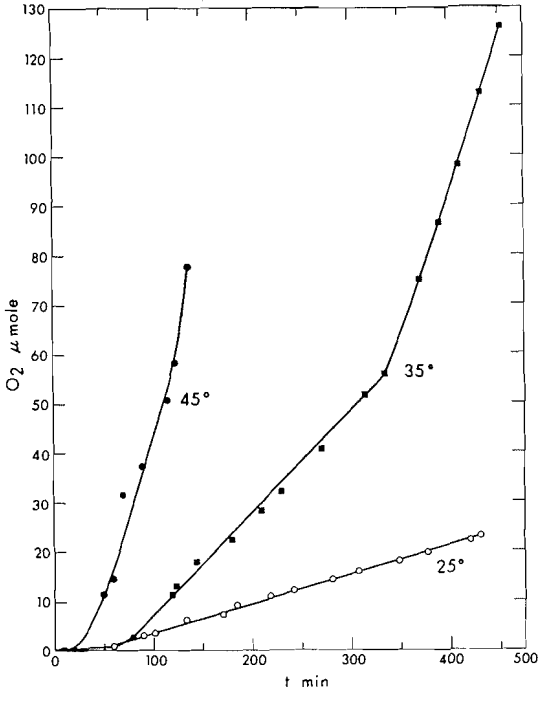

FIG. 5. Oxygen uptake at different temperatures. Olefin **1** (119 μmole) in acetic acid (71 μmole) and benzene (2.8 cm³) and in air.

The induction periods continued to vary in a disconcerting fashion.

The rates of oxygen uptake were dependent on temperature as shown by the results of Fig. 5. These results show an increasing rate of oxygen uptake at a single temperature and a greater increase in rate between 45° and 35° than between 35° and 25°.

Electron Spin Resonance Spectra

Measurements were made with a Varian Model 4500, fitted with a TE102 100 kc cavity and a 100 kc modulation attachment. Sample B showed electron spin resonance (e.s.r.) absorption to the extent of 1.5×10^{18} spins/g of freshly dried solid. The signal consisted of 2 overlapping lines of widths 31.5 and 12.6 G with g values of 2.0071 and 2.0029, respectively. The number of spins dropped rapidly with time at first but reached a steady state (up to 1 year) at about 3.2×10^{17} spins/g.

In the experiment described under polarography the sample taken at 645 min had 1.4×10^{16} spins/ml. After 1175 min the solution had 2.4×10^{16} spins/ml. After gelation had occurred (2400 min) the supernatant liquid still contained free radicals but less than 2×10^{15} spins/ml.

Nuclear Magnetic Resonance Spectra

Measurements were made with an Hitachi Model R20 nuclear magnetic resonance (n.m.r.) spectrometer at 60 Mc, and tetramethylsilane was used as internal reference. Olefin **1** (0.2 g) was dissolved in C_6D_6 (10 ml) in a 20 ml Erlenmeyer flask and left open to the air. After an aliquot was taken for n.m.r. analysis (*A*) acetic acid (1 drop) was added and aliquots for measurements were taken after

Discussion

The facile air oxidation of **1** in benzene containing a small amount of acetic acid, and which affords a gel, is undoubtedly a free radical chain reaction. This is demonstrated by the independence of the reaction to oxygen pressure, except at very low concentrations of oxygen. The occurrence of definite but variable induction periods, followed by an increasing rate of oxygen uptake, is also suggestive of a free radical chain reaction (Fig. 4). Moreover, the inhibiting action shown by catechol and ionol indicates a free radical chain mechanism.

Formaldehyde is the only reaction product which has been definitely determined. However, the presence of certain functional groups was established. The formanilide group in the solid reaction material was determined by i.r. spectroscopy. There was strong i.r. absorption at 1670 cm^{-1}. The compound formanilide absorbs at 1673 cm^{-1}. The formyl group was also determined as formic acid by a Duclaux distillation. Demethylated products were considered to be present as a direct result of formaldehyde evolution. Moreover, the optical spectra indicated a hypsochromic shift due to demethylation and (or) formylation.

Polarographic studies indicated the presence of the peroxide function. The cathodic wave at -0.8 to -0.9 V vs. s.c.e. corresponds to what would be expected for a hydroperoxide wave (Fig. 2). The lower wave at -0.12 V may be associated with some oxygen complex of **1**, which is also revealed in the visible spectrum (Fig. 1). The present authors believe that some of the peroxide function is involved in a polymeric peroxide structure and that this may possibly account for the gelation which occurs and which is reproducible. An indication of a possible polymeric peroxide structure is the solubilization which occurs with Raney Nickel treatment. This type of polymeric peroxide would be different from previously isolated addition polymeric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

peroxides (10, 11), since it would be a condensation polymeric peroxide. It is significant that no appreciable change occurred in the i.r. absorption spectra with the Raney Nickel treatment. This supports the view that polymer formation and not formylation was responsible for gelation. In this connection it may also be significant that a sample of the supernatant liquid taken after gelation and mixed with pentane afforded a precipitate which showed intense formyl i.r. absorption, and which was more intense than the i.r. absorption for the solid sample B.

The polymer presumably decomposes in the mass spectrometer to afford a series of formylated and demethylated compounds with mass spectra peaks at *m/e* 448, 462, 476, 490, 504, 518, 532, 546, and 560. The compounds $C_{31}H_{32}N_4O$ and $C_{33}H_{32}N_4O_3$, whose formulae were determined by high resolution mass spectrometry might be formulated as **4** or **5** or their isomers.

From the similarity of the optical spectra of **1** to that of the diiodide under the same conditions (Fig. 1 and ref. 2) we favor a similar complex (cation radical) of **1** with oxygen. The *g* values of the e.s.r. signals which are low and at 2.0029 are suggestive of the cation radical of **1** (2). The broader e.s.r. signals at *g* equal to 2.0071, are probably due to radicals with the electron on oxygen rather than carbon, although these values are low for true peroxy or alkoxy radicals (12).

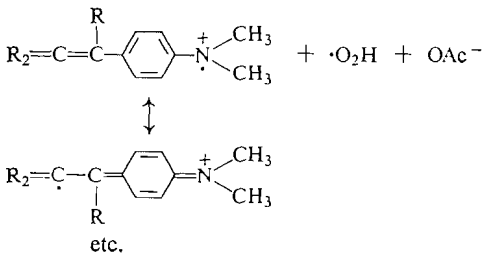
A plausible primary oxidation mechanism involves the formation of a cation radical and is shown by Scheme 1*a* and *b*.

Compound **1** + O_2 ⇄ **1** ..... O_2

1 ..... O_2 + HOAc ⇄ $\mathbf{1}^{\cdot+}$ + $\cdot O_2H$ + OAc^-

SCHEME 1*a*

1 .... O_2 + HOAc ⇄



6

R = $(CH_3)_2NC_6H_4^-$

SCHEME 1*b*

It is possible that the small amount of acetic acid adjusts the polarity in favor of **6** and not the separated ion pair (13). Whatever its nature, **6** (the cation radical) disappears under anaerobic conditions to form oxidation products (Fig. 1). Addition of oxygen brings about the reappearance of **6** and from the time course of the formation of **6** (Fig. 1) the reaction must be autocatalytic.

It is interesting that the formulation of the cation radical of **1** is similar to the structures of the dimethylaminophenyl substituted methyl radicals studied by Conant and Bigelow (4). There must be delocalization of the odd electron of $\mathbf{1}^{\cdot+}$ and interaction with the electrons of the C—H bonds of the side chain to account for the reactivity of the C—H bond and which affords such products as formaldehyde and peroxides.

The n.m.r. spectra (Fig. 6) show that line broadening of the spectra occurred almost immediately upon mixing. This is characteristic of the presence of the cation radical **6** in exchange with the parent compound **1** (14). It is to be noted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

that the presence of free radicals is apparent by the n.m.r. technique much sooner than by the conventional e.s.r. experiment. The broadening of all the n.m.r. signals is suggestive of extensive electron delocalization in the free radical. As the oxidation proceeds, broadening increases up to 24 h for some of the aromatic signals. However, at this time, non-broadened signals due to nonparamagnetic products are apparent. Further developments in this direction are impeded by precipitation of products from solution. This experiment leaves little doubt concerning the formation of the ion radical **6** and that it is a key intermediate in the oxidation of **1**. It is possible that **6** is also the intermediate in the oxidation of **1** in pure acetic acid. The complex $\mathbf{1}^{\cdot+} + \cdot O_2H + OAc^-$ would then become $\mathbf{1}^{++} + O_2H^- + OAc^-$. We conclude therefore that oxidation to the dication or oxidation of side chains depends on the polarity of the system.

The insertion of 4 *p*-phenylene groups into the structure of the electron rich *N,N,N',N'*-octamethyltetraaminoethylene (**3**) gives rise to the structure of compound **1** with lowered electron donor strength. This lowering is indicated by the high degree of reversibility shown in the oxidation of **1** by iodine in non-aqueous solvents, and in which an equilibrium exists between $\mathbf{1}^{++}$, $\mathbf{1}^{\cdot+}$, **1**, and elementary iodine. It is also known that **1** adds two atoms of sodium in ether (15), and thereby shows some acceptor character. Compound **3** does not react with lithium in diethylamine (16).

It is quite probable that the relatively higher electron "richness" of **3** accounts for certain differences in the chemical behavior of **1** and **3**. Compound **3** undergoes auto-oxidation in the presence of protonic compounds, emits chemiluminescence and affords high yields of products which involve a cleavage of the C=C bond (7).

In the present work, no split products such as Michler's ketone have been detected in the solid polymer or in the solid from the filtrate. The oxidation of **1** affords side chain products and the molecular skeleton remains intact. The oxidation of **3** lacks an induction period and is dependent on oxygen pressure (17). The reverse of this is indicated for the oxidation of **1**. Very interesting is the fact that ionol, an inhibitor of free radical chain reactions, is an effective catalyst for the oxidation of **3** in cyclohexane (7). Catechol and ionol, on the other hand, prevent the uptake of oxygen in the system compound **1**, benzene, and acetic acid.

While the oxidation of **1** in benzene and acetic acid is a free radical chain reaction, and the oxidation of **3** in hexane and octanol apparently is not (17), the reactions may resemble each other under certain conditions. Thus, according to Urry and Sheeto (7), when dilute solutions of **3** in decane and octanol at $-25°$, or in dioxane at 0°, are shaken with oxygen, an e.s.r. signal develops in 20 min and remains constant for about 2 h, which implies a steady state of chain carrying radicals. Also, Urry and Sheeto oxidized **3** in methanol-d_4 and found a broadening of the n.m.r. spectrum. This is probably indicative of free radical reactions, although the authors did not comment on this fact. Again, it is interesting that Kuwata and Geske (18) found that strong e.s.r. signals occurred during the controlled potential oxidation of **3**.

We believe that the final oxidation products of **1** involve reactions which are similar to those studied by Horner and his students (5,6). One example of this similarity is the formation of the product $C_6H_5N(CH_3)CH_2OOCH_2(CH_3)NC_6H_5$, which Horner found and investigated, and which on pyrolysis gave rise to hydrogen and formanilide. We have found that the pyrolysis of product B increased the formanilide band in the i.r. and also afforded hydrogen. At this time a discussion of a probable mechanism for side chain oxidation is not warranted. It should be mentioned that Horner *et al.* noted that the auto-oxidation of dimethylaniline initiated by benzoyl peroxide afforded a series of reactions as shown

$$(CH_3)_2N{-}C_6H_5 \xrightarrow{O_2} \text{complex}$$

$$\xrightarrow{O_2} C_6H_5N(CH_3)CH_2OOH \rightarrow C_6H_5NHCH_3 + CH_2O$$

$$C_6H_5N(CH_3)CH_2OOH + H^+ \rightarrow C_6H_5N(CH_3)CH_2OO{-}CH_2(CH_3)NC_6H_5.$$

SCHEME 2

in Scheme 2. Since **1** is polyfunctional with respect to this series of reactions, polymer formation, as indicated by gelation, results.

Acknowledgments

We are very grateful for the continued help and encouragement given to us by Professor Harry Gunning. We appreciate very much the

discussions we have had with Drs. W. A. Ayer, R. J. Crawford, D. Darwish, K. Kopecky, and D. Tanner. We are much indebted to Dr. A. M. Hogg, Mr. A. I. Budd, and Mr. J. Olekszyk for the determinations and interpretation of mass spectra. Thanks are due to Mr. John F. Fryer for the pyrolysis experiments. We acknowledge with thanks the financial aid (R.B.S.) of the National Research Council of Canada.

Etude du comportement thermique de l'alcool diméthyl allylique

CLAUDE ROUX[1] ET FRANÇOISE KATZANEVAS
Institut Français du Caoutchouc, Paris, France

Reçu le 15 mai 1969

Le comportement à la chaleur de certains monométhylbuténols a été étudié, sur les produits chromatographiquement purs, en milieu neutre. Le méthyl-3 butène-2 ol, dont la structure peut être rattachée à celle de l'alcool allylique par substitution, possède un comportement particulier. Il subit, en effet, la déshydratation à partir de 140 °C et conduit à la formation d'isoprène, du dimère et du trimère de ce diène et à un polymère dont la structure est, en majorité, celle du polyisoprène 1,4 et 3,4, la structure 1,4 étant prédominante.

Canadian Journal of Chemistry, 47, 4455 (1969)

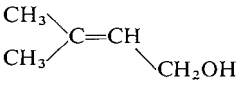
Introduction

Le mécanisme de la biosynthèse du caoutchouc naturel et des isoprénoides met en jeu des pyrophosphates d'alcényle de structure simple: les pyrophosphates de méthyl-3 butène-2 yle et méthyl-3 butène-3 yle.

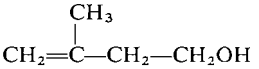
Le premier motif des chaînes polyisopréniques serait alors dû au pyrophosphate de méthyl-3 butène-2 yle et tous les motifs suivants au pyrophosphate de méthyl-3 butène-3 yle (1). Dans un milieu différent un autre mécanisme pouvant être envisagé (2).

Il nous a paru intéressant d'étudier le comportement des alcools insaturés correspondant au radical alcényle des pyrophosphates indiqués et, en particulier, la stabilité thermique en milieu neutre.

Ces deux alcools sont le méthyl-3 butène-2 ol et le méthyl-3 butène-3 ol dont les formules semi-développées:

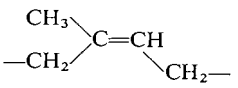


Méthyl-3 butène-2 ol



Méthyl-3 butène-3 ol

mettent en évidence l'analogie partielle de structure avec le motif polyisoprénique unitaire:

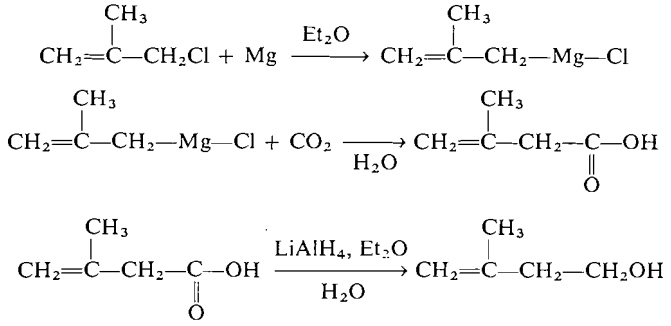


Partie expérimentale

Synthese des Alcools

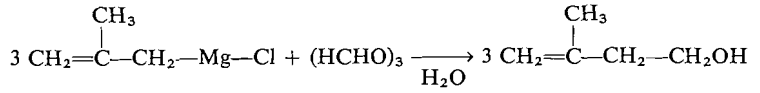
Méthyl-3 butène-3 ol

Cet alcool a été préparé selon la méthode de Lynen *et al.* (3) et d'Eggerer et Lynen (4), avec un rendement voisin de 40% par rapport au chlorure de méthallyle de départ:



[1]Adresse actuelle: Département de Chimie, Université de Montréal, Montréal, Canada.

Pour éviter la réduction par l'hydrure de lithium aluminium, il est possible de traiter le dérivé organomagnésien par le trioxane à ébullition pendant 72 h; on obtient ainsi directement l'alcool après hydrolyse et le rendement est amélioré d'environ 9% par rapport à la réduction.



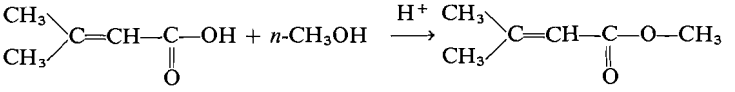
Méthyl-3 butène-2 ol

Trois méthodes ont été utilisées pour la synthèse de cet alcool:

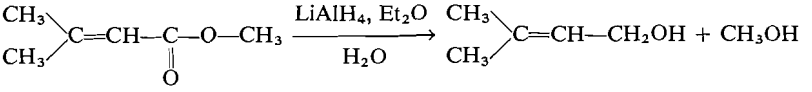
(i) A partir d'acide méthyl-3 butène-2 oique (commercial)

Pour avoir un rendement quantitatif dans un temps raisonnable, il faut tout d'abord sécher l'acide organique parfaitement; on y parvient facilement par extraction azéotropique de l'eau par le benzène; les autres méthodes de dessication ne donnant que des résultats médiocres.

Estérification de l'acide organique par un fort excès de méthanol anhydre en présence d'acide sulfurique en quantité catalytique:



L'ester est ensuite réduit par l'hydrure de lithium aluminium avec un rendement supérieur à celui de la réduction directe de l'acide d'environ 18%.

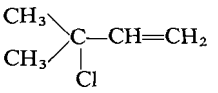


Le rendement moyen sur différentes opérations est de l'ordre de 88% par rapport à l'acide de départ.

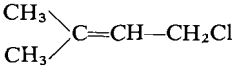
(ii) A partir d'isoprène (Claisen)

L'isoprène peut fixer l'acide chlorhydrique en donnant selon les conditions de température, les deux chlorures suivants:

Vers 0 °C on obtient préférentiellement le chlorure tertiaire:

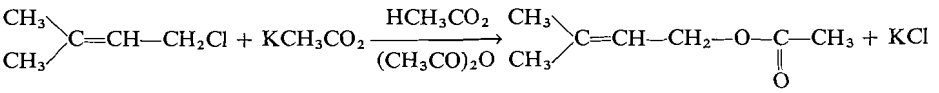


Vers 15–20 °C on obtient préférentiellement le chlorure primaire:



La réaction a été effectuée à partir d'acide chlorhydrique concentré en excès (20% en mole), par simple agitation rapide de l'isoprène et de l'acide aqueux.

Ce chlorure a été transformé en acétate par la méthode préconisée par Halsall et Hands (5).



La saponification de cet ester par la soude dissoute dans le méthanol conduit à l'alcool désiré.

Le rendement par rapport à l'isoprène mis en oeuvre est faible et voisin de 11%.

(iii) A partir de méthyl-2 butène-3 ol-2 (commercial)

Vers −20 °C l'action du tribromure de phosphore sur ce carbinol conduit au bromo-1 méthyl-3 butène-2 et non pas au bromo-3 méthyl-3 butène (6)

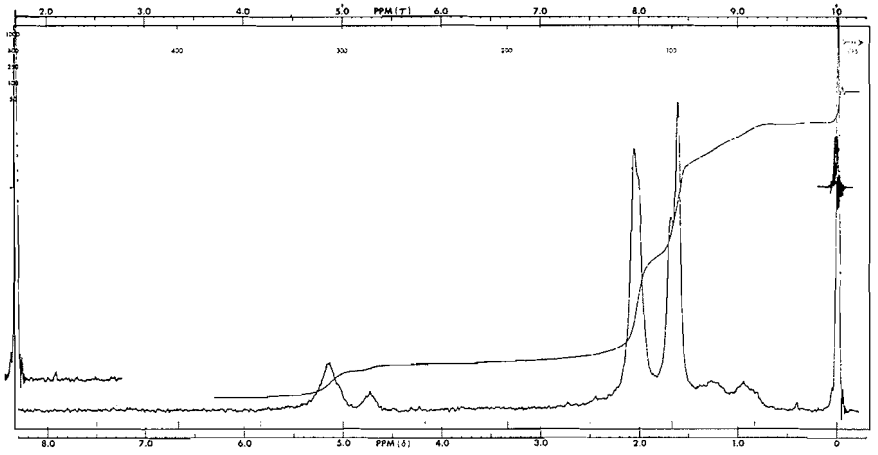

FIG. 1. Spectre r.m.n. du polymère.

Ce bromure primaire traité de la même façon que le chlorure obtenu dans la méthode précédente a fourni l'acétate dont nous avons tiré l'alcool avec des rendements très voisins.

La pureté de ces alcools a été vérifiée par chromatographie en phase gazeuse (c.p.g.) sur une colonne de dix pieds dont la phase liquide stationnaire est constituée de silicones, le gaz vecteur étant l'hélium.

Ces deux alcools avaient été rectifiés plusieurs fois sur colonne à distiller à bande tournante dont l'efficacité théorique est de soixante-dix plateaux.

Les spectres de résonance magnétique nucléaire (r.m.n.) ont été effectués sur appareil Varian A60, en utilisant comme solvant le tétrachlorure de carbone.

Les spectres d'absorption infra-rouge (i.r.) ont été effectués sur appareil Beckmann IR 8, à partir de films de polymère obtenus de solutions.

Les masses moléculaires moyennes en nombre ont été déterminées par tonométrie sur appareil Mechrolab, le solvant utilisé étant soit le chloroforme, soit le benzène.

Les réactions concernant la stabilité des alcools sont faites en tubes scellés, en étuve régulée à ± 1 °C sur les produits purs.

Résultats et Discussion

Il a été constaté que dans des conditions identiques, seul le méthyl-3 butène-2 ol subissait une transformation.

Parmi les produits de la réaction, il a été possible d'isoler les mélanges ou corps suivants, certains identifiés par comparaison avec des témoins en c.p.g. et spectrographie i.r.:

(*a*) de l'eau;

(*b*) un mélange de deux diènes (p.e.$_{760}$ 35–40 °C), dont l'un est de l'isoprène;

(*c*) un mélange des alcools suivants: méthyl-3 butène-2 ol non réagi et méthyl-3 butène-3 ol (p.e.$_{760}$ 128–136 °C);

(*d*) un mélange de deux hydrocarbures (p.e.$_{760}$ 178–182 °C) de formule $(C_5H_{10})_n$ non identifié, mais pouvant correspondre à une dimérisation de l'isoprène ($n = 2$);

(*e*) un liquide (p.e.$_{50}$ 178–180 °C) pouvant correspondre à un trimère ($n = 3$);

(*f*) des traces d'un corps à odeur terpénique très prononcée;

(*g*) un polymère solide.

Parmi les deux diènes, l'un est l'isoprène, l'autre ne peut être, par élimination–déduction, que du méthyl-3 butadiène-1,2 ou diméthylallène dissymétrique (à partir du méthyl butane on ne peut déduire que deux diènes, l'un conjugué, l'autre cumulé).

L'étude en r.m.n. du polymère obtenu a donné les résultats suivants: analogie avec un polymère obtenu par polymérisation thermique de l'isoprène (7). La fig. 1 représente le spectre r.m.n. de ce polymère.

En spectrographie i.r. (7), la même analogie a été constatée. La fig. 2 représente le spectre i.r. de ce polymère.

Les masses moléculaires moyennes en nombre Mn, obtenues à différentes températures de réaction sont données dans le tableau I.

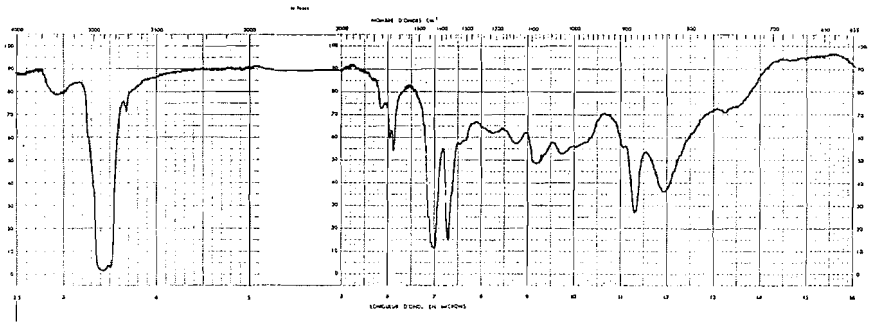

FIG. 2. Spectre i.r. du polymère.

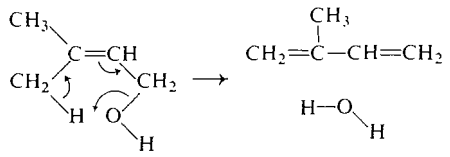
Mécanisme

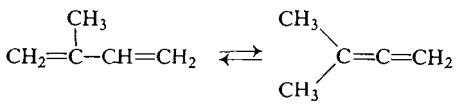
Pour expliquer la déshydratation de cet alcool, en milieu neutre, l'hypothèse de réarrangement de l'alcool primaire en alcool tertiaire fut envisagée: la facilité de déshydratation des alcools augmente avec la substitution (8). Cette hypothèse fut abandonnée après vérification que le carbinol correspondant (méthyl-2 butène-3 ol-2) ne subissait pas la déshydratation dans les mêmes conditions.

Dans cette réaction qui peut être qualifiée de *Thermique* (en effet, seule l'énergie thermique intervient), l'hypothèse d'un transfert électronique (9) n'est pas à rejeter; elle donne une représentation assez concrète de la réaction, un transfert à six centres pouvant être envisagé:



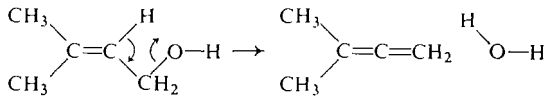
La présence supposée de méthyl-3 butadiène-1,2 (en mélange avec l'isoprène, structure du polymère obtenu) pourrait être attribuée:

(i) Soit à une isomérisation qui a été constatée,



mais dans d'autres conditions (10).

(ii) Soit à une déshydratation du méthyl-3 butène-2 ol, selon un autre mécanisme, peut-être moins favorisé que le transfert à six centres, et qui serait à quatre centres.



Conclusion

De ces deux alcools, seul celui de structure allylique subit la déshydratation dans les conditions indiquées.

L'étude du comportement des autres isomères se poursuit, en particulier celle du méthyl-2 butène-2 ol dans lequel la double liaison carbone–carbone occupe la même position que dans le méthyl-3 butène-2 ol.

Steroids and steroidases. IX.[1] Activation parameters and the mechanism of base- and enzyme-catalyzed isomerizations of androst-5-ene-3,17-dione. The nature of the active center of the $\Delta^5 \rightarrow \Delta^4$-3-ketosteroid isomerase of *Pseudomonas testosteroni*[2]

J. Bryan Jones and Donald C. Wigfield

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 5, Ontario

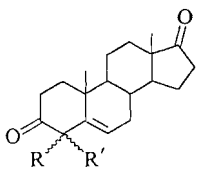
Received May 28, 1969

Determination of the activation parameters for the acid-, base-, and enzyme-catalyzed isomerizations of androst-5-ene-3,17-dione has revealed that the facility of the enzymic process is mainly due to an extremely low enthalpy of activation of 5.0 kcal mole^{-1}. Further circumstantial evidence regarding the nature of the reacting groups at the active center has also been obtained, and a mechanism of enzyme action is proposed employing tyrosine and histidine as the principal amino acids responsible for catalyzing the isomerization.

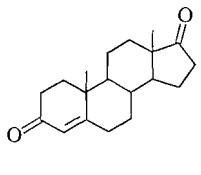
Canadian Journal of Chemistry, 47, 4459 (1969)

Introduction

The $\Delta^5 \rightarrow \Delta^4$-3-ketosteroid isomerase of *Pseudomonas testosteroni* is, at the present time, probably the most intensively studied of the enzymes of steroid metabolism, particularly from the mechanistic viewpoint (1). One of the reasons for the interest in this enzyme is that it is the most active yet discovered, having a molecular activity of 16.7×10^6 for the isomerization of androst-5-ene-3,17-dione (**1**) to androst-4-ene-3,17-dione (**2**). The rate of enzymic isomerization is several orders of magnitude greater than those of the related acid- or base-catalyzed processes, and in order to gain an insight into the reasons for the vastly greater efficiency of the enzymic isomerization, the determinations of the activation parameters for the 3 types of catalyses were undertaken.



1



2

Experimental

Compounds

The criteria of purity applied, the methods and analytical instrumentation used, specifications of the chromatographic supplies, solvents, etc. were as described previously (2).

*Androst-5-ene-3,17-dione (**1**, R,R′ = H)*

This compound was prepared by a Pfitzner–Moffatt oxidation of 3β-hydroxy-androst-5-en-17-one (2).

*4,4-Dideuterioandrost-5-ene-3,17-dione (**1**, R,R′ = D)*

Androst-5-ene-3,17-dione (100 mg) in methanol-*d* (1.5 ml) was heated under reflux for 36 h. The solution was then concentrated to half-volume by rotary evaporation at 20° and on cooling the resulting solution to −20°, deuterated androst-5-ene-3,17-dione (65 mg) crystallized out. Thin-layer chromatographic (t.l.c.) and infrared (i.r.) analyses showed traces only of isomerized androst-4-ene-3,17-dione contaminants. Deuterium elemental analysis[3] indicated 4.80 atom% excess of deuterium which corresponds overall to 80% exchange of two hydrogen atoms. From the relative intensities of the mass spectral peaks at *m/e* 286, 287, 288, and 289 respectively, the deuterated androst-5-ene-3,17-dione sample was estimated to consist of unchanged starting material **1** (R,R′ = H) (8.9%); **1** (R = H,R′ = D) (25.2%); the required dideutero compound **1** (R,R′ = D) (63.2%); and a trideutero compound (2.8%). That the main exchange had occurred at C-4 and not elsewhere in the molecule was confirmed by the kinetic isotope effect of 4.1 observed for the acid-catalyzed isomerization reaction.

Phenolic Compounds

2-, 3-, and 4-Hydroxypyridine, phenol, and *p*-nitrophenol were obtained commercially (Aldrich or B.D.H.) and were recrystallized to constant melting point and until each sample showed only a single spot on t.l.c. analysis.

3,4-Dinitrophenol

This compound was prepared by nitration of *m*-nitrophenol (2.5 g) with 6 *N* nitric acid (3). Separation of the desired product from 2,3-dinitrophenol and 2,5-dinitrophenol was achieved by the fractional crystallization procedure recommended (3). Chromatography of

the product so obtained on Florisil with benzene – ether (1:1) elution yielded 3,4-dinitrophenol, pale yellow needles from benzene (0.45 g) m.p. 133–134° (lit. (3) m.p. 134°); i.r. ($CHCl_3$) ν_{max} 3597 and 1344 cm^{-1}.

Imidazole (Eastman White Label)

This compound was recrystallized twice from benzene prior to use to give needles m.p. 89.5–90°.

General Isomerization Kinetics Procedures

All isomerizations and treatment of data[4] were carried out as described previously (4). As before all runs were carried out at least twice and the reproducibility was ±3% except for the variable temperature enzyme catalyzed reactions. For the latter the errors were within the limits ±6%.

Base-catalyzed Isomerizations of Androst-5-ene-3,17-dione by Aqueous Sodium Hydroxide Solutions of Varying pH

A 40% (w/v) stock solution of sodium hydroxide in CO_2-free distilled water was prepared and was then stored in an air-tight polyethylene bottle. Successive dilutions of this solution with CO_2-free distilled water gave solutions with p*H* within the desired range of 10.5–12.0. To avoid the involvement of activity coefficients the p*H* of each solution was determined directly with a p*H* meter. Kinetic data were obtained with 3.0 ml reaction volumes of the following composition: aqueous sodium hydroxide solution of known p*H* (2.95 ml), methanolic 0.05% androst-5-ene-3,17-dione solution (0.05 ml). Absorbance measurements were taken against a control cuvette containing no steroid.

The pseudo first order rate constants calculated for the various p*H* values are recorded in Table I.

C-4 Deuterium Kinetic Isotope Effect for Base-catalyzed Isomerizations of Androst-5-ene-3,17-dione

Kinetic data were obtained as described above using an aqueous sodium hydroxide solution of p*H* 10.0 as the catalyst. The pseudo first order rate constants for androst-5-ene-3,17-dione and the deuterated sample containing 63.2% of 4,4-dideuterioandrost-5-ene-3,17-dione were 0.148 and 0.046 min^{-1} respectively.

Determinations of the Activation Parameters for the Acid-, Base-, and Enzyme-catalyzed Isomerizations of Androst-5-ene-3,17-dione

Acid- and base-catalyzed isomerization studies were carried out on solutions composed of 2.95 ml of aqueous hydrochloric acid p*H* 0.88, or 0.05 *M* Tris[5] – HCl buffer solution p*H* 8.82, respectively, to which was added 0.05 ml of an 0.05% methanolic androst-5-ene-3,17-dione solution. Rates were measured at ~5° intervals between 15 and 40°. The enzyme-catalyzed reactions were studied as described previously (4) and the initial isomerization rates were determined at ~5° intervals in the range 15–30°. All temperatures were measured with a U.S. National Bureau of Standards thermometer and are accurate to within ±0.03°; a correction was made for the small temperature differential between the thermostatted bath and the reaction cell jacket.

For the acid- and base-catalyzed isomerizations, the pseudo first order rate constants obtained were converted to the appropriate second order rate constants using the p*H* of the solutions as a guide to the respective hydrogen ion and hydroxide ion concentrations. The relative initial rates of enzymic isomerization were converted to the respective first order rate constants using the value of 16.7×10^6 for the molecular activity[6] of the isomerase at 25° (1). The relevant data are quoted in Table II. Arrhenius plots gave good straight lines in each case and the activation parameters were calculated by the standard methods (5, 6) and are recorded in Table III.

Catalysis by Hydroxypyridines, Phenols, and Imidazole

The data on the effect of 2-, 3-, and 4-hydroxypyridine, phenol, *p*-nitro-, and 3,4-dinitrophenol, and of imidazole on the isomerization of **1** (R,R′ = H) to **2** were obtained with 3.0 ml reaction volumes made up of 0.05 *M* Tris – HCl buffer solution p*H* 8.58 (2.90 ml) containing the catalyst (0.14 μmole ml^{-1}) and methanolic substrate solution (0.81 μmole ml^{-1}; 0.10 ml). The pseudo first order rate constants k'_{cat} describing the net effect of the catalysts were obtained by subtraction of the rate constant of the uncatalyzed isomerization determined under the same conditions. The results are summarized in Table IV.

Results and Discussion

A prerequisite to any meaningful comparison of the acid-, base-, and enzyme-catalyzed processes is a knowledge of the rate determining step for each isomerization pathway.

The mechanism of the acid-catalyzed isomerization of Δ^5-3-ketosteroids has been studied by Nes and his co-workers (7) who showed the reaction to be first order with respect to both steroid and to hydrogen ion concentrations, and by Malhotra and Ringold (8) who observed a primary deuterium kinetic isotope effect of 4.1 when the C-4 hydrogen atoms of the substrate were replaced by deuterium. These data support the mechanism proposed (8) in which protonation of the C-3 carbonyl group is followed by rate determining loss of a C-4 hydrogen during the enolization step. The enzyme catalyzed isomerization was similarly shown to proceed with rate

[4]Typical sets of data for each type of isomerization condition are recorded in the Ph.D. thesis of D. C. Wigfield, University of Toronto, 1967.

[5]Tris(hydroxymethyl)aminomethane.

[6]The molecular activity (16.7×10^6) can be regarded as the first order rate constant for the rate determining step of the formation of products from the enzyme-**1** (R,R′ = H) complex at 25° at p*H* 7.0 (1). The arbitrary first order rate constants k' obtained at various temperatures were converted to the true relative rate constants k by multiplication by $16.7 \times 10^6/k'_{25°}$.

For personal use only.

determining C-4β proton loss,[7] the deuterium kinetic isotope effect being 5.35 (8).

Analogous mechanism of action studies had not been carried out on the base-catalyzed reaction partly due to the complications of multiple product formation encountered initially (7). However the subsequent delineation of satisfactory conditions for base-mediated isomerizations (4) enabled a mechanistic study of the process to be carried out.

The previous data on base isomerizations of androst-5-ene-3,17-dione (**1**, R,R′ = H) and other Δ^5-3-keto steroids, had demonstrated a first order dependence on the steroid concentration (4). In order to determine the order of reaction with respect to the hydroxide ion, the p*H* dependence of the pseudo first order rate constant for androst-5-ene-3,17-dione isomerization was determined. Aqueous sodium hydroxide solutions, rather than buffer solutions of the same p*H*, were used in order to avoid any possible influence by the components of the buffer. The data obtained are summarized in Table I. The restriction of the p*H* range studied to 10.61–11.72 was dictated by two factors: at p*H* values > 12.0 the half-life of the reaction (~10 s) was too small for accurate measurements to be made and at p*H* < 10.0, the possibility of multiple product formation existed. A plot of $\log_{10}k'$ against p*H* gave a straight line (Fig. 1) of unit slope, thus showing the reaction to be first order with respect to the hydroxide ion. Thus both the acidic and basic catalytic processes are second order overall.

The next aspect of the base catalysis mechanism considered was the identification of the rate determining step. While it might have been anticipated that, in common with the acid- and enzyme-catalyzed reaction, this would be loss of a C-4 proton during enolization, it was obviously necessary to establish this point before attempting a comparison of the three processes. For this purpose, 4,4-dideuterioandrost-5-ene-3,17-dione (**1**, R,R′ = D) was required. The method which had proven satisfactory for C-4 deuteration of 17β-hydroxyandrost-5-en-3-one, *viz.* heating the Δ^5-3-ketone in D_2O–diglyme (8), caused extensive isomerization of **1** to **2** before deuteration at C-4 was sufficiently complete.[8] This difficulty was obviated by deuteration of **1** (R,R′ = H) in methanol-*d* under reflux. That the sample obtained was predominantly (63.2%) the dideuterated compound **1** (R,R′ = D) was established by the deuterium elemental and mass spectral analytical results, and by the deuterium kinetic isotope effect of 4.1 observed for the acid catalyzed isomerization reaction. These data are in excellent agreement with those reported by

TABLE I

Rates of isomerization of androst-5-ene-3,17-dione as a function of p*H**

p*H*	k' (min^{-1})

11.02	0.79
11.28	1.3
11.55	2.8
11.72	3.5

*All measurements taken at 25° with a steroid concentration of 0.03 μmole ml^{-1} using aqueous sodium hydroxide solutions of appropriate p*H*.

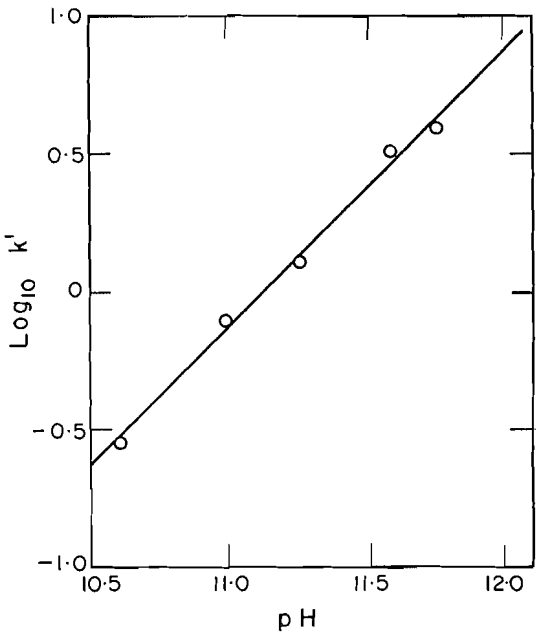

FIG. 1. Plot of $\log_{10}k'$ against p*H* for the base-catalyzed isomerization of androst-5-ene-3,17-dione.

[7]Disappointingly, the data on the stereospecificity of proton abstraction, mechanism of action etc. for mammalian isomerases (9–11) do not parallel those established for the *P. testosteroni* enzyme.

[8]Torgov and his co-workers have also reported isomerization to be a problem in this solvent mixture (11).

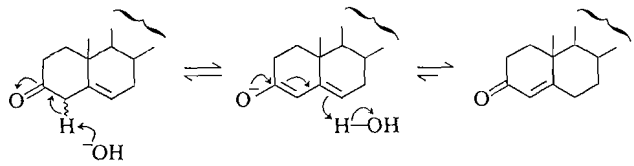

FIG. 2. The mechanism of base-catalyzed isomerization of Δ^5-3-ketones.

Malhotra and Ringold (8) for the analogous 17β-hydroxy substrates.[9]

The k_H/k_D ratio observed for the base-catalyzed isomerizations of **1** (R,R′ = H) and **1** (R,R′ = D) was 3.2 thus establishing that, as for the acid and enzyme reactions, loss of the C-4 hydrogen atom is the rate determining step. The initial runs were carried out in Tris – HCl buffer solutions of p*H* 8.82 (which provided an optimum rate of reaction for measurement purposes) and the data obtained indicated that deuterium–hydrogen exchange prior to isomerization might be occurring at a significant rate. Re-examination of the isomerization in aqueous sodium hydroxide solution of p*H* 10.0 confirmed this view and when the results were treated in the usual first order manner, a plot was obtained that curved upwards until eventually a straight line was obtained whose slope was equal to that observed previously for the isomerization of the non-deuterated substrate. The effect of this competitive C-4 deuterium exchange reaction was minimized by taking readings every few seconds for the first 3 min of the reaction. The first order plot based on such measurements afforded a relatively straight line from which the kinetic isotope effect value of 3.2 was obtained. The fact that this value is slightly smaller than the 4.1 obtained for the acid-catalyzed process is probably due, at least in part, to our inability to eliminate completely the effect of the C-4 exchange process. The total data are consistent with the mechanism proposed in Fig. 2. Removal of a C-4 hydrogen by a hydroxide ion gives the enolate anion which can reprotonate either at C-4 to regenerate the starting material, or at C-6 to give the product. In view of the observed facility of the deuterium exchange process, it seems likely that the intermediate enolate anion may pick up a proton at C-4 and C-6 with comparable ease. At first sight this result might seem to contradict the results of Ringold and Malhotra (8, 12) who have shown that in *t*-butyl alcohol, the enolate anion preferentially reprotonates at C-4 whereas the neutral enol selectively picks up a hydrogen atom at C-6 under conditions of kinetic control. However in the present work the enolate anion was generated in aqueous solution in which it would be expected to be better solvated, and hence more stable, than in *t*-butyl alcohol.

In order to determine the activation parameters for the isomerizations catalyzed by acid, base, and enzyme, the rates were measured at various temperatures. The acid- and base-catalyzed rates of isomerization of androst-5-ene-3,17-dione were measured at 5° intervals between 15 and 40°, and the pseudo first order rate constants obtained were converted to the corresponding second order rate constants by dividing by the hydrogen ion and hydroxide ion concentrations[10] respectively. The corresponding measurements on the enzyme-catalyzed reaction were carried out in the temperature range 15–30°. At temperatures greater than 30° the enzyme began to show the effects of heat denaturation. That such inactivation was a reversible process was demonstrated by keeping the enzyme at 40° for 30 min, and then reassaying it at 25°. No detectable loss of activity was apparent. The

[9]The deuteration patterns of the substrates used by Malhotra and Ringold (8) and in this investigation are very similar, thus enabling direct comparisons to be made of the kinetic isotope effects observed in this and the previous (8) investigation. In neither study have the k_H/k_D values been corrected for the presence of non-C-4 deuterated species in the samples assayed.

[10]These were calculated from the p*H* of the reaction solution. 0.05 *M* Tris – HCl buffer p*H* 8.82 was used as the base-catalyst since the range of isomerization rates was optimized at this p*H* (aqueous sodium hydroxide solution of the same p*H* could not be used since multiple product formation was observed under such conditions (4)). The catalytic effects of the components of the buffer solution on the rate of reaction were not taken into account. This is not considered to affect the validity of the data since (*a*) the buffer used was a dilute one and (*b*) the comparison of dilute Tris – HCl and sodium hydroxide solutions as catalysts in the isomerization and deuterium exchange experiments of **1** (R,R′ = D) showed them to be indistinguishable in their activities.

relative rate constants obtained from the rate data were converted to true first order rate constants using the value of 16.7×10^6 obtained by Talalay (1) for the molecular activity of the enzyme with androst-5-ene-3,17-dione as the substrate.

The results are summarized in Table II from which it is seen that the relative rates of isomerizations catalyzed by acid, base, and enzyme are in the approximate ratio 1:700: 1.7×10^7. This demonstrates very dramatically the efficiency of the enzyme relative to the chemical catalysts.

The activation parameters for the three processes were calculated from the appropriate Arrhenius equations. The Arrhenius plots all gave good straight lines (Fig. 3) and the values of the various parameters[11] are recorded in Table III.

From these results it is clear that the great

[11]A preliminary account of these results has been published (13).

§Reference 17.

facility of the enzymic process is mainly due to its extremely low enthalpy of activation of 5.0 kcal mole^{-1}. This low value indicates that the C-4β-H bond cleavage in the rate determining step is accompanied by an energetically compensating bond formation. This is in accord with the mechanism proposed by Malhotra and Ringold (8) (Fig. 4). The entropy of activation of −16.8 e.u. is also consistent with this type of mechanism since the rate determining step involves charge development in the transition state.

Attention was then directed towards further attempts to identify the acidic and basic groups at the active center. As was recently pointed out (4), the fluorescence (1) and nitration (14) results of Talalay and his co-workers and data on 17-deoxy-substrates (4) make the phenolic group of a tyrosine residue an attractive candidate for the acidic group designated as HA. In order to assist in evaluating the validity of this suggestion, the catalytic effects of various phenols, particularly those of the hydroxypyridine type found to be so effective in catalyzing glucose mutarotation (15), were measured. The results, which are summarized in Table IV, showed that the

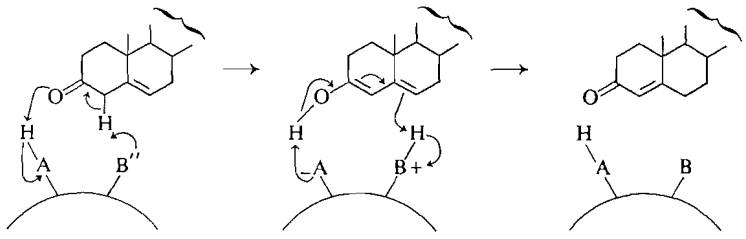

FIG. 4. Mechanism of isomerase action proposed by Malhotra and Ringold (8).

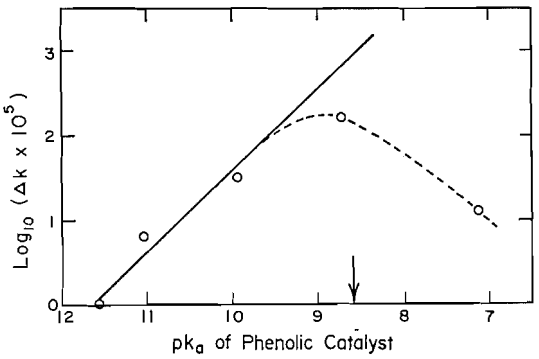

FIG. 5. Brønsted catalysis plot for the phenol-catalyzed isomerizations of androst-5-ene-3,17-dione. The arrow indicates the pH of the Tris – HCl buffered reaction medium.

catalytic effects were small and indicated that the isomerization was subject to general acid catalysis by phenols. A plot of the logarithm of the rate constants against the pK_a of the phenols (Fig. 5) showed that the Brønsted catalysis law was obeyed, provided that the proportion of the phenol present as the conjugate base was not significant. When the rate constants, corrected for the proportions of the phenolic catalysts present as the conjugate bases at pH 8.58, were used in the Brønsted law calculations, a linear plot was again obtained and its slope of 0.67 confirmed that the isomerization was relatively sensitive to general acid-catalysis by phenols.[12] No special rate accelerations ascribable to the bifunctional nature of the hydroxypyridines were detected, and the effects of the ring nitrogen atoms were manifested only in their overall influence on the pK_a of the compound.

The above results thus indicate that a phenolic group can assist in the isomerization of Δ^5-3-ketones but that phenolate anions are insufficiently powerful bases to act as general base-catalysts (cf. ref. 18). These data are thus consistent with the postulate (4) that the phenolic group of a tyrosine residue may well be the acidic group responsible for full or partial protonation of the carbonyl group of the substrate during enzyme-catalyzed isomerization.

[12]Although the linearity of such a plot is strongly indicative of predominant general acid-catalysis, a referee has correctly pointed out that variable pH and concentration studies would be required before it could be unequivocally stated that the contribution of general base-catalysis to the overall rate was insignificant.

With regard to the nature of the basic catalytic group B (Fig. 4), the body of evidence pointing to the presence of an imidazole group of a histidine residue at the active center is substantial (1, 14). In fact Talalay (1) has proposed an elegant mechanism in which he suggested that the imidazole group could act as the complete protonating–deprotonating unit responsible for the hydrogen transfer. Whether or not the geometry of the transition states involved would be favorable to such a situation is open to debate and our analysis, based on the use of Dreiding models, suggests that although the initial removal of the C-4 proton could occur as proposed by Talalay, the subsequent transfer of this hydrogen to C-6 would require considerable puckering of the steroid skeleton. Furthermore, since such a mechanism represents an essentially bimolecular reaction in contrast to the termolecular situation implied in the Malhotra and Ringold postulate (Fig. 4), imidazole itself should be capable of at least partial simulation of the enzymic process by acting as a bifunctional catalyst.[13] That imidazole, alone or mixed with phenol, is in fact (Table IV) not a very effective catalyst would appear to weigh against the Talalay mechanism. We feel that it is more probable that the imidazole group of the active center histidine is in fact the basic group responsible for the removal of the C-4 proton and its subsequent transfer to C-6, and the mechanism we consider to be most consistent with all the present and previous data (1, 4, 8, 14) is shown in Fig. 6. The involvement of both a tyrosine phenolic group (pK_a ~ 10–11 (19)) and a histidine imidazole function (pK_a ~ 6–7 (19)) as the catalytic groups, rather than the imidazole residue alone, is further supported by the pH-activity profile of the enzyme (1) which shows a flat maximum in the pH range 6–9. The decrease in activity at pH > 9 can be rationalized in terms of this mechanism, since the increasing predominance of the phenolate anion as the pH is increased, would correspondingly reduce the contribution to the overall catalytic process made by the carbonyl protonation step. However, obviously several other equally valid rationalizations for the effect of high pH on the enzyme can be put forward.

Experiments involving substrate analogues

[13]This would again be analogous to the hydroxypyridine catalysis of the mutarotation of glucose (15).

designed to react irreversibly with the basic or nucleophilic amino acid residues of the active center are in progress, and it is hoped that the data obtained will help to clarify the roles of histidine and tyrosine in the enzymic process, and also provide information on their orientation with respect to rings A and B of the substrates.

Synthesis of olivomycose (2,6-dideoxy-3-*C*-methyl-L-*arabino*-hexose)

E. H. WILLIAMS, W. A. SZAREK, AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received July 10, 1969

Oxidation of methyl 4,6-*O*-benzylidene-2-deoxy-α-L-*arabino*-hexopyranoside (**1**) with ruthenium tetroxide gave the 3-ketone **2** in high yield. A Wittig reaction between methylenetriphenylphosphorane and compound **2** gave methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-*C*-methylene-α-L-*erythro*-hexopyranoside (**3**), which was hydrated by the oxymercuration–demercuration procedure to afford methyl 4,6-*O*-benzylidene-2-deoxy-3-*C*-methyl-α-L-*arabino*-hexopyranoside (**4**). The reaction of compound **4** with *N*-bromosuccinimide gave methyl 4-*O*-benzoyl-6-bromo-2,6-dideoxy-3-*C*-methyl-α-L-*arabino*-hexopyranoside (**5**) in high yield. Treatment of compound **5** with lithium aluminium hydride followed by acid-catalyzed hydrolysis of the resultant product, gave L-olivomycose (**6**).

L'oxydation par le tétroxyde de ruthénium du méthyl 4,6-*O*-benzylidène-2-désoxy-α-L-*arabino*-héxopyranoside (**1**) conduit avec un très bon rendement à la cétone **2**. Une réaction de Wittig entre le composé **2** et le méthylènetriphénylphosphorane donne le méthyl 4,6-*O*-benzylidène-2,3-didésoxy-3-*C*-méthylène-α-L-*érythro*-héxopyranoside (**3**), qui par hydratation par la réaction d'oxymercuration–démercuration donne le méthyl 4,6-*O*-benzylidène-2-désoxy-3-*C*-méthyl-α-L-*arabino*-héxopyranoside (**4**). Par réaction de **4** avec la *N*-bromosuccinimide on obtient avec un trés bon rendement le méthyl 4-*O*-benzoyl-6-bromo-2,6-didésoxy-3-*C*-méthyl-α-L-*arabino*-héxopyranoside (**5**). Le traitement de **5** avec l'hydrure de lithium et d'aluminium conduit, après hydrolyse acide du mélange réactionnel, au L-olivomycose (**6**).

Canadian Journal of Chemistry, **47**, 4467 (1969)

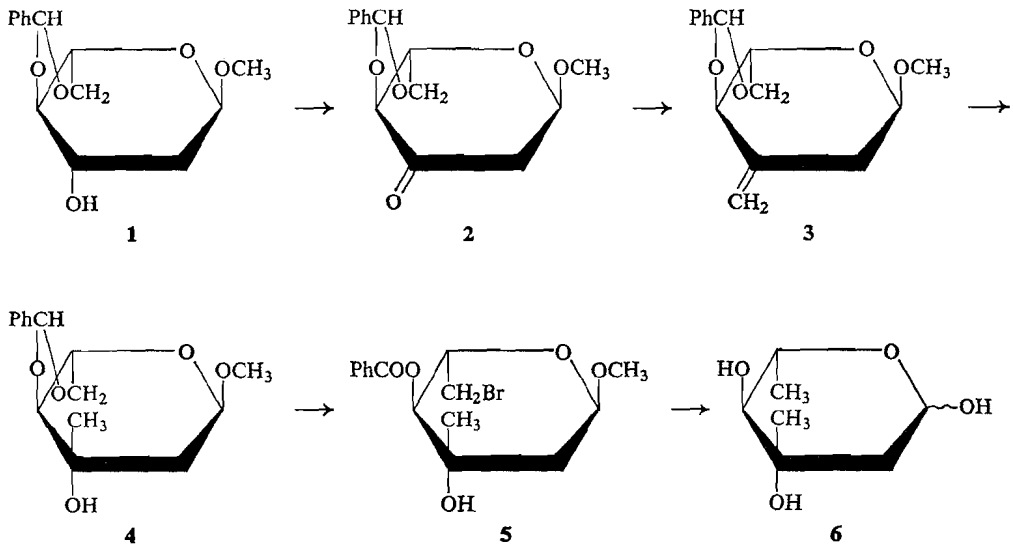
Introduction

Olivomycose is a branched-chain sugar which occurs as its 4-*O*-acetyl and 4-*O*-isobutyryl derivatives in olivomycin, a mixture of antibiotics produced by *Streptomyces olivoreticuli* (1). The 4-*O*-acetyl derivative is a component also of the carcinostatic antibiotic chromomycin A_3, and has been named chromose B (2). On the basis of nuclear magnetic resonance (n.m.r.) and chemical evidence, the structure of 2,6-dideoxy-3-*C*-methyl-L-*arabino*-hexose (**6**) was assigned to olivomycose; the sugar is, therefore, epimeric with L-mycarose at C-3. Syntheses of DL-epimycarose from non-carbohydrate precursors have been reported (3). We describe now the preparation of the L-enantiomer from 2-deoxy-L-*arabino*-hexose, a synthesis which corroborates the structure and stereochemistry previously assigned to olivomycose.

Results and Discussion

2-Deoxy-L-*arabino*-hexose, commonly known as 2-deoxy-L-glucose, can be prepared from 3,4,5,6-tetra-*O*-acetyl-1,2-dideoxy-1-nitro-L-*arabino*-hex-1-enitol by the method of Sowden and Fischer (4), which involves selective hydrogenation of the ethylenic bond, using palladium black as catalyst, and acid hydrolysis of the *aci*-salt of the resultant 1,2-dideoxy-1-nitroalditol (Nef reaction). In the present work two modifications of this procedure were employed; the double bond in 3,4,5,6-tetra-*O*-acetyl-1,2-dideoxy-1-nitro-L-*arabino*-hex-1-enitol was selectively reduced with sodium borohydride (5), and the de-*O*-acetylated product was converted into 2-deoxy-L-*arabino*-hexose by oxidative denitration with potassium permanganate (6). Methyl 2-deoxy-α-L-*arabino*-hexopyranoside was prepared from the free sugar, by the method described by Hughes *et al.* (7) for the D-enantiomer, and then treated with benzaldehyde and zinc chloride to give methyl 4,6-*O*-benzylidene-2-deoxy-α-L-*arabino*-hexopyranoside (**1**) (8).

Oxidation of compound **1** with ruthenium tetroxide, according to the improved procedure of Lawton *et al.* (9), afforded methyl 4,6-*O*-benzylidene-2-deoxy-α-*erythro*-hexopyranosid-3-ulose (**2**) (8) in 84% yield. The D-enantiomer of the 3-ketone **2** has been prepared from methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*arabino*-hexopyranoside using chromium trioxide in pyridine (10), ruthenium tetroxide (11), and methyl sulfoxide – acetic anhydride (12) as oxidants; a 90% yield of the ketone was reported with the last procedure. In our hands, however, treatment of compound **1** with methyl sulfoxide – acetic anhydride gave an approximately 1:1 mixture of **2** and another compound; the two components



could be separated by chromatography on silica gel, with 3:7 ethyl acetate – chloroform as eluent. The new compound was formulated as methyl 4,6-*O*-benzylidene-2-deoxy-3-*O*-(methylthio)-methyl-α-L-*arabino*-hexopyranoside on the basis of spectroscopic and chemical evidence. Its n.m.r. spectrum in chloroform-*d* showed a 2-proton singlet at τ 5.18 that may be assigned to the protons of an —OCH_2S— group, and a 5-proton multiplet in the region τ 7.5–8.1 that may be assigned to an *S*-methyl group and the two protons at C-2. Treatment with mercuric chloride and cadmium carbonate in aqueous acetone regenerated the starting compound **1**. The formation of (methylthio)methyl ethers, by treatment of carbohydrate derivatives with methyl sulfoxide – acetic anhydride, has been reported previously (13).

It has been shown (8) that addition of methylmagnesium iodide to methyl 4,6-*O*-benzylidene-2-deoxy-α-L-*erythro*-hexopyranosid-3-ulose (**2**) is highly stereoselective giving predominantly the axially-oriented tertiary alcohol (Fig. 1*a*). In compound **2** attack by the Grignard reagent from the side resulting in the formation of the axial alcohol is sterically more favorable than attack from the side resulting in the formation of the equatorial alcohol; considerable steric interaction would be expected between the attacking species and the axial methoxyl group at C-1 in the latter route. The addition product was converted then into L-mycarose (2,6-dideoxy-3-*C*-methyl-L-*ribo*-hexose) (8). L-Olivomycose is epimeric with L-mycarose at C-3. Brown *et al.* (14) have reported that the hydration of many cyclic and bicyclic olefins by the oxymercuration–demercuration procedure gives predominantly the tertiary alcohol formed by addition of water to the tertiary center from the less hindered side. The procedure provides a convenient route to isomeric alcohols epimeric with those obtained from a Grignard synthesis, since the addition of alkyl Grignard reagents to related ketones gives predominantly the tertiary alcohol formed by addition of the alkyl group from the less hindered side. Thus, application of the oxymercuration–demercuration procedure to methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-*C*-methylene-α-L-*erythro*-hexopyranoside (**3**) afforded methyl 4,6-*O*-benzylidene-2-deoxy-3-*C*-methyl-α-L-*arabino*-hexopyranoside (**4**) in 72% yield (see Fig. 1*b*). The branched-chain unsaturated sugar **3** was obtained by the reaction of methylenetriphenylphosphorane with the 3-ketone **2** according to the procedure described by Lance and Szarek (15). The infrared (i.r.) spectrum of compound **4** in carbon tetrachloride ($c < 0.005$ *M*) showed strong absorption at 3640 cm^{-1}, unlike the spectrum of methyl 4,6-*O*-benzylidene-2-deoxy-3-*C*-methyl-α-D-*ribo*-hexopyranoside (10), which showed strong absorption at 3538 cm^{-1}. The low O—H stretching frequency observed for the latter compound was considered to indicate the presence of 1,3-diaxial, hydrogen-bonded interaction (16).

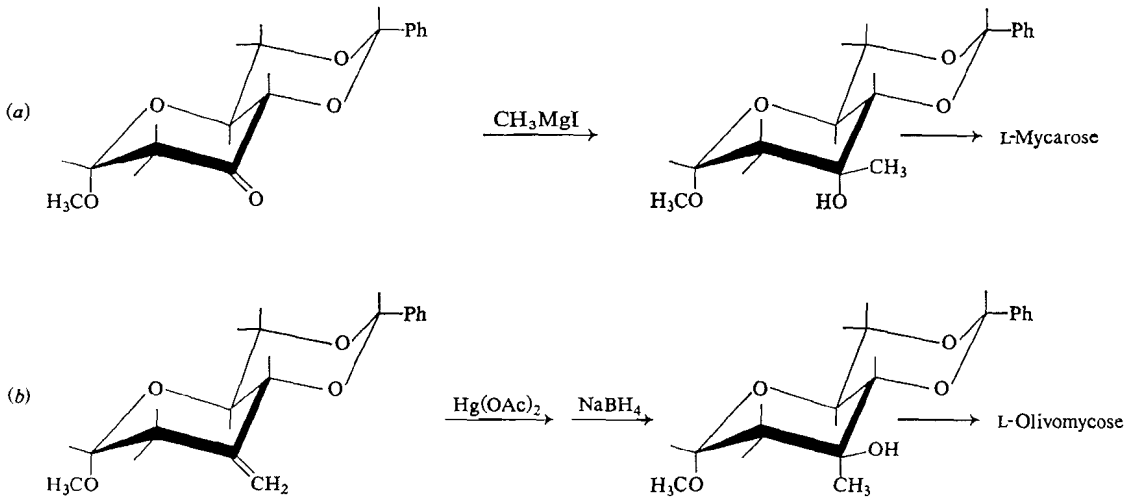

FIG. 1. (*a*) Addition of methylmagnesium iodide to methyl 4,6-*O*-benzylidene-2-deoxy-α-L-*erythro*-hexopyranosid-3-ulose (**2**) (8); (*b*) hydration of methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-*C*-methylene-α-L-*erythro*-hexopyranoside (**3**) by the oxymercuration–demercuration procedure.

Such interaction does not arise in compound **4** with the *arabino* configuration. The preparation of the D-enantiomer of **4**, by reduction with lithium aluminium hydride of one of the *spiro*-epoxides produced in the reaction of methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose with diazomethane, has been reported (17).

The benzylidene ring in compound **4** was opened by treatment with *N*-bromosuccinimide in boiling carbon tetrachloride (18) to give methyl 4-*O*-benzoyl-6-bromo-2,6-dideoxy-3-*C*-methyl-α-L-*arabino*-hexopyranoside (**5**). When compound **5** was heated with lithium aluminium hydride in tetrahydrofuran at reflux temperature, debromination and debenzoylation occurred to give a product which afforded the crystalline free sugar (**6**) by acid-catalyzed hydrolysis. The physical constants of **6** were in good agreement with those reported previously (1) for L-olivomycose.

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141 automatic polarimeter at 21 ± 2°. Infrared spectra were measured on a Beckman-IR5A spectrophotometer. The n.m.r. spectra were determined at 60 MHz in chloroform-*d* and tetramethylsilane as internal standard. Thin-layer chromatography (t.l.c.) was performed with Silica Gel G as the adsorbent. The developed plates were air dried, sprayed with 5% ethanolic sulfuric acid and heated at about 150°. The term "petroleum ether" refers to the fraction of b.p. 60–80°. Paper chromatography was carried out by the descending method at room temperature on Whatman No. 1 filter paper in butan-1-ol:ethanol:water, 3:1:1 (v/v). The sugars were detected by spraying the chromatograms with a 1:1 mixture of vanillin (1% in ethanol) and perchloric acid (3% in water) and heating (19).

Methyl 4,6-O-Benzylidene-2-deoxy-α-L-arabino-hexopyranoside (1)

To a stirred solution of 3,4,5,6-tetra-*O*-acetyl-1,2-dideoxy-1-nitro-L-*arabino*-hex-1-enitol (4) (20 g) in diglyme (100 ml) and ethanol (200 ml), a solution of sodium borohydride (15 g) in ethanol (200 ml) was added dropwise over a period of 15 min. Stirring was continued at room temperature for 1 h; carbon dioxide was bubbled into the mixture during the reaction. The reaction mixture was filtered, and the filtrate was diluted with chloroform (500 ml) and washed with water. Evaporation of the solvent gave a residue, which was recrystallized from ether to yield 3,4,5,6-tetra-*O*-acetyl-1,2-dideoxy-1-nitro-L-*arabino*-hexitol (15.5 g, 78%), m.p. 90–91°; $[\alpha]_D$ −28.2° (*c*, 2.0 in chloroform). Sowden and Fischer (4) report m.p. 91–92° and $[\alpha]_D^{26}$ +29.4° (*c*, 2.5 in chloroform) for the D-enantiomer.

3,4,5,6-Tetra-*O*-acetyl-1,2-dideoxy-1-nitro-L-*arabino*-hexitol (15 g) was dissolved in *M* aqueous sodium hydroxide solution (300 ml). To the solution was added *M* magnesium sulfate (165 ml) and then water to a final volume of 3 l. A solution of potassium permanganate (4 g) in water (400 ml) was added dropwise, with stirring, to the mixture, cooled in an ice–water bath, over a period of 3 h. Stirring was continued at 0–5° for 30 min, and then at room temperature for 1 h. The mixture was filtered, and the filtrate was concentrated to a volume of 500 ml and passed through Rexyn-101 (H^+) and Duolite A-4 (OH^-) ion-exchange resins. Concentration of the eluate

gave a colorless, chromatographically homogeneous (paper chromatography) syrup (6 g, 89%) with the same R_f as an authentic sample of 2-deoxy-L-*arabino*-hexose.

Methyl 2-deoxy-α-L-*arabino*-hexopyranoside was prepared from 2-deoxy-L-*arabino*-hexose, by the method described by Hughes *et al.* (7) for the D-enantiomer, and then converted into methyl 4,6-*O*-benzylidene-2-deoxy-α-L-*arabino*-hexopyranoside (**1**) as reported previously (8).

Methyl 4,6-O-Benzylidene-2-deoxy-α-L-erythro-hexopyranosid-3-ulose (2)

This compound was prepared by oxidation of methyl 4,6-*O*-benzylidene-2-deoxy-α-L-*arabino*-hexopyranoside (**1**) (1 g) with a mixture of ruthenium dioxide and potassium metaperiodate in chloroform, in the presence of potassium carbonate, by the procedure described by Lawton *et al.* (9). The crystalline product was recrystallized from ether–petroleum ether to give white needles (0.8 g, 84%), whose physical constants were the same as those reported previously (8) for compound **2**.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-C-methylene-α-L-erythro-hexopyranoside (3)

To a solution of methylenetriphenylphosphorane [prepared, as described by Lance and Szarek (15), from methyltriphenylphosphonium bromide (1.4 g) and sodium amide (0.21 g)] in ether (10 ml) was added dropwise, with stirring and at reflux temperature, a solution of ketone **2** (0.7 g) in ether (10 ml). When addition was complete, the mixture was filtered, and the filtrate was concentrated to dryness; the residue was extracted several times with hot petroleum ether. Evaporation of the solvent gave a syrup, which was chromatographed on silica gel, with 3:7 ethyl acetate–petroleum ether as eluent, to yield a crystalline product. Recrystallization from ethanol–water gave compound **3** (0.45 g, 69%), m.p. 120°; $[\alpha]_D$ −137.3° (*c*, 1.0 in ethanol); n.m.r. data: τ 2.34–2.8 (5-proton multiplet, aromatic H's), 4.35 (-proton singlet, benzylidene-methine H), 4.78–5.15 (2-proton multiplet, 2 vinyl H's), 5.15–5.3 (1-proton multiplet, H-1), 6.66 (3-proton singlet, OMe), 7.38–7.58 (2-proton multiplet, 2H-2's).

Anal. Calcd. for $C_{15}H_{18}O_4$: C, 68.7; H, 6.9. Found: C, 68.9; H, 7.3.

Methyl 4,6-O-Benzylidene-2-deoxy-3-C-methyl-α-L-arabino-hexopyranoside (4)

Compound **3** (0.40 g) was added with stirring to a mixture of mercuric acetate (0.516 g) in water (2.5 ml) and tetrahydrofuran (2 ml). The reaction mixture was stirred for 30 min at room temperature, and then 3 *M* sodium hydroxide (3.5 ml) followed by a solution of 0.5 *M* sodium borohydride in 3 *M* sodium hydroxide (2 ml) were added. The mixture was filtered, and the filtrate was extracted several times with chloroform. The extracts were washed with water, dried over magnesium sulfate, and concentrated to yield a crystalline product. Recrystallization from ethanol–water gave compound **4** (0.30 g, 72%), m.p. 77–79°; $[\alpha]_D$ −100° (*c*, 0.2 in ethanol). Flaherty *et al.* (17) report m.p. 79–79.5° and $[\alpha]_D$ +122° (ethanol) for the D-enantiomer.

The i.r. spectrum of compound **4** in carbon tetrachloride ($c < 0.005$ *M*) showed strong absorption at 3640 cm^{-1}; n.m.r. data: τ 2.37–2.78 (5-proton multiplet, aromatic H's), 4.42 (1-proton singlet, benzylidene-methine H), 5.15–5.36 (1-proton multiplet, H-1), 6.65 (3-proton singlet, OMe), 7.57–7.74 (1-proton, OH), 7.95–8.12 (2-proton multiplet, 2H-2's), 8.53 (3-proton singlet, C-3 Me).

Methyl 4-O-Benzoyl-6-bromo-2,6-dideoxy-3-C-methyl-α-L-arabino-hexopyranoside (5)

A solution of compound **4** (0.20 g) and *N*-bromosuccinimide (0.14 g) in carbon tetrachloride (20 ml) containing barium carbonate (0.70 g) was heated at reflux temperature with vigorous stirring for 1 h. The reaction mixture was filtered, and the filtrate concentrated to a syrup, which was chromatographed on silica gel, with 3:4 ethyl acetate–petroleum ether as eluent, to yield a crystalline product. Recrystallization from ether–petroleum ether gave compound **5** (0.22 g, 86%), m.p. 115°; $[\alpha]_D$ −66.2° (*c*, 0.2 in chloroform); λ_{max} (Nujol) 5.72 (OBz), 6.2, 14.0 μm (Ph); n.m.r. data: τ 1.83–2.05, 2.33–2.75 (multiplets, 5 protons, aromatic H's), 4.97 (1-proton doublet, $J_{4,5}$ 10 Hz, H-4), 5.06–5.24 (1-proton multiplet, H-1), 6.6 (3-proton singlet, OMe), 7.42 (1-proton singlet, OH), 7.85–8.0 (2-proton multiplet, 2H-2's), 8.55 (3-proton singlet, C-3 Me).

Anal. Calcd. for $C_{15}H_{19}O_5Br$: C, 50.0; H, 5.3; Br, 22.3. Found: C, 50.3; H, 5.4; Br, 22.0.

2,6-Dideoxy-3-C-methyl-L-arabino-hexose (Olivomycose) (6)

A mixture of compound **5** (0.20 g) and lithium aluminium hydride (0.30 g) in tetrahydrofuran (20 ml) was heated at reflux temperature for 6 h. The product was isolated in the usual manner, and chromatographed on silica gel, with ethyl acetate as eluent, to yield a syrup (0.060 g); λ_{max} (film) 2.8–2.9 μm (OH), no absorption attributable to benzoate. The t.l.c. (2:3 ethyl acetate–petroleum ether) showed the presence of a major component with R_f 0.2, and a small amount of a component which migrated slightly faster.

A solution of the syrup obtained above (0.050 g) in 0.2 *N* sulfuric acid (3 ml) was kept overnight at room temperature. The solution was neutralized with Duolite A-4 (OH^-) ion-exchange resin and concentrated to yield a crystalline product. Recrystallization from ethyl acetate–petroleum ether gave olivomycose (**6**) (0.030 g, 55%), m.p. 102–103°; $[\alpha]_D$ −13.8° (initial), −22.2° (after 20 min and after 2 h) (*c*, 1.0 in water). For olivomycose m.p. 103–106° and $[\alpha]_D^{26}$ −13° (immediately after dissolution), −22° (after 20 min and 1.5 h) (*c*, 1.1 in H_2O) have been reported (1).

Addition of pseudohalogens to unsaturated carbohydrates. III. Synthesis of 3-deoxy-3-*C*-nitromethyl-D-allose, a branched-chain nitro sugar[1]

W. A. SZAREK, J. S. JEWELL, I. SZCZEREK,[2] AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received June 24, 1969

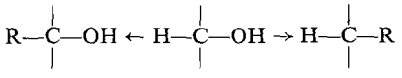
Addition of nitryl iodide to 3-deoxy-1,2:5,6-di-*O*-isopropylidene-3-methylene-α-D-*ribo*-hexofuranose (**2**), followed by treatment of the product with sodium borohydride, gave crystalline 3-deoxy-1,2:5,6-di-*O*-isopropylidene-3-*C*-nitromethyl-α-D-allofuranose (**3**); the branched-chain unsaturated sugar (**2**) was prepared by way of a Wittig reaction with 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (**1**). Acid-catalyzed hydrolysis of **3** afforded 3-deoxy-3-*C*-nitromethyl-D-allose, which exists predominantly in the β-D-furanose form (**4**).

L'addition d'iodure de nitryle au 3-deoxy-1,2:5,6-di-*O*-isopropylidène-3-methylene-α-D-*ribo*-hexofuranose (**2**), le produit obtenu étant traité au borohydrure de sodium, donne le 3-desoxy-1,2:5,6-di-*O*-isopropylidène-3-*C*-nitromethyl-α-D-allofuranose cristallisé (**3**); le sucre à double liaison exocyclique (**2**) a été préparé par réaction de Wittig par le 1,2:5,6-di-*O*-isopropylidène-α-D-*ribo*-hexofuranos-3-ulose (**1**). L'hydrolyse catalysée par les acides de **3** conduit au 3-desoxy-3-*C*-nitromethyl-D-allose, qui existe de manière prédominante sous la forme β-D-furanose (**4**).

Canadian Journal of Chemistry, 47, 4473 (1969)

Introduction

Branched-chain sugars may be divided into two groups, according to whether branching occurs in the carbon chain by substitution of hydrogen (Type A) or of a hydroxyl group (Type B)



Type A Type B

Those found in plants are of Type A, whereas those produced by micro-organisms are of both types. Several methods are available for the synthesis of branched-chain sugars of Type A, but only a few syntheses of Type B sugars have been reported (3, 4). Recently the application of the Wittig reaction with phosphonoacetic acid trimethyl ester (5) and alkylidene phosphoranes (6) to keto sugar derivatives to afford branched-chain unsaturated carbohydrates was described; the former condensation products are readily converted into saturated branched-chain sugars (Type B) having a free terminal primary hydroxyl function. A Wittig reaction between diethyl cyanomethylphosphonate and a keto sugar gave a branched-chain unsaturated carbohydrate containing a nitrile group; reduction of this compound afforded a branched-chain amino sugar (7).

Two other recently reported routes to Type B branched-chain sugars involve the application of the oxo reaction to unsaturated carbohydrates (8), and the synthesis of cyanodeoxy sugars by the opening of carbohydrate epoxides (9). The preparation of branched-chain dinitro sugar derivatives, namely methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-2-nitroalkyl-β-D-glucopyranosides and methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-2-nitroalkyl-β-D-galactopyranosides, by Michael addition has been reported also (10). In continuation of our studies on the addition of pseudohalogens to unsaturated carbohydrate derivatives (1, 2), we have now prepared a branched-chain (Type B) nitro sugar, 3-deoxy-3-*C*-nitromethyl-D-allose (**4**), by way of the addition of nitryl iodide to the branched-chain unsaturated sugar **2**. The olefinic substrate (**2**) had been used previously for the synthesis of a Type B branched-chain sugar by a photochemical addition reaction (11).

Results and Discussion

Oxidation of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose with methyl sulfoxide – acetic anhydride (12) gave 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (**1**), which was obtained in crystalline form in 54% yield by distillation of its crystalline hydrate (13). Reaction of methylenetriphenylphosphorane with

3 4

the 3-ketone (**1**) afforded the branched-chain unsaturated sugar, 3-deoxy-1,2:5,6-di-*O*-isopropylidene-3-methylene-α-D-*ribo*-hexofuranose (**2**). The Wittig reaction was performed in ether, and involved preparing the ylid in liquid ammonia with sodium amide as the base, and then replacing the ammonia by ether (6).

Nitryl iodide (prepared *in situ* by the reaction of silver nitrite and iodine in ether solution) has been shown to add to unsaturated sugars to produce β-nitro iodides; sugars which contain terminal unsaturated linkages form 2-iodo-1-nitro-adducts (1, 2). The new derivatives are frequently unstable on standing, but are converted readily into α-nitroolefins by sodium hydrogen carbonate in boiling benzene. The double bonds in the latter compounds can be selectively reduced with sodium borohydride. In the present work, reaction of compound **2** with nitryl iodide in ether gave a syrup, which on treatment with sodium borohydride in methanol afforded crystalline 3-deoxy-1,2:5,6-di-*O*-isopropylidene-3-*C*-nitromethyl-α-D-allofuranose (**3**). The *allo* configuration for compound **3** was assigned by nuclear magnetic resonance (n.m.r.) spectroscopy. The spectrum of compound **3** itself in chloroform-*d* was of little value in establishing the configuration, but a solution in deuterium oxide containing a small proportion of NaOD gave a spectrum which could be assigned, with the aid of spin decoupling, to the nitronate anion **3***a* (Fig. 1). The spectrum showed a 1-proton doublet at τ 3.85 attributable to H-3′ with $J_{3',3} = 7.5$ Hz, and a 1-proton doublet at τ 4.05 attributable to H-1 with $J_{1,2} = 3.8$ Hz. Irradiation of H-1 caused the triplet centered at τ 5.02 to collapse to a doublet with a splitting of 4.8 Hz. The triplet was assigned, therefore, to H-2, and the coupling constant $J_{2,3} = 4.8$ Hz. In 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose and its derivatives, the signal for H-2 is a triplet, and values of ca. 4 Hz for $J_{2,3}$ have been reported (5, 11), unlike 1,2-*O*-isopropylidene-α-D-*xylo*-hexofuranose derivatives, in which the coupling between H-2 and H-3 is very small and results in the spectral pattern for H-2 being a doublet (14). The 1-proton multiplet at τ 6.85 in the spectrum of **3***a* was assigned to H-3, since the signal simplified to a quartet with splittings of 4.8 and 10.0 Hz ($J_{3,4}$) on irradiation of H-3′. Irradiation of H-2 also caused the multiplet to collapse to a quartet, in addition to causing the H-1 doublet to appear as a broad band. The value for $J_{3,4}$ is significantly larger than the range of values observed for $J_{3,4}$ (2.7–3.0 Hz) in 1,2-*O*-isopropylidene-α-D-*xylo*-hexofuranose derivatives (14). After acidification of the sodium nitronate solution with hydrochloric acid or acetic acid, compound **3** could be recovered. If DCl in deuterium oxide was used for acidification, both the hydrogens at C-3′ in **3** were exchanged by deuterium atoms.

Acid-catalyzed hydrolysis of compound **3** with Rexyn-101 resin (H^+) gave 3-deoxy-3-*C*-nitromethyl-D-allose (**4**) as a glass. The n.m.r. spectrum (Fig. 2) of the equilibrium solution in deuterium oxide at ambient temperature (30°) had 3 readily discernible signals of total intensity one, which could be assigned to anomeric protons. These signals were a doublet at τ 4.53 with a

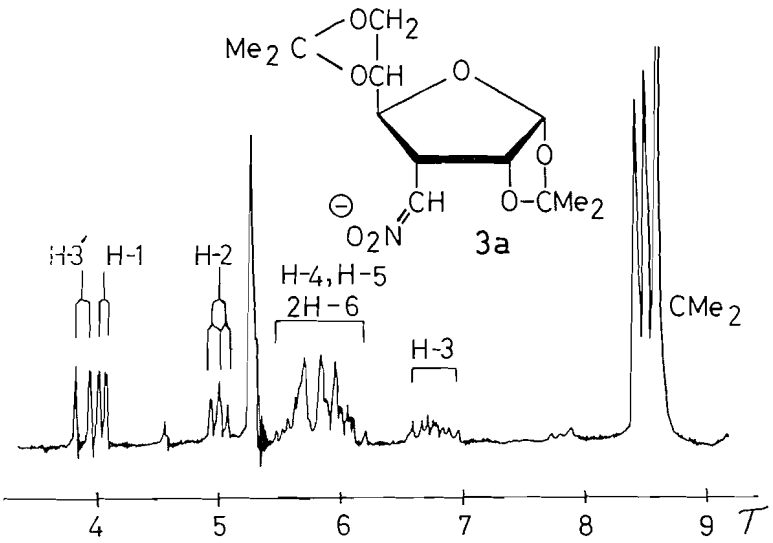

FIG. 1. The 60 MHz n.m.r. spectrum of 3-*C*-(*aci*-nitromethyl)-3-deoxy-1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose sodium in deuterium oxide (sodium 4,4-dimethyl-4-silapentane-1-sulfonate as internal standard).

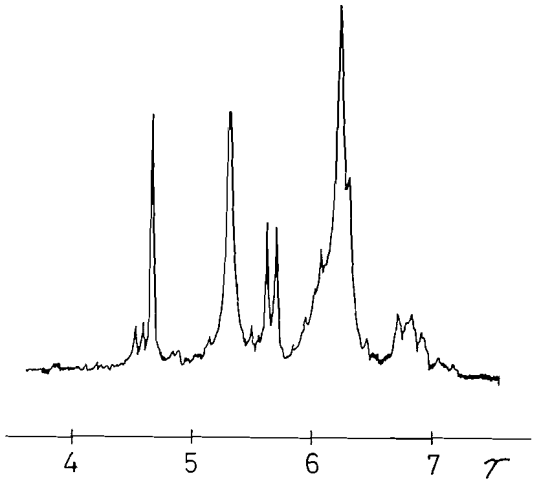

FIG. 2. The 60 MHz n.m.r. spectrum of 3-deoxy-3-*C*-nitromethyl-D-allose (**4**) in deuterium oxide (sodium 4,4-dimethyl-4-silapentane-1-sulfonate as internal standard).

splitting of 4.3 Hz, a singlet at τ 4.62, and a doublet at τ 4.87 with a splitting of 3.2 Hz; the relative intensities were 16:79:5. The n.m.r. spectrum of D-allose itself in deuterium oxide has been determined previously (15, 16); integration of the anomeric signals in the spectrum obtained at 40° (16) showed that the mixture contained 5% of the α-D-furanose, 7% of the β-D-furanose, 16% of the α-D-pyranose, and 71% of the β-D-pyranose forms. The spacing for the anomeric doublet of the predominant β-D-allopyranose form was 8.2 Hz (15). Evidently, the presence of the singlet at τ 4.62 in the spectrum of 3-deoxy-3-*C*-nitromethyl-D-allose suggests that the compound exists predominantly in the β-D-furanose form (**4**) in aqueous solution (17). Further evidence for the presence of the furanose form(s) was provided by the observation that the hydrolysis product gave, on a paper chromatogram, a substance which reacted with a spray reagent based upon the liberation of formaldehyde by acidified metaperiodate solution (18).

Experimental

Melting points are uncorrected and were determined with a Fisher–Johns apparatus. Optical rotations were measured using a Perkin–Elmer model 141 automatic polarimeter at 21 ± 2°. Thin-layer chromatography (t.l.c.) was performed on Brinkmann pre-coated aluminium sheets with silica gel as the sorbent in the following solvent systems (v/v): (A) chloroform – ether, 3:1; (B) ether – ethyl acetate, 3:2. The developed plates were air dried, sprayed with 5% ethanolic sulfuric acid, and heated at about 150°. Paper chromatography was carried out by the descending method on Whatman No. 1 filter paper in 1-butanol – ethanol – water, 3:1:1. Infrared (i.r.) spectra were recorded on a Beckmann-IR5A spectrophotometer. Nuclear magnetic resonance spectra were measured on a Varian T-60 spectrometer in chloroform-*d* with tetramethylsilane (τ 10.00) as internal standard, unless otherwise stated; coupling constants were measured at 250 or 100 Hz sweep widths.

1,2:5,6-Di-O-isopropylidene-α-D-ribo-hexofuranos-3-ulose (1)

A solution of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (13.0 g) in methyl sulfoxide (75 ml) and acetic anhydride (50 ml) was left for 24 h at room temperature. The reagents were removed by evaporation at low temperature (19), and the residue was distilled, b.p. 104°/0.02 Torr. Trituration of the distillate with water gave the crystalline hydrate of **1** (13). Distillation of this product afforded **1** as a clear syrup which crystallized spontaneously (6.9 g, 54%), m.p. 39–40°, $[\alpha]_D$ +139° (*c*, 1.0 in chloroform); λ_{max} (KBr) 5.61 (C=O), 7.20 μm (CMe_2).

3-Deoxy-1,2:5,6-di-O-isopropylidene-3-methylene-α-D-ribo-hexofuranose (2)

Methyltriphenylphosphonium bromide (10.7 g) was added to a solution of sodium amide (0.80 g) in liquid ammonia (100 ml) under nitrogen. Anhydrous ether (125 ml) was added, and the ammonia removed by evaporation. To the bright yellow solution of methylenetriphenylphosphorane was added dropwise with stirring a solution of compound **1** (5.6 g) in anhydrous ether. The reaction mixture was stirred for 2 h, and then filtered. The filtrate was washed with dilute sulfuric acid and water, and concentrated to give a clear syrup which was extracted with petroleum ether (100 ml). The solvent was evaporated, and compound **2** was obtained as a syrup by distillation (3.4 g, 60%), b.p. 71–72°/0.02 Torr, $[\alpha]_D$ +75° (*c*, 1.0 in chloroform); R_f 0.85 (solvent A), 0.68 (solvent B); λ_{max} (KBr) 6.05 (C=C), 7.31 μm (CMe_2); n.m.r. data: τ 4.22 (1-proton doublet, $J_{1,2}$ = 3.8 Hz, H-1), 4.45–4.65 (2-proton multiplet, 2 vinyl H's), 5.19 (1-proton doublet, H-2), 5.30–6.22 (4-proton multiplets, H-4, H-5, 2H-6's), 8.50, 8.58, 8.63 (3-, 3-, and 6-proton singlets, CMe_2).

Anal. Calcd. for $C_{13}H_{20}O_5$: C, 60.9; H, 7.9. Found: C, 60.9; H, 8.1.

3-Deoxy-1,2:5,6-di-O-isopropylidene-3-C-nitromethyl-α-D-allofuranose (3)

Compound **2** (3.80 g) was added portionwise to a stirred mixture of freshly prepared silver nitrite (2.6 g) and iodine (4.05 g) in anhydrous ether (50 ml), and stirring was continued for 6 h at room temperature in the dark. The reaction mixture was filtered, and the filtrate was concentrated to a dark red syrup. To a solution of this material in methanol (25 ml) was added with stirring sodium borohydride (ca. 1.5 g). After 1 h, the solution was treated with acetic acid until the p*H* was 6. Concentration of the solution gave a syrup which crystallized from water. Recrystallization from ethanol – water gave compound **3** as needles (2.30 g, 51%), m.p. 86–87°, $[\alpha]_D$ +80° (*c*, 1.0 in chloroform); R_f 0.56 (solvent A), 0.66 (solvent B); λ_{max} (KBr) 6.45 (C—NO_2), 7.30 μm (CMe_2); n.m.r. data: τ 4.18 (1-proton doublet, $J_{1,2}$ = 3.8 Hz, H-1), 5.06–5.36 (3-proton multiplets, H-2 and CH_2NO_2), 5.72–6.50 (4-proton multiplets, H-4, H-5, 2H-6's), 7.20 (1-proton multiplet, H-3).

Anal. Calcd. for $C_{13}H_{21}NO_7$: C, 51.5; H, 7.0; N, 4.6. Found: C, 51.1; H, 6.9; N, 4.7.

3-Deoxy-3-C-nitromethyl-D-allose (4)

Compound **3** (300 mg) in water (10 ml) was stirred with 2 g of Rexyn-101 resin (H^+) at 60° for 4 h. The resin was then removed by filtration, and the filtrate was shaken briefly with a small amount of Duolite A-4 resin (OH^-) to remove any trace of acid. Concentration of the solution gave a colorless glass (203 mg), $[\alpha]_D$ +42° (constant, during 24 h) (*c*, 1.0 in water). Paper chromatography showed the presence of only one substance, $R_{rhamnose}$ 1.3, with *p*-anisidine hydrochloride (20) and a formaldehyde-detecting spray reagent (18). The n.m.r. spectrum is shown in Fig. 2; the i.r. spectrum (film) had a broad band centered at 3.07 μm (OH) and a broad band centered at 6.42 μm (C—NO_2).

Anal. Calcd. for $C_7H_{13}NO_7 \cdot \frac{1}{2}H_2O$: C, 36.2; H, 6.1; N, 6.1. Found: C, 36.8; H, 5.9; N, 5.8.

Branched-chain sugar nucleosides. IV. 9-(3-Deoxy-3-*C*-"hydroxymethyl"-β(and α)-D-allofuranosyl and ribofuranosyl)adenine

ALEX ROSENTHAL AND MATEJ SPRINZL
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received June 25, 1969

Hydroboration followed by alkaline hydrogen peroxide oxidation of 1,2:5,6-di-*O*-isopropylidene-3-*C*-methylene-α-D-*ribo*-hexofuranose (**2**) yielded 3-deoxy-3-*C*-"hydroxymethyl"-1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose (**3**) and partially hydrolyzed **3** in a total yield of 88%. Compound **3** was hydrolyzed selectively to the 1,2-monoisopropylidene derivative **5**, which was converted via benzoylation followed by acetolysis into the 1,2-diacetate **7**. Condensation of the latter compound with chloromercuri-*N*-benzoyladenine in the presence of titanium tetrachloride, followed by deblocking with methanolic sodium methoxide, yielded 9-(3-deoxy-3-*C*-"hydroxymethyl"-β(and α)-D-allofuranosyl)adenine in yields of 44 and 4% respectively, based on **7**. The over-all yield of **10** based on **3** is 20%. Sodium metaperiodate oxidation of **10**, followed by sodium borohydride reduction of the *aldehydo*-derivative, afforded 9-(3-deoxy-3-*C*-"hydroxymethyl"-β-D-ribofuranosyl)adenine (**11**) in 81% yield.

Direct acetolysis of **3**, followed by conversion of the mixture of peracetates into a mixture of glycosyl chlorides, and finally condensation of the latter with **8** gave the blocked crystalline β-D-nucleoside **9** in an over-all yield of about 9%, based on **3**. Subsequent unblocking of **9** gave a nucleoside having the same physical constants as **10**.

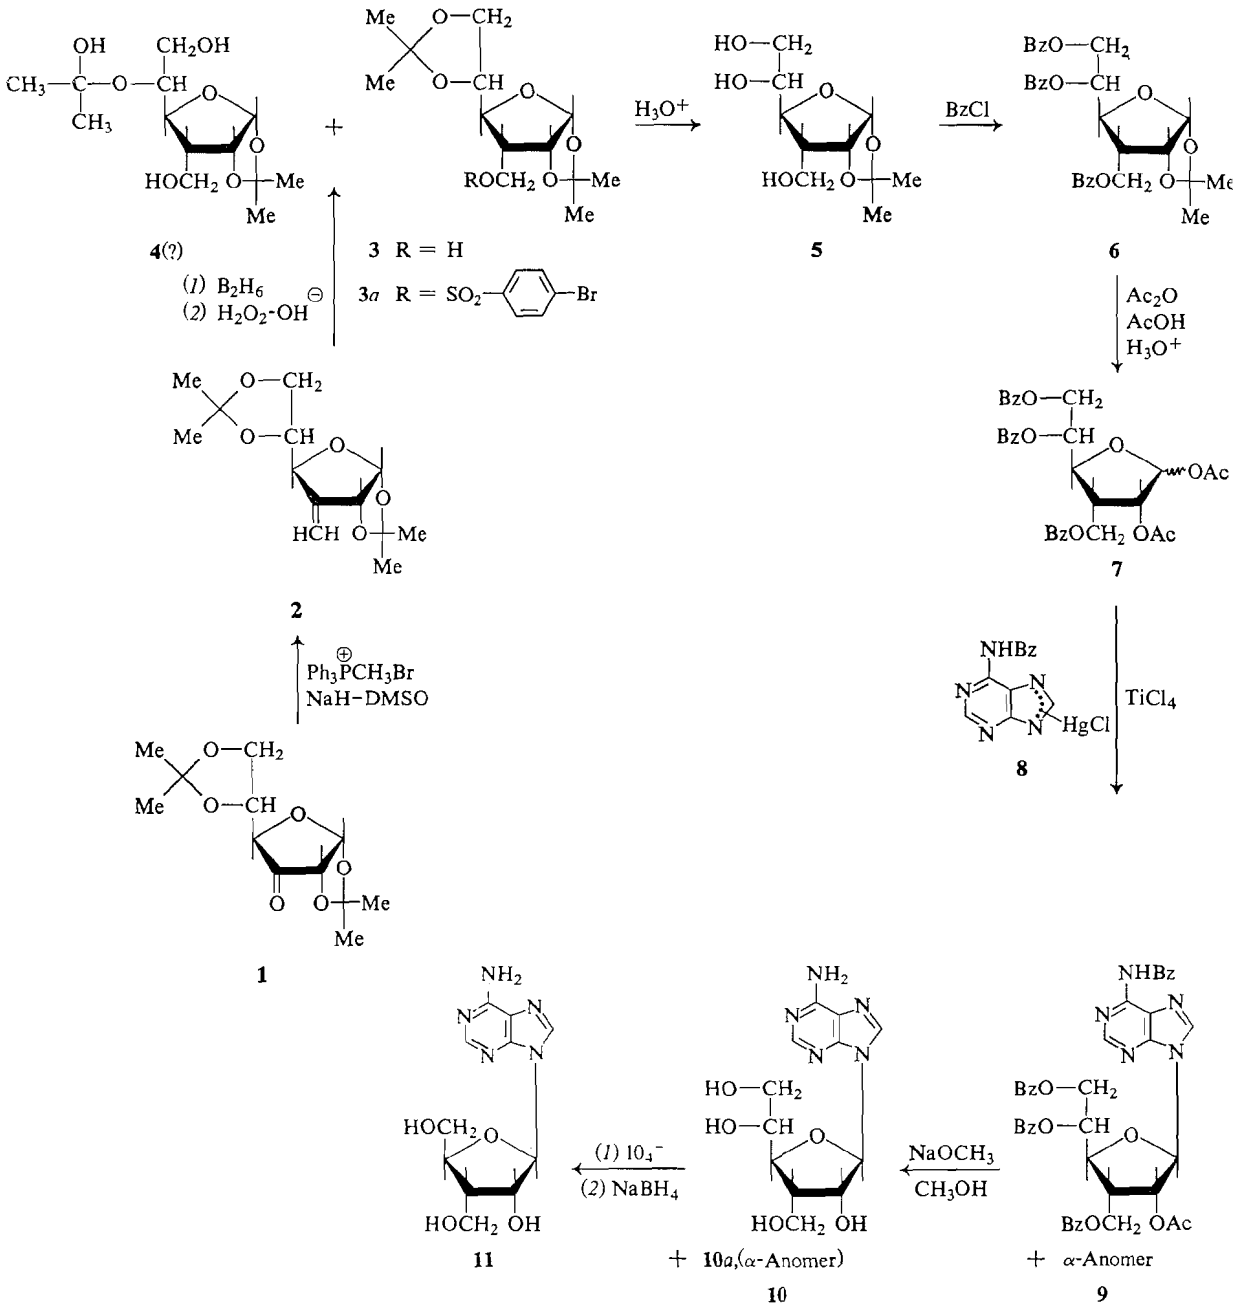
In continuation of our studies on the synthesis of branched-chain sugar nucleosides (1–3) we now wish to report the synthesis of two nucleosides having a hydroxymethyl group on C-3 of the furanosyl ring. The starting material for this research was 1,2:5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose (**1**) which was converted into the branched-chain unsaturated sugar 1,2:5,6-di-*O*-isopropylidene-3-*C*-methylene-α-D-ribofuranose (**2**) by application of a Wittig reaction to **1** (3). It was envisaged that hydroboration of the methylene group on C-3 of **2** might give the desired product. Previous workers (4, 5) have reported the application of the hydroboration reaction (6) to carbohydrates containing either a terminal or endocyclic double bond to yield hydration products in low yield. Both in the general field and in the few carbohydrates investigated hydroboration was found to proceed in an *anti*-Markownikov manner. When the hydroboration reaction (4, 5) was first applied to **2** using a stoichiometric amount of diborane then only a negligible yield of the diborane-unsaturated sugar adduct was formed. However, when a very large excess of diborane was allowed to react with **2** followed by an immediate alkaline hydrogen peroxide oxidation of the adduct, then two compounds **3** and **4** in the ratio of 3:1 were formed in 88% yield. These substances were separated by column chromatography. Compounds **3** and **4** showed identical H-2 resonances (triplet) thus confirming that each was formed via hydroboration. Because of the much slower thin-layer chromatography (t.l.c.) mobility of **4** than that of **3** it was reasoned that a partial hydrolysis of **3** might have occurred during the reaction or work-up of **3**. This postulation was confirmed by carrying out a selective hydrolysis of **3** and **4** to afford an identical substance **5** from each. The structure of **3** was readily ascertained from its proton magnetic resonance (p.m.r.) spectrum. As already indicated above the H-2 signal of **3** appears as a triplet (two overlapping doublets) at τ 5.28 showing that H-2 is coupled to H-3 and to H-1. Because H-2 of the glucofuranose derivatives (in which H-3 is *trans* to H-2) gives a doublet (no measurable or less than 0.7 Hz coupling between H-2 and H-3) (7), it was inferred that H-2 and H-3 of **3** must be in a *cis* orientation. This is supported by the fact that the H-2 signal of 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose is a triplet. Therefore, **3** is undoubtedly 3-deoxy-3-*C*-"hydroxymethyl"-1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose. Compound **3** was readily converted into its crystalline *p*-bromobenzenesulfonate derivative.

Benzoylation of **5** in the usual way afforded 1′,5,6-tri-*O*-benzoyl-3-deoxy-3-*C*-"hydroxymethyl"-1,2-*O*-isopropylidene-α-D-allofuranose (**6**) in 88% yield. Acetolysis of the latter with acetic anhydride – acetic acid – sulfuric acid gave



the anomeric mixture of diacetates **7** in 65% yield. Condensation of **7** with 6-benzamidochloromercuripurine (**8**) by the titanium tetrachloride method (1) gave a mixture of blocked nucleosides **9** which was immediately unblocked with methanolic sodium methoxide to give a mixture of the β-D (and α-D)-nucleosides **10** in the ratio of 11:1. Fractional crystallization of this mixture from 80% methanol–water afforded crystalline 9-(3-deoxy-3-*C*-"hydroxymethyl"-β-D-allofuranosyl)adenine (**10**) in 44% yield, based on the diacetate **7**. After the solvent from the

For personal use only.

mother liquor was evaporated to dryness, the residue was partially separated by gradient elution chromatography on Dowex 1 × 2 (OH^-) resin (5) using water, followed by aqueous methanol as developers, to afford pure β-D-anomer and a mixture of the α-D- and β-D-anomers (**10**). The latter was separated by preparative paper chromatography to yield the syrupy α-D-anomer of **10** in about 4% yield.

The assignment of structure of both anomers of **10** was based on ultraviolet (u.v.), optical rotatory dispersion (o.r.d.), and p.m.r. spectra. Such evidence, although not unequivocal when only one anomer is available, as in our first investigation (1), is more definitive for the proof of structure of both anomers **10** because a comparison of the physical measurements of both could be made. For example, as expected, **10***a* gave a positive Cotton effect whereas **10** showed the normal negative Cotton effect. From a mechanistic viewpoint, it is surprising that branched-chain sugars having either a hydroxyethyl or methyl group on C-3 gave only the β-D-anomeric nucleoside (1, 3) whereas the hydroxymethyl analogue reported herein afforded both anomers.

In order to prepare the ribo nucleoside **11**, the β-D-allo-nucleoside (**10**) was degraded by sodium metaperiodate to the *aldehydo* nucleoside. The latter was immediately reduced with sodium borohydride to yield crystalline 9-(3-deoxy-3-*C*-"hydroxymethyl"-β-D-ribofuranosyl)adenine (**11**) in 81% yield. In the latter nucleoside, nuclear magnetic resonance (n.m.r.) evidence (H-1 gave a doublet having $J_{1,2} = 2$ Hz) substantiates the β-anomeric configuration of **11** and of **10**.

In an attempt to increase the over-all yield of **10** from **3**, the latter was subjected to fewer steps as outlined below. Acetolysis of **3** followed by treatment of the resulting mixture of peracetates with anhydrous hydrogen chloride in ether gave a mixture of glycosyl halides. This mixture was not purified but was condensed with **8** to afford a mixture of compounds. The main fluorescing component of this mixture was separated by preparative t.l.c. on silica gel to yield a crystalline blocked nucleoside in an overall yield of about 9% which was deblocked with methanolic sodium methoxide affording a non-crystalline nucleoside having the same R_f and u.v. spectrum as that of an authentic sample of **10**. The low yield of **9** might be ascribed to the fact that acetolysis of **3** probably yielded both the allopyranose and allofuranose peracetates because of ring opening during the reaction (t.l.c. of the peracetate mixture showed at least three components and n.m.r. revealed three low field signals that might be attributed to three anomeric hydrogens of three different peracetates); the allofuranose peracetates on treatment with hydrogen chloride would be converted into a mixture of allofuranosyl chlorides but the α-allopyranose peracetate would be unaffected since it is known that only the β-pyranose peracetate reacts with anhydrous hydrogen chloride in ether.

In an attempt to shed additional light on the chemistry of branched-chain sugars, the blocked branched-chain sugar **3** was unblocked by two different routes. In the first method, when **3** or **7** was subjected to acetolysis followed by treatment with methanolic sodium methoxide, a mixture of four distinct compounds (as evidenced by paper chromatography) was formed. When the major component having the highest R_f was separated by preparative chromatography and allowed to stand in water, it surprisingly gave a complex mixture of substances which could not be separated. In the second procedure **3** was hydrolyzed with dilute acid to give a mixture of three substances, two of which only had the same R_f as those obtained by acetolysis and saponification of **3**.

Experimental

General considerations were similar to those previously described (1, 3). Silica gel G was used in the t.l.c. For column chromatography Silica gel Woelm 100–200 mesh, activity grade II, was used.

Hydroboration Followed by Alkaline Hydrogen Peroxide Oxidation of 1,2:5,6-Di-O-isopropylidene-3-C-methylene-α-D-ribo-hexofuranose (2) to Yield 3-Deoxy-3-C-"hydroxymethyl"-1,2:5,6-di-O-isopropylidene-α-D-allofuranose (3)

Into a solution of compound **2** (3) (1.3 g, 0.005 mole) in anhydrous tetrahydrofuran (16 ml) was slowly bubbled a large excess of commercial diborane for 4 h at room temperature. It is essential that the tetrahydrofuran be saturated with diborane. In preliminary experiments a stoichiometric amount of diborane gave a negligible yield of product in which diborane had added to the olefinic double bond of the sugar. After the reaction mixture was cooled to 0° a 50% aqueous mixture of tetrahydrofuran (5 ml) was added dropwise with vigorous stirring, followed by the addition of 2 *N* sodium hydroxide (15 ml) and then 30% hydrogen peroxide (8 ml). The reaction mixture was allowed to come to room temperature and stirred for a further 0.5 h. After the solvent was removed under reduced pressure, the residue was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

dissolved in 40 ml water and the aqueous solution extracted with 4 × 20 ml of ether. The combined ether extracts were dried over magnesium sulfate, filtered, and evaporated under reduced pressure to afford 1.23 g (88%) of a syrup. An aliquot of this product was separated by preparative t.l.c. on silica gel G using a 1:1 mixture of benzene–ethyl acetate as developer into two components having R_f's of 0.5 and 0.2 in the ratio of 3:1. The faster moving component (**3**) was a syrup, $[\alpha]_D^{22}$ + 103° (*c* 2, chloroform), τ($CDCl_3$), 4.25 (d, $J_{1,2}$ = 4 Hz, H-1), 5.28 (t, H-2), 6.1 (m), 6.95 (peak due to H of OH), 7.9 (m, H-3), 8.6 (two isopropylidene groups). The slower moving fraction **4** had $[\alpha]_D^{22}$ + 96° (*c* 1, chloroform) and τ($CDCl_3$) 4.25 (d, $J_{1,2}$ = 4 Hz, H-1), 5.28 (t, H-2), 6.25 (m), 6.95 (s, due to OH), 7.9 (m, H-3), 8.4–8.9 (two isopropylidene groups). Selective hydrolysis (1) of **3** and of **4** using 0.1 *N* sulfuric acid yielded the same compound **5**, described in a subsequent section.

*1-O-p-Bromophenylsulfonyl-3-deoxy-3-C-"hydroxymethyl"-1,2:5,6-di-O-isopropylidene-*α-D-*allofuranose (3a)*

An amount (0.137 g) of **3** in anhydrous pyridine (0.5 ml) was allowed to react with freshly recrystallized *p*-bromophenylsulfonyl chloride (0.141 g) at room temperature for 1 h. After adding 10 ml water, the solid precipitate was removed by filtration and recrystallized from methanol to yield 0.186 g (76%) of **3***a*, m.p. 101–102°; $[\alpha]_D^{22}$ + 71° (*c* 1, chloroform); R_f 0.35 (10:1 benzene–ethyl acetate); τ($CDCl_3$) (100 Mc) 2.25 (m, phenyl), 4.28 (d, $J_{1,2}$ = 3.8 Hz, H-1), 5.38 (t, H-2), 5.7–6.5 (m), 7.7 (m, H-3), 8.65 (two isopropylidene groups).

Anal. Calcd. for $C_{19}H_{25}BrO_8S$: C, 46.25; H, 4.93; Br, 16.20; S, 6.50. Found: C, 46.21; H, 5.14; Br, 16.41; S, 6.72.

*3-Deoxy-3-C-"hydroxymethyl"-1,2-O-isopropylidene-*α-D-*allofuranose (5)*

Selective hydrolysis (1) of the mixture of **3** and **4** (1.12 g) using 0.1 *N* sulfuric acid gave 0.89 g (95%) of **5**, $[\alpha]_D^{22}$ + 75° (*c* 1, chloroform); R_f 0.45 (3:1 benzene–methanol); τ($CDCl_3$), 4.2 (d, $J_{1,2}$ = 3.5 Hz, H-1), 5.22 (t, H-2), 5.8–6.4 (m), 7.8 (m, H-3), 8.55 (d, one isopropylidene group).

*1,5,6-Tri-O-benzoyl-3-deoxy-3-C-"hydroxymethyl"-1,2-O-isopropylidene-*α-D-*allofuranose (6)*

Benzoylation of 0.7 g of **5** in the usual way gave 1.22 g (88%) of **6** which was purified by column chromatography on silica gel using 10:1 benzene–ethyl acetate as developer. Compound **6** was crystallized from chloroform, m.p. 80–81°; $[\alpha]_D^{22}$ + 24° (*c* 3, chloroform); τ($CDCl_3$) 2–2.5 (m, phenyl), 4.1 (d, $J_{1,2}$ = 3.8 Hz, H-1), 5.15 (t, H-2), 5.2–5.7 (m), 7.8 (m, H-3), 8.5 (d, isopropylidene group).

Anal. Calcd. for $C_{31}H_{30}O_9$: C, 68.12; H, 5.53. Found: C, 68.89; H, 5.69.

*1,2-Di-O-acetyl-1,5,6-tri-O-benzoyl-3-deoxy-3-C-"hydroxymethyl"-*β*(and* α*-)-*D*-allofuranose (7)*

The benzoate **6** (1.10 g) was acetolyzed for 3 days in the usual way (1, 3) to afford 0.77 g (65%) of **7** as a syrup, $[\alpha]_D^{22}$ 0° (*c* 2, chloroform); R_f 0.4 (10:1 benzene–ethyl acetate); τ($CDCl_3$) 1.9–2.5 (m, phenyl groups), 3.90 (s, H-1; ratio of β:α anomer, about 5:1).

*9-(3-Deoxy-3-C-"hydroxymethyl"-*β*-(and* α*-)-*D*-allofuranosyl)adenine (10)*

A mixture of 0.59 g (0.001 mole) of **7**, 0.530 g (0.001 mole) of 6-benzamidochloromercuripurine (**8**), 0.3 g of Celite, and 25 ml of anhydrous xylene was freed of moisture by distilling off the xylene under reduced pressure. To the residue were then added 20 ml of ethylene dichloride and 5 ml of the solvent was distilled off. To the reaction mixture, which was kept under reflux, was then added dropwise a solution of 1,2-dichloroethane (3 ml) and titanium tetrachloride (0.12 ml) and the resulting solution refluxed for 4 h. The cooled reaction mixture was poured with stirring into 25 ml saturated sodium bicarbonate, stirred for a further 0.5 h, filtered, and the Celite cake washed with 3 × 20 ml chloroform. The chloroform extract was washed with 30% aqueous potassium iodide (10 ml) and then water (2 × 20 ml), dried over magnesium sulfate, filtered, and evaporated to dryness. The residue was dissolved in 15 ml methanol, norited, and evaporated to dryness. Extraction of the residue with boiling petroleum ether (30–60°) left the solid blocked nucleoside **9** (0.42 g, 56%), R_f 0.3 (1:2 benzene–ethyl acetate) and τ($CDCl_3$), 0.7 (m), 1.4 (m), 2.0 (m), 2.5 (m), 3.9 (s), 5.3 (m), 7.9 (m).

The blocked nucleoside **9** (0.42 g) was allowed to react with 0.1 *N* methanolic sodium methoxide and the product worked-up as described previously (3) to give after crystallization from 80% aqueous methanol 0.118 g (67%) of the β-D-anomer (**10**), m.p. 238°, $[\alpha]_D^{22}$ −12° (*c* 2, water); λ_{max} (H_2O) 261 (ε = 12 600); R_f (adenine), 0.68 on Whatman No. 1 paper (water as developer); τ(D_2O) (60°), 4.1 (d, $J_{1',2'}$ = 3 Hz, H-1'); $[\phi]_{269}$ −390°, $[\phi]_{259}$ 0°, $[\phi]_{245}$ +145° (*c* 0.003, water).

Anal. Calcd. for $C_{12}H_{17}N_5O_5$: C, 46.30; H, 5.50; N, 22.50. Found: C, 46.24; H, 5.66; N, 22.70.

The mother liquor from the above recrystallization was evaporated to dryness and the residue then dissolved in 20 ml water. The aqueous solution was twice extracted with 10 ml portions of ether. The aqueous layer which showed the presence of three fluorescent materials was applied to 10 ml (1 cm diam) of a column of Dowex 1 × 2 (OH^-) resin. Fractionation of the zones was achieved as described previously (3, 8) using water followed by 30% methanol and finally 60% aqueous methanol (each about 100 ml). From the 30% methanol eluant there was obtained an additional amount of 0.023 g of β-D-nucleoside **10**. The α-D-anomer **10***a*, contaminated with a little β-D-anomer, was obtained from the 60% aqueous methanol eluant. This mixture was separated by preparative paper chromatography using water as developer to afford 0.0124 g (4%) of α-D-anomer **10***a*, having R_{Ad} = 0.85; λ_{max} (H_2O) 258 (ε = 11 800); $[\alpha]_D^{22}$ = +24° (*c* 1, water). The o.r.d. curve of the α-D-anomer showed a positive Cotton effect in the region of 260 mμ. An attempt to convert syrupy α-D-anomer **10***a* into crystalline material led to accidental loss of all material.

Sodium Metaperiodate Oxidation and Reduction of the β-D-*allo-Nucleoside **10** to Yield 9-(3-Deoxy-3-C-"hydroxymethyl"-*β*-*D*-ribofuranosyl)adenine (11)*

The β-D-nucleoside **10** (0.155 g) was degraded by a previously described procedure (3) to yield on recrystallization 0.113 g (81%) of ribo nucleoside **11**, m.p. 213–214°; $[\alpha]_D^{22}$ −26° (*c* 1, water); λ_{max} (H_2O) 261 (ε =

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

13 400); R_{Ad} 0.96; τ(methyl sulfoxide-d_6) (100 Mc), 1.66 (s, H-2), 1.94 (s, H-8), 2.83 (s, NH_2), 4.18 (d, $J_{1,2} = 2$ Hz, H-1), 4.42 (d), 4.86 (m), 5.52 (m), 6.00 (m), 6.4 (m), 7.68 (m, H-3′, near methyl sulfoxide peak).

Anal. Calcd. for $C_{11}H_{15}N_5O_4$: C, 46.97; H, 5.36; N, 24.90. Found: C, 46.94; H, 5.37; N, 24.75.

Direct Conversion of **3** *into* β-D-*allo-Nucleoside* **10**

An amount of 0.47 g of branched-chain sugar **3** was subjected to acetolysis in the usual way (3) to yield 0.48 g (67%) of a mixture of at least 3 peracetates. The R_f's of the major components of the mixture were 0.62 and 0.55 using 1:1 benzene–ethyl acetate; $[\alpha]_D^{22}$ 0° (*c* 2, $HCCl_3$); τ($CDCl_3$) 3.9 (s), 4.0 (small peak), 4.75 (d, $J_{1,2} = 5$ Hz). The ratio of these peaks was about 4:1:2. Preparative t.l.c. of an aliquot of the peracetates gave two components having different n.m.r.'s (the faster moving component showed H-1 as a singlet at τ 3.90 whereas the slower component exhibited the doublet at τ 4.75).

An aliquot of the mixture of peracetates (0.100 g) was allowed to react with anhydrous hydrogen chloride in ether (20 ml) at room temperature for 1 day. After the solvent was removed under reduced pressure 5 ml of anhydrous toluene was added to the residue and the solvent again removed under vacuum. The resulting glycosyl halide was dissolved in anhydrous xylene and allowed to react under reflux conditions for 5 h and the product worked-up in the usual way (2). Thin-layer chromatography of the product (1:2 benzene–ethyl acetate) revealed 5 spots. Preparative t.l.c. of the mixture on silica gel G gave 9-(1,2,5,6-tetra-*O*-acetyl-β-D-allofuranosyl)-6-benzamidopurine 0.015 g (9%); R_f 0.4. This nucleoside was recrystallized from methanol, m.p. 135–135°; $[\alpha]_D^{22}$ −18° (*c* 1, $CHCl_3$); λ_{max} (ethanol) 262 mμ (ε 6400).

Anal. Calcd. for $C_{26}H_{29}O_{20}N_5$: N, 12.15. Found: N, 12.20.

The above blocked nucleoside was allowed to react with sodium methoxide according to the method previously described, λ_{max} (H_2O) 261; R_f (adenine) 0.68 (compared directly with authentic **10** on the same sheet of paper).

Attempts to Prepare Unblocked Branched-chain Sugars of Compound **3**

The mixture of peracetates described in the previous section was separated into 2 components by preparative t.l.c. on silica gel G and each component (0.050 g) was then deacetylated with methanolic sodium methoxide. Paper chromatographic examination using ethyl acetate, pyridine, water 8:2:2 as developer revealed that each fraction gave 4 identical spots having R_{Gl} 1.1, 1.4, 1.6, and 2.8. The fastest moving zone was eluted with water (0.015 g) and had $[\alpha]_D^{22}$ + 46° (*c* 1, water). Rechromatography of this zone after standing for several days showed that this component had changed into a mixture of compounds which were poorly resolved. Attempts to crystallize this compound were unsuccessful. The same complicated mixture of compounds (by paper chromatography) was obtained when compound **7** was treated with methanolic sodium methoxide.

When compound **3** (0.270 g) was hydrolyzed with 1% sulfuric acid (5 ml) at 60° for 1.5 h and the product worked-up in the usual way, 3 major components having R_{Gl} of 1.1, 1.4, and 1.86 were obtained.

Reçu le 5 Juin, 1969

Nous rapportons la séparation, par recristallisation, des deux formes tautomères, imido et amido, des dérivés chloroacetylés et α-chloropropionylés de l'amino-2 benzothiazole. Le choix du solvant permet non seulement l'obtention de l'une ou de l'autre forme séparément, mais aussi le passage de l'une à l'autre.

La structure de chaque forme tautomère a été déterminée au moyen de leurs spectres infrarouges et ultraviolets.

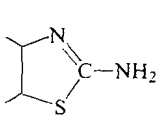
The isolation by crystallization of the tautomeric imido and amido forms of the chloroacetyl and α-chloropropionyl-2 aminothiazoles is reported. A judicious choice of solvents leads to the separation of one or the other tautomer and also allows interconversions.

The structure of each form has been determined from the corresponding ultraviolet and infrared spectra.

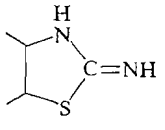
Canadian Journal of Chemistry, 47, 4483 (1969)

Dès 1926, Hunter et son collaborateur (1*a*, *b*) ont montré que l'aminobenzothiazole et ses dérivés existent sous deux formes tautomères (I) et (II).

Dans une étude récente sur la tautomérie des composés hétérocycliques par spectroscopie infrarouge (i.r.) et ultraviolet (u.v.), Peresleni et ses collaborateurs ont prouvé un tel équilibre tautomère pour les dérivés acylés et alcoylés de l'amino-2 thiazole, de l'amino-2 benzothiazole, (2*a*) de l'amino-2 thiazoline (2*b*,*c*), et de l'amino-2 thiazolone-4 (2*d*); ils constatèrent aussi que les deux formes tautomères sont présentes dans le même cristal bien que l'examen cristallographique n'ait montré qu'une seule forme cristalline (2*b*).



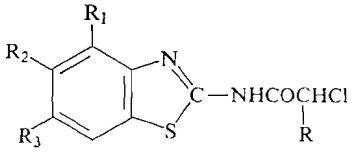
I



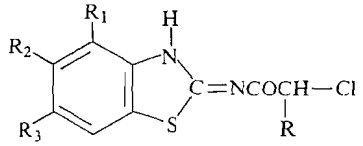
II

Nous avons également remarqué durant nos travaux (3) sur les dérivés de l'aminobenzothiazole que ces composés chloroacylés se présentent dans la plupart des cas, indépendamment de leur mode de préparation mais selon les moyens de recristallisation, sous deux formes cristallines donnant la même analyse élémentaire mais ayant des points de fusion et des spectres différents.

Dans le présent mémoire, nous établissons que ces formes cristallines différentes d'un dérivé chloroacylé de l'aminobenzothiazole sont deux tautomères et appartiennent aux structures imido et amido de l'équilibre tautomère (III et IV).



III



IV

Un exemple, entre-autres, l'(α-chloropropionylamino)-2 benzothiazole (R = CH_3, $R_1 = R_2 = R_3 = H$), par recristallisation dans le mélange benzène–éther de pétrole s'obtient sous deux formes cristallines, que nous avons séparé mécaniquement, et dont les points de fusion sont: 114–115 (*a*) et 124–125 °C (*b*). Par nouvelle cristallisation dans un autre solvant de l'une des deux formes cristallines on obtient de nouveau, presque toujours, un mélange de deux

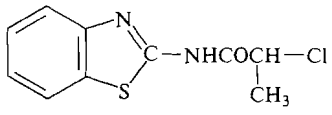
tautomères *a* et *b* ayant les mêmes points de fusion 114–115 et 124–125 °C.

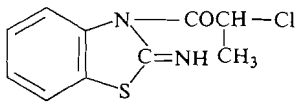
En outre, par recristallisation des deux formes dans le cyclohexane et pour l'exemple choisi, on parvient à un seul composé solide *b* de point de fusion 124–125 °C tandis que par l'utilisation d'une grande quantité d'éther de pétrole on parvient au composé solide *a* de point de fusion 114–115 °C.

L'analyse élémentaire de ces deux substances donne la même formule brute, néanmoins, les spectres infrarouges à l'état solide sont très différents.[1]

En effet, les spectres i.r. présentent dans la région de 1500 à 1720 cm^{-1}, pour les deux formes *a* et *b*, trois bandes intenses, mais la position de chacune est différente pour chaque tautomère. Ainsi pour la forme *a*, on trouve ces trois bandes à 1720, 1605, et 1566 cm^{-1} et pour la forme *b* elles sont fortement déplacées et se trouvent respectivement à 1680, 1608, et 1560 cm^{-1}. Nous pensons que la forme *a* correspond au tautomère ayant la structure amido. Nous attribuons la bande à 1720 cm^{-1} à l'absorption caractéristique du groupement carbonyle légèrement déplacée vers des fréquences plus élevées, la bande à 1605 cm^{-1} au noyau aromatique, et la bande à 1566 cm^{-1} à la liaison C=N du cycle thiazolique (6).



V



VI

La forme *b* correspond au tautomère ayant la structure imido. Nous attribuons par conséquent la bande 1680 cm^{-1} à l'absorption du groupement fonctionnel imido (C=N—C=O) (3*b*), la bande 1608 cm^{-1} au noyau benzénique, et enfin la bande à 1560 cm^{-1} à l'absorption du (C=N) exocyclique.

[1]Nous avons exclu la possibilité de formation de deux isomères (V) et (VI) car l'acylation conduit seulement aux dérivés exocycliques de l'azote contrairement à l'alkylation qui fournit les composés alkylés en position 3 sur l'azote cyclique (2,4,5).

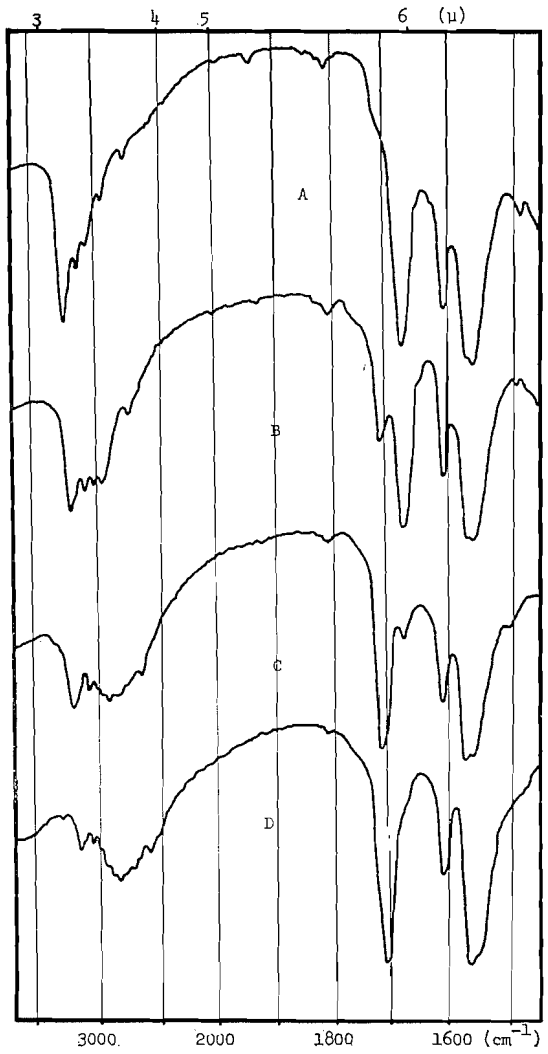


FIG. 1. Spectres i.r. dans KBr de l'(α-chloropropionylamino)-2 benzothiazole A: forme imido, D: forme amido, B et C mélanges des deux formes.

Dans la Fig. 1 nous rapportons quatre spectres i.r. à l'état solide (dans KBr) qui illustrent ces données. Les spectres A et D correspondent respectivement à la forme imido et amido pures tandis que les spectres B et C sont des mélanges des deux tautomères tels qu'obtenus par recristallisations.

Par comparaison nous avons dressé dans le tableau I: (*i*) Les valeurs de trois bandes caractéristiques de la forme imido pour le (α-chloropropionylimino)-2 methyl-3 benzothiazoline (**8**) et le (chloroacetylamino)-2 methyl-3 benzothiazoline (**9**). (*ii*) Les valeurs de trois bandes

caractéristiques de la forme amido d'une part et de la forme imido d'autre part pour les dérivés chloroacylés qui montrent les mêmes facilités de séparation des deux formes tautomères que l'(α-chloropropionylamino)-2 benzothiazole; en l'occurence, le (chloroacetylamino)-2 methoxy-6 benzothiazole (**3**), le (chloroacetylamino)-2 ethoxy-6 benzothiazole (**4**), et le (chloroacetylamino)-2 benzothiazole (**2**). (*iii*) Les valeurs spectrales des trois autres dérivés chloroacylés dont malgré les nombreuses tentatives de recristallisation dans différents solvants nous n'avons isolé qu'une forme cristalline. Nous les avons classés d'après les bandes caractéristiques de leurs spectres i.r. pris dans KBr. Il est vraisemblable que les deux formes existent à l'état solide si nous nous référons aux spectres u.v. (Fig. 4) soit que dans ces cas particuliers la résolution soit faible, soit que l'une des deux formes prédomine.

Leurs spectres i.r. pris en solution dans le chloroforme et le dioxanne, rapportés à la Fig. 2, laissent prévoir l'existence des deux formes, si on

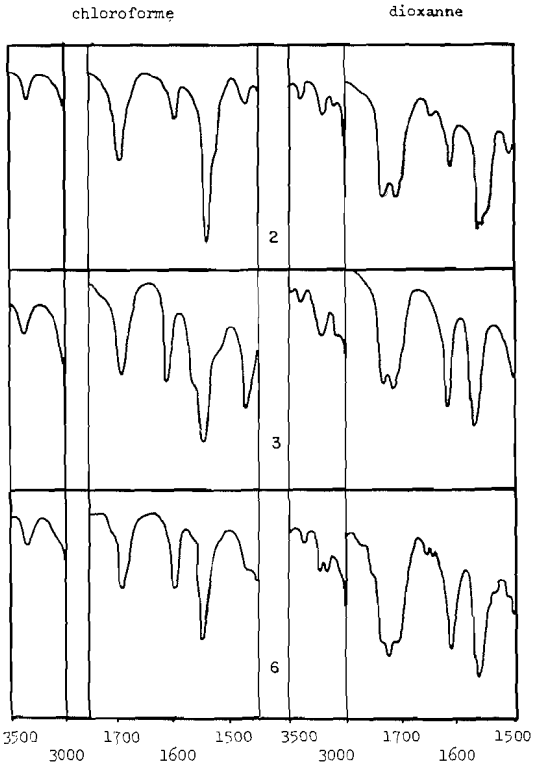

FIG. 2. Spectres i.r. des composés **2**, **3**, et **6** en solution dans le dioxanne et dans le chloroforme.

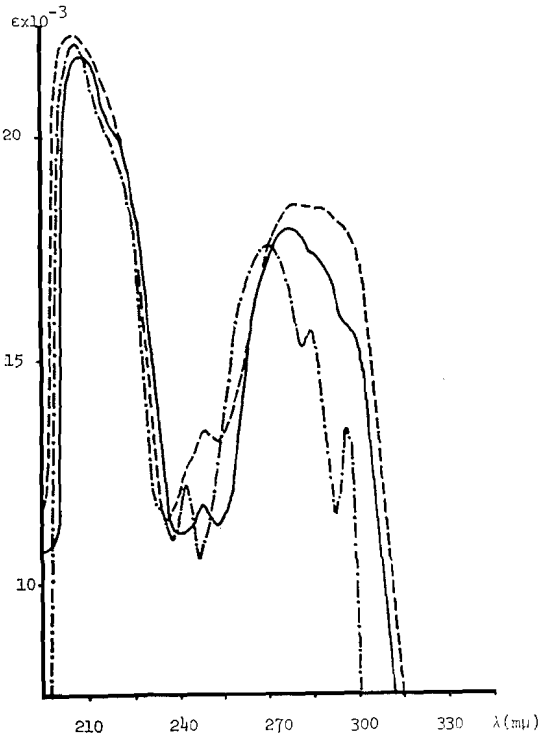

FIG. 3. Spectre u.v. de composé **1**; —— dans l'éthanol; - . - . - . dans le *n*-hexane; - - - - - dans HCl *N*/10.

les compare dans les composés **2** et **3** que nous avons démontré précédemment peuvent être un mélange des deux tautomères.

Les spectres u.v. de ces mêmes composés résumés au tableau I sont représentés par les Figs. 3–5, dans trois solvants différents. Nous remarquons d'une part que la (chloroacetylamino)-2 methylbenzothiazoline **9** de structure imino bien caractéristique présente un maximum d'absorption dans la région 313 mμ lequel de même que le coefficient d'absorption (ε_{max} 22 200–22 220) est peu modifié sous l'influence de la polarité du solvant (2*b*).

D'autre part les composés **1–4** qui par cristallisation ont donné les deux formes cristallines, comme nous l'avons montré par l'analyse i.r., voient leurs maxima d'absorption se déplacer vers le visible avec la polarité du solvant (Fig. 3): nous attribuons l'absorption aux longueurs d'ondes plus élevées à la présence de la forme imido (système conjugué (—C=N—C=O) tandis que l'absorption aux plus faibles longueurs d'ondes à la forme amido (—N=C—NH—

C=O). Nous sommes par conséquent tentés de faire une correlation entre la possibilité de séparer les deux formes cristallines et le déplacement des maxima de ces substances sous l'influence de solvants; à l'inverse à considérer, la Fig. 4 qui montre un faible déplacement de maxima du composé **5** comme nous l'avons mentionné, la séparation de deux formes cristallines ne s'est pas révélée possible. Toutefois nous ne pouvons pas conclure à l'inexistence de deux formes tautomères.

Enfin dans le spectre de résonance magnétique nucléaire (r.m.n.) de l'(α-chloropropionyl-amino)-2 benzothiazole le signal de NH amido se manifeste à 660 c.p.s. et celui de NH imido à 627 c.p.s. Malheureusement la faible solubilité de ces composés dans tous les solvants ne nous a pas permis d'en effectuer une étude comparative.

Partie expérimentale

Les points de fusion ont été déterminés avec un appareil à tubes capillaires et sont rapportés non corrigés. Les spectres i.r. ont été enregistrés sur un spectrophotomètre Beckmann IR-4, vérifiés avec un film de polystyrène, pris soit l'état solide soit en pastilles de KBr en dispersion dans le nujol; aussi en solution dans le $CHCl_3$, CCl_4, et dioxanne. Les spectres u.v. ont été déterminés sur un appareil Beckmann DK-1 dans l'alcool, cyclohexane et HCl *N*/10.

Préparations des (chloroacylamino)-2 benzothiazoles

Méthode A. A une solution de 0.1 mole d'amino-2 benzothiazole dans 200 ml de $CHCl_3$ on met 0.11 mole de Na_2CO_3 dans 75 ml d'eau sous agitation magnétique puis on ajoute goutte à goutte une solution de 0.11 mole de chlorure de chloroacide dissout dans 20 ml d'éther anhydre (durant 30 min). Le mélange est filtré et lavé à l'eau. Les eaux mères sont décantées et la couche chloroformique est ensuite lavée à l'acide chlorohydrique 5%, $NaCO_3$ 5% puis à l'eau. On sèche sur Na_2SO_4 anhydre, on évapore le chloroforme et on récupère encore une petite quantité du dérivé chloroacylèque l'on rejoint au composé déjà recueilli par filtration.

Méthode B. A une solution de 0.1 mole d'amino-2 benzothiazole dans 15 ml de benzène anhydre sous agitation magnétique, on ajoute goutte à goutte pendant 30 min 0.12 mole de chlorure de chloroacide dissout dans 30 ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

de benzène anhydre (7, 8). On continue l'agitation pendant 1 h en chauffant (65–70 °C) puis à reflux et on évapore le 1/3 du solvant; on refroidit, on décante, on lave au bicarbonate de sodium, puis à l'eau, on sèche sur P_2O_5.

Méthode C. A une solution de 0.065 mole d'amino-2 benzothiazole dans 100 ml d'acétone contenant 13.6 g de CH_3COONa anhydre on ajoute goutte à goutte pendant 15–20 min 0.075 mole de chlorure de chloroacide (9). On maintient l'agitation et chauffe à 60 °C durant 1 h; on refroidit, puis ajoute 25 ml de HCl 5 *N* et 100 ml d'eau. Le mélange est filtré, lavé à l'eau puis séché sur P_2O_5.

*(α-Chloropropionylamino)-2 benzothiazole (**1**)*

Préparé selon les méthodes A (rendement 45%) et B (rendement 70%). Par recristallisation dans le mélange benzène–éther de pétrole on obtient deux formes cristallines (*a*) p.f. 114–115 °C et (*b*) 124.5 °C. Par recristallisation dans le cyclohexane on obtient p.f. 124.5 °C. Par recristallisation dans une grande quantité d'éther de pétrole on obtient p.f. 114–115 °C.

Anal. calc. pour $C_{10}H_9ON_2ClS$: C, 49.89; H, 3.77; N, 11.63; Cl, 14.73; S, 13.33. Trouvé (*a*): C, 49.73; H, 3.67; N, 11.61; Cl, 14.77; S, 13.27; (*b*): C, 49.73; H, 3.92; N, 11.56; Cl, 14.70; S, 13.25.

*(Chloroacetylamino)-2 benzothiazole (**2**)*

Préparé selon les méthodes A (rendement 48%), B (rendement 96%), et C (rendement 85%). Par recristallisation dans le mélange des solvants benzène–éther de pétrole on obtient deux formes p.f. 158–160 °C et p.f. 168–170 °C; CH_3COOH aqueux: p.f. 158–160 °C; cyclohexane: p.f. 168–170 °C. (Lit.: p.f. 156 °C (8), 158–159 °C (9), 167 °C (7).)

*(Chloroacetylamino)-2 methoxy-6 benzothiazole (**3**)*

Préparé selon les méthodes B (rendement 85%) et C (rendement 81%). Par recristallisation dans le mélange des solvants benzène–éther de pétrole ou toluène–éther de pétrole on obtient deux formes: p.f. 164–166 °C et p.f. 180–182 °C; CH_3COOH aqueux: p.f. 174 °C; cyclohexane: p.f. 180–182 °C (lit.: p.f. 188 °C (8)).

*(Chloroacetylamino)-2 éthoxy-6 benzothiazole (**4**)*

Préparé selon les méthodes B (rendement 78%) et C (rendement 84%). Par recristallisation dans le mélange des solvants benzène–éther de pétrole on obtient deux formes: p.f. 180–181 °C et p.f. 185–186 °C; CH_3COOH aqueux: p.f. 186 °C; éther de pétrole: p.f. 180 °C (lit.: p.f. 174 °C (8); p.f. 169–170 °C (9)).

*(Chloroacetylamino)-2 chloro-6 benzothiazole (**5**)*

Préparé selon les méthodes B (rendement 76%) et C (rendement 86%). Par recristallisation dans le mélange des solvants benzène–éther de pétrole ou toluène–éther de pétrole on obtient une seule forme: p.f. 212–213 °C. (Lit.: p.f. 212 °C (9).)

*(Chloroacetylamino)-2 chloro-4 benzothiazole (**6**)*

Préparé selon les méthodes B (rendement 68%) et C (rendement 80%). Par recristallisation dans le mélange benzène–éther de pétrole; p.f. 186.8 °C. (Lit.: p.f. 182 °C (8).)

*(Chloroacetylamino)-2 dimethyl-5,6 benzothiazole (**7**)*

Préparé selon la méthode C (rendement 88%). Par recristallisation dans le mélange benzène–éther de pétrole au toluène–éther de pétrole on obtient une seule forme; p.f. 244° avec décomposition.

Anal. calc. pour $C_{11}H_{11}ON_2SCl$: C, 51.88; H, 4.36; N, 11.01; Cl, 13.91. Trouvé: C, 51.93; H, 4.18; N, 11.04; Cl, 14.00.

Imino-2 methyl-3 benzothiazoline

A une solution de 15 g d'amino-2 benzothiazole dans 50 ml d'éthanol absolu on ajoute 15 ml de CH_3I et on porte à reflux pendant 3 h. Après refroidissement on filtre et on lave avec de l'éther anhydre (rendement 90%), on prend 15 g de ce sel, le dissout à chaud dans l'eau puis on ajoute une solution de NaOH à 15% pour le rendre fortement basique. Après refroidissement on filtre on lave à l'eau et on sèche, rendement 83% p.f. 123–124 °C. (Lit.: p.f. 123 °C (10) après recristallisation des benzène–éther de pétrole.)

*(α-Chloropropionylimino)-2 methyl-3 benzothiazoline (**8**)*

Préparé selon la méthode A (rendement 94%). Recristallisation dans le mélange benzène–éther de pétrole p.f. 98–99 °C.

Anal. calc. pour $C_{11}H_{11}ON_2SCl$: C, 51.87; H, 4.36; N, 11.00; S, 12.58; Cl, 13.92. Trouvé: C, 52.00; H, 4.16; N, 11.08; S, 19.66; Cl, 14.09.

*(Chloroacétylimino)-2 methyl-3 benzothiazoline (**9**)*

Préparé selon la méthode A (rendement 94%). Recristallisation dans le mélange benzène–éther de pétrole: p.f. 159–160 °C.

Anal. calc. pour $C_{10}H_9ON_2SCl$: C, 49.89; H, 3.77; N, 11.64; S, 13.32; Cl, 14.73. Trouvé: C, 49.42; H, 4.05; N, 11.81; S, 13.35; Cl, 14.88.

Ring B conformation in 9,10-dihydroanthracenes by nuclear magnetic resonance[1]

F. GARCIA JIMENEZ, M. C. PEREZAMADOR, AND J. R. ALCAYDE[2]
Instituto de Química, Universidad Nacional Autónoma de México, México D. F., México

Received March 14, 1969

The nuclear magnetic-resonance data of some 9,10-dihydroanthracenes with substituents on the aromatic rings allow the assignment of a pseudoboat conformation for the central ring. The dihedral angle formed by the two planes in the molecule changes according to the substituents.

Canadian Journal of Chemistry, 47, 4489 (1969)

The conformation of the central ring in some 9,10-dihydroanthracenes has been studied by several workers. It appears that some of these compounds have a pseudoboat conformation, with the molecule folded about the axis through the methylenes of the central ring, and a dihedral angle of 145° as in 9,10-dihydroanthracene (1), while others have a planar structure (2). The present paper is a contribution to the study of this problem.

The 9,10-dihydroanthracenes studied (2,6-dimethoxy-2,3,6,7-tetramethoxy- and 1,2,3,5,6,7-hexamethoxy-9,10-dihydroanthracene) were obtained by the Robinson's method (3), with some minor modifications, starting with the corresponding substituted benzyl alcohol. No 9,10-dihydroanthracene was obtained applying the same method with 5-bromo- and 5-chloroveratryl alcohol.

The 2,6-dimethoxy-9,10-dihydroanthracene (m.p. 245°) has not been reported in the literature. The spectroscopic data are consistent with the assigned structure, which was also confirmed by converting the product into 2,6-dimethoxyanthracene (4).

Discussion

The preparation of 9,10-dihydroanthracenes by this method is strongly dependent both on the nature and the position of the aromatic substituents. The high degree of selectivity is remarkable since the attack always occurs at positions *para* to the methoxyl groups. The low yield (10%) obtained with 3,4,5-trimethoxy benzyl alcohol, and the negative results with 5-bromo- and 5-chloro-veratryl alcohol and particularly in cases where the substituents are in close proximity to the reactive sites in the molecule provide support for this explanation.

Nuclear Magnetic Resonance Data Analysis

In the 9,10-dihydroanthracenes the signals of the aliphatic protons at C_9 and C_{10} correspond to an A–B system with different coupling constants and variable chemical shifts depending on the substituents. The chemical shifts for axial and equatorial protons as well as the mean chemical shifts may be explained by a combination of electronic and stereoelectronic effects.

In 9,10-dihydroanthracene itself there is only one signal for the methylene protons at 3.87 p.p.m. (5). This has been explained by a rapid interconversion between two extreme boat conformations (6). In 2,6-dimethoxy-9,10-dihydroanthracene, the introduction of two methoxyl groups in positions 2 and 6 reduces the rate of interconversion and the differences between the axial and the equatorial protons are now evident. The axial protons absorb at 3.51 and 3.73 p.p.m. and the equatorial protons at 4.67 and 4.87 p.p.m. (Table I). This difference is due to the shielding of the axial hydrogens by the aromatic magnetic fields. Considering that positions 2 and 6 are relatively far away from the hydrogens in 9 and 10, the steric effect of the two methoxyl groups seems remarkable.

With two more methoxyl groups in positions 3 and 7 (in 2,3,6,7-tetramethoxy-9,10-dihydroanthracene), the electromagnetic effect increases

TABLE I

Coupling constants and chemical shifts of some 9,10-dihydroanthracenes

Compound	J (c.p.s.)	Chemical shift (p.p.m.) A*	Chemical shift (p.p.m.) B*	ΔA–B	Mean chemical shift (p.p.m.)	Reference
9,10-Dihydroanthracene	0	3.87		0	3.87	5
2,6-Dimethoxy-9,10-dihydroanthracene	13.5	3.51, 3.62	3.73–4.67, 4.87 4.77	1.15	4.19	—
2,3,6,7-Tetramethoxy-9,10-dihydroanthracene	13.5	3.63, 3.50	3.37–4.60, 4.83 4.72	1.20	4.11	—
2,3,4,6,7,8-Hexamethoxy-9,10-dihydroanthracene	13.5	3.87, 3.96	4.09–4.32, 4.56 4.44	0.48	4.20	—
9-Terbutyl-9,10-dihydroanthracene	19	3.79	4.23	0.44	4.01	7
9,10-Diterbutyl-9,10-dihydroanthracene	0	3.94		0	3.94	7

*A = axial protons; B = equatorial protons.

the difference between the axial and the equatorial protons (3.63, 3.37, and 4.60, 4.83). In addition, there is an increased shielding both for axial and equatorial protons which results in a smaller mean chemical shift.

The introduction of two more methoxyl groups in positions 1 and 5 (in 1,2,3,5,6,7-hexamethoxy-9,10-dihydroanthracene) causes a different kind of effect which cannot be readily explained in terms of shielding due to substituents as in the above mentioned case. The interaction of the substituents with the equatorial protons in 9 and 10 forces the molecule to an even more planar conformation, thereby increasing the dihedral angle formed by the two halves of the molecule. The difference between the axial and the equatorial protons is thus diminished (3.87, 4.09 and 4.32, 4.56) together with the total electromagnetic shielding. This is also observed in 9-*tert*-butyl-9,10-dihydroanthracene (7).

The steric effect can be anticipated to become more critical with an increase in temperature and therefore the difference between the chemical shifts of the equatorial and the axial protons should therefore decrease. In agreement with this expectation we have found experimentally that the difference in the chemical shifts between axial and equatorial protons in 1,2,3,5,6,7-hexamethoxy-9,10-dihydroanthracene is diminished by 2 c.p.s. between −20 and 55°.

From the nuclear magnetic resonance (n.m.r.) spectra analysis it may be deduced that in the 9,10-dihydroanthracenes the chemical shifts of the axial and the equatorial protons is largely dependent on the dihedral angle formed by the two planes in the molecule. This angle is variable and dependent on the substituents, particularly in positions 1,4,5,8,9, and 10.

Experimental[3]

2,6-Dimethoxy-9,10-dihydroanthracene

m-Methoxy benzyl alcohol (5 g) was mixed with 20 ml of Lucas reagent (8), followed by 5 drops of acetic acid. The mixture was stirred for 12 h at room temperature. It was then diluted with water and extracted with ethyl acetate. Evaporation of the solvent left a dark yellow oil which was chromatographed on SiO_2, eluting with 80:20 ethyl acetate–hexane. The crystalline fraction yielded white crystals (495 mg) of m.p. 245° (sealed tube); λ_{max} 207, 230, 282, and 289 mμ (ε, 29 200, 15 900, 2740, and 2740); ν_{max} 2990, 2930, 2915, 2860, and 2830; 1610, 1575, 1495, 1472, and 1415; 1285, 1250, 1200, 1143, 1095, 1074, 1040; 930, 867, 820, 800, 785, 752, 730, 710, and 700 cm^{-1}; n.m.r. spectrum: 3.62 (2H, doublet, J = 13 c.p.s.) and 4.77 (2H, doublet, J = 13 c.p.s.); 3.75 (6H, singlet); ABX system, 6.64 (2H, multiplet, J = 8 and 2.5 c.p.s.), 6.9 (2H, doublet, J = 2.5 c.p.s.), 7.29 (2H doublet, J = 8 c.p.s.).

[3]Melting points were determined in a Kofler block and are uncorrected. The infrared spectra were run in a Perkin–Elmer 521 spectrometer, in KBr. The ultraviolet spectra were determined in a Perkin–Elmer 450 spectrophotometer, in hexane solution. The n.m.r. spectra were run in a Varian A-60 spectrometer using TMS as internal standard. The elemental analysis was carried out by Dr. Franz Pascher, Bonn, Germany.

2,6-Dimethoxyanthracene

To 100 mg of 2,6-dimethoxy-9,10-dihydroanthracene were added 500 mg of lead oxide (litharge) and the mixture heated at 200° for 5 h. The reaction product was sublimed *in vacuo*, yielding pale yellow crystals (40 mg) which, when recrystallized from ethyl acetate, afforded white crystals of m.p. 260° (lit. (4) 257°, from benzene); the ultraviolet spectrum is in agreement with that reported for the product (4).

2,3,6,7-Tetramethoxy-9,10-dihydroanthracene

Veratryl alcohol (2 g) was mixed with 10 ml of concentrated hydrochloric acid and stirred for a few minutes. The thick paste so formed was filtered and washed with water, resulting in 1.540 g of white crystals, m.p. 220–224°. These were recrystallized from ethyl acetate raising the m.p. to 227° (lit. (3) 227°, from benzene); ν_{max} 2995, 2950, 2934, and 2908; 1675, 1603, 1584, 1500, 1457, 1390, and 1340; 1180–1270, 1130, 1080, 1015; 990, 935, 865, and 838 cm^{-1}; n.m.r. spectrum: 3.5 (2H, doublet, J = 13 c.p.s.) and 4.72 (2H, doublet, J = 13 c.p.s.): 3.82 (12H, singlet): 6.84 (4H, singlet).

1,2,3,5,6,7-Hexamethoxy-9,10-dihydroanthracene

3,4,5-Trimethoxy benzyl alcohol (2 g) was mixed with 10 ml of concentrated hydrochloric acid and stirred for 1 h. The reaction mixture was diluted with water and extracted with ethyl acetate. After evaporation of the solvent an orange oil was obtained. This oil crystallized from ethanol–water yielding 200 mg of white crystals with m.p. 199–201° (lit. (9) 202–203°, from ethanol). No change in the m.p. was observed after recrystallization from ethyl acetate; ν_{max} 3000, 2960, 2937, and 2833; 1710, 1570, 1490, 1464, 1450, 1430, 1400, and 1332; 1287, 1192, 1160, 1115, 1057, and 1033; 990, 960, 910, and 850 cm^{-1}; n.m.r. spectrum: 3.96 (2H,doublet, J = 13 c.p.s.) and 4.44 (2H, doublet, J = 13 c.p.s.); 3.78 (6H, singlet); 3.82 (6H, singlet), and 3.99 (6H, singlet); 7.26 (2H, singlet).

Concerning the problems involved with use of external references for variable temperature chemical shift measurements[1]

B. J. Blackburn,[2] Frank E. Hruska,[3] and Ian C. P. Smith
Biochemistry Laboratory, National Research Council of Canada, Ottawa 7, Canada

Received July 10, 1969

The importance of making bulk susceptibility corrections to nuclear magnetic resonance chemical shifts measured versus an external reference is emphasized. The special significance of this correction for variable temperature studies is demonstrated by comparing data obtained with external and internal references for uridine-5′-phosphate. Opposite trends in chemical shift and inaccurate activation energies can result.

En utilisant une référence externe en résonance magnétique nucléaire pour déterminer et comparer des déplacements chimiques, il est très important de tenir compte de l'effet dû à la susceptibilité magnétique. Nous nous sommes servi de l'uridine-5′-phosphate et de références internes et externes pour bien démontrer l'importance de cette correction, spécialement lorsqu'on varie la température. Nous soulignons également la possibilité de variations de déplacements chimiques en sens opposés et la mise en garde contre le danger d'obtenir des énergies d'activation inexactes si de telles corrections ne sont pas appliquées.

Canadian Journal of Chemistry, 47, 4491 (1969)

The use of external reference compounds for measurement of nuclear magnetic resonance (n.m.r.) chemical shifts is becoming increasingly widespread (1–4). This is principally to avoid

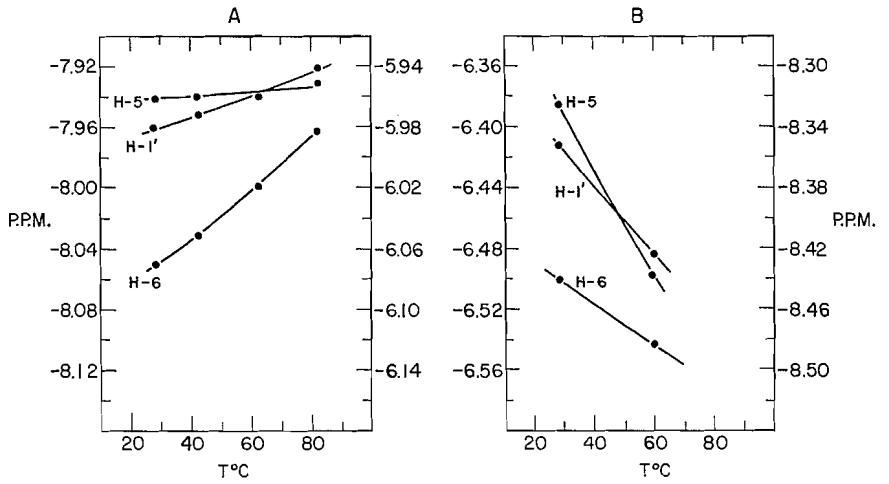

FIG. 1. The chemical shift of the H-5, H-6, and H-1′ protons of uridine-5′-monophosphate as a function of temperature: (*A*) relative to internal DSS; (*B*) relative to external TMS (4). The shift of the H-6 proton is given by the extreme scales; the shifts of the H-5 and H-1′ protons are given by central scales. In (*A*) the uridine-5′-monophosphate was 0.1 *M* in D_2O, p*D* 7.0, the DSS was 0.15 *M*, and the spectra were obtained on a Varian HA-100 spectrometer operating in frequency sweep mode. In (*B*) the uridine-5′-monophosphate was 0.045 *M* in D_2O, p*D* 6.3.

contamination of the samples and is particularly important for biologically significant compounds. The chemical shifts so measured should, however, be corrected for bulk magnetic susceptibility effects if the data are to be meaningfully compared with those of other workers. If variable temperature measurements are made, *changes* in the correction for a given solvent–external reference pair *must* be considered. Even at fixed temperatures, variations due to different capillaries and to different solvent systems are important.

Problems arising from the use of external references are demonstrated vividly in recent studies of the temperature dependence of the proton chemical shifts of nucleosides, nucleotides, and oligonucleotides (4, 5). For example, in Fig. 1, we show the temperature dependence for the protons at positions 5, 6, and 1′ in uridine-5′-monophosphate. The data in Fig. 1*A* were obtained by measurement relative to the internal reference sodium 3-(trimethylsilyl)-propanesulfonate (DSS); those of Fig. 1*B* are taken from the published work of Ts'O *et al.* (4) and were measured relative to an external capillary of tetramethylsilane (TMS). It is clear from Fig. 1 that the trends of the chemical shifts are opposite in direction. These opposing trends, which are a consequence solely of the choice of reference, can lead to errors in the interpretation of the chemical shift data. In Fig. 2*A*, we present the temperature dependence for the following proton shifts: (*1*) external hexamethyldisiloxane, (HMS), relative to the methyl resonance of aqueous DSS, δ (HMS–DSS), (*2*) external HMS relative to the methyl protons of aqueous ethyl alcohol, δ (HMS–EA), and (*3*) external TMS relative to aqueous tetramethylammonium bromide, δ (TMS–TMAB). In each instance, temperature elevation from 5 to 60 °C results in increased shielding of the external reference relative to the internal reference in excess of 0.1 p.p.m. In Fig. 2*B* are shown the chemical shift data for DSS relative to the methyl protons of ethyl alcohol, δ (DSS–EA), both dissolved in the same aqueous solution. Only a slight temperature dependence is observed.

Figure 2 suggests that the variations of the apparent chemical shift of the external reference with temperature are due mainly to changes in the bulk susceptibility of the surrounding heavy water solution. When these corrections are applied to the data in Fig. 1*B*, they follow the same trend as those in Fig. 1*A*. This demonstrates the importance of either using an internal reference, or making bulk susceptibility corrections with an

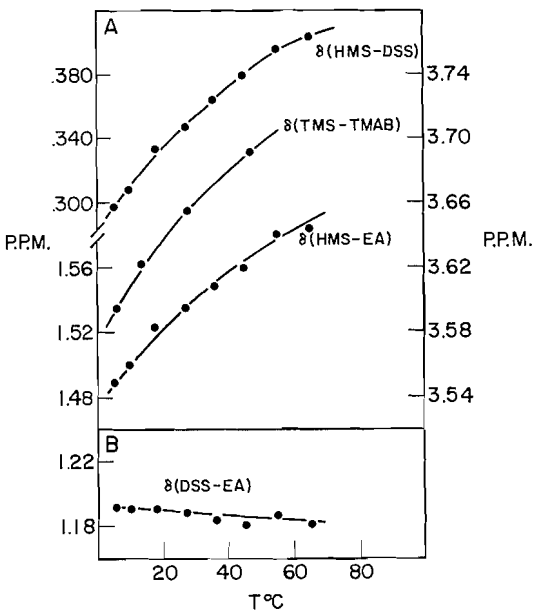

FIG. 2. (*A*) Shift of external HMS relative to internal aqueous DSS [δ(HMS–DSS), upper left-hand scale], shift of external HMS relative to methyl resonance of aqueous ethyl alcohol [δ(HMS–EA), lower left-hand scale], and the shift of external TMS relative to aqueous tetramethylammonium bromide [δ(TMS–TMAB), right-hand scale], all as a function of temperature. (*B*) Shift of internal DSS relative to methyl resonance of ethyl alcohol as a function of temperature in aqueous solution. A positive shift indicates a resonance at higher field. All solutions were in D_2O, p*D* 7.0 ± 0.2. Concentrations were: DSS, 0.15 *M*; EA, 0.05 *M*; TMAB, 0.01 *M*. Spectra were measured on a field-swept Varian A60A n.m.r. instrument with calibrated sweep.

external reference, when variable temperature measurements are made; otherwise, incorrect trends and calculated activation energies will result.[4]

The procedure for making such corrections is simple. The n.m.r. data for the compound of interest are obtained under the desired conditions using a reference compound in a concentric external capillary. The sample is then replaced by a solution of similar composition, but with the compound of interest substituted by an internal reference. The chemical shift of the external reference relative to the internal reference is then added algebraically to the shift of the compound of interest relative to the external reference, thus yielding the chemical shift of the compound of interest relative to the internal reference. To ensure that the susceptibility of the compound of interest makes no contribution to this correction, the procedure should be followed for at least two concentrations of the compound of interest.

D-glucose with nitromethane. Following the finding of conditions leading to the successful condensation of D-glucose with nitromethane to yield 1-deoxy-1-nitro-D-*glycero*-D-*ido*-heptitol and 1-deoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol (2), the preparation of 2-acetamido-2-deoxy-D-*glycero*-D-*gulo*-heptose and 2-acetamido-2-deoxy-D-*glycero*-D-*ido*-heptose from these derivatives, became a possibility.

Acetylation of 1-deoxy-1-nitro-D-*glycero*-D-*ido*-heptitol (2) afforded 2,3,4,5,6,7-hexa-*O*-acetyl-1-deoxy-1-nitro-D-*glycero*-D-*ido*-heptitol which on refluxing in benzene solution in the presence of sodium bicarbonate afforded 3,4,5,-6,7-pentaacetoxy-D-*gluco*-1-nitro-1-heptene. The 3,4,5,6,7-pentaacetoxy-D-*gluco*-1-nitro-1-heptene with saturated methanolic ammonia afforded a mixture of the 2-acetamido-1,2-dideoxy-1-nitro-heptitols from which the major component, 2-acetamido-1,2-dideoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol was obtained crystalline in 70% yield. This derivative underwent a modified (3) Nef (4) reaction to yield 2-acetamido-2-deoxy-D-*glycero*-D-*gulo*-heptose. The identity of the heptose was established by the identification of 2-acetamido-2-deoxy-gulitol (5) as the major product produced by borohydride reduction of the major compound produced by the action of one mole portion of metaperiodate on one mole part of the 2-acetamido-2-deoxyheptose (1, 6).

The mother liquors remaining after the removal of the 2-acetamido-1,2-dideoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol, contained presumably a mixture of 2-acetamido-1,2-dideoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol and 2-acetamido-1,2-dideoxy-1-nitro-D-*glycero*-D-*ido*-heptitol and, when subjected to the modified Nef reaction, the mixture afforded 2-acetamido-2-deoxy-D-*glycero*-D-*gulo*-heptose and 2-acetamido-2-deoxy-D-*glycero*-D-*ido*-heptose which were separated by cellulose column chromatography. The 2-acetamido-2-deoxy-D-*glycero*-D-*ido*-heptose could not be obtained in a completely pure state but after treatment with one mole part of metaperiodate it gave a major product which on borohydride reduction afforded 2-acetamido-2-deoxyiditol (5), thus establishing the identity of the heptose.

Experimental

Paper chromatography was performed by the descending method on Whatman No. 1 filter paper using either (*a*) pyridine–ethyl acetate–water (2:5:5 v/v, top layer) or (*b*) 1-butanol–ethanol–water (3:1:1 v/v) as the mobile phase. Compounds were detected with either alkaline silver nitrate (7) or *p*-anisidine hydrochloride (8) spray reagents and their rates of movement are quoted relative to D-glucose (R_G).

Gas–liquid partition chromatography was carried out using a Hewlett-Packard 402 gas chromatograph with a hydrogen flame detector and fitted with glass U tubes (4 ft × 6 mm × 3 mm i.d.) packed with 10% (w/w) neopentylglycol sebacate polyester on 80–100 mesh acid washed Chromosorb W. Development was made with helium at a flow rate of 90 ml/min and a column temperature of 245 °C, and retention times are quoted relative to hexa-*O*-acetyl-D-glucitol (T_G).

Melting points were determined on a hot stage and are corrected. Optical rotations were determined at 22 °C with a Perkin–Elmer 141 polarimeter. Solutions were concentrated under reduced pressure below 40 °C.

2,3,4,5,6,7-Hexa-O-acetyl-1-deoxy-1-nitro-D-*glycero*-D-*ido-heptitol*

1-Deoxy-1-nitro-D-*glycero*-D-*ido*-heptitol (2) (3 g) in acetic anhydride (25 ml) was treated with one drop of concentrated sulfuric acid and the mixture was heated for 35 min on a boiling water bath. The cooled reaction mixture was poured into an ice and water mixture (200 ml) and the product was extracted with chloroform in the usual way. The product crystallized from benzene and after recrystallization from ethanol, gave pure crystalline 2,3,4,5,6,7-hexa-*O*-acetyl-1-deoxy-1-nitro-D-*glycero*-D-*ido*-heptitol (5 g; 82%) which had m.p. 85–87 °C and $[\alpha]_D$ + 53.5° (*c*, 3.6 in chloroform).

Anal. Calcd. for $C_{19}H_{27}NO_{14}$: C, 46.24; H, 5.51; N, 2.83. Found: C, 46.23; H, 5.59; N, 2.67.

The 2,3,4,5,6,7-hexa-*O*-acetyl-1-deoxy-1-nitro-D-*glycero*-D-*ido*-heptitol was converted in the usual way (2), in almost quantitative yield to 3,4,5,6,7-pentaacetoxy-D-*gluco*-1-nitro-1-heptene having m.p. and mixture m.p. 106–107 °C.

2-Acetamido-1,2-dideoxy-1-nitro-D-*glycero*-D-*gulo-heptitol*

3,4,5,6,7-Pentaacetoxy-D-*gluco*-1-nitro-1-heptene (5 g) was suspended in methanol (50 ml) and dry ammonia gas was bubbled through the solution until all the solid material had dissolved. The mixture was kept at 0 °C for 24 h and, after aeration to remove most of the volatile material, a crystalline mass was obtained which after collection, and recrystallization from ethanol, gave pure 2-acetamido-1,2-dideoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol (2.23 g, 69%) which had m.p. 142–143 °C and $[\alpha]_D$ + 7.5° (*c*, 2.7 in water).

Anal. Calcd. for $C_9H_{18}N_2O_8$: C, 38.30; H, 6.43; N, 9.92. Found: C, 38.80; H, 6.70; N, 10.06.

On paper chromatography the product gave a single silver nitrate-positive spot which had R_G 2.70 (solvent *a*) and R_G 2.50 (solvent *b*).

2-Acetamido-2-deoxy-D-*glycero*-D-*gulo-heptose*

2-Acetamido-1,2-dideoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol (1.25 g) was dissolved in a solution of $Ba(OH)_2 \cdot 8H_2O$ (1.4 g) in water (22 ml) and the solution was added dropwise with stirring to an ice cold solution of con-

centrated sulfuric acid (2.3 g) in water (9.6 ml). After 30 min, the reaction mixture was neutralized ($BaCO_3$), filtered, and the filtrate was concentrated to a syrup (0.96 g) which paper chromatography (solvent *a*) showed to be essentially a single compound having R_G 1.23. It was the only material detected by *p*-anisidine hydrochloride but the silver nitrate spray revealed the presence of several very minor impurities. The 2-acetamido-2-deoxy-D-*glycero*-D-*gulo*-heptose, obtained chromatographically pure by cellulose column chromatography using 1-butanol one half saturated with water as the mobile phase, had $[\alpha]_D$ $-45° \rightarrow -53°$ (*c*, 0.87 in water; equilibrium value).

Anal. Calcd. for $C_9H_{17}NO_7$: C, 43.03; H, 6.82; N, 5.58. Found: C, 42.76; H, 6.65; N, 5.45.

*Degradation of 2-Acetamido-2-deoxy-*D*-glycero-*D*-gulo-heptose to 2-Acetamido-2-deoxy-*D*-gulitol*

2-Acetamido-2-deoxy-D-*glycero*-D-*gulo*-heptose (39 mg) in water (1 ml) was treated with sodium metaperiodate (34 mg) in water (3 ml) and after 2 h, sodium borohydride (50 mg) was added. The mixture after acidification with acetic acid was concentrated to dryness and the residue was acetylated in the usual manner (5). Gas–liquid chromatographic analysis of the product gave a chromatogram with a major peak (ca. 95%) having T_G 3.33 corresponding in retention time with 1,3,4,5,6-penta-*O*-acetyl-2-acetamido-2-deoxy-D-gulitol and very minor peaks having T_G 0.36, 0.85, and 1.80. The major peak is distinguished from 1,3,4,5,6-penta-*O*-acetyl-2-acetamido-2-deoxy-D-iditol which had T_G 3.10.

*2-Acetamido-2-deoxy-*D*-glycero-*D*-ido-heptose*

The mother liquors remaining after the removal of 2-acetamido-1,2-dideoxy-1-nitro-D-*glycero*-D-*gulo*-heptitol from the product of the action of ammonia on 3,4,5,6,7-pentaacetoxy-D-*gluco*-1-nitro-1-heptene were concentrated to a syrup (ca. 1 g) which was subjected to the modified Nef reaction, in the way described above for the synthesis of 2-acetamido-2-deoxy-D-*glycero*-D-*gulo*-heptose, to yield a product (0.8 g) which on paper chromatography showed two major components having R_G 1.23 and 2.10 (solvent *a*).

The above product was separated by cellulose column chromatography using 1-butanol one half saturated with water as the mobile phase to yield pure 2-acetamido-2-deoxy-D-*glycero*-D-*gulo*-heptose (0.3 g) having R_G 1.23 (solvent *a*) and 2-acetamido-2-deoxy-D-*glycero*-D-*ido*-heptose (0.35 g) having R_G 2.10 (solvent *a*) which was contaminated with small amounts of unknown impurities having similar chromatographic mobilities. Attempts to purify the heptose via its 2,5-dichlorophenylhydrazone derivative were unsuccessful. A portion of the 2-acetamido-2-deoxy-D-*glycero*-D-*ido*-heptose fraction (20 mg) was oxidized with periodate and the product reduced in the way described for 2-acetamido-2-deoxy-D-*glycero*-D-*gulo*-heptose gave a fully acetylated final product which on gas–liquid chromatography gave a major peak (T_G 3.10) corresponding with 1,3,4,5,6,7-penta-*O*-acetyl-2-acetamido-2-deoxy-D-iditol together with minor components having T_G 0.85 and 1.70 which were not identified.

Lignans of western red cedar (*Thuja plicata* Donn). IX. Plicatinaphthalene

HAROLD MACLEAN AND B. F. MACDONALD

Department of Fisheries and Forestry, Canadian Forestry Service, Forest Products Laboratory, Vancouver 8, B.C.

Received June 27, 1969

The last of nine lignans detectable by thin-layer chromatography in the hot-water soluble extractives of western red cedar (*Thuja plicata* Donn) heartwood has been determined as 6-hydroxy-2(hydroxymethyl)-7-methoxy-4-(3′,4′-dihydroxy-5′-methoxyphenyl)-3-naphthoic acid lactone (plicatinaphthalene **2**) by spectrometric methods, by degradation studies of derivatives, and by preparation of its trimethyl ether derivative **3** from dehydroanhydropicropodophyllin by opening of the methylenedioxy group with boron trichloride.

Canadian Journal of Chemistry, 47, 4495 (1969

Introduction

Previous work has elucidated the structural relationship of eight lignans present in the heartwood of western red cedar (*Thuja plicata* Donn), two of which were 4-aryltetrahydronaphthalenes, five were substituted dibenzyl butyrolactones, and the eighth was a 4-aryl-α-naphthol lactone (1). All of these lignans have the usual guaiacyl substitution pattern in the A ring with either a monomethylated pyrogallyl or syringyl pattern

in the pendant C ring. The last lignan component of the hot-water soluble extractives detectable by thin-layer chromatography (t.l.c.) (2) is now shown to be a derivative of plicatin (**1**) (3) in which the two tertiary hydroxyls have been removed and the B ring aromatized to a naphthalene nucleus (**2**). This component has been given the trivial name plicatinaphthalene.

This compound was recovered from the hot-water soluble components by extraction with chloroform. A trituration of the recovered chloroform solubles with petroleum ether followed by benzene removed the thujaplicins and other terpenoids (2), and the residue was chromatographed on polyamide powder followed by microcrystalline cellulose to yield crystalline plicatinaphthalene (**2**).

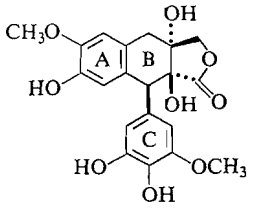
The structure of plicatinaphthalene was inferred by spectrometric identification. The molecular weight of 368 was determined by low-resolution mass spectrometry. This spectrum was similar to plicatinaphthol (1) in that the molecular ion was the only major peak, all others being less than 8%, indicative of the stable aromatic system of the compound (4). Also similar to plicatinaphthol, the compound was nearly insoluble in deuteriochloroform, but with ethanol of crystallization was sufficiently soluble in deuterioacetone to confirm all protons as to species and number by nuclear magnetic resonance (n.m.r.) spectrum. Ultraviolet (u.v.) and infrared (i.r.) spectra are in agreement with the proposed structures for plicatinaphthalene and its derivatives. Here again similarities with plicatinaphthol (1) exist in that the lactone ring appeared at lower wave number, 1735 cm^{-1}, than usually found for lactones.

Plicatinaphthalene was crystallized from ethanol, dichloromethane and spontaneously from acetone-d_6, being least soluble in the former and most soluble in the latter. Crystals from ethanol changed from transparent to opaque at 158–160°, began discoloring at 240° and melted with decomposition between 248–254°. The transition at 158–160° was indicated as resulting from ethanol of crystallization, since crystals dried at 100° under vacuum for 3 h, when dissolved in acetone-d_6, recrystallized from the acetone-d_6 during the n.m.r. spectral run giving a strong spectrum of ethanol and acetone-d_5 (5) superimposed on a weaker spectrum of plicatinaphthalene. A second n.m.r. spectrum run in pyridine showed the plicatinaphthalene–ethanol ratio was 1:1 in the crystals from ethanol which had also been dried at 100° under vacuum for 3 h. Crystals which had been heated beyond the 158–160° transition point were much less soluble in acetone-d_6 and showed only the spectrum of plicatinaphthalene.

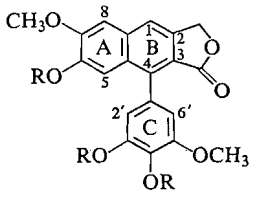
Plicatinaphthalene recrystallized from dichloromethane and dried at 100° under vacuum for up to 7 h, melted at 158–160° with foaming, recrystallized on the melting point stage between 180 and 210°, and melted with discoloration and decomposition as for crystals from ethanol. When the melting point of this compound was taken on a Mettler FP-1 (automatic melting point determination) at 0.2°/min its melting point was recorded at 157.4°. The presence of dichloromethane in the crystals before, and its absence after, the primary melt was shown by use of the C—Cl band of dichloromethane at 735 cm^{-1} in comparative i.r. spectra. The spontaneously recrystallized material from the n.m.r. spectrum in acetone-d_6 underwent identical melting characteristics as for dichloromethane. Here again the presence of the acetone-d_6 before the transition point at 158–160°, and its absence after, was shown by detection and disappearance of a carbonyl band at 1695 cm^{-1} in comparative i.r. spectra.

If any of the three crystallization products are heated to 200° and allowed to cool, then on reheating no phase change occurs at 158°, but only melting with decomposition at 248–254°. From the above data, it would seem that plicatinaphthalene undergoes a monotropic phase change (6) at 157.4° with release of the solvent from which it has been crystallized, followed by a crystal change to its more stable form and finally melting with decomposition at 248–254°. In the case of ethanol it becomes only opaque, but in the case of the other two solvents in which it is more soluble, an actual melting takes place at the first transition point.

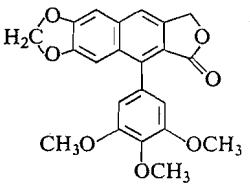
The n.m.r. spectra of a trimethyl (**3**) and a triacetyl (**5**) derivative confirmed the presence of two methoxyl and three hydroxyl groups in the original plicatinaphthalene andw ere confirmatory both as to species and number of protons required for each compound. The spectrum of the trimethyl ether derivative (**3**) was extremely simple owing to the lack of coupling, all peaks being singlets whose width at half-height indicated less than one Hz coupling in the *para* and *peri* aromatic positions, the *meta* protons of the



1



2 R = H 4 R = C_2H_5
3 R = CH_3 5 R = Ac



6

symmetrical pendant ring being a sharp 2-proton singlet. A similar situation existed in the triacetyl derivative (**5**) spectrum except that the latter two protons (C-2′, C-6′) were present as doublets owing to the magnetic asymmetry in ring C introduced by the acetyl groups.

Mass spectrum of the trimethyl derivative (**3**) gave a molecular ion of 410 as the base peak, an M-15 of 30% indicating loss of a methyl group from one of the methoxyl groups and an M-30 peak of 5%, probably loss of two methyl groups. Many other peaks occurred, but none were greater than 4% as would be expected from the stabilized aromatic nucleus (4).

Final proof of structure of plicatinaphthalene trimethyl ether (**3**), which identified the position of the lactone ring, was provided by its partial synthesis from podophyllotoxin obtained from podophyllin resin (7). Podophyllotoxin was epimerized to picropodophyllin by sodium acetate (8), thence to apopicropodophyllin, and finally to the naphthalene derivative, dehydroanhydropicropodophyllin (**6**) (9). The methylenedioxy ring of the latter compound was opened with boron trichloride and remethylated with diazomethane to yield trimethyl plicatinaphthalene (**3**), identical with the natural methylated derivative by n.m.r. and i.r. spectroscopy.

The substitution pattern of the pendant ring C was established by alkaline permanganate oxidation of a triethyl ether derivative (**4**) with subsequent detection of 3,4-diethoxy-5-methoxybenzoic acid by paper chromatography and t.l.c. The substitution pattern of the A ring and additional proof of structure for plicatinaphthalene (**2**) were shown by its preparation from plicatin (**1**) by aromatization with phosphorous oxychloride (11). To ensure that plicatinaphthalene was not an artifact being produced by the mild organic acid conditions of the hot-water extraction procedure, plicatin was refluxed for 8 h in aqueous acetic acid at p*H* 3 and for 6 h in glacial acetic acid and did not produce any plicatinaphthalene detectable by chromatography.

Experimental

The following equipment and materials were used: melting points, Fisher–Johns heated block (uncorrected); i.r. spectra, Perkin–Elmer 521 grating spectrometer (KBr disks); u.v. spectra, Beckman DK-2 spectrophotometer (ethanol); n.m.r., Varian HA-100 (tetramethylsilane $\delta = 0$ as internal standard in the solvents shown); low-resolution mass spectrum, Atlas CH-4, University of British Columbia. The t.l.c. values were obtained with silica gel G (Merck) as adsorbent, benzene–ethanol–acetic acid (90:10:1) as developer, with u.v. light followed by nitric acid–sulphuric acid (1:1) spray and heat as detector. Paper chromatograms were developed with 2% aqueous acetic acid and detected with potassium ferricyanide-ferric chloride reagent (mixed 1% solutions).

Plicatinaphthalene (2)

The aqueous layer from a hot-water extract of western red cedar heartwood (1 kg moisture-free basis) was extracted with chloroform (3 × 500 ml). After evaporation of the chloroform solvent the residue (6.8 g) was triturated with petroleum ether (65–110°) (150 ml) and then with benzene (150 ml) to remove thujaplicins, thujic acid, methyl thujate, and other terpenoids. The remainder (3 g) was dissolved in benzene–formic acid (9:1) and chromatographed on a polyamide (Woelm) column (3 cm × 40 cm), eluting with the same solvent. The fractions were monitored by t.l.c. The band between R_f 0.16 and 0.24 was further chromatographed on a cellulose column using water as the eluting solvent to yield, after recrystallization from ethanol, 6-hydroxy-2-(hydroxymethyl)-7-methoxy-4-(3′,4′-dihydroxy-5′-methoxyphenyl)-3-naphthoic acid lactone (plicatinaphthalene) (120 mg), $C_{20}H_{16}O_7$; t.l.c. R_f 0.16, and papergram R_f 0.14; u.v. blue fluorescent; m.p., crystals become opaque at 158–160°, discoloration began at 240° and finally melted with decomposition at 248–254°. Crystals from dichloromethane, melted (Mettler FP-1) 157.4° (see Discussion in text).

The spectra gave: λ_{max} in mμ (log ε), 259 (4.36) (shifting to 278 mμ in alkaline media), 315 (3.88), 356 (3.64); ν_{max} 3380 (broad hydroxyl), 1735 (lactone) cm^{-1}; n.m.r. plicatinaphthalene with ethanol of crystallization in deuterioacetone from which plicatinaphthalene crystallized out during the spectral run (all plicatinaphthalene peaks were singlets), 8.20, 7.55, 7.39 (1H each-phenols, quenched overnight by deuterium exchange with the

solvent), 7.74, 7.31, 7.10 (1H each, C-1, C-5, and C-8), 6.39 (2H, C-2′ and C-6′), 5.28 (2H, lactone methylene), 3.96 and 3.75 (3H each, methoxyls), and the remainder of spectrum consisted of large peaks for ethanol and acetone-d_5 (5). No additional protons were detected when the spectrum was offset 400 Hz. Total protons: 16; mass spectrum (low-resolution), parent ion = base peak 368, all other peaks were less than 8%.

Trimethyl Plicatinaphthalene (3)

Plicatinaphthalene (100 mg) was dissolved in methanol (40 ml) with warming. On cooling, excess diazomethane in ether (5 ml) was added each h for 5 h at room temperature with stirring and allowed to stand overnight. The product (t.l.c. R_f 0.71) was recrystallized from ethanol to yield 2-(hydroxymethyl)-6,7-dimethoxy-4-(3′,4′,5′-trimethoxyphenyl)-3-naphthoic acid lactone, (**3**) (50 mg), $C_{23}H_{22}O_7$, m.p. 238–239 °C.

The spectra gave: λ_{max} in mμ (log ε), 258.5 (4.60), 315 (3.85), and 350 (3.57); ν_{max}, no hydroxyl band, 1746 (lactone) cm^{-1}; n.m.r. (deuteriochloroform) (all peaks are sharp singlets), 7.66, 7.15, and 7.10 (1H each, C-1, C-5 and C-8) 6.58 (2H, C-2′ and C-6′), 5.34 (2H, lactone methylene), 4.02, 3.94, and 3.77 (3H each, C-6, C-7 and C-4′ methoxyls), and 3.82 δ (6H, C-3′ and C-5′ methoxyls); mass spectrum, parent ion = base peak 410, M-15 (30%), M-30 (5%), remaining peaks were all less than 4 percent.

Triacetyl Plicatinaphthalene (5)

Plicatinaphthalene (85 mg) was dissolved with warming in acetic anhydride (10 ml) and left standing for 3 h. The reaction mixture was heated on a steam bath for 1 h, *p*-toluenesulphonic acid (25 mg) added, and the mixture heated for an additional h. It was cooled overnight and added slowly to ice water (200 ml) with stirring. After filtering, the crude acetate was purified by recrystallization from dichloromethane to yield 2-(hydroxymethyl)-6-acetoxy-7-methoxy-4-(3′,4′-diacetoxy-5′-methoxyphenyl)-3-naphthoic acid lactone (**5**) (30 mg), $C_{26}H_{22}O_{10}$, t.l.c. R_f 0.61, m.p., 221–222 °C.

The n.m.r. spectrum (deuterioacetone) gave: 7.98, 7.54, 7.43 (1H each, singlets, C-1, C-5, C-8), 6.98 and 6.77 (1H each, doublets, J = 1 Hz, C-2′ and C-6′), 5.40 (2H, singlet, lactone methylene), 3.96 and 3.81 (3H each, singlets, methoxyls), 2.28 and 2.23 δ (3H and 6H, singlets, acetyls).

Triethyl Plicatinaphthalene (4)

Plicatinaphthalene (220 mg) in dry acetone (100 ml) containing anhydrous potassium carbonate (5 g) was treated with diethyl sulfate (1 ml per h) for 3 h on 2 consecutive days. After filtration and solvent removal, the product was purified on an alumina column by benzene to ethanol gradient elution to yield, after crystallization from ethanol, 6-ethoxy-2-(hydroxymethyl)-7-methoxy-4-(3′,4′-diethoxy-5-methoxyphenyl)-3-naphthoic acid lactone (**4**) (126 mg); t.l.c. R_f 0.80; m.p. 210–211°.

Permanganate oxidation and detection of 3,4-diethoxy-5-methoxy benzoic acid was carried out as previously described (10).

Synthesis of Trimethyl Plicatinaphthalene (3) from Podophyllin Resin

Podophyllotoxin was extracted from crude podophyllin resin (7). Podophyllotoxin (5 g) was dissolved in absolute ethanol (100 ml) containing anhydrous sodium acetate (1 g) and refluxed overnight (8). Hot water (200 ml) was added and the solution brought to a boil. On cooling, picropodophyllin (3.5 g) precipitated. The crude picropodophyllin (3.5 g) was converted to apopicrodophyllin (2.07 g) and thence to dehydroanhydropicropodophyllin (**6**) (1.6 g) by the method of Schrecker and Hartwell (9).

The methylenedioxy ring of dehydroanhydropicropodophyllin (**6**) (150 mg) was opened with boron trichloride and remethylated with diazomethane as previously described (1) to form 2-(hydroxymethyl)-6,7-dimethoxy-4-(3′,4′,5′-trimethoxyphenyl)-3-naphthoic acid lactone (**3**) (82 mg), which on recrystallization from ethanol (32 mg) was identical by mixture melting point, i.r. and n.m.r. spectra with trimethyl plicatinaphthalene (**3**).

Preparation of Plicatinaphthalene (2) from Plicatin (1)

Plicatin (15 mg), dissolved in pyridine (5 ml), was treated with $POCl_3$ (5 ml) and left overnight at room temperature. The reaction mixture was added dropwise to water (40 ml) which was then extracted with ethyl acetate (3 × 50 ml). After solvent removal, the residue showed 2 products by paper chromatography, R_f 0.77 (plicatin) and R_f 0.14 (plicatinaphthalene) which was confirmed by its naphthalene u.v. spectrum.

Aromatic nucleophilic substitutions. Reactions of chloro- and nitro-substituted benzenes

P. S. RADHAKRISHNAMURTI AND JANARDAN SAHU
Department of Chemistry, Khallikote College, Berhampur (Ganjam), Orissa, India

Received May 12, 1969

The kinetics of the reaction of 2,4-dinitro-1-chlorobenzene with various aromatic bases to give 2,4-dinitrodiphenylamines have been studied in alcohol, alcohol–acetonitrile, alcohol–dimethylformamide, and alcohol – dimethyl sulfoxide mixtures. No base catalysis has been observed under these conditions. ρ Values have been computed. In the reaction of *o*-chloro- and *p*-chloronitrobenzene with hydroxide in 50% dimethyl sulfoxide, the reactivity of both the isomers has been found to be identical, in contradiction to the previously reported observations.

Introduction

Singh and Peacock (1,2) were the earliest workers to study the reaction of 2,4-dinitro-1-chlorobenzene with amines in alcohol as solvent. The reactions have been found to be second order and there was no base catalysis reported. Other important workers in the field were Blanksma and Schreinemachers (3), Brady and Cropper (4), Rheinlander (5), and van Opstall (6) who arrived at similar conclusions. LeRoux *et al.* (7) and Bennett and Vernon (8) have studied the simplest of all nucleophilic displacements with these compounds; viz, when the reagent is a halide ion, either isotopically distinguished from, as in the former case, or chemically different from the halogen present in the organic compound, as in the latter case. The work was extended to the fluoro derivative and other bases like pyridine and picolines by Chapman and co-workers (*9a–e*) who arrived at similar conclusions as the previous investigators did with the chloro derivatives. Kingsbury (10) and Suhr (11) studied the action of dipolar aprotic solvents in the reaction of benzylamine with these halides. The speed can be attributed to the fact that DMSO molecules in, or arranged about, the transition state for a reaction in DMSO – methanol mixtures, lower the free energy of the transition state relative to that for a reaction in pure methanol.

Bunnett and Pruitt (12) studying the reaction of 2,4-dinitro-1-chlorobenzene with piperidine in 80% dioxan – water observed only an uncatalyzed reaction as did all the previous investigators. But, subsequently, Ross *et al.* (*13a–f*) have published a series of papers questioning the validity of postulating a simple uncatalyzed reaction for this amine reaction and confirmed that, with a series of aliphatic amines in various solvents, this reaction is catalyzed by bases. In their work on aniline with 2,4-dinitro-1-chlorobenzene in ethanol and in ethanol – ethyl acetate (50%), Ross and Kuntz (14) found that, due to charge transfer complexing, there is a decrease in the measured rate constant with an increase in concentration of the base. No sure choice can be made between the two alternatives: the first, that aniline and 2,4-dinitro-1-chlorobenzene are in equilibrium with a charge transfer complex and that concurrently they react to form products; the second, that the two reagents are in equilibrium with a complex which decomposes to products. It is clearly seen from the previous work that, though plausible explanations have been advanced to account for all the results both in terms of the one step mechanism and the two step intermediate complex mechanisms, it is best to conclude that no definite choice can be made between the two possibilities.

The present investigation is intended to study the effect of dipolar aprotic solvents like acetonitrile, dimethylformamide, and dimethyl sulfoxide under perfectly homogeneous conditions and also to correlate structure and reactivity in a systematic manner. Absence or presence of amine catalysis is also investigated.

Experimental

Materials

All the bases and the substrates used were obtained from British Drug House (B.D.H.) and were purified and distilled before use. The physical constants of the compounds are as follows: 2,4-dinitro-1-chlorobenzene, m.p. 52 °C; aniline, b.p. 183 °C; *p*-toluidine, m.p. 45 °C; *m*-toluidine, b.p. 199 °C; *p*-chloroaniline, m.p. 70 °C;

and *m*-chloroaniline, b.p. 230 °C. Acetonitrile, dimethylformamide, and dimethyl sulfoxide were of B.D.H. A.R. grade and were used without further purification. Alcohol was of absolute grade. Second order rate constants were calculated by using the least squares method.

Preparation of Indicator and Solutions

Ferric alum indicator, potassium thiocyanate, and silver nitrate solutions required for kinetic studies were prepared using standard procedures (15).

Procedure

The solution of the substrate and the base in the mixed solvent after attaining the required temperature was mixed in a narrow mouthed stoppered bottle. Five ml aliquots of the reaction mixture were quenched in standard silver nitrate solution at different intervals of time and the excess of silver nitrate solution determined by Volhard's method (16).

Results and Discussion

We have studied this reaction with 2,4-dinitro-1-chlorobenzene and a series of substituted aromatic primary amines and in some cases with different concentrations of amines in alcohol as solvent. We find that there is no amine catalysis and the reactions are straightforward second order reactions within the concentration ranges studied.

The concentration ranges are 0.025 to 0.075 M for the amine, but as against the reported homogeneous reactions with aliphatic amines, there has been extensive precipitation of the product with all the aromatic amines studied towards the last stages of the reaction, and the precipitate is found to be insoluble in excess alcohol or water but soluble in dimethyl sufoxide, dimethylformamide, and acetonitrile. The rate constants have been computed from the initial percentages in all cases for the purpose of comparison. To this date this is the first case of a report of precipitation with alcohol as solvent in these reactions.

Hence to have homogeneous conditions, the kinetics were studied in 80:20% (v/v) mixtures of alcohol with acetonitrile, dimethylformamide, and dimethyl sulfoxide. Perfect homogeneity has been found in all cases. The reactivity is alcohol – dimethyl sulfoxide > alcohol – dimethylformamide > alcohol > alcohol – acetonitrile. The rate constants are given in Tables I–IV.

A plot of log k vs. pK_a shows linearity. A plot of log k vs. σ shows linearity with the rate constants obtained in pure alcohol, alcohol – acetonitrile, alcohol – dimethylformamide, and alcohol – dimethyl sulfoxide mixtures. The ρ values are −2.74, −2.77, −2.90, and −2.82 for alcohol and mixed solvents respectively. This shows that bond formation is an important feature in these reactions. Electron releasing groups in the base are accelerating the process. It is pertinent to point out that as alcohol is used as solvent, the amine – alcohol interaction will not cause significant disturbance in the nucleophilic aromatic displacements studied. The reactions are consistently slower in the alcohol – acetonitrile mixtures than in pure alcohol. It can be rationalized that as the reaction is a dipole–dipole reaction, an increase in dielectric constant increases the kinetic rate. This seems to be true except in the case of acetonitrile mixtures. Alternatively, the higher reaction rate in alcohol – dimethyl sulfoxide mixtures is due to the special solvent effect due to DMSO. A major portion of the solvent effect can be associated with the dramatic influence of DMSO upon the solvation shell geometry.

Table V shows that there is no amine catalysis. Increase of concentration of the amine does not cause much change in the rate.

In the latter case there has been an increase of 6% which can be taken to be either a small general co-solvent effect or it can be safely remarked that as far as weak bases like aromatic primary amines are concerned, there does not seem to be any amine catalysis as found earlier for the stronger aliphatic amines by Ross and co-workers. Our investigations are confirmed by the very recent work of Ross in systems containing hydroxylic solvents (17).

In addition we wish to record some interesting observations on the hydroxide reactions with *o*-chloronitrobenzene and *p*-chloronitrobenzene in 50% aqueous dimethyl sulfoxide at 80 °C. "It has long been known that for displacements with primary and secondary amines, *o*-nitrohalobenzenes react more rapidly than *p*-nitrohalobenzenes, but, that, in substitutions which do not involve the removal of a proton, as in reactions with alkoxides or thiophenoxides, it is the *p*-nitrohalobenzenes which react more rapidly." (18). This statement needs revision on the basis of the present work. Hydroxide reactions

TABLE V

Second order rate constants (l mole^{-1} min^{-1} × 10^3) for 2,4-dinitro-1-chlorobenzene – aniline reaction at 50 ± 0.02 °C

Solvent	Concentration (M)	k
100% Alcohol	1:1 (0.02494 : 0.02612)	14.18
	1:2 (0.02570 : 0.05115)	15.55
	1:3 (0 02475 : 0 07660)	14.48
Alcohol – acetonitrile (80:20 % v/v)	1:1 (0 02490 : 0 02500)	8.536
	1:2 (0.02478 : 0.05000)	8.459
	1:3 (0 02461 : 0 07505)	9.035
Alcohol – DMSO (80:20 % v/v)	1:1 (0 02523 : 0 02498)	23.97
	1:2 (0 02526 : 0 05050)	22.50
	1:3 (0 02503 : 0 07670)	23.86
Alcohol – DMF (80:20 % v/v)	1:1 (0.02522 : 0 02575)	17.93
	1:2 (0 02522 : 0.05065)	18.05
	1:3 (0.02522 : 0.07560)	17.48

in dimethyl sulfoxide at 80 °C show that the *o*- and *p*-nitrohalobenzenes react with identical rates. With *n*-butylamine neither isomer reacts. The reactions were facile in 1:10 stoichiometry. The rates were almost identical for *ortho* and *para* isomers and *m*-chloronitrobenzene did not even react under these conditions. It was also found when 1-nitro-2,5-dichlorobenzene was subjected to the same reaction in dimethyl sulfoxide, there was substitution of one of the chlorines yielding 1-nitro-5-chloro-2-hydroxybenzene. When 1-nitro-3,4-dichlorobenzene was hydrolyzed similarly, it yielded 1-nitro-3-chloro-4-hydroxybenzene, confirming that a chlorine at the *meta* position does not get hydrolyzed. The rate constants are 10 times higher than those for *o*-chloro- and *p*-chloronitrobenzenes as seen from Table VI.

TABLE VI

Second order rate constants (l mole^{-1} min^{-1} × 10^3) at 80 ± 0.02 °C in 50% aqueous dimethyl sulfoxide

Photo-addition of indene and acrylonitrile: orientation and stereochemistry of the cycloadducts

R. M. BOWMAN AND J. J. MCCULLOUGH
Department of Chemistry, McMaster University, Hamilton, Ontario
AND
J. S. SWENTON
Department of Chemistry, The Ohio State University, Columbus, Ohio

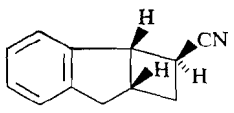
Received June 24, 1969

The cyclobutanes obtained on photosensitized cyclo-addition of indene and acrylonitrile have been reinvestigated and the structures formerly assigned (1) have been unambiguously confirmed. The photo-addition of indene and cyanoacetylene has been shown to smoothly afford a single adduct, 7-cyano-2,3-benzobicyclo[3.2.0]hepta-2,6-diene.

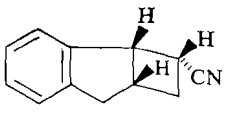
Canadian Journal of Chemistry, **47**, 4503 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In earlier papers (1) we reported that indene and acrylonitrile react on acetophenone sensitization to yield a small amount of indene dimer and two isomeric nitrilic adducts. The latter were assigned structures **1***a* and **1***b* on the basis of their mode of formation and interconvertibility by strong base. The stereochemistry was tentatively assigned from the nuclear magnetic resonance (n.m.r.) spectra (**1***b*). Recently in connection with studies on the photochemistry of a carbomethoxy benzonorcaradiene, the nitriles **1***a* and **1***b* were used for structural correlation (2). During the course of this study it was deemed advisable to confirm the location of the nitrile group chemically, since the photoproduct from the benzonorcaradiene appeared to be without precedent. Furthermore, the discovery that cyanoacetylene adds to indene furnished a chemical method of establishing with certainty the stereochemistry of the nitrile group.

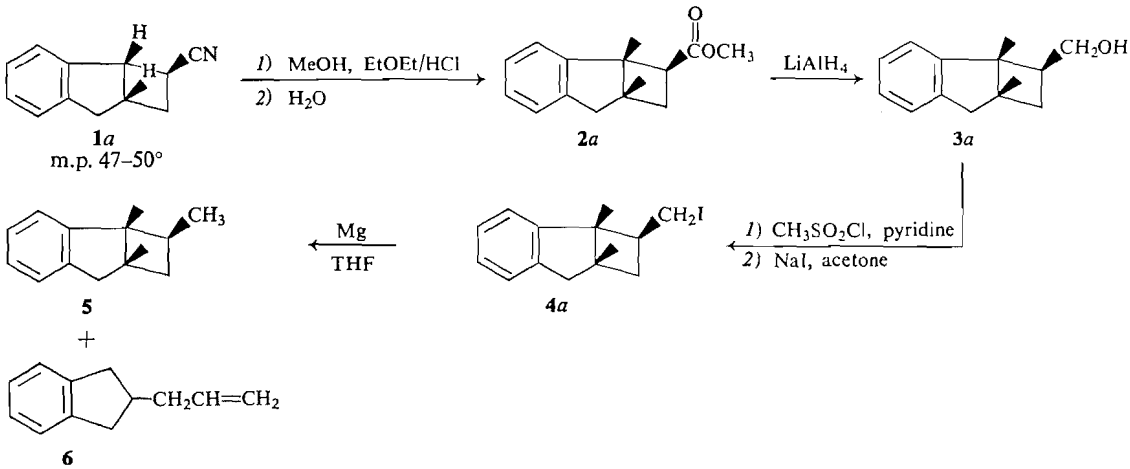


1*a* m.p. 49°

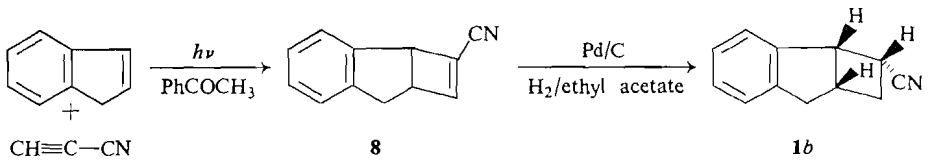


1*b* m.p. 70°

The orientation of the nitrile group was established by degradation of the nitrile, m.p. 47–50° as shown in Scheme 1. The key step in this sequence was ring-opening of the cyclobutyl carbinyl iodide **4***a* on reaction with magnesium (3) to afford 2-allylindane. The degradation product proved to be identical with a 2-allylindane prepared by coupling 2-indanyl magnesium iodide and allyl bromide.



SCHEME 1



SCHEME 2

There still remained the problem as to the stereochemistry of the nitrile groups in the cycloadducts. The tentative assignment of stereochemistry made on the basis of the n.m.r. spectra (**1***b*) earlier was further supported by the methoxy resonance positions of the esters **2***a* and **2***b*. While **2***a* showed the methoxy singlet at 6.23 τ, the resonance in the ester **2***b* occurred at 6.58 τ suggestive of shielding by the aromatic ring.

A rational approach to elucidation of the configuration at C-7 would involve addition of indene to cyanoacetylene to afford the cyanocyclobutene having the same carbon skeleton as **1***a* and **1***b*. Since ample precedent exists for hydrogenation involving addition from the less hindered side to afford the *endo*-nitrile, the success of this method depended on the ease and direction of the cyanoacetylene addition.

On photolysis of a mixture of indene and cyanoacetylene in ethanol using a Corex filter (or with acetophenone as sensitizer and a Pyrex filter), a single product was formed, at a somewhat slower rate than the adducts of indene and acrylonitrile (**1***b*). The progress of the reaction was followed by vapor phase chromatography (v.p.c.), and one new peak appeared. On termination of the photolysis, chromatography on silica gel afforded the adduct, m.p. 80–81°, molecular ion of *m/e* 167 and infrared (i.r.) band at 2210 cm^{-1} (nitrile). In the n.m.r. spectrum (CCl_4, 100 Mc.p.s.), peaks appeared at 2.7–3.1 τ, multiplet, area 4 (aromatics); 2.38 τ, singlet, area 1 (vinylic); 5.54 τ, doublet, area 1 (methine); and at 6.7–7.1 τ, multiplet, area 2 (methylene).

The spectral data are consistent with the structure of the required cyanocyclobutene **8**. Hydrogenation of **8** at 1 atm in ethyl acetate gave a quantitative yield of **1***b*, m.p. and mixed m.p. 67–68°, identical by i.r. and n.m.r. spectra. Obtaining **1***b* as the only product in the hydrogenation established both the position of the nitrile group in the cyclobutene **8**, and the *cis* stereochemistry (4) of **1***b*, see Scheme 2.

It is interesting that the adducts formed in the acrylonitrile– and cyanoacetylene–indene additions have the orientation which would result from closure of the more stable biradical intermediate (5). In the cyanoacetylene case, the electronic structure of the cyano-group is such that it can stabilize an adjacent vinyl radical, while retaining conjugation with the π-system of the C≡C linkage.

We also report that the adducts **1***a* and **1***b* formed so efficiently in the sensitized addition of indene and acrylonitrile, are formed in the direct irradiation. They are accompanied by the isomeric 6-cyanobenzobicyclo[3.2.0]hept-2-enes, and cyanoethylindenes (1). Separation of the cyclobutanes from this reaction mixture is difficult if not impossible by chromatography alone, and was achieved by oxidizing the indenes with permanganate, followed by chromatography of the cyanocyclobutane mixture and fractional crystallization of the solid isomers. The operations are described in the Experimental.

Experimental

Except where stated otherwise, the instruments and materials described previously were used (**1***b*). Gas chromatography was performed at 165° using a 5 ft × 1/8 in. column of 5% QF-1 on Chromosorb W, with helium at 30–35 ml/min as carrier gas.

*Conversion of exo-7-Cyano-2,3-benzobicyclo[3.2.0]hept-2-ene (**1a**) to exo-7-Carbomethoxy-2,3-benzobicyclo[3.2.0]hept-2-ene (**2a**)*

A 270 ml mixture of anhydrous ether–methanol (200:70) was saturated with dry hydrogen chloride. 5.0 g (0.029 mole) of nitrile **1***a* added, and the reaction mixture magnetically stirred at 0° for 8 h. After cautious addition of 200 ml of water the mixture was allowed to warm to room temperature over a period of 3 h. The reaction mixture was then poured into 1 l of cold water, the organic layer separated, and the aqueous layer extracted, 3 × 75 ml of ether. The organic layers were combined, dried over $CaSO_4$, and the ether distilled to yield 5.66 g of crude ester. Purification by v.p.c. (5% PDEAS on 60–80 Chromosorb W—10 ft × 1/4 in.—150°) yielded a colorless liquid ester. The n.m.r. spectrum (CCl_4) exhibited the aromatic protons as a singlet, 2.71 τ (4H); a low field broad absorption, 6.03 τ (1H); the methoxy group, 6.23 τ (3H); and complex structured absorption from 6.46–8.38 τ (6H).

exo-7-Carboxy-2,3-benzobicyclo[3.2.0]hept-2-ene (7a)

Hydrolysis of the *exo*-ester (**2a**) followed by chromatography on deactivated silica gel and recrystallization from hexane:methylene chloride yielded a crystalline acid, m.p. 85–87°.

Anal. Calcd. for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43. Found: C, 76.46; H, 6.43.

Conversion of endo-7-Cyano-2,3-benzobicyclo[3.2.0]hept-2-ene to Ester 2b and Acid 7b

The conversion of **1b**–**2b** and subsequent hydrolysis to **7b** were analogous to the transformations **1a**–**2a** and **2a**–**7a**. The prominent features of the n.m.r. spectrum of **2b** were aromatic absorption centered at 3.00 τ (4H); a broad peak centered at 6.00 τ (1H); the methoxy resonance appeared as a singlet at 6.58 τ overlapping a structured absorption (6.43–6.83 τ), the total area being 4H; and two broad structured absorptions centered at 7.10 τ (3H) and 7.76 τ (2H). Hydrolysis of the ester yielded an acid which was recrystallized from hexane/methylene chloride to yield a white crystalline material, m.p. 141–143°.

Anal. Calcd. for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43. Found: C, 76.56; H, 6.44.

$LiAlH_4$ Reduction of exo-7-Carbomethoxy-2,3-benzobicyclo[3.2.0]hept-2-ene (2a)

The crude ester, 5.66 g (0.028 mole), obtained from hydrolysis of the corresponding nitrile in 50 ml of anhydrous ether was added dropwise to a slurry of 1.5 g of $LiAlH_4$ in 250 cc of anhydrous ether. The mixture was refluxed for 5 h followed by decomposition of the excess hydride and reduction complex by cautious addition of 6.0 ml of water. Filtration of the solution followed by distillation of the ether afforded 5.06 g of light yellow oil. Crystallization of the oil from hexane yielded a total of 4.0 g (0.023 mole) of **3a** as white needles, m.p. 55.0–56.5°.

Anal. Calcd. for $C_{12}H_{12}O$: C, 82.72; H, 8.10. Found: C, 82.76; H, 8.19.

Conversion of Alcohol 3a to Iodide 4a

Reaction of 3.3 g (0.02 mole) of alcohol **3a** with methane sulfonyl chloride in pyridine at 0° in the usual manner afforded after work-up 5.0 g of crude mesylate as a light yellow oil. The mesylate without further purification was refluxed for 10 h in 200 ml of acetone containing 20 g of sodium iodide. After filtration of the solid and evaporation of the acetone, the residue was transferred to a separatory funnel with 100 ml of water and 150 ml of ether. The organic layer was washed with 100 ml of 10% $NaHSO_3$, 10% $NaHCO_3$, and saturated NaCl. The yellow oil obtained after drying of the organic layer and removal of solvent was chromatographed on silica gel to 4.54 g (85%) of a nearly colorless oil which slowly darkened on standing.[1]

Anal. Calcd. for $C_{12}H_{13}I$: C, 50.70; H, 4.58; I, 44.71. Found: C, 51.05; H, 4.65; I, 43.85.

Reaction of Iodide 4a with Magnesium in Tetrahydrofuran

The general procedure of Hill *et al.* (3) was utilized. In a typical procedure, the Grignard was refluxed for 3 h followed by quenching with water. Vapor phase chromatographic analysis (10% SE-30 on 60–80 Chromosorb P—10 ft × 1/4 in.—120°) showed two major reaction products. The ratio of the two products was dependent upon reaction conditions varying from 1:3 to 1:1 in two different runs. The material of lower retention time was identified as *exo*-7-methyl-2,3-benzobicyclo[3.2.0]hept-2-ene on the basis of its i.r., n.m.r., and mass spectra. The material of longer retention time was identified as 2-allylindane by comparison of its i.r. and n.m.r. spectrum with that of an authentic sample synthesized by the procedure below.

2-Iodoindane

The 2-iodoindane was prepared in 65% purified yield by iodide displacement of the mesylate of 2-indanol as in the **3a**–**4a** conversion. Recrystallization from hexane yielded white crystals, m.p. 52–53°. The n.m.r. spectrum showed the aromatic protons as a singlet at 2.91 τ (4H), the methine hydrogen as a pentuplet centered at 5.46 τ (1H, J = 6 c.p.s.), and the benzylic protons as a doublet centered at 6.66 τ (4H, J = 6 c.p.s.).

Anal. Calcd. for C_9H_9I: C, 44.30; H, 3.72; I, 52.20. Found: C, 44.29; H, 3.74; I, 52.16.

2-Allylindane

The mixture of 2-iodoindane, 1.16 g (4.8 mmoles), and magnesium, 0.15 g (6.5 mmoles), in 25 ml of anhydrous ether was stirred at room temperature for 1 h during which the Grignard reagent formed. The solution was heated to reflux and 1.1 g (6.3 mmoles) of allyl bromide in 5 ml of ether were added dropwise. After 30 min reflux the reaction mixture was poured into 100 ml of 5% HCl. Work-up in the usual manner afforded a light yellow liquid from which the 2-allylindane was isolated in 31% yield by preparative v.p.c. (10% SE-30 on 60–80 Chromosorb P—10 ft × 1/4 in.—120°). Prominent bands in the i.r. were the double bond absorption at 6.07 μ, and the bands at 10.09 and 10.95 μ characteristic of a monosubstituted ethylene. The n.m.r. spectrum showed the aromatic protons as a singlet, 2.97 τ (4H), complex vinyl absorption from 3.83–4.58 τ (1H), two structured signals centered at 4.90 and 5.13 τ having an area of 2H, and structured absorption from 6.70–8.0 τ (7H).

Anal. Calcd. for $C_{12}H_{14}$: C, 91.08; H, 8.92. Found: C, 90.93; H, 8.83.

Cyanoacetylene

Cyanoacetylene was prepared in 70–85% yield by phosphorus pentoxide dehydration of propiolamide in the manner described by Murahashi *et al.* (6). Decalin was the reaction medium and the cyanoacetylene was swept from the reaction flask in a slow stream of nitrogen and collected in a wide U-tube cooled in dry ice – acetone. The colorless solid had m.p. 7–8° and λ_{max} (EtOH) mμ(log ε_{max}) 210 (2.20), 219 (2.24), 229 (2.00), and 243 (0.78).

Photocondensation of Indene and Cyanoacetylene

Cyanoacetylene (4.60 g; 0.090 mole) and indene (1.03 g; 0.009 mole) in 95% ethanol (400 ml) were irradiated in the usual manner for 4 h (1*b*). A Corex sleeve was used. Monitoring by v.p.c. indicated that one major volatile component was formed. The solvent was evaporated and the residue taken up in ether and filtered through

[1]This decomposition apparently precluded an accurate analysis.

Celite. The crude product was chromatographed on silica gel (2.5 × 38 cm). Benzene was used as eluent throughout and 100 ml fractions were collected. Fraction 1 contained residual indene (590 mg) and fractions 6–9 contained a gum (116 mg) which gave a single peak on gas–liquid chromatography with a retention time of 2.8 min. The combined fractions 6–9 afforded colorless prisms (81 mg) m.p. 80–81°, from light petroleum (b.p. 30–60°). The i.r. spectrum (KBr) showed bands at 2210 (nitrile) and 1575 (C=C) cm^{-1}, while the n.m.r. spectrum (see above) and the mass spectrum (molecular ion *m/e* 167 and strong peaks at *m/e* 116 and 115) showed the product to be cyano-2,3-benzobicyclo[3.2.0]-hepta-2,6-diene.

Anal. Calcd. for $C_{12}H_9N$: C, 86.18; H, 5.44; N, 8.38. Found: C, 86.05; H, 5.45; N, 8.27.

Acetophenone Sensitized Photo-addition of Indene and Cyanoacetylene

A solution of indene (1.03 g; 0.009 mole), cyanoacetylene (4.60 g; 0.090 mole), and acetophenone (1.00 g; 0.0083 mole) in benzene (300 ml) was irradiated in the usual way for 3 h using a Pyrex filter. Chromatography as described in the previous experiment gave the cyanocyclobutene **8**, m.p. 80–81° (from light petroleum) (180 mg), found in fractions 4–6. Fractions 7–12 contained a yellow oil, which contained **8** plus adducts of the latter with indene and benzene, detected by ions of *m/e* 283 and 245 respectively in the mass spectrum.

Hydrogenation of the Indene – cyanoacetylene Photo-adduct

The cyanocyclobutene **8**, from the above addition reactions, (51 mg) in ethyl acetate (10 ml) was hydrogenated at atmospheric pressure and ambient temperature over 10% palladium on charcoal catalyst (10 mg), (Matheson, Coleman and Bell). Hydrogen uptake (6.9 ml, theoretical 6.7 ml) was complete in 5 min, and v.p.c. on the filtered solution showed one peak, retention time 4.2 min. Evaporation gave *cis*-7-cyano-2,3-benzobicyclo-[3.2.0]hept-2-ene as needles, m.p. 67–67.5° from light petroleum, (46 mg, 90%). This was identical with the higher-melting adduct from the sensitized indene – acrylonitrile reaction (1), by mixed m.p. (67–68°) and i.r. and n.m.r. spectra comparison.

Anal. Calcd. for $C_{12}H_{11}N$: C, 85.16; H, 6.57; N, 8.28. Found: C, 85.29; H, 6.64; N, 8.16.

Isolation of the Cyclobutane Adducts from the Direct Irradiation of Indene and Acrylonitrile

Indene (5.50 g; 0.0477 mole) and acrylonitrile (30.0 g; 0.566 mole) in 95% ethanol (1 l) were irradiated for 4.5 h precisely as described previously (1*b*), except that a Corex sleeve was used. The reaction mixtures from two runs were combined and evaporated. The residue was freed from indene and polymer by filtration through a 2.5 × 30 cm column of silica gel; benzene eluted the indene, and the adducts were eluted with 1:1 benzene – ether. The adduct mixture from the latter fractions was dissolved in *tert*-butyl alcohol (100 ml) and water (100 ml) was added; this mixture was stirred at ambient temperature while carbon dioxide was bubbled through. A total of 3.5 g of potassium permanganate was added, in 0.5 g portions at 10 min intervals. The mixture was acidified (litmus) with 10% H_2SO_4, and sodium bisulfite was added until all the precipitate dissolved. The organic layer was separated, and the aqueous phase was extracted with ether (3 × 50 ml). The combined organic solutions were washed with water, 10% Na_2CO_3 solution, and finally water, and dried ($MgSO_4$). On evaporation, 2.8 g of oil were obtained, which showed 3 components on v.p.c., retention times 3.1, 3.4, and 4.2 min, ratio (by areas) 25:10:65, respectively. This ratio was unchanged by further permanganate treatment. The mixture was chromatographed on a 3 × 75 cm column of silica gel, which was eluted with benzene – light petroleum (9:1) (3 l), then with benzene; 200 ml fractions were collected. Fractions 23–25 contained the 3.1 min component (66 mg); 26–30 (327 mg) were mixtures of all three components and the component of retention time 4.2 min was found in fractions 31–37. Fractions 23–25 were combined and crystallized twice from light petroleum, b.p. 30–60°, to afford *trans*-7-cyano-2,3-benzobicyclo-[3.2.0]hept-2-ene (1*a*), m.p. and mixed m.p. 48–50°. Fractions 31–37 were oily, but on repeated crystallization from light petroleum, b.p. 30–60°, *cis*-7-cyano-3-benzobicyclo[3.2.0]hept-2-ene, m.p. and mixed m.p. 68–70°, was obtained. The mother liquors from these crystallizations (of the *cis*-compound) gave an oil on evaporation; this oil had an n.m.r. spectrum very similar to that reported for 6-cyano-benzobicyclo[3.2.0]hept-2-ene (1*b*), and had a retention time of 4.2 min, the same as the *cis*-7-cyano-compound.

Une nouvelle méthode de synthèse des peptides de la cystine

BERNARD MARINIER ET MICHÈLE BÉRUBÉ
Research Laboratories, Frank W. Horner Limited, Montréal, Québec

Reçu le 13 août 1969

La synthèse du glutathion oxydé à partir de l'acide djenkolique illustre une nouvelle méthode de préparation des peptides de la cystine. L'oxydation par le brome d'un peptide de l'acide djenkolique constitue l'étape essentielle et originale de cette méthode.

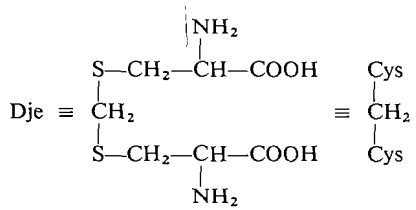
The synthesis of oxidized glutathione from djenkolic acid is used to expose a new method of preparation of cystine peptides. The brominative oxidation of a djenkolic acid peptide is the essential and original step of this method.

Canadian Journal of Chemistry, 47, 4507 (1969)

Jusqu'à présent, deux méthodes ont été utilisées pour synthétiser les peptides cycliques de la cystine. La première date de la synthèse de l'oxytocine par du Vigneaud et ses collaborateurs en 1954 (1): elle consiste à utiliser des cystéines protégées par des groupes benzyles durant la synthèse peptidique proprement dite, puis, à la fin, à éliminer les groupes protecteurs et à provoquer la cyclisation par oxydation des groupes SH en disulfure. Le rendement de ces dernières opérations est généralement assez bas à cause de la formation de polymères. D'autres chercheurs, notamment Zervas *et al.* (2), Hiskey et Smith (3), et Kamber et Rittel (4) utilisèrent avec des succès divers le groupe protecteur trityle pour protéger le SH des cystéines, mais le principe de la méthode demeura toujours le même et consiste à utiliser des cystéines durant la synthèse peptidique puis à les oxyder en cystine, avec ou sans formation de thiols, à la fin de la synthèse.

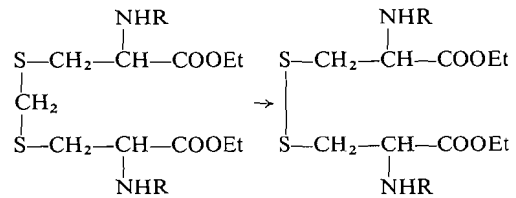
La deuxième méthode consiste à utiliser un peptide dissymétrique non cyclique de la cystine et à cycliser par formation d'une liaison peptidique. Cette méthode semble cependant n'avoir été mise en pratique qu'une seule fois (5) car on démontra très tôt qu'un peptide ou un dérivé dissymétrique non cyclique de la cystine est peu stable et tend à se décomposer en un mélange de peptides ou de dérivés symétriques (6).

L'acide djenkolique (**1**) est un mercaptal obtenu par la condensation de la formaldéhyde avec la cystéine (7). Bien que semblable à la cystine, cette molécule est beaucoup plus stable de sorte



1

que la préparation de dérivés dissymétriques stables est possible (8) ainsi que celle de peptides dissymétriques. L'hypothèse de travail fut que la cyclisation de tels peptides par formation d'une liaison peptidique fournirait des composés qui, par élimination du méthylène central et oxydation consécutive, donnerait des peptides cycliques de la cystine. Cette communication montre un premier point, à savoir qu'il est possible de préparer un peptide symétrique de la cystine à partir du peptide symétrique correspondant de l'acide djenkolique.



1*a* R = Cbo— **2** R = Cbo—
3 R = C_6H_5CO— **4** R = C_6H_5CO—

Cbo— = $C_6H_5CH_2OCO$—

Pour éliminer le méthylène central, une hydrolyse ne put être utilisée mais on trouva

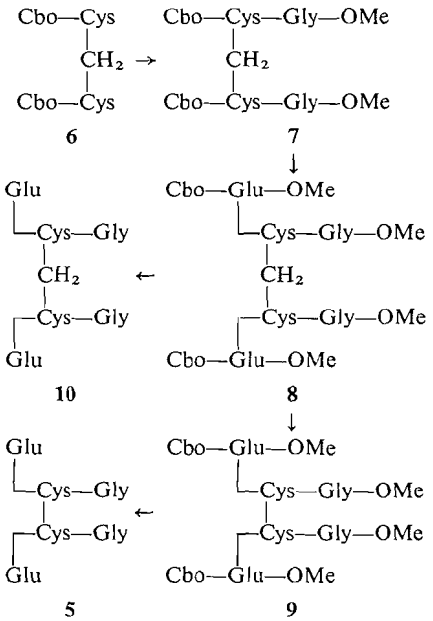
For personal use only.

qu'une oxydation par le brome (9) pouvait dans certaines conditions effectuer la transformation avec des rendements très satisfaisants. Ainsi, le dicarbobenzoxy-L-djenkolate de diéthyle (**1***a*) fut traité par un équivalent de brome dans le chloroforme anhydre, puis le composé d'addition formé fut hydrolysé par l'eau ou le bicarbonate de sodium pour donner le dicarbobenzoxy-L-cystinate de diéthyle (**2**) avec un rendement de 76% et, en prolongeant le temps d'hydrolyse, le dibenzoyl-L-djenkolate de diéthyle (**3**) fut transformé en dibenzoyl-L-cystinate de diéthyle (**4**) avec un rendement de 77%.



La synthèse du glutathion oxydé (**5**), un peptide naturel non cyclique de la cystine, fut ensuite entreprise. L'acide dicarbobenzoxy-L-djenkolique (**6**) (8) fut d'abord condensé avec 2 équivalents de glycinate de méthyle par la méthode des anhydrides mixtes (10) pour donner avec un rendement de 95% le tripeptide dicarbobenzoxy-L-djenkolyl-bis(glycinate de méthyle) (**7**). Ce tripeptide fut débarrassé de ses groupes carbobenzoxy par HBr dans l'acide acétique (11) puis condensé avec le carbobenzoxy-L-glutamate d'α-monométhyle (12) par la méthode des anhydrides mixtes: le pentapeptide bis-γ-L-[*N*-carbobenzoxy-L-glutamyl-α-(*O*-méthyl)]-L-djenkolyl-bis(glycinate de méthyle) (**8**) fut obtenu avec un rendement de 84%. Ce pentapeptide fut traité par le brome dans le chloroforme anhydre puis le complexe bromé fut hydrolysé par le bicarbonate de sodium en milieu hétérogène durant 20 h pour donner le pentapeptide correspondant de la cystine **9** avec un rendement de 68.5%. L'enlèvement des groupes protecteurs de ce peptide au moyen d'une saponification suivie d'une scission des groupes carbobenzoxy par HBr dans l'acide acétique donna le dibromhydrate du glutathion oxydé ne montrant qu'une seule tache à la chromatographie sur papier. Le peptide libre **5** fut obtenu en filtrant la solution aqueuse ajustée au p*H* 2.85 à travers une colonne de Séphadex G-10. Le rendement de ces dernières opérations fut de 69% ce qui donne un rendement global de 38% à partir de l'acide djenkolique. Le peptide contient les acides aminés constituants Glu, Cys, et Gly dans le rapport attendu et son indice de rotation est de −94° (litt., −93.9° (13); −92.8° (14)). A la chromatographie sur papier, il ne donne qu'une seule tache ayant le même R_f que le produit commercial et donne un test de disulfure positif (15).

L'analogue **10** du glutathion oxydé contenant de l'acide djenkolique au lieu de la cystine fut aussi préparé en effectuant la même séquence de réactions sur le pentapeptide **8**. Cet analogue qui fut obtenu avec un rendement global de 57% donne un indice de rotation de −34.2° mais un R_f identique à celui du glutathion oxydé. De plus, à l'analyse il ne donne pas uniquement de l'acide glutamique, de la glycine, et de la cystéine mais aussi de l'acide djenkolique, de l'acide thiazolidine-carboxylique-4 et un inconnu, ces trois derniers produits étant caractéristiques de l'hydrolyse de l'acide djenkolique en tube scellé; l'addition de la cystéine à ces trois produits donne le rapport Glu:Cys:Gly attendu.

La synthèse d'un peptide cyclique de la cystine via son analogue contenant de l'acide djenkolique est présentement en cours.

Remerciements

Sulfene[1]

J. F. KING, P. DE MAYO, AND D. L. VERDUN[2]
Department of Chemistry, University of Western Ontario, London, Ontario

Received September 15, 1969

Evidence indicating the existence of sulfene ($CH_2{=}SO_2$) as a discrete species in the gas phase is presented.

Canadian Journal of Chemistry, **47**, 4509 (1969)

The existence of sulfene ($CH_2{=}SO_2$) as a transitory intermediate has been deduced from the evidence of product analysis[3] and rate studies (3). We now report experiments in the gas phase which provide independent support for the intermediacy of sulfene and further define its properties.

We have recently employed flash thermolysis (1) for the generation of sulfenes (1, 4), but though it was concluded that the sulfene was probably formed in those instances, it rapidly underwent the further reactions illustrated in Scheme 1. To gain further evidence for this scheme and to investigate the possibility of producing sulfene under conditions sufficiently mild that we might trap the sulfene outside the hot zone of the apparatus, we have studied the flash thermolysis of chlorosulfonylacetic acid (**1**). Using the previously described apparatus (1)[4] and trapping the products on a cold-finger coated with methanol and cooled with liquid nitrogen, we found (see Scheme 2) that **1** was converted to formaldehyde (isolated as dimethoxymethane) in good yield at 940°. This observation is consistent with, and presumably analogous to, the formulation proposed in Scheme 1. At 640° a relatively low yield of dimethoxymethane (~8%) was obtained, the major product being methanesulfonyl chloride (~50%). The most significant result from the viewpoint of the question of sulfene formation, however, was a small but reproducible yield (2.6%) of methyl methanesulfonate. The workup and identification of the products of the reaction were carried out following a procedure which was shown by control experiments to lead to no methyl methanesulfonate by reaction of methanol with the methanesulfonyl chloride. That at least half of the methyl methanesulfonate arose from sulfene was rigorously established by using methanol-*d* as the trapping agent. In two such runs the methyl methanesulfonate produced was found to contain 50.4 and 63.0% of $CH_2DSO_2OCH_3$, the remainder being $CH_3SO_2OCH_3$; the methanesulfonyl chloride contained 3.0 and 3.3% CH_2DSO_2Cl in the same runs. These results require that a species capable of supplying

Sulfene[1]

J. F. KING, P. DE MAYO, AND D. L. VERDUN[2]
Department of Chemistry, University of Western Ontario, London, Ontario

Received September 15, 1969

Evidence indicating the existence of sulfene ($CH_2{=}SO_2$) as a discrete species in the gas phase is presented.

Canadian Journal of Chemistry, **47**, 4509 (1969)

The existence of sulfene ($CH_2{=}SO_2$) as a transitory intermediate has been deduced from the evidence of product analysis[3] and rate studies (3). We now report experiments in the gas phase which provide independent support for the intermediacy of sulfene and further define its properties.

We have recently employed flash thermolysis (1) for the generation of sulfenes (1, 4), but though it was concluded that the sulfene was probably formed in those instances, it rapidly underwent the further reactions illustrated in Scheme 1. To gain further evidence for this scheme and to investigate the possibility of producing sulfene under conditions sufficiently mild that we might trap the sulfene outside the hot zone of the apparatus, we have studied the flash thermolysis of chlorosulfonylacetic acid (**1**). Using the previously described apparatus (1)[4] and trapping the products on a cold-finger coated with methanol and cooled with liquid nitrogen, we found (see Scheme 2) that **1** was converted to formaldehyde (isolated as dimethoxymethane) in good yield at 940°. This observation is consistent with, and presumably analogous to, the formulation proposed in Scheme 1. At 640° a relatively low yield of dimethoxymethane (~8%) was obtained, the major product being methanesulfonyl chloride (~50%). The most significant result from the viewpoint of the question of sulfene formation, however, was a small but reproducible yield (2.6%) of methyl methanesulfonate. The workup and identification of the products of the reaction were carried out following a procedure which was shown by control experiments to lead to no methyl methanesulfonate by reaction of methanol with the methanesulfonyl chloride. That at least half of the methyl methanesulfonate arose from sulfene was rigorously established by using methanol-*d* as the trapping agent. In two such runs the methyl methanesulfonate produced was found to contain 50.4 and 63.0% of $CH_2DSO_2OCH_3$, the remainder being $CH_3SO_2OCH_3$; the methanesulfonyl chloride contained 3.0 and 3.3% CH_2DSO_2Cl in the same runs. These results require that a species capable of supplying

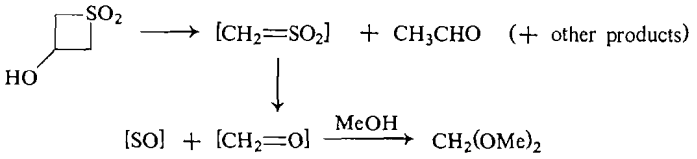
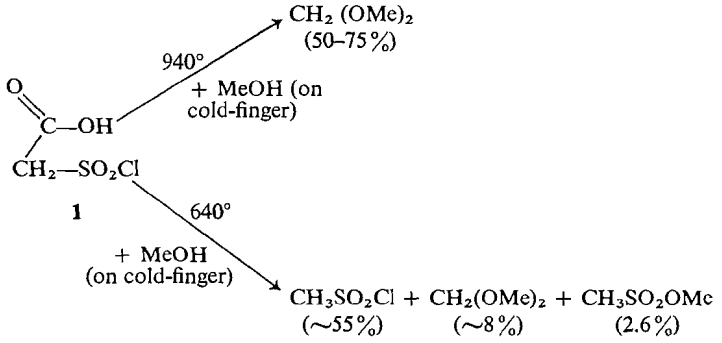


SCHEME 1



SCHEME 2

the structural unit CH_2SO_2 in a reaction with methanol-*d* at 77 °K be formed in the hot zone of the apparatus and travel to the cold-finger and react there. The only reasonable CH_2SO_2-supplying species in this experiment is sulfene itself, which must therefore be a discrete, volatile compound capable of existence for a finite period of time.[5]

In all likelihood the undeuterated ester is also formed from the sulfene, the proton arising ultimately from the hydrogen chloride produced in the reaction. The small proportion of the deuterium in the methanesulfonyl chloride may arise by reaction of sulfene with DCl formed by the exchange between HCl and CH_3OD. This in turn suggests that at least part of the CH_3SO_2Cl derives from sulfene and hydrogen chloride, though whether or not this is the major source of the sulfonyl chloride cannot be ascertained at present. By summing the yields of methyl methanesulfonate, dimethoxymethane, and CH_2DSO_2Cl we obtain the value of 12% as the probable minimum conversion to sulfene in the reaction. Because of the uncertainty surrounding the origin of the CH_3SO_2Cl and also of certain

[5]The mass spectra of the samples of methyl methanesulfonate from the runs with methanol-*d* clearly show the absence of any significant amount (i.e. less than 2%) of $CHD_2SO_2OCH_3$. The formation of $CH_2DSO_2OCH_3$ in the absence of a significant amount of $CHD_2SO_2OCH_3$ is the key piece of evidence supporting the intermediacy of sulfene, and this conclusion is not dependent on arguments based on control experiments; the latter experiments, however, are strongly suggestive and form the basis for the comments in the final paragraph.

Photochemistry of imines: concerning the formation of dihydrophotodimers from *N*-diphenylmethylenebenzylamine

Bert Fraser-Reid, Angus McLean, and E. W. Usherwood

Received September 10, 1969

Department of Chemistry, University of Waterloo, Waterloo, Ontario

When alcohol solutions of *N*-diphenylmethylenebenzylamine (**1***d*) are irradiated in the presence of benzophenone with light of intensity ~200 W there is predominant formation of the *unsymmetrical* dihydrophotodimer (**4**) and no symmetrical dimers are detected. The dihydromonomer (**2***d*) is also produced. However, when a more intense light source (450 W) is used *no dimer of any sort* is formed although the dihydromonomer is still produced. The formation of the unsymmetrical dihydrodimer (**4**) cannot be attributed entirely to secondary reactions of the dihydromonomer (**2***d*) since irradiation of the latter produces both symmetrical (**7**) and unsymmetrical (**4**) dihydrodimers in the ratio 1:2.

Canadian Journal of Chemistry, 47, 4511 (1969)

Recently, Okada and co-workers (1) reported that irradiation of *N*-benzoyldiphenylketimine (**1***a*) in alcoholic solvent led to quantitative reduction of the C—N double bond to give the corresponding amide, **2***a*. In order to explain these results, they (1) sought precedent in a report by Fischer (2) which stated that benzophenone sensitized irradiation of *N*-diphenylmethylenebenzylamine (**1***d*) in alcohol had also caused reduction of the C—N double bond, the amine **2***d* formed thereby being the only product reported (2). It was therefore suggested (1) that the carbonyl group of **1***a* provided "intramolecular chemical sensitization" for the reduction (**1***a* to **2***a*) in the same manner that benzophenone provided *intermolecular* chemical sensitization for the reduction of **1***d* to **2***d* (2).

In a recent examination of the mechanism of photoreduction of aryl *N*-alkylimines, Padwa (3) also cited Fischer's report (2), and noted that a number of imines with the general structure **1** (and including **1***a* and **1***d*) were "photoreduced to the corresponding amine(s) as opposed to (the) dihydrophotodimer(s)". It was further

imine **1***d leads to predominant formation of a dihydrophotodimer.*

Our studies support the report (1) that irradiation[1] of **1***a* causes quantitative conversion to the saturated amide (**2***a*). Similarly, **1***b* and **1***c* are converted to **2***b* and **2***c* respectively. Absence of the hoped for photodimers was considered due to the steric unfavorability of the tetraphenylethane linkage that would have to be forged, and in order to test this hypothesis, the structural *N*-alkyl equivalent of amide **1***a*, namely imine **1***d*, was irradiated[1] in the presence of benzophenone. The residue obtained on evaporation of the solution contained apart from benzophenone, three components *A*, *B*, and *C*, which were fractionated on a preparative layer chromatogram (Table I, entry (a)). Component *A* was identical to the product of catalytic hydrogenation of imine **1***d*; i.e. it was amine **2***d*,[2] however, it represented only 12% of the total fractions *A* + *B* + *C*. Component *B*, readily identified as **3**,[3] constituted 35% of the total fractions.

The major photoproduct, component *C*, had a molecular weight[4] which required it to be dimeric[3] but an exchangeable proton in the nuclear magnetic resonance (n.m.r.) spectrum dispensed with azetidines such as **5**, claimed to be produced on irradiation of some Schiff's bases (4). A 2-line pattern at τ 5.55 and 5.70 and a 4-line pattern centered at τ 6.85, both sets being of equal intensity, eliminated **6**. There remained only two possibilities, **4** or **7**, and of these **4** is clearly favored by the n.m.r. data. The remote possibility that a phenomenal conformation of **7** might accommodate the observed spectrum was discounted since both patterns of protons were not coupled. Hence photoproduct *C* is formulated as **4**, and all the n.m.r. signals can be conveniently assigned: τ 5.55, benzhydryl methine proton; τ 5.70, other methine proton; τ 6.85, an AB system (J_{AB} = 12.6 Hz) arising from benzylic protons made non-equivalent by barriers to free rotation (7).

However, in order to substantiate this assignment, a sample of **7** was sought by irradiation[1] of imine **8**, (c.f. 3) an isomer of **1***d*. The photoproduct (Table I, entry (*b*)) contained a dimer in 58% yield which was also obtainable by aluminum-amalgam induced coupling of **8** (8). It was therefore the desired dimer (**7**) and its n.m.r. spectrum was distinguished from that of component *C* in that instead of the 4-line pattern at τ 6.85, it (**7**) displayed a 2-proton singlet at τ 6.40.

When the irradiation was carried out using the same concentrations of reactants, and a 450 W Hanovia lamp as described by Padwa (3), dimer **4** was indeed not detected although the monomer (**2***d*) was produced (Table I, entry (c)). However when the same concentration of reactants was irradiated using a *200* W Hanovia lamp (whose intensity is nearer to that of the Rayonet source), dimer **4** was in fact formed, although its ratio was considerably reduced (Table I, entry (d)). Comparison of entries (a) and (d) indicate that there is a marked effect on the ratio of photodimer (**4**) to monomer (**2***d*) when the concentration of sensitizer is varied. However the crucial absence of photodimer **4** when the 450 W Hanovia lamp is used (compare entries (c) and (d)) indicate that the light intensity effect is a real one and therefore that the photochemical behavior of **1***d* is very sensitive to the radiation source.

Conceivably, the principal reaction pathway could be via reduction of **1***d* to **2***d*; the latter on further irradiation could react to give **3** and **4**. However, this possibility is unappealing in view of entry (c), Table I; apart from the unfavorable ratio in which **3** and **4** are produced there, the symmetrical dimer (7) is seen to constitute 1/3 of the total dimeric photoproduct whereas it is usually (entries (a) and (d)) absent. Again the possibility of photoaddition of amine **2***d* to imine

[2]For the hydrochloride of **2***d* m.p. and mixed m.p. = 265–267° (*2a*).

[3]All new compounds gave satisfactory micro analyses and spectral data.

8 7 2*d*

1*b* (entry (f); Table I) is also unlikely to be the only reaction pathway to **4**, in view of the product ratios.

In order to be comprehensive, a mechanistic interpretation of the photochemistry of *N*-diphenylmethylenebenzylamine (**1***d*) must account for the formation of the novel unsymmetrical dimer **4**. Studies designed to investigate the mode of formation of **4** and the origin of the intensity effect are underway and will be reported upon in due course.

Influence de la structure du prépolymère sur la température de transition vitreuse de polyuréthanes réticulés

GUY PERRAULT

Centre Canadien de Recherches et Perfectionnement des Armes, Québec, Québec

Reçu le 5 mai, 1969

Une étude a été faite de l'influence de la structure du prépolymère sur la température de transition vitreuse (T_g) de polyuréthanes élastomériques réticulés. Ces prépolymères sont des polysébaçates obtenus à partir d'une famille d'alkyl-N bis(hydroxy-2 alkyl)amines. Ils permettent, en variant les substituants alkyls, d'étudier l'effet d'allongement des chaînes latérales (C_1 à C_{18}) et l'effet d'addition d'interactions *gauches* au sein de la chaîne. Les résultats mettent en évidence que dans ce système, l'effet d'addition des interactions *gauches*, est plus importante que l'effet d'allongement des substituants latéraux. T_g est augmenté de 9 °C par interaction *gauche* introduite dans un segment de diol. La comparaison est faite avec d'autre systèmes.

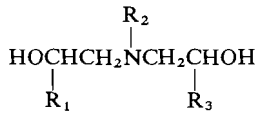
The influence of prepolymer structure on glass transition temperatures (T_g) of cross-linked polyurethanes has been studied with polysebacates from a homologous family of N-substituted bis(2-hydroxyalkyl)amines. The tertiary amine segments have made it possible to study the effect of lengthening the side chains (C_1–C_{18}) and inserting *gauche* interactions in the polymeric chain. The results show that in this system, adding *gauche* interactions has more effect on T_g than lengthening the side chains. Each time a *gauche* interaction is introduced in the diol segments, T_g increases by 9 °C. Comparisons with other systems are also presented.

Canadian Journal of Chemistry, 47, 4515 (1969)

Introduction

Plusieurs relations ont été proposées pour relier la structure moléculaire des homopolymères et des copolymères à leur température de transition vitreuse (T_g) (1–7). De ces approches, il est possible d'anticiper un minimum de T_g pour un minimum d'énergie en conformations gauches des segments, c'est-à-dire un minimum de rigidité de la chaîne, causé par un minimum dans la barrière de potentiel aux rotation internes, et pour une quantité maximisée de groupes latéraux à longue chaîne, c'est-à-dire pour un maximum de volume libre au sein du réseau.

Toutefois, ces concepts ne s'appliquent pas directement aux élastomères réticulés. En particulier dans le cas des polyuréthanes réticulés, plusieurs facteurs influencent le T_g. Notons l'effet de la concentration des groupes uréthanes (8, 9), l'effet du degré de réticulation (10), de la nature de l'agent de cuisson ainsi que maintes autres composantes (11). Cependant, il est à noter, comme le font remarquer certains auteurs (8), que la structure des produits initiaux, entre autres le prépolymère, a très peu d'effet sur les propriétés de l'élastomère final.



1

Une famille de prépolymères, des polysébaçates de la diisopropanolamine substituée sur l'azote (**1**; $R_1 = R_3 = CH_3$, R_2 = alkyl) avait déjà été utilisée pour étudier l'effet de la basicité d'un azote au sein de la chaîne polymérique sur les propriétés de l'élastomère (12).

Au cours d'expériences subséquentes, il est apparu que ce système pouvait être utilisé pour étudier à la fois l'effet de l'allongement d'une chaîne latérale (**1**, R_2) sur le T_g de l'élastomère réticulé, et l'effet d'introduction de conformations *gauches* (**1**, R_1 et R_3). Il est en effet facile de constater en se référant aux projections (Newman) de la liaison α,β à l'azote que si les radicaux R_1 et R_3 sont des groupes méthyle où éthyle des interactions *gauches* CH_3—N ou O—N seront

introduites augmentant la rigidité de la chaîne. La Fig. 1 représente ces interactions pour les deux

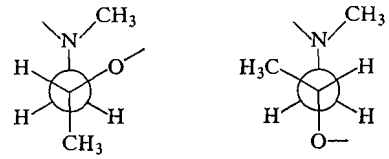


FIG. 1. Interaction *gauche* introduite par un substituant méthyle.

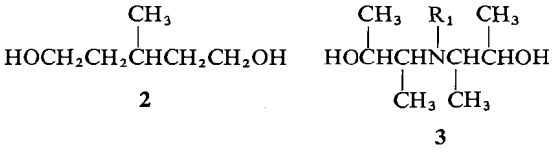
conformations les plus stables dans le cas d'un substituant méthyle. Il semblait donc qu'en travaillant dans des conditions constantes, il serait possible d'évaluer l'effet de structure du prépolymère.

Les polysébaçates de ces produits ont été préparés et les polyuréthanes obtenus dans des conditions expérimentales constantes. Quelques dérivés supplémentaires (**2** et **3**) ont été ajoutés à cette série pour fin de comparaison.

Partie Experimentale

La préparation et les propriétés de la plupart des diols ont déjà été publiées (13–15). Le méthyl-3 pentanediol-1,5 (**2**) est disponible commercialement. Deux nouvelles amines ont été préparées selon la méthode déjà décrite (13) par condensation de l'époxy-2,3 butane sur l'amine primaire correspondante, ce sont la méthyl-N bis-(hydroxy-3 butyl)-2 amine (**3**, R = CH_3) (*Eb*: 85–87 °C/0.1 mm).



2 **3**

Anal. Calcd. pour $C_9H_{21}O_2N$ (**3**, R = CH_3): C, 61.67; H, 12.08; N, 7.99. Trouvé: C, 61.34; H, 11.79; N, 8.01.

Pour l'hexyl-N bis(hydroxy-3-butyl)-2 amine (**3**, R = C_6H_{13}) (*Eb*: 65–68 °C/0.05 mm).

Anal. Calcd. pour $C_{14}H_{31}O_2N$ (**3**, R = C_6H_{13}): C, 68.52; H, 12.73; N, 5.90. Trouvé: C, 68.36; H, 12.84; N, 5.90.

Les analyses élémentaires ont été faites par Organic Microanalyses à Montréal.

Les polysébaçates ont été préparés en vrac par chauffage à 175 °C durant quatre h, d'une mole d'acide sébacique et de 1.3 mole de diol. Un barbotage constant d'azote a été maintenu pour agiter le mélange et entraîner l'eau formée au travers d'une colonne Vigreux qui sert à condenser les vapeurs de diol. Après ce temps, le chauffage a été continué à la même température sous pression réduite (<0.1 mm) durant quatre h additionnelles afin d'enlever l'excès de diol et les traces d'eau. Ces conditions expérimentales ont été adoptées afin d'atteindre un compromis entre un poids moléculaire trop bas et un nombre d'acidité trop élevé, et aussi pour éviter l'uniformisation des propriétés des polysébaçates par équilibration. Les poids moléculaires (M_n) des polysébaçates (Tableau I) ont été déterminés par analyse des fonctions hydroxylées (16). La correction a été faite pour le nombre d'acidité qui se situe entre 0 et 5, la grande majorité des produits étant autour de 1.

Les polyuréthanes ont été obtenus par cuisson sous vide à 60 °C durant 48 h, d'une mole de polysébaçate, deux moles de polyol Niax LHT 240 (Union Carbide Chemicals) et un excès de 10% de l'agent de cuisson, soit le diisocyanate de tolyle (TDI), soit un diisocyanate polymérique, le DDI-1410, (General Mills Company).

Les températures de transition vitreuse (T_g) et le contenu énergétique de la transition des polysébaçates on été mesurées sur un calorimètre à balayage thermique différentiel (DSC 1B de Perkin–Elmer) calibré avec de l'octane, du décane et du dodécane entre −90 et 0 °C. Le taux de chauffage du DSC a été fixé à 5 °C par min. Un taux de 10 °C par min ne provoquait pas de variation sensible dans la température de transition. La température de transition a été prise au point de rencontre entre le prolongement de la ligne de base et l'extrapolation du début du pic de transition. Un exemple représentatif est reproduit à la Fig. 2 avec le polyuréthane du polysébaçate de propyl-N (hydroxy-2 propyl,hydroxy-2 éthyl)amine (**1**, $R_1 = CH_3$, $R_2 = C_3H_7$, R_3 = H).

Le contenu énergétique de la transition des polysébaçates d'hexyl-N bis(hydroxy-2 alkyl)amine a été évalué par le décalage de la ligne de base avant et après la transition, tel qu'illustré à la Fig. 3 avec le polysébaçate d'hexyl-N-bis(hydroxy-2-propyl)amine (**1**, $R_1 = R_3 = CH_3$, $R_2 = C_6H_{13}$). Ce décalage a été divisé par le nombre de mole d'échantillon utilisé pour pouvoir établir facilement la relation avec les interactions butane-*gauche* qui sont en kcal/mole.

La reproductibilité des températures de transition vitreuse est de ±3 °C. Une variation de ±10% sur la quantité de TDI fait varier le T_g de ±1 °C. La même variation sur la quantité de DDI amène des fluctuations de ±3 °C. Une cuisson de quatre jours au lieu de deux jours, n'influence pas de façon notable le T_g de sorte qu'il est permis de supposer que la cuisson est complète

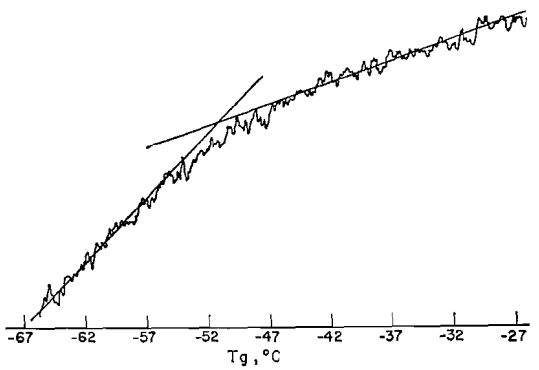


FIG. 2. Détermination du T_g du polyuréthane obtenu avec le polysébaçate de propyl-N (hydroxy-2 propyl, hydroxy-2-éthyl)amine (**1**, $R_1 = CH_3$, $R_2 = C_3H_7$, R_3 = H).

après deux jours. De plus, une variation de ±20% dans le poids moléculaire du polysébaçate provoque une fluctuation au hasard de ±3 °C. Tout ceci permet de s'attendre à une précision de ±3 °C sur les T_g.

Resultats et Discussion

Les T_g mesurés pour les polyuréthanes sont rassemblés au Tableau I. L'examen de ce tableau peut être séparé en quatre parties, la première considérant l'effet des chaînes latérales et la seconde, l'effet d'introduction de conformations *gauches*. Une troisième section mentionne un résultat sur l'effet de mobilité de l'azote, et finalement une quatrième section compare les transitions mesurées sur les polyesters initiaux à celles des polyuréthanes.

Effet des Chaînes Latérales

Vu la complexité des systèmes d'élastomères réticulés, et la très grande variété de causes qui puissent venir influencer le T_g de chacun des produits individuellement, il est préférable de profiter du nombre relativement élevé de produits disponibles et d'examiner les tendances des T_g moyens. Soulignons que ces moyennes ne sont pas matématiquement consistantes et qu'il ne faut pas attacher trop d'importance aux valeurs absolues de ces moyennes. Leur rapport relatif a l'avantage toutefois, de refléter les tendances du Tableau I en éliminant les déviations trop grandes. Il est cependant possible en n'utilisant que le Tableau I de suivre l'argumentation.

Ainsi si la moyenne des T_g du Tableau I est calculée pour tous les produits ayant la même chaîne latérale en R_2, les résultats du Tableau II sont obtenus. Il apparaît alors à l'examen de ce tableau, que la chaîne latérale a un léger effet sur le T_g.

Dans le cas des polyuréthanes cuits au TDI, le T_g passe par un minimum pour une chaîne de

$C_{16}H_{33}$	−48	−44	−48
$C_{18}H_{37}$		−31	−48

6 à 8 atomes, et la diminution maximale de T_g qu'il est possible d'obtenir en variant la longueur de R_2 est de 10 °C. Pour les polyvinyles non-réticulés avec groupes alkoxydes latéraux de différentes longueurs, il a été rapporté aussi, un minimum de T_g pour une chaîne latérale de 6–8 atomes (17*a*); toutefois dans ce cas la diminution est de 50 °C. Il faut remarquer cependant qu'avec les polyvinyles la chaîne latérale se répète à tous les deux atomes de carbone tandis que dans le système élastomérique adopté ici, il n'y a qu'une chaîne latérale par segment de diol dans le prépolymère. Ceci amène une dilution de l'effet global. Ajoutons que dans le cas des polymères sans réticulation, le T_g des polyméthylmétacrylate diminue continuellement à mesure que la chaîne latérale est allongée jusqu'à 12 atomes de carbone (17*b*).

Avec le DDI comme agent de cuisson, le minimum de T_g est atteint pour une chaîne longue de 12 atomes et l'effet total n'est que de 6 °C. Dans ce cas, l'agent de cuisson est plus gros que le TDI, les chaînes se trouvent encore plus diluées dans le réseau et leur effet est plus petit.

Effet d'Introduction des Interactions Gauches

Au Tableau III, la moyenne des T_g a été faite cette fois pour illustrer l'effet des interactions *gauches*, c'est-à-dire selon la nature des substituants R_1 et R_3.

Dans le cas de la cuisson au TDI, le minimum de T_g est atteint lorsqu'il n'y a pas de conformations *gauches* ajoutées dans la chaîne par les substituants R_1 et R_3 soit lorsque R_1 et R_3 sont des hydrogènes. L'effet total pour cette série de produits est de 23° entre le T_g des produits sans conformation *gauche* et le T_g des produits les plus influencés par ces conformations.

Avec le DDI, évidemment le minimum de T_g est atteint avec la même série de produits ($R_1 = R_3 = H$) mais l'effet total n'est que de 15 °C. Encore une fois la diminution de l'effet total est attribuable au grossissement de l'agent de cuisson.

Il est à souligner ici qu'un T_g moyen de −58 °C est obtenu pour l'ensemble des produits où aucune interaction *gauche* additionnelle n'est introduite à l'aide des substituants R_1 et R_3. Si une conformation *gauche* est introduite

TABLEAU III

Moyenne des T_g °C selon les conformations *gauches* introduites dans les diols **1**

Substituants		T, poylsébaçates (°C)	T_g, polyuréthanes (°C)	
R_1	R_3		TDI	DDI
CH_3	CH_3	−53	−40	−47

For personal use only.

(R_1 = CH_3 ou C_2H_5, R_3 = H) par segment de diol, le T_g moyen devient de -45 °C, et si deux interactions *gauches* sont ajoutées, (R_1 = R_3 = CH_3 ou C_2H_5) le T_g passe à -39 °C. Il était donc intéressant de confirmer cette tendance avec des produits homologues qui permettent l'introduction d'un plus grand nombre d'interactions *gauches* par segment de diol. Cette possibilité se présente avec les polysébaçates d'alkyl-N bis-(hydroxy-3-butyl)-2 amines (**3**) qui permettent l'introduction de 4 interactions *gauches* par segment de diol comme le montre la Fig. 4 pour

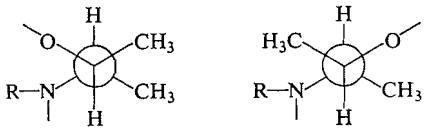

FIG. 4. Deux interactions *gauches* introduites par liaison en α, β de l'azote pour les produits **3**.

une des 2 liaisons C—C en α,β de l'azote dans les conformations les plus stables. Avec le polyuréthane de ces produits, donc pour 4 interactions *gauches* le T_g est de -21 °C. L'ensemble donne une augmentation du T_g de 9 °C par conformation *gauche* introduite.

Effet de la Mobilité de l'Azote

En théorie, il était plausible de prévoir que l'azote tertiaire au sein de la chaîne pourrait par sa mobilité, diminuer la rigidité de la chaîne et concourir à la baisse du T_g.

Pour obtenir tout au moins une indication sur cette hypothèse, le polyuréthane du polysébaçate de méthyl-N-bis(hydroxy-2-éthyl)amine (**1**, R_1 = R_3 = H, R_2 = CH_3) a été comparé au polyuréthane du polysébaçate de méthyl-3-pentanediol-1,5 (**2**). Il est à remarquer que ces 2 produits ont exactement la même structure sauf que l'atome d'azote est remplacé par un carbone dans le second cas. Les T_g obtenus, $-58°$ pour le produit azoté et $-55°$ pour l'autre, indique que cet effet, s'il existe, n'est pas très grand.

Polyesters

Afin de vérifier à l'aide d'une approche différente la relation entre le T_g et la rigidité de la chaîne soit le nombre de conformation *gauche*, la température de transition à basse température a été mesurée sur un certain nombre de polyesters (*cf.* Tableau I). Il est à noter que la nature de cette transition des polyesters n'a pas été déterminée, et qu'il se peut qu'il ne s'agisse pas d'une transition vitreuse.

Les moyennes ont été faites comme dans le cas des polyuréthanes; elles se trouvent aussi aux Tableaux II et III. D'après les tendances générales des résultats, soit température de transition minimum pour une chaîne de 6 atomes, de même que pour l'absence d'interaction *gauche* (R_1 = R_3 = H), il est plausible de supposer que cette température de transition mesurée pour les polyesters est associée aux mêmes transformations physiques que le T_g mesuré pour les polyuréthanes.

Or s'il est posé que les interactions *gauches* introduites par les substituants R_1 et R_3 ont le même contenu énergétique que les interactions *gauches* butane ou pentane (18), soit respectivement 0.8 kcal/mole pour l'interaction entre deux CH_3 et 0.5 kcal/mole entre un CH_2 et un CH_3, il devrait y avoir une relation linéaire entre l'énergie de la transition et l'énergie des interactions *gauches*. L'hypothèse sur l'énergie des interactions *gauches* a d'ailleurs été vérifiée par résonance magnétique nucléaire (15). La Fig. 5 reproduit cette relation pour l'énergie de transition telle que mesurée par calorimétrie. Les résultats de ces mesures sont compilés au Tableau IV. Cette relation confirme tout au moins que la transition mesurée est associée à un changement de mobilité des segments de chaîne qui contiennent les interactions *gauches* introduites par les substituants R_1 et R_3.

Conclusions

En se plaçant dans des conditions idéales, il est possible de mettre en évidence des effets de structure du prépolymère sur le T_g d'élastomères

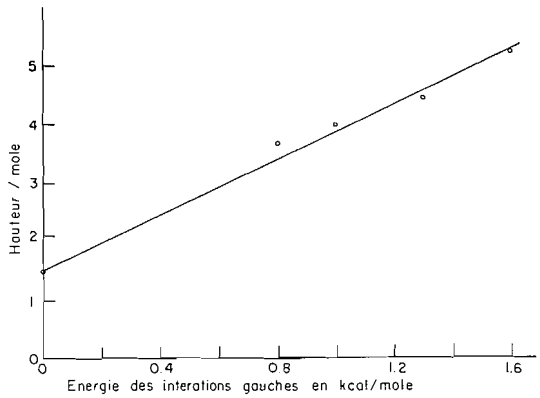

FIG. 5. Relation entre l'énergie de transition mesurée et l'énergie des interactions *gauches* calculée pour les polysébaçates d'hexyl-N bis(hydroxy-2 alkyl)amines.

TABLEAU IV

Energie de transition des polysébaçates des diols **1**, $R_2 = C_6H_{13}$

Substituants		Hauteur/ mole	Energie des conformations *gauches* introduites (kcal/mole)
R_1	R_3		
H	H	1.5	0
H	C_2H_5	1.9	0.5
H	CH_3	3.7	0.8
C_2H_5	C_2H_5	4.0	1.0
C_2H_5	CH_3	4.4	1.3
CH_3	CH_3	5.3	1.6

réticulés. Avec le modèle choisi, l'effet des interactions *gauches* amène des variations de 9 °C par interaction introduite dans un segment de diol. Il a été possible d'augmenter le T_g de 36 °C en changeant les substituants du diol qui ne se trouve qu'à une concentration de 8 équivalents par 100 équivalents de réactifs initiaux. Par contre, l'effet d'allongement d'une chaîne latérale n'est que de 10 °C. Cet effet est maximale pour une chaîne de 6 à 8 atomes de carbone.

Remerciements

Tous mes remerciements s'adressent à Mlle M. Talbot qui a synthétisé les produits et à Yves Giguère qui a préparé les polyuréthanes et mesuré la plupart des T_g. L'assistance du groupe du Dr. R. MacDonald et de M. Bédard nous a aussi été profitable. Je tiens aussi à remercier le Dr. M. Tremblay pour son encouragement.

Catalytic reduction of dimethylsulfoxide by molecular hydrogen using rhodium(III) complexes

B. R. JAMES, F. T. T. NG (MISS), AND G. L. REMPEL
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia
Received June 30, 1969

Dimethylsulfoxide is reduced by molecular hydrogen under mild conditions to dimethylsulfide and water in the presence of rhodium(III) complexes as catalysts. The kinetics of the systems using $RhCl_3.3H_2O$ and *cis*-$RhCl_3(Et_2S)_3$ have been investigated, and a mechanism involving reduction of coordinated dimethylsulfoxide in a rhodium(III) hydride complex is postulated. The catalytic efficiency of the systems decreases slowly due to the production of inactive rhodium(I) species.

Introduction

We have recently been interested in the homogeneous hydrogenation of olefinic substrates using platinum metal complexes (1–3), and have found that catalytic activity is very dependent on the solvent medium used. The activity of rhodium chloride complexes was very much enhanced in the coordinating aprotic solvent N,N-dimethylacetamide (DMA) (1). As part of these general studies, we attempted to investigate catalytic activity in dimethylsulfoxide (DMSO); it soon became clear that a hydrogenation reaction occurred in the *absence* of any organic substrate. This has been shown to be a catalytic reduction of the solvent and these studies are described in this paper. DMSO has come to be widely used as an advantageous medium for inorganic chemical reactions because of its ability to dissolve fairly high concentrations of many inorganic solutes (4, 5), and has been used extensively as an oxidizing agent in organic synthesis (5, 6). A few Group III–V main group halides have been shown to reduce DMSO (6); most transition metal halides form coordination compounds (7), although niobium and tantalum pentahalides do abstract the oxygen atom of the sulfoxide to form the corresponding oxyhalide and halogen substituted sulfides (8). The present investigation shows that molecular hydrogen can be activated by rhodium(III) complexes for reduction of DMSO to dimethylsulfide (DMS) and is considered important in view of the present extensive use of this solvent.

Experimental

Rhodium(III) trichloride was obtained as $RhCl_3.3H_2O$ from Platinum Chemicals. Dimethyl and diethylsulfides were Eastman Organic chemicals and were used without further purification. The cyclo-octene was obtained from K and K Laboratories. 1,2,3-trichlotris(diethylsulfide) rhodium(III) (9) and the cyclo-octene complex, $[(C_8H_{14})_2RhCl]_2$ (10), were prepared according to the literature. Prepurified H_2 was obtained from Canadian Liquid Air Co. and was passed through a Deoxo catalytic purifier before use. Deuterium was obtained as C.P. grade (99.5%) from Matheson Co. DMSO (Baker Analyzed grade) was purified by storing over CaH_2 under N_2 for long periods, followed by distillation under reduced pressure; it was collected onto Linde 4A molecular sieve and stored under N_2.

The kinetics of the hydrogenation reactions were studied by measuring the rate of gas uptake at constant pressure using the apparatus and procedure described earlier (11). The initial concentration of Rh(III) in these experiments was in the range 0.01–0.03 *M*. The partial pressure of H_2 was varied from 130–800 mm. The solubility of H_2 in DMSO is quite small but was determined to be about 6×10^{-5} *M* atm^{-1} at 80 °C. Dimethylsulfide and water, the products from the H_2 reduction of DMSO, were separated from the reaction mixture by distillation and identified in the distillate by gas chromatography using a dinonyl phthalate column. The water was also readily detected and estimated by the ^1H nuclear magnetic resonance spectrum of the distillate (Varian A.60, TMS external standard). Visible and ultraviolet spectra were recorded on a Perkin–Elmer 202 spectrophotometer, and infrared spectra were recorded on a Perkin–Elmer 137 spectrophotometer using Nujol mulls or KBr disks.

Results

Stoichiometry

The visible absorption spectrum of a solution of $RhCl_3.3H_2O$ in DMSO changed slowly with time at room temperature, presumably due to equilibration between complexes. This change could be accomplished rapidly by heating to 80°, and the steady spectrum of the orange solution showed absorption maxima at 360 mμ (ε 380) and 435 mμ (ε 270). Such solutions were found to absorb hydrogen at measurable rates from 70–90°. Figure 1 shows such an uptake at 80° for

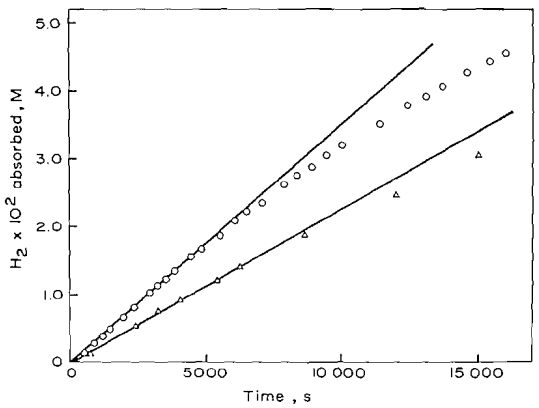

FIG. 1. Rate plots at 80°, 746 mm H_2, DMSO solution: Δ, 0.02 *M* $RhCl_3.3H_2O$; ○, 0.02 *M* $RhCl_3(Et_2S)_3$.

a 0.02 *M* Rh(III) solution; a linear uptake plot is observed for about 3 h and then the rate falls off very slowly. There is no obvious stoichiometric relationship between the H_2 uptake and the rhodium used; an uptake was followed up to 1.0 *M* of H_2 for a solution 0.03 *M* in Rh. In the absence of rhodium complex, there was no measureable uptake over 3 h. No reactions other than equilibration were observed between $RhCl_3.3H_2O$ and DMSO in the absence of H_2 under the conditions of the kinetic experiments.

The visible absorption spectra of solution samples taken during the linear uptake region were unchanged from that of the starting solution, showing that the reaction is catalytic with respect to Rh(III); no Rh(III) hydride species were detected.

Analysis for the reaction products in solution, after the reaction in which 1.0 *M* H_2 had been consumed, gave dimethylsulfide and water, both about 1 mole for each mole of H_2 absorbed. The overall reaction which occurs in the presence of $RhCl_3.3H_2O$ is thus

[1] $$(CH_3)_2SO + H_2 \rightarrow (CH_3)_2S + H_2O$$

A similar catalyzed reaction has been observed using the complex *cis*-$RhCl_3(Et_2S)_3$, although the linear rates are somewhat greater for this system (Fig. 1). The initial equilibrated $RhCl_3(Et_2S)_3$/DMSO solution showed absorption maxima at 370 mμ (ε 500) and 430 mμ (ε 300).

The gradual fall-off in the hydrogenation rate is paralleled by a decrease in the intensity of the orange solutions, and after a 15 h experiment with the trichloride system the final solution is yellow, showing a single absorption maximum at 390 mμ (ε 425) indicating likely formation of the Rh(I) state (1, 12). This solution is stable in air for many hours at room temperature, but on heating to 80° under oxygen overnight an orange solution again results with the characteristic 2-peak spectrum of a Rh(III) species (λ_{max} 380 mμ, ε 410; λ_{max} 430 mμ, ε 300).

Kinetics

The H_2-uptake plots were analyzed by measuring the rates in the long linear region. Tables I and II summarize the kinetic data obtained for the

$RhCl_3.3H_2O$ system and the $RhCl_3(Et_2S)_3$ system, respectively. The rate is first order in rhodium and hydrogen, and the data have been fitted to the rate law

$$[2] \qquad -d[H_2]/dt = k[Rh(III)][H_2]$$

to obtain the k values listed in the Tables. For the trichloride system, k was independent of added dimethylsulfide (0.1 M) although the linear rate fell off much more rapidly for this experiment; there was no significant dependence on acid and there was no measurable kinetic isotope effect within experimental error using deuterium gas. The addition of up to 2.2 M H_2O had no effect on k for the diethylsulfide system; higher concentrations of water (up to 40% by volume) increased the rate by a factor of about 2.5.

Discussion

The Reduction Reaction

The rate law for the reaction together with spectroscopic data show that hydrogen reacts with a rhodium(III) species to give an intermediate which is then decomposed to DMS, water, and the initial rhodium(III) complex. In polar solvents such as water and ethanol, reactions of molecular hydrogen with rhodium(III) complexes can give rise to intermediate hydrides formed through heterolytic splitting of the H_2 molecule (1, 13)

$$[3] \qquad Rh(III) + H_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Rh(III)H + H^+$$

(ligands omitted)

In the highly polar DMSO (dielectric constant 49 at 20°) this is again likely to be the rate determining step. Such reactions show little measurable isotope effect (1, 14). We have, of course, no rate data on the dependence on the DMSO concentration but, since the hydride intermediate contains coordinated DMSO, the most obvious subsequent step is its rapid decomposition to the products with regeneration of the rhodium catalyst

$$[4] \qquad HRh(III)(DMSO) \xrightarrow[\text{fast}]{H^+} DMS + H_2O + Rh(III)$$

The essential independence of k on acid is consistent with the back reaction [3] not competing with reaction [4].

Johnson and Walton (15) have isolated the complex $RhCl_3(DMSO)_3$ from solutions of the trichloride trihydrate in DMSO, and it is likely that this is the species present in our equilibrated solutions of the trichloride salt; also, according to Gutmann (16), the donor strength of DMSO is greater than for water, the concentration of which will be a maximum of about 0.1 M (3 times the rhodium concentration). $RhCl_2H(DMSO)_3$ is the most likely intermediate produced in reaction [3].

The detailed path of reaction [4] is uncertain.

DMSO complexes of transition metals are well known with coordination generally being through the oxygen atom (17). However, complexes of platinum(II), palladium(II), and iridium(III) have been shown to contain DMSO bonded through the sulfur atom (18); these conclusions were originally drawn from infrared spectra, particularly in the S—O stretching region, but have been verified by X-ray work. The cation $Pd(DMSO)_4^{2+}$ contains both sulfur-bonded and oxygen-bonded ligands (19). Johnson and Walton (15) draw no definite conclusion from far infrared data about the bonding in the $RhCl_3(DMSO)_3$ complex, but the existence of the strong S—O band at 1120 cm^{-1} in a sample that we made strongly suggests (20) bonding of the DMSO through the sulfur atom. Sulfur appears the likely donor atom in a rhodium(II) acetate – DMSO complex (21). Rhodium is on the border line of the class *a* – class *b* metals (22); in the thiocyanate complex $[Rh(SCN)_6]^{3-}$ however, bonding is through the "softer" sulfur atom (23). A plausible mechanism for reaction [4] can be written assuming sulfur bonding

[5] 
1 2

Protonation of the basic oxygen atom (24) would give **2**. Nucleophilic attack by the coordinated hydride (a typical insertion reaction of an unsaturated moiety into a metal–hydride bond (25)) would lead to elimination of water and dimethylsulfide, either free or coordinated depending on the stability of rhodium dimethylsulfide complexes. The constancy of the initial reaction rate and visible spectrum indicates that the DMS is not coordinated in this region. In the system with added DMS the more rapid fall-off in rate suggests that DMS may well coordinate as its concentration builds up (see later discussion). No effect is observed by the addition of up to 2.2 *M* water; water therefore does not cause the retardation in rate and is also unlikely to be coordinated to the rhodium at this concentration. Little can be said about the increase in rate at the high water concentration; aquo complexes may be involved, and also the solubility of hydrogen is some 10 times greater in water (26) than in DMSO.

An interesting possibility for the overall reduction reaction is that intermediate **2** is formed directly in a single concerted step by the approach of a H_2 molecule to the rhodium–DMSO complex; the heterolytic splitting of the H_2 molecule would be "built into" such a mechanism which would be indistinguishable from the kinetic point of view.

The diethylsulfide system is about twice as active at 80° as the trichloride system; the visible absorption spectrum shows a different rhodium(III) complex is initially present in solution and it must have coordinated diethylsulfide. This system was investigated primarily to see if rhodium complexes containing such sulfur ligands were less active than those derived from $RhCl_3.3H_2O$; diethylsulfide will be a somewhat stronger donor ligand than dimethylsulfide. The conclusion is that the fall-off in rate is not due to coordination of dimethylsulfide to *trivalent* rhodium. The activation parameters for the trichloride and diethylsulfide systems were estimated from good Arrhenius plots to be $\Delta H^{\ddagger} = 27.0 \pm 1$ kcal $mole^{-1}$, $\Delta S^{\ddagger} = +18 \pm 3$ e.u.; $\Delta H^{\ddagger} = 16.8 \pm 0.5$ kcal $mole^{-1}$, $\Delta S^{\ddagger} = -9 \pm 1$ e.u., respectively. The significance of the difference is not clear but it may be related to a difference in the charges of the reacting complexes. In the diethylsulfide system, for example, cationic species of the type $[RhCl_2(Et_2S)(DMSO)_3]^+$ could be present. In some related systems in dimethylacetamide, in which $RhCl_3.3H_2O$ and $RhCl_3(Et_2S)_3$ have been reduced to rhodium(I) complexes through rhodium(III) hydride intermediates, the diethylsulfide system again showed a lower enthalpy of activation and a more unfavorable entropy factor (1).

The Fall-Off in Catalytic Activity

Rhodium(III) hydride complexes readily dissociate into rhodium(I) species (1, 27, 28)

[6] $$Rh(III)H \rightarrow Rh(I) + H^+$$

The experimental data strongly indicate that in the region of lower rate some rhodium(I) com-

plexes are present. Reaction [6] is a fast reaction (1) and hence the production of rhodium(I) will depend on the comparative rates of the decomposition of the hydride according to reaction [6] and its reaction with DMSO according to a reaction such as [5]. Production of rhodium(I) could be more favorable at higher concentrations of dimethylsulfide since this ligand is expected to stabilize the lower valent state (more class *b* character). Attempts to isolate a pure inorganic complex at the end of a long reaction, when the presence of rhodium(I) is indicated, have not been successful, and we can find no reports on the production of rhodium(I) alkyl sulfide complexes. However, an isolated impure orange solid gave strong infrared bands at 1120, 1020, and 980 cm^{-1}. The first is attributed to the S—O stretch of a sulfur-bonded DMSO (20) and the latter two may be assigned to CH_3 rocking modes of coordinated DMSO or DMS (20). Rhodium(I) is likely to bond through the sulfur atom of DMSO.

The kinetic data could also be consistent with a rate determining hydrogen reduction to rhodium(I) through reactions [3] and [6], followed by a rapid oxidation of the rhodium(I) by DMSO. However, DMSO complexes of low valent transition metals such as manganese(II) (17), ruthenium(II) (29), and iridium(I) (3) are known and also our final reaction solutions appear to contain rhodium(I), so such a mechanism seems unlikely and we strongly favor reaction through a rhodium(III) hydride. Solutions of the complex $[(C_8H_{14})_2RhCl]_2$ containing the labile cyclooctene ligand (10) also showed no redox reaction with DMSO at 80°.

The observation that the final yellow solution was oxidized slowly by oxygen back to rhodium(III) suggested that use of a hydrogen/oxygen mixture might prevent the slow fall off in reaction rate. In an experiment using a mixture of 500 mm H_2 and 250 mm O_2 with 0.03 *M* $RhCl_3.3H_2O$, the initial rate was that expected for the reaction in the absence of oxygen; however, the rate now showed autocatalytic behavior before reaching a steady rate of 1.3×10^{-5} *M* s^{-1}, some 3 times faster than the initial rate, and showed no signs of falling off over a 3 h period. It is of interest that Trocha-Grimshaw and Henbest (30) have recently reported that solutions of $RhCl_3$ or $H[Cl_4Rh(DMSO)_2]$ in hot isopropanol/water mixtures catalyze the air oxidation of DMSO to dimethyl sulfone although no mechanism was suggested. We find that solutions of $RhCl_3.3H_2O$ in DMSO showed no reactivity towards oxygen (80°, 1 atm O_2) and it seems likely that the alcoholic medium is necessary to furnish intermediate hydride species (31). These workers state that hydrides are the most effective catalysts. Rhodium(I) complexes are known to activate molecular oxygen through an oxidative addition reaction (32) and these could well be produced from the rhodium(III) hydrides according to reaction [6]. Hence, from these considerations, it seemed possible that the increase in rate of gas uptake in our experiment using the hydrogen/oxygen mixture might be due to an induced catalytic oxidation through the rhodium(III) hydride intermediates or the slowly produced rhodium(I) species. And indeed, isolation of the products from further reactions using such mixtures yielded mainly dimethyl sulfone (readily identified by infrared and melting point) and only small amounts of dimethylsulfide and water, confirming the catalytic oxidation. The fact that neither our initial rhodium(III) solutions nor our final rhodium(I) solutions from the hydrogenation experiments showed any catalytic activity towards oxygen indicates that rhodium(III) hydrides may be directly involved as the oxygen carriers. No catalytic oxidation was observed using solutions of $[(C_8H_{14})_2RhCl]_2$ in DMSO, although we have found that this complex does activate molecular oxygen in other solvents (33).

Effect of an external heavy atom on the photochemistry of monofluorobenzene vapor

A. Cook, G. P. Semeluk, and I. Unger
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received June 30, 1969

Spectrofluorometric techniques have been used to study the effect of added xenon on the singlet and triplet yields of monofluorobenzene vapor excited by 2670, 2520, and 2470 Å radiation. For each wavelength examined, the fluorescent yield was found to decrease with increasing xenon pressure and plots of $1/\Phi_f$ vs. P_{Xe} are linear. The sensitized emission of biacetyl technique was used to determine triplet yields. The effect of xenon on the emission yield of biacetyl excited directly at 4358 Å was also examined and it was found that xenon reduced the phosphorescent yield of biacetyl. Plots of $1/\Phi_p$ vs. P_{Xe} were found to be linear, for all cases of sensitized as well as directly excited emission. At 2470 Å both the fluorescence yield and the triplet yield initially increase with increasing Xe pressure, but when the Xe pressure exceeds about 30 Torr the behavior at this wavelength is the same as it is at the other two wavelengths.

The data suggest that xenon enhances intersystem crossover in both monofluorobenzene (FB) and biacetyl (BiA). The important process in the former is $^1FB + Xe \rightarrow {}^3FB + Xe$, while in the latter is $^3BiA + Xe \rightarrow BiA + Xe$. A mechanism consistent with the experimental observation is presented.

Introduction

Singlet–triplet transitions may be enhanced by the presence of either an internal heavy atom (1) or an external heavy atom (2). The former is generally referred to as McClure enhancement, while the latter is usually called Kasha enhancement. Robinson (3) has shown that Xe, present as a solvent, will promote intersystem crossover in the solid phase. Wilkinson and co-workers (4, 5) and Cundall and Voss (6) have noted the same phenomenon with Xe dissolved in liquids. A recent gas phase study (7) has shown that Xe quenches the singlet state of small aromatic molecules, presumably because of promotion of singlet to triplet crossover.

This paper describes the results of an investigation of the effect of Xe on the singlet and triplet yields of monofluorobenzene excited at 2470, 2520, and 2670 Å. Monofluorobenzene was chosen as the test molecule since it does not show any appreciable dissociation when irradiated by 2520 and 2670 Å radiation, and since its basic photochemistry in this spectral region is now fairly well understood (8–11). Since monofluorobenzene does not show any phosphorescent emission in the gas phase, it was necessary to use an indirect technique (sensitized emission of biacetyl (12)) to measure triplet yields. It was therefore necessary to determine the effect of Xe on triplet biacetyl molecules. This was accomplished by irradiating biacetyl directly at 4358 Å and following the emission yield as a function of Xe pressure.

Experimental

The fluorobenzene used in this study was obtained from the Aldrich Chemical Company and shown by vapor phase chromatography to have an impurity content $\leqslant 0.02$ mole %. The biacetyl, also obtained from Aldrich, was stored in a blackened bulb. The "Research Grade" xenon obtained from Matheson had the quoted impurities: nitrogen, 2 p.p.m.; oxygen, 1 p.p.m.; krypton, 10 p.p.m. Both the fluorobenzene and biacetyl as well as the xenon were used without further purification.

The high vacuum line employed in this study was grease and Hg free, using Hoke packless diaphragm metal valves exclusively. Emission measurements were made on a modified Aminco-Bowman Spectrophotofluorometer (SPF) (13). The entrance slit of the excitation monochromator was set at 0.5 mm and the exit slits on this monochromator were 1.0, 0.5, and 1.0 mm. This slit combination provides an optimum light intensity, with a concomitant band pass of 70 Å.

The light source was a 200 W xenon–mercury compact arc lamp operated on a d.c. power supply, both supplied by American Instrument Company, Incorporated (Aminco). Fluorescence and sensitized emission were detected by means of an E.M.I. 6256B (S 13 response) photomultiplier tube. The signal generated by this tube was amplified and then recorded by a Moseley 7030 AM X–Y recorder. Absorption measurements were performed with an R.C.A. 935 single stage phototube, the signal being read on a Keithley Instruments Model 410, micro-microammeter. The cell used in this study was a flow-through cuvette type, 1 cm × 1 cm and 4.6 cm high, polished on all four sides (Aminco Number 4–8115). All experiments were carried out at room temperature $\simeq 27$ °C.

Quantum yields of fluorescence and of sensitized emission were obtained by a technique in which a calibration factor for the system was determined based on the accurately determined quantum yield of a reference material (9). In this case, benzene and benzene–biacetyl mixtures were used as the reference materials.

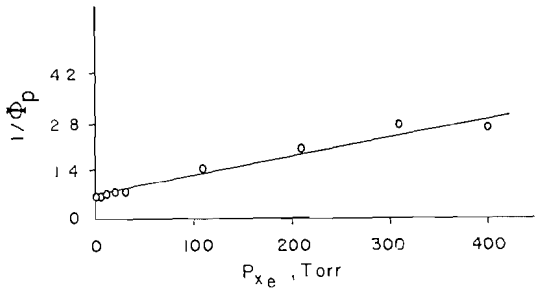

FIG. 1. Variation of $1/\Phi_p$ as a function of P_{Xe}. P_{BIA} = 5 Torr, λ_{ex} = 4358 Å.

Results and Discussion

The addition of Xe to 5 Torr of BiA excited at 4358 Å results in a decrease in the emission yield of BiA. A plot of $1/\Phi_p$ vs. [Xe] is linear (see Fig. 1) and obeys the relationship

$$[1] \qquad 1/\Phi_p = 6.67 + 292\,[Xe]$$

Addition of Xe to FB excited at 2670 and 2520 Å decreases the fluorescent yield, giving a linear dependence of $1/\Phi_f$ on [Xe] (see Fig. 2 and Table I). The relationship obeyed, for λ_{ex} = 2670 Å, is

$$[2] \qquad 1/\Phi_f = 4.67 + 53.9[Xe]$$

while for λ_{ex} = 2520 Å, the relationship is

$$[3] \qquad 1/\Phi_f = 4.3 + 55[Xe]$$

When the excitation wavelength is 2470 Å, addition of Xe up to a partial pressure of 30 Torr causes a rise in the fluorescent yield. Beyond this pressure the fluorescent yield has the same behavior as that noted at 2670 and 2520 Å (see Table I). For λ_{ex} = 2470 Å and Xe pressures

†λ_{ex} = 2470 Å, P_{FB} = 10.21 Torr; $1/\Phi_f$ = 11.60 + 444[Xe].

greater than 30 Torr, the applicable equation is

$$[4] \qquad 1/\Phi_f = 11.6 + 444[Xe]$$

Fluorescent yields reported here are based on the fluorescent yield of benzene equal to 0.18 (14).

Addition of Xe to mixtures of 10 Torr of FB and 5 Torr BiA irradiated at 2670 and 2520 Å causes the sensitized emission of BiA to decrease (see Fig. 3 and Table II). Plots of $1/\Phi_p$ vs. [Xe] are linear and obey the following equations

$$[5] \qquad 1/\Phi_p = 4.1 + 5.2 \times 10^2[Xe] \qquad \lambda_{ex} = 2670 \text{ Å}$$

$$[6] \qquad 1/\Phi_p = 3.5 + 7.65 \times 10^2[Xe] \qquad \lambda_{ex} = 2520 \text{ Å}$$

For an exciting wavelength of 2470 Å, initial addition of Xe to mixtures of FB and BiA results in an increase in the sensitized emission yield of BiA. Addition of Xe, beyond a pressure of

		8.05	410.40

*λ_{ex} = 2520 Å, P_{FB} = 9.88 Torr, P_{BiA} = 5.00 Torr; $1/\Phi_p = 3.5 + 765[Xe]$.
†λ_{ex} = 2470 Å, P_{FB} = 10.98 Torr, P_{BiA} = 5.63 Torr; $1/\Phi_p = 3.9 + 237[Xe]$.

30 Torr, causes the sensitized emission yield to decrease according to the equation

$$[7] \qquad 1/\Phi_p = 3.9 + 2.37 \times 10^2[Xe]$$

The data are summarized in Table II. The triplet yields given here are based on the triplet yield of benzene equal to 0.63 (15).

The photochemical behavior of BiA excited at 4358 Å is well known (16) and is adequately described by reactions [8] through [12′] below. Data obtained in the presence of xenon indicate that only one additional reaction, [12′], need be considered.

[8] $\quad BiA + h\nu \rightarrow {}^1BiA^I$
[9] $\quad {}^1BiA^I \rightarrow {}^3BiA^I$
[10] $\quad {}^1BiA^I \rightarrow BiA + h\nu_f$
[11] $\quad {}^3BiA^I \rightarrow BiA + h\nu_p$
[12] $\quad {}^3BiA^I \rightarrow BiA$
[12′] $\quad {}^3BiA^I + Xe \rightarrow BiA + Xe$

In the above scheme Arabic numerals represent spin multiplicity, Roman numeral I represents the first excited state. The reaction

$$ {}^1BiA^I + Xe \rightarrow {}^3BiA^I + Xe$$

need not be considered since intersystem crossover in BiA is almost 100% efficient (17). Steady state treatment of the above scheme yields for the phosphorescent emission efficiency of BiA

$$[13] \quad 1/\Phi_p = \frac{k_{11} + k_{12}}{k_9 k_{11}}(k_{10} + k_9) + \frac{k_{12'}}{k_9 k_{11}}(k_9 + k_{10})[Xe]$$

Equation [13] predicts that a plot of $1/\Phi_p$ vs. [Xe] should be linear with slope $= k_{12'}(k_9 + k_{10})/k_9 k_{11}$, which is confirmed experimentally (see Fig. 1). It has been shown that $k_9 \gg k_{10}$ (18), thus the slope of the line in eq. [13] becomes $k_{12'}/k_{11}$. Since k_{11} has been given as $10^2\ s^{-1}$ (18), this yields

$$k_{12'} = 4.64 \times 10^{-17}\ \text{mole}^{-1}\ \text{cc}\ s^{-1}$$

For systems involving FB and Xe, as well as FB, Xe, and BiA, the following additional reactions must be considered

[14] $\quad FB + h\nu \rightarrow {}^1FB^I$
[15] $\quad {}^1FB^I \rightarrow FB + h\nu'$
[16] $\quad {}^1FB^I \rightarrow {}^3FB^I$
[16′] $\quad {}^1FB^I + Xe \rightarrow {}^3FB^I + Xe$
[17] $\quad {}^1FB^I + FB \rightarrow 2FB$
[18] $\quad {}^3FB^I \rightarrow FB$
[19] $\quad {}^1FB^I + BiA \rightarrow {}^1BiA^{II} + FB$
[20] $\quad {}^3FB^I + BiA \rightarrow {}^3BiA^I + FB$
[21] $\quad {}^1BiA^{II} \rightarrow$ Dissociation
[22] $\quad {}^1BiA^{II} + M \rightarrow {}^1BiA^I + M$

The symbols used in these have the same meaning as previously, but Roman numeral II indicates the second excited state, and M represents any molecule capable of accepting vibrational energy. The evidence for the occurrence of most of the above reactions has been adequately discussed previously and rate constants for the various steps at different exciting wavelengths have also been given (11). In the absence of BiA, steady state treatment gives for the fluorescent yield of FB

$$[23] \quad 1/\Phi_f = \frac{k_{15} + k_{17}[FB] + k_{16} + k_{16'}[Xe]}{k_{15}}$$

At constant [FB], eq. [23] predicts that plots of $1/\Phi_f$ vs. [Xe] should be linear with slope $k_{16'}/k_{15}$. The experimental evidence (Fig. 2 and Table I) shows that this is indeed the case. Since k_{15} has been previously evaluated (11), $k_{16'}$ may be determined from the data. Values of $k_{16'}$ at various exciting wavelengths are listed in Table III.

TABLE III
Summary of values of rate constants for various exciting wavelengths

λ_{ex}, Å	$k_{16'}$, mole^{-1} cc s^{-1}	$k_{12'}$, mole^{-1} cc s^{-1}
2670	3.14×10^{-12}	1.45×10^{-16}
2520	4.02×10^{-12}	2.44×10^{-16}
2470	3.76×10^{-12}	6.77×10^{-17}

In the presence of BiA, eq. [24] is obtained for the sensitized emission yield of BiA.

$$[24] \qquad \frac{1}{\Phi_p} = \frac{(k_{11} + k_{12} + k_{12'}[\mathrm{Xe}])(k_{15} + k_{17}[\mathrm{FB}] + k_{16} + k_{16'}[\mathrm{Xe}] + k_{19}[\mathrm{BiA}])}{k_{11}(k_{16} + k_{16'}[\mathrm{Xe}])}$$

Since $k_{16} \gg k_{16'}[\mathrm{Xe}]$ even at high pressures of Xe, eq. [24] may be reduced to

$$[25] \qquad \frac{1}{\Phi_p} = \frac{(k_{11} + k_{12} + k_{12'}[\mathrm{Xe}])(k_{15} + k_{17}[\mathrm{FB}] + k_{16} + k_{19}[\mathrm{BiA}])}{k_{11}k_{16}}$$

which suggests a linear dependence of $1/\Phi_p$ on [Xe] at constant pressures of FB and BiA. The experimental evidence (Fig. 3 and Table II) confirms this. Equation [25] also yields

$$[26] \qquad \text{Slope/intercept} = \frac{k_{12'}}{k_{11} + k_{12}}$$

The values of k_{11} and k_{12} have been determined (18), and thus values of $k_{12'}$ for various exciting wavelengths can be calculated, these are given in Table III.

The fluorescent yield and the sensitized emission yield both increase initially on addition of Xe when the exciting wavelength is 2470 Å. A possible explanation for these phenomena could be the vibrational deactivation of very hot $^1FB^I$ molecules by collisions of the "second kind" (19), which would prevent them from dissociating and hence increase the singlet and triplet yields.

An analytical method for determining rate constants using a periodical irradiation technique

W. KAWAKAMI[1] AND H. S. ISBIN

Department of Chemical Engineering, University of Minnesota, Minneapolis, Minnesota 55455

Received June 16, 1969

A new analytical method is presented for the determination of rate constants using a periodical irradiation technique. This method is applicable to reactions which have both a first and a second order termination for the chain radical concentration, and is illustrated for the radiolysis of aqueous solutions of chloral hydrate by ^{137}Cs γ rays. The apparent rate constant of first order termination, and the mean chain life time of the chain radical were determined to be 1.10 s^{-1}, and 0.25 s for 400 rad/min, at 22 °C, respectively.

Canadian Journal of Chemistry, 47, 4531 (1969)

Noyes and Leighton (1) discussed the graphical method of determination of rate constants based on the rotating sector method. Melville (2), Bartlett and Swain (3–5), and Matheson, Auer, Bevilaqua, and Hart (6) applied this method to polymerization reactions. Freeman, Van Cleave, and Spinks (7) examined the radiolysis of aqueous solution of chloral hydrate by this method. They found a mean chain life time of about 0.1 s for 21 rad/min of γ rays of ^{60}Co. On the other hand, Lotz and Schmidt (8) determined the rate constant of the first order termination of this reaction by measuring the increasing rate of the reaction rate at the initial stage of irradiation. They found the apparent rate constant to be 2.35 s^{-1} and a mean chain life time to be 0.2 s for 430 rad/min of X-rays at 20 °C.

Shepp (9) applied the rotating sector method to reactions which have a first and a second order termination and determined the rate constants of the photolysis of acetone using a graphical method. This method, however, requires knowing the value of the ratio of first-to-second order termination reaction rates. Measurement of the ratio is difficult, and may not be possible for polymerization reactions.

The purpose of this paper is to report an analytical method by which rate constants can be determined when a periodical irradiation experiment is carried out together with continuous irradiation experiments. In this method it is not necessary to know the ratio of both termination rates. Hence, it is applicable to determination of rate constants of polymerization reactions which have both a first and second order termination.

[1]On leave from the Takasaki Radiation Chemistry Research Establishment, Japan Atomic Energy Research Institute, Takasaki, Gumma, Japan. Present address: Japan Atomic Energy Research Institute, Takasaki Radiation Chemistry Research Establishment, Watanuki-machi, Takasaki, Gumma-ken, Japan.

Theory

The chain reaction to be considered is as follows

Initiation

$$M \xrightarrow{\sim\sim} R\cdot$$

Reaction rate $= GI$

Propagation

$$R\cdot + D \xrightarrow{k_1} R\cdot + C$$

Reaction rate $= k_1[R\cdot][D] \equiv K[R\cdot]$

Termination

$$R\cdot + S \xrightarrow{k_2} \text{Stable byproduct}$$

Reaction rate $= k_2[R\cdot][S] \equiv k[R\cdot]$

$$2R\cdot \xrightarrow{l} \text{Stable byproduct}$$

Reaction rate $= l[R\cdot]^2$

where M and D are reactants, C is the product, and S is a scavenger. The concentrations of M, D, and S are assumed to be constant. R· is the chain carrier radical and, for convenience, the concentration will be designated by n. G is a constant, I is the dose rate, k_1, k_2, and l are rate constants, K and k are the apparent rate constants.

Continuous Irradiation

The chain radical concentration is given by

$$[1] \qquad \frac{dn}{dt} = GI - kn - 2ln^2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The rate of production of the product at steady state is termed X and is expressed by

$$[2] \qquad X = Kn = A[(1 + BI)^{\frac{1}{2}} - 1]$$

where

$$A = Kk/4l$$

$$B = 8lG/k^2$$

Periodical Irradiation

Consider a periodical exposure of the solution to a radiation field which is varied between two limits. The concentration of the chain radical at ith high and low dose rate intervals at time t are

$iT \leqslant t < iT + \eta T$ (ith high dose rate interval)

$$[3] \qquad \frac{dn}{dt} = GI_1 - kn - 2ln^2$$

$iT + \eta T \leqslant t < (i + 1)T$

(ith low dose rate interval)

$$[4] \qquad \frac{dn}{dt} = GI_2 - kn - 2ln^2$$

where T is the period, η is the fraction of the period that the dose rate is I_1, and i is an integer representing the number of periods. Introducing

$$Y = X/A$$

$iT \leqslant t < iT + \eta T$

$$[5] \qquad \frac{dY}{dt} = \frac{k}{2}(a - Y)(a + 2 + Y)$$

$iT + \eta T \leqslant t < (i + 1)T$

$$[6] \qquad \frac{dY}{dt} = \frac{k}{2}(b - Y)(b + 2 + Y)$$

where

$$a = (1 + BI_1)^{\frac{1}{2}} - 1$$

$$b = (1 + BI_2)^{\frac{1}{2}} - 1$$

When

$$i \gg 1$$

$iT \leqslant t < iT + \eta T$

$$[7] \quad \ln\left(\frac{a + 2 + Y}{a - Y}\right) = k(a + 1)(t - iT) + \ln\left(\frac{a + 2 + M}{a - M}\right)$$

$iT + \eta T \leqslant t < (i + 1)T$

$$[8] \quad \ln\left(\frac{Y + b + 2}{Y - b}\right) = k(b + 1)(t - iT - \eta T) + \ln\left(\frac{N + b + 2}{N - b}\right)$$

where N and M are initial values of Y at the low and high dose rate intervals, and are given by solutions of the following equations

$$[9] \qquad \left(\frac{a + 2 + N}{a - N}\right)\left(\frac{a - M}{a + 2 + M}\right) = u^k$$

$$[10] \qquad \left(\frac{M + 2 + b}{M - b}\right)\left(\frac{N - b}{N + b + 2}\right) = v^k$$

where

$$u = \exp[\eta(a + 1)T]$$

$$v = \exp[(1 - \eta)(b + 1)T]$$

The overall reaction rate which corresponds to the average reaction rate over one period, $\bar{Y}$, should be expressed by

$$[11] \quad \bar{Y} = \frac{1}{T}\int_{iT}^{(i+1)T} Y\,dt = \frac{2}{kT}\ln\left[\left(\frac{M + a + 2}{N + a + 2}\right)\left(\frac{N + b + 2}{M + b + 2}\right)\right] + \eta a + (1 - \eta)b$$

Rearranging eq. [11]

$$[12] \qquad \left(\frac{M + a + 2}{N + a + 2}\right)\left(\frac{N + b + 2}{M + b + 2}\right) = w^k$$

where

$$w = \exp\left[\frac{T}{2}(\bar{Y} - \eta a - (1 - \eta)b)\right]$$

A and B can be determined by continuous irradiation experiments and $\bar{Y}$ can be obtained by periodical irradiation experiments, where I_1, I_2, η, and T are known. Since a and b can be calculated, k is determined from eqs. [9], [10], and [12].

Experimental

The method described in this paper was applied to the radiolysis of aqueous solutions of chloral hydrate. Although the mechanism of this reaction has not been clearly established, the reaction rate is reported to be expressed by the same function of dose rate (8, 11, 12) as shown in eq. [2]. Since the dose rate dependency of reaction rate has an important meaning in this method,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

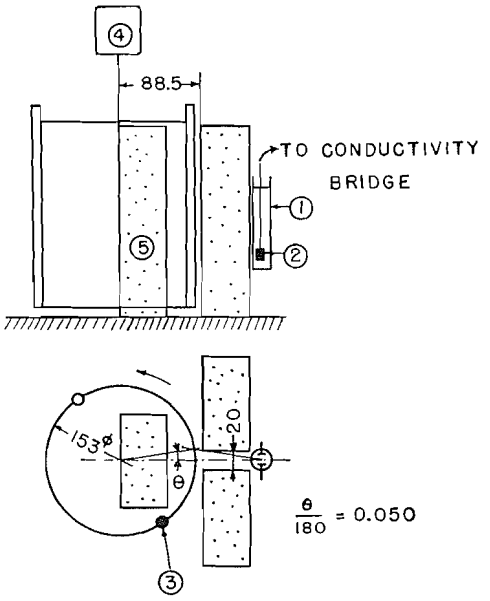

FIG. 1. Experimental apparatus. (1) reactor (20 mm$^{\phi}$, 50 cc Pyrex glass), (2) electrodes (tungsten, cell constant = 0.27 cm^{-1}), (3) source (^{137}Cs, 900 Ci, 10 mm$^{\phi}$ × 200 mm), (4) motor for rotating the source, (5) shielding leads (50 × 100 × 200 mm^3).

this reaction is considered to be applicable for the examination of this method.

The experimental apparatus is shown in Fig. 1. All experiments were carried out in the presence of dissolved oxygen (9–11) at 22 °C. The concentration of hydrochloride, which is the main product, is determined by measuring the specific conductivity (8, 10–13). Chloral hydrate from the Mallinckrodt Co. was used without further purification. The water used was distilled from alkaline potassium permanganate solution. The initial concentration of chloral hydrate was 1.0 mole/l.

The dose rate at high and low dose rate intervals was 400 and 0.0 rad/min, respectively. The value of η, determined by the geometry (Fig. 1), was 0.050, and the period was varied from 0.2 to 30 s.

Results and Discussions

The results for the continuous irradiation experiments are shown in Fig. 2. In this figure, the curve according to an approximate equation is also shown, from which A and B have been evaluated as 0.45 × 10^{-5} mho/cm min and 0.10 min/rad, respectively. These values agree very well with the results of McIntosh, Eager, and Spinks (12), using the conversion factor of 3.49 moles per l of acid per mho per cm.

The experimental results are listed in Table I together with values of k calculated by using the

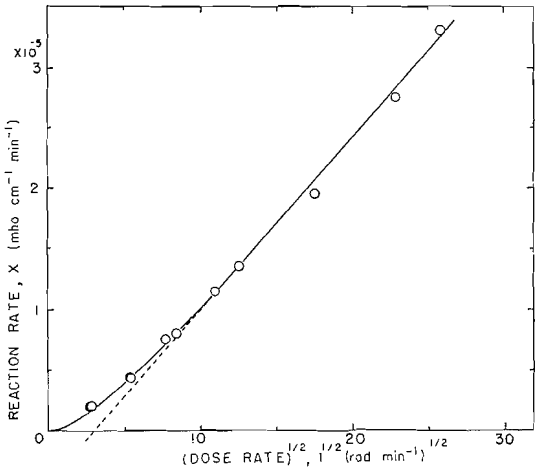

FIG. 2. Rate of formation of hydrochloric acid under continuous irradiation vs. (dose rate)$^{1/2}$. The solid line is based on eq. [2], and the dotted line is based on $X = A(BI)^{1/2} - A$; ○ denotes measured value.

method described in this paper. k is determined to be 1.10 s^{-1} by taking the average of the calculated values, except Runs 1, 2, 6, and 11.

In Fig. 3, the results for the periodical irradiation experiments are shown. The curve in the figure is based on eq. [11], using $B = 0.10$ min/rad, $k = 1.10$ s^{-1}, $I_1 = 400$ rad/min, $I_2 = 0.0$ rad/min, and $\eta = 0.050$. When the initiation rate G is known, l and K can be determined from the following relations

$$l = \frac{k^2 B}{8G}$$

$$K = \frac{kAB}{2G}$$

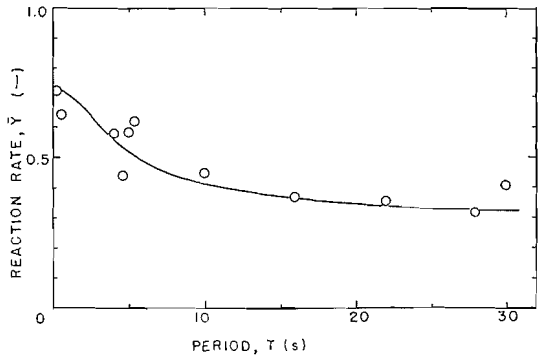

FIG. 3. Effect of periodical irradiation of the solution with ^{137}Cs γ-rays. The solid line is based on eq. [11], ○ denotes measured value.

TABLE I

Periodical irradiation of aqueous solution of chloral hydrate: summary of experimental data and calculated values of k

Run No.	Period T(s)	Reaction rate $\bar{Y}$(—)	k* (s^{-1})	k† (s^{-1})
1	0.2	0.718	4.13	—
2	0.54	0.640	4.54	—
3	4.0	0.580	0.92	1.23
4	4.6	0.437	1.89	1.98
5	5.0	0.585	0.71	0.97
6	5.4	0.649	0.46	0.76
7	10.0	0.448	0.81	0.85
8	16.0	0.367	0.98	0.98
9	22.0	0.352	0.84	0.84
10	28.0	0.311	1.33	1.32
11	30.0	0.405	0.37	0.38

*The solutions of eqs. [9], [10], and [12].
†Based on eq. [16].

An approximation method for determining k is shown below.

Introducing

$$y = 1/(M + a + 2)$$

$$x = 1/(N + a + 2)$$

into eqs. [9], [10], and [12]

$$[13] \qquad y = u^k x - \frac{u^k - 1}{2(a + 1)}$$

$$[14] \qquad y = w^{-k} x + \frac{1 - w^{-k}}{a - b}$$

$$[15] \qquad y = (vw)^{-k} x + \frac{1 - (vw)^{-k}}{a + b + 2}$$

are obtained.

When $u^k \gg 1$, and $v^k \gg 1$, which are realized for longer period experiments

$$x = 1/(2a + 2)$$

and

$$y = 1/(a + b + 2)$$

Hence, from eq. [14], k is given by

$$[16] \qquad k = \frac{1}{T} \frac{2 \ln \left[\frac{(a + b + 2)^2}{4(a + 1)(b + 1)} \right]}{\bar{Y} - \eta a - (1 - \eta) b}$$

The approximate values of k based on eq. [16] are also listed in Table I.

The chain radical life time τ is defined (1) by

$$\tau = \frac{\text{No. of radicals per unit vol.}}{\text{No. of radicals disappearing per unit vol. per unit time}}$$

At steady state with continuous irradiation, τ is calculated by

$$[17] \qquad \tau = n/GI = \frac{2}{k(a + 2)}$$

Using eq. [17], the chain life time at 400 rad/min is found to be 0.25 s.

For reactions in which k is zero, by considering eqs. [18], [19], and [20] instead of eqs. [2], [7], and [8], I/K can be determined. This is equivalent to the method of Noyes and Leighton.

$$[18] \qquad X = F\sqrt{I}$$

$$[19] \qquad \frac{dX}{dt} = \frac{2I}{K}(c - X)(c + X)$$

$$[20] \qquad \frac{dX}{dt} = \frac{2I}{K}(d - X)(d + X)$$

where

$$F = K\left(\frac{G}{2}\right)^{\frac{1}{2}}$$

$$c = F\sqrt{I_1}$$

$$d = F\sqrt{I_2}$$

Kinetics of the reaction of methyl iodide with sulfite and thiosulfate ions in aqueous solution[1]

R. A. HASTY[2] AND S. L. SUTTER
Pacific Northwest Laboratory, Battelle Memorial Institute, Richland, Washington 99352

Received June 30, 1969

The rate of reaction of methyl iodide with sulfite ion is determined. In addition, the rate of reaction of methyl iodide with thiosulfate ion is reexamined and the rate of reaction of methyl iodide with bisulfite ion is estimated. A pronounced effect of ionic strength on the reaction rate in the methyl iodide – sulfite ion system is observed, this effect does not occur in the methyl iodide – thiosulfate ion system. The second order reaction rate constant and activation energy for the reaction of methyl iodide with the respective nucleophiles are: SO_3^{2-}, 4.4×10^{-2} M^{-1} s^{-1}, 18.6 kcal $mole^{-1}$; HSO_3^-, 1×10^{-3} M^{-1} s^{-1}, 18.4 kcal $mole^{-1}$; and $S_2O_3^{2-}$, 3.1×10^{-2} M^{-1} s^{-1}, 19.4 kcal $mole^{-1}$.

Canadian Journal of Chemistry, 47, 4537 (1969)

Introduction

The reaction of methyl iodide with nucleophiles such as sulfite, bisulfite, sulfate, or thiosulfate ions presents an opportunity to compare and correlate the reactivity with non-kinetic properties of these nucleophiles. The reaction of methyl iodide is the simplest of the nucleophilic displacement reactions of the alkyl halides and should be the most easily understood. Excellent correlation of the reaction rate constant with the oxidative dimerization potential (1) is obtained with a number of nucleophiles (2–4). Fluoride ion is the only exception to the correlation. The reaction rate of methyl iodide with thiosulfate ion has been reported (3, 4) and is reexamined in this work. The determination of the rates of reaction of sulfite, bisulfite, and thiosulfate ions with methyl iodide are reported in this paper. In addition, the effect of ionic strength on the reaction rate is determined for both the thiosulfate ion and sulfite ion reaction with methyl iodide. The comparison of the two reactions presents an extreme contrast in two reactions which in most aspects are very similar.

Experimental

The gas chromatographic system utilized in this study has been described (5). The preparation of methyl iodide solutions and the details of the kinetic measurements are also reported. The only unusual feature of the chromatographic separation and detection of the gas which exits from the reaction vessel containing acidic solutions (pH 4.5) from observations reported earlier is the appearance of the chromatographic peak due to SO_2. The elution of SO_2 from the chromatographic column occurs after the elution of O_2 and before the elution of CH_3I. A small caustic scrubber removes SO_2 from the gas stream. Methyl iodide is not removed by this scrubber.

Sodium sulfite, sodium bisulfite, and sodium thiosulfate, reagent grade, are used without purification to prepare the reaction solution. The total sulfite or thiosulfate concentrations of the reaction solutions are determined by titration with potassium iodate standard solutions in the presence of carbon tetrachloride. The disappearance of iodine from the carbon tetrachloride layer is taken to be the end point of the titration.

The determination of the rate of reaction of methyl iodide in very dilute solutions (ca. 10^{-8} M) has been described (5). The rate of disappearance of methyl iodide from the reaction solution, k_{obsd}, and the total amount of methyl iodide which is sparged from the reaction vessel are determined for at least four flow rates of the sparge gas. The rate of reaction of methyl iodide in the solution is obtained from a graphical representation of $(1/k_{obsd})$ vs. the amount of methyl iodide recovered from the reaction vessel.

Results

Preliminary experiments at 24.70 °C, a pH of 12.05, and 0.020, 0.040, and 0.080 M sulfite ion gave 0.84×10^{-3}, 1.65×10^{-3}, and 3.3×10^{-3} s^{-1} for the pseudo first order reaction of methyl iodide. This demonstrates that the rate expression is first order with respect to the sulfite ion concentration. Although these measurements are not obtained at constant ionic strength ($\mu = 0.11$, 0.17, and 0.29, respectively), subsequent measurements at constant ionic strength verify the conclusion. The lack of an ionic strength effect in these preliminary results is attributed to the small variation of ionic strength coupled with the experimental uncertainties. The rate expression is also first order with respect to the methyl iodide

concentration, as demonstrated by the exponential decrease of methyl iodide concentration from the reaction vessel.

The effects of pH, chloride ion concentration, and ionic strength on the reaction rate are determined. The results of these measurements are given in Table I. Hydrochloric acid is added in some experiments to partially neutralize the sodium hydroxide and obtain solutions of a desired pH. In order to determine the effect of chloride ion on the rate of reaction, the chloride ion concentration is varied. The second order reaction rate constant is reduced ca. 30% in these experiments. Since this reduction in the observed rate constant could be due either to the increase in chloride ion concentration or to the increased ionic strength of the solution, sodium sulfate is added to adjust the ionic strength of the solutions. These results demonstrate that the rate constant is decreased as the ionic strength of the solution is increased. They are displayed in Fig. 1.

The temperature dependence of the sulfite and bisulfite reactions with methyl iodide are determined from the measurement of the reaction rate of methyl iodide at 33 and 49 °C and are reported in Table II.

The rate of reaction of methyl iodide with sodium thiosulfate is determined at constant and variable ionic strength. The results of these measurements are reported in Table III.

Discussion

Thiosulfate, sulfite, and bisulfite ions react with methyl iodide by a simple displacement mechanism (S_N2). The kinetics of these processes are straight forward as are most displacement reac-

tions which involve methyl iodide (1, 3, 6). The only complication is the hydrolysis by hydroxide ion in the case of the slower reactions. The rate of reaction can be generalized in the form

$$[1] \quad -\frac{d[CH_3I]}{dt} = k_2[CH_3I][N] + k_h[CH_3I][OH^-]$$

where N represents the nucleophile.

In the case of the sulfite ion as the nucleophile, the sulfite–bisulfite equilibria profoundly affects the observed rate of reaction of methyl iodide as shown in Table I. In the case of the sulfite–bisulfite equilibria, the term which involves the nucleophile in eq. [1] is separated into two parts and the term which involves hydroxide is neglected.

$$[2] \quad -\frac{d[CH_3I]}{dt} = k_2'[CH_3I][N](x) + k_2''[CH_3I][N](1-x)$$

where [N] is the total sulfite–bisulfite ion concentration and x is the sulfite ion fraction of the total. In theory, the fraction of sulfite ion can be calculated from the dissociation constant (6) of bisulfite ion of 5.6×10^{-8} but, in practice, the ionic strength is too high to permit reliable estimation of the activity coefficients of bisulfite or sulfite ions. Reasonable agreement between the observed decrease in reaction rate and the fraction of sulfite ion is obtained when values of the activity coefficient calculated by the formula cited by Conway (7) are employed.

Although the bimolecular reaction rate constant for sulfite ion with methyl iodide can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

determined, the bimolecular reaction rate constant for bisulfite ion with methyl iodide can only be approximated. At a pH of 4.5, the sulfite ion composes approximately 1% of the total bisulfite–sulfite concentration when the equilibrium constant is considered and activity coefficients are estimated as before. Thus, the bimolecular reaction rate constant for bisulfite ion with methyl iodide of 0.064 M^{-1} min^{-1} is only an upper limit. It should be noted that this value is close to that predicted by the Edwards correlation (1). The high ionic strength of the bisulfite solutions which is required because of the low reactivity of bisulfite ion with methyl iodide also requires that caution be used when stating this reaction rate constant.

In the case of thiosulfate ion, the dissociation constant of bithiosulfate ion (6) is 10^{-2}. The bithiosulfate ion is less than 1% of the thiosulfate concentration at pH greater than 4.

The effect of ionic strength is first noted in the studies which involved the dependence of reaction rate of sulfite–bisulfite with methyl iodide upon the pH. Extension of the ionic strength studies is made for both the sulfite and thiosulfite reaction with methyl iodide at high pH to preclude the formation of other species. The two reactions, i.e., sulfite – methyl iodide and thiosulfate–methyl iodide, although quite similar (both are reactions of dinegatively-charged ion with a dipole reaction and both have the same order-of-magnitude reaction rate constant), exhibit extremely contrasting dependence upon ionic strength.

The thiosulfate – methyl iodide reaction rate constant is $(3.1 \pm 0.1) \times 10^{-2}$ M^{-1} s^{-1} at 24.70 °C which is in excellent agreement with previously reported values (3, 4) at much higher methyl iodide concentrations (10^{-2} M compared to 10^{-8} M in this work). The reaction rate constant is independent of ionic strength up to an ionic strength of 0.65.

In contrast, the sulfite ion – methyl iodide reaction rate constant is very strongly dependent upon ionic strength of the solution as shown in Fig. 1. The Hückel extension of the Debye–Hückel treatment for activity coefficients (ref. 8, p. 229) to include a second term $b\mu$, where b is a constant which is related to the dielectric saturation of the medium and μ is the ionic strength of the medium, is an attempt to explain the effect of ionic strength on ion–dipole reactions. The relationship can then be derived that

$$\log k\mu = \log k_0 + \Delta b\mu \quad [3]$$

where k is the reaction rate constant (at ionic strength μ or zero) and Δb is the difference of the constant, b, between the transition state and the reactants. For Δb much less than unity the expression can be written as

$$k\mu = k_0 + \Delta b\mu \quad [4]$$

Normally Δb is small and there is little or no dependence of the rate constant of an ion–dipole reaction on the ionic strength as in the case of the thiosulfate – methyl iodide reaction. In the case of the sulfite – methyl iodide reaction, Δb is sufficiently large to cause the decrease of reaction rate constant for the sulfite – methyl iodide reaction to be nearly as large as in ion–ion reactions (ref. 8, p. 219).

An alternative quantitative treatment such as proposed by Amis (9) results in too small a predicted decrease of the reaction rate constant for the sulfite – methyl iodide reaction (10% decrease going from ionic strength of 0 to 1 as compared to ca. 40% decrease observed). Perhaps the principal reason for the poor quantitative correlation is the inability to accurately estimate values of the dielectric constant and distance of closest approach of the ion and dipole.

Extrapolation of the rate constant presented in Fig. 1 in accord with eq. [4] gives the bimolecular reaction rate constant at zero ionic strength and 24.7 °C to be 4.4×10^{-2} M^{-1} s^{-1}.

The activation energies of the reaction are summarized in Table IV. For the thiosulfate – methyl iodide reaction the activation energy of 19.44 ± 0.89 kcal $mole^{-1}$ is somewhat higher

TABLE IV

Summary of Arrhenius parameters for various nucleophiles

Nucleophile	k_2 at 25 °C (mole l^{-1} s^{-1})	$\log_{10} A$ (mole l^{-1} s^{-1})	E_a (kcal $mole^{-1}$)
SO_3^{2-}	4.4×10^{-2}	12.3	18.6 ± 0.6
HSO_3^-	1×10^{-3}	10.5	~ 18.4
$S_2O_3^{2-}$	$(3.1 \pm 0.1) \times 10^{-2}$	12.75	19.4 ± 0.9

but in agreement with 18.88 kcal mole^{-1} previously reported. The activation energy of the sulfite – methyl iodide reaction is 18.6 $\pm$ 0.6 kcal mole^{-1}. The activation energy of the bisulfite – methyl iodide reaction is ca. 18.4 kcal mole^{-1} but, because of the uncertainty of the sulfite ion contribution, this value is only an approximation.

Chelate-exchange titrimetry in nonaqueous solvents. I. Determination of dithizone and metal dithizonates

PETER GREY AND G. C. B. CAVE
Department of Chemistry, McGill University, Montreal, Quebec

Received[1] December 7, 1967

A new spectrophotometric titration method is proposed for determination of the amounts of metal chelates present in nonaqueous solvents. The titrant is a standard solution of a chelating agent which quantitatively displaces the chelate anion of the metal chelate. The method is exemplified by the titration of μg amounts of the dithizonates of Ag, Pb, Cu(II), Cd, Zn, and In in chloroform, both in the absence and the presence of free dithizone. Some binary and ternary mixtures were also successfully analyzed for the individual metal dithizonates. The titrant was a standard solution of sodium diethyldithiocarbamate in ethanol. Precision and accuracy were good. The preparation and analysis of the metal dithizonates are described. New titrimetric procedures are also proposed and shown to be satisfactory for determination of the free dithizone content of a chloroform solution.

Canadian Journal of Chemistry, 47, 4543 (1969)

Introduction

The present work demonstrates that a chelating agent in a nonaqueous solvent can be a useful titrant for metal chelates present in low dielectric-constant solvents. The overall reaction is the quantitative replacement of the chelate anion of the undissociated metal chelate by the titrant. The term chelate-exchange titration seems appropriate. The example studied is the spectrophotometric titration of μg amounts of the dithizonates of Ag, Pb, Cu(II), Cd, Zn, and In in chloroform; the titrant was sodium diethyldithiocarbamate in ethanol. The initial presence of free dithizone in the chloroform solution was found not to affect the accuracy of the results.

Růžička and Starý (1) were the first to suggest the possibility of using chelate-exchange titrations, in particular for the determination of the metal content of the organic solvent phase from a solvent extraction procedure. Extraction of metals as neutral, undissociated chelates into low dielectric-constant solvents is widely used as a separation procedure. The choice of dithizonates for the present study was dictated by the wide use of dithizone in solvent extractions.

In analytical chemistry, chelating agents have been used chiefly as selective precipitants for metals present in aqueous solution. Their use as titrants has not been widely exploited, and apparently not at all when the sample for titration was a metal chelate in a low dielectric-constant solvent. Brummet and Hollweg (2) quantitatively formed, with a given metal salt, a metal chelate in 4:1 benzene–methanol by addition of a chelating agent. They then determined the liberated hydrogen ions by a conventional potentiometric titration. Underwood and Underwood (3) determined metal 8-hydroxyquinolates by a conductometric titration with potassium methoxide in ethylenediamine. Chelating agents have also been used as titrants in spectrophotometric titrations of metals, mostly in aqueous solutions. For example, aminocarboxylic acids have been widely used as titrants in aqueous solutions (4, 5). Several workers (6–10) have titrated metal ions directly with organic chelating agents, in nonaqueous solvents. However, they used ionizing solvents which dissolved and dissociated the metal salt prior to titration. Accordingly, their technique differs in an important way from the proposed chelate-exchange method.

Experimental

Apparatus

Spectrophotometric Titration Assembly

A Beckman Model DU manual spectrophotometer with a conventional tungsten lamp source was used, but the Beckman cell compartment was replaced by a specially constructed one.

The special cell compartment was made of nonmagnetic material and was light tight. Its shape and dimensions duplicated those of the conventional Beckman compartment for cells of 100 mm path length. It accommodated one 65 ml rectangular glass titration cell of path length 50 mm, flanked by 2 hollow rectangular copper tanks through which constant-temperature water was circulated. The temperature of the thermostatted solution in the cell was measured with a copper–constantan thermocouple. However, close temperature control would be

[1]Revision received July 24, 1969.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 188.143.235.115 on 09/06/12
For personal use only.

unnecessary in many practical titrations. The shutter opening of the Beckman phototube compartment was covered with a thin, fused-silica plate which prevented any organic solvent vapors from entering the phototube compartment.

A 1 in. × 1/8 in. disk of silicone elastomer was countersunk in the removable lid of the cell compartment and covered a hole bored vertically through the center of the lid. Through this disk, a platinum–rhodium needle which served as the buret tip was inserted so that the tip of the needle was below the surface of the solution for titration.

A calibrated 1 ml Koch microburet with a detachable tip and a Luer joint at the tip was used to deliver the titrant. This buret had a 2-way Teflon stopcock and a 60 ml reservoir for titrant. The glass capillary tip normally supplied with the buret was replaced by a stiff platinum–rhodium hypodermic needle 2 in. long and 28 standard gauge bore. This needle was fitted with a Kel-F Luer joint to provide a direct, tight fitting connection to the buret[2].

Titration cells were of 2 capacities. For macrotitrations, a 65 ml rectangular glass cell was used. For microtitrations, a conventional cuvet, 10 mm × 10 mm × 45 mm high, was used in a Plexiglass frame that fitted snugly between the 2 copper tanks that comprized the thermostat in the cell compartment.

The macro and micro cells had covers to prevent evaporation of solvent. Each cover consisted of a sandwich of 1/8 in. silicone elastomer between two 1/8 in. aluminum plates bolted together. Coincident holes bored through the centers of the aluminum plates, but not through the elastomer, allowed the buret needle and the thermocouple wires to be passed through the silicone septum into the titration cell. A thin smear of silicone grease placed along the top edge of the cell prior to a titration provided an effective seal between the cell and this cover.

Stirring of the solution during a titration was with a conventional magnetic stirrer mounted immediately under the cell compartment. For the macro cell, a 1/2 in. Teflon-coated magnetic bar was used, and for the micro cell, a specially made 1/4 in. bar.

Glassware

All volumetric glassware was calibrated with the solvent used.

Red, low-actinic glass 50 ml and 100 ml volumetric flasks and 125 ml separatory funnels with Teflon stopcocks were used for solutions of dithizone and metal dithizonates.

Glassware that had contained nonaqueous solutions of metal dithizonates and metal 8-hydroxyquinolates was found to have a thin adhering film of the metal chelate that was very difficult to remove by customary washing techniques. An effective washing technique was the following. The glassware was rinsed first with acetone, then with water. It was then filled with a warm 4:1 mixture of concentrated sulfuric acid – concentrated nitric acid, and left for 1 h. After draining, it was thoroughly rinsed, first with ion-exchanged water, then with absolute alcohol. It was air dried for ordinary use; but for studies with very dry solvents, dry nitrogen was used instead of air.

Reagents

Solvents

Chloroform and carbon tetrachloride were Analar grade, further purified according to the method of Biddle (11). To the final chloroform distillate, 1% of ethanol was added as a preservative.

Methanol (Fisher) and ethanol (Gooderham and Worts) were absolute grade, used without further purification.

Benzene was Fisher "Spectranalysed" grade. Further purification was unnecessary; purified dithizone was not measurably oxidized by this solvent sample, over a period of 1 month.

Solids

Diphenylthiocarbazone (dithizone) was Fisher reagent grade, further purified before use. The major impurity was the oxidation product, diphenylthiocarbadiazone. Purification was carried out entirely in subdued light and in low-actinic glassware. The method of Mathre and Sandell (12) was used, with Barnes' modification (13) that the sulfur dioxide was added as a saturated aqueous solution, instead of as a gas. For a product of highest purity, the above procedure had to be carried out in its entirety 3 times; 4 times were used in the present work. The product was stable when stored in a tightly stoppered bottle in the dark. Its purity was determined by 2 methods: (*i*) gravimetric determination of sulfur as $BaSO_4$, after oxidation of the solid sample with a mixture of concentrated nitric acid and solid potassium chlorate (14) (Anal. Calcd. S in $C_{13}H_{12}N_4S$, 12.51%. Found: 12.48 ± 0.06%); (*ii*) spectrophotometric titration of a solution of the sample in benzene, the titrant being a 4×10^{-4} *M* standard solution of silver nitrate in a 1:20 methanol–benzene solvent. The procedure is original, and is given below. The product assayed 99.93 ± 0.22% dithizone by this method.

Sodium diethyldithiocarbamate was Fisher reagent grade, further purified by 2 recrystallizations from ethanol. The product was collected on a glass frit, washed with ice-cold ethanol, and dried in vacuo over Drierite for a week (15). Its purity was determined by 2 methods: (*i*) gravimetric determination of sodium as Na_2SO_4 by a conventional procedure (16) (Anal. Calcd. Na in $C_5H_{10}NS_2Na$: 13.42%. Found: 13.39 ± 0.08%); (*ii*) gravimetric determination of the diethyldithiocarbamate radical by precipitation with cupric ion (17) (Anal. Calcd. $C_5H_{10}NS$: 86.58%. Found: 86.56 ± 0.19%).

Dithizonates of Ag(I), Pb, Cu(II), Cd, Zn, and In were prepared by following the procedure described by Mathre and Sandell (12) for the preparation of lead dithizonate. The starting materials were specially purified metal salts and purified dithizone; the chloroform and carbon tetrachloride solvents were also purified as described above. The final products were dried in a stream of dry nitrogen in a dry-box, then in vacuo over potassium hydroxide for 2 weeks in the dark. All the operations were carried out in subdued light, and the vessels were of red, low-actinic glass. The prepared solids were stable when stored in tightly stoppered bottles in the dark.

The purity of the prepared metal dithizonates was determined by 2 methods.

[2]Needles fitted with joints were obtained from the Hamilton Company, Whittier, California.

(*i*) Assay for the metal, after decomposition of the chelate by wet oxidation with a 1:1 mixture of concentrated nitric acid and 30% (vol.) hydrogen peroxide (18). At least 3 such treatments were found necessary for complete decomposition, with evaporation of the solution to moist dryness after each treatment; 4 treatments were used as a precaution. Even then, decomposition of indium dithizonate was incomplete; evaporation to fumes of concentrated sulfuric acid was a necessary additional step. Because the zinc assay was by polarography, decomposition of its dithizonate was by a different method, namely 4 evaporations to moist dryness with aqua regia; the sodium stannate present as a preservative in the hydrogen peroxide would have interfered in the polarographic analysis.

(*ii*) Spectrophotometric titration of the dithizone liberated on treating the lead, zinc, cadmium, and indium dithizonates with acid. Thus, the solid sample was mechanically shaken for 6–12 h with 50 ml of 0.1 *N* hydrochloric acid containing 1% of a saturated aqueous solution of sulfur dioxide and 50 ml of benzene in a low-actinic glass flask. The sulfur dioxide prevented air oxidation of the liberated dithizone (13). The dithizone in an aliquot of the benzene phase was then titrated with a 4×10^{-4} *M* standard solution of silver nitrate in a 1:20 methanol–benzene mixture. The detailed procedure is given below. In the case of silver dithizonate, the dithizone was liberated for titration by using a 6% solution of potassium iodide in 0.25 *N* sulfuric acid, as recommended by Irving and Ramakrishna (19). Chloroform solutions of primary and secondary dithizonates of copper(II) were not decomposed by diluted acid. Therefore, a gravimetric analysis supplanted the spectrophotometric titration; the sulfur was determined as $BaSO_4$, after oxidation of the chelate.

The results of the analyses of the metal dithizonates by the 2 procedures described above are given in Table I.

Standard Solutions

(a) Sodium diethyldithiocarbamate, 2.5×10^{-3} M in Ethanol

A 0.025 *M* stock solution of sodium diethyldithiocarbamate in ethanol was prepared from a weighed amount of the purified, dried salt. Working standard solutions were prepared by 10- and 100-fold dilution of the stock solution with ethanol and were standardized by a spectrophotometric titration procedure described below. All solutions were freshly prepared each day, because they were found to deteriorate with time.

(b) Metal dithizonates, 5×10^{-5} N in Chloroform

Standard solutions were prepared in chloroform from accurately weighed amounts of the prepared salts. Preparations were done in subdued lighting, and solutions were kept in red, low-actinic glassware. Aliquots of the standard solutions were taken in replicate for standardization by the following methods: (*i*) For dithizonates of Pb, Cd, Zn, and In, the aliquot was shaken with 0.1 *N* hydrochloric acid. The aqueous phase, containing the metal, was separated and after conventional treatment it was assayed polarographically for the metal. (*ii*) For primary and secondary dithizonates of copper(II), the aliquot was evaporated to dryness. The residue was decomposed by wet oxidation with a 1:1 mixture of concentrated nitric acid and 30% hydrogen peroxide by following the procedure described above for the assaying of solid metal dithizonates for the metal. The final

residue was taken up with 2 ml of concentrated hydrochloric acid, evaporated to moist dryness, and then taken up with 0.1 *N* hydrochloric acid. The copper was determined colorimetrically by using zinc dibenzyldithiocarbamate (20). (*iii*) For silver dithizonate, the aliquot was shaken with a 6% solution of potassium iodide in 0.25 *N* sulfuric acid. The aqueous phase, containing the silver, was separated and evaporated to dense fumes. The cooled residue was processed by a conventional procedure, and a final nitrate solution was assayed polarographically for silver (21).

Analytical Procedures

General Procedure for Chelate-Exchange Titrations (Procedure I)

In the present investigation, the procedure has been applied to the titration of metal dithizonates in chloroform with standard solutions of sodium diethyldithiocarbamate in ethanol. However, it apparently is of rather general validity for nonaqueous chelate-exchange titrations.

The Beckman spectrophotometer with the special cell housing was used. For some titrations the wavelength chosen was 615 mμ, the absorbance peak for free dithizone; for others it was the absorbance peak of the metal dithizonate being titrated.

The spectrophotometric blank was purified chloroform in the titration cell. The spectrophotometer was adjusted for this blank prior to the titration, and checked for absence of drift by reinserting the blank after the titration.

The 1 ml Koch microburet was rinsed and filled with titrant (sodium diethyldithiocarbamate in ethanol). An aliquot of the chloroform solution of the metal dithizonate for analysis was transferred by pipet into the 65 ml titration cell and then diluted to 50 ± 2 ml with purified chloroform.

Stirring with the magnetic stirrer was adjusted to a rapid rate and was continuous throughout the titration. The sandwich cover of the titration cell (with thermocouple leads in place when registration of temperature was required) was placed on the cell and the lid of the compartment was put in place. The microburet was clamped in position, with the platinum–rhodium needle pushed through the silicone elastomer septum of the compartment lid and the cell cover so that the needle tip dipped into the solution for titration.

Titrations were performed with the cell compartment thermostatted at 25 °C. However, for purely practical titrations, close control of temperature was unnecessary; variations of ± 3 °C did not affect the results.

Constant increments of titrant were added, and the absorbance was read after each addition. Since the total volume of titrant was only about 0.25 ml, it was unnecessary to apply a dilution correction to the absorbance readings.

A plot of absorbance vs. volume of titrant gave the titration graph. The equivalence point was found by extrapolation of the 2 straight line arms of the graph. By drawing these arms by eye, a satisfactory estimate of the equivalence point was obtained. However, in the present work, the equivalence point was found by algebraic solution of the least-squares equations for the 2 straight line arms of the graph.

Titrations were also performed in the 4.5 ml titration cell. The sample volume was 2.5 ml. The procedure was that used for the 65 ml cell, except that the cell was housed in the Plexiglass frame mentioned above, and also it was necessary to correct the absorbance readings for dilution of the sample by the titrant.

Spectrophotometric Titration of Dithizone Solutions (Procedure II)

A rapid, accurate method was developed for the determination of dithizone in benzene.

Reagent grade silver nitrate was recrystallized twice from water, dried at 110 °C, then for 15 min at 225 °C. This product was used as a primary standard.

An 8×10^{-3} *M* stock standard solution of silver nitrate in methanol was prepared, and an aliquot was diluted 20-fold with benzene to provide the working standard solution. All solutions were stored in red, low-actinic glassware. The stock solution was stable for at least a month. The working solution was prepared fresh daily, because its titer was found to decrease significantly after about 48 h.

For the titration, a 100 μl sample of the benzene solution of dithizone was transferred to the 65 ml titration cell by using a calibrated, self-filling micropipet reserved exclusively for dithizone solutions. Fifty ml of benzene were added. The 1 ml Koch microburet contained the working standard solution of silver nitrate in 1:2 methanol–benzene. The titration was carried out by following Procedure I, above. The spectrophotometric blank was benzene. The wavelength setting was 618 mμ, at which the molar absorptivity of dithizone was 3.47×10^4 and that of silver dithizonate was negligibly small.

Standardization of Diethyldithiocarbamate Solutions (Procedure III)

A rapid, accurate method was developed for the standardization of ethanol solutions of sodium diethyldithiocarbamate.

A 1.8×10^{-4} *M* standard solution of copper(II) nitrate in ethanol was prepared from British Drug Houses electrolytic grade metal, which was the primary standard. The weighed metal was dissolved in 1:1 nitric acid and the solution was evaporated to moist dryness. The residue was dissolved in water and the solution again evaporated to moist dryness. The residue was dissolved and diluted to volume with ethanol.

A measured aliquot of the standard solution of copper(II) nitrate was transferred to the 65 ml titration cell and diluted to 50 ml with ethanol. The 1 ml Koch microburet contained the sodium diethyldithiocarbamate solution to be standardized.

The titration was carried out by following Procedure I, above. The spectrophotometric blank was ethanol. The wavelength setting was 435 mμ, which was the absorption peak of copper diethyldithiocarbamate in ethanol.

Tests for Equilibrium

In the titration of the metal dithizonates in chloroform by sodium diethyldithiocarbamate, tests confirmed that equilibrium existed at each stage of the titration. Thus, increments of a standard solution of the titrant, corresponding to 0.5, 1.0, and 1.5 equivalents of metal dithizonate taken, were added to the latter solution in the titration cell thermostatted at 25 °C. Absorbance measurements were made over a 2 h period. For the metal dithi-

For personal use only.

zonates studied, namely those of Ag, Pb, Cu(II), Cd, Zn, and In, equilibrium was reached almost instantaneously, and the absorbance readings remained constant thereafter for the 2 h period.

Choice of Wavelength

Titrations of the metal dithizonates were conducted at 2 wavelengths in the visible region. One was at the absorption peak of the metal dithizonate, and the other was at 615 mμ, which is a peak of dithizone. The diethyldithiocarbamates of sodium and of the titrated metals other than copper absorb only in the ultraviolet region; the use of this region is not explored in the present paper.

Results and Discussion

Standarization of Sodium Diethyldithiocarbamate Solutions

The precision and accuracy of the proposed method were measured. Aliquots of a 1.8×10^{-4} *M* standard solution of $Cu(NO_3)_2$ in ethanol were titrated against 2.5×10^{-3} and 2.3×10^{-4} *M* standard solutions of sodium diethyldithiocarbamate in ethanol by following Procedure III, above. The results are given in Table II, and a typical titration graph is shown in Fig. 1. Both the precision and the accuracy are good.

Standardization of Dithizone Solutions

Heretofore, the so-called extractive titration with silver nitrate (12, 19, 22) apparently was the only method available for the standardization of dithizone solutions. The presently proposed method avoids the disadvantages of the extractive titration method and is rapid and convenient to use.

The titer of the 8×10^{-3} *M* standard stock solution of silver nitrate in methanol was measured by high-frequency titrimetry (23), at intervals over a period of a month. When the standard solution was stored in low-actinic glassware, the total change over the month was less than 0.1%; when stored in ordinary glassware, it was about 0.6%. The standard working solution was prepared by dilution of the 8×10^{-3} *M* stock solution with benzene in the ratio 1:20. This solution was prepared fresh daily for use. Over a 12 h period, the titer changed by less than 0.1%. Over a 30 day period it changed by about 1%.

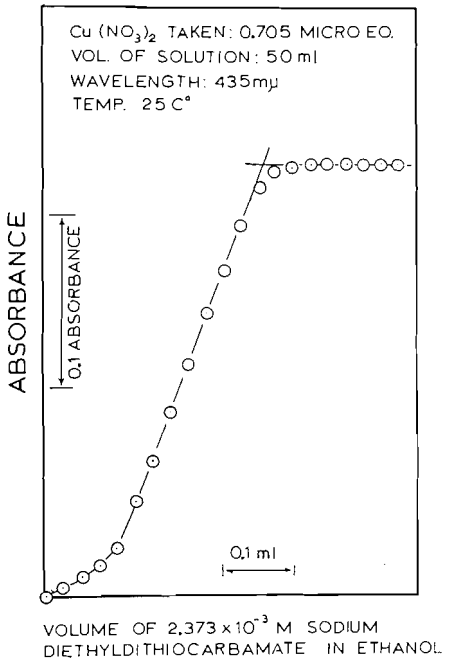

FIG. 1. Typical titration graph for the standardization of an ethanol solution of sodium diethyldithiocarbamate with copper(II) nitrate in ethanol.

The precision and accuracy of the proposed method were measured. Thus, aliquots of a 2×10^{-3} *M* standard stock solution of dithizone in benzene were diluted with benzene to provide 2×10^{-4} and 2×10^{-5} *M* standard solutions. The molarities of these 3 standard solutions were checked by measuring their absorbances at

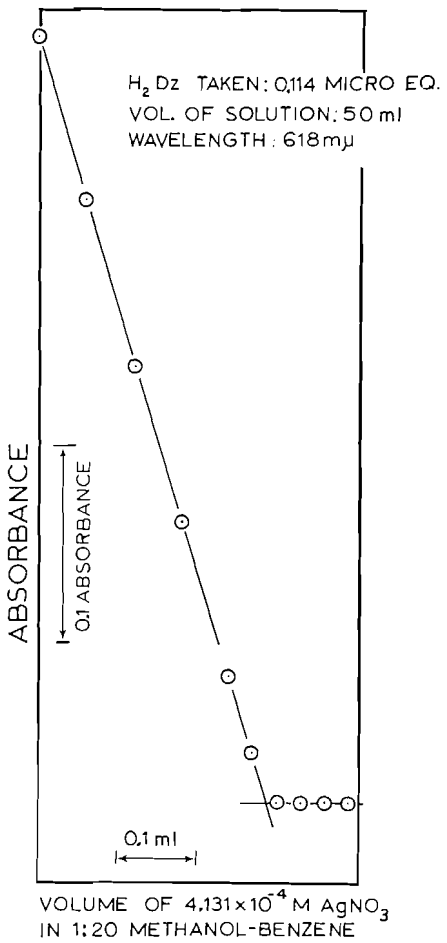

FIG. 2. Typical titration graph for the standardization of a benzene solution of dithizone with a standard solution of $AgNO_3$ in 1:20 methanol–benzene.

618 mμ, the molar absorptivity of dithizone being known. Replicate aliquots, 0.1 ml for the 2×10^{-3} *M* solution, 1 ml and 10 ml, respectively, for the other 2 solutions, were diluted to 50 ml with benzene. The resulting solutions were titrated by Procedure II, using a 4×10^{-4} *M* standard solution of silver nitrate in 1:20 methanol–benzene. The results are in Table III. A typical titration graph is shown in Fig. 2.

The precision of the method is good. Based on the dithizone reagent being 100% pure, the accuracy also is good; dithizone purity has been noted above. The molarities of the dithizone solutions as found from the measured absorbances at 618 mμ merely provide confirmation of the values given for the concentrations of the standard solutions.

Titration of Metal Dithizonates with Sodium Diethyldithiocarbamate

Aliquots of 5×10^{-5} *N* standard solutions of the primary dithizonates of Ag, Pb, Cu(II), Cd, Zn, and In in chloroform were separately titrated in replicate against a standard solution of sodium diethyldithiocarbamate in ethanol. For titrations in the 65 ml cell, 5 ml aliquots were diluted to 50 ml with chloroform; for titrations in the 4.5 ml cell, 0.5 ml aliquots were diluted to 2.5 ml. The general procedure for chelate-exchange titrations (Procedure I) was used. The metal dithizonates had been purified and analyzed (Table I). The titrant had been standardized by Procedure III. The titrations were performed at 2 wavelengths: (*i*) 615 mμ, the absorption peak of free dithizone in chloroform; (*ii*) the absorption peak of the primary metal dithizonate.

The titration results are in Table IV. Typical titration graphs for titrations performed at the absorption peak of the metal dithizonate are shown in Fig. 3. Also shown in this figure is a titration graph typical of all titrations performed at 615 mμ.

The degree of curvature in the titration graph around the end point decreased in the order

$$Ag > Zn \approx Cd > Pb > In > Cu$$

The dithizonates of Hg(II), Bi, Co(II), and Ni gave titration graphs with such excessive curvature that the arms could not be extrapolated to a precise intersection point. Their study was therefore not pursued.

In applications of chelate-exchange titrimetry, an initial excess of dithizone may be present in the nonaqueous solution of the metal dithizonate. Table IV shows that precision and accuracy are good up to at least a 4-fold initial excess of dithizone over metal dithizonate, and 6-fold in the case of indium. At the sample concentrations used, an excess of dithizone greater than 4-fold produced absorbance readings greater than 2, except for indium. The 4-fold initial excess of dithizone increased very slightly the curvature of the silver dithizonate titration graph; the increase in curvature was still less for the other metals, and least for copper(II).

In exploratory studies, several binary and

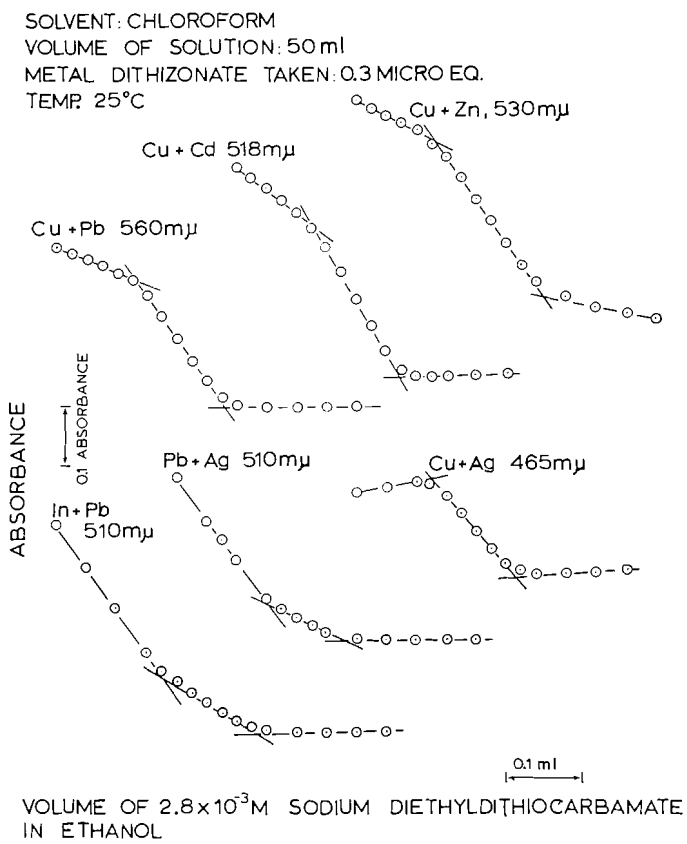

FIG. 4. Typical titration graphs for the chelate-exchange titration of binary mixtures of metal dithizonates in chloroform with a standard solution of sodium diethyldithiocarbamate in ethanol.

ternary mixtures of metal dithizonates in chloroform were titrated against sodium diethyldithiocarbamate in ethanol. The following 1:1 or 1:1:1 mixtures gave indefinite end points due to the curvature of the arms of the titration graph: Ag–Zn, Ag–Cd, Zn–Cd, Zn–Pb, Ag–Zn–Cd, Ag–Zn–Pb, Ag–Zn–Cu, Ag–Cd–Pb, and Zn–Cd–Pb. However, the mixtures listed in Table V gave satisfactory end points; but only equi–equivalent ratios were studied.

Typical titration graphs for mixtures are shown in Figs. 4 and 5. In these figures, the metals are listed in the order of appearance of their end points.

In the titration of a mixture, 1 wavelength was in general found to give much sharper end points than other possible choices. For example, for ternary mixtures, the best wavelength was that of the absorption peak of the second metal dithizonate titrated. All the graphs in Figs. 4 and 5 are for the best wavelength.

Factors Affecting the Shape of Titration Graphs

In the absence of side reactions, sodium dithizonate would be a product of the titrations. Its existence was not proven in the present work. However, the titrated solutions were green at the end point and absorbed strongly at 615 mμ, the peak for dithizone. Moreover, Fig. 3 shows no change immediately after the end point, and the absorptivity calculated therefrom agrees reasonably well with that of dithizone.

If the dithizonate product and reactant are NaHDz and $M(HDz)_n$ respectively, then one of the factors that would determine the slope of the first arm of the titration graph would be

$$a_{NaHDz} - a_{M(HDz)_n}/n$$

where a denotes molar absorptivity. This quantity was approximately calculated for the titration graphs of single metal dithizonates, on the basis of available data. The absorptivities of the metal dithizonates in chloroform had been measured

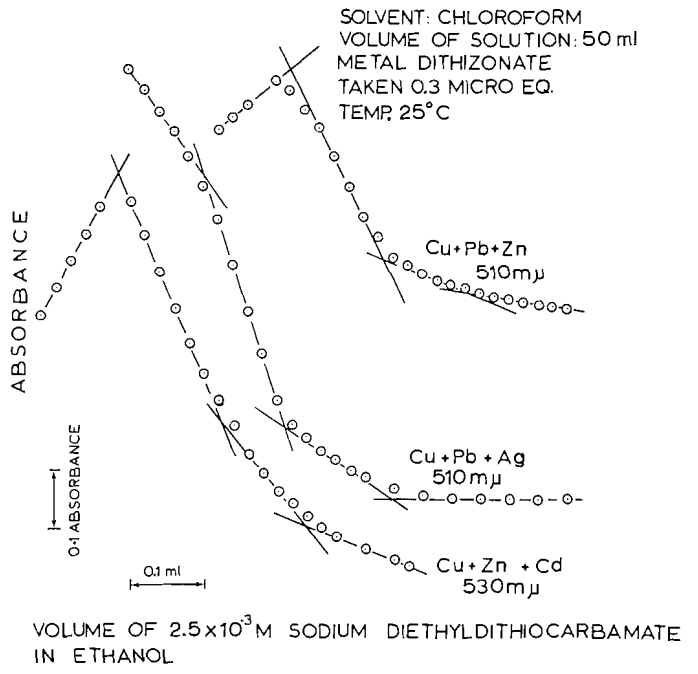

FIG. 5. Typical titration graphs for the chelate-exchange titration of ternary mixtures of metal dithizonates in chloroform with a standard solution of sodium diethyldithiocarbamate in ethanol.

in this laboratory, but instead of the unavailable absorptivity of sodium dithizonate, that of dithizone in benzene was used. The calculated values differed by about 50% from the values read from the titration graphs. Moreover, the nonzero slopes of the second arms of the titration graphs for copper and cadmium in Fig. 3 were not explained; zinc also had a nonzero slope.

In the titration of binary mixtures, the ratio of the slopes of the first and second arms of the titration graphs (Fig. 4) were in moderate agreement with values calculated from absorptivities as outlined above; but the absolute slopes were out by 50–100%. Finally, in the titration of ternary mixtures, the slopes of the arms of the titration graphs are anomalous with respect to the titration graphs of single metals.

The nature of the species participating in these chelate-exchange reactions, including intermediates and adducts, together with the relevant equilibrium constants, are required before the titration graphs can satisfactorily be predicted.

Chelate-exchange titrimetry in nonaqueous solvents. II. Determination of 8-quinolinol and metal 8-quinolinates

PETER GREY AND G. C. B. CAVE
Department of Chemistry, McGill University, Montreal, Quebec

Received[1] December 7, 1967

Chelate-exchange titrimetry has been applied to the determination of μg amounts of some metal 8-quinolinates in benzene. The titrant was a standard solution of diphenylthiocarbazone in benzene. Accuracy and precision were good in the cases of Pb, Cu(II), Cd, Zn, and In. Very slow reaction rates made titrations of Ag and Ni impracticable, and chelate-exchange was negligible in the case of Co(II). A new titrimetric method is also shown to be precise and accurate for the determination of free 8-quinolinol in benzene; the titrant was a standard solution of $Cu(NO_3)_2$ in ethanol.

Canadian Journal of Chemistry, 47, 4555 (1969)

Introduction

In a previous communication (1), a new type of titrimetric analysis was described, namely, the spectrophotometric titration of a metal chelate in a low dielectric-constant solvent with a standard solution of a chelating agent in a nonaqueous solvent. It was exemplified by the titration of some metal dithizonates in chloroform with a standard solution of sodium diethyldithiocarbamate in ethanol.

In the present investigation, the method has been applied to the determination of μg amounts of metal 8-quinolinates in benzene by titration with a standard solution of diphenylthiocarbazone in benzene. New features, not observed in the previous metal dithizonate titration, were evident in the present systems. In particular, some limitations of the general method of chelate-exchange titrimetry are exemplified and studied in detail. The larger values of the equilibrium constants and the faster reaction rates of the metal dithizonate – sodium diethyldithiocarbamate systems made a study of these factors less convenient in this system than in the present system.

Experimental

Apparatus

The spectrophotometric titrations were performed by using the previously described apparatus (1) without modification. The macro titration cells were 65 ml, the micro cells, 4.5 ml.

All glassware was specially cleaned, and volumetric glassware was calibrated, in the manner previously described (1). Red, low-actinic glass 50 ml and 100 ml volumetric flasks and 125 ml separatory funnels with Teflon stopcocks were used for the light sensitive solutions of diphenylthiocarbazone, 8-quinolinol, and the metal 8-quinolinates.

[1]Revision received July 24, 1969.

Reagents

Solvents

Benzene was Fisher "Spectranalysed" grade. Further purification was found to be unnecessary; purified dithizone was not measurably oxidized by this solvent sample, over a period of 1 month. For some experiments, the benzene was dried before use by percolation twice through fresh columns of silica gel, followed by treatment with calcium hydride (2). Water was not found in the dried product by a Karl Fischer potentiometric titration (3).

Ethanol was "absolute" reagent grade, used without further purification.

Water was purified by distillation, followed by passage through a 46 cm long column of Fisher "Rexyn" 1-300 research grade, mixed-bed ion-exchange resin. The metal content of the product was found to be negligible on testing with diphenylthiocarbazone in carbon tetrachloride.

Carbon tetrachloride was Analar grade, further purified as previously described (1).

Solids

Diphenylthiocarbazone (hereafter called dithizone) was reagent grade, further purified by using a previously described procedure (1). The product was stored in a tightly stoppered bottle in the dark.

8-Quinolinol (hereafter called oxine) was reagent grade, further purified by recrystallization from ethanol, followed by vacuum sublimation of the product at 100 ± 1 °C (4). The sublimed crystals were dried in vacuo over Drierite for 2 weeks in the dark and then stored in the dark. They assayed 100 ± 0.2% by a conventional bromometric method (5). The m.p. was 75.6–76.1 °C; lit. 75.8 °C (6).

The oxinates of Ag, Pb, Cu(II), Cd, Zn, Co(II), Ni(II), and In were prepared according to the respective procedures described by Hollingshead (7). The starting materials were the purified oxine and reagent grade metal salts that were further purified by standard methods. The purity of these starting materials was checked by analysis.

Each of the prepared metal oxinates was analyzed for metal content and for oxine content. For the metal assays, replicate samples were decomposed with a mixture of concentrated nitric acid and 30% hydrogen peroxide as previously described (1) for the decomposition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of metal dithizonates. Whereas the dithizonates required repetitive treatment with the mixture in order to effect complete decomposition, the oxinates needed only one treatment. The assay methods were conventional ones; they are tabulated along with the analytical results in Table I. The oxine content of the metal oxinate was determined on a separate sample by a colorimetric procedure described below (Procedure I). Results are in Table I.

Standard Solutions

Standard solutions of dithizone, 1×10^{-3} *M*, were prepared in benzene and stored in red, low-actinic glassware. These solutions were standardized against a standard solution of silver nitrate in ethanol by using a previously described spectrophotometric titration procedure (1).

Standard solutions of oxine in benzene were prepared from accurately weighed amounts of the analyzed solid. They were standardized by Procedure II, below.

Standard stock solutions of the metal oxinates in benzene were prepared as saturated solutions at 25 °C. From these solutions, standard 5×10^{-5} *N* working solutions were prepared in benzene and standardized. In the case of zinc, cadmium, and nickel oxinates, the "Spectranalysed" grade benzene contained enough water to have produced the less soluble dihydrates of the metal oxinates. These dihydrates become anhydrous only at 130 °C, the drying temperature used in the preparation of the solids. Therefore, in order to get sufficiently high concentrations, the standard solutions of these oxinates were prepared with the specially dried benzene, in a dry box flushed with dry nitrogen.

Miscellaneous Reagents

Sodium hydroxide, used in the preparation of cadmium dithizonate, was prepared from reagent grade sodium chloride by passage through a column of Amberlite IRA-410 resin in the hydroxide form (10). The product was stored in polypropylene.

Ammonia and hydrochloric acid were reagent grade, further purified by conventional distillation into previously steamed polyethylene bottles. The products, after adjustment of pH where necessary, were shown to be free from heavy metals by shaking them with a carbon tetrachloride solution of dithizone.

Nitric acid and sulfuric acid were Nichols reagent grade, used without further purification. Each new bottle of acid was tested for metals with dithizone, after appropriate initial treatment. In every case, the metal content introduced by these acids during an analysis that employed them was less than the standard deviation for that analytical method.

The other reagents were reagent grade, used without further purification.

Standardization of Metal Oxinate Solutions

Aliquots of each standard solution were evaporated to dryness. Except for lead, zinc, and cadmium, the residues were then decomposed by the 1:1 mixture of concentrated nitric acid and 30% hydrogen peroxide used in the analysis of the solids. Decomposition of lead oxinate was unnecessary. For zinc and cadmium oxinates, decomposition was effected by repeated use of aqua regia; the sodium stannate present as a preservative in the hydrogen peroxide would have interfered in the subsequent polarographic analysis for zinc and cadmium.

The subsequent treatment of the residues depended on the metal, as follows

Silver

The residue was dissolved in water, the solution carefully neutralized with ammonia, then diluted to volume with a 1:1 mixture of 1 *M* potassium nitrate and 1 *M* potassium thiocyanate, and the silver determined by polarography (13).

Lead

The residue was both dissolved and diluted to volume with 0.1 *N* hydrochloric acid, and the lead determined polarographically after addition of gelatin as a maximum suppressor.

Copper(II)

The residue was dissolved in concentrated hydrochloric acid and the solution evaporated to dryness. The residue was dissolved in 0.1 *N* hydrochloric acid, and the copper

extracted with four 5 ml portions of a 1% solution of zinc dibenzyldithiocarbamate in carbon tetrachloride (11). The combined organic phases were diluted to volume, and the absorbance was read at 435 mμ.

Cadmium

The residue was treated and analyzed by the procedure used for lead oxinate.

Zinc

The residue was both dissolved and diluted to volume with a 1:1 mixture of 1 *M* ammonia – 1 *M* ammonium chloride, and the zinc determined polarographically after addition of gelatin as a maximum suppressor.

Nickel

After solution of the residue in concentrated ammonium hydroxide, the nickel was determined colorimetrically at 445 mμ by the dimethylglyoxime method (15).

Cobalt

The cobalt in the dissolved residue was determined colorimetrically, by the conventional nitroso-R-salt method (14).

Indium

The residue was both dissolved and diluted to volume with 2.5 *N* hydrochloric acid which contained 4% of hydrazine hydrochloride, 20 ml of a saturated aqueous solution of sodium formate per 100 ml of solution, and 0.04% starch. The indium was then determined by polarography (12).

Colorimetric Determination of Oxine in a Metal Oxinate (Procedure I)

Use was made of the quantitative conversion of oxine and metal oxinates into H_2Ox^+ ions in 0.1 *N* hydrochloric acid. This ion has two absorption peaks, one at 358 mμ ($a \sim 1660$) and another at 252 mμ ($a \sim 43\,000$) (16). The colorimetric analysis described here is essentially that proposed by Deterding and Harding (17) for the determination of magnesium oxinate.

Replicate 0.1 g samples of the solid were both dissolved and diluted to volume with 0.1 *N* purified hydrochloric acid, in red, low-actinic 100 ml volumetric flasks. An aliquot was diluted exactly 20-fold with 0.1 *N* hydrochloric acid, in a similar flask. Its absorbance was read against 0.1 *N* hydrochloric acid, at 358 mμ in a 10 mm cuvet. The calibration curve was prepared from standard solutions of the purified oxine reagent (as primary standard) in 0.1 *N* hydrochloric acid. Beer's law was obeyed.

Spectrophotometric Titration of Oxine Solutions (Procedure II)

The method was similar to that previously developed for the determination of the dithizone content of chloroform solutions (1), except that the titrant was copper(II) nitrate in ethanol.

A 2×10^{-3} *M* standard solution of copper(II) nitrate in ethanol was prepared from British Drug Houses electrolytic grade metal, which was the primary standard. The weighed metal was dissolved in 1:1 nitric acid, and the solution was evaporated to moist dryness. The residue was dissolved in water, and the solution was again evaporated to moist dryness. The residue was dissolved and diluted to volume with ethanol.

The titration apparatus and procedure were identical to those reported for the determination of dithizone (1). Thus, an aliquot of the oxine solution in benzene was pipetted into a 65 ml titration cell and diluted to 50 ml with benzene. It was then titrated with the 2×10^{-3} *M* standard solution of copper(II) nitrate in ethanol. The spectrophotometric blank was benzene. The wavelength was set at 420 mμ, the absorption peak of copper(II) oxinate in benzene; the molar absorptivity was 5900. The products of the titration were undissociated nitric acid and copper(II) oxinate.

General Procedure for Chelate-Exchange Titrations (Procedure III)

Titrations of metal oxinates, except those of zinc and cadmium, were carried out by using the apparatus and procedure previously described (1) for the titration of metal dithizonates, but in the present case, the titrant was dithizone and the solvent was benzene.

For a macrotitration, a 5 ml aliquot of a 5×10^{-5} *N* solution of the metal oxinate in benzene was diluted to 50 ± 0.2 ml with benzene in the 65 ml titration cell; for a microtitration, a 0.5 ml aliquot was diluted to 2.5 ± 0.01 ml in the 4.5 ml cell. These solutions were thermostatted at 25 °C for titration. The small dilution tolerances of ±0.2 ml and ±0.01 ml were chosen so as to permit use of the data for other, theoretical purposes not reported here; for practical titrations, tolerances of ±2 ml and ±0.1 ml are suggested. Temperature control, also, was to enable other, theoretical use to be made of the data; otherwise, variations of at least ±3 °C could be tolerated during a titration.

The titrants were 1×10^{-3} *M* (macro) and 1×10^{-4} *M* (micro) standard solutions of dithizone in benzene. Titrations were conducted in a dark room lit only by a 40 W red light bulb placed near the titration apparatus. This light source was shown not to change the titer of the dithizone solutions over an 8 h period.

Chelate-Exchange Titration of Zinc and Cadmium Oxinates (Procedure IV)

Procedure III was followed, except for the program used to introduce the titrant. For titrations at 618 mμ, where only dithizone absorbs, an accurately measured excess of titrant was added all at once to the metal oxinate solution in the titration cell; usually about 50% excess was added. The resulting solution was allowed to stand for 20 min, thermostatted at 25 °C for cadmium and 42 °C for zinc. Then several measured increments of titrant were added in the usual way from the microburet, in order to obtain points for the second branch of the titration graph. Because the slope and the absorbance of the first branch were 0, extrapolation of the second branch back to the volume-of-titrant axis gave the end point.

For titrations at the wavelength of the absorption peak of the metal dithizonate, the titration was essentially as in Procedure III. The titration was begun by adding a few increments of titrant over a 10 min period, in order to obtain the first branch of the titration graph. Then a measured excess of titrant was added all at once, in order to carry the titration well past the end point. The reaction was then left for 20 min. Finally, a few additional increments were added at the normal rate, in order to obtain the second branch of the titration graph.

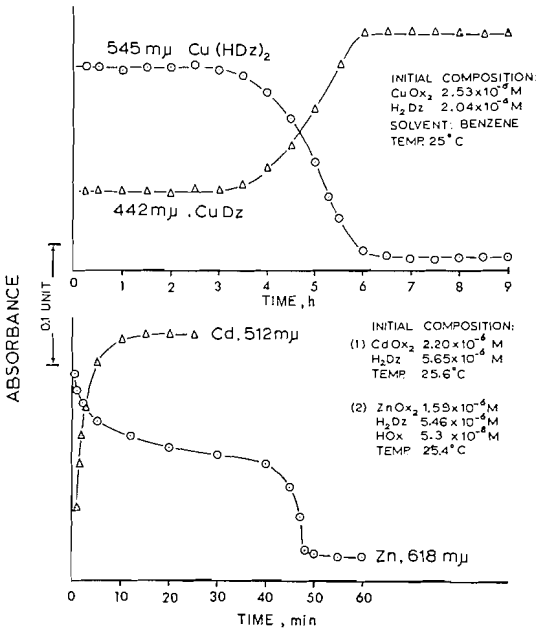

FIG. 1. Reaction rates in benzene for some metal oxinates with dithizone, at 25 °C.

Tests for Equilibrium

Benzene solutions of dithizone were mixed separately with benzene solutions of the oxinates of lead, copper(II), and indium, in the molar ratios 2:1, 1:1, and 1:2. In all cases, constant absorbance readings were obtained almost instantaneously, and no change was observed thereafter over a 2 h period. However, the copper(II) system was not in equilibrium. In Fig. 1, absorbance readings for the copper oxinate – dithizone system are shown over a 9 h period. One curve shows the absorbance readings at 545 mμ, which is the absorption peak of primary copper(II) dithizonate. The other curve is at 442 mμ, which is an absorption peak of secondary copper(II) dithizonate. Advantage was taken of the essentially constant absorbance readings over the first 2 h to perform titrations that proved to be entirely reliable. An explanation of the rate curves will be given elsewhere.

The reactions of dithizone with zinc and cadmium oxinates were too slow for direct titrations to be useful; rate curves for them are also in Fig. 1. The reaction mechanisms were not sought in the present work. Due to the slowness of these rates, a modified form of Procedure III was necessary for titrations and it is given in Procedure IV. It gave entirely satisfactory results, although it is somewhat inconvenient.

The reactions of dithizone with silver(I) oxinate and with nickel oxinate were much slower than with zinc oxinate; titrations were impracticable. Finally, dithizone apparently did not react at all with cobalt(II) oxinate.

Results and Discussion

Determination of Oxine in Solutions

The precision and accuracy of Procedure II, above, were measured. A 10^{-2} *M* standard stock solution of oxine in benzene was prepared from an accurately weighed amount of the purified solid, which assayed 100 ± 0.2%. Standard working solutions were prepared by accurate dilution of the stock solution with benzene. Aliquots of these working solutions were diluted to 50 ml with benzene, then were titrated spectrophotometrically at 420 mμ against a 2×10^{-3} *M* standardized solution of copper(II) nitrate in ethanol by following Procedure II. The results are in Table II. Precision and accuracy evidently are good.

A typical titration graph is shown in Fig. 2. For the data in Table II, the first break was taken as the end point. This first break occurred when the molar ratio of copper to oxine was 1:2; the second break occurred when this ratio was 1:1. The slope of the first branch corresponded to the molar absorptivity of $CuOx_2$. Therefore, it is proposed that the first break represents the formation of $CuOx_2$. The further addition of an equal amount of copper(II) nitrate led to the second break, at which the absorbance was 1/2

that for the first break. It is suggested that the second break may therefore be due to the conversion of $CuOx_2$ into $[CuOx^+, NO_3^-]$ ion pairs.

Titration of Metal Oxinates by Dithizone

The results of replicate macro- and micro-titrations of the oxinates of Pb, Cu(II), Cd, Zn, and In are given in Table III. As noted there, the titrations were performed both at the absorption peak of the particular metal oxinate, and also at 618 mμ, the absorption peak of free dithizone. In addition, the effect of the initial presence of free oxine on the accuracy and precision of the results was studied. For that purpose, the initial molar ratio of free oxine to metal oxinate was varied between 0 and 100.

In Fig. 3, typical titration graphs for copper(II) oxinate vs. dithizone titrant are shown for 2 wavelengths, 618 mμ, where dithizone absorbs, and 545 mμ, where copper(II) dithizonate absorbs. The general shapes of these graphs are typical of those obtained for the other metal oxinates studied, although there were minor differences. For example, in the case of titrations at 618 mμ, the slope of the first branch of the graph was characteristic of the metal. Thus, the slope for zinc and cadmium was 0 because their

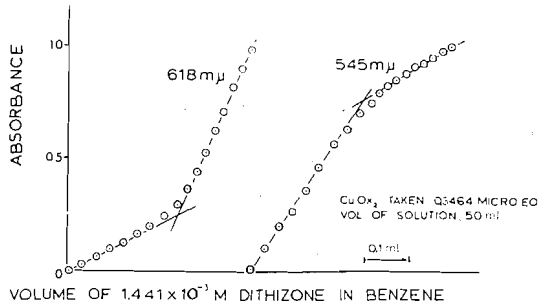

FIG. 3. Typical titration graphs for the titration of copper(II) oxinate in benzene with a standard solution of dithizone in benzene, at 25 °C.

106.6	0.366	0.375	0.367	0.374	16	42	5.1	35

*Molarity of titrant, 1.365×10^{-3} *M*; normality of copper(II) oxinate solution, 6.926×10^{-5} *N*; volume of solution for titration, 50 ml; amount of copper(II) oxinate taken for titration, 0.3463 μeq. Each analytical result is the mean of 5 titrations.
†The manual method consisted in drawing the "best" lines through the titration points and reading their intersection points.

dithizonates have negligible absorbance at 618 mμ, whereas the corresponding slopes for copper and lead were positive but different. Curvature of the first branch of the indium graph for 618 mμ dictated that titrations be performed at 505 mμ, where its dithizonate strongly absorbs.

Statistical Treatment of the Titration Data

The data for statistical analysis are drawn from Tables III and IV; but some sets of variances have been pooled because they were homogeneous, and to avoid redundancy some molar ratios of oxine to metal oxinate are omitted in the cases of Pb, Cd, and Zn.

In all the statistical tests, the 5% level of significance was used.

Method of End Point Determination

End points for all the titrations were found as follows: the least-squares lines for the 2 linear branches of the titrations graph were solved algebraically for their intersection point. In the case of copper, this method was supplemented by observing the intersection point of the 2 lines drawn manually as nearly as possible through the points on each arm of the titration graph.

The mean values ($n = 5$) and the corresponding variances of the end points found for copper by the 2 methods are given in Table IV. The application of Bartlett's criterion (18) showed that the variances of the least-squares method were homogeneous when various ratios of oxine to copper oxinate were used, while those of the manual method were not.

For each of the other metals also, variances of the end point found by the least-squares method were homogeneous when various ratios of oxine to metal oxinate were taken. Moreover, the variances of the end point were homogeneous for all metals titrated, when similar amounts of metal were taken. It is concluded that the nature of the metal, and the amount of free oxine initially present in the solution for titration, had no significant effect on the precision of the titrations.

Effect of Initial Free Oxine

An expected application of these chelate-exchange titrations is the determination of metal oxinates extracted from aqueous solutions. Some free oxine would be coextracted. Therefore, it was necessary to determine whether or not free oxine, initially present in the solution for titration, affected the accuracy of the result. Therefore, the relevant data for each metal in Tables III and IV were treated by a conventional analysis-of-variance technique for a 2-stage grouping. Thus, estimates were obtained for (*i*) the variance (σ_{HOx}^2) due to the effect of oxine, (*ii*) the variance (σ_λ^2) due to wavelength, and (*iii*) the variance (σ_r^2) due to random fluctuations. These values are exemplified in Table V for the copper system.

It was concluded from the statistical analysis that the initial presence of free oxine had a significant effect on the value of the end point in the cases of copper and indium, but not in the cases of lead, cadmium, and zinc. A correction factor is described below which was successfully applied to the determination of copper in the presence of oxine.

It is possible quantitatively to explain (*i*) the large discrepancy between the amount of indium taken and the amount found as shown in Table III, and (*ii*) the significant effect of initial free

‡σ_{HOx}^2 is variance due to the effect of oxine.
§σ_λ^2 is variance due to wavelength.

oxine on the end point. Our studies have shown that in this and other chelate-exchange titrations, mixed chelates are formed. In the case of indium, the formation constants for these mixed chelates, and also the overall formation constant for the titration, have been calculated and found to be relatively low. These calculations are to be presented elsewhere.

Effect of the Choice of Wavelength

Each metal had been titrated in replicate at 2 different wavelengths; the data are in Table III. These data had been incorporated in the statistical analysis described in the preceding section. From that analysis of variance, it was concluded in every case that the end points obtained at the 2 wavelengths were not significantly different from one another for a given molar ratio of initial oxine to metal oxinate. Moreover, the variances for all the macrotitrations in Table III had been shown to be homogeneous; similarly for all the microtitrations. Therefore it was concluded that the precision of the titrations was independent of the wavelength used.

Correction Factor for Initial Oxine in Copper Titrations

It was concluded above that oxine initially present affected the accuracy of a copper titration. In Fig. 4 are plots of % error in the determination of copper, vs. the initial molar ratio of free oxine to copper oxinate, for 2 wavelengths and for 2 different amounts of copper. The points are the experimental data, from Tables III and IV. The broken lines are regression lines calculated by least squares. A regression analysis confirmed their linearity.

In practice, an approximate but satisfactory value for the free oxine content of the copper oxinate solution may be obtained by either of 2 convenient methods: (*i*) titration of a separate sample of the copper oxinate solution with a

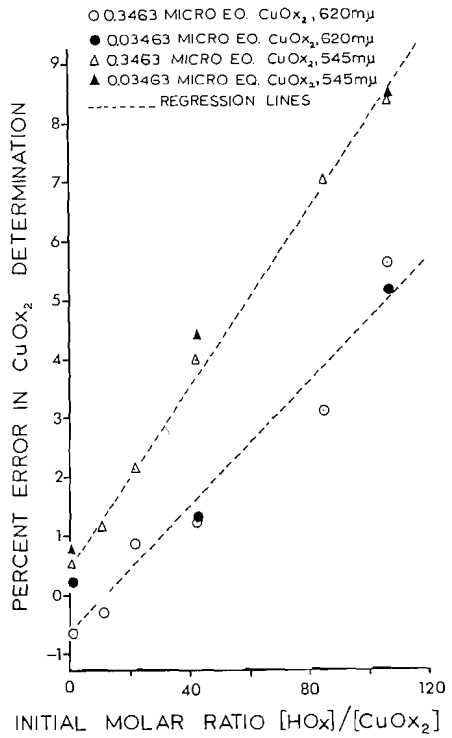

FIG. 4. Correction curves for the titration of benzene solutions of copper oxinate with a standard solution of dithizone in benzene in the initial presence of free oxine, at 25 °C.

standard solution of copper(II) nitrate in ethanol, at 420 mμ as prescribed in Procedure II; (*ii*) direct measurement of the absorbance at 315 mμ of the copper oxinate solution, where oxine has a peak and where copper(II) oxinate absorbs much less. From either measurement, and from the value found by titration for the copper oxinate content of the solution, a first approximation may be obtained for the molar ratio of initial oxine to copper oxinate. From the regression line in Fig. 4, an approximate value for the % error

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

may then be obtained. By iteration, the initial result for the copper content may then be corrected to the necessary degree.

The Slopes of the Titration Graphs

The shapes of the titration graphs depend on the nature of the participating species, including mixed complexes and adducts, and on their formation constants. This information for selected systems will be the subject of a separate report. However, it should be noted here that in Fig. 3, the titration graphs for copper(II) oxinate, the corresponding rate curves in Fig. 1, and the titration graph in Fig. 2 are explained by the coexistence in these nonequilibrium systems of primary and secondary copper(II) dithizonates. Thus, in Fig. 3 the first arm of the graph represents the conversion of copper(II) oxinate into a mixture of secondary and primary dithizonates, with the primary dithizonate predominating and quantitatively replacing the secondary dithizonate as the titration proceeds. After the end point, the slope of the second arm of the titration graph corresponds accurately to the measured absorptivity of dithizone.

Mössbauer spectra of toluene-3,4-dithiolene and *cis*-1,2-bistrifluoromethyl-1,2-ethylenedithiolene complexes of iron(III)

T. BIRCHALL
Department of Chemistry, McMaster University, Hamilton, Ontario

Received August 11, 1969

The Mössbauer spectra of a number of dithiolene complexes of iron have been examined at 77 °K. The data obtained are discussed in relation to the known structural data.

Canadian Journal of Chemistry, 47, 4563 (1969)

Introduction

Transition metals form many and varied complexes with the bidentate sulfur ligands dithiocarbamate and 1,2-dithiolate. Mössbauer spectroscopy has been used to study complexes of these ligands with iron, and much useful information about the structure and nature of the bonding has been obtained (1–5). Continuing the earlier studies (4, 5), data on complexes of iron with the toluene-3,4-dithiolene and bistrifluoromethyl-1,2-dithiolene ligands are reported.

Experimental

The Mössbauer spectra were recorded on an apparatus previously described (6). All chemical shifts are relative to sodium nitroprusside taken as zero. As only small quantities of the compounds were available (20–50 mg) the samples were packed into holders made by drilling an appropriately-sized hole in 1/16 in. lead sheet in an attempt to achieve 10 mg of iron/cm^2. This resulted in rather small sample areas with the consequence that long counting periods were necessary to obtain a spectrum. Spectra at room temperature were often barely detectable and even at liquid nitrogen temperature, the resonance absorption often only amounted to 1–3% of the total counts. Only data obtained at liquid nitrogen temperature are reported here and these are thought to be accurate to ±0.03 mm/s.

Results and Discussion

All the data are summarized in Table I. The chemical shifts (δ) are typical of iron(III) and differ little from the shifts of analogous compounds reported earlier (5). These are then, apart from **7** and **8**, presumably also five-coordinate complexes. The toluene-3,4-dithiolene series has been arranged in order of decreasing quadrupole splitting which is also the order of increasing chemical shift. However, apart from the Δ value for compound **7**, these variations are for the most part within the experimental error. There appears to be no correlation between the strength of the nitrogen base occupying the fifth coordination site and either of the Mössbauer parameters. In the case of the 4-aminopyridine complex, **7**, it is felt that the quadrupole splitting is significantly smaller than that for the other toluene-3,4-dithiolene complexes, **1**–**6**. A similar effect was noted in the corresponding maleonitrile series (5)

and, again, strongly suggests that the lone pair of the free NH_2 group of one unit is forming a weak donor bond to the vacant sixth position of the iron atom of another unit, as shown in Fig. 1. In this way every iron atom achieves essentially six-coordination, though the Fe——NH_2 bond is probably very long. Only an X-ray structure determination could confirm this. The effect of six-coordination is seen in compound **8**, where the quadrupole splitting of 1.97 mm/s is considerably lower than the value obtained for the five-coordinate pyridine adduct i.e., 2.61 mm/s (5). This indicates a more symmetric environment

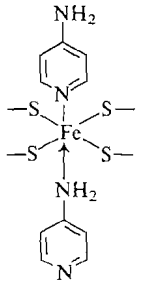

FIG. 1. Donor bond of NH_2 group to Fe of another unit.

at the iron. The quadrupole splitting in compound **8** is nevertheless still large. Recent X-ray structure determinations on the ions $\{Co[S_2C_2(CN)_2]_2$-(*o*-phen)$\}^-$ and $\{Co[S_2C_6H_3.CH_3]_2$(*o*-phen)$\}^-$ indicate that the arrangement about the cobalt is octahedral in both complexes (7). In addition it was found that the Co—S bond *trans* to a nitrogen atom is shorter by $\sim$ 0.035 Å than when *trans* to another sulfur. One would expect the $\{Fe[S_2C_2(CF_3)_2]_2$(*o*-phen)$\}^-$ to have a similarly distorted structure and a considerable quadrupole splitting would be expected from a formally d^5 iron in this environment, even if there was no extensive π-delocalization onto the ligands.

Comparison of the data for compounds **9–11** illustrates the effect of electron delocalization from the metal to the ligand upon the Mössbauer parameters. Strong π-type interactions result in a decrease in chemical shift as 3d electrons are removed from the iron nuclear environment. This is the result of a decrease in screening of the "s" electrons from the nuclear charge and a resultant increase in "s" electron density. Since $\delta r/r$ is negative for ^{57}Fe (ref. 8, p. 54), a decrease in chemical shift means an increase in "s" electron density. One can immediately arrange ligands in order of π-bonding capabilities with a decreasing ability to accept electrons via π-bonding in the series NO > Et_3P > Py. The substituted pyridines and quinolines are identical in this respect, showing no variation in chemical shift.

Removal of electron density from the metal in the above manner also has a marked influence on the quadrupole splitting, which decreases as the degree of π back-donation increases. While the change in quadrupole splitting might be a direct consequence of the back donation of electrons onto the axial ligand in the case of the triethylphosphine complex, this is probably not so for the nitrosyl compound. A quite different situation pertains in the nitrosyl compound as compared to compounds **9** and **10** (Table I). $\{Fe(pyridine)$-$[S_2C_2(CN)_2]_2\}^-$ has spin $S = 3/2$ (9) and it is probable that compounds **9** and **10** have the same electronic arrangements. The nitrosyl complex **11** has an extra electron, supplied by the NO group which in itself would markedly affect the asymmetry at the iron nucleus. In addition, the strong π-bonding to the NO antibonding orbitals results in a complete change in the molecular orbital scheme to give a diamagnetic complex (10). All of these factors undoubtedly contribute to the lower quadrupole splitting.

Comparison of the Mössbauer parameters for the toluene-3,4-dithiolene series with the other dithiolenes (5) reveals that the series reported here exhibit a much larger quadrupole splitting than all others, except perhaps those involving the tetrachlorobenzene-1,2-dithiolene ligand. Table II lists the Mössbauer parameters for the five-coordinate pyridine adducts and one notes a 25% increase in quadrupole splitting down the series with virtually no change in chemical shift. The same ordering of ligands has been noted by

TABLE II

Mössbauer parameters of some iron dithiolene adducts with pyridine

Compound	Chemical shift, δ mm/s	Quadrupole splitting, Δ mm/s
$[Fe(S_2C_2(CN)_2)_2.py]^-$*	0.59	2.41
$[Fe(S_2C_2(CF_3)_2)_2.py]^-$*	0.59	2.61
$[Fe(S_2C_6Cl_4)_2.py]^-$*	0.59	3.02
$[Fe(S_2C_6H_3.CH_3)_2.py]^-$	0.62	3.10

McCleverty *et al.* (10) for similar series and is taken as being indicative of an increase in acceptor ability of the dithiolene ligand. One would have to argue that a synergic mechanism operates, to replace by stronger σ bonds, electron density that is removed by a π mechanism in order to explain the constant chemical shift. However in the $[S_2C_2(CF_3)_2]$ series discussed above and in many other complexes, notably the nitroprussides (ref. 8, p. 258), it is found that strong π back-donation lowers the chemical shift indicating that the electron density removed is not replaced by a synergic mechanism. Clearly we must look elsewhere for an explanation.

The constant values for the chemical shift in these complexes indicates that no marked changes in electronic environment are occurring at the iron nucleus. The variation in asymmetry must be looked for in subtle changes in molecular structure. Unfortunately the crystal structures of very few of these compounds have been reported. Rae (11) has reported the structure of the dianionic $Fe(NO)[S_2C_2(CN)_2]_2$ and Hamilton and Bernal (12) that of the dimeric $[(n\text{-}C_4H_9)_4N][FeS_2C_2(CN)_2]_2$ complex. Both complexes have iron atoms in five-coordinate square pyramidal situations; four sulfurs and one NO group in the former and five sulfurs in the latter case. The iron – basal sulfur distances are 2.26–2.29 and 2.20–2.28 Å, respectively. In the former case (11) the variation in Fe—S distances is barely outside the standard deviations but in the dimeric maleonitrile complex, the differences are significant and a field gradient at the ion would be expected from such a situation.

Of more interest are the displacements of the Fe above the basal plane of sulfurs. These are 0.51 and 0.36 Å, respectively. Such a significant difference would have a pronounced effect on the symmetry at the iron and on the disposition of the nonbonding sulfur lone pairs which would, in turn, influence the iron environment. This change in structure has also been noted in analogous cobalt systems (13). Gray and co-workers (13) summarize the structures of some square planar, four-coordinate, and square pyramidal, five-coordinate cobalt dithiolene complexes of varying overall charge. The height of the cobalt above the basal plane varies considerably in these complexes, while the Co—S distances remain virtually constant. Unfortunately, information on a series of iron–dithiolene complexes such as those listed in Table II is not available. Such a study appears to be essential for a complete understanding of the Mössbauer data.

Photochemical and thermal isomerizations of *cis*- and *trans*-cinnamic acids, and their photostationary state[1]

MARTIN B. HOCKING
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received May 13, 1969

cis-Cinnamic acid was prepared photochemically from the *trans* isomer according to a published method, but was isolated by vacuum distillation. The photostationary state of these acids has been determined for moderately concentrated solutions of each isomer exposed to unfiltered ultraviolet. The position of the *cis–trans* thermal equilibrium approached from all *cis*- and from all *trans*-isomers has been tested without solvent and found to lie at, or very close to, 100% *trans*. Kinetic examination of the rates of these isomerizations shows that they fit a kinetic expression of the form $-d[cis]/dt = k[cis][H^+]$.

Introduction

This investigation was initiated primarily to determine the proportion of *cis*-cinnamic acid formed by heating the *trans*-acid, and whether or not vacuum distillation could separate this mixture. Even though the *cis–trans* thermal equilibrium of the cinnamic acids lies well on the side of the *trans*-acid, because of the large boiling point difference (*trans*, 300 °C; *cis*, 265 °C), it was thought that an equilibrium mixture could possibly be separated by distillation.

The two isomeric cinnamic acids were required initially to establish the position of the thermal equilibrium by experiment, and to determine temperatures at which the rate of equilibration was sufficiently fast to be useful. *cis*-Cinnamic acid was prepared by a published photochemical method (1), which led to our determination of the photostationary state for cinnamic acid using unfiltered ultraviolet irradiation.

Photochemical isomerizations of cinnamic acids have received considerable attention. Sunlight has been used in a number of experiments (2–4) on *trans*-cinnamic acid with the predominant result being a cyclobutane-type dimerization to truxillic or truxinic acids; however, the formation of small amounts of the *cis* isomer was also observed (4). The early ultraviolet irradiation work of Stoermer (5, 6) of benzene solutions of *trans*-cinnamic acid yielded fair conversions to the *cis* (m.p. 68 °C). He found that irradiation of *cis*-cinnamic acid yielded a proportion of the two lower stability allotropes (m.p. 42 and 58 °C) of *cis*-cinnamic acid which he was unable to isolate (5).

Vaidya (1) used unfiltered ultraviolet irradiation in his more recent photochemical preparations of *cis*-cinnamic acid. Using a saturated methanolic solution of the *trans*-acid, yields of 25 to 30% of the m.p. 42 °C allotrope were isolated by trituration and fractional crystallization of the irradiated solution. Comparison of the photochemical results of ultraviolet irradiation with the results observed in sunlight has led to the empirical suggestion that the different products are solely due to the different relative intensities of short and long wavelength radiation (7). Most recently, Lindenfors (8, 9) has used ultraviolet irradiation to prepare ring substituted monochloro- and dichloro-*cis*-cinnamic acids from the corresponding *trans*-compounds using an ion exchange resin for isolation.

Thermal isomerizations of cinnamic acid or its derivatives have not been as frequently investigated as the photochemical transformations. Noyce and his co-workers (10) have carefully measured the rates of aqueous sulfuric acid catalyzed isomerizations of *cis*-cinnamic acid and conclude that the kinetics are first order in cinnamic acid. Neat thermal isomerizations have previously been reported only for the *cis*-methyl ester. Kistiakowsky and Smith (11) have determined the rate constants for the vapor phase isomerization of the *cis*-ester to the *trans* at several temperatures in the range 202 to 387 °C and conclude from the magnitude of these that the "... mechanism ... is essentially different from the mechanical rotation around the double bond. ..."

Results and Discussion

Preparation of cis-Cinnamic Acid

The procedure used to prepare *cis*-cinnamic acid was that reported by Vaidya (1), which

[1]Contribution No. 171.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

involved ultraviolet irradiation of a saturated methanolic solution of the *trans*-isomer and fractional crystallization of the solvent extracted *cis*-isomer. Analysis of the *cis*- and *trans*-cinnamic acid mixtures obtained during the preparations and isomerizations was by integration of the respective vinylic proton resonances in nuclear magnetic resonance (n.m.r.) spectra of the mixtures (details are given in Experimental). A complication in the irradiation step of our preparations was the formation of a significant proportion of ester, a finding noted by others (9, 12), at least in sunlight. Stoermer and Ladewig (13) claimed that ester formation occurred only if traces of strong mineral acid were present, and Lindenfors (9) suggested that even in its absence, the catalytic effect of the glass vessel would be sufficient to bring this about. The latter author also found very little effect on the rate or equilibrium of photolytic isomerizations with large changes in the solvent dielectric; however, the photolytic instability of acetonitrile (14) unfortunately made its use inappropriate. In our photostationary state experiments with cold methanol solutions, no esterification took place. Apart from the temperature and the somewhat more dilute solutions, the latter experiments were identical to the preparative ones and are an indication of one way in which ester formation may be avoided.

Isolation of *cis*-cinnamic acid formed on irradiation by trituration and crystallization was attempted several times but was found to be relatively ineffective. From a *cis*-acid content of 39% obtained in one irradiation experiment, a trituration and crystallization gave an improvement of only 14% in the *cis*-content of the crystals obtained. Because of the limited effectiveness of this technique, vacuum distillation of the *cis*-acid from irradiated material was tried. The success of vacuum distillation for isolation of the *cis*-cinnamic acid was measured in two ways. The first was the significant improvement of *cis* concentration found in the distillate, even without a packed column. This yielded initially a 37% improvement which, upon successive distillations, dropped to 14 and 9%. The total amount of *cis*-cinnamic acid remained constant, however, indicating that no isomerization occurred during distillation.

The m.p. 42 °C allotrope of *cis*-cinnamic acid is the predominant form usually isolated on simple recovery of the *trans*-isomer after ultraviolet irradiation (1, 5). Some of this allotrope may have crystallized from an initial fraction of the distillate, but the m.p. 58 °C allotrope was the main product. It is surprising, though, that this is so since the allotrope melting at 68 °C is the only one previously reported to have crystallized from a distillate (15). The m.p. 58 °C form was converted to the m.p. 68 °C form as confirmation of the identity of the former.

Photostationary State

A solution of *trans*-cinnamic acid in a quartz flask was irradiated with unfiltered ultraviolet to determine whether or not a higher equilibrium proportion of *cis*-isomer was obtainable in this way than by irradiation with only the longer wavelength ultraviolet used by Vaidya. The data of Lindenfors (9) have indicated a decreasing *cis*-isomer concentration at the photostationary state with increasing wavelength of the ultraviolet radiation.

Using 0.002 and 0.003 *M* solutions in water and 313 mμ irradiation Vaidya (1) obtained photostationary equilibria of 75 and 72% *cis*-isomer, respectively, approached from both all *cis*- and all *trans*-cinnamic acid. Lindenfors (9), using water-filtered ultraviolet on 0.00423 *M* solutions in benzene, ethanol, or formic acid obtained a photoequilibrium of 82% *cis*-isomer, approached from the all *trans*-isomer side only. Our result of 60% *cis*-isomer at photoequilibrium (Table VII) in unfiltered ultraviolet, for a 0.27 *M* solution in methanol approached from pure *trans*- and pure *cis*-isomer, is somewhat lower than the earlier figures. Vaidya's result, a higher concentration yielding lower *cis* concentration at photoequilibrium, has been noted for the photostationary states of other olefins (16). It therefore indicates a real trend in this system which may in part explain the lower [*cis*] equilibria in our experiments carried out at much higher concentrations. The variation in wavelengths, different solvents, and different spectral profiles for the lamps used are probably also important variables contributing to this difference. Use of an appropriate sensitizer might greatly enhance the *cis*-isomer proportion at equilibrium (17).

Thermal Isomerizations

Purified *trans*-cinnamic acid failed to yield any *cis*-isomer when heated at 257.5, 200, and 143.5 °C for extended periods of time. It is estimated that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

if 1% or more *cis*-isomer were present it would have been detected.

To determine whether or not the absence of the *cis*-isomer on heating of the *trans*-isomer was due to the position of the equilibrium or merely to inadequate conditions for attaining it, similar experiments at 182, 163.5, and 143.5 °C were conducted with *cis*-cinnamic acid. Less than 0.7% of *cis*-acid was present at thermal equilibrium in all of the runs but data from intermediate aliquots indicated that the *cis*-to-*trans* isomerization proceeded quite smoothly (see Experimental).

When the data were plotted as a first order reaction the plots showed a definite upward curvature. On second order coordinates a good straight line fit could be obtained for the data up to 70% isomerization, but beyond this the rates were faster than that predicted by the initial straight line. At this stage a number of mathematical tests of reaction order were applied in an objective attempt to differentiate between first and second order, but these too gave an *apparently* ambiguous conclusion (Table I). Also an attempt to obtain a computer fit of the data to first or second order coordinates, either to complete reaction (Table II) or through the region of reasonable visual fit to 70% isomerization, failed to sharply define the order. However, the manual plots, the tests of reaction order, and the evident bowing of the data in opposite senses for the computer-obtained best lines all suggested that an order intermediate between first and second was operative in these isomerizations.

On these bases it was assumed that a three-halves order expression [1], which upon integration yields eq. [2]

$$[1] \qquad \frac{-\mathrm{d}[cis]}{\mathrm{d}t} = k[cis]^{3/2}$$

$$[2] \qquad 2[cis]^{-1/2} = kt + C$$

might apply. When the cinnamic acid isomerization data were plotted on coordinates of $[cis]^{-1/2}$ vs. time, quite good straight lines at all three temperatures up to about 90% isomerization were obtained (Fig. 1). In fact, comparison of the fit, the intercepts, and the errors in the slopes by computer showed that the three-halves order plots generally fitted better to 90% conversion than the first or second order plots did to only 70% conversion. Table II gives the overall comparison on the basis of 90% isomerization and a comparison of the 50% isomerization slopes with those of 90%. For the three-halves order computer plot at 143.5 °C the % error in the slope is not so markedly improved over the plots with other orders, but in four other criteria, the fit, the extent to which the points show a definite trend from the line (bowing), the minimization of the deviation from the theoretical intercept, and in the smallest change in the slope when

plotted to differing extents of reaction, the improvement is well demonstrated at all temperatures (Table III). Therefore, the isomerization of neat *cis*-cinnamic acid at these temperatures is considered to proceed by three-halves order kinetics.

In order to rationalize the three-halves order in terms of a plausible reaction path, one can introduce a first-order dependence of the isomerization rate on the concentration of hydrogen ion in the system. From the expression for the dissociation of a weak acid, eq. [3], the hydrogen ion concentration is defined by eq. [4].

$$[3] \qquad K_{\text{diss.}} = \frac{[\text{H}^+][cis^-]}{[cis]}$$

$$[4] \qquad [\text{H}^+] = K_{\text{diss.}}{}^{1/2}\,[cis]^{1/2}$$

$$[5] \qquad \frac{-\text{d}[cis]}{\text{d}t} = k'[cis]\cdot[\text{H}^+]$$

Substitution of eq. [4] into eq. [5], the appropriate expression for a first-order dependence of the rate on concentration of both *cis*-acid and hydrogen ion, yields an expression [6]

$$[6] \qquad \frac{-\text{d}[cis]}{\text{d}t} = k'K_{\text{diss.}}{}^{1/2}[cis]^{3/2}$$

which is analogous to the experimentally determined expression [1] with $k = k'K_{\text{diss.}}{}^{1/2}$. The constant of integration in eq. [2] is, at time zero, $2\,[cis_0]^{-1/2}$ and, since $[cis_0]$ for 100% *cis*-cinnamic acid liquid is about 7.15 moles/l (21), C has a calculated value of 0.748 moles$^{-1/2}$ l$^{1/2}$. Because the three-halves order data of Table II are from plots of $[cis]^{-1/2}$ vs. t, the slopes and intercepts quoted represent $\frac{1}{2}k$ and $\frac{1}{2}C$, respectively. Thus, the rate constants for use with eq. [2] are $1.49 \pm 0.09 \times 10^{-6}$, $6.78 \pm 0.07 \times 10^{-6}$, and $2.74 \pm 0.04 \times 10^{-5}$ moles$^{-1/2}$ l$^{1/2}$ s^{-1} at 143.5, 163.5, and 182.0 °C, respectively, while the experimentally-determined values for C are 0.792, 0.748, and 0.750, in very good agreement with the calculated value.

All the preceding mathematical interpretation has been based, for simplicity of treatment and understanding, on the substitution of eq. [4] for $[\text{H}^+]$ in the rate expression. To be rigorously correct the gradually increasing contribution of hydrogen ion from the dissociation of *trans*-cinnamic acid must also be taken into account. By dividing the *trans*-isomer dissociation equation by that of the *cis*, eq. [3], and substituting the quantity $([cis_0] - [cis])$ for $[trans]$ in the resulting expression, with rearrangment we obtain the concentration equivalence eq. [7]

$$[7] \qquad [trans^-] = \frac{K_{\text{diss}.t}}{K_{\text{diss}.c}}\cdot[cis^-]\cdot\frac{[cis_0]-[cis]}{[cis]}$$

$$[8] \qquad [\text{H}^+] = [cis^-] + [trans^-]$$

Substitution of eq. [7] in eq. [8] and squaring gives us eq. [9]

$$[9] \qquad [\text{H}^+]^2 = K_{\text{diss}.t}\,[cis_0] + (K_{\text{diss}.c} - K_{\text{diss}.t})\,[cis]$$

which expresses the hydrogen ion concentration yielded by both *cis*- and *trans*-cinnamic acids in terms of only the *cis* concentration. Equation [9] can be verified by substituting the concentration equivalence $[cis_0] - [trans]$ for $[cis]$.

When the values obtained for the concentration of hydrogen ion using eq. [9] are compared with those obtained using the simple eq. [3], good correspondence is demonstrated to 50% isomerized (Table IV). Only when $[\text{H}^+]$ ap-

proaches zero does the discrepancy become serious. It should be pointed out that the approximation of $[H^+]$ by using expression [3] lies only in interpretation and explanation of the three-halves order kinetics which, if $[H^+]$ of eq. [9] were used, would still give terms in $[cis]^{3/2}$. The latter course yields a very much more complicated rate expression since $[H^+]$ of eq. [9] is solved by a power series. Subsequent integration of this can be accomplished but the result makes plotting or mechanistic interpretation next to impossible.

An Arrhenius plot of the rate constants derived from the slopes of the three-halves order plots (Fig. 2) yields an activation energy of 28.5 ± 0.7 kcal/mole (one standard deviation) with a preexponential factor of 1.3×10^9 $mole^{-1/2}\, l^{1/2}\, s^{-1}$. This compares with a value of 24.0 ± 1.0 kcal/mole derived by Noyce *et al.* (10).

Noyce and co-workers (10) found 50% sulfuric acid catalyzed isomerizations of *cis*-cinnamic acid at 70 °C to be first order in cinnamic acid, with a rate constant of 4.13×10^{-5} s^{-1}. In their study, the high concentration of hydrogen ion evidently removed the dependence of the rate of isomerization upon its concentration, making the latter system essentially pseudo-first order. However, they have found also a first order dependence of the rate constant k (eq. [10])

$$[10] \quad \frac{-d[cis]}{dt} = k \cdot [cis] = k' \cdot [a_{H^+}] \cdot [cis]$$

upon the activity of the hydrogen ion and from their data, one can obtain a value of 1.91×10^{-8} $mole^{-1}\, l\, s^{-1}$ for the concentration independent rate constant k' at 70 °C.

An extrapolation of the Arrhenius equation for neat *cis*-cinnamic acid isomerization permits a comparison of the rate constant at 70 °C with that of strong acid catalyzed isomerization by Noyce *et al.* The rate constant obtained, 7.85×10^{-10} $mole^{-1/2} l^{1/2} s^{-1}$, when divided by $(K_{diss.})^{1/2}$ for *cis*-cinnamic acid[2] becomes 6.65×10^{-8} $mole^{-1}\, l\, s^{-1}$. Although our experimental conditions for the kinetic investigations are quite different from those of Noyce *et al.*, the fact that the rate constants are of the same order of magnitude is an indication that the same mechanism is operative in the two systems.

[2] $K_{diss.}^{25°} = 1.4 \times 10^{-4}$ for *cis*-cinnamic acid in an aqueous system. It may be significantly different for non-aqueous acid at 70 °C.

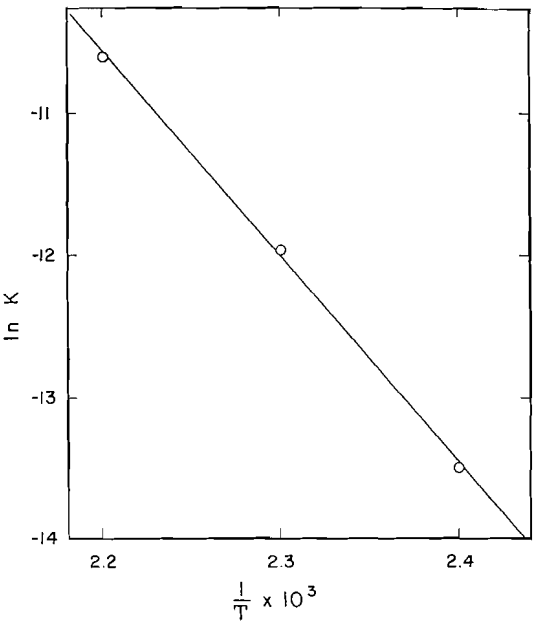

FIG. 2. Arrhenius plot of *cis*-cinnamic acid thermal isomerizations.

Thermal isomerization of methyl *cis*-cinnamate in the vapor phase was reported by Kistiakowsky and Smith (11) to proceed with a specific rate of 3.44×10^{-6} s^{-1} at 292 °C, relatively much slower than our neat free acid isomerizations. Hence, the credibility of our data when compared with a system which would be expected to show less facile isomerization is high.

The dependence of the rate of the thermal isomerization of the neat acid upon hydrogen ion activity can be rationalized by assuming that isomerization is preceded by a rate-determining protonation of the double bond, **1**, or of the carbonyl group, **2**, of *cis*-cinnamic acid followed by single bond rotation to the conformer required to yield *trans*-cinnamic acid prior to proton elimination.

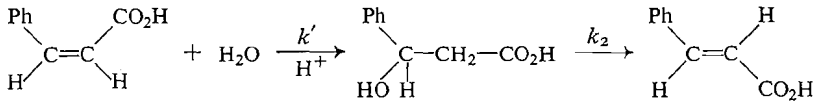
3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Since *cis*-cinnamic acid is four times more highly dissociated than the *trans* acid, 1.4×10^{-4} vs. 3.5×10^{-5} for $K_{diss.}$, respectively (15), the *cis*-acid is not only the initial source of hydrogen ions but continues to be the predominant source to more than 70% isomerization (see Table IV). This may be, in part, the explanation for the long term validity of the substitution $[H^+] = K_{diss.}[cis]^{-1/2}$.

The likelihood of β-lactone intermediacy in this isomerization is low because an α,β-unsaturated acid cannot be made to form a β-lactone (22), and S_N2 displacement by an available nucleophile has been shown (23) to be the mode of opening. In this case the only available nucleophile, cinnamate anion, would yield intermolecular esters, which are not observed. Even if transitory β-lactone intermediacy was a fact, since it is fixed in conformation, the substituents cannot epimerize. Intermolecular ester formation, **3**, from intermediates **1** or **2**, even though there is established precedence (24), is probably not occurring here because no ester is observed.

Noyce and co-workers (10) concluded as a result of their kinetic studies that the intermediate **4**, formed by the addition of



4

water across the double bond, was involved in the isomerization. In the present system involvement of this intermediate can be ruled out. The much lower rates observed in the neat than in the aqueous system must be attributable either to the involvement of a different intermediate (i.e. **1** or **2**) or to the very significantly lower hydrogen ion concentrations in the neat isomerizations, or to both factors.

Experimental

trans-Cinnamic acid used was reagent grade material supplied by Eastman Kodak, unless otherwise stated. Melting points and boiling points were not corrected. Infrared (i.r.) spectra were obtained on a Perkin–Elmer model 337 spectrometer. Nuclear magnetic resonance (n.m.r.) spectra were obtained at room temperature in deuteriochloroform on a Varian A60 instrument, the sweep width of which was routinely calibrated, except where otherwise indicated. Shifts are reported in p.p.m. from internal tetramethylsilane and coupling constants in c.p.s. Ultraviolet irradiations were performed using an unfiltered Hanovia 325 W high pressure quartz mercury arc lamp (model 65A-10 4¼ in. arc length) no more than 2–3 in. from the irradiated vessel. The apparatus for the irradiation experiments was wrapped with aluminum foil leaving a 6 in. opening top and bottom. To the top opening a 6 in. air exhaust hose was fitted which partially cooled and vented the whole apparatus.

Preparation of cis-Cinnamic Acid

(a) Without Water Cooling, Work-up by Successive Solvent Trituration or Crystallization

A solution of *trans*-cinnamic acid (100 g) in warm dry methanol (480 ml) was placed in a quartz flask fitted with a water condenser and drying tube ($CaSO_4$) and irradiated at the boiling point for 100 h. The residual oily crystals remaining on removal of the solvent consisted of 49% *trans*- and 39% *cis*-acids, with 7% *trans*- and 5% *cis*-methyl esters (determined by n.m.r.). Isomerization was achieved without esterification in photostationary state experiment (see below). Trituration of this residue with cold petroleum ether (p.e., 3 × 80 ml) and evaporation of the solvent yielded a yellow oil (11.7 g), which comprised most of the total ester content, plus a small amount of the *cis*-acid (i.r. and n.m.r.). Trituration of the solid residue from above with hot p.e. (5 × 80 ml) yielded 13.5 g of crystals on evaporation of the solvent. Recrystallization of the latter from p.e. (150 ml) with a trace of ether yielded a first crop (3.0 g; 53% *cis*-acid) melting at 72–82 °C with prior sintering, and a second crop (1.0 g) melting at 45–75 °C.

In another preparative experiment, when 270 g of *trans*-cinnamic acid had been irradiated, the residue on solvent evaporation and ester removal by cold trituration was fractionally crystallized from ethanol (1500 ml). After four crops of crystals (last crop, 19 g, melting at 115–129 °C) the residue (70 g) consisted of 44% *cis*-acid (n.m.r.).

(b) Without Water Cooling, Effect of Pyrex vs. Quartz on Isomerization Rate

A solution of *trans*-cinnamic acid (380 g) dissolved in warm methanol (900 ml) was divided into three equal portions. One portion was irradiated in a new Pyrex flask, one in an internally frosted (etched) Vycor flask, and one in a new transparent fused quartz flask. Isomerization progress at roughly equal irradiation intensities was as follows: Pyrex, 2 days, 4% *cis*; 9 days, 21% *cis*; etched Vycor, 2 days, no *cis*; quartz, 4 days, 21% *cis*; 7 days, 35% *cis*.

(c) Fractional Distillation

After a preliminary small scale vacuum distillation was found to considerably enhance the proportion of *cis* in the distillate with very little loss of total *cis* content by thermal isomerization to the *trans*, this was the method by which isolation of the *cis*-isomer was carried out. In all the distillations described below, an unpacked,

vacuum-jacketed column (35 × 1 cm) was used, and the distilland was kept below 145 °C, usually in the range 130–140 °C to avoid significant *cis* isomerization. Details of three successive distillations of enriched *cis*-acid fractions are given in Table V.

From the last distillation, fraction 4 melted at 34–40 °C, and fraction 5 at 49–55 °C. A portion of fraction 5 was recrystallized from p.e. to a constant m.p. (3 times) of 58–60 °C. Melting points of 32, 42, 58, and 68 °C are quoted (25) for the four crystalline polymorphic forms of *cis*-cinnamic acid. Confirmation that the recrystallized material was 58 °C melting point acid and not the impure 68 °C melting point acid was obtained by conversion of a small finely ground sample of the 58 °C m.p. acid to the 68 °C m.p. one. The sample was sealed in a glass tube and cooled to −196 °C for 15 min, then allowed to warm to room temperature for 15 min before opening (26). The m.p. was now 64–66 °C. Attempts to use sunlight for conversion of the 58 °C m.p. to the 68 °C m.p. acid (27) in quartz for 12 days gave material which partly melted at 187 °C and the remainder at 232–233 °C, probably a mixture of truxinic and/or truxillic acids (28). In Pyrex, 12 days of sunlight yielded material melting partly at 66–72 °C, partly at 130–135 °C, and the remainder at 170–200 °C from the *cis*. This was probably a mixture of 68 °C m.p. *cis*- and *trans*-cinnamic acids, plus some β-truxinic acid (lit. m.p. for the latter two compounds are 135 and 206 °C, respectively (28)).

Nuclear Magnetic Resonance Spectra and Analysis of Cinnamic Acids and Esters

The coupling between the two vinylic protons of the cinnamic acids yielded a doublet for each (29) in both the *cis*- (J = 12.5 c.p.s.) and the *trans*-isomers (J = 16 c.p.s.), the coupling of either of which was not significantly changed on esterification (cf. ref. 29). The aromatic proton resonance gave a multiplet 26 cycles wide for the *trans* (centered at 7.45 p.p.m.) and two groups of multiplets over a total of 33.5 cycles for the *cis* (centered at 7.47 p.p.m.), again unchanged on esterification. The remaining shifts are tabulated below.

Analysis of acid mixtures was accomplished by integra-

Carboxyl or ester	11.80	3.60	—	3.73

tion of the *cis*- and *trans*-vinylic proton resonances and calculation of the proportions of each present from these integrals. In acid–ester mixtures, integrals were obtained for the *cis*- and *trans*-ester methyl resonances. Where more than 2 or 3% of one or both esters were present with the acids, the figure obtained for a one proton equivalence from the methyl integrals was subtracted from the respective vinylic integrals, a procedure necessary because, though the ester vinylic protons gave visibly distinct bands from the acid vinylic protons, they were not sufficiently so for accurate separate integration on a 500 cycles sweep width. No account was taken of the higher molecular weight of the esters in the calculation of percentages from the integrals; hence the percentages in the acid–ester mixtures represent mole %. At no time was there any sign of the formation of truxinic or truxillic acids in the solution ultraviolet or thermal isomerizations.

Photostationary State of the Cinnamic Acids

A solution of *cis*-cinnamic acid (2 g) in dry methanol (50 ml) was placed in a fused quartz test tube fitted with a water-cooled Pyrex cold finger reaching to the bottom of the solution, a short thermometer, and a drying tube ($CaSO_4$). An identical parallel experiment was set up using 2 g of *trans*-cinnamic acid. The two tubes were irradiated equidistant from the ultraviolet source for 3 days and aliquots were withdrawn, concentrated by boiling off some of the methanol, and analyzed by n.m.r. for the proportions of *cis* and *trans* present. The solution temperature was kept at 14 °C during the whole period of irradiation. No esters were formed during these experiments (see refs. 7 and 9). Progress of the isomerization is shown in Table VII.

TABLE VII

72	60.2	59.0

Thermal Isomerizations of the Cinnamic Acids

(a) trans-Cinnamic Acid

The commercial material (50 g) was wastefully recrystallized from ethanol (100 ml) and dried at 80 °C for 24 h, yielding colorless cinnamic acid (26 g), m.p. 134–136 °C. Portions of this recrystallized material (6 g) were placed in three stoppered test tubes, which were then heated in the vapor–liquid equilibrium of boiling flasks of diphenyl (257.5 °C), diethyl malonate (200.0 °C), and amyl acetate (143.5 °C). Aliquots were then removed from each of these tubes at intervals during a total time of 49 h for the 257.5 °C bath and 336 h for both the 200 °C and the 143.5 °C baths, and examined for the presence of *cis*-cinnamic acid by n.m.r. There was none present in any aliquot.

An aliquot from the *trans*-acid heated at 257.5 °C for 7½ h still crystallized (yellow crystals) but an aliquot after 23 h cooled to a brown glass without crystallizing. At 200 and 143.5 °C, even after 336 h heating, the aliquots of *trans*-acid still crystallized, though the crystals were brown.

(b) cis-Cinnamic Acid

In a way similar to the isomerization experiments of the *trans* species above, three approximately 1 g portions of *cis*-cinnamic acid were isomerized. One was carried out at 143.5 °C, as previously with the *trans*, and the others in the liquid–vapor equilibria of boiling cyclohexanol (163.5 °C) and ortho-dichlorobenzene (182.0 °C), temperatures being measured before and after a run with the same calibrated thermometer. With aliquots from the 163.5 °C run containing less than 10% of either isomer, analysis was sharpened by use of a computer of average transients attachment on the n.m.r. and using from 20 to 50 scans of the area of interest, before integrating. The last two aliquots of the 163.5 °C run were determined on a Varian HA 100 instrument and are estimated to be reliable to ± 0.1% *cis*-acid. The progress of these isomerizations is summarized in Table VIII. There was no evidence of any dimerization.

In calculations and plots of the above data it was found that the last point in each run deviated considerably from the norm set by the others, and in the 182 °C run had obviously been taken some time after complete isomerization. Consequently, these points and in addition the 75 and 98 h points for the 163.5 °C run which also showed significant deviation (possibly because of some sublimation of *cis*-acid from the small amount remaining at this extent of reaction) were omitted for the kinetic calculations. Concentration calculations to convert the above data into moles/l were made using 7.15 moles/l as the concentration of neat liquid *cis*-cinnamic acid at 133 °C, having allowed for the slightly higher density of *cis*-cinnamic acid. The concentration of liquid *trans*-cinnamic acid at 133 °C, calculated from a density measurement of Weger (21) is 7.13 moles/l, but for

Infrared spectra of aqueous sodium benzoates and salicylates in the carboxyl-stretching region: chelation in aqueous sodium salicylates

G. E. DUNN AND R. S. MCDONALD
Department of Chemistry, the University of Manitoba, Winnipeg 19, Manitoba
Received June 9, 1969

Infrared spectra in the frequency region 1300–1760 cm^{-1} are reported for 41 substituted sodium benzoates and 10 substituted sodium salicylates in deuterium oxide solution, and for 9 substituted salicylic acids in chloroform and carbon tetrachloride solutions. Carboxylate stretching frequencies of benzoates and salicylates correlate poorly with substituent constants, but the asymmetric frequencies of benzoates and salicylates correlate well with each other, and the asymmetric frequencies of benzoates correlate well with the asymmetric frequencies of the corresponding nitrobenzenes. It is suggested that, among substituted aromatic compounds, group vibrations which couple with the ring vibrations may correlate well with similar vibrations of other groups, but not with coupled vibrations of different symmetry, uncoupled vibrations, or substituent constants. Chelation in chloroform solutions of salicylic acid dimers can be detected by its influence on substituent effects, but infrared spectra provide no good evidence for chelation in aqueous sodium salicylates.

There are a number of interesting problems concerning the ionization of benzoic acids which can be attacked by means of infrared spectrophotometry. Well-known examples are provided by the numerous correlations which have been made between the infrared absorptions corresponding to O—H and C=O stretching vibrations of carboxylic acids and interactions of the carboxyl group with other functional groups in the same molecule (substituent effects and chelation), in identical molecules (dimerization), or in different molecules (solvation and ionization).

Since molecular vibration frequencies are governed by atomic masses and the shape of the potential energy well in which they find themselves, it is to be expected that the carboxyl O—H and C=O stretching frequencies will be altered when these atoms form hydrogen bonds to other groups. Thus, it is not surprising to find that the O—H frequency decreases by about 500 cm^{-1} when benzoic acid in carbon tetrachloride dimerizes, or by about 200 cm^{-1} when it chelates with an *o*-methoxy group. Similarly, the C=O frequency decreases by about 50 cm^{-1} on dimerization, or chelation with an *o*-hydroxy group (1).

Also, it is to be expected that benzoic acid substituents too remote from the carboxyl group to chelate with it may alter the carboxyl frequencies by changing the electron densities in the bonds through inductive and resonance effects. Not only are such frequency changes observed, but both the O—H and C=O stretching frequencies of benzoic acids in carbon tetrachloride have been shown to be linearly related to the Hammett σ-constants, and therefore to the pK's of the acids in water (1–7). This is somewhat surprising, since ionization constants reflect substituent effects on the free-energy difference between the acid and its anion, both solvated by water. It might be reasonable to guess that the electronic displacements produced by a meta or para substituent on the solvated benzoic acid molecule could have parallel effects on the carboxyl stretching frequencies and the free energy of the acid. Then, if substituents were to have no effect, or a parallel but quantitatively different effect, on the free energy of the anion, ionization constants and carboxyl frequencies of the solvated acids would be linearly related. This leads to the expectation that, if solvent effects are small, constant, or proportional to frequency, the carboxyl frequencies of benzoate ions should be constant or linearly related to pK. Until very recently there has been no data to test this hypothesis.

A related problem is that of the abnormally large dissociation constant of salicylic acid in water. This is commonly attributed to stabilization of the monoanion by an intramolecular hydrogen bond (chelation) between the carboxylate oxygen and the ortho phenolic group. The infrared spectrum of salicylic acid in carbon tetrachloride and other nonpolar solvents shows the decrease in O—H and C=O frequencies expected for chelation (8–13), but this is hardly helpful. What is required is that chelation should

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

stabilize the anion more than the acid, and that this relationship should persist in aqueous solution where chelation will encounter severe competition from intermolecular hydrogen bonding with the solvent. It is perhaps not unreasonable that such should be the case, since the negative charge on the anionic oxygens should increase chelation, but this has never been adequately demonstrated by experiment.

Information pertinent to both of these problems might be obtained from the spectra of substituted benzoic acids and their salts in aqueous solution but when the present work was begun, no such data were available. In the interim, Lindberg has reported spectra of 21 substituted benzoates in aqueous solution (14). The scarcity of such data is no doubt due in part to the opacity of water to infrared radiation of the frequencies characteristic of carboxyl stretching vibrations. However, deuterium oxide is sufficiently transparent in the range 1700–1300 cm^{-1} to permit examination of substituent effects on carbon–oxygen stretching frequencies in aqueous solution, and the present work reports the absorption spectra of 41 benzoic and 10 salicylic acids in this region. Unfortunately, most of the acids are not sufficiently soluble in deuterium oxide to produce C=O absorptions which would penetrate the solvent absorption, so the investigation was confined to the much more soluble sodium salts. In a number of cases, it was necessary to use ^{18}O-enriched salts in order to identify the carbon–oxygen frequencies conclusively.

Experimental

Materials

All the benzoic acids were commercial products except *m*-methoxybenzoic acid. It was synthesized by methylation of *m*-hydroxybenzoic acid with dimethyl sulfate. The preparations of 4- and 5-methoxysalicylic acids have been previously described (15), as have those of 4- and 5-fluoro- and 4-bromosalicylic acids (16). The other salicylic acids were commercial products, as were nitrobenzene, *o*- and *p*-nitrophenol, sodium benzoate, and sodium salicylate. Sodium *p*-hydroxybenzoate was prepared by dissolving *p*-hydroxybenzoic acid in the theoretical amount of 0.4 *M* aqueous sodium hydroxide, evaporating the water, and drying the residue at 100° for 24 h.

Solvents

Carbon tetrachloride was purified by refluxing it with 5% aqueous sodium hydroxide for 3 h, washing with water, then with concentrated sulfuric acid 3 times or until colorless, again with water, and drying over first calcium chloride then magnesium sulfate. It was distilled, and distillate collected between 76.0 and 76.2°.

Chloroform was purified from its alcohol stabilizer by the method of Fieser (17) and stored in the dark over chromatographic alumina. Under these conditions, it will keep for a few weeks without developing any spurious absorptions in either the infrared or ultraviolet regions. Spectra of benzoic acids obtained in this solvent and in hydrocarbon-stabilized chloroform (Matheson, Coleman, and Bell) were identical, so that the latter solvent was used in much of the work.

Potassium bromide was International Crystal Laboratories Spectrograde, and heavy water was certified by the supplier (Merck, Sharpe, and Dohme of Canada) to be 99.7 mole % deuterium oxide.

^{18}O-Labelled Benzoates

Labelling of the carboxyl group with ^{18}O was accomplished by hydrolyzing the acid chlorides in water containing 42.1 atom % ^{18}O according to the supplier (Yeda Research and Development Co. Ltd., Rehovoth, Israel). The acid chlorides were prepared by refluxing the appropriate acids in a 10-fold excess of thionyl chloride and distilling off the thionyl chloride, then the substituted benzoyl chloride, under vacuum. About 20 μl or 20–30 mg (0.15 mmol) of the acid chloride was transferred to a small flask with standard taper joint which was immediately placed on a vacuum line, cooled in liquid nitrogen, and evacuated. Then about 1 g of ^{18}O-labelled water was distilled into the flask from an adjacent bulb on the vacuum line, the flask was closed off and heated in a boiling water bath for 0.5 to 16 h. The short time was used for salicylic acid to minimize decarboxylation; longer times were required for hydrolysis of some of the solid chlorides. The ^{18}O-water storage bulb was then frozen in liquid nitrogen and the labelled water was distilled back into it from the reaction flask. The flask was removed from the vacuum line and 1 ml of a 0.20 *M* solution of sodium hydroxide in D_2O was added to it. The resulting solution was used to record the spectrum.

The amino-, hydroxy-, and thiohydroxy-benzoic acids could not be converted to their chlorides by the above procedure, so they were not labelled. Salicylic acid was converted to its chloride by the method of Kahovec and Kohlrausch (18).

Spectra

All spectra were recorded by a Perkin–Elmer double-beam, grating spectrophotometer, Model 337, equipped with expanded scale readout attachment coupled to a Brown recording potentiometer. The instrument was used at its smallest slit width, scanning at 39 cm^{-1}/min and recording at 40 s/in. Since both frequency and chart speed are linear with respect to time, this produced a recorder trace of about 26 cm^{-1}/in. For spectra of D_2O solutions, the indene peaks at 1797.7 and 1288.0 cm^{-1} were used to calibrate the scale for each sample by beginning a scan with indene in a 0.1 mm cell, recording from 1850 to 1700 cm^{-1}, then replacing indene by sample, recording to 1300 cm^{-1}, restoring the indene and recording to 1250 cm^{-1}, all without stopping the scan. Frequencies calculated by interpolation were reproducible to 0.3 cm^{-1} and should be accurate to $\pm$ 1 cm^{-1}. They are reported to the nearest cm^{-1}. Spectra in carbon tetrachloride and chloroform were calibrated by the same procedure using the polystyrene peaks at 1844.0 and 1601.2 cm^{-1}. These are not as sharp as the indene peaks, so the reproducibility of frequency is reduced to about 0.5 cm^{-1}.

Samples of benzoates and salicylates in deuterium oxide were prepared by making 0.15 *M* solutions of the acids in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

a 0.20 *M* solution of sodium hydroxide in deuterium oxide. The dianions of the hydroxybenzoates were obtained by the same procedure, using 1.0 *M* sodium hydroxide solution. Samples were scanned in 0.05 mm cells with calcium fluoride windows. Frequencies at the absorption peaks were the same with either deuterium oxide or air in the reference beam. Spectra of the substituted salicylic acids were recorded at concentrations such that the monomer and dimer absorptions were about equally intense. This was found to require concentrations of about 1.5×10^{-3} *M* in carbon tetrachloride or 2.5×10^{-3} *M* in chloroform. These solutions were scanned in a 5 mm cell with sodium chloride windows.

Results

Figure 1 shows the spectrum of sodium benzoate in deuterium oxide through the region 1350–1650 cm^{-1}. The upper solid line shows sodium benzoate and the dotted line shows ^{18}O-labelled sodium benzoate, both run against air. Since the carboxyl oxygens are only about 40% labelled, the spectra of labelled and unlabelled acids are not resolved, but the peaks at 1548 and 1390 cm^{-1} are seen to be broadened on the low-frequency side, showing that these are absorptions by the carbon–oxygen bonds. The lower solid line was obtained by scanning a 0.15 *M* solution of the labelled benzoate against a 0.09 *M* solution of unlabelled benzoate in the reference beam, so that most of the absorption by solvent and unlabelled salt cancels out. The carbon–oxygen peaks have shifted to 1538 and 1380 cm^{-1}, respectively, a decrease in frequency of 10–11 cm^{-1}. While this may not be a satisfactory method of determining isotopic shifts,

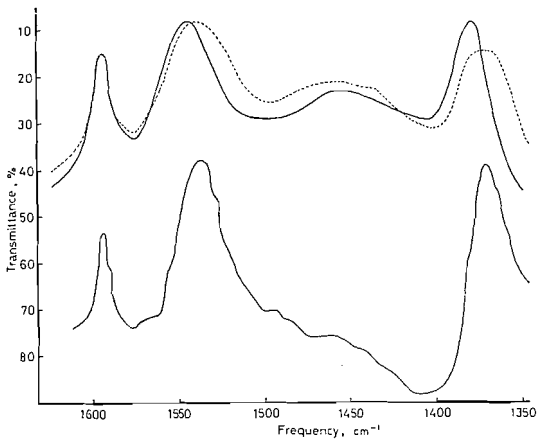

FIG. 1. Infrared spectra of sodium benzoate in deuterium oxide. Upper solid line, unlabelled salt; dashed line, salt containing 40% of ^{18}O; lower solid line, salt containing 40% ^{18}O vs. 60% of its concentration of unlabelled salt.

because the solution contains a mixture of benzoates containing zero, one, and two ^{18}O atoms, the peak broadening is quite adequate to ensure correct identification of the carbon–oxygen frequencies.

Edsall first assigned the carbon–oxygen stretching frequencies in the carboxylate ion (19). He studied the Raman spectra of a number of dicarboxylic acids and their salts and found a band near 1400 cm^{-1} in all the salts, which he assigned to the

$$[O\cdots\underset{|}{C}\cdots O]^-$$

symmetric stretching frequency by analogy with the corresponding 1380 cm^{-1} peak of the nitro group. Similarly, an infrared band near 1580 cm^{-1} was assigned to the asymmetric stretching frequency. Gore, Barnes, and Petersen found corresponding peaks at 1410 and 1560 cm^{-1} in the infrared spectra of sodium acetate in deuterium oxide solution (20), and Erlich found peaks at 1412 and 1550 cm^{-1} for sodium polymethacrylate in the same solvent (21).

The symmetric and asymmetric peaks for sodium benzoate were found in thin films at 1411 and 1554 cm^{-1} by Davies and Jones (22), in potassium bromide pellets at 1413 and 1554 cm^{-1} by Stimson (23), and in Nujol mulls at 1413 and 1552 cm^{-1} by Green, Kynaston, and Lindsey (24). The last-named authors found these bands at 1392 and 1544 cm^{-1} in the Raman spectrum of aqueous sodium benzoate. Chapman, Lloyd, and Prince found the symmetric and asymmetric infrared absorptions of aqueous sodium benzoate at 1395 and 1553 cm^{-1}, respectively (25). Subsequently, in a study of sodium benzoate in deuterium oxide, Hoshino, Hosoya, and Nagakura found infrared absorptions at 1599 and 1550 cm^{-1} and assigned the one at 1599 cm^{-1} to the asymmetric carboxylate vibration (26). Figure 1 shows that this assignment is incorrect; the 1599 cm^{-1} peak (we find it at 1595 cm^{-1}) is not produced by a carbon–oxygen bond since it is not affected by ^{18}O labelling. On the basis of the earlier assignments, we attribute the carboxylate peaks at 1391 and 1548 cm^{-1} in Fig. 1 to the symmetric and asymmetric

$$[O\cdots\underset{|}{C}\cdots O]^-$$

stretching frequencies, respectively.

Carbon–oxygen stretching absorptions were found at similar frequencies in the spectra of all

*Frequencies identified by ^{18}O labelling.
†Identification of the carboxylate frequency is uncertain.
‡There is only one intense, unsymmetrical peak in the 1500–1600 cm^{-1} region. In the *o*-Cl and *o*-NO_2 cases ^{18}O labelling produces a shoulder at ~1570 cm^{-1}, which suggests that the aromatic and asymmetric carboxylate frequencies are not resolved.

the substituted benzoates; 1377–1406 cm^{-1} for symmetric and 1533–1566 cm^{-1} for asymmetric vibrations. They are recorded in Table I. In 14 cases, the carbon–oxygen stretching bands were identified by ^{18}O labelling. These are indicated by asterisks in Table I. In most cases, the remaining spectra resembled the spectrum of one of the labelled acids with a chemically similar substituent so closely that the peaks could be identified without labelling.

Lindberg has reported frequencies for 16 of the benzoates in Table I (14). For a few substituents (H, *p*-NH_2, *p*-OMe), these agree closely with our values, but in most cases Lindberg's frequencies for both carboxylate and non-carboxylate vibrations are 3–5 cm^{-1} less than ours. The out-

standing exception is the salicylate ion, for which Lindberg's frequencies are all 6–9 cm^{-1} greater than ours. This is unfortunate, since it tends to confuse deductions concerning chelation in salicylates. However, our salicylate values can not be the result of an error arising from a bad sample or a single bad measurement, since 10 substituted salicylates from a wide variety of sources were examined and the frequencies for sodium salicylate are in excellent agreement with the others. For example, the asymmetric frequency for salicylate is precisely that predicted by the Hammett relationship from the substituted salicylates. It will, therefore, be assumed for the purposes of this paper that the frequencies reported here are at least internally consistent.

The peak at 1595 cm^{-1} in Fig. 1 is no doubt the same as the one found by Hoshino, Hosoya, and Nagakura at 1599 cm^{-1} and by Chapman, Lloyd, and Prince at 1602 cm^{-1}. The latter authors attribute it to a carbon–carbon stretching vibration (25). Such bands have been observed by many workers in a great variety of aromatic compounds, and their intensities are very sensitive to the nature of substituents on the aromatic nucleus. All the benzoates, salicylates, and salicylic acids examined in this work have from one to three bands in the 1575–1620 cm^{-1} region which we have listed in the tables under the heading "aromatic" without any other justification than that they are not carboxylate or nitro absorptions. Their intensities are highly variable, being weakest in the *m*-substituted acids and strongest in the *o*-substituted ones. The *o*-chloro-, *o*-bromo-, *o*-iodo-, and *o*-nitro-benzoates show only one very intense peak, with small low-frequency shoulders in the region 1500–1600 cm^{-1}, which is very probably a superposition or combination of aromatic and asymmetric carboxylate absorptions, since it is broadened by ^{18}O labelling. We could find no correlation of these aromatic frequencies with substituent or ionization constants. Most benzoates had peaks between the symmetric and asymmetric ones. These are not important for the purpose of this work and are listed for information only.

The spectrum of sodium salicylate is of particular interest in connection with the expected intramolecular hydrogen bonding of the salicylate ion. Green, Kynaston, and Lindsey found the asymmetric stretching frequency of sodium salicylate in Nujol mull at 1582 cm^{-1} but were not able to

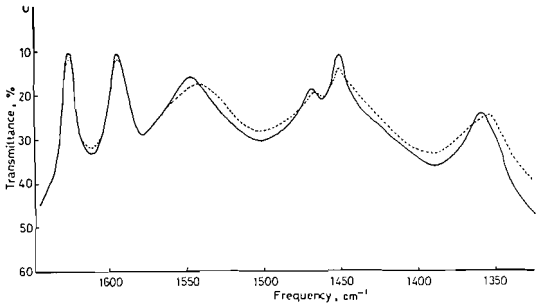

FIG. 2. Infrared spectra of sodium salicylate in deuterium oxide. Solid line, unlabelled salt; dashed line, salt containing 40% of ^{18}O.

decide between peaks at 1407 and 1376 cm^{-1} for the symmetric stretching frequency (24). Chapman, Lloyd, and Prince examined sodium salicylate in deuterium oxide and found peaks at 1621, 1593, and 1377 cm^{-1} (25). They assigned the 1377 and 1621 cm^{-1} peaks to the symmetric and asymmetric carboxylate stretching frequencies, respectively, and the one at 1593 cm^{-1} to an aromatic stretch. Our spectra of deuterium oxide solutions of sodium salicylate unlabelled and labelled with ^{18}O are shown in Fig. 2. It is seen that the carbon–oxygen stretching frequencies are at 1376 and 1546 cm^{-1}, and we assign these to the symmetric and asymmetric frequencies, respectively. The broad peak at 1546 cm^{-1} is not mentioned by Chapman, Lloyd, and Prince, but it is in the region where all the other substituted benzoates have asymmetric carboxylate absorptions, and ^{18}O-substitution produces a distinct broadening on its low-frequency side, whereas the peaks at 1617 and 1589 cm^{-1} are not affected at all. These are probably both aromatic stretching frequencies. Spectra of the substituted salicylates resembled that of the parent compound sufficiently to make assignment of the carboxylate stretching frequencies possible without labelling. They are recorded in Table II.

The spectra of most of the salicylic acids from which the above salicylates were derived have not been reported previously, so they were recorded in carbon tetrachloride and chloroform. The latter solvent was used because the nitrosalicylic acids were not sufficiently soluble in carbon tetrachloride to produce satisfactory spectra. The results are reported in Table III. Edsall first assigned the aliphatic carboxylic acid peaks near 1720 and 1670 cm^{-1} in nonpolar solvents to the C=O stretching frequencies of the

monomeric and dimeric forms of the acid, respectively (27), and this assignment has been amply confirmed by other workers. Brooks, Eglinton, and Morman found the monomeric and dimeric frequencies of a large series of benzoic acids in carbon tetrachloride in the regions 1737–1760 cm^{-1} and 1691–1715 cm^{-1}, respectively (6). They also studied a series of 21 alkyl- and aryl-substituted salicylic acids and found the monomer and dimer absorptions to be shifted to the regions 1668–1703 and 1640–1670 cm^{-1}, respectively (12). Our values of 1696, 1663 cm^{-1} for salicylic acid in carbon tetrachloride may be compared with 1698, 1663 cm^{-1} by Brooks and co-workers, or 1696, 1662 cm^{-1} by Josien and co-workers (7) for the same acid in the same solvent.

Discussion

Benzoates and Nitrobenzenes

Considered by itself, the carboxylate group consists of two carbon–oxygen bonds back-to-back on the same carbon atom. Consequently, the two carbon–oxygen vibrations of the same symmetry are strongly coupled and give rise to two widely separated vibration frequencies, the average of which represents the hypothetical uncoupled carbon–oxygen vibration. In these respects, the carboxylate group resembles the carbon dioxide molecule and, as in that molecule, the composite vibrations are commonly labelled "symmetric" and "antisymmetric". Strictly speaking, of course, these terms are not applicable to the carboxylate vibrations because the carboxylate group is not an isolated unit but is attached through its carbon to another molecular moiety. In the case of the benzoates, these terms are particularly inappropriate because the other moiety is the aromatic nucleus, which is composed of atoms having masses and bond strengths similar to those of the carboxylate group and vibrating in modes some of which have the same symmetry as the carboxylate vibrations. It is, therefore, to be expected that there will be some coupling between the carboxylate and aromatic ring vibrations.

How these multi-nuclear vibrations will be affected by substituents on the aromatic ring is difficult to predict. Empirically, many good correlations have been found between substituent constants and frequencies of vibrations, such as carbonyl, which are largely insulated from the aromatic ring by mass, bond strength, or symmetry considerations (8). On the other hand, no such correlations are known between substituent constants and aromatic ring vibrations. Hence, if it is assumed that carboxylate frequencies will have characteristics of both the carbonyl and aromatic ring vibrations, it may be too optimistic

to expect a good correlation between substituent constants and carboxylate frequencies.

Figure 3, where the symmetric and asymmetric frequencies, and the average of these, are plotted against Hammett's σ (28) for 24 *m*- and *p*-substituted benzoates, shows that the correlation is, in fact, not good. Although there is a tendency for frequency to increase with increasing σ in all 3 cases, the scatter is large. The correlation is better for the asymmetric frequencies (correlation coefficient, $r_{\nu_{as}\sigma_{mp}} = 0.80$; $\rho = 20.2 \pm 3.2$) than the symmetric ones ($r_{\nu_s\sigma_{mp}} < 0.01$, $\rho = 1.0 \pm 1.7$), but this is largely because the frequency spread is larger in the former case. In fact, the Hammett relationship predicts the symmetric frequencies with a standard error of $\pm 3\ cm^{-1}$ compared to $\pm 5\ cm^{-1}$ for the asymmetric ones, but the range of frequencies covered is only $9\ cm^{-1}$ for the symmetric as compared to $42\ cm^{-1}$ for the asymmetric frequencies. Averaging the symmetric and asymmetric frequencies produces no improvement ($r_{\nu_{ave}\sigma_{mp}} = 0.72$; $\rho = 9.8 \pm 2.0$), and the symmetric and asymmetric frequencies do not correlate with each other ($r_{\nu_s\nu_{as}} < 0.01$).

Lindberg, using 14 substituents of which 10 are the same as ours, also found the asymmetric frequencies to give a poor fit to the Hammett relationship, and the symmetric frequencies a worse one (14). Among the asymmetric frequencies, he observed a tendency for meta and para points to fall on separate lines. This tendency is not evident in our data. The scatter of the 8 meta points is particularly bad ($r_{\nu_{as}\sigma_m} = 0.56$) so that the fit is improved somewhat when they are omitted ($r_{\nu_{as}\sigma_p} = 0.84$; $\rho = 21.6 \pm 3.6$) but there is little evidence for a separate line. Lindberg also suggested that *p*-substituents having unshared electron pairs on the atom next to the aromatic ring (+M substituents) fall on a separate line from other *p*-substituents. This was a tentative proposal, because his substituents included only 2 without unshared pairs. Eight of our 16 *p*-substituents are not of the +M type and they show little evidence of forming a separate line ($r_{\nu_{as}\sigma_p} = 0.88$; $\rho = 27.4 \pm 5.5$).

If the poor fit of the benzoate frequencies to the Hammett relationship is the result of mixing of the carboxylate and aromatic ring vibrations as postulated above, the nitro group should show a similar behavior. Nitro and carboxylate groups have the same symmetry and very nearly the same force constants, mass, and size. The only major difference between the two groups is the charge on the carboxylate group.

Stretching frequencies of aromatic nitro groups have been examined by a number of workers. Brown plotted the frequencies of 5 *m*- and 5 *p*-substituted nitrobenzenes in chloroform against σ and found a fair correlation for asymmetric frequencies but a poor one for symmetric frequencies (29). Kross and Fassel used 15 *p*-substituted nitrobenzenes and found a better correlation of the asymmetric frequencies with σ^- than with σ (30). On the other hand, Yates and Thompson found a better correlation of the asymmetric frequencies of 11 *m*- and *p*-substituted nitrobenzenes with σ^+ than with σ (47). Katritzky and Simmons published an extensive list of aromatic nitro frequencies in chloroform (31), but did not attempt a correlation with substituent constants. Twenty-two of Katritzky's substituents are the same as ours, so it is possible to compare benzoate frequencies in aqueous solution with nitrobenzene frequencies in chloro-

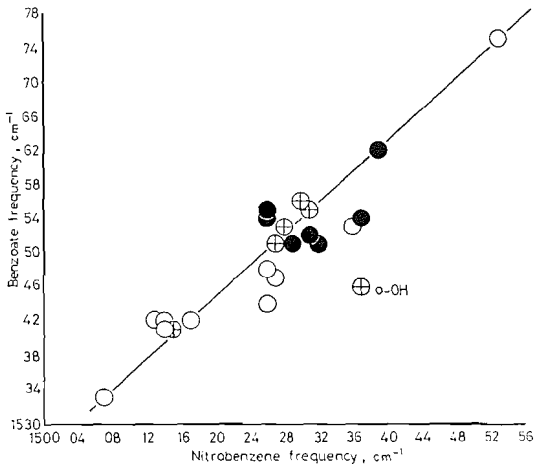

FIG. 4. Asymmetric frequencies of benzoates vs. those of nitrobenzenes. ○ are *p*-substituents; ● are *m*-substituents; ⊕ are *o*-substituents. Frequencies of *p*-substituted nitrobenzenes are from ref. 30; those of *o*- and *m*-substituted nitrobenzenes, from ref. 31.

form. The comparison has to be confined to asymmetric frequencies, however, because the range of symmetric frequencies is too small to permit reliable correlation.

Figure 4 shows a fairly good correlation between the asymmetric benzoate and nitro frequencies, not only for *m*- and *p*-substituents, but (excepting *o*-hydroxy) for *o*-substituents as well ($r_{\nu_{CO_2},\nu_{NO_2}} = 0.92$; $\nu_{CO_2} \pm 3 = 0.91\nu_{NO_2} + 162$). Excluding ortho, or ortho and meta, substituents have almost no effect on the correlation. It is apparent that substituent effects on the asymmetric vibration frequencies are similar for the aromatic carboxylate and nitro groups, but different from those on other vibrations more effectively insulated from the aromatic ring.

A possible reason for the different substituent effects on insulated and uninsulated vibrations might be that substituents exert their influence through different blends of polar and resonance effects in the two cases. This interpretation is encouraged by the observation of Kross and Fassel (30) and Yates and Thompson (47) that asymmetric nitro frequencies fit σ^- or σ^+ better than σ, and by Rao's successful use of combinations of σ, σ^-, and σ^+ in some correlations (8). A convenient method for testing this hypothesis has recently been provided by Swain and Lupton, who have separated the polar and resonance contributions to substituent effects in the form of field and resonance parameters, $\mathcal{F}$ and $\mathcal{R}$ (32). These can be recombined in any proportion appropriate to the system under investigation. Correlation with vibration frequencies take the form

$$\nu = f\mathcal{F} + r\mathcal{R} + \nu_0$$

which can be solved for f and r, the field and resonance weighting factors, and ν_0, the frequency of the unsubstituted parent compound.[1] Clearly, the blend of $\mathcal{F}$ and $\mathcal{R}$ will be different for *m*- and *p*-substituents so that these must be treated separately.

For *p*-substituted benzoates, the multiple correlation coefficient is $r_{\nu_{as}\mathcal{F}\mathcal{R}} = 0.83$ and the standard error in the calculated ν_{as} is 4 cm^{-1}. For *m*-substituted benzoates, the figures are $r_{\nu_{as}\mathcal{F}\mathcal{R}} = 0.46$, standard error in ν_{as} = 4 cm^{-1}. Comparison of these numbers with those given earlier for the correlation with σ ($r_{\nu_{as}\sigma_p} = 0.84$; $r_{\nu_{as}\sigma_m} = 0.56$) shows that the correlation with $\mathcal{F}$ and $\mathcal{R}$ is no better than that with σ. The same is true for Katritzky's nitrobenzene frequencies, whether for *p*-substituents ($r_{\nu_{as}\mathcal{F}\mathcal{R}} = 0.86$; $r_{\nu_{as}\sigma_p} = 0.92$) or *m*-substituents ($r_{\nu_{as}\mathcal{F}\mathcal{R}} = 0.82$; $r_{\nu_{as}\sigma_m} = 0.81$). Evidently vibration frequencies in the functional groups of benzoates or nitrobenzenes do not correlate well with any blend of polar and resonance effects.[2]

Apparently there is a fundamental difference in substituent effects between insulated and uninsulated frequencies. The fact that it is the insulated frequencies which correlate well with substituent constants seems to suggest that substituent effects on equilibria and rates are also largely localized in the bonds undergoing reaction.

Salicylates and Salicylic Acids

When this investigation was begun, it was hoped that the correlation between carboxylate vibration frequencies and substituent constants might be good enough to permit detection of

[1]In order to apply Swain and Lupton's computer program (ref. 32, footnote 32) to infrared frequencies, it is necessary to convert it to double precision form, or else to replace ν by some function of frequency with the same number of digits and decimal places as $\mathcal{F}$ and $\mathcal{R}$; for example, $\nu \times 10^{-3} - 1$.

[2]For nitrobenzenes this conclusion is weakened by the correlations found with σ^- (30) and σ^+ (47). The discrepancy is due, in part, to the different choice and limited number of substituents used in each case, but mainly to disagreement among the various workers concerning the asymmetric nitro frequencies of *p*-nitrophenol and *p*-nitroanisole.

chelation between carboxylate and phenolic groups of salicylates in aqueous solution. However, as has been pointed out above, this did not prove to be the case. The correlations of salicylate frequencies with σ ($r_{\nu_{as}\sigma_{mp}} = 0.81$; $r_{\nu_{s}\sigma_{mp}} = 0.58$) are neither better nor worse than those of benzoates.

On the other hand, the correlation of asymmetric salicylate frequencies with asymmetric benzoate frequencies is considerably better ($r_{\nu_{as}\nu_{as}} = 0.92$), suggesting that the poor correlations of both salicylate and benzoate frequencies with substituent constants are caused by the same factors, most probably coupling of the carboxylate and ring frequencies.

The carbonyl frequencies of benzoic acids in carbon tetrachloride have been shown to give good correlations with σ; for the monomer, Rao *et al.* (8) report $r_{\nu_m\sigma_{mp}} = 0.96$, and for the dimer, $r_{\nu_d\sigma_{mp}} = 0.99$. The correlations for salicylic acids in chloroform are also good ($r_{\nu_m\sigma_{mp}} = 0.93$; $r_{\nu_d\sigma_{mp}} = 0.94$) but not quite as good as those for the benzoic acids. The possibility that the decrease in correlation coefficient is caused by chelation will be considered in the next section.

Chelation in Salicylic Acids and Salicylate Anions

It is a well known fact that salicylic acid is a much stronger acid than benzoic acid or its *m*- and *p*-hydroxy derivatives, and the increased acidity is commonly attributed to chelation between the *o*-phenolic group and the carboxyl oxygen. That such chelation exists in crystalline salicylic acid and in solutions of salicylic acid in nonpolar solvents is demonstrated by a wide variety of evidence based on data from X-ray crystallography, infrared and ultraviolet absorption spectroscopy, vapor pressures, and other physical properties (references quoted in refs. 16 and 33). The fact that the carbonyl vibration frequencies of the substituted salicylic acids in chloroform reported in Table III are almost uniformly 48 cm^{-1} less for the monomers and 35 cm^{-1} less for the dimers than the corresponding frequencies of benzoic acids (6) may be taken as additional evidence for chelation in the salicylic acids. Hydroxyl groups in the *m*- and *p*-positions of benzoic acid have no such effect on the carbonyl frequency (5, 34).

Chelation between the phenolic hydroxyl and the carbonyl groups of substituted salicylic acids should influence the correlation between carbonyl frequencies and substituent effects by providing a second path through which the substituent can influence the frequency; namely, through the chelate hydrogen bond. Jaffe (35) has proposed that such dual path substituent effects can be handled by an extension of the Hammett equation which, for vibration frequencies, would take the form

$$\nu = \rho_1\sigma + \rho_2\sigma^- + \nu_0$$

where $\rho_1\sigma$ refers to the carboxyl group and $\rho_2\sigma^-$ to the phenolic group. He suggests that this 2-parameter equation may be considered to give a better correlation than the usual 1-parameter Hammett equation if ρ_2 turns out to be significant at the 95% confidence level or better, when the correlation coefficient between σ referred to the carboxyl group and σ^- referred to the phenolic group is 0.9 or less for the substituents used. For our salicylic acid substituents $r_{\sigma\sigma^-} = 0.61$, so they are suitable for studying the contribution by $\rho_2\sigma^-$ to the vibration frequency. Application of the monomer data to the 2-parameter equation yields $\rho_1 = 25.7 \pm 4.1$ cm^{-1}; $\rho_2 = -4.3 \pm 3.1$ cm^{-1}. Obviously, substituent influence on the monomer vibration frequencies through the chelate pathway is small compared to that through the direct one. Student's *t*-test on ρ_2 and its standard deviation indicate that it is significant only at the 80% confidence level. For the dimer frequencies, transmission through chelation is more important: $\rho_1 = 26.4 \pm 2.5$ cm^{-1}; $\rho_2 = -7.9 \pm 3.0$ cm^{-1}. The *t*-test on ρ_2 indicates significance at greater than 97.5% confidence level.

Why dimerization should increase the importance of chelation on the substituent effect is not clear.[3] Table III shows that changing solvent from carbon tetrachloride to chloroform decreases the monomer frequency by 5–6 cm^{-1} for all the salicylic acids, whereas it increases the dimer frequency by 1–2 cm^{-1}. Similar, but larger (7–17 cm^{-1}) solvent shifts are found in benzoic acids and are attributed to intermolecular hydrogen bonding of monomer with chloroform (6). Possibly such intermolecular hydrogen bonding

[3]Evidence that a fit to the 2-parameter equation does have physical significance is found in the fact that when the equation is applied to the carbonyl frequencies of benzoic acids, either monomer or dimer (6), where no chelation is possible, ρ_2 never differs from zero at more than 50% confidence level.

in salicylic acid monomers reduces the importance of chelation.

Although chelation of salicylic acids in nonpolar solvents is generally accepted, there is less agreement about chelation in hydroxylic solvents where intermolecular hydrogen bonding with solvent may compete with chelation. From the abundant literature on the subject, one may quote examples of contradictory views by several recent workers. Among those favoring retention of the intramolecular hydrogen bond of salicylic acid in aqueous solution are Scheraga and co-workers, from the temperature dependence of pK (36), and Prince and co-workers, on the basis of infrared spectra (25). On the other hand, Puar and Grunwald concluded from the rates of proton exchange that chelation of salicylic acid in methanol solution is negligible (37).

Whatever the extent of chelation in aqueous solutions of salicylic acid, it is clear that in order to account for the great acidity of salicylic acid, chelation must be much stronger in aqueous salicylate monoanion. Here the evidence is very meager. Voroshin and Vlasov interpreted the ultraviolet spectra of salicylic acid and sodium salicylate in alcohol as showing that the acid "has a strong intramolecular hydrogen bonding which is retained even during salt formation" (38), but their data can be interpreted otherwise. Scheraga and co-workers concluded from the temperature dependence of pK that the intramolecular hydrogen bond is about equally strong in aqueous salicylic acid and sodium salicylate (36). Dunn and Kung could find no transmission by chelation of substituent effects on the ionization of salicylic acids in aqueous solution (33) although Dunn and Penner did find such transmission in benzene solution (16). This leaves the infrared data of Chapman, Lloyd, and Prince (25) as apparently the only substantial evidence (other than that from acidity) for intramolecular hydrogen bonding of salicylate monoanion in aqueous solution.

Chapman, Lloyd, and Prince based their interpretation on the observation that the asymmetric frequency of a strongly hydrogen-bonded carboxylate group is uniformly about 35 cm^{-1} higher than that of a non-hydrogen-bonded carboxylate group (39). They reported the asymmetric stretching frequency of sodium salicylate in deuterium oxide solution at 1621 cm^{-1} and, by comparing this with their asymmetric frequency for sodium benzoate, 1553 cm^{-1}, they concluded that aqueous sodium salicylate is strongly chelated. However, as has been pointed out above, the assignment of the 1621 cm^{-1} frequency to the asymmetric carboxylate vibration is incorrect. This is probably a ring-stretching frequency, and the asymmetric stretching frequency is found at 1546 cm^{-1}, at no great displacement from that of benzoate at 1548 cm^{-1}. The same is true of all the substituted salicylates shown in Table II; the asymmetric frequency of a salicylate is only a few cm^{-1} different from that of the corresponding benzoate.

Our own data do not provide any evidence for intramolecular hydrogen bonding of salicylate monoanion in water. Among the infrared data, the only systematic relationships we have are the correlation between the asymmetric stretching frequencies of salicylates and benzoates, and of benzoates and nitrobenzenes. The parallelism between salicylate and benzoate frequencies argues against chelation in salicylates, but the correlation is perhaps not good enough to permit a firm conclusion. In the benzoate–nitrobenzene correlation, the fact that ortho as well as meta and para substituents fit the linear relationship suggests that, as would be expected, steric as well as electronic substituent effects are similar for the carboxylate and nitro groups. In Fig. 4, however, the *o*-hydroxy point falls well outside the spread of the other points from the line. The salicylate frequency can not be seriously in error because, as was pointed out above, it is consistent with those of all the substituted salicylates in Table II. Apparently this one point is anomalous. The interesting question then is, which frequency is anomalous? Is the nitro frequency abnormally high or is the benzoate frequency abnormally low? If the anomaly is attributed to chelation, then it would appear to be *o*-nitrophenol which is anomalous, because it is generally believed that *o*-nitrophenol is chelated in nonpolar solvents (40–42) and that chelation increases the asymmetric frequency of the carboxylate group (39). It would follow, then, that the salicylate anion in aqueous solution is less chelated than is *o*-nitrophenol in chloroform.

Bellamy has suggested that symmetric nitro frequencies are more sensitive to ortho effects than are the asymmetric ones (43). Examination of the symmetric frequency values for *o*-substituted benzoates in Table I at first seems to

TABLE IV

Infrared frequencies of benzoates and nitrobenzenes in various media

				1502	1500
	Symmetric	1342	1345	1344	1341
o-Nitrophenol	Asymmetric	1535	1540	‡	1521
	Symmetric	1335	1332	~1339‡	1338

*Neat liquid.
†Two peaks are found in the asymmetric region; no assignment is attempted.
‡Not sufficiently soluble to give a measurable frequency.

suggest that the same may be true for benzoates. Most *o*-substituents increase the symmetric frequency, possibly by forcing the carboxylate group out of the plane of the ring, while *o*-hydroxy and *o*-amino substituents decrease the symmetric frequency, presumably by chelating with the carboxylate group. However, comparison of the frequencies of *o*-substituted anions with those of the corresponding *p*-substituted ones shows a parallel trend. In fact, if the O^- substituent (which will be abnormal because of strong coulomb effects in the dianion) is omitted, there is a surprisingly good correlation between the symmetric frequencies of *o*- and *p*-substituted benzoates, with the spread of ortho frequencies about three times that of the para. Consequently, the data could better be taken to indicate that ortho symmetric vibration frequencies are more sensitive to electronic effects than are the para, as is the case with many reaction rates (44). However, in view of the poor correlation of symmetric benzoate frequencies with either substituent constants or nitrobenzene frequencies, it seems unwise to base any conclusions about structure on this analysis.

Some additional data for comparison of *o*-nitrophenol and salicylate monoanion are presented in Table IV. There it is seen that in the solid state or in carbon tetrachloride solution, where chelation is believed to be strong (24, 42), a *p*-hydroxy substituent has only a small effect on the symmetric and asymmetric frequencies of both benzoate and nitrobenzene, but an *o*-hydroxy substituent produces a pronounced increase in the asymmetric frequency and decrease in the symmetric frequency of both groups. This behavior is believed to be characteristic of chelation in carboxylate ions (39). The effect is larger in the benzoates (30 cm^{-1}) than in the nitrobenzenes (13 cm^{-1}), consistent with the stronger chelation expected for the negatively charged carboxylate group. In deuterium hydroxide solution, however, the *o*-hydroxy group produces no such dramatic frequency changes. Since *o*-nitrophenol is generally believed to be unchelated in hydroxylic solvents (45, 46), the implication is that the same is true of sodium salicylate.

It may be concluded, then, that the infrared data of Fig. 4 and Table IV show that any intramolecular hydrogen bond of sodium salicylate in water is considerably weaker than that of *o*-nitrophenol in carbon tetrachloride or chloroform. Although the infrared data do not provide any positive evidence for chelation of salicylate monoanion in water, they are not convincing enough to exclude it entirely either. However, they do suggest that such chelation is surprisingly weak to produce the well known large effect on the ionization constant of the acid.

Nature of the coordination bond in metal complexes of substituted pyridine derivatives. IV. Skeletal vibration spectra and the substituent effect upon the coordination bond of the pyridine complex of zinc(II) ion

PATRICK T. T. WONG[1] AND D. G. BREWER
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received June 20, 1969

Far infrared spectra of the complexes $Zn(pyridine)_2X_2$, where X = Cl or Br, have been investigated in the region 350–20 cm^{-1}. Eight infrared-active skeletal modes of these complexes have been observed, and a tentative assignment of these absorption bands has been made. The previous investigation of the effect of substituents upon the coordination bond of the copper–pyridine complex has been extended to the zinc–pyridine complex in the present paper. It was found that the relative zinc–pyridine bond strength, affected by the substituents, is determined by both the relative σ-contribution and π-contribution to the bond, rather than mainly by the σ-contribution as in the system of copper complexes. The force constants associated with the zinc–pyridine coordination bond of a series of 4-substituted pyridine complexes have been calculated by a normal coordinate treatment described in previous papers in this series.

Canadian Journal of Chemistry, 47, 4589 (1969)

Introduction

The infrared spectra of zinc–halide complexes of pyridine in the low frequency region (700–200 cm^{-1}) have been studied recently (1, 2), and two of the infrared-active zinc–halide modes and one of the infrared-active zinc–pyridine modes have been observed. However, no infrared spectra of these complexes below 200 cm^{-1} have been reported thus far. The present work has been undertaken to extend the far infrared spectra of these complexes to 20 cm^{-1}, in order to establish all the infrared-active skeletal vibrations of the pyridine complexes of zinc chloride and zinc bromide.

The substituent effects upon the coordination bond strength, as well as the magnitude of the π-bonding contribution to this bond, in dichlorobis(pyridine)copper(II) have been previously reported (3, 4). It has been found that both the σ- and π-bonding contributions to the coordination bond are influenced considerably by the nature of the substituents on the fourth position of the pyridine ring. The magnitude of π-bonding in the metal–pyridine bond seems to depend more on the properties of the substituents than on those of the metal ions themselves. For instance, the π-bonding ability of zinc(II) ion is much lower than that of copper(II) ion (5); but, when these two metal ions coordinate with 4-substituted pyridines of electron attracting groups, almost the same amount of π-bonding exists in the coordination bond of the analogous complexes of these two metals (3). Since the relative magnitude of σ-bonding is much stronger than that of π-bonding in the copper(II) complexes of 4-substituted pyridines (5), the change in the π-bonding strength due to the substituents does not appreciably affect the relative magnitude of the total M—N (ligand) bond strength among these copper complexes. The relative metal–ligand bond strength of a series of 4-substituted pyridine complexes of copper(II) ion is therefore mainly determined by the relative σ-bonding ability of these substituted pyridines.

An attempt has been made to study the substituent effect upon both the σ- and π-contribution to the total metal–pyridine bond strength in the present work. A metal ion with both lower σ-bonding ability and lower π-bonding ability, (viz. zinc(II) ion) has been selected for this purpose. Moreover, the effect of the substituents upon the metal–halogen bond of the zinc–pyridine complex has also been examined.

In previous papers (4, 6), normal coordinate calculations have been made for a series of metal complexes of substituted pyridines with a simplified model in which only a 1:1 complex had been considered. In the present work, in addition to performing this same normal coordinate treatment for a series of zinc(II) complexes of substituted pyridines, a normal coordinate analysis,

taking the tetrahedral skeletal sites into account, has been made for zinc(II)–pyridine complex, and will be reported separately (17).

Experimental

The reagents and the preparation of the zinc complexes, ZnL_2Cl_2, where L = pyridine, 4-methylpyridine, 4-carbinylpyridine, 4-acetylpyridine, 4-pyridinecarboxamide, 4-carbomethoxypyridine, and 4-cyanopyridine, have been reported elsewhere (3). The method for the preparation of the pyridine complex of zinc bromide, $ZnPy_2Br_2$ (Py = pyridine), was similar to that for zinc chloride.

Anal. Calcd. for $ZnPy_2Br_2$: C, 34.83; H, 3.41; N, 6.77; Zn, 15.81. Found: C, 34.94; H, 3.51; N, 6.70; Zn, 16.00.

The infrared spectra of the complexes in the region of 4000–400 cm^{-1} were recorded on a Perkin–Elmer Model 521 spectrometer under conditions which have been described in a previous paper of this series (4).

The far infrared spectra in the 400 cm^{-1} – 20 cm^{-1} region were recorded on a Perkin–Elmer Model 301 spectrometer. The complexes were recorded as mulls in Nujol with low-density polyethylene windows. The spectra in Figs. 1 and 2 were replotted by means of an IBM 360 computer from the % transmittance scale measured by the instrument on a linear optical density scale, after subtracting the stray light and the background absorption.

Results and Discussion

I. The Skeletal Vibration Spectra of Pyridine–Zinc Complexes

The infrared spectra in the 400–20 cm^{-1} region of dichlorobis(pyridine)zinc(II) and dibromobis(pyridine)zinc(II) are shown in Figs. 1 and 2, respectively, and the maximum absorption frequencies are listed in Table I. It has been reported that the lowest internal fundamental frequency of the pyridine molecule is 374 cm^{-1} (7), and that this band is shifted toward higher frequency by coordination of pyridine with metal ions (4, 8). Therefore the absorption bands in Figs. 1 and 2 are obviously not due to the internal fundamentals of the pyridine molecule.

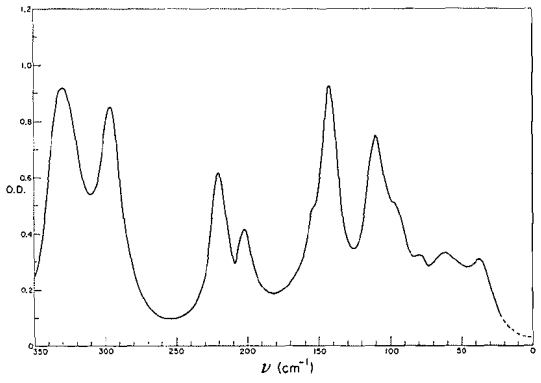

FIG. 1. Infrared spectra (350–20 cm^{-1}) of dichlorobis(pyridine)zinc(II) complex.

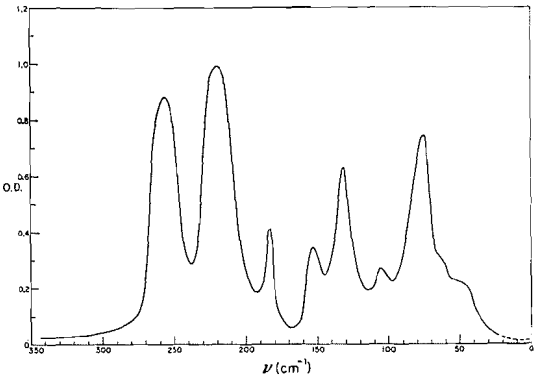

FIG. 2. Infrared spectra (350–20 cm^{-1}) of dibromobis(pyridine)zinc(II) complex.

TABLE I

*Masked by ν_2.

Porai-Koshits *et al.* (9) have studied the structure of this pyridine complex of zinc chloride and reported that the molecule has a tetrahedral configuration, with 2 pyridine molecules and 2 chlorine atoms at the 4 tetrahedral sites. A similar structure for the zinc bromide complex has also been reported (1). This skeletal structure of the complexes belongs to C_{2v} symmetry. Neglecting the perturbations of the other complex molecules in the unit cell, 8 normal vibrations ($4A_1 + 2B_1 + 2B_2$) are expected to be infrared-active, of which 5 normal modes ($2A_1 + 2B_1 + 1B_2$) are halogen-sensitive.

However, it is seen in the spectrum of the pyridine complex of zinc chloride that there are 7 halogen-sensitive bands (324.6, 292.4, 201.1, 142.4,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

109.6, 79.5, and 62.0 cm^{-1}), which shift to lower frequencies in the spectrum of the analogous complex of zinc bromide (255.8, 219.2, 183.1, 131.2, 76.8, 63.0, and 53.0 cm^{-1}, respectively). Apparently, some of these halogen-sensitive bands belong to lattice modes, which are expected in this frequency region, and are sensitive to the molecular mass of the complex molecules.

The two higher frequency bands (ν_1 and ν_2) are assigned to Zn—X stretching modes, since the frequency ratio of these bands in the zinc chloride complex relative to the zinc bromide complex is about 0.77. This has been used as a guide to the magnitude of the halogen dependence of the metal–halogen stretching frequencies for the tetrahedral metal chlorides and bromides with the first row transition metal ions (10). This also indicates that the coupling of the metal–halogen vibrations is insignificant, as has been observed by several authors (1, 2, 11).

Comparing the spectra in Figs. 1 and 2 with those of the complexes of zinc halides and other metal halides (12–14), the halogen-sensitive bands at 201.1, 109.6, and 79.5 cm^{-1} (zinc chloride) and 183.1, 76.8, and 63.0 cm^{-1} (zinc bromide) are assigned to X—M—X bending modes. In the spectra of a series of metal chloride complexes, a band at a similar position to the ν_9 mode in the pyridine – zinc chloride complex has been assigned to the Cl—M—Cl bending mode or to the lattice vibration (12). In the present work, the assignment of this band to the X—M—X bending mode is preferred, since, having regard for the ratio of the square root of the molecular masses of the complexes of zinc chloride and bromide, the frequency of this mode in the chloride complex shifts to too low a frequency in the spectrum of the bromide complex. The frequencies of this mode in both the pyridine complexes of zinc chloride and zinc bromide are even lower than those of the corresponding bands in the 4-methylpyridine complexes (15).

The ν_6 and ν_{10} modes are also halogen-sensitive and the frequencies of these two bands shift to lower frequencies in the sequence Cl > Br. However, it is different from the other halogen-sensitive bands in that the shift is related to the molecular mass of the complexes of zinc chloride and bromide. The frequency ratios (the chloride complex to the bromide complex) also are close to the inverse ratio of the square root of the molecular masses. The same relationship is also observed between these bands in the pyridine complexes and in those of the 4-methylpyridine complexes (15). Therefore, these bands are reasonably assigned to lattice modes.

It has been observed (1, 2, 16) that for a series of complexes MX_2–nL, where L is a pyridine derivative, the frequencies of the M—L modes are at approximately the same position for the analogous chloro-, bromo-, and iodo-complexes with a given central metal. For the tetrahedral dichlorobis(pyridine derivatives)metal complexes, the spectra are characterized by two strong M—Cl stretching bands and one medium M—L stretching band in the 400–200 cm^{-1} region. The spectra of the zinc–pyridine complexes have the same characteristics, and thus the ν_3 and ν_5 modes are assigned to the M—L stretching vibrations and ν_8 to the L—M—L bending mode, respectively. Although the ν_3 mode of the zinc bromide complex does not appear in the spectrum (since it probably overlaps with the strong Zn—Br stretching band), the assignment of the ν_3 band to M—L stretching agrees with those reported in the literature recently (1, 2) and is comparable with the assignment in the spectra of 4-methylpyridine complexes of zinc chloride and zinc bromide (15).

A weak band ($\sim$35 cm^{-1}) in the spectrum of the pyridine – zinc chloride complex is probably due to a lattice vibration and is not observed in the spectrum of the pyridine – zinc bromide complex.

II. Effect of Substituents upon the Coordination Bond

The infrared spectra in the region 350–150 cm^{-1} have been measured for a series of zinc complexes of the type $Zn(4\text{-R-pyridine})_2Cl_2$ (R = CH_3, CH_2OH, H, $COCH_3$, $CONH_2$, $COOCH_3$, and CN) and the maximum absorption frequencies are listed in Table II. The spectra of all these zinc complexes of 4-substituted pyridines have features similar to those of the zinc – pyridine complex, viz., they are characterized by two strong metal–chlorine stretching bands and two medium metal–nitrogen (ligand) stretching bands in this region. Therefore, it can be reasonably assumed that the substituents on the fourth position of the pyridine ring do not change the stereoconfiguration of the zinc complexes (1).

It is seen from Table II that the M—Cl stretching frequencies of the pyridine complex are affected considerably by the substituents on the

TABLE II

The metal–halogen and metal–pyridine stretching frequencies of the zinc complexes of substituted pyridines

Complex	Absorption bands (cm^{-1})			
	ν(M—Cl)	ν(M—Cl)	ν(M—N)	ν(M—N)

$Zn(4\text{-}CONH_2Py)_2Cl_2$	328.5	294.3	227.5	209.9
$Zn(4\text{-}COOCH_3Py)_2Cl_2$	329.0	298.2	229.9	203.6
$Zn(4\text{-}CNPy)_2Cl_2$	337.3	299.2	214.8	176.3

fourth position of the pyridine ring. On the whole, analogous to the case of the copper(II) complexes (4), the zinc–chlorine stretching frequencies shift to higher frequencies due to the effects of both electron-releasing substituents and electron-attracting substituents. This phenomenon is apparently due to the delocalized nature of the coordination bonds in the complexes (4), and the same interpretation as for the copper complexes can be applied to the present case.

However, the substituent effect on the metal–halogen stretching frequency of the zinc–pyridine complex is not as straightforward as in the case of the copper–pyridine complex. As shown in Table II, there is an exception in that one of the zinc–chlorine frequencies of the 4-carbinylpyridine complex, in which the CH_2OH is an electron-releasing group, is even lower than that of the pyridine complex. This is probably due to the fact that the dπ–dπ zinc-to-chlorine bond is much weaker than the zinc–chlorine σ-bond, since the π-bonding ability of zinc is much weaker than that of copper (5). Therefore, only a small increase in the electron density on the zinc atom results from the effect of the weakly electron-releasing group, CH_2OH, and this does not provide enough dπ–dπ bonding to overcome the decreased bond strength of the zinc–chlorine σ-bond.

The zinc–nitrogen stretching frequencies of the zinc–pyridine complex are also shifted by the effects of the substituents on the fourth position of the pyridine ring. These effects, as expected, are larger than those on the zinc–chlorine stretching frequencies, since the former ones are more directly involved in any shifts in electron density due to the substituent. The effects of electron-releasing groups on the zinc–nitrogen stretching frequency are similar to the effects of these same groups on the copper–nitrogen stretching mode (4).

The effects of electron-attracting substituents on the Zn—N (ligand) stretching frequencies of the Zn–pyridine complexes are, however, quite different from those in the Cu–pyridine complex. In the copper complexes (4), the M—N stretching frequencies shift to lower frequencies due to the effects of electron-attracting substituents, and increasingly stronger electron-attracting groups give a lower M—N stretching frequency. In the case of the zinc complexes, the converse is true, except for the CN group, which leaves the M—N stretching frequency unchanged. Therefore, the relationship between the electron-attracting ability of the substituents and the M—N stretching frequencies, as observed in the case of the copper complexes, is no longer valid. Since the M—N stretching frequency correlates to the M—N bond strength (3, 4, 6), these differences between the zinc and copper complex systems may be interpreted as being due to the different nature of their bonding. It has been reported (5) that the σ-bonding contribution in the zinc complexes is much weaker than that in the analogous copper complexes, and, for ordinary complexes, or complexes of substituted pyridine with electron-releasing groups in the fourth position of the pyridine ring, the π-contribution in the zinc complexes is also very much weaker. In fact, with zinc, this π-contribution is smaller than in the analogous complexes of any of the first-row transition metals. However, as we have indicated, this π-bonding ability is no longer characterized by the metal ions themselves, but by the nature of the substituted groups (3). It turns out that for a given

electron-attracting substituent, the π-bond in the zinc and copper systems is comparable and increases as electron-attracting ability of the substituent increases. However, the σ-bond in the copper complexes is so strong that any small change in π-bonding does not give a significant change in the total bond strength. Therefore, the relative total bond strength in these copper complexes follows the same trend as would be expected for just the σ-bonding contribution. On the other hand, in the zinc complexes the σ-bonding is relatively very weak, and the π-bonding is strongly influenced by electron-attracting substituents. Therefore, the π-bond in these zinc complexes makes a significant contribution to the total bond strength. The R_π values (3) show that the π-bond strength in the zinc complexes of 4-substituted pyridine with $-CONH_2$, $-COCH_3$, and $-COOCH_3$ as substituents is about double that in the pyridine complex. Therefore, the higher M—N frequencies and the increased total coordination bond strength of the zinc complexes with these substituted pyridines over that with pyridine itself are understandable. The M—N frequency of the 4-cyanopyridine zinc complex is the only one which has the same magnitude as that of pyridine complex, although the π-bond strength in the former is about 3 times higher than that in the latter. This is probably due to the extremely weak σ-bond in the 4-cyanopyridine complex. A rough calculation, using the stability constants of the pyridinium ion and the 4-cyanopyridinium ion (3), shows that the σ-bonding ability of 4-cyanopyridine is only about 0.04% that of pyridine. The compensation due to the increase in π-bonding, and the decrease in the σ-bonding caused by the substitution of a CN group on the fourth position of pyridine, gives the observed total bond strength in the zinc-4-cyanopyridine complex.

The symmetrical M—N stretching frequency of the 4-acetylpyridine is not observed in the spectrum. However, the asymmetrical M—N stretching and the M—Cl stretching frequencies of this complex are very similar to those of the 4-carbo-

methoxylpyridine complex. The normal coordinate analysis in Section III shows that a calculated value of 237 cm^{-1} of this mode is obtained if a similar M—N stretching force constant to that of the 4-carbomethoxylpyridine complex is used.

III. Normal Coordinate Analysis

In previous papers (4, 6) a 1:1 complex model has been used for the normal coordinate analysis of a series of metal complexes of substituted pyridine derivatives. The calculated results agreed with the observed ones satisfactorily, since only very weak coupling between the skeletal modes was indicated by a clear separation of the halogen-sensitive bands from the metal–nitrogen (ligand) bands.

In the present work, as a preliminary step, the same 1:1 complex model is used for the normal coordinate treatment of the systems of the zinc-(II) – substituted pyridine complexes. Again, only 21 in-plane vibrations are calculated.

Since the results of the previous studies showed that the coupling between the M—N (ligand) vibration and the internal substituted-pyridine modes is also very weak, a further refinement of the normal coordinate analysis for the skeletal modes, considering the substituted-pyridines as point masses, has been attempted. Full details of this analysis and the comparison of the results obtained by these 2 methods are reported elsewhere (17).

For the 1:1 complex model of the zinc complexes, the internal coordinates, the symmetry coordinates, and the **G** matrix constructed on the basis of these coordinates, are similar to those described previously (4, 6). To construct the **F** matrix, shown in Table III, the modified Urey–Bradley force field (4) is used. The force constants of the C—H stretching modes are not included in this **F** matrix, and have been removed by the high-frequency separation method (18). The corresponding elements of the **F** matrix are given[2] in Tables IV and V.

Removal of 7 of the 9 redundancies is accomplished by the coordinates transformations (4). Two remaining redundant conditions are again left in the secular equations as a check on the calculation.

[2]Tables IV and V have been placed in the Depository of Unpublished Data. Photocopies may be obtained free of charge, upon request, from: Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada.

The molecular parameters used in this calculation are similar to those listed in a previous paper (4), except r_6, which is 2.06 Å. In view of the transferability of the Urey–Bradley force constants and the small change in the spectra of the zinc complexes compared with those of the copper complexes, the force constants related to the internal vibrations of the ligands in this calculation are identical with those of the copper complexes (4). Only the metal–nitrogen (ligand) stretching force constants are refined in this calculation and are listed in Table VI.

The eigenvalues of the secular equation of the zinc complexes obtained by the **QR** transformation (19) compare favorably with the observed ones, as shown in Table VII. These results show that the Urey–Bradley force constants of the ligands of the copper complexes (4) are transferable to the zinc systems, except the carbon–metal bending force constants and some of the ring vibrational force constants, leading to lower calculated frequencies of the ν_1 mode of the zinc complexes than the observed ones.

As expected, the resulting zinc–nitrogen (ligand) stretching force constants of this series of zinc complexes give the same order as that of the zinc–nitrogen (ligand) stretching frequencies, viz.

$$CH_3Py > CH_2OHPy > COOCH_3Py > CONH_2Py > Py > CNPy$$

Therefore the conclusion reached in the previous paper (4), that the magnitude of the metal–ligand stretching frequency can be used as a measure of the coordination bond strength for copper complexes of pyridine derivatives, is also valid for the zinc complexes of 4-substituted pyridines.

Acknowledgments

We wish to thank Dr. E. Whalley and Dr. M. Falk of the National Research Council of Canada for the use of their instruments and Mr. M. Sears for the preparation of the pyridine – zinc bromide complex.

Solvent reorganization for hydrolysis with hydrogen participation[1]

Y. INOMOTO[2], R. E. ROBERTSON, AND G. SARKIS[3]

Received July 24, 1969

A study of the rates of hydrolysis of 3-Me-2-butyl bromide and methanesulfonate in water leads to values of ΔC_p^* of -80 and -40 cal deg^{-1} mole^{-1}, respectively. The product was about 85–95 % *t*-pentanol, the remainder being olefin. The value of ΔC_p^* for the solvolysis of the methanesulfonate in D_2O was -44 cal deg^{-1} mole^{-1}. The kinetic solvent isotope effect (k.s.i.e.) for the latter was unusually low (k.s.i.e. = 1.047 at 5 °C and 1.025 at 25 °C). Deuteration at C-3 led to a reduction in the rate of hydrolysis by a factor of about 2.25. This is consistent with an activation process involving "hydrogen participation" as previously reported by Winstein and Takahashi for solvolysis of the corresponding tosylate in acetic acid. In contrast to the latter work, the reaction in water appears to be uncomplicated.

Canadian Journal of Chemistry, 47, 4599 (1969)

Introduction

In extending our examination of solvent reorganization accompanying the hydrolysis of solutes giving evidence of neighboring group participation (1), we report here the results of such a study involving hydrogen participation for the hydrolysis of 3-methyl-2 butyl methanesulfonate in H_2O and D_2O and the corresponding bromide in H_2O. Evidence for hydrogen participation for the solvolysis of this latter compound in acetic acid was discussed previously by Winstein and Takahashi (2), although they regarded the participation of hydrogen under their conditions as somewhat marginal. Because of this estimate, a question was raised as to the effect a change in solvent would have on the mechanism. Acetic acid is not a good ionizing solvent and is a weak nucleophile, while water is a good ionizing solvent and a fair nucleophile. At the time the work was initiated there was some uncertainty as to whether secondary halides hydrolyzed in water by an S_N1, S_N2, or mixed mechanism. If the mechanism were S_N1, the better ionizing solvent would render hydrogen participation less important than in acetic acid; if S_N2, then the $\Delta C_p^{\neq}$ value should reflect this fact. Our criterion at that time was that $\Delta C_p^{\neq}$ for hydrolytic displacement of a halide by an S_N2 mechanism would have a value of about -55 cal deg^{-1} mole^{-1}, while for reaction by an S_N1 mechanism the corresponding value would be -80 cal deg^{-1} mole^{-1}. As a result of this study and related work we now recognize that this latter criterion involves an oversimplification and probably a misconception as well.

Experimental

3-Methyl-2-butyl Methanesulfonate

This compound was prepared by the method of Tipson (3) from pure methylisopropylcarbinol and purified by double distillation under reduced pressure (0.1 mm Hg) with a bath at 60–65 °C: n_D^{25} 1.4305; neutralization equivalent 165.1, Calcd. 166.2.

Anal. Calcd. for $C_6H_{14}O_3S$: C, 43.33; H, 8.49. Found: C, 43.19; H, 8.30.

The sample proved to be kinetically pure from estimation of solvolytic behavior in water.

3-Methyl-2-butyl Bromide

This compound was prepared by the method used by Cason and Corrcia (4) for synthesizing 3-bromopentane, with slight modification. The crude product was purified by the method of Bailey and Hirsch (5). A mixture of 300 ml of dimethyl sulfoxide, 33.3 g (0.323 mole) NaBr, and 62.4 g (0.258 mole) of 3-methyl-2-butyl *p*-toluenesulfonate was stirred at room temperature for 64 h. The reaction mixture was distilled directly under reduced pressure (ca. 15 mm Hg; bath, 55–65 °C) and distillate boiling between 32–39 °C (50 mm Hg) collected. The distillate was stirred with 30 ml water at room temperature for 2 h. The water layer was extracted once with 50 ml ether, the combined ether extract and organic layer being shaken with 50 ml concentrated HCl for 2 min. The ethereal solution was washed with ice-water, then with cold saturated $NaHCO_3$ solution, twice with H_2O, and then dried over $CaCl_2$. Two distillations gave 6.0 g (12 %) of pure material: b.p. 39–40° (55 mm) (lit. (5) b.p. 49.8–51.0° (75 mm)); n_D^{24} 1.4452.

Anal. Calcd. for $C_5H_{11}Br$: C, 39.75; H, 7.34; Br, 52.91. Found: C, 39.71; H, 7.17; Br, 52.82.

Vapor phase chromatography (v.p.c.) of the sample gave but 1 peak, using a 20 wt. % polypropylene oxide on Chromosorb W column with a He flow rate of 60 cc/min. Retention time was 37.5 min. The compound was shown to be kinetically pure by the use of a large scale Guggenheim plot (6).

Solvent

H_2O was distilled and passed through an ion exchange column containing Fisher Rexyn-1-300. D_2O was obtained from Merck, Sharpe, and Dohme or Atomic Energy Commission of Canada. This was redistilled

TABLE I

Products of hydrolysis in water ($CaCO_3$ present)

Substrate	Solvolysis temperature (°C)	Product yield (%)	
		2-Me-2-butene	*t*-Pentanol
3-Me-2-Bu-mesylate	2	5.4	94.6
	22	6.3	93.7
3-Me-2-Bu-bromide	35	6.7	93.3
	51	16.6	83.4

from sodium, then from $NaDSO_4$ through a scaled-down Stuart–Wormwell still (7) where the hot vapors and condensate contacted only quartz.

Analysis of Products

The analysis of products was done by vapor phase chromatography and also by direct titration of the olefin produced. A mixture of 0.6–0.7 mmole of the compound, 5 ml of water, and sufficient precipitated calcium carbonate to neutralize the acid were placed together with a small magnetic stirring bar in a sealed tube and allowed to react for 20 half-lives. The sealed tubes were thoroughly cooled in an ice bath prior to opening for analysis. Analyses were done in quadruplicate.

Olefin Determination

The content of the olefin in the solvolysis products was determined by an iodometric back titration of the excess bromine (8). To the solvolytic mixture was added 2.5 cc of carbon tetrachloride and 5 cc of water. The resulting mixture was kept at 0 °C for 10 min. Two cc of a 0.2 *N* solution of bromine in carbon tetrachloride was then added to the mixture, which was kept at 0 °C for another 10 min with occasional shaking.

The mixture was titrated, after addition of 2.5 cc of 20% potassium iodide solution, with 0.1 *N* standard sodium thiosulfate, using starch as an indicator. The yield of olefin was calculated by averaging the results for 3 separate solvolysis mixtures.

Vapor Phase Chromatography

A Poropack Q (80–100 mesh) column was used at 120° for olefin separation and 180° for the alcohols. The kind and amounts of solvolytic products are listed in Table I.

In the absence of calcium carbonate, the olefin yield increased by about 10% in the case of the methanesulfonate, some 1,2 as well as 2,3 isomer being found (v.p.c.), with a corresponding decrease in alcohol. This was regarded as an artifact, and since it became apparent that the reaction probably followed an S_N1 mechanism, the question of product was not pursued. The fact that the products found for hydrolysis in water were simpler than those reported by Winstein and Tagahashi (2) is not surprising if allowance is made for the difference in solvent properties.

Kinetics

Rates were determined by a conductance method, in stirred Queen type cells (9) using either a conventional bridge (10) or, in the later part of the work, our Auto-RAM system (11). Temperature control and measurement, and calculations were the same as previously reported (11).

Results and Discussion

Average rate data for the hydrolysis of the methanesulfonate in H_2O and D_2O are given in Table II; corresponding data for the hydrolysis of the bromide in H_2O are given in Table III.

The temperature dependence of the rate in each case was fitted by a least-mean-square method to an equation of the form

$$[1] \quad \log_{10} k = \frac{A}{T} + B \log T + C$$

The corresponding equations are as follows

3-Methyl-2-butyl bromide in H_2O

$$[2] \quad \log_{10} k = \frac{-10628.888}{T} - 40.03150 \log T + 130.60409$$

3-Methyl-2-butyl mesylate in H_2O

$$[3] \quad \log_{10} k = \frac{-7030.13779}{T} - 18.89552 \log T + 67.64076$$

3-Methyl-2-butyl mesylate in D_2O

$$[4] \quad \log_{10} k = \frac{-7300.50548}{T} - 20.99025 \log T + 73.72049$$

Quasi-thermodynamic parameters (10) characterizing the reactions based on transition state assumptions and on the approximation that $d\Delta C_p^{\ddagger}/dT = 0$ are given in Table IV. It is recognized that the latter approximation is least

Winstein and Takahashi (2) have discussed the mechanism of solvolysis of 3-methyl-2-butyl tosylate in acetic acid in terms of two independent processes, (*a*) anchimerically unassisted solvolysis and (*b*) a mechanism in which the tertiary hydrogen provides neighboring group assistance. Evidence based on a comparison of k_H/k_D for the solvolysis of the corresponding methanesulfonate (MeS) in water indicates a similar anchimeric assistance occurs in the present study. An approximate value of the rate of solvolysis of $(CH_3)_2CDCH(MeS)CH_3$ at 25.5° is 1.04×10^{-3} s^{-1} for 91% D; the corresponding value for the protium compound is 2.145×10^{-3} s^{-1}. These values lead to about the same value of the k_H/k_D ratio for the methanesulfonate as was found for the solvolysis of the tosylate in two solvents (Table V). Having due regard for the fact that the methanesulfonate is a somewhat poorer leaving group than the tosylate ($k_{Tos}/k_{MeS} = 3.4$ at 25 °C for solvolytic displacement from isopropyl (10)), it will be apparent from Table V that the degree of anchimeric assistance is just about the same for hydrolysis in water as for the tosylate under much poorer ionizing conditions but possibly conditions favoring such interaction. It would appear that the products of hydrolysis in water are simpler than for reaction in acetic acid, the major product being the tertiary alcohol (Table I). This is consistent with a transition state involving hydrogen participation and the transfer of the tertiary H to C-2 with attack of a water molecule on C-3 to yield the tertiary alcohol, subsequent to the transition state.

The fact that accurate rates, a very low k.s.i.e. (below), and about the same value of $\Delta C_p^{\ddagger}$ was obtained in D_2O as in H_2O confirm that in this reaction the "neighboring hydrogen" was not exchanging with the solvent in the activation process. However, two facts in connection with the

*For 100% deuteration.

†The loss of deuterium occurred during the synthesis since exchange under solvolytic conditions would have made rate determination unreliable and was not expected in any case (12). However, the presence of 9% of the protonated impurity would increase the rate by a small but indeterminate degree depending on the extent of the reaction prior to time $t = 0$. The ratio given is therefore a lower limit.

solvolytic studies in D_2O remain unexplained. The kinetic solvent isotope effect for the solvolysis of the methanesulfonate (from smoothed data, eqs. [3], [4]) was found to be 1.047 at 5.00 °C and 1.024 at 25.00 °C. These values are somewhat lower than those previously found for the solvolysis of the sulfonates (average value 1.09)[4]. In addition, we were unable to find conditions which would give reproducible rates for the solvolysis of the 3-methyl-2-Br-butane in D_2O; in the majority of attempts the change in resistance with time did not appear to conform to a first order relationship. None of these difficulties was apparent in our results in H_2O for either the bromide or the methanesulfonate, or for the latter in D_2O. The possibility of exchange of deuterium in the case of 3-methyl-2-butyl bromide was recognized as a possibility but not proven.

[4]Robertson and Laughton (13) reported a value of k.s.i.e. = 1.046 for the hydrolysis of neopentyl methanesulfonate. It is probable that this reaction is accompanied by rearrangement but this possibility was not confirmed.

The argument that the solvolytic displacement of X from 3-methyl-2-butyl X, in water, occurs by a single mechanism has been used previously (14, 15) and may be summarized as follows. If solvolysis occurs by two mechanisms, it is improbable that each will have the same temperature coefficient, hence the one having the higher coefficient will become successively more important as the temperature increases. This trend will add a positive component to $\Delta C_p^{\ddagger}$ and the resultant $\Delta C_p^{\ddagger}$ will be less negative than "normal". Clearly such a criterion depends on our ability to define the limits of normality for the type of reaction under consideration. This positive effect on $\Delta C_p^{\ddagger}$ is quite different from that resulting from impurities. Thus, the presence of a faster reacting impurity in the case of crotyl chloride resulted in a spurious value of $\Delta C_p^{\ddagger}$ of -130 cal deg^{-1} mole^{-1} (14). The 91% deuterated mesylate, in the present study, gave an apparent $\Delta C_p^{\ddagger} < -100$ cal deg^{-1} mole^{-1}, compared to a real value of about -45 cal deg^{-1} mole^{-1}.

TABLE VI

Comparison of $\Delta C_p^{\ddagger}$ values for hydrolysis in water

Compound	$\Delta C_p^{\ddagger}$ (cal deg^{-1} mole^{-1})	Reference	Compound	$\Delta C_p^{\ddagger}$ (cal deg^{-1} mole^{-1})	Reference
3-Me-2-butyl bromide	−80	This work	*t*-Butyl chloride	−83	18
3-Br-2-Me-2-butanol	−77	1	2,2-Dichloropropane	−75	19
2-Cl-ethyl methyl sulfide	−71	1	*trans*-γ-Methyl allyl chloride	−82	15
4-Br-butyl methyl ether	−46	1	2,2-Dibromopropane	−81	19
α-Br-isobutyrate	−78	17	Isopropyl bromide	−59	20
			Cyclohexyl bromide	−59	10
			Cyclopentyl bromide	−68	10

These latter results illustrate the sensitivity of $\Delta C_p^{\ddagger}$ to certain types of reactive impurities. No evidence of such an impurity was detected in the protium compounds, hence the large negative value of $\Delta C_p^{\ddagger}$ (-80 cal deg^{-1} mole^{-1}) for the solvolysis of 3-methyl-2-butyl bromide in water was taken as evidence of extensive solvent reorganization in the activation process and similar to values found for molecules reacting by an S_N1 mechanism (Table VI). Values of $\Delta C_p^{\ddagger}$ for the hydrolysis of the secondary halides, isopropyl, cyclohexyl, and cyclopentyl bromides are included. From this comparison it is clear that the $\Delta C_p^{\ddagger}$ value found here for the hydrolysis of the 3-Me-2-butyl bromide is more negative than the corresponding value found for some secondary bromides and in the same range as values found for halides which probably react unambiguously by an S_N1 mechanism. Following the argument given above, and in contrast with the conclusion reached by Winstein and Takahashi (2) for the solvolysis of the corresponding tosylate in acetic acid, it seems unlikely that the solvolysis of this halide occurs in water by mixed kinetics. The same conclusion seems equally likely for the mechanism of solvolysis of the corresponding methanesulfonate where $\Delta C_p^{\ddagger} = -40 \pm 3$ cal deg^{-1} mole^{-1} for solvolysis in water. The corresponding value for solvolysis in D_2O is -44 ± 3 cal deg^{-1} mole^{-1}.

These latter values lie very close to those for the hydrolysis of isopropyl benzenesulfonate and methanesulfonate. If anchimeric assistance predicates solvent reorganization associated with an S_N1 mechanism in the hydrolysis of the bromide, it is even more likely to do so with the solvolysis of the sulfonates. This seemingly inevitable conclusion raises an anomaly. In previous papers we have accounted for the more negative values of $\Delta C_p^{\ddagger}$ which characterize the S_N1 displacement of halides from tertiary carbon in terms of the requirement for additional solvent reorganization about the quasi-cation (10). It seemed logical that the same reasoning apply to the value of -80 cal deg^{-1} mole^{-1} found for the displacement of the bromide in this study, compared to a value of about -50 which characterizes displacement from primary halides and -60 for secondary halides. Why then should there be no corresponding difference between the value of $\Delta C_p^{\ddagger}$ for the hydrolysis of methyl methanesulfonate (-35 cal deg^{-1} mole^{-1}) and that for isopropyl methanesulfonate (-35 cal deg^{-1} mole^{-1}), or for 3-Me-2-butyl methanesulfonate ($\Delta C_p^{\ddagger} = -44$ cal deg^{-1} mole^{-1})? One possible suggestion is that the presence of the sulfonic group localizes the breakdown of water structure, an interpretation which is consistent at least with the reduced kinetic solvent isotope effects which characterize the hydrolysis of this series of compounds (16). The similarity in the products (Table I) for the hydrolysis of bromides and methanesulfonates is consistent with the creation of some common intermediate which can react with adjacent water molecules. Neither reason provides a necessary and sufficient condition to explain the difference in $\Delta C_p^{\ddagger}$. Intuitively we feel that if the bromide reacts by an S_N1 mechanism, as seems likely on the above evidence, then the methanesulfonate does so as well. This leaves the lack of sensitivity of $\Delta C_p^{\ddagger}$ to an expected change in mechanism of solvolysis in the sulfonate series

an open question. This conclusion led to a reconsideration of our criterion (admittedly based on a limited number of examples) that the hydrolysis of halides reacting by an S_N1 mechanism (Table VI) is normally characterized by much more negative values of $\Delta C_p^{\ddagger}$ than those reacting by an unambiguous S_N2 mechanism. Quite aside from the problem raised above with respect to the $\Delta C_p^{\ddagger}$ for the hydrolysis of the secondary sulfonates, there are the intermediate values of $\Delta C_p^{\ddagger}$ already noted for the unassisted solvolysis of secondary halides. For the purposes of this paper, we note that the $\Delta C_p^{\ddagger}$ value determined for the 3-methyl-2-butyl bromide here implies extensive solvent reorganization at the transition state characteristic of those halides reacting by an S_N1 mechanism. The more general problem will be dealt with in a forthcoming paper (21).

Some years ago, Hoffmann proposed that the value of the rate ratio k_{Tos}/k_{Br} be used as a criterion of mechanism, though he omitted to specify the limits which define any particular mechanism (22). In the presence of a strong nucleophile and a poor ionizing medium, this ratio may be less than unity. Under good ionizing conditions and with favorable structure, values greater than 1000 are found. The ratio obtained here for $k_{Mes}/k_{Br} = 25.5$, which is equivalent to $k_{Tos}/k_{Br} = 53$, i.e., about 1/2 the value given for displacement from isopropyl, but well above the value of the ratio (17–5) which characterizes the hydrolysis of primary compounds in water.

Whatever the quantitative utility of this ratio in terms of mechanistic distinction, there is undoubted value to be gained from examining the probable reasons for variation in this ratio and relating these to other criteria of mechanism. Hoffmann notes that the value of the k_{Tos}/k_{Br} ratio for gas phase dehydrohalogenation follow a similar pattern to that found for solvolysis, the difference being that the activation energies in solution are reduced by about 1/2 and there is some indication that the spread of the values may be reduced as well. In the gas phase, the ratio apparently reflects the ability of an R-group to support the partial or total loss of an electron, coupled to the relative advantage the "electronically versatile" tosylate has over bromide to accommodate the complementary acquisition of charge. This intrinsic difference revealed in the gas phase experiments provides a quantitative answer to the curious fact that while $\Delta S^{\ddagger}$ for a series of sulfonates showed a wider change for $(\Delta S^{\ddagger}_{isopropyl} - \Delta S^{\ddagger}_{ethyl})$ than for the corresponding halides, the $\Delta C_p^{\ddagger}$ values showed just the opposite tendency (20). Thus, $(\Delta S^{\ddagger}_{isopropyl} - \Delta S^{\ddagger}_{ethyl})$ for the hydrolysis of mesylate is 8.3 e.u., and for bromide is 4.6 e.u. The corresponding values[5] for $(\Delta S_I^{\ddagger} - \Delta S_{ethyl}^{\ddagger})$ from the present study are 6.6 e.u. for the mesylate and 3.68 e.u. for the bromide. In both systems, the value of $\Delta C_p^{\ddagger}$ for the hydrolysis of the sulfonates are about the same, while the value of the $\Delta\Delta C_p^{\ddagger}$ for the bromides are, respectively, -10 and -32 cal deg^{-1} $mole^{-1}$. We know of no reason to question the assumption that $\Delta C_p^{\ddagger}$ is a more sensitive indicator of solvent reorganization than $\Delta S^{\ddagger}$, at least for hydrolysis in water. Hence, the above comparison points to the existence of important factors, other than solvent reorganization, which contribute to $\Delta S^{\ddagger}$. For solutes which react by an S_N1 mechanism, these factors seem to be related to the ease with which the solute becomes thermally activated. In this connection, it is probable that the nature of the solvent as well as the solute is significant in determining $\Delta S^{\ddagger}$, but a detailed study designed to relate the properties of the solute to variations in $\Delta S^{\ddagger}$ has yet to be made. An indication of the possibility of individual difference may be gained from a consideration of the variation in k_{Tos}/k_{Br} reported by Hoffmann (22) for the solvolysis of the 2-pentyl compounds: k_{Tos}/k_{Br} has the values 498 in formic acid, 105 in water, 73 in ethanol. For the neophyl series ($PhMe_2CCH_2X$) the corresponding values are 14 – 106. The corresponding $Y + 3$ values (23) which purport to measure the relative ionizing power of the solvent are 5.05, 6.49, and 0.97; the lack of correlation with the latter solvent property is obvious. Hoffmann suggests that these anomalies and others he discusses may be related to a desolvation of the nonclassical carbonium ion formed in the transition state. Our interpretation would be to attribute the difference to variations in the charge distribution which determines the initiation of exothermic solvation or of more specific interaction with the quasi-cation, individually. This is implied in Hoffmann's postulate that "the faster an S_N1 (E_1) reaction, the more ionic its transition state". This statement is consistent with the requirement that the more

[5] $\Delta S_I^{\ddagger}$ is for 3-Me-2-butyl methanesulfonate.

diffuse the charge, the higher the charge level required on the ion as a whole to exceed solvent–solvent interaction, and to result in secondary solvent–cation interaction leading to the completion of the reaction. The fact that those structures which release electrons better, solvolyze faster was established early in the work of Ingold and his co-workers (24) and is related to the inherent hypothetical $\Delta F_g^{\ddagger}$ (22). A graded series of increasingly reactive structures would probably show a parallel increase in $\Delta S_g^{\ddagger}$, as we have already noted.

We disagree with Hoffmann's conclusion that the more polar solvent necessarily favors the more polar transition state. It is a recognized fact that a reactant with structural characteristics which favor an S_N1 mechanism will show a very strong rate dependence on the ionizing properties of the solvent. Water is a better ionizing solvent than acetic acid, but the values of the k_{Tos}/k_{Br} ratio are higher in the latter. The relation of charge level to ionizing properties cannot be resolved by a simple hypothesis because at the transition state not only solvation properties, but also nucleophilic properties of the solvent are involved, as well as charge distribution and steric considerations of the quasication. The tosyl group undoubtedly disperses charge better than the bromide, thus facilitating both the S_N1 and S_N2 mechanism. In the S_N2 displacement of the sulfonic group from a primary carbon, the spare electrons on the oxygen provide available sites for solvent interaction; thus nucleophilic displacement is achieved with less requirement for overlap, an inference supported by the relative α-deuterium isotope effects (25).

From these observations, we are led to conclude that while the k_{Tos}/k_{Br} ratio forms an interesting basis for inspection, it should be regarded as a supplementary indication of possible mechanistic difference, the common lot of most comparable tests.

It would be simple to conclude on the basis of the above evidence that hydrogen participation in the hydrolysis of 3-Me-2-butyl bromide is characterized by solvent reorganization characteristic of an S_N1 mechanism. Neighboring group participation has been shown previously to result in reduced (as well as enhanced) values of the kinetic solvent isotope effect (26). The example reported here may be regarded as a further example of the same phenomenon. Obviously, to draw attention to such similarity is not equivalent to providing a satisfactory explanation, and further work will be required in this area.

Organoantimony compounds. II. Studies on tetraphenylantimony(V) derivatives[1,2]

R. G. GOEL
Department of Chemistry, University of Guelph, Guelph, Ontario

Received July 11, 1969

Tetraphenylantimony halides, pseudohalides, carboxylates, nitrate, sulfate, selenate, and chromate have been synthesized. The infrared spectra, molecular weights, and electrical conductances of these compounds have been investigated to elucidate the chemical constitution. The compounds have molecular, monomeric constitution in benzene solutions. Infrared results indicate that with the exception of the acetate and the oxalate, all the compounds have 5-coordinate structures. The acetate is 6-coordinate in the solid state and 5-coordinate in bromoform or chloroform solution. The oxalate is indicated to be 6-coordinate in the solid state as well as in chloroform solution. The electrical conductivities of the bromide, chloride, thiocyanate, trifluoroacetate, and the nitrate in nitromethane correspond to those of 1:1 electrolyte. The conductivities of the other compounds indicate little dissociation in this solvent.

Canadian Journal of Chemistry, 47, 4607 (1969)

Introduction

The first tetraphenylstibonium compound, Ph_4SbBr, was reported by Chatt and Mann (1). Since then other tetraphenylantimony derivatives have been described in the literature (2). By analogy with tetraphenylphosphonium and tetraphenylarsonium acid derivatives, the analytical applications of tetraphenylantimony derivatives have also been explored. The tetraphenylphosphonium and arsonium halides and nitrates are known to have ionic constitution (3). However, the chemical constitution of the analogous antimony derivatives has not been established. Investigations were therefore initiated in this laboratory to establish the nature of tetraphenylantimony acid derivatives. While this work was in progress X-ray crystallographic studies on tetraphenylantimony methoxide (4) and hydroxide (5) were reported. The X-ray studies have shown that both the compounds have molecular, trigonal bipyramidal structures.

Very recently, studies on some tetraphenylantimony–acetylacetonate (6, 7) and –oxinates (7, 8) have also appeared. In these compounds an octahedral configuration around the antimony atom is indicated. In this paper the results of infrared spectral, electrical conductance, and molecular weight studies on tetraphenylantimony halides, pseudohalides, carboxylates, nitrate, sulfate, selenate, chromate, and the oxalate are reported.

[1]For part I of this series, see ref. 17.

[2]Presented in part at the 52nd Annual Conference of Chemical Institute of Canada, Montreal. May 26–28, 1969.

Experimental

Preparations

Tetraphenylantimony bromide was prepared by the method of Willard, Perkins, and Blicke (9). Other tetraphenylantimony derivatives were prepared by the reaction of the bromide with the appropriate silver salt, using benzene or methanol as the solvent. After removing the solvent the solid residue was recrystallized from petroleum ether or a mixture of benzene and petroleum ether. The compounds were characterized by elemental analyses, molecular weight determinations, infrared spectra, and melting points.

Measurements

Infrared spectra were recorded on a Beckman Model IR-12 double beam spectrophotometer. Solid samples were prepared as mulls in Nujol or halocarbon oil and the spectra were obtained using KRS-5 and polyethylene windows. Spectra of the solutions were obtained using silver chloride or potassium bromide demountable liquid cells. Spectra of the solid samples were measured in the 4000 to 200 cm^{-1} region. The spectra in solutions were measured only in selected frequency regions. The electrical conductivities were measured with a Yellow Springs Instrument Co. Inc. Model 31 conductivity bridge. A conductance cell with bright platinum electrodes and a ground glass stopper was used. The cell constant was determined by use of standard aqueous solutions of potassium chloride.

The molecular weights were determined with a Hitachi–Perkin–Elmer Model 115 vapor osmometer. Melting points were measured with a Gallenkamp melting point apparatus in glass melting point tubes with one open end. Elemental analyses were carried out by Dr. A. B. Gygli, Microanalytical Laboratory, Toronto.

Solvents

Analytical and spectrograde solvents from Fisher, Baker, or Matheson Coleman and Bell were used without further purification. In the conductance measurements, the conductance of the solvent was measured in each case and corrections to the observed conductances were made.

*Solvent: benzene; concentration range: 10^{-2}–10^{-3} mole/kg.
†Percentage N: found, 8.90; calcd., 9.10.

Results and Discussion

The compounds are nonhygroscopic and soluble in organic solvents such as methanol, nitromethane, benzene, chloroform, and carbon disulfide. About half of the compounds are also soluble in petroleum ether. With the exception of the chromate, the compounds are stable under ordinary conditions. The chromate decomposes slowly at room temperature and on exposure to light. However, it can be stored in a refrigerator without any decomposition.

Molecular Weight and Conductance

The analytical and molecular weight data and melting points of the investigated compounds are recorded in Table I. The molecular weight data clearly show that all the compounds exist as molecular and monomeric species in benzene.

The electrical conductances of these compounds were measured in nitromethane at 25 °C in the concentration range of 10^{-3} to 10^{-4} M. The equivalent conductances, Λ_e, as a function of the square root of the concentration in equivalents per l., $\sqrt{c}$, are shown in Figs. 1, 2, and 3. The plots of Λ_e against $\sqrt{c}$ for tetraphenylantimony bromide, chloride, nitrate, thiocyanate, and the trifluoroacetate give straight lines. The equivalent conductances of these compounds occur in the same range as observed for tetraphenylarsonium chloride in nitromethane. Thus the above compounds can be considered as 1:1 electrolyte in nitromethane. However, the observed conductances of tetraphenylantimony fluoride, cyanate, azide, acetate, and trichloroacetate are significantly lower than those of tetraphenylarsonium chloride. Also, the

plots of the Λ_e against $\sqrt{c}$ are not straight lines. The conductance data of these compounds thus indicate a small degree of dissociation in nitromethane. In fact, the conductivities of the fluoride are so low that it may be considered to be a nonelectrolyte in nitromethane. Since the molecular structure of tetraphenylantimony hydroxide has been established, the conductances of this compound were measured to provide a comparison. The plot of Λ_e against $\sqrt{c}$ for the hydroxide is also shown in Fig. 2. The conductances of the trichloroacetate are found to be very close to those of the hydroxide.

The equivalent conductance of a 10^{-3} *M* solution of a uni–bivalent electrolyte in nitromethane has been reported (10) to be 80 Ω^{-1} cm^{-2} $equiv.^{-1}$. The observed conductances of tetraphenylantimony sulfate, selenate, chromate, and the oxalate are significantly lower. Also, the plots of Λ_e against $\sqrt{c}$ do not give straight lines. Thus, all four $(Ph_4Sb)_2X$ compounds appear to behave as weak electrolytes in nitromethane.

Infrared Spectra

The infrared spectroscopic results provide further support for the molecular constitution of these compounds. The infrared spectra of all the compounds show almost identical absorption bands due to the phenyl groups. The absorption bands due to the anion groups can therefore be assigned with confidence. The observed absorption frequencies associated with the anion group, X, in the Ph_4SbX compounds are listed in Table II. In the case of the acetate and haloacetates, only the (COO) stretching frequencies are listed. In the spectra of tetraphenylantimony fluoride, a strong absorption band is observed at 400 cm^{-1}. This band does not occur in the spectrum of the bromide or the chloride and it can be assigned to the (Sb—F) stretching frequency. The Sb—F stretching frequency in trimethylantimony difluoride (11) occurs at 475 cm^{-1}, and the Sb—OH stretching frequency in tetraphenylantimony hydroxide (5) is reported at 528 cm^{-1}. The antimony–halogen stretching frequency in the spectra of the bromide and chloride are not observed in the 4000–250 cm^{-1} region.

The absorption bands due to the N_3, CNO, and SCN groups compare very well with those reported (12) for other covalent organometallic pseudohalides. The frequencies of the cyanate

and the thiocyanate indicate that both the cyanate and the thiocyanate groups are involved in bonding through the nitrogen atom (12, 13).

In the infrared spectrum of tetraphenylantimony acetate in the solid state, the (COO) symmetric and asymmetric stretching frequencies occur at 1395 and 1555 cm^{-1}, respectively. However, in bromoform or chloroform solutions these frequencies are observed at 1370 and 1625 cm^{-1}, respectively. In the solid state the C—O—O stretching frequencies are of the same order as reported for the free acetate ion or bidentate acetate ligand (14). However, C—O—O stretching frequencies in solution are as expected for monodentate acetate group (14). The spectrum of the solid tetraphenylantimony acetate can best be interpreted in terms of a 6-coordinate structure. The ionic structure can be ruled out in view of the conductance and molecular weight data and the solubility of this compound in hot petroleum ether. The significant increase in the difference between the C—O—O asymmetric and symmetric stretching frequencies in the chloroform or bromoform solution suggests a 5-coordinate structure in solution. The observed solid state infrared spectra of tetraphenylantimony trifluoro- and trichloro-acetate and tetraphenylantimony nitrate are consistent with 5-coordinate structures containing a unidentate X group (11, 15, 16).

The infrared absorption frequencies due to the anion group, X, in the tetraphenylantimony sulfate, selenate, chromate, and the oxalate are listed in Table III. The spectra of the sulfate, selenate, and the chromate, clearly indicate that the tetrahedral symmetry of the anion group, X, has been reduced to at least C_{2v}. The spectral data indeed are in accord with the presence of bridging X groups (11, 17). Although in the case of the tetraphenylantimony sulfate only 3 stretching frequencies due to the sulfate group can be assigned with confidence, the spectra of the selenate and the chromate clearly show 4 strong, well resolved bands which can be assigned to the stretching frequencies due to the coordinated selenate or chromate group (11, 17). Similarly, in the low frequency region 4 absorption frequencies due to the selenate or chromate group are observed. In this region only 3 frequencies can be assigned to the sulfate group, the fourth frequency in the 470–450 cm^{-1} region is presumably masked by the strong phenyl band in

this region. The possibility of the lowering of the anion group symmetry due to the solid state effects can be ruled out, because no significant change was observed in the anion group stretching frequencies when spectra were recorded in carbon disulfide solutions.

The infrared spectrum of tetraphenylantimony oxalate shows only one O—C—O stretching frequency at 1625 cm^{-1}. The other absorption bands which can be assigned to the oxalate group are observed at 1310, 788, and 375 cm^{-1}. The spectrum of the tetraphenylantimony oxalate thus differs significantly with that of triphenylantimony oxalate (17), which shows 2 strong (O—C—O) stretching bands at 1740 and 1655 cm^{-1} and for which a 5-coordinate bridging structure is proposed. The oxalate frequencies in tetraphenylantimony oxalate correspond to the presence of either a free oxalate ion or a symmetrical oxalate group functioning as bichelate ligand (18). In view of the conductance and molecular weight data, the coordinated structure containing a symmetrical bichelate oxalate group and a 6-coordinate antimony atom is more probable than an ionic structure. The infrared spectrum of chloroform solution of this compound also shows only 1 absorption band due to (O—C—O) stretching vibration, and the position of this band is not changed in solution. Therefore, unlike the tetraphenylantimony acetate, the structure of the tetraphenylantimony oxalate does not change in solution.

Regarding the infrared frequencies associated with the antimony–carbon stretching vibrations, no definite assignments can be made due to the presence of the phenyl absorption bands. A recent study (19) of the vibrational spectra of triphenyl compounds of the main group V elements indicates that in the case of triphenylantimony, the (Sb—C) stretching vibrations occur below 300 cm^{-1}. However, due to overlap with the phenyl ring vibrations the assignments cannot be made unequivocally. Absorption frequencies due to the antimony–ligand stretching vibrations could not be identified in any compound with the exception of tetraphenylantimony fluoride. These frequencies are most likely to occur near 300 cm^{-1} or lower, and again due to the presence of the phenyl bands no conclusion can be reached about them.

In conclusion, the results of this study indicate that the tetraphenylantimony derivatives investigated are nonionic and monomeric in benzene. The electrical conductances in nitromethane show a significant degree of ionization in the case of the bromide, chloride, thiocyanate, trifluoroacetate, and the nitrate. This indicates appreciable ionic character of the Sb—X bond in these compounds. The conductances of the fluoride, azide, cyanate, acetate, trichloroacetate, sulfate, selenate, chromate, and the oxalate do not show any significant ionization in nitromethane, and in these compounds the Sb—X bond can be described as being more covalent. With the exception of the acetate and the oxalate, all the compounds appear to have a 5-coordinate structure in the solid state. The acetate appears to have a 6-coordinate structure in the solid state, but a 5-coordinate structure in solution. The oxalate appears to be 6-coordinate in the solid state as well as in solution. The reason for this difference in the mode of coordination of the carboxylate group is not clear at present. The

difference between the constitution of the tetraphenylantimony acid derivatives and the corresponding phosphorus and arsenic halides and nitrates is in accord with the reported (20, 21) differences in the properties of tertiary organometallic dihalides, R_3MX_2, (R = methyl or phenyl, M = group VB atom) of the group VB elements. However, the structural aspects of organometallic derivatives of group VB elements have not been extensively investigated, and further experimental studies are required in order to rationalize the stereochemistry of organometallic derivatives of group VB elements in the +5 oxidation state.

Thermal expansion and structure in water and aqueous solutions

LOREN G. HEPLER
Department of Chemistry, University of Lethbridge, Lethbridge, Alberta
Received July 17, 1969

The thermodynamic equation $(\partial C_P/\partial P)_T = -T(\partial^2 V/\partial T^2)_P$ is used as a basis for relating thermal expansion to structure (at several temperatures and pressures) of water and "normal" liquids. Similar considerations lead to a relation between the sign of $(\partial^2 \overline{V}_2{}^0/\partial T^2)_P$ for solutions and classification of solutes as structure-making or structure-breaking.

Canadian Journal of Chemistry, 47, 4613 (1969)

A variety of evidence has led to the view that water is a partly "structured" liquid that can be loosely described as a sort of partly broken down ice. Possibly the simplest useful description of liquid water, is that in which the water is pictured as being a mixture of two species; one a bulky icelike species with relatively low density and the other a denser species that is formed by breaking (or bending) the hydrogen bonds that maintain the ice-likeness of the bulky species. Since both increasing temperature and increasing pressure would have the effect of increasing the fraction of the dense species at the expense of the bulky species, this simple model can account qualitatively for the maximum in density, the unusually high heat capacity, and several other properties of water. Some of the properties of aqueous solutions have also been interpreted in terms of the "structure-making" or "structure-breaking" characteristics of various solutes. This paper is concerned with the relation between these structural ideas and the thermal expansion of water and of aqueous solutions.

Partial molal heat capacities of aqueous electrolytes are commonly negative. An early explanation (for example, Lewis and Randall (1)) that is consistent with other properties of aqueous electrolytes is that these solutes break up the bulky aggregates and thereby decrease the effective heat capacity of the water. Since increasing pressure would also break up the bulky aggregates, the same reasoning suggests that the heat capacity of pure water should decrease with increasing pressure. We therefore expect $(\partial C_P/\partial P)_T$ to be negative and use the thermodynamic equation

$$[1] \qquad \left(\frac{\partial C_P}{\partial P}\right)_T = -T\left(\frac{\partial^2 V}{\partial T^2}\right)_P$$

in predicting that $(\partial^2 V/\partial T^2)_P$ for water is positive. Because increasing temperature also breaks up the bulky aggregates, we expect that the magnitude of $(\partial C_P/\partial P)_T$ should decrease with increasing temperature, which requires that $T(\partial^2 V/\partial T^2)_P$ should also decrease with increasing temperature. Similarly, we expect that $T(\partial^2 V/\partial T^2)_P$ should decrease with increasing pressure. Since a variety of evidence suggests that D_2O is a more structured liquid than is H_2O, we also expect that the magnitude of $(\partial C_P/\partial P)_T$ and thence $T(\partial^2 V/\partial T^2)_P$ would be larger for D_2O than for H_2O.

Kell (2) has tabulated values of density (ρ) and coefficient of thermal expansion ($\alpha = (1/V)(\partial V/\partial T)_P$) for H_2O(liquid) at 1 atm. over a range of temperatures. These values have been used with the equation

$$[2] \qquad \left(\frac{\partial^2 V}{\partial T^2}\right)_P = \frac{M}{\rho}\left[\alpha^2 + \left(\frac{\partial \alpha}{\partial T}\right)_P\right]$$

in which M represents the molecular weight, to obtain values of $(\partial^2 V/\partial T^2)_P$ and thence the values of $T(\partial^2 V/\partial T^2)_P$ that are shown in Fig. 1. Densities of D_2O(liquid) tabulated by Kell (2) also lead to the (molar) values of $T(\partial^2 V/\partial T^2)_P$ that are shown in Fig. 1. Here it might be noted that small irregularities in $(\partial^2 V/\partial T^2)_P$ for D_2O in the ranges of 35–45 and 65–75 °C have been smoothed in constructing the figure. Specific volumes tabulated by Kell and Whalley (3) have been used in calculating the (slightly smoothed) values of $T(\partial^2 V/\partial T^2)_P$ for H_2O(liquid) under pressures of 200 and 1000 bars as also shown in Fig. 1.

The curves in Fig. 1 show the predicted differences in $T(\partial^2 V/\partial T^2)_P$ for H_2O and D_2O at 1 atm. and confirm the predicted effect of pressure on H_2O. At higher temperatures the values of $T(\partial^2 V/\partial T^2)_P$ increase very slightly

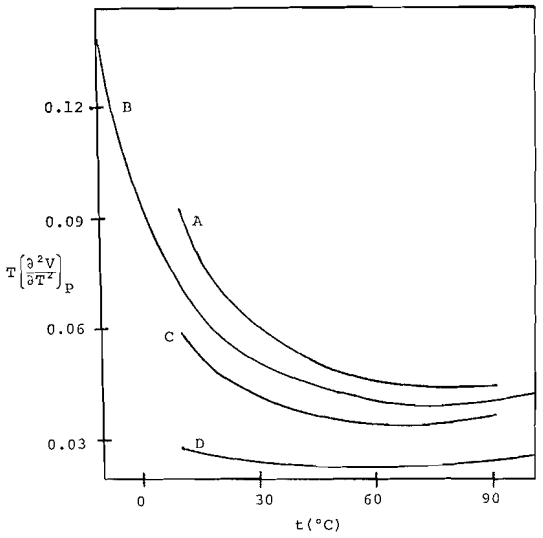

FIG. 1. Thermal expansion data: *A* (D_2O, 1 atm); *B* (H_2O, 1 atm); *C* (H_2O, 200 bars); *D* (H_2O, 1000 bars).

with increasing temperature, in contrast with the decrease observed at lower temperatures that was predicted earlier on the basis of structural arguments. This slight increase of $T(\partial^2 V/\partial T^2)_P$ at higher temperatures can be rationalized as follows.

According to the structural model described earlier, water becomes more like a normal liquid as the temperature (or pressure) increases. In order to ascertain what constitutes "normal" variation of volume with temperature, density data for a number of liquids (*n*-heptane, diethylether, CCl_4, ethanol, benzene, and mercury) have been used to obtain corresponding values of $T(\partial^2 V/\partial T^2)_P$ over a range of temperatures. Although the highest values (for ether and heptane) of $T(\partial^2 V/\partial T^2)_P$ are some 500 times the smallest values (for Hg), the temperature dependence of this quantity falls within the relatively narrow range of an increase of about 1–2% per degree. At 100 °C we find that $T(\partial^2 V/\partial T^2)_P$ for water is increasing by only about 0.2% per degree, and even at 140 °C the increase is still less than 0.5% per degree. Thus we see that the volumetric behavior of water, even at high temperature, is still consistent with a structural model in which it is assumed that increasing temperature and pressure break down structure and cause water to approach "normal" behavior.

Extension of the approach described here to aqueous solutions should contribute to understanding of structure-making/breaking by various solutes. We begin by differentiating the thermodynamic equation of state $(\partial H/\partial P)_T = V - T(\partial V/\partial T)_P$ with respect to n_2 (P, T, and n_1 constant) and then with respect to T (n_1, n_2, and P constant) to obtain

$$[3] \qquad \left(\frac{\partial \bar{C}_P}{\partial P}\right)_T = -T\left(\frac{\partial^2 \bar{V}_2}{\partial T^2}\right)_P$$

Since present considerations are limited to consequences of solute–solvent interactions, we choose to apply eq. [3] to partial molal properties of the solute at infinite dilution as indicated subsequently by the superscript zero.

As already mentioned, partial molal heat capacities of electrolytes are commonly negative. The common explanation (1) in terms of structure-breaking leads to the prediction that $(\partial \bar{C}_P{}^0/\partial P)_T$ should be positive. On the basis of this reasoning and eq. [3], it is seen that structure-breaking solutes should have negative $(\partial^2 \bar{V}_2{}^0/\partial T^2)_P$. Similar reasoning shows that positive $(\partial^2 \bar{V}_2{}^0/\partial T^2)_P$ should be associated with structure-making solutes.

Although interpretation of the experimental data is not entirely certain, a variety of evidence (4–6) suggests that alcohols (in dilute solutions) are structure-making solutes. On this basis and our reasoning concerning the sign of $(\partial \bar{C}_P/\partial P)_T$, we expect that $(\partial^2 \bar{V}_2{}^0/\partial T^2)_P$ should be positive for aqueous alcohols. The most obvious confirmation of this expectation is the figure presented by Alexander (7) in which $\bar{V}_2{}^0$ values for methanol, ethanol, *i*-propanol, *i*-butanol, and *i*-pentanol are plotted against temperature (0–60 °C). Franks and Smith (4)[1] have obtained $\bar{V}_2{}^0$ values for the four isomeric butanols at four temperatures (0.5–40 °C), while Friedman and Scheraga (8) have reported $\bar{V}_2{}^0$ values for nine alcohols at four temperatures (1–50 °C). All of the $\bar{V}_2{}^0$ vs. temperature curves for alcohols (4, 7, 8) are of the general shape illustrated in Fig. 2, with the positive $(\partial^2 \bar{V}_2{}^0/\partial T^2)_P$ expected for structure-makers.

Dunn's measurements (9) have led to $\bar{V}_2{}^0$ values for NaCl, KBr, KCl, $BaCl_2$, and $CaCl_2$ at eight temperatures from 0.5 to 65 °C. The general shape of graphs of $\bar{V}_2{}^0$ against T is shown

[1]References to earlier work, with particular emphasis on volumetric properties, are cited in this paper.

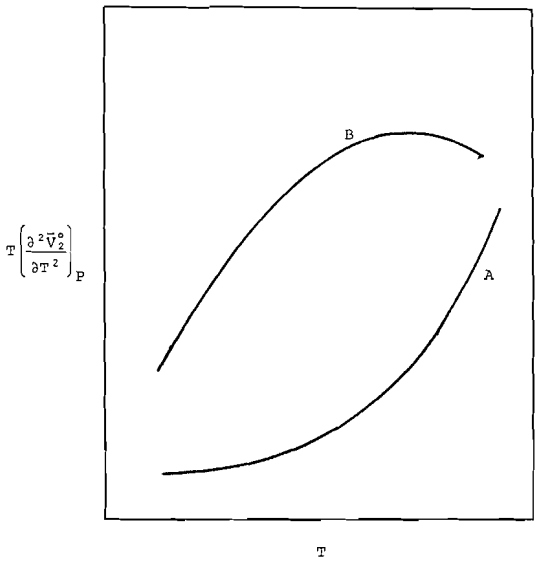

FIG. 2. Typical thermal expansion data for aqueous solutes: Curve *A* is associated with structure-making solutes and curve *B* with structure-breaking solutes.

in Fig. 2, with $(\partial^2 \bar{V}_2^0/\partial T^2)_P$ negative as expected for structure-breaking solutes. Bull and Breese (10) have recently published a graph of apparent molal volume of KCl (dilute solution) against temperature that is in agreement with the general shape of the curve in Fig. 2 based on Dunn's data (9). Data from Ellis (11, 12) for LiCl, NaCl, KCl, CsCl, $MgCl_2$, $CaCl_2$, $SrCl_2$, and $BaCl_2$ up to 200 °C also lead to negative $(\partial^2 \bar{V}_2^0/\partial T^2)_P$. Other data from Millero (13) confirm that $(\partial^2 \bar{V}_2^0/\partial T^2)_P$ is negative for most aqueous salt solutions. Thus the volumetric data indicate that these electrolytes should be regarded as structure-breaking solutes in water. We also conclude from the high temperature data that water at temperatures well above the normal boiling point is still sufficiently structured that structure-breaking solutes can "find" structure to break.

Gopal and Siddiqi (14) have reported $\bar{V}_2^0$ values for four tetraalkylammonium iodides (methyl, ethyl, propyl, and butyl) at temperatures ranging from 25–80 °C. Values of $(\partial^2 \bar{V}_2^0/\partial T^2)_P$ are positive, indicating that these solutes are all net structure-makers, as previously suggested on other grounds for some R_4NX compounds. The magnitude of $(\partial^2 \bar{V}_2^0/\partial T^2)_P$ increases in going from methyl to ethyl to propyl to butyl compounds in this series. This is consistent with the idea that structure-making is in the form of "iceberg" formation about the hydrocarbon parts of these ions, with the extent of structure-making increasing as the amount of hydrocarbon increases. Millero and Drost-Hansen (15) have previously pointed out that volumetric properties of aqueous alcohols and tetraalkylammonium salts are similar, with both having volumetric properties different from those of most electrolytes.

The $\bar{V}_2^0$ values for aqueous urea, given by Stokes (16), show that $(\partial^2 \bar{V}_2^0/\partial T^2)_P$ is negative, which indicates that urea should be regarded as a structure-breaking solute.

Masterton (17) has reported $\bar{V}_2^0$ data for benzene, methane, ethane, and propane in aqueous solution at several temperatures. For benzene, $(\partial^2 \bar{V}_2^0/\partial T^2)_P$ is very close to zero. The resulting conclusion that benzene is neither a strong structure-maker nor a strong structure-breaker may be explained in terms of a balance between iceberg formation and structure-breaking due to poor fit of planar benzene molecules into the partly tetrahedral structure of water. Masterton's data (17) indicate that $(\partial^2 \bar{V}_2^0/\partial T^2)_P$ values are negative for methane, ethane, and propane. Thus the approach developed in this paper leads to the conclusion that these solutes are structure-breakers in aqueous solution. On the basis of different reasoning, Masterton (17) has previously suggested a "breaking down of the cage-like structure of water molecules around the aliphatic hydrocarbon molecules". Thus both this paper and Masterton disagree with the common idea that methane, ethane, and propane are net structure-makers as a result of iceberg formation about the solute molecules.

Although classification of solutes as structure-makers or -breakers has proven useful in several connections, it must be recognized that the entire concept of structure in water and aqueous solutions is only partly satisfactory (18). One problem is that we are unable to be entirely specific about the structure that is being made or broken by various solutes or as a result of changes in temperature and pressure. A further difficulty is that we have no unambiguous numerical measure of structure-making/breaking. Therefore, it should not be surprising that there are disagreements between conclusions based on different approaches. A similar situation is known in connection with the useful but poorly

defined concept of hydration number, where it is common for different approaches to lead to different numbers.

Since the conclusion of this paper concerning classification of alcohols and the larger tetraalkylammonium ions as structure-makers is in agreement with several earlier workers, no detailed comments on these solutes are required. On the other hand, several earlier workers have concluded that $(CH_3)_4N^+$ and possibly $(C_2H_5)_4N^+$ ions are structure-breakers, in contrast to our conclusion that these ions are structure-makers. Similarly, the present conclusion that urea is a structure-breaker is contrary to conclusions of some earlier workers.

First, we consider the reliability of the data (14) we have used for the R_4N^+ salts. Since the most dilute solutions investigated were about 0.05 *M*, the extrapolation to infinite dilution to obtain desired $\overline{V}_2^0$ values is of considerable importance. Gopal and Siddiqi (14) did these extrapolations "as required" by Masson's equation with empirical limiting slope based on their own data for solutions more concentrated than about 0.05 *M*. Redlich and Meyer (19) have shown the inadequacies of this extrapolation procedure and have also shown how such extrapolations should be done in accord with the Debye–Huckel theory. Accurate measurements on R_4NX compounds (only at 25°) reported by Conway, Verrall, and Desnoyers (20) show that Gopal and Siddiqi (14) used incorrect slopes (wrong sign for three of their four solutes!) for extrapolation to infinite dilution. Although we conclude that the accuracy of the reported (14) $\overline{V}_2^0$ values is not high, it is likely that these values do lead to the correct sign for $(\partial^2 \overline{V}_2^0/\partial T^2)_P$ for the larger R_4N^+ ions. On the other hand, it is possible that the reported values lead to an incorrect sign for $(\partial^2 \overline{V}_2^0/\partial T^2)_P$ for aqueous $(CH_3)_4NI$. Further measurements are required to settle this uncertainty.

The conclusion in this paper [assuming that the available data lead to the correct sign for $(\partial^2 \overline{V}_2^0/\partial T^2)_P$] that $(CH_3)_4NI$ is a structure-maker is in disagreement with some earlier workers. For example, Gopal and Siddiqi (14) have concluded from the concentration dependence of their apparent molar volumes that this solute is a structure-breaker, but it is the present author's opinion that their interpretation should have given greater consideration to solute–solute interactions and may therefore be mistaken. Other evidence that $(CH_3)_4N^+$ ion is a structure-breaker comes from results of conductance (21) and viscosity (22) measurements, although a Referee has suggested that the viscosity data might also be interpreted to indicate that $(CH_3)_4N^+$ is a structure-maker.

Conway and Laliberté (23) have reported $\overline{V}_2^0$ values for NaF, NaCl, NaBr, $(C_2H_5)_4Br$, and $(C_4H_9)_4Br$ in both H_2O and D_2O at 25 °C. They concluded from their results that the first three salts are structure-breakers and the latter two salts are structure-makers, in agreement with conclusions of this paper. Similar accurate data for $(CH_3)_4N^+$ halides and also other electrolytes with charges greater than ± 1 will be useful.

Earlier workers (24–28) are in poor agreement as to whether urea should be classed as a structure-maker or structure-breaker, although the most recent work (28) and some earlier workers are in agreement with our conclusion that urea is a structure-breaker. Further, the inadequate logic leading to an earlier suggestion (26) that urea is a structure-maker has been pointed out (18).

A Referee has pointed out that Krishnan and Friedman (29) have found evidence for a "saturation" effect in structure-making by alcohols and R_4N^+ ions. That is, structure-making does not increase without limit as hydrocarbon size increases. The same Referee has also suggested that diffusion data from Witherspoon and Sarat (30) can be interpreted to support the idea presented in this paper that the gaseous hydrocarbons are structure-breakers.

Chloryl compounds. Part II. Chloryl hexafluoroarsenate and chloryl fluoride[1]

H. A. CARTER, W. M. JOHNSON, AND F. AUBKE
Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received June 30, 1969

The infrared and Raman spectra of chloryl hexafluoroarsenate have been obtained. The observed vibrations have been interpreted in terms of an ionic compound $ClO_2^+AsF_6^-$, where strong cation–anion interaction results in a symmetry lowering of the AsF_6^- ion. The compound together with chloryl fluoride produces the chloronium cation ClO_2^+(solv) in solution of fluorosulfuric acid. The solvolysis of $FClO_2$ is studied by conductometry and ^{19}F nuclear magnetic resonance (n.m.r.) in order to elucidate the observed anion–cation interaction for ClO_2AsF_6 more fully. ^{19}F n.m.r. studies of $FClO_2$ and related molecules have been used to discuss the bonding in chloronium compounds.

Introduction

A limited number of chloryl compounds have been known for some time (1). They can be easily divided into 2 groups. Chloryl fluoride, $FClO_2$ (2), and its reaction products with strong Lewis acids such as BF_3, AsF_5, and SbF_5 (3–5) are colorless, moderately reactive compounds. On the other hand, chloryl fluorosulphate, ClO_2SO_3F (3, 5), and dichloryl trisulfate, $(ClO_2)_2S_3O_{10}$ (6), are deep red colored solids at room temperature and are highly reactive compounds. The red color in these compounds fades to a faint yellow at liquid air temperature. (Similar behavior is found for chlorine dioxide.) All substances have been postulated to contain the chloronium cation, ClO_2^+ (3, 7, 8). Such a cation has recently been found to exist in a solution of fluorosulfuric acid (9) when ClO_2SO_3F and $(ClO_2)_2S_3O_{10}$ were used as solutes. The cation is red colored.

The present study is intended to resolve the apparent contradiction regarding the chloronium cation in the solid state by extending the solution studies to the colorless compounds $FClO_2$ and ClO_2AsF_6, and by studying the vibrational spectra of ClO_2AsF_6 and ClO_2SbF_6. No detailed structural investigation on any one of the solid compounds has yet been reported. Only the infrared (i.r.) and Raman spectra of $FClO_2$ (10, 11), have been well investigated. Assignment of 5 bands in the i.r. spectrum of Cl_2FAsF_6 as being due to the ClO_2^+ cation has been briefly mentioned in a recent paper (12) but no discussion of these bands has yet been published.

It was found necessary also to record the ^{19}F nuclear magnetic resonance spectrum of ClO_2F together with a number of related molecules, and to discuss the bonding in this molecule on the basis of the presently available information.

[1]For Part I, see ref. 9.

Experimental

General

All volatile materials were handled in a monel metal vacuum line. The solids were transferred in a dry box containing a purified nitrogen atmosphere. All chloryl compounds encountered in this investigation were found to be hygroscopic and highly reactive. They explode violently on contact with oxidizable material.

Materials

Elemental fluorine (Allied Chemical Corp.) was purified from HF by passing the gas in a metal flow system over sodium fluoride. Arsenic pentafluoride (Peninsular Chemical Research) and antimony pentafluoride (Alpha Inorganic Chemical Corp.) were purified by trap-to-trap distillation. Chlorine dioxide was prepared from $KClO_3$ and H_2SO_4 in the presence of oxalic acid (15). Chloryl fluoride was prepared using 2 methods: (*a*) reaction of $KClO_3$ with BrF_3 in monel metal reactors according to Woolf (5), (*b*) direct fluorination of chlorine dioxide at −50 °C in a quartz apparatus (16). Method (*a*) was found to be safe but yields a slightly impure yellowish product. Method (*b*) yields a very pure, colorless product but involves all the hazards of handling ClO_2. The purity of ClO_2F was checked on the basis of the i.r. spectrum.

Chloryl hexafluoro-arsenate and -antimonate were prepared by reacting a very slight excess of chloryl fluoride with a known amount of pentafluoride in a ~100 ml thin-wall monel, 2-part reactor, equipped with a Hoke valve according to Woolf (5). The reaction was followed by weight changes. The ClO_2AsF_6 was purified by high vacuum sublimation.

Solutions of $FClO_2$ in fluorosulfuric acid were prepared by distilling purified chlorylfluoride in a metal vacuum line from a storage vessel into a weighing burette kept at −80 °C and containing a known quantity of doubly distilled HSO_3F. This stock solution was used for addition to the acid in the conductivity cell.

Infrared Spectra

The i.r. spectra were recorded on a Perkin–Elmer 457 Grating Infrared Spectrophotometer in the region of

4000–250 cm^{-1}. Silver chloride and KSR-5 windows were used (Harshaw Chemicals). Due to the high reactivity of the chloryl compounds, no mulling agents were used.

Raman Spectra

A Cary 81 Spectrophotometer equipped with a Spectra Physics Model 125 laser as a source of exciting light was used. The solid samples were contained in flat-bottom Pyrex tubes (6 mm o.d.).

Conductivity Measurements

Fluorosulfuric acid (Allied Chemical Co.) was purified by double distillation under nitrogen atmosphere. This technique and the design of the conductivity cells have been described by Barr *et al.* (19). A Wayne Kerr Universal Bridge B 221A was used for the measurements. The cells were contained in a constant temperature oil bath of 25.00 ± 0.01 °C with a Sargent Thermonitor Model ST.

^{19}F n.m.r. Spectra

These were obtained with a Varian HR100 spectrometer. The ClO_2F samples were contained in quartz tubes using $CFCl_3$ in quartz capillaries as an external standard.

Results and Discussion

A. The Vibrational Spectrum of ClO_2AsF_6

The recorded absorption frequencies for the infrared spectra of ClO_2AsF_6 and ClO_2SbF_6 and the Raman spectrum of ClO_2AsF_6 are listed in Table I, together with the frequencies for $KAsF_6$.

The interpretation of the spectra will be restricted to the hexafluoroarsenate for the following reasons: (1) the compound can be purified by sublimation, (2) the formation of polyanions is unlikely, (3) the AsF_6^- ion has been well characterized previously (12, 20–22, 24). Possible molecular structures for ClO_2AsF_6 are (*a*) an ionic solid $ClO_2^+AsF_6^-$, (*b*) a molecular 1:1 adduct $ClO_2F.AsF_5$ with bridging over F, and (*c*) the same, with bridging over oxygen.

For model (*a*) the chloronium cation would be isoelectronic to sulfur dioxide, the symmetry C_{2v}, with 3 vibrational modes i.r.- as well as Raman-active. This is confirmed by the findings shown in Table II. The vibration ν_3 is similar to that of SO_2(s) (25*c*), which is split into 2 i.r.- and Raman-active components by the crystalline field. Noteworthy is that the average stretching frequencies for the ClO_2 group are lower than that for SO_2: $\bar{\nu}_{SO_2} = 1233\ cm^{-1}$ vs. $\bar{\nu}_{ClO_2} = 1166\ cm^{-1}$ (i.r.) or 1168 cm^{-1} (Raman) in ClO_2AsF_6. This is unexpected considering the increase in nuclear charge on chlorine. The same vibrations are slightly shifted for the ClO_2SbF_6 spectrum by about 8 to 10 cm^{-1} to higher wavenumbers. Similar shifts have been known to occur for similar complexes containing the NO^+ cation, (26) and have been explained as being due to anion–cation interaction. Some chlorine–oxygen stretching vibrations are listed in Table III together with the SO_2 values.

For a corresponding AsF_6^- anion with O_h symmetry, 2 infrared-active vibrations, ν_3 (F_{1u}) and ν_4 (F_{1u}) are expected together with 3 Raman-active vibrations, ν_1 (A_{1g}), ν_2 (E_g), and ν_5 (F_{2g}).

The observed i.r. spectrum apparently does not confirm these expectations. Not only are the 2 expected vibrations ν_3 and ν_4 shifted, compared to the generally accepted positions of 700–690 and 392 cm^{-1}, but the region of strong absorption reveals a shoulder at 725 cm^{-1} and a broad 685 cm^{-1} absorption. (A similar observation has

been made by Clark and O'Brien for the i.r. spectrum of $(CH_3)_3SnAsF_6$ (23), where the AsF_6 group acts as a bridging group and the symmetry appears to be lowered to D_{4h}.) ν_4 appears to be split into a doublet and, in addition, a reasonably strong absorption at 563 cm^{-1}, which is not found in the ClO_2SbF_6 spectrum, is observed. It must therefore be due to the AsF_6^- group.

The Raman spectrum also shows more vibrations than expected. Again all positions are slightly shifted to lower frequencies. From the position of the expected E_g mode, ν_2, at 572 cm^{-1}, it is concluded that it is identical with the observed 563 cm^{-1} vibration in the infrared spectrum. The occurrence of the ν_2 vibration in the i.r. region has been reported previously for $NF_4^+AsF_6^-$ (20), $AsCl_4^+AsF_6^-$ (44), and $ClF_2^+AsF_6^-$ (21). The interpretation of the 563 cm^{-1} vibration as ν_2 presents a departure from the assignment in ref. 12. All reported frequencies agree quite well with ours. The 725 cm^{-1} vibration is also weakly Raman active, and the possibility that this vibration is a combination mode seems rather unlikely. From these findings, it seems safe to say that the symmetry of the AsF_6 group is lowered considerably from expected O_h to possible C_{2v} symmetry, causing a partial breakdown in the selection rules and general shift of all frequencies in comparison with other AsF_6 compounds. The tentative assignment of the observed frequencies is shown in Table II. The reason for the observed symmetry lowering can be seen in appreciable anion–cation interaction, already reflected in the shifts of the ClO stretching vibrations (Table III).

Anion–cation interaction is not too surprising for these compounds, and is also found in 2

reported structures based on X-ray diffraction for ICl_2SbCl_6 (27) and BrF_2SbF_6 (28), resulting in a distorted octahedral environment for antimony.

In conclusion, a strictly ionic formulation of ClO_2AsF_6 is not supported by the infrared and Raman spectrum, unless allowance is made for appreciable anion–cation interaction and a subsequent lowering of symmetry for the AsF_6^- ion. This model explains the observed spectrum quite well.

Noteworthy also is that the ClO stretching frequencies for $FClO_2$ do not show a similar wide split to the corresponding stretching frequencies of ClO_2AsF_6, but the values of $\bar{\nu}_{ClO_2}$ are almost identical for all chloryl compounds. In similar systems, e.g. FNO (29) vs. $NOAsF_6$ (26), FNO_2 (30) vs. NO_2SbF_6 (31), and F_3NO (17) vs. F_2NOAsF_6 (13, 14), stretching frequencies are substantially raised on complexation.

B. Solution Studies

The solvent HSO_3F was selected since previous work on the ClO_2^+ cation had shown that this ion is capable of existence in this solvent (9).

The solutes are all soluble and behave as bases in this solvent. The solutions are highly conducting. Specific conductivities of various concentrations are listed in Table IV. The solutions of ClO_2AsF_6 are yellow to reddish colored, the color being characteristic for the ClO_2^+ cation; the solute $KAsF_6$ gives rise to a colorless solution. However, whereas $KAsF_6$ is only moderately soluble, the limiting molality being 5.0×10^{-2} at 25.0 °C, the ClO_2 compound is soluble to a far greater degree, up to 1–2 *M*. Both solutions are conducting, and are remarkably similar. The specific conductivity plots vs. molality are shown in Fig. 1. The specific conductances of the ClO_2AsF_6 solutions are slightly higher than the ones for $KAsF_6$, whereas the situation was reversed when ClO_2SO_3F and KSO_3F were compared as solutes (9). The electronic absorption spectrum indicates the formation of the ClO_2^+ cation as expected. The differences in solubilities and conductivities for the 2 solutes are unexpected. Since the concentration ranges were found to be too low for meaningful Raman and

^{19}F n.m.r. studies, greater attention was focussed on the solvolysis of $FClO_2$ in fluorosulfuric acid.

Solutions of ClO_2F in HSO_3F were red colored and highly conducting. The ultraviolet–visible absorption spectrum agrees well with the reported one (9) and the ^{19}F n.m.r. spectrum indicates the presence of HF as the only fluorine-containing species besides the solvent. The γ values, defined as the number of moles of fluorosulfate anions produced per mole of solute, are higher than the reference KSO_3F values, which is not unexpected since KF has also been found to be more conducting than KSO_3F (19) (because HF behaves as a weak base in HSO_3F). In addition, $FClO_2$ prepared according to Woolf (5) was used in this part of the study, and the preparation of the solution in a Pyrex container may have resulted in side reactions and a very slightly higher conductivity value. At concentrations below 10^{-2} M, γ values (32) slightly less than 1 are obtained. This is very likely due to the presence of SO_3 as an impurity in the HSO_3F which behaves as an acid in this solvent system (19). The solvolysis can be formulated as follows

$$FClO_2 + HSO_3F \rightarrow ClO_2^+(solv) + HF + SO_3F^-$$

$$HF + HSO_3F \rightleftarrows H_2F^+ + SO_3F^-$$

This would result in γ values > 1.0. The described solvolysis was studied previously by Schmeisser and Fink (4), who postulated the equilibrium

$$FClO_2 + HSO_3F \rightleftarrows HF + ClO_2SO_3F$$

It is reasonable to assume that in dilute solutions, HF and ClO_2SO_3F will be solvolyzed and the equilibrium shifted to the right.

It is interesting to note that the colorless chloryl compounds gave rise to a red colored ClO_2^+ cation. Considering the fact that SO_2 is colorless, the ClO_2^+, isoelectronic but colored, needs some explanation. The absorption spectrum of ClO_2^+ shows an absorption maximum at 2700 Å with a molar extinction coefficient of 1950, and a shoulder at about 3300 Å. In addition, strong absorption occurs at 2200 Å. Since the expected ground state for ClO_2^+ would be $^1A_1$, the 2 bands of the lower energy region can be assigned as due to the transitions $^1A_1 \rightarrow {}^1B_1$ and $^1A_1 \rightarrow {}^1B_2$, using the model proposed by Walsh (33) for triatomic molecules. The former is of lower energy, and by branching off into the visible region, this transition, involving the antibonding b_1'' orbital, is responsible for the color. Transitions into the same orbital are largely responsible for the color of ClO_2 (33). Since the energy spacing is similar, the angle OClO, 117.4°, for ClO_2 (34) is not too different from an expected angle of $\sim 120°$ for ClO_2^+ (the angle for SO_2 is found to be 119.5°) (35). Such a similarity is expected. ClO_2^+-containing solutions are also faintly yellow colored at liquid air temperature as shown for the red chloryl compounds and chlorine dioxide.

The corresponding absorption bands for SO_2 have been observed at 3740 and 2940 Å (36), but they are of far lower intensity (ε_{max} for the stronger band is ~ 400) and do not reach into the visible region. The low energy transitions of ClO_2 are also far higher in intensity than corresponding SO_2 bands.

The concept of isoelectronic molecules can, it seems, be applied to suggest similar molecular structures. However, an extension to electronic transitions and color should be done with extreme care. The absence of any color in ClO_2AsF_6 and ClO_2SbF_6 indicates that the interaction between the ClO_2^+ cation and fluorine in the AsF_6^- or SbF_6^- anion may involve the b_1'' orbital, which is weakly bonding for O—O but antibonding for O—Cl. The degree of interaction will affect the overall Cl—O bond order and the bond strength, as reflected in the differences in $\bar{\nu}_{Cl-O}$, the average stretching frequency. Such a model, whereby the b_1'' orbital takes part in bonding, can be invoked to explain the bonding in $FClO_2$. Even though the exact structure is not known, vibrational spectroscopy (11) provides some idea about this molecule. The symmetry appears to be C_s. The ClO stretching force constant has been found to be 9.07 mdyn/Å compared to 6.9 for the ClO_2 (37) molecule. The Cl—F force constant of 2.53 mdyn/Å, however, is the smallest reported. The overall bonding situation, short and strong element–oxygen bond, usually weak and long element–fluorine bond, becomes reminiscent of the situation in FNO (38) and FNO_2 (39) as well as for O_2F_2 (40) and O_2F (41) where the observed element–fluorine bonds are found to be longer than the normal single bonds.

In addition, extremely low field chemical shifts in the ^{19}F nuclear magnetic resonance spectrum have been found for these fluorides. We have therefore recorded the spectrum and compared it to the chemical shift values of the isoelectronic

*In p.p.m. from the external standard $CFCl_3$.

molecule, SOF_2, and the odd-electron molecule fluorides. The results are shown in Table V.

The spectrum was taken at −80 °C and consisted of a broad, unresolved signal due to spin–quadrupole interaction with the isotopes Cl^{35} and Cl^{37} Only for the highly symmetrical $FClO_3$ with C_{3v} symmetry is fine structure detectable (42). The chemical shift of −328 p.p.m. is indeed very low, the lowest reported for fluorine attached to a second period element and lower than the value for SOF_2. Since the ultraviolet–visible spectrum of $FClO_2$ (16) gives no evidence for any low lying excited states, fluorine appears to be highly deshielded.

The description of the bonding in all these compounds can be based on a description of the O_2F_2 bonding by Lipscomb (40). It is seen to involve a high-lying singly occupied antibonding π^* orbital of O_2 and a singly occupied $2p$ orbital on fluorine resulting in a highly delocalized multicenter bonding. These ideas have been extended by Spratley and Pimentel (41) and the bonding type has been labelled $[\pi^*–p]$ bonding. Preliminary attempts to describe this bond type in a more quantitative manner have been reported (43), but no completely satisfactory bonding description is available at the present. There seems no doubt, however, that the bonding in $FClO_2$ is very similar in principle to the bonding of the other odd electron molecule fluorides and O_2F_2. It is therefore feasible that this interaction is retained when $FClO_2$ reacts with AsF_5 and SbF_5, causing no alteration in the ClO bond order as evidenced by the vibrational spectrum.

Attempts to investigate the vibrational spectra of the red chloryl compounds have not been too successful since these compounds are far more reactive. No satisfactory spectra have yet been obtained.

AND

S. P. TYFIELD
Department of Chemistry, University of Toronto, Toronto, Ontario

Received July 23, 1969

Hexacarbonylrhenium perchlorate, $[Re(CO)_6]ClO_4$, reacts on heating above 120° with 1,2-bis(diphenylphosphino)ethane and with triphenylphosphine to form respectively $[Re(CO)_4(Ph_2C_2H_4PPh_2)]ClO_4$ and *trans*-$Re(CO)_3(PPh_3)_2Cl$. The stereochemistry of *trans*-$Re(CO)_3(PPh_3)_2Cl$ was established by dipole moment and infrared measurements. Other phosphines failed to yield clean products. The reactions of phosphines and other ligands with $[Re(CO)_6]ClO_4$ are discussed, in particular the reaction with triphenylphosphine in which the perchlorate is reduced to chloride and incorporated by rhenium to form *trans*-$Re(CO)_3(PPh_3)_2Cl$.

Canadian Journal of Chemistry, 47, 4627 (1969)

Introduction

The substitution reactions of the neutral (1), and to a lesser extent, the anionic metal carbonyls (2) have received considerable attention, but little work has been reported of the reactions of the metal carbonyl cations (3). The first binary metal carbonyl cation $[Re(CO)_6]^+$ was reported by Hieber and Kruck in 1961 (4). Hitherto the investigation of the lability and extent of carbonyl substitution of $[Re(CO)_6]^+$ by both neutral and ionic ligands has been limited to the substitution by a tridentate arsine, v-triars, to form $[Re(CO)_3$-v-triars$]^+$ (5), by several carbonylate anions to form mixed metal–metal carbonyls (6), and by $H_2{}^{18}O$ in acid media whereupon oxygen exchange occurs (7). The reactions of the perchlorate salt of $[Re(CO)_6]^+$ with a number of phosphorus(III). and other ligands are described. Part of this work has been previously reported (8).

Results

The reaction of hexacarbonylrhenium perchlorate with 1,2-bis(diphenylphosphino)ethane (diphos) produced, on heating in cyclohexanone above 120°, the substituted carbonyl cation $[Re(CO)_4$diphos$]ClO_4$. Alternatively this salt may be obtained by high pressure carbonylation of *cis*-$Re(CO)_3$(diphos)Cl in the presence of aluminum chloride, followed by precipitation of the perchlorate from an aqueous-methanol solution. Recently an analogous carbonylation reaction has been used to prepare some $[Re(CO)_4L_2]^+$ cations, where L_2 is an olefin–phosphine chelating ligand (9).

The $[Re(CO)_4$diphos$]ClO_4$ is a white, air stable salt (1:1 electrolyte in nitrobenzene). Its infrared spectrum in the terminal carbonyl stretching region consists of four bands characteristic of octahedral *cis*-$ML_2(CO)_4$ (10) species. There are also present bands assignable to uncoordinated perchlorate (11) at 1100 (s, broad), 937 (w), and 634 cm^{-1} (m).

In contrast, triphenylphosphine reacts in diglyme or cyclohexanone with $[Re(CO)_6]ClO_4$ to form a neutral complex, the previously unreported *trans*-$Re(CO)_3(PPh_3)_2Cl$. The *cis* isomer is well known (12). The product was characterized by elemental analysis, conductimetry, dipole moment measurements, mass and infrared spectroscopy, and a molecular weight determination.

The stoichiometry of the triphenylphosphine reaction was found to be as follows

$$[Re(CO)_6]ClO_4 + 5\ PPh_3 \rightarrow Re(CO)_3(PPh_3)_2\ Cl + 2\ CO + CO_2 + 3\ PPh_3O$$

The carbon dioxide was estimated by absorption by lithium hydroxide, and the triphenylphosphine oxide produced was determined spectrophotometrically in acetonitrile by use of the intense ν_{P-O} absorption at 1185 cm^{-1}.

The source of the chlorine in the product is the perchlorate, which was confirmed by using ^{36}Cl labelled perchlorate. A radiochemical count of the product showed that incorporation of ^{36}Cl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was essentially quantitative. This confirms that in the absence of chlorine containing solvents, there was no other source of chlorine present in the starting material besides perchlorate.

The reactions of other phosphines, such as trisdimethylaminophosphine, triethyl and tri-*n*-butyl phosphines, as well as trimethyl and triphenyl phosphites with $[Re(CO)_6]ClO_4$ were studied. In no case was it possible to isolate clean products, although their identity could be tentatively assigned by comparison with the products of the reaction of the ligands with $Re(CO)_5Cl$. Among the products obtained from the latter reactions were *trans*-$Re(CO)_3(Tdp)_2Cl$ and *cis*-$Re(CO)_2L_3Cl$, where L is $P(OPh)_3$, PPh_2Me, and PPh_2H. Phosphorus trichloride failed to react with $[Re(CO)_6]ClO_4$.

The reaction with aliphatic nitrogen ligands, namely piperidine and tetramethylethylenediamine, resulted in the isolation of rhenium carbonyl. With both pyridine and α,α'-bipyridyl a variety of products was obtained, of which rhenium carbonyl and respectively *cis*-$Re(CO)_3py_2Cl$ or *cis*-$Re(CO)_3BipyCl$ were isolated. Continued refluxing of $Re(CO)_5Cl$ with pyridine failed to yield a dicarbonyl derivative, $Re(CO)_2py_3Cl$.

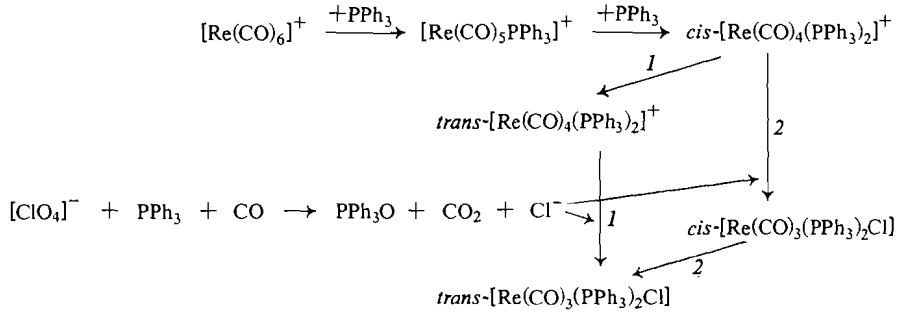
Discussion

It was considered at the outset of this study that the $[Re(CO)_6]^+$ cation would react in an analogous manner to the isoelectronic neutral tungsten hexacarbonyl, suitably modified by the presence of a formal positive charge on rhenium. It appears that the higher metal carbonyl stretching frequencies (13, 14) and the lower intensity of the T_{1u} vibration (15) of $[Re(CO)_6]^+$ compared with $W(CO)_6$ are consistent with poorer metal–carbonyl π back donation for the cation (16). This has recently been substantiated by a Raman intensity study (17). If the metal–carbonyl bond fission is crucial in carbonyl substitution reactions, then the $[Re(CO)_6]^+$ would be more readily substituted than $W(CO)_6$ on the basis that reduced M—CO π-bonding corresponds to reduced overall M—CO bonding (16). In fact it was found that $[Re(CO)_6]^+$ was reluctant to lose carbon monoxide and required forcing conditions, as does tungsten hexacarbonyl. However, it is not possible to meaningfully compare the reactivities of $[Re(CO)_6]^+$ and $W(CO)_6$ without kinetic data, which was not obtainable due to the absence of a suitable solvent for $Re(CO)_6ClO_4$. These results prompted us to study the whole vibrational spectrum of $[Re(CO)_6]^+$, which we have already reported (18). This work yielded the surprising result that the tungsten–carbon stretching force constants were almost identical.

The perchlorate anion was chosen because of its poor tendency to complex, stability to reduction (19), and ease of isolation of $[Re(CO)_6]ClO_4$. The salt is thermally stable, only exploding on heating above 180°. It may be kept indefinitely in air or light and is hygroscopic. It was dried before use.

The reaction between diphos and $[Re(CO)_6]ClO_4$ is analogous to that of $W(CO)_6$ (20) to form $[Re(CO)_4diphos]ClO_4$. With triphenylphosphine or any other unidentate phosphorus (III) ligand, a neutral rhenium pentacarbonylchloride derivative is formed. The stoichiometry of the triphenylphosphine reaction indicates that the phosphine is largely responsible for the reduction of perchlorate, but carbon dioxide is formed, presumably by oxidation of displaced carbon monoxide. When triphenylphosphine and sodium perchlorate were heated in diglyme under analogous reaction conditions (130°, 2–3 h in N_2 atmosphere), both phosphine oxide and chloride ion were detected, but the reaction is slow. Diglyme is not oxidized under these conditions. This suggests that the rhenium complex may be important in the perchlorate reduction. The involvement of rhenium is possible in view of the fact that triphenylphosphine oxide may be complexed to rhenium carbonyl chloride (21) and tungsten hexacarbonyl (22), and the oxide can be displaced from the tungsten complex by PPh_3. Further perchlorate complexes are known for a number of metals (23). The reaction of triphenylphosphine oxide with $[Re(CO)_6]ClO_4$ failed to produce a stable product, although carbon monoxide was displaced.

A reaction scheme for the PPh_3 reaction remains unresolved, although several plausible paths may be suggested in the light of further observations. Firstly, *trans*-$[Re(CO)_4(PPh_3)_2]ClO_4$, a possible reaction intermediate, reacts under analogous conditions to those used for $[Re(CO)_6]ClO_4$ with PPh_3 to form *trans*-$Re(CO)_3(PPh_3)Cl$. Attempts to prepare *trans*-$[Re(CO)_4(PPh_3)_2]ClO_4$ by using a stoichiometric amount of PPh_3 with $[Re(CO)_6]ClO_4$ resulted in



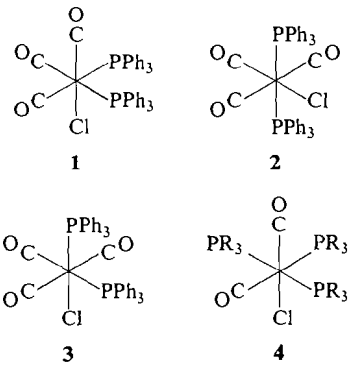
SCHEME 1

the incomplete conversion to the *trans*-chloride. Further, if *cis*-$Re(CO)_3(PPh_3)_2Cl$ is heated with triphenylphosphine under the same conditions, thermal isomerization to the *trans* isomers occurs, as is reported for the iodide (24).

Scheme 1 is tentatively proposed. Either or both routes *1* or *2* may be involved.

The reactions of trimethyl and triphenyl phosphites, trisdimethylaminophosphine (Tdp), and several alkyl phosphines with $[Re(CO)_6]ClO_4$ appear to occur analogously to the triphenylphosphine reaction to produce substituted rhenium chlorocarbonyl complexes. Although these compounds were not isolated, their identity was established by comparison with the infrared spectra of the products of the reaction of the ligands with $Re(CO)_5Cl$. With triphenylphosphite both *cis*-$Re(CO)_2(P(OPh)_3)_3Cl$ and *cis*-$Re(CO)_3[P(OPh)_3]_2Cl$ are obtained, as is reported for the reaction with $Re(CO)_5I$ (24). All the chlorocarbonyl products contained *cis* configuration of carbonyls with the one exception of trisdimethylaminophosphine reacting with $Re(CO)_5Cl$ and $[Re(CO)_6]ClO_4$ to form *trans*-$Re(CO)_3(Tdp)_2Cl$. This has a similar infrared spectrum to *trans*-$Re(CO)_3(PPh_3)_2Cl$ and a well resolved 1:2:1 triplet proton resonance, consistent with the *trans* disposition of phosphines (25).

The stereochemistry of *trans*-Re $CO)_3(PPh_3)_2$-Cl was elucidated from its infrared spectrum and dipole moment. There are three isomers of $Re(CO)_3(PPh_3)_2Cl$ which are, in terms of the carbonyls, one *cis* and two *trans* isomers (**1**, **2**, and **3**). The *cis* and the *trans* isomers may be distinguished by inspection of their infrared-active carbonyl stretching absorptions. The *cis* should give rise to three strong bands (2 A' + A''), while the *trans* forms should show two strong bands ($A_1 + B_1$) and a higher energy band of low intensity (A_1). (See Figs. 1 and 2).



The rhenium–chlorine stretching vibration may be used to distinguish the two *trans* isomers. It has been noted that the metal–chlorine stretching frequency in octahedral (26 and references therein) and square planar complexes (27 and references therein) is markedly influenced

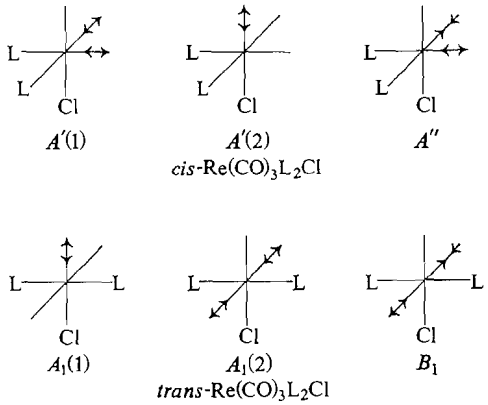


FIG. 1. Normal modes of stretching vibrations of *cis*- and *trans*-$Re(CO)_3L_2Cl$.

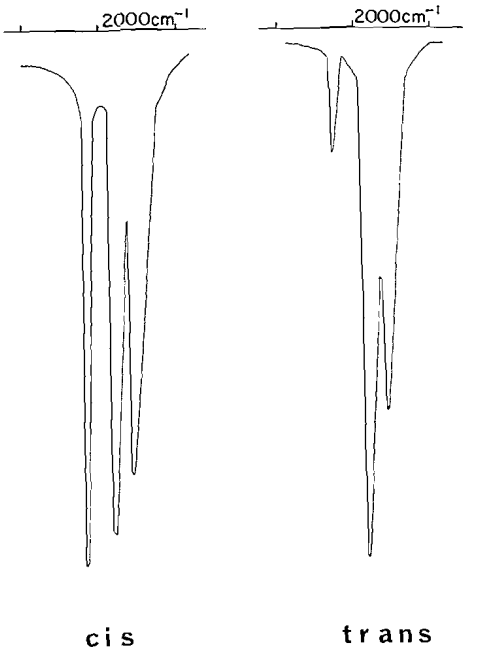

FIG. 2. Chloroform solution spectra of *cis*- and *trans*-$Re(CO)_3(PPh_3)_2Cl$.

by the *trans* ligand. For example the Pt—Cl stretching band is reduced in the order of *trans* ligand CO > R_3P. The effect is appreciable, so that for the $[PtLCl_3]^-$ (27), $\nu_{Pt-Cl} = 322$ cm^{-1} (Cl *trans* to CO), $\nu_{Pt-Cl} = 279$ cm^{-1} (Cl *trans* to PPh_3). A comparison of the ν_{Re-Cl} of *cis*- and *trans*-$[Re(CO)_3(PPh_3)_2Cl]$ and $Re(CO)_5Cl$ (28) at 281, 275, and 294 cm^{-1}, respectively, indicates that the unique carbonyl of the *trans* isomer is *trans* to a chlorine rather than the phosphine, that is, type **2**.

The stereochemistry is confirmed by a dipole moment study, Table I. The dipole moment of *trans*-$Re(CO)_3(PPh_3)_2Cl$ is close to that of $Re(CO)_5Cl$ (3.4 and 2.5 D, respectively) when compared to that of *cis*-$Re(CO)_3(PPh_3)_2Cl$ (7.2 D). By Chatt's method of estimating dipole moments (29), the isomer type **2** is the only form consistent with a dipole moment of the same magnitude as $Re(CO)_5Cl$. Both *cis* (type **1**) and the other *trans* isomer (type **3**) would have greater values. The corresponding manganese complexes have been studied by Angelici *et al.* (30). It is interesting to note that *trans* complexes of manganese are readily formed from their *cis* isomers whereas, with the notable exception of *cis*-$Re(CO)_3(PPh_3)_2Cl$,

cis-$Re(CO)_3(P(OPh)_3)_2Cl$	5.22
cis-$Re(CO)_3(PPh_3)_2Cl$	7.27
trans-$Re(CO)_3(PPh_3)_2Cl$	2.54

the rhenium *cis* complexes are found not to isomerize or else to be further substituted to *cis*-$Re(CO)_2L_3Cl$, type **4**.

Similarly, the *cis* configuration of *cis*-$Re(CO)_2(PPh_2H)_3Cl$ was established by infrared spectroscopy to have a configuration of type **4**. The values of ν_{CO} and ν_{ReCl} are presented in Tables II and III.

The proton nuclear magnetic resonance (n.m.r.) of *cis*-$Re(CO)_3(PPh_2Me)_2Cl$ (31 and references therein) and *cis*-$Re(CO)_3(PPh_2H)_2Cl$ (32) give rise to symmetrical doublets as expected for simple splitting of the hydrogen resonances by a single ^{31}P nucleus, supporting the type **1** stereochemistry. *cis*-$Re(CO)_3(P(OMe)_3)_2Cl$ gives a symmetric triplet band in which the outer resonances are more intense than the central resonance, as is noted for *cis*-$Mo(CO)_4(P(OMe)_3)_2$ (33). ^{31}P spectra were precluded by the low solubility of the complexes.

The mass spectra of *cis*- and *trans*-$Re(CO)_3(PPh_3)_2Cl$ were run to see if there was any difference in the cracking pattern. In fact, the spectra are identical. Very strong peaks for PPh_3 and PPh_3O are obtained with faint peaks at high mass for some rhenium-containing fragments. There are no molecular ions (P) observed, but $(P—CO)^+$, $(P—2CO)^+$, $(Re(PPh_3)Cl)^+$, and $Re(\langle\bigcirc\!\!\bigcirc\!\!\bigcirc\!\!\bigcirc\rangle_P)^+$ are of appreciable intensity. Further, there are weak peaks at *m/e* 744 (P − 300), 666 $(744 - C_6H_6)^+$, 588 $(666 - C_6H_6)^+$, and 538 $(Re(CO)_2(PPh_3)_2Cl)^+$.

The various stereochemistries of the rhenium chlorocarbonyl complexes prepared in this study may be rationalized in terms of the *trans* directive effect of ligands which favor the formation of *cis* carbonyl complexes (1, 12), and the steric effect of the substituting ligands which favor the

formation of stable, *trans* disubstituted tricarbonyl chloride complexes, particularly for triphenylphosphine. The reason for the formation of rhenium carbonyl on reaction with nitrogen ligands remains unclear at present.

Experimental

Infrared spectra were recorded on Perkin–Elmer 225 and 247 spectrophotometers, ^1H n.m.r. spectra were recorded on Varian A60 and HA-100 spectrophotometers using TMS as an internal reference for $CDCl_3$ solutions. Elemental analyses were carried out by the Microanalytical Laboratory of Bristol University. Melting points are uncorrected and determined by means of an electrothermal melting point apparatus. Conductivities were measured in AnalaR nitrobenzene by use of a Cambridge conductivity bridge. Dipole moments in benzene and mass spectral results were determined by ICI Petrochemical and Polymer Laboratories, Runcorn.

All reactions were conducted under a nitrogen atmosphere.

Hexacarbonylrhenium perchlorate was prepared from pentacarbonylrhenium, aluminum trichloride, and carbon monoxide using methods in literature (4, 5). The $[Re(CO)_6]ClO_4$ was precipitated from chilled water by the addition of 60% perchloric acid, washed with ether, and dried in vacuo. Yields were high (90%).

The other reagents used were commercial samples or were prepared according to methods in literature.

A. Preparation of 1,2-Bis(diphenylphosphino)-ethanetetracarbonylrhenium(I) Perchlorate

(*i*) Hexacarbonylrhenium perchlorate (0.5 g, 1 mole) and 1,2-bis(diphenylphosphino ethane) (0.88 g, 2 moles) were heated (120°, 1 h) in cyclohexanone (15 ml). The product was precipitated by the addition of ether and recrystallized from acetone–ether.

Anal. Calcd. for $C_{30}H_{24}O_8P_2ClRe$: C, 45.2; H, 3.0; O, 16.1. Found: C, 45.15; H, 3.3; O, 15.8.

$\Lambda_{0.001\ M}(C_6H_5NO_2) = 19.5\ ohm^{-1}\ cm^2\ mole^{-1}$. It decomposes at 205° without exploding. The salt is soluble in polar solvents including chloroform, insoluble in benzene, carbon tetrachloride, and ether. It appears to be indefinitely stable in air.

(*ii*) *cis*-Chloro-1,2-bis(diphenylphosphino)ethanetricarbonylrhenium (1 g, 1 mole) and aluminum trichloride (1 g, 6 moles) with benzene (3 ml) were autoclaved with carbon monoxide (350 atm) for 30 h (75°). The product was hydrolyzed and extracted with chilled water (15 ml), washed with ether, and recrystallized from acetone–ether (0.6 g, 53% yield).

Anal. Calcd. for $C_{30}H_{24}O_8P_2ClRe$: C, 45.2; H, 3.0. Found: C, 45.6; H, 3.0.

B. Preparation of trans-Chlorobis(triphenylphosphine)-tricarbonylrhenium

(*i*) Hexacarbonylrhenium perchlorate (0.4 g, 1 mole) and triphenylphosphine (1.2 g, 5 moles) in diglyme (10 ml) were heated (130°, 2–3 h) until carbon monoxide ceased to evolve and product precipitated out. The reaction is slow to start and results in the gradual dissolution of starting materials, which eventually dissolve completely. The white product was collected on cooling,

washed with ether (15 ml), recrystallized from chloroform–pentane (0.49 g, 54% yield).

Anal. Calcd. for $C_{39}H_{30}O_3P_2ClRe$: C, 56.4; H, 3.6; Cl, 4.3. Found: C, 55.9; H, 3.9.

The solid decomposes above 230°. Molecular weight found[1] 829.6, required 829.8. $\Lambda_{0.001\ M}(C_6H_5NO_2)$ = 0.33 $ohm^{-1}\ cm^2\ mole^{-1}$.

(*ii*) *trans*-Bis(triphenylphosphine)tetracarbonylrhenium perchlorate (0.25 g, 1 mole), prepared by the literature method (34), and triphenylphosphine (0.29 g, 4 moles) were reacted under the same conditions as (*i*).

Found: C, 55.7; H, 3.4; Cl, 4.3.

(*iii*) *cis*-Chlorobis(triphenylphosphine)tricarbonylrhenium (0.3 g, 1 mole) and triphenylphosphine (0.2 g, 2 moles) were heated (150°) under nitrogen or in vacuo for 2 h. The product was washed with ether (10 ml) and recrystallized from chloroformpentane.

Found: C, 55.8; H, 3.5.

C. Reaction of Hexacarbonylrhenium Perchlorate with Other Ligands

The reaction of hexacarbonylrhenium perchlorate with a variety of phosphines and phosphites, that only yield infrared spectral evidence of the nature of the products, are listed in Table IV. The reactions of several other ligands are included. Authentic rhenium carbonyl chloride derivatives were prepared from chloropentacarbonylrhenium by treatment with excess ligand in diglyme (12, 24).

The unreported $Re(CO)_3L_2Cl$ complexes prepared from $Re(CO)_5Cl$ were characterized. Infrared and ^1H n.m.r. results are reported in Tables II, III, and V. Elemental analyses of complexes are given in Table VI.

D. The Investigation of the Reaction of Triphenylphosphine with Hexacarbonylrhenium Perchlorate

(i) Production of Triphenylphosphineoxide

The quantity of PPh_3O produced in *B*(*i*) was determined by use of the intense P—O stretching vibration ($\nu_{P—O}$ = 1185 cm^{-1}, CH_3CN solution). After the reaction *B*(*i*), for which PPh_3 was checked to be free of PPh_3O, the diglyme solution was dried in vacuo and the solid dissolved in acetonitrile. Comparison with a standard plot of intensity of the band vs. concentration showed that approximately 3 ± 0.5 moles of PPh_3O were produced per mole of $[Re(CO)_6]ClO_4$.

(ii) Production of Carbon Dioxide

The CO_2 evolved in reaction *B*(*i*) was estimated gravimetrically by absorption on Lithasorb (LiOH). Approximately 1.0 ± 0.1 mole of CO_2 was collected per mole of $[Re(CO)_6]ClO_4$.

(iii) Incorporation of ^{36}Cl into trans-$Re(CO)_3(PPh_3)_2Cl$

The reaction *B*(*i*) was repeated using a sample of ^{36}Cl labelled perchlorate, obtained by equilibrating $K^{36}ClO_4$ (from the Radiochemical Centre, Amersham) with $[Re(CO)_6]ClO_4$ in nitromethane. $[Re(CO)_6]^{36}ClO_4$ was obtained by taking the filtered nitromethane solution to dryness in vacuo. The product was counted in acetonitrile solution. After repeating reaction *B*(*i*) with $[Re(CO)_6]^{36}ClO_4$, the product precipitated on cooling, and was washed with ether, dried in vacuo, and counted in acetonitrile solution.

Specific activities were recorded using a 20th Century

Spin–lattice relaxation of 1,2-dichloroethane in different solvents[1]

E. BOCK
Parker Chemistry Laboratory, University of Manitoba, Winnipeg, Manitoba

AND

E. TOMCHUK
Department of Physics, University of Winnipeg, Winnipeg, Manitoba

Received June 11, 1969

The spin–lattice relaxation time of the 1,2-dichloroethane molecule has been determined in 6 different nonmagnetic or weakly magnetic solvents at 20 °C, *viz*: deuterated benzene, carbon disulfide, deuterated 1,2-dichloroethane, carbon tetrachloride, and deuterated chloroform. From the experimental results the relaxation rate in infinitely dilute solution, the so called intramolecular relaxation rate, was determined for each solvent. It was found that the observed intramolecular relaxation rate could be successfully interpreted as arising solely from a dipole–dipole relaxation mechanism. It was further found that the individual differences in the value of the intramolecular spin–lattice relaxation rate of the 1,2-dichloroethane molecule in different solvents could be accounted for in terms of weak complex formation between the solute and solvent molecules.

Introduction

A number of workers have reported on the anomalous dielectric behavior (enhanced relaxation times and electric dipole moments) of the 1,2-dichloroethane molecule in aromatic and highly polarizable solvents (1–4). All of the work on the microdynamical behavior of the 1,2-dichloroethane molecule in different solvents reported heretofore has been carried out employing dielectric relaxation studies. We thought it, therefore, not inappropriate to repeat and in some cases, to extend some of the earlier investigations using an entirely different method of investigation from the usual dielectric relaxation method, viz. the pulsed nuclear magnetic relaxation method. We are aware of only one paper in the literature, a paper by Linder (5), in which an attempt was made to study the motional properties of the 1,2-dichloroethane molecule in the liquid state. We have reasons to believe that Linder's data are in error. Thus, he reports a spin–lattice relaxation time for pure liquid 1,2-dichloroethane of 0.8–0.6 s in the temperature region from room temperature to the melting point, 234 °K. Furthermore, he attributes the very considerable scatter of his experimental results to the action of light on his samples of 1,2-dichloroethane. We, on the other hand, find that the spin–lattice relaxation time of a carefully degassed sample of liquid 1,2-dichloroethane over the same temperature region varies between 8.35 s at 20 °C and 3.0 s at the melting point, and that of a liquid sample saturated with air has a relaxation time of ~2.6 s at room temperature. Moreover, we did not detect any effect of light on the relaxation time of the sample, not even after the latter was exposed for several h to a mercury ultraviolet lamp or a 500 W projection lamp. Since Linder has not given any details regarding the purity of his molecules or preparation of samples (indeed it is not clear from his description of his experimental procedure whether he did remove dissolved oxygen from his samples), we are not able to give any explanation for the observed discrepancy except to note that any paramagnetic impurity would tend to lower the spin–lattice relaxation time, and that therefore any lowering of the spin–lattice relaxation time may be taken as a certain indication of the presence of impurities in the sample.

In an earlier paper we reported on the spin–lattice relaxation time of 1,2-dichloroethane in deuterated benzene and carbon disulfide (6). In this paper we have extended our earlier work and report on the spin–lattice relaxation of 1,2-dichloroethane molecule in 4 additional solvents, viz. chloroform-*d*, acetone-d_6, 1,2-dichloroethane-d_4, and carbon tetrachloride.

Experimental

Solvents

All deuterated solvents (isotopic purity 99–99.5%) were obtained from Merck, Sharp, and Dohme of Canada, Ltd. and were used without further purification.

[1]Presented in part at the XXII International Congress of Pure and Applied Chemistry, Sydney, Australia. August 20–27, 1969.

TABLE I

Extrapolated values of T_1^{-1} for 1,2-dichloroethane molecule in different solvents, and the viscosity, η, dipole moment, μ, and density, d, of the different solvents at 20 °C

Solvent	$T_{0_1}^{-1}$ ($s^{-1} \times 10^2$)	η (cP)	μ (D)	d (g/cm^3)	δ* ($s^{-1} \times 10^2$)
Benzene-d_6	3.19	0.652	0	0.8790	0.44
Chloroform-d	5.77	0.563	1.01	1.4916	0.58
Acetone-d_6	4.92	0.325	2.86	0.7908	0.49
1,2-Dichloroethane-d_4	7.94	0.833	1.6	1.2564	0.42
Carbon tetrachloride	5.27	0.965	0	1.5942	0.71
Carbon disulfide	1.44	0.367	0	1.2628	0.72

*δ is the standard deviation from the straight-line plot of the experimental data.

The carbon disulfide, Fisher certified reagent, was purified using a standard purification method (7). The carbon tetrachloride, *spectro-quality reagent*, was obtained from Matheson, Coleman, and Bell Co., and was used without further purification.

Solute

The 1,2-dichloroethane was obtained from Eastman Organic Chemicals. It was redistilled once under reduced pressure and stored in a dark bottle.

Apparatus and Procedure

The spin–lattice relaxation time of all samples was determined at 20 ± 0.1 °C on a PS-60A NMR Specialties pulsed nuclear magnetic resonance (n.m.r.) spectrometer using a 180–90° pulse sequence (8). All experimental solutions were carefully degassed by repeated (8 or more) freeze–pump–thaw cycles. Further details of the experimental procedure are described elsewhere (6, 9).

Results and Discussion

The experimental results are summarized in Table I. Included in this Table are the pertinent properties of the different solvents, containing protons in natural abundance, viz. viscosity, electric dipole moment, and density. Also included is the standard root-mean-square deviation, δ, of the experimental points from a straight-line plot of the form $T_1^{-1} = T_{0_1}^{-1} + Cx$, where T_1^{-1} is the reciprocal of the measured spin–lattice relaxation time T_1, $T_{0_1}^{-1}$ is the reciprocal of the extrapolated value of T_1^{-1}, i.e. the intramolecular contribution to the relaxation rate, C is a constant, and x the mole fraction of the solute in solution. The extrapolated value of T_1^{-1}, $T_{0_1}^{-1}$, was then used, following a slightly modified method of Powles (10) to calculate a molecular reorientation time, τ_r. The modification consisted of treating all protons in the calculation of the constant A in eq. [1], below, as equivalent protons. This modification is applicable in all those cases where an average response only is recorded from chemically shifted protons, as pointed out by Goldammer and Zeidler (11)

$$[1] \qquad T_{0_1}^{-1} = A\tau_r$$

$$[2] \qquad A = \frac{\hbar^2\gamma^4}{2n}\sum_{i=1,i\neq j}^{n}\sum_{j=1,i\neq j}^{n} d_{ij}^{-6}$$

Here $\hbar$ is Planck's constant; γ, magnetogyric ratio of the proton; n, number of protons per molecule; and d_{ij}, distance between proton i and proton j.

The required structural data for the calculation of d_{ij} were taken from the literature (12). The thus calculated values of τ_r are summarized in Table II. From a perusal of Table II it is clear that the different values of τ_r in the different solvents cannot be accounted for solely in terms of the different viscosities of the various solvents. Thus, acetone has a viscosity which is somewhat lower than that of CS_2, yet τ_r in acetone is approximately 3 times that in CS_2. In order to facilitate the comparison of the different τ_r values we have "normalized" the latter by the following procedure. The τ_r value in CS_2, a liquid which we regard for the sake of this comparison as an "inert" liquid, was multiplied by the ratio of the viscosity of a particular solvent to that of carbon disulfide. The resulting value, designated as τ_r' in Table II, may then be regarded as the reorientation time that the solute molecule would have if in the absence of solute–solvent interactions its reorientation were hindered by viscous forces only. Such an analysis of the experimental data is a reasonable one, since it is expected on the basis of the simple Debye theory for disorientation of electric dipoles that τ_r be proportional to the viscosity of the medium, η (13). It is true that more elaborate expressions for τ_r have been proposed from time to time in the literature (14), in which the bulk viscosity is replaced by a so-called empirical viscosity and which, in addition, con-

Carbon disulfide	1.57	1.57	—	—

tain a structure factor which reflects the role of the solvent. However, in the absence of any detailed knowledge of either the empirical viscosity or the structural factor, it may be permissible to analyze the data in terms of the albeit approximate but much simpler Debye expression. The corrected, or normalized, values of τ_r may now be used to further analyze the experimental data. Thus according to Eyring's theory of rate processes, the relaxation time of a process is connected with the activation free energy ΔG^* for that process by the expression

$$[3] \qquad \tau = Ae^{\Delta G^*/RT}$$

Here ΔG^* is the free energy of activation; R, the gas constant; T, the absolute temperature; and A, a constant. If it is assumed that both reorientation times, τ_r, the measured reorientation time, and τ_r', the corrected reorientation time, obey an expression of the form of eq. [3], then the ratio of τ_r/τ_r' should yield the difference between the free energy of activation for the 2 reorientation processes, viz. the reorientation process that actually takes place in the particular solvent and the reorientation process which would take place in the same solvent if the processes were governed only by the viscosity of the solvent. The values of the difference in the free energy of activation for the 2 processes, designated as $\Delta\Delta G^*$, calculated with the aid of eq. [3] are summarized in Table II. It is interesting to note that the largest values of $\Delta\Delta G^*$ are found for those solvents the molecules of which possess permanent electric dipole moments, and that the values of the $\Delta\Delta G^*$'s roughly parallel the magnitude of the electric dipole moment of the solvent molecules. Moreover, if a rough estimate is made of the solute–solvent electric dipole–dipole interaction energy using the well known expression

$$[4] \qquad 2\mu_A\mu_B/r^3 = E$$

where μ_A and μ_B are the dipole moment of the solute and solvent molecule, respectively, and r is the distance between the 2 interacting dipoles, there results an interaction energy which is very nearly equal to the difference in the activation free energy $\Delta\Delta G^*$ of the 2 processes. (See last column of Table II.)

The values of r in eq. [4] were estimated from the known densities of the various liquids, assuming close packing of the spheres in the liquid. From the rather close agreement of the $\Delta\Delta G^*$ values and the dipole–dipole interaction energy values, it would appear that the main retarding mechanism of molecular reorientation of polar molecules in a polar solvent is the dipole–dipole interaction between the dipole moments of the solute and solvent molecules.

The calculated values of $\Delta\Delta G^*$ for the 2 nonpolar solvents, i.e., benzene and carbon tetrachloride, may be rationalized in terms of specific solute–solvent interactions in the case of benzene, and in terms of the large bond polarizability of the C—Cl bond and the relatively large number of such bonds per molecule in the case of the carbon tetrachloride.

That benzene in particular, and aromatic solvents in general, interact with the 1,2-dichloroethane molecule is well known. Thus, Chitoku and Higasi (1) concluded from their work on the dielectric relaxation of 1,2-dichloroethane in

TABLE III
Comparison of dielectric, τ_D, and magnetic, τ_r, relaxation times of 1,2-dichloroethane in different solvents

Solvent	τ_r (ps)	τ_D (ps)	η (cP)

benzene, *p*-xylene, and other nonpolar solvents, that the *gauche* conformer of 1,2-dichloroethane forms a 1:1 complex with aromatic solvents. There are also a number of infrared studies (15) and dipole moment studies (1) which support this conclusion, viz., that aromatic solvents do interact preferentially with the 1,2-dichloroethane molecule. Our results, obtained by yet another method, are in general agreement with these conclusions.

In the case of carbon tetrachloride it is not too difficult to imagine that the extra hindrance to molecular reorientation of the 1,2-dichloroethane molecule arises from dipole – induced-dipole type of interaction, or, in general, as the result of the polarizability of the C—Cl bond. From nuclear magnetic resonance work on chemical shifts of different haloethanes and other molecules in different solvents, including CCl_4, it is known that CCl_4 is far from being an inert solvent. Thus McClellan and Nicksic (16), who investigated the chemical shift of a large number of haloethanes in CCl_4, conclude that these molecules i.e., the haloethanes, exhibit not only self-association, but that they also form loose complexes with the CCl_4 by perhaps forming hydrogen bonds between the chlorine atoms of the CCl_4 and the protons of the haloethane molecules. Our results support both of these conclusions. For we do find that both the molecular reorientation time and $\Delta\Delta G^{\ddagger}$ are exceptionally large when deuterated 1,2-dichloroethane is used as the solvent, and that in the case of CCl_4 both of these quantities are significantly larger than is the case for CS_2.

In conclusion, it is interesting to note that our values for the molecular reorientation time in benzene and carbon disulfide are in fair agreement with those reported by Chitoku and Higasi (1) which they derived from dielectric relaxation studies, viz., 3.43×10^{-12} s and 3.69×10^{-12} s, respectively, for benzene and 1.57×10^{-12} s and 1.56×10^{-12} s, respectively, for carbon disulfide, where the last quoted value represents the "viscosity corrected" value of Chitoku and Higasi in *n*-hexane solution. The close agreement between our values and those obtained by dielectric relaxation methods suggests that the intramolecular nuclear magnetic relaxation mechanism is dominated by the dipole–dipole relaxation mechanism and that other mechanisms such as spin–rotation relaxation mechanisms are of minor importance. Although our values of τ_r for benzene and carbon disulfide are in fair agreement with the dielectric relaxation results of Chitoku and Higasi, it is only proper to also point out that there is no agreement between our value of τ_r in CCl_4 (5.74×10^{-12} s) and their value (2.15×10^{-12} s) in the same solvent. We confess that we are at a loss to explain this discrepancy. Intuitively, one would expect that collisions between CCl_4 and 1,2-dichloroethane molecules, because of the large polarizability of the C—Cl bond, would be much more "sticky" than collisions between a cyclohexane molecule and a 1,2-dichloroethane molecule, and we would therefore expect that the reorientation time of the 1,2-dichloroethane molecule in CCl_4 should be much longer than in cyclohexane. However, Chitoku and Higasi, who measured the dielectric relaxation of 1,2-dichloroethane molecule in both solvents, found almost identical reorientation times, viz., 2.15×10^{-12} s in CCl_4 and 2.16×10^{-12} s in cyclohexane.

Salting-in and salting-out of polar nonelectrolytes

J. E. DESNOYERS AND F. M. ICHHAPORIA
Département de Chimie, Université de Sherbrooke, Sherbrooke, Québec
Received July 14, 1969

The solubility of toluene and benzaldehyde was measured in NaBr and $(n\text{-Pr})_4$NBr aqueous solutions at 25 °C, and the solubility of benzoic acid and nitrobenzene was measured in the same systems at 10, 25, and 40 °C. The apparent molal volumes of the four nonelectrolytes were also determined from the densities of the saturated aqueous solutions.

The volumes of mixing of the nonelectrolytes in water are all negative but become less so as their polarity increases. With the exception of benzoic acid, the salting-out by NaBr and the salting-in by $(n\text{-Pr})_4$NBr both decrease with increasing polarity of the nonelectrolytes. Both salting effects increase with temperature. These trends can be explained with existing theories of salting-out and salting-in.

Introduction

In previous studies (1, 2) on the solubility of nonelectrolytes in salt solutions, the influence of ionic hydration and size of the nonelectrolytes were investigated; it was suggested that the salting-out effect was primarily electrostatic in nature, while salting-in by hydrophobic ions was caused mainly by structural hydration attractive forces. More recent work (3–5) on structural interaction in aqueous electrolyte solutions has shown that solvent-induced attractive forces exist between two hydrophobic solutes and repulsive forces between an hydrophobic solute and an hydrophilic one. Consequently, it is most probable that structural interactions are also involved in the salting-out of nonelectrolytes by hydrophilic salts.

Most of the recent studies on the salting effects have been restricted to nonpolar nonelectrolytes. Apart from the compilations of Long and McDevit (6), few correlations between the salting effects and the polarity of the nonelectrolyte have been attempted, especially in the case of hydrophobic salts. In order to establish meaningful relations, it is important that the polar nonelectrolytes be similar in nature and size and have low solubilities (to minimize self-interactions (6)). The four benzene derivatives, i.e., toluene, benzoic acid, benzaldehyde, and nitrobenzene, should fulfil these conditions. As typical hydrophilic and hydrophobic salts, sodium bromide and tetrapropylammonium bromide were chosen. The temperature dependence of the salting constants were also determined in two cases (nitrobenzene and benzoic acid).

To determine the effective size of the nonelectrolytes in solution, their apparent molal volumes were measured from the density of the saturated solutions.

Experimental

Tetrapropylammonium bromide, sodium bromide, and benzoic acid were of Baker Analyzed Reagent Grade and were used as such after drying under vacuum for 24 h. The nonelectrolytes, nitrobenzene, benzaldehyde, and toluene, were all redistilled, and the fractions collected were those boiling respectively at 210.8 (nitrobenzene), 178.1 (benzaldehyde), and 110.6 °C (toluene).

The salt solutions were saturated with the nonelectrolytes at 25 °C by vigorously agitating them with an excess of nonelectrolyte for 20 h in a constant temperature bath maintained at 25.0 ± 0.1 °C. After equilibrium had been reached, the agitation was stopped and the saturated solutions were left in the bath for another 4 h to attain complete phase separation of the excess nonelectrolyte. Aliquots of the saturated solution were then pipetted out and diluted 1:1, care being taken to submerge the tip of the pipette below the surface of the water to minimize liquid surface exposure. In the case of the saturated solution of benzoic acid, the excess acid was removed by filtration in a specially designed closed system immersed in the bath.

Refractive index measurements using a Waters Model R-4 Laboratory Differential Refractometer were carried out to determine the concentration of the various saturated solutions. Salt solutions of the same concentration as those containing the nonelectrolytes were used in the reference cell, and the rate of flow through both cells was maintained constant. The salting-out by NaCl and the salting-in by $(n\text{-Pr})_4$NBr of benzene were carried out as a check of the technique and the salting-out constant for NaCl and the salting-in constant for $(n\text{-Pr})_4$NBr were, within experimental error, identical with those obtained earlier by an ultraviolet absorption method (2).

The solubilities of the nonelectrolytes in water at 25 °C were determined by extrapolation from a plot of changes of refractive index as a function of known concentration of the solution. From this method, the solubilities obtained at 25 °C are: 0.0588 (toluene), 0.192 (nitrobenzene), 0.757 (benzaldehyde), and 0.337 g/100 ml of water (benzoic acid). As a check of the solubility of benzoic acid, the saturated solution was titrated against standardized

TABLE I

Solubility ratio S/S_0 of benzene derivatives

		S/S_0							
			φCOOH				φNO$_2$		
Salt	c moles l^{-1}	φCH$_3$ 25 °C	10 °C	25 °C	40 °C	φCHO 25 °C	10 °C	25 °C	40 °C

	0.3	1.511	1.510	1.606	1.662	1.259	1.162	1.219	1.254
	0.4	1.684	1.744	1.820	2.004	1.380	1.193	1.288	—
	0.5	1.907	—	2.094	2.301	1.483	1.260	1.372	1.429

NaOH solution. The value (0.331 g/100 ml) agrees satisfactorily with that obtained from the refractive index. The probable error in the determination of solubilities is of the order of 1 to 2%. In all the measurements water was redistilled from an alkaline permanganate solution using an all-glass still and was equilibrated with atmospheric CO_2.

The densities of the saturated solutions, containing a slight excess of nonelectrolyte, were determined with a densimeter (3). Although this technique is in principle capable of high precision ($\pm$ 2 × 10^{-6}g ml^{-1}), the accuracy of the derived apparent molal volume ϕ_v is limited by the uncertainty in the solubility concentration and by the rate of evaporation of the volatile nonelectrolytes. The uncertainty in ϕ_v is probably of the order of $\pm$ 0.05 ml mole^{-1}.

Results and Discussion

The influence of the salt concentration c on the solubility ratio S/S_0 can be expressed at low salt concentration by the relation

$$[1] \qquad \ln S/S_0 = k_s c$$

As written, a positive value for the salting constant k_s indicates salting-in and a negative one, salting-out. The solubility ratios of the four nonelectrolytes studied are given in Table I and the derived k_s in Table II along with the molar and apparent molal volumes and the solubilities of the nonelectrolytes. The molar volume of benzoic acid in the liquid state is not known. The apparent molal volume of benzoic acid was therefore determined in nitrobenzene with a pycnometer. This apparent molal volume is, inside experimental error, independent of concentration and may therefore be taken as the molar volume of "liquid benzoic acid" at 25 °C.

As expected, the volume of mixing, $\Delta V = \bar{V}_{NE} - V$ are all negative and become less so as the polarity of the nonelectrolyte increases. This behavior is consistent with the view that the volume of mixing of nonelectrolytes in water is related to the hydrophobic hydration of the nonelectrolytes (7, 8); as the polarity of the nonelectrolyte increases, the hydrophobic character decreases and so does ΔV.

The salting-out and the salting-in of nonelectrolytes decrease as the dipole moment of the nonelectrolyte increases with the exception of benzoic acid; benzoic acid has the largest salting-out and salting-in constants in spite of the fact that it is much more polar than toluene. The size of the molecules cannot be responsible for this apparent anomaly since all four nonelectrolytes have very similar partial molal volumes. A more plausible explanation is that benzoic acid ionizes in water and that the benzoate ion is much more soluble than the neutral molecule. Any factor which will influence the ionization constant of benzoic acid will consequently also influence its solubility. The present data would therefore suggest that the ionization of benzoic acid decreases in the presence of NaBr and increases with (n-Pr)$_4$NBr. This conclusion is supported by the work of Lucas (9, 10) who has studied the ionization of weak acids and bases in electrolyte solutions and has observed similar trends.

The variation of the salting-out constant ($k_{so} = -k_s$) of the three aprotic nonelectrolytes with their dipole moment is in the order predicted by most electrostatic theories. For example, Conway, Desnoyers, and Smith (1) and Desnoyers and Jolicoeur (4) have suggested that the limiting k_{so} should have two contributions. The first term takes into account the removal, by ions, of water

molecules from their solvent role and is proportional to the volume of the hydrated ion, V_h

$$[2] \qquad k_{hyd} = V_h/1000$$

The second term allows for the distribution of nonelectrolytes and solvent molecules beyond the radius r_h of the hydrated ion; the ion will preferentially attract the more polar molecules.

$$[3] \qquad k_{elect} = \frac{(Ze)^2}{2000\varepsilon_0{}^2 kTr_h}\left(\overline{V}_{NE}\varepsilon_0 - \frac{9}{2}P_{NE}\right)$$

where ε_0 is the dielectric constant of water and $\overline{V}_{NE}$ is the partial molal volume of the nonelectrolyte. The total molar polarization P_{NE} of the nonelectrolyte is related to the dipole moment μ_0 of the nonelectrolyte by an approximate form of the Kirkwood–Onsager theory

$$[4] \qquad \frac{9}{2}P_{NE} \simeq \frac{2}{9}\frac{\pi N}{kT}(n^2 + 2)^2\mu_0{}^2$$

where n is the refractive index of the nonelectrolyte.

Using a reasonable value for the hydration number of NaBr, 4.8 (4), the mean parameters V_h and r_h may be estimated (4). Therefore, from the known $\overline{V}_{NE}$ and μ_0 (Table II), the k_s of the four nonelectrolytes may be estimated at 25 °C and are given in Table II. Although the absolute values do not agree too well, the correct trend with increasing polarity is predicted for the aprotic nonelectrolytes. It therefore seems that the salting-out theory of Conway *et al.* (1) can be used as a rough guide for the salting-out of polar nonelectrolytes.

We should bear in mind, however, that the above treatment ignores all structural interactions, and it has been well established (4, 5) that important structural repulsive forces exist between an hydrophobic (nonelectrolyte) and an hydrophilic solute (electrolyte). This structural hydration contribution is in the same direction as the hydrophilic hydration contribution to k_s (eq. [2]), and it is difficult to distinguish between the two. It is suspected, however, that the high specificity of salting-out to the nature of the ions can be to a large extent attributed to structural interactions.

With the exception of benzoic acid, the salting-in of polar nonelectrolytes by $(n\text{-Pr})_4\text{NBr}$ decreases with the polarity of the nonelectrolyte. This supports the suggestion (2) that salting-in is caused by hydrophobic attractive forces. Short-range attractive forces (van der Waals, charge–dipole, etc.) between the large ions and the nonelectrolytes cannot be the main reason for salting-in, since they usually become more important as the polarity of the nonelectrolyte increases; an increasing k_s with polarity would then be expected. On the other hand, if hydrophobic hydration is involved, the order is predicted correctly; a polar nonelectrolyte will increase the structure of water less than the equivalent nonpolar one and structural salting-in will be less.

The thermodynamic functions of transfer from water to electrolyte solutions are often derived from solubility data (6). Since the solubility ratio S/S_0 is equal to f_0/f (the ratio of the activity coefficients of the nonelectrolyte in water and in the electrolyte solutions) the free energy of transfer is given by

$$[5] \qquad \Delta G_t = -RT \ln \frac{f_0}{f} = -RT \ln \frac{S}{S_0} = -RTk_s c$$

Also, from the Gibbs–Helmholtz equation, the heat of transfer is

$$[6] \qquad \Delta H_t = RT^2 \frac{\mathrm{d}k_s c}{\mathrm{d}T}$$

These functions are not true functions of transfer since the nonelectrolytes are at equal activities in both systems, rather than at equal concentrations. Still, they should not differ too significantly and should yield at least the correct order of magnitude and sign. The ΔH_t estimated from the temperature dependence of k_s were found to be

ϕCOOH–NaBr	− 360	cal mole^{-1}
ϕNO_2–NaBr	− 400	cal mole^{-1}
ϕCOOH–$(n\text{-Pr})_4$NBr	+1900	cal mole^{-1}
ϕNO_2–$(n\text{-Pr})_4$NBr	+1500	cal mole^{-1}

The large positive ΔH_t associated with salting-in are typical of hydrophobic interactions. When a nonelectrolyte is dissolved in water, the structure of water is increased and the heat of solution is negative. However, a solution containing hydrophobic ions is already more structured than water,

and less ordering needs to take place during the dissolution of a nonelectrolyte. The heat of solution will therefore be less exothermic than in water and a positive ΔH_t will result.

A similar simple model cannot be used for the interpretation of ΔH_t from water to alkali halide solutions. Direct calorimetric measurements of ΔH_t of ethyl acetate, nitromethane, and acetic acid (11, 12) from water to alkali halide solutions show that ΔH_t can be positive or negative depending on the particular system studied, and it seems that other factors in addition to structural hydration changes contribute to ΔH_t.

Recently, some of the theories of liquids, e.g. the scaled-particle theory (13), the two-structure model of Ben–Naim (14, 15) and Ben–Naim and Egel–Thal (16), have been successfully applied to the solution of simple gases in electrolyte solutions. These theories account for the dependence of the solubility on salt concentration and for the thermodynamic functions of transfer. It would be most useful to test these theories for a large number of combinations of nonelectrolytes (gases, liquids, and solids) and electrolytes. For example, CsCl sometimes salts-in nonelectrolytes (9, 11), while electrostatic theories predict that this electrolyte should always salt-out nonelectrolytes. Careful solubilities and thermodynamic functions of transfer measurements would also be warranted for a larger variety of salts before the nature of the electrolyte–nonelectrolyte interactions can be fully understood.

Dielectric studies. Part XXV. Methoxy group rotation in anisole and three para-substituted anisoles

D. B. FARMER

Received June 12, 1969

The dielectric absorption at several microwave frequencies of anisole, *p*-methylanisole, and *p*-bromoanisole in the solvent *p*-xylene, and *p*-dimethoxybenzene in the solvent cyclohexane has been investigated at 4 to 6 temperatures. Anisole, *p*-methylanisole, and *p*-dimethoxybenzene were all found to relax mainly by methoxy group rotation, whereas the relaxation process in *p*-bromoanisole was very largely molecular relaxation. In the literature, considerable divergence exists for the analyses of the dielectric data of anisole and substituted anisoles into contributions from two relaxation times and the magnitude of the weight factors governing each relaxation process. Such divergencies have been explored and justifiable analyses established for these systems where the weight factors governing the relaxation processes are shown to be roughly of the same order as those estimated from group moment data. The weight factor for molecular relaxation in the pure liquid appears considerably greater than that for a dilute solution of it in a non-polar solvent.

Canadian Journal of Chemistry, 47, 4645 (1969)

Introduction

Results of dielectric studies on anisole, trifluoromethoxybenzene, and methoxypentafluorobenzene in the solvent cyclohexane at a single temperature have been reported previously and their significance discussed (1). It was found in all the above molecules that there was a contribution to the total dielectric absorption from methoxy or trifluoromethoxy group rotation. It was decided to carry out a further study of molecules containing methoxy groups, particularly on those where group rotation should be the predominant relaxation process, with a view to obtaining more precise values for group relaxation and to establish these values better by work at a variety of temperatures.

A number of previous studies has been carried out on aromatic methoxy compounds (2–4), and a detailed study of four such compounds is now reported. Serious discrepancies exist amongst different workers with respect to analysis of the anisole data which justify its re-examination. *p*-Methylanisole has been chosen for examination, since group moment calculations suggest it may relax predominantly by methoxy group relaxation which would, of course, lead to more accurate group relaxation parameters. *p*-Dimethoxybenzene presented an interesting case where both the methoxy groups have the possibility of relaxing, while *p*-bromoanisole merits examination since, from assessment from group moments, it would appear to have a large weight factor (C_1) for molecular relaxation, and, hence, analysis of its dielectric data would help to assess the validity of group moment calculation of the C values for these aromatic methoxy compounds.

Experimental

Apparatus

The apparatus and techniques employed have been described previously (5, 6) and the errors assessed (7). The dielectric constant (ε') and loss factor (ε'') were determined by a bridge method at 70.0, 35.11, 23.98, 16.20, 9.313, and 6.700 GHz. The static dielectric constant (ε_0) was measured with a heterodyne beat apparatus at 2 MHz.

Purification of Materials

The commercially available liquids were dried prior to distillation, then distilled using a (30 theoretical plates) spinning band column and a small center fraction collected. *p*-Dimethoxybenzene was recrystallized twice from petroleum ether and then dried. The observed boiling and melting points compared well with literature values, and the compounds were shown to have no detectable impurities by gas–liquid chromatography.

Results

The evaluation of the high frequency dielectric constant (ε_∞), distribution coefficient (α), mean relaxation time (τ_0), discrete relaxation times (τ_1

TABLE I

Dielectric constant and loss data for anisole, *p*-methylanisole, and *p*-bromoanisole in the solvent *p*-xylene and for *p*-dimethoxybenzene in the solvent cyclohexane at specified weight fractions (ω_2)*

*ε' and ε'' are the measured values, while ε'_{calcd} and ε''_{calcd} are the values estimated from τ_1, τ_2, and C_1 values in Table II.

and τ_2), weight factors (C_1 and C_2), and dipole moment (μ) has been described previously (6).

The dielectric constant and loss data are presented in Table I. The experimental values of ε' and ε'' are compared with those calculated from the Budó equations (7, 8) using the τ_1, τ_2, and C_1 values given by computer analysis. These values are listed in Table II, together with the mean relaxation time, weight fraction, dipole moment, static and high frequency dielectric constant, and distribution coefficient.

Discussion

Studies of the dielectric absorption of anisole have all indicated that the observed mean relaxation time is too short to be attributed solely to a

*These values are much too long but are discussed in text.

molecular relaxation process and that there is a contribution to the total dielectric absorption from methoxy group rotation (2, 3, 9). This contribution would appear to be quite large since the τ_0 value in decalin is 10.8×10^{-12} s at 20 °C (2) compared with our interpolated value in *p*-xylene at 20 °C of about 10×10^{-12} s; thus, about a fourfold increment in the macroscopic viscosity in decalin has produced only a slight increment in the observed relaxation time. Furthermore, measurements on anisole in the highly viscous solvent nujol ($\eta = 211$ cP at 20 °C) yielded a mean relaxation time of 19.5×10^{-12} s (2), again indicating that the weight factor for methoxy group rotation predominates, since any appreciable contribution from molecular relaxation would have the effect of considerably lengthening the mean relaxation time.

In order to determine the success of the analysis of dielectric data into group and molecular relaxation times of a molecule, it would be useful to have an accurate assessment of the weight factors calculated from group moment data. For mono-substituted benzene compounds a check on the validity of the data employed in estimating C_1 is obtained by the determination of the weight factor data of para-substituted derivatives of the parent compound, for if C_1 (experimental) is approximately equal to C_1 (calculated) in these compounds, then this would support the initial C_1 calculation, providing the para-substituents chosen do not lead to appreciable mutual conjugation between the 2 substituent positions. Generally, C_1 values in the literature are quoted without any reason being given for the change in C_1 from one compound to a fairly similar compound. In addition, many erroneous results exist which require further explanation. For example, Forest and Smyth (3) find that the C_1 value for anisole in benzene at 20 °C is 0.2, but Klages and

Zentek (10) report a C_1 value of 0.8 for anisole in the same solvent at the same temperature. Clearly one of these results must be in considerable error. Further, Grubb and Smyth obtained a value of ~ 0.4 for anisole in Nujol (2), while Vaughan, Roeder, and Provder (11) quoted ~ 0.75 for liquid anisole. An attempt will now be made to justify both the observed relaxation times and C_1 values for anisole, *p*-methylanisole, and *p*-bromoanisole.

C_1 for anisole may be calculated from group moments. The dipole moment of a para-substituted anisole, where the moment of the para-substituent is in a direction parallel to the long axis and away from the ring, may be related to the moments of the mono-substituted compound by the equation

$$\mu_{p\text{-Xanisole}} = [(\mu_{\text{anisole}})^2 + (\mu_{C_6H_5X})^2 + 2\mu_{\text{anisole}} \cdot \mu_{C_6H_5X} \cdot \cos\theta]^{\frac{1}{2}}$$

where θ is the angle formed by the total dipole moment vector of the anisole molecule and that of the chlorobenzene molecule, where the latter moment lies on the long axis. When X = Cl, since the dipole moments of *p*-chloroanisole and chlorobenzene are 2.32 and 1.58 D, respectively (12, 13), and our experimental value for anisole is 1.19 D, then the angle subtended on the long axis towards the ring is 67° 40′, which leads to a C_1 value of 0.15. From the group moment data of Forest and Smyth (3), however, a C_1 value of 0.43 results. Thus there is a fair degree of latitude in the calculated value.

The values of τ_1 and τ_2 obtained from the computer analysis, with C_1 fixed at 0.15, are listed in Table II. With such a small weight factor on the molecular relaxation process, the τ_1 values are fairly inaccurate. However, an analysis for a $C_1 = 0.33$ (see Table II) leads to more satisfactory τ_1 values which are slightly less than to be expected for molecular relaxation of a molecule of this size and shape. From the molecular size, the τ_1 value might be expected to lie between that of bromobenzene and iodobenzene, the values for which are, respectively, 14- and 18 $\times 10^{-12}$ s at 15 °C in *p*-xylene (14). The value of C_1 is within 0.1 of that calculated from the Forest and Smyth group moment data (3). In our experience, C_1 values as obtained from an analysis of dielectric data are rarely accurate to better than ± 0.1. It would seem that for anisole, a C_1 value of 0.3 ± 0.15 would account for both extremes of calculated values and the one obtained from the dielectric data.

p-Methylanisole has been chosen because the methyl group moment is directed into the ring and opposes the resultant fixed component of the moment from the anisole part of the molecule on the long axis so this molecule would be expected to have more internal rotation than anisole, i.e., C_2 should be greater for *p*-methylanisole. Since the mean relaxation times of *p*-methylanisole are shorter than that of anisole at four temperatures and the molecular relaxation time of anisole is considerably shorter than that of *p*-methylanisole, the results bear out this point of view. Calculations based on our group moment data indicate that the intramolecular relaxation predominates and therefore the mean relaxation time tends to that of the group relaxation time τ_2. It is evident from Table II that the mean relaxation times of *p*-methylanisole are not appreciably longer than the group relaxation times of anisole. The observed relaxation time of 9.0 $\times 10^{-12}$ s for *p*-methylanisole in *p*-xylene at 25 °C is to be compared with a molecular relaxation time of 23 $\times 10^{-12}$ s for *p*-bromotoluene (14), a molecule which Courtald models indicate is slightly less in size. That there is a large contribution from group relaxation to the total dielectric absorption in *p*-methylanisole is thus supported by this appreciable difference in the two relaxation times.

For *p*-bromoanisole, group moment calculations give a C_1 value of 0.76, suggesting that this molecule will relax predominantly by molecular rotation. This is borne out by the long mean relaxation time value which is, for example, at 25 °C, $\tau_0 = 27 \times 10^{-12}$ s in *p*-xylene. Analysis of the data in terms of two relaxation times gave an average C_1 value of 0.83, which compares well with the calculated value. The τ_2 values, while not very accurate owing to the small weight factor on this process, are of the same order of magnitude for group rotation in anisole and *p*-methylanisole.

p-Dimethoxybenzene was studied in cyclohexane at four temperatures, and a mean relaxation time of 6.9 $\times 10^{-12}$ s was obtained at 25 °C which compares with a τ_2 value of 6.4 $\times 10^{-12}$ s for anisole in cyclohexane at 25 °C (10). Previous workers have examined *p*-dimethoxybenzene in benzene at 20 °C and obtained values of 9.7 $\times 10^{-12}$ and 6.2 $\times 10^{-12}$ s (3, 4). An excellent log

For personal use only.

τ_0 T vs. $1/T$ plot was obtained from the data in Table II and helped to establish our mean relaxation time values. It would seem likely that group rotation is the predominant relaxation process present in *p*-dimethoxybenzene. *p*-Bromoanisole, a molecule just less in size than *p*-dimethoxybenzene, has a molecular relaxation time of 31×10^{-12} s in *p*-xylene at 25 °C, and hence the observed short relaxation time of *p*-dimethoxybenzene would suggest that group relaxation is the principal one in this compound, as is also borne out by the small or zero α values. For the case where the end groups are freely rotating, Williams (15) has shown that the resultant dipole moment (μ) is related to the group dipole moment (μ_g) and the angle (θ) that they subtend with the long axis of the molecule by the equation $\mu = \sqrt{2}\,\mu_g \sin\theta$. For *p*-dimethoxybenzene, the methoxy group moment is 1.2 D, and θ, derived from the group moment calculations in anisole, is 67° 40′ and therefore, by substitution in the above equation, $\mu = 1.6$ D, which is in good agreement with the observed value of 1.7 D.

In conclusion, it would seem that to obtain convincing analyses of dielectric data into contributions from 2 relaxation times, it is preferable to employ several frequencies (as widely spaced as feasible) and carry out the examination at a few temperatures to establish consistent behavior. Further, it is desirable to examine a variety of molecules with varying C_2 contributions and justify the magnitude of the C_2 values obtained from the analyses by group moment calculations, although establishment of more precise group moments is desirable. For anisole, *p*-methylanisole, and *p*-bromoanisole, the experimental and calculated C_2 values are of a similar order of magnitude, while the linear log τ_0 T vs. $1/T$ plots help to establish the consistency of the dielectric data.

It is difficult to reconcile our C_1 of 0.3 ± 0.15 for anisole in *p*-xylene with that of ~ 0.75 for the pure liquid obtained by Vaughan, Roeder, and Provder (11) and recently confirmed by Garg and Smyth (16). It would seem, however, that the appreciable difference in C_1 value between that for pure liquid anisole and that for a dilute solution of it in a non-polar solvent is genuine and worthy of more detailed study.

Bromine chloride clathrate gas hydrate[1]

D. N. GLEW AND D. A. HAMES
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received August 13, 1969

Bromine chloride hydrate, prepared free of excess halogen, has been analyzed directly to give the formula $BrCl \cdot 7.77 \pm 1.58\ H_2O$. The halogen is found to be bromine-rich in the hydrate and bromine-deficient in the aqueous solution at 5 °C. Aqueous solutions in equilibrium with the hydrate between 1 and 15 °C have been analyzed and yield the bromine chloride hydrate enthalpy of fusion 10 450 ± 860 cal/mole which leads to the formula $BrCl \cdot 7.28 \pm 0.60\ H_2O$. It is concluded that bromine chloride forms a normal clathrate-type gas hydrate of formula $BrCl \cdot 7.34\ H_2O$, and that the frequently quoted formula $BrCl \cdot 4\ H_2O$ is wrong.

Canadian Journal of Chemistry, 47, 4651 (1969)

Introduction

The formula of chlorine hydrate is $Cl_2 \cdot 7.27\ H_2O$ (1) and that of bromine hydrate is $Br_2 \cdot 8.4\ H_2O$ (2), whereas an early study of bromine chloride hydrate gives the formula $BrCl \cdot 4H_2O$ (3). It is probable that bromine chloride forms a clathrate hydrate similar to those of chlorine and bromine so that the reported water content of the bromine chloride hydrate appears to be erroneously low. Since the molar volume of bromine chloride is not very different from that of chlorine or bromine we would expect BrCl molecules either to fill the medium sized cavities of the cubic structure Type-I hydrate lattice (4) giving a formula $BrCl \cdot 7.66H_2O$, or to fill the two larger types of cavities in the tetragonal lattice (5) giving the formula $BrCl \cdot 8.6H_2O$.

The use at low temperatures of aqueous bromine chloride or "bromine chloride water" as a brominating agent is limited by the formation of bromine chloride hydrate below 18 °C (3). In this study the maximum bromine chloride concentration attainable in the presence of the hydrate has been measured over the temperature range 1 to 15 °C. In addition, the equilibrium Br/Cl atomic ratio has been determined for both the hydrate and aqueous phases.

Experimental

Materials

Bromine chloride with a Br/Cl atomic ratio 0.9969 was prepared by the weighed addition of 99.99 wt. % liquid chlorine to 99.98 wt. % purified grade bromine, both supplied by The Dow Chemical Company. The bromine chloride was used in liquid form to minimize composition changes. Water was laboratory distilled.

[1]Contribution No. 175.

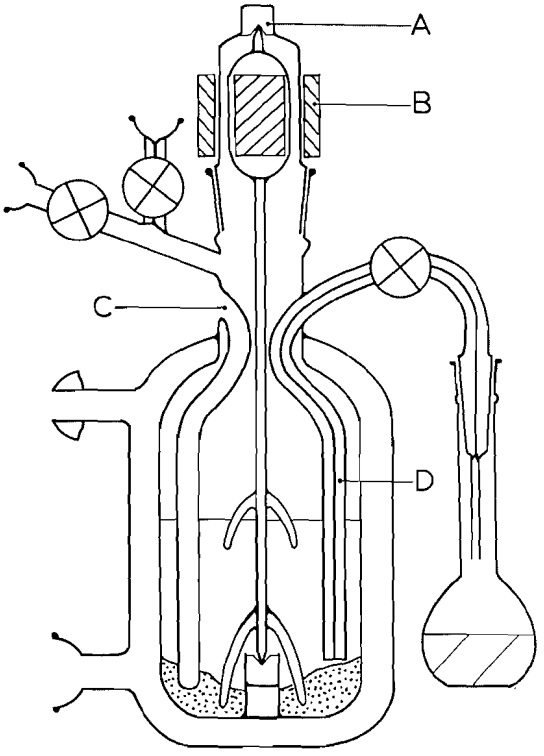

FIG. 1. Magnetic stirred hydrate cell.

Apparatus

The thermostatted cell of about 500 ml volume used for all experiments is shown in Fig. 1. The stirrer, mounted on Teflon bearings A, is driven by a composite copper–steel armature sealed into the glass casing at the upper end of the shaft. The armature is rotated inductively by stator B. Cell temperatures, constant to ±0.01 °C, were maintained by the circulation of thermostatted glycol–water through the outer jacket. The cell temperature was measured differentially with respect to a stainless steel block within the thermostat using a 5-junction copper–constantan thermocouple contained

For personal use only.

in thermowell C. The temperature of the stainless steel block was measured using a standardized platinum resistance thermometer and Mueller bridge.

Method

(a) Hydrate–Solution Equilibration and Analysis

In order to suppress the hydrolysis of aqueous bromine chloride (6), all experiments were carried out in *M*/40 sulfuric acid solutions. Approximately 250 ml of the *M*/40 sulfuric acid were added to the weighed cell, dissolved air was removed by evacuation, and the cell reweighed. The cell was returned to its normal position, liquid from the thermostat at 5 °C was circulated through the cooling jacket, and the cell liquid stirred.

Bromine chloride samples of between 10 and 20 cm^3 were frozen at −80 °C in a small, weighed, evacuated container, and the weighed bromine chloride was added to the cell via the upper 12/2 hemispherical joint.

In the first day, the cell was shaken vigorously 3 or 4 times, the circulating liquid temperature was increased progressively until only a small quantity of the hydrate remained, and this temperature was maintained until all traces of liquid bromine chloride had disappeared. The cell was cooled slowly to between 2 and 3 °C below the operating temperature and maintained there overnight. The cell temperature was then increased to the preselected operating level, and aqueous samples were withdrawn and analyzed for both halogens at regular intervals until equilibrium was obtained.

A small helium pressure differential of 15 Torr above atmospheric, applied to the cell at the lower 12/5 hemispherical joint, was used to express 5–10 ml samples of aqueous bromine chloride via sampling tube *D* into a weighed 50 ml volumetric flask containing 25 ml *M*/5 NaOH. The flask was weighed, 4 ml formic acid added to reduce the halogen to halide ion, and the solution made up to volume and reweighed. Weighed aliquots were titrated potentiometrically for bromide and chloride ions with *M*/10 $AgNO_3$ using a Beckman pH meter with Ag wire indicator and calomel reference electrodes (7). End points were improved by adding 10 drops 1% aqueous Dowfax 9N-40 and approximately 3 mole % 1-propanol. To allow for the systematic effect of the well-known late bromide end point in mixed bromide–chloride titrations (8), the method was standardized using a series of 9 mixtures in which the Br/Cl ionic ratio was varied over the range 0.7 to 1.7. All halogen concentrations are expressed as molality *m*, mole/1000 g water.

(b) Hydrate Formula Determination

After the attainment of equilibrium, the aqueous phase was expressed from the cell via *D*, leaving the drained solid hydrate with some adhering mother liquor. The hydrate was dissolved by the weighed addition to the cell of 250 ml *M*/20 HNO_3 at about 5 °C, and final concentrations of bromine chloride and sulfate ion were determined. The final solution was removed from the cell and weighed. The sulfate ion level was used to calculate the amount of mother liquor adhering to the hydrate, based on the assumption that no sulfate is incorporated into the bromine chloride hydrate lattice. Water in the hydrate was calculated as the total weight of water, minus the weight of water adhering to the hydrate, minus the weight of water from the *M*/20 HNO_3. Bromine chloride in the hydrate was calculated as the total weight of bromine chloride after dissolution of the hydrate, minus the weight of bromine chloride in the solution adhering to the hydrate, allowing for the weight of bromine chloride in the gas phase.

Solutions were analyzed for sulfate ion by the addition of a known excess of *M*/200 $BaCl_2$, filtration of matured barium sulfate precipitate, and back-titration of the excess barium with *M*/100 ethylenediaminetetraacetic acid disodium salt using Eriochrome black T indicator. The EDTA reagent was standardized with known calcium solutions.

Results and Discussion

The hydrate formed initially on the stirrer at the gas–liquid interface, appearing as a finely divided light orange precipitate which gradually changed into a dark red crystalline solid with continuous stirring for 24 h. On the surface of any liquid bromine chloride, a coherent, thin, and impervious hydrate layer formed which entrapped the bromine chloride and inhibited its dissolution into the aqueous phase. To ensure complete dissolution of all liquid bromine chloride the aqueous solution was heated slowly until only few hydrate crystals remained and then was cooled slowly to grow hydrate crystals without reprecipitation of liquid bromine chloride. The cell was cooled just below and then increased to the operating temperature to take advantage of the more rapid approach to equilibrium from subsaturation (9). Without these precautions we were unable to dissolve all of the liquid bromine chloride despite continuous vigorous stirring for 3 weeks. It is apparent that the method of preparation used by Anwar–Ullah (3) will invariably yield a hydrate contaminated by excess liquid bromine chloride and will give a hydrate formula too rich in bromine chloride and deficient in water.

The first 3 columns of Table I show the variation with temperature of the total halogen (bromine plus chlorine) molality, m_2, and the Br/Cl ratio for the aqueous phase in equilibrium with solid bromine chloride hydrate. Columns 4 and 5 show the Br/Cl ratio and the water/halogen mole ratio for the hydrate in equilibrium with the aqueous phase at 5 °C. The final 2 columns show the mass balance for the experiment giving a comparison of the bromine chloride and water as determined by analysis relative to their initial values.

The measurements at 5 °C establish that the

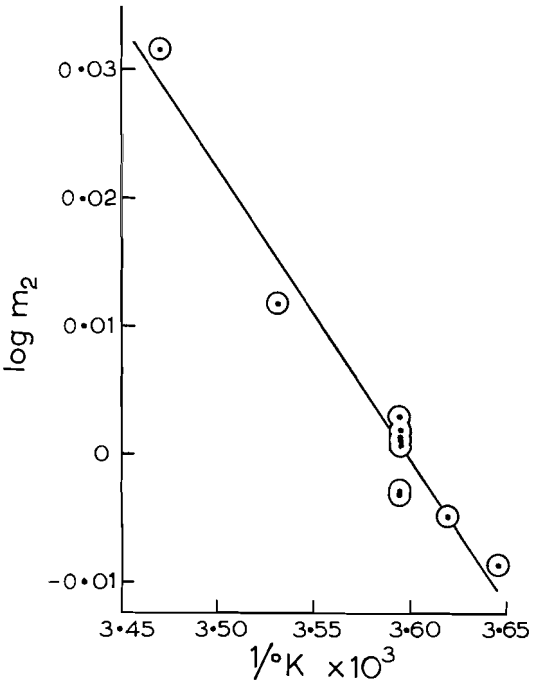

FIG. 2. Temperature dependence of the aqueous bromine chloride molality m_2 in equilibrium with the hydrate.

bromine chloride is bromine-rich in the hydrate phase and is bromine-deficient in the aqueous phase, although all experiments started with liquid bromine chloride having a Br/Cl ratio of 0.9969. The 6 independent direct analyses of the hydrate give the mean formula and standard error $BrCl \cdot 7.77 \pm 1.58\ H_2O$.

In Fig. 2, a plot of log m_2 against the reciprocal of the absolute temperature is presented where the straight line, evaluated by the method of least squares, is given by

$$[1] \qquad \log m_2 = -2284/T + 8.216_4$$

from which the standard error on a single determination is found to be 6.5%. From eq. [1] we find that the standard enthalpy of fusion of solid bromine chloride hydrate to give aqueous bromine chloride is $\Delta H^0(h \rightarrow l_1) = 10\,450 \pm 860$ thermochemical cal/mole. Assuming that the gaseous bromine chloride heat of solution in water $\Delta H^0(g \rightarrow l_1)$ is equal to its heat of reaction with ice to form hydrate $\Delta H^0(s_1 g \rightarrow h)$, as is found for both chlorine and bromine (10), we can obtain a second water/halogen ratio for the bromine chloride hydrate from $\Delta H^0(h \rightarrow l_1)/1436.3$ giving the formula $BrCl \cdot 7.28 \pm 0.60\ H_2O$, in agreement with our value by direct analysis. In conclusion, a weighted mean formula $BrCl \cdot 7.34 H_2O$, with an error of less than $0.60 H_2O$, is obtained from the two independent methods of determination and shows that bromine chloride forms a normal clathrate-type gas hydrate (4, 5).

Metal chelates of 2-(2′-thienyl)-8-hydroxyquinoline: anomalous ratios of formation constants

A. CORSINI AND E. J. BILLO[1]

Department of Chemistry, McMaster University, Hamilton, Ontario

Received July 30, 1969

The ligand 2-(2′-thienyl)-8-hydroxyquinoline has been synthesized and the solution stability of some of its metal chelates determined. The finding that $\log K_1 < \log K_2$ is attributed to strong steric interaction between the 2-substituent and coordinated water on addition of the first ligand. This interaction results in distortion toward tetrahedral geometry. Previously unexplained data for other 2-substituted 8-hydroxyquinolines have been interpreted in terms of this effect.

Canadian Journal of Chemistry, **47**, 4655 (1969)

Introduction

Successive stepwise formation constants of metal complexes usually decrease in a regular manner with increasing coordination of the metal ion, owing primarily to statistical, electrostatic, and steric effects. These effects have been discussed by Rossotti (1) and Manning (2 and references therein). In some instances, the ratio of successive formation constants, K_n/K_{n+1}, can provide valuable information about the nature of the complex. Large values of the ratio are indicative of changes in the stereochemistry of the metal ion and of π-bonding and steric packing effects (1, 3). Small values (i.e., $K_n \leqslant K_{n+1}$) have been attributed to changes in ground state configuration of the metal ion and steric interactions (1, 4). In the special case of bis complexes of dimethylglyoxime, the small values have been attributed to hydrogen bonding (5, 6).

During a study of new potentially terdentate ligands, 2-(2′-thienyl)-8-hydroxyquinoline (THQ) was prepared. In the present report, the findings obtained with this ligand in its reactions with selected metal ions are summarized. The unusually small values of K_1/K_2 have been explained in terms of steric interactions between coordinated water and the first incoming ligand. Examples from the literature are cited to show that this effect occurs with several ligands containing suitable substituents close to donor atoms.

Experimental

Microanalyses were by Alfred Bernhardt, Elbach über Engelskirchen, West Germany.

2-(2′-Thienyl)-8-hydroxyquinoline

To an ether solution (200 ml) containing 17 g of thiophene, a 1.6 *M* solution (125 ml) of *n*-butyllithium in hexane was added dropwise. An ether solution (200 ml) of 32 g of 8-methoxyquinoline (7) was added over 1 h. The mixture was stirred for 2 h and water (300 ml) was added. The ether layer and ether extracts of the aqueous phase were evaporated, leaving a deep red oil. Oxidation of this oil on boiling (15 min) with nitrobenzene (100 ml) and removal of excess nitrobenzene under reduced pressure yielded 2-(2′-thienyl)-8-methoxyquinoline, b.p. 230 °C/8 mm Hg, which rapidly crystallized on cooling. Yield, 33 g. Recrystallization from ether gave yellow needles, m.p. 110–111 °C.

2-(2′-Thienyl)-8-methoxyquinoline (17.5 g) in 48% HBr (150 ml) was refluxed for 24 h. The hydrobromide of THQ, which crystallized on cooling, was dissolved in warm water. Neutralization yielded 6.0 g of THQ, which formed colorless needles from ethanol, m.p. 71.5–72.0 °C.

Anal. Calcd. for $C_{13}H_9ONS$: C, 68.68; H, 4.00; N, 6.16; S, 14.11. Found: C, 68.97; H, 3.71; N, 6.28; S, 14.35.

The mass spectrum (ionization potential, 80 eV; ionizing current 50 μA) gave the correct molecular weight and the infrared spectrum showed absorption bands in the characteristic regions. The proton nuclear magnetic resonance spectrum (60 Mc, HMDS internal standard, dioxane solvent) showed that substitution occurred in the 2-position. The resonance assigned to the alpha hydrogen in 8-hydroxyquinoline (8) is absent in the spectrum of the thienyl derivative. Also, splitting of the H_A resonance by H_x is absent.

All common laboratory chemicals were of suitable purity for the purpose intended. Reagent-grade dioxane was purified as described elsewhere (9). Stock solutions (0.01 *M*) of metal ions were prepared from the perchlorate salts and standardized by accepted EDTA methods. For qualitative tests with metal ions, an ethanolic solution of THQ (0.1%) was used. Standard solutions of THQ in dioxane were used for potentiometric titrations.

In screening tests with 29 metal ions, 11 ions reacted with THQ in borate buffer (pH 10), and only 5 (Cu(II), Hg(II), Pd(II), Fe(III), Rh(III)) reacted in acetate buffer (pH 5). THQ is much more selective than 8-hydroxyquinoline and merits consideration as an analytical reagent.

Solid metal chelates were prepared by addition of an excess of THQ (in dioxane) to an aqueous solution of the metal ion, and dropwise addition of NaOH solution until

The magnetic susceptibilities of the Ni(II) and Co(II) complexes were determined at room temperature by the Guoy method. $Hg[Co(CNS)_4]$ was used as a standard. The molar susceptibilities were corrected for diamagnetism of the ligands using Pascal's constants (10). For the Ni(II) and Co(II) complexes, U_{eff} was 3.21 and 4.50 B.M., respectively.

Absorption spectra of the Ni(II) and Co(II) complexes (in 50% v/v dioxane–water) were taken in the range 250–750 mμ, with a Cary Model 14 spectrophotometer.

All equilibrium measurements were made in 50% v/v dioxane–water at 25 °C and $\mu = 0.10$ ($NaClO_4$). Ligand protonation constants (Table I) were determined potentiometrically and spectrophotometrically (Hitachi Perkin–Elmer 139 spectrophotometer) using the equations

$$\log K_{OH} = p_cH + \log \frac{\bar{n}_H}{1 - \bar{n}_H}$$

and

$$\log K_{NH} = p_cH + \log \frac{A_{HL} - A}{A - A_{H_2L^+}}$$

Chelate formation constants (Table I) were determined potentiometrically essentially as described elsewhere (9). The general equations of Hearon and Gilbert (11) were used for calculation of $\bar{n}$, [L] data. The stepwise formation constants were calculated from this data by a linear least-squares fit of the equation

$$\frac{\bar{n}}{(1 - \bar{n})[L]} = \frac{(2 - \bar{n})[L]}{(1 - \bar{n})} \cdot K_1K_2 + K_1$$

to the $\bar{n}$, [L] data, where values of $\bar{n}$ used were restricted to the ranges 0.2–0.8 and 1.2–1.8.

For all titrations, a ligand-to-metal molar ratio of 6:1 was used. The pH range of complex formation was 4–5 for Cu(II) and 6–7 for the other metal ions. Because of the possibility of metal-ion hydrolysis, which would lead to erroneous results, the titrations were repeated at a molar ratio of 20:1. No significant change in the formation constants was obtained, showing that hydrolysis was not an interfering factor.

For potentiometric measurements, the correction factor for converting pH-meter readings to $-\log [H^+]$ in the solvent medium used was -0.08 ± 0.01; p_cK_w was 15.33 ± 0.02. These values are in close agreement with previously reported values (12, 13).

Results and Discussion

The second protonation constant, $\log K_{NH}$, of THQ is considerably lower than the corresponding constant for 8-hydroxyquinoline (Tables I and II). The large decrease (2.7 log units) is the result of sterically inhibited solvation of the protonated nitrogen by the thiophene ring. Comparable decreases in basicity have been observed for 2-phenyl-8-hydroxyquinoline (17) and 2-(*o*-hydroxyphenyl)quinoline (15).

Two features of the chelate formation constants are of interest. First, the overall formation constants, $\log \beta_2$, are 3 to 7 units smaller than the formation constants of the corresponding 8-hydroxyquinoline chelates, and 1.8 to 2.5 log units smaller than those of the similar ligand, 2-phenyl-8-hydroxyquinoline (Tables I and II). This lower stability is due partly to differences in basicity in donor atoms, and partly to steric interference to coordination by the thiophene group[2]. The latter effect is well illustrated by molecular models. Failure of the sulfur atom to coordinate is not surprising since the thienyl

[2]The enhanced selectivity of THQ is due to these basicity and steric effects.

sulfur in 2-(2'-thienyl)pyridine is a very weak donor (19).

Second, for each metal ion, log K_2 > log K_1 (Table I). This unusual feature is also the result of sterically inhibited coordination. Williams *et al.* (20, 21) and Irving and Mellor (4) have observed that in the series 1,10-phenanthroline, 2-methyl- and 2,9-dimethyl-1,10-phenanthroline, the first formation constant for the Cu(II) chelate decreases markedly (despite increasing ligand basicity), while the second formation constant is less sensitive to substitution. In the mono-complex, steric interaction occurs between the methyl substituent(s) and one or more water molecules remaining in the coordination plane of the Cu(II) ion. This interaction causes distortion of the structure of the mono-ligand complex from a square-planar toward a tetrahedral arrangement, in which the interaction is reduced. The distortion results in a decrease in log K_1. Substitution of the second ligand on the distorted structure occurs without any serious decrease in stability. As the degree of steric interaction is increased, the separation between the two formation constants decreases. In the case of the THQ complexes, the steric interaction is very large and the first formation constant is considerably smaller than the second.

The data of Table II, collected from the literature, support this hypothesis. Values of log K_1 and log K_2 are listed for several 2-alkyl-8-hydroxyquinolines and for 2-phenyl-8-hydroxyquinoline. With increasing size of the 2-alkyl substituent, the separation between log K_1 and log K_2 decreases until in most cases, log K_1 < log K_2. The effect is even more pronounced with the 2-phenyl derivative.

Although the difference between log K_1 and log K_2 varies in magnitude with the size of the substituent, it should not be assumed that the effect is the direct result of solely the steric effect. An enthalpy effect arising from a sterically forced change in coordination number must also be considered. If the mono-ligand species is tetrahedral, its formation from the hexa-aquo complex would involve the breaking of 4 M—H_2O bonds, while addition of the second ligand would involve the rupture of only 2 such bonds. The net result would be to cause a separation between the log K_1 and log K_2 values in the direction observed.

Examination of molecular models indicates that the occurrence of negative values of log K_1/K_2 for substituted phenylazo-5-pyrazolones (22–24) may also originate from a steric effect of the type described above. Recently, Snavely *et al.* reported the same steric effect for the similarly substituted 3-pyrazolones (25). It was found that the Ni(II) and Co(II) complexes of meta and para substituted azo-5-pyrazolones are precipitated from aqueous solution as $ML_2(H_2O)_2$, while complexes of the ortho substituted derivatives do not appear to contain water of hydration. In the present work, elemental[3], thermal[4], and infrared analyses indicated that the chelates of Co, Ni, Cu, and Zn with THQ are anhydrous. Formation of non-hydrated, presumably 4-coordinate solid complexes is consistent with a pseudo-tetrahedral configuration in solution.

[3]The elemental analyses, although not particularly good, do suggest on an overall basis the absence of water in the solid complexes.

[4]No loss in weight was observed on drying the complexes at 150 °C. The dihydrates of the bis-8-hydroxyquinoline complexes of Cu(II), Ni(II), Co(II), and Zn(II) lose water at or below this temperature (26).

In order to obtain more positive information on the solution structure of the complexes, an attempt was made to determine the magnetic moments of the Ni(II) and Co(II) complexes of THQ in solution; however, the solubility of these complexes in the usual non-polar solvents proved to be too low to yield meaningful results. Accordingly, the (room temperature) magnetic moments of the solids were measured. Since $U_{eff} = 3.21$ B.M. for the Ni(II) complex of THQ, a planar structure for the solid can be eliminated. The magnetic moment is not inconsistent with an octahedral or tetragonal structure, but these structures can be ruled out on the basis of the 2:1 stoichiometry of the isolated compound. The magnetic moment is lower than expected (3.6–4.0 B.M.) for true tetrahedral Ni(II) complexes (27), but Sacconi and co-workers (28, 29) have found that the magnetic moments of Ni(II) complexes in a distorted tetrahedral environment are also lower (e.g., $U_{eff} = 3.34$ B.M. for bis(N-isopropylsalicylaldiminato)nickel(II). For the solid Co(II) complex of THQ, $U_{eff} = 4.50$ B.M. This value is in agreement with the value (4.47) for the bis(N-butylsalicylaldiminato)cobalt(II) complex, which is tetrahedral (30, 31), and is within the range (4.3-4.8 B.M.) observed for tetrahedral Co(II) complexes (27). The value is well above the range (2.4–2.8 B.M.) found for square and tetragonal complexes (32). An octahedral structure can be eliminated on the basis of stoichiometry.

Although the magnetic moments indicate a tetrahedral or distorted tetrahedral structure for the solid complexes, they do not necessarily reflect the structure of the species in solution, and in this regard should be interpreted with caution. Unfortunately, no information on the solution structure of the Ni(II) or Co(II) complexes could be obtained from the ultraviolet and visible absorption spectra. The spectra, which were similar, exhibited a very intense band ($\varepsilon \sim 2 \times 10^4$) at 300 mμ, a shoulder ($\varepsilon \sim 5 \times 10^3$) at 340 mμ and a shoulder ($\varepsilon \sim 1 \times 10^3$) at 400 mμ. These bands originate from the bound ligand. The spectra are featureless from about 450 to 750 mμ and provide no evidence to support the solution structure.

Finally, the same steric effect proposed in the present work to explain the values of log K_1/K_2 for the solution complexes of 2-substituted-8-hydroxyquinolines has recently been found in solid complexes. Chia and Livingstone (33) have reported that in the complexes of 2-methyl-8-methylthioquinoline, the 2-methyl group causes severe steric hindrance to other ligands in a square plane; magnetic moments and reflectance spectra indicated pseudo tetrahedral configuration about the metal ion.

Adsorption of gases on 4A synthetic zeolite

R. J. HARPER, G. R. STIFEL[1], AND R. B. ANDERSON
Department of Chemical Engineering, McMaster University, Hamilton, Ontario

Received July 30, 1969

Equilibrium data are presented for the adsorption of permanent gases and C_1 and C_2 hydrocarbons on Linde 4A synthetic zeolite from 50 °C down to the boiling point of the adsorbate or to a temperature at which the rate was very slow. The Freundlich equation often fits isotherms accurately; however, these linear logarithmic plots seem to be only portions of a more general non-linear relationship. Generalized Polanyi plots did not yield a unique characteristic curve for individual adsorbates at different temperatures nor for groups of adsorbates; nevertheless, these plots are useful in estimating the relative strength of adsorption of gases. Ar, O_2, CH_4, and C_2H_6 were the least strongly adsorbed, followed in order of increasing strength by N_2, CO, CO_2, and C_2H_2. Ethylene was strongly but anomalously adsorbed. For the gases studied, the quadrupole moment seems to be the principal factor determining strong adsorption.

Canadian Journal of Chemistry, 47, 4661 (1969)

Introduction

Molecular sieves of the aluminosilicate type have been widely studied because of their interesting structural and adsorptive properties and their practical use in separative processes and catalysis. Barrer has made major contributions in studies of natural zeolite minerals, the preparation of new types of molecular sieves, and the structures and adsorption properties of natural and synthetic zeolites; his earlier work has been summarized (1–3). Type A synthetic zeolites have been available commercially since 1954 and have found extensive practical use in separation, drying, and purification of gases. Many papers have described the behavior of these zeolites in separative processes, but detailed adsorption studies of single permanent gases and C_1- and C_2-hydrocarbons have been less comprehensive. The most extensive investigations of this type were made by Breck and co-workers (4–6). Russian workers have investigated adsorption on Type A sieves, notably Dubinin *et al.* (7–10), Kel'tsev and co-workers (11–14), Kiselev and co-workers (15–17), and Kvitkovskii and co-workers (18, 19).

Most of the present data were obtained in a study of rates of adsorption of permanent gases and C_1- and C_2-hydrocarbons on 4A sieves. Equilibrium adsorption data are presented for N_2, O_2, CO, CO_2, Ar, CH_4, C_2H_6, C_2H_4, and C_2H_2 from 50 °C down to about the boiling point of the gases or to temperatures at which the adsorption was so slow that equilibrium required longer than 24 h.

[1]Present address: Uniroyal Research Center, Guelph, Ontario.

Type A zeolite contains approximately spherical cavities of 11.4 Å diameter at the center of each unit cell, each cavity being connected in a cubic arrangement with 6 similar cavities by rings of 8 oxygen atoms forming a restricted opening 4.2 Å in diameter. The 4A sieve studied in the present paper contain sodium as the exchangeable cation. The 8 sodium ions per cavity are located near the apertures and decrease their diameter to about 3.5 Å.

Experimental

A sample of 4A molecular sieve powder was supplied by the Linde Division of Union Carbide. To avoid difficulties in handling this fine powder in evacuation and adsorption measurements, the zeolite was compressed to form an aggregate of sufficient strength for the present purposes by the following procedure: the powder was immersed in water for 1 day, dried in air at 120 °C, and then pressed in a 1-in. die at about 12 000 p.s.i. for 2 or 3 min. The large pellet was then crushed and sieved to yield aggregates varying in size from 1 to 2 mm. The sample was dried in air at 350 °C for 36 h, placed in an adsorption tube and evacuated at 450 °C for 12 h. Adsorption data are given per gram of sample after this treatment. Evacuations at 450 °C for several days yielded the same rate and equilibrium data. At the end of this heating period and at the start of the adsorption experiments, the pressure in the vacuum system was less than 10^{-5} Torr. The same sample of adsorbent was used for a number of adsorption measurements.

Adsorption measurements were made in a Pyrex volumetric system, similar to the Brunauer, Emmett, and Teller apparatus (20) but also equipped with a manostat and a calibrated burette. Dead space in the sample bulb was determined using helium at −196, −118, −98, −78, −37, 0, 30, and 50 °C. Appropriate plots of these data were made assuming a fraction of the volume was at room temperature and the remainder at the temperature of the bath. Deviations from the linear plots, which indicated significant adsorption of helium, were found

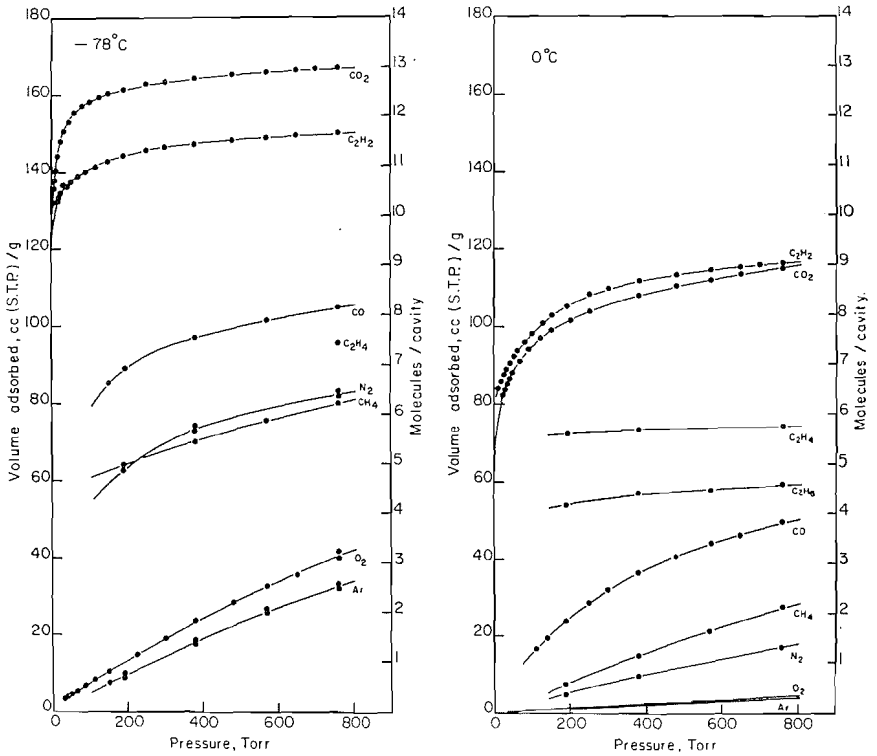

FIG. 1. Adsorption isotherms on 4A molecular sieve at −78 and 0 °C.

only at −196 °C, and the dead space factors at temperatures below −118 °C were obtained by extrapolation. Corrections for non-ideality of adsorbates were made. Adsorption measurements were accurate to about ±0.1 cc. Gases of purity better than 99.8% were obtained from Matheson of Canada, Ltd., and Canadian Liquid Air Co., Ltd. They were condensed or frozen in traps in the adsorption system at −196 °C, evacuated, and subsequently distilled into storage bulbs. Helium was passed through activated carbon at −196 °C.

Temperatures were maintained by liquid baths; those of liquid nitrogen, liquid oxygen, acetone – dry ice with CO_2 bubbled through the mixture, and ice could be maintained at constant temperatures without difficulty. Intermediate temperatures were obtained at the melting points of organic compounds: isopentane, −162 °C; ethanol, −119 °C; methanol, −102 °C; chloroform, −65 °C; ethylene dichloride, −37 °C. The solid phase was maintained by periodically adding liquid nitrogen and stirring. Temperatures were measured by a chromel–alumel thermocouple and could be maintained within ±1 °C of the values quoted above for long periods of time. Temperatures of 30 and 50 °C were maintained with water baths.

130							8.0
150							7.9

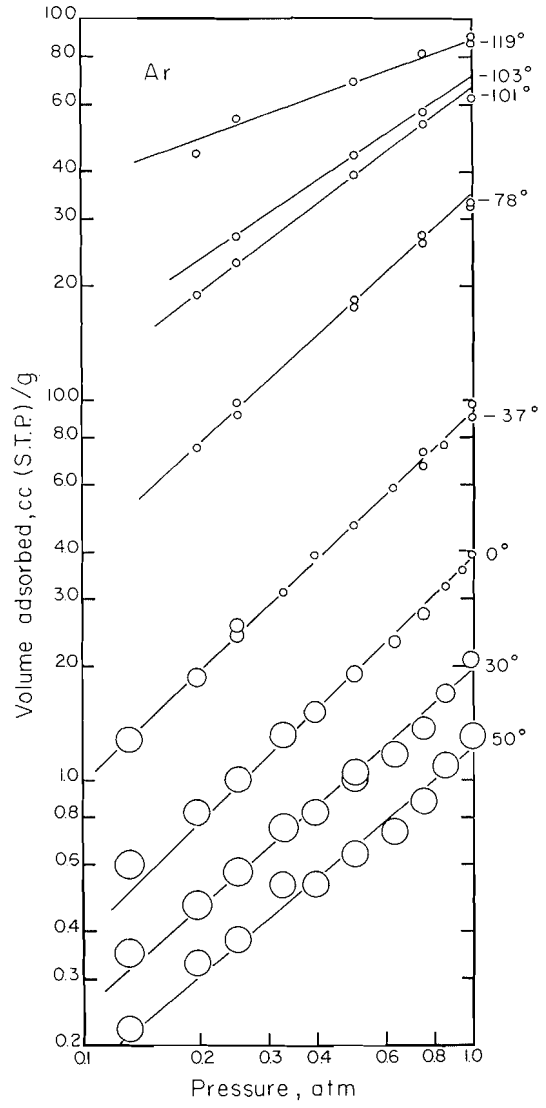

FIG. 2. Logarithmic plots of isotherms for argon on 4A molecular sieve.

Time required for equilibration varied from minutes to 24 or more hours. For argon at −195 °C and 0.2 atm, the apparatus failed after 65 days, when 133 cc (S.T.P.)/g had been adsorbed. In this case only, the equilibrium value, 176 cc (S.T.P.)/g, was estimated by matching this partial rate curve with others for argon at higher temperatures. The leak rate in the adsorption system was zero, except in a few instances when stopcock grease failed, usually because the ambient temperature exceeded 35 °C.

Results

Adsorption isotherms were determined in the following temperature ranges: N_2, −118 to 30 °C; O_2, −196 to 50 °C; CO, −118 to 50 °C; CO_2, −78 to 50 °C; Ar, −196 to 50 °C; CH_4, −78 to 50 °C; C_2H_6, 0 to 50 °C; C_2H_4, −78 to 30 °C; and C_2H_2, −78 to 50 °C. The lowest temperatures were usually determined by either the vapor pressure or slow rate of equilibration. Hysteresis was not observed in any of the isotherms. Isotherms at −78 and 0 °C are presented in Fig. 1. All of the isotherms are plotted logarithmically in Figs. 2, 3, and 4. Many are rather accurately represented by the Freundlich isotherm, $V = kp^n$, where V is amount adsorbed, k and n are constants, and p the pressure of adsorbate. Values for n are given in Table I. Some isotherms could be approximated by 2 linear portions, and in this case both slopes are given.

Isosteric heats of adsorption are presented in Table II. Evaluation of heats of adsorption from isotherms of nearly rectangular shape was difficult and often the experimental data did not extend to low enough pressures; therefore, data are not reported over the entire range of adsorbates, temperatures, and amounts adsorbed. Isobars at 1 atm are presented in Fig. 5, where the amount adsorbed is plotted as the fraction of the pore volume filled by adsorbate. The method of

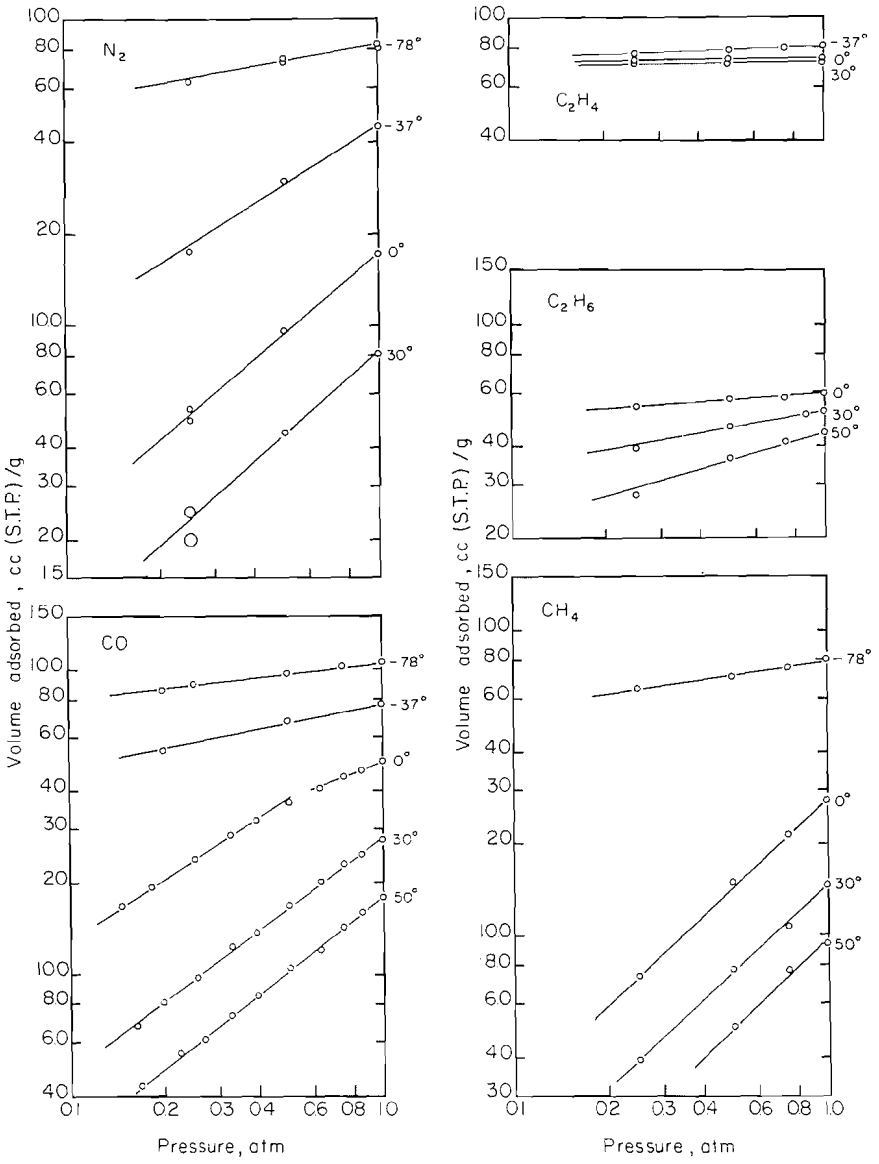

FIG. 3. Logarithmic plots of isotherms for nitrogen, carbon monoxide, methane, ethylene, and ethane on 4A molecular sieve.

estimating pore volume and adsorbate density is described in the next section.

Discussion

The A zeolites are interesting adsorbents because they are crystalline and their structure has been established (4, 5). From the unit cell dimension, 12.32 Å, and the density of the hydrated zeolite, 1.99 g/cm^3, the number of unit cells per gram of dehydrated 4A sieve is calculated as 3.454×10^{20}, close to the value reported by Dubinin (21). Each unit cell contains a large, essentially spherical cavity of 11.4 Å diameter and 776 Å^3 volume. The six passages of 4.2 Å diameter connecting the cavities of adjacent unit cells contribute 38 Å^3 to the accessible volume to yield a total of 814 Å^3. Hence the pore volume is 0.281 cc/g anhydrous 4A zeolite.

Most of our adsorption data are presented as cc(S.T.P.)/g and molecules per cavity; 100 cc(S.T.P.)/g is equivalent to 7.785 molecules per cavity. In the present work the largest number of molecules per cavity was 15. Other adsorption data are presented as the fraction of the pore volume filled by adsorbate, with the adsorbate assumed to have the density of the liquid at the normal boiling point and to pack in the cavities the same as in the liquid. Of course, neither of these assumptions is correct; however, the "fraction of pore volume filled" provides a useful index for comparing data.

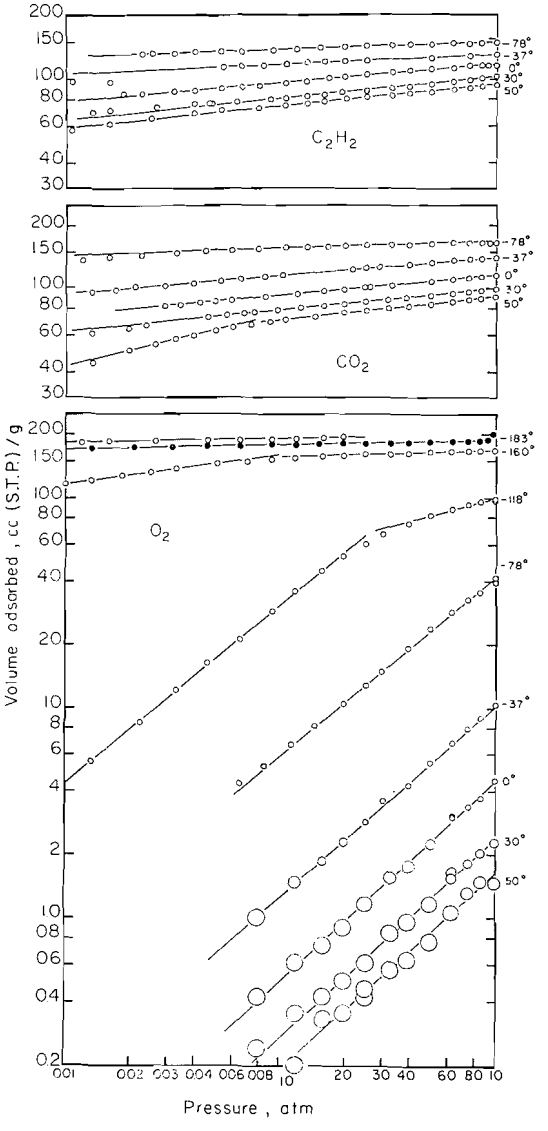

FIG. 4. Logarithmic plots of isotherms for oxygen, carbon dioxide, and acetylene on 4A molecular sieve.

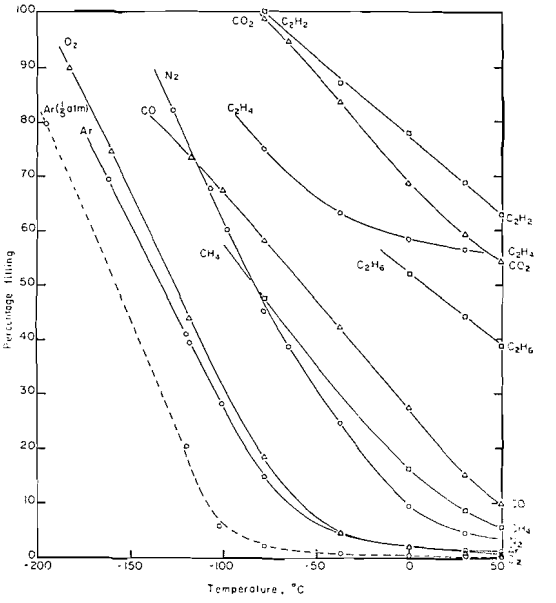

FIG. 5. Adsorption isobars on 4A molecular sieve, where volume adsorbed is expressed as fractional filling of pores assuming the density of adsorbate equals the density of liquid at its normal boiling point. Solid curves for 1 atm; broken curve for 1/5 atm.

All of the isotherms reported in this paper are plotted logarithmically in Figs. 2 to 4, because these plots are frequently linear and because of economy of presentation. Although some isotherms are accurately represented by the Freundlich equation, the linear logarithmic plots often seem to be portions of a sigmoidal curve with a small slope at high pressures and low temperatures, changing to a larger slope at lower pressures or higher temperatures, and in some cases assuming a slightly smaller slope at low pressures or high temperatures. The shape of the Polanyi plots, to be described subsequently, is consistent with this postulate. On linear coordinates, the initial portions of the argon isotherms from 0 to 50 °C are linear but extrapolate to 0.2 cc(S.T.P.)/g at zero pressure; however, above 50 cm Hg these argon isotherms bend upward slightly. All other isotherms seem to extrapolate to the origin. Linear isotherms have been reported for argon and other rare gases on A and X sieves at −78 °C and higher temperatures (22–27), and the Freundlich equation has

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

been generally satisfactory for rare gases on molecular sieves (28–30).

Nitrogen and methane isotherms are approximately linear at 0 °C and above, values of n being about 0.90 and 0.95, respectively. However, carbon monoxide isotherms have considerable curvature, even at 50 °C ($n = 0.80$). For the 5A zeolite, Freundlich exponents have been reported to increase from 0.895 to 1.0 as temperature is increased from −78 °C (31). In the present work, methane and nitrogen adsorb in equal amounts at −78 °C, but more methane is adsorbed at 0 °C; however, the adsorption of carbon monoxide exceeds N_2 and CH_4 at all temperatures. On NaX zeolites in the range −120 to −60 °C, more nitrogen was adsorbed than argon and the nitrogen isotherm had more curvature (32). Thus, for gases with boiling points in the range −195 to −161 °C, the adsorption on the 4A sieve does not follow the observations made for activated carbons, where the amount adsorbed at a given temperature and pressure increases with decreasing boiling point of adsorbate.

Gases with boiling points near −78 °C, carbon dioxide, ethane, ethylene, and acetylene, yielded nearly rectangular isotherms with the Freundlich exponent n at 30 °C having values of 0.10, 0.18, 0.014, and 0.10, respectively. This result is not unexpected, because in comparing argon and ethane on a reduced temperature basis, −78 °C for argon corresponds to +121 °C for ethane. Nearly rectangular isotherms have been reported for acetylene on A and X sieves at 0–40 °C (33). In the present work acetylene and CO_2 are adsorbed in the largest amounts in the range −78 to +50 °C, followed by ethylene and ethane. Ethylene adsorption decreases slowly with increasing temperature, the values of n remain small to 30 °C, and rate curves (34) show anomalies. These results suggest that a chemisorption process possibly accompanied by polymerization may occur to an increasing extent with increasing temperature. However, ethylene was quantitatively desorbed at 50 °C and essentially zero pressure (liquid N_2 trap) and mass spectrometric analysis of the desorbed gas showed only ethylene.

For adsorption isobars and generalized Polanyi plots in Figs. 5, 6, and 7, respectively, the amount adsorbed is given as the percentage of the pore space filled assuming that the adsorbate has the density of normal liquid at its boiling point and that packing in the pores is the same as in the liquid. For all of the isobars, the amount adsorbed decreased with increasing temperature, as expected for equilibrium data, and no maxima were observed as has been reported for adsorption for fixed periods of time (35). For gases with appreciable rates of adsorption at temperatures near their boiling points, the percentage filling of pore volume approached 100: argon, 80; oxygen, 90; and carbon dioxide and acetylene, about 100. The isobars for ethylene decreased less rapidly with temperature than expected, and this anomalous behavior has been considered earlier.

Dubinin, *et al.* (9, 10) reported that on CaA and NaX sieves the molar volume of some adsorbates was near the molar volume of the liquid and for others widely different. Barrer and Gibbons (36) found that the sorption, calculated as normal liquid, on synthetic faugasite at saturation pressure corresponded satisfactorily to the volume of the larger cavities. Nevertheless, small strongly adsorbed molecules can apparently penetrate the sodalite cages of some zeolites (37) and this phenomenon may occur to a limited extent in the present work.

A generalized Polanyi equation has been shown to correlate adsorption data on charcoal reasonably well (38–40), and the method of Grant and Manes (40) was applied to the present data on the 4A zeolite. The characteristic curve in terms of volume of adsorbate as a function of the adsorption potentials, ϕ, per unit volume of adsorbate, where

$$\phi = (RT/V) \ln p_0/p$$

is plotted, assuming that the density of adsorbate equals the density of liquid at the boiling point. Here V is the molar volume based on this density, and p is the pressure of adsorbate. The values of vapor pressure, p_0, were estimated from a plot of $\log p_0$ vs. T^{-1}, extrapolated above the critical temperature where necessary (40).

For the 4A zeolite, the generalized Polanyi plots do not yield unique characteristic curves for each adsorbate nor a general curve for all gases, as shown for oxygen and acetylene in Fig. 6. For each gas the curves for different temperatures have the same shape but are displaced. Other estimates of molar volume of adsorbate (38) or no volume correction generally led to no improvement. The plots for C_2H_2 lie significantly to the right of those for O_2.

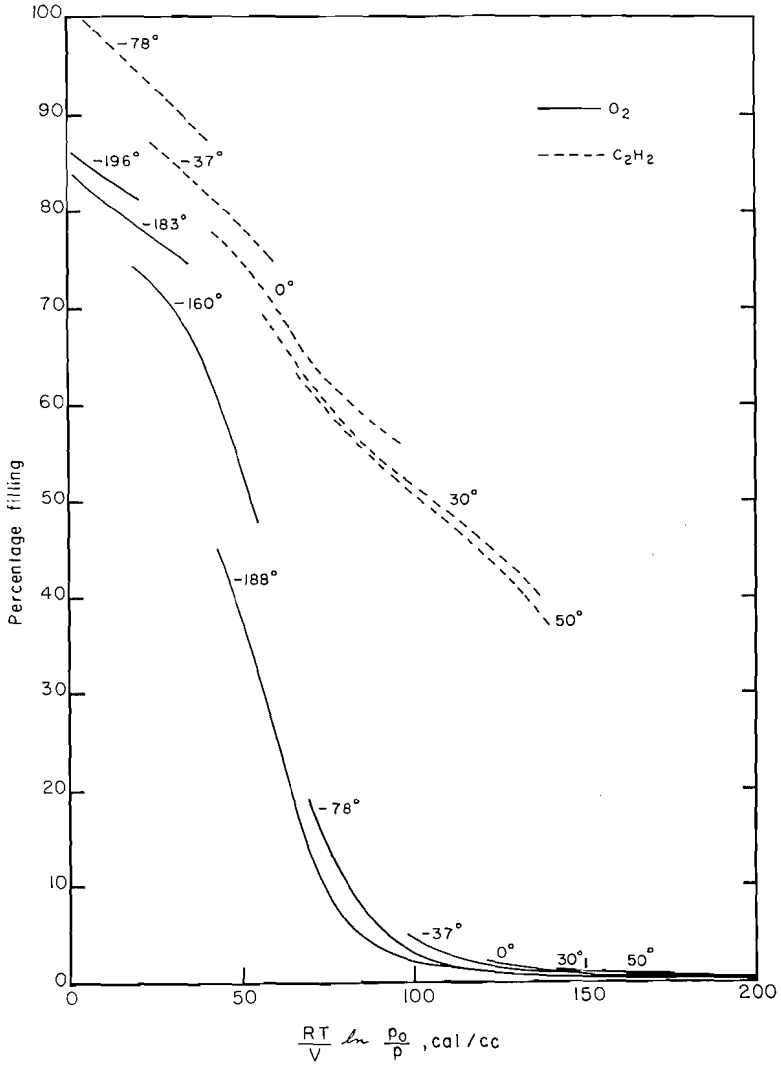

FIG. 6. Generalized Polanyi plots for oxygen and acetylene on 4A molecular sieve. See Fig. 5 for significance of vertical scale.

Despite the failure of the Polanyi plots to provide unique characteristic curves for individual adsorbates or groups of adsorbates, these plots are a useful way of comparing adsorption data on a single graph. For example, the conclusion that acetylene is more strongly adsorbed than oxygen at a given fractional filling can be made unambiguously from Fig. 6. The characteristic curves could be represented by bands having a width of ± 5 to 10% of the fractional filling. However, we have chosen to pass curves through points for pressures from 0.25 to 1.0 atm as shown in Fig. 7. At a fractional filling of pores of 0.4, the adsorption potentials per unit volume increased in the following order

$$Ar < O_2 < C_2H_6 \cong CH_4 < N_2 < CO < CO_2 < C_2H_2$$

with ethylene behaving anomalously. The fact that the generalized Polanyi equation correlates adsorption data on charcoal better than on the 4A molecular sieve might have been anticipated, as adsorption on charcoal is relatively nonspecific

compared with adsorption on zeolites; furthermore, the pores in charcoal are larger so that packing of molecules is a less serious problem. Because the greatest number of molecules adsorbed per large cavity is only about 15, the number that can be packed in a cavity at different temperatures may vary significantly.

From Fig. 7 and Table II, the adsorption of C_2H_2, CO_2, C_2H_4 (from 0 to 50 °C), CO, and N_2 seems to be stronger than O_2, Ar, CH_4, and C_2H_6. The first group of molecules have moderately large quadrupole moments and CO also has a small dipole moment. Correlations between polarizability and heats of adsorption, heats of adsorption minus heats of liquefaction, or adsorption potential per unit volume were poor. The enthalpies and potentials for gases having quadrupole and dipole moments lay significantly above a curve through data for O_2, Ar, CH_4 and, for potentials, C_2H_6. Barrer and Gibbons (36) have attributed the strong adsorption of CO_2 and NH_3 on X-type sieves to quadrupole and dipole moments, respectively. The strongly adsorbed molecules also have double or triple bonds. The adsorption of CO_2 is the most rapid of the gases studied in the present paper, and CO_2 is also rapidly and strongly adsorbed on coal (41, 42). On amorphous silica–alumina adsorbed CO_2 yields a characteristic infrared spectrum which has been suggested as an index for cracking activity (43). The surfaces of A and X sieves are polar and large electrical fields have been postulated near the exchangeable cations. However, the apparent correlation between adsorption and quadrupole and dipole moments may not be an adequate explanation of the present observation, because specific interactions between highly charged sites and molecules containing multiple bonds might be expected.

Surface areas were not estimated from adsorption isotherms, because the basic premises of surface area determination do not hold for A, X, and Y zeolites and some other microporous solids (44). Specifically, the initial part of the adsorption isotherm is not limited by the number of molecules required to cover the surface but by the number that fills the pore volume. Thus, the areas of the large cavities plus channels of A and X zeolites calculated from structural data are about 1200 and 1400 m^2/g compared with gas adsorption values of 600 to 900 m^2/g that are often quoted (5, 45, 46).

Fluorocarbon-bridged di(tertiary phosphine) complexes of Group VIB metal carbonyls

W. R. CULLEN, D. F. DONG, AND J. A. J. THOMPSON
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received June 11, 1969

A series of complexes of the general formula $(C_6H_5)_2PC{=}CP(C_6H_5)_2(CF_2)_nM(CO)_4$, n = 2, 3, or 4; M = Cr, Mo, or W have been prepared. The properties of the new complexes, in particular their infrared spectra, are discussed.

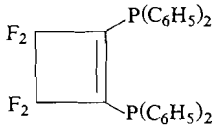
Canadian Journal of Chemistry, 47, 4671 (1969)

Introduction

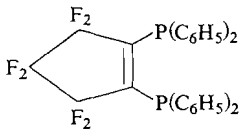
It is well known that di(tertiary phosphines) such as **1** react with the hexacarbonyls of chromium, molybdenum, and tungsten to displace 2 carbon monoxide groups and give the tetracarbonyl complex (e.g., Reaction [1]) (1)

[1] 
1

In the course of investigations of the complexing abilities of the fluorocarbon-bridged di(tertiary phosphines) ffos (**2***a*), and $f_6$fos (**2***b*) (2–5)

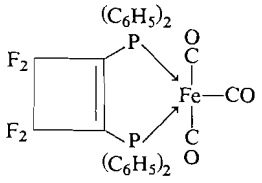


2*a*

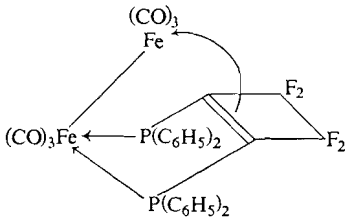


2*b*

we have found that there are two main products from the reactions of these ligands with iron carbonyls. These have the formulae[1] (P—P)Fe(CO)$_3$ and (P—P)Fe$_2$(CO)$_6$ and, using ffos as an example, the structures **3** and **4**, respectively (5, 6)



3



4

The yield of the Fe$_2$(CO)$_6$ compound is much lower when $f_6$fos is used and thus it was of interest to find what would happen when the ring size was further increased. For this reason, $f_8$fos, **5**, has been synthesized (see below) and found to react

[1]In this paper the symbol P—P is used to indicate a chelating di(tertiary phosphine).

with iron carbonyls to give a compound analogous to **3** but not to **4** (7). In order to see if this result can be explained by an increase or decrease in the donor–acceptor abilities of the new phosphine ligands, the compounds $(P—P)M(CO)_4$ (M = Cr, Mo, W) have been synthesized to examine their infrared spectra in the carbonyl stretching region. This paper is also an expansion of an investigation of complexes of Group VIB metals briefly described in an earlier publication (2).

Experimental

The hexacarbonyls, $M(CO)_6$ (M = Cr, Mo, W), were obtained commercially and used without further purification. The di(tertiary phosphines), 1,2-bis(diphenylphosphino)tetrafluorocyclobutene (ffos), and 1,2-bis(diphenylphosphino)hexafluorocyclopentene ($f_6$fos) were prepared from published procedures (4, 8). 1,2-Bis(diphenylphosphino)octafluorocyclohexene ($f_8$fos) was prepared as described below.

Infrared spectra were obtained using a Perkin–Elmer Model 457 Grating Spectrometer and were calibrated against polystyrene and cyclohexane. ^1H and ^{19}F nuclear magnetic resonance (n.m.r.) spectra were recorded on Varian Associates' A-60 and HA-100 instruments, respectively. Microanalyses were performed by the Pascher Mikro-analytisches Laboratorium, Bonn, West Germany and by Mr. P. Borda of this Department.

Preparation of (P—P)M(CO)$_4$

Three general methods of preparation of the new complexes are outlined below. The method used for a specific complex is shown in Table I.

Method A

A benzene solution (15–20 ml) containing a 1:1 mole ratio of ligand to hexacarbonyl was heated at 150 °C in an evacuated Carius tube for 17 to 46 h. At the end of the reaction period the initially orange or colorless solution had become deep red (except for ffosW(CO)$_4$, which was amber). The reaction solution was filtered to remove any suspended impurities and then solvent was removed at reduced pressure. The resulting yellow-to-red solid was dissolved in benzene and recrystallized by addition of hexane or by slow evaporation of the solvent.

Method B

A solution of the hexacarbonyl (~1 mmole) and the ligand (1 mmole plus a 10% excess) in toluene or cyclohexane was refluxed under a nitrogen atmosphere for 3–7 h. The solvent was removed to give a red solid which was redissolved in benzene. The solution was filtered and crystals of the benzene solvate were obtained by the addition of hexane to the solution or by slow evaporation of solvent.

Method C

An acetone solution (15 ml) containing approximately equimolar amounts of ligand and hexacarbonyl was irradiated by ultraviolet light (100 W Hanovia lamp 10 cm from the tube) for 18 h in a sealed Carius tube. The contents of the tube were evaporated to dryness and dissolved in hot benzene. The solution was filtered and the solvent allowed to evaporate slowly to afford crystals of the product.

Reaction of $f_6$fos with $[C_6H_3(CH_3)_3]W(CO)_3$

The tungsten compound (0.38 g, 1 mmole) and $f_6$fos (0.54 g, 1 mmole) were refluxed in cyclohexane for 14 h. No reaction products were detected. The tungsten compound (0.38 g, 1 mmole) and $f_6$fos (2 mmole) in benzene solution were heated (150°) in a sealed tube (20 h). The solvent was removed, and the solid residue chromatographed on Fluorisil. The main product, identified as $f_6$fosW(CO)$_4$ (0.23 g, 27%) eluted as a red band using 30% benzene in petroleum ether. Only trace amounts of other products were isolated.

1,2-Bis(diphenylphosphino)octafluorocyclohexene, ($f_8$fos)

Diphenylphosphine (3.72 g, 20 mmoles) and decafluorocyclohexene (2.62 g, 10 mmoles) were heated (100°) in a sealed Carius tube for 21 h. The gummy orange-red reaction product was extracted from the tube with benzene (100 ml). The orange solution was filtered to remove unidentified solid impurities and the solvent was removed at reduced pressure. Trituration of the oil thus obtained under petroleum ether (b.p. 30–60°) initiated solidification. The crude solid was recrystallized from hexane to yield 3 g (50%) of orange, crystalline product, m.p. 135°.

Anal. Calcd. for $C_{30}H_{20}F_8P_2$: C, 60.6; H, 3.4. Found: C, 61.1; H, 3.6.

Principal infrared bands (CCl_4 solution) were: 3080(w), 3060(w), 1485(w), 1435(m), 1340(m), 1315(w), 1215(s), 1195(vs), 1175(vs), 1163(vs), 1113(vs), 1090(m), 1070(w), 1035(vs), 980(s), 694(s). The ^{19}F n.m.r. spectrum ($CHCl_3$ solution, $CFCl_3$ internal standard) shows two poorly resolved, equal-area resonances at 101 (triplet) and 135 p.p.m. (multiplet) upfield from $CFCl_3$.

Results and Discussion

Three of the new Group VIB carbonyl derivatives described here were prepared in good yield using the previously unreported 1,2-bis(diphenylphosphino)octafluorocyclohexene, $f_8$fos, **5** (Reaction [2]). The preparation and properties of this ligand warrant some comment as they differ somewhat from those of the better-known ffos and $f_6$fos. Unlike the latter ligands, which can be prepared by simply mixing the reactants at room temperature or below (2, 8), the cyclohexene derivative is obtained in about 50% yield by heating the phosphine and olefin at 100° or higher (Reaction [2])

[2] 
5

[3] 
Recently, Stockel, Megson, and Beachem (9, see also (10)) reported that perfluorocyclohexene and 1,2-dichlorooctafluorocyclohexene do not give phosphobetaines when reacted with tertiary phosphines. In comparison, the 4- and 5-membered ring systems reacted readily. The difference in reactivity was attributed to lack of double-bond strain in the cyclohexene ring. A similar argument in the present case can be made.

F_8fos is a bright-orange, crystalline, air-stable solid. In solution it is indefinitely stable to light or air[2]. To our knowledge this is the first reported case of a so highly colored simple phosphine. In contrast, both ffos and $f_6$fos are white and the $(C_6H_{11})_2P$ analog (11) pale yellow.

The three fluorocarbon-bridged ligands could all form complexes by using the double bond alone (no known examples) or by acting as a chelating phosphine (reaction [3] (2, 5)) or both (4). However, as is also reported for the related ligand $(C_6H_5)_2PCH{=}CHP(C_6H_5)_2$, **6** (12), we have found that they act only as chelating ligands when reacted with Group VIB carbonyls. Thus the complexes $(P{-}P)M(CO)_4$ (M = Cr, Mo, W) have been prepared by reaction of the ligand with the hexacarbonyl in hydrocarbon solvent (reaction [3]). Where M = Cr and W, complete reaction occurred only when the reactants in benzene solution were heated to 150° in sealed evacuated Carius tubes. The greater lability of the carbonyl groups of $Mo(CO)_6$, which has been well documented in the literature, enabled us to prepare the corresponding $Mo(CO)_4$ derivatives by refluxing the reactants in toluene for a few hours. One of the complexes, $f_6$fosCr$(CO)_4$, was prepared by ultraviolet irradiation of an acetone solution of the reactants for several hours.

The new complexes are highly colored, stable, and crystalline. Other $(P{-}P)M(CO)_4$ derivatives are white or yellow (1). The complexes of $f_6$fos and $f_8$fos are somewhat unusual in their ability to form extremely strong solvates which, in the case of the $f_6$fos derivatives, analyze well for the general formula $(P{-}P)M(CO)_4\frac{1}{2}S$ (M = Cr, Mo, W; S = benzene, cyclohexane, chloroform). On heating, all solvates lose solvent at about 30° below their melting or decomposition points. The light colored unsolvated complexes of $f_6$fos were obtained by vacuum sublimation at moderately high temperatures. The $f_8$fos analogues of Mo and W formed similar dark red solvates with benzene and could be obtained unsolvated as bright-orange plates by recrystallization from boiling *n*-heptane. Only $f_8$fosCr$(CO)_4$ could be desolvated by treatment in vacuo at refluxing toluene temperatures.

All the new complexes reported here are stable in most solvents. However, it was noted that the $Mo(CO)_4$ derivatives decomposed in the space of a few hours in carbon tetrachloride, the decomposition being easily followed by the appearance of new bands in the infrared carbonyl stretching region. Both the chromium and tungsten derivatives were stable indefinitely in this solvent. We cannot explain this anomaly at the present time but it may involve an oxidative addition reaction similar to that known for MCl_4 (M = Ge, Sn) with (bipy)$Mo(CO)_4$ (13).

Chatt and Watson (14) reported some years ago that the mesitylene metal tricarbonyls reacted with di(tertiary phosphines). They obtained, in addition to the expected dicarbonyl derivatives $(P{-}P)_2M(CO)_2$, considerable amounts of the tetracarbonyl compound, $(P{-}P)M(CO)_4$, and suggested that carbonyl groups on one molecule could exchange with ligand on another. In the present investigation there was no reaction between mesitylenetungsten tricarbonyl and $f_6$fos in refluxing cyclohexane. However, when the reaction was run in benzene solution in a sealed tube at 150°, the main product was the tetracarbonyl compound $f_6$fosW$(CO)_4$ with very little, if any, $(f_6fos)_2W(CO)_2$ being formed.

Infrared Spectra

The infrared spectra of the new complexes in

[2]The color was first believed to be due to contamination. However, chromatography on a Fluorisil column and repeated crystallization wrought no change.

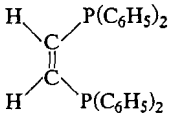
the carbonyl stretching region are listed in Table II. The spectra of complexes of related saturated (**1**) and unsaturated (**6**) ligands are also given for comparison.

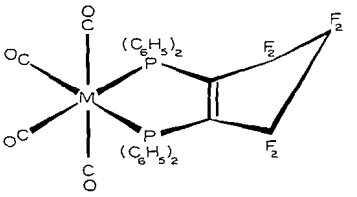


6

Firstly, it is to be noted that there is very little difference between the carbonyl spectra of the two hydrocarbon bridged ligands. It has been suggested that the complexes of **1** have slightly higher frequencies than those of **6**, indicating a slightly higher π-acceptor strength for **1** (12). However, comparison is being made here between spectra run in different solvents. The spectrum of $C_2H_4[P(C_6H_5)_2]_2Mo(CO)_4$ has been reported in hydrocarbon solvent as being 2028, 1932, 1919, and 1906 cm^{-1} (15). Thus it seems that the inductive effect in the sp^2 carbon atoms and the presence of the unsaturated bridging system have little effect. However, the spectra of the fluorocarbon bridged species are at higher wavenumber than the others. This seems to indicate that it is the inductive effect of the fluorine atoms in the bridge which is responsible for the apparent increase in π-acceptor strength.

Secondly, there is no significant difference in the spectra of the complexes of the fluorocarbon bridged ligands, apart from the extra band of the $f_6$fos complexes which is discussed below. Thus, any difference in reactivity of the fluorocarbon ligands is unlikely to arise because of donor–acceptor differences. This leaves geometrical factors (including ring strain) as the main cause. The spectra of the compounds (P—P)$Fe(CO)_3$ (P—P = **2***a*, **2***b*, **5**, or **1**) show this same trend (5, 7); that is, the fluorocarbon bridged complexes have almost identical spectra which occur at higher wave numbers than the hydrocarbon bridged compounds.

Thirdly, the spectrum of $f_6$fos$Fe(CO)_3$ shows four bands, one more than that expected for a compound with C_{2v} symmetry (5). This same feature is seen in the $M(CO)_4$ complexes of $f_6$fos where four bands are predicted yet five are observed. Dobson (16) has found six carbonyl stretching bands in the spectrum of (DTO)$Cr(CO)_4$ (DTO = $(CH_3)_3CSC_2H_4SC(CH_3)_3$) and has made the suggestion that another species such as a 5-coordinate one, in which one end of the ligand is dissociated, is present in solution. It is possible that the extra band in the chromium $f_6$fos complex is due to a similar phenomenon; however, we are not happy with this explanation, especially since the "explanation" would presumably need to be used to account for the extra band in *all* the $f_6$fos complexes. The complex **7** contains two 5-membered rings, one of which is shown to be



7

puckered; the other could be also. It is possible that the combination of these two puckered rings could give rise to two distinct isomers in solution which have a long enough lifetime to be detected by infrared spectroscopy. Two 5-membered rings seem to be necessary since the ffos and $f_8$fos complexes show no unusual features. However, geometrical considerations such as the bite of the ligand which could stabilize certain conformations should not be ignored completely. It is also possible that the cyclopentene ring in a complex such as **7** can exist as two conformers with different energies, such as the planar–bent forms suggested for certain cyclobutanes (17). If the lifetime of any conformer in solution was short, then n.m.r. experiments would show only the average chemical shift of the fluorine atoms, as was found to be the case.

The extra bands observed by Dobson may have a similar origin, since two isomers are possible for rings containing two coordinated sulfur atoms. One of these is shown in projection in **8**. The energy barrier to interconversion of the two forms, which should be detectable by n.m.r. studies, would be small (18).

Synthesis of some organophosphorus compounds: a study of the electron spin resonance spectra of the free radical anions formed by the reactions of 4,4′-bis(diphenylphosphine)biphenyl with alkali metals

MAHDY H. HNOOSH[1] AND RALPH A. ZINGARO
Chemistry Department, Texas A&M University, College Station, Texas 77843

Received June 16, 1969

By the halogen–lithium interconversion method, 4,4′-bis(diphenylphosphine)biphenyl (**1**) was prepared. Under different reaction conditions, mono- and di-oxygenated products were obtained. An attempt to prepare **1** by the Grignard reagent method failed to give the expected product but

$$C_6H_5(OH)(O)PC_6H_4C_6H_4P(O)(OH)C_6H_5$$

was obtained. Bis(diphenylamine)phenylphosphine was also prepared. Tetraphenyldiphosphine monoxide resulted from an attempt to prepare N-diphenylaminodiphenylphosphine. The mechanism of this reaction is discussed. Infrared spectroscopy, elemental analysis, and activation analysis for the determination of oxygen content were performed for the identification of the above compounds.

Reactions of **1** with sodium–potassium alloy in tetrahydrofuran (THF) and 1,2-dimethoxyethane (DME) gave a radical anion which was identified by its electron spin resonance spectra at different temperatures.

Canadian Journal of Chemistry, 47, 4679 (1969)

Introduction

The utilization of the halogen–lithium interconversion method (1) has been found to be useful for the synthesis of a variety of organometallic compounds. Curtis and Allred (2) have utilized the reaction between *n*-butyl lithium and the corresponding halogenated biphenyl for the preparation of the compounds 4-$(CH_3)_3MC_6H_4C_6H_5$ and 4,4′-$(CH_3)_3MC_6H_4C_6H_4M(CH_3)_3$, where M = Si, Ge, or Sn.

Cowley and Hnoosh (3) reported the preparation of 4,4′-$(CH_3)_2P$—$C_6H_4C_6H_4$—$P(CH_3)_2$. Both investigations also included electron spin resonance (e.s.r.) studies of the free radical anions formed by the reduction of these compounds with alkali metals.

In the present investigation the preparation of the compound 4,4′-$(C_6H_5)_2PC_6H_4C_6H_4P(C_6H_5)_2$ is reported and its reactions with alkali metals in tetrahydrofuran (THF) and 1,2-dimethoxyethane (DME) have been studied by e.s.r. spectroscopy. The interest in the e.s.r. study of the latter compound lies in the comparison with that of triphenylphosphine (4) and its oxide (3), where a phenyl group has been shown to cleave from the phosphorus atom in their reactions with alkali metals in the same solvents.

Sisler and Smith (5) reported the preparation of N-diphenylaminodiphenylphosphine by means of the reaction of chlorodiphenylphosphine with sodium diphenylamine produced by the reaction of diphenylamine with NaH in diglyme. In this work a similar approach has been used for the preparation of bis(diphenylamino)phenylphosphine. In addition, an attempt to prepare $[(C_6H_5)_2N](C_6H_5)_2P$ under different conditions from those previously reported (5) resulted in the formation of the unexpected product, tetraphenyldiphosphine monoxide $(C_6H_5)_2P$—$P(O)(C_6H_5)_2$. This reaction appears to be similar to that reported for the production of tetraphenyldiphosphine dioxide by the reaction of diphenylphosphine chloride in the presence of a tertiary amine like diethylaniline (6).

Experimental

Reagents

All the chemical reagents used in this work were obtained from the usual commercial sources. *n*-Butyl lithium was in the form of a hexane solution. It was pumped from the storage container into the reaction vessel under a pressure of dry nitrogen in order to avoid atmospheric contamination. 4,4′-Dibromobiphenyl was used following recrystallization from butanol. Sodium hydride was used in the form of a 50% dispersion in oil. Diethylene glycol dimethyl ether (diglyme) was dried over CaH_2 and distilled prior to its use. THF and DME were purified by distillation after drying over CaH_2 and potassium metal.

The sodium–potassium alloy which was used in the

[1]Present address: Ashland Chemical Co., Research Center, P.O. Box 1503, Houston, Texas 77001.

For personal use only.

reduction of 4,4′-bis(diphenylphosphine)biphenyl was prepared by mixing proper amounts of sodium and potassium metals after they were first cleaned by treatment with benzene and then ether. They were sublimed by heating under vacuum in the reaction apparatus used for free radical generation.

Apparatus

All infrared spectra were recorded on a Beckman Model IR-12 spectrometer using KBr pellets. The e.s.r. spectra were measured using the X-band of a Varian V-4502-15 e.s.r. spectrometer.

Oxygen determinations were performed using the neutron activation and analysis system at the Activation Analysis Research Lab., Texas A&M University. Weighed amounts of dry primary standard grade benzoic acid in polyethylene vials were used as standards. The unknown samples and standards were subjected to the same experimental conditions. The other elemental analyses were performed by the Galbraith Laboratories, Inc., Knoxville, Tennessee.

Preparation of 4,4′-Bis(diphenylphosphine)biphenyl, 4,4′-$(C_6H_5)_2PC_6H_4C_6H_4P(C_6H_5)_2$

To 31.2 g (0.1 mole) of 4,4′-dibromobiphenyl dissolved in 200 ml of anhydrous ether contained in a 1 l three-necked flask, equipped with a mechanical stirrer, a reflux condenser, and dropping funnel, 12.8 g (0.2 mole) of *n*-butyl lithium (in hexane) was added dropwise, with stirring, under an atmosphere of dry nitrogen at room temperature. The lithium exchange reaction was essentially complete after 30 min. Chlorodiphenylphosphine, $(C_6H_5)_2PCl$, (22.05 g, 0.2 mole) was added dropwise to the lithium compound. After 3 min the brown color began to fade and a yellowish precipitate formed The reaction was slightly exothermic. The mixture was stirred for 2 h after completion of the $(C_6H_5)_2PCl$ addition. It was then refluxed for 2 h and allowed to cool under nitrogen. The reaction mixture was hydrolyzed with saturated aqueous ammonium chloride solution. The ether layer plus washings were dried overnight over anhydrous sodium sulfate. The ether solution was then evaporated under reduced pressure, and the brown-yellow product was recrystallized first from ethanol and then from a mixture of ether and petroleum ether. This resulted in a yield of 51.2% of white crystals which melted at 195 °C.

Anal. Calcd. for $(C_6H_5)_2P—C_6H_4C_6H_4—P(C_6H_5)_2$: C, 82.76; H, 5.37; P, 11.87. Found: C, 82.79; H, 5.52; P, 11.67.

In this reaction it was found that if the conditions were changed slightly, different products were formed. In one run, all steps up to the hydrolysis were carried out in a similar manner. The reaction flasks, while hot, were opened to the air and hydrolyzed with saturated ammonium chloride solution with stirring. Evaporation of the organic layer yielded another quantity of solid product. The solid product from the water layer was recrystallized from ethanol and then *n*-butanol. The white crystals melted at 205–206 °C.

The analysis is in agreement with a stoichiometry which suggests the compound 4,4′-bis(diphenylphosphine)biphenyl monoxide.

Anal. Calcd. for 4,4′-$(C_6H_5)_2PC_6H_4C_6H_4P(O)(C_6H_5)_2$: C, 80.29; H, 5.23; P, 11.62. Found: C, 80.26; H, 5.18; P, 11.62.

A second solid was obtained from the organic layer which was recrystallized first from ethanol and then *n*-butanol; m.p. 265–266 °C. The analysis suggests the compound 4,4′-bis(diphenylphosphine oxide)biphenyl.

Anal. Calcd. for 4,4′-$(C_6H_5)_2(O)PC_6H_4C_6H_4P(O)(C_6H_5)_2$: C, 77.97; H, 5.05; P, 11.30. Found: C, 77.49; H, 5.49; P, 11.01.

Activation analysis for oxygen gave 5.54%, compared with the calculated value of 5.68%.

An attempt to prepare 4,4′-bis(diphenylphosphine)biphenyl by the use of Grignard reagent in THF with I_2 to catalyze the reaction resulted in the formation of 4,4′-bis(diphenylphosphoric acid)biphenyl, 4,4′-$C_6H_5(OH)(O)P—C_6H_4C_6H_4—P(O)(OH)C_6H_5$, which was identified by chemical analysis, infrared spectrum, and molecular weight determination.

Preparation of Bis(diphenylamino)phenylphosphine $[(C_6H_5)_2N_2]PC_6H_5$

A solution of 33.8 g, (0.2 mole) of diphenylamine in 150 ml of dry (over CaH_2) diethylene glycol dimethyl ether (diglyme) was added to a suspension of 14 g of NaH (50% dispersion in oil) in 300 ml of diglyme. When the evolution of hydrogen was over, 18 g (0.1 mole) of $C_6H_5PCl_2$ was added, with stirring, to the mixture. The solution was warmed to 110 °C and kept at this temperature for 2 h. The solid reaction product (sodium chloride) was filtered hot, and washed with dry ether. The filtrate and the ether washings were combined and the solvents removed under reduced pressure. The residue was recrystallized from ethanol and then ether. The resulting crystals melted at 139–140 °C.

Anal. Calcd. for $[(C_6H_5)_2N]_2PC_6H_5$: C, 81.02; H, 5.67; P, 7.01; N, 6.30. Found: C, 80.27; H, 5.74; P, 7.54; N, 6.25.

This compound was found to be exceedingly sensitive to air and moisture. On standing, even in a desiccator, the crystals turned yellow and then bluish green.

Attempts to prepare diphenylaminodiphenylphosphine $[(C_6H_5)_2N](C_6H_5)_2P$ as reported (5) with slightly different conditions resulted in the formation of tetraphenyldiphosphine monoxide. The diphenylamine was added to the NaH suspension dropwise at room temperature. After the addition of $(C_6H_5)_2PCl$ the mixture was refluxed for about 2 h. Then the precipitate was filtered, while hot, in the atmosphere. The organic solvent was evaporated under reduced pressure and the product was recrystallized from ethanol and then ether. The compound melted at 122 °C and the yield was 17.2%.

The elemental analysis fits the stoichiometry of the compound

$$(C_6H_5)_2P—\overset{\overset{O}{\|}}{P}(C_6H_5)_2$$

Determination of the oxygen content by oxygen analysis gave very good results compared with the calculated value.

Anal. Calcd. for $(C_6H_5)_2P—PO(C_6H_5)_2$: C, 74.61; H, 5.18; P, 16.06; O, 4.15. Found: C, 74.82; H, 4.96; P, 15.90; O, 4.20.

The Reactions of 4,4′-Bis(diphenylphosphine)biphenyl with Alkali Metals

These reactions with alkali metals were carried out in an apparatus specially designed for this purpose which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was connected to a vacuum line of conventional design. The compound was permitted to react in the reaction bulb after the metals were heated and condensed as shiny mirrors on this bulb and after the solvent was distilled under vacuum into the same bulb. Samples were taken after various times and at various temperatures.

Results and Discussion

I. Syntheses and Infrared Spectra

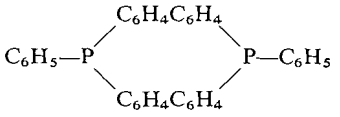
During the synthesis of 4,4′-bis(diphenylphosphine)biphenyl it was noted that two kinds of products, the monoxide and the dioxide, were obtained when the reaction mixture was opened to air and hydrolyzed while hot, immediately following the reflux period. The stability of this compound toward oxidation is not surprising in view of the fact that each phosphorus atom bears three aryl substituents. The formation of a monoxide is quite unusual and further illustrates the oxidative stability of this molecule. The formation and isolation of the stable monoxide suggests that this species may be the first one formed during the atmospheric oxidation process.

A comparison of the infrared spectra of the unoxygenated compound and that of the oxygenated products has been made. The absorption band of principal interest is the fundamental P—O stretching vibration, ν_s(P—O). Zingaro and Hedges reported P—O stretching frequencies of a number of organophosphine oxides (7). These were found over the range 1144–1206 cm^{-1}. Kuchen and Buchwalt (8) reported P—O stretching frequencies for tetraphenyl diphosphine dioxide at 1180 cm^{-1}. In the present study strong bands have been observed at 1196 and 1190 cm^{-1} for the di- and monoxide, respectively. These bands were absent in the infrared spectrum of the unoxygenated compound.

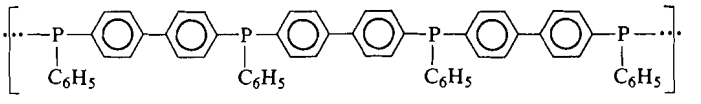
Attempts to prepare 4-diphenylphosphinebiphenyl in the same manner, i.e., by the halogen–lithium interconversion reaction, failed to give the desired product. It appears that the reaction of mono-halogenated biphenyl with *n*-butyl lithium proceeds with difficulty, or not at all. This may be due to the fact that the carbon–bromine bond is much stronger than when there is present another C—Br bond in the opposite position (4′) on the biphenyl. The failure of this reaction may also be due to the extreme sensitivity of the product toward oxygen and water.

In the attempt to prepare the 4,4′-bis(diphenylphosphine)biphenyl via the Grignard reagent using I_2 as a catalyst, the desired product was not formed. As described in the experimental part, 4,4′-bis(phenylphosphonic acid)biphenyl was obtained. This means that the chlorodiphenylphosphine underwent cleavage of one phenyl group and then reacted with 4,4′-dibromobiphenyl. This was followed by hydrolysis and oxidation. However, the mechanism of this unusual reaction remains indefinite. The infrared spectrum also shows the principal absorption bands expected for this molecule, including ν_s(P—O) at 1183 cm^{-1} and ν_s(P—O—H) at 1131 cm^{-1}.

Attempts to prepare the compound



by the reaction of $C_6H_5PCl_2$ with 4,4′-dibromobiphenyl by the halogen–lithium interconversion method resulted in a very low yield of noncrystalline solid which may be a polymer of the following type.



The material was formed in very small quantities and was found to be exceedingly insoluble in the usual organic solvents.

The reaction of diphenylamine with chlorodiphenylphosphine proceeded as expected. The synthesis of diphenylaminodiphenylphosphine $[(C_6H_5)_2N](C_6H_5)_2P$ was accomplished in the manner described (5) by the following reaction sequence.

$$(C_6H_5)_2NH + NaH \xrightarrow{\text{Diglyme}} (C_6H_5)_2NNa + H_2$$

$$(C_6H_5)_2NNa + (C_6H_5)_2PCl \longrightarrow [(C_6H_5)_2N](C_6H_5)_2P + NaCl$$

In this reaction the addition of the diphenylamine solution to the NaH suspension was not carried

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

out dropwise, but both reagents were mixed together completely prior to the reaction. When the addition was carried out in a dropwise manner without heat, the expected product was not obtained. The product obtained was tetraphenyldiphosphine monoxide. Comparison of the infrared spectrum of this compound with that for the dioxygenated compound (8) showed that the spectra are essentially superimposible. Both possess a strong absorption band for the P—O stretching frequency in the region of 1180 cm^{-1}.

The manner of the formation of tetraphenyl diphosphine monoxide is similar to that reported by Quin and Anderson (6) who utilized phosphinous chlorides for the formation of the phosphorus–phosphorus bond. They reported a similar case in which they obtained tetraphenyldiphosphine dioxide from the reaction of chlorodiphenylphosphine in the presence of an amine like diethylaniline, a very small amount of water, and air.

In the present case, as in that reported by Quin and Anderson, in order to account for the formation of the diphosphine monoxide it was necessary to assume that both hydrolytic and oxidative reactions are involved

$$2(C_6H_5)_2PCl + 2(C_6H_5)_2NH + H_2O + 0.5\ O_2 \rightarrow (C_6H_5)_2\overset{\overset{O}{\|}}{P}—P(C_6H_5)_2 + 2(C_6H_5)_2NH_2Cl$$

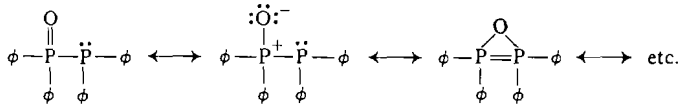
The diphenylamine hydrochloride was isolated and unequivocally characterized.

In the present study, when the amine solution was added dropwise to the sodium hydride without heat, it did not react. When the chlorodiphenylphosphine was added, the amine probably functioned as a catalyst in the formation of the diphosphine. In the case just referred to (6), it was reported that the amine plays a vital role as no coupling occurs in its absence. In this process, phosphorus–phosphorus bond formation precedes the hydrolysis and oxidation steps, and the amine is involved in the coupling reaction, but in a manner different from that of metals when they participate in coupling reactions since the amine cannot function as a reducing agent. It is quite possible that an amine–phosphinous chloride complex, similar to those which have been reported to form between amines and phosphorus trihalides (9) is first formed. The complex is susceptible to attack by a second molecule of phosphinous chloride, with displacement of the amine (10). The intermediate which forms would be of the type

$$[(C_6H_5)_2\ddot{P}—\overset{+}{P}(C_6H_5)_2Cl]Cl^-$$

which is easily hydrolyzed and oxidized. It is to be noted that in this process the same kind of atom is involved, first in electrophilic, and then in nucleophilic behavior.

It is difficult to account for monoxide formation without the formation of any dioxide. The stability of the monoxide may be the most important factor. Resonance among the following structures may explain this stability



The preparation of bis(diphenylamino)phenylphosphine proceeded in the manner expected. This compound is very sensitive to moisture and oxygen. The sensitivity toward oxidation is to be expected because of the availability of unbonded electron pairs on both the nitrogen and phosphorus atoms.

II. Electron Spin Resonance Studies of the Reactions of 4,4′-Bis(diphenylphosphine)-biphenyl with Alkali Metals in THF and DME

These reactions proceeded similarly with lithium, sodium, potassium, and sodium–potassium (NaK) alloy in both THF and DME. When each reaction started, a purple color developed. This color intensified as the reaction mixture was permitted to stand for longer times in contact with the alkali metal as the solution warmed to room temperature. At the latter temperature the color became deep violet.

The sample prepared by the reaction of this compound with sodium–potassium alloy in THF gave the best resolved e.s.r. spectrum. This spectrum, Fig. 1, which was recorded at temperatures between −65 and −10 °C consists of 23

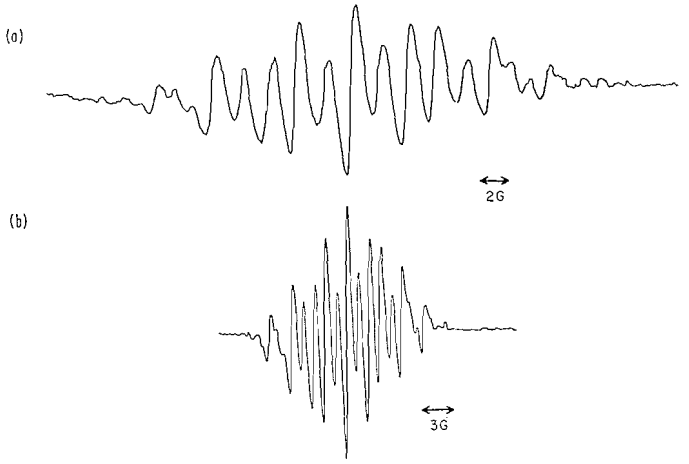


FIG. 1. Electron spin resonance spectrum of the free radical anion formed by the reaction of 4,4′-bis(diphenylphosphine)biphenyl with sodium–potassium alloy in THF: *a*, at −10 °C; *b*, at −65 °C.

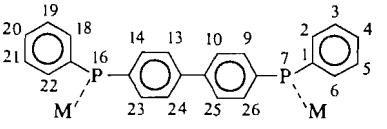
lines. The overlap of the lines reduces the number of the lines from the expected 105 to 23. According to the hyperfine splitting constants and relative line intensities, these lines arise from the interaction of the unpaired electron of the radical anion with three different sets of equivalent nuclei. First, there is a triplet with a hyperfine splitting constant of 3.05 G which arises from the interaction with 2 phosphorus nuclei (spin of 1/2). These 3 lines have relative intensities of 1:2:1. Each of these 3 lines splits into 7 as a result of the interaction with a set of 6 equivalent protons. The hyperfine splitting constant of the splitting is 2.05 G and the relative line intensities are 1:6:15:20:15:6:1. The resultant lines each split into 5 lines of relative intensities 1:4:6:4:1, having a hyperfine splitting constant of 1.02 G. This is caused by the interaction with 4 equivalent protons. The 4 lines at both extreme ends of the spectrum almost disappear because of their low intensities.

The 6 equivalent protons are those on 2 phenyl groups. They are the 2 in the ortho position and the 1 in the para position of each phenyl group. The ortho and para positions in the phenyl group usually have very similar electron densities as in triphenylphosphine (4) and its oxide (3). Since each phenyl group should be attached to a separate phosphorus atom, this means that the reaction of this compound with alkali metals resulted in cleavage of 1 phenyl group from each phosphorus atom. The set of 4 equivalent protons which caused the quintet splitting are on the biphenyl part of the molecule, namely, at positions 9, 14, 23, and 26. This analysis suggests the following radical–anion structure



The resolution of the e.s.r. spectrum appeared to be temperature dependent. As the temperature of the sample was raised to room temperature, the resolution of the spectrum decreased, particularly in the middle portion of the spectrum. In this poorly resolved spectrum, Fig. 2, the central lines became broader and, as a result, some lines disappeared. However, additional splitting appeared, especially for those lines at the extreme ends of the spectrum. This additional splitting is in the form of a quintet which is caused by the interaction of a set of four equivalent protons. The hyperfine splitting constant of this quintet is 0.4 G and the relative intensities

are 1:4:6:4:1. These protons are believed to be in positions 10, 13, 24, and 25. No alkali metal splitting was observed.

Infrared studies on rotational isomerism. IV. 2-Cyanoethanol

MICHEL SCHNEIDER AND PAUL A. GIGUÈRE
Département de Chimie, Université Laval, Québec, Québec

Received August 22, 1969

From the infrared spectra of the vapor measured between 4000 and 200 cm^{-1}, 2-cyanoethanol was found to exist as *gauche* and *trans* isomers in roughly equal proportions around 100 °C. The *gauche* form is the more stable of the two, as in 2-chloro- and 2-bromo-ethanol, but the enthalpy difference is less than half as large; at most 0.7 kcal $mole^{-1}$. This indicates some weak (about 1 kcal $mole^{-1}$) intramolecular hydrogen bonding between the OH group and the π electrons of the C≡N bond.

In the solid, two distinct crystalline phases have been observed. Crystal II, consisting of *gauche* molecules only, is normally obtained; for instance by annealing the vitreous solid from low temperature deposition of the vapor. Crystal I, which contains the two isomers, may be obtained irreversibly from the melt of crystal II under controlled conditions.

On the other hand there was no indication in the spectra of a cyclic tautomer as suggested recently.

Les spectres infrarouges de la vapeur pris entre 60 et 140 °C ont confirmé la présence dans le 2-cyanoéthanol ($CN—CH_2—CH_2—OH$) de deux isomères de rotation, le *gauche* et le *trans*, en proportions à peu près égales. L'isomère *gauche* est le plus stable des deux, comme dans le 2-chloro- et le 2-bromo-éthanol; cependant la différence d'enthalpie est moins de la moitié de ceux-ci, soit 0.7 kcal $mole^{-1}$ tout au plus. Ceci doit être attribué à une liaison hydrogène intramoléculaire faible (environ 1 kcal $mole^{-1}$) entre le groupe OH et les électrons π de la liaison C≡N.

Tout commele 2-chloroéthanol, le 2-cyanoéthanol peut exister sous deux phases cristallines distinctes. La phase normale (II) faite de molécules *gauches* seulement, peut se transformer par fusion ménagée en une phase métastable (I) qui contient les deux isomères.

Par ailleurs on ne trouve dans les spectres aucune indication d'une forme tautomère cyclique telle que proposée récemment.

Canadian Journal of Chemistry, 47, 4685 (1969)

Introduction

Continuing this series of investigations on rotational isomerism in the 2-substituted ethanols (1), we have considered next 2-cyanoethanol, also called hydracrylonitrile, ethylene cyanohydrin or, as a derivative of propane, 3-hydroxypropanenitrile, or β-hydroxypropionitrile. Published information on the molecular configuration of this compound is scanty and in part contradictory. An early Raman study of the liquid (2) has led to no definite conclusion in that respect. Electron diffraction by the vapor (3) has been interpreted in terms of one isomer only, the *trans*. In contrast the two isomers were found to be present in dilute solutions in carbon tetrachloride (4), the *gauche* being only slightly more stable (by 0.14 ± 0.03 kcal $mole^{-1}$). Since stabilization by solvent could be suspected in that case, it seemed desirable to apply the spectroscopic methods to the free molecule.

Experimental

The commercial product (Hopkins and Williams) was distilled repeatedly under 13–15 Torr pressure in a current of dry nitrogen until the final middle fraction passing at 106–107 °C was colorless and pure as shown by the absorption spectrum. It could be kept in that condition for a few weeks if stored in the cool, in a dark flask under nitrogen atmosphere. Because of its low volatility, of the order of 0.1 Torr at room temperature, a 10 m multiple reflection cell heated electrically was used, as described previously (5). The liquid sample kept at 50 °C in a side flask was entrained in a current of dry nitrogen. The spectra were recorded at various temperatures of the vapor cell from 70 to 140 °C. Above that range, decomposition became noticeable as shown in particular by the bands of ammonia in the 700–1100 cm^{-1} region and the C=O bands at 1700–1800 cm^{-1}.

Discussion of Results

The main evidence for the two rotational isomers in the vapor of 2-cyanoethanol comes, of course, from the O—H bands at 3 μ. These consist of two overlapping doublets (Fig. 1) of which that at higher frequency, 3682/3674 cm^{-1}, increases in intensity with temperature. Accordingly it must belong to the less stable isomer and, logically, to the "free" OH group of the *trans*, as in 2-chloro- and 2-bromo-ethanol (5). Further confirmation of this comes from the P- and R-branch separation calculated as explained below. The average frequency difference of some 38 cm^{-1} between the O—H stretching of the two isomers (compared with 15 cm^{-1} in CCl_4 solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

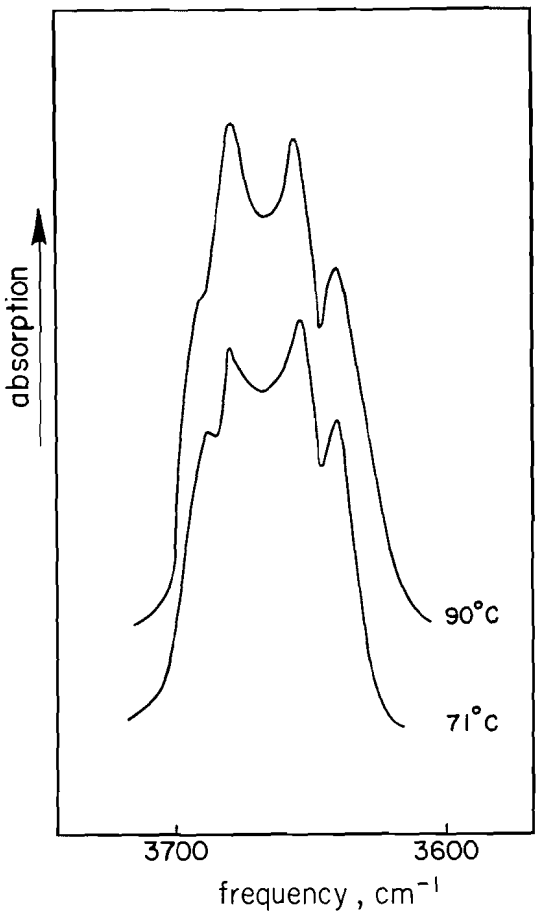

FIG. 1. The O—H stretching bands of 2-cyanoethanol vapor.

(4)) is of the same magnitude as in the 2-haloethanols. However, as explained before, for that type of molecule, this parameter is not a direct measure of the importance of the hydrogen bond. Because the spectra of the deuterated alcohol CN—CH_2—CH_2—OD are not available, identification of the other OH modes must rest on analogy with related molecules. Thus the band at 1332 cm^{-1} in the midst of the CH_2 wagging group is assigned tentatively to the OH bending of the *gauche* isomers. The corresponding *trans* mode is probably lying around 1170 cm^{-1} among the CH_2 twisting bands. As for the OH torsions, only that of the *gauche* molecule could be identified, namely with the 296 cm^{-1} band which also shows a marked temperature effect.

The spectra of the liquid and the vapor in the region from 4000 to 1500 cm^{-1} have the same general appearance as those of 2-chloro- and 2-bromo-ethanol, except of course for the C—N stretching band near 2260 cm^{-1}. The latter shows no sign of any doubling in the vapor, even at the higher temperature of our measurements, 140 °C. Therefore, it is not affected by rotational isomerism as may be gathered from the geometry. Surprisingly, its intensity in the vapor spectra is quite low; less than 10% of that of the strongest bands. This peculiarity has already been noticed in other molecules with a cyano group near to an oxygen atom (6). On the other hand, the C—CN vibrational frequency at 990 cm^{-1} in the *gauche* isomer is shifted down by some 50 cm^{-1} in the *trans* isomer (Table I). The present assignment agrees with that of Fujiyama *et al.* for succinonitrile (7). It is further confirmed by our force constant calculations (8). In a recent study of the related molecules X—CH_2—CH_2—CN (where X = Cl, Br, and I) Wyn-Jones and Orville-Thomas (9) concluded that the C—C and the C—CN stretching modes are strongly coupled. Accordingly they assigned to them the bands at 984 and 907 cm^{-1}, respectively, assuming they have the same frequency in the two rotational isomers. We doubt if these two modes are strongly coupled since their force constants and bond lengths are fairly different. Assignment of the other experimental frequencies was made by analogy with the other 2-substituted ethanols. The various bending modes of the skeleton, in particular those of the CCN group, were identified first in the solid phase spectra, as explained below.

Enthalpy Difference

The spectra of 2-cyanoethanol vapor do not lend themselves as well as those of the 2-haloethanols to intensity measurements. Indeed, the characteristic bands of the rotational isomers are either rather weak, poorly developed (e.g. the CCC bending mode of the *trans* conformer), or overlapped (e.g. the C—CN stretching of the *gauche*). Eventually the O—H stretching bands had to be used in spite of their strong overlap. Optical density measurements lead to a value of $\Delta H = 0.7$ kcal $mole^{-1}$ with a large estimated uncertainty; viz. $\pm$ 0.3 kcal $mole^{-1}$. From the near equal intensity of the two doublets in the temperature range covered here (Fig. 1), it might be concluded that the two isomers are present in roughly equal amounts. However, this is

assuming that the absorption coefficients are about the same for both isomers. Not to be overlooked, also, is the possibility of nonbonded *gauche* isomers which will be even more important here than in the 2-haloethanols, in view of the still weaker intramolecular hydrogen bonds. For these reasons we consider the above value of ΔH as a maximum. The much lower value, 0.14 kcal $mole^{-1}$, found in dilute CCl_4 solutions (4) confirms the existence of an appreciable solvent effect. Recently Fletcher (10) has reported surprisingly strong interactions between so-called inert solvents and various alcohols in dilute solutions.

By analogy with succinonitrile (11) and the 1–2 halocyanoethanes (9), for which the *trans* form is the most stable, it is clear that in 2-cyanoethanol the *gauche* form is stabilized by some interaction of the OH group with the CN group. The latter is well known to be a fairly good proton acceptor through the lone pair orbital along the C≡N bond. In the present case, however, the geometry is much less favorable. Presumably the OH group points towards the cyanogen carbon so that the π electrons of the latter may be visualized as the acceptor. Considering that in 1–2 chlorocyanoethane the *trans* isomer is more stable by 0.38 kcal $mole^{-1}$ (9), we estimate the energy of the intramolecular hydrogen bond in 2-cyanoethanol as 1 kcal $mole^{-1}$ at the most. The weakness of this hydrogen bond is further confirmed by the low frequency of the OH torsion mode in the *gauche* isomer, 296 cm^{-1}, not much above that of methanol, 270 cm^{-1} (12).

The present conclusion on rotational isomers in 2-cyanoethanol raises a question about the electron diffraction study (3) which detected only the less stable conformer, the *trans*. Here the uncertainty as to temperature of the vapor in the diffractometer is of little consequence in view of the low ΔH of isomerization. Interference from certain diffraction centers is always a possibility with such rather complex molecules. Still, it is surprising that the radial distribution curve shows no indication whatsoever of a maximum near 2.95 Å, the expected O . . . CN distance in the *gauche* molecule. Using the bond lengths and angles found or assumed by Yamaha, we have calculated the moments of inertia of the *trans* isomer (Table II). The same parameters were used for the *gauche*, with an azimuthal angle of 65°, close to that found by microwave for the 2-haloethanols (13). From these data the separation of the P and R branches of vibrational bands were calculated by the usual method (14). The results, 12 cm^{-1} for the *trans* and 16 cm^{-1} for the *gauche* isomer, agree satisfactorily with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

experimental ones. The barrier to internal rotation about the C—C bond, estimated from the reduced moments of inertia (Table II), was 3.1 kcal mole^{-1} based on a torsional frequency of 130 cm^{-1} for the *gauche* molecule, and 3.6 kcal mole^{-1} using a frequency of 115 cm^{-1} for the *trans*. The latter is probably too high, which may account for the discrepancy.

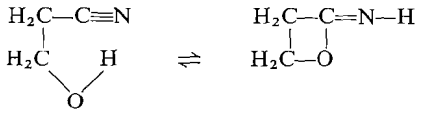
Spectra of the Solid Phases

As in general with hydroxylic compounds, the solid obtained by rapid cooling of the liquid 2-cyanoethanol was vitreous in nature. Crystalline spectra could be obtained by slow cooling, down to about −80 °C, of a liquid film between plates of NaCl, AgCl, CsBr, or polyethylene. Usually crystallization occurred after 30–60 min at that temperature. The crystal thus obtained, hereafter called crystal II after the accepted convention,[1] showed the infrared bands of the *gauche* isomer only, as expected. Now, since 2-chloroethanol was found to crystallize in a second form, crystal I, we tried to reproduce the same phenomenon in the cyano alcohol. This was achieved eventually by annealing a film of the vitreous solid between two windows of polyethylene at liquid nitrogen temperature. Around −87 °C a new form of crystal appeared as a white powder. Its far infrared spectrum revealed more bands than in crystal II. As experienced before, phase I turned out to be much more difficult to prepare on a crystalline support of the ionic type, e.g. NaCl, CsBr, etc. Details of the experimental procedure as well as the temperature relationships will be reported elsewhere.

Assignment of the various bands in crystal I (Table III) is based on the spectra of the liquid which is known to contain both *trans* and *gauche* isomers. The major differences between the two crystalline spectra occur at low frequency, especially below 350 cm^{-1}. The new bands were very useful in assigning the various bending modes of the skeleton; e.g. the CCN out-of-plane and the torsional modes. In the middle infrared the broad band at 649 cm^{-1} was assigned to OH torsion on the basis of a strong temperature effect; indeed, it is shifted by some 25 cm^{-1} to lower frequency at −90 °C. The multiplet structure may be due to combinations with lattice modes or again to different crystallographic sites for the OH groups. Unaccountably two bands are missing in the spectra of crystal I, namely the CCC bending and the C—CN stretching of the *trans* isomer. The former was detected only in the Raman spectrum of the liquid, and the latter is extremely weak even in the liquid, for some unknown reason. Finally, it may be noted that the relative intensities of the crystal I bands are practically the same as in the liquid, contrary to crystal II.

The Presumed Cyclic Tautomer

Matsui and Ishimoto (15) have reported spectroscopic data indicating that in the ω-cyanoalkanols, the electrophilic hydrogen of the hydroxyl group may lead to cyclization through the cyano group. In particular, in the case of 2-cyanoethanol they have observed in the infrared spectrum of the liquid at room temperature a medium intensity band at 1772 cm^{-1} which they assigned to the C=N stretching mode of a cyclic iminolactone tautomer, **2**, supposedly in equilibrium with **1**. We have never observed such an



1 **2**

absorption band in the pure compound. Only at higher temperature in the vapor, when decomposition set in, did the C=O bands gradually emerge in that region. Incidentally, the spectra of 3-cyanopropanol and 4-cyanobutanol published by the Japanese authors also show a band at 1770 cm^{-1} besides the stronger ones at 1695 and 1676 cm^{-1}, respectively, which they correctly assigned to the C=N stretching. Furthermore, tautomer **2**, if present in appreciable concentration, should exhibit some other characteristic bands contrary to observations. Therefore, we conclude that the available data provide no

[1]By mistake this convention was not observed in our previous paper (5).

Coordination compounds of olefins with anhydrous silver salts. IV. Complexes with some endocyclic monoolefins[1]

H. W. QUINN AND R. L. VANGILDER
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Canada

Received June 25, 1969

A study has been made of the changes in the infrared and nuclear magnetic resonance (n.m.r.) spectra of cyclopentene, cyclohexene, cycloheptene, and *cis*-cyclooctene, and of their 1-methyl-substituted analogues upon formation of the silver tetrafluoroborate complexes, $AgBF_4 \cdot 2$olefin. Based on the perturbation of the double bond stretching frequency in the olefin, the order of decreasing strength of the silver ion – olefin interaction is cyclopentene > cyclohexene > *cis*-cyclooctene ≈ cycloheptene.

Introduction

Endocyclic monoolefins produce, in general, more stable silver ion complexes than do the corresponding *cis*-2-olefins (1, 2). The difference has been attributed to the effect of ring strain upon the π basicity of the olefin and thus upon the strength of the coordinate bond (1). Distribution studies with aqueous $AgNO_3$ (1) have produced the order of increasing complex stability

cyclopentene > cycloheptene
> cyclohexene > *cis*-cyclooctene

By contrast, the order obtained by a gas chromatographic technique employing $AgNO_3$ dissolved in ethylene glycol (2) is

cis-cyclooctene > cycloheptene
> cyclopentene > cyclohexene

The difference has been attributed in part (2) to differences in the physical state of the systems or to the different solvents employed.

Our earlier studies (3, 4) of the silver tetrafluoroborate complexes of acyclic monoolefins have indicated a relationship between the low frequency shift of the double bond stretching vibration and the strength of the silver ion – olefin coordinate bond. The present study was undertaken with the aim of establishing, by use of the above criterion, a relative order of strength of the coordinate bond between $AgBF_4$ and the cycloolefins having from 5 to 8 carbon atoms in the ring, and a comparison of that order with those reported earlier for the relative stability of the complexes. The investigation has involved determination of complex stoichiometry and of the changes in the infrared and n.m.r. spectra of the olefins upon complexing.

[1]Contribution No. 173.

Experimental

Anhydrous silver tetrafluoroborate was prepared from silver fluoride and boron trifluoride as previously described (3) or purchased from Peninsular Chemical Research Inc., Gainesville, Florida. The purchased material was thoroughly degassed to remove traces of hydrogen fluoride and stored under petroleum ether.

Cyclopentene and cyclohexene were Phillips Research Grade and Pure Grade materials, respectively. The other olefins were obtained either from Columbia Organic Chemical Company or from Aldrich Chemical Company with 95 mole% minimum purity. When required for satisfactory determination of spectral shifts, the olefin was purified by preparative-scale gas chromatography.

Determination of Complex Stoichiometry

(a) Cyclopentene

Anhydrous $AgBF_4$ (2.969 g, 15.25 mmoles) was exposed at 25 °C to cyclopentene vapor in equilibrium with its liquid in a reservoir at 0 °C (130 Torr). After 16 h, the olefin uptake was 1.900 g (27.94 mmoles) yielding the system of stoichiometry $AgBF_4 \cdot 1.829C_5H_8$. The temperature of the olefin reservoir was raised to 24 °C (olefin pressure = 366 Torr) and over 24 h an additional 0.861 g (12.66 mmoles) was absorbed yielding $AgBF_4 \cdot 2.773C_5H_8$. The temperature dependence of the complex dissociation pressure was determined between 0 and 30 °C for the latter system employing a mercury manometer read to ± 0.01 mm with a cathetometer. The dissociation pressure of the complex with an olefin: silver mole ratio of 2:1 or less was too low to be measured with this technique.

A 1.930 g (9.91 mmoles) sample of $AgBF_4$ exposed at 25 °C to cyclopentene vapor in equilibrium with liquid in a reservoir at 24 °C over a period of 4 days absorbed 1.913 g (28.13 mmoles) C_5H_8 to yield $AgBF_4 \cdot 2.834C_5H_8$. Upon cooling the reservoir at 0 °C for 20 h and at −80 °C for 6 h, 0.565 g (8.31 mmoles) olefin was removed from the system to leave a complex of stoichiometry $AgBF_4 \cdot 1.997C_5H_8$.

(b) Cyclohexene

$AgBF_4$ (0.396 g, 2.03 mmoles) was exposed at 25 °C

over a period of 4 days to cyclohexene vapor in equilibrium with its liquid at 0 °C (25 Torr). The salt absorbed 0.316 g (3.85 mmoles) olefin to yield $AgBF_4 \cdot 1.893C_6H_{10}$.

(c) Other Olefins

Infrared and n.m.r. spectra of $CDCl_3$ solutions of the olefin–$AgBF_4$ systems indicate the 2:1 olefin:silver ratio for the most stable complex with each olefin. Beyond the 2:1 stoichiometry, the infrared spectrum has bands corresponding to uncomplexed olefin and the proton chemical shifts in the n.m.r. spectrum are smaller, indicative of averaging of the spectra of complexed and free olefin molecules (4).

Spectroscopic Studies

The infrared spectra were obtained from fluorolube and Nujol mulls or $CDCl_3$ solutions of the complexes on either a Beckman IR-9 or a Perkin–Elmer 221 recording spectrophotometer employing cells with KBr windows. The n.m.r. spectra of deuterochloroform solutions of the complexes were recorded with a Varian A60 proton resonance spectrometer and the chemical shifts are expressed in c.p.s. with respect to tetramethylsilane as an internal standard.

Results and Discussion

Stoichiometry of Complexes

As has been observed with the cycloolefin complexes of $AgNO_3$ (5–7) and $AgClO_4$ (7, 8), the most stable complexes of $AgBF_4$ with the endocycloolefins have an olefin:silver ion mole ratio of 2:1. Cyclopentene has been found also to form the much less stable 3:1 complex which at 25 °C has an equilibrium dissociation pressure of about 206 Torr (the saturation vapor pressure of C_5H_8 at 25 °C is 280 Torr). For the dissociation equilibrium

$$AgBF_4 \cdot 3C_5H_8(s) \rightleftharpoons AgBF_4 \cdot 2C_5H_8(s) + C_5H_8(g)$$

the dissociation pressure equation, $\log P$ (Torr) $= 12.727 - 3105/(273.2 + t\,(°C))$ (over the range 0–30 °C), yields values for the standard enthalpy change and standard entropy change (at 25 °C and 1 international atm. pressure) of 14.20 ± 0.04 kcal mole^{-1} and 45.05 ± 0.01 cal mole^{-1} degree^{-1}, respectively. The $\log P$ vs. $1/T$ dissociation line for the 3:1 complex intersects the saturation vapor pressure line for cyclopentene, as defined by its Antoine equation (9), at about 40 °C.

The 3:1 complexes have not been detected with the other cycloolefins studied but it must be observed that the pursuit of them has not been diligent.

Infrared Spectra

The spectra of the complexes are quite analogous to those of the free olefins with the largest frequency shifts being observed for the double bond stretching mode (shift to lower frequency) and the out-of-plane deformation mode at about 700 cm^{-1} for the olefinic hydrogens (shift to higher frequency). The latter shift amounts to 59 cm^{-1} for cyclopentene and 33 cm^{-1} for cyclohexene (4). With the complexes of the other cycloolefins, the complexity of this region of the spectrum of the Nujol mulls made it impossible to accurately define the deformation band. With the $CDCl_3$ solution, there was strong solvent absorption in this region.

In Table I are reported the double bond stretching frequencies, $\nu_{C=C}$, for the olefins in $CDCl_3$ solution and for the complexes either in solution or as Nujol mulls or both. The study has included the parent hydrocarbons from cyclopentene to *cis*-cyclooctene, their 1-methyl-substituted analogues, and the 3-methyl- and 4-methyl-cyclohexenes.

There appears to be little dependence of $\nu_{C=C}$ for the complexed olefin upon the anion of the silver salt. For the cyclopentene and cyclohexene complexes the values of $\nu_{C=C}$ are quite comparable to those obtained from the Raman spectra of aqueous $AgNO_3$ solutions of the olefins (10). Similarly, the value of $\nu_{C=C}$ from the Nujol mull of $AgBF_3 \cdot 2C_6H_{10}$ is essentially identical to that obtained from the mull of $AgClO_4 \cdot 2C_6H_{10}$ (8). On the basis of the $\Delta\nu_{C=C}$ values from the solution spectra, the order of relative perturbation of the double bond by the silver ion appears to be

cyclopentene > cyclohexene
> *cis*-cyclooctene ≈ cycloheptene

The difference between the $\Delta\nu_{C=C}$ values for the latter two olefins is not greater than the uncertainty in the values themselves.

As has been observed with the acyclic olefins (3, 4), methyl substitution at the double bond results in a stronger interaction between the olefin and silver ion as evidenced by the greater perturbation in $\nu_{C=C}$ upon complex formation. This effect is undoubtedly due to an increase in the π basicity of the olefin as a result of the electron releasing inductive effect of the methyl substituent. Despite this evidence for stronger coordinate bonding, the 1-methyl-substituted cycloolefins have been reported (1, 2, 11) to form less stable complexes than do the parent hydrocarbons, presumably as a result of the steric effect of the

*ν_o and ν_c represent n.m.r. chemical shift of olefinic protons in olefin and complex, respectively.

substituent group. With the 1-methyl-substituted cycloolefins, the order of relative double bond perturbation, i.e. of $\Delta\nu_{C=C}$, upon complexation is

1-methylcyclopentene > 1-methylcyclohexene
> 1-methyl-*cis*-cyclooctene ≈ 1-methylcycloheptene

identical to the order shown by the parent hydrocarbons.

The difference between the relative magnitude of the double bond perturbation upon complexation and the order of complex stability previously observed may be largely attributable to steric effects. While the double bond perturbation may be a measure of the strength of the interaction between the olefin and silver ion and closely related to the enthalpy change upon complexation (3), the complex stability will be more directly related to the free energy change which reflects the contribution of steric effects to the entropy change.

The relative magnitude of $\Delta\nu_{C=C}$ for 3-methyl- and 4-methyl-cyclohexene parallels the calculated relative basicity of the double bond in 3-methyl- and 4-methyl-cycloolefins (11), but it is the inverse of the relative stability of the $AgNO_3$ complexes as determined by the gas chromatographic technique (12).

Nuclear Magnetic Resonance Spectra

In Table I are recorded the values of the chemical shift for the olefinic protons in both free and complexed olefins. The greater shielding of these protons in cyclohexene and *cis*-cyclooctene than cyclopentene and cycloheptene parallels the ^{13}C chemical shifts for the trigonal carbon atoms (13). As has been observed with other olefins (4), formation of the silver ion complex results in a deshielding of the olefinic protons by about 30–50 c.p.s. There was also observed upon complexing a deshielding of the methylene protons adjacent to the double bond of about 10 c.p.s. in the parent cycloolefin and of 10–20 c.p.s. in the 1-methyl-substituted olefins, the magnitude of the latter increasing with increasing ring size. Similarly, the protons of the 1-methyl substituents were deshielded by about 20 c.p.s.

An attempt to relate the magnitude of the deshielding of the olefinic protons to the strength of the coordinate bond for either series of cycloolefins would produce a quite different order of relative bond strength from that obtained from the values of $\Delta\nu_{C=C}$. Since with the 1-methyl-substituted olefins the proton deshielding upon complexing is smaller than with the parent compounds while, on the other hand, the change in the double bond stretching frequency is greater, it is obvious that both sets of data cannot be used satisfactorily for determination of relative bond strengths. It is our view that the infrared data provide a better basis for such an assessment. As has been discussed previously (4), the deshielding of the olefinic protons as a result of the σ-component of the coordinate bond is at least partially compensated by a shielding effect produced by the π-component involving metal d-electrons. The fact of net deshielding indicates a stronger

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

σ- than π-component. Others have suggested also that this is the case (1). The observed smaller deshielding with the 1-methyl-substituted olefins is probably a result of asymmetric positioning of the silver ion with respect to the double bond which places it closer to the 2-carbon thereby permitting more effective d-electron shielding at C_2 than at C_1 (4).

Some new tetrakis(*p*-tolyl)cyclobutadiene molybdenum complexes

A. EFRATY[1]
Department of Chemistry, University of Waterloo, Waterloo, Ontario

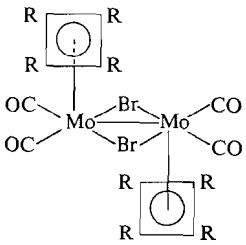
Received June 2, 1969

Tetrakis(*p*-tolyl)cyclobutadiene molybdenum dicarbonyl bromide dimer and (tetrakis(*p*-tolyl)cyclobutadiene)(cyclopentadienyl)molybdenum carbonyl bromide were prepared and their structures studied by proton magnetic resonance. An improved synthesis of tetraphenylcyclobutadiene molybdenum dicarbonyl bromide dimer is also described.

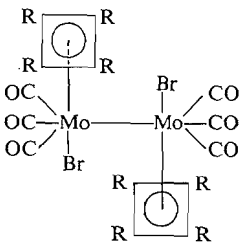
Canadian Journal of Chemistry, 47, 4695 (1969)

Introduction

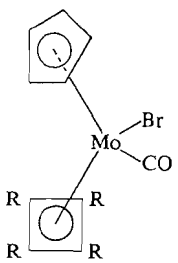
Tetraphenylcyclobutadiene molybdenum dicarbonyl bromide dimer (**1**; R = Ph) was originally prepared by Maitlis and Games (1) and characterized as a tetraphenylcyclobutadiene molybdenum tricarbonyl bromide dimer, **2**. Recently, however, this compound has been shown, by a crystal structure study (2), to contain a tetraphenylcyclobutadiene ring, bromine bridges, and two carbonyl groups per molybdenum atom. Moreover, a relatively short Mo—Mo distance was detected which together with the reported diamagnetism of this compound suggested a strong metal–metal interaction. In this work additional information in support of structure (**1**; R = To = *p*-tolyl) is presented; also the structure of (tetrakis(*p*-tolyl)cyclobutadiene)(cyclopentadienyl)molybdenum carbonyl bromide (**3**; R = To) is discussed.



1



2



3

Results and Discussion

The molybdenum complex (**1**; R = Ph), on which the crystal structure study was performed (2), was isolated from the reaction of tetraphenylcyclobutadienepalladium bromide dimer with molybdenum hexacarbonyl in refluxing *p*-xylene. Under these conditions the product was obtained in 18% yield after 10 min of reaction. A similar reaction carried out in boiling benzene for a period of 67 h was previously reported (1) to afford only 7% yield of (**1**; R = Ph). The infrared spectrum of (**1**; R = Ph), isolated here, was identical to that of the material originally reported (1) and the proton magnetic resonance (p.m.r.) spectrum consisted of a singlet at 2.76 τ due to the phenyl protons.

Tetrakis(*p*-tolyl)cyclobutadiene molybdenum dicarbonyl bromide dimer (**1**; R = To) was prepared in 14% yield from tetrakis(*p*-tolyl)cyclobutadienepalladium bromide dimer and molybdenum hexacarbonyl by an exactly analogous reaction. The infrared spectrum of (**1**; R = To) showed two carbonyl stretching bands of similar intensity at 1965 and 2020 cm^{-1} as expected for a dicarbonyl compound of this nature, and the p.m.r. spectrum consisted of an AB quartet pattern centered at 2.94 τ and a singlet at 7.69 τ due

[1]Present address: Department of Chemistry, University of Georgia, Athens, Georgia, U.S.A.

For personal use only.

to the AA'BB' and methyl protons of the *p*-tolyl groups.

Another novel molybdenum complex whose structure was investigated was the (tetrakis-(*p*-tolyl)cyclobutadiene)(cyclopentadienyl) molybdenum carbonyl bromide (**3**; R = To). This complex was prepared by the method previously reported (3) for (**3**; R = Ph). The infrared spectrum of (**3**; R = To) was similar to that of (**3**; R = Ph) and showed one carbonyl stretch at 1984 cm^{-1}. The p.m.r. spectrum contained three sharp singlets at 3.0, 4.7, and 7.8 τ due to the AA'BB' *p*-tolyl, cyclopentadienyl, and methyl protons, with the expected intensity ratio of 16:5:12, respectively. The absence of an AB quartet pattern in the p.m.r. spectrum of (**3**; R = To) was at first surprising since all the known tetrakis(*p*-tolyl)cyclobutadiene metal complexes (4–7) appear to contain this characteristic splitting pattern. However, a sharp singlet for the AA'BB' *p*-tolyl protons implied the presence of equivalent *p*-tolyl groups as expected of a tetrakis(*p*-tolyl)cyclobutadiene ring.

Experimental

Cyclopentadienylmolybdenum tricarbonyl dimer (8), tetraphenylcyclobutadienepalladium bromide dimer (9), and tetrakis(*p*-tolyl)cyclobutadienepalladium bromide dimer (10) were prepared by known procedures. All reactions were carried out under oxygen free nitrogen. Infrared spectra were measured on a Nujol mull; and p.m.r. spectra were obtained in deuterochloroform solution with tetramethylsilane as internal reference. Melting points were determined in evacuated capillaries but are not corrected. Light petroleum refers to the fraction of b.p. 30–60°.

*Tetraphenylcyclobutadiene molybdenum dicarbonyl bromide dimer (**1**; R = Ph)*

Molybdenum hexacarbonyl (2.0 g, 7.6 mmoles) was added slowly to a refluxing suspension of tetraphenylcyclobutadienepalladium bromide dimer (1.0 g, 0.8 mmole) in *p*-xylene (50 ml) over a 5 min period. Reflux was continued for an additional 5 min, then the reaction mixture was filtered hot and the filtrate reduced in volume to 5 ml. This solution was chromatographed on an alumina column prepared using light petroleum. An orange band which was eluted with light petroleum–benzene (1:1) mixture gave, after the evaporation of the solvents and recrystallization from dichloromethane and ethanol, red crystals of (**1**; R = Ph) (0.16 g, 18%), m.p. 283° decomp. (lit. (1) 280° decomp).

The infrared spectrum showed two strong terminal carbonyl bands at 1975 and 2025 cm^{-1} (lit. (1) 1976 and 2026 cm^{-1}). The p.m.r. spectrum consisted of a singlet at 2.76 τ. This sample was analyzed by X-ray diffraction (2).

*Tetrakis(p-tolyl)cyclobutadiene molybdenum dicarbonyl bromide dimer (**1**; R = To)*

This complex was prepared in 14% yield by the same procedure described for (**1**; R = Ph). The m.p. was 233–235° decomp.

Anal. Calcd. for $C_{68}H_{56}O_4Br_2Mo_2$: C, 63.40; H, 4.37; Br, 12.41; mol. wt., 1289. Found: C, 63.34; H, 4.40; Br, 12.20; mol. wt., 1333 (osmometric in CH_2Cl_2).

The infrared spectrum showed two strong terminal carbonyl bands at 1965 and 2020 cm^{-1}, and the p.m.r. spectrum consisted of an AB quartet centered at 2.92 τ (2.74, 2.87, 2.97, and 3.11 τ; J_{AB} = 8 c.p.s.) and a singlet at 7.69 τ with the intensity ratio of 4:3.

*Tetrakis(p-tolyl)cyclobutadiene)(cyclopentadienyl) molybdenum carbonyl bromide (**3**; R = To)*

Tetrakis(*p* - tolyl)cyclobutadienepalladium bromide dimer (1.20 g, 0.9 mmole) and cyclopentadienylmolybdenum tricarbonyl dimer (0.7 g, 2.9 mmoles) were refluxed and stirred in benzene (50 ml) for a period of 48 h. The hot reaction mixture was filtered; the filtrate reduced in volume to 10 ml and then chromatographed on an alumina column prepared using light petroleum. Excess molybdenum dimer was removed with benzene and then a pale orange band was rapidly eluted with ether. The orange ether solution was taken to dryness and the solid obtained recrystallized from methanol–dichloromethane mixture to afford (**3**; R = To) (0.07 g, 6%), m.p. 286–288° decomp.

Anal. Calcd. for $C_{38}H_{33}OBrMo$: C, 66.90; H, 4.88; Br, 11.72; mol. wt., 681. Found: C, 66.61; H, 4.92; Br, 11.60; mol. wt., 662 (osmometric in CH_2Cl_2).

The infrared spectrum showed a strong terminal carbonyl band at 1984 cm^{-1} and the p.m.r. spectrum consisted of three singlets at 3.0, 4.71, and 7.80 τ with intensity ratio 16:5:12.

Dielectric and nuclear magnetic resonance properties of a clathrate hydrate of cyclopropane[1]

Y. A. MAJID, S. K. GARG, AND D. W. DAVIDSON
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received July 3, 1969

Dielectric relaxation data and proton magnetic resonance spectra are given for the structure I clathrate hydrate of cyclopropane. Vapor pressures have been measured along the structure I – structure II – gas equilibrium line missing from the recent phase diagram of Hafemann and Miller.

Canadian Journal of Chemistry, 47, 4697 (1969)

For personal use only.

Although cyclopropane was expected (1) to form a clathrate hydrate, the formation of solid in the cyclopropane–water system has been studied only very recently. Hafemann and Miller (2) have now provided a phase diagram based on vapor pressure measurements. Their data (circles in Fig. 1) showed 4 stable quadruple points and the existence of 2 hydrates which were identified as clathrate hydrates of von Stackelberg's (3) structures I and II. In systems with excess water, structure I (HI) was found to be stable below −16.0 °C and again above 1.5°; structure II (HII) at intermediate temperatures.

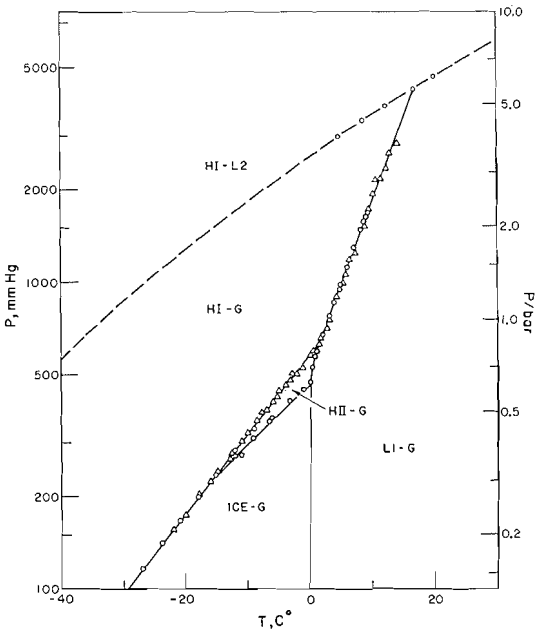

FIG. 1. Phase diagram of the cyclopropane–water system. ○, data from ref. 2; △, this work.

From dielectric, p.m.r., and composition measurements, we had concluded before we were aware of the work of Hafemann and Miller (2) that cyclopropane forms a structure I hydrate. We outline these results here, together with vapor pressure measurements which, combined with the previous ones (2), define the region of stability of structure II.

Hydrate for all measurements was prepared at about 0 °C from deaerated conductivity water and gaseous cyclopropane (Matheson, vapor phase chromatographic impurity less than 0.1%) at a pressure of about 44 p.s.i.a. The reaction vessel was vigorously shaken for about a day. Analyses of the volume of gas evolved when hydrate was thermally decomposed gave compositions within a few percent of $C_3H_6 \cdot 7\frac{2}{3}H_2O$, the composition of a structure I hydrate with all the large, but none of the small, cages occupied by cyclopropane.

Vapor pressures were measured with powdered samples, initially almost completely structure I hydrate, heated at an average rate of 0.1° per min. Some of our data, along with the more precise data of Hafemann and Miller (2), are shown in Fig. 1. The only significant difference lies in the region between −16 and 1.5°, where the previous data define the HII–ice–gas equilibrium line; ours, the HI–HII–gas line. This difference is attributable to the higher cyclopropane content of our samples. The limited field of stability of HII is bounded by these lines and the short HII–LI–gas line. Although trimethylene oxide is known (4) to form hydrates of the same 2 structures, there is no evidence of a low temperature bound to the stability of either.

The upper quadruple point (16.2°, 5.6 bar) of the cyclopropane–water system is some 11° higher than that for the propane–water system (5.4°,

[1]NRCC No. 10 924.

TABLE I

Dielectric parameters of cyclopropane hydrate

Temperature (°C)	ε_0 (exp)	ε_∞ (exp)	α	τ_0 (exp) (s)	ε_0 (ass)	τ_0 (corr) (s)	δ
−32.4	52.8	2.9	0.06	1.3×10^{-4}	63.0	1.6×10^{-4}	0.003
−49.6	51.2	2.8_6	0.10	5.7×10^{-4}	67.5	7.7×10^{-4}	0.005
−66.8	57.2	2.8_5	0.16	2.7×10^{-3}	72.8	3.7×10^{-3}	0.004
−83.7	55.6	2.8_4	0.21	1.1×10^{-2}	78.9	1.7×10^{-2}	0.005

5.5 bar) (5), which should give cyclopropane an advantage in the hydrate formation stage in processes under development for the desalination of sea water (see, for example, ref. 6). Propane forms a structure II hydrate only (5). Its largest van der Waals diameter (~6.3 Å) is too large to enable propane to fit into the 14-hedral cages of structure I which can, however, readily accommodate cyclopropane (maximum diameter ~5.3 Å).

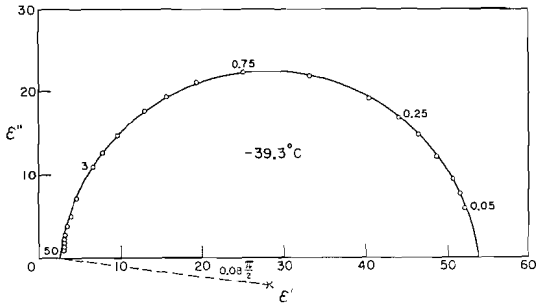

FIG. 2. Complex permittivity locus of cyclopropane hydrate. Frequencies are in kHz.

The complex permittivity loci of structure I hydrate pressed into disks (Fig. 2 shows an example) were well defined at temperatures between −30 and −100 °C. The shapes are similar to those of other structure I hydrates, the Cole–Cole circular arc parameters α which approximately describe the shapes being intermediate between those found for ethylene oxide hydrate (7) and for the hydrates of argon and nitrogen (8). At relatively high frequencies consistent departures from the Cole–Cole representation took the form of a steeper approach to the ε' axis. This behavior is commonly observed in the clathrate hydrates and suggests the presence of a number of discrete closely-grouped reorientational relaxation times instead of the continuous distribution to which the Cole–Cole arc corresponds. A general treatment of relaxation of water molecules in solids with nonequivalent water sites and orientations (9) predicts as many as 10 discrete relaxation times in structure I hydrates.

A few of the dielectric results are given in Table I. The differences between the measured static permittivities, ε_0 (exp), and those expected, ε_0 (ass), for structure I hydrates of nonpolar molecules have been used to estimate corrections to the relaxation times for the presence of small air gaps making up a fraction δ of sample thickness (8).

The Arrhenius energy of relaxation (~10 kcal mole^{-1} at temperatures above −70 °C) is appreciably higher than for other structure I hydrates where relatively high populations of Bjerrum defects appear to be produced by interaction with polar guest molecules (ethylene oxide, trimethylene oxide) or by occasional substitution of lattice water molecules by small hydrate-forming molecules (argon, nitrogen) (8). As for the case of argon and nitrogen, the (extrapolated) value of the relaxation time τ_0 at 0 °C (~15 μs) is very similar to that of ice I (22 μs).

Figure 3 shows typical derivative curves of the proton magnetic resonance absorption signal of samples in sealed tubes, measured at 16 MHz as previously described (10). The narrow and wide lines clearly defined at all temperatures between −196 and −10 °C, arise from the protons of cyclopropane and water, respectively. The relative intensity and width of the narrow lines show that all cyclopropane molecules are executing rapid, effectively isotropic rotation within their cages. Thus, for a Gaussian line shape, the second moment of the narrow component at −196°, corrected for modulation broadening, is 3.7 G^2, that estimated by the method previously described (10) for rapidly rotating cyclopropane in a rigid water lattice, 3.6 G^2. The experimental value at −30° is 2.6 G^2.

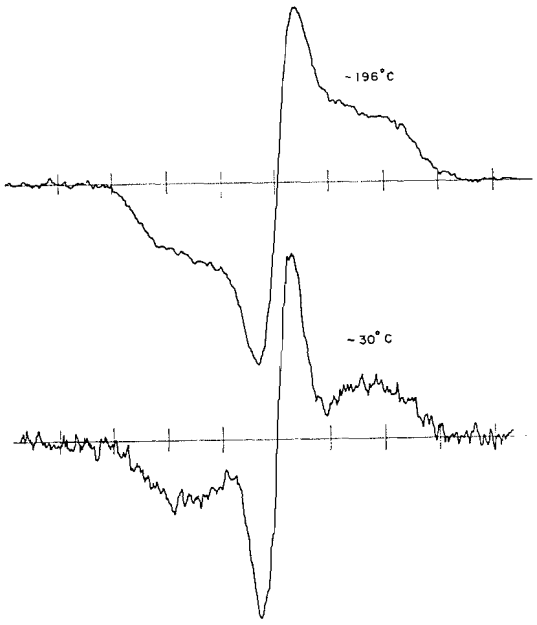

FIG. 3. Derivative curves of ^1H absorption lines. Scale lines are 5 G apart. Radio frequency field 6 mG, modulation field 0.85 G, time constant 3 s, sweep rate 2 G/min.

The wide line characterizes the rigid water lattice until it begins to narrow at about $-20°$. As in the similar case of SF_6 hydrate (10), line narrowing by diffusion of water molecules appears not to occur at such a low temperature as in hexagonal ice, a result which supports the interstitial mechanism of diffusion in ice (11).

Spectra of Co(II) in molten nitrates and dimethyl sulfone

K. W. FUNG AND K. E. JOHNSON
Department of Chemistry, University of Saskatchewan, Regina Campus, Regina, Saskatchewan

Received June 30, 1969

The electronic spectrum of Co(II) in $LiNO_3$–KNO_3, $AgNO_3$–KNO_3, and dimethyl sulfone containing excess $LiNO_3$–KNO_3 resembles that of the dodecahedral $[Co(NO_3)_4]^{2-}$ ion and parameters for this symmetry and the approximation T_d are calculated. $Co(ClO_4)_2$ yields an octahedral species in dimethyl sulfone.

Canadian Journal of Chemistry, **47**, 4699 (1969)

The spectrum of $CoCl_2$ dissolved in $LiNO_3$–KNO_3 eutectic melt was obtained by Gruen (1). He compared the single band in the visible region (extinction coefficient approximately 100) with the more intense system of bands, resembling those of $CoCl_4^{2-}$, obtained on adding a large excess of chloride and deduced that Co(II) was octahedrally coordinated by nitrate (1), perhaps by four nitrate groups (2). Recently, Duffy and Ingram (3) drew attention to the similarity of the spectra of Co(II) in KNO_3–$Ca(NO_3)_2$ glass, of $[CH_3(C_6H_5)_3As]_2[Co(NO_3)_4]$ (4) and, for the visible region, of Co(II) in $LiNO_3$–KNO_3 melt. The $[Co(NO_3)_4]^{2-}$ ion was shown to contain four bidentate nitrates giving a dodecahedral coordination to Co(II) (5). As reported elsewhere (6), the spectra of Co(II) in several sulfate melts are similar and can be successfully accounted for in terms of D_{2d} symmetry. Here we report our findings, including the near infrared spectra for $Co(NO_3)_2$ in several systems.

Experimental

Anhydrous cobalt nitrate was prepared according to Addison and Logan (7). $LiNO_3$–KNO_3, $NaNO_3$–KNO_3, and KNO_3–$AgNO_3$ eutectics were prepared by fusing

together dry reagent grade salts and bubbling dry nitrogen through the melts. Spectra were recorded with a Beckman DK-2A spectrophotometer as discussed previously (6, 8) and were analyzed into Gaussian components by the method of Chatt *et al.* (9).

Cobalt perchlorate and dimethyl sulfone were prepared according to Liu *et al.* (10).

Results

Figure 1 shows the spectrum of Co(II) in $LiNO_3$–KNO_3 and $AgNO_3$–KNO_3 eutectic melts. A stable solution of $Co(NO_3)_2$ in $NaNO_3$–KNO_3 was not obtainable. Figure 2 shows the spectra obtained for dimethyl sulfone solutions of $Co(NO_3)_2$ and $Co(ClO_4)_2$ alone and with added $LiNO_3$–KNO_3. Details of all the bands are collected in Table I.

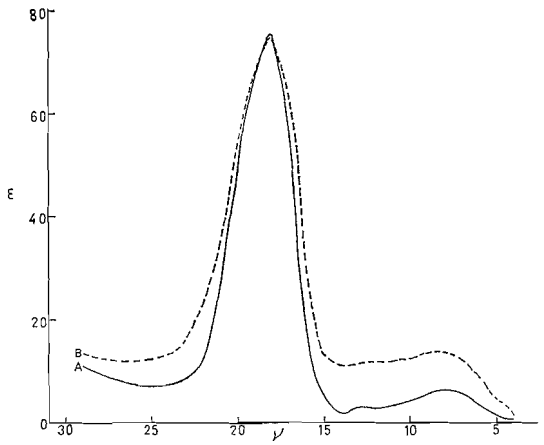

FIG. 1. Spectrum of $Co(NO_3)_2$ in *A*, $LiNO_3$–KNO_3 and *B*, $AgNO_3$–KNO_3, both at 156 °C.

Discussion

The molten salt spectra do indeed resemble those of Co(II) in KNO_3–$Ca(NO_3)_2$ glass (3), the $[Co(NO_3)_4]^{2-}$ ion (4, 5) and the sulfate melts (6) and may be assigned to a first approximation in tetrahedral symmetry or, more precisely, in dodecahedral symmetry, with the parameters listed in Table I.

The intensity of the visible band in $LiNO_3$–KNO_3 is somewhat lower than that recorded by Gruen (1), but he did not start from anhydrous $Co(NO_3)_2$.

$Co(ClO_4)_2$ dissolved in dimethyl sulfone gave rise to a typical octahedral spectrum (11) which was unaffected by the addition of $LiClO_4$, but changed to the dodecahedral spectrum on adding $LiNO_3$–KNO_3. On the other hand, $Co(NO_3)_2$ in dimethyl sulfone gave a dodecahedral spectrum, but of intermediate intensity which increased to

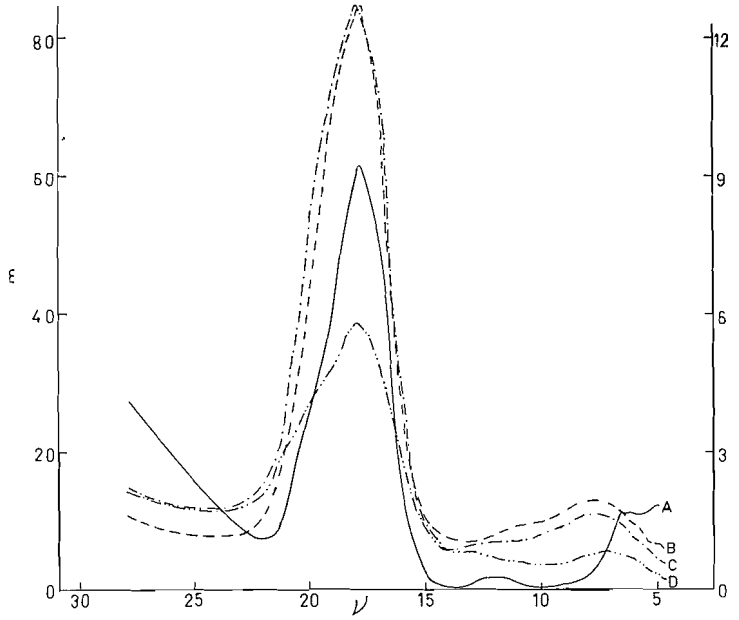

FIG. 2. Spectra of *A*, $Co(ClO_4)_2$ (right-hand ordinate); *B*, $Co(ClO_4)_2$ + $LiNO_3$–KNO_3; *C*, $Co(NO_3)_2$ + $LiNO_3$–KNO_3; and *D*, $Co(NO_3)_2$ (*B*, *C*, and *D* left-hand ordinate). All in dimethyl sulfone at 128 °C.

the usual value (largest $\varepsilon_{max} \sim 80$) on adding $LiNO_3$–KNO_3. This could mean either the formation of $[Co(NO_3)_4]^{2-}$ and octahedral $Co(DMSO_2)^{2+}$ or of a dodecahedral cationic complex on the addition of $Co(NO_3)_2$ to dimethyl sulfone.

A comparison with the sulfate melts (6) places nitrate as a slightly weaker ligand than sulfate ($\Delta_{NO_3^-} = 4.8$ kK vs. $\Delta_{SO_4^{2-}} = 5.1$ kK) and with less tendency toward covalent bonding ($\beta_{NO_3^-} = 0.90$ vs. $\beta_{SO_4^{2-}} = 0.74$).

Mesure directe de la constante d'ionisation de l'ammoniac liquide entre −77 et −36 °C

MAURICE RENAUD
Département de Génie métallurgique, Ecole Polytechnique, Montreal, Québec

Reçu le 13 juin, 1969

La constante d'ionisation de l'ammoniac liquide a été mesurée à l'aide d'une pile de concentrations entre −77 et −36 °C. Sur ce domaine de température, le pK passe de 33.1 ± 0.3 à −36 °C à 37.8 ± 0.3 à −77 °C. Les valeurs mesurés confirment celles calculées à partir des valeurs thermodynamiques de l'ammoniac liquide, de l'ion ammonium et de l'ion amidure. L'expression $pK = 9.0 + 5.7\,(10^3/T)$ rend bien compte des valeurs du pK de l'ammoniac liquide sur le domaine de température étudié.

The ionization constant of liquid ammonia has been measured with a concentration cell between −77 and −36 °C. Between these temperatures, pK increased from 33.1 ± 0.3 at −36 °C to 37.8 ± 0.3 at −77 °C. These measured data confirm those calculated with thermodynamic values of liquid ammonia, ammonium ion, and amide ion. The formula $pK = 9.0 + 5.7\,(10^3/T)$ can represent the values of the pK of liquid ammonia for the studied temperatures.

Canadian Journal of Chemistry, 47, 4702 (1969)

Introduction

L'ammoniac liquide est un solvant capable de dissoudre des quantités notables de sels ioniques. Comme par ailleurs il est très basique et que de ce fait il ne réagit pas avec la plupart des métaux, divers auteurs ont envisagé son emploi, soit pour obtenir les métaux les plus électronégatifs par voie humide, soit pour réaliser des piles à fortes différences de potentiel.

Bien que son pK soit une des propriétés qui confèrent le plus d'originalité à l'ammoniac liquide, la littérature n'en signale qu'une mesure, celle réalisée par Pleskov et Monoszon (1) en 1935. Nous avons donc cherché à mesurer le pK dans tout le domaine de température pour lequel l'ammoniac est liquide à pression ordinaire.

Pour effectuer nos mesures nous avons utilisé une pile de concentrations semblable à celle décrite par Pleskov et Monoszon (1). Elle est constituée de deux électrodes à hydrogène en platine platiné trempant dans deux compartiments séparés par une paroi de verre fritté

$$H_2/Pt/NH_4Cl_{am} \;||\; KNH_{2am}/Pt/H_2$$

compartiment a ||compartiment b

the usual value (largest $\varepsilon_{max} \sim 80$) on adding $LiNO_3$–KNO_3. This could mean either the formation of $[Co(NO_3)_4]^{2-}$ and octahedral $Co(DMSO_2)^{2+}$ or of a dodecahedral cationic complex on the addition of $Co(NO_3)_2$ to dimethyl sulfone.

A comparison with the sulfate melts (6) places nitrate as a slightly weaker ligand than sulfate ($\Delta_{NO_3^-} = 4.8$ kK vs. $\Delta_{SO_4^{2-}} = 5.1$ kK) and with less tendency toward covalent bonding ($\beta_{NO_3^-} = 0.90$ vs. $\beta_{SO_4^{2-}} = 0.74$).

Mesure directe de la constante d'ionisation de l'ammoniac liquide entre −77 et −36 °C

MAURICE RENAUD
Département de Génie métallurgique, Ecole Polytechnique, Montreal, Québec

Reçu le 13 juin, 1969

La constante d'ionisation de l'ammoniac liquide a été mesurée à l'aide d'une pile de concentrations entre −77 et −36 °C. Sur ce domaine de température, le pK passe de 33.1 ± 0.3 à −36 °C à 37.8 ± 0.3 à −77 °C. Les valeurs mesurés confirment celles calculées à partir des valeurs thermodynamiques de l'ammoniac liquide, de l'ion ammonium et de l'ion amidure. L'expression $pK = 9.0 + 5.7\,(10^3/T)$ rend bien compte des valeurs du pK de l'ammoniac liquide sur le domaine de température étudié.

The ionization constant of liquid ammonia has been measured with a concentration cell between −77 and −36 °C. Between these temperatures, pK increased from 33.1 ± 0.3 at −36 °C to 37.8 ± 0.3 at −77 °C. These measured data confirm those calculated with thermodynamic values of liquid ammonia, ammonium ion, and amide ion. The formula $pK = 9.0 + 5.7\,(10^3/T)$ can represent the values of the pK of liquid ammonia for the studied temperatures.

Canadian Journal of Chemistry, 47, 4702 (1969)

Introduction

L'ammoniac liquide est un solvant capable de dissoudre des quantités notables de sels ioniques. Comme par ailleurs il est très basique et que de ce fait il ne réagit pas avec la plupart des métaux, divers auteurs ont envisagé son emploi, soit pour obtenir les métaux les plus électronégatifs par voie humide, soit pour réaliser des piles à fortes différences de potentiel.

Bien que son pK soit une des propriétés qui confèrent le plus d'originalité à l'ammoniac liquide, la littérature n'en signale qu'une mesure, celle réalisée par Pleskov et Monoszon (1) en 1935. Nous avons donc cherché à mesurer le pK dans tout le domaine de température pour lequel l'ammoniac est liquide à pression ordinaire.

Pour effectuer nos mesures nous avons utilisé une pile de concentrations semblable à celle décrite par Pleskov et Monoszon (1). Elle est constituée de deux électrodes à hydrogène en platine platiné trempant dans deux compartiments séparés par une paroi de verre fritté

$$H_2/Pt/NH_4Cl_{am} \;||\; KNH_{2am}/Pt/H_2$$

compartiment a ||compartiment b

Principe des Mesures

Les électrodes à hydrogène en platine platiné

étant réversibles dans l'ammoniac liquide (2) la tension mesurée aux bornes de la pile s'écrit

$$[1]\quad U_a - U_b = \frac{RT}{F}[\ln x.y - \ln K] + E_j$$

où x est l'activité des ions NH_4^+ dans le compartiment a, y est l'activité des ions NH_2^- dans le compartiment b, E_j est le potentiel de jonction entre les deux compartiments

$$[2]\quad pK = \frac{F}{2.303RT}[(U_a - U_b) - E_j] - \log x.y$$

$U_a - U_b$ étant mesuré aux bornes de la cellule il faut déterminer E_j et log $x.y$ pour pouvoir calculer pK.

Sachant que

$$NH_4^+, Cl^- \rightleftharpoons NH_4^+ + Cl^- \qquad \text{avec } K = 1.2 \times 10^{-3} \text{ à } -34\,^\circ\text{C} \quad (3)$$

et

$$K^+, NH_2^- \rightleftharpoons K^+ + NH_2^- \qquad \text{avec } K = 1 \times 10^{-4} \text{ à } -40\,^\circ\text{C} \quad (4)$$

Nous avons effectué les mesures avec des concentrations en chlorure d'ammonium et en amidure de potassium suffisamment faibles pour que ces sels soient à peu de chose près entièrement dissociés.

Le calcul du potentiel de jonction n'a pu être fait que pour la température de $-34\,^\circ$C. A cette température les conductivités équivalentes limites des ions mis en jeu sont celles portées au Tableau I.

TABLEAU I

Mesure directe de la constante d'ionisation de l'ammoniac liquide entre -77 et $-36\,^\circ$C

Ions	Conductivités équivalentes limites Ω^{-1} cm^{-1} equiv.$^{-1}$	
NH_4^+	142	(5)
K^+	177	(6)
NH_2^-	166	(6)
Cl^-	171	(7)

En posant que le gradient d'activité des ions au travers de la paroi poreuse est linéaire l'expression générale [3] devient [4].

$$[3]\quad E_j = -\frac{RT}{F}\int_a^b \sum_i \frac{t_i}{Z_i}\frac{da_i}{a_i}$$

$$[4]\quad E_j = \frac{RT}{F}\frac{11y + 29x}{343y - 313x}\ln\frac{343\,y}{313\,x}$$

Le rapport des conductivités équivalentes limites des ions K^+ et NH_4^+ varient peu en fonction de la température: de 1.25 à $-34\,^\circ$C à 1.38 à $-65\,^\circ$C (8). Nous considérerons donc que la valeur du potentiel de jonction est constante sur tout le domaine de température considéré.

Technique Expérimentale

La solution de chlorure d'ammonium est obtenue par dissolution dans l'ammoniac liquide d'une masse connue de sel. Celle d'amidure de potassium l'est par décomposition catalytique d'une solution de concentration connue de potassium dans l'ammoniac liquide.

Pour obtenir une solution de concentration connue de potassium, on distille sous vide un volume connu de ce métal. Pour ce faire on opère en deux étapes: premièrement on fait condenser une goutelette de potassium dans un tube capillaire dont on connaît le diamètre. Après avoir mesuré la longueur de la goutelette on scelle le tube capillaire entre celle-ci et la réserve de métal. Il ne reste plus alors qu'à distiller cette goutelette dans le compartiment b de la cellule de mesure.

Cette série d'opérations effectuées on condense de l'ammoniac dans la cellule. Après quelques heures, voir un jour ou deux la solution de potassium s'est entièrement transformée en une solution d'amidure par décomposition catalytique au contact du noir de platine des électrodes (9).

Pendant toute la durée de l'expérience la cellule est immergée dans un bain de méthanol dont la température est maintenue constante à $\pm 0.5\,^\circ$C.

Résultats

Les mesures ont été effectuées avec des solutions de concentrations suivantes: compartiment a, 8×10^{-5} mole de NH_4Cl/l; compartiment b, 2×10^{-5} mole de KNH_2/l.

Comme à ces concentrations-ci le coefficient d'activité calculé par la théorie de Debye et Hückel est pratiquement égal à 1 nous considérons que les activités des ions sont égales à leurs concentrations.

Par ailleurs, pour tenir compte des constantes d'ionisation des sels utilisés nous écrivons

$$\log x.y = -9 \pm 0.2$$

A l'aide de ces valeurs nous pouvons calculer le potentiel de jonction donné par [4]

$$E_j = 2\text{ mV}$$

Le tableau II réunit les mesures expérimentales $U_a - U_b$ lues à ± 3 mV et les valeurs du pK déduites de l'expression [5]

$$[5]\quad pK = 5.04\frac{10^3}{T}[(U_a - U_b) - 2 \times 10^{-3}] + 9$$

−36.0	4.22	1.133	33.1

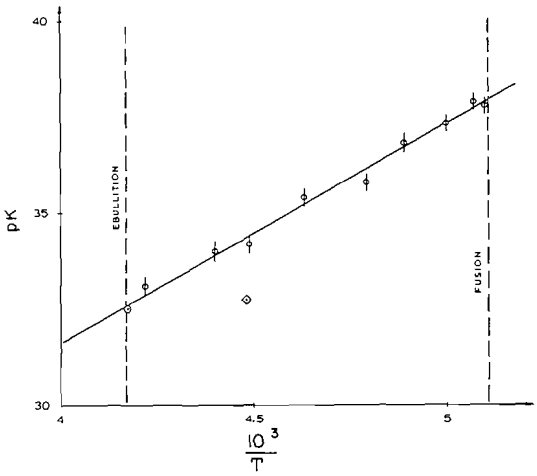

FIG. 1. pK vs. $1/T$; ⊕, nos mesures; ◇, mesure de Pleskov et Monoszon; ⊙, valeur calculée par Coulter *et al.* (10).

La Fig. 1 représente les valeurs du pK portées en fonction de $1/T$. On y remarque que la valeur mesurée par Pleskov et Monoszon à −50 °C (1) se place nettement au-dessous de nos résultats alors que celle calculée par Coulter *et al.* (10) se trouve confirmée.

En utilisant la méthode des moindres carrés on obtient l'expression [6] qui représente la droite passant au mieux à travers tous les points expérimentaux portés sur la Fig. 1

$$[6] \qquad pK = 9.0 + 5.7(10^3/T)$$

Cette expression permet de calculer les fonctions thermodynamiques de la réaction d'ionisation. On obtient $\Delta H^0 = 26$ kcal mole^{-1} et $\Delta S^0 = -41$ cal mole^{-1} deg^{-1}. Ces valeurs sont en accord avec celles mesurées calorimétriquement $\Delta H^0 = 26.1$ kcal mole^{-1} (11) et $\Delta S^0 = -40.1$ cal mole^{-1} deg^{-1} (10).

La relation [6] peut donc être retenue pour exprimer le pK de l'ammoniac liquide sur le domaine de température considérée.

Studies on complex compounds. VI. Coordination compounds of copper and biologically active cyclohexylamine derivatives[1]

C. H. MISRA, SURENDRA S. PARMAR[2], AND J. P. BARTHWAL[3]

Department of Pharmacology and Therapeutics, King George's Medical College, Lucknow University, Lucknow-3, India

Received[4] October 16, 1968

Five complexes of copper(II) chloride and different cyclohexylamine derivatives were synthesized, the copper:ligand ratios are 1:2. These complexes were characterized by analyses, infrared (700–3500 cm^{-1}) and visible spectra, and conductance. The results have indicated participation of nitrogen atom adjacent to the cyclohexyl ring in coordination.

Initial antibacterial and antifungal evaluation of mercury coordination compounds of the biologically active amines have indicated facilitation of the activity of mercuric chloride on coordination (1). Such facilitation could presumably account for the interference with cellular metabolism of the organisms (2) by the inhibition of certain enzyme system(s) by organo mercury compounds. Our continuing interest in the coordination compounds (3–5) and the greater affinity of the bivalent copper for nitrogen and oxygen to facilitate ready formation of coordination compounds with ammonia, alkyl and aryl substituted amines, heterocyclic bases, amino acids, amino phenols, and other nitrogen and oxygen containing compounds led us to examine the possibility of the synthesis of the complexes of cupric chloride with pharmacologically active cyclohexylamine derivatives. Complexes of copper with cyclohexylamines have not so far been reported. It is hoped that the investigations with such coordination compounds will prove useful in the elucidation of the role of complex formation in their activity in the central nervous system (6).

Experimental

Materials

The cyclohexylamine derivatives used in the present study were N-cyclohexyl-β-alanine, N-(2-hydroxyethyl)-cyclohexylamine, N-(2-cyanoethyl)cyclohexylamine, 2-cyclohexylamino-1-phenylethanol, and N-(3-aminopropyl)cyclohexylamine. Cupric chloride, as $CuCl_2.2H_2O$, was analytical grade. Absolute ethanol and purified anhydrous cyclohexanol (7) were used throughout these experiments.

Analyses

The copper content of the complexes was estimated gravimetrically as thiocynate (8) or as the pyridine complex (9). Chlorine content was assayed gravimetrically (3). The nitrogen content of these coordination compounds was determined by well known combustion methods.

Preparation and Properties of the Copper Complexes

The preparation of the copper coordination compounds and determination of their conductance, absorption spectra, and the infrared spectra were carried out following the methods reported earlier (8, 10). All complexes reported in Table I were stable at room temperature. No change of the nature of these complexes could be observed on heating up to 120° except for the complex obtained from N-(3-aminopropyl)cyclohexylamine, which is highly hygroscopic in nature.

Results and Discussion

Conductance measurements (Table I) have indicated the electrolytic nature of all the complexes which presumably give three ions in ethanol (11) except the one synthesized from N-(3-aminopropyl)cyclohexylamine. The higher molar conductance of dichloro-bis[N-(3-aminopropyl)cyclohexylamine]copper(II) dihydrate as compared to that of a non-electrolyte may presumably account for solvolysis (12, 13) caused by the absorption of the moisture. The characteristic absorption of these complexes suggests a square planar configuration. The observed analytical data and the presence of an intense OH stretching vibration bands in the infrared spectra (Table II) provide further support for this structure in the absence of experiments with the use of deuterium to establish the exact nature of water in these complexes.

Isolation of the initial step in the thermal decomposition of di-*tert*-butyl peroxide

C. K. YIP AND H. O. PRITCHARD
Centre for Research in Experimental Space Science, York University, Downsview, Ontario

Received September 2, 1969

The thermal decomposition of di-*tert*-butyl peroxide in the presence of propane has been studied at total pressures up to 100 atm. At the highest propane concentrations, the major product of the decomposition is *tert*-butyl alcohol, and extrapolation to infinite propane pressure indicates that the initial step in the peroxide decomposition is exclusively the formation of two *tert*-butoxy radicals. The activation energy for the abstraction of hydrogen from propane by *t*-BuO radicals is discussed.

Canadian Journal of Chemistry, 47, 4708 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In the gas-phase thermal decomposition of di-*tert*-butyl peroxide, it is generally accepted that the reaction takes place, by and large, through the sequence

[1] DTBP → 2 *t*-BuO

[2] *t*-BuO → CH_3 + CH_3COCH_3

so that the overall process is

[1*a*] DTBP → $2CH_3$ + $2CH_3COCH_3$

A selection of pertinent references is collected together in ref. 1. The presence of the *tert*-butoxy radical should lead to the formation of *tert*-butyl alcohol via

[3] *t*-BuO + RH → *t*-BuOH + R etc.

but in the gas-phase decomposition, the relative rate constants and concentrations are such that less than 1% of the *t*-BuO radicals are able to abstract to form the alcohol (2). However, in the presence of more reactive substrates, such as ethylenimine (3), acetaldehyde, acrolein (4), and hydrogen chloride (5), considerable stabilization of the *tert*-butoxy radical via reaction [3] has been observed; nitric oxide has also been used to trap the *t*-BuO radical (6). The formation of *t*-BuOH is well known in the liquid-phase decomposition of the peroxide (7, 8). However, it has never been proved that reaction [1] is the sole mechanism of the decomposition, and since there are two other channels [1*a*] and

[1*b*] DTBP → *t*-BuO + CH_3 + CH_3COCH_3

which differ very little in endothermicity from channel [1] itself (9), it is important to try to establish whether such two-bond or three-bond processes contribute to the overall reaction.

Experimental

The purification of di-*tert*-butyl peroxide has been described previously (1). Propane was of Research Grade, supplied by Phillips Petroleum Company; the principal impurity was stated to be ethane. The material was subjected to normal degassing procedures, with extended pumping at 77 °K, and the product was free from any impurities detectable by mass-spectrometric or gas-chromatographic techniques.

The reactions were carried out in the manner described previously (1, 10) by condensing about 10^{-4} mole of the peroxide together with the required quantity of propane into a 10 cc Hoke stainless steel pressure vessel. The vessel, sealed by a needle valve, was heated for the required time in an oil bath, after which the reaction was quenched by cooling the vessel. The contents were then transferred to the vacuum system and the bulk of the propane removed by carefully controlled distillation using two LeRoy stills. The residue was then transferred by vacuum technique to the inlet of a gas phase chromatograph and the yields of acetone and *tert*-butyl alcohol were determined using a 4 m column packed with Porapak P at 90 °C; no detectable decomposition of the peroxide occurred during the analytical procedure.

Results and Discussion

The critical temperature of propane is 96 °C, and thus to ensure a homogeneous system, experiments were performed only above the critical point, at 100.4, 112.0, and 124.0 °C. Each experiment was taken to about 5% peroxide decomposition and the results are plotted in Fig. 1 in the form [acetone]/[*t*-BuOH] produced vs. $[C_3H_8]^{-1}$. In view of the experimental difficulties in separating quantitatively some 5×10^{-6} mole of acetone/alcohol mixture from some 10^{-1} mole of propane by distillation, we regard each of the three sets of data as an acceptable straight line passing through the origin. Hence we conclude that at infinite propane pressure, when all the *t*-BuO radicals will be trapped by reaction [3], no acetone is formed, and so the two-bond and three-bond breaking channels [1*a*] and [1*b*] can be discounted.

If these two mechanisms are ignored, inspection of the reaction scheme [1], [2], [3] shows that the slopes of the plots in Fig. 1 are simply k_2/k_3, from which we find that when T = 100.4, 112.0, 124.0 °C, k_2/k_3 = 0.51, 0.89, 1.23 mole l^{-1}, respectively, corresponding roughly to $E_2 - E_3$ =

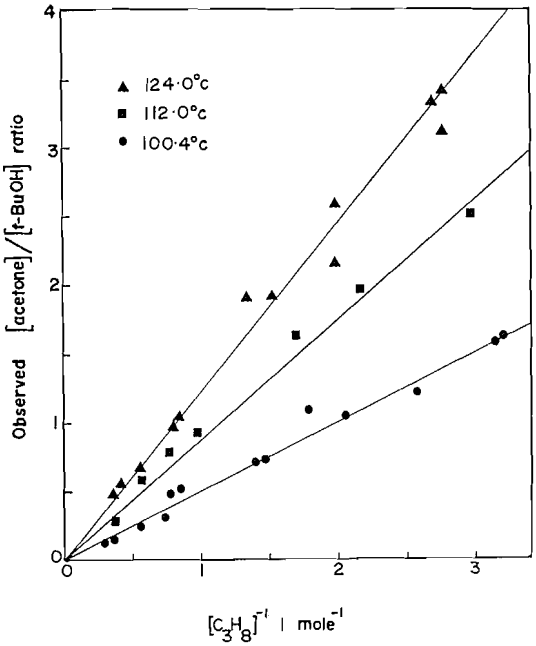

FIG. 1. Variation of the [Acetone]/[*t*-BuOH] ratio as a function of propane pressure in the range 10–100 atm.

11.0 kcal/mole. It is generally agreed that the activation energy E_2 for the dissociation of the *t*-BuO radical is pressure dependent (6, 11–13), but there is little consistency amongst the actual values of E_2 that have so far been determined. At low pressures, usually in the fall-off region, values from 11 to 17 kcal have been quoted (3, 11), and at infinite pressure, values of 15.5 and 22.8 kcal have been suggested (6, 11). Hence, it is not possible at this stage to quote a value for E_3, but we observe that our data is consistent with other data in the literature to the extent that when RH = toluene (8), $E_2 - E_3 = 11.3$ kcal/mole, and it is well known that both propane and toluene exhibit very similar activation energies in abstraction reactions with a variety of free radicals.

Finally, we note that the measurement of [acetone + *t*-BuOH] production leads to rate constants for reaction [1], and within the limited accuracy of this experiment (±20%) the observed values for k_1 are independent of pressure up to the highest pressures used at each of the three temperatures; the independence of k_1 on pressure was only established up to 15 atm in our previous work (1).

Free radical halogenation of deuteriochloroform

DENNIS D. TANNER, MELVYN W. MOSHER[1], AND N. J. BUNCE[2]
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received July 14, 1969

The vapor phase chlorination and bromination of deuteriochloroform has been carried out in the presence of the corresponding hydrogen halide. The halogenations demonstrated the reversibility of the abstraction reaction by atomic bromine while the chlorination reactions failed to show any evidence for a reversible abstraction.

Canadian Journal of Chemistry, 47, 4709 (1969)

As part of a series of studies of reversible free radical abstractions of hydrogen from saturated carbon (1–3), we have reinvestigated the vapor phase chlorination and bromination of chloroform. Both these halogenations have previously been indicated, on kinetic evidence (4, 5), to involve reversible abstraction of a hydrogen

TABLE I

Photobromination of deuteriochloroform with bromine in the presence of hydrogen bromide

	Reactants			Products	
Reaction	$CDCl_3$* (mmoles)	HBr (mmoles)	Br_2 (mmoles)	$CHCl_3$† (atom %)	$CBrCl_3/CHCl_3$
2	7.59	83	2.14	65	1.18
3	7.28	83	1.86	65	2.38
4	8.10	83	3.78	32	0.36

*0.31 atom % ^1H.
†Analyzed by n.m.r.; total of $CHCl_3$ + $CDCl_3$ vs. CCl_3Br was determined by gas–liquid phase chromatography.

atom from chloroform by the halogen atom as in reaction [1].

[1] $$HCCl_3 + X^{\cdot} \rightleftharpoons HX + {}^{\cdot}CCl_3$$

In order to attempt to demonstrate chemically the reversibility of hydrogen abstraction, deuteriochloroform was halogenated in the vapor phase in the presence of a large excess of the corresponding hydrogen halide, and the recovered chloroform was analyzed by nuclear magnetic resonance (n.m.r.) for the ^1H which it should incorporate if reaction [1] is reversible. The reactions were carried out at the ambient temperature and initiated photolytically by the use of two 200 W tungsten lamps placed a few inches from the reaction chamber, a 3.3 l Pyrex glass bulb.

When deuteriochloroform (7.3 mmoles), initially containing 0.31 atom % ^1H, was chlorinated by elemental chlorine (2.5 mmoles) in the presence of 62.2 mmoles hydrogen chloride, n.m.r. analysis of the recovered deuteriochloroform showed no detectable increase in ^1H content when all the chlorine had reacted. This result suggests that if any reversible hydrogen abstraction occurs in this system, its extent must be below the level of detection for our experiment. Furthermore, this result is not unexpected, since simple bond energy calculations indicate that the reverse of reaction [1] is endothermic by some[3] 12 (7.5) kcal/mole (6, 7).

Similar calculations for the bromination of chloroform give for the reversal reaction $\Delta H \sim -3\ (-8)$ kcal/mole. Sullivan and Davidson (5) have proposed that the thermally initiated bromination of chloroform is completely reversible with the overall equilibrium constant $K = [CCl_3Br]\,[HBr]/[CHCl_3]\,[Br_2] \simeq 2$.

Deuteriochloroform was, therefore, photobrominated with molecular bromine in the presence of hydrogen bromide. The chloroform recovered after the reaction was analyzed for incorporation of ^1H (Table I).

The results given in Table I show that, unlike the case of chlorination of deuteriochloroform, bromination of this substrate involves a considerable degree of reversible hydrogen abstraction. Although reversible hydrogen abstraction has long been recognized as being important in free-radical brominations (3, 5, 8–10, and references cited in (10)), this is, to our knowledge, only the second occasion (11) on which it has been demonstrated chemically.

Experimental

Materials

Deuteriochloroform was from Columbia Chemical Corporation and contained 0.31 atom % of ^1H. Chlorine, hydrogen bromine, and hydrogen chloride were obtained from Matheson Chemical. Molecular bromine, reagent grade, was from the Shawinigan Chemical Co. All materials were distilled before use.

Gas Phase Bromination of Deuteriochloroform in the Presence of Hydrogen Bromide

Three 3.3 l evacuated bulbs were filled with hydrogen bromide to a pressure of 154 mm Hg. The hydrogen bromide was frozen and a mixture of deuteriochloroform and bromine (7.59 mmoles, 2.14 mmoles, reaction [2]; 7.28 mmoles, 1.86 mmoles, reaction [3]; 8.10 mmoles, 3.78 mmoles, reaction [4]) was vacuum transferred into each of the bulbs in turn. The reaction bulbs were degassed, the contents allowed to warm in the dark until the contents had vaporized, and then allowed to stand 30 min. The bulbs were irradiated with two 200 W incandescent lamps placed 3 in. from the reaction. One bulb (reaction [4]) was irradiated 4.5 days while the other two were irradiated for 8 days.

After the irradiation was stopped the bromine color

[3]The values in parentheses were calculated from data given in ref. 6.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

was still pronounced. The bulbs were placed in a methanol slush (−98°) and the hydrogen bromide removed by distillation. The remaining material was vacuum transferred into a small flask. Methylene chloride was added as a standard and the amount of hydrogen incorporation was determined by comparison of the n.m.r. singlet of the hydrogens of methylene chloride to the singlet for the hydrogen of chloroform. The amount of total chloroform and product, bromotrichloromethane, was determined from the area ratios of these materials to that of the standard on a 10 ft. × 1/4 in. SE-30 gas–liquid phase chromatographic column programmed from 50 to 120°. The results are shown in Table I.

Gas Phase Chlorination of Deuteriochloroform in the Presence of Hydrogen Chloride

Hydrogen chloride was placed in two 3.3 l evacuated bulbs to a pressure of 350 mm Hg. Molecular chlorine (62 ml, standard temperature and pressure) was transferred into each bulb and frozen. Deuteriochloroform (7.3 mmoles, reaction [5]; 7.6 mmoles, reaction [6]) was vacuum transferred into the bulb and the contents of the bulbs degassed and allowed to warm in the dark until the material had completely vaporized. The bulbs were irradiated with two 200 W incandescent lamps placed 2 in. from the reaction mixture until the chlorine color had disappeared plus an additional 3 h. Isolation and analysis of the organic material from each reaction vessel was carried out in the same manner as above. No increase in the ^1H content of the deuteriochloroform was detected.

Spectrofluorometric studies. VI. Photochemistry of toluene vapor excited in the 2480–2660 Å region

S. L. Lem, G. P. Semeluk, and I. Unger

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick, Canada

Received July 18, 1969

The fluorescent yields and triplet yields of toluene vapor as a function of exciting wavelengths and pressure have been determined. The sensitized emission of biacetyl technique was used to determine triplet yields. The sums of fluorescent yield and triplet yield at 2660, 2600, and 2540 Å are near unity. The data reported here confirm recently published results on toluene wherein the *cis–trans* isomerization of olefins technique was used as a triplet probe.

Canadian Journal of Chemistry, **47**, 4711 (1969)

Of the several methods for detecting triplet states of those molecules which do not phosphoresce in the gas phase, the two most commonly used are the *cis–trans* isomerization of olefins technique first described by Cundall and co-workers (1, 2) and the sensitized emission of biacetyl technique (3). The advantages and disadvantages of these two techniques have been discussed (4). Recently (5) toluene triplet yields determined by the Cundall method, as well as fluorescent yields, have been reported for excitation in the 2480–2668 Å region. The results of a similar study using the biacetyl technique to determine triplet yields are reported herein.

Fluorometric grade toluene and benzene obtained from the Hartman–Leddon Company were used without further purification. Biacetyl, obtained from the Aldrich Chemical Company, was purified by bulb-to-bulb distillation and stored in a blackened bulb. The studies were carried out in a mercury- and grease-free high vacuum line, equipped with Hoke packless diaphragm metal valves. All emission measurements were performed on a modified Aminco–Bowman

TABLE II

Stern–Volmer relations between fluorescence yields and concentrations of toluene and of biacetyl at 20 Torr toluene*

λ_{ex} (Å)	Equation of line	Pressure range (Torr)
2570	$1/\Phi_f = 2.63 + 1.21 \times 10^2$ [T]	2.5–23.6
2600	$1/\Phi_f = 2.24 + 5.35 \times 10^2$ [T]	2.2–23.6
2630	$1/\Phi_f = 2.37 + 1.85 \times 10^2$ [T]	2.6–24.0
2660	$1/\Phi_f = 2.29 + 3.55 \times 10^2$ [T]	2.9–24.7
2480	$1/\Phi_f = 8.25 + 6.53 \times 10^4$ [BiA]	0.1–5.4
2540	$1/\Phi_f = 3.98 + 3.67 \times 10^4$ [BiA]	0.1–5.6
2600	$1/\Phi_f = 2.82 + 3.45 \times 10^4$ [BiA]	0.1–5.4
2660	$1/\Phi_f = 2.59 + 3.48 \times 10^4$ [BiA]	0.1–5.4

*All concentrations are in units of moles l^{-1}.

spectrophotofluorometer. Experimental details have been given previously (6). It must be noted that the band pass for the current work was approximately 70 Å, whereas Burton and Noyes (5) used a band pass of 32 Å.

Fluorescent yields and triplet yields, corrected for self-quenching and singlet quenching by BiA, of toluene vapor, excited at four different wavelengths, are given in Table I. The fluorescent yields reported in this study are based on the value 0.18 (7) for the fluorescent yield of benzene. From Table I, it is seen that the fluorescent yields obtained in this study are between 10 and 20% higher than those reported by Burton and Noyes (5). This difference is possibly due to the difference of viewing geometry used in the two studies. Our cells have a 1 cm path, with the viewing zone (between 0.45 and 0.55 cm from the incident "face" of the vapor) defined by a careful selection of three appropriately sized and placed non-reflecting apertures placed between the cell and the monochromator. Burton and Noyes used a 5.3 cm path T-cell, viewing the emission from a window 1.5 cm diameter at a distance of 1.5 cm from the inside of the incident face of the cell. In the event that Beer's Law is not strictly obeyed, or that the extinction coefficients of the benzene calibrant and toluene differ significantly, the calculated yields tend to be somewhat lower than true yields and the discrepancy is more pronounced for longer absorption paths (8).

Our triplet yields were calculated from a value of 0.63 (9) (instead of 0.72) for the triplet yield of benzene, and are substantially in agreement with those recently reported (5), although they appear to be 10% lower because of this choice. Since there is some disagreement in the literature regarding the *cis–trans* branching ratio of the *cis*-butene-2, (10–12) but substantial agreement about the biacetyl yield, there is reason to prefer the lower triplet yield of benzene and indirectly, therefore, the lower triplet yields for toluene. It is also evident that choosing the higher yield of benzene would lead to the conclusion that the sum of singlet and triplet yields are larger than unity at several wavelengths. Our data confirm the observation (5) that the singlet-to-triplet ratio is independent of exciting wavelength (see Table I), and support the conclusion that intersystem crossover and fluorescence occur from the lower vibrational levels of the excited singlet.

The summary of Stern–Volmer relations listed

in Table II indicate that although there is some self-quenching in toluene for excitation above 2540 Å, this is a 100-fold smaller than quenching by biacetyl.

The ozone yield from the radiolysis of gaseous oxygen has been measured to be $G(O_3) = 12.8 \pm 0.6$ at 10^{26}–10^{27} eV g^{-1} s^{-1} and to be $G(O_3) = 6.2 \pm 0.6$ at 10^{16} eV g^{-1} s^{-1}. The latter result depends on a new determination of the stoichiometry of the oxidation of iodide by ozone. It is proposed that the difference in yields between the two dose rates is due to differences in ion-recombination processes.

Canadian Journal of Chemistry, 47, 4715 (1969)

Introduction

The yield of ozone from the radiolysis of gaseous oxygen has been proposed (1) as an optical dosimeter for use in pulse radiolysis studies where optical observations of transients are made. Ghormley, Hochanadel, and Boyle (1) report the ozone yield to be $G(O_3) = 13.8 \pm 0.7$ at a dose rate of 6×10^{25} eV g^{-1} s^{-1} and suggest that this is not significantly different from the yield observed at low dose rates (2, 3).

To confirm their conclusions we have determined the ozone yield in the radiolysis of oxygen at both high and low dose rates. We have compared the yield of ozone from the radiolysis of oxygen with the yield of nitrogen from the radiolysis of nitrous oxide at both 10^{26}–10^{27} eV g^{-1} s^{-1} and at 10^{16} eV g^{-1} s^{-1}.

Our value for $G(O_3)$ at the high dose rates agrees within experimental error with that of Ghormley *et al.* (1). However, both our low dose rate work and the re-examined data of other workers (2, 3) give yields of ozone that are significantly lower than the high dose rate values.

It is important to explain the difference in yields between the two dose rates before the acceptance of the system as a dosimeter.

Experimental

A Febetron 705 pulsed electron accelerator was used for high dose rate irradiations and a Gammacell 220 for low dose rate irradiations. The silica irradiation cells and experimental procedures have already been described (4, 5). The dose absorbed in the cells was measured by nitrous oxide dosimetry using $G(N_2) = 12.4$ for the high dose rates (6, 7) and $G(N_2) = 10.0$ for the ^{60}Co γ dose rates (8). The dose rate obtained with the Febetron was varied by using a scattering foil (9) and placing the irradiation cell at various distances from it.

We employed both optical and chemical procedures for ozone determination. The optical method is essentially that described by Sears and Sutherland (3), except that a 10 cm absorption cell and a Perkin–Elmer 450 spectrophotometer were used. The extinction coefficient of ozone at 254 mμ is 135 cm^{-1} at standard temperature and pressure. This was established absolutely by DeMore and Raper (10) who measured the pressure increase on decomposition of ozone to oxygen.

For low doses and low oxygen pressures the above method does not have enough sensitivity. In these cases the ozone was determined by the iodide method. Potassium iodide solution phosphate buffered at pH 7 was introduced into the cooled reaction cell immediately after irradiation. The amount of I_3^- formed was determined by measuring the absorbance at 358 mμ and reference to a calibration curve prepared using standard iodine–iodide solutions. Comparison of the optical and iodide methods for identical irradiations shows that under these conditions one molecule of ozone produces 1.52 ± 0.05 molecules of I_3^-. The stoichiometry of the iodide method at various pH's has been previously discussed. Byers and Saltzmann (11), assuming a stoichiometry of 1:1 for neutral solutions, obtain a ratio of O_3:I_3^- of 1.54:1 for 1 *N* alkaline solution. Ingols, Fetner, and Eberhardt (12) give the stoichiometry at pH 9 to be 1:1 but at pH 2 give O_3:I_3^- to be approximately 1:2. Neither of these determinations can be considered absolute. However, if the latter (12) determination at pH 9 is correct and can

be applied to the 1 *N* alkaline solution of Byers and Saltzmann, then in neutral iodide their (11) result would give O_3:I_3^- of 1:1.54. This agrees well with our value for this ratio.

Results

The amount of ozone formed under various conditions is shown in Fig. 1. The Febetron results are for single irradiation pulses. Analyses were complete within 10 min after irradiation and on further standing there was no significant decrease in the measured optical density for at least 30 min. At both temperatures, the yields per unit dose were independent of pressure (in the range 30 to 800 Torr) and of dose rate (in the range 10^{26} to 2×10^{27} eV g^{-1} s^{-1}). The slope of the best line through the results gives $G(O_3) = 12.8 \pm 0.6$.

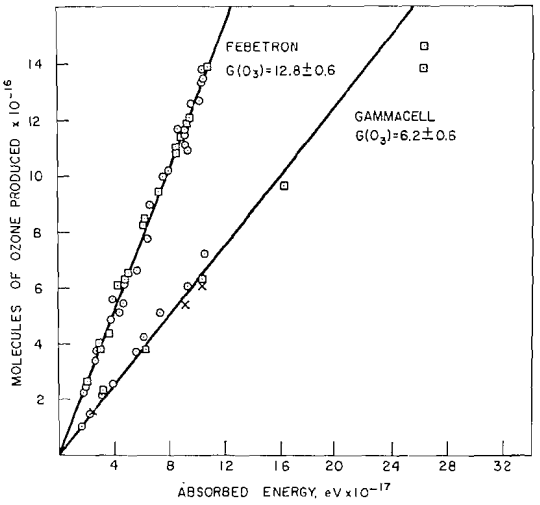

FIG. 1. Amount of ozone produced in the radiolysis of oxygen under various conditions. Febetron results: ○, 298 °K; □, 195 °K; Gamma cell results: ○, taken from ref. 2 both for 77 and 195 °K; □, taken from ref. 3 both for 77 and 195 °K; ×, present work at 77 °K. The units for both molecules of ozone and absorbed dose for the Febetron results must be multiplied by 10, i.e., the maximum absorbed energy is 1.12×10^{19} eV.

The lower line in Fig. 1 gives the amount of ozone formed in the radiolysis of oxygen at low dose rates ($\sim 10^{16}$ eV g^{-1} s^{-1}). Included are values taken directly from the paper of Sears and Sutherland (3) and also from the work of Johnson and Warman (2), who determined ozone by the iodide method at pH 7, assuming a stoichiometry of 1:1. The values of these latter authors have been corrected to $G(N_2) = 10.0$ instead of the value they used of $G(N_2) = 12.5$ for the nitrous oxide dosimeter (8) at this low dose rate and also for the stoichiometry observed by us for the iodide method of ozone determination. The line drawn represents the best slope and corresponds to an initial yield of $G(O_3) = 6.2 \pm 0.6$. The only values discordant with this are those of Sears and Sutherland (3) for irradiations at 77 °K with doses above 2×10^{18} eV g^{-1} which give $G(O_3) = 10.5 \pm 0.5$. These are outside the range of values plotted in Fig. 1.

Discussion

The present yield of $G(O_3) = 12.8 \pm 0.6$ for the radiolysis of oxygen at Febetron dose rates does not seriously disagree with that of Ghormley, Hochanadel, and Boyle (1) ($G(O_3) = 13.8 \pm 0.7$). Our value may be more reliable because the geometry of their cells made it difficult to calculate the integrated mean dose over the effective light path.

Of much greater significance is the difference of a factor of about 2 between the yields at Febetron dose rates and those at ^{60}Co γ-ray dose rates. A possible explanation of this difference lies in different ion-combination reactions at the two dose rates.

The principal ions formed in the irradiation of oxygen are O_2^+ and e with a small proportion of O^+ (13). Dissociative excitation leads to the formation of O atoms and all oxygen atoms formed in the system react with O_2 to give O_3, at least at reasonably low doses.

[1] $$O + 2O_2 \rightarrow O_3 + O_2$$

Electrons can undergo a three body attachment to yield O_2^-

[2] $$e + 2O_2 \rightarrow O_2^- + O_2$$

At 10^{27} eV g^{-1} s^{-1} the lifetime of the positive ions with respect to neutralization is 5×10^{-9} s. Thus the actual lifetime of the ions will closely follow the irradiation pulse and ion recombination reactions such as reaction [3] will be predominant

[3] $$O_2^+ + O_2^- \rightarrow 2O + O_2$$

All such recombination processes are highly exothermic and will almost certainly produce two oxygen atoms per event. Thus the yield of ozone from ionic precursors will be $2G(e)$.

As we have previously pointed out (4), at low

dose rates O_2^- will undergo a charge transfer reaction with ozone

[4] $$O_2^- + O_3 \rightarrow O_2 + O_3^-$$

The rate constant for this reaction, k_4 equals 3×10^{-10} cm^3 molecule^{-1} s^{-1} (14), so that all electrons captured by oxygen in reaction [2] will be transferred to ozone at ozone concentrations above 0.1 p.p.m. (i.e. 3×10^{12} molecules cm^{-3}) for dose rates of 10^{16} eV g^{-1} s^{-1}. The typical mean ion lifetime at these dose rates is of the order of 10^{-2} s.

For these conditions, then, the main neutralization reaction must involve the O_3^- ion. A possible neutralization reaction is

[5] $$O_2^+(nO_2) + O_3^- \rightarrow O_3 + (n+1)O_2$$
$$\text{or} \quad O + (n+2)O_2$$

If this is so then at low dose rates there will be no net contribution to the ozone yield from ionic processes and $G(O_3)$ should correspond to the yield of oxygen atoms from dissociative excitation. The extent of clustering of O_2^+ will be greater at low dose rates and this could also account for the lack of dissociative neutralization in reaction [5]. At high dose rates the yield is enhanced by the contribution from ion combination processes discussed above. This increase should be equal to twice the ion yield. From $W_{O_2} = 30.6$ eV per ion pair (15 and references therein, 16), G(ion pair) = 3.27 and $G(O_3)$ for Febetron conditions should equal [low dose yield + $2G(e)$] = 6.2 + 6.55 = 12.75, which is in good agreement with the observed value.

It may be noted that various additives which have electron scavenging capabilities have no significant effect on the yields of ozone at low dose rates (3), in agreement with the above conclusion. Preliminary experiments show that at Febetron dose rates both SF_6 and cyclo-C_4F_8 reduce the ozone yield to close to $G(O_3) = 6.0$.

Further work on this system is in progress and will be reported later. However, it is already clear that the yield of ozone, $G(O_3) = 12.0$–13.0 at Febetron dose rates, is correct and that the difference between it and the low dose rate yields is due to changes in ion combination reactions.
