Since the D_η coefficients have been ignored by most authors, little is known about its significance. It is reasonable to expect that structural salting-in would produce an increase in viscosity since all attractive forces will make the slipping of one molecule past another more difficult. An increase in D_η with increasing hydrophobic character is therefore normal. The negative sign of D_η with CH_3NH_3Br could be an indication that this pair of ions breaks the water structure. Work is presently under way (22) to study the significance of this coefficient with other systems.

Electron paramagnetic resonance studies on copper(II) benzoate

F. G. HERRING AND R. C. THOMPSON
Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

AND

C. F. SCHWERDTFEGER
Department of Physics, The University of British Columbia, Vancouver 8, British Columbia

Received August 16, 1968

An electron paramagnetic resonance (e.p.r.) study at 9.1 and 12.0 GHz on polycrystalline copper(II) benzoate has given the following Spin Hamiltonian parameters for the binuclear molecule: $D = 0.3311 \pm 0.0006$ cm^{-1}, $E = 0.0147 \pm 0.0003$ cm^{-1}, $g_x = 2.048 \pm 0.004$, $g_y = 2.074 \pm 0.004$, $g_z = 2.345 \pm 0.004$. Using the average g value of 2.160 ± 0.004 obtained from e.p.r. and previously published magnetic susceptibility studies, $2J$ is estimated to be 333 cm^{-1}.

Introduction

The magnetic properties of binuclear copper(II) alkyl- and aryl-carboxylates, molecules in which two copper ions are connected by four bridging carboxylate groups, have been studied extensively (1–7). The first e.p.r. studies, on single crystals of copper(II) acetate monohydrate were carried out by Bleaney and Bowers (1), Kumagi, Abe, and Shimada (2), and by Abe and Shimada (3). These workers found that the e.p.r. spectra could be accounted for by employing the appropriate Spin Hamiltonian for a $S = 1$ system. The lack of extensive e.p.r. studies on analogous systems is no doubt due to the fact that many of the complexes in question here do not readily form single crystals.

The work of Wasserman, Snyder, and Yager (8) has shown that it is possible to obtain the Spin Hamiltonian parameters of a triplet state from the e.p.r. spectra observed in polycrystalline samples. The object of the present work was to apply these techniques to the Cu(II) benzoate system, which can be obtained only in a polycrystalline form, and to determine the appropriate Spin Hamiltonian parameters for this molecule in its triplet state. In order to do this, it proved necessary to carry out experiments at two microwave frequencies.

During the course of this work two similar studies appeared on copper(II) cyanoacetate (9) and copper(II) propionate monohydrate (10). These studies also demonstrated the feasibility of obtaining the Spin Hamiltonian parameters of an inorganic $S = 1$ system from the e.p.r. spectra of a polycrystalline sample.

Experimental

Whereas copper(II) acetate apparently exists only in a binuclear form with magnetic properties of a system with a singlet ground state and a triplet excited state, such is not the case for copper(II) benzoate where the magnetic properties depend on the method of preparation (6, 7). The samples studied in the present work were obtained from acetone solution as described previously (6). This method yields material which is largely binuclear but which contains a small (ca. 5%) and slightly variable percentage of copper ions in a form in which the magnetic concentration is weaker than in the binuclear form. The e.p.r. work described below has shown that the Spin Hamiltonian parameters of the binuclear species are unaffected (to within experimental error) by this fact (Table II).

Electron paramagnetic resonance spectra were obtained at 9.1 GHz and 12.0 GHz.

Results and Discussion

The spectrum of polycrystalline copper(II) benzoate observed at 77 °K with a microwave frequency of 9.1 GHz is shown in Fig. 1. This spectrum is typical of a triplet state in which $D > h\nu$, i.e. we observe resonances (designated using the notation of Wasserman *et al.* (8)) H_{z1}, H_{z2}, H_{x2}, H_{y2}; these are shown in Fig. 1. The resonance observed at about 3000 G is due to copper ions in a different form to the binuclear species. This was confirmed by variable temperature studies which showed, as is to be expected, that the signals due to the triplet decrease as the temperature is lowered whereas the other resonance increases in intensity. We have made no attempt to analyze this part of the spectrum but note the similarity between it and the spectrum of polycrystalline Zn doped copper(II) acetate (11). We note that the four resonances are insufficient

to determine unambiguously the Spin Hamiltonian parameters. Consequently, we carried out measurements at the second frequency. In this case $D < h\nu$ and therefore we should observe all six $\Delta m = \pm 1$ transitions. Unfortunately it was not possible to observe the H_{z2} and H_{y1} transition due to the lack of sensitivity of the instrument at 12.0 GHz. However, those lines observed and their assignments are given in Table II.

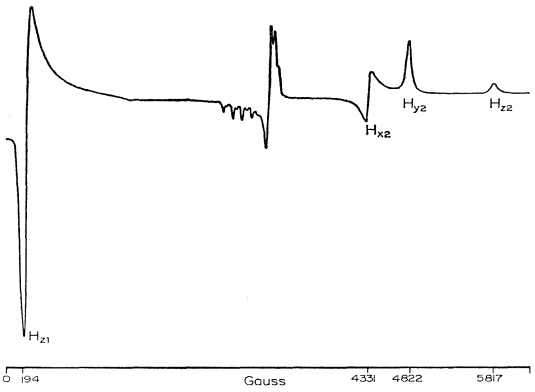

FIG. 1. Electron paramagnetic resonance spectrum of copper(II) benzoate (sample 1) at 77 °K. $H_0 = 3266.8$ G.

The Spin Hamiltonian parameters were obtained from the experimental data at both frequencies by employing an extended Newton–Raphson (12) technique to eq. [13] of Wasserman *et al.* (8). These calculations have been put in the form of a FORTRAN program for an IBM 7044. This program uses any five resonances at the corresponding microwave frequencies and solves for D, E, g_x, g_y, and g_z. A word of caution is necessary here; if one chooses five resonances that are far away from zero field (e.g. H_{x2}, and H_{y2} at 12.0 GHz and H_{x2}, H_{y2}, and H_{z2} at 9.1 GHz), then the technique employed converges on a local minimum which gives D, E, g_x, g_y, and g_z which are in error to $\pm 20\%$. However, if any one of the lower lines (i.e. H_{x1}, H_{y1}, H_{z1}) is employed with the high field lines, then reliable parameters are obtained. Presumably this condition arises because of the long extrapolation required to zero field when using exclusively high field lines.

The values of the Spin Hamiltonian parameters obtained are given in Table I, together with the values for Cu(II) acetate for comparison. Table II gives the observed and calculated resonances.

The foregoing experimental work has tacitly assumed that the D tensor and g tensor are

TABLE I

Spin Hamiltonian parameters for $Cu_2(C_6H_5CO_2)_4$ and $Cu_2(CH_3CO_2)_4(H_2O)_2$ (3)

	Value

D	0.3311 ± 0.0006 cm^{-1}	0.345 ± 0.005 cm^{-1}
E	0.0147 ± 0.0003 cm^{-1}	0.007 ± 0.003 cm^{-1}
g_x	2.048 ± 0.004	2.053 ± 0.005
g_y	2.074 ± 0.004	2.093 ± 0.005
g_z	2.345 ± 0.004	2.344 ± 0.01

diagonal in the same axis system. We note that Kokoszka, Allen, and Gordon (4) observed that the D and g tensors of dichlorobispyridine-*N*-oxide copper(II) are not diagonal in the same axis system. However, as was pointed out in ref. 4, the pseudodipolar interaction has the same set of principal axes as the dipolar interaction in the copper acetate monohydrate complex and since we expect copper(II) benzoate to be similar to the acetate homologue, as is evidenced by the similarity in magnetic data, we conclude that most probably the g and D tensors have the same principal axis system. The fact that E for the benzoate is twice as large as that for the acetate suggests that there is a greater deviation from tetragonal symmetry in the former molecule.

Magnetic susceptibility data on a number of preparations of copper(II) benzoate have been reported in the literature. Using curve-fitting techniques, Lewis and Mabbs (7) were able to fit their magnetic susceptibility data for copper(II) benzoate (preparation 5, ref. 7) to the theoretical expression for binuclear copper(II) molecules. Using our average g value of 2.160 and the data of Lewis and Mabbs, a good fit is obtained with $2J$ (singlet–triplet separation) $= 333$ cm^{-1} and $N\alpha$ [temperature-independent paramagnetic contribution for copper(II)] $= 80 \times 10^{-6}$ c.g.s.e.m.u. (Fig. 2). For two other preparations of copper(II) benzoate previously reported, it is possible to account for the magnetic data in terms of a mixture of the binuclear form with a small percentage of magnetically dilute copper(II) for which $X_{Cu} = 0.43/T + 80 \times 10^{-6}$ (Fig. 2). For those preparations which yielded samples of even higher magnetic susceptibilities, attempts to account for their magnetic properties in the manner described above were unsuccessful. It appears that as the percentage of binuclear species decreases the assumption that the remaining

The solid lines are calculated on the basis of (*a*) 100%, (*b*) 95%, and (*c*) 93% of the copper ions in the binuclear form and the remaining copper ions in the magnetically dilute form.

copper ions are magnetically dilute is incorrect. For these samples it is possible that those copper ions which are not coupled in pairs are bonded together in a highly polymeric form of copper(II) benzoate in which "super-exchange" takes place via bridging carboxylate groups. It has been suggested that interactions of this type occur in some forms of copper(II) formate (13).

Similar e.p.r. studies on pyridine and aniline adducts of copper(II) arylcarboxylates are now in progress.

Mass spectra of organometallic compounds. VI. Some indenylmetal derivatives and related compounds[1]

R. B. KING[2]
Mellon Institute, Pittsburgh, Pennsylvania
and
Department of Chemistry, University of Georgia, Athens, Georgia

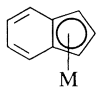
Received June 12, 1968

The mass spectra of the following complexes have been investigated: (*a*) the indenylmolybdenum carbonyl derivatives $CH_3Mo(CO)_3C_9H_7$, π-$C_3H_5Mo(CO)_2C_9H_7$, π-$CH_3SCH_2Mo(CO)_2C_5H_5$, and $C_9H_7Mo(CO)_2I$; (*b*) the bisindenyl derivative $(C_9H_7)_2Fe$; (*c*) the series of compounds $C_5H_5FeC_9H_7$, $C_5H_5FeC_9H_9$, and $C_5H_5FeC_9H_{11}$ with different degrees of hydrogenation of the π-indenyl ligand. The following features of particular interest were noted: (*a*) evidence for the existence of small amounts of the new compound π-$C_3H_5Mo(CO)_2C_9H_6C_3H_5$ in the sample of π-$C_3H_5Mo(CO)_2C_9H_7$; (*b*) evidence for the pyrolysis of $C_9H_7Mo(CO)_2I$ to give $[C_9H_7MoI_2]_2$ and $(C_9H_7)_2MoCOI$; (*c*) evidence for the fragmentation of $C_9H_7Fe^+$ to give the ion $C_9H_7^+$ and a neutral iron atom; (*d*) evidence for parallel pathways for fragmentation of the parent ion from $C_5H_5FeC_9H_{11}$ involving elimination of CH_3, C_2H_4, C_3H_5, C_5H_6, and H_2. Diagnostic features from the mass spectrum for the presence of a π-indenyl ligand in a complex appear to be the ions $C_9H_8^+$, $C_9H_7^+$, $C_7H_5^+$, $C_5H_3^+$, and $C_9H_7^{2+}$.

Canadian Journal of Chemistry, **47**, 559 (1969)

Introduction

Previous papers have discussed the mass spectra of a great variety of π-cyclopentadienyl derivatives including metallocenes (2–8) and cyclopentadienylmetal carbonyl derivatives (9–11). Fusion of a benzene ring to a π-cyclopentadienyl ligand gives the π-indenyl ligand (**1**), which like the π-cyclopentadienyl ligand forms a variety of metal complexes. This paper reports the mass spectra of several π-indenyl derivatives.



1

Experimental

The mass spectra were run on a standard Associated Electrical Industries, Ltd., MS-9 mass spectrometer located at the Mellon Institute. Tables containing these mass spectral data may be obtained upon request[3]. In addition Fig. 1 depicts the mass spectra of four representative compounds. The operating conditions were 70 eV electron energy, 200–230° inlet temperature, resolution of 1000, and 8 kV accelerating voltage. Samples were introduced directly into the ion source using a metal probe. The standard galvanometer recorder was used to measure the output signal from the electron multiplier. The relative ion intensities were estimated by measurement of the heights of the peaks on the galvanometer recorder chart with a millimeter scale. Values relative to an arbitrary value of 100.0 assigned to a selected intense metal-containing ion are reported in the Tables.

This work dealt entirely with compounds of iron or molybdenum. Natural iron contains 91.6% of the isotope ^{56}Fe. The *m/e* values reported for ions containing iron are for ions containing ^{56}Fe. Natural molybdenum contains a mixture of isotopes forming a characteristic pattern that is diagnostic of the presence of molybdenum in a given ion. The *m/e* values for ions containing molybdenum are given just for the ions containing ^{96}Mo, although in all cases the characteristic multiline pattern containing ions with different molybdenum isotopes was observed.

For transitions not involving ions of the multiisotopic metal molybdenum, metastable ions were sometimes observed as much weaker and broader peaks often at non-integral *m/e* values. These metastable ions provide excellent corroboratory evidence regarding suggested modes of fragmentation of certain of the observed ions (12). Because of the weakness and breadth of the metastable ions, they were only unequivocally observed for transitions involving the strongest ions of the spectrum and for those involving only essentially monoisotopic elements.

Except for $C_5H_5FeC_9H_9$, the compounds used in this study were prepared by methods adequately described in the literature[4].

Preparation of $C_5H_5FeC_9H_9$

A suspension of 50 mmoles of ferrous chloride was prepared by boiling for 16 h under reflux 33 mmoles of

anhydrous ferric chloride, 17 mmoles of iron powder, and 250 ml of redistilled tetrahydrofuran. A purple-brown suspension apparently (15) containing lithium cyclononatetraenide was obtained by stirring for 20 h at room temperature a mixture of 100 mmoles of lithium wire, 50 mmoles of chlorobicyclo[6,1,0]-nonatriene (15), and 150 ml of redistilled tetrahydrofuran. A solution of sodium cyclopentadienide was prepared by treatment of a suspension of 50 mmoles of sodium dispersion in 100 ml redistilled tetrahydrofuran with excess cyclopentadiene.

The ferrous chloride suspension was cooled in a $-78°$ bath and treated first with the lithium cyclononatetraenide and then with the sodium cyclopentadienide. The reaction mixture was allowed to warm to room temperature and finally boiled 16 h under reflux.

After cooling to room temperature solvent was removed at $\sim 25°/25$ mm. The residue was extracted with 400 ml of dichloromethane in four portions. The extracts were filtered through alumina. Solvent was removed from the filtrate at $\sim 25°/25$ mm. The resulting orange-brown residue was extracted with ~ 200 ml of pentane. After reducing the volume of these extracts to ~ 100 ml, the solution was chromatographed on a 2×50 cm alumina column. The chromatogram was developed with pentane. A yellow-orange band of ferrocene followed by a smaller orange band of $C_5H_5FeC_9H_9$ was observed. Both bands were eluted with pentane. From the first band 1.3 g (14% yield) of ferrocene was obtained. The product from the second band was dissolved in pentane and the filtered solution cooled overnight at $-78°$. The orange crystals which formed were separated and sublimed at 70°/0.25 mm to give 0.038 g ($\sim 0.3\%$ yield) of red-orange $C_5H_5FeC_9H_9$, m.p. 107–109°. This meager yield was very erratic; this preparation often failed completely.

Anal. Calcd. for $C_{14}H_{14}Fe$: C, 70.6; H, 5.9; Fe, 23.5. Found: C, 69.9; H, 5.9; Fe, 23.6.

Discussion

A. General Comments

The mass spectra of π-cyclopentadienylmetal derivatives (2–11) generally exhibit the metal-free ions $C_5H_6^+$, $C_5H_5^+$, and $C_3H_3^+$ arising from the π-cyclopentadienyl ligand. Apparently the π-C_5H_5 ligand can either come off as such or abstract a proton from elsewhere and be removed as $C_5H_6^+$. Furthermore, the $C_5H_5^+$ ion can eliminate a neutral acetylene (C_2H_2) fragment forming $C_3H_3^+$. Related acetylene-elimination processes are well-established to occur in normal benzenoid aromatic compounds (16).

The data obtained in this work indicate that typical metal-free ions in the mass spectra of π-indenyl derivatives arising from the π-indenyl ligand include $C_9H_8^+$, $C_9H_7^+$, $C_7H_5^+$, and $C_5H_3^+$. A π-C_9H_7 ligand can thus either come off as such or abstract a proton from elsewhere and be removed as $C_9H_8^+$. The $C_9H_7^+$ ion can undergo two successive acetylene (C_2H_2) eliminations giving first $C_7H_5^+$ and then $C_5H_3^+$. In some cases the acetylene eliminations were supported by the presence of appropriate metastable ions. The fragmentation of the C_9H_7 ligand in π-indenyl derivatives thus appears to follow a pattern similar to the fragmentation of the C_5H_5 ligand in π-cyclopentadienyl derivatives.

A further feature of the mass spectra of certain π-indenyl derivatives is the presence of metal-free ions of the type $C_{18}H_n^+$ (n = mostly 14 but sometimes 13 or 12). These apparently arise from coupling of two indenyl groups possibly after pyrolytic cleavage of the metal–indenyl bond. Analogous ions of the type $C_{10}H_n^+$ (n = 10, 9, and/or 8) have occasionally been observed in the mass spectra of π-cyclopentadienyl derivatives.

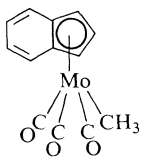
In many compounds doubly charged ions of the type $C_9H_n^{2+}$ (n = most often 7 but occasionally also 8 or 6) are also observed. Similar doubly charged ions of the type $C_5H_n^{2+}$ have not been reported to occur in the mass spectra of π-C_5H_5 derivatives.

B. Indenylmolybdenum Carbonyl Derivatives

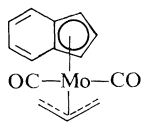
1. $CH_3Mo(CO)_3C_9H_7$: The parent ion in the mass spectrum of $CH_3Mo(CO)_3C_9H_7$ (**2**) exhibits stepwise loss of its carbonyl groups. However, after one carbonyl group is lost, fragmentation of the methyl group competes with further loss of carbonyl groups. Also loss of the last carbonyl group from the monocarbonyl ion $CH_3MoCOC_9H_7^+$ (*m/e* 254) is accompanied by dehydrogenation giving the carbonyl-free ion $C_{10}H_8Mo^+$ (*m/e* 224). The involvement of the methyl hydrogens in this dehydrogenation is suggested by the fact that the loss of the last carbonyl group from the methyl-free monocarbonyl ion $C_9H_7MoCO^+$ (*m/e* 239) gives the carbonyl-free ion $C_9H_7Mo^+$ (*m/e* 211) without accompanying dehydrogenation.

The carbonyl-free ions $C_{10}H_8Mo^+$ (*m/e* 224) and $C_8H_7Mo^+$ (*m/e* 211) both undergo acetylene (C_2H_2) eliminations giving $C_8H_6Mo^+$ (*m/e* 198) and $C_7H_5Mo^+$ (*m/e* 185), respectively. The remaining molybdenum ions in the mass spectrum

of $CH_3Mo(CO)_3C_9H_7$ appear to arise from some $Mo(CO)_6$ present as an impurity or decomposition product.



2



3

The usual metal-free ions found in the mass spectra of π-indenyl derivatives (see above) are also observed in the mass spectrum of $CH_3Mo(CO)_3C_9H_7$. These include $C_9H_8^+$, $C_9H_7^+$, $C_7H_5^+$, $C_5H_3^+$, $C_9H_8^{2+}$, and $C_9H_7^{2+}$. In addition there appears to be a strong tendency for the formation of an acetyl ion CH_3CO^+ (*m/e* 43). Also the ion $CH_3COC_9H_7^+$ (*m/e* 158) appears to come from acetylation of the π-indenyl ligand. The ion $C_{10}H_{10}^+$ (*m/e* 130) can arise by methylation of a π-indenyl ligand. It appears to undergo dehydrogenation to give $C_{10}H_9^+$ (*m/e* 129) and $C_{10}H_8^+$ (*m/e* 128).

2. π-$C_3H_5Mo(CO)_2C_9H_7$ (3): The parent ion $C_3H_5Mo(CO)_2C_9H_7^+$ (*m/e* 308) first loses one carbonyl group giving the monocarbonyl ion $C_3H_5MoCOC_9H_7^+$ (*m/e* 280). Loss of the second carbonyl group is accompanied by dehydrogenation giving the carbonyl-free ion $C_3H_3MoC_9H_7^+$ (*m/e* 250). This fragmentation scheme is completely analogous to that observed (11) for the corresponding π-cyclopentadienyl derivative $C_3H_5Mo(CO)_2C_5H_5$.

One further fragmentation pathway in this mass spectrum involves loss of the π-allyl ligand giving the ion $C_9H_7Mo^+$ (*m/e* 211). Successive eliminations of acetylene (C_2H_2) from $C_9H_7Mo^+$ (*m/e* 211) give the ions $C_7H_5Mo^+$ (*m/e* 185) and $C_5H_3Mo^+$ (*m/e* 159). Similar successive eliminations of acetylene (C_2H_2) from $C_3H_3MoC_7H_5^+$ ($=C_{10}H_8Mo^+$, *m/e* 224) give the ions $C_8H_6Mo^+$ (*m/e* 198) and $C_6H_4Mo^+$ (*m/e* 172). The doubly charged ions $C_3H_3MoC_9H_7^{2+}$ (*m/e* 125), $C_3H_3MoC_7H_5^{2+}$ (*m/e* 112), and $C_8H_7Mo^{2+}$ (*m/e* 105.5) are also observed.

The usual metal-free ions found in the mass spectra of π-indenyl derivatives (see above) are also observed in the mass spectrum of $C_3H_5Mo(CO)_2C_9H_7$ (**3**). The additional metal-free ions $C_6H_n^+$ ($n = 9$ or 11), $C_3H_nCO^+$ ($n = 5$ or 7), $C_3H_5^+$, and $C_3H_3^+$ arise from coupling, carbonylation, cleavage, and dehydrogenation of the π-allyl ligand, respectively.

The mass spectrum of $C_3H_5Mo(CO)_2C_9H_7$ (**3**) also exhibited the ions $C_3H_5Mo(CO)_2C_9H_6C_3H_5^+$ (*m/e* 348), $C_3H_5MoCOC_9H_6C_3H_5^+$ (*m/e* 320), and $C_3H_3MoC_9H_6C_3H_5^+$ (*m/e* 290) in relatively low abundances. These ions appear to arise from π-allyl-π-(allylindenyl)-molybdenum dicarbonyl, $C_3H_5Mo(CO)_2C_9H_6C_3H_5$, present as an impurity. This impurity could either have been present in the original sample or could have been produced by a pyrolysis reaction in the mass spectrometer. In the latter case the allyl group of one molecule of $C_3H_5Mo(CO)_2C_9H_7$ would allylate the π-indenyl group of another molecule producing the compound $C_3H_5Mo(CO)_2C_9H_6C_3H_5$. The mass spectral data give no indication of the position of allyl substitution in the indenyl system.

The former possibility that the $C_3H_5Mo(CO)_2C_9H_7$ used for this work contains a small amount of $C_3H_5Mo(CO)_2C_9H_6C_3H_5$ raises an interesting point. The compound $C_3H_5Mo(CO)_2C_9H_7$ was prepared by the published procedure (13). This consists of reducing the binuclear compound $[C_9H_7Mo(CO)_3]_2$ with sodium amalgam in tetrahydrofuran followed by addition of allyl chloride. The reduction of $[C_9H_7Mo(CO)_3]_2$ with sodium amalgam in tetrahydrofuran has been assumed to give the sodium salt $Na[Mo(CO)_3C_9H_7]$. However, it is conceivable that some of the disodium derivative $Na[Mo(CO)_3C_9H_6Na]$ might be formed. This disodium derivative would be expected to react with allyl chloride to give $C_3H_5Mo(CO)_2C_9H_6C_3H_5$. If the assumption of equal ionization efficiencies for $C_3H_5Mo(CO)_2C_9H_7$ and $C_3H_5Mo(CO)_2C_9H_6C_3H_5$ is made, then the amount of $C_3H_5Mo(CO)_2C_9H_6C_3H_5$ present in the sample of $C_3H_5Mo(CO)_2C_8H_7$ would be about 2%. In the previous work on $C_3H_5Mo(CO)_2C_9H_7$ an impurity of ~ 2% of $C_3H_5Mo(CO)_2C_9H_6C_3H_5$ would have escaped detection.

3. π-$CH_3SCH_2Mo(CO)_2C_9H_7$: Much of the mass spectrum of π-$CH_3SCH_2Mo(CO)_2C_9H_7$ (**4**) is very similar to that of its π-cyclopentadienyl analogue π-$CH_3SCH_2Mo(CO)_2C_5H_5$ (17). The parent ion (*m/e* 328) first undergoes stepwise loss of carbonyl groups giving the carbonyl-free ion $CH_3SCH_2MoC_9H_7^+$ (*m/e* 272). This ion then appears to lose methane (CH_4) giving the ion $C_{10}H_8SMo^+$ (*m/e* 256), which is the most

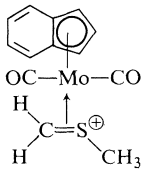
abundant metal-containing ion in the mass spectrum. This behavior exactly parallels that of π-$CH_3SCH_2Mo(CO)_2C_5H_5$ where $C_6H_6SMo^+$ is the most abundant metal-containing ion in the mass spectrum (17).

The other significant metal-containing ion in the mass spectrum of π-$CH_3SCH_2Mo(CO)_2C_9H_7$ is $C_9H_7MoSH^+$ (*m/e* 244) apparently formed by elimination of ethylene from $CH_3SCH_2MoC_9H_7^+$ (*m/e* 272). The formation of $C_9H_7MoSH^+$ (*m/e* 244) in the mass spectrum of π-$CH_3SCH_2Mo(CO)_2C_9H_7$ closely parallels the formation (17) of $C_5H_5MoSH^+$ in the mass spectrum of the π-cyclopentadienyl analogue π-$CH_3SCH_2Mo(CO)_2C_5H_5$.

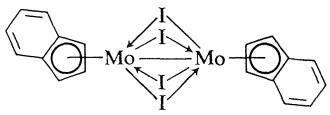


4

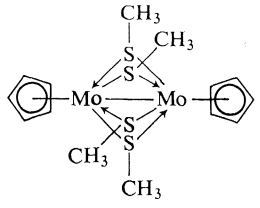
The usual metal-free ions found in the mass spectra of π-indenyl derivatives are observed in the mass spectrum of π-$CH_3SCH_2Mo(CO)_2C_9H_7$. Also observed are the ions $C_9H_7CO^+$ (*m/e* 143) and CH_3CO^+ (*m/e* 43), arising from carbonylation of the indenyl ligand and methyl substituent, respectively. The ions $C_{10}H_9^+$ (*m/e* 129) and $C_{10}H_8^+$ (*m/e* 128) may arise from insertion of a carbon atom of the π-CH_3SCH_2 ligand into the C_9H_7 ligand. The assignments of several of the metal-free ions were unclear.

4. $C_9H_7Mo(CO)_2I$: Reaction of the binuclear compound $[C_9H_7Mo(CO)_3]_2$ with iodine gives a brown solid formulated as the dicarbonyl $C_9H_7Mo(CO)_2I$ on the basis of analytical data. The mass spectrum (Table IV) of this brown solid indicated that the $C_9H_7Mo(CO)_2I$ had completely decomposed by pyrolysis in the mass spectrometer.

The highest *m/e* ion in the mass spectrum of this brown solid could be assigned to $(C_9H_7)_2Mo_2I_4^+$ (*m/e* 930). This corresponds to the parent ion of an unknown compound $[C_9H_7MoI_2]_2$ of structure **5**. This structure **5** would correspond to structure **6** for the organosulfur derivative $[C_5H_5Mo(SCH_3)_2]_2$, (18). Structure **5** is related to structure **6** by substituting π-indenyl rings for π-cyclopentadienyl rings and by substituting bridging iodine atoms for bridging CH_3S groups.



5



6

The parent ion of **5**, $(C_9H_7)_2Mo_2I_4^+$ (*m/e* 930), appears to undergo stepwise loss of iodine atoms resulting finally in $(C_9H_7)_2Mo_2^+$ (*m/e* 422). The iodine bridges can thus be removed in $[C_9H_7MoI_2]_2$ (**5**) without disturbing the molybdenum–molybdenum bond believed to be in **5** by analogy with $[C_5H_5Mo(SCH_3)_2]_2$ (**6**), where a molybdenum–molybdenum bond is required to explain the diamagnetism. The intermediate ions $(C_9H_7)_2Mo_2I_n^+$ (n = 3, 2, and 1) can also undergo π-C_9H_7 cleavage giving the corresponding ions $C_9H_7Mo_2I_n^+$ (n = 3, 2, and 1). The doubly-charged ions $(C_9H_7)_2Mo_2I_n^{2+}$ (n = 4 or 3) were also observed.

An additional series of ions containing one carbonyl group is observed in the mass spectrum which cannot arise from $[C_9H_7MoI_2]_2$. The highest *m/e* ion in this second series corresponds to $(C_9H_7)_2MoCOI^+$ (*m/e* 481) suggesting that bisindenylmolybdenum carbonyl iodide is a second pyrolysis product of $C_9H_7Mo(CO)_2I$. The presence of ions from $[C_9H_7MoI_2]_2$ and from $(C_9H_7)_2MoCOI$ in the mass spectrum of $C_9H_7Mo(CO)_2I$ suggests that its pyrolysis proceeds according to the following equation:

$$6C_9H_7Mo(CO)_2I \xrightarrow{\Delta} [C_9H_7MoI_2]_2 + 2(C_9H_7)_2MoCOI + 2Mo + 10CO$$

The ion $(C_9H_7)_2MoCOI^+$ (*m/e* 481) appears to fragment either by loss of its carbonyl group giving $(C_9H_7)_2MoI^+$ (*m/e* 453) or by loss of its iodine atom giving $(C_9H_7)_2MoCO^+$ (*m/e* 354).

The mass spectrum of this brown solid also exhibits some metal-containing ions which can arise either from $[C_9H_7MoI_2]_2$ or from

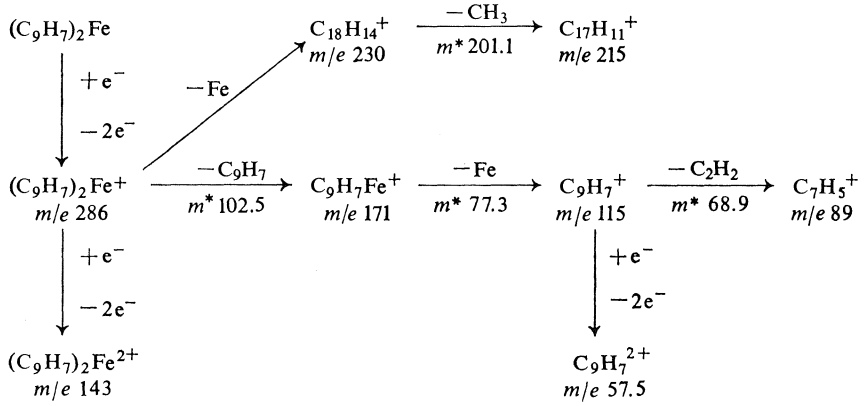


FIG. 2. Fragmentation scheme of $(C_9H_7)_2Fe$.

$(C_9H_7)_2MoCOI$, since they correspond to fragments of either species. The highest *m/e* ion among these "ambiguous" ions is $C_9H_7MoI^+$ (*m/e* 338). This ion $C_9H_7MoI^+$ (*m/e* 338) can eliminate acetylene (C_2H_2) giving the ion $C_7H_5MoI^+$ (*m/e* 312). The ion $(C_9H_7)_2Mo^+$ (*m/e* 326) can arise by processes such as molybdenum elimination from $(C_9H_7)_2Mo_2^+$ (*m/e* 422) (a fragment of $[C_9H_7MoI_2]_2$) or by carbon monoxide elimination from $(C_9H_7)_2MoCO^+$ (*m/e* 354) (a fragment of $(C_9H_7)_2MoCOI$). The great ease of carbon monoxide elimination from metal carbonyl ions suggests the latter process to be much more likely. The ion $(C_9H_7)_2Mo^+$ (*m/e* 326) can undergo a second ionization giving the dipositive ion $(C_9H_7)_2Mo^{2+}$ (*m/e* 163). The two remaining metal-containing ions are $C_9H_7Mo^+$ (*m/e* 211) and its acetylene-elimination product $C_7H_5Mo^+$ (*m/e* 185) expected to be present in the mass spectra of all π-indenylmolybdenum derivatives.

The usual metal-free ions found in the mass spectra of π-indenyl derivatives are also observed in the mass spectrum of this brown solid. These include $C_9H_8^+$, $C_9H_7^+$, $C_7H_5^+$, $C_5H_3^+$, and $C_9H_7^{2+}$. In addition the ion $C_{18}H_{14}^+$ (*m/e* 230) arising from the coupling of two indenyl ligands is observed in relatively high abundance. Such coupling of indenyl ligands would be expected to occur readily in $(C_9H_7)_2MoCOI$ owing to the presence of two indenyl ligands on one metal atom. Most of the remaining hydrocarbon ions are possible fragmentation products of $C_{18}H_{14}^+$ (*m/e* 230). The iodide ligand in both $[C_9H_7MoI_2]_2$ and $(C_9H_7)_2MoCOI$ can account for the ions HI^+ (*m/e* 128) and I^+ (*m/e* 127).

C. Indenyliron Derivatives and Hydrogenation Products

1. $(C_9H_7)_2Fe$: Figure 2 depicts the main features of the fragmentation scheme of $(C_9H_7)_2Fe$ (7). The parent ion in this mass spectrum first loses one of its indenyl ligands giving the ion $C_9H_7Fe^+$ (*m/e* 171). This ion then loses its iron atom giving the indenyl ion $C_9H_7^+$ (*m/e* 115). Both of these processes are supported by the presence of appropriate metastable ions. The only other iron ion present in significant abundance is the doubly charged parent ion $(C_9H_7)_2Fe^{2+}$ (*m/e* 143). The "bare" iron ion Fe^+ (*m/e* 56) is only observed in low abundance. Apparently the indenyliron ion ($C_9H_7Fe^+$, *m/e* 171) fragments almost exclusively by elimination of a neutral iron atom according to the following equation

$$\underset{m/e\ 171}{C_9H_7Fe^+} \xrightarrow{m^*\ 77.4} \underset{m/e\ 115}{C_9H_7^+} + Fe$$

This contrasts with the behavior of the corresponding cyclopentadienyliron ion ($C_5H_5Fe^+$, *m/e* 121) which fragments mainly by elimination of a neutral C_5H_5 fragment according to the following equation

$$\underset{m/e\ 121}{C_5H_5Fe^+} \xrightarrow{m^*\ 25.8} \underset{m/e\ 56}{Fe^+} + C_5H_5$$

Metal-free ions in the mass spectrum of $(C_9H_7)_2Fe$ (7) include the usual ions present in π-indenyl complexes (see above). In addition the ion $C_{18}H_{14}^+$ (*m/e* 230) arising from the coupling of two C_9H_7 groups is observed. This $C_{18}H_{14}^+$ (*m/e* 230) ion appears to fragment by loss of a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

neutral methyl (CH_3) fragment giving the $C_{17}H_{11}^+$ (*m/e* 215) ion.

2. $C_5H_5FeC_9H_7$: Figure 3 depicts the main features of the fragmentation scheme of $C_5H_5FeC_9H_7$ (**8**). The parent ion in this mass spectrum can lose either its indenyl ligand giving the ion $C_5H_5Fe^+$ (*m/e* 121) or its cyclopentadienyl ligand giving the ion $C_9H_7Fe^+$ (*m/e* 171). The ratio of the relative abundance of $C_9H_7Fe^+$ to that of $C_5H_5Fe^+$ is only 0.071, indicating that the tendency for the parent ion to lose its π-indenyl ligand is much greater than the tendency for the parent ion to lose its π-cyclopentadienyl ligand, in accord with the chemical indications (14) of the lower stability of metal-π-indenyl bonds compared with the analogous metal-π-cyclopentadienyl bonds. Further fragmentation of $C_5H_5Fe^+$ (*m/e* 121) results in elimination of a C_5H_5 fragment giving Fe^+ (*m/e* 56) whereas further fragmentation of $C_9H_7Fe^+$ (*m/e* 171) results in elimination of a neutral iron atom giving $C_9H_7^+$ (*m/e* 115) as discussed above.

The metal-free ions $C_9H_7^+$ (*m/e* 115), $C_7H_5^+$ (*m/e* 89), and $C_5H_3^+$ (*m/e* 63) result from the π-indenyl ligand as discussed above. The metal-free ions $C_5H_6^+$ (*m/e* 66), $C_5H_5^+$ (*m/e* 65), and $C_3H_3^+$ (*m/e* 39) result from the π-cyclopentadienyl ligand. The ions $C_{14}H_{11}^+$ (*m/e* 179) and

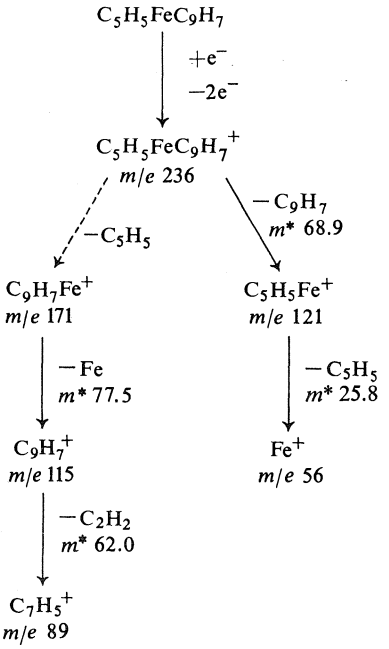

FIG. 3. Fragmentation scheme of $C_5H_5FeC_9H_7$.

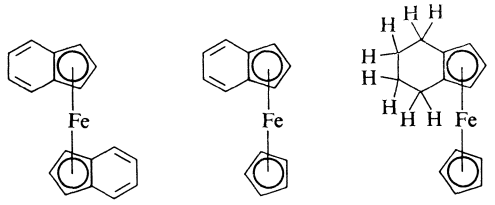
$C_{14}H_{10}^+$ (*m/e* 178) result from coupling of the indenyl and cyclopentadienyl ligands followed by dehydrogenation.



7 8 9

3. $C_5H_5FeC_9H_{11}$: Hydrogenation of $C_5H_5FeC_9H_7$ (**8**) at atmospheric pressure in the presence of a palladium catalyst has been shown to give $C_5H_5FeC_9H_{11}$ (**9**). The mass spectrum of the hydrogenated product $C_5H_5FeC_9H_{11}$ (**9**) was compared with that of $C_5H_5FeC_9H_7$ (**8**) and found to be somewhat more complex owing to possibilities of dehydrogenation processes. Figure 4 depicts the principal features of the fragmentation scheme of $C_5H_5FeC_9H_{11}$ (**9**).

Four decomposition processes for the parent ion in the mass spectrum of $C_5H_5FeC_9H_{11}$ were identified from metastable ions:

1. Elimination of CH_3 (methyl)

$$\underset{m/e\ 240}{C_5H_5FeC_9H_{11}^+} \xrightarrow{m^*210.6} \underset{m/e\ 225}{C_5H_5FeC_8H_8^+} + CH_3$$

This process must necessarily involve a hydrogen shift.

2. Elimination of C_2H_4 (ethylene)

$$\underset{m/e\ 240}{C_5H_5FeC_9H_{11}^+} \xrightarrow{m^*\ 187.4} \underset{m/e\ 212}{C_5H_5FeC_7H_7^+} + C_2H_4$$

Two adjacent sp^3 carbon atoms in the six-membered ring of the C_9H_{11} ligand can be eliminated as ethylene.

3. Elimination of C_3H_5 (allyl)

$$\underset{m/e\ 240}{C_5H_5FeC_9H_{11}^+} \xrightarrow{m^*\ 164.9} \underset{m/e\ 199}{C_5H_5FeC_6H_6^+} + C_3H_5$$

The $C_5H_5FeC_6H_6^+$ ion formed in this reaction has also been isolated in the form of stable salts (19, 20).

4. Elimination of $C_5H_6 + H_2$ in one step

$$\underset{m/e\ 240}{C_5H_5FeC_9H_{11}^+} \xrightarrow{m^*\ 123.2} \underset{m/e\ 172}{C_9H_8Fe^+} + C_5H_6 + H_2$$

The presence of an appreciable abundance of $C_9H_{10}Fe^+$ (*m/e* 174) also suggests elimination of

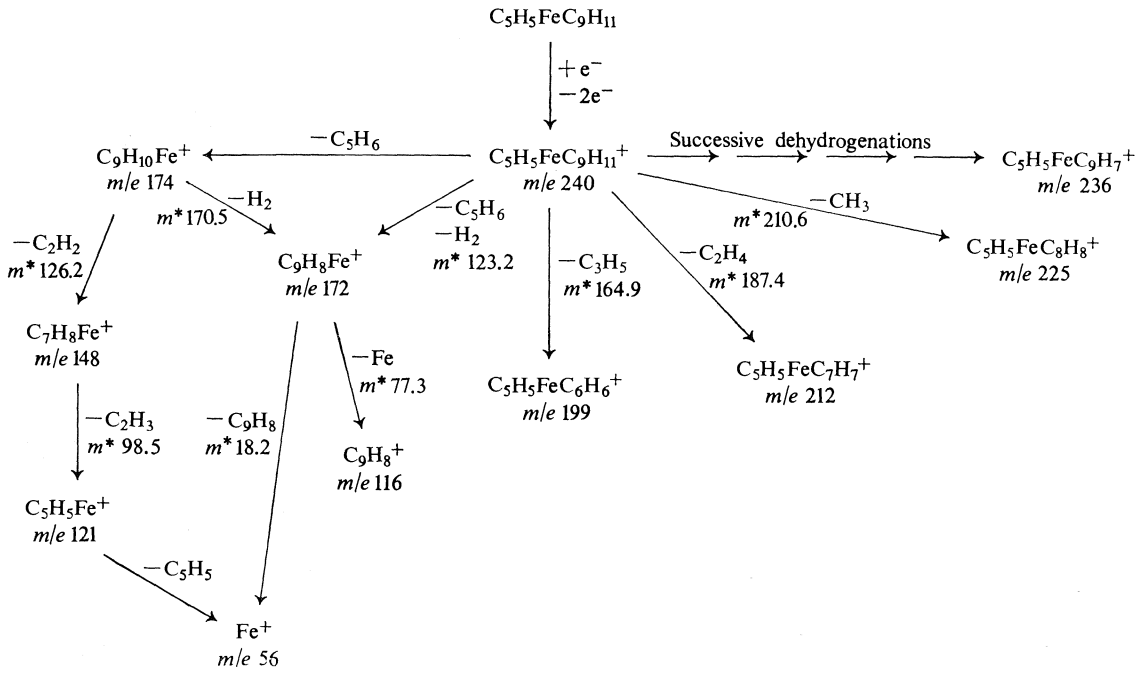


FIG. 4. Fragmentation scheme of $C_5H_5FeC_9H_{11}$.

C_5H_6 from the parent ion $C_5H_5FeC_9H_{11}^+$ (*m/e* 240).

The presence of the ions $C_5H_5FeC_9H_n^+$ (n = 10, 9, 8, and 7) in the mass spectrum of $C_5H_5FeC_9H_{11}$ (**9**) suggests that the parent ion can undergo dehydrogenation of its sp^3 carbon atoms giving sp^2 carbon atoms. Similar dehydrogenation processes involving carbonyl-free ions have been noted in the mass spectra of olefin-metal carbonyl derivatives (21).

The ion $C_7H_8Fe^+$ (*m/e* 148) can result by acetylene (C_2H_2) elimination from the ion $C_9H_{10}Fe^+$ (*m/e* 174). Other fragmentation processes of several types can result in the iron-containing ions $C_6H_6Fe^+$ (*m/e* 134) and $C_5H_5Fe^+$ (*m/e* 121). The "bare" iron ion Fe^+ (*m/e* 56) is also observed as the third most abundant metal-containing ion.

The metal-free ions arising from a π-C_9H_{11} ligand differ from those arising from a π-C_9H_7 ligand discussed above. A negligible abundance of $C_9H_{11}^+$ (*m/e* 119) is observed suggesting that the π-C_9H_{11} ligand undergoes dehydrogenation before the C_9H_{11} can be eliminated as an ion. The ions arising from the π-C_9H_{11} ligand in the mass spectrum of $C_5H_5FeC_9H_{11}$ include at least $C_9H_9^+$, $C_9H_8^+$, $C_9H_7^+$, $C_7H_7^+$, and $C_3H_5^+$. The ions $C_5H_5^+$ and $C_3H_3^+$ appear to arise from the π-C_5H_5 ligand. The fragment ions with 10, 11, and 12 carbon atoms probably arise from coupling both the C_5H_5 and C_9H_{11} ligands followed by various elimination processes.

4. $C_5H_5FeC_9H_9$: The mass spectral studies on $C_5H_5FeC_9H_7$ (**8**, Fig. 3) and $C_5H_5FeC_9H_{11}$ (**9**, Fig. 4) made interesting the study of a partially hydrogenated derivative $C_5H_5FeC_9H_9$. Such a compound has not yet been reported in the literature. However, a study of the reaction of ferrous chloride with a mixture of lithium cyclononatetraenide (15) and sodium cyclopentadienide had yielded a few mg of a material of apparent composition $C_5H_5FeC_9H_9$. The mass spectrum of this very rare compound of unknown structure was investigated. The composition $C_5H_5FeC_9H_9$ was confirmed. Main features of the fragmentation scheme of this complex are depicted in Fig. 5.

The parent ion in the mass spectrum of $C_5H_5FeC_9H_9$ undergoes both dehydrogenation giving $C_5H_5FeC_9H_8^+$ (*m/e* 237) and $C_5H_5FeC_9H_7^+$ (*m/e* 236) and acetylene elimination giving $C_5H_5FeC_7H_7^+$ (*m/e* 212). A second acetylene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

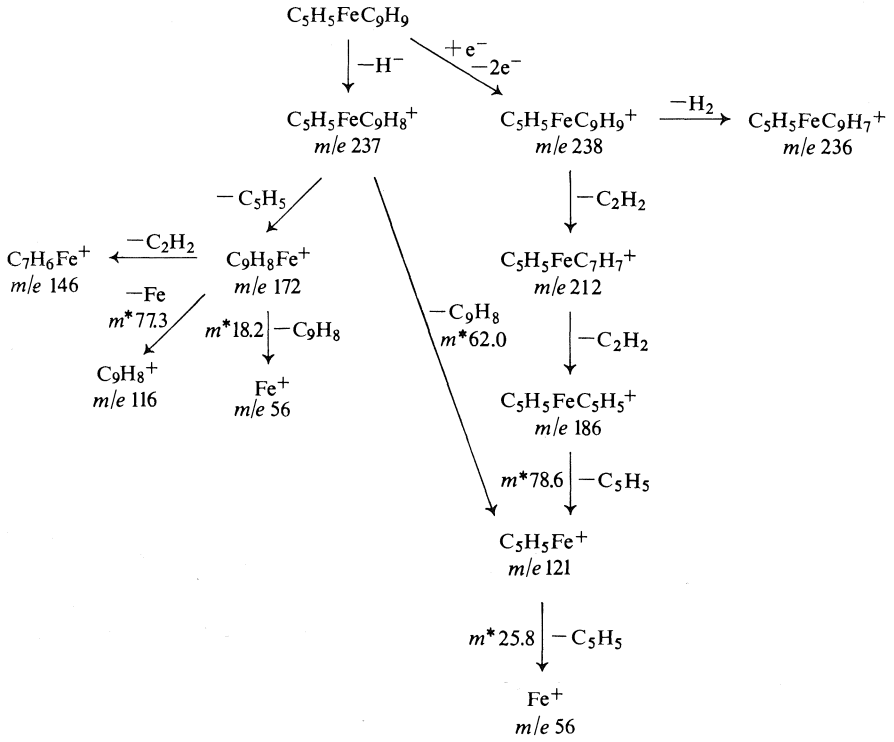

FIG. 5. Fragmentation scheme of $C_5H_5FeC_9H_9$.

elimination gives $C_5H_5FeC_5H_5^+$ (*m/e* 186). This ion (possibly the ferrocene ion) loses successively its two C_5H_5 rings giving first $C_5H_5Fe^+$ (*m/e* 121) and then the "bare" iron ion Fe^+ (*m/e* 56).

The most abundant iron-containing ion in the mass spectrum of $C_5H_5FeC_9H_9$ is $C_5H_5FeC_9H_8^+$ (*m/e* 237). Its formation may occur by hydride elimination from the parent neutral compound, e.g.

$$\underset{m/e\ 238}{C_5H_5FeC_9H_9} \longrightarrow \underset{m/e\ 237}{C_5H_5FeC_9H_8^+} + H^-$$

The $C_5H_5FeC_9H_8^+$ (*m/e* 237) ion can either lose its C_9H_8 ligand giving $C_5H_5Fe^+$ (*m/e* 121) or its C_5H_5 ligand giving $C_9H_8Fe^+$ (*m/e* 172). Further fragmentation of the $C_9H_8Fe^+$ (*m/e* 172) ion involves rupture of the bond between the C_9H_8 ligand and the iron atom giving a C_9H_8 fragment and an Fe fragment. The positive charge can remain with either fragment; both possibilities are supported by the appropriate metastable ions.

The most abundant hydrocarbon ions in the mass spectrum of $C_5H_5FeC_9H_9$ are $C_9H_8^+$ (*m/e* 116) and $C_9H_7^+$ (*m/e* 115). The $C_9H_7^+$ (*m/e* 115) ion appears to undergo stepwise loss of two acetylene (C_2H_2) fragments giving first $C_7H_5^+$ (*m/e* 89) and then $C_5H_3^+$ (*m/e* 63). Both of these acetylene eliminations are supported by the presence of appropriate metastable ions. The $C_5H_6^+$ (*m/e* 66), $C_5H_5^+$ (*m/e* 65), and $C_3H_3^+$ (*m/e* 39) ions are generally observed in the mass spectra of π-cyclopentadienyl derivatives and thus probably arise (at least partially) from the π-C_5H_5 ligand in $C_5H_5FeC_9H_9$. The $C_{14}H_{10}^+$ (*m/e* 178) ion appears to arise by coupling of the C_5H_5 and C_9H_9 ligands followed by dehydrogenation.

The mass spectral data on this new but very rare complex $C_5H_5FeC_9H_9$ do not provide unequivocal structural evidence. Prior observations on various π-allyl (11) and olefin (21) complexes suggest that in carbonyl-free ions carbon atoms bearing two hydrogen atoms tend to lose easily one of these hydrogen atoms. The parent ion $C_5H_5FeC_9H_9^+$ tends to lose two hydrogen atoms easily. This suggests that it contains two CH_2 groups and has a bicyclic structure. The relative abundances of the $C_9H_8Fe^+$ and $C_5H_5Fe^+$ ions are nearly equal suggesting that

For personal use only.

the C_9H_9 ligand is as strongly bonded to the iron atom as the π-C_5H_5 ligand. The π-C_9H_9 ligand is probably a substituted π-cyclopentadienyl ligand. The most probable structure for $C_5H_5FeC_9H_9$ appears to be **10**. The more symmetrical placement of the uncomplexed double bond in the six-membered ring of the C_9H_9 ligand is chosen because the melting point (107°) of $C_5H_5FeC_9H_9$ is higher than that of either $C_5H_5FeC_9H_7$ (72°) or $C_5H_5FeC_9H_{11}$ (40°) and because of the greater abundance of $C_5H_5FeC_9H_8^+$ than that of either $C_5H_5FeC_9H_9^+$ or $C_5H_5FeC_9H_7^+$. In this structure (**10**) for $C_5H_5FeC_9H_9$ with non-adjacent CH_2 groups in the C_9H_9 ligand, elimination of two hydrogen atoms to give $C_5H_5FeC_9H_7^+$ is likely to occur individually rather than simultaneously as H_2. Individual rather than simultaneous elimination of hydrogen atoms from $C_5H_5FeC_9H_9$ is more consistent with the observed greater abundance of $C_5H_5FeC_9H_8^+$ than either $C_5H_5FeC_9H_9^+$ or $C_5H_5FeC_9H_7^+$.

Dimethylboric anhydride: a convenient preparation and full characterization

G. F. LANTHIER AND W. A. G. GRAHAM
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 25, 1968

Dimethylboric anhydride, $(CH_3)_2BOB(CH_3)_2$, has been prepared by limited hydrolysis of dimethylboron chloride and complete characterization has been carried out. The Lewis acid character of boron and the donor strength of oxygen have been studied using tensimetric and nuclear magnetic resonance techniques.

Evidence for boron–oxygen π-bonding obtained from complex formation studies, using trimethylboron as a reference acid, is presented and discussed. The reduced acidity of the boron atoms, in comparison with trimethylboron, is discussed in terms of boron–oxygen π-bonding.

Canadian Journal of Chemistry, 47, 569 (1969)

Introduction

Dimethylboric anhydride, $(CH_3)_2BOB(CH_3)_2$, contains two electron-accepting atoms bridged by one electron-donating atom, and could conceivably behave as either a Lewis acid or a Lewis base. In the former case, both mono- and di-adducts might be possible. Although this interesting compound was first prepared by McKennon in 1936 (1), very few references to it are found in the literature (2–4).

In view of the interesting Lewis amphoteric character of the compound, some studies of complex formation have also been carried out using tensimetric (5) and nuclear magnetic resonance (n.m.r.) techniques.

Experimental

A. Apparatus

Preparation and purification of the compounds were carried out in a standard high vacuum apparatus to which a gas–liquid chromatography system was attached. The gas–liquid chromatography system comprised a Gow–Mac stainless steel gas-density thermistor detector Model #140, used in conjunction with a Gow–Mac power supply #9999. The sample introduction system, connected to the high vacuum apparatus by a Teflon valve, was operated by a pair of 3-way valves (Hoke, C-415K). Nitrogen carrier gas was rerouted through the introduction system by simultaneously closing a bypass 2-way valve (Hoke, C-413K) and opening both 3-way valves. Good separation characteristics were found for a 10-ft, 7-mm inner diameter column, packed with 30–60 mesh celite and containing 20% by weight of Fisher paraffin oil. Purified sample was collected in two U-traps lightly packed with glass wool, through which the effluent gases could be directed and frozen out at liquid nitrogen temperatures.

The mass spectrum was obtained using an Associated Electrical Industries (A.E.I.) MS-9 spectrometer. The infrared spectrum was obtained using a Perkin–Elmer Model 421 spectrometer in conjunction with a 5 cm gas cell with potassium bromide windows. Nuclear magnetic resonance spectra were run on a Varian A-60 spectrometer; sample tubes were flamed lightly under vacuum, and were sealed off after the components of the solution had been distilled in from the vacuum system.

B. Materials

Dimethylboron chloride was prepared by reacting equimolar quantities of boron trichloride (Matheson of Canada, Ltd., C.P. grade) with tetramethyltin (M & T Chemicals, Inc.) in a stainless steel Hoke cylinder at 140 °C for 12 h. The use of alkyltin compounds for the preparation of alkylboron halides has been described in the literature (6, 7). The reaction conditions employed in this study gave an improved yield (approximately 95% based on boron trichloride). The other major product was dimethyltin dichloride. The crude dimethylboron chloride was purified chromatographically to remove small amounts of hydrogen chloride, trimethylboron, methylboron dichloride, and boron trichloride. Dimethylboric anhydride was prepared by reacting appropriate quantities of dimethylboron chloride and water in a Pyrex vessel. Although the reaction is rapid at room temperature, repeated condensation and re-warming facilitates complete mixing of the two phases. Essentially quantitative yields of HCl and crude dimethylboric anhydride are obtained. Purification is best carried out by initial trap-to-trap distillation through a −78.5 °C trap to remove hydrogen chloride, followed by sublimation of the material from a cold trap (allowed to warm from −196 °C to room temperature by simply removing the liquid nitrogen) into a −78.5 °C trap, through which traces of more volatile materials readily pass. After purification, the yields of pure dimethylboric anhydride were approximately 85%.

Trimethylboron was prepared by the reaction of 2 moles of boron trichloride with 3 moles of tetramethyltin. Chromatography indicated yields greater than 95% in all experiments. Trimethylphosphine was prepared by the Grignard route using dibutylether solvent, and purified through its silver iodide complex (8). Both of these compounds, as well as commercially available trimethylamine, dimethylether, and dimethylsulfide, were purified chromatographically. As an indication of purity of the aforementioned compounds, the vapor pressures at specific temperatures are listed, along with the literature

values: dimethylboron chloride, 635 mm at 0 °C (lit. (9), 634 mm at 0 °C); trimethylboron, 85.5 mm at −63.5 °C (lit. (10), 85.6 mm at −63.5 °C); trimethylphosphine, 158 mm at 0 °C (lit. (8), 158.5 mm at 0 °C); trimethylamine, 681 mm at 0 °C (lit. (11), 681.7 mm at 0 °C); dimethylether, 33.8 mm at −78. 5 °C (lit. (12), 34.4 mm at −78.5 °C); and dimethylsulfide, 166.8 mm at 0 °C (lit. (13), 167 mm at 0 °C).

Results

A. Characterization

Dimethylboric anhydride as prepared and purified above was found to have a molecular weight of 97.5 using the gas density method (calculated 97.72). The vapor pressure of the liquid was measured at several temperatures between −20.2 and +10.0 °C, with results as given in Table I. Values calculated using the least square equation $\log P_{liq} = 8.459 - 1718/T$ are also given. From the equation, the heat of vaporization is calculated as 7.86 kcal, the boiling point +34.8 °C, and the Trouton constant 25.5. The melting point is −21.2 °C using the magnetic plunger of Stock (14). The vapor pressure of the solid material was determined at three temperatures as shown in Table I. These values determine the equation $\log P_{solid} = 13.63 - 3028/T$, from which the heat of sublimation is calculated to be 13.86 kcal.

Mass spectral data are reported in Table II. While the molecular ion is too weak for a mass determination at high resolution, the fragment at 83 *m/e* was shown in this way to be $C_3H_9B_2{}^{11}O$. The observed and calculated masses differ by less than 1 p.p.m.

Infrared data are reported in Table III, where tentative assignments have been made as discussed later.

The ambient temperature proton n.m.r. spectrum of dimethylboric anhydride in CS_2, $CHCl_3$, $CFCl_3$, and C_7D_{14} consisted of a single broad resonance (half-width: 3.5 c.p.s.) 0.43 p.p.m. downfield from tetramethylsilane (TMS). Varying the concentration between 2 and 20 mole % did not affect the chemical shift.

B. Complex Formation

Trimethylamine – Dimethylboric Anhydride

The saturation pressures obtained from a 4.5 cc[1] sample of dimethylboric anhydride treated with a carefully matched volume of trimethylamine are recorded in Table IV. Values are substantially less than calculated for an ideal solution, presumably the result of complex formation by the equilibrium

$$(CH_3)_2BOB(CH_3)_2 \cdot N(CH_3)_3 \rightleftarrows (CH_3)_2BOB(CH_3)_2 + N(CH_3)_3$$

The saturation pressures in Table IV correspond to the equation $\log P_{mm} = 10.43 - 2816/T$, implying a "boiling point" of 99.5 °C and a Trouton constant of 34.6.

TABLE IV

Saturation pressures of trimethylamine – dimethylboric anhydride

Temperature (°C)	Observed pressure (mm)	Calculated pressure[a] (mm)
24.6	9.6	9.5
28.3	12.4	12.5
34.6	19.2	19.4
36.3	21.4	21.7
42.5	32.0	32.8
44.8	37.7	38.0
54.3	69.3	68.9
58.3	87.4	87.4

[a]Calculated from $\log P_{mm} = 10.43 - 28.6/T$.

[1]The abbreviation cc in this paper refers to gas volumes at standard temperature and pressure. Pressures were measured using a cathetometer reading to 0.01 mm and errors in the calculated volumes are considered to be about 1%.

The 1:1 adduct (4.5 cc) was treated with an additional 4.5 cc of trimethylamine. After standing for 15 h at −78.5 °C, 4.5 cc of trimethylamine were recovered by pumping through a −196 °C trap, while the sample remained at −78.5 °C, indicating that a 2:1 complex, if it does exist at this temperature, is very weak.

The above equilibrium was studied in the gas phase using a sample prepared by treating 2.7 cc of dimethylboric anhydride with a matched volume of trimethylamine. In the temperature range 47.0 to 72.0 °C, dissociation ranged from 72 to 85%. The variation of pressure with temperature and other data are recorded in Table V. A check of the dissociation pressures as the sample was cooled showed that no decomposition had taken place. Variation of the equilibrium constant with temperature is represented by the equation $\log K_p(\text{atm}) = 5.007 - 2073/T$. Therefore, for the above reaction, the enthalpy and entropy of dissociation are: $\Delta H^0 = 9.5$ kcal and $\Delta S^0 = +22.9$ e.u.

Trimethylphosphine – Dimethylboric Anhydride

The addition compound was formed in the tensimeter by bringing together 18.8 cc of dimethylboric anhydride and a matched volume of trimethylphosphine. In the gas phase at room temperature, the complex was found to be 98% dissociated. The saturation pressures of the liquid reported in Table VI determine the equation $\log P_{mm} = 9.077 - 2019/T$, from which one calculates a "boiling point" of 52.6 °C and the Trouton constant as 28.4.

Dimethylether – Dimethylboric Anhydride

Dimethylether was treated with a matched volume of dimethylboric anhydride. The volumes in the gas phase at room temperature were found to be additive. Furthermore when the mixture was cooled to −78.5 °C the pressure above the liquid was slightly greater (6%) than that calculated using Raoult's law. It may be concluded that an adduct does not form down to −78.5 °C.

Dimethylsulfide – Dimethylboric Anhydride

Dimethylsulfide was treated with a matched volume of dimethylboric anhydride. The volumes in the gas phase at room temperature were found to be additive. At temperatures below −45.2 °C, the pressures observed were only 10% below those expected for pure dimethylsulfide. This presumably indicates some degree of insolubility of dimethylboric anhydride in dimethylsulfide at

TABLE VI

Saturation pressures of trimethylphosphine–dimethylboric anhydride

Temperature (°C)	Observed P_{mm}	Calculated P_{mm}[a]
−15.0	18.1	18.1
−10.0	25.7	25.5
− 6.0	33.2	33.2
− 4.0	36.4	37.8
0.0	48.6	48.6
4.0	61.1	62.2
5.0	65.8	66.0
7.4	75.4	76.1
10.0	89.6	88.7
15.0	119.9	118.9
20.0	156.5	155.2

[a]Calculated from $\log P_{mm} = 9.077 - 2019/T$.

these temperatures and it may be concluded that a complex is not formed.

Trimethylboron – Dimethylboric Anhydride

A 49.6 cc sample of trimethylboron was treated with an equivalent amount of dimethylboric anhydride in the tensimeter. Below −78.5 °C, the observed pressures were within 5% of those expected for pure trimethylboron. These data would suggest that dimethylboric anhydride is quite insoluble in trimethylboron at these temperatures and it may be concluded that a complex is not formed.

Dimethylboron Chloride – Dimethylboric Anhydride

A 24.1 cc sample of dimethylboron chloride was treated with a matching volume of dimethylboric anhydride in the tensimeter. After standing 6 h at −78.5 °C, the observed pressure was 7.7 mm, essentially the same as that of pure dimethylboron chloride at −78.5 °C. We conclude that no complex is formed and that dimethylboric anhydride is insoluble in dimethylboron chloride in this temperature region.

Nuclear Magnetic Resonance Studies of Complexes

Room temperature n.m.r. data are listed in Table VII. Chemical shifts of the protons on dimethylboric anhydride show shifts to high field when complexed to a Lewis base, while the Lewis base protons are shifted to lower field. Comparing this data to the tensimetric data shows the magnitude of the chemical shift increases as the strength of the complex increases,

in agreement with work done by other workers (15–17). The single resonance observed for the dimethylboron chloride – dimethylboric anhydride system will be discussed in the next section.

Discussion

The original synthesis of dimethylboric anhydride involved dehydration of dimethylboric acid using phosphorus pentoxide (1):

$$2(CH_3)_2BOH + P_2O_5 \rightarrow 2HPO_3 + (CH_3)_2BOB(CH_3)_2$$

In our hands, this method proved unsatisfactory. The products obtained were highly variable, and a pure compound exhibiting the reported vapor pressure of 118 mm at 0 °C (1) could not be isolated. We were thus led to seek an alternative route, and report here a convenient, reproducible method involving partial hydrolysis of dimethylboron chloride, which gives rise to easily separable products:

$$2(CH_3)_2BCl + H_2O \rightarrow (CH_3)_2BOB(CH_3)_2 + 2HCl$$

A similar reaction has been used to prepare diphenylboric anhydride (18) and di-*n*-butylboron anhydride (19).

Although an elemental analysis of dimethylboric anhydride was not carried out, the preparative method, the gas density molecular weight, and the accumulated spectroscopic data establish the identity of the compound beyond all doubt.

Mass Spectrum

It is evident from the spectrum that rearrangements are taking place. For example, the base peak at 43 *m/e* was shown by its exact mass to be $CH_4B^{11}O$. Only one metastable peak at 20.3 *m/e* was observed, corresponding to

$$(CH_3)_2B^{11}OB^{11}(CH_3)^+ \rightarrow (CH_3)_2B^{11+} + (CH_3)B^{11}O$$

Suggested assignments of other peaks are listed in Table II. The presence of only one observable metastable peak, coupled with occurrence of rearrangement, allows little interpretation of the fragmentation pattern. The isotopes of boron simplify identification of boron-containing ions.

The region of 33, 33.5, and 34 *m/e* is of some interest. The peak at 33.5 must be due to a doubly charged ion, and $(CH_3)B^{10}OB^{11}(CH_3)^{2+}$ is our assignment. The peak at 34 has a C^{13} isotope peak at 34.5, indicating it is also a doubly charged ion, assigned to be $(CH_3)B^{11}OB^{11}(CH_3)^{2+}$. Any C^{13} isotope peak of the peak at 33 is masked by the 33.5 peak mentioned. The removal of two electrons from a molecule is facilitated by the presence of π-electron density (20). The presence of these peaks, and also a small peak at 26.5 attributed to $CH_3B^{11}B^{11}O^{2+}$, support the evidence for B–O π interaction recently reported for this compound (21).

Infrared Spectrum

The C—H stretching frequencies require no comment. In accord with Lehmann *et al.* (22), who place all B—C asymmetric stretching frequencies in the range from 1116 to 1138 cm^{-1}, we assign the 1135 cm^{-1} absorption to the B—C asymmetric stretch. The B—C symmetric stretch is assigned to the weak absorption at 730 cm^{-1}, following Ulmschneider and Goubeau (23), who have similarly assigned absorptions at 718 and 738 cm^{-1} in dimethylboric acid. From the work of Lehmann *et al.* on trimethylboron (22) and tetramethyldiborane (24), it is clear that the absorptions at 1165 and 940 cm^{-1} may be assigned to CH_3 rocking modes.

There is general agreement that in methylboron compounds the asymmetric methyl deformation occurs in the region of 1450 cm^{-1}, while the symmetric mode occurs in the region 1350–1300 cm^{-1} (25). On this basis, we assign the absorption at 1320 cm^{-1} to the symmetrical methyl deformation, while the band due to asymmetric methyl deformation presumably lies within the very broad absorption centered at 1405 cm^{-1}.

The B—O stretching frequencies are somewhat difficult to assign. Ulmschneider and Goubeau (23) assign a weak shoulder at 1276 cm^{-1} in the spectrum of dimethylboric acid to the B—O stretch. No equivalent exists in the spectrum of the anhydride. Abel *et al.* (26) report two B—O stretching frequencies[2] for diphenylboric anhydride at 1262 and 1378 cm^{-1}. It is conceivable that both symmetric and asymmetric modes of the B—O—B group, as well as the symmetric CH_3 deformation mentioned previously, are contained in the broad band at 1405 cm^{-1}.

Complex Formation

The results of the tensimetric studies provide interesting information about the donor strength

[2]Diphenylboric anhydride, as synthesized in this laboratory, exhibited a strong absorption at 1262 cm^{-1}, although there was no appreciable absorption at 1378 cm^{-1}.

of the oxygen atom towards acceptor molecules, and the acceptor strength of the boron atoms toward strong Lewis bases, such as trimethylamine. This information, when examined with reference to other acceptor–donor systems, provides some insight into the B—O bond, and the effects of π-bonding in this bond (21).

Examining first the data on oxygen base strength, it is evident that dimethylboric anhydride does not behave as a Lewis base towards trimethylboron. This is not unexpected, since no complex is formed between dimethylether and trimethylboron under equivalent conditions (27). Unfortunately, the boron trihalides, which are stronger Lewis acids, cannot be used since the following cleavage reaction occurs (2):

$$3(CH_3)_2BOB(CH_3)_2 + 2BX_3 \rightarrow 6(CH_3)_2BX + B_2O_3$$

However, if a dimethylboron halide were used, the products would be identical with the reactants:

$$(CH_3)_2BOB(CH_3)_2 + (CH_3)_2B^*Cl \rightleftarrows (CH_3)_2B^*OB(CH_3)_2 + (CH_3)_2BCl$$

In fact, the single resonance observed in the room temperature spectrum of this system (Table VII) is consistent with a rapidly exchanging system of this nature. Dimethylboron chloride, a stronger acceptor than trimethylboron, shows no indication of complex formation, and it may be concluded that the basicity of oxygen in dimethylboric anhydride is rather low.

The results of the study of the Lewis acid characteristics of dimethylboric anhydride show that it is considerably weaker than trimethylboron. The enthalpies of dissociation of $(CH_3)_2BOB(CH_3)_2 \cdot N(CH_3)_3$ and $(CH_3)_3B \cdot N(CH_3)_3$ are 9.5 and 17.62 kcal (28), respectively. The trimethylphosphine adduct of dimethylboric anhydride is completely dissociated in the gas phase, while $(CH_3)_3B \cdot P(CH_3)_3$ is not (29). Finally dimethylsulfide forms a recognizable adduct at −78.5 °C with trimethylboron (27) but not with dimethylboric anhydride.

Nuclear Magnetic Resonance Data

The n.m.r. data support the tensimetric results fully. Tensimetric studies show that only trimethylamine, of the bases studied, was strong enough to form a measurable complex in the gas phase. The large upfield shift of the B–methyl resonance in the 1:1 $Me_4B_2O \cdot NMe_3$ sample, as compared to the B–methyl resonance in the free Me_4B_2O, is consistent with the formation of a strong complex (15). The large downfield shift of the N–methyl resonance in the 1:1 $Me_4B_2O \cdot NMe_3$, as compared to the N–methyl resonance of free NMe_3 is also to be expected (16, 17). The lack of any change of chemical shift for all resonances in the samples involving dimethylether, dimethylsulfide, and trimethylboron indicate little or no complex formation, in accord with the results of the tensimetric studies. In the case of trimethylphosphine the small shifts of the P-methyl and B-methyl resonance are in accord with the weak complexing found in tensimetric work.

It is feasible to discuss these results in terms of the boron–oxygen bond, presuming that two competitive effects are involved. Purely inductive effects would be expected to increase the acceptor strength of the boron atoms relative to trimethylboron, oxygen being more electronegative than CH_3; this effect would also increase the donor strength of the oxygen atom relative to dimethylether, since $B(CH_3)_2$ is more electropositive than CH_3. On the other hand the effect of π-bonding involving oxygen lone pairs and the vacant boron 2p orbitals would be to weaken both the Lewis acidity of boron and the Lewis basicity of oxygen.

Nuclear magnetic resonance studies of hindered rotation in dimethylmethoxyboron and dimethylboric anhydride indicate a significant amount of π-bonding in these compounds (21). It is, therefore, reasonable to attribute the lower Lewis acidity of dimethylboric anhydride to this effect. The lack of evidence for a 2:1 complex between trimethylamine and dimethylboric anhydride is not inconsistent with this interpretation. When one of the two boron atoms is "electronically saturated" due to complexing with trimethylamine, the vacant p orbital is no longer available to an oxygen lone pair. Therefore, the decreased delocalization of oxygen lone-pair electrons should increase the double bond character between oxygen and the remaining uncomplexed boron atom, thereby lowering the Lewis acidity towards excess trimethylamine.

Further studies involving variable temperature n.m.r. techniques which support the above interpretations are in progress and will shortly be completed.

A theory of circular dichroism

V. LAWETZ AND D. A. HUTCHINSON
Department of Chemistry, Queen's University, Kingston, Ontario

Received May 7, 1968

An expression for circular dichroism is derived by a method in which the radiation field, in addition to the molecules, is quantized. From the total scattering cross sections for right and for left circularly polarized photons, the respective absorption coefficients are determined. A formula for the circular dichroism is obtained from the difference between the absorption coefficients. The present result is in agreement with the semi-classical result of Condon, Altar, and Eyring.

Introduction

The phenomenon of circular dichroism is a manifestation of the difference in absorption coefficients for left and right circularly polarized light. This difference is measured near an absorption peak in the spectrum of an optically active molecule (1). Usually electronic transitions are involved so that measurements are made in the visible or ultraviolet region.

The parameter used to express the extent of circular dichroism, analogous to the angle of rotation per unit length in optical rotation, is the ellipticity Ψ per unit path length. The ellipticity is defined by an angle whose tangent is the ratio of the minor to the major amplitude of the emergent light beam. From this definition, it can be shown that (2)

$$[1] \qquad \tan \Psi = \tanh \frac{\varepsilon_l - \varepsilon_r}{4} l$$

where ε_l and ε_r are the absorption coefficients for left and right circularly polarized light, respectively, and l is the path length. If, as is usually the case, the arguments in eq. [1] are small the circular dichroism is

$$[2] \qquad \Psi/l = (\varepsilon_l - \varepsilon_r)/4$$

Several authors (3–5) have discussed circular dichroism using classical theories; others (2, 6) have used the semiclassical approach in which the molecules are treated by quantum mechanics but the radiation is treated classically. Condon, Altar, and Eyring (6), used the latter approach and obtained the following expression for the ratio of the difference $\varepsilon_l - \varepsilon_r$ to the mean $\varepsilon = (\varepsilon_l + \varepsilon_r)/2$

$$[3] \qquad \frac{\varepsilon_l - \varepsilon_r}{\varepsilon} = \frac{2k}{mck_{ng}} \frac{\text{Im } \langle n|\hat{\boldsymbol{L}}|g\rangle \cdot \langle g|\hat{\boldsymbol{R}}|n\rangle)}{|\langle n|\hat{\boldsymbol{R}}|g\rangle|^2}$$

In this expression, m is the mass of an electron, c is the velocity of light, $\hbar\boldsymbol{k}$ is the momentum of a photon in the incident light beam and the term $\hbar ck_{ng}$ is the energy difference between an excited state $|n\rangle$ and the ground state $|g\rangle$ of the molecule. $\hat{\boldsymbol{L}}$ and $\hat{\boldsymbol{R}}$ are the angular momentum operator and the coordinate operator respectively.

Condon *et al.* (6) give expressions for both the optical rotation and circular dichroism; the expressions are valid for all frequencies of the incident light. Condon's results are obtained by an intuitive extension of the classical theory of light dispersion.

More recently a number of papers have appeared in which the problem of optical birefrigence is treated from a general point of view. Stephen (7) introduced the idea of treating double refraction as a scattering problem in quantum field theory; Stephen's approach used the Stokes operator and did not require the idea of refractive index. Hameka (8) used the Heitler–Ma (9) perturbation method to attack the problem. Atkins and Barron (10) gave a general discussion based on the *S*-matrix approach, the use of Stokes operators, and diagrammatic perturbation theory. Go (11, 12) extended the work of Stephen (7) and Hameka (8) to a situation where the orientational distribution of the solute molecules is arbitrary.

The point of view taken in this paper is more restricted. The method used is essentially that of an earlier paper (13) on optical rotation. For the problem of circular dichroism it yields the result in a fairly direct manner.

The model consists of a system sufficiently dilute so that multiple photon scattering processes are unimportant. In addition, the attenuation of a light beam, on passing through the system, is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

taken to be a consequence only of scattering. From this idealized model it can be shown that the attenuation of intensity $I(\boldsymbol{k})$ of a light beam is given by

$$\frac{dI(\boldsymbol{k})}{dz} = -N\bar{\sigma}_T(\boldsymbol{k})I(\boldsymbol{k})$$

where N is the number of molecules per unit volume and $\bar{\sigma}_T(\boldsymbol{k})$ is the Euler angle average of the total photon scattering cross section $\sigma_T(\boldsymbol{k})$ of a molecule. Since the absorption coefficient $\varepsilon(\boldsymbol{k})$ is defined by

$$\frac{dI(\boldsymbol{k})}{dz} = -\varepsilon(\boldsymbol{k})I(\boldsymbol{k})$$

the result

$$[4] \qquad \varepsilon(\boldsymbol{k}) = N\bar{\sigma}_T(\boldsymbol{k})$$

follows immediately. Thus if the total scattering cross sections for right and left circularly polarized light are known, the respective absorption coefficients and the circular dichroism are readily obtained. A description of the method of calculation is given in the next section.

Calculations and Results

The circular dichroism is large when the frequency of the incident light is near an absorption frequency of the molecule. Thus if the theory of circular dichroism is to be developed by scattering theory, a resonance scattering description is required. As given by Dirac (14), the total scattering cross section for photons is

$$[5] \quad \sigma_T(\boldsymbol{k}) = 4\pi\left(\frac{2\pi}{\hbar c}\right)^2 \frac{b}{2}\frac{|\langle 0n|\,\hat{V}|\boldsymbol{k}g\rangle|^2}{(k - k_{ng} - a)^2 + (b/2)^2}$$

where $$a = (\hbar c)^{-2}\sum_r \int d\boldsymbol{k}'' \frac{|\langle 0n|\,\hat{V}|\boldsymbol{k}''r\rangle|^2}{k - k_{ng} - k''}$$

and $$\frac{b}{2} = \pi\sum_r\left(\frac{k'}{\hbar c}\right)^2 \int\int d\Omega|\langle 0n|\,\hat{V}|\boldsymbol{k}'r\rangle|^2$$

$$k' = k - k_{ng}$$

The kinetic energy of an incident photon is $\hbar ck$, $|0n\rangle$ represents an excited state of the molecule with no photons present, $|\boldsymbol{k}g\rangle$ describes the ground state of the molecule and a photon of momentum $\hbar\boldsymbol{k}$ and $|\boldsymbol{k}''r\rangle$ describes the r-th state of the molecule and a photon of momentum $\hbar\boldsymbol{k}''$. $\hat{V}$ is the interaction of the radiation field with an electron. The quantities a and $b/2$ are identified, respectively, with the level shift and the half-width of a transition.

The interaction potential, in terms of the photon creation operators $\hat{s}_\sigma(\boldsymbol{k})$ and annihilation operators $\hat{s}_\sigma\dagger(\boldsymbol{k})$, is (13)

$$[6] \quad \hat{V} = (\alpha^{\frac{1}{2}}\hbar/2\pi m)\sum_\sigma\sum_{\boldsymbol{k}} k^{-\frac{1}{2}}[\hat{s}_\sigma(\boldsymbol{k})e^{-i\boldsymbol{k}\cdot\hat{\boldsymbol{r}}}\hat{p}_\sigma\dagger + \hat{s}_\sigma\dagger(\boldsymbol{k})e^{i\boldsymbol{k}\cdot\hat{\boldsymbol{r}}}\hat{p}_\sigma]\rho_\sigma{}^{-\frac{1}{2}}(\boldsymbol{k})$$
$$+ (\alpha\hbar^2/8\pi^2 m)\sum_\sigma\sum_{\boldsymbol{k}}\sum_{\sigma'}\sum_{\boldsymbol{k}'} k^{-\frac{1}{2}}k'^{-\frac{1}{2}}[\hat{s}_\sigma(\boldsymbol{k})e^{-i\boldsymbol{k}\cdot\hat{\boldsymbol{r}}}\hat{s}_{\sigma'}(\boldsymbol{k}')e^{-i\boldsymbol{k}'\cdot\hat{\boldsymbol{r}}}\boldsymbol{e}_\sigma\cdot\boldsymbol{e}_{\sigma'}$$
$$+ \hat{s}_\sigma(\boldsymbol{k})e^{-i\boldsymbol{k}\cdot\hat{\boldsymbol{r}}}\hat{s}_{\sigma'}\dagger(\boldsymbol{k}')e^{i\boldsymbol{k}'\cdot\hat{\boldsymbol{r}}}\boldsymbol{e}_\sigma\cdot\boldsymbol{e}_{\sigma'}{}^* + \hat{s}_\sigma\dagger(\boldsymbol{k})e^{i\boldsymbol{k}\cdot\hat{\boldsymbol{r}}}\hat{s}_{\sigma'}(\boldsymbol{k}')e^{-i\boldsymbol{k}'\cdot\hat{\boldsymbol{r}}}\boldsymbol{e}_\sigma{}^*\cdot\boldsymbol{e}_{\sigma'}$$
$$+ \hat{s}_\sigma\dagger(\boldsymbol{k})e^{i\boldsymbol{k}\cdot\hat{\boldsymbol{r}}}\hat{s}_{\sigma'}\dagger(\boldsymbol{k}')e^{i\boldsymbol{k}'\cdot\hat{\boldsymbol{r}}}\boldsymbol{e}_\sigma{}^*\cdot\boldsymbol{e}_{\sigma'}{}^*]\rho_\sigma{}^{-\frac{1}{2}}(\boldsymbol{k})\rho_{\sigma'}{}^{-\frac{1}{2}}(\boldsymbol{k}')$$

In the above, $\alpha = e^2/\hbar c$ is the fine structure constant and $\rho(\boldsymbol{k})$ is the density of states function used in replacing an integration by a summation in the description of the radiation field. The $\boldsymbol{e}_\sigma$ are unit vectors describing the states of polarization: $\boldsymbol{e}_+ = 2^{-\frac{1}{2}}(\boldsymbol{e}_1 - i\boldsymbol{e}_2)$ for left circularly polarized light and $\boldsymbol{e}_- = 2^{-\frac{1}{2}}(\boldsymbol{e}_1 + i\boldsymbol{e}_2)$ for right circularly polarized light. The unit vectors $\boldsymbol{e}_1$, $\boldsymbol{e}_2$, and the propagation vector $\boldsymbol{k}$ form a right-handed cartesian system. The quantities a and $b/2$ can be treated as constants as they both involve integration over all photon states. Therefore only the term $|\langle 0n|\,\hat{V}|\boldsymbol{k}g\rangle|^2$ is needed in order to show the difference between the absorption coefficients.

Due to the previous limitation to one photon processes, only the first two terms of $\hat{V}$ are retained. Firstly consider

$$\langle 0n|\,\hat{V}|\boldsymbol{k}g\rangle = (\alpha^{\frac{1}{2}}\hbar/2\pi mk)^{\frac{1}{2}}\langle n|e^{i\boldsymbol{k}\cdot\hat{\boldsymbol{r}}}\hat{p}_\sigma|g\rangle$$

Now $e^{i\boldsymbol{k}\cdot\hat{\boldsymbol{r}}}$ is approximated to $\hat{\mathbf{1}} + i\boldsymbol{k}\cdot\hat{\boldsymbol{r}}$, then

$$[7] \qquad \langle 0n|\,\hat{V}|\boldsymbol{k}g\rangle = (\alpha/k)^{\frac{1}{2}}(\hbar/2\pi m)(\langle n|\hat{p}_\sigma|g\rangle + i\langle n|\boldsymbol{k}\cdot\hat{\boldsymbol{r}}\hat{p}_\sigma|g\rangle)$$

Hence

$$[8] \qquad |\langle 0n|\,\hat{V}|\boldsymbol{k}g\rangle|^2 = (\alpha/k)(\hbar/2\pi m)^2[|\langle n|\hat{p}_\sigma|g\rangle|^2 - 2\,\mathrm{Im}\,(\langle n|\boldsymbol{k}\cdot\hat{\boldsymbol{r}}\hat{p}_\sigma|g\rangle\langle g|\hat{p}_\sigma\dagger|n\rangle)]$$

The square of the last term in eq. [7] is neglected in eq. [8] because it is an order of magnitude smaller than those which have been retained.

The method described by Hameka (15) is used to evaluate the quantities in eq. [8]. The result is

$$[9]\quad |\langle 0n|\hat{V}|kg\rangle|^2 = (\hbar c k_{ng}/2\pi)^2[k^{-1}|\langle n|\hat{x}_o|g\rangle|^2 - \mathrm{Im}\,(\langle n|\hat{x}_o\hat{x}_\sigma|g\rangle\langle g|\hat{x}_\sigma\dagger|n\rangle) \pm (mck_{ng})^{-1}\,\mathrm{Im}\,(\langle n|\hat{l}_\sigma|g\rangle\langle g|\hat{x}_\sigma\dagger|n\rangle)]$$

where in the last quantity the plus sign refers to a left circularly polarized incident light beam and the minus sign to a right circularly polarized incident light beam. $\hat{l}_\sigma$ is the σ-component of the orbital angular momentum operator $\hat{\mathbf{l}}$ and $\hat{x}_\sigma$ is the σ-component of the coordinate operator $\hat{r}$. The o-component of a vector operator is parallel to the propagation vector $\boldsymbol{k}$ of the incident light.

An Euler angle average is calculated for all of the terms in eq. [9] in order to account for the different orientations of the molecule. The required formulae for determining the Euler angle averages are

$$(a_\pm b_\mp)_{\mathrm{avg}} = (\boldsymbol{a}\cdot\boldsymbol{b})/3$$

$$(a_+ b_- c_o)_{\mathrm{avg}} = -i(\boldsymbol{a}\times\boldsymbol{b})\cdot\boldsymbol{c}/6$$

where $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$ are any three vectors. If two or more of the vectors $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$ are identical, the scalar triple product vanishes. Thus the Euler angle average of the electric dipole – electric quadrupole term of eq. [9] vanishes. Thus the following results are obtained for the Euler angle average of the total scattering cross sections from eq. [9]

$$[10]\quad \bar{\sigma}_T(\boldsymbol{k},\pm) = \frac{(4\pi\alpha k_{ng}/3)(b/2)}{(k-k_{ng}-a)^2+b/2)^2}\,[(k_{ng}/k)|\langle n|\hat{\mathbf{R}}|g\rangle|^2 \pm (mc)^{-1}\,\mathrm{Im}\,(\langle n|\hat{\mathbf{L}}|g\rangle\cdot\langle g|\hat{\mathbf{R}}|n\rangle)]$$

In eq. [10], capital letters are used for the operators to indicate that the matrix elements of their components are evaluated with respect to a coordinate system fixed in the molecule.

From eqs. [4] and [10], the circular dichroism is

$$[11]\quad \frac{\Psi}{l} = \frac{2\pi N\alpha k_{ng}}{3mc}\,\frac{b}{2}\,\frac{\mathrm{Im}\,(\langle n|\hat{\mathbf{L}}|g\rangle\cdot\langle g|\hat{\mathbf{R}}|n\rangle)}{(k-k_{ng}-a)^2+(b/2)^2}$$

The results of Condon, Altar, and Eyring (6), eq. [3], follow in a similar way. If Condon's (2) expression for the circular dichroism, which is applicable for all frequencies, is restricted to frequencies near resonance it reduces to eq. [11]. This, along with the rederivation of Condon, Altar, and Eyring's result, suggests that the method of this paper is valid in so far as it goes.

Received June 25, 1968

The heat of reaction of ruthenium metal with bromine in basic solution, according to the equation

$$Ru(c) + 3Br_2(l) + 8OH^-(aq) = RuO_4^{2-}(aq) + 6Br^-(aq) + 4H_2O$$

has been measured calorimetrically. In addition, the heat of oxidation of barium ruthenate hydrate by sodium periodate to form RuO_4(aq) has been determined. From these heats of reaction, and several other heats measured here, the heats of formation of several ruthenium species have been calculated. The more important of these are: Na_2RuO_4(aq), $\Delta H_f = -224.1 \pm 0.8$; RuO_4^{2-}(aq), $\Delta H_f = -109.4 \pm 1.0$; RuO_4(aq), $\Delta H_f = -57.5 \pm 1.1$; RuO_4(l), $\Delta H_f = -57.0 \pm 1.1$ kcal/mole.

There is a paucity of thermodynamic data on compounds of ruthenium. The heats of formation of only a few compounds have been reported. The heats of formation of RuO_2 and $RuCl_3$ have been determined. Several investigations have led to the heat of formation of RuO_4. In two of these (1–3), lengthy temperature extrapolations were required to obtain the heat of formation of the compound at 25°. This resulted in rather large limits of uncertainty. In the third investigation (4) the heat of formation was determined by measuring the heat of the reduction of RuO_4 by ammonia. A later paper (5) questioned the validity of the reported reaction products. In addition to the above enthalpy data, the potentials of three couples, Ru^{2+}–Ru^{3+} (6), $Ru(NH_3)_6^{2+}$–$Ru(NH_3)_6^{3+}$ (7), and RuO_4^{2-}–RuO_4^- (8) have been reported. The polarographic potential of the RuO_4^-–RuO_4 couple is also known (9).

The enthalpies of formation of aqueous species of ruthenium are extremely desirable, since so much of the chemistry of this element is performed in that medium. It is necessary to have a reliable enthalpy of formation of at least one well-characterized compound or ion, which can be related through chemical reactions to other aqueous species. Both RuO_2 and $RuCl_3$ are unsatisfactory compounds on this basis. For this reason we have made an independent determination of the heat of formation of RuO_4 and also that of RuO_4^{2-}.

Experimental

The Calorimeter

This has been described previously (10). To facilitate the complete removal of the ampul contents into the solution, 40 mesh silicon carbide was added on top of the solid sample in some cases. No heat effect was observed when ampuls containing only the silicon carbide were broken under normal reaction conditions. In all calorimetric runs a volume of 45.1 ml of solution was used. Electrical determinations of the energy equivalent were made in every run. In all cases, except the reaction of ruthenium with bromine, the electrical calibration was performed after the chemical reaction. Experimentally it was shown that the energy equivalent determined before and after the chemical reaction was the same within experimental accuracy.

Reagents

Bromine was obtained from Michigan Chemical Corporation with a stated purity of 100.0%. Sodium periodate, $NaIO_4$, was Baker and Adamson reagent grade. This was washed with dilute nitric acid and dried for 2 h at 105°. Titration with sodium thiosulfate of the iodine liberated in the reduction of the sodium periodate in acid solution gave an assay of 100.04%.

G. F. Smith reagent grade perchloric acid was used. All solutions were standardized with standard sodium hydroxide solution.

Sodium hydroxide solutions were made carbonate-free by dilution of a concentrated solution. In cases where barium ion would not interfere, a small amount of barium chloride was added to the solution of base. These solutions were filtered prior to use.

Ruthenium metal powder was obtained from K and K Laboratories with a purity of 99.9%. Some samples of this metal were reduced with hydrogen at 500° for 1–2 h prior to use. There was no observable difference in the heats measured in these runs.

Sodium ruthenate solutions were prepared from ruthenium chloride (Engelhard Industries). The ruthenium chloride was suspended in 1.0 *M* NaOH and bromine was added dropwise until the solid dissolved completely. The resulting ruthenate–perruthenate solution was filtered and 30% hydrogen peroxide was added

dropwise. After reduction of the perruthenate to ruthenate was complete, the solution was heated to destroy excess hydrogen peroxide. The concentration and purity of the ruthenate solutions were determined spectrophotometrically. For a pure ruthenate solution the ratio of absorbance at 465 mμ to that at 385 mμ is 2.06 (11). In all solutions used this ratio was within 1% of the desired value. The absorbance at the isosbestic point, 415 mμ, was used to determine the total concentration.

$BaRuO_4 \cdot H_2O$ (12) was prepared by adding barium chloride solution slowly with stirring to the basic ruthenate solution described above. The red solid which separated from solution was separated by filtration and washed with 0.01 *M* NaOH. The solid was dried and stored in a vacuum desiccator with P_2O_5.

Anal. Calcd. for $BaRuO_4 \cdot H_2O$: 42.86% Ba, 31.54% Ru. Found: 43.2% Ba, 30.8% Ru.

Calorimetric Reactions

The key reaction in determining the heats of formation reported herein is that between bromine and ruthenium metal in an alkaline solution. An excess of ruthenium metal powder was suspended with rapid stirring in 0.97 *M* sodium hydroxide. A weighed sample of liquid bromine was sealed in the sample ampul. The chemical reaction was initiated by breaking the ampul to introduce the bromine into solution. The calorimeter was opened and an aliquot of the solution was removed for analysis, as soon as a sufficient drift line for extrapolation purposes had been recorded. The solution was analyzed spectrophotometrically for ruthenate, after centrifuging to remove excess ruthenium metal. The yield was calculated from the ruthenium analysis and the weight of bromine used.

Results

Several chemical reactions of ruthenium metal, to produce RuO_4(aq) under conditions attainable within the calorimeter, were investigated. Several attempts were also made to find reactions in which well characterized aqueous species could be reduced to the free metal. None of these resulted in reactions which met all of the criteria necessary to yield a useful heat of formation.

It was found, however, that the addition of Br_2(l) to a 1.0 *M* NaOH solution, in which finely divided ruthenium metal was suspended, produced a solution in which all of the metal oxidized was in the form of ruthenate ion. Unfortunately, the reaction was not quantitative. The yield, based on moles of bromine added, depended upon stirring speed, particle size, and the excess of ruthenium present. In the calorimetric runs the yield of ruthenate ranged from 21.5 to 43.8%. In trial runs performed in normal glassware the course of the reaction was followed visually. The solution first became green, the color of RuO_4^-. This changed within a few minutes to the red color of ruthenate ion. The spectrum of the solution, after removal of the excess metal, proved to be that of pure ruthenate within 10 min after initiating the reaction. The spectrum also revealed the absence of BrO^- ion, *only* when an excess of metal was present. On this basis, it was assumed that all bromine which did not oxidize ruthenium to ruthenate underwent disproportionation to BrO_3^- and Br^-. It would appear that the mechanism leading to the final reaction products is quite complicated. In Table I the heats of reaction observed, when Br_2(l) is added to the basic suspension of ruthenium metal, have been summarized. The yield was determined by spectrophotometric analysis of the solution, after centrifuging to remove the ruthenium metal, and is also given in Table I.

The following interpretation of this heat data has been made. Consider the reactions

$$[1] \quad Ru(c) + 3Br_2(l) + [a\text{NaOH}, b\text{H}_2\text{O}] = [\text{Na}_2\text{RuO}_4, 6\text{NaBr}, (a-8)\text{NaOH}, (b+4)\text{H}_2\text{O}]$$

$$[2] \quad 3Br_2(l) + [a\text{NaOH}, b\text{H}_2\text{O}] = [5\text{NaBr}, \text{NaBrO}_3, (a-6)\text{NaOH}, (b+3)\text{H}_2\text{O}]$$

in which the square brackets are used to indicate the composition of the solution. Both of these reactions are competing during the calorimetric run. The observed heat is therefore given by the expression

$$[3] \quad \Delta H_{\text{obs}}(\text{kcal/mole Br}_2) = \frac{\Delta H_1}{3} + \frac{f_D}{3}(\Delta H_2 - \Delta H_1)$$

where f_D is the fraction of Br_2 undergoing disproportionation and the number subscripts on ΔH refer to the number of the reaction equation.

The data in Table I was fit by the best least squares straight line. This is shown in Fig. 1. By equating the intercept of this line to $\Delta H_1/3$ and the slope to $(\Delta H_2 - \Delta H_1)/3$, we calculate $\Delta H_1 = -121.8 \pm 0.8$ kcal and $\Delta H_2 = -41.1 \pm 1.4$ kcal, which is in good agreement with the value of -41.0 kcal calculated from the National Bureau of Standards Tables (13). In the calculation the tabulated heats of formation at infinite dilution were used. This excellent agreement tends to substantiate the validity of reaction [2] as the competing side reaction.

The heats for the following reactions are necessary to complete the thermochemical cycle for

[4] $Na(c) + 1/2Br_2(l) + 1/6[Na_2RuO_4, (a - 8)NaOH, (b + 4)H_2O] = 1/6[Na_2RuO_4, 6NaBr, (a - 8)NaOH, (b + 4)H_2O]$

[5] $Na(c) + 1/8[(a - 8)NaOH, (b + 4)H_2O, Na_2RuO_4] = 1/2H_2(g) + 1/8[aNaOH, (b - 4)H_2O, Na_2RuO_4]$

[6] $H_2(g) + 1/2O_2(g) + 1/4[aNaOH, (b - 4)H_2O, Na_2RuO_4] = 1/4[aNaOH, bH_2O, Na_2RuO_4]$

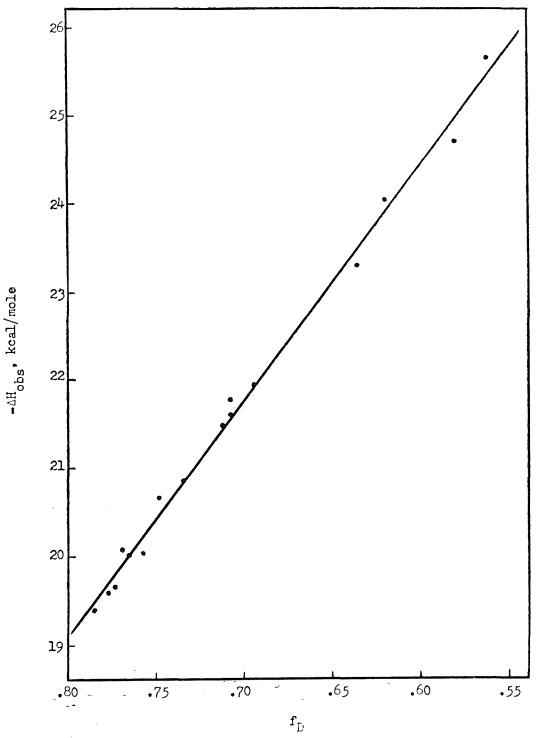

FIG. 1. The observed heat of reaction of bromine with ruthenium metal as a function of the reaction yield: f_D is the fraction of the bromine undergoing reaction [2], the line shown was calculated by least squares.

evaluation of the desired enthalpy of formation. The enthalpy changes for reactions [4] and [5] are the apparent heats of formation in the medium used. It was assumed that the heat of formation of NaBr(aq) in 0.97 *M* NaOH was not significantly different from that in 0.97 *M* NaBr. The heat of formation of water in the solution is not significantly different from that of pure water, −68.315 kcal/mole. The appropriate summation of reactions [1] and [4] through [6] leads to the equation

[7] $$Ru(c) + 2Na(c) + 2O_2(g) + [aNaOH, bH_2O] = [Na_2RuO_4, aNaOH, bH_2O]$$

$$\Delta H_7 = \Delta H_1 - \Delta 6H_4 + 8\Delta H_5 + 4\Delta H_6 = (-121.8) - 6(-86.67) + 8(43.63) + 4(-68.315)$$

$$= -224.1 \pm 0.8 \text{ kcal/mole}$$

ΔH_7 is the enthalpy of formation of sodium ruthenate in the basic solution. We estimate this formal enthalpy to be within a few tenths of a kcal of that at infinite dilution. Using the heat of formation of $Na^+(aq)$ at infinite dilution we calculate the heat of formation of $RuO_4^{2-}(aq)$ as −109.4 kcal/mole. Once again this is expected to be very close to the standard enthalpy of formation for ruthenate ion.

To obtain the heat of formation of $RuO_4(aq)$ a means of transferring ruthenate ion from basic solution to an acidic solution containing sodium periodate was necessary. For this purpose we chose to use $BaRuO_4 \cdot H_2O$. The addition of excess barium chloride dihydrate to a ruthenate solution causes the precipitation of this compound. Precipitation is incomplete under the conditions used in our calorimetric runs. Experimentally a solution of ruthenate was analyzed spectrophotometrically and an accurately measured volume (45.1 ml) was placed in the calorimeter. After adjusting the temperature to 25.00°

the ampul containing a weighed sample of $BaCl_2 \cdot 2H_2O$ was broken. Following the calorimetric run, an aliquot of the solution was filtered and its spectrum recorded. The number of moles of solid formed was calculated from the change in ruthenium concentration. The measured heats are summarized in Table II. In Table III is the heat of solution of $BaCl_2 \cdot 2H_2O$ in 0.97 *M* NaOH in the absence of ruthenate ion. The heat of precipitation of $BaRuO_4 \cdot H_2O$ was calculated by attributing the appropriate portion of the heat observed to the heat of solution of $BaCl_2 \cdot 2H_2O$ and the remainder of the heat to the reaction:

[8] $[Na_2RuO_4, a\text{NaOH}, (b + 2)H_2O, BaCl_2] = BaRuO_4 \cdot H_2O(c) + [2\text{NaCl}, a\text{NaOH}, (b + 1)H_2O]$

This is the enthalpy change shown in the last column of Table II.

	Average	4.065±0.019

The conversion of the barium ruthenate into ruthenium tetroxide in aqueous solution was accomplished by dissolution of the compound in a solution which was 1.019 *M* $HClO_4$ and 0.100 *M* $NaIO_4$. These conditions were found to be the best for achieving a rapid reaction and avoiding formation of a barium iodate precipitate. The concentration of ruthenium tetroxide was measured spectrophotometrically, following each run. Under the conditions used the ruthenium tetroxide found was within 0.5% of the quantity of barium ruthenate which was dissolved. The reaction which takes place is

[9] $BaRuO_4 \cdot H_2O(c) + [c\text{HClO}_4, d\text{NaIO}_4, eH_2O] = [RuO_4, Ba(ClO_4)_2, (c - 2)\text{HClO}_4, \text{NaIO}_3, (d - 1)\text{NaIO}_4, (e + 1)H_2O]$

Because there is a possibility that the barium ruthenate is slightly contaminated by barium carbonate, the limits of error have been estimated to include any uncertainty arising from this impurity. The heats for the following additional reactions are needed to calculate the heat of formation of RuO_4 in this acidic solution

[10] $BaCl_2 \cdot 2H_2O(c) + [a\text{NaOH}, bH_2O, Na_2RuO_4] = [BaCl_2, a\text{NaOH}, (b + 2)H_2O, Na_2RuO_4]$

[11] $\text{Na(c)} + 1/2Cl_2(g) + 1/2[a\text{NaOH}, (b + 1)H_2O] = 1/2[2\text{NaCl}, a\text{NaOH}, (b + 1)H_2O]$

[12] $H_2(g) + 1/2O_2(g) + [a\text{NaOH}, bH_2O] = [a\text{NaOH}, (b + 1)H_2O]$

[13] $1/2H_2(g) + 1/2Cl_2(g) + 1/2[RuO_4, Ba(ClO_4)_2, (c - 2)\text{HClO}_4, (d - 1)\text{NaIO}_4, \text{NaIO}_3, (e + 1)H_2O] = 1/2[RuO_4, BaCl_2, c\text{HClO}_4, (d - 1)\text{NaIO}_4, \text{NaIO}_3, (e + 1)H_2O]$

[14] $BaCl_2 \cdot 2H_2O(c) + [RuO_4, c\text{HClO}_4, (d - 1)\text{NaIO}_4, \text{NaIO}_3, (e - 1)H_2O] = [RuO_4, BaCl_2, c\text{HClO}_4, (d - 1)\text{NaIO}_4, \text{NaIO}_3, (e + 1)H_2O]$

[15] $\text{NaIO}_4(c) + [RuO_4, c\text{HClO}_4, (d - 1)\text{NaIO}_4, \text{NaIO}_3, (e - 1)H_2O] = [RuO_4, c\text{HClO}_4, d\text{NaIO}_4, \text{NaIO}_3, (e - 1)H_2O]$

[16] $\text{NaIO}_3(c) + [RuO_4, d\text{NaIO}_4, c\text{HClO}_4, (e - 1)H_2O] = [RuO_4, c\text{HClO}_4, d\text{NaIO}_4, \text{NaIO}_3, (e - 1)H_2O]$

[17] $H_2(g) + 1/2O_2(g) + [RuO_4, c\text{HClO}_4, d\text{NaIO}_4, (e - 1)H_2O] = [RuO_4, c\text{HClO}_4, d\text{NaIO}_4, eH_2O]$

[18] $\text{Na(c)} + 1/2I_2(c) + 2O_2(g) = \text{NaIO}_4(c)$

[19] $\text{Na(c)} + 1/2I_2(c) + 3/2O_2(g) = \text{NaIO}_3(c)$

The appropriate sum of these equations gives the reaction

[20] $\mathrm{Ru(c)} + 2\mathrm{O_2(g)} + [c\mathrm{HClO_4}, d\mathrm{NaIO_4}, e\mathrm{H_2O}] = [\mathrm{RuO_4}, c\mathrm{HClO_4}, d\mathrm{NaIO_4}, e\mathrm{H_2O}]$

$$\Delta H_{20} = \Delta H_7 + \Delta H_8 + \Delta H_9 + \Delta H_{10} - 2\Delta H_{11} - \Delta H_{12} + 2\Delta H_{13} - \Delta H_{14} + \Delta H_{15} - \Delta H_{16} + \Delta H_{17} + \Delta H_{18} - \Delta H_{19}$$

The enthalpy changes in reactions [12] and [17] were assumed to be equal to the heat of formation of pure water, −68.315 kcal/mole. The heats of reactions [9], [10], [14], [15], and [16] are closely approximated by the experimentally measured heats reported in Tables III to VII. The apparent heats of formation of sodium chloride and hydrochloric acid in the reaction media were calculated to be −97.52 and −39.34 kcal/mole, respectively. These calculations were made using the data from the National Bureau of Standards (13) using the same assumptions made above with sodium bromide. The heat of formation of $NaIO_4$(c) used was set equal to −105.15 kcal/mole, in accord with previous calorimetric studies in our laboratory (10). The enthalpy change of reaction [19] was calculated from tabulated data (13), using the heat of solution of $NaIO_3$(c) in water that was measured by Spencer and Hepler (14). Using these data the heat of formation of RuO_4 in 1 *M* $HClO_4$ is found to be −57.5 ± 1.1 kcal/mole.

TABLE VII

Heat of solution of $NaIO_3$(c) in 1.019 *M* $HClO_4$ at 25.00 °C

Sample weight (mg)	Heat absorbed (cal)	ΔH_{15} (kcal/mole)
89.63	2.171	4.793
89.89	2.179	4.797
89.34	2.162	4.789
	Average	4.793±0.003

The heat of solution of RuO_4(l) in 1 *M* $HClO_4$ was measured to obtain a heat of formation of the pure compound. Because the melting point of RuO_4 is 25.5° these calorimetric runs were made at 26° to be sure of the physical state of the compound. The results of these runs are given in Table VIII. The heat of formation of RuO_4(l) is thus found to be −57.0 ± 1.1 kcal/mole. The heat of formation of RuO_4(c) and RuO_4(g) were calculated from heats of vaporization and sublimation reported by Nikol'skii (15, 16). The heats of formation as determined in this work are summarized in Table IX.

TABLE VIII

Heat of solution of RuO_4(l) in 1.019 *M* $HClO_4$ at 26.00 °C

Sample (moles × 10^4)*	Heat evolved (cal)	$-\Delta H_{obs}$ (kcal/mole)
2.87	0.155	0.54
3.02	0.123	0.41
4.49	0.226	0.50
4.11	0.163	0.40
	Average	0.46±0.06

*Because RuO_4 is somewhat unstable, the size of the sample was calculated from the concentration of the solution, after completion of the calorimetric run. The weight of the sample was not determined.

TABLE IX

Heats of formation of some ruthenium compounds at 25 °C

Substance	ΔH_f (kcal/mole)
Na_2RuO_4(aq)	-224.1 ± 0.85
RuO_4^{2-}(aq)	-109.4 ± 1.0
$BaRuO_4\cdot H_2O$(c)	-309.8 ± 0.9
RuO_4(aq)	-57.5 ± 1.1
RuO_4(l)	-57.0 ± 1.1
RuO_4(c)	-59.6 ± 1.3
RuO_4(g)	-46.4 ± 1.4

Discussion

The heat of formation for ruthenium tetroxide reported here does not have as high a precision as we had initially hoped to obtain. The inability to find a "clean" reaction for the oxidation of the metal accounts for most of the uncertainty in the final number. The value we have determined is more negative by 2.0 kcal/mole than that obtained in the previous calorimetric work by Nikol'skii and Ryabov (4). The agreement with the value given by Bell and Tagami, however, is excellent (3).

The heat of formation of ruthenate ion is the first value of that quantity which has been reported. A comparison of the heat of formation of RuO_4^{2-}(aq) to that of other tetrahedral dinegative ions such as CrO_4^{2-}(aq), MoO_4^{2-}(aq), and WO_4^{2-}(aq), is initially somewhat surprising. For the Group VI transition elements the heats of formation of these ions are all more negative than -213 kcal/mole and become more negative with increasing atomic number. Heat of formation data for other MO_4^{2-} ions, where M is a transition metal, is presently unavailable. The free energy of formation of MnO_4^{2-}(aq) is given by Latimer (17) as -120.42 kcal/mole. By combining this with an estimated entropy of 4 cal deg^{-1} mole^{-1} for the ion, a value of -160 kcal/mole may be calculated for the heat of formation of manganate ion. Based on the chemical behavior of ferrate(VI) ion and the potential data of Grube and Gmelin (18) obtained in 40% sodium hydroxide, a lower limit of the heat of formation of this ion may be estimated to be -100 kcal/mole. Admittedly these numbers are very crude estimates, but they are sufficient to establish a definite trend, and make the measured value for ruthenate ion seem quite reasonable.

Effect of metal–oxygen bond on the sensitivity of atomic-absorption spectroscopic technique[1]

VEDULA S. SASTRI, CHUNI L. CHAKRABARTI[2], AND DOUGLAS E. WILLIS
Chemistry Department, Carleton University, Ottawa 1, Canada

Received July 4, 1968

Studies on sensitivity in atomic absorption spectroscopy of nickel, tin, titanium, zirconium, hafnium, niobium, and tantalum, as metallocenes and as simple salts or oxy-salts, have shown that the metal–oxygen bonded species in solution (as in the case of simple salts or oxy-salts or complexes with ligands having oxygen atom as the donor) contributes to the total amount of metal oxide in flames, and hence, depopulates the ground electronic state of the atom in flames. In the case of the metals which form oxides of high dissociation energy, sensitivity is enhanced if the metals in solution are not bonded to oxygen as in metallocenes or fluoro complexes. The importance of the dissociation equilibrium and the reduction equilibrium in populating the ground electronic state of the atom has been assessed, and an irregular correlation has been established of enhancement in sensitivity with the metal–oxygen dissociation energy.

Canadian Journal of Chemistry, **47**, 587 (1969)

Introduction

A flame is most commonly used for atomization of samples in atomic absorption spectroscopy. The number of free atoms that exist in the flame per unit time (1) is governed by three factors: (*a*) the solution flow rate into the flame; (*b*) the aspiration efficiency (2) of the aspirator–burner–flame combination; and (*c*) the fraction of the sample salt existing as atoms in flame gases. The latter fraction, called the atomization efficiency (3), is influenced by ionization, incomplete dissociation of the salts introduced, and compound formation of the atom of interest with flame gas products. The atomization efficiency for 22 elements in an acetylene–air flame has been measured by de Galan and Winefordner (4), and atomization problems have been studied by Willis (5). Also, the degree of dissociation of many elements in flames has been investigated (6–8). The depressing effect of phosphate and aluminium on calcium when present in the same solution and the absence of the depressing effect when calcium and phosphate or aluminium are introduced simultaneously but through separate atomizers in the flame shows the importance of the state of combination of the metal at the time of evaporation of the solvent (9). Amos and Willis (10), and also, Bond and O'Donnell (11) reported enhancement of the absorption signal of titanium, tantalum, hafnium, and zirconium, in the presence of fluoride ion as compared to the absorption signal of these elements in the absence of fluoride ion. The objective of the present work is to elucidate the role played by the metal–oxygen bonded species in the sensitivity of the atomic-absorption spectroscopic technique so that such knowledge can be used to enhance the sensitivity of this technique.

Theory

The chemistry of titanium, zirconium, hafnium, niobium, and tantalum shows that these elements exist in solution as oxy or hydroxy species (11–13). These elements also readily form complexes with ligands containing oxygen atom as the donor, and also form fluoro or oxo-fluoro complexes in highly acidic solution (13). Since the metal–oxygen bond energies for the oxides of these elements are high (ranging from 157 to 194 kcal $mole^{-1}$), poor sensitivities are obtained when simple hydrolyzed salts are used in atomic absorption spectroscopy. Free atoms are formed (9) in flames by thermal dissociation of the metal oxide and reduction of the oxide by carbonaceous flame gases. The dissociation energy of the oxide, and the temperature and the reducing nature of the flame, would determine the relative importance of the dissociation equilibrium and the reduction equilibrium. The various equilibria involved—starting from the dissolution of a sample in a solvent to the formation of atoms by thermal dissociation of the oxide and reduction of the oxide by carbonaceous flame gases are as follows. Hydrated metal ion in aqueous solution undergoing the hydrolysis reaction:

$$[1] \qquad M(H_2O)_x^{n+} \rightleftharpoons [M(OH)(H_2O)_{x-1}]^{(n-1)+}$$

[2] Vaporization of the solvent

Vaporization of the solute MX to form gaseous particles:

[3] $$MX(s) \rightleftharpoons MX(g)$$

The formation of the gaseous metal atoms from the gaseous solute:

[4] $$MX(g) \rightleftharpoons M(g) + X(g)$$

The reaction of the gaseous metal with oxygen in the flame to form the metal oxide:

[5] $$M(g) + O(g) \rightleftharpoons MO$$

The metal oxide undergoes reduction by carbonaceous material in the flame to form gaseous metal atoms:

[6] $$MO + C \rightleftharpoons M(g) + CO(g)$$

In the above equilibria, M stands for the metallic part; X stands for the non-metallic part including oxygen; O stands for oxygen; g stands for the gaseous state; and s stands for the solid state.

The reactions [2–6] are kinetically controlled in the sense that the efficiency of reaction [2] and the combined efficiency of reactions [3–6] to form free metal atoms will depend on the time taken for the particles to pass through the part of the flame traversed by the light beam. Hence, for the determination of elements which form refractory compounds, it was important to choose a flame which had both low burning velocity and high temperature. Such a flame was nitrous oxide – acetylene flame, which was used for titanium, zirconium, hafnium, niobium, and tantalum, whereas air–acetylene flame was used for tin and nickel.

Dissociation Equilibrium

It is well-known from the flame emission spectra (14–16) of tin, nickel, titanium, zirconium, hafnium, niobium, and tantalum, that when these elements are introduced into flames which are normally used, they form more or less refractory oxides, e.g., SnO, NiO, TiO, ZrO, HfO, NbO, and TaO. Pungor (17) and Pungor and Konkoly-Thege (18) confirmed that the same oxide (and in the case of some alkali metals, to some extent, the same hydroxide) is produced irrespective of the anion present. Molecular compounds and oxides other than monoxides can also be formed but only monoxides will be considered here for the sake of simplicity. The concentration of atoms, under normal circumstances, is determined by the degree of dissociation of the molecular compounds, introduced or formed in the flame (19). The degree of dissociation of several oxides (BaO, AlO, TiO) in flames normally used is extremely small (7, 15–17, 19). The dissociation constants are computed as follows:

For the dissociation equilibrium

[7] $$XY \rightleftharpoons X + Y$$

of a diatomic molecule XY the dissociation constant K_n is defined as

[8] $$K_n = \frac{[X][Y]}{[XY]}$$

where all concentrations are expressed as number per cm^3. K_n is computed (20) from the equation:

[9] $$\log K_n = 20.432 + \frac{3}{2}\log\frac{M_x M_y}{M_{xy}} + \log Z_x Z_y + \log B - \log g + \frac{1}{2}\log T + \log\left(1-10^{-0.625\omega/T}\right) - \frac{5040}{T}V_d$$

where M is the molecular weight; Z is the partition function; B is the rotational constant; g is the statistical weight of XY; T is the absolute temperature; ω is the vibrational constant; and V_d is the dissociation energy. It is assumed that only the lowest electronic level contributes substantially to the partition function of the molecule XY and that the excited electronic states of XY do not contribute to its electronic partition function.

Equation [9] shows that K_n is dependent exponentially on both the dissociation energy and the temperature.

Experimental

Reagents

Reagents used were analytical-reagent grade: nickel(ous) chloride, stannic chloride, titanium oxy-oxalate, zirconium oxy-chloride, hafnium oxy-chloride, niobium oxalate, tantalum oxalate, cyclopentadienyl compounds of nickel, titanium, zirconium, hafnium, and in the case of tin, niobium, and tantalum, the compounds

Acetylacetone	1.2	Not used in this study
Acetone	2.8	”

$Sn(CH_3)_2Cl_2$, $KNbF_6$, and $KTaF_6$, respectively. Other reagents included chemically pure acids, freshly distilled organic solvents, and doubly distilled water.

Apparatus

A Techtron AA-3 spectrophotometer was used with a meter readout and a Sargent recorder Model SRL. A Techtron 5 cm nitrous oxide – acetylene burner was used in the case of titanium, zirconium, hafnium, niobium, and tantalum. A Techtron 10 cm air–acetylene burner was used in the case of nickel and tin. Standard hollow cathode lamps were used for all the elements except nickel, for which a high-intensity hollow cathode lamp was used.

Experimental Conditions

Experimental details pertaining to the lines of the elements, the height above the burner-top traversed by the light beam, lamp current, spectral width, fuel flow rates, type of flame, and flame velocity are summarized in Table I. Table II shows the flow rates of the solvents at the constant flow rate of the aspirating gas (as shown in Table I). The nitrous oxide – acetylene flame had a feather 2 cm high without the samples (including the solvents).

Procedure for Solvent Extraction

(*a*) Titanium, which was present in aqueous solution containing an excess of cupferron, was extracted with an equal volume of methyl isobutyl ketone according to the procedure given by Furman *et al.* (21).

(*b*) Zirconium and hafnium, which were present singly in aqueous solution, were extracted with an equal volume of acetylacetone according to the procedure given by Stary (22).

Results and Discussion

The optimum experimental conditions shown in Table I were established separately for each element. The absorbance produced under the optimum experimental conditions was the gross absorbance, from which the blank absorbance value for each solution nebulized was subtracted in order to arrive at the net absorbance, which was recorded.

Sensitivity (defined as the concentration in p.p.m./1 % absorption, obtained under optimized experimental conditions) has been shown in the Tables instead of absorbance values because sensitivity data offer direct comparison of the elements, whereas absorbance data have to be converted to the sensitivity data before comparison. The sensitivity data were calculated by extrapolation of the absorbance values obtained with the lowest concentrations of the elements. It was experimentally established for each element that the absorbance varied linearly with the concentration in the region of low absorbances.

In order to assess the contributions of the various equilibria to the total amount of the metal oxide introduced and formed in flames, and hence, to the sensitivity of the metals, absorption signals given by nickel, tin, titanium, zirconium, hafnium, niobium, and tantalum, present as different compounds (listed below) were studied. The compounds were: (*1*) cyclopentadienyl compounds in which the metal was not bonded to oxygen (23); (*2*) complexes containing ligands with oxygen atom as the donor; and (*3*) simple or oxy-salts. In the case of both (*2*) and (*3*) the metal was bonded to oxygen (12–13). Also, the effect of variation of other experimental parameters, e.g., solvents, and flow rates of fuels and oxidants were studied. In arriving at the net contribution of the metal–oxygen bonding (reaction [1]) to the sensitivity, the experimental conditions were so adjusted as to eliminate marked change in the flame caused by switching solvents. This was done in every case and the net effect of the metal–oxygen bonding on the sensitivity was assessed.

Table III shows the values of the dissociation constants calculated by means of eq. [9] and the dissociation energy of the metal oxide and the temperatures of the two flames. If one inserts into the dissociation constant expression (eq. [8]) the concentration of atomic oxygen 1×10^{17} (expressed as number per cm^3) found in slightly reducing air–acetylene flames (30–33) (similar to the air–acetylene flame used in this study), one obtains, as a rough estimate, the ratio, metal oxide/free metal atom, equal to 10^2/1 for the least refractory oxide, NiO. The concentration of atomic oxygen in the nitrous oxide – acetylene flame was not known, and so the ratio, metal oxide/free metal atom, in nitrous oxide – acetylene flame could not be estimated.

Reduction Equilibrium

The reaction $2C + O_2 \rightleftarrows 2CO$ releases 256 kcal mole^{-1} at 25 °C. One can make approximate

3.2	10	16.3	1.44	90	65
3.5	10	16.3	1.40	77	44
4.0	10	27.2	1.59	102	65
4.5	10	40.8	2.05	172	97

comparison of the free energies of formation of the oxides under standard conditions by using enthalpy change instead of free energy change in the thermodynamic relationship:

[10] $$\Delta G^0 = \Delta H^0 - T\Delta S^0$$

where ΔG^0 stands for free energy change; ΔH^0 stands for enthalpy change; ΔS^0 stands for entropy change; and T stands for absolute temperature.

The dissociation energy of almost all metal oxides is less than 200 kcal $mole^{-1}$. When both the metal and carbon compete for the oxygen in a flame, carbon should undergo the reaction $2C + O_2 \rightarrow 2CO$ in preference to the metal undergoing the reaction $2M + O_2 \rightarrow 2MO$. However, if one were to use rigorously eq. [10] by taking into account also the entropy change, carbon becomes an even better competitor than metal for the oxygen, as can be seen from reactions [11–13] below. Because of the favorable entropy change in the reaction:

[11] $$2MO(c) + C \rightarrow 2M\ (s\ or\ g) + CO_2$$

and particularly in the reaction:

[12] $$2MO(c) + 2C \rightarrow 2M\ (s\ or\ g) + 2CO$$

where (c) stands for crystalline solid, reduction with carbon becomes more and more favorable as the temperature of the flame is increased (34). If the temperature of the flame is less than the boiling point of the metal oxide, then the increase of entropy in the following reaction, [13], favors still more the reduction of the metal oxide by carbon, especially when the temperature of the flame is greater than the boiling point of the metal. Thus, at the boiling point of tin (2270 °C) the entropy for the reaction:

[13] $$2Sn + O_2 \rightarrow 2SnO\ (s)$$

decreases further, as the reaction now involves the ordering of three gaseous molecules into the solid oxide. Thus, at temperatures around 2000 °C carbon is thermodynamically capable of reducing almost all metal oxides (34). This is why a reducing flame not only greatly increases the sensitivity but is also essential even for detection of some of the elements that form refractory oxides. However, theoretical considerations given earlier have shown that high temperature and low burning velocity are also important; even the reduction process becomes more favorable at high temperature.

The effect of the reducing nature of the nitrous oxide – acetylene flame is shown in Table IV. Since the flame becomes stoichiometric (and hazardous) around the acetylene flow rate of 3.0 l/min (with the pressure of nitrous oxide held constant at 10 p.s.i.) the flow rate of acetylene was not decreased below 3.2 l/min. The Table shows moderate enhancement of sensitivity with increase of the acetylene flow rate from 3.2 l/min to 3.5 l/min; at the latter flow rate the flame had a feather 2 cm high. The sensitivity fell off with further increase in the flow rate of acetylene.

The contribution of the metal–oxygen bonding in the solution (reaction [1]) to the total amount of the metal oxide introduced and formed in the flame was assessed from Tables V–IX. It can be seen from these tables that the sensitivity was enhanced when the metals were present as metallocenes or fluoride complexes. This enhancement of sensitivity could not be accounted for by the increased flow rate of the solvents (see Table IX). Since the flow-rate of acetylene was adjusted (holding the flow rate of the oxidant constant) to eliminate any change in the flame caused by switching the solvents (see Table I), this enhancement could not be attributed to the temperature or the reducing nature of the flames. Such enhancements can be explained satisfactorily in the following way. In the case of the elements with

high M—O bond energies and a great tendency to exist as oxo or hydroxo complexes in solution, or which form complexes with ligands having oxygen atom as the donor, the usual process of obtaining the elements or their compounds in aqueous solution or in organic solvents results in the M—O species being present in the solution (11–13). When such a solution is aspirated into a flame, the M—O species in the solution contributes greatly to the total amount of the metal oxide in the flame, and hence, reduces greatly the population of the free metal atoms in the flame. However, if the metal atoms can be present in the solution without being bonded to oxygen, as in metallocenes (23), then the total amount of the metal oxide is formed entirely in the flame as a result of the equilibrium (reaction [5]), and is thus much less than that present in the former case. That this hypothesis is, at least, qualitatively correct is borne out by the data of Tables V and IX, in which comparison has been made of the enhancement obtained with the metal present, as oxo or hydroxo complexes or as complexes having oxygen atom as the donor, and as metallocenes or fluoride complexes. The greatest enhancements were obtained when the metals were present as metallocenes or fluoride complexes. This hypothesis is further supported by the authors' work (35) on the nature of "chemical" interferences with the elements which form oxo or hydroxo species in solution; in the case of the element which forms with another element refractory compounds ("chemical" interference) when both are present in the same solution, the former bonded to oxygen as in oxo or hydroxo complexes, no interference was observed when the former was present as a metallocene in solution (absence of metal–oxygen bond).

Enhancement of sensitivity with metallocenes or fluoro-complexes would occur only with those metals for which the degree of atomization is very small at the flame temperature and the flame velocity, if simple salts or oxy-salts or complexes of the metals containing metal–oxygen bonds, are used. If the temperature of the flame is below the boiling point and the latent heat of vaporization of the solvent and the solute, and if the flame furnishes energy less than the dissociation energy of the metal oxide formed, then the degree of atomization will be very small. Thus, the dissociation of metal oxides having dissociation energy roughly over 130 kcal mole^{-1} will not be

complete in a flame which has a temperature of ~ 3000 °C. It is in the case of the metals which form oxides of high dissociation energy that the sensitivity can be enhanced if the metals are present as metallocenes or fluoro-complexes. The smaller the degree of atomization is, the greater would be the enhancement of sensitivity given by the metallocenes or fluoro-complexes as compared to simple salts or oxy-salts or complexes of the metals containing metal–oxygen bond. The dissociation process described earlier is an important part of the complex atomization process. In the case where the other factors of the atomization process have minor influence on the degree of atomization, there should exist a correlation between the dissociation energy of the oxide and the degree of atomization. However, the above assumption, and the picture of bonding in solution, and the molecular compounds formed in flames, although conceptually correct, is a vast over-simplification. In actual solutions, other species also may be formed. In actual flames, compounds other than oxides would also be formed, ionization at high temperature would not be negligible, etc., and all these equilibria would influence the degree of atomization. However, the experimental evidence shown in Table V points to a correlation (although an irregular one) between the dissociation energy of the oxide and the enhancement ratio; nickel and tin showing the smallest enhancement ratio, titanium, and tantalum showing the largest enhancement ratio.

Tables VI, VII, and VIII show the effect of organic solvents on titanium, zirconium, and hafnium. In many of these cases the enhancement in sensitivity given by an element used as a particular compound e.g., $(C_2H_5)_2TiCl_2$ in different solvents roughly parallels the flow rate of the solvents, the exceptions being acetone in Table VI, and methyl isobutyl ketone in Tables VI and VII, where a decrease in the sensitivity was noted. Besides, the flow rates of solvents there are other parameters, e.g., solution viscosity, surface tension, density, and volatility of the solution, which directly influence the aspiration efficiency and

Ta	Aqueous solution	4.5	Ta-oxalato complex and Ta-fluoro complex

thereby, also the atomization efficiency. This complex interrelationship of the parameters involved makes it difficult to isolate quantitatively the effect of one variable such as the flow rate of the solvent on the sensitivity.

Table IX shows the enhancement ratios (given in Table V) for the same element in two different compounds present in the same solvent. Because the same solvent was used the effect of the solvent was assumed to cancel out. The enhancement may be attributed to the fact that the metals in the form of cupferrate, acetylacetonate, simple or oxy-salts, are bonded to oxygen atom (i.e., the metal–oxygen bond is present in solution), whereas the metal–oxygen bond is absent in the solutions of metallocenes and fluoro-complexes. Such enhancements should be observable in the case of all metals which in aqueous solution exist as oxo and hydroxo complexes or which form complexes with ligands having oxygen atom as the donor, and which have high metal–oxygen bond energies, and also provided that the corresponding metallocenes are soluble in the solvents of interest.

Besides the physical properties of the solvents mentioned above, chemical reactions with the solvents, such as formation of solvates, alteration of the chemical equilibria in flames by products of combustion, etc. must also be taken into account. Organic solvents may also change slightly the temperature of the flame in spite of the measures taken in this study to keep the flame conditions constant (which was to decrease the acetylene flow rate to match the amount of organic solvents introduced into the flame). However, the enhancement ratios (see Table IX) obtained with the same solvent (either aqueous or organic) provide conclusive evidence that any change in the flame conditions caused by switching solvents under the experimental conditions maintained could have only a minor effect on the sensitivity. Thus, the major cause for the enhancement effect must be the well-established fact (12, 13, 23) that when the metals were present as metallocenes or fluoro-complexes in aqueous or organic solvents there was no metal–oxygen bond present in the solutions, whereas when the metals were present as oxo or hydroxo complexes or as complexes with ligands with oxygen atom as the donor there was metal–oxygen bond in solution.

An alternative interpretation has been suggested by a referee. The alternative interpretation is given in this paragraph and is followed by the authors' comments given in the next paragraph. In this interpretation, the reactions involved in the mechanism of atomization can be divided into the rate-controlled processes and the equilibrium-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

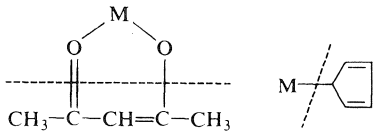
controlled processes. The rate-controlled processes are the processes of solvent dispersion, solvent evaporation, and solute volatilization—the last is also the most important process. The process of solute volatilization is dependent on the form of the metal compound introduced into the flame. Therefore, the differences between M—O bonded species and M—X bonded species, could be the effect on solute volatilization rather than the effect on dissociation equilibrium, i.e. nonvolatile solutes could be formed.

The alternative interpretation given in the above paragraph is applicable to cases when nonvolatile molecular compounds are formed, but is less satisfactory in the cases of metallocenes and metal complexes dealt with in this paper. For example, the metal acetylacetonates and cupferrates are as readily volatilized as the metallocenes at the flame temperature used, but the cleavage of the bond in the vapor state occurs thus:



Metal acetylacetonate Metallocene

This is the reason why the metallocenes give a higher sensitivity compared to metal acetylacetonates and cupferrates. However, there is no conflict between these two interpretations—the difference is on the emphasis placed on different processes in the mechanism of atomization. The interpretation given in the body of the paper emphasizes the dissociation and reduction equilibria in the cases of the molecular compounds with high dissociation energy, where these equilibria are important; whereas the interpretation given in this paragraph emphasizes the rate of solute volatilization in the cases of nonvolatile molecular compounds, where the rate of volatilization is important. However, both the interpretations are extreme cases, and neither of them is applicable to all systems. In most cases, perhaps, the actual mechanism involves both in varying degrees, as has been separately reported by Chakrabarti *et al.* (36).

Conclusions

1. For the metals which form refractory oxides in flames, low sensitivities are obtained if the metals are used as simple or oxy-salts, or as complexes with ligands having oxygen atom as the donor, dissolved in aqueous or organic solvents; this is due to the presence of metal–oxygen bond in solution which adds to the metal oxides formed in flames.

2. In the case of the above metals, the sensitivities can be enhanced if the metal–oxygen bond in solution can be avoided or reduced by using metallocenes or fluoro-complexes in aqueous or organic solvents.

Spectrofluorometric studies. V. 1,2,4- and 1,3,5-Trifluorobenzene

G. P. SEMELUK, R. D. S. STEVENS, AND I. UNGER
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received July 24, 1968

The variation of fluorescence yield as a function of exciting wavelength for the title compounds has been examined. 1,3,5-Trifluorobenzene shows a maximum in fluorescence yield at an exciting wavelength λ_{ex} = 2680 Å; for 1,2,3-trifluorobenzene, this maximum occurs near 2740 Å. Triplet yields for both molecules, based on the biacetyl sensitized emission technique, have been determined at various exciting wavelengths. The maximum triplet yield of 1,3,5-trifluorobenzene = 0.40 and occurs at λ_{ex} = 2640 Å, while that of 1,2,4-trifluorobenzene = 0.64 at λ_{ex} = 2780 Å. The triplet of the 1,2,4 isomer appears to lie below the triplet of *cis*-butene-2 and thus the olefin *cis–trans* isomerization technique cannot be used as a diagnostic for the triplet state of this molecule. The effect of two inert gases, cyclohexane and *cis*-butene-2, on both fluorescence and triplet yield has been studied.

Introduction

Recently, Wilzbach, Harkness, and Kaplan (1) reported that benzene-1,3,5-d_3 irradiated at 2480 and 2537 Å in both liquid and gas phases undergoes intramolecular rearrangement. That benzene and benzene derivatives excited in the 2500 Å region undergo this type of reaction has been known for some time (2–5). There has been some speculation about a possible connection between quantum deficit $[1 - (\Phi_s + \Phi_T)]$ and quantum yield of intramolecular rearrangement (6). It has also been suggested that vibrational excitation in upper electronic states may play a role in this type of reaction (1). We have been quite interested in the above mentioned effect and have chosen the fluorinated benzenes as model compounds, for reasons given elsewhere (7). If any correlation is to be established between quantum deficit and/or extent of vibrational excitation, and phototransposition of ring carbon atoms, then obviously it will first be necessary to determine singlet and triplet yields of the molecules involved, and the dependence of these yields on exciting wavelength and pressure. 1,3,5-Trifluorobenzene (1,3,5-TFB) and 1,2,4-trifluorobenzene (1,2,4-TFB) are particularly interesting to study, since the former has D_{3h} symmetry while the latter possesses C_s symmetry. This paper presents a summary of a study of the type outlined above, carried out in the gas phase, for 1,3,5- and 1,2,4-TFB.

Experimental

The 1,2,4-TFB used was obtained from two sources, K and K Laboratories, Inc., and Peninsular Chemresearch Inc. The 1,2,4-TFB obtained from K and K Laboratories was purified by preparative vapor phase chromatography while the material obtained from Peninsular Chemresearch was found to be sufficiently pure to be used without further treatment. The 1,3,5-TFB was also obtained from Peninsular Chemresearch and found to be chromatographically pure. Biacetyl was obtained from the Aldrich Chemical Company and was purified by bulb-to-bulb distillation, and stored in a blackened bulb. Fluorometric grade benzene and cyclohexane obtained from the Hartman–Ledden Company were used without further purification. Similarly, Philips research grade *cis*-butene-2 having less than 0.1% impurity was used without further purification.

A grease and mercury free high vacuum line, equipped with Hoke packless metal diaphragm valves exclusively, was employed in this study. The pumping section of the high vacuum system was of conventional design.

Pressure measurements were carried out by means of a spiral gauge obtained from National Research Council (NRC) in Ottawa. Pressures below 5 Torr were obtained by expansion into an accurately calibrated volume. The cell used was a flow-through cuvette type, 1 cm × 1 cm × 4.5 cm, polished on all four sides, and was obtained from Aminco.

Mixing was accomplished by an all glass circulating pump obtained from NRC Ottawa. All emission measurements were performed on a modified Aminco–Bowman spectrofluorometer. Experimental details concerning the modification, light source, procedures of emission and absorption measurements have been given previously (7).

Singlet yields for directly excited fluorinated benzenes can be arrived at directly from fluorescence measurements. These molecules, however, do not exhibit any phosphorescence in the gas phase and thus indirect techniques must be used to estimate triplet yields. In the present instance, the biacetyl sensitized emission technique (8) was used to determine triplet yields. The quantum yields of fluorescence of TFB and of sensitized emission of Biacetyl (BiA) were obtained by a relative method, which has been described in detail elsewhere (9).

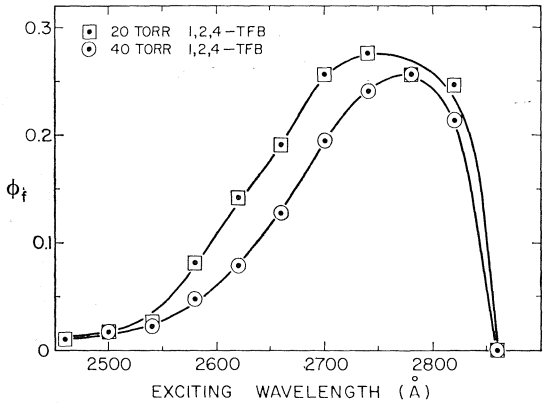

FIG. 1. Fluorescent yield ϕ_f of 1,2,4-trifluorobenzene as a function of exciting wavelength.

on a Coleman, Model EPS-3T Hitachi spectrophotometer shows that the molecule absorbs between 2800 and 2250 Å apparently into a closely spaced vibrational band system. The maximum fluorescence yield, ϕ_f, is produced by $\lambda_{ex} \simeq$ 2780 Å. Figure 1 shows how the fluorescence yield varies with the exciting wavelength. Fluorescence of 1,2,4-TFB is selfquenched at $\lambda_{ex} >$ 2540 Å and plots of I/ϕ_f versus [1,2,4-TFB] are linear. Plots of $1/\phi_f$ versus [BiA] at constant [1,2,4-TFB] are also linear. These quenching data are summarized in Table I. Addition of *cis*-butene-2 (*cis*-B-2) or cyclohexane (CH) to 1,2,4-TFB has no effect on the fluorescence yield, as is indicated in Table II.

The triplet yield of 1,2,4-TFB was examined at three exciting wavelengths 2540, 2700, and 2780 Å. Excitation at any of these wavelengths in the presence of BiA produces a sensitized emission of BiA. Additions of *cis*-B-2 to mixtures of BiA and 1,2,4-TFB have no significant effect on sensitized emission yield (Table III). On the other hand, addition of CH to mixtures of BiA and 1,2,4-TFB increases the sensitized emission yield. A satisfactory linear representation of this functional dependence is obtained when total pressure divided by sensitized emission yield is plotted against cyclohexane pressure, as illustrated in Fig. 2. At constant pressure of 1,2,4-TFB the

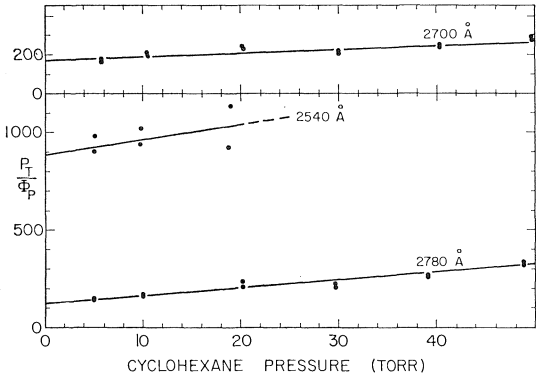

FIG. 2. Dependence of sensitized emission yield ϕ_P in mixtures of biacetyl and 1,2,4-trifluorobenzene on total pressure P_T, and cyclohexane pressure P_{CH} for some exciting wavelengths.

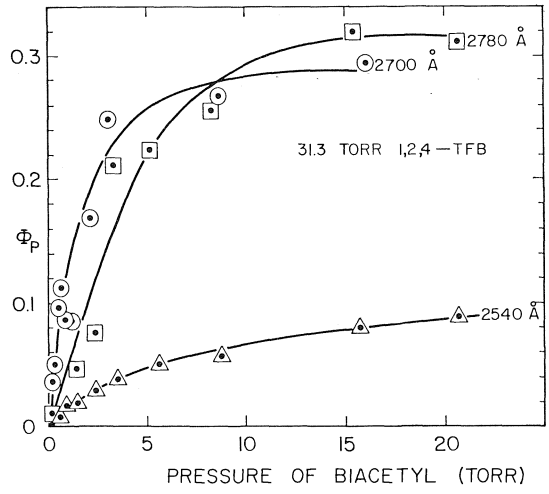

FIG. 3. Variation of sensitized emission yield ϕ_P as a function of biacetyl pressure at constant pressure of 1,2,4-trifluorobenzene.

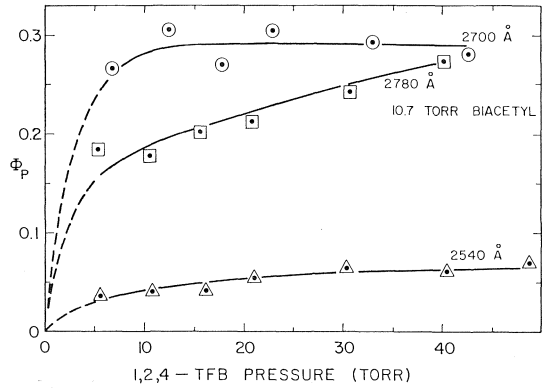

FIG. 4. Variation of sensitized emission yield ϕ_P as a function of 1,2,4-trifluorobenzene pressure at a constant biacetyl pressure of 10.7 Torr.

sensitized emission yield increases rapidly with increasing biacetyl pressure. It then levels off, but does not appear to go through a maximum for the exciting wavelengths examined. The same phenomenon is observed when the biacetyl pressure is held constant while the 1,2,4-TFB pressure is increased. These results are given in Figs. 3 and 4. The triplet yields at the highest biacetyl pressure used are 0.1 for λ_{ex} = 2540 Å, 0.44 at λ_{ex} = 2700 Å, and 0.64 at λ_{ex} = 2780 Å.

B. 1,3,5-Trifluorobenzene

The absorption spectrum of 1,3,5-TFB shows weak absorption ($\varepsilon \simeq 120$) in the 2700 to 2200 Å region, with a closely spaced (30 to 40 Å) vibration band system. Fluorescence resulting from excitation in the 2700–2200 Å region is very weak. In contrast to the behavior of the less highly fluorine-substituted benzenes, the fluorescent yield versus λ_{ex} curve shows only one structural feature, a maximum at 2680 Å (Fig. 5). The fluorescence excited at 2640 and 2680 Å is self-quenched, giving linear plots for $1/\phi_f$ vs. 1,3,5-TFB pressure (Fig. 6).

Because of the combination of very weak absorption with very weak fluorescence our experimental conditions did not allow a systematic

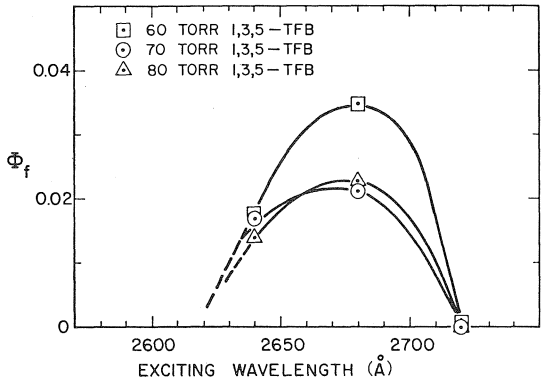

FIG. 5. Variation of fluorescent yield of 1,3,5-trifluorobenzene as a function of exciting wavelength for three different pressures.

investigation of the effect of biacetyl on the fluorescent yield. Thus, relatively large pressures of 1,3,5-TFB (50/100 Torr) must be used in order to obtain appreciable emission. This limited the maximum biacetyl pressure to about 8 Torr, since pressures in excess of this produced condensation on the cell windows.

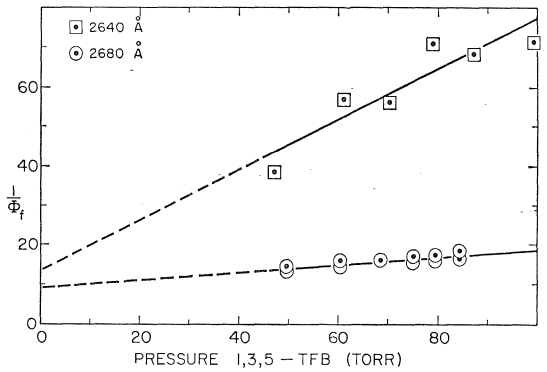

FIG. 6. Stern–Volmer type plots for 1,3,5-trifluorobenzene fluorescent yield at two wavelengths.

A series of experiments, however, did show that cyclohexane and *cis*-butene-2 were ineffective as quenchers of the fluorescence. The addition of up to 50 Torr cyclohexane to 81 Torr of 1,3,5-trifluorobenzene did not affect the fluorescent yield by more than 1%, while up to 60 Torr of *cis*-butene-2 added to 81 Torr of 1,3,5-TFB, did not alter the yield by more than 5%. Similarly, the addition of up to 28 Torr of cyclohexane to a mixture of 81 Torr 1,3,5-TFB and 8 Torr biacetyl did not change the yield by more than 1%.

81.0	8.17	28.8	0	0.35

*Exciting wavelength 2680 Å.

A sensitized emission of BiA is observed in mixtures of 1,3,5-TFB and BiA excited by 2640 and 2680 Å radiation. This sensitized emission rises rapidly with increasing BiA pressure, then appears to level off, but does not go through a maximum, presumably because the biacetyl pressure is limited experimentally to about 8 Torr. These data are summarized graphically in Fig. 7. The maximum triplet yield (uncorrected for biacetyl quenching of the singlet) under these experimental limitations is about 0.4, at λ_{ex} = 2640 Å.

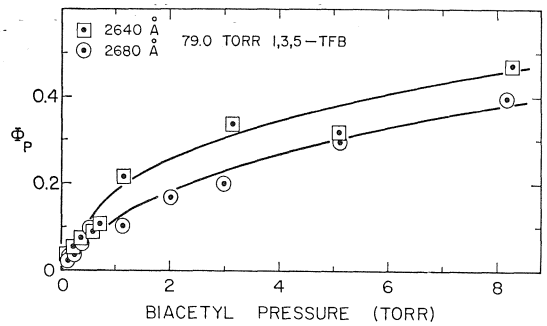

FIG. 7. Variation of sensitized emission yield ϕ_p for mixtures of 1,3,5-trifluorobenzene with biacetyl as a function of biacetyl pressure at two exciting wavelengths.

When excitation is at 2680 Å, increasing pressures of 1,3,5-TFB at constant biacetyl pressure produce a decrease in the triplet yield. The relationship is adequately summarized by the equation

$$\frac{1}{\phi_p} = 2.29 + 1.49 \times 10^2 P_{TFB}(\text{Torr})$$

Values of rate constants and quenching cross sections for 1,3,5- and 1,2,4-trifluorobenzene at various exciting wavelengths

Exciting wavelength (Å)	k_2 (s^{-1})	k_3 (s^{-1})	k_4 (l $mole^{-1}$ s^{-1})	TFB cross section (Å²)	k_7 (l $mole^{-1}$ s^{-1})	Biacetyl cross section (Å²)
			1,2,4-Trifluorobenzene			
2580	1.7×10^{8}	1.1×10^{9}	1.1×10^{12}	190		
2620	1.0×10^{8}	2.3×10^{8}	4.6×10^{11}	78		
2660	7.5×10^{7}	1.8×10^{8}	1.8×10^{11}	31		
2700	5.6×10^{7}	9.5×10^{7}	6.4×10^{10}	11	1.2×10^{11}	19
2740	5.2×10^{7}	1.0×10^{8}	3.0×10^{10}	5.1		
2780	5.7×10^{7}	1.4×10^{8}	1.6×10^{10}	2.8	1.8×10^{11}	28
2820	5.8×10^{7}	1.6×10^{8}	1.0×10^{10}	1.8		
			1,3,5-Trifluorobenzene			
2640	9.1×10^{7}	1.2×10^{9}	1.1×10^{12}	18		
2680	7.5×10^{7}	6.2×10^{8}	1.4×10^{11}	24		

where P_{TFB} refers to the pressure of 1,3,5-TFB. Addition of *cis*-butene-2 to mixtures of 1,3,5-TFB and BiA sharply reduces the triplet yield, while addition of cyclohexane to these mixtures slightly increases the yield (Table IV).

Discussion

In a previous communication from this laboratory (10) a mechanism for the photochemical reactions of monofluorobenzene was presented. The same mechanism, which appears to hold equally well for 1,2,4- and 1,3,5-trifluorobenzene, is presented below to make it easier for the reader to follow the discussion.

[1] $F + h\nu \rightarrow {}^1F^I$

[2] ${}^1F^I \rightarrow F + h\nu$

[3] ${}^1F^I (+ M) \rightarrow {}^3F^I (+ M)$

[4] ${}^1F^I + F \rightarrow 2F$

[5] ${}^1F^I \rightarrow$ isomerization

[6] ${}^3F^I (+ M) \rightarrow F (+ M)$

[7] ${}^1F^I + BiA \rightarrow {}^1BiA^{II} + F$

[8] ${}^3F^I + BiA \rightarrow {}^3BiA^{I*} + F$

[9] ${}^3BiA^{I*} \rightarrow$ dissociation

[10] ${}^3BiA^{I*} + M \rightarrow {}^3BiA^I + M$

[11] ${}^1BiA^{II} \rightarrow$ dissociation

[12] ${}^1BiA^{II} + M \rightarrow {}^1BiA^I + M$

[13] ${}^1BiA^I \rightarrow {}^3BiA^I$

[14] ${}^1BiA^I \rightarrow BiA + h\nu_f$

[15] ${}^3BiA^I \rightarrow BiA + h\nu_p$

[16] ${}^3BiA^I \rightarrow BiA$

[17] ${}^3F^I \rightarrow$ isomerization

In the scheme shown above, F represents either a 1,3,5- or 1,2,4-TFB molecule in its ground state. BiA denotes ground state biacetyl. The Arabic numerals indicate spin multiplicity while the Roman numerals denote first and second excited states. M represents any quenching molecule, and the asterisk denotes a vibrationally excited molecule. Quenching of ${}^3BiA^I$ by BiA has been omitted from this scheme, even though recently it has been shown to occur (11), since the rate constant for this step is very small.

Application of steady state treatment to the mechanism gives for the fluorescent yield ϕ_f

$$[18] \quad \frac{1}{\phi_f} = \frac{k_2 + k_3 + k_5}{k_2} + \frac{k_4[F]}{k_2} + \frac{k_7[BiA]}{k_2}$$

Equation [18] predicts that plots of $1/\phi_f$ versus [F] at zero [BiA] should be linear and that plots of $1/\phi_f$ versus [BiA] at constant [F] should also be linear. This is observed experimentally, as indicated in Fig. 2 and Table I.

The integrated molar absorptivities of both 1,2,4- and 1,3,5-TFB have been given (12). These values were used to determine τ_0, the mean radiative lifetime of the two species. From the fluorescence yields, τ, the actual radiative lifetime, may now be determined (13); and from these, k_2, the reciprocal of τ. All the reported studies on phototransposition of ring carbon atoms show that k_5 is very small (14). Assuming that it is likewise negligible in the present case, k_3, k_4, k_7, and quenching cross sections can be calculated at various exciting wavelengths. These are summarized in Table V, and are, of course, somewhat dependent on mechanistic details. For example, if it is not assumed that fluorescence and intersystem crossover and isomerization

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

occur from the same vibrational level, as is implied by reactions [2], [3], and [5], and if rate constants for vibrational deactivation to these *different* levels from some higher level are included, then the quenching cross sections given in Table V will be somewhat high. The precision of our measurements does not justify the inclusion of such mechanistic refinements.

In applying the steady state approximation to the case of sensitized emission, [12] and [13] may be neglected (15). The sensitized yield ϕ_p is then given by

$$[19] \qquad \frac{1}{\phi_p} = \frac{(k_{15}+k_{16})(k_9+k_{10}[M])(k_6+k_{17}+k_8[BiA])(k_2+k_3+k_4[F]+k_5+k_7[BiA])}{k_{15}k_{10}k_8k_3[M][BiA]}$$

No further approximation need be made to explain the effect of cyclohexane on the sensitized emission yield of mixtures of the TFB and BiA as is summarized, for example, in Fig. 2, since eq. [19] predicts that at constant [F] and [BiA], plots of P_T/ϕ_p vs. P_{CH}, where P_T is the total pressure and P_{CH} the pressure of cyclohexane, should be linear with positive intercept at $P_{CH} = 0$ and relatively small positive slopes.

In the absence of cyclohexane but at moderate pressures of either BiA or F or both, it is expected that $k_{10}[M] > k_9$, so that eq. [19] may be approximated by

$$[20] \qquad \frac{1}{\phi_p} = \frac{(k_{15}+k_{16})(k_6+k_{17}+k_8[BiA])(k_2+k_3+k_4[F]+k_5+k_7[BiA])}{k_3k_{15}k_8[BiA]}$$

Equation [20] predicts that at low biacetyl pressures, ϕ_p should increase linearly with [BiA], and that as the pressure of BiA becomes larger, it should eventually reach a maximum and decrease. Although our experimental observations on 1,2,4-TFB confirm the low pressure predictions, the higher pressure behavior could not be studied because it was not possible to introduce high enough pressures into the system. This suggests that for this molecule reaction [6] remains competitive with reaction [8] throughout the range under study and is in contrast to the behavior of benzene (8) and fluorobenzene (10). There is as yet no evidence for the relative importance of reaction [17], although it is expected that k_{17} will be small (14).

Equation [20] also describes to a satisfactory extent the behavior of the sensitized emission from mixtures of 1,3,5-TFB and BiA. At constant biacetyl pressure, $1/\phi_p$ was a linear function of [TFB]. However, as is evident from Fig. 7, it is not possible to say with certainty that there is a well defined initial linear portion to the ϕ_p vs. biacetyl pressure curve at constant TFB pressure. The biacetyl pressures experimentally possible were not high enough to observe a maximum in this plot.

It is worth noting the several features of the photochemistry of these two trifluorobenzenes which are distinctly different from those of other fluorinated benzenes.

1. The fluorescent yield as a function of exciting wavelength shows only the one maximum, rather than the combination of minima and maxima observed in the other fluorinated benzenes which we have investigated. This is presumably due to the closer spacing of the vibrational band systems in these two molecules. The relatively large band pass used in the present study ensures that excitation will occur simultaneously into at least two vibrational bands, thus obscuring any differences in behavior due to different vibrational excitation.

2. Our data indicate that the triplet of 1,2,4-TFB must be relatively short-lived and thus considerably larger pressures of BiA are required to pick up all the 1,2,4-TFB. They also suggest that reaction [6] of the proposed mechanism must be unimolecular, otherwise the triplet yield would behave differently with increasing pressures of 1,2,4-TFB, CH, and BiA. It should be noted, however, that a mechanism more detailed in its handling of the vibrational deactivation steps, such as has been mentioned, does not necessarily require the latter conclusion.

3. *cis*-Butene-2 readily quenches the triplet of benzene (16), monofluorobenzene (17), metadifluorobenzene (7), ortho- and para-difluoroben-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

zene (9), and that of 1,3,5-trifluorobenzene. It does not, however, quench the triplet of 1,2,4-TFB. Therefore, it seems likely that the triplet energy of *cis*-B-2 is either very close to, or slightly below that of 1,2,4-TFB. Cundall (18) estimates the triplet energy of *cis*-B-2 to be about 72 kcal mole^{-1}. A simple Hückel molecular orbital calculation (7) indicates that the singlet of 1,2,4-TFB may lie about 10% lower in energy than the singlet of benzene, and lower than the singlet of any of the above mentioned fluorinated benzenes. The shifts in the 0,0 band position in the ultraviolet spectra of these compounds (19) confirm this calculation qualitatively, although not to the extent of 10%. If the triplet energy of 1,2,4-TFB happens to be 10% lower than that of benzene, it would lie at approximately 73.5 kcal mole^{-1}, making energy transfer from it to triplet *cis*-B-2 very unlikely.

The somewhat unsatisfactory nature of the data on 1,3,5-TFB indicates the exercise of caution in reaching any firm conclusions regarding this molecule. A reinvestigation using a much higher intensity source and a much narrower exciting band width is obviously necessary. This will be carried out as soon as it becomes experimentally feasible.

Acknowledgments

The authors gratefully acknowledge a grant from the Associated Alumni of the University of New Brunswick towards the purchase of the instrumentation used in this study, and financial and other assistance from the National Research Council of Canada.

Complexing, exchange, and redistribution reactions of some Group III and Group V fluorides and their anions[1]

S. BROWNSTEIN
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received July 18, 1968

Complexing, fluorine exchange, and redistribution reactions were studied for systems containing BF_3, PF_5, AsF_5, SbF_5, and their anions BF_4^-, PF_6^-, AsF_6^-, and SbF_6^-. Fluorine resonance spectra were obtained for $PSbF_{11}^-$ and $AsSbF_{11}^-$. Silver and tetrabutylammonium were used as cations in methylene chloride as solvent.

Canadian Journal of Chemistry, 47, 605 (1969)

Introduction

Complexing and fluorine exchange reactions have been reported for the fluorides of boron and phosphorus in methylene chloride solution (1–3). Although $B_2F_7^-$ was the only fluorine bridged species which could be identified, in those cases where the mechanism of fluorine exchange could be investigated, fluorine bridged intermediates were suggested. Fluorine bridging of SbF_5 with itself and with SbF_6^- has been reported in more polar solvents (4, 5). This study concerns the other Group V fluorides and mixtures of them, since it was thought that fluorine bridging should be a common phenomenon amongst these compounds.

Experimental

Tetra-*n*-butylammonium hexafluoroarsenate ($TBAAsF_6$) and hexafluoroantimonate were prepared in the same way that the hexafluorophosphate had been made previously (6). Vapor pressure measurements and fluorine resonance spectra, as well as reagent purification and storage, were accomplished as described in earlier papers already cited. However, in two instances it was necessary to obtain fluorine resonance spectra at 25.1 MHz as well as 94.1 MHz to confirm details of spectral interpretation. Antimony pentafluoride was twice fractionally distilled under vacuum in an interconnected distillation assembly (5). Samples were transferred by distillation on a vacuum system and at no time was the reagent allowed to come in contact with the atmosphere.

Results and Discussion

A summary of the results of this and previous studies is presented in Table I. In each case where reactions of the type $MF_{x+1}^- + NF_y \rightarrow MF_x + NF_{y+1}^-$ are reported, this conclusion was reached by pressure measurements of the gas evolved during the reaction. This was accomplished in the same apparatus used for determining complex formation with BF_3 (1). The solubility difference between the different gases was quite sufficient to make this distinction. In addition the non-volatile products were isolated and their identities confirmed by X-ray powder diffraction patterns. As an example of the information used to determine complex formation, the uptakes of BF_3, PF_5, and AsF_5 by $TBASbF_6$ at -20 °C are shown in Fig. 1.

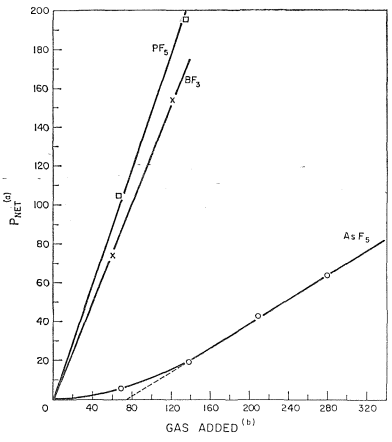

FIG. 1. Pressure above a $TBASbF_6$ solution at -20 °C. (*a*) *P* in mm Hg, (*b*) arbitrary units.

The presence or absence of fluorine exchange was established by fluorine resonance spectroscopy, where either a single averaged line was observed with rapid exchange or separate lines from the various species were observed in the absence of exchange. Figure 2 is the fluorine resonance spectrum of a CH_2Cl_2 solution of BF_3 and $TBAAsF_6$. The characteristic resonance lines of BF_3 and AsF_6^- indicate that fluorine exchange between them is slow on the nuclear

PF_5+PF_5	None	Probably fluorine exchange	(2)
$PF_5+TBAPF_6^-$	None	Rapid fluorine exchange	(3)
$PF_5+TBAAsF_6$	None	Rapid fluorine exchange	[b]
$TBAPF_6+AsF_5$	$PF_5+TBAAsF_6$		[b]
$PF_5+TBASbF_6$	None at 30 °C	Rapid fluorine exchange	[b]
	$TBAPSbF_{11}$ at −96 °C	Slow fluorine exchange	[b]
$AsF_5+TBAAsF_6$	$TBAAs_2F_{11}$	Rapid fluorine exchange	[b]
$AsF_5+TBASbF_6$	$TBAAsSbF_{11}$	Rapid fluorine exchange 30 °C	[b]
		Slow fluorine exchange −96 °C	[b]
$AsF_5+AgSbF_6$	$AgAsSbF_{11}$		[b]
SbF_5+HSbF_6	HSb_2F_{11}		(5)

[a]TBA is used as an abbreviation for tetra-*n*-butylammonium.
[b]This work.

magnetic resonance (n.m.r.) time scale. Only a single broad line was observed for $TBAAsF_6^-$ at −60 °C because of averaging of arsenic–fluorine spin coupling due to quadrupole relaxation (7). At room temperature the rate of quadrupole relaxation had slowed sufficiently to allow the observation of four very broad lines. This is in accord with the theory of quadrupole relaxation (8).

At room temperature the fluorine resonance spectrum of an equimolar solution of PF_5 and $TBASbF_6$ in methylene chloride is a single broad line. On lowering the sample temperature to −60 °C, two broad lines are observed. At −96 °C a pair of relatively sharp lines and a pair of broad lines are observed. The sharp doublet (half width of 14 Hz) has $J = 940$ Hz and $\delta = 70.2$. The broad doublet (half width of 120 Hz) has five times the total area of the sharp one and $J = 913$ Hz, $\delta = 65.2$. The chemical shifts and spin coupling constants were confirmed by measurements at both 94.1 and 25.1 MHz. In all the spectra a sharp doublet is present from POF_3. This is an impurity in the PF_5 employed and is produced after long storage of PF_5 in glass vessels. It appears to be inert in the present samples. Both sets of lines, not arising from POF_3, are attributed to fluorine directly bonded to phosphorus.

The chemical shifts and phosphorus–fluorine spin coupling constants for PF_6^- are $\delta = 71.0$ and $J = 711$ Hz (3). For PF_5 the corresponding values are $\delta = 65.4$ and $J = 947$ Hz (2). The values of 916 (9) and 930 Hz (10) previously reported for PF_5 were the peak separations of broadened and somewhat coalesced lines, and are therefore smaller than the actual spin coupling constant.

It is rationalized that a signal is not observed from fluorine bonded to antimony because the quadrupole broadening of the antimony–fluorine spin coupling produces an unobservably broadened line. With $TBASbF_6$ alone in methylene chloride and with solutions of BF_3 and $TBASbF_6$, the signal expected for fluorine bonded to antimony is also not observed. The bonding of PF_5 to SbF_6^- is much weaker than that of AsF_5 and SbF_5 since vapor pressure measurements give no evidence of complex formation at −20 °C. Perhaps this weak bond does not cause a sufficient distortion of the octahedral symmetry of SbF_6^- to allow a narrowed signal because of rapid quadrupole averaging.

If the structure of $PSbF_{11}^-$ is that of two octahedra joined at one corner by a bridging fluorine, there will be three types of fluorine bonded to phosphorus. The assignment of the bridging fluorine, four equatorial fluorines, and one apical fluorine among the two sets of peaks is not straightforward. One possible assignment is that the apical and equatorial fluorines give rise to the broad peak. A large spin coupling and small chemical shift between these fluorine nuclei would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

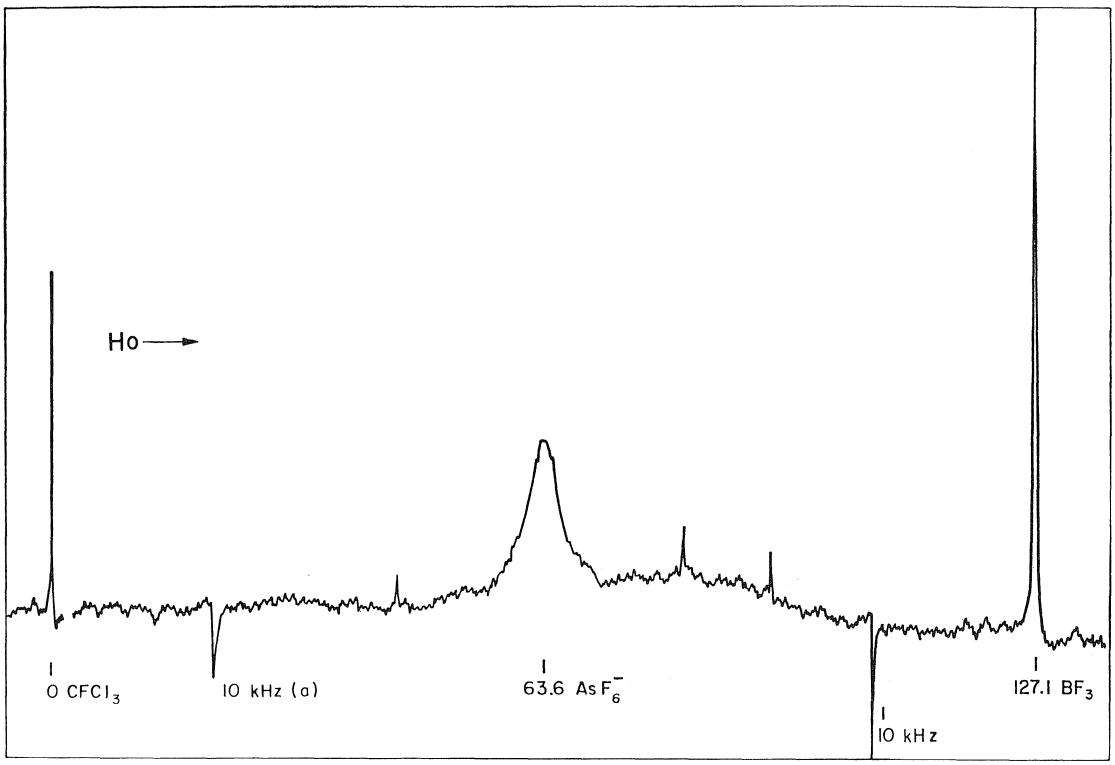

FIG. 2. The fluorine resonance spectrum of a CH_2Cl_2 solution of BF_3 and $TBAAsF_6$ at -60 °C. (*a*) The 10 kHz peaks of reversed phase are sidebands which occur because of operation in a "time division" mode.

give rise to many lines. Further spin coupling to the fluorines on antimony would produce a still greater multiplicity and yield a single broad envelope. The absence of further observable spin coupling in the two sharp peaks attributed to the bridging fluorine is not readily explicable. It is to be expected that the bridging fluorine will occur at higher magnetic field, between the position for fluorine on phosphorus and that for fluorine on antimony. The fluorine resonance spectrum of $PSbF_{11}^-$ is shown in Fig. 3.

At room temperature the fluorine resonance spectrum of an equimolar solution of AsF_5 and $TBASbF_6$ is a broad structureless line. As the temperature is lowered, two prominent lines appear and gradually sharpen. By -96 °C, four sets of well-resolved lines are observed. Chemical shift and spin coupling constants were confirmed from spectra at both 25.1 and 94.1 MHz. The 94.1 MHz spectrum of $AsSbF_{11}^-$ at -95 °C is shown in Fig. 4. Since it was found that $CFCl_3$ was not inert as an internal reference in this system, CF_4 was used as internal reference and a correction made for the chemical shift between it and $CFCl_3$. The assignment of chemical shifts and spin coupling constants is presented in Table II. Evidently there is sufficient asymmetry of the electric field about the arsenic and antimony nuclei for quadrupole relaxation to average all traces of arsenic or antimony–fluorine spin coupling. The two most intense absorption regions at 50.5 and 118 p.p.m. are assigned to fluorine on arsenic and antimony, respectively. This agrees with the values of 63.6 p.p.m. for AsF_6^- and 107 p.p.m. for the equatorial fluorines in the complex $SbF_5 \cdot SO_2$ (11). The quintet centered at 138.9 p.p.m. is assigned to the terminal fluorine on antimony, in agreement with a chemical shift of 141 p.p.m. for the apical fluorine in $SbF_5 \cdot SO_2$ (11). The remaining quintet at 92.9 p.p.m. is then assigned to the terminal fluorine on arsenic. By comparison, the apical fluorine in $AsF_5 \cdot (CH_3)_2O$ has a chemical shift of 83 p.p.m. (12). Spin coupling between the terminal and equatorial

TABLE II

Chemical shifts and spin coupling constants for $AsSbF_{11}^-$

	δ^a	$J_{AB}{}^b$	J_{BC}	J_{DE}
F_A	92.9	126		
F_B	50.5	126	47	
F_C	118		47	
F_D	118			112
F_E	138.9			112

[a]Chemical shifts are in p.p.m. to high field of $CFCl_3$.
[b]Spin coupling constants are in Hz.

fluorines on arsenic is observed in the multiplets of both species. However, spin coupling between the equatorial and bridging fluorines is only observed in the peaks of the equatorial fluorines on arsenic, since the bridging fluorine and the equatorial fluorines on antimony overlap in a complex multiplet. Similarly, spin coupling between the equatorial fluorines and the terminal fluorine on antimony can only be observed for the peaks attributed to the terminal fluorine. The absence of spin coupling between terminal and bridging fluorines is consistent with results for complexes of boron, phosphorus, and arsenic fluorides with proton containing Lewis bases where long range coupling to an apical fluorine is not observed (12, 13).

Additional evidence for the formation of $AsSbF_{11}^-$ comes from the infrared spectrum of a KBr pellet containing the solid product obtained after evaporation of all readily volatile material from a methylene chloride solution of equimolar quantities of AsF_5 and $TBASbF_6$. The infrared spectra for $TBAAsF_6$, $TBASbF_6$, and $TBAAsSbF_{11}$ are shown in Fig. 5. It was not possible to isolate pure solid $TBAAsSbF_{11}$ by evaporation of solvent from a solution, since varying amounts of AsF_5 were lost by this procedure. Therefore, the infrared spectrum is not that of a compound with stoichiometric composition.

Conclusion

In addition to B—F—B and Sb—F—Sb fluorine bridge bonding, which has previously been reported, evidence is presented for P—F—Sb, As—F—As, and As—F—Sb bridge bonding. At room temperature the fluorines exchange rapidly between the different chemical environments.

The silver–calcium phase diagram[1]

W. A. ALEXANDER[2], L. D. CALVERT, A. DESAULNIERS, H. S. DUNSMORE[3], AND D. F. SARGENT[4]
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received September 23, 1968

The silver–calcium system has been reinvestigated over the whole composition range by thermal analysis, X-ray diffraction, and metallography. A novel technique has been used to prepare and examine these reactive alloys. In the course of this project four intermetallic compounds have been observed for the first time; while two others, viz., Ag_2Ca and AgCa, which were reported before by others, have been confirmed. Three of the new compounds are: Ag_8Ca_3, Ag_3Ca_5, and $AgCa_3$, while the fourth was not isolated or examined in detail. Two other compounds which were described in earlier work as Ag_4Ca and Ag_3Ca, have been found to be Ag_9Ca_2 and Ag_7Ca_2, respectively. Major modifications have been made in the liquidus curve and possible reactions in the solid state are indicated.

Introduction

The application of silver–calcium alloys to the preparation of skeletal silver catalysts for the oxidation of ethylene to ethylene oxide provided the initial incentive for this work. The calcium is removed from the silver–calcium alloys by oxidation at 350 °C in steam, followed by leaching in 20% acetic acid. Occasional variability in catalyst activities suggested that the crystal structure of the calcium–silver alloy might be a factor worth investigation. Since the available phase diagram was obviously incomplete and possibly in error in the part of major interest to us, the reinvestigation of the whole system was undertaken.

The only thermal analysis of this system is that of Baar (1) whose results are uncertain for part of the system and his procedure casts some doubt on all the results. According to Hansen and Anderko (2) a number of other partial investigations have been made, principally the X-ray examination of Degard (3). Several others (4–8) have made limited examinations of the system by various methods including X-ray diffraction. Elliott (9) mentions the review of Kripyakevich (10), who discusses the results of Calvert *et al.* (11) on the CaAg structure and relates them to similar structures. Other than the structure determinations of Calvert and Rand (12) and Rand and Calvert (13), no other work on this system has been found.

Experimental

All alloys were prepared from high purity metals. The silver was "Mint Grade" granules with the following spectrographic analysis, in parts per million (p.p.m.) (13): Pb, 10; Fe, 4; Si, 5; Cd, 20; Ca, 1; Mg, 1; Cu, Sn, and Na, not visible. The calcium was made by Dominion Magnesium Limited by thermal reduction and was distilled six times before use. Spectrographic analysis showed (13): Mg, 2; Fe, 2.5; Mn, 1; Si, 2; Ba, 2.5; Sr, 2.5 p.p.m.; while Cu, Pb, Zn, Cd, Ni, Sb, Li, Cr, Al, and Ag were not visible. The nitrogen content of the calcium varied from 100 to 260 p.p.m., but was only about 100 to 110 p.p.m. in the alloy, even after observing six cooling curves. Although Bevan and Richardson (14) state that oxygen will have only a slight effect on the melting point, others, particularly Smith *et al.* (15), Wolfson (16), and Messing *et al.* (17), have indicated the importance of extreme care in melting calcium and its alloys.

The apparatus is similar to that used by Freeth and Raynor (18) for a similarly reactive system and is shown in Fig. 1. After completing the cooling curves, the stirrer was withdrawn, the alloy superheated 100 – 150 °C, mixed by tilting the furnace, and cast into the cold mold in the side-arm. An argon atmosphere purified by slow passage over calcium shavings at 650 – 700 °C was maintained over the alloy at a positive pressure of about 2 cm Hg. The melt was stirred at about 40 r.p.m.

In some early work at low calcium contents the charges weighed in argon were dropped into the melt vessel with a stream of argon issuing from it. It was soon evident that greater precautions were needed and a simple distillation tube was adopted. This comprised a tube 2.3 cm internal diameter (i.d.) with a 1 mm wall, made into a right angled assembly, each leg being about 25 cm long. The first leg was cut at 45° at one end and made up as shown in Fig. 1 later to form the lower 18 cm of this vessel. The second half of the vessel was a simple tube welded at the bottom and also cut at 45° to match the first half. A small iron baffle with two thin plates was fixed in this tube above the calcium. A screen with 6.4 mesh per cm was welded into the 45° joint between the two tubes. A stainless steel tube 7.9 mm i.d., with about 0.5 mm wall and about 8 cm long, was welded over a hole near the 45° joint for evacuation and sealing off. The charge of silver granules, too large to pass through the

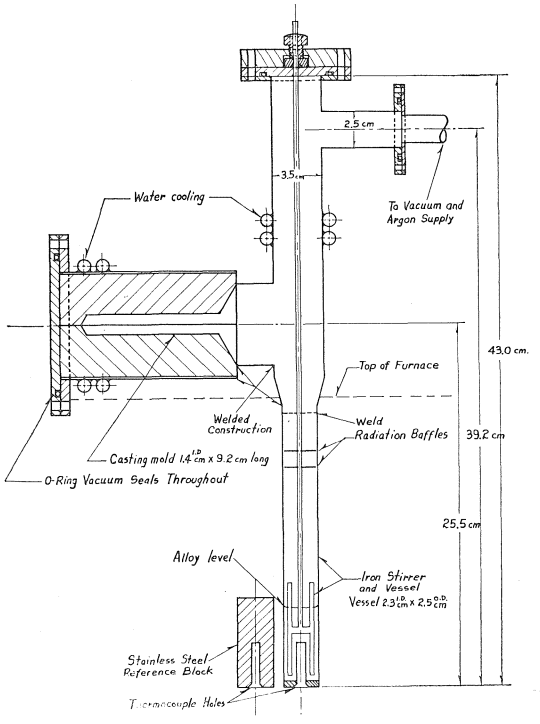

FIG. 1. Melting and casting vessel. The heated portion and mold were of mild steel, while the upper portion of the case was partly of stainless steel. The O-rings were lightly lubricated, while the stirrer shaft ring was well lubricated with "Myvane" from Distillation Products Co., Rochester, New York.

screen, was placed in the end with the thermocouple well. The required weight of calcium crystals, pressed into pellets if necessary, was put in the opposite end with the baffle to prevent the possible entrainment of oxide or nitride in the vapor stream. The whole vessel was degassed at suitable elevated temperatures and the side-arm sealed off at less than one micron pressure (19). Three of these tubes could be placed in a vacuum furnace at one time in a temperature gradient. With the calcium at about 940 °C and the silver or the alloy at about 830 °C distillation of the calcium was complete in about two weeks. Any leaks were indicated by a "mushroom" growth of calcium oxide on the outside and such alloys were discarded.

The tubes were opened in an argon-filled "dry box" by sawing off the thermocouple or alloy end, which was then stoppered. This stoppered end was removed from the dry box and welded to the cooling curve vessel with a vigorous stream of argon flowing over the alloy surface. Thus only the top surface of the ingot could be exposed to a somewhat impure argon atmosphere and the results were reasonably reproducible.

The cooling curves using platinum–rhodium thermocouples were recorded automatically at 6 s intervals with a six point recorder, both directly and in a differential manner, with the stainless steel block as the reference temperature. The thermocouple was calibrated in pure metal baths after each alloy. There was no systematic drift and the variations from alloy to alloy were almost always less than ± 0.3 °C. The cooling rate was automatically controlled at about $\frac{1}{2} - \frac{3}{4}°$ per min by a chromel–alumel differential thermocouple arrangement between the alloy and the furnace winding. The setup was sufficiently sensitive to show reproducibly the Curie point of the mild steel container, or the energy imput due to the stirring.

Top and bottom analyses were made for each casting. These differed up to a few tenths wt. % in most cases with the maximum being about 1 wt. %. The analyses accounted for 99.6 – 99.9 wt. % as calcium and silver, the remainder being undoubtedly oxide and nitride formed during sampling and weighing for analysis, which were done in air. No other metals were found by the wet chemical analysis. No correction has been applied to the calcium contents from chemical analysis.

The errors in our measurements are evidently additive and may be estimated as follows. The thermocouple calibration error due to temperature gradients in the bath, loss along the wires and the like, are estimated to be $\pm 0.3°$. The recorder errors were minimized by comparison with a sensitive (± 0.01 °C) potentiometer at regular 9 min intervals and are estimated at about ± 0.2 °C. Thus the error in a temperature read from the chart is believed to be about ± 0.5 °C. The errors in estimating an arrest point are larger for a liquidus — up to ± 1 °C, and smaller for a eutectic arrest — usually about ± 0.1 °C, since these lasted for several minutes and the temperature was essentially constant. Thus the error in estimating a liquidus is believed to be not greater than ± 1.5 °C and a eutectic about ± 0.6 °C. The reproducibility is of course somewhat better due to some of these errors being constant or systematic.

Results and Discussion

It is probable that small amounts of impurities such as calcium oxide, nitride, or hydride have only a minor effect on the arrests of alloys with low calcium content. Some early experiments without the final careful techniques confirmed the data of Baar (1) in this region. Up to 18% Ca[5] the system in Fig. 2 is drawn from these and two later experiments. In Fig. 2 the actual points are all from later experiments with the higher accuracy. The liquidus points are evidently reasonably consistent but the eutectic or solid state arrests are not very reproducible from alloy to alloy. These arrests sometimes changed in duration for successive observations with the same alloy, especially in the case of the more reactive alloys with about 60–75% calcium. The probable cause is gradual contamination by impurities from the upper part of the vessel. This must be small since

[5]Unless otherwise specified all percentages are atomic percent.

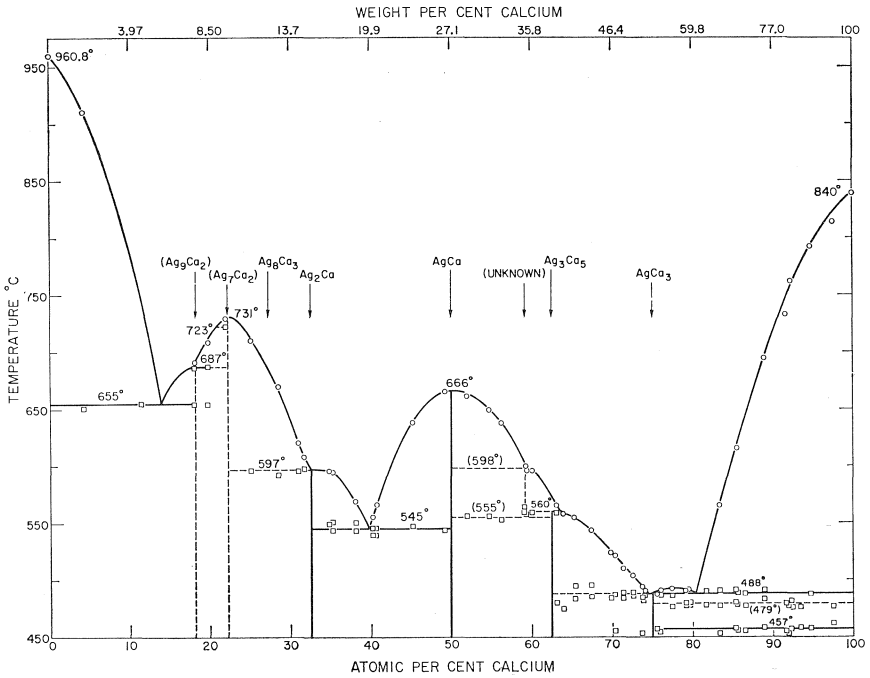

FIG. 2. The calcium–silver system. ○, liquidus or first arrests; □, solid state or secondary arrests.

the transformation temperature of calcium is very sensitive to impurities (15) and these arrests remained reasonably constant. Also high temperature X-ray examination of various alloys with more than 75% calcium showed a constant transformation temperature for the calcium phase of about 450 °C.

Figure 2 has been drawn to fit the experimental data of the later experiments and the data and confirmations from X-ray diffraction. In some instances and especially in the solid state reactions much further work is desirable, which would amplify and probably modify our results. It would also appear that a higher order of purity of the alloys, avoiding the pickup of impurity during melting, would be necessary for this purpose. The same is true of metallography. We examined alloys only up to 53% calcium, both chill-cast and after various annealing treatments, and the results were in agreement with the diagram proposed here. Beyond this composition the brittleness and high reactivity of the alloys make metallography very difficult. At 53% calcium, the alloys were suitably etched by a few minutes' exposure to moist laboratory air.

The low calcium eutectic was found at 655 °C in essential agreement with Baar (1) and the composition was not redetermined. The peritectic reaction at 687 °C and about 18% Ca also is not in great disagreement with Baar's values of 683 °C and 15%. The cooling curves indicate a maximum of about 731 °C at 22% Ca and a pronounced second arrest at 723 °C on the lower calcium side. Some early X-ray diffraction examination of single crystals from a chill cast ingot showed the compounds Ag_9Ca_2 and Ag_7Ca_2 in place of Ag_4Ca and Ag_3Ca. The compound Ag_8Ca_3 has been described in detail from X-ray single crystal analysis by Calvert and Rand (12), although thermal analysis has shown no indication of its presence. The crystal was obtained from an ingot containing 22.2% Ca which was annealed at 695 °C for 4 days and quenched. It is thus probable that solid state reactions occur in this composition and temperature range which we have not observed.

The peritectic at 597 °C, the low slope of the liquidus at the Ag_2Ca composition, and the eutectic at 545 °C are all essentially the same as those of Baar (1). A eutectic near 33% Ca and the

For personal use only.

formation of Ag_2Ca by congruent melting are also possibilities. The eutectic composition indicated at 39.8% is also in agreement with Baar (1). The compound AgCa melting at 666 °C is also in close agreement with the results of Baar (1). X-ray photographs agree (11) with these results for Ag_2Ca and AgCa and in addition high temperature X-ray observations indicate the existence of two crystal forms of AgCa.

In the region from 50–80% Ca our results differ very considerably from the previous work. On the basis of X-ray powder diffraction photographs of as-cast alloys with no annealing, a new compound of unknown composition has been observed between AgCa and Ag_3Ca_5 and in the same sample with either or both of these compounds. Moreover, the unknown compound is sometimes absent from a sample containing AgCa and Ag_3Ca_5. There is a possibly fortuitous indication of a peritectic at about 59% Ca and 598 °C and the diagram is drawn concordantly.

The compound Ag_3Ca_5 has been analyzed by single crystal X-ray diffraction (13) and hence the indication of its formation at 560 °C by peritectic reaction is probably accurate. The relationships of the unknown compound with the neighboring AgCa and Ag_3Ca_5 are tentatively drawn to fit our experimental data. It is also quite possible that further examination would show a different relation such as the existence of the unknown down to room temperature. On the other hand the compound X was not always present when expected, which might indicate some complexity in the reactions by which it is formed or disappears.

Between the compound Ag_3Ca_5 and pure calcium the data suggest the presence of two eutectics with the congruently melting compound $AgCa_3$. The latter's structure has been clearly elucidated by X-ray diffraction[6]. $AgCa_3$ was always found in association with the pure calcium phase in alloys with higher calcium content and with Ag_3Ca_5 on the opposite side. Although the X-ray crystal structure analysis indicates a nominal composition of 75% for $AgCa_3$, congruent melting of a compound at about 77.5% is still possible since the stoichiometry of the compound was not specifically studied in the X-ray work, but no variation in lattice parameter was observed. Regarding the solid state arrests in this region, viz., two at about 455 °C between 70 and 75% and the scattered ones at about 479 °C from about 77 to 98%, which were not always observed, these are most probably indications of solid state transformations which we did not investigate further.

The liquidus arrests from pure calcium to the first eutectic at about 80.5% are very weak and sometimes were not observed at all, even with the sensitivity we achieved. However, there seems to be little doubt of the general course of this liquidus line. The melting point of calcium at 840 °C is in agreement with what we believe to be the most reliable literature values (17, 20).

The X-ray photographs of these alloys indicated little or no range of solid solution in all cases, including that of the terminal metals with the adjacent compounds.

[6]Unpublished investigation.

Kinetics of the thermal decomposition of cyclobutanone[1]

ARTHUR T. BLADES
Research Council of Alberta, Edmonton, Alberta

Received May 17, 1968

The thermal decomposition of cyclobutanone into cyclopropane and carbon monoxide has been shown to occur simultaneously with the major decomposition to ethylene and ketene. The relative rate constant expression is given by $k_{C_3H_6}/k_{C_2H_4} = 0.65 \exp(-6000/RT)$. Both reactions are pressure sensitive below 10 Torr and this quasi-unimolecular behavior is most pronounced in the cyclopropane forming reaction, consistent with the higher activation energy. The data are also discussed in relation to the photochemical decomposition and it is shown that cyclopropane formation from the ground singlet is an important feature of the photolysis at 3130 Å.

Introduction

The photochemical decomposition of cyclobutanone yields ethylene, ketene, cyclopropane, propylene, and carbon monoxide (1, 2). Recent studies (3, 4) suggest that these products arise from the two primary reactions

[1] $\text{cyclo-}C_4H_6O \xrightarrow{h\nu} C_2H_4 + CH_2CO$

and

[2] $\text{cyclo-}C_4H_6O \xrightarrow{h\nu} \text{cyclo-}C_3H_6 + CO$

In reaction [2], the partitioning of the residual energy of the photon between the products is such that some of the cyclopropane may isomerize to propylene. The formation of this product is therefore favored by low pressure and short wavelength.

On the basis of benzene photosensitization studies, Denschlag and Lee (5) have proposed that the cyclopropane arises from the excited triplet cyclobutanone. The formation of ethylene on the other hand, has been attributed (6) to the decomposition of the vibrationally excited ground singlet following internal conversion from the first excited singlet. The relative rates of the two processes [1] and [2] may, therefore, be determined not by the rates of chemical processes but by the rates of change of the electronic configuration, processes which might be expected to be less sensitive to absorbed energy. The invariance of the product ratio with wavelength under certain conditions (3, 4) is in keeping with this evaluation.

From the variation of the quantum yields of ethylene, cyclopropane, and propylene, Magee (7) has proposed that only propylene arises from the triplet while the other products arise from the excited singlet. While these data are somewhat compelling, the suggestion that the cyclopropane, formed with energies in excess of the activation energy for its conversion to propylene (3, 4), does not isomerize at low pressures, is untenable.

In the pyrolysis of cyclobutanone, the major process is reaction [1], only 0.5% of the hydrocarbon product being cyclopropane (8). The major reaction has been shown to be homogeneous and first order over the pressure range 10–88 Torr, the rate constant being given by

$$k = 3.6 \times 10^{14} \exp(-52\,000/RT)\ \text{s}^{-1}$$

There is no evidence that the cyclopropane arises by reaction [2] but this would seem to be a reasonable assumption by analogy with the photolysis. Since the pyrolysis involves only the ground singlet, however, and the source of the cyclopropane is believed to be the triplet, some inconsistency exists between the pyrolytic and photolytic systems. This paper is concerned with the kinetics of the pyrolytic formation of cyclopropane.

Experimental

The pyrolyses were carried out in a Pyrex reactor (84 cc) employing standard high vacuum techniques. The commercial cyclobutanone was purified by gas chromatography and was degassed prior to use. In the gas chromatographic analysis of the products (35 ft diisooctyl phthalate on firebrick, 0 °C, 30 cc/min, H_2 carrier), the flame ionization detector response was monitored by a digital integrator.

Results

The products of the pyrolysis were confirmed to be ethylene and ketene, with about 0.5% cyclopropane (and CO). Propylene was always detected but was less than 1% of the cyclopropane.

[1]Contribution No. 429 from the Research Council of Alberta, Edmonton, Alberta.

At constant temperature (350°) and pressure (10 Torr) the ratio of products was independent of reaction time up to 75% reaction. Rate constants for ethylene formation agreed within experimental error with those previously reported (8).

The effect of pressure on the rate of ethylene formation was determined in the range 0.7 to 16 Torr and on the relative rates of cyclopropane and ethylene formation in the range 1.3–19.5 Torr. These data are shown in Fig. 1. The temperature coefficient of the relative rates of the two processes was determined from 316–393° at 15 Torr, and an Arrhenius plot of this data is shown in Fig. 2. The relative rate expression derived from this data is

$$k_{C_3H_6}/k_{C_2H_4} = 0.65 \exp(-6000 \pm 500/RT)$$

When combined with the rate expression for the major reaction (8), the rate constant for cyclopropane formation is

$$k = 2.34 \times 10^{14} \exp(-58\,000/RT)\,s^{-1}$$

Similar behavior was observed in various reaction vessels of different surface to volume ratio and the rates were independent of the presence of a 100-fold excess of toluene.

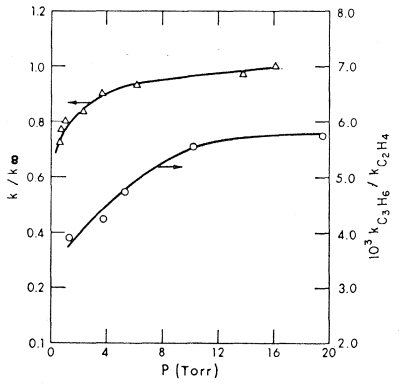

FIG. 1. Pressure effects in the decomposition of cyclobutanone. Δ, left hand scale, k/k_∞ for ethylene formation; ○, right hand scale, $10^3 k_{C_3H_6}/k_{C_2H_4}$.

Discussion

Cyclopropane might arise in the pyrolysis of cyclobutanone either by a direct decomposition or by a series of consecutive reactions of the major products, ketene and ethylene. This latter possibility is ruled out since reaction time did not affect the product ratio and the formation of cyclopropane, like ethylene, must be first order. Since the chain-inhibitor, toluene, and surface to volume ratio also failed to influence the rates of either process, both reactions must be homogeneous unimolecular decompositions.

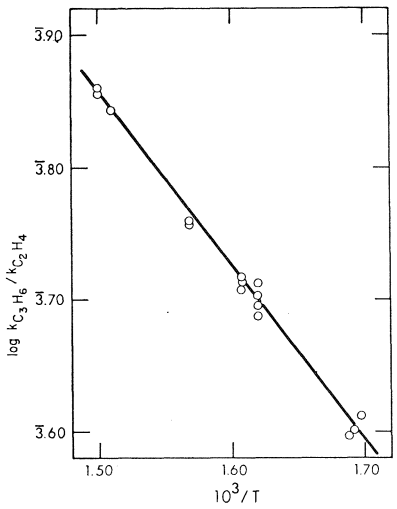

FIG. 2. Arrhenius plot of the relative rates of cyclopropane and ethylene formation.

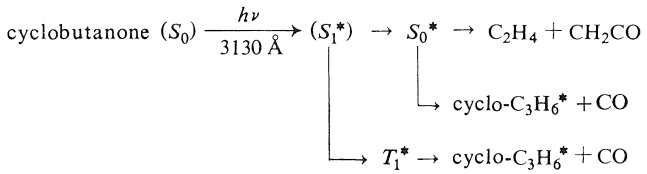
The pressure effects in these competitive homogeneous reactions illustrate an effect previously observed in intramolecular hydrogen isotope effects (9). The decline in the rate constant for ethylene formation below 10 Torr implies pseudo-unimolecular behavior for this reaction, while the decline in the relative rate constants implies that the cyclopropane-forming reaction is more susceptible to pressure decrease. Since the latter process has the higher activation energy, and these products arise preferentially from the more highly excited cyclobutanone, such behavior is to be expected independent of subtle differences between the two mechanisms. Calculations of Rice–Ramsperger–Kassel (R.R.K.) theory "S" value, the number of degrees of freedom contributing to activation, are therefore not meaningful for the minor process.

The Arrhenius parameters for the decomposition of cyclobutanone to ethylene and ketene have been estimated by O'Neal and Benson (10) on the basis of a mechanism involving the intermediate diradical $\cdot CH_2CH_2COCH_2\cdot$. Resonance in this diradical contributes significantly in reducing the



entropy of activation and the activation energy. If the decomposition to cyclopropane occurs via the diradical $\cdot CH_2CH_2CH_2CO\cdot$, such resonance does not exist, and the activation energy for this process would be expected to be greater by the carbonyl resonance energy which has been estimated at about 8 kcal/mole (10). This difference is in reasonable agreement with the 6 kcal/mole observed. The accompanying higher entropy change would be partially offset by a smaller entropy increase due to internal rotation in the radical formation, and hence the frequency factors for the two processes are similar. The activated complex must lead directly to cyclopropane and CO since the intermediate formation of trimethylene is energetically forbidden.

This pyrolysis study has shown that cyclopropane is an alternate decomposition product of ground singlet cyclobutanone. Since the photolysis mechanism of Lee *et al.* (6) involves the decomposition of this species, but allows only for ethylene as a product, it is desirable to estimate how significant an error this implies. Using the R.R.K. theory expression for the specific rate constants, assuming 15 Kassel oscillators (6), it can be estimated that for photolysis at 3130 Å, about 7% of the ground singlet will decompose to cyclopropane. The ratio of ethylene to cyclopropane at 3130 Å is 2.45 (6) and therefore, of the cyclopropane formed, about 18% would be predicted to arise from the ground singlet decomposition. Evidence for this significant contribution to the cyclopropane in photolysis is provided by the quenching studies of Lee *et al.* (6). They observed a 10% decrease in C_3H_6 formation in the same pressure range where ethylene had decreased about 66%. While they attribute this to a minor quenching of the cyclobutanone triplet, an alternate explanation would be that this results from quenching of that part of the ground singlet which would otherwise have produced the cyclopropane. On this basis, it would appear that about 15% of the cyclopropane arises from the ground singlet at 3130 Å, in excellent agreement with that predicted from the pyrolysis data, and modification of the photolysis mechanism seems justified.

At shorter wavelengths, the proportion of the ground singlet decomposing to cyclopropane would be greater and this prediction is in keeping with a slight decrease in the C_2H_4 to C_3H_6 ratio with decreasing wavelength. This decrease is, however, twice that predicted on the basis of the classical theory and may result wholly or in part from a variation in the relative rates of intersystem cross-over and internal conversion with absorbed energy.

Heats of mixing and dielectric constants of some partially miscible liquid pairs

A. N. CAMPBELL AND E. M. KARTZMARK
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received May 2, 1968

The physical properties mentioned in the title have been determined for the six systems: (*a*) aniline–hexane, (*b*) methanol–cyclohexane, (*c*) methanol – carbon disulfide, (*d*) acetic anhydride – carbon disulfide, (*e*) acetic anhydride – cyclohexane, and (*f*) triethylamine–water, over the complete range of composition. All six systems are partially miscible, above or below a critical solution temperature (c.s.t.).

From the experimental data, the partial molal heats of mixing have been calculated, using the Redlich and Kister equations. The enthalpy of hydrogen bonding in the triethylamine–water compound appears to be about −1.33 kcal per hydrogen bond.

The orientation polarization, according to the Syrkin formula, appears always to exhibit negative deviation from ideality, at least over part of the concentration range.

Canadian Journal of Chemistry, 47, 619 (1969)

Previous work from this laboratory has dealt with congruent concentrations (1) of the six systems, (*a*) aniline–hexane, (*b*) methanol–cyclohexane, (*c*) methanol – carbon disulfide, (*d*) acetic anhydride – carbon disulfide, (*e*) acetic anhydride – cyclohexane, and (*f*) triethylamine–water. Another paper (2) is confined to the system aniline–hexane, and deals with excess volume, vapor pressure, surface tension, and viscosity. The present work deals with the same systems and studies the properties mentioned in the title.

For those liquid systems which form two layers, the change of volume on mixing is usually positive but this is not always the case. That it should not be true of the system triethylamine–water, where both ΔV and ΔH are strongly negative, is not surprising since we have shown that here a compound is formed (3), which probably continues to exist, to some extent undissociated, even at room temperature.

The density measurements, however, show that ΔV is negative over the whole concentration range for the system aniline–hexane, and over a part of the range for methanol – carbon disulfide, and there is no possibility of compound formation between aniline and hexane. According to Bellemans (4), upper critical solution phenomena occur in endothermal mixtures but a lower critical point can only occur in exothermal mixtures.

Experimental

The method of determining heat of mixing has been described previously (5, 6). The purity of materials was the same as previously described (1).

The dielectric constants were determined with a Sargent oscillometer, the sample being thermostated at a temperature high enough or low enough to ensure homogeneity over the complete concentration range (7). Determinations with this instrument cannot be made on substances having higher electrical conductances than the alcohols, although we found it possible to use conductance water as a calibration point. No measurements could, however, be made on mixtures of triethylamine and water, containing considerable quantities of water, because of the high electric conductance. Dilute solutions of triethylamine in water gave apparent dielectric constants as high as 120, obviously due to the electric conductance.

Results

TABLE I

Heats of mixing

Acetic anhydride – carbon disulfide*

Composition	ΔH	Composition	ΔH
4.26	207.5	53.03	434.5
8.89	274.5	59.70	393.7
12.93	291.8	69.41	358.9
18.98	327.2	70.84	380.0
25.16	398.0	74.30	347.7
31.55	442.8	85.83	212.3
39.78	449.4		

*Composition in mole % acetic anhydride, ΔH in cal/mole mixture, $T = 34.2$ °C.

Methanol – carbon disulfide*

Composition	ΔH	Composition	ΔH
15.20	147.4	51.23	192.0
28.47	195.6	69.93	162.8
39.15	192.7	79.52	151.3
44.34	194.8	82.74	127.0
47.55	189.0	95.48	40.56

*Composition in mole % methanol, ΔH in cal/mole mixture, $T = 36.5$ °C.

Drucker and Weissbach (8) have determined the heats of mixing of solutions of methanol and carbon disulfide outside of the gap, at 20 °C. Insofar as the results are comparable, they are in good agreement.

TABLE I (*Concluded*)

Methanol–cyclohexane*

Composition	ΔH	Composition	ΔH
6.99	205.0	63.14	270
13.01	240.3	72.33	247.1
24.26	284.0	80.52	198.1
31.26	296.4	86.80	155.5
41.90	293.5	90.80	133.4
52.05	296.7	95.83	69.6

*Composition in mole % methanol, ΔH in cal/mole mixture, $T = 50.5$ °C.

According to Mondain–Monval (9) the heat of mixing of methanol–cyclohexane has a value of 4 cal/g, at the maximum. This amounts to 253 cal/mole and is to be compared with our value of 300 cal at the maximum (40 mole % methanol). Wood (10) calculates a value of 800 cal/mole mixture, a value which is obviously absurd.

Acetic anhydride – cyclohexane*

Composition	ΔH	Composition	ΔH
3.60	236.9	50.86	705.2
10.45	378.0	63.22	646.7
19.49	543.7	71.21	549.6
37.28	711.3	82.36	380.0
39.24	715.8	90.52	296.6
44.05	733.4		

*Composition in mole % acetic anhydride, ΔH in cal/mole mixture, $T = 59.0$ °C.

Hexane–aniline*

Composition	ΔH	Composition	ΔH
5.02	166.4	39.51	676.7
12.57	382.3	40.04	654.2
23.58	580.3	51.04	733.0
26.20	633.4	60.13	667.3
26.58	599.5	66.25	717.6
27.71	586.1	68.70	603.6
33.00	629.9	80.00	590.0
38.42	662.3		

*Composition in mole % hexane, ΔH in cal/mole mixture, $T =$ 66.5 °C.

Composition	ΔH	Composition	ΔH
0.59	−47.0	28.85	−537.8
3.62	−220.7	41.41	−575.1
6.18	−250.7	55.87	−357.4
7.52	−248.7	57.08	−408.0
22.98	−515.9	67.20	−331.3

*Composition in mole % triethylamine, ΔH in cal/mole mixture $T = 10$ °C.

The results of Copp and Everett (11) are in fair agreement with ours, as regards the shape of the curve and the value H^E at the maximum, but whereas they obtain a maximum value of −595 cal/mole at a composition of 25 mole % triethylamine, our maximum value is −580 cal at 41 mole % triethylamine. Copp and Everett's curve is, however, buite flat at the top and a small error on their part or ours would qring the compositions into agreement.

Discussion

The heats of mixing can be represented by the Redlich and Kister equation (12), viz.

$$H^E = X_1X_2[A + B(X_1 - X_2) + C(X_1 - X_2)^2]$$

where X_1 = mole fraction of the component first named.

The constants for the above equation were determined from our data, using a least squares fit, on the computer. The program was essentially that of Myers and Scott (13). The constants, together with the σ values, or deviations of the constants, are given in Table III.

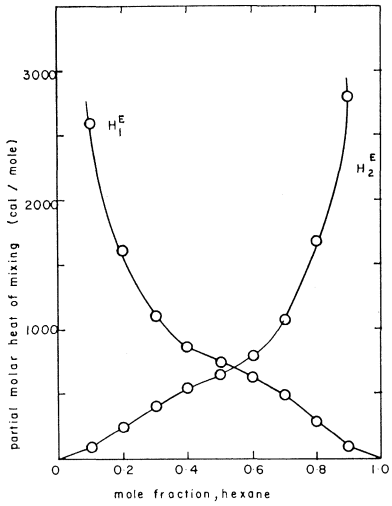

FIG. 1. Partial molar excess enthalpies: aniline–hexane.

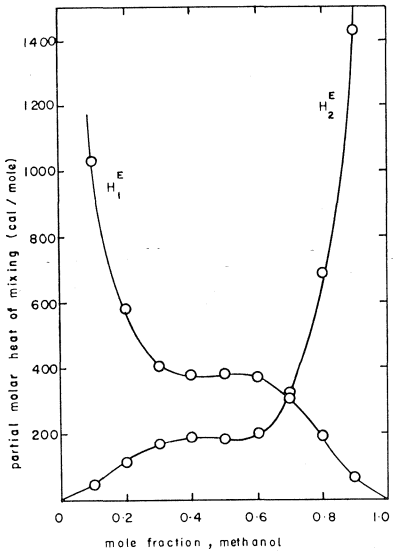

FIG. 2. Partial molar excess enthalpies: methanol–cyclohexane.

TABLE III

Constants of the Redlich and Kister equation and their deviations

System	A	σ	B	σ	C	σ
Acetic anhydride – carbon disulfide	1708	79	442.2	138	1195	352
Methanol – carbon disulfide	761.0	11	158.6	27	588.6	59

Acetic anhydride – cyclohexane	2822	76	703.7	167	1167	362
Hexane–aniline	2779	58	−206.6	123	1713	345
Triethylamine–water	−1683	178	−1315	677	−2304	1520

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Using the above constants, the partial molar heats of mixing can be calculated from the equations

$$H_1^E = (1 - X_1)^2[(A + B(4X_1 - 1) + C(2X_1 - 1)(6X_1 - 1)]$$

$$H_2^E = X_1^2[A + B(4X_1 - 3) + C(2X_1 - 1)(6X_1 - 5)]$$

The results are expressed graphically in Figs. 1 to 6.

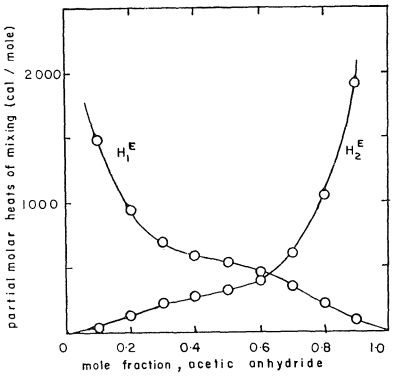

FIG. 3. Partial molar excess enthalpies: acetic anhydride – carbon disulfide.

All heats of mixing are positive except those of triethylamine–water, which are strongly negative[1]. The partial molar heats of mixing require no comment, except those of triethylamine–water. In view of the equilibrium existing in solution, viz.

$$(C_2H_5)_3N + 2H_2O \rightleftarrows (C_2H_5)N_3 \cdot 2H_2O$$

the limiting value of the partial molar heat of mixing of triethylamine in infinite excess of water may represent the enthalpy of formation of the compound. The calculation was therefore carried out for low mole fractions of triethylamine (0.01 and 0.05). The limiting value is -2650 cal. This gives a value of -1.325 kcal for the hydrogen bond.

When dielectric constant is plotted against mole fraction, negative deviation from straight line behavior is usually observed. The exception to this is the system acetic anhydride – carbon disulfide,

[1]This is in agreement with the predictions of Haase and Rehage (14) who state that an upper critical solution temperature is associated with a positive enthalpy of mixing and a lower critical solution temperature with a negative.

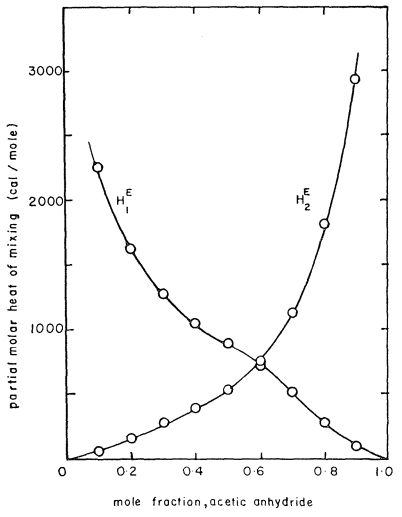

FIG. 4. Partial molar excess enthalpies: acetic anhydride – cyclohexane.

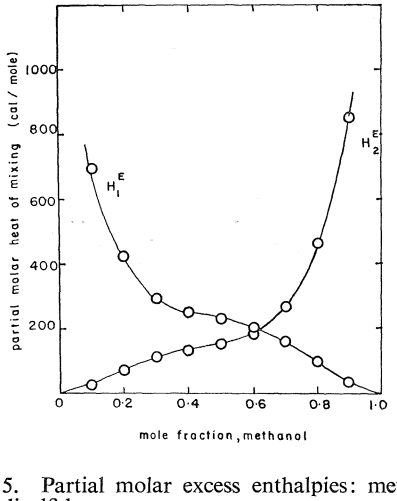

FIG. 5. Partial molar excess enthalpies: methanol – carbon disulfide.

which shows slightly positive deviation. We have not used our results for triethylamine–water, because we do not think these results are reliable in the presence of appreciable amounts of water.

The molar polarization,

$$P = \left(\frac{\varepsilon - 1}{\varepsilon + 2}\right) \cdot \left(\frac{X_1M_1 + X_2M_2}{d}\right)$$

as a function of mole fraction, shows strong positive deviation from linearity. Finally, we

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

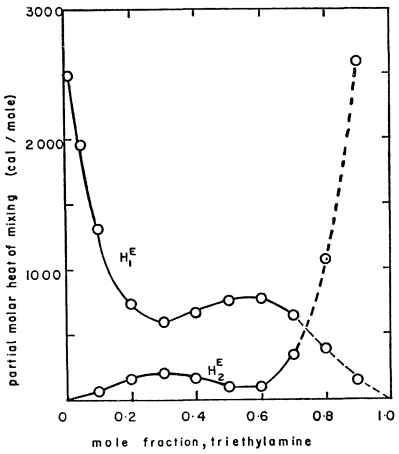

FIG. 6. Partial molar excess enthalpies: triethylamine–water.

owe to Syrkin (16) a formula for orientation polarization, viz.

$$P_i = \frac{P - X_1R_1 - X_2R_2}{1 - \left(\frac{\varepsilon - 1}{\varepsilon + 2}\right)^2}$$

where P is the molar polarization and R_1, R_2 are the molar refractions of the pure components. When these results are plotted against mole fraction, negative deviation is always observed, at least over part of the concentration range, a behavior which, according to Syrkin, is attributable to dipole – induced dipole interaction, dipole association, or a decrease in hydrogen bonding with dilution. It does not necessarily follow, however, that a mixture of polar and non-polar liquids shows negative deviation from additivity of Syrkin polarization. Thus, the behavior of a benzene–nitrobenzene mixture is ideal and this mixture does not show partial miscibility. On the other hand, mixtures of acetic acid with carbon tetrachloride, which are completely miscible, show marked negative deviation from additivity.

We determined the refractive indices of all solutions at the temperatures of investigation of the other properties (above the c.s.t.). In every case, the molar refraction was so close to that calculated from the mixture rule that the slight differences might be attributed to experimental error. This is to be expected if, as the Clausius–Mosotti theory teaches, the molar refraction represents the true volume of matter in a mole.

Medium effects in nuclear magnetic resonance. VII. Vapor phase studies of hydrogen bonding in methanol and methanol–trimethylamine mixtures[1]

A. D. H. Clague[2], G. Govil[3], and H. J. Bernstein
Division of Pure Chemistry, National Research Council of Canada, Ottawa 2, Canada

Received September 20, 1968

The self association of methanol, and the intermolecular association of methanol and trimethylamine have been examined in the vapor phase using nuclear magnetic resonance spectroscopy. Values of ΔH and ΔS for the two systems have been found to be -4.1 ± 0.5 kcal/mole and -17.5 ± 3 e.u., and -5.8 ± 0.7 kcal/mole and -22.6 ± 3 e.u., respectively.

Introduction

While extensive nuclear magnetic resonance (n.m.r.) studies (1, 2) have been made on hydrogen bonding in the condensed phase, little work has been done in the gas phase. Thermodynamic studies in the gas phase are especially valuable since the hydrogen bond will be least modified by a medium effect. Further, in such systems it is possible (3–5) to estimate the contributions of interactions other than hydrogen bonding, to the observed chemical shifts in n.m.r. Recently (6), we have shown that n.m.r. can be used with success for the study of hydrogen bonding in the gas phase. In this paper, we report the n.m.r. results on the self association in methanol and its association with trimethylamine (TMA).

Experimental

Spectroquality methanol and Matheson Co. trimethylamine (99.0% minimum purity) were used without further purification. All sample handling was carried out on a vacuum line.

All spectra were recorded on a Varian A-60A spectrometer fitted with a variable temperature probe calibrated with ethylene glycol. Owing to the construction of the probe assembly of the Varian A-60A the portion of a normal n.m.r. tube surrounded by the plastic spinner cone remains at a different temperature than the portion below it. There was a tendency for methanol to condense on this cooler portion, resulting in loss of signal. Thus, to maintain the reactants in the vapor phase as well as to prevent a temperature gradient along the tube it is necessary to encapsulate them entirely within the temperature controlled portion of the probe. A normal 5 mm outer diameter 4 mm inner diameter n.m.r. tube was modified in the following way. The closed end of the tube was removed and the tube was extended by about 5 cm with a piece of Pyrex tubing having the same diameter. Using standard glass blowing techniques a glass plug was formed in the original portion of the tube about 9.5 cm from the position of the joint. A benzene capillary was inserted via the Pyrex extension and a constriction was pulled at the position of the joint. The tube was attached to the line by means of the Pyrex extension.

A known pressure of each gas was allowed into a bulb of known volume then condensed into the tube using a liquid nitrogen bath. The tube was sealed at the point of the constriction. Every effort was made to ensure as symmetric a seal as possible since this point represents the bottom of the tube and any asymmetry would interfere with the spinning qualities of the tube. A separate tube was used for each experiment, and the tube volumes were determined volumetrically after the n.m.r. data had been recorded.

In order to relate accurately the pressure of methanol to its concentration, the bulb of measured volume was filled with a series of different pressures of methanol; in each case the gas was condensed in a weighing bottle and weighed on a Mettler Microgramatic balance. By plotting the weight of methanol against pressure a calibration curve was obtained from which the true weight of methanol in any sample could be read. Trimethylamine has practically no tendency for self-association and therefore its concentration was determined from the ideal gas laws.

Spectra were recorded at intervals up to 200 °C. In samples containing a high concentration of methanol, the starting temperature was about 100 °C to ensure complete vaporization of the sample. For samples containing methanol alone, the shift of the hydroxyl proton was measured relative to the signal from benzene using 4 observations and the standard deviation was found to be between 0.5 to 1.0 Hz, depending on the temperature and pressure. In most of the mixtures with TMA it was found necessary to enhance the signals using a Varian time average computer (CAT-1024). About 9 to 25 traces were added by triggering the CAT on a side band of the benzene signal, generated by an audio oscillator close to the expected position of the OH signal. The audio oscillator was calibrated by a frequency counter. The instabilities in the spectrometer caused a further broadening of the accumulated signal and therefore the accuracy of the shift measurements was no better than $\sim \pm 1.5$ Hz. In each case, the measured shifts were converted relative to the shift of ethane gas at 10 atm pressure using the relation between temperature and chemical shift of benzene relative to above standard described previously in ref. (6).

Results and Discussion

(A) Self Association of Methanol

The reaction for the dimerization of methanol (M) can be written as

$$\underset{a-x}{M} \rightleftharpoons \underset{x/2}{\tfrac{1}{2}(MM)}$$

where a is the total concentration of methanol in g-moles/l (dimer + monomer) and $x/2$ is the amount present as dimer. The equilibrium constant (K_{C_1}) for dimerization is given by

$$[1] \qquad K_{C_1} = \frac{x}{2(a-x)^2}$$

and is related to the enthalpy (ΔH_1) and entropy (ΔS_1) for the reaction by

$$[2] \qquad R \ln (K_{C_1}/RT) = \Delta S_1 - \Delta H_1/T$$

where R is the gas constant and T is the absolute temperature.

Since the rate (on the n.m.r. scale) at which the hydrogen bonds are formed and broken is fast, one observes only one signal from the proton involved in hydrogen bond formation. The observed chemical shift (δ_0) of this proton is related to that in the free form (δ_M) and the bonded form (δ_{MM}) by the relation

$$[3] \qquad \delta_0 = [(a-x)\delta_M + x\delta_{MM}]/a$$

Thus, if δ_M and δ_{MM} are known, a knowledge of δ_0 enables one to calculate x and vice versa.

The chemical shift for the OH signal at zero pressure ($\delta_M{}^0$) in free methanol can be obtained by extrapolation of the high temperature shifts for samples 1–3 in Table I. This gives $\delta_M{}^0 = 58 \pm 2$ Hz relative to C_2H_6, which corresponds to 208 Hz relative to the CH_3 peak in methanol. The corresponding value (7) in CCl_4 solution is 172 Hz indicating the presence of some additional interactions which affect the chemical shift in CCl_4 solutions.

At higher pressures δ_M in the vapor can be estimated from eq. [4]

$$[4] \qquad \delta_M = \delta_M{}^0 + (p_M/RT)\sigma^{MM}$$

where σ^{MM} is a correction for the diamagnetic anisotropy, electric field, and van der Waal interactions and p_M is the pressure of methanol. σ^{MM} can be calculated provided certain molecular parameters are known. Details of such calculations are given in Appendix and the calculated shifts δ_M for the three samples at different temperatures are given in Table I.

From eqs. [1–3] one sees that these involve three unknowns, namely ΔH_1, ΔS_1, and δ_{MM}. It is possible to solve for them from the experimental data on δ_0 using a minimization procedure given in a previous paper [6]. One obtains

$$\delta_{MM} = 0 \pm 40 \text{ Hz relative to } C_2H_6$$

$$\Delta H_1 = -4152 \pm 500 \text{ cal/mole}$$

$$\Delta S_1 = -17.47 \pm 3.0 \text{ e.u.}$$

The calculated shifts using the mean values of the above parameters have been included in Table I for comparison.

Self association in methanol has been studied earlier by other physical methods. Weltner and Pitzer (8) using P–V–T curves and heat capacity measurement showed that methanol exists in dimeric and tetrameric forms with ΔH and ΔS values of -3220 cal/mole and -16.5 e.u. for dimer and $-24\,200$ cal/mole and -81.3 e.u. for tetramer. More accurate measurements of Kretschmer and Wiebe (9) gave ΔH as -4000 and $-22\,100$ cal/mole, respectively, for dimer and tetramer. Using these values it is seen that the amount of tetramer present under the conditions used in this experiment is negligible, hence the good fit between observed and calculated chemical shifts using only 3 variables. If an appreciable amount of tetramer is present one has to use three additional parameters in the minimization but the accuracy in the estimate of six unknowns from the observed chemical shift is unlikely to be good (10).

The enthalpies of dimerization and tetramerization for methanol have also been measured by an infrared method (11) (-3500 and $-18\,400$ cal/mole, respectively). Again the measured values are in good agreement with the n.m.r. result.

Using the infrared values for equilibrium constant Becker, Liddel, and Shoolery (12) estimated $\delta_{MM} - \delta_M$ for alcohols as -2.3 p.p.m. for cyclic dimer and -1.2 p.p.m. for open dimer in CCl_4 solutions. The latter value is in good agreement with the observed result of -1 ± 0.7 p.p.m. for the difference in gas phase where open dimers are known to exist (7).

(B) Methanol–Trimethylamine System

For such a system, there are two competing reactions

$$\underset{a-x-y}{\mathrm{M}} \rightleftharpoons \underset{x/2}{\tfrac{1}{2}(\mathrm{MM})}$$

and

$$\underset{a-x-y}{\mathrm{M}} + \underset{b-y}{\mathrm{N}} \rightleftharpoons \underset{y}{\mathrm{MN}}$$

where b is the starting concentration of TMA (referred to as subscript N) in g-moles/l. We have

$$[5] \qquad K_{C_1} = \frac{x}{2(a-x-y)^2}$$

for the first reaction, and corresponding to eqs. [1–4] we have for the second reaction

$$[6] \qquad K_{C_2} = \frac{y}{(a-x-y)(b-y)}$$

$$[7] \qquad R \ln (K_{C_2}/RT) = \Delta S_2 - \Delta H_2/T$$

$$[8] \qquad \delta_0 = [(a-x-y)\delta_M + x\delta_{MM} + y\delta_{MN}]/a$$

with

$$[9] \qquad \delta_M = \delta_M{}^0 + [p_M\sigma^{MM} + p_N\sigma^{MN}]/RT$$

where K_{C_2}, ΔH_2, and ΔS_2 are the equilibrium constant, enthalpy, and entropy for the second reaction, p_M and p_N are the partial pressures of methanol and TMA respectively, δ_{MN} is the shift of the hydroxyl proton in the complex MN, and σ^{MN} is a correction similar to σ^{MM} whose value has been calculated in the Appendix.

One can eliminate y from eqs. [5] and [8] to obtain eq. [10]

$$[10] \qquad x^2 + 2(f-g)x + f^2 = 0$$

where

$$f \equiv a \cdot \frac{\delta_0 - \delta_{MN}}{\delta_{MN} - \delta_{MM}}$$

and

$$g \equiv \frac{(\delta_M - \delta_{MN})^2}{4K_{C_1}(\delta_{MN} - \delta_{MM})^2}$$

Selecting the physically acceptable solution of x gives

$$[11] \qquad x = g - f - [g^2 - 2gf]^{1/2}$$

while rearrangement of [8] gives y in terms of x

$$[12] \qquad y = a\left(\frac{\delta_M - \delta_0}{\delta_M - \delta_{MN}}\right) - x\left(\frac{\delta_M - \delta_{MM}}{\delta_M - \delta_{MN}}\right)$$

Since K_{C_1}, δ_{MM}, and δ_M are known, eqs. [6], [7], [11], and [12] again involve three unknowns only, namely, δ_{MN}, ΔS_2, and ΔH_2.

A graphical method for estimating δ_{MN} has been suggested (13) using data for mixtures where $b > a$. In such cases the self association is suppressed e.g. $y > x$ and $b \gg y$. Using these approximations in eqs. [6], [8], and [12] one obtains

$$[13] \qquad \frac{a}{y(\delta_M - \delta_{MN})} \simeq \frac{1}{\delta_M - \delta_0} \simeq \frac{1}{\delta_M - \delta_{MN}} + \frac{1}{bK_{C_2}(\delta_M - \delta_{MN})}$$

Thus, the double reciprocal plot of $(\delta_M - \delta_0)$ and b at a constant temperature, gives $\delta_M - \delta_{MN}$. Using such a technique one obtains

$$\delta_{MN} = -250 \pm 100 \text{ Hz}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The values of ΔH_2 and ΔS_2 can now be obtained by a least squares method using the data on the observed chemical shifts (δ_0). For all the mixtures, x and y are estimated using eqs. [11] and [12] for each sample and temperature at which δ_0 has been measured and substituted in eq. [6] to obtain values of K_{C_2} at different temperatures. ΔH_2 and ΔS_2 are solved by the linear least squares fitting to the values of R ln K_{C_2} as estimated above.

The values thus obtained are

$$\Delta H_2 = -5847 \pm 700 \text{ cal/mole}$$

$$\Delta S_2 = -22.64 \pm 3.0 \text{ e.u.}$$

The calculated chemical shifts δ_c with the above values of δ_{MN}, ΔH_2, and ΔS_2 are given in Table II along with the observed chemical shifts. These fit within the standard error ($\Delta\delta_0$) in the measurement of δ_0. The possible errors in ΔH_2 and ΔS_2 have been estimated using the criterion that the overall fit between the observed and calculated chemical shifts, $\phi = \sum_i(\delta_c - \delta_0)_i^2$, where i runs over all the experimental measurements, is less than $\sum_i(\Delta\delta_0)_i^2$. The accuracy of ΔH_2 and ΔS_2 measurements compares favorably with that expected by other physical methods.

The accuracy in the estimation of δ_{MN} can be improved if the OH chemical shift in methanol in samples containing higher proportions of TMA could be studied. Under the present experimental conditions this was not feasible.

Appendix

For gases having low quadrupole moments σ^{MM} and σ^{MN} in eqs. [4] and [9] can be estimated from the equation (3)

$$[A\text{-}1]\quad \sigma^{ij} = \tfrac{2}{3}\pi\chi_{vj} - (N\pi/1080)(\chi_{\parallel} - \chi_{\perp})_j \{\tau^2 H_9(y) + (y^4\tau^4/70)H_{15}(y) + \ldots.\}$$
$$- (\pi NA/6y^2)[\mu_j\{(\tau/3)H_6(y) + (y^4\tau^3/200)H_{12}(y) + \ldots.\} + (4a_j\mu_i/r_0{}^3y^2)\{H_6(y) + (\tau^2y^4/40)H_{12}(y) + \ldots.\}]$$
$$- (\pi NB/3y^4)[(2\mu_j{}^2/r_0{}^3)\{H_6(y) + (\tau^2y^4/40)H_{12}(y) + \ldots.\} + (a_j\mu_i\mu_j/r_0{}^6)\{y^2\tau H_{12}(y) + \tau^3y^6/60)\,H_{18}(y) + \ldots.\}]$$
$$- (\pi NB/y^4r_0{}^3)a_jI_j[H_6(y) + (y^4\tau^2/48)H_{12}(y) + \ldots.]$$

where μ_i, μ_j are the dipole moments, a_j the polarizability, I_j the ionization potential, χ_{vj} the volume susceptibility, and $(\chi_{\parallel} - \chi_{\perp})_j$ is the magnetic anisotropy, N is the Avogadro's number, and A and B are the bond parameters. τ and y are related by [A-2] and [A-3] to the parameters ε and r_0 of the "Stockmayer potential" tabulated by Hirschfelder *et al.* (14) for a number of gases while the functions $H_n(y)$ have been tabulated by Buckingham and Pople (15).

$$[A\text{-}2]\qquad \tau = \mu_i\mu_j/(\varepsilon r_0{}^3)$$

$$[A\text{-}3]\qquad y = (4\varepsilon/kT)^{1/2}$$

Following values were used for the calculation of σ^{MM} and σ^{MN}

Variable	Values for M (CH_3OH)	Values for N (TMA)
χ_m	-21.4×10^{-6}	-63.0×10^{-6} e.m.u.
$(\chi_{\parallel} - \chi_{\perp})$	0	0
ε/k	452	425
μ_0	1.70×10^{-18}	0.67×10^{-18} e.s.u.
r_0	3.67	4.34 A
a	3.23×10^{-24}	7.93×10^{-24} cm^3
I	17.4×10^{-12}	15.05×10^{-12} ergs

One also needs the bond parameters A and B for such calculations. Terms involving B make only little contribution and its values show comparatively small variations from one compound to another from its mean value of 0.5×10^{-18} e.s.u. The value of A changes significantly from one bond type to another (3–5). We have estimated an approximate value of A for the O—H bond by assuming that in intramolecular hydrogen bonds (orthophenols) the chemical shift change (from ortho to meta) is caused by electric field and magnetic anisotropy effect. Using the known molecular geometry for such molecules and $B = 0.5 \times 10^{-18}$ e.s.u. we find $A \simeq 25 \times 10^{-12}$ e.s.u. Substituting these values we obtain

$$\sigma^{MM} = -178.5 \text{ p.p.m. at } 343\ ^\circ\text{K}$$
$$-138.5 \text{ p.p.m. at } 443\ ^\circ\text{K}$$
$$\sigma^{MN} = -226.9 \text{ p.p.m. at } 343\ ^\circ\text{K}$$
$$-204.1 \text{ p.p.m. at } 443\ ^\circ\text{K}$$

Since these terms account for less than 10% of the observed shift an error in A of 100% is tolerable.

Normal coordinate analysis of dialkyldithiocarbamate and its selenium analogue

G. DURGAPRASAD, D. N. SATHYANARAYANA, AND C. C. PATEL
Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore, India

Received August 20, 1968

The infrared spectrum of N,N-dimethyldithiocarbamate complex of nickel(II) has been recorded in the range 2000–250 cm^{-1}. Normal coordinate analyses have been made for nickel dimethyldithiocarbamate and nickel dimethyldiselenocarbamate complexes and their infrared spectra indexed. The frequency shifts observed on alkyl substitution have been discussed. The M—Se stretching frequency occurs about 100 cm^{-1} lower in the diselenocarbamate complex as compared to M—S frequency of the dithiocarbamate.

Canadian Journal of Chemistry, 47, 631 (1969)

A few papers (1–9) have appeared since the publication of the infrared spectral studies of dithiocarbamate complexes of metals by Chatt *et al.* (10), where dithiocarbamate acts as a uninegative bidentate ligand. The chief interest has been the C=N stretching frequency which occurs around 1480–1550 cm^{-1}, which helps in estimating the contribution of each of the three canonical forms to the total structure. Very few investigators (5–9) mention one or two bands other than C=N. Nakamoto *et al.* (5), however, studied the infrared spectra of metal complexes of $S_2CNH_2^-$ and S_2CNHR^- (R being an alkyl group) and assigned their spectra on the basis of a normal coordinate treatment made for $Pt(S_2CNH_2)_2$, 1:1 complex. In spite of this, it has been found difficult to assign metal–sulfur and other frequencies in dialkyldithiocarbamate complexes (7, 8). A normal coordinate calculation has, therefore, been made for nickel dimethyldithiocarbamate to guide our assignments. The change observed on alkyl substitution has been pointed out from a comparison with the spectra of $S_2CNH_2^-$ complexes.

Since the spectra of selenium compounds are very similar to their corresponding sulfur compounds (vide infra), the calculations have also been made for nickel dimethyldiselenocarbamate with the same set of force constants as those of nickel dimethyldithiocarbamate.

Experimental

N,N-Dimethyldithiocarbamate complex of nickel(II) was prepared by adding aqueous solution of sodium dimethyldithiocarbamate to an aqueous solution of $NiCl_2.6H_2O$. The precipitate obtained was purified by washing with water followed by ether, and dried. The infrared spectra of the complex were recorded by Perkin–Elmer spectrophotometers models 137 and 21. The spectrum in the region 1800–250 cm^{-1} is given in Fig. 1

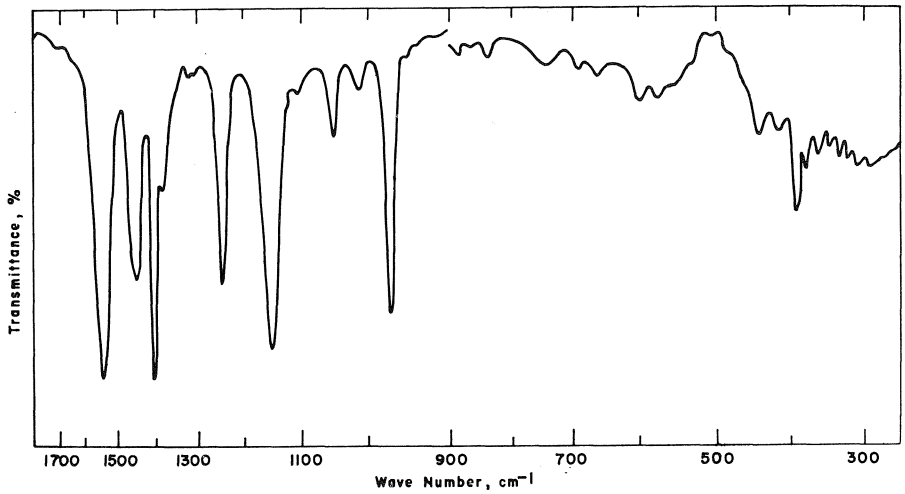

FIG. 1. Infrared spectrum of bis(N,N-dimethyldithiocarbamato)nickel(II).

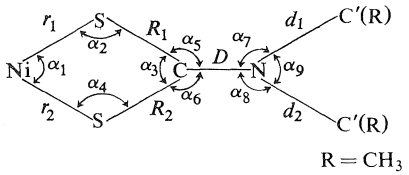

FIG. 2. Internal coordinates of nickel dimethyldithiocarbamate (1:1).

Normal Coordinate Treatment

The calculation has been made for 1:1 complex as shown in Fig. 2. In the present calculations, the methyl groups are treated as "point masses". The molecule is planar and belongs to the point group C_{2v}. The 15 vibrations are grouped into 11 in-plane vibrations ($6A_1 + 5B_2$) and 4 out-of-plane vibrations ($2A_2 + 2B_1$). Only the in-plane vibrations are considered here. The structural parameters for dithiocarbamate (11) and diselenocarbamate (12) are taken from the literature and are given in Table I.

TABLE I

Structural parameters

Nickel dithiocarbamate parameters	Nickel diselenocarbamate parameters
$r_1=r_2=2.212$ Å	$r_1=r_2=2.404$ Å
$R_1=R_2=1.707$ Å	$R_1=R_2=1.91$ Å
$D=1.33$ Å	$D=1.36$ Å
$d_1=d_2=1.485$ Å	$d_1=d_2=1.52$ Å
$\alpha_1=79°$	$\alpha_1=80°$
$\alpha_2=\alpha_4=85°$	$\alpha_2=\alpha_4=86°$
$\alpha_3=111°$	$\alpha_3=108°$
$\alpha_5=\alpha_6=124.5°$	$\alpha_5=\alpha_6=126°$
$\alpha_7=\alpha_8=121°$	$\alpha_7=\alpha_8=\alpha_9=120°$
$\alpha_9=118°$	

The symmetry coordinates with their approximate description are given in Table II. The method used is Wilson's **GF** matrix method (13). The secular equations for both A_1 and B_2 involve one redundant coordinate, each of which gives zero frequency in the solution.

The potential field used is of Urey–Bradley type (14). The best set of force constants obtained after several trials of computation is given in Table III. The force constants are of the same order as that used by Nakamoto *et al.* (5). The observed and calculated frequencies of nickel dimethyldithiocarbamate are given in Table IV. Potential energy distribution for this complex is given in Table V.

The calculations were carried out on a National Elliott 803 computer.

TABLE III

Force constants in mdyn/Å

Force constant	Value	Force constant	Value	Force constant	Value
K_r	2.02	H_{α_1}	0.30	F_{SS}	0.62
K_R	2.78	H_{α_2}	0.10	F_{SN}	0.28
K_D	6.68	H_{α_3}	0.52	F_{CM}	0.10
K_d	4.36	H_α	0.26	F_{RC}	0.48
		H_{α_7}	0.20	F_{RR}	0.32
		H_{α_9}	0.36		

Discussion

(a) Dithiocarbamate

The observed and calculated frequencies listed in Table IV agree fairly well, the maximum deviation being about 2%. The effect of alkyl substitution may be realized by comparing the present

data with those of the complexes of $S_2CNH_2^-$ (5). The C═N stretching frequency which is a pure band is raised by more than 100 cm^{-1} (from ~1430 cm^{-1}) on alkylation. Since the alkyl groups are electron donating, the increase in frequency can be taken to indicate an increase in the C═N bond order.

The C═S stretch in $Pt(S_2CNH_2)_2$ occurs at 820 cm^{-1} as coupled vibration, coupling being with NH_2 rock (5). In the deuterated complex, the band is lowered to 710 cm^{-1} and is coupled with ND_2 rock (5). In nickel dimethyldithiocarbamate, the C═S band is practically pure and occurs at 975 cm^{-1}. The shift of C═S frequency is in the opposite direction to that observed for C—S vibration, which is a fairly coupled vibration. The increase of C═S frequency may indicate increased $p\pi$–$p\pi$ bonding of carbon and sulfur. It has been noted by Chatt *et al.* that in dithiocarbamate ligand, the —NR_2 group acts as a very strong electron releasing moiety, forcing the sulfur atoms to accept electrons from it (10). This electron drift into sulfur atoms will increase their electron donor capacity, which makes the formation of strong complexes with metals possible. It may, therefore, be expected that dialkyldithiocarbamates should be stronger donors than $S_2CNH_2^-$. This is also borne out by the M—S

frequencies of the respective nickel(II) complexes of these ligands. The M—S frequency of the nickel complex of the former ligand occurs at 410 cm^{-1}, while that of the latter (5) near 380 cm^{-1}. The assignment of 975 cm^{-1} band for C═S is justified from infrared spectra of the selenium analogue in which the band has been found to shift to lower frequency (15) as expected. The C—S frequency in the nickel dimethyldithiocarbamate has been found at 600 cm^{-1}, while it occurs at 622 cm^{-1} in platinum dithiocarbamate (5), $Pt(S_2CNH_2)_2$.

The M—S stretching frequencies occurring in the A_1 vibrations are strongly coupled with ring deformation and other bending modes of vibrations, while the M—S stretching frequency occurring at 410 cm^{-1} in the B_2 vibrations is a pure band. It may be noted that Moore and Larson (7) place the probable M—S stretching frequencies around 500 cm^{-1} in molybdenum dialkyldithiocarbamates, and Bagnall *et al.* (8) around 300 cm^{-1} in actinide complexes of dialkyldithiocarbamates, but definite assignment was not made by the latter investigators because of the occurrence of too many bands in the region. The M—S stretch occurs in the region 405–410 cm^{-1} in copper and zinc complexes, which have different structures. Thus the band is quite insensitive. The band at 385 cm^{-1} for C—N—C′ bending is justified since a strong band at 360 cm^{-1} has been assigned to similar C—N—C′ bending in N,N′-dimethylformamide (16).

A comparison of dithiocarbamates and N-alkyldithiocarbamates with N,N-dialkyldithiocarbamates is interesting. The bands at 1438, 820, 622, and 375 cm^{-1} in $Pt(S_2CNH_2)_2$ for C⋯N stretching, C═S stretching, C—S stretching, and M—S stretching, respectively, are observed at 1560, 665, 612, and 357 cm^{-1} in N-methyldithiocarbamate complex (5). It is argued that since the electron donating tendency of the alkyl group is expected to increase the C═N bond order and "decrease the C—S and Pt—S bond orders", the direction of the band shifts in N-alkyldithiocarbamate is in accordance with the predictions (5). In dialkyldithiocarbamates, the bands are observed at 1550, 975, 600, and 410 cm^{-1} region for the respective vibrations mentioned above. It is clear that the above argument for the C═S and M—S bond orders being decreased on electron donation from alkyl groups does not seem to hold. In fact, an increase in C═N, C═S, and M—S stretching frequencies is expected. Coucouvanis and Fackler found that dithiocarbamate square planar complex of nickel(II) forms adducts with nitrogen bases more easily than do the dialkyldithiocarbamates (4). This indicates that dialkyldithiocarbamates are better donors than dithiocarbamates. This is in accordance with the prediction that dialkyldithiocarbamate should be a better donor because of electron flow from $—NR_2$ group, as discussed before. The trend in the shift of M—S and C—S frequencies in N-alkyldithiocarbamate is unexpected. Since the molecule lacks symmetry, coupling of the vibrations not possible in dithiocarbamate and its dialkyl derivatives may be held responsible for this shift.

Apart from the bands discussed above, the well-known methyl deformation modes, asymmetric and symmetric, occur at 1445 (s) and 1400 (vs) cm^{-1}, and the methyl rocking vibrations at 1148 (s) and 1050 (m) cm^{-1} in nickel dimethyldithiocarbamate. The other bands observed for the same complex in the region 700–300 cm^{-1} are 676, 650, 590, 550, 375, 355, 341, 327, 315, and 302 cm^{-1}. All these bands are weak or very weak in intensity.

(b) Nickel Dimethyldiselenocarbamate

The substitution of selenium for sulfur, called "selenation" similar to deuteration, can be useful for assignment of the infrared bands. Jensen and Nielsen (17) have observed that the spectra of sulfur and their corresponding selenium compounds are almost identical except that the bands connected with sulfur are shifted by about 30–100 cm^{-1} lower in the selenium compounds. The force field for selenium compound is not expected to differ widely from that of the sulfur compounds. We have, therefore, carried out normal coordinate analysis for nickel dimethyldiselenocarbamate, using the force constants of nickel dimethyldithiocarbamate. The chief interest in these calculations is the assignment of the metal–ligand vibrations, in particular, and the shift in other frequencies, in general. The calculated frequencies along with their assignments are given in Table VI. Unfortunately, we could not get the spectrum of nickel dimethyldiselenocarbamate to "evaluate" the data. However, we

TABLE VI

Frequencies (cm^{-1}) of nickel dimethyldiselenocarbamate and their assignment

Mode	Calcd. frequency	Assignment

were able to get the infrared spectra of nickel diethyldiselenocarbamate in the NaCl and KBr regions (18). The spectrum has bands at 1520, 987, 570, and 415 cm^{-1} which could be assigned to ν(C═N), ν(C′—N) coupled with δ(C′NC′), ν(C—Se), and ν(C′—N) coupled with ν(M—Se), respectively, in the A_1 vibrations, the calculated frequencies being 1547, 977, 574, and 390 cm^{-1}. The bands are also observed at 1278 and 950 cm^{-1}, the calculated frequencies being 1278 and 946 cm^{-1}, for ν(C′—N) and ν(C═Se), respectively, for the B_1 type of vibrations. In the spectra of ethyl and methyl compounds, no major changes in the bands listed above are expected unless coupling with CH_2 or C—C vibrations affects these bands. The above comparison is therefore taken to be valid. The agreement between the calculated and available observed frequencies lends confidence to the assignment of the bands of diselenocarbamate. The assignment of the infrared frequencies in the selenium compound is similar to that of the sulfur compound, the C═S stretching frequency being lowered on selenation by about 35 cm^{-1}. The lowering is in conformation with the observation of Jensen *et al.* (15). Some of the bands are not affected as expected and only the metal–ligand frequency seems to have been affected largely. The metal–selenium stretching frequency occurring at 308 cm^{-1} (B_2) is lower by about 100 cm^{-1} as compared to the metal–sulfur frequency at 410 cm^{-1}. The calculation is thus of particular interest in assigning the metal–ligand stretching frequency and other frequencies in the far infrared region.

Acknowledgments

The authors wish to thank Professor M. R. A. Rao for his keen interest in the work. The help of Dr. K. J. Rao, Indian Institute of Technology, Kanpur, in recording a spectrum, is warmly acknowledged. Thanks are also due to Messrs. A. M. Pathan and B. S. N. Murthy of Hindustan Aeronautics Ltd., Bangalore, for their assistance in computation.

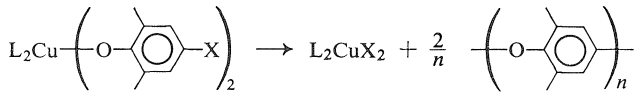
Phenoxo complexes of copper(II)

J. F. HARROD[1]
General Electric Research & Development Center, Schenectady, New York 12301

Received August 14, 1968

A series of phenoxo complexes of copper(II) containing a variety of halophenoxo ligands and a variety of amine ligands has been prepared. The thermal stability of the complexes with regard to the decomposition reaction:



was found to be lower with those ligands, L, which increase the oxidizing power of the copper(II) and vice versa.

The intense absorption bands in the visible region exhibited by these complexes have been assigned to a metal-to-ligand charge transfer process.

Canadian Journal of Chemistry, 47, 637 (1969)

Introduction

The preparation and properties of transition metal alkoxo derivatives have been studied in great detail (1). The aryloxo derivatives, on the other hand, have been virtually ignored, except for chelating ligands which utilize an aryloxy function. Although innumerable compounds are known containing such chelating ligands as salicylaldehydate, 8-hydroxyquinolinate, and 2-azophenolate, the specific properties of the aryloxy–metal bond have not been investigated.

A series of simple phenoxotitanium complexes was prepared by Funk *et al.* (2), from a variety of substituted phenols. More recently, a structural study by Watenpaugh and Caughlin (3) has shown the dimeric dichlorodiphenoxotitanium-(IV) to contain both linear and bridging phenoxo groups, as well as titanium in an unusual five-coordinate state. The latter authors commented on the unusual color of phenoxotitanium complexes, but did not advance a satisfactory explanation.

The classical use of iron(III) for the colorimetric determination of phenols has prompted several investigations (4, 5) to seek the origin of the characteristic intense colors obtained. There is general agreement that phenoxoiron(III) complexes are responsible for the colors, but the evidence is largely circumstantial and no stoichiometric complex has ever been isolated, or characterized.

A series of bis(phenoxo)bis(pyridine)copper-(II) complexes was prepared and characterized by Blanchard *et al.* (6) using a variety of substituted phenols. Such complexes are of considerable chemical interest because of the important industrial (7) and biological (8) role of copper(II) in the selective catalytic oxidation of phenols. A remarkable property of certain 4-halophenoxocopper(II) complexes is their tendency to undergo thermal decomposition (6), according to the generalized reaction [1], where L represents a neutral ligand and X is a halogen atom. It has been suggested (6) that the initiating step, both in reaction [1] and in the catalytic oxidative coupling of phenols (7), is ligand-to-

[1] 
metal charge transfer to produce a phenoxy radical and a copper(I) species.

The present study was undertaken to answer two questions. Firstly, what is the dependence of the thermal stability of phenoxocopper(II) complexes on the nature of the neutral ligand. Secondly, what is the cause of the intense colors

[1]Present address: Chemistry Department, McGill University, Montreal, Quebec.

of phenoxocopper(II) complexes. (They are brown to purple in solution, dark brown to black crystals.)

Experimental

(1) Preparation of Phenoxo Complexes from Aqueous Solutions

Complexes derived from acidic phenols (in the present work this means those with at least two halide substituents) were prepared easily and in high yield from aqueous solutions of reagents. The standard procedure was to add the required amount of neutral ligand to a solution of $CuSO_4.5H_2O$ (0.02 mole) in distilled water (50 ml). A second solution containing the phenol (0.04 mole) and sodium hydroxide (0.04 mole) in water (50 ml) was then slowly added to the copper solution with vigorous stirring. The resulting dark brown slurry was filtered, washed with water, and dried. Recrystallization of pyridine complexes was effected by dissolution in a minimum of hot benzene, filtration, and addition of excess methanol to the hot benzene filtrate. The tetramethyl- and tetraethylethylenediamine complexes were recrystallized from hot toluene–hexane solutions. The yields of these complexes were essentially quantitative. Analyses of some representative complexes are given in Table I.

(2) Preparation of Complexes from Bis(2,4,6-trichlorophenoxo)bis(pyridine)copper(II)

The high solubility of the pyridine complex in benzene permitted the simple preparation of other complexes by displacement of the pyridine in benzene solution.

Treatment of a hot saturated solution of the pyridine complex in benzene (about 5.0 g of complex in 50 ml of benzene) with a boiling solution of 2,2′-dipyridyl (1.6 g in 10 ml benzene), followed by dilution of the mixture with an equal volume of boiling hexane, yielded black crystals of the dipyridyl complex on cooling to room temperature. The yield (5.0 g) was essentially quantitative. The *o*-phenanthroline complex was prepared by the same method.

The ammonia, ethylamine, and ethylenediamine complexes were quite insoluble in benzene and could be precipitated by careful addition of the appropriate ligand to a benzene solution of the pyridine complex at room temperature. The ammonia complex was best prepared by bubbling gaseous ammonia into the benzene solution. The other amine ligands were added as solutions in benzene. Addition of excess of these saturated amine ligands resulted in the formation of ionic complexes by expulsion of the phenoxo ligand from the coordination sphere. The ionic complexes were blue, whereas the neutral complexes were light brown in the case of ammonia and ethylamine, and bright orange in the case of ethylenediamine.

Analyses of some derivatives prepared from the pyridine complex are given in Table I.

The orange bis(ethylenediamine) complexes with trihalophenols were also easily prepared by the aqueous solution method described above.

(3) Spectra of Complexes

Visible and ultraviolet spectra were measured with a Perkin–Elmer 202 recording spectrophotometer.

Infrared spectra were measured with a Perkin–Elmer Model 521 grating spectrometer. Samples were studied in carbon tetrachloride solution and dispersed in potassium bromide pellets.

Results

Types of Phenoxocopper(II) Compounds

Most amine ligands were found to yield tetracoordinate complexes of the type $L_2Cu(OPh)_2$ (L = monofunctional amine ligand; OPh = halosubstituted phenoxo ligand) using the methods described above. A notable exception was ethylenediamine which yielded complexes containing two ethylenediamine ligands per copper(II) ion by both synthetic methods.

Saturated aliphatic amines (including ethylenediamine) in excess yielded blue ionic complexes, soluble in water, in which the phenoxo ligand had presumably been expelled from the coordination sphere. This phenomenon was not

For personal use only.

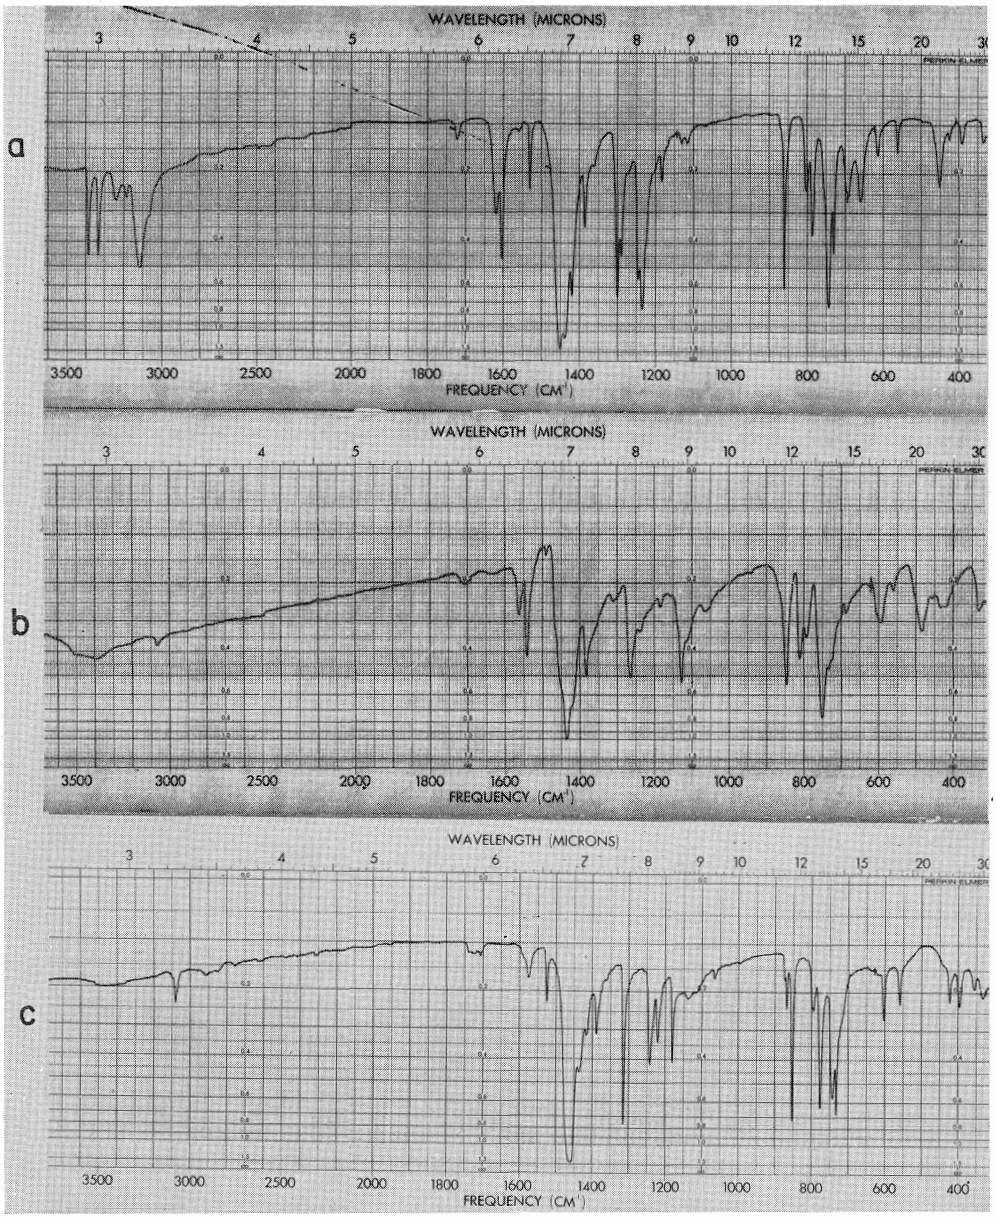

FIG. 1. Infrared spectra of (*a*) bis(trichlorophenoxo)diamminecopper(II), (*b*) copper(II)trichlorophenolate, and (*c*) sodium trichlorophenolate.

observed with unsaturated aromatic bases. In fact pyridine was found to be an excellent solvent for the $Py_2Cu(OPh)_2$ complexes and their spectra were qualitatively the same in pyridine as in benzene. It may thus be concluded that pyridine has virtually no tendency to increase the coordination number of these tetracoordinate complexes, nor to displace the phenoxo ligand.

A fourth type of complex was obtained by the aqueous solution method if the reaction was carried out in the absence of any added neutral ligand. The dark brown amorphous compounds

TABLE III

Thermal stability of trichlorophenoxocopper(II) complexes

Neutral ligand	Thermal behavior
Biquinolyl, triphenylphosphine	Complexes too unstable to be isolated
2,6-Dimethylpyridine	Stable enough to be isolated as solid. Lifetime in benzene ~ hours at room temperature*
Ammonia ethylamine	Rapid decomp. at ~ 90 °C in solid state. Lifetime in benzene ~ days at room temperature*
Pyridine	Sharp decomp. at 125–127 °C in solid. Lifetime in benzene ~ months at room temperature,* ~ 12 h at 80 °C
None	Sharp decomp. at 143–145 °C in solid
2,2′-Dipyridyl	m.p., 175–177 °C; decomp. ~ 195 °C
Tetraethylethylenediamine	m.p., 167–168 °C
Tetramethylethylenediamine	m.p., 182–184 °C. Lifetime in benzene ~ years†
o-Phenanthroline	m.p., 220 °C; decomp. ~ 220 °C

*These observations were made on numerous solutions prepared for spectroscopic and other measurements.
†One solution of this complex which had been stored for two years, was found to be completely decomposed. The isolated polymer was found to have $M_n \sim 80\,000$, by far the highest molecular weight ever obtained by thermal decomposition of phenoxy complexes.

obtained had the stoichiometry $Cu(OPh)_2$, and were characterized by their almost complete insolubility. The only solvent found for these compounds was dimethylformamide and reprecipitation by addition of water to dimethylformamide solutions gave dark brown crystalline compounds containing coordinated dimethylformamide.

Infrared Spectra of the Tetracoordinate Complexes

Table II lists some of the principal infrared absorptions exhibited by a series of trichlorophenoxocopper(II) complexes. A comparison between the spectrum of the pyridine complex and the spectra of sodium trichlorophenolate and dibromobis(pyridine)copper(II), indicates that all of the bands of the former may be accounted for in terms of complexed pyridine and a trichlorophenolate anion, except for minor frequency shifts. The same is true of the other complexes, including the bis(ethylenediamine) complex. The only obvious deviation occurs with the simple copper trichlorophenolate which contains no neutral ligands.

The spectra of sodium trichlorophenolate, copper trichlorophenolate, and bis(trichlorophenoxo)diamminecopper(II) are shown in Fig. 1. The most significant variations in these spectra occur in the 1200–1300 cm^{-1} region, the region in which the C—O vibrations of the phenoxy group are expected to occur. Although the ammine complex spectrum is somewhat different from that of sodium trichlorophenolate in this region, the difference is small compared to that of the copper trichlorophenolate.

Thermal Stability of (Trichlorophenoxo)-copper(II) Complexes

All of the trichlorophenoxo complexes thus far prepared were found to decompose according to eq. [1]. The ease of decomposition was found qualitatively to vary to a considerable degree, depending on the nature of the neutral ligand. Addition of biquinolyl, or triphenyl phosphine to benzene solutions of the pyridine complex resulted in rapid production of poly(dichlorophenyleneoxide) at room temperature, whilst the dipyridyl complex was stable for several years in benzene solution. Some qualitative data on the thermal decomposition of solutions, or pure compounds are shown in Table III.

In all cases of decomposition, the poly(dichlorophenyleneoxide) was isolated and characterized according to previously described procedures (6). The copper chloride complexes resulting from decomposition were only characterized in the case of the pyridine complex (Py_2CuCl_2), the uncomplexed copper trichlorophenolate ($CuCl_2$), and the tetramethylethylenediamine complex referred to in footnote (marked †) to Table III (dichlorotetramethylethylenediaminecopper(II)).

Electronic Spectra of Phenoxocopper(II) Complexes

The spectrum of bis(trichlorophenoxo)bis-(pyridine)copper(II) is shown in Fig. 2. This spectrum was typical of all the phenoxo complexes examined and may be discussed in terms of four regions.

A ligand band system in the 40 to 50 kK (1 kK = 1000 cm^{-1}) region was observed in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

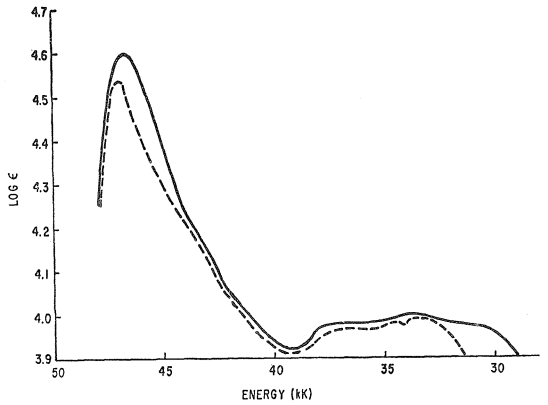

FIG. 2. Ultraviolet spectra of: ------, trichlorophenol; and ——, bis(trichlorophenoxo)bis(pyridine)copper(II) (in methanol solution).

methanol solution. Within the sensitivity and resolution of the instrument, these high energy ligand bands were not significantly altered by complexing and were not studied in any detail.

In benzene all of the complexes examined obeyed the Beer–Lambert law. Three band systems were observed at $\lambda_{max} \sim 35$, ~ 27, and ~ 20 kK. The spectrum of the tetramethylethylenediamine complex is shown in Fig. 3. The 35 kK band system, arising, at least partly, from a phenolate ligand transition, was strongly perturbed by varying the neutral ligands of the complex. The changes occurring in this band, with trichlorophenoxocopper(II) complexes, are illustrated for several neutral ligands in Fig. 4. The 27 kK band appeared as a shoulder on the low energy tail of the 35 kK band, and was present in all of the complexes examined. This band did not appear to change intensity, or position, on varying the neutral ligands.

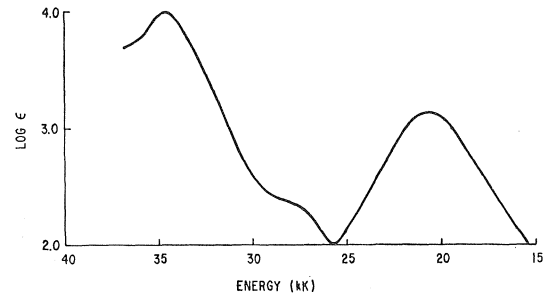

FIG. 3. Spectrum of bis(trichlorophenoxo)-*N*,*N*,*N*′,-*N*′-tetramethylethylenediaminecopper(II) in the ultraviolet–visible region (in benzene solution).

The band in the 19 to 23 kK region is mainly responsible for the intense colors of the phenoxocopper(II) complexes. The absorption maximum for this band was found to undergo shifts on substituting different neutral ligands into a given phenoxo complex. Data for a number of complexes in benzene and other solvents are given in Table IV.

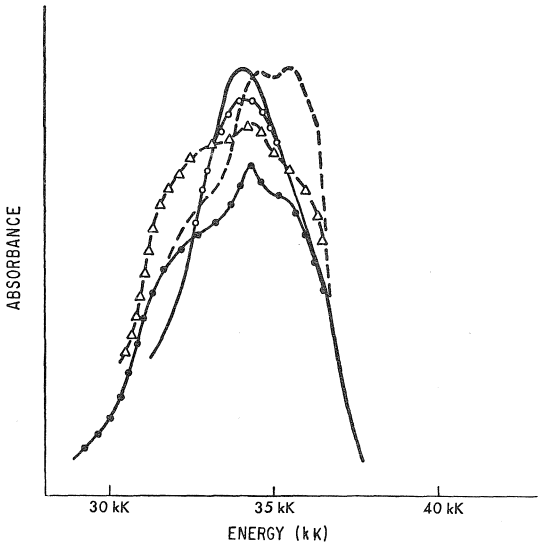

FIG. 4. Effect of amine ligands on the 35 kK band system of trichlorophenoxocopper(II) complexes. ------, pyridine; —●—●—, NH_3; —△—, $C_2H_5NH_2$; —○—, tetramethylethylenediamine; ——, tetraethylethylenediamine.

The Structure of Phenoxocopper(II) Complexes

Chemical analysis, molecular weight data, and infrared spectra obtained in the present study and those reported in ref. 6, all indicate that the majority of phenoxocopper(II) complexes are four-coordinated and monomeric.

A determination of the crystal structure of bis(trichlorophenoxo)*N*,*N*,*N*′,*N*′tetramethylethylenediaminecopper(II) has recently been completed (9). In this complex the copper(II) ion is coordinated by two nitrogens and two oxygens in an approximately square planar arrangement. There is a small tetrahedral distortion giving an angle of ca. 20° between the N—Cu—N and the O—Cu—O planes. A schematic representation of the molecule is shown in Fig. 5.

Perhaps the most important property of this molecule, as far as the present study is concerned,

is the Cu—O—C bond angle of ca. 120° and the resulting very close approach of the two rings of the phenoxo ligands. That this close approach was not primarily responsible for the charge transfer bands observed in the present study may be concluded from the fact that these bands were also observed in the complexes with monodentate ligands. The pyridine complex had no detectable dipole moment and must be *trans*, a configuration which would make close approach of the ligand rings impossible.

Discussion

Thermal Stability of Trichlorophenoxo Complexes

If, as has been previously suggested (6), the initiation step in the thermal decomposition reaction [1] is a ligand-to-metal electron transfer, the nature of the neutral ligand should strongly influence the thermal stability of the starting complex. After a thorough study of the effect of amine ligands on the redox potential of the Cu(II)/Cu(I) system, James and Williams (10) concluded that the order for stabilization of Cu(II) was ethylenediamine ≫ 2,2′-bipyridyl > 1,10-phenanthroline > pyridine ~ ammonia ≫ 2,2′-biquinolyl. The most important factors governing this sequence were the chelate effect (Cu(II) forms chelates readily, Cu(I) is reluctant to form chelates) and the π-acceptor property of the ligand. The latter was invoked by James and Williams (10) to explain the order of potentials of the dipyridyl and phenanthroline complexes. The anomalous position of the biquinolyl ligand in the series was attributed to its poor ability to chelate, due to steric interference by the 8,8′ hydrogens.

In the present study a striking correlation was found to exist between the thermal stability of phenoxocopper(II) complexes and the position of the amine ligand in the James and Williams sequence of oxidation potentials. Those complexes containing amine ligands which preferentially stabilize copper(I) were found to be markedly less stable than those containing ligands expected to enhance the stability of copper(II). Although no oxidation potential data are available for tetraalkylethylenediamine complexes, they would certainly be expected to stabilize copper(II) and the phenoxo complexes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

containing such ligands were found to be exceptionally resistant to thermal decomposition.

The Electronic Spectra of Phenoxocopper(II) Complexes

The outstanding feature of the visible–ultraviolet spectra of phenoxocopper(II) complexes is the general occurrence of an intense band in the 20 kK region. The intensity of this band is too high for a simple d → d transition and at first sight it was tempting to assign the band to a ligand-to-metal charge transfer process. Examination of the experimental observations argued against such an assignment. The evidence may be summarized as follows:

(*i*) Complexes with a low energy ligand-to-metal charge transfer would be expected to decompose more readily than those with a higher energy charge transfer. In fact, complexes which have absorption at lower energy have been found to be much more thermally stable than complexes with absorption at high energy.

(*ii*) The thermal stability of complexes follows the sequence of oxidation potentials for Cu(I)/Cu(II) couples in the presence of various amine ligands. For example, the thermal stability of 2,4,6-trichlorophenoxo complexes was found to be in the sequence: *o*-phenanthroline ~ bipyridyl > pyridine ~ NH_3 > biquinolyl. The energy of the 20 kK band followed the inverse of this sequence.

(*iii*) In the series of complexes of 4-chloro-, 2,4-dichloro-, 2,4,6-trichloro-, and pentachlorophenol, with the same neutral ligand, the absorption moves progressively to lower energy. This shift is in a direction contrary to that expected for a ligand-to-metal charge transfer, on the basis of the expected ease of oxidation of the corresponding phenoxide ion.

This evidence strongly suggests the origin of the 20 kK band to be a metal-to-ligand charge transfer, rather than the reverse. On the basis of chemical intuition, the latter proposition seems unlikely. In effect, it requires the donation of an electron by Cu(II), a good oxidizing agent, to a phenoxide ion, already carrying negative charge and normally considered to be a reducing species. However, a qualitative study of the ligand and metal energy levels indicates that such a transition is not unlikely.

The existence of metal-to-ligand charge transfer has been postulated and discussed at some length by Jørgensen (11). He suggested that charge transfer bands in certain pyridine and *o*-phenanthroline complexes may originate from the excitation of an electron in an atomic-like orbital on the metal ion to an antibonding π* orbital on the ligand. Such a transition could certainly be postulated to occur in phenoxo complexes.

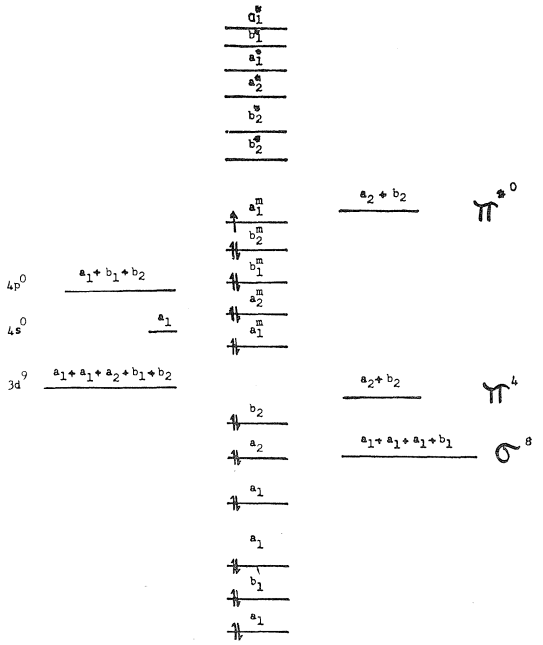

FIG. 6. Schematic molecular orbital diagram for a *cis*-bis(phenoxo)copper(II) complex.

A qualitative molecular orbital energy level diagram for *cis*-bis(trichlorophenoxo) complexes is shown in Fig. 6. It is assumed that the molecule exhibits ideal C_{2v} symmetry and that the neutral ligands only contribute orbitals of σ symmetry. The phenoxo ligands were assumed to contribute σ-orbitals, a set of low energy and a set of high energy π-orbitals. The molecular orbital diagram for a *trans*-complex (D_{2h}) would not differ qualitatively from Fig. 5, nor would the inclusion of π-orbitals from the neutral ligands cause serious change.

The existence of metal-to-ligand charge transfer may be understood in terms of excitation from $b_2{}^m$, or $a_1{}^m$ orbitals (largely associated with the metal) to $b_2{}^*$, or $a_2{}^*$ orbitals (ligand antibonding π-orbitals associated largely with oxygen). Similarly, a ligand-to-metal charge

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

transfer band would be expected as a result of excitations from the highest energy a_1 σ-bonding orbital, and/or the a_2 and b_2 π-bonding orbitals to a_1^m. Such transitions are almost certainly responsible for the manifold of bands in the 35 kK region (c.f. Fig. 3). It is interesting to note that the latter bands do in fact extend to lower energy in those complexes exhibiting poor thermal stability. The shifts of the 20 and 35 kK band systems in opposing directions suggest that the primary effect of the amine ligands is to raise, or lower, the metal orbitals relative to the phenoxo ligand orbitals.

The effect of solvent on the metal-to-ligand charge transfer is not easily interpreted. Solvation at the vacant coordination positions above and below the plane of the complex should raise the average energy of the metal orbitals. The low value for the transition energy in pyridine compared to hexane, benzene, and chloroform is in accord with such an interpretation. The slightly higher value in tetrahydrofuran and the much higher values in methanol or ethanol, must, however, be considered anomalous. In the latter solvents a specific effect, such as hydrogen bonding to the phenoxy oxygen, may be operative.

Conclusions

The properties of phenoxocopper(II) complexes indicates that phenolate ligands can participate in both metal-to-ligand and ligand-to-metal charge transfer. In the case of copper(II) complexes, both types of transition are at relatively low energy and the energies of the transitions are quite sensitive to the character of both the phenolate and the other ligands present in the complex.

At present the most probable initiation step for decomposition of phenoxocopper(II) complexes involves homolysis of the Cu—O bond via ligand-to-metal charge transfer. There is no evidence to date to suggest that the low energy metal-to-ligand charge transfer has any relationship to the chemistry of decomposition. A detail study of the kinetics and mechanism of this reaction is in progress.

Ion–molecule reactions in vinyl chloride and vinyl bromide

J. A. HERMAN[1], J. J. MYHER[2], AND A. G. HARRISON
Department of Chemistry, University of Toronto, Toronto 5, Ontario

Received June 24, 1968

The following ion–molecule reactions involving fragment ions in vinyl chloride have been studied and rate constants measured for ions of 2.4 eV exit energy.

$$C_2H_2^+ + C_2H_3Cl \rightarrow C_2H_3Cl^+ + C_2H_2 \qquad k = 1.9 \times 10^{-9}\ cm^2\ molecule^{-1}\ s^{-1}$$

$$C_2H_3^+ + C_2H_3Cl \rightarrow C_2H_4Cl^+ + C_2H_2 \qquad k = 1.5 \times 10^{-10}\ cm^3\ molecule^{-1}\ s^{-1}$$

$$C_2H_3^+ + C_2H_3Cl \rightarrow C_4H_5^+ + HCl \qquad k = 5.6 \times 10^{-10}\ cm^3\ molecule^{-1}\ s^{-1}$$

The reaction of the $C_2H_3Cl^+$ molecule–ion produces $C_3H_4Cl^+$, $C_4H_5Cl^+$, and $C_4H_6Cl^+$ both in a second order and a third order reaction. The apparent rate coefficient for the second order reaction is approximately $1 \times 10^{-11}\ cm^3\ molecule^{-1}\ s^{-1}$ while that for the third order reaction is approximately $1 \times 10^{-25}\ cm^6\ molecule^{-2}\ s^{-1}$. The product distributions from both the second and third order reactions have been determined.

In vinyl bromide the $C_2H_3^+$ ion produces $C_4H_5^+$, $C_4H_6^+$, and $C_2H_4Br^+$ while the $C_2H_3Br^+$ ion reacts to form $C_4H_6Br^+$ both in a second order and a third order reaction.

Canadian Journal of Chemistry, 47, 647 (1969)

Introduction

Recently Baldeschwieler *et al.* (1), using ion cyclotron resonance (i.c.r.) spectroscopy, have studied the ion–molecule reactions occurring in gaseous vinyl chloride subject to electron bombardment. They have shown that reaction of $C_2H_3Cl^+$ with neutral vinyl chloride yields three products: $C_3H_4Cl^+$, $C_4H_5Cl^+$, and $C_4H_6Cl^+$, while reaction of $C_2H_3^+$ yields $C_4H_5^+$ and $C_2H_4Cl^+$. In addition to identifying the primary reactions they have followed the consecutive reactions to a high order at relatively low pressure by using appropriate ion trapping conditions to increase the reaction time. However, they have not reported rate constants for the primary reactions. As part of our study (2–4) of the ionic reactions in unsaturated systems we have investigated the ionic reactions in vinyl chloride using a conventional medium pressure mass spectrometer. Our reaction identification is essentially in agreement with that made previously; however, we find that the $C_2H_3Cl^+$ ion disappears both by second and third order reactions. The rate constants (and product distributions) for both reactions have been determined as well as the rate constants for the other primary reactions.

The ion–molecule reactions of vinyl bromide have been investigated briefly.

[1]Visiting scientist 1967–1968, permanent address: Department of Chemistry, Laval University, Quebec.
[2]Holder of NRCC Studentships 1963–1966.

Experimental

The experiments were carried out on the medium pressure mass spectrometer previously described (5). The pertinent operating conditions were a source temperature of approximately 100 °C and a primary ion travel distance of 0.54 cm. Pressure studies were carried out at repeller fields corresponding to either 2.4 or 3.4 eV ion exit energy. The ionizing electron beam was pulsed and primary ion residence times were measured directly by the deflection technique previously described (5). Source pressures were measured directly using an MKS Baratron capacitance micromanometer.

The vinyl chloride and vinyl bromide were obtained from Matheson Company and were purified by bulb-to-bulb distillation prior to use. No impurities were detected in the mass spectra.

Results and Discussion

Vinyl Chloride

Figures 1 and 2 show a typical pressure plot obtained at 2.4 eV ion exit energy and 20 eV nominal electron energy. The normalized intensities of the $C_2H_2^+$, $C_2H_3^+$, and $C_2H_2Cl^+$ ions show the exponential decrease with increasing pressure characteristic of reactive primary ions, while the intensity of the $C_2H_3Cl^+$ ion shows an initial increase followed by a decrease, indicating that it is the product of an ion–molecule reaction as well as a reactant ion. The product ions observed are $C_2H_4Cl^+$, $C_4H_5^+$, $C_3H_4Cl^+$, $C_4H_5Cl^+$, and $C_4H_6Cl^+$. The intensities of the first two increase in the manner expected for secondary ions; however, the shape of the curves for the latter three suggest that they are formed by a

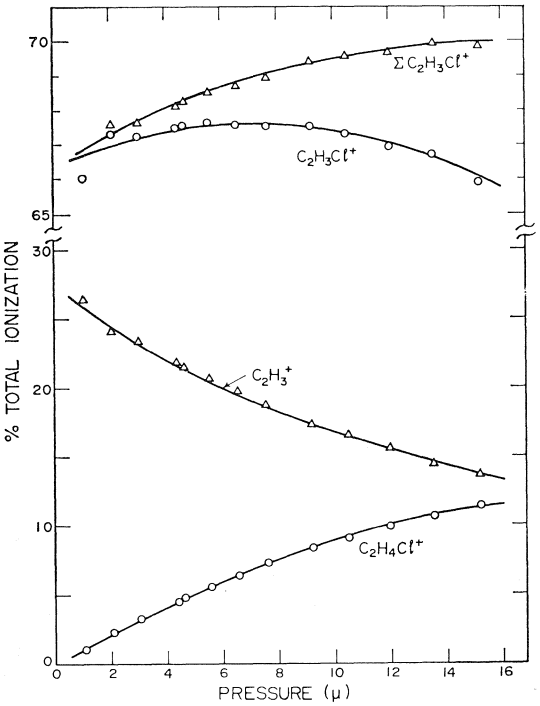

FIG. 1. Pressure plot vinyl chloride, 2.4 eV ion exit energy, 20 eV electron energy.

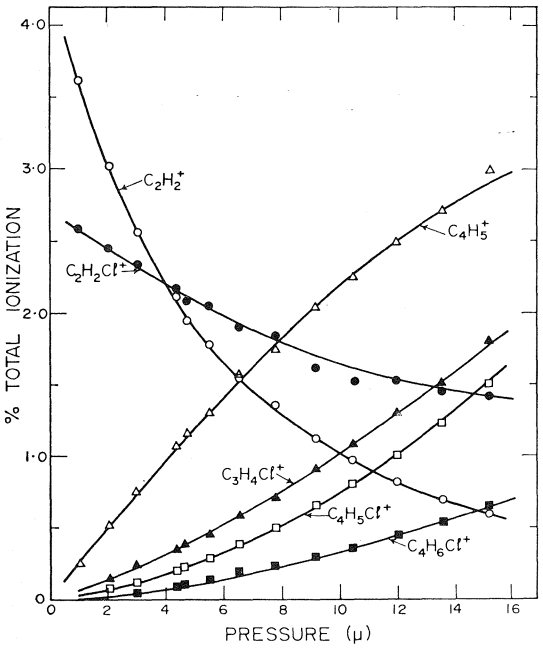

FIG. 2. Pressure plot vinyl chloride; conditions as for Fig. 1.

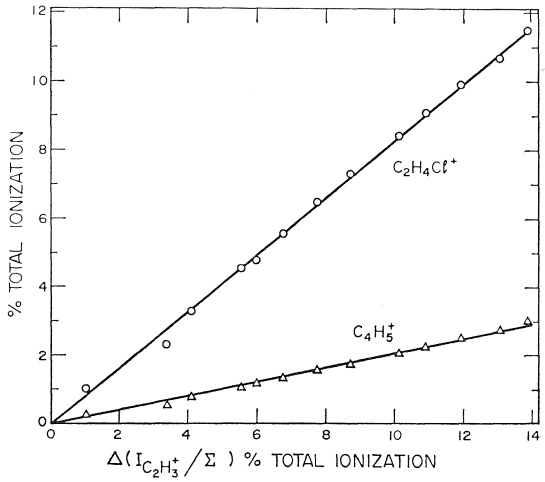

FIG. 3. $C_2H_4Cl^+$ and $C_4H_5^+$ intensities as function of $C_2H_3Cl^+$ reacted.

reaction which is second order in neutral vinyl chloride concentration.

Plots of the normalized $C_2H_4Cl^+$ and $C_4H_5^+$ intensities versus $\Delta(I_{C_2H_3^+/\Sigma})$ (i.e. the $C_2H_3^+$ reacted) are linear (Fig. 3) and give slopes which sum to approximately unity, indicating that $C_2H_3^+$ reacts to give only these products (reactions [1] and [2]).

[1] $C_2H_3^+ + C_2H_3Cl \rightarrow C_2H_4Cl^+ + C_2H_2$

[2] $C_2H_3^+ + C_2H_3Cl \rightarrow C_4H_5^+ + HCl$

Four runs at 2.4 eV ion exit energy gave a total rate constant for the disappearance of $C_2H_3^+$ of $7.1 \pm 0.3 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} with approximately 21% of the total reaction yielding $C_4H_5^+$. Three runs at 3.4 eV ion exit energy gave a total disappearance rate constant of $5.7 \pm 0.2 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} with approximately 18% of the reaction yielding $C_4H_5^+$.

The rate constant for disappearance of the small $C_2H_2Cl^+$ ion current was found to be approximately 5×10^{-10} cm^3 molecule^{-1} s^{-1}; however, the products of the reaction could not be identified and the ion may react either by proton transfer or by charge transfer.

Since the reaction of $C_2H_3^+$ accounts for the formation of both $C_4H_5^+$ and $C_2H_4Cl^+$ and no other significant products were observed, we conclude that $C_2H_2^+$ reacts by charge transfer. Indeed, if we assume, in agreement with earlier work (1) and the results presented below, that $C_3H_4Cl^+$, $C_4H_5Cl^+$, and $C_4H_6Cl^+$ originate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

from the reaction of $C_2H_3Cl^+$, we observe that the sum of the reactant and product ion currents, labelled $\sum C_2H_3Cl^+$ in Fig. 1, increases significantly with pressure, the increase being of the same magnitude as the decrease in the $C_2H_2^+$ ion current. Two determinations at 2.4 eV ion exit energy gave a rate constant of 1.9×10^{-9} cm^3 $molecule^{-1}$ s^{-1} and two determinations at 3.4 eV ion exit energy gave a rate constant of 1.8×10^{-9} cm^3 $molecule^{-1}$ s^{-1} for the charge transfer reaction [3].

[3] $C_2H_2^+ + C_2H_3Cl \rightarrow C_2H_3Cl^+ + C_2H_2$

As mentioned above, the shapes of the curves (Fig. 2) for the $C_3H_4Cl^+$, $C_4H_5Cl^+$, and $C_4H_6Cl^+$ product ions suggest that these products are formed in reactions which are predominantly second order in neutral molecule concentration. However, the interpretation of the results in Figs. 1 and 2 is complicated by the fact that the precursor $C_2H_3Cl^+$ ion is itself formed by reaction [3]. Therefore, we have carried out a number of runs at low electron energy where $C_2H_3Cl^+$ was the only significant primary ion. A typical pressure plot is shown in Fig. 4 for ions of 2.4 eV exit energy produced by electrons of 10.5 eV nominal electron energy, where

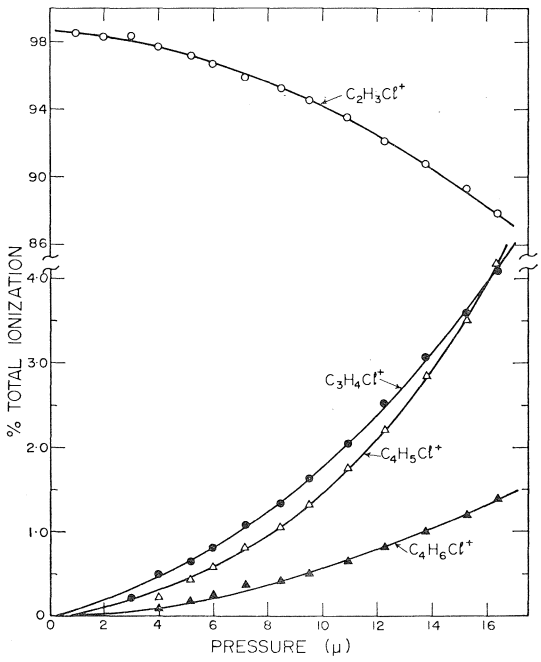

FIG. 4. Pressure plot vinyl chloride, 2.4 eV ion exit energy, 10.5 eV electron energy.

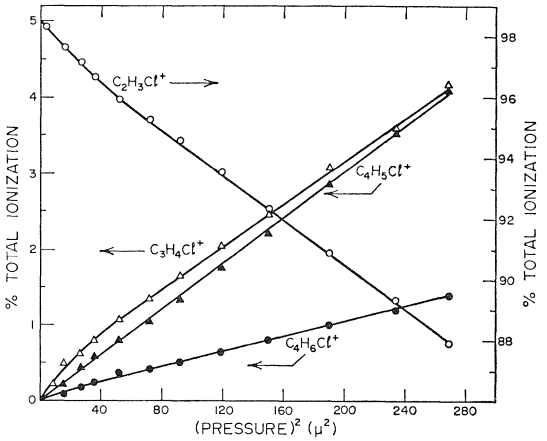

FIG. 5. Ion intensities vs. P^2.

$C_2H_3Cl^+$ comprises > 98% of the total ionization at low pressures. Neither the decrease of the $C_2H_3Cl^+$ intensity with pressure nor the increase of the product ion intensities with pressure are characteristic of reactions which are first order in neutral reactant concentration. Figure 5 shows a plot of the normalized product ion intensities as a function of the square of the ion source pressure. All plots are linear at higher pressures with a slight drop-off at lower pressures indicating that these ions are produced predominantly by reactions second order in neutral concentration with a possible small first order contribution at low pressures. Similarly the disappearance of $C_2H_3Cl^+$ is linear with P^2 at higher pressures, the initial non-linear portion indicating a small contribution from a reaction which is first order in neutral C_2H_3Cl. We, therefore, conclude that the formation of the $C_3H_4Cl^+$, $C_4H_5Cl^+$, and $C_4H_6Cl^+$ products is the sum of two reactions, one first order in C_2H_3Cl (reaction [4]) and one second order in C_2H_3Cl (reaction [5]).

[4] $C_2H_3Cl^+ + C_2H_3Cl \rightarrow C_3H_4Cl^+ + CH_2Cl$
$\rightarrow C_4H_5Cl^+ + HCl$
$\rightarrow C_4H_6Cl^+ + Cl$

[5] $C_2H_3Cl^+ + 2C_2H_3Cl \rightarrow C_3H_4Cl^+ + \text{neutrals}$
$\rightarrow C_4H_5Cl^+ + \text{neutrals}$
$\rightarrow C_4H_6Cl^+ + \text{neutrals}$

For the two concurrent reactions [4] and [5] at low total conversion of reactant we may write

$$[6] \qquad \frac{I_{S_x^+}}{\Sigma I_{p^+} \cdot P} = k_{4X}tK + k_{5X}tK^2P$$

TABLE I

Rate constants and product distribution from reaction of $C_2H_3Cl^+$

Run	Nominal electron energy (eV)	% of second order reaction			k_4 (total) ($\times 10^{11}$)	% of third order reaction			k_5 (total) ($\times 10^{25}$)
		$C_3H_4Cl^+$	$C_4H_5Cl^+$	$C_4H_6Cl^+$		$C_3H_4Cl^+$	$C_4H_5Cl^+$	$C_4H_6Cl^+$	
A	20	59	23	18	1.87	37	49	14	0.68

where $I_{S_{x^+}}$ is the ion current for product ion X^+ formed by second order and third order reactions with rate constants k_{4X} and k_{5X} respectively, ΣI_{p^+} is the sum of reactant and product ion intensities, P is the ion source pressure, t is the reaction time, and K is the proportionality constant relating the source concentration to the measured source pressure. A plot of the left hand side of eq. [6] vs. the source pressure for each product ion should lead to straight lines, the slope of each being proportional to the third order rate constant and the intercept proportional to the second order rate constant. The data from Figs. 4 and 5 are plotted in this manner in Fig. 6 where it can be seen that satisfactory straight lines result. The results for this plot and others carried out at higher electron energies are summarized in Table I.

The total second order rate constant k_4 is of the order of 10^{-11} cm^3 molecule^{-1} s^{-1}, a factor of 10^2 less than is normally observed for exothermic bimolecular ion–molecule reactions. The rate constant as well as the product distribution appear to be dependent on the ionizing electron energy. The reasons for the low bimolecular rate

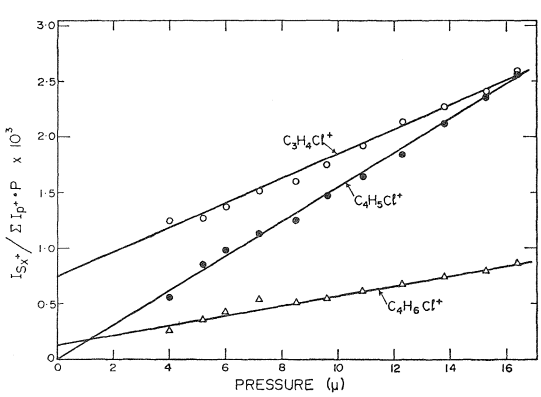

FIG. 6. $I_{S_X^+}/\Sigma I_{p^+}\cdot P$ vs. pressure, vinyl chloride.

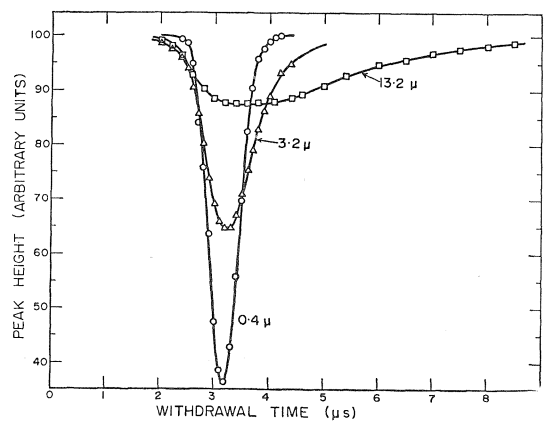

FIG. 7. Withdrawal curves for $C_2H_3Cl^+$ as function of pressure.

are not readily apparent. A possible explanation will be discussed below. In any event it is apparent that the majority of collisions do not lead to reaction but to reversion to reactants with or without charge exchange. In this regard it is significant that the withdrawal curves for $C_2H_3Cl^+$ (Fig. 7) show significant broadening and extend to very long withdrawal times as the source pressure is increased. This indicates that at the higher pressures a significant fraction of the $C_2H_3Cl^+$ ions have been retarded in their passage out of the ionization chamber through formation of a collision complex of finite lifetime which reverts to reactants with or without charge transfer. The charge transfer reaction has been detected in the i.c.r. work (1). The rate constant for the third order reaction shows a small but significant increase with decreasing electron energy, the opposite effect to that shown for the second order reaction. On the other hand, the product distribution from the third order reaction is independent of electron energy and is distinctly different from the distribution observed for the

second order reaction. The mechanism of the third order reaction cannot be elucidated from the present work.

Following the completion of our work Dr. T. O. Tiernan communicated to us the results (6) of a study of the ion–molecule reactions in vinyl chloride, using a tandem mass spectrometer (7), which provide considerable insight on the reactions of the vinyl chloride molecule ion. It is appropriate to compare our results obtained by conventional mass spectrometric techniques with those obtained by the tandem instrument.

Using the tandem instrument, Tiernan *et al.* (6) have bombarded C_2H_3Cl with $C_2D_3Cl^+$ ions of 0.3 eV energy. At low pressures of C_2H_3Cl (5 μ), where higher order ionic reactions should not occur, they observed the isotopically mixed products $C_3H_xD_{4-x}Cl^+$, $C_4H_xD_{5-x}Cl^+$, and $C_4H_3D_3Cl^+$ in the ratio 0.73:0.11:0.15. At high pressures of C_2H_3Cl (25 μ) in addition to the above products, they observed $C_3H_4Cl^+$, $C_4H_5Cl^+$, and $C_4H_6Cl^+$ in the ratio 0.42:0.36:0.23. Obviously the complex decomposing to form these latter products cannot contain deuterium and must be formed from two molecules of C_2H_3Cl. They propose the following mechanism, written in the present case for non-deuterated reactants

$$[7] \quad C_2H_3Cl + e \rightarrow C_2H_3Cl^{+*} + 2e$$

$$[8] \quad C_2H_3Cl^{+*} + C_2H_3Cl \rightarrow (C_4H_6Cl_2)^{+*} \rightarrow \text{products}$$

$$[9] \quad C_2H_3Cl^{+*} + C_2H_3Cl \rightarrow C_2H_3Cl + C_2H_3Cl^{+}‡$$

$$[10] \quad C_2H_3Cl^{+}‡ + C_2H_3Cl \rightarrow (C_4H_6Cl_2)^{+} \rightarrow \text{products}$$

The initial electron impact process is considered to lead to internally excited vinyl chloride ions $C_2H_3Cl^{+*}$ which react to form complexes (reaction [8]), which, because of their high excitation, revert to reactants so rapidly that only a small fraction survives for a sufficient length of time to undergo the structural rearrangements necessary to produce the condensation products. The vinyl chloride ion produced in the charge transfer reaction [9] is considered to be of lower energy content, with the result that the collision complex of reaction [10] is much longer lived and forms the observed products with high efficiency.

In general our results are consistent with this reaction scheme although they do suggest some modification of the details. Our product distribution from the second order reaction (Table I) is in quite good agreement with the distribution observed at low pressures of C_2H_3Cl in the tandem experiments. Further, our distribution for the third order reaction is also in reasonable agreement with that observed for the non-deuterated products formed at high C_2H_3Cl pressures in the tandem instrument.

As discussed above, the withdrawal curves (Fig. 7) indicate that a significant fraction of the $C_2H_3Cl^+$ ions have been retarded in their passage out of the ionization chamber. However, this broadening of the withdrawal curves is not consistent with a charge transfer reaction proceeding without momentum transfer as is implied by reaction [9] of the Tiernan mechanism. For such a charge transfer reaction simple kinematic considerations indicate that the product ions should have withdrawal times peaked relatively sharply at times a factor of 1.4 greater than the unreacted primary ions. The curves in Fig. 7 show no such contribution peaked[3] at 4.5 μs and we conclude that charge transfer without momentum transfer does not occur. On the other hand charge transfer through complex formation would lead to product ions with average withdrawal times approximately 1.1 times greater than the reactant ions and the broadening in Fig. 7 is consistent with this mechanism. Thus we would suggest that the charge transfer reaction, written as reaction [9], is better written as an alternative mode of fragmentation of the complex formed in reaction [8]. It is, of course, possible that a significant fraction of the complexes revert to reactants without charge transfer. In any event, since the collision rate constant k_8 is probably of the order of 10^{-9} cm^3 molecule^{-1} s^{-1} while the rate of formation of condensation products, $k_4 = 1 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}, only $\sim 1\%$ of the complexes form the observed C-3 and C-4 products. Thus we would suggest that the mechanism is more properly written as follows.

$$[7] \quad C_2H_3Cl + e \rightarrow C_2H_3Cl^{+*} + 2e$$

$$[8] \quad C_2H_3Cl^{+*} + C_2H_3Cl \rightarrow (C_2H_3Cl)_2^{+*}$$

$$[9a] \quad [C_2H_3Cl]_2^{+*} \rightarrow \text{products}$$

$$[9b] \quad \rightarrow C_2H_3Cl + C_2H_3Cl^{+}†$$

[3]In argon and krypton, where charge transfer without momentum transfer does occur, large peaks are observed in the withdrawal curves peaked at withdrawal times a factor of 1.4 greater than primary ions for gas pressures of ~ 4 μ (Jones and Harrison, unpublished results).

[10] $C_2H_3Cl^+\dagger + C_2H_3Cl \rightarrow [C_2H_3Cl]_2{}^+\dagger$

[11*a*] $[C_2H_3Cl]_2{}^+\dagger \rightarrow$ products

[11*b*] $\rightarrow C_2H_3Cl^+\dagger + C_2H_3Cl$

In the initial stages reaction [9*b*] will be much faster than reaction [10] leading to an overall third order rate constant for formation of $[C_2H_3Cl]_2{}^+\dagger$ $k = k_{9b}k_{10}t$ where t is the reaction time. The assumptions that $k_{9b} \approx 10^{-9}$ cm^3 molecule^{-1} s^{-1} (i.e., that 99% of the initial collision complexes lead to $C_2H_3Cl^+\dagger$) and that all the complexes of reaction [10] lead to observed products, leads to a predicted third order rate constant approximately a factor of 10 greater than the experimental rate constant. This suggests that a significant fraction (up to 90%) of the complexes, $[C_2H_3Cl]_2{}^+\dagger$, do not lead to observed products and leads us to include reaction [11*b*] in the reaction scheme.

Tiernan *et al.* (6) have suggested that the complex formed in reaction [8] is very short lived because of its high internal excitation energy while that formed in reaction [10] has a longer lifetime because of its lower energy content and that the differing product distributions in the second and third order reactions are determined by this internal excitation. Our results on the effect of electron energy on the second order reaction are not entirely consistent with this suggestion. One would expect on this basis that as the electron energy is lowered the internal excitation of the complex formed in reaction [8] should decrease with a corresponding increase in the lifetime and the rate of formation of observable products. In fact the observed rate constant (Table I) decreases. Further if the product distribution of the third order reaction represents that for "cool" complexes one would expect, as the electron energy is decreased, that the product distribution from the second order reaction should approach that observed for the third order reaction. Such is obviously not the case. In these two aspects our results do not support the suggestions of Tiernan *et al.* (6). One possible explanation is that the ions formed in the initial electron impact process are in various electronic states which react to form the observed products with different efficiencies and with different product distributions and the ion formed by charge transfer is in an electronic state (or states) distinctly different from those formed by electron impact.

Vinyl Bromide

The ion–molecule reactions in vinyl bromide were investigated briefly at low electron energies where $C_2H_3{}^+$ and $C_2H_3Br^+$ were the only significant primary ions. The products observed were $C_4H_5{}^+$, $C_4H_6{}^+$ (in minor yield), $C_2H_4Br^+$, and $C_4H_6Br^+$. The $C_4H_5{}^+$, $C_4H_6{}^+$, and $C_2H_4Br^+$ appeared to originate predominantly from reaction of the $C_2H_3{}^+$ fragment ion although in all cases the plot of the product ions intensity versus the $C_2H_3{}^+$ disappearance showed on upward curvature at higher pressures. Further the log plots for the disappearance of $C_2H_3{}^+$ were not linear and the explanation of both phenomena may be that $C_2H_3{}^+$ is formed by a third order reaction of $C_2H_3Br^+$. The $C_4H_6Br^+$ ion originated from the reaction of $C_2H_3Br^+$ and, as in the vinyl chloride system, the overall reaction is the sum of a second order and a third order contribution. Figure 8 shows a typical plot of the data in the form of eq. [6]. Three such determinations gave the following rate constants for ions of 2.4 eV exit energy.

[12] $C_2H_3Br^+ + C_2H_3Br \rightarrow C_4H_6Br^+ + Br$

$k = 6.5 \pm 0.2 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1}

[13] $C_2H_3Br^+ + 2C_2H_3Br \rightarrow C_4H_6Br^+ + ?$

$k = 5.5 \pm 0.2 \times 10^{-26}$ cm^6 molecule^{-2} s^{-1}

It is probable that the mechanism of reaction [13] is similar to that of the third order reaction in vinyl chloride. The $C_3H_4Br^+$ and $C_4H_5Br^+$, analogous to the $C_3H_4Cl^+$ and $C_4H_5Cl^+$ ions formed in vinyl chloride, were not observed. A more detailed comparison of the reactions in the vinyl halides and in ethylene will be made in the following paper (8).

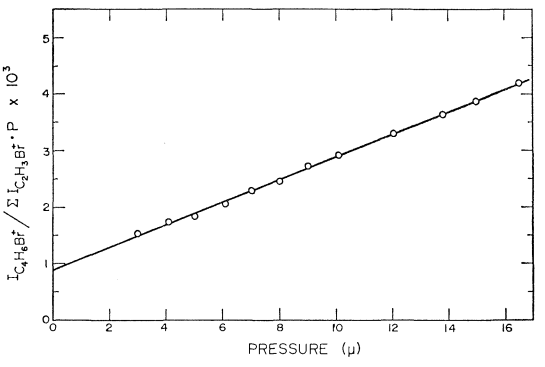

FIG. 8. $I_{C_4H_6Br^+}/\Sigma I_{C_2H_3Br^+}\cdot P$ vs. pressure, vinyl bromide.

Recoil studies of some light-mass products from the proton-induced fission of ^{238}U at intermediate energies[1]

G. B. SAHA AND L. YAFFE
Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Quebec
Received August 15, 1968

The recoil properties of ^{66}Ni, ^{67}Cu, and ^{72}Zn produced in the fission of ^{238}U by protons of 40–85 MeV energy have been studied radiochemically by the thick target – thick catcher technique. The average kinetic energy of each product has been calculated from the ranges by use of known range–energy relationships. The calculated impact velocity $v_{\parallel}$ shows that these fission products are formed predominantly via a compound nucleus mechanism in this energy region. The average total kinetic release in fission is found to be insensitive to the bombarding energy.

Introduction

The study of recoil ranges of fission products has proved to be of considerable interest in providing useful information about the fission process. A number of investigations involving measurements of recoil ranges (1–8) have been made by the use of a thick target – thick catcher technique. All these experiments involve the measurement of the average ranges of fission products and the subsequent conversion of the ranges into kinetic energies of these products by the use of a suitable range–energy relationship. Attempts have been made to correlate these results with the fission mechanism. In some of these studies (1, 5, 7, 8), additional information about the cascade deposition energy and the angular distribution of fission fragments has also been gathered. All these experiments have, however, been performed for either thermal fission or high-energy proton fission (> 150 MeV) of heavy elements. We have investigated the recoil properties of fission products in the energy range of 40–85 MeV. This study is of particular interest since a transition from compound nucleus formation to a direct interaction is generally believed to take place in this energy range.

We have measured the recoil ranges of the low-mass fission products, ^{66}Ni, ^{67}Cu, and ^{72}Zn, in 40–85 MeV proton fission of ^{238}U by the thick target – thick catcher technique. The kinetic energies of the fission products have been calculated and attempts have been made to explain these energies in terms of coulombic repulsion between two charged centers at the moment of scission. Information about the momentum transfer in the initial impact between the incident proton and ^{238}U nucleus has been obtained. In addition a correlation between our results and higher energy data has been attempted.

Experimental Procedure

The targets used in the present work consisted of uranium foils of normal isotopic composition having a superficial density of about 140 mg/cm^2. High purity aluminium foils (0.0008 in. thick) were used as catchers. The target foil was cleaned with nitric acid prior to bombardment, and then sandwiched between two aluminium catcher foils. The dimensions of the catcher foils were larger than that of the target so that any recoils originating in the edge of the target were all caught. An additional aluminium foil was introduced in the stack in order to determine the activation correction due to impurities in the catcher. The entire assembly was wrapped with a 0.0008 in. thick aluminium foil and then fixed on a target holder which in turn was attached to the cyclotron probe for irradiation.

Irradiations were performed in the internal circulating beam of protons in the McGill synchrocyclotron. The duration of bombardment was about 1 h and the beam current was of the order of 1 μA. The activation correction amounted to about 2% for all the nuclides studied. In the forward–backward recoil experiments the target assembly was irradiated perpendicular to the beam and in the "perpendicular" experiments irradiations were performed with the target stack at about 10° to the beam. The beam energy was selected by placing the stack at a radius corresponding to a desired energy and irradiations were made at 40, 55, 70, and 85 MeV. In view of the energy spread in the beam ($\sim \pm 2$ MeV) the energy degradation in the stack was calculated to be small and therefore neglected.

After irradiation, the appropriate foils were separated and dissolved in suitable acids. The chemical procedures for the separation of Ni, Cu, and Zn are given elsewhere (9).

The characteristic radiations and half-lives (10) of all nuclides that have been studied are given in Table I. Also

[1]This research received financial support from the National Research Council of Canada.

TABLE I

Pertinent decay properties of the nuclides of interest

Nuclide	Half-life	β^- radiation (MeV)	Abundance (%)	Remarks
^{66}Ni	55 h	0.20	100	maintains secular equilibrium with 5.1 min ^{66}Cu
^{67}Cu	61.5 h	0.40	45	
		0.48	35	
		0.58	20	
^{72}Zn	46.5 h	0.30	95	maintains transient equilibrium with ^{72}Ga
		1.60	5	
^{72}Ga	14.1 h	0.96	35	
		0.66	17	
		0.68	24	
		1.51	7	
		2.53	5	
		3.17	5	
^{66}Cu	5.1 min	1.59	9	
		2.63	91	

given in the table are the relevant decay properties of the daughters of some of these nuclides since they were measured along with their precursors.

The beta activities of ^{66}Ni, ^{67}Cu, and ^{72}Zn were measured by a low-background beta proportional counter. The counter had a background of less than 1 count/min and a dead time of about 300 μs. The characteristic behavior of the counter was monitored regularly with a ^{36}Cl standard source.

In general, in a recoil experiment, three samples of each nuclide, corresponding to the activities of the target and two catchers, are measured. Thus three samples each of ^{66}Ni, ^{67}Cu, and ^{72}Zn were measured over several half-lives and the activity ratios obtained after correcting for the chemical yield. The activity ratios obtained at different intervals agreed within 1–2% with each other and an average of these ratios was taken. Since ^{72}Zn maintains a transient equilibrium with ^{72}Ga, the shapes of the growth–decay curves for all three samples must be identical with respect to the time axis for proper comparison. This was ensured by precipitating $ZnHg(SCN)_4$ from the target and the catchers at the same time.

The ^{66}Ni and ^{72}Zn nuclides decay by emitting low-energy beta rays and thus self-absorption in the solid samples makes the activity measurements difficult. However, these nuclides are in equilibrium with their daughters which emit high-energy beta radiation. These two nuclides were, therefore, measured with a 200 mg/cm^2 thick aluminium absorber in order to stop all low energy beta rays, thus obviating any self-absorption correction. A self-absorption correction was, however, applied to the activities of ^{67}Cu.

Results

(a) Treatment of Recoil Data

In a typical forward–backward recoil experiment, the fractions F and B of the total activity of a given nuclide that were found in the forward and backward Al catcher foils, respectively, were measured. Similarly in the perpendicular experiments, where the foils lie at about 10° to the beam, the fractions P of the total activity of a given nuclide observed in the top or bottom catchers were also measured. In the latter experiment the activities in the top and bottom catchers were almost the same and were averaged. The fractions F, B, and P were corrected for the scattering of the recoils at the uranium–aluminium interface and for the edge-effect of the target. These effects have been investigated by Panontin and Sugarman (11). Following Niday's (3) suggestion, Sugarman *et al.* (8) gave the following expression for the scattering correction factor

$$[1] \quad W_{(Pb)}(F, B, \text{or } P)_{(Pb)} = [0.922 + 3.4 \times 10^{-4}A]\, W_{(Al)}(F, B, \text{or } P)_{(Al)}$$

Here A is the mass member of the fission product of interest, W is the thickness of the catcher, and the subscripts Pb and Al refer to the quantities as measured with lead or aluminium catchers, respectively. This expression assumes that the scattering effect is the same in both uranium and lead foils. The correction factor for the edge effect for the uranium foil used was taken to be 0.97 as suggested by Sugarman and co-workers (8, 11). Thus the quantities F, B, and P were corrected by multiplying by 0.97 and the factor given by eq. [1]. Corrections for fission products produced by secondary neutrons and protons arising from nuclear interactions in the target and other foils were calculated to be small and were neglected.

Sugarman and co-workers (8) and Winsberg (12) have independently derived equations relating F, B, and P with three other important quantities, the range R, the velocity parameter η, and the anisotropy parameter b/a. Sugarman *et al.* (8) have analyzed their results on the basis of a vector model. The vector model assumes that the incident particle imparts an average velocity v to the struck nucleus in the cascade process. Then the struck nucleus undergoes fission either before or after the evaporation of neutrons. The fission fragments acquire an average velocity V in the moving frame of reference and the angular distribution of V is given by the form $a + b\cos^2\theta$. The velocity parameter η is given by v/V. The components of η along the parallel and perpendicular directions to the beam are denoted by $\eta_{\parallel}$ and $\eta_{\perp}$ respectively. One assumes a range–energy relationship given by $R = kV^N$ where k and N are empirical constants.

With $\eta_{\perp} = 0$, the Sugarman (8) equations were solved by successive approximations of various values for R, $\eta_{\parallel}$, and b/a until these values did not change. The derived values of the range R, the velocity parameter $\eta_{\parallel}$, and the anisotropy parameter b/a are given in Table II. Sugarman *et al.* (8) have deduced $\eta_{\perp}$ from a knowledge of the dependence of $\eta_{\perp}$ on $\eta_{\parallel}$ at 450 MeV. In the absence of such information we have not attempted to obtain a value for $\eta_{\perp}$ in the present energy range.

In column 1 of Table II are given the proton bombarding energies in MeV. Columns 2, 3, and 4 present the experimentally determined data for $2W(F+B)$, $4WP$, and $W(F-B)$ in units of mg/cm² of uranium. The values of R, $\eta_{\parallel}$, and b/a are shown in columns 5, 6, and 7, respectively.

Errors have been estimated, on the basis of random uncertainty involved in the determination of activities, chemical yields, and target thickness, for W, F, and B. An estimated total error of ±22% has been uniformly quoted for the values of $2W(F+B)$, $4WP$, and $W(F-B)$ for all nuclides at all energies even though it may be somewhat larger at the lowest energies because of the low activity produced. Since R is proportional to the above measured quantities, the error in R will be of the same order. Based on the same considerations as above, the error estimated for $\eta_{\parallel}$ is ±30%.

(b) Range–Energy Relationship

The average range R, given in mg/cm², can be used to calculate the kinetic energy of the fission fragments. In order to do this a suitable range–energy relationship is necessary. An empirical range–energy relationship often used by Sugarman *et al.* (8) and others is of the form

$$[2] \qquad R = CT_p^{N/2}$$

where C and N are constants dependent on mass numbers of both recoiling ions and stopping atoms. The values of C and N have been deduced by fitting to the experimental results. T_p is the average kinetic energy of the recoiling ion.

(hereafter denoted by L.S.S.) have deduced a universal range–energy relationship

$$[3] \qquad \rho(\varepsilon) = (2/k)\,\varepsilon^{1/2} - \Delta(k,\varepsilon)$$

where $\rho(\varepsilon)$ and ε are the dimensionless variables of the range and kinetic energy respectively; k is a parameter dependent on the masses and charges of the recoiling ions and stopping atoms; $\Delta(k,\varepsilon)$ is a term which corresponds to the nuclear stopping and is given by L.S.S. in their paper. The values of $\rho(\varepsilon)$, ε, and k are given by

$$[4] \qquad \rho(\varepsilon) = 4\pi a^2 NRM_1M_2(M_1 + M_2)^{-2}$$

$$[5] \qquad \varepsilon = aT_pM_2[Z_1Z_2e^2(M_1 + M_2)]^{-1}$$

$$[6] \qquad k = \frac{0.0793\xi Z_1^{1/2}Z_2^{1/2}(M_1 + M_2)^{3/2}}{M_1^{3/2}M_2^{1/2}(Z_1^{2/3} + Z_2^{2/3})^{3/4}}$$

Here a is $0.8853\,a_0(Z_1^{2/3} + Z_2^{2/3})^{-1/2}$, where a_0 is the Bohr radius in the hydrogen atom; R is the range in cm; ξ is approximately given by $Z_1^{1/6}$; N is the number of stopping atoms per cc; Z_1 and Z_2 are the charge numbers; and M_1 and M_2 are the mass numbers of the recoiling ions and stopping atoms, respectively.

Equation [3] can be used to calculate T_p provided $\Delta(k,\varepsilon)$ is known. On the other hand, ε, that is, T_p, must be known before $\Delta(k,\varepsilon)$ can be calculated. In a recoil experiment, only R is known and T_p is to be calculated. Therefore, eq. [3] is relatively complicated to apply in our case. Noshkin and Sugihara (7) analyzed the recoil data of thermal-neutron fission of ^{235}U for different catchers such as Al, Zr, Au, and U. They used the kinetic energy data of Milton and Fraser (14) for several mass numbers and checked the applicability of the L.S.S. range–energy relationship. They showed by this analysis that all the thermal fission data could be fitted by the following relationship

$$[7] \qquad \rho(\varepsilon) = \frac{1.3}{k}\,\varepsilon^{1/2}$$

We have used eqs. [2] and [7] for the determination of the kinetic energy of the individual fission products studied.

(c) Kinetic Energy Calculation

It is to be noted that eq. [7] has a charge dependence of the range–energy relationship through eqs. [4], [5], and [6]. The average charge, $\bar{Z}$, for an isobaric chain is the most probable charge, Z_p, at a given bombarding energy. For a cumulatively-formed species, which is the case for all nuclides in the present study, the average charge $\bar{Z}$, i.e. the charge of each member of the chain weighted by its independent fractional yield is

$$[8] \qquad \bar{Z} = \frac{\sum f_i Z_i}{\sum f_i}$$

where f_i is the fractional yield of the ith member of the chain and summations are taken over isobaric nuclides of charges less than and equal to that of the observed nuclide.

The fractional yield, f_i, can be obtained from the charge dispersion curves of fission products. The charge dispersion curves have often (15, 16) been assumed to have the following Gaussian form

$$[9] \qquad P(Z) = \frac{1}{\sqrt{(c\pi)}}\exp\left[\frac{-(Z - Z_p)^2}{c}\right]$$

The standard deviation, c, is related to the full-width at half-maximum, d_i, by the relation $c = 0.361\,d_i^2$ (17). If this is substituted into eq. [9], the following results

$$[10] \qquad f_i(Z_i) = \left(\frac{0.940}{d_i}\right)\exp\{-2.77[(Z_i - Z_p)/d_i]^2\}$$

where Z_i is the nuclear charge of the nuclide of interest, and Z_p is the most probable charge for the chain. Davies and Yaffe (18) and Parikh *et al.* (19) gave the full-width at half-maximum of the charge dispersion for masses 130–144 in ^{238}U fission by protons of energies 20–85 MeV. Unfortunately, there is yet no such information available regarding the width of the charge dispersion for the low-mass region at these energies. However, it can easily be shown that although $f_i(Z_i)$ changes with variation in d_i, the average charge $\bar{Z}$ remains almost unchanged. Under these circumstances we chose arbitrarily the data of Davies and Yaffe and the values are given in Fig. 1.

The most probable charges, Z_p, to be used in eq. [10], for different isobaric chains were calculated using both the equal charge displacement (e.c.d.) and unchanged charge division (u.c.d.) postulates (20). These give

$$[11] \qquad \text{for e.c.d., } Z_p = \tfrac{1}{2}(Z_c + Z_A - Z_{(A_c - A - \bar{\nu}_T)})$$

$$[12] \qquad \text{for u.c.d., } Z_p = \frac{Z_c A}{A_c - \bar{\nu}_T}$$

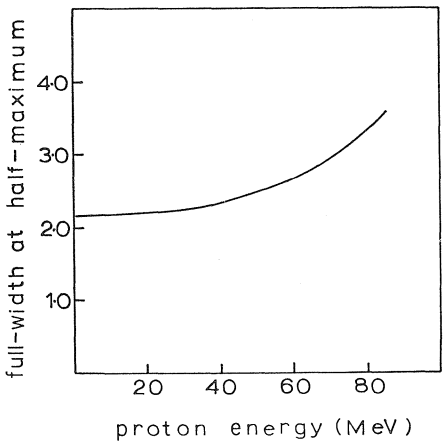

FIG. 1. Variation of full-width at half-maximum of charge dispersion curves (A = 130–144) with proton bombarding energy (ref. 18).

Here Z_c and A_c are the charge and mass numbers of the fissioning nucleus; Z_A is the most stable charge associated with the chain mass A; $\bar{\nu}_T$ is the average total number of neutrons emitted in fission. $\bar{\nu}_T$ was obtained from an energy-dependent relationship given by Unik and Huizenga (21, 22)

$$[13] \qquad \bar{\nu}_T = 1.9 + 0.12E^* \qquad \text{where } E^* \text{ is the excitation energy of the fissioning nucleus calculated on the basis of compound nucleus formation.}$$

Using the above information we have calculated $\bar{Z}$ for a measured fission product with the Z_p values obtained by both e.c.d. and u.c.d. methods. The appropriate value for $\bar{Z}$ was substituted in eqs. [5] and [6], and the kinetic energy, T_p, of each of the observed fission products was calculated from eq. [7] and the range R given in Table II. The kinetic energies of different products are listed in Table IV along with average charges $\bar{Z}$. The error in T_p is $\pm$ 22%.

We have also calculated the kinetic energies of the observed fission products by the use of eq. [2]. The values of C and N have been taken from Sugarman *et al.* (8). These authors have listed these values as a function of mass number through the analysis of range–energy data for heavy ions and fission fragments in thermal fission. The values chosen for C and N are given in Table III. The kinetic energies calculated by eq. [2] are also included in Table IV. It should be pointed out that for the mass region of our interest, no charge dependence of the range–energy relationship has been postulated in using eq. [2].

TABLE III

Once the kinetic energy, T_p, of a fission product is known, its average velocity, V, can be calculated from the expression $T_p = \frac{1}{2}AV^2$. The impact velocity $v_{\parallel}$ imparted to the struck nucleus is then obtained by multiplying the measured $\eta_{\parallel}$ values by V. The error in $v_{\parallel}$ (from $\eta_{\parallel}$) is $\pm 30\%$. The values of $v_{\parallel}$ as deduced from the e.c.d. and u.c.d. methods, and eq. [2] are tabulated in Table IV. The last column of Table IV gives the impact velocity, v_{CN}, of the compound nucleus.

Discussion

From our recoil experiment we have derived three important quantities, viz. the kinetic energy T_p of the fission product, the initial velocity component $v_{\parallel}$ imparted to the fissioning nucleus along the beam direction, and the anisotropy parameter b/a for the angular distribution of the fission velocity V. An attempt will be made in the following section to obtain from these quantities relevant information about the fission mechanism and other related properties.

The kinetic energies of the fission products, ^{66}Ni, ^{67}Cu, and ^{72}Zn have been calculated by three methods as described earlier. Considering the uncertainties involved ($\pm 22\%$) as seen from Table IV, one cannot discriminate between the values obtained by the use of the three methods. This is also true for the values of the impact velocity, $v_{\parallel}$.

As can be seen from Table II, there is no systematic trend in the variation of the values of b/a with bombarding energy, which can be applied equally well to all nuclides. The anisotropy factor b/a is very sensitive to the $(F + B)$ and P values and a small variation in either of these introduces a large error in b/a. It is known (7, 8), however, that the anisotropy factor does change with bombarding energy and the mass number of the fission product. It would be expected that the b/a values should be large for products arising from highly asymmetric fission, and they are in general seen to be large in magnitude, except in the case of ^{72}Zn.

The impact velocity $v_{\parallel}$ of the struck nucleus along the beam direction has been used at higher energies to deduce the average deposition energy of the fissioning nucleus (5, 7, 8). This has usually been done from analysis of the Monte Carlo cascade calculation of Metropolis *et al.* (23) made by Porile (24) at 460 MeV and higher energies. Although we could make such an analysis for our energy region from the results of Metropolis *et al.* (23), a comparison between the values of v_{CN} and $v_{\parallel}$ indicates that this analysis is not worthwhile. It is apparent from Table IV that, in general, the compound nucleus velocity v_{CN} is the same as $v_{\parallel}$ at all bombarding energies. Any discrepancy that is observed between v_{CN} and $v_{\parallel}$ is attributable to the errors in the determination of $v_{\parallel}$. We can conclude that ^{66}Ni, ^{67}Cu, and ^{72}Zn or the corresponding primary fission fragments arise from the compound nuclei formed in the interaction of the protons with ^{238}U nuclei. This conclusion was also drawn from the excitation function studies of these nuclides (9). As $\eta_{\perp}$ is zero in compound nucleus information, no inconsistency is thus introduced by our neglect of $\eta_{\perp}$. Correlation with the compound nucleus mechanism does not, however, mean that no direct interaction takes place at these energies. It has been pointed out by several authors (5, 7, 8, 25) that the light-mass products such as ^{66}Ni, ^{67}Cu, and ^{72}Zn probably arise from a fissioning nucleus having high deposition energy. Thus it appears that that fraction of the total reaction which forms compound nuclei yields these products, whereas those leading to partial energy transfer would give rise to relatively more symmetric fission products.

The kinetic energies of ^{66}Ni, ^{67}Cu, and ^{72}Zn obtained on the basis of the u.c.d. hypothesis have been plotted in Fig. 2. Also included in the figure are the data of Noshkin and Sugihara (7) at 150 MeV and those of Alexander *et al.* (5) at 720 MeV. Regardless of the slight mass difference, the kinetic energies of these products in the bombarding regions of 40–85 MeV are nearly the same within experimental error. At higher energies, however, there may be a small decrease in kinetic

TABLE V

Total kinetic energy release at different energies

Bombarding energy (MeV)	Measured kinetic energy of the products T_p (MeV)			Total kinetic energy T_0 (MeV)			Average total kinetic energy $\overline{T}_0$ (MeV)
	^{66}Ni	^{67}Cu	^{72}Zn	^{66}Ni	^{67}Cu	^{72}Zn	
40	127	130	95	172	183	139	150±33
55	115	107	127	156	151	185	180±40
70	103	120	110	144	169	160	160±35
85	93	125	112	129	176	164	160±35

energies. A smaller share of the kinetic energy for these products at higher bombarding energy would probably indicate the emission of relatively massive charged particles carrying various amounts of kinetic energies.

The kinetic energy T_p of the fission products measured can be used to calculate the total kinetic energy release in fission. Because of conservation of momentum, the total kinetic energy is shared by the fragments in the ratio of their masses. Thus the total kinetic energy T_0 is related to that of the primary fragments of masses A_1 and A_2 by the following expression

$$[14] \qquad T_0 = T_{\text{prim}}\left(1 + \frac{A_2}{A_1}\right)$$

If the u.c.d. hypothesis is again invoked, then A_2/A_1 is equal to $(93 - Z_1)/Z_1$ with Z_1 and $(93 - Z_1)$ as the charges of the primary fragments. Since only neutrons rather than any charged particles are expected to be evaporated from the primary fragments, the average charge of the primary fragments should be equal to that of the products observed. Moreover, as neutron evaporation will not cause a very appreciable change in the kinetic energy of the fragments, the average kinetic energy T_p of the products can be approximated to be that of the primary fragments. Thus, from the measured T_p values of each observed product and the average charges, $\overline{Z}$, of the chain, as calculated on the basis of the u.c.d. hypothesis, the total kinetic energies corresponding to each observed fission product have been calculated from eq. [14]. They are given in Table V along with the T_p values of the individual products. Finally the average total kinetic energy $\overline{T}_0$ at a given bombarding energy can be calculated from

$$[15] \qquad \overline{T}_0 = \frac{\sum \sigma_i (T_0)_i}{\sum \sigma_i}$$

by weighting the T_0 values with the yield σ_i of each product. The values of σ_i have been given elsewhere (9). With these values, the $\overline{T}_0$ values have been calculated and are given in Table V and in Fig. 3. These values have an uncertainty of ±22%. Also included in Fig. 3 are published data at higher energies. However, the average $\overline{T}_0$ value given by us is not a very representative average value of the total kinetic energy release in fission in the sense that it has been weighted only with respect to the yields of a very narrow region of light-mass fission products.

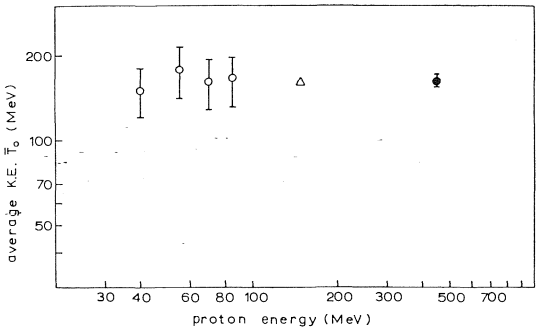

FIG. 3. Variation of average total kinetic energy, $\overline{T}_0$, as a function of proton bombarding energy: ○, this work; △, ref. 7; ●, ref. 8.

It is apparent from Fig. 3 that the total kinetic energy of the fragments is insensitive to the bombarding energy. It has been maintained that the kinetic energy of the fragments results from the Coulombic repulsion between two complementary fragments at scission. The insensitivity of $\overline{T}_0$ to the bombarding energy indicates that this Coulomb energy does not depend on excitation energy. In other words, the average distance between the two charge centers of the fragments at the point of scission would seem to be the same at all these excitation energies (22, 26).

A value of 163 MeV has been obtained for the average kinetic energy release in fission of ^{238}U by protons of energy 40–85 MeV. This value is comparable with other data (7, 8).

Acknowledgments

We are grateful to Dr. R. E. Bell, Director of the Foster Radiation Laboratory, for ready access to the cyclotron and associated facilities. Mr. R. H. Mills, as always, cheerfully performed the irradiations.

Neutralization of dilute aqueous aluminium sulfate solutions with a base[1]

S. Shah Singh
Soil Research Institute, Canada Department of Agriculture, Ottawa, Canada
Received July 30, 1968

A theoretical treatment of the neutralization of dilute $Al_2(SO_4)_3$ solutions with a base is presented and is supported by the experimental data. The formation of soluble complex $AlSO_4^+$; the first-stage hydrolysis product, $AlOH^{2+}$, and the precipitation of amorphous aluminium hydroxy sulfate are the reactions controlling the conditions in solution up to 80% of neutralization with respect to aluminium. Beyond 80% of neutralization there is slow replacement of SO_4^{2-} by OH^- in the amorphous precipitate of aluminium hydroxy sulfate.

Introduction

The hydrolysis of aluminium salts has been the subject of extensive investigations. The products of hydrolysis reported range from monomers to a variety of complex aluminium species, ionic and neutral, mononuclear and polynuclear. Chernov (1) found that the monomeric hydrolysis mechanism adequately described the chemistry of dilute aqueous aluminium chloride in the concentration range of 10^{-4} to 10^{-2} *M*. Frink and Sawhney (2) reported that potentiometric titration curves of dilute aluminium salt solutions can be predicted by a simple reaction scheme which combines the first-stage hydrolysis reaction, the formation of $AlOH^{2+}$, with the concomitant precipitation of $Al(OH)_3$. From a general treatment of the titration of aluminium chloride with a base, Turner (3) concluded that the relative rates of hydrolysis, formation of polynuclear hydroxy-aluminium cations, precipitation and crystallization had an important effect on the shape of the experimental titration curves. However, with fast titrations, hydrolysis to monomers and precipitation of amorphous $Al(OH)_3$ played the major roles in controlling conditions in solution. Turner (3) did not give any treatment for the neutralization of dilute aqueous solutions of aluminium sulfate. Frink and Sawhney (2), although they did not show any neutralization curves for aluminium sulfate, claimed in their text that their simple treatment of hydrolysis to monomers and concomitant precipitation of $Al(OH)_3$ could be applied to neutralization curves of dilute aqueous aluminium sulfate solutions. It has been reported in the literature (4) that an amorphous precipitate of aluminium hydroxy sulfate is formed when a solution of aluminium sulfate is neutralized with a base, and that this precipitate has a fairly constant solubility (5). It is apparent, therefore, that Frink and Sawhney's (2) conclusions obviously are not consistent with this result.

Evidence reported in this paper indicates that curves for the fast titration of dilute aluminium sulfate solutions can be predicted by the first-stage hydrolysis reaction (6, 7), the formation of soluble complex $AlSO_4^+$ (8), and the precipitation of aluminium hydroxy sulfate, which has a constant ionic product $[Al][OH]^{3-x}[SO_4]^{x/2}$. They cannot be predicted from the first-stage hydrolysis reaction and the precipitation of $Al(OH)_3$ as concluded by Frink and Sawhney (2).

Theoretical

The assumptions used to calculate the curves for the neutralization of aqueous solutions of aluminium sulfate with a base are that the soluble complex $AlSO_4$, the first-stage hydrolysis product, AlOH, and an amorphous precipitate of aluminium hydroxy sulfate, $[Al(OH)_{3-x}(SO_4)_{x/2}]$, are formed and that the precipitate has a definite solubility product. The charges on the ions are omitted for the sake of convenience. The equilibrium constants relationship used are

$$[1] \qquad [Al][OH]^{3-x}[SO_4]^{x/2} = K_s$$

$$[2] \qquad \frac{[AlSO_4]}{[Al][SO_4]} = K_{SO_4}$$

$$[3] \qquad \frac{[AlOH][H]}{[Al]} = K_1$$

$$[4] \qquad [H][OH] = K_w$$

where square brackets denote concentrations in

[1]Contribution No. 283.

moles/l, the K's are constant for any given ionic strength. Equation [1] expresses the concentration solubility product of amorphous aluminium hydroxy sulfate, K_w is the ionic product of water at any given ionic strength, K_1 is the constant of first stage of hydrolysis of aluminium, and K_{SO_4} is the equilibrium constant of reaction

$$Al + SO_4 \rightleftharpoons AlSO_4$$

According to the assumptions mentioned above, since all of the aluminium and sulfate are present in some form of ions or as the precipitate aluminium hydroxy sulfate, it follows that

$$[5] \quad [Al]_t = [Al] + [AlOH] + [AlSO_4] + [Al(OH)_{3-x}(SO_4)_{x/2}]$$

$$[6] \quad [SO_4]_t = [SO_4] + [AlSO_4] + x/2[Al(OH)_{3-x}(SO_4)_{x/2}]$$

where $[Al]_t$ and $[SO_4]_t$ denote the total Al and SO_4 in the system. From the formula of each species in eq. [5] it also follows that

$$[7] \quad B = [AlOH] + (3 - x)[Al(OH)_{3-x}(SO_4)_{x/2}] - [H]$$

where B is the amount of base added in equivalents/l of the system. Subtracting $1/(3 - x)$ of eq. [7] from eq. [5] it gives

$$[8] \quad [Al]_t - \frac{1}{3-x}B = [Al] + \frac{2-x}{3-x}[AlOH] + [AlSO_4] + \frac{1}{3-x}[H]$$

It can be seen from eqs. [1] and [4], that

$$[9] \quad [Al] = \frac{K_s[H]^{3-x}}{K_w{}^{3-x}[SO_4]^{x/2}}$$

from eq. [3]

$$[10] \quad [AlOH] = \frac{K_1[Al]}{[H]}$$

and from eqs. [2] and [6]

$$[11] \quad [AlSO_4] = \frac{K_{SO_4}\{[Al]\}\{[SO_4]_t - x/2[Al(OH)_{3-x}(SO_4)_{x/2}]\}}{1 + K_{SO_4}[Al]}$$

$\{[SO_4]_t - x/2[Al(OH)_{3-x}(SO_4)_{x/2}]\}$ in eq. [11] will be referred to as $[SO_4]_t'$ in the following equations for simplicity.

Equations [8], [9], [10], and [11] can be combined to give

$$[12] \quad [Al]_t - \frac{1}{3-x}B = \frac{K_s[H]^{3-x}}{K_w{}^{3-x}[SO_4]^{x/2}} + \frac{2-x}{3-x}\frac{K_sK_1[H]^{2-x}}{K_w{}^{3-x}[SO_4]^{x/2}} + \frac{K_sK_{SO_4}[SO_4]_t'[H]^{3-x}}{K_w{}^{3-x}[SO_4]^{x/2} + K_sK_{SO_4}[H]^{3-x}} + \frac{1}{3-x}[H]$$

Equation [12] is a general equation, which can be solved for a given value of x and the neutralization curve of a particular concentration of Al in aluminium sulfate can be constructed provided K_s in eq. [1] is known for that value of x. Equation [12] will be simplified for two values of x and calculated curves will be compared with experimental curves for different concentrations of Al.

If x is zero, eq. [1] becomes

$$[13] \quad [Al][OH]^3 = K_s'$$

and accordingly eq. [12] can be simplified to

$$[14] \quad [Al]_t - \frac{1}{3}B = \frac{K_s'[H]^3}{K_w{}^3} + \frac{2}{3}\frac{K_s'K_1[H]^2}{K_w{}^3} + \frac{K_s'K_{SO_4}[SO_4]_t'[H]^3}{K_w{}^3 + K_s'K_{SO_4}[H]^3} + \frac{1}{3}[H]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Equation [14] is similar to that of Frink and Sawhney (2) except that [14] contains an extra term to take account of soluble complex $AlSO_4$.

The other form to which eq. [12] is simplified, is for the precipitation of amorphous aluminium hydroxy sulfate of an approximate composition $[Al(OH)_{2.5}(SO_4)_{0.25}]$. The value of x in this case is 0.5. With this assumption eq. [1] becomes

$$[15] \qquad [Al][OH]^{2.5}[SO_4]^{0.25} = K_s''$$

and by using [15], eq. [12] can be simplified to

$$[16] \qquad [Al]_t - 0.4B = \frac{K_s''[H]^{2.5}}{K_w{}^{2.5}[SO_4]^{0.25}} + 0.6\,\frac{K_s''K_1[H]^{1.5}}{K_w{}^{2.5}[SO_4]^{0.25}} + \frac{K_s''K_{SO_4}[SO_4]_t'[H]^{2.5}}{K_w{}^{2.5}[SO_4]^{0.25} + K_s''K_{SO_4}[H]^{2.5}} + 0.4\,[H]$$

Equation [15] can be simplified, where $[Al][OH]^{2.5}$ becomes a constant for a particular concentration of aluminium sulfate solution. The maximum variation in sulfate concentration due to its precipitation from zero neutralization to 100% neutralization of Al is 17% and, as is apparent from eq. [15], SO_4 is raised to the power of 0.25; any change in SO_4 is thus insignificant in eq. [15]. For a particular concentration of aluminium sulfate solution, therefore,

$$[17] \qquad [Al][OH]^{2.5} = \frac{K_s''}{[SO_4]^{0.25}} = K_s'''$$

Combining eqs. [16] and [17] gives

$$[18] \qquad [Al]_t - 0.4B = \frac{K_s'''[H]^{2.5}}{K_w{}^{2.5}} + 0.6\,\frac{K_s'''K_1[H]^{1.5}}{K_w{}^{2.5}} + \frac{K_s'''K_{SO_4}[SO_4]_t'[H]^{2.5}}{K_w{}^{2.5} + K_s'''K_{SO_4}[H]^{2.5}} + 0.4\,[H]$$

Equations [14] and [18] can be used for calculations up to 100% neutralization. For calculations beyond 100%, an extra term for $Al(OH)_4$ can be introduced, and the following relationship given by Kittrick (9) can be used in solving the equations.

$$\frac{(Al(OH)_4)(H)^4}{(Al)} = 10^{-23.30}$$

The numerical values used for various equilibrium constants at zero ionic strength to solve eqs. [14] and [18] are $K_{SO_4} = 10^{3.20}$ (8); $K_1 = 10^{-5.02}$ (6); $K_w = 10^{-14.00}$; $K_s' = 10^{-31.80}$ (2); and $K_s'' = 10^{-28.60}$. These values were corrected for the different ionic strength by using ionic activity coefficients calculated from the Debye–Hückel equation with values for the parameter a_i "the distance of closest approach" taken from Klotz (10).

Experimental

A stock solution of concentration 0.1 N was prepared from analytical grade $Al_2(SO_4)_3.18H_2O$ in CO_2-free distilled water. This stock solution was used to prepare a second stock solution of 10^{-2} M Al. The concentration of aluminium in the second stock solution was determined by an 8-quinolinolate extraction method (11). Appropriate aliquots of the second stock solution were diluted to concentrations of 1.00×10^{-3} and 1.00×10^{-4} M Al. Twenty ml portions were titrated with CO_2-free NaOH. The 10^{-2}, 10^{-3}, and 10^{-4} M solutions were titrated with 1 N, 0.1 N, and 0.01 N NaOH, respectively. A combination of a Beckman expanded-scale pH meter and a motor driven Metrohm buret was used to follow the titration curves. Absolute accuracy of the buret was ± 0.002 ml. The drop rate of NaOH from the buret was adjusted so that a titration to 100% of neutralization was completed in about 25 min.

At different degrees of neutralization of aluminium the suspensions were filtered through 10 mμ pore size millipore filters. The liquid phase was collected in a test tube and the solid precipitate remained on the filter membrane. The liquid phase was analyzed for aluminium and sulfate. Aluminium was determined by 8-quinolinolate extraction method (11) and sulfate was determined by direct titration with barium perchlorate, using thorin as an indicator (12).

Results and Discussion

The experimental neutralization curves and the calculated curves according to eqs. [14] and [18] for solution concentrations 1.00×10^{-2}, 10^{-3}, and 10^{-4} M Al as $Al_2(SO_4)_3$ are shown in Fig. 1.

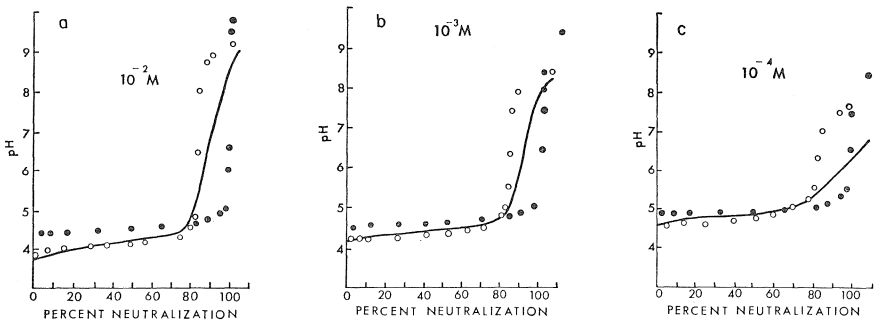

FIG. 1. Neutralization of dilute aqueous solutions of $Al_2(SO_4)_3$ with NaOH: (*a*) 10^{-2} *M* Al; (*b*) 10^{-3} *M* Al; (*c*) 10^{-4} *M* Al. Smooth curve, experimental; closed circles, calculated according to eq. [14], and open circles, calculated according to eq. [18].

A precipitate was visible to the naked eye during the neutralization of dilute solutions of aluminium sulfate with NaOH. Smooth solid curves in the figure are experimental ones; closed and open circles represent eqs. [14] and [18].

It is apparent that eq. [18], which is based on the assumption that $Al(OH)_{2.5}(SO_4)_{0.25}$ is the precipitate formed, fits the experimental data well to about 80% of neutralization[2] but beyond this degree of neutralization the experimental pH values do not increase as rapidly as shown by the calculated curve. The calculated curves according to eq. [14], in which it was assumed that $Al(OH)_3$ is the precipitate formed, do not agree at all with the experimental values for the 10^{-2} and 10^{-3} *M* Al solutions. For the 10^{-4} *M* solution the agreement is fairly good with both calculated curves to 80% of neutralization but a close examination shows that the agreement with eq. [18] is the better of the two.

It can be concluded, therefore, that first-stage hydrolysis to AlOH, formation of the soluble complex $AlSO_4$ and precipitation of an aluminium hydroxy sulfate controls conditions in solution during the first 80% of neutralization of dilute solutions of $Al_2(SO_4)_3$ with NaOH.

The fact that the curve calculated from eq. [14] also agrees with the experimental results for the first 80% of neutralization does not mean that the reactions at the low concentration are different from those at the two higher concentrations. The curves represented by eqs. [14] and [18] agree rather well at the 10^{-4} concentration, because under these conditions $[Al][OH]^{2.5}[SO_4]^{0.25}$ is $10^{-28.6}$, and $[Al][OH]^3$ is $10^{-32.1}$, a value not greatly different from the ion product $10^{-31.8}$, which was used in the calculations for eq. [14] for the solubility product of the $Al(OH)_3$ precipitated (2). With the 10^{-2} and 10^{-3} *M* solutions $[Al][OH]^3$ values calculated from $10^{-28.6}$ for $[Al][OH]^{2.5}[SO_4]^{0.25}$ are $10^{-33.0}$ and $10^{-32.7}$, respectively, which are considerably lower than $10^{-31.8}$. This is the main cause of the differences at these concentrations between the experimental curves and those calculated from eq. [14].

Beyond about 80% of neutralization, the deviation of the experimental curves from those calculated according to eq. [18] indicates a significant change in the reactions. The pH of the experimental curves is lower than the calculated pH. This is due to slow replacement of SO_4 by OH in the amorphous precipitate of aluminium hydroxy sulfate, because of the heterogeneous nature of the system. If it were a homogeneous system, one would expect a rapid replacement.

In order to test the validity of this explanation the liquid phase was analyzed for SO_4 and Al concentration during the neutralization. It was found (Table I) that the Al concentration was decreased to a greater extent than that expected if $Al(OH)_3$ were formed, until at about a degree of neutralization of 80% or higher, the Al concentration was essentially zero. The SO_4 concentration in the liquid phase decreased as titration progressed to about 80% of neutralization and then increased. These results from the chemical analysis thus agree with the explanation that up to 80% of neutralization a precipitate of aluminium hydroxy sulfate of an approximate composition of $Al(OH)_{2.5}(SO_4)_{0.25}$ is formed and

[2]% of neutralization means always with respect to aluminium.

90	1.04	—	—	12.95
95	0.52	—	—	13.60
100	0	—	0.24	14.00

*Calculated assuming all the base added formed $Al(OH)_3$ or $Al(OH)_{2.5}(SO_4)_{0.25}$.

beyond this degree of neutralization the reaction is the replacement of SO_4 from the amorphous precipitate with OH. The results reported by Hsu and Bates (4) also agree with this interpretation. They found that over the range of NaOH/Al = 0.3 to 2.1 the amount of precipitate increased with increasing ratio but the composition of the precipitate was approximately constant.

The presence of polynuclear aluminium in the liquid phase was checked by extracting with 8-quinolinol for different length of time (11). Okura *et al.* (11) found that with 10 s extraction time, only aluminium ions with the degree of polymerization at or very close to unity were determined in the chloroform extraction and any delay caused considerable depolymerization of the higher aluminium complex. In the present investigation, there was a very small change in the aluminium concentration determined in the chloroform separation, when extraction time with 8-quinolinol was 24 h as compared with zero time. This change was, however, not enough to cause any significant influence on the shape of the neutralization curve, or the calculated composition of the precipitate.

In summary, it is concluded that the first-stage hydrolysis of aluminium, the formation of $AlSO_4$, and the precipitation of aluminium hydroxy sulfate of the approximate composition $Al(OH)_{2.5}(SO_4)_{0.25}$ were the reactions responsible for controlling the conditions in solution up to 80% of neutralization when aqueous solutions in the concentration range of 10^{-2} to 10^{-4} *M* Al as aluminium sulfate were neutralized with a base. Beyond 80% of neutralization, there was replacement of SO_4 by OH in the precipitate.

Isomerization of methyl isocyanide sensitized by vibrationally excited ethane

D. H. SHAW, B. K. DUNNING, AND H. O. PRITCHARD
Centre for Research in Experimental Space Science, York University, Toronto, Ontario

Received September 5, 1968

The isomerization of methyl isocyanide in the presence of methyl radicals takes place by two mechanisms. One is the simple free-radical displacement reaction which has been described previously. The other is through a direct transfer of energy from vibrationally excited ethane molecules. The vibrationally sensitized component can be quenched by increasing the total pressure.

Canadian Journal of Chemistry, **47**, 669 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In the past five years, numerous examples have been found in which a vibrationally excited haloethane eliminates a hydrogen halide molecule (1, 2). Typically, the excited ethane is formed when two methyl-type radicals combine, e.g.

$$CH_3 + CCl_3 \rightarrow CH_3CCl_3^*$$

although other methods of formation have also been tried (3, 4); then, if the pressure is not too high, an elimination, e.g.

$$CH_3CCl_3^* \rightarrow CH_2{:}CCl_2 + HCl$$

takes place before the ethane can be stabilized by collisions with the surrounding gas. However, no reaction of vibrationally excited ethane formed by the combination of methyl radicals has yet been reported. Two reactions seem possible, viz.

$$C_2H_6^* \rightarrow C_2H_4 + H_2$$

and

$$C_2H_6^* \rightarrow CH_2 + CH_4$$

but neither of them has been observed despite the fact that efforts have been made on several occasions to find them (5). In the experiments described below, we set out to determine whether a vibrationally excited ethane molecule could transfer sufficient energy to another molecule to sensitize a chemical reaction, and we chose the isomerization of methyl isocyanide to test this idea. To avoid complications due to electronic excitation of molecules in the system, the thermal decomposition of di-*tert*-butyl peroxide was used as the source of methyl radicals.

Materials and Experimental Technique

Methyl isocyanide, ethyl isocyanide, di-*tert*-butyl peroxide, and carbon dioxide were prepared and/or purified as described previously (6, 7); 1,1-difluoroethane was obtained from Matheson of Canada Ltd.

Experiments were performed in the temperature range 85–130 °C by heating mixtures of methyl isocyanide, di-*tert*-butyl peroxide (DTBP), and CO_2 in a 10 cc Hoke stainless steel pressure vessel. Initial quantities of about 2×10^{-4} and 3×10^{-5} moles, respectively, of isocyanide and peroxide were chosen to give some 10–20% isomerization (6), and pressures of CO_2 up to 60 atm were added to the reaction mixture. At the end of the reaction, the contents of the pressure vessel were pumped into the vacuum system; the methane, ethane, and CO_2 were removed by careful distillation with two Leroy stills (7); and the residue was analyzed by gas chromatography (6) for the final concentrations of methyl isocyanide, acetone, methyl cyanide, and di-*tert*-butyl peroxide. No methyl acetate was detected, even at the highest pressures, indicating that methyl radicals do not react significantly with CO_2 at these temperatures.

Results and Discussion

The sequence of reactions previously proposed (6) for the methyl-radical catalyzed isomerization of methyl isocyanide is

[1] $$DTBP \rightarrow 2CH_3 + 2CH_3COCH_3$$

[2] $$CH_3 + CH_3 \rightarrow C_2H_6$$

[3] $$CH_3 + CH_3NC \rightarrow CH_3CN + CH_3$$

whence, by using the integrated form of the rate expression, the apparent rate constant

$$k_3^* = \frac{1}{t}\left(\frac{k_2 v}{k_1[\mathrm{DTBP}]_{av}}\right)^{\frac{1}{2}} \ln \frac{[CH_3NC]_i}{[CH_3NC]_f}$$

where t is the length of the run, v is the volume of the reaction vessel, and the value for k_1 is that taken from ref. 7.

Without the addition of CO_2, the apparent rate constants k_3^* which we obtained are very similar to those found previously (6). However, as the CO_2 pressure is increased, k_3^* falls and eventually becomes constant above about 10 atm total pressure, as shown in Fig. 1. We postulate that this behavior can be accounted

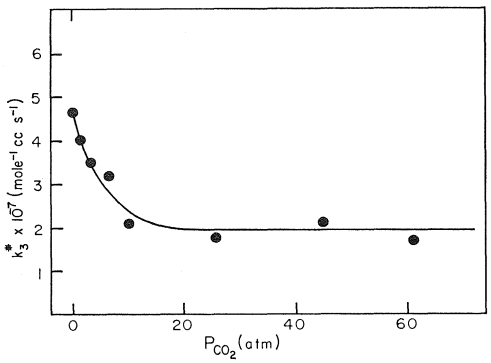

FIG. 1. Pressure dependence of the rate of isomerization of methyl isocyanide by methyl radicals at 110 °C.

for by the following modification to the above sequence of reactions

[2*a*] $CH_3 + CH_3 \rightarrow C_2H_6^*$

[2*b*] $C_2H_6^* + M \rightarrow C_2H_6$

[4] $C_2H_6^* + CH_3NC \rightarrow C_2H_6 + CH_3CN$

We envisage that process [2*b*] involves a series of stepwise deactivations, and in this reaction C_2H_6 represents an ethane molecule which has had sufficient of its vibrational energy removed so as to make it ineffective in reaction [4]. Reaction [4] as written also represents an overall process, which in detail probably takes place by a sharing of the vibrational excitation between the two partners, producing $CH_3NC\dagger$, which may then isomerize, or may be deactivated. Whilst some information is available (8) on the lifetime of vibrationally excited $CH_3NC\dagger$, we are not yet in a position to be able to make a theoretical analysis of the pressure dependence of k_3^*. All we can say at the moment is that at sufficiently high pressure, reaction [4] will be suppressed, as observed in Fig. 1.

The pressure dependence of k_3^* is not altered by using a 75 cc reaction vessel, indicating that no major surface effect is involved. Behavior similar to that shown in Fig. 1 was observed at all temperatures in the range 85–130 °C, except that the pressure dependence was slightly less marked at the higher temperatures. The result of this is that the high-pressure limit of the rate constant is represented by

$$k_3^{(\infty)} \approx 10^{17} \exp\,[-(16\,400 \pm 1000)/RT] \text{ mole}^{-1} \text{ cc s}^{-1}$$

We believe that this rate-constant expression requires further substantiation before it is accepted with confidence, since previous examples of "high" frequency factors in free-radical reactions have eventually proved to be incorrect (9, 10). In fact, it appears likely that it may be due to a certain amount of self-heating at the highest temperatures, since at 130 °C, the rate of production of heat is of the order of 5×10^{-5} cal cc^{-1} s^{-1}.

These experiments were then repeated using ethyl isocyanide, which is similarly isomerized by methyl radicals according to the reaction scheme (6)

[3*a*] $CH_3 + C_2H_5NC \rightarrow CH_3CN + C_2H_5$

[3*b*] $C_2H_5 + C_2H_5NC \rightarrow C_2H_5CN + C_2H_5$

It was found that both the rates of formation of methyl cyanide and isomerization of ethyl isocyanide were independent of pressure. This is consistent with our proposal since, being a more complicated molecule, the vibrationally excited $C_2H_5NC\dagger$ would have perhaps 100 times the lifetime of $CH_3NC\dagger$ with respect to isomerization. Hence the isomerization of C_2H_5NC would be at its high-pressure limit at rather less than 1 atm, and as the total pressure in most of the unpressurized experiments was about 0.1 atm, no conspicuous effect would be expected on increasing the pressure. Since methyl and ethyl isocyanide are so similar, both as regards their rates and heats of isomerization, their different behavior in this respect effectively rules out self-heating as the direct cause of the pressure effect described above.

The most unusual aspect of our proposed reaction scheme is the apparent existence of energy chains. If we compare the final compositions after a pair of comparable 2 h runs at 110 °C, we find

	Composition $\times 10^6$ moles			
Condition	DTBP	C_2H_6	CH_3NC	CH_3CN
No CO_2	31	(0.4)	181	32
45 atm CO_2	29	(0.4)	150	10

whence k_3^* works out to be 4.5×10^7 and 2.1×10^7 mole^{-1} cc s^{-1}, respectively; the ethane concentrations were not measured in these particular experiments, but were calculated from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the previously known behavior of the system (6, 7). Assuming that at the high pressure, all the isomerization takes place by reaction [3], we conclude that at low pressure, some kind of chain occurs, since the pressure effect far exceeds the number of moles of C_2H_6* which can partake directly in reaction [4]. Since reaction [3] is only 15 kcal/mole exothermic, and the activation energy for the thermal isomerization is 38 kcal/mole (11), no amount of internal excitation of the products could lead to a sensitization reaction; nor is it likely, since the activation energy of [3] is probably around 8–10 kcal/mole, that the CH_3 radical produced in [3] could carry sufficient excitation to react spontaneously with another isocyanide molecule. Thus, we are forced to conclude that it is only those vibrationally hot $CH_3CN‡$ formed in reaction [4] that can propagate a chain; reaction [4] must, therefore, be rewritten as

[4*a*] $C_2H_6^* + CH_3NC \rightarrow C_2H_6 + CH_3NC†$

[4*b*] $CH_3NC† \rightarrow CH_3CN‡$

[4*c*] $CH_3CN‡ + CH_3NC \rightarrow 2CH_3CN‡$

whence the chain length in essentially undiluted CH_3NC appears to be of the order of 30–50. (In this respect, it should be remembered that we found it necessary to postulate reaction [4*c*] in the ultraviolet photolysis of CH_3NC (12) to account for a quantum yield in excess of unity.)

We also decomposed di-*tert*-butyl peroxide in the presence of 1,1-difluoroethane to see if vibrationally excited ethane would sensitize the elimination of hydrogen fluoride. No vinyl fluoride was found. Hence either the lifetime of $CH_3CHF_2†$ is too long at 0.1 atm, or else the hot ethane molecule does not impart sufficient vibrational energy to the difluoroethane to cause it to decompose; since the critical energy for this process is greater than 50 and probably nearer 60 kcal (13) as opposed to the 38 kcal required to isomerize the isocyanide (11), the latter is probably the more meaningful explanation.

Coordination compounds of methyl gallium hydrides[1]

A. STORR AND V. G. WIEBE
Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received August 15, 1968

Although the organo hydride derivatives of boron and aluminium are well characterized, little work has been reported on the corresponding gallium systems. The present study was initiated to determine the relative stabilities of organo gallium hydride derivatives as compared to the stabilities of the corresponding compounds of boron and aluminium. Various preparative routes in this new class of gallium compounds have been investigated. These include the use of organo mercury and organo lithium reagents in reactions with gallium hydride compounds and their halogen substituted derivatives, and also equlibration reactions between gallium hydride and organo gallium compounds. Both infrared and proton magnetic resonance spectroscopy techniques have been used extensively in following the progress of these reactions and in the characterization of the products.

Canadian Journal of Chemistry, **47**, 673 (1969)

Introduction

Coordination compounds of gallane, GaH_3, and halogenogallanes, $GaH_{3-n}X_n$ (where X = halogen and $n = 1$ or 2), with amines and phosphines have been investigated extensively over the past few years (1–5). Similarly the coordination chemistry of the simpler gallium alkyls has been thoroughly studied (6, 7). In contrast, however, very little work has been carried out on the chemistry of organogallanes and none has been reported on coordination compounds of the type $D{\cdot}GaH_{3-n}R_n$, (where D represents a Lewis base, e.g. Me_3N; R represents a simple alkyl group, Me and Et; and $n = 1$ or 2).

The low thermal stability of known uncoordinated alkyl gallanes, of the type R_2GaH (8), suggested that the most profitable line of approach to the desired compounds would be via substitution reactions involving introduction of organo groups into coordinated gallium compounds. Several methods of synthesis were attempted, the first of which involved the reaction of trimethylamine-gallane with dimethylmercury in benzene or ether as solvent.

[1] $$Me_3NGaH_2Me + \tfrac{1}{2}H_2 + \tfrac{1}{2}Hg \xrightarrow[(ii)C_6H_6]{(i)Et_2O} Me_3NGaH_3 + \tfrac{1}{2}Me_2Hg$$

A second method involved the lithium hydride reductions of trimethylamine adducts of methylgallium halides.

[2] $$Me_3NGaMe_2Cl + LiH \xrightarrow{Et_2O} Me_2NGaMe_2H + LiCl$$

$$Me_3NGaMeCl_2 + 2LiH \xrightarrow{Et_2O} Me_3NGaMeH_2 + 2LiCl$$

A third and more advantageous route employed the reaction of lithium methyl with halogenogallanes.

[3] $$Me_3NGaH_2Cl + LiMe \xrightarrow{Et_2O} Me_3NGaH_2Me + LiCl$$

$$Me_3NGaHCl_2 + 2LiMe \xrightarrow{Et_2O} Me_3NGaHMe_2 + 2LiCl$$

Finally, equilibration reactions between trimethylamine-gallane and trimethylamine trimethyl gallium, in either ether or benzene as solvent, gave quantitative yields of the methylgallanes.

[4] $$Me_3NGaH_3 + 2Me_3NGaMe_3 \longrightarrow 3Me_3NGaHMe_2$$

$$2Me_3NGaH_3 + Me_3NGaMe_3 \longrightarrow 3Me_3NGaH_2Me$$

Experimental

Materials were handled in a conventional high vacuum line or in a glove box under an atmosphere of oxygen-free dry nitrogen. All solvents were thoroughly dried and redistilled before use.

Starting Materials

Trimethylamine-gallane and trimethylamine-trideuteriogallane were prepared as previously described (2). Trimethylamine-chlorogallanes were also obtained by

[1]Presented in part at the Third International Symposium on Organometallic Chemistry, Munich, 1967. Abstracts, p. 270.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

standard procedures (4). Trimethyl gallium was prepared by reacting a slight excess of gallium metal with dimethyl mercury in a sealed Carius tube (9). Methylgallium chlorides were prepared by standard procedures (10–12). Trimethylamine trimethyl gallium and trimethylamine methyl gallium chlorides were prepared by condensing excess trimethylamine onto the appropriate gallium acceptor moiety, followed by removal of excess amine at −10 °C under vacuum. Trimethylamine-alane was prepared by the method of Ruff and Hawthorne (13). Trimethylamine trimethyl aluminium was prepared from trimethyl aluminium and trimethylamine. Trimethyl boron was prepared by a Grignard reaction (14) and its trimethylamine adduct by the above method. Trimethylamine-borane was obtained by reacting lithium borohydride with trimethylamine hydrochloride in ether solution (15). Dimethyl mercury and lithium methyl were obtained from Alfa Inorganics. The latter reagent was obtained as an ether solution, the concentration of which was determined prior to each experiment.

Preparations of Methyl Gallane Derivatives

Method A

In a typical reaction trimethylamine-gallane (0.373 g, 2.83 mmoles) and dimethyl mercury (0.328 g, 1.42 mmoles) were dissolved in 50 ml of benzene and the solution refluxed under a nitrogen atmosphere. Graying occurred after a short time and the reaction was terminated after about 1 h and the reaction mixture filtered. The filtrate was concentrated by removal of benzene at low temperature (−20 °C) and the resulting solution examined by infrared (i.r.) and nuclear magnetic resonance (n.m.r.) techniques to establish the presence of the desired product, Me_3NGaH_2Me.

Method B

Trimethylamine-dichloromonomethylgallane, $Me_3NGaMeCl_2$, (0.178 g, 0.828 mmole) in 50 ml of ether was reacted with excess lithium hydride (0.032 g, 4.0 mmoles), initially at −20 °C, and then at room temperature for 2 h. The reaction mixture was then filtered and the ether solvent removed from the filtrate held at −40 °C. The paste-like product, "Me_3NGaH_2-Me", was dissolved in benzene and examined spectroscopically (i.r. and n.m.r.).

To prepare the dimethyl derivative, "$Me_3NGaHMe_2$", by this method trimethylamine-monochlorodimethylgallane, Me_3NGaMe_2Cl (0.271 g, 1.395 mmoles) in 50 ml of ether was reacted with lithium hydride (0.0274 g, 3.42 mmoles) and the product again examined spectroscopically.

Method C

In a typical experiment trimethylamine-monochlorogallane Me_3NGaH_2Cl (0.369 g, 2.22 mmoles) dissolved in 30 ml of ether was reacted with an ether solution of lithium methyl (3.51 ml of 0.63 *M*, 2.21 mmoles). The reaction mixture was stirred for several hours at room temperature and then the lithium chloride was filtered off. The ether solvent was removed from the filtrate at low temperature (−40 °C) to leave a liquid product. This product could be sublimed, and analyzed for Me_3NGaH_2-Me.

Anal. Calcd. for $C_4H_{14}GaN$, (mol. wt. 145.7): Ga, 47.8; H (hydrol.), 1.37. Found, (mol. wt. 175): Ga, 46.9; H (hydrol.), 1.38.

In an analogous manner, $Me_3NGaHCl_2$, (0.247 g, 1.23 mmoles) in 50 ml of ether, and an ether solution of LiMe (1.3 ml of 1.89 *M*, 2.46 mmoles) were reacted for several hours to yield an oily product after removal of the lithium chloride precipitate and the ether solvent. Again the product could be sublimed, and analyzed correctly for $Me_3NGaHMe_2$.

Anal. Calcd. for $C_5H_{16}GaN$, (mol. wt. 159.7): Ga, 43.6; H (hydrol.), 0.62. Found, (mol. wt. 172): Ga, 42.9; H (hydrol.), 0.62.

Method D

Trimethylamine-monomethylgallane, Me_3NGaH_2Me, was prepared by simply mixing together trimethylamine-gallane (0.608 g, 4.62 mmoles) and trimethylamine trimethyl gallium (0.398 g, 2.30 mmoles) in benzene solution. Similarly for the preparation of the dimethyl derivative, $Me_3NGaHMe_2$, trimethylamine-gallane (0.232 g, 1.76 mmoles) and trimethylamine trimethyl gallium (0.612 g, 3.51 mmoles) were mixed together in benzene. The resultant clear solutions were then examined spectroscopically (i.r. and n.m.r.).

To obtain a solvent-free species by this method ether was found to be a superior solvent since it could be removed at much lower temperatures from the product solution. The products obtained on removal of ether solvent had identical physical characteristics to those of the compounds obtained via route C.

The deuterated analogues, trimethylamine-monomethylbideuteriogallane, Me_3NGaD_2Me, and trimethylamine-dimethylmonodeuteriogallane, $Me_3NGaDMe_2$, were prepared by method D using trimethylamine-trideuteriogallane, Me_3NGaD_3, and trimethylamine trimethyl gallium, Me_3NGaMe_3, as starting materials.

The corresponding alane compounds, Me_3NAlH_2Me and $Me_3NAlHMe_2$, were also obtained by route D as previously described by Peters *et al.* (16). Investigation of the borane systems gave no indication of equilibration between Me_3NBH_3 and Me_3NBMe_3 as evidenced by p.m.r. data.

Analytical Methods

The samples were analyzed for hydrolyzable hydrogen, (i.e. Ga—H), by treatment with water using a method similar to the one previously described (2). Gallium was determined by the 8-hydroxyquinolate method (2) after first removing the methyl groups from the metal by boiling the sample for several hours with concentrated hydrochloric acid (17).

Cryoscopic molecular weight determinations were carried out in benzene solution under strictly anhydrous conditions in a nitrogen-flushed system.

Spectra

Definitive i.r. spectra were recorded on a Perkin–Elmer model 457 spectrometer (4000–250 cm^{-1}) and routine spectra on Perkin–Elmer infrared models 137E and K24.

Proton magnetic resonance spectra were obtained on Varian HA-100 and A-60 instruments. The benzene (or cyclohexane) solutions were prepared in the glove box and the sample tubes sealed off to avoid atmospheric hydrolysis. All τ values are referred to benzene as $\tau_{C_6H_6}$ = 2.84 p.p.m. or to cyclohexane as $\tau_{C_6H_{12}}$ = 8.54 p.p.m.; (τ_{TMS} = 10.00 p.p.m.). Cyclohexane has the advantage

For personal use only.

that all the proton peaks in this solvent are concentration independent, but it has the disadvantage that the solvent peak often obscures the N—Me peak which appears at $\tau \simeq 8.0$ p.p.m. At higher concentrations, the proton signals in benzene solutions show a concentration dependence but in this work this effect was minimized by working at lower concentrations. In addition, with benzene as solvent, the N—Me region is no longer obscured in the spectra.

Signals due to Ga—H and Al—H protons were not observed, principally because of the low concentrations but also perhaps because of nuclear quadrupole broadening (3, 5).

Results and Discussion

Synthetic Methods

No reaction was observed between Me_2Hg and Me_3NGaH_3 (Method A) in benzene or ether solvent at room temperature, and at higher temperatures the yield of product was low due to thermal instability of both the gallane starting material (2) and the methylgallane product. The presence of finely divided gallium metal from the initial thermal decomposition of starting material probably catalyzes the decomposition of the product. This type of autocatalytic process has been noted in other gallium systems (18, 19). That a definite reaction did take place, rather than merely decomposition of starting material, is evidenced by both the p.m.r. and i.r. spectra of the product solution and the appearance of mercury in the product mixture. The low yields in this reaction are in contrast to the corresponding system in alane chemistry where quite high yields are reported from the reaction at elevated temperatures (16).

The reduction of methylchlorogallanes (Method B) with lithium hydride proved to be a very unsatisfactory route to the methylgallane derivatives, and, although some reduction was evident from the p.m.r. and i.r. spectra of the products, compounds free from chlorine could not be isolated. Even with higher reaction temperatures and longer reaction times similar incomplete reductions were noticed in the alane systems (16). Higher reaction temperatures in the gallane systems are prohibited because of the thermal instability of the products.

The reactions involving lithium methyl (Method C) proceed smoothly at room temperature and yield pure products free from chlorine. The equilibration reactions (Method D) gave quantitative yields of the methyl-gallanes. In both methods C and D, the products could be purified by sublimation under high vacuum.

Physical Properties

The trimethylamine-methylgallanes are liquids at room temperature and exhibit extended melting point ranges (approx. 0–20 °C). These long melting point ranges may indicate that there is a change in the degree of polymerization in going from the solid to the liquid, a behavior observed for compounds of the type Me_2NGaMe_2, (20), or perhaps that some dissociation or disproportionation of the complexes occurs.

The molecular weights of the compounds Me_3NGaH_2Me and $Me_3NGaHMe_2$ were determined cryoscopically in benzene solution. The results indicate a slight degree of association (1.20 and 1.08, respectively) which probably occurs via dipole–dipole interaction rather than through bridged dimers, which would involve unstable 5-coordinate gallium species. These results may, however, represent only a *mean* molecular weight in each case, since, as is described later, a number of different gallium species probably co-exist in the benzene solutions.

Proton Magnetic Resonance Data

The p.m.r. spectra of Me_3NGaH_2Me and $Me_3NGaHMe_2$, in benzene or cyclohexane, both show, at the same positions, three distinct Ga—Me signals which have different integrated intensities in the two samples (Fig. 1). The approximate Ga—Me peak separations were ~ 5 c.p.s. at 60 Mc/s and ~ 8 c.p.s. at 100 Mc/s, thus demonstrating that signals arise from three

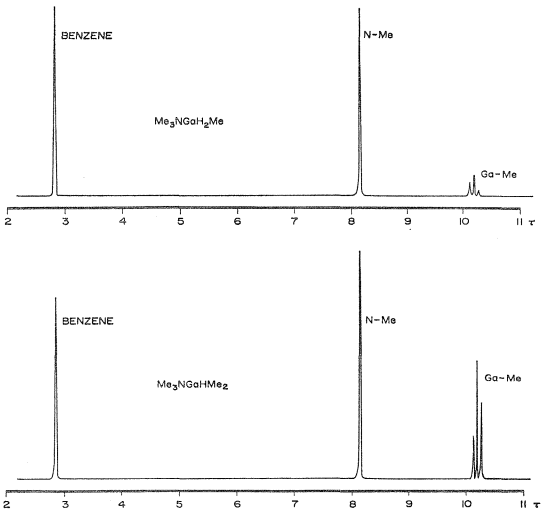

FIG. 1. Nuclear magnetic resonance spectra of Me_3NGaH_2Me and $Me_3NGaHMe_2$ in benzene at 60 Mc/s.

different species and not from spin–spin coupling. It seems probable, therefore, that an equilibrium is established in solution in which all four possible species are present: Me_3NGaMe_3, Me_3NGaH_2Me, $Me_3NGaHMe_2$, and Me_3NGaH_3.

Thus for Me_3NGaH_2Me in benzene the three Ga—*Me* signals appear at τ = 10.24, 10.17, and 10.09 p.p.m. with the single N—Me resonance occurring at τ = 8.10 p.p.m. The signals are assigned in Table I which also includes the percentage of each compound in solution. The signal at 10.24 occurs at the same position as the Ga—Me signal in an authentic sample of Me_3NGaMe_3 and its assignment follows directly. The monomethyl- and dimethyl-gallane derivatives are assigned on the basis of peak area ratios and on chemical shifts expected on substituting hydrogen for methyl on gallium. Thus with the introduction of the more electronegative hydrogen atom the remaining methyl groups become less shielded and give signals at lower field positions. The percentages given in Table I are calculated from the area ratios of the Ga—Me signals and the area ratio of the single N—Me signal. For the compound $Me_3NGaHMe_2$ in benzene solution the data listed in Table II were obtained. Similarly, three Ga—Me signals were observed for each of the deuterated compounds Me_3NGaD_2Me and $Me_3NGaDMe_2$ in benzene solution and almost identical proportions of the various species were present as compared to the hydrido compounds. In cyclohexane a similar pattern resulted with the three Ga—*Me* signals appearing at τ = 10.57, 10.51, and 10.42 p.p.m. for the hydrido compounds.

TABLE I

Proton magnetic resonance data for Me_3NGaH_2Me in benzene solution

Species	τ (Ga—Me)	Peak area ratio	% of species
Me_3NGaMe_3	10.24	1.00	3.1
$Me_3NGaHMe_2$	10.17	4.85	22.9
Me_3NGaH_2Me	10.09	5.00	47.0
Me_3NGaH_3	—	—	27.0

TABLE II

Proton magnetic resonance data for $Me_3NGaHMe_2$ in benzene solution

Species	τ (Ga—Me)	Peak area ratio	% of species
Me_3NGaMe_3	10.24	1.60	16.0
$Me_3NGaHMe_2$	10.16	3.10	46.4
Me_3NGaH_2Me	10.08	1.00	30.0
Me_3NGaH_3	—	—	7.6

This same set of three Ga—Me signals was observed in the product solutions from all four experimental routes (A–D). Solutions obtained via route B, however, gave additional Ga—Me signals which are probably due to partially reduced species of the type $Me_3NGaHClMe$, or to compounds of the form $LiGaH_3Me$. The equilibria between the four species does not appear to be time dependent since two spectra taken on the same sample one month apart showed no change. Variation of the solvent from benzene to cyclohexane seems to have little effect on the percentage of each species present but merely displays the Ga—Me signals at higher field.

It is interesting to note that in all the spectra taken only a single sharp peak was observed for the N—Me resonance. In solutions of Me_3NGaH_2Me and $Me_3NGaHMe_2$, the Me_3N groups must be exchanging rapidly, and indeed the N—Me peak positions appear to be in the average position between the extremes of Me_3NGaMe_3 and Me_3NGaH_3.

The p.m.r. of the chloro compounds, Me_3NGaMe_2Cl and $Me_3NGaMeCl_2$, in benzene solution showed only a single resonance in the Ga—Me region of the spectrum at room temperature. Presumably the greater efficiency of the chlorine as a bridging group over methyl or hydrogen (21) leads to a specific single compound or to a very rapid exchange process.

The behavior of the methylgallanes in benzene and cyclohexane solutions at room temperature prompted us to re-examine the corresponding alane compounds, Me_3NAlH_2Me and $Me_3NAlHMe_2$, under similar conditions. Peters *et al.* (16) explained the "doublet" appearing above 10τ in the p.m.r. spectra of these compounds in cyclohexane solution in terms of dimerization involving hydrogen and/or methyl bridging groups. A close re-examination of this p.m.r. study showed not two, but three distinct signals in the Al—Me region of the spectrum in both benzene and cyclohexane solutions. Figure 2 depicts the Al—Me region of the spectra observed in benzene solution at 100 Mc/s and Table III collects the data obtained from both solvents. Examination of the spectra showed a

	$Me_3NAlHMe_2$	10.53	3.43	21.8
	Me_3NAlH_2Me	10.47	3.00	38.5
	Me_3NAlH_3	—	—	35.4
$Me_3NAlHMe_2$	Me_3NAlMe_3	10.58	4.14	29.3
	$Me_3NAlHMe_2$	10.53	3.57	38.3
	Me_3NAlH_2Me	10.47	1.00	21.2
	Me_3NAlH_3	—	—	11.2

peak separation of ~ 5.5 c.p.s. at 100 Mc/s and ~ 3.5 c.p.s. at 60 Mc/s showing the Al—Me peaks to be field dependent as were the Ga—Me peaks. These trimethylamine–methylalane spectra show a close resemblance to the corresponding gallane spectra and lead us to propose a similar set of aluminium compounds co-existing in solution. Table IV lists the various proportions of each species present worked out on the above assumption.

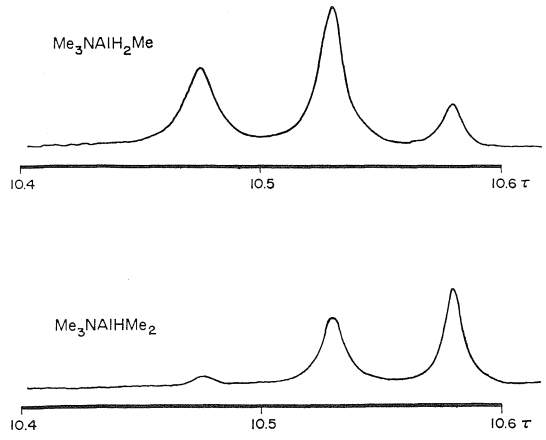

FIG. 2. Nuclear magnetic resonance spectra (Al—Me region) of Me_3NAlH_2Me and $Me_3NAlHMe_2$ in benzene at 100 Mc/s.

On the basis that the trimethylamine adducts of methylgallanes and methylalanes yield a series of equilibrium products in solution an examination of the analogous boron systems was carried out. The compounds Me_3NBMe_3 and Me_3NBH_3 were mixed in 1:2 and 2:1 mole ratios in benzene but no exchange of either Me_3N groups or Me/H groups was evident from the n.m.r. spectra (Fig. 3). The data are summarized in Table V. The slight shift in Me—N and B—Me peaks in the mixtures is due probably to dipole–dipole interactions rather than to alkyl or amine exchange.

Infrared Data

The i.r. spectra of the compounds Me_3NGaH_2-Me, $Me_3NGaHMe_2$, and their deuterated analogues Me_3NGaD_2Me and $Me_3NGaDMe_2$ were recorded in benzene solution. As observed in previously reported spectra of gallane derivatives (2, 4), the strongest absorptions were attributable to Ga—H(D) stretching and deformation frequencies. These are listed and assigned in Table VI. The expected decrease by a factor of about $\sqrt{2}$ in going from Ga—H to Ga—D frequencies was observed. Two distinct Ga—H stretching frequencies were evident for the compounds Me_3NGaH_2Me and $Me_3NGaHMe_2$. The band

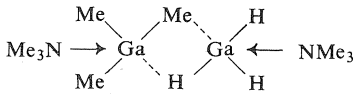
at 1840 cm^{-1} is very close to the one occurring in the spectrum of Me_3NGaH_3 in benzene solution (4) and could be due to this species in the equilibrium mixture. The strong absorption at 1770 cm^{-1} could then be assigned to methylgallanes in the solutions.

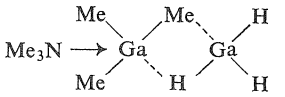
Mechanism of Exchange

From the p.m.r. and i.r. data there is strong evidence that the four compounds $Me_3NGaH_{3-n}Me_n$, where n = 0, 1, 2, or 3, co-exist in solution. The intermediate that gives rise to these species must presumably be reached via a bridged gallium species



This bridged intermediate could then dissociate to give the original compounds or to give new species. The latter can then lead to a mixture containing all the four different species postulated.

An alternative mechanism could involve a bridged dimer containing both five-coordinate and four-coordinate gallium atoms



In this case the four-coordinate gallium is derived from a three-coordinate gallium atom, e.g. GaH_3, $GaHMe_2$, etc. from which the Me_3N has dissociated. Both these mechanisms have been proposed for exchange reactions involving adducts of the type Me_3NAlMe_3 and Me_3NAlMe_2X where X = halogen (22).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

A further possibility would be for both compounds to dissociate in solution to yield free amine and three-coordinate gallium species. The gallium entities could then form a dimer species which, on dissociation, could produce mixed methylgallanes or the original species. Finally recombination with amine would yield the series of trimethylamine methylgallanes

$$Me_3NGaMe_3 \rightarrow Me_3N + GaMe_3$$

$$Me_3NGaH_3 \rightarrow Me_3N + GaH_3$$

$$GaMe_3 + GaH_3 \rightleftarrows \begin{matrix} Me & Me & H \\ & Ga \cdots Ga & \\ Me & H & H \end{matrix}$$

$$\rightleftarrows Me_2GaH + MeGaH_2$$

$$Me_3N + Me_2GaH \rightarrow Me_3NGaMe_2H$$

$$Me_3N + MeGaH_2 \rightarrow Me_3NGaMeH_2$$

A dissociation mechanism of this type has been proposed by DeRoos and Oliver to account for the exchange reaction occurring between Me_3NGaMe_3 and excess Me_3Ga (23).

In the present case the latter mechanisms, involving three-coordinate gallium species, seem unlikely, since benzene solutions of Me_3NGaH_2Me were found not to hydrogallate ethylene, a process to be expected if three-coordinate species of the type, GaH_2Me, are present in the solution (24).

Similar mechanisms can be proposed for the observed behavior of the methylalane adducts. The absence of exchange in the boron systems is presumably due on the one hand to the inability of boron to form five-coordinate intermediates of this type, and on the other to the absence of three-coordinate BH_3 and BMe_3 units (from dissociation of the adducts). If these three-coordinate species were *both* formed they would readily rearrange to give a series of methylboranes (25, 26) and hence, on recombination with amine, the mixed adducts.

In summary, it appears that the compounds Me_3NGaH_2Me and $Me_3NGaHMe_2$ are comparable to Me_3NGaH_3 in thermal stability and much more stable thermally than the uncoordinated alkylgallanes (8, 27). However, the gallane derivatives are much less stable than the corresponding borane (15) and alane (16) compounds.

Dielectric studies. Part XXIII. Relaxation data and apparent dipole moments of aniline and some disubstituted aromatic amines

S. W. TUCKER (MISS)
Chemistry Department, University of Aston in Birmingham, England

AND

S. WALKER
Chemistry Department, Lakehead University, Port Arthur, Ontario

Received August 13, 1968

Dielectric studies have been carried out at microwave frequencies on dilute solutions of aniline, *p*-chloro-, *p*-bromo-, and *m*-chloro-anilines, and *o*-, *m*-, and *p*-toluidines at 25 °C in cyclohexane and *p*-xylene. The static dielectric constant has also been measured at 2 MHz. In addition *o*- and *m*-toluidines have been measured at 50 °C and *p*-toluidine at 15, 35, and 50 °C.

The dielectric results, particularly those at 70.01 GHz, establish that there is more than one relaxation process present and the data have been analyzed on a two relaxation time model, the longer of which τ_1, is identified as molecular relaxation. The cause of the lower electric dipole moments found from this method as opposed to the non-dielectric absorption methods is discussed. It follows that there is either an additional higher frequency dispersion or (and) a high atomic polarization for aniline and *o*-, *m*-, and *p*-toluidines. Work at still higher frequencies is required to study this further and to establish more precise values of τ_2.

Canadian Journal of Chemistry, **47**, 681 (1969)

When two polar solutes of similar size and shape are independently examined in a particular non-polar solvent and the solute is present at low concentration, then, providing there is no appreciable molecular interaction and the solute molecules undergo no intramolecular motion (such as group re-orientation), similar observed relaxation times are to be expected. The observed relaxation time would then be the molecular relaxation time. Such considerations were embodied in the work of Fischer (1) and used to identify the lack of rigidity in certain molecules. In general, when the observed relaxation time is shorter than that anticipated, it suggests a contribution from an additional relaxation process(es). This appears the case for aniline in benzene (2) at 20 °C since the observed relaxation time is 4.3×10^{-12} s which is to be compared with a molecular relaxation time of 7.5×10^{-12} s for chlorobenzene in cyclohexane (3) at 25 °C.

This present work aimed to examine whether such a shortening of the relaxation time of primary aromatic amines in non-polar solvents was a general phenomenon. Further, it seemed likely that measurements at 70.01 GHz would help to establish any contribution from a short relaxation time more precisely. It was considered worthwhile to carry out measurements in the two solvents in order to assess whether the dipole moments and relaxation times were highly dependent on specific solvent effects.

Experimental

The apparatus and procedure for determining the dielectric constant and loss have been described previously (4).

Materials

The liquid amines were all distilled from a spinning band column of 35 theoretical plates and then dried. The observed boiling points were compared with literature values, and the compounds were shown to have no detectable amounts of impurities by infrared and gas chromatographic techniques.

The solids were recrystallized from appropriate solvents and dried until their melting points agreed with those in the literature.

Experimental Results

ε_∞ was estimated from the high frequency intercept of the Cole–Cole plot and the accuracy of this procedure has been considered previously (5). The dielectric data at different frequencies were then analyzed into contributory relaxation times by assuming that each relaxation process undergoes Debye behavior. The theory has been given by Budó (6).

Consideration of the real and imaginary parts of the complex dielectric constant yields

$$[1] \qquad \frac{\varepsilon''}{\varepsilon_0 - \varepsilon_\infty} = \frac{C_1\omega\tau_1}{1 + \omega^2\tau_1^2} + \frac{C_2\omega\tau_2}{1 + \omega^2\tau_2^2}$$

TABLE I

*The τ_1 and τ_2 estimates for *p*-toluidine in *p*-xylene were obtained from the limiting slopes of the plot of ε' vs. $\varepsilon''\omega$.

$$[2] \quad \frac{\varepsilon' - \varepsilon_\infty}{\varepsilon_0 - \varepsilon_\infty} = \frac{C_1}{1 + \omega\tau_1^2} + \frac{C_2}{1 + \omega^2\tau_2^2}$$

and eq. [1] was solved using an Elliott 803 computer for the weight factor C_1 and the two relaxation times τ_1 and τ_2.

Dipole moments were obtained from the Debye equation for dilute solutions

$$[3] \quad \mu_m = 0.012812\,\{[(\varepsilon_0 - \varepsilon_\infty)/w_2] \times [3TM_2/(\varepsilon_1 + 2)^2 d_1]\}^{1/2}$$

where ε_1 is the static dielectric constant of the solvent, d_1 is its density, T is the absolute temperature, M_2 the molecular weight of the solute, and w_2 the weight fraction of the solute.

The mean relaxation times τ_0 were deduced from the equation

$$\frac{v}{u} = (\omega\tau_0)^{1-\alpha}$$

in which v is the distance on the Cole–Cole plot between the static dielectric constant (ε_0) and the experimental point, u is that between the point and the very high frequency value ε_∞; α is the distribution coefficient.

The dielectric constant and loss data are presented in Table I. The experimental values ε'_{obsd} and ε''_{obsd} are compared with those calculated from eqs. [1] and [2]. The terms ε'_{calcd} and ε''_{calcd} calculated using the τ_1, τ_2, and C_1 values given by computer analysis are listed in Table II, together with the mean relaxation time and electric dipole moment.

The absorption of *p*-xylene has been subtracted at 23.98, 34.86, and 70.01 GHz from the measured results and these corrected values are quoted as ε'_{obsd} and ε''_{obsd}.

Plots of ε' vs. $\varepsilon''\omega$ can be useful for indicating the presence of more than one relaxation process (7). For Debye behavior, the plot is a straight line of slope τ but for two relaxation times, sufficiently distinct in magnitude, a curve is obtained. The extremes of slope then indicate τ_1 and τ_2 but the steeper slope gives a value less than the true τ_1 and the lesser slope longer than τ_2.

The results for *p*-toluidine gave extended Cole–Cole plots, and because of insufficient accuracy

*$\varepsilon_{\infty calcd}$ values estimated from literature dipole moments are compared with the microwave $\varepsilon_{\infty obsd}$ values at 25 °C. The static dielectric constants of cyclohexane and *p*-xylene at 25 °C are 2.016 and 2.263 respectively.

of the 70.01 GHz results it was not possible to determine ε_∞ with sufficient accuracy to deduce τ_1 and τ_2 from eq. [2]. Estimates of the two relaxation times were obtained from ε' vs. $\varepsilon''\omega$ plots. The τ_1 and τ_2 values derived from the limiting slopes of these plots for *p*-toluidine are given in Table II.

Discussion

The results at 25 °C for substituted anilines yield estimates for two relaxation times. Courtauld models indicate that the methyl and chloro groups are of similar sizes to that of the amino group and thus, the τ_1 value of the amine, for example, may be compared with that of the corresponding chloro-substituent where the latter can be regarded as a rigid molecule characterized by a molecular relaxation time in the microwave region. Justification for the analyses may be gained by comparison of the τ_1 values for the amines with those of the corresponding methyl or chloro substituents (see Table III).

Since Williams (8) has recently given a comprehensive account of the internal re-orientation motion feasible for the τ_2 process of aniline and alkylamines the actual mechanism will not be considered further here except to note that his treatment expresses τ_2 in terms of τ_1 and an internal re-orientation time. It should be noted though that the error in τ_2 could be appreciable and work at higher frequencies (e.g. in the far infrared region) is desirable to establish more precise values.

From Table II it may be observed that the α values for a given solute in cyclohexane and *p*-xylene tend to be less in the latter solvent. However, within our experience, relaxation time values are up to $\sim 10\%$ longer in *p*-xylene than cyclohexane for molecular relaxation of rigid molecules. For a constant C_1,α would increase with the

τ_1/τ_2 ratio (9) and, thus, it follows that the variable α in the solvents cyclohexane and *p*-xylene is more likely to be due to an intermolecular effect. This also fits in better with the variable C_2 values in the two solvents.

For the halo-substituted anilines where the moment is high (> 2.5 D), the C_2 values are ~0.1 or less, whereas for aniline, *o*-, *m*-, and *p*-toluidine whose moments are less than ~ 1.5 D, the C_2 values are ~ 0.2 or greater. Thus, the τ_2 process becomes more detectable when the moment is low and for *p*-toluidine, which has the lowest moment of ~ 1.1 D an ε' vs. $\varepsilon''\omega$ plot clearly indicates the presence of more than one relaxation process.

The dipole moments obtained by the microwave method are lower than those from the non-dielectric absorption procedure (see Tables IV and V). This is particularly so when the moment of the compound is ~ 1.5 D or less for *o*-, *m*-, and *p*-toluidine but this discrepancy is much smaller for those compounds the dipole moment of which is ~ 3D.

TABLE V

Apparent dipole moments calculated from the data of Smyth and co-workers in benzene at 20 °C compared with literature values

Solute	Maximum mole fraction	μ_m	μ_{lit}
Aniline	0.05	1.43	1.50
1-Naphthylamine	0.026	1.46	1.55
2-Naphthylamine	0.027	1.53	—
p-Toluidine	0.057	1.07	1.33

For small solutes at low concentrations, the alteration in the ε_∞ value for slight increases in concentration is very small and in the absence of any additional dispersion ε_∞ would tend to ε_1. Inspection of the experimental ε_∞ values in Table II, bearing in mind that at 25 °C, ε_1 (cyclohexane) = 2.016, ε_1 (*p*-xylene) = 2.263, indicates significant differences between ε_∞ and ε_1. In conjunction with eq. [3] this could account for the evaluation of apparently low dipole moments. Table IV gives ε_∞ values which have been calculated for the solutions from (*a*) literature dipole moments obtained by non-dielectric absorption methods and (*b*) our measured values. The non-dielectric absorption methods and non-microwave methods such as the Guggenheim (10) for determining dipole moments involves n_D^2 in place of ε_∞. However, this approximation cannot be justified when there is an unusually high atomic polarization and would result in the value for the dipole moment being too high. The microwave method for evaluating dipole moments does not involve such an approximation although, if an additional higher frequency dipole relaxation existed, then our ε_∞ values would not be the ones required for eq. [3] but would be too large and would account for the μ_m being too small. Thus, two possible explanations may be advanced to account for the divergent dipole moment values.

Schneider (11) has measured the dielectric absorption of aniline in dilute benzene solution at 20 °C and found its dipole moment to be 1.30 D and the molecular relaxation time to be 5.4×10^{-12} s in the molar fraction range, 0.001 to 0.01. The dielectric loss curve showed a Debye type relaxation process characterized by a single relaxation time and the equation

$$\varepsilon'' = m(a_0 - a_\infty)\frac{\omega\tau}{1 + \omega^2\tau^2}$$

where m is the molar fraction of aniline and a_∞ is the slope of the straight line when the dielectric constant measured in the far infrared region is plotted against molar fraction. He suggests that the low dipole moment value, as opposed to that obtained by the non-dielectric absorption method, could be explained by the presence of an unusually large atomic polarization arising from a low frequency vibration of the amino group. The good agreement between our apparent moments for aniline in *p*-xylene and cyclohexane and Schneider's in benzene, where the concentration was appreciably lower, suggests that the major cause of the lower moment is not association.

Smyth and his co-workers have not quoted their dipole moments. From their microwave data we have calculated the moments (see Table V) from the equation

$$\mu_m = 0.012812\,\{(a_0 - a_\infty)\,TM_1/(\varepsilon_1 + 2)^2 d_1\}^{1/2}$$

where M_1 is the molecular weight of the solvent, and a_0 and a_∞ are the slope of ε_0 and ε_∞ vs. mole fraction of solute respectively. It should be noted that for 1- and 2-naphthylamine the difference between a_D (the slope of n_D^2 vs. mole fraction) and a_∞ has been taken "to indicate a second dispersion region at higher frequencies" (2).

Hadni (12) observed a band at 269.5 cm^{-1} in the far infrared spectrum of methylamine. Stewart (13) has calculated a torsional frequency of 225 cm^{-1} for methylamine, assuming a large moment of inertia of the alkyl group along the C—N axis, and a sinusoidal two minima rotational potential function having a barrier height of 3.3 kcal/mole. This torsional oscillation band is not found in the gas phase and is not observed for secondary aliphatic amines.

Evans (14) has observed a band at 420 cm^{-1} for dilute solutions of aniline in benzene which in the vapor phase appears at 440 cm^{-1}. He has assigned this band to the first overtone of a torsional mode of the C—NH_2 group, and by a similar method to Stewart, has calculated the fundamental frequency of the torsional mode to be 216 cm^{-1} and the barrier height to internal rotation to be 3.54 kcal/mole, which is similar to that of methylamine.

Torsional movement in aniline and substituted anilines could account for our dipole moments being lower than those calculated by the Guggenheim and Halverstadt–Kumler methods.

When all the available evidence is taken into account, it is not clear whether the dipole moment difference by the two approaches is to be attributed to a high atomic polarization contribution as favored by Schneider (11) for aniline or to a second dispersion at higher frequencies as proposed by Grubb and Smyth (2) for 1- and 2-naphthylamine.

In conclusion, the present work on aromatic amines in the inert solvent cyclohexane and the weakly donor solvent *p*-xylene establishes the presence of (at least) one shorter relaxation (τ_2) process other than that for molecular relaxation. This is readily apparent from an ε' vs. $\varepsilon''\omega$ plot for *p*-toluidine by virtue of the 70.01 GHz point. In addition, the dipole moment by the non-dielectric absorption approach differs from that obtained here. Either an additional higher frequency dispersion or a high atomic polarization exists for aniline, *o*-, *m*-, and *p*-toluidine.

A novel aromatic ketone photoproduct: para-coupling of a phenyl-ketyl radical

B. D. CHALLAND[1]
Chemistry Department, University of Western Ontario, London, Ontario

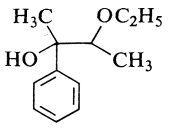
Received September 18, 1968

Three minor products from the irradiation of acetophenone in ether are described, and the mechanism of their formation is discussed.

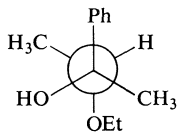
Canadian Journal of Chemistry, **47**, 687 (1969)

Irradiations of aromatic ketones in hydrogen-donating solvents have long been known to give mixtures of reduction products, predominantly pinacols (1), and recent publications concerning the mechanism of the photoreduction of benzophenone to benzopinacol (2–5) have prompted this report. During the course of other investigations it was found that irradiation of acetophenone in ether/cyclohexane solvent gave, as expected, the acetophenone pinacols in good yield (6). The product mixture also contained three minor constituents which were separated chromatographically and identified.

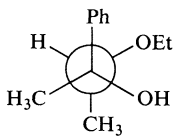
Two butan-2-ol derivatives were isolated in 6% yield each and the gross structure **1**, for both of them, was assigned from their spectra. The infrared (i.r.) spectra of each showed a monosubstituted phenyl, a hydroxyl group (probably tertiary) and no carbonyl, and differed only in details of the "fingerprint region". The proton magnetic resonance (p.m.r.) spectra, however, differed appreciably. Both showed the presence of one singlet, one doublet, and one triplet methyl group, but in one case (compound **1*a***) the doublet and triplet were well-separated, and in the other (compound **1*b***) almost superimposed. Three protons on carbon adjacent to oxygen appeared as complex multiplets in each, the patterns differing in detail. These were consistent with the A, B, and A′ portion of an ABX_3 pattern superimposed on an $A'X'_3$ (7, 8). Five aromatic protons and one hydroxyl were present in each compound. The compounds **1*a*** and **1*b*** were evidently diastereoisomeric and on the basis of the relative chemical shifts of the methyl groups, and the anticipated preferred conformations (9), the structures were tentatively proposed as shown.



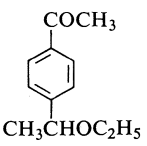
1



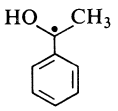
1*a*



1*b*



2



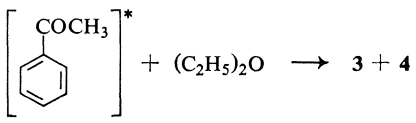
3

4

The third minor product, **2** (3% yield after purification), was also identified by its spectra. Ultraviolet (u.v.) and i.r. spectra showed that the compound was a substituted aromatic ketone, and all the non-equivalent protons were clearly resolved in the p.m.r. spectrum. The *p*-substitution of the acetophenone was apparent from

[1]Present address: Chemistry Department, University of Southampton, Southampton, SO9 5NH, England.

the pattern of the aromatic protons, two symmetrical doublets of two protons each. The possibility of a dimeric structure was considered to be incompatible with the observed p.m.r. spectrum, which was very well-defined.



The generally accepted mechanism for photoreduction of aromatic ketones involves abstraction of a hydrogen atom from the solvent by the ketone in the excited triplet state to give two radicals, in this case **3** and **4**. Subsequent combination of these radicals would give the two butan-2-ol derivatives, **1**, which were observed. Such compounds are well-known as minor products from photoreduction reactions; for example, irradiation of benzophenone in toluene, which acts as a hydrogen donor, gives **5** as well as benzopinacol (10).

The substituted acetophenone, **2**, however, is apparently a photoproduct of a new type. Its formation can be rationalized by postulating that the delocalized ketyl radical, **3**, is attacked at the *p*-position by the ethoxyethyl radical, **4**, to give the enolic intermediate **6**, which would be expected to be oxidized by air to the observed product, **2**, during workup of the reaction mixture. Alternatively the dehydrogenation might have been effected by acetophenone in the excited triplet state. The intermediate is analogous to **7** and **8**, both of which have been reported to be the oxygen-sensitive intermediate in the photoreduction of benzophenone by alcohols (3–5). The isolation of **2**, therefore, tends to confirm the mechanism of benzophenone photoreduction as recently proposed (3–5), and suggests that this mechanism is common to aromatic ketone photoreduction by hydrogen donors other than alcohols.

Experimental

Nitrogen was bubbled through a solution of acetophenone (4.73 g) in 50% ether/cyclohexane (250 ml) for 1 h, and the solution was then irradiated under nitrogen with light of λ_{max} 350 nm ("black light" phosphor lamps through Pyrex; Rayonet reactor) for 2¼ h. Evaporation of the solution and chromatography on a silicic acid column (5% ether/benzene eluent) afforded recovered acetophenone (2.54 g), ***1a*** (162 mg, 7% yield), ***1b*** (150 mg, 6% yield), **2** (70 mg, 3% yield), and a mixture of the acetophenone pinacols (1.30 g).

*Compound **1a*** had p.m.r. peaks at τ 9.16 (3H, d, J = 6.5 Hz), 8.84 (3H, t, J = 7 Hz), 8.49 (3H, s), 7.30 (1H, exchanges with D_2O, s), 6.1–6.9 (3H, m), 2.5–3.0 (5H, m); u.v. λ_{max}^{hexane} at 206 nm (ε 8600), 258 nm (ε 190).

Anal. Calcd. for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34. Found: C, 74.17; H, 9.42.

*Compound **1b*** had p.m.r. peaks at τ 9.00 (3H, d, J = 6.5 Hz), 8.93 (3H, t, J = 7 Hz), 8.61 (3H, s), 7.21 (1H, exchanges with D_2O, s), 6.2–7.1 (3H, m), 2.5–3.0 (5H, m); u.v. λ_{max}^{hexane} at 206 nm (ε 8400), 258 nm (ε 200).

Anal. Found: C, 74.35; H, 9.32.

p-(1-Ethoxyethyl)acetophenone, **2**, had i.r. ν_{max} 1685 cm^{-1}; p.m.r. peaks at τ 8.83 (3H, t, J = 7 Hz), 8.62 (3H, d, J = 6.5 Hz), 7.51 (3H, s), 6.69 (2H, q, J = 7 Hz), 5.62 (1H, q, J = 6.5 Hz), 2.68 (2H, d, J = 8 Hz), 2.18 (2H, d, J = 8 Hz); u.v. λ_{max}^{hexane} at 248 nm (ε 15 000), 320 nm (ε 670).

Abstraction of hydrogen from hydrogen sulfide by methyl radicals

PETER GRAY, A. A. HEROD[1], AND L. J. LEYSHON[2]
School of Chemistry, Leeds University, Leeds 2, England

Received August 27, 1968

The methyl radical attack on H_2S has been investigated briefly using azomethane as the radical source. The results indicate that the previous rate-constants for the abstraction reaction are too high and that CF_3 radicals may react with H_2S faster than CH_3 radicals.

Canadian Journal of Chemistry, 47, 689 (1969)

The reaction of methyl radicals with hydrogen sulfide has been investigated using the photolysis of azomethane as the source of methyl radicals. Previous workers generated methyl radicals from acetone (1) and acetaldehyde (2, 3) and obtained conflicting results. These earlier data are open to objection on several grounds: in the acetone work (1) the temperature range (50 to 200 °C) included a region (50 to 120 °C) where the Arrhenius relationship for methyl radical attack on acetone is non-linear; no account was taken of this. Furthermore, it was necessary to decompose large amounts of H_2S; the assumption that SH radicals reformed H_2S is unlikely since hydrogen sulfide was consumed during the reaction, other secondary reactions producing methane could be important. Secondary reactions may also have interfered in the work using acetaldehyde (2, 3) because the aldehyde decomposition is complex in the presence of thiols (4). Although the present work is not conclusive, it indicates that the previous rate-constants are too high.

The experimental method was basically as has been described previously (5) although some modification was necessary because ethane and hydrogen sulfide cannot be separated by low-temperature fractionation. In the bulk of the experiments the ethane content of the C_2H_6/H_2S mixtures was estimated by gas chromatography using an alumina column which retained H_2S. Two samples of azomethane were employed; one had been used in previous experiments (5) and the second yielded Arrhenius parameters for the attack of methyl radicals on azomethane of $\log_{10} A = 10.98 \pm 0.04$ (A in $cm^3\ mole^{-1}\ s^{-1}$) and $E = 7.65 \pm 0.08$ kcal $mole^{-1}$ over the temperature range 93 to 174 °C. H_2S (Matheson C.P. grade) was distilled through a trap at −80 °C. The purity of the reactants was checked by gas chromatography and mass spectrometry. From 10 experiments between 99 and 171 °C Arrhenius parameters for the reaction

$$CH_3 + H_2S \rightarrow CH_4 + SH$$

were found to be $\log_{10} A = 10.7 \pm 0.4$ and $E = 2.9 \pm 0.7$ kcal $mole^{-1}$, with $\log_{10} k = 9.20$ at 150 °C. Support for these results is afforded by experiments where ethane was estimated differently; before measurement of the ethane, the C_2H_6/H_2S mixture was treated with KOH pellets after which mass spectrometry indicated the complete removal of H_2S. Using this technique, $\log_{10} k$ (k in $cm^3\ mole^{-1}\ s^{-1}$) was 8.87 at 147 °C, which can be compared with the corresponding figure of 9.19 by the first method. The agreement is satisfactory considering the rapid rates of reaction and the small amounts of ethane produced. H_2S decomposition was limited to between 6 and 10% throughout the work.

The present results are compared with previous work and related systems in Table I (all rate-constants are relative to Shepp's rate-constant for methyl radical combination (6)). It is clear that the present rate-constants are lower than previous values by about an order of magnitude at 150 °C. We have already drawn attention to possible sources of error in the earlier work. The apparently normal isotope effect (3) between H_2S and D_2S ($A_H/A_D = 0.75$, $E_D - E_H = 1.15$ kcal $mole^{-1}$) is of little consequence since a "normal" isotope effect has been found for the hydroxyl group of isopropanol (9) although secondary reactions interfere there also. The same feature has been demonstrated for the amino group of formamide (10). The lower reactivity of H_2S can be supported by reference to the literature. The overall reactivity of the alkyl thiols (4, 11) CH_3SH, C_2H_5SH, and i-C_3H_7SH increases with

$CF_3 + H_2S$	11.6	3.9	9.6	8

*Parameters modified according to ref. 7.
†Abstraction from the SH group.

increasing molecular weight, and by analogy with alcohols, amines, and hydrocarbons, the first member of the series (H_2S) is expected to be the least reactive. The earlier results for H_2S indicate that this compound is the most reactive of the series but we find that the SH bond reactivity of H_2S is the same as for methane thiol (7). The S—H bond strengths in H_2S and CH_3SH are about the same (and probably near 90 kcal $mole^{-1}$ (12)) so that similar reactivities would be expected.

Further support for the low rate-constants reported here comes from the CF_3 radical attack on H_2S (8). It is to be expected that the A-factor ratio (A_{CF_3}/A_{CH_3}) for attack on a substrate should be unity. The normally higher activation energy for H abstraction from hydrocarbons by CH_3 radicals as against CF_3 radicals leads to a difference in reactivity which may be reduced or even reversed with polar substrates such as H_2S (8, 13). The present results show that the CF_3 radical is slightly more reactive than the CH_3 radical to H_2S; the literature indicates that CF_3 and CH_3 radicals show similar reactivities to HI (14, 15) where A_{CF_3}/A_{CH_3} is 0.17, $E_{CH_3} - E_{CF_3}$ is 1.8 kcal $mole^{-1}$ and k_{CF_3}/k_{CH_3} is 1.4 at 150 °C, but that CF_3 radicals are less reactive than CH_3 to HBr (13, 14, 16) where A_{CH_3}/A_{CF_3} is 8.3, $E_{CF_3} - E_{CH_3}$ is 1.5 kcal $mole^{-1}$, and k_{CH_3}/k_{CF_3} at 150 °C is 50, and to $SiHCl_3$ (17, 18) where A_{CH_3}/A_{CF_3} is 20, $E_{CH_3} - E_{CF_3}$ is 1.6 kcal $mole^{-1}$, and k_{CH_3}/k_{CF_3} is 2.7 at 150 °C. The Arrhenius parameters obtained here contain large standard errors since the temperature range investigated was small, however, if A_{CF_3}/A_{CH_3} is set equal to unity (8) then our rate-constants yield an activation energy of about 5 kcal $mole^{-1}$, a more reasonable value than the low measured ones and one that compares well with the alkyl thiols.

Concerning the so-called "isohydric point"

W. A. E. McBryde
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received July 25, 1968

Evaluation of the formation function $\bar{n}$ for a system of monomeric and polymeric (condensed) acids in mutual equilibrium can account for the appearance of a network of formation curves with a crossover point at a fixed value of the coordinates $\bar{n}$, pH. The value of $\bar{n}$ at this isohydric point is equal to $1 - z/n$, where n is the degree of condensation and z the basicity of the condensed acid. A third formation curve is unlikely to pass through the same isohydric coordinates, so that the system is very probably restricted to two predominant species in equilibrium. These conclusions confirm the work of Carpéni and collaborators, but appear to have been derived in a different way.

Canadian Journal of Chemistry, 47, 691 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In a recent article in this journal Carpéni (1) has given an account summarizing the experimental and theoretical aspects of almost 20 years of work by himself and his associates concerning the interpretation of titration curves for solutions of acids in which condensation or association has taken place[1]. The distinctive feature of Carpéni's work has been the observation and interpretation of a point of convergence among titration curves in various suitably concentrated solutions of the acids believed to undergo condensation. The presence of such a convergence point, called by Carpéni an isohydric point, is regarded as symptomatic of the presence in the titrated solution of a single isopoly condensed species in equilibrium with the starting acid (or, in principle, two different isopoly species in equilibrium with one another), and to rule out significant concentrations of other species. Moreover, the degree of neutralization, X, as defined by the author, found where the isohydric point occurs is said to be capable of defining the degree of condensation (n) and the charge (z) of the condensed species in accordance with the relationship $X_i = (z/n)_m$, in which m is a multiplicity index that can be found from the data.

While the occurrence of isohydric networks in the systems investigated cannot be seriously questioned as an experimental fact, the inferences to be drawn from the appearance and coordinates of an isohydric point may not be immediately obvious to the reader encountering them for the first time. A somewhat different explanation of the origin of the isohydric point than that outlined by Carpéni has occurred to the writer, and is offered here in corroboration of that already published (1, and references therein).

[1]Copies of an English translation of (1) may be obtained, upon request, from the author.

To begin with, it may be desirable to point out that the quantity x defined by Carpéni is indeed the fraction of the (monomer) acid titrated, and thus the relationship between pH and x is a true titration curve. The quantity X is equivalent to the degree of deprotonation of the acid, and for a monobasic simple acid HA is in fact equal to $1 - \bar{n}$, where $\bar{n}$ is the formation function, or average number of protons bound per atom of A (2, 3). While it is quite true that values of x and X often coincide, it may nevertheless not be desirable, in the interest of precise definition, to describe the relationship between pH and X as a "titration curve". In what follows it is intended to develop the relationship between pH and $\bar{n}$, but it will be evident that this does bear directly on the function studied by Carpéni. Perhaps also it should be mentioned that the expression pH in this paper, as in Carpéni's, is used with the significance as identically equal to $-\log [H^+]$.

Suppose we consider a primitive acid HA which undergoes reversible polymerization to form an acid $(HA)_n$ or H_nA_n which is z-basic. Suppose the polyacid undergoes ionization to form $H_{n-1}A_n$, $H_{n-2}A_n, \cdots, H_{n-z}A_n$ by the transfer of $1, 2, \cdots, z$ protons to the solvent. It is recognized that other hydrogen atoms may be eliminated in the course of condensation reactions

$$(\text{e.g. } 5H_3BO_3 \rightleftarrows 2H^+ + HB_5O_9^{2-} + 6H_2O)$$

but what is proposed here in general can readily be adapted to such specific instances.

The equilibria and associated equilibrium constants which must be considered are then defined by eqs. [1] to [3].

$$[1] \quad nHA \rightleftarrows H_nA_n \qquad k_{cn} = [H_nA_n]/[HA]^n$$

$$[2] \quad HA \rightleftarrows H + A \qquad k_{11} = [H][A]/[HA]$$

[3] $H_nA_n \rightleftarrows H + H_{n-1}A_n$

$$k_{n1} = [H][H_{n-1}A_n]/[H_nA_n] = \beta_{n1}$$

. . . . .

. . . . . .

$$H_nA_n \rightleftarrows zH + H_{n-z}A_n$$

$$\beta_{nz} = [H]^z[H_{n-z}A_n]/[H_nA_n]$$

These equilibrium constants are written as concentration quotients, incorporating the assumption that the experimental data to which they relate have been secured under conditions predisposing to the maintenance of constant activity coefficients. Charges have been omitted from the formulae for simplicity and for generality.

We may put for C_A, the total analytical concentration of acid in all forms

$$[4] \qquad C_A = [HA] + [A] + n\{[H_nA_n] + [H_{n-1}A_n] + \cdots + [H_{n-z}A_n]\}$$

$$[5] \qquad C_A = [HA]\left\{1 + \frac{k_{11}}{[H]}\right\} + nk_{cn}[HA]^n\left\{1 + \frac{\beta_{n1}}{[H]} + \frac{\beta_{n2}}{[H]^2} + \cdots + \frac{\beta_{nz}}{[H]^z}\right\}$$

For the formation function, $\bar{n}$ (degree of protonation)

$$[6] \qquad \bar{n} = \frac{[HA] + n[H_nA_n] + (n-1)[H_{n-1}A_n] + \cdots + (n-z)[H_{n-z}A_n]}{C_A}$$

$$[7] \qquad \bar{n} = \frac{1 + k_{cn}[HA]^{n-1}\left\{n + (n-1)\frac{\beta_{n1}}{[H]} + \cdots + (n-z)\frac{\beta_{nz}}{[H]^z}\right\}}{1 + \frac{k_{11}}{[H]} + nk_{cn}[HA]^{n-1}\left\{1 + \frac{\beta_{n1}}{[H]} + \cdots + \frac{\beta_{nz}}{[H]^z}\right\}}$$

Equation [7] shows that in a system of acids such as we are considering, the formation function $\bar{n} = f([H])$ is not independent of [HA], and accordingly will not be independent of C_A. This is analogous to the case of metal complexes: for mononuclear complexes $\bar{n}$ is independent of C_M, but this no longer applies when polynuclear complexes form.

We should now consider three particular cases:

Case 1. Suppose k_{cn} is extremely small, so that practically no polymerization occurs. In this case we may neglect all the terms of higher order in [HA] in eq. [7], and put

$$[8] \qquad \bar{n} \approx \frac{1}{1 + k_{11}/[H]} \approx \frac{[H]}{[H] + k_{11}}$$

The variation in $\bar{n}$ with pH in this case is well known, and is shown in Fig. 1(*a*), and that for $1 - \bar{n}$, in Fig. 1(*b*).

Case 2. Suppose k_{cn} is extremely large, so that practically all the original acid is converted to and remains as polymer. If this were to happen we

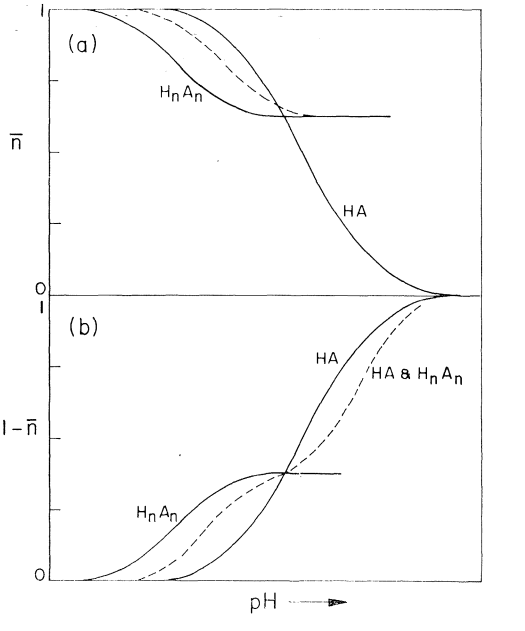

FIG. 1. Plot of $\bar{n}$ and $1 - \bar{n}$ versus pH of HA and H_nA_n.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

could neglect the first terms in numerator and denominator of eq. [7] and put

$$[9] \quad \bar{n} \approx \frac{n + (n-1)\frac{\beta_{n1}}{[H]} + \cdots + (n-z)\frac{\beta_{nz}}{[H]^z}}{n\left\{1 + \frac{\beta_{n1}}{[H]} + \cdots + \frac{\beta_{nz}}{[H]^z}\right\}}$$

This function will have unity as its maximum value when [H] is large compared to the several β's, and will have its minimum value when [H] becomes small compared to the values of β. The minimum value will be $\bar{n}_{min} = (n - z)/n = 1 - z/n$. We show a representative plot for $\bar{n}$ in Fig. 1(*a*) and for $1 - \bar{n}$ in Fig. 1(*b*).

As Carpéni has pointed out, the polymerized acids will generally be stronger than the corresponding primitive acids, so accordingly we show the formation function in a region of lower pH in Fig. 1(*a*) and 1(*b*). The relative position of these curves, in consequence of these differences in strength, imposes the requirement that there must be a crossover point in the $\bar{n}$ or $1 - \bar{n}$ curves as shown in Fig. 1 by the solid lines.

The crossover point suggested by Fig. 1 will occur at $1 - \bar{n} = z/n$. Should the strength of the polymerized acid not be markedly greater than that of the monomer, the formation curve will be like that shown by the broken line in Fig. 1(*a*) and in this event the crossover could occur at a slightly different value of $\bar{n}$ or $1 - \bar{n}$.

Case 3. The situation described in Case 2 is really rather improbable, in the sense that in the course of a titration of this mixture of acids the concentration of HA will decrease, and that of H_nA_n will decrease even faster (an x-fold decrease in [HA] will be matched by an x^n-fold decrease in $[H_nA_n]$). This is the alkaline degradation of which Carpéni speaks. So it is clear that we must consider mixtures of monomer and polymer together. In this event we must use the entire expression for $\bar{n}$ [7]. This may be more simply represented as

$$[10] \quad \bar{n} = \frac{ac + pkc^n}{bc + qkc^n}$$

in which $c = [HA]$, $k = k_{cn}$, and a, b, p, and q are functions of [H]. In the case being discussed a has the value of unity, but this is only the case for a monobasic primitive acid.

Now as Fig. 1 shows, there is a single value of pH or [H] at which the $\bar{n}$ or $1 - \bar{n}$ curves intersect. For this particular value, [H]′, there will be corresponding fixed values a', b', p', and q', and from the limiting cases just considered it follows that

$$[11] \quad \bar{n}' = a'/b' = p'/q'$$

In general, eqs. [8], [9], and [10] will lead to different values of $\bar{n}$ for the same pH. But at the single value pH′ it is obvious from combining [10] and [11] that $\bar{n} = \bar{n}'$.

For mixtures of monomer and polymer in any proportions resulting from a titration or from various initial values of C_A, it follows that the functions $\bar{n}$ or $1 - \bar{n}$ will lie intermediate between those suggested by eqs. [8] and [9], but that at one particular value, pH′, the corresponding value, $\bar{n}'$, will be independent of the concentration of the acid taken. The course of such an intermediate function $1 - \bar{n}$ is shown in Fig. 1(*b*) as a broken line. Several such curves could be drawn, each for a different value of C_A, to produce a network with a common crossover point.

This derivation seems to account for the appearance of an isohydric point in such a system of acids; and the coordinates X_i and pH_i for this point in Carpéni's notation are identical with $1 - \bar{n}'$ and pH′. Moreover in most cases the crossover point in the network of $1 - \bar{n}$ curves will occur, as explained previously, at $1 - \bar{n} = z/n$, which is the same conclusion as that reached by Carpéni.

As we have noted, the situation described under Case 2 is not apt to be encountered just as described; in other words, a solution of pure polymeric acid is not apt to arise and remain polymerized to generate a formation curve throughout a range of pH in the manner suggested by Fig. 1(*b*). Consequently the network of formation curves observed will probably not include this particular limiting case.

Finally we turn to another aspect of the isohydric phenomenon reported by Carpéni, namely the inference from the appearance of an isohydric point that the condensation equilibria involve only *two* predominating species, any others being in negligible proportions. What we have done is to show that if two species, a monomeric and a polymeric acid, are present, an isohydric network must result; and Carpéni said as much. Now we must ask what would happen if another polymeric species, say H_vA_v, were included in significant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

concentrations with the constituents already assumed? For an isohydric point to arise in this case it would be necessary for the formation curve of the third species to pass through the coordinates $\bar{n}'$, pH′. For this to happen it would be necessary in the formation function

$$\bar{n} = \frac{ac + pk_nc^n + rk_vc^v}{bc + qk_nc^n + sk_vc^v}$$

for the ratio r/s, the analogue of [9] for H_vA_v, to achieve the same value as p/q when [H] = [H]′. We cannot say categorically that this is impossible, but can assert that it is highly improbable, except for the case where H_vA_v generates the same $\bar{n}_{min}$ as H_nA_n and both polymeric acids are stronger than HA. Moreover the coincidence of three formation curves at pH′ would be altogether impossible if H_vA_v led at high pH to a minimum value of $\bar{n}$ that was larger than $\bar{n}_{min}$ for H_nA_n, for in that event $1 - \bar{n}$ for H_vA_v would always be smaller than $1 - \bar{n}'$.

From the foregoing considerations it seems highly probable that an isohydric point in a network of formation curves does signify in most cases the presence of two principal species in solution. One could modify the treatment given above to include the possibility of an isohydric network arising from equilibria between two condensed species, but in that case the monomer would have to be in negligible concentration. There does seem, however, to be a possible risk in applying this inference to a system of condensible acids where an isohydric point is not clearly defined. (In the accounts given by Carpéni of experiments on such systems it is admitted that the coordinates of the isohydric point are not always sharply defined by the data.) It seems quite possible that two different polymeric species might arise whose formation curves would lead to minimum values of $\bar{n}$ that are not very different. These would intersect the formation curve of the primitive acid at nearly the same pH. For instance, suppose we had the following cases:

$$H_5A_5 \rightleftarrows 2H^+ + H_3A_5^{2-} \quad z/n = 0.40$$
$$H_7A_7 \rightleftarrows 3H^+ + H_4A_7^{3-} \quad z/n = 0.43$$

Would we be prepared to conclude from an indistinct isohydric "point" at, say, $1 - \bar{n} = 0.41$ that we had one or other of the above species in our solution, and not perhaps both according to the value of C_A, etc.? It has been shown that in hydrolysis of metal cations it is often difficult from the data to make a choice from among two or more possible polynuclear species (4).

Mechanism of oxidation of alcohols with N-bromo succinimide

N. Venkatasubramanian and V. Thiagarajan
Department of Chemistry, Vivekananda College, Madras, India

Received August 20, 1968

The kinetics of the oxidation of a number of aliphatic and aromatic secondary alcohols with N-bromo succinimide has been investigated. Electron-withdrawing substituents retard the reaction considerably and electron-releasing substituents increase the rate of oxidation. The Taft ρ* value is −2.56. *Cis*- and *trans*-4-*t*-butyl cyclohexanols are oxidized at nearly the same rates. There is also a good correlation between the rates of the NBS oxidations and Br_2 oxidations of these alcohols. The results are interpreted in terms of a cyclic mechanism involving a rate-determining abstraction of the alpha hydrogen as a hydride anion.

Canadian Journal of Chemistry, **47**, 694 (1969)

The mechanism of the N-bromo succinimide (NBS) oxidation of alcohols has not yet been established, though the use of NBS as a versatile oxidizing agent is well known (1). It is generally accepted that in polar solvent media a "positive" bromine is the attacking species (2, 3). The following tentative mechanisms have been proposed on the basis of preparative work (see ref. (2) for reaction [1], and ref. (3) for reaction [2]). Langbein and Steinert (4) concluded in a kinetic investigation on the oxidation of 3,17-α-dihydroxy-21-bromo-11,20-pregnane-dione by NBS,

[1] 
a hypobromite intermediate

[2] 
a substituted intermediate

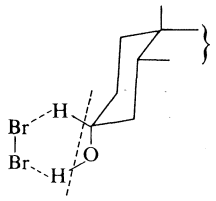
that the oxidation was brought about by molecular bromine:

[3] $\rangle CHOH + 2\rangle N{-}Br \rightarrow \rangle C{=}O + 2\rangle NH + Br_2$

[4] $\rangle CHOH + Br_2 \rightarrow \rangle C{=}O + 2HBr$

[5] $2HBr + 2\rangle N{-}Br \rightarrow 2\rangle NH + 2Br_2$

It is believed that [5] is 10^4 times faster than [4]. These authors proposed a cyclic mechanism involving the attack of the steroidal molecule by a Br_2 molecule embodying a rate-determining breakage of the secondary hydrogen as a hydride ion.



In a previous communication (5) we reported that the NBS oxidation of alcohols is composed of two stages, an initial slow reaction superceded by a faster one involving the attack of Br_2 molecules on the alcohol moiety. We have further shown that the second stage is completely suppressed by added mercuric acetate[1].

TABLE I

Second order rate constants for NBS oxidation of some aliphatic and aromatic secondary alcohols*

Alcohol	$k_2 \times 10^4$ l mole^{-1} s^{-1}
Aliphatic	
Propanol-2	1.51
Butanol-2	2.70
Pentanol-2	2.73
Hexanol-2	3.63
Octanol-2	3.95
1,3-Dichloro-propanol-2	0.45
1-Methoxy-propanol-2	0.88
1-*n*-Butoxy-propanol-2	1.12
Aromatic	
α-Phenyl ethanol	8.54
Benzhydrol	15.17
4-Chloro-benzhydrol	6.04

*[ROH] = 0.1 *M*, [NBS] = 0.01 *M*, and [Hg(OAc)$_2$] = 0.01 *M*.

In this communication, we wish to report the results of the rate measurements on the NBS oxidation of a number of alcohols with suitable electronegative and electropositive substituents. All these reactions were carried out in the presence of Hg^{2+}. This would mean that what has been followed by us is the pure NBS oxidation, uncontaminated with any Br_2 oxidation. It must be pointed out that the kinetic work of Langbein and Steinert (4) differs from our work in that no attempt was made in the former to prevent the product HBr from reacting with NBS. Table I consists of the second order rate constants for the oxidation of the alcohols in 70% HOAc – 30% H_2O at 45 °C and at pH = 4. The alcohols chosen here are smoothly and quantitatively oxidized to the corresponding

[1]One of the referees has suggested that added mercuric acetate would buffer the Br_2 concentration at a low level as follows, and that bromine is actually the reactant:

(*i*) NBS + Br^- → Br_2 + S

(*ii*) $2Br^- + Hg(OAc)_2 \leftrightarrows HgBr_2 + 2OAc^-$

We feel that this is unlikely for the following reasons. (*a*) Equilibrium (*ii*) is most unlikely in the solvent system of 70% HOAc – H_2O with a sodium acetate concentration of 0.2 *M*. (*b*) The Br^- formed is most likely to exist as $HgBr_4^{2-}$ or $Hg(OAc)_2Br_2^{2-}$. (*c*) The reaction exhibits identical kinetics in the presence of added $HgCl_2$ also. (*d*) If the oxidation were to proceed by buffered bromine, the reaction order would not be as simple as observed. Further, the rate constants for NBS and Br_2 oxidation must be identical, whereas they actually differ markedly.

TABLE II

Second order rate constants for the NBS and Br_2 oxidations of *cis*- and *trans*-4-*t*-butyl cyclohexanols*

Alcohol	$k_2 \times 10^2$ (l mole^{-1} s^{-1}) NBS oxidation	Br_2 oxidation
cis-4-*t*-Butyl cyclohexanol	0.198	6.70
trans-4-*t*-Butyl cyclohexanol	0.180	6.48

*[ROH] = 0.1 *M*, [NBS] = 0.01 *M*, and [Hg(OAc)$_2$] = 0.01 *M*.

ketones by NBS. Preliminary runs on the bromination of the products, ketones, were found to be very slow compared to the rate of oxidation. Further, as the order of the oxidations with respect to the organic substrate was shown to be one in preliminary runs, the oxidations were generally carried out with a large excess of alcohol, whereby product bromination was reduced to the minimum. The kinetics were followed by estimation of unreacted NBS by iodometry.

We find in the aliphatic series that electronegative substituents(—Cl,—OCH_3,—*n*-OC_4H_9, etc.) decrease the oxidation rate, while electropositive substituents (alkyl groups) increase the rate of oxidation. A Taft plot for the NBS oxidation shows points for the aliphatic alcohols lying on the same line and $\rho^* = -2.56$, pointing to an electron deficient carbon center in the transition state of the oxidation. It is interesting to observe that the value for Br_2 oxidation of the same series of alcohols reported earlier (6) was more or less the same ($\rho^*_{Br_2\ oxidation} = -2.6$).

A point-to-point correspondence between the Br_2 oxidation of these secondary alcohols and the NBS oxidation of the same alcohols is well brought out by Fig. 1, wherein log $k_{Br_2\ oxidation}$ is plotted against log $k_{NBS\ oxidation}$. This linear free-energy correlation would, therefore, point to a close similarity between the mechanisms for Br_2 and NBS oxidations.

Table II gives the second order rate constants

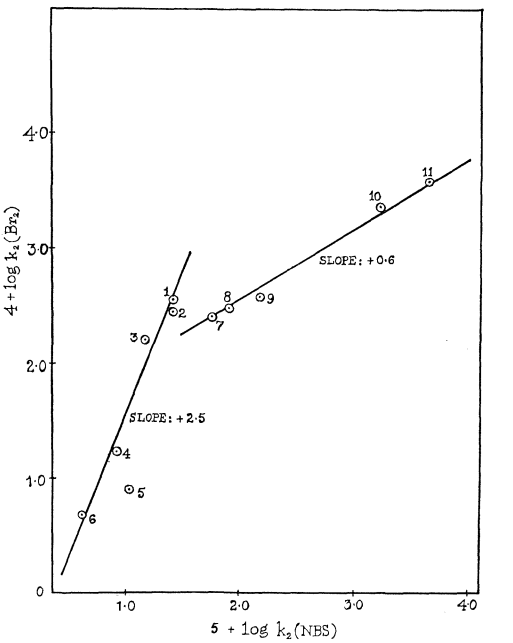

FIG. 1. Linear free-energy correlation in the oxidation of aliphatic and aromatic secondary alcohols with Br_2 and NBS. 1, Pentanol-2; 2, butanol-2; 3, propanol-2; 4, 1-methoxy propanol-2; 5, 1-*n*-butoxy propanol-2; 6, 1,3-dichloro-propanol-2; 7, 4-chloro-benzhydrol; 8, α-phenyl ethanol; 9, benzhydrol; 10, α-tetralol; 11, naphthyl-1-methyl carbinol.

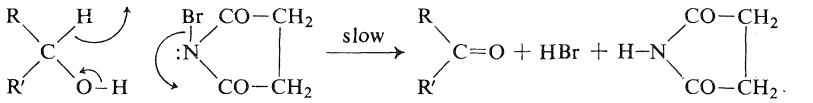
for the NBS and Br_2 oxidations of a pair of stereoisomeric alcohols, *cis*- and *trans*-4-*t*-butyl cyclohexanols. As in the case of Br_2 oxidation, we observe an insensitivity of the NBS oxidation to the configuration of the alcohol. In the Br_2 oxidation, this insensitivity is traced to the cyclic nature of the transition state (7). We may thus conclude that the NBS and Br_2 oxidations proceed by similar mechanistic pathways.

We propose from the evidence detailed above, the following *cyclic* mechanism for the NBS oxidation of alcohols involving a rate-determining loss of the secondary hydrogen as a hydride ion

[6]



This is further substantiated by the fact that ω, the slope of a Bunnett plot (8) (log $k + H_0$ vs. log a_{H_2O}), has a large negative value pointing to considerable carbonium ion character in the transition state.

It is also interesting to observe from Fig. 1 that while the points for the aliphatic alcohols fall on the same line (slope = +2.5), the points for those alcohols which have a phenyl or naphthyl ring directly attached to the reaction center fall on yet

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

another straight line with a smaller slope (slope = +0.6). In the mechanism proposed above, the transition state possesses a carbonium ion character. In the case of alcohols having an aryl ring attached to the reaction center, this positive charge will be stabilized by a resonance participation and the reduced positive slope can be attributed to this effect.

Calculation of the bond lengths in sulfur-containing heterocyclic systems

T. ŽIVKOVIĆ AND N. TRINAJSTIĆ[1]

Institute "Rudjer Bošković", Zagreb, Croatia, Yugoslavia

Received August 20, 1968

The equations $l_{CC} = 1.532 - \frac{0.242p_{CC}}{1 + 0.240p_{CC}}$ and $l_{CS} = 1.829 - 0.262p_{CS}$ are proposed for use in the calculation of bond lengths in sulfur heterocycles.

Canadian Journal of Chemistry, **47**, 697 (1969)

We propose the following equations for use in the calculation of the carbon–carbon and carbon–sulfur bond lengths in sulfur-containing heterocyclic compounds

$$[1] \qquad l_{CC} = 1.532 - \frac{0.242p_{CC}}{1 + 0.240p_{CC}}$$

$$[2] \qquad l_{CS} = 1.829 - 0.262p_{CS}$$

where l_{ij} is the bond length of the bond i–j, and p_{ij} is the corresponding bond order.

Equation [1] is a different form of the first theoretical expression for this phenomenon developed by Coulson in 1938 and published (1) in 1939. We have derived eq. [1] in the following manner: if one considers that the bond length in the first approximation is proportional to the π-electron density between the atoms i and j, one should take into account not only the bond orders p_{ij}, but also the product $p_{ij}S_{ij}$, where S_{ij} is the overlap integral for pπ orbitals centered on atoms i and j. Therefore, we propose to use the following relationship

$$[3] \qquad l_{ij} = l_0 - k\,p_{ij}\,S_{ij}$$

In the first approximation S_{ij} can be expressed as:

$$[4] \qquad S_{ij} = S_0 + S_1\,\Delta l_{ij}$$

By substituting [4] into [3] and using

$$[5] \qquad c_0 = k\,S_0$$

and

$$[6] \qquad c_1 = -k\,S_1$$

we obtain

$$[7] \qquad l_{ij} = l_0 - c_0\,p_{ij} - c_1\,\Delta l_{ij}\,p_{ij}$$

If one now considers the carbon–carbon bonds, constants l_0, c_0, and c_1 are obtained by using experimental data for C—C bond lengths in ethane 1.5324 Å (2), ethylene 1.337 Å (3), and acetylene 1.205 Å (4), respectively. Bond orders for C—C bonds in these compounds are 0, 1, and 2, respectively. Equation [1], thus obtained, has been checked on a number of hydrocarbons and has reproduced experimental bond lengths quite well. It gives the best agreement with experimental values for the bond lengths between sp^2 hybridized carbon atoms. Therefore, we suggest that

Calculation of the bond lengths in sulfur-containing heterocyclic systems

T. ŽIVKOVIĆ AND N. TRINAJSTIĆ[1]

Institute "Rudjer Bošković", Zagreb, Croatia, Yugoslavia

Received August 20, 1968

The equations $l_{CC} = 1.532 - \frac{0.242p_{CC}}{1 + 0.240p_{CC}}$ and $l_{CS} = 1.829 - 0.262p_{CS}$ are proposed for use in the calculation of bond lengths in sulfur heterocycles.

Canadian Journal of Chemistry, **47**, 697 (1969)

We propose the following equations for use in the calculation of the carbon–carbon and carbon–sulfur bond lengths in sulfur-containing heterocyclic compounds

$$[1] \qquad l_{CC} = 1.532 - \frac{0.242p_{CC}}{1 + 0.240p_{CC}}$$

$$[2] \qquad l_{CS} = 1.829 - 0.262p_{CS}$$

where l_{ij} is the bond length of the bond i–j, and p_{ij} is the corresponding bond order.

Equation [1] is a different form of the first theoretical expression for this phenomenon developed by Coulson in 1938 and published (1) in 1939. We have derived eq. [1] in the following manner: if one considers that the bond length in the first approximation is proportional to the π-electron density between the atoms i and j, one should take into account not only the bond orders p_{ij}, but also the product $p_{ij}S_{ij}$, where S_{ij} is the overlap integral for pπ orbitals centered on atoms i and j. Therefore, we propose to use the following relationship

$$[3] \qquad l_{ij} = l_0 - k\,p_{ij}\,S_{ij}$$

In the first approximation S_{ij} can be expressed as:

$$[4] \qquad S_{ij} = S_0 + S_1\,\Delta l_{ij}$$

By substituting [4] into [3] and using

$$[5] \qquad c_0 = k\,S_0$$

and

$$[6] \qquad c_1 = -k\,S_1$$

we obtain

$$[7] \qquad l_{ij} = l_0 - c_0\,p_{ij} - c_1\,\Delta l_{ij}\,p_{ij}$$

If one now considers the carbon–carbon bonds, constants l_0, c_0, and c_1 are obtained by using experimental data for C—C bond lengths in ethane 1.5324 Å (2), ethylene 1.337 Å (3), and acetylene 1.205 Å (4), respectively. Bond orders for C—C bonds in these compounds are 0, 1, and 2, respectively. Equation [1], thus obtained, has been checked on a number of hydrocarbons and has reproduced experimental bond lengths quite well. It gives the best agreement with experimental values for the bond lengths between sp^2 hybridized carbon atoms. Therefore, we suggest that

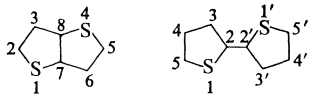
	1—5	0.4933	1.700		
	2—3	0.7286	1.382	1.357	0.025
	2—2′	0.3075	1.463	1.480	0.017
	3—4	0.5757	1.410	1.433	0.023
	4—5	0.7635	1.376		

this formula be used for predicting the carbon–carbon bond lengths only in planar conjugated systems.

On the other hand, eq. [2] is obtained by a least-squares linear fit to the bond order – bond length curve presented in our earlier work (5). This formula is useful for calculating the bond lengths between the σ-bivalent sulfur and the sp^2 hybridized carbon atom.

Results

We have considered 1,4-thiophthene (**1**) and 2,2′-bithiophene (**2**) (a topology of these two molecules is given in Fig. 1) as examples. The l.c.a.o.-s.c.f.-m.o. π-bond orders, calculated, and experimental (6, 7) values for carbon–carbon and carbon–sulfur bond lengths are given in Table I. Generally speaking, the agreement between the calculated and observed values is quite good. The difference between the calculated and experimental values is in the range of 0.002–0.025 Å. This is within the limits of the experimental error. Only the result for the bond 7–8 in 1,4-thiophthene is out of this range. This particular bond has been rather extensively studied (8–11), but the theoretical results obtained for the bond length were always too large. The best agreement was obtained when Schomaker (10) corrected the calculated result for distortion; he obtained 1.38 Å. Results from different m.o. calculations are greater by 0.030 Å or more than the experimentally observed value 1.36 Å (6). On the other hand, our calculations for 2,2′-bithiophene predict different values for lengths of all bonds in the thiophene ring. But, experimental measurements (electron diffraction studies in gas phase (7)) indicate that the bonds 1–2 and 1–5 are of equal lengths and that 2–3 and 4–5 are also of equal lengths[2].



1 **2**

FIG. 1. Atomic skeletal structure and numbering of atoms for 1,4-thiophthene (**1**) and 2,2′-bithiophene (**2**).

Finally, we would like to comment on the results for 1,4-thiophthene reported by Clark[3] (12). It seems to us that his equation ($l_{CS} = 1.802 - 0.229p_{CS}$) slightly underestimates the experimental values for C—S bonds. At the same time his results for C—C bonds are in agreement with ours.

Acknowledgments

We would like to thank Professor C. A. Coulson (Oxford) for helpful comments concerning eq. [1]. We would also like to thank Dr. B. Matković (Zagreb) and Professor M. Randić (Zagreb) for helpful discussions.

[2]Recent X-ray measurements by Visser, Heeres, Wolters, and Vos (13) have given different values for lengths of all bonds in the thiophene ring, but unfortunately their results are not very accurate (the estimated standard deviations are approximately 0.02 Å for C—S and 0.03 Å for C—C bonds).

[3]We thank Dr. Clark for sending us preprint of his results from m.o. calculations on three isomeric thiophthenes.

Thermochemistry of the aqueous manganous ion[1]

L. M. GEDANSKY[2] AND L. G. HEPLER
Department of Chemistry, University of Lethbridge, Lethbridge, Alberta

Received September 23, 1968

Heats of solution of $MnSO_4$(c) have been measured and combined with heats of dilution to yield $\Delta H^0 = -15.3$ kcal/mole for the standard heat of solution. This value leads to $\Delta H_f^0 = -52.9$ kcal/mole for Mn^{2+}(aq). Calculations with data from the literature give $\Delta G_f^0 = -55.1$ kcal/mole for Mn^{2+}(aq). Combination of this value with our ΔH_f^0 gives $\bar{S}_2^0 = -16.2$ gibbs/mole for Mn^{2+}(aq). Our ΔH_f^0 value for Mn^{2+}(aq) is compared with other values derived from calculations based on data taken from the literature.

Canadian Journal of Chemistry, **47**, 699 (1969)

Introduction

Thermodynamic data already available now provide a means of calculating ΔG_f^0 for Mn^{2+}(aq) and thence E^0 for the Mn/Mn^{2+} oxidation potential. But the situation with respect to the ΔH_f^0 and $\bar{S}_2^0$ for Mn^{2+}(aq) is not nearly so satisfactory and should be resolved experimentally for several reasons. For example, once the ΔH_f^0 of Mn^{2+}(aq) is reliably known, heat of solution data permit calculation of ΔH_f^0 values for a number of compounds of manganese. It will also be useful to have complete and reliable thermodynamic data for Mn^{2+}(aq) because of its d^5 electronic configuration and its consequent use as a "reference" divalent ion with Ca^{2+}(aq) and Zn^{2+}(aq) in connection with consideration of ligand field stabilization effects.

Largely as a result of considerations outlined above, measurements of the heat of solution of $MnSO_4$(c) in water and the calculations reported here have been carried out.

Experimental

Three samples of $MnSO_4$(c) were prepared for calorimetric measurements. The first was prepared by recrystallization of Baker analyzed reagent, followed by drying at 400 °C for several days. The second was prepared in exactly the same manner from Fisher certified reagent. The third sample was prepared by further heating of a portion of the second sample at 450 °C overnight. All three samples appeared to be identical and led to consistent heats of solution.

The calorimetric apparatus used for these measurements was patterned after one previously described (1). The calorimeter consisted of a Dewar vessel suspended in a brass can submerged in a water bath which was maintained at constant temperature. Temperature in the calorimeter was determined with two 100 Ω thermistors wired in parallel and connected to a Leeds and Northrup G-2 Mueller bridge with a Liston–Becker model 14 breaker amplifier and zero-center meter. The thermistors and a manganin heater (300 Ω) were contained in a glass spiral filled with mineral oil. All of the calorimetric data (in terms of the defined calorie, 4.184 J) reported here were obtained with 950 ml of water in the Dewar at 25.00 ± 0.15 °C. Operation of the calorimeter was checked by heats of solution of THAM and KCl, with results indicating that uncertainties range from about 0.05 to 0.10 cal. The heat associated with breaking sample bulbs was 0.03 ± 0.02 cal, which was taken into account in calculating reported ΔH values.

Results and Calculations

The results of our determinations of the heat of solution of $MnSO_4$(c) in water are summarized in Table I.

Since the most dilute solution formed in our measurements was about 1×10^{-3} *M*, there is

1.27342	−14.62

an appreciable heat of dilution to zero concentration that must be considered in obtaining the desired ΔH^0 of solution. No relevant data for $MnSO_4$(aq) are available, but we do have data (2, 3) for aqueous sulfates of Cd^{2+}, Cu^{2+}, Ni^{2+}, and Zn^{2+}. We use these as a guide in graphical estimation of the heats of dilution, which are then combined with the data in Table I to give $\Delta H^0 = -15.3$ kcal/mole for the standard heat of solution of $MnSO_4$(c) to yield Mn^{2+}(aq) and SO_4^{2-}(aq). The total uncertainty (due to uncertainties in calorimetric measurements and in estimated heats of dilution) is not more than ± 0.2 kcal/mole.

Calorimetric determinations by Southard and Shomate (4) of the heats of solution of Mn(c) and $MnSO_4$(c) in aqueous sulfuric acid permitted them to calculate a ΔH_f^0 value for $MnSO_4$(c). We have used more recent data (5) for aqueous sulfuric acid in combination with their data to obtain $\Delta H_f^0 = -254.9$ kcal/mole for $MnSO_4$(c). Combination of this ΔH_f^0 with the most recent (5) ΔH_f^0 for SO_4^{2-}(aq) and our ΔH^0 of solution of $MnSO_4$(c) leads to $\Delta H_f^0 = -52.9$ kcal/mole for Mn^{2+}(aq). Total uncertainty in this value is about ± 0.3 kcal/mole. It should be noted that uncertainties in the data for sulfuric acid and sulfate ion largely cancel out in evaluation of the desired ΔH_f^0 for Mn^{2+}(aq).

We now turn to calculation of the ΔG_f^0 for Mn^{2+}(aq). Mah (6) has reviewed data on MnO_2(c) and recommended adoption of $\Delta H_f^0 = -124.4$ kcal/mole for this compound. Combination of this ΔH_f^0 with entropies from Kelley and King (7) gives $\Delta G_f^0 = -111.3$ kcal/mole for MnO_2(c). On the basis of earlier investigations and the careful experimental work of Covington, Cressey, Lever, and Thirsk (8), we adopt $E^0 = -1.239$ V for the standard oxidation potential to be associated with the Mn^{2+}/MnO_2(c) half reaction in acidic solution. Combination of this potential with $\Delta G^0 = -nFE^0$ and the ΔG_f^0 value for MnO_2(c) cited above gives us $\Delta G_f^0 = -55.1$ kcal/mole for Mn^{2+}(aq). This ΔG_f^0 leads to $E^0 = 1.20$ V for the standard oxidation potential for

[1] $$Mn(c) = Mn^{2+}(aq) + 2e^-$$

We combine the ΔG_f^0 and ΔH_f^0 values for Mn^{2+}(aq) with entropies of manganese and hydrogen to obtain its $\bar{S}_2^0 = -16.2$ gibbs/mole[3].

Now we turn to brief consideration of earlier investigations that have yielded data relevant to our measurements and calculations.

Two investigations (9, 10) are in good agreement for the heat of solution of $MnCl_2$(c). Combinations of these values with small estimated heats of dilution give $\Delta H^0 = -17.5$ kcal/mole for the standard heat of solution of $MnCl_2$(c). Other heat of solution measurements (11) have led to $\Delta H_f^0 = -115.2$ kcal/mole for $MnCl_2$(c), and high temperature data (12, 13) lead to $\Delta H_f^0 = -116.9$ kcal/mole. Combination of these values with the ΔH^0 of solution leads to $\Delta H_f^0 = -52.8$ and -54.4 kcal/mole for Mn^{2+}(aq). Walkley (14) has reported $\Delta H_f^0 = -53.2$ and -52.8 (recalculated by Zordan and Hepler (15)) kcal/mole for Mn^{2+}(aq). Our $\Delta H_f^0 = -52.9$ kcal/mole for Mn^{2+}(aq) is in excellent agreement with all but one of the values cited in this paragraph, and it is probable that the disagreement between our value and that derived from high temperature data (12, 13) is almost entirely due to uncertainties in the high temperature data.

There is one other path by which the ΔH^0 of Mn^{2+}(aq) can be calculated. Zordan and Hepler (15) have used E^0 for the MnO_2/MnO_4^-(aq) potential with the ΔG_f^0 of MnO_2(c) to obtain $\Delta G_f^0 = -107.6$ kcal/mole for MnO_4^-(aq). Then the ΔG^0 of solution of $KMnO_4$(c) calculated from its solubility and activity coefficient in saturated solution was combined with its ΔH^0 of solution to yield ΔS^0 of solution and thence $\bar{S}_2^0 = 46.5$ gibbs/mole for MnO_4^-(aq). Combination of this $\bar{S}_2^0$ with the ΔG_f^0 gave $\Delta H_f^0 = -129.9$ kcal/mole for MnO_4^-(aq). Still further combination of this

[3]Although we know of no action yet taken by the I.U.P.A.C. or other international organization, we follow W. F. Giauque (and others, more recently) in using *gibbs* to represent the combination cal/deg.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ΔH_f^0 with a calorimetrically determined heat of reduction of MnO_4^-(aq) to Mn^{2+}(aq) led to $\Delta H_f^0 = -53.4$ kcal/mole for Mn^{2+}(aq). Considering the many different data and steps in this calculation, this latter value agrees well with the value derived directly from our data.

Acknowledgments

Hydrodynamically induced crystallization of isotactic polystyrene

A. G. WIKJORD AND R. ST.JOHN MANLEY
Physical Chemistry Division, Pulp and Paper Research Institute of Canada
and
Department of Chemistry, McGill University, Montreal, Quebec

Received November 8, 1968

This report provides a brief preliminary account of the solution crystallization of isotactic polystyrene under the influence of velocity gradients. During crystallizations from 1,3,5-trimethylbenzene and cyclohexanol solutions, the polymer appears in a number of morphological forms which are composed of microfibrillar units. In isotactic polystyrene produced by heterogeneous Ziegler–Natta catalysis, similar microfibrillar units are observed. It is suggested, therefore, that these two apparently different processes have a common underlying mechanism in the formation of the microfibrils. The possible mechanisms of fibril formation are discussed.

Canadian Journal of Chemistry, **47**, 703 (1969)

There have been relatively few reports of the crystallization of isotactic polystyrene from solution (1–3). It crystallizes from solution only with difficulty, perhaps because of substantial steric hindrance of the bulky phenyl groups (4).

The purpose of the present communication is to report preliminary observations on the crystallization of isotactic polystyrene from solutions subjected to shear forces. It is now recognized that fibrillar structures are generally produced when linear and stereoregular polymers are crystallized under conditions in which the chain molecules are oriented (5–7). Similar structures are often generated in heterogeneous Ziegler–Natta catalysis (8). In regard to both of these processes, polyethylene has received the most attention to date. The results presented here for polystyrene may help to clarify the mechanism of fibril formation in these systems.

The polystyrene used was a high molecular weight sample (Dow Chemical Company) which was extracted with methyl ethyl ketone prior to use to remove atactic and stereoblock components. The resulting polymer had a viscosity-average molecular weight of 2×10^6. In the crystallization experiments, two solvents, 1,3,5-trimethylbenzene, a good solvent, and cyclohexanol, a poor solvent, were employed. In a typical experiment, a 0.5% solution was prepared by refluxing the polymer in the appropriate solvent; the polymer was then crystallized in the turbulent flow created by a stirring rod rotating at a constant speed of 2000 r.p.m. Crystallizations were conducted isothermally: in 1,3,5-trimethylbenzene, appreciable yields were obtained at temperatures ranging from −25 to 125 °C; in cyclohexanol, it was only feasible to operate between the theta point (83.5 °C) and 140 °C. Above the latter temperature, recovery was negligible.

When the crystallized polystyrene was viewed in the swollen state under the light microscope, it appeared as distinct structural entities or "macrostructures". The morphology of the macrostructure varied with the conditions of growth. For example, in crystallizations from trimethylbenzene over a 150 °C temperature range (at 25 °C intervals), the following macrostructures were observed: spherical particles 15–40 μ in diameter (−25 °C), irregularly shaped globules 100–500 μ in size (0 °C), fibres with diameters up to 1 mm (25–125 °C), and ring-shaped structures (100–125 °C). The detailed morphology of these macrostructures will be discussed in a separate paper. However, it may be noted here that they are not the primary products of crystallization but apparently result from the hydrodynamically induced aggregation of finer fibrillar elements of structure. These microfibrillar units will be discussed in the following.

Regardless of the temperature of growth of the macrostructures, upon mechanical disruption, they broke up exclusively into microfibrillar

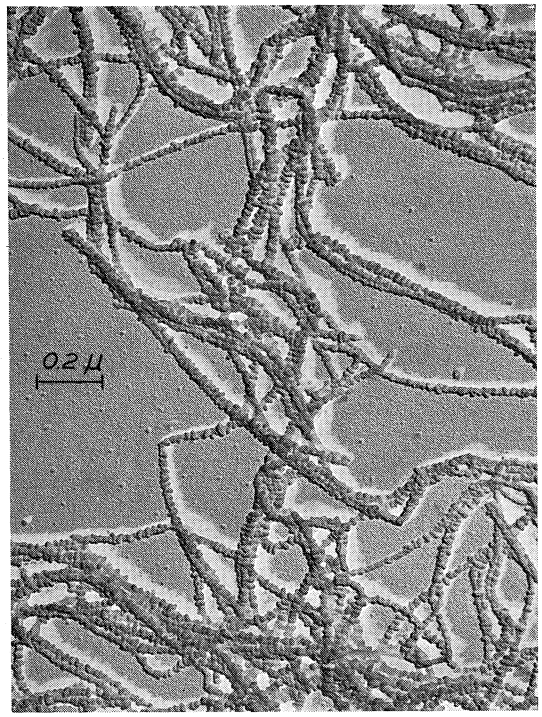

FIG. 1. Microfibrils crystallized under shear from a 0.5% solution of isotactic polystyrene in 1,3,5-trimethylbenzene at 100 °C. Electron micrograph, Pt shadowed.

units as depicted in Fig. 1. These constituent microfibrils were also found in the early stages of the crystallization when the macrostructures were not yet developed. The microfibrils showed little variation in diameter within a given preparation or from one preparation to another; they are characterized by overgrowths periodically spaced along their lengths, a feature common to many fibrillar polymer crystals (5–8).

It is noteworthy that there is a close parallel between the stirrer-crystallization of polystyrene and the heterogeneous Ziegler–Natta polymerization of this polymer (8). The polystyrene produced in both of these processes have similar morphological features as seen in the polarizing microscope and consist of elementary microfibrils which are essentially indistinguishable in the electron microscope. Both processes, apparently, are characterized by a remarkable facility of the crystallization process in comparison to crystallizations from solution under quiescent conditions. One is therefore led to believe that similar growth mechanisms operate in the two processes.

The crystallization of the polystyrene chains into microfibrils occurs virtually simultaneously to the application of the shear field in the stirred systems or to the initiation of the polymerization reaction in the Ziegler–Natta systems. This step is the most fundamental one in terms of the crystallization process and allows for a number of interesting interpretations. In the shear-induced crystallizations, hydrodynamic forces may play the role of decreasing the conformational entropy of the system by uncoiling molecules into more extended and ordered conformations, the 3_1 helix being the most favored energetically. Alignment of these helical chains in the streamlines of flow would promote nucleation. In the case of Ziegler–Natta catalysis, local convection currents created by the heat of reaction at the active sites may play a similar role. Alternatively, it is possible that the catalyst promotes nucleation by the helical placement of monomer units, one at a time, to the growing chain. In this way, the polystyrene chains would grow directly into the conformation which they assume in the solid state and not the random coil which requires a subsequent conformational change for crystallization. The possibility that the catalyst may play a role in preserving the symmetry of the helix was originally proposed about a decade ago by Szwarc (9). However, a recent report (10) suggests that polystyrene may exist under certain conditions in the helical conformation in solution in the absence of any perturbing forces (i.e. shear or catalyst). Under conditions where a large part of the molecule already exists in a helical conformation, the shear stresses or catalyst surface would have the more limited function of bringing the helical chains into close proximity so that they may crystallize.

This work appears to support the proposition derived earlier on the basis of studies on polyethylene (7) that hydrodynamically-induced crystallizations and fluid-bed Ziegler–Natta polymerizations have similar underlying crystallization mechanisms.

The crystal structure of tetraphenylcyclobutadiene molybdenum dicarbonyl bromide

M. MATHEW AND GUS J. PALENIK
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received November 25, 1968

The crystal structure of tetraphenylcyclobutadiene molybdenum dicarbonyl bromide has been determined by X-ray diffraction. Previously, the compound has been formulated incorrectly as tetraphenylcyclobutadiene molybdenum tricarbonyl bromide.

Canadian Journal of Chemistry, **47**, 705 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Tetraphenylcyclobutadiene molybdenum dicarbonyl bromide, the first proven example of a cyclobutadiene ring bonded to a second or third row transition element, is a novel compound containing bromine bridges, the cyclobutadiene moiety, and a strong metal–metal interaction. Not only was the compound incorrectly formulated by Maitlis and Games (1) as a tricarbonyl, **1**, but also the presence of the cyclobutadiene rings was questioned by Cotton and Wilkinson (2) in a popular textbook. Recently, Baird (3) has cited the incorrectly formulated compound as an example of a molybdenum–molybdenum bond. To prevent further errors regarding this compound, we wish to report that our crystal structure study has shown that the compound is correctly formulated as the dimer, **2**, which contains only two carbonyl groups per molybdenum atom.

Crystal data: triclinic with $a = 11.306 \pm 0.004$, $b = 13.681 \pm 0.004$, $c = 17.561 \pm 0.010$ Å, $\alpha = 105.58 \pm 0.01°$, $\beta = 91.14 \pm 0.02°$, $\gamma = 108.50 \pm 0.05°$, $d_m = 1.59$ g/cm^3, $d_c = 1.585$ g/cm^3, $Z = 2$ dimers. The space group $P\bar{1}$ was indicated by the intensity statistics and the subsequent analysis confirms this choice.

A small, equidimensional crystal (0.10 mm) was used for intensity measurements. Intensity data were collected on a General Electric XRD-6 automated by Datex Corporation, using the stationary crystal – stationary counter method. Of the 8851 reflections within the range of $2\theta \leq 135.0°$ (Cu K_α), 8089 were observed above the threshold count. No absorption corrections were applied.

A three dimensional Patterson synthesis was computed and the positions of 2 molybdenum and 2 bromine atoms were located. A Fourier synthesis, phased with the 2 molybdenum and 2 bromine atoms, revealed the positions of all the light atoms. A difference Fourier synthesis using all 68 atoms for phasing did not indicate the presence of any additional carbonyl groups. The refinement was completed by the method of least squares using the full matrix. After four cycles of least squares refinement with individual isotropic thermal parameters, the *R*-index was 0.091.

The compound crystallizes as a dimer, **2**. The 2 molybdenum atoms are linked through bromine bridges (average Mo—Br distance 2.638 ± 0.001 Å). The Mo—Mo distance of 2.954 ± 0.001 Å is shorter than the distance of 3.222 Å found in $[C_6H_5Mo(CO)_3]_2$ (4). The short Mo—Mo distance together with the reported diamagnetism suggests the presence of a metal–metal bond. Each molybdenum is also

Pyrrolidone hydrotribromide: a brominating agent with selectivity for ketones

D. V. C. Awang and Saul Wolfe
Department of Chemistry, Queen's University, Kingston, Ontario

Received January 13, 1969

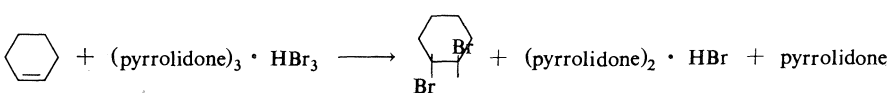
The relative reactivities of a ketone, an olefin, and an enol acetate towards bromination in tetrahydrofuran by "pyrrolidone–bromine complex", (pyrrolidone)$_3$·HBr$_3$ (PHT), are ketone ≫ olefin ≫ enol acetate. The conversion of benzalacetone to $C_6H_5CH{=}CHCOCH_2Br$ is given as an example. The selectivity of PHT is enhanced by dilution and is diminished upon addition of pyrrolidone to the reaction mixtures. The selectivity of phenyltrimethylammonium tribromide (PTAT) is not as great as that of PHT and is subject to acid catalysis.

At a sufficiently low concentration in a nonpolar solvent, the enol of cyclohexanone reacts at least 1 000 000 times faster with molecular bromine than does cyclohexene. This observation suggests that the selectivity of perbromides may be due to their ability to furnish a low equilibrium concentration of bromine when dissolved in solvents of low polarity.

Canadian Journal of Chemistry, **47**, 706 (1969)

Selective bromination of a ketone in the presence of a double bond has been achieved by the action of phenyltrimethylammonium tribromide (PTAT) (1, 2) upon dihydrocarvone (3) and by the action of cupric bromide upon several unsaturated steroidal ketones (4). The purpose of this communication is to demonstrate that pyrrolidone hydrotribromide (PHT), a new reagent (5), possesses selectivity for ketones superior to that of PTAT, and that molecular bromine, in low concentration and in a solvent of low dielectric constant, also displays selectivity for ketones.

PHT is a stable red crystalline solid, m.p. 89–91°, whose analysis corresponds to a molecular formula $(C_4H_7NO)_3{\cdot}HBr_3$. The compound is soluble in tetrahydrofuran and its reaction with cyclohexene in this solvent proceeds as follows



1

Pyrrolidone hydrotribromide: a brominating agent with selectivity for ketones

D. V. C. Awang and Saul Wolfe
Department of Chemistry, Queen's University, Kingston, Ontario

Received January 13, 1969

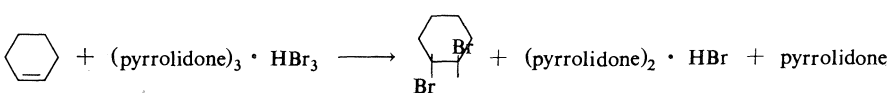
The relative reactivities of a ketone, an olefin, and an enol acetate towards bromination in tetrahydrofuran by "pyrrolidone–bromine complex", (pyrrolidone)$_3$·HBr$_3$ (PHT), are ketone ≫ olefin ≫ enol acetate. The conversion of benzalacetone to $C_6H_5CH{=}CHCOCH_2Br$ is given as an example. The selectivity of PHT is enhanced by dilution and is diminished upon addition of pyrrolidone to the reaction mixtures. The selectivity of phenyltrimethylammonium tribromide (PTAT) is not as great as that of PHT and is subject to acid catalysis.

At a sufficiently low concentration in a nonpolar solvent, the enol of cyclohexanone reacts at least 1 000 000 times faster with molecular bromine than does cyclohexene. This observation suggests that the selectivity of perbromides may be due to their ability to furnish a low equilibrium concentration of bromine when dissolved in solvents of low polarity.

Canadian Journal of Chemistry, **47**, 706 (1969)

Selective bromination of a ketone in the presence of a double bond has been achieved by the action of phenyltrimethylammonium tribromide (PTAT) (1, 2) upon dihydrocarvone (3) and by the action of cupric bromide upon several unsaturated steroidal ketones (4). The purpose of this communication is to demonstrate that pyrrolidone hydrotribromide (PHT), a new reagent (5), possesses selectivity for ketones superior to that of PTAT, and that molecular bromine, in low concentration and in a solvent of low dielectric constant, also displays selectivity for ketones.

PHT is a stable red crystalline solid, m.p. 89–91°, whose analysis corresponds to a molecular formula $(C_4H_7NO)_3{\cdot}HBr_3$. The compound is soluble in tetrahydrofuran and its reaction with cyclohexene in this solvent proceeds as follows



1

TABLE I

Selectivities of PHT and PTAT in competitive bromination experiments in tetrahydrofuran at 25°[a]

Entry	Substrate mixture[b]	Brominating agent (molarity)	Product ratio[c]
1	A+B	PTAT (0.5)	1.38[f]

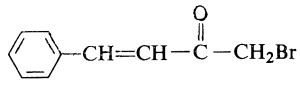
14	B+E	PHT (0.1)[d]	>100.[h]
15	D+F	PHT (0.1)[d]	>100.[i]

[a]A solution of the brominating agent of the stated molarity (20 ml) was added dropwise in the dark to a solution containing equimolar quantities of the two substrates in tetrahydrofuran (20 ml).
[b]A, cyclohexene; B, cyclohexanone; C, 3-pentanone; D, cyclohexenyl acetate; E, 4-methylcyclohexenyl acetate; F, 4-methylcyclohexanone.
[c]Determined by quantitative gas chromatography.
[d]One mole-equivalent of pyrrolidone was added to the substrate mixture.
[e]One drop of concentrated H_2SO_4 was added to the substrate mixture.
[f]Bromoketone/dibromoolefin.
[g]The product is dibromoolefin.
[h]The product is 2-bromocyclohexanone.
[i]The product is 2-bromo-4-methylcyclohexanone.

the hemihydrobromide **1** being precipitated from the solution as colourless needles as the reaction proceeds. The precipitation of **1** provides a convenient visual assay of the extent of reaction and also facilitates isolation of the product.

Entries 1–12 of Table I summarize the results of competition experiments in which PTAT or PHT were allowed to react, in tetrahydrofuran, with a mixture of an olefin and a ketone. Entries 13–15 show the results of competition experiments with PHT in which an enol acetate was included. Several conclusions follow immediately: (*i*) PHT exercises greater "ketoselectivity" than does PTAT (cf. entries 1 and 5; 4 and 6 for cyclohexanone–cyclohexene competitions, and entries 8 and 11; 7 and 10 for 3-pentanone–cyclohexene competitions); (*ii*) the selectivity of both reagents is enhanced upon dilution of the perbromide solutions (cf. entries 1, 2, and 3; 10 and 12); (*iii*) a catalytic amount of acid dramatically enhances the selectivity of PTAT (entries 8 and 9); (*iv*) under the conditions of these experiments the relative susceptibilities towards bromination are ketone ≫ olefin ≫ enol acetate. The synthetic implications of such a reactivity sequence are clear. Thus, benzalacetone was smoothly converted with PHT in tetrahydrofuran to bromomethylstyryl ketone, **2**, m.p. 46–47° (Found: C, 52.92; H, 4.25.). Previous attempts to achieve selective bromination of benzalacetone have led to the dibromide (6).



2

In both PTAT and PHT brominations the hydrogen bromide or acetyl bromide liberated as a result of bromoketone formation can be trapped effectively as the insoluble compound **1** or as the insoluble acetylium salt of pyrrolidone by prior addition to the reaction mixture of an equimolar amount of pyrrolidone. Although this causes some loss of selectivity (entries 2 and 4; 7 and 8; 10 and 11), the selectivity can be restored by dilution of the brominating agent (entries 10 and 12). It is then possible to brominate a ketone in the presence of both a double bond and an acid

TABLE II

Effects of solvent and concentration upon the relative reactivities towards bromine of cyclohexene and cyclohexanone at 25°[a]

Run	Solvent	Substrate solution Moles	Substrate solution Volume (ml)	Bromine solution Moles	Bromine solution Volume (ml)	Maximum effective bromine concentration (M)[b]	Ratio of bromoketone to dibromoolefin[c]
1	CCl_4	0.01	20	0.01	20	1×10^{-3}	0.43
2	CCl_4	0.01	100	0.01	100	5×10^{-5}	0.54
3	CCl_4	0.01	1000	0.01	1000	5×10^{-7}	3.17
4	CCl_4	0.005	500	0.0025[d]	500	5×10^{-7}	13.3
5	CCl_4	0.0025	500	0.00125	500	2.5×10^{-7}	>199
6	C_2H_5OH	0.01	20	0.01	20	1×10^{-3}	0.14
7	CH_3COOH	0.01	20	0.01	20	1×10^{-3}	0.16
8	tetrahydrofuran[e]	0.01	20	0.01	20	1×10^{-3}	1.0

[a]The bromine solution was added dropwise in the dark to a rapidly stirred solution of olefin and ketone.
[b]Calculated on the basis that each drop was efficiently dispersed and reacted before the addition of the next drop.
[c]Determined by quantitative gas chromatography.
[d]An induction period of 30 min was observed after the addition of the first few drops of the bromine solution. The color was suddenly discharged and the reaction then proceeded as in [a].
[e]About 60% of the HBr liberated in the substitution reaction reacted with the solvent to form 4-bromo-1-butanol. For this reason tetrahydrofuran was not used for the detailed concentration studies although this would have permitted a closer approximation of the conditions usually employed for perbromide brominations.

sensitive group. Thus, the production of 4-bromo-1-butanol or 1-acetoxy-4-bromobutane, usually formed by cleavage of the solvent by the liberated HBr or AcBr, is completely suppressed under these conditions as is the hydrolysis of an enol acetate if bromination of a ketone function is occurring elsewhere in the molecule. However, enol ethers react readily with a saturated tetrahydrofuran solution of **1** to regenerate the parent ketones.

The difference in selectivity between PHT and PTAT can be understood in terms of acid catalysis of enolization since the hemipyrrolidonium ion is an acid and the tetrasubstituted ammonium ion is not. In the latter case, catalysis of enolization has to be achieved by the HBr produced when the small amount of enol originally present undergoes bromination. If this is trapped by base, enolization is effectively stalled; conversely, as with free bromine reactions (7), a small amount of acid catalyzes the reaction.

We suggest that the phenomenon which we have termed ketoselectivity may result from the ability of these various reagents to furnish a low equilibrium concentration of molecular bromine when dissolved in solvents of low dielectric constant. For example, with PTAT equilibria [1]–[4] can be written (8). The forward reactions of [1] and [3], and, therefore, [4], can be expected to be discouraged in media of low polarity with the result that [2], which produces molecular bromine, becomes the most significant relationship.

$$[R_4N^+Br_3^-] \rightleftarrows R_4N^+ + Br_3^- \quad [1]$$

$$[R_4N^+Br_3^-] \rightleftarrows [R_4N^+Br^-] + Br_2 \quad [2]$$

$$[R_4N^+Br^-] \rightleftarrows R_4N^+ + Br^- \quad [3]$$

$$Br_2 + Br^- \rightleftarrows Br_3^- \quad [4]$$

If this reasoning is correct it should be possible to observe ketoselectivity even with molecular bromine by employing a sufficiently dilute solution in a solvent of low polarity. The cyclohexene vs. cyclohexanone competition experiments which are summarized in Table II demonstrate that in carbon tetrachloride addition to the double bond can be completely suppressed by lowering the effective concentration of molecular bromine. Taking into account the fact that the ketone contains only 10^{-2}–10^{-6}% of enol (9) it appears that under these conditions the enol is at least 1 000 000 times as reactive as the olefin.

It is hoped that further studies will provide an acceptable explanation of this rate difference. An intriguing speculation is that under the conditions where ketoselectivity is observed the enol reacts via a cyclic six-membered transition state (10, 11).

Luminescence in the thermal decomposition of 3,3,4-trimethyl-1,2-dioxetane

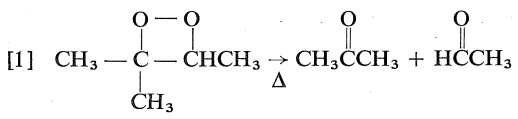
KARL R. KOPECKY AND CEDRIC MUMFORD
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received November 25, 1968

Luminescence is observed during the thermal decomposition of 3,3,4-trimethyl-1,2-dioxetane to acetone and acetaldehyde. The wavelength maximum of the luminescence is at 430–440 mμ when the decomposition is carried out at 60° in benzene solution. This shows that the decomposition of the dioxetane is a concerted electrocyclic reaction which forms a carbonyl compound in the excited singlet state, and confirms the suggestion that bioluminescence is due to the decomposition of 1,2-dioxetanes.

Canadian Journal of Chemistry, **47**, 709 (1969)

Acetone and acetaldehyde are produced in quantitative yield (1) from the thermal decomposition of 3,3,4-trimethyl-1,2-dioxetane, **1**, according to eq. [1]. In carbon tetrachloride the reaction has an activation energy of 25 kcal/mole.



[1] $CH_3-\underset{\displaystyle CH_3}{\overset{\displaystyle O-O}{\underset{|}{C}}}-CHCH_3 \xrightarrow[\Delta]{} CH_3\overset{\displaystyle O}{\overset{\|}{C}}CH_3 + H\overset{\displaystyle O}{\overset{\|}{C}}CH_3$

1

This is a surprisingly large value in view of the weak oxygen–oxygen bond, the probable strain in the molecule, and the stability of the products. It has been suggested (2) on the basis of orbital symmetry rules (3) that the concerted decomposition of a 1,2-dioxetane must produce one of the carbonyl products in an excited electronic state. This would also account for the relative stability of **1**. We wish to report the direct confirmation of this prediction.

A faint bluish luminescence is observed when a benzene solution of **1** is heated above 70° in the dark. The luminescence wavelength maximum is at 430–440 mμ when **1** is decomposed in benzene at 60°, see Fig. 1. The position of the maximum appears to be dependent upon the concentration

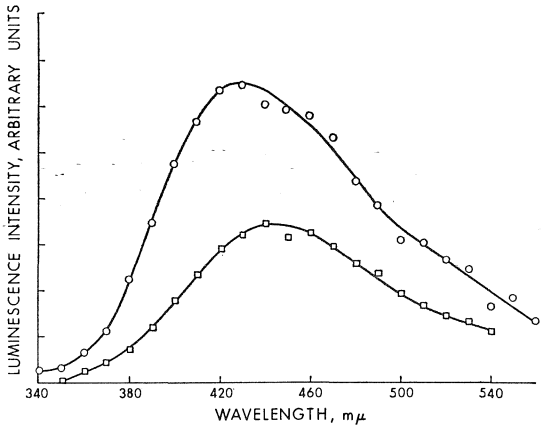


FIG. 1. Spectrum of luminescence from solutions of **1** in benzene at 60°. Initial concentrations: □, 0.21 *M*; ○, 0.021 *M*. The two curves are not on the same scale. The spectra were scanned manually using a Bausch and Lomb 500 mm monochrometer in conjunction with an RCA 1P28 photomultiplier tube. The emission intensity is corrected for photomultiplier response.

of the products, shifting to somewhat longer wavelength with increasing initial concentration of **1** and with time during a run. Comparison of the position of this maximum with the positions of the fluorescence wavelength maxima of acetone (4, 5) and acetaldehyde (6) makes it apparent that

one of these compounds is produced in the excited singlet state upon decomposition of **1**. Two types of fluorescence (4) are observed from acetone: monomer emission with wavelength maximum at 345 mμ (4) at low concentrations and eximer emission with wavelength maximum reported at 405 (4) and 415 mμ (5) at higher concentrations (0.02 and 0.2 *M*, respectively) in hexane at 25°. The fluorescence wavelength maximum of acetaldehyde is at about 420 mμ (6), and it is likely that the position of the maximum in solution is also concentration dependent (4). Short wavelength luminescence corresponding to emission from a "monomeric" excited carbonyl compound (4) is not expected from the decomposition of **1** at any initial concentration, because the excited carbonyl compound is necessarily formed together with another carbonyl compound in the same solvent cage.

The position of the O→O band of neither acetaldehyde (6) nor acetone (5) is known so that it is not yet possible to decide which of these compounds is produced in the excited state from **1**.

Further evidence that the luminescence observed in the decomposition of **1** is the result of emission from a decomposition product and not as a result of an emission from **1** during the act of decomposition is obtained from energy transfer experiments. The faint blue luminescence from a 0.07 *M* degassed benzene solution of **1** at 80° becomes invisible to the eye beside the very much brighter greenish-white luminescence from a degassed benzene solution 0.07 *M* in **1** and 0.0036 *M* in biacetyl. The intensity of emission from the latter solution is clearly many times greater than that from the former. This greatly increased intensity of luminescence is not the result of an induced decomposition of **1** by biacetyl. The first order rate constant, k_d, for decomposition of **1**, 0.1 *M* in benzene, is 5.5×10^{-4} s^{-1} at 60°. In the presence of 0.2 *M* biacetyl the rate is still first order and k_d is 11×10^{-4} s^{-1}. These results indicate that there is energy transfer to biacetyl from the fairly long-lived triplet state (formed by intersystem crossing from the excited singlet state) of one of the carbonyl products of the decomposition of **1**. Energy transfer to biacetyl from the excited singlet state of acetone becomes very inefficient when the concentration of biacetyl is below 0.01 *M*, while energy transfer from the triplet state of acetone remains efficient even at much lower concentrations of biacetyl (7).

Significantly greater intensities and changes in the color of luminescence are also observed from decomposition of solution of **1** containing 0.1 *M* anthracene (deep blue luminescence) and pyrene (light blue luminescence), indicating energy transfer from the excited singlet state of one of the carbonyl compounds from **1**. Intensities are greater because these materials fluoresce much more efficiently, ϕ ca. 0.5 (8), than does acetone, $\phi = 0.01$ (5).

The results indicate that the decomposition of **1** is a concerted process and confirm the prediction (2) that an electronically excited carbonyl compound must be formed in the decomposition of 1,2-dioxetanes. They also lend strong support to the proposal (2, 9) that luminescence observed in many biological systems (see refs. 9*c* and 10 for reviews), model compounds (11) and many other systems (2, 12) may result from the decomposition of transient 1,2-dioxetanes.

The 1,2-dioxetanes from many of these latter systems seem to have a very transitory existence at ambient temperatures. The excited singlet state of acetone appears to lie between 83 and 87 kcal/mole above the ground state (5) and that of acetaldehyde must have a similar energy. The carbonyl compounds formed during luminescence of the biological and model systems are highly conjugated (9–11) and their excited singlet states should lie at energies much lower than those of the excited singlet states of acetone and acetaldehyde. Also, the 1,2-dioxetanes in these systems would be substituted by groups more bulky than the methyl groups of **1** and should thus be more strained. The extremely high rates of decomposition of these 1,2-dioxetanes (which must be several orders of magnitude greater than that of **1**) then become understandable.

Acknowledgments

Evidence for reversible intermediate formation in cyclopentenone cycloaddition[1]

P. DE MAYO, A. A. NICHOLSON, and M. F. TCHIR
Department of Chemistry, University of Western Ontario, London, Ontario

Received November 18, 1968

The usual kinetics for product formation lead to variable values of k_d, the rate constant for decay of the responsible triplet. On the assumption that at least one intermediate is formed which gives either products, or reverts to starting materials, a value near 10^8 s^{-1} is obtained for k_d both from cyclopentene and hex-3-ene cycloadditions.

Canadian Journal of Chemistry, **47**, 711 (1969)

Recent work (1–4) has shown that cyclopentenone cycloaddition proceeds through a triplet[2]. On the assumption that the triplet reacts irreversibly with the substrate to give the product, and with the usual steady state assumptions the expression

$$[1] \qquad \frac{1}{\Phi} = \frac{1}{\Phi_{ic}} + \frac{1}{\Phi_{ic}} \cdot \frac{k_d}{k_r} \frac{1}{[\text{olefin}]}$$

may be derived (3) for the quantum yield of cycloaddition. A plot of the reciprocal quantum yield versus the reciprocal of the olefin concentration should give the efficiency of triplet formation (intercept) and the ratio of k_d/k_r. Previous results (3) and those recorded in Table I clearly indicate that the triplet yield is variable for different olefins, and does not approach the value of near unity determined by the triplet counting technique. Further, the determined values of k_d (3) varied with the olefin concentration.

If the assumption is made that k_r refers to the formation of an intermediate which may either, directly or by a number of intramolecular steps, go on to give product, or may itself (or a subsequent intermediate) decay to regenerate starting materials, then it may be shown that

$$[2] \qquad \frac{1}{\Phi} = \frac{1}{k} + \frac{1}{k}\left(\frac{k_d}{k_r}\right)\frac{1}{[\text{olefin}]}$$

where $$k = \Phi_{ic}\left(\frac{k_1}{k_1 + k_2}\right)$$

Here k_1 is the (composite) rate constant for

product formation from the intermediate, and k_2 that of its decay. If Φ_{ic} is taken as unity (3) then the intercept of a plot of $1/\Phi$ vs. reciprocal olefin concentration represents that portion of the intermediate that closes to give adducts.

From Stern–Volmer plots[3] and those of $1/\Phi$ vs. reciprocal olefin concentration (3) k_d and k_r may be evaluated (Table II).

The values of K_d obtained may be compared with that of 5.7×10^6 s^{-1} obtained by Chapman *et al.* (5) for isophorone and 3.9×10^7 s^{-1} by Zimmerman *et al.* (6) for a hydrophenanthrone[4,5].

The value is now independent of olefin concentration and (approximately[4]) of olefin[6].

The values of k_r are much higher than those recorded (5), for instance, for isophorone dimerization (10^6 M^{-1} s^{-1}) and, indeed, are faster than the rate constant for the addition of thiyl radicals to pent-2-ene (8)[7]. They approach radical recombination rates (9). Whether the intermediate is of the π-complex type supposed by Corey *et al.* (10) or is the 1,4-diradical, or whether both are involved, remains to be ascertained. It is noteworthy that the existence of a reversible step in cycloaddition in the literature has hitherto received little serious attention[8]. Experiments are in progress to define more accurately the nature of the intermediate.

[3]Using 2,5-dimethyl-2,4-hexadiene as quencher.

[4]Professor P. Wagner (Michigan State) has informed us that he has obtained a value of k_d for cyclopentenone near 10^8 s^{-1} from a study of its dimerization. We thank Professor Wagner most cordially for this information. It should be noted that the absolute value of k_d depends on a number of factors such as the method used for computing diffusion rates and the efficiency of exothermic quenching (7) and so is subject to some uncertainty.

[5]The value of k_d seems high for decay of a spectroscopic triplet to the ground state (by two orders of magnitude) but slow for an internal conversion (12).

[6]Although cyclopentene was used immediately after purification it was found extremely difficult to maintain this condition.

[7]Schuster *et al.* (13) give 3×10^8 M^{-1} s^{-1} for cyclopentenone dimerization.

[8]For the relevance of such processes in oxetane formation see the discussion by Yang *et al.* (11). See also ref. 14.

Inefficiency and reversibility in the photodimerization of 2-cyclopentenone

PETER J. WAGNER[1] AND DAVID J. BUCHECK[2]
Chemistry Department, Michigan State University, East Lansing, Michigan 48823

Received November 26, 1968

The maximum efficiency for photodimerization of cyclopentenone in acetonitrile is 36%. The intermediacy of metastable dimeric species, 64% of which revert to two ground state molecules, is indicated.

Canadian Journal of Chemistry, 47, 713 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

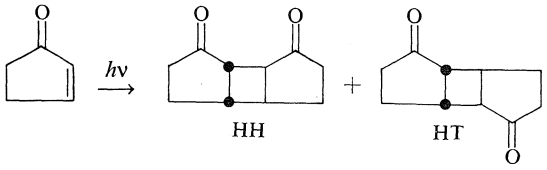
The photodimerization of cyclopentenone has been shown to proceed from an excited triplet state (1). The dependence of the HH/HT product ratio on concentration apparently reflects a polar solvent effect (1, 2).



We have performed kinetic studies on the photodimerization in acetonitrile, with the following results. First, the HT/HH dimer ratio is 55/45 from 0.1 to 3.0 *M* ketone. Apparently the acetonitrile is sufficiently polar that varying concentrations of ketone do not change the effective solvent polarity.

TABLE I

Kinetic results for photodimerization of cyclopentenone in acetonitrile

[Cyclopentenone], M^{-1}	Φ_{DIM}*	$k_q\tau$, M^{-1}	$1/\tau$, 10^8 s^{-1}
1.52	—	9.1	10.5
1.00	0.34	12.5	7.7
0.75	—	16.5	5.9
0.50	0.32	26.5	3.7
0.375	0.31	—	—
0.25	0.29	—	—

*Absolute values ±0.02; relative values ±0.002.

Table I contains values for quantum yields of dimer formation and cyclopentenone triplet state lifetimes as a function of cyclopentenone concentration. These values were determined as follows. Degassed samples containing 0.003 *M* isophthalonitrile as internal standard and varying amounts of 1,3-pentadiene as quencher were irradiated in parallel at 3130 Å. Yields of dimer formation at <4% conversion were determined by vapor-phase chromatographic analysis. The acetophenone sensitized *cis*-to-*trans* isomerization of 1,3-pentadiene (3) was used to measure light intensity. Stern–Volmer analysis of relative quantum yields as a function of quencher concentration yielded values of $k_q\tau$, where k_q is taken to be 1.0×10^{10} M^{-1} s^{-1} (4, 5).

To the common mechanism for photodimerization, which assumes irreversible addition,

$$[1] \qquad CP_0 \xrightarrow{h\nu} CP^{1*} \longrightarrow CP^{3*}$$

$$[2] \qquad CP^{3*} \xrightarrow{k_i} CP_0$$

$$[3] \qquad CP^{3*} + CP_0 \xrightarrow{k_a} \text{dimers}$$

the following familiar kinetic expressions apply, where Φ_{isc} is the quantum yield

$$[4] \qquad \tau^{-1} = k_i + k_a[CP]$$

$$[5] \qquad \Phi_{DIM}^{-1} = \Phi_{isc}^{-1}(1 + k_i k_a^{-1}[CP]^{-1})$$

of intersystem crossing.

Analysis of the lifetime data according to eq. [4] yields values of $7.6 \pm 2 \times 10^7$ s^{-1} for k_i and 6.7×10^8 M^{-1} s^{-1} for k_a. Analysis of the quantum yield data according to eq. [5] yields an intercept of 0.36^{-1} and a k_i/k_a value of 0.06, the latter in good agreement with the individual values.

The important point we wish to make is that the moderately low quantum yields are not due to rapid physical decay of the triplet nor to a low intersystem crossing efficiency. Extrapolation of the efficiency with which 0.5 *M* cyclopentenone sensitized the *cis*-to-*trans* isomerization of 1,3-pentadiene to infinite diene concentration indicates that Φ_{isc} is unity, in agreement with de Mayo's recent report (6) and Leermakers' earlier data (2).

[1]Fellow of the Alfred P. Sloan Foundation, 1968–1970.
[2]N.I.H. Predoctoral Fellow, 1966–1969.

These results reveal that a major source of inefficiency is missing from the above mechanistic scheme. Furthermore, the majority of return to ground state ketone must occur after the triplet state has reacted. Consequently, a two-step photodimerization mechanism is indicated. Only 36% of the initial dimeric photoproduct, quite possibly a 1,4-biradical (7, 8), proceeds to stable dimer, the rest dissociating to two ground state cyclopentenone molecules.

$$[6] \qquad CP^{3}* + CP_0 \xrightarrow{k_a} *CP\text{–}CP*$$

$$[7] \qquad *CP\text{—}CP* \xrightarrow{k_{-a}} 2\ CP_0$$

$$[8] \qquad *CP\text{—}CP* \xrightarrow{k_c} \text{dimers}$$

$$[9] \qquad \Phi_{DIM}^{-1} = \Phi_{isc}^{-1}\phi_c^{-1}(1 + k_i k_a^{-1}[CP]^{-1})$$

$$[10] \qquad \phi_c = k_c(k_c + k_{-a})$$

Equation [4] is not a good general expression for the quantum yield of photocycloaddition; eq. [9] replaces it (9, 10). de Mayo has reached the identical conclusion in his studies of the photocycloaddition of cyclopentenone to various olefins (6, 11). As is the case in Type II photoelimination (7), the relationship between quantum efficiencies and triplet state reactivities is not direct. This phenomenon apparently is widespread among nonconcerted triplet state reactions.

It should be pointed out that there are probably two ϕ_c values, one for head-to-tail dimerization and one for head-to-head dimerization. Therefore solvent effects on product ratios are a composite of effects on two competing k_a values and two ϕ_c's. Further work will be devoted to separating these effects.

Metal ion initiated halogenation reactions of *N*-haloamines[1]

DENNIS D. TANNER AND MELVYN W. MOSHER[2]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received July 5, 1968

The metal ion catalyzed chlorination of hydrocarbon substrates by *N*-chloroamines and imides in acid media proceeds by a free radical chain mechanism. Reactions of four different *N*-chloro halogenating reagents with cuprous chloride, ferrous sulfate, and ferrous chloride initiators have been investigated. Contrary to the previously reported observations no experimental differences were observed in the halogenation reactions of individual *N*-halo compounds or with the different initiators. The chain carrying species in all cases was shown to be the chlorine atom and the radical chain process showed identical reactivity to that of photo-chlorination by molecular chlorine.

Canadian Journal of Chemistry, 47, 715 (1969)

Introduction

In recent years considerable attention has been given to the radical chain reactions of *N*-haloamines, amides, and imides. Divalent nitrogen species have been proposed as reactive intermediates in the free radical addition reactions of these positive halogen compounds with olefins (1–14) as well as in their halogenation reactions involving hydrogen abstraction.

The reactions leading to abstraction by nitrogen radicals fall into two classifications, those involving intramolecular abstraction and those involving intermolecular abstraction. In the case of the intramolecular reactions (i.e. to give δ halogenation) a further division can be noted; whether they proceed by a chain sequence with or without acid catalysis. The acid-catalyzed reactions comprise the reactions of *N*-haloamines and are usually referred to under the general heading of the Hofmann–Löffler–Freytag Reaction (15, 16). The intramolecular reactions (i.e. to give δ halogenation) proceeding under neutral conditions are the reactions of *N*-haloimides (17) and *N*-haloamides (18, 19) and can be generally referred to as "Barton type" reactions for these classes of compounds.

Since it has been established that the intermolecular free radical halogenation reactions of *N*-haloamides and *N*-haloimides proceed under neutral conditions by a process involving halogen atom abstraction in the chain propagating step (20–22), only examples of acid-catalyzed intermolecular chain halogenation reactions can claim to involve nitrogen radical abstraction. The photo-initiated reaction of *N*-iodosuccinimide in trifluoroacetic acid to abstract hydrogen from trifluoroacetic acid (23), and the metal ion initiated, acid-catalyzed chain halogenation reactions of *N*-haloamines (24–28), which have been extensively studied by Minisci and co-workers, remain to our knowledge the only examples of chain reactions involving intermolecular hydrogen transfer by divalent nitrogen.

The metal ion initiated halogenation reactions of *N*-haloamines, as reported, seemed a unique, synthetically useful, and theoretically interesting reaction. Minisci has proposed the mechanism of the reaction to involve hydrogen abstraction by a protonated aminium radical (see Scheme 1) (24–28).

The relationship between the reactivity (i.e., the ability of the aminium radical to differentiate between different hydrogens in the same molecule) of the nitrogen radical and the structure of the starting *N*-chloro- and *N*-bromoamine has been studied (24, 25, 28). The authors reported varying distributions of products in the chlorina-

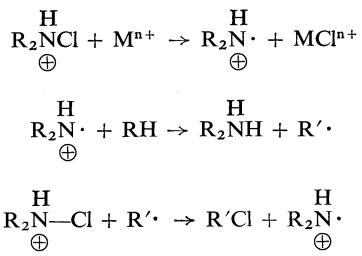
[2]University of Alberta Postdoctoral Fellow (1967–1969).



Scheme 1

tion of chlorocyclohexane with several *N*-chloroamines (25). Furthermore they claim that by varying the metal ion used to initiate the reaction (27), variations in the product compositions were obtained for a number of organic halogenations.

A proper selection of *N*-haloamine, initiator, and substrate would allow one to selectively substitute chlorine or bromine at a desired position in the substrate molecule. In order to realize the full synthetic usefulness of this reaction a more detailed investigation of these halogenations has been undertaken.

It was immediately apparent that an inconsistency in the proposed mechanism for these reactions existed. The variability of the product distribution with the initiator used argues for a more complicated sequence of reactions than had been proposed, since no account had been taken of the role of the metal ion in the product determining abstraction reaction.

Results and Discussion

The ferrous sulfate initiated chlorination of methyl butyrate with *N*-chlorodiethylamine in sulfuric acid – acetic acid solvent has been reported to give the distribution of products seen in Table I, reaction 1 (27). Comparison of this product distribution with that found for the photo-initiated chlorination of the ester in carbon tetrachloride with molecular chlorine is seen in Table I, reaction 3. When reaction 1 was repeated the product distribution shown in reaction 2 was obtained.

It was found, however, that when the mixture of chlorinated esters obtained in reaction 3 was placed in the sulfuric acid – acetic acid solvent, allowed to stand for the same length of time, and temperature as was reported for the *N*-chloroamine halogenation, after re-isolation of the resultant mixture and re-analysis by gas–liquid partition chromatography, the product distribution was seen to change, reaction 4, Table I. An analogous test of the stability of the brominated esters showed similar results.

*Values are averages of the results of three or more independent experiments. Duplicate analyses were obtained for each experiment; the individual experimental values agreed to within ±5%.
†Taken from ref. 27.

The mechanism proposed for halogenation by *N*-haloamines was based on the comparison of the differences in product distributions reported for halogenation reactions between molecular halogen and the *N*-chloroamine, and that *N*-bromodimethylamine and *N*-chlorodimethylamine gave the same isomer distributions (26). The obvious instability of the brominated and chlorinated esters in sulfuric acid – acetic acid mixtures casts some doubt on the reliability of these mechanistic conclusions.

The halogenation products from the chlorination in acid media of 1-chlorobutane or 1-chloropropane were found to be stable for the length of time required for the completion of the reaction. These substrates were used to determine the relative reactivity of the different hydrogens in the reactants towards the abstracting radical in the halogenation process.

It was found for *N*-chlorodiethylamine that catalytic amounts of cuprous chloride (2%) were sufficient to cause a 96% conversion of the active halogen to halogenated 1-chloropropane in 7 h, while under identical conditions in the absence of cuprous ions no halogenation could be detected. The catalytic effect of trace amounts of cuprous ion was convincing evidence for a radical chain process.

The photo-chlorination of 1-chloropropane (0.1 *M*) with molecular chlorine (1.4×10^{-4} *M*) in the sulfuric acid – acetic acid mixture gave a quantitative yield of the three chlorinated 1-chloropropanes; in the presence of cuprous chloride (5×10^{-5} *M*) identical results were obtained. The cuprous chloride (8.4×10^{-4} *M*)

initiated chlorination of 1-chloropropane (0.1 *M*) with *N*-chlorodiethylamine (3.5×10^{-3} *M*) in the acid media gave a 96% yield of the chlorinated substrate. The high yield of chlorides in the copper-catalyzed chlorinations by both molecular chlorine and the chloroamine was good evidence for the lack of copper-catalyzed oxidation of the intermediate radicals (Scheme 2) (29–32).

$$R_2\overset{\oplus}{N}HCl + M^{n+} \rightarrow R_2\overset{\oplus}{N}H + MCl^{n+}$$

$$R_2\overset{\oplus}{N}H + R'H \rightarrow R_2\overset{\oplus}{N}H_2 + R'\cdot$$

$$R'\cdot + M^{(n+1)+} \rightarrow R'^{\oplus} + M^{n+}$$

$$R'^{\oplus} + Y^{\ominus} \rightarrow R'Y$$

Scheme 2

The production of carbonium ion intermediates in concentrated sulfuric acid – acetic acid was inconsistent with the formation of high yields of chlorination products in this media. The possibility of the inclusion of an oxidation–reduction process in the mechanistic scheme for halogenation, therefore, seems unlikely.

The product distributions for chlorination of the methyl esters reported by Minisci *et al.* (27) were compared to the distributions found by Singh and Tedder (33) for the chlorination of these same esters by molecular chlorine in carbon tetrachloride solvent. Since dramatic solvent effects have been noted for chlorinations of hydrocarbons with molecular chlorine (34–36), the photo-initiated chlorination of 1-chlorobutane and 1-chloropropane was carried out in carbon tetrachloride and in the sulfuric acid – acetic acid solvent. The halogenation patterns for the two substrates in these solvents are compared in Table II.

TABLE II

Comparison of the isomer distribution for 1-chloropropane and 1-chlorobutane with solvent*

	Cl—CH_2—CH_2—CH_3			
Cl_2/CCl_4	11.8	57.6	30.7	
Cl_2,H_2SO_4/HOAc	16.0	54.1	29.9	
	Cl—CH_2—CH_2—CH_2—CH_3			
Cl_2/CCl_4	10.5	27.6	45.3	13.7
Cl_2,H_2SO_4/HOAc	5.4	20.9	52.0	21.6

*Values are averages of the results of 3 or more independent experiments and duplicate analyses were obtained for each experiment. The individual experimental values agreed to within ±5%.

The variation in the product distribution for the two substrates in the two different solvents was small. As a check on the analytical procedure (i.e. isolation and analysis), and to rule out the possibility of any larger effects with other substrates, the comparisons of the isomer distributions and relative reactivities for the halogenations studied were made with the results obtained from photo-initiated halogenations run in the acid solvent.

Attempts to obtain hydrogen selectivities for the abstracting radical in the *N*-chloroamine halogenations proved unsuccessful. When halogenations of isobutane (1°/3° abstraction ratios) were attempted in the acid media isobutyl chloride was obtained and only traces of *t*-butyl chloride could be detected by g.l.p.c. analysis. Similar results were obtained in the chlorination of 2,3-dimethylbutane. These results illustrated the instability of the tertiary chlorides to the acid media.

Hydrogen abstraction from negatively substituted hydrocarbons has been shown to be substantially influenced by polar interactions between the abstracting radical and the electron withdrawing substituent (37–39). Aminium radicals generated from chloroamines derived from amines having a wide range of basicities would be expected to show a varying range of polar interactions with substituted hydrocarbons. The cuprous ion initiated halogenation patterns for the chlorination of 1-chloropropane with *N*-chlorodiethylamine, *N*,*N*-dichloropropylamine, *N*-chloropiperidine, and *N*-chlorosuccinimide are shown in Table III.

TABLE III

Comparison of the isomer distribution for 1-chloropropane with various halogenation agents*

	Cl—CH_2—CH_2—CH_3		
N,*N*-Dichloropropylamine	16.9	51.6	31.5
N-Chloropiperidine	16.8	51.7	31.4
N-Chlorodiethylamine	16.6	51.4	32.0
N-Chlorosuccinimide	16.9	51.6	31.3
Cl_2/hν	17.2	50.7	32.2
N-Bromodiethylamine	39.2	60.8	Trace
Br_2/hν	40.4	59.6	Trace

*Values are averages of the results of 3 or more independent experiments and duplicate analyses were obtained for each experiment. The individual experimental values agreed to within ±1%.

It can be seen that within experimental error the *N*-chloroamines, *N*-chlorosuccinimide, and the photo-initiated chlorination reactions with molecular chlorine gave identical results.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The photo-initiated bromination of 1-chloropropane with molecular bromine and its cuprous ion initiated bromination with *N*-bromodiethylamine gave the same distribution of brominated products. The isomer distributions for the bromination and chlorination reactions are clearly different and in the case of the two *N*-halodiethylamines must proceed through two intermediates which differ in their selectivities (see Table III).

Furthermore, it was found that cuprous chloride, ferrous sulfate, and ferrous chloride initiation of the four *N*-chloro compounds studied gave isomer distributions for the halogenation of 1-chloropropane which were indistinguishable experimentally from the results obtained for the photo-initiated chlorination of that substrate with molecular chlorine in solvent sulfuric acid (see Table IV).

TABLE IV

Comparison of the isomer distribution of 1-chloropropane with various initiators*

	Cl—CH_2—	—CH_2—	—CH_3
$FeSO_4$	15.6	53.9	30.5
$FeCl_2$	15.9	55.2	29.7
CuCl	16.9	51.4	32.0
hν (without acid)	17.6	51.0	31.2
$Cl_2h\nu$	17.2	50.7	32.2

*Values are averages of the results of 3 or more independent experiments and duplicate analyses were obtained for each experiment. The individual experimental values agreed to within ±4%.

The results clearly show, at least with the substrate investigated, that neither the *N*-chloro reagent involved nor the initiator used shows any effect on the isomer distribution for halogenation. The evidence indicates that the mechanisms for the reactions studied were all radical chain reactions involving atomic chlorine as the abstracting species. The radical chain proposed for the chlorination reactions is identical with the reaction sequence established in neutral media for halogenation by *N*-bromo- and *N*-chlorosuccinimide (20–22, 40), (see Scheme 3).

$$RH + Cl\cdot \rightarrow R\cdot + HCl$$

$$HCl + R'_2\overset{\oplus}{N}HCl \rightarrow Cl_2 + R'_2\overset{\oplus}{N}H_2$$

$$Cl_2 + R\cdot \rightarrow RCl + Cl\cdot$$

Scheme 3

The chlorine atom chain mechanism was considered by the earlier workers in their studies, but was rejected on the basis of their previously discussed results. They furthermore rejected the possibility of the operation of the halogen atom chain, since they reported that in sulfuric acid – acetic acid media anhydrous hydrogen chloride did not react with the *N*-chloroamines they studied (27). Contrary to their findings we found that when excess anhydrous hydrogen chloride was stirred with an acid solution of the *N*-chloroamines, an immediate reaction took place with the liberation of a nearly quantitative yield of molecular chlorine. The observed reaction between hydrogen chloride and *N*-chloroamines in acid media is in agreement with the observation of Komori *et al.* (41) in the same systems.

Further evidence for the chlorine atom chain was obtained by the competitive halogenation of a series of substituted and unsubstituted hydrocarbons. The relative rates of the cuprous chloride initiated reactions of cyclohexane to the various substrates with the four *N*-halo compounds are compared with the photo-initiated reaction with molecular chlorine. The results are listed in Table V.

TABLE V

Relative reactivities of hydrocarbons toward *N*-chlorodiethylamine and molecular chlorine*

	Relative reactivity/molecule†	
	N-Chlorodiethylamine	Cl_2
Cyclohexane	1.00	1.00
Cyclopentane	0.84±0.07‡	0.83±0.04
2,3-Dimethylbutane	0.83±0.10‡	0.89±0.06
Norbornane	0.68±0.03	0.74±0.08
2,2,3,3-Tetramethylbutane	0.59±0.03	0.65±0.01
1-Chlorobutane	0.36±0.03‡	0.36±0.08

*Values are averages of the results of 3 or more independent experiments and duplicate analyses were obtained for each.
†The experimental errors were those reported for *N*-chlorodiethylamine.
‡Identical results were obtained with *N*-chlorosuccinimide and *N*,*N*-dichloropropylamine.

The use of relative reactivities as a probe for the investigation of the intermolecular selectivities of a specific radical has the advantage that the ratio of rate constants is obtained from the determination of the relative consumption of the two substrates, and that this value is not affected by the subsequent fate of the intermediates involved. Within experimental error the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

relative rates for the cuprous chloride initiated halogenation reactions of *N*-chlorodiethylamine, *N*-chlorosuccinimide, and *N,N*-dichloropropylamine were found to be identical with the relative rates determined for the photo-initiated chlorination reactions of molecular chlorine.

The initiation reaction for the production of chlorine atoms by the interaction of the appropriate metal ion and an *N*-halo compound can arise by one of two paths; either (1) the reduction of the *N*-chloroammonium salt to the neutral amine and a chlorine atom, or (2) the production of an aminium radical and a chloride ion. The chloride ion can subsequently react with the *N*-halo compound to produce molecular chlorine (see Scheme 4). No direct evidence is available for a choice between either of these initiation reactions.

$$(1)\quad \overset{\oplus}{R_2NHCl} + M^{n+} \rightarrow R_2NH + Cl + M^{(n+1)+}$$

or

$$(2)\quad \overset{\oplus}{R_2NHCl} + M^{n+} \rightarrow R_2NH + M^{(n+1)+} + Cl^-$$

$$R_2\overset{\oplus}{N}HCl + Cl^- \rightarrow Cl_2 + R_2NH$$

Scheme 4

Conclusion

The metal ion catalyzed chlorination of hydrocarbon substrates by *N*-chloroamines and imides proceeds by a free radical chain mechanism. The chain carrying species in these halogenations is the chlorine atom, and the selectivity and reactivity of the reagents are unaffected by the structure of the *N*-halogenating agent or the metal ion catalyst used to initiate the reaction. No evidence is found for metal ion promoted oxidation–reduction reactions of the intermediates involved.

Experimental

Materials

The method of Coleman (42) was used to prepare the *N*-haloamines. These were used without further purification. Iodometric titration showed a purity of 90–102%. Phillips research grade cyclohexane, 2,3-dimethylbutane, cyclopentane, *n*-butane, and *i*-butane were used without further purification. All other substrates were commercially available; their purity was checked by gas–liquid partition chromotography and they were distilled when necessary.

Chlorination of Methyl Butyrate

Methyl butyrate (0.1 *M*) in carbon tetrachloride was added to a solution of chlorine (0.04 *M*) in carbon tetrachloride. The solution was degassed by the freeze–thaw method and then irradiated in sealed Pyrex ampoules until the chlorine color had disappeared. The reaction mixture was analyzed upon a 10 ft × $\frac{1}{8}$ in. DEGS g.l.p.c. column. Three of the four chlorination product peaks were identified by their identical retention times on 2 different g.l.p.c. columns with commercially available compounds. The chloromethyl butyrate was assigned by elimination and by comparison of this substitution pattern with that obtained from the reaction of molecular chlorine.

Methyl butyrate was chlorinated by the method of Minisci *et al.* (27, 28) using *N*-chlorodiethylamine and iron sulfate. The reaction products were isolated and analyzed on a 10 ft × $\frac{1}{8}$ in. DEGS g.l.p.c. column.

Effect of Sulfuric Acid – Acetic Acid upon Chlorinated Methyl Butyrate, 1-Chloropropane, and 1-Chlorobutane

The mixture obtained in the chlorination of methyl butyrate with molecular chlorine in carbon tetrachloride was subjected to the reaction reported for the *N*-chloroamine chlorination and the resultant mixture was reisolated using this isolation procedure (24) and reanalyzed.

When this procedure was repeated for the monochlorinated 1-chloropropanes and 1-chlorobutanes the reanalyzed isomer distributions were found to remain unchanged. The monochlorinated 1-chloropropanes and 1-chlorobutanes were identified and quantitated by the method previously reported by this laboratory (39).

Bromination of 1-Chloropropane

Bromination products of 1-chloropropane were analyzed on a 25 ft × $\frac{1}{8}$ in. 5% Polar g.l.p.c. column. The products were identified by comparison with the previously reported bromination of 1-chloro-propane with molecular bromine (33).

Catalytic Effect of Cuprous Chloride

The formation of the three dichlorinated 1-chloropropanes was observed from the reaction of *N*-chlorodiethylamine (2.9×10^{-3} *M*), 1-chloropropane (0.1 *M*), and cuprous chloride (5.2×10^{-5} *M*). The mixture was degassed and shaken for 7 h, 1,4-dichlorobutane was added as an external standard and the organic layer analyzed as above. Molar amounts of the chlorination products were calculated from calibration plots of area ratios vs. mole ratios for 1,4-dichlorobutane vs. the authentic samples. The yield of the three dichlorinated 1-chloropropanes was found to be 96%.

Photo-initiated Chlorination of 1-Chloropropane and 1-Chlorobutane with Molecular Chlorine in Sulfuric Acid/Acetic Acid

Heterogeneous mixtures of a solution of 1-chloropropane (0.1 *M*) and chlorine (1.4×10^{-4} *M*) and 10 ml of 85/15 sulfuric acid/acetic acid solution were placed in Pyrex ampoules, degassed and sealed. The mixtures were continuously shaken and irradiated at room temperature for 15 min. The yield of the three dichlorinated 1-chloropropanes was determined to be 98% based upon 1,4-dichlorobutane as an external standard.

Heterogeneous mixtures of a solution of 1-chloropropane (0.1 *M*) and chlorine (1.4×10^{-4} *M*) and 10 ml of 85/15 sulfuric acid/acetic acid solution containing

For personal use only.

cuprous chloride (5×10^{-5} *M*) were placed in Pyrex ampoules, degassed and sealed. The mixtures were continuously shaken and irradiated at room temperature for 15 min. The yield of the three dichlorinated 1-chloropropanes was determined to be 96% based upon 1,4-dichlorobutane as an external standard.

An identical procedure was carried for the photoinitiated chlorination and isolation of the halogenation products of 1-chlorobutane. The four dichlorinated butanes were analyzed by the method previously reported (39).

Chlorination of 1-Chloropropane by N-Chlorodiethylamine

To 1-chloropropane (0.1 *M*) – and *N*-chlorodiethylamine (3.5×10^{-3} *M*) in a Pyrex ampoule were added 10 ml of sulfuric – acetic acid (85/15) containing cuprous chloride (8.4×10^{-4} *M*). The ampoules were degassed and shaken for 3 h. The yield of the three dichlorinated 1-chloropropanes was determined to be 96% using 1,4-dichlorobutane as an external standard.

Chlorination of 1-Chloropropane and 1-Chlorobutane with Molecular Chlorine in Carbon Tetrachloride

The 1-chlorohydrocarbons were chlorinated and quantitated by the method previously reported (39).

Chlorination with N-Haloamines and Imides

To a mixture of the accurately weighed *N*-haloamine or imide (0.126 *M*) in 50 ml of sulfuric acid/acetic acid (85/15) were added the hydrocarbon (1.9 *M*) and the finely powdered metal ion initiator (0.126 *M*). The reaction mixture was stirred rapidly at room temperature for 2 h and then poured on ice, and the organic layer was separated, washed with 5% sodium bicarbonate solution, and dried over magnesium sulfate. The dried reaction mixture was then examined by gas–liquid partition chromatography. The isolation method was shown to be suitable for this analysis by subjecting known synthetic mixtures to this procedure.

In an alternative method an accurately weighed portion of the *N*-haloamine or imide (0.126 *M*) was added to the hydrocarbon (1.9 *M*) in Pyrex ampoules. The solution was frozen and a solution of the metal initiator in sulfuric acid/acetic acid (85/15) was added to give a metal ion concentration between 0.0126 and 0.063 *M*. The tubes were degassed by the freeze–thaw method and the sealed ampoules were continuously shaken for 1–4 h. The ampoules were opened and the organic layer was examined by gas–liquid partition chromatography.

The values obtained by both of the above methods gave results within experimental error. The latter method was used exclusively in the competition reactions.

Detection of Chlorine from N-Chloroamines

In a Pyrex ampoule was placed a standard solution containing 2×10^{-3} *M* of the *N*-chloroamine in sulfuric acid/acetic acid (85/15). The contents were frozen and dry hydrogen chloride was condensed on the frozen solution. The ampoule was connected to a vacuum line and the system evacuated and allowed to warm. An instant reaction commenced with the evolution of a gas. The gas was fractionated through a series of traps and found to freeze at between −98 and −105° as a yellow solid. The literature value reported for chlorine was −101.5° (43). The material was identified as chlorine by comparison of its retention on a Polypak 1 (6 ft × $\frac{1}{8}$ in.) g.l.p.c. column and by its mass spectrum. The yield of chlorine was approximated to be 100% by comparing peak areas obtained from known concentrations of chlorine with the areas of the gas obtained from the reaction.

Competitive Chlorination of Hydrocarbons

The competitive chlorinations using molecular chlorine, *N*-chloroamines, or imides were carried out by the method previously reported (39). The relative reactivities were calculated by the method previously reported in this laboratory (44). The values obtained are reported in Table V.

Lignin and related compounds.[1] I. A comparative study of catalysts for lignin hydrogenolysis[2]

J. M. Pepper and Y. W. Lee

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received August 16, 1968

A detailed comparative study has been made of the effectiveness of various catalysts for the hydrogenolysis of spruce wood lignin. The catalysts studied were Raney nickel, 10% palladium–charcoal, 5% rhodium–charcoal, 5% rhodium–alumina, 5% ruthenium–charcoal, and 5% ruthenium–alumina. Lignin degradation products were obtained initially as a chloroform-soluble fraction which was then divided and studied as diethyl ether-soluble and -insoluble fractions. Gas–liquid chromatographic separation of the ether-soluble fraction made possible the characterization and quantitative estimation of many of the lower molecular weight lignin degradation products.

The data indicate that rhodium, palladium, and a limited amount of Raney nickel produce similar results as do ruthenium and an excess of Raney nickel; however, with the latter catalysts the degradation is more severe. In particular, rhodium–charcoal and palladium–charcoal appear to offer interesting advantages as catalysts for lignin hydrogenolysis.

Canadian Journal of Chemistry, 47, 723 (1969)

Previous work in these and other laboratories (1–3), has contributed to the acceptance of catalytic hydrogenolysis as a valuable approach to the study of lignin structure through the production of significant lignin degradation products. The production of 3-guaiacyl-1-propanol (dihydroconiferyl alcohol) and/or 2-guaiacyl-1-ethanol from softwoods and of the corresponding 4-hydroxy-3,5-dimethoxyphenyl (syringyl) analogues from hardwoods have added strong support to the belief that oxygen ether linkages exist in positions both β and γ to the guaiacyl and/or syringyl nuclei. This realization coupled with the appreciable yields (up to 25% of the lignin) of such products retaining, as essentially they do, the 3-carbon propyl side chain, have led to a continuation of this procedure as a method of study of lignin structure in these laboratories.

In this earlier work (2) it was shown that, under similar conditions of hydrogenolysis, there was little difference in the yields and in the nature of the products obtained whether Raney nickel catalyst (10 g/50 g wood meal) or 10% Pd—C (1 g/10 g wood meal) were used. It was noted, however, that under conditions wherein the relative amount of Raney nickel catalyst was increased (10 g/10 g wood meal) significant differences appeared in the nature of the products and, in particular, the amount of dihydroconiferyl alcohol markedly decreased while at the same time the amounts of two unidentified compounds increased.

It was therefore of interest to examine more closely the effect of the relative amount of Raney nickel catalyst and also of other catalysts which might be expected to have similar or related catalytic properties. To this end a study was made of the hydrogenolysis of preextracted spruce sapwood (10 g) under conditions that were reported previously (4) but with the following catalyst systems: Raney nickel (RaNi, 1 g), Raney nickel (RaNi, 10 g), 10% palladium–charcoal (Pd—C, 1 g), 5% rhodium–charcoal (Rh—C, 1 g), 5% rhodium–alumina (Rh–alumina, 1 g), 5% ruthenium–charcoal (Ru—C, 1 g), and 5% ruthenium–alumina (Ru–alumina, 1 g). After removing the residual pulp and catalysts by filtration, the dioxane water solution was extracted thoroughly with chloroform, the excess solvents removed, and the residue, labelled the chloroform-soluble fraction was weighed. Results recorded in Table I, and indicate to a first approximation the efficiency of lignin extraction. In certain cases, small samples were removed for determination of the methoxyl content.

Preliminary experiments involving gas–liquid chromatography had shown that a diethyl ether extraction of the chloroform-soluble fraction, permitted an essentially complete separation of

[1]Several previous publications dealing with the chemistry of lignin and related compounds have resulted from work done in these laboratories. A list of such references is available from J. M. Pepper.

the lower from the higher molecular weight lignin degradation products. Accordingly, to facilitate subsequent study, each chloroform-soluble fraction was divided into a diethyl ether-soluble and a diethyl ether-insoluble portion. The weights of such fractions and some representative methoxy contents are also presented in Table I.

The poor reproducibility in some cases is believed to be due primarily to the difficulty in controlling the loss of lower boiling products during the procedure of removing the excess solvent systems. Although this would affect the relative abundance of the lower molecular weight to the higher molecular weight derivatives so obtained, it is the relative amounts of the compounds in the latter group which are perhaps of more significance (*vide infra*).

Of the seven catalytic systems, that of 5% Rh on charcoal appears to be significantly different from the others and appears to possess an activity which encourages further study. The readily reproducible high yields of the chloroform-soluble fraction, which, because of its high methoxyl content may be considered to be lignin in origin, represent essentially complete lignin recovery from the original wood meal. For this product, too, the amount that is ether-soluble (ca. 70%) is much greater than the percent ether-solubility of the $CHCl_3$-soluble fractions obtained using the other catalysts. Assuming that such greater ether-solubility reflects the greater abundance of lower molecular weight substances, this fraction would enable one, through a more detailed chemical examination, to identify a larger portion of the lignin degradation products.

To complete this comparable study of these different catalysts, representative samples of the ether-soluble fractions obtained by the use of each catalyst system, were chromatographed using a 6 ft × $\frac{1}{8}$ in. column packed with 10% UCW98 on Chromosorb W (DMCS treated, acid washed, 60–80 mesh). Details of these chromatograms are given in Figs. 1 and 2. The indicated identity of the compounds represented by the major peaks has been determined by a comparison of the retention times with those of authentic samples.

Using coumarin as the internal standard, the relative abundance of each of these compounds was determined and is given in Table II in terms of the percentage, by weight, of the original Klason lignin that it represents.

From the data recorded in Figs. 1 and 2 and in Table II, the following conclusions may be drawn. There is a significant difference between the hydrogenolysis products obtained using any of Raney Ni (1 g), Pd—C, Rh—C, and Rh–alumina on the one hand and those obtained

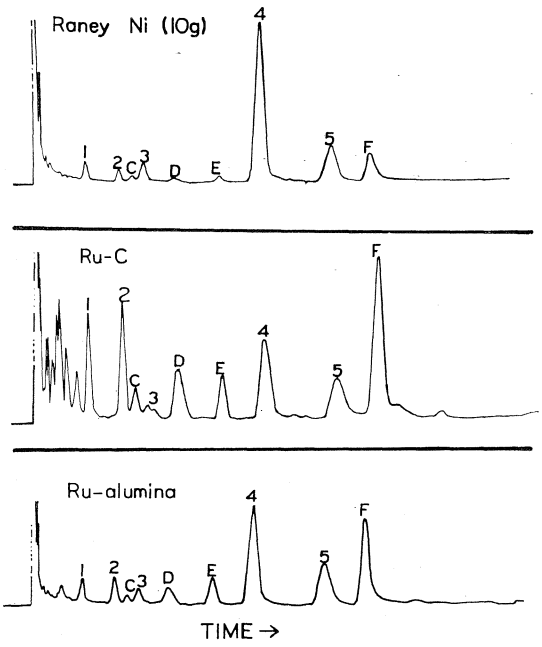

FIG. 2. Gas–liquid chromatograms of spruce lignin hydrogenolysis products: C, 4-methylguaiacol; D, 4-ethylguaiacol; E, 4-*n*-propylguaiacol; F, dihydroconiferyl alcohol; compounds **1**, **2**, **3**, **4**, **5** unidentified cyclohexyl derivatives.

using any of Raney Ni (10 g), Ru—C, and Ru–alumina on the other. For each of the former type, 4-*n*-propylguaiacol and dihydroconiferyl alcohol are the two major products, the relative amount in each case being different, whereas for members of the latter type several products are obtained in addition to these two. A preliminary examination of the unidentified compounds represented by the peaks 1–5 reveals that they are cyclohexyl derivatives, probably resulting from the further reduction and hydrogenolysis of dihydroconiferyl alcohol. Details of the chemical nature of these compounds and their relationship to dihydroconiferyl alcohol will be reported in a forthcoming publication. It is clear that the three catalyst systems making up this group may be regarded as more severe and although of possible interest for synthetic studies would appear of less value for studies in lignin chemistry. The possibility exists though that other new and significant results may be obtained using catalysts as yet untested, or in amounts different to those previously studied.

It is particularly interesting to note that, using the Pd—C catalyst, about 68% of the total ether-soluble fraction, representing some 24% of the

‡Percent of original Klason lignin.

lignin, is accounted for as the one compound, dihydroconiferyl alcohol. In the case of the Rh—C catalyst it may be noted that over 90% of the ether-soluble fraction is accounted for by two compounds, 4-*n*-propylguaiacol and dihydroconiferyl alcohol, which together represent some 34% of the original lignin. The increased recovery of lignin degradation products in the case of Rh—C over Pd—C is accounted for almost exactly by the second product, 4-*n*-propylguaiacol, with the yields of dihydroconiferyl alcohol essentially the same in each case (20–23%). If it is assumed that these monomeric fractions are released as a result of an ether cleavage reaction, the above observations could be interpreted as follows. Two types of ether linkages may exist in the lignin: $-CH_2-O-X$ and $-CH_2-O-Y$, where X and Y represent chemically different species. Hydrogenolysis, using Pd—C, may result in the selective cleavage of the $-O-\vdots X$ bond of only the $-CH_2-O-X$ type of linkage, thereby releasing dihydroconiferyl alcohol. With Rh—C, on the other hand, cleavage of this linkage occurs in a similar way to produce the dihydroconiferyl alcohol, but, as well, cleavage of the $-CH_2-O-Y$ type occurs at the $-CH_2-\vdots O-Y$ bond, releasing the 4-*n*-propylguaiacol.

Experimental

White spruce sapwood (*Picea glauca* Moench (Voss)) was ground to ca. 20 mesh in a Wiley mill, extracted 48 h with ethanol–benzene (1:1), and air dried. Found: Klason lignin, 27.3; moisture, 2.18.

Raney nickel catalyst was prepared according to Pavlic and Adkins (5) with the exception that the washing under a hydrogen atmosphere was omitted. The catalyst was stored under cold dioxane. The dioxane was purified according to Fieser (6). The rhodium and ruthenium catalysts were obtained from K & K Laboratories, Inc., and the palladium catalyst was obtained from Matheson, Coleman and Bell.

General Reaction Procedure

Preextracted, air-dried spruce wood meal (10 g), catalyst (1 g or 10 g), and dioxane:oxygen-free water (1:1 v/v, 150 ml) were mixed in a 1410-ml capacity bomb of an Aminco hydrogenator. The reactor was flushed twice with hydrogen and then filled to an initial pressure of 500 p.s.i.g. The temperature was raised (about 120°/h) and controlled automatically at 195 ± 5° for 5 h. During this heating period and later until the room temperature had been reached, the reactor was rocked continuously.

The reactor contents were suction-filtered. The residual wood meal and catalyst were washed with dioxane–water (1:1) until the washings were colorless. The washings and original filtrate were combined, transferred to a separatory funnel, and extracted with 4 × 200 ml portions of chloroform. This extract was dried over anhydrous sodium sulfate, filtered, and concentrated under reduced pressure keeping the temperature below 50°. This chloroform-soluble fraction was dried to essentially constant weight in a desiccator over Drierite.

Either this total chloroform-soluble portion, or the residue remaining after the removal of a small sample for methoxyl analysis, was then extracted under reflux with anhydrous ether (2 × 200 ml). Both the ether-soluble fraction obtained by removal of the excess ether under reduced pressure and the residual ether-insoluble fraction were dried to essentially constant weight in a vacuum desiccator over Drierite.

Gas–liquid Chromatographic Analysis of the Ether-soluble Products

All analyses were conducted using an F & M Chromatograph, model 5750 with hydrogen flame detector and temperature programming. The column (⅛ in. × 6 ft) was packed with 10% UCW98 (silicone rubber) on Chromosorb W (60/80 mesh, DMCS treated, acid washed). The chromatograms were obtained under identical conditions of a helium flow rate of 40 ml/min; temperature programmed from 100 to 200 °C at 4°/min; injection temperature 260°; detector temperature 270°; and recorder chartspeed, 0.5 in./min. Identification of peaks was made by comparison of retention times with those obtained from authentic samples under identical conditions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The quantitative analytical data reported in Table II were obtained as follows using coumarin as the internal standard. The thermal response factor, f, for each compound was first determined from a mixture of known amounts of the authentic sample and internal standard using the formula $f = A_i/A_s \cdot W_s/W_i$ where A_i and A_s are peak areas of the coumarin and pure sample and W_i and W_s are the corresponding weights of coumarin and sample comprising the mixture. Subsequently using a known weight of the ether-soluble fraction to which has been added a known weight of coumarin, from the peak areas and calculated response factors for each compound, the relative abundance of the products was obtained.

Reference Compounds

Guaiacol, 4-methylguaiacol, 4-ethylguaiacol, 4-*n*-propylguaiacol, and dihydroconiferyl alcohol were available, their source or preparation having been reported previously (4). Dihydroconiferyl alcohol, which, until recently, had been prepared in these laboratories as a viscous oil, was now obtained as a white solid, recrystallized from ethanol, m.p. 62–64.5°.

Meisenheimer complexes of some 1-substituted-3,5-dinitrobenzenes

M. I. Foreman and R. Foster
Chemistry Department, University of Dundee, Dundee, Scotland

Received July 10, 1968

It has been shown by nuclear magnetic resonance spectroscopy that both 3,5-dinitrobenzonitrile and 3,5-dinitrobenzotrifluoride form Meisenheimer-type σ-complexes with various nucleophiles in solution. In some cases attack appears to occur at both the 2- and 4-positions.

Canadian Journal of Chemistry, **47**, 729 (1969)

σ-Complexes formed by the action of nucleophiles on aromatic systems containing electron-accepting groups have received considerable attention recently (1). Products of this type were first described by Meisenheimer (2) who prepared them by the action of alkali metal alkoxides on picryl ethers. Such products are now often referred to as Meisenheimer complexes (or salts, or compounds). The stable products which were prepared by Meisenheimer are now generally represented by the structure **1** (1). Recently Servis (3) has shown that in certain cases the ion **2** is formed initially, which is then rapidly converted to **1**. The structures of these complexes are most readily determined by high resolution nuclear magnetic resonance (n.m.r.) spectroscopy of solutions of the ions (1). By such means it has also been conclusively demonstrated that the ion **3** is formed by the action of the alkoxide ion OR′ on 1,3,5-trinitrobenzene (4).

Although Meisenheimer complexes have been obtained from various 1-X-substituted-2,4,6-trinitrobenzenes (1), very few complexes derived from 1-X-3,5-dinitrobenzenes have been studied (5). If the substituent X is an electron-attracting group then the compound would be expected to behave in a similar fashion to 1,3,5-trinitrobenzene. However, due to the non-equivalence of the 2- and 4-positions in the former group of compounds, two products are possible by attack of a nucleophile Nu^- at an unsubstituted position, namely **4** and **5**. The visible absorption spectra of a number of 1-X-3,5-dinitrobenzenes in the presence of nucleophiles show two maxima not present in the spectra of the original substituted nitrobenzenes in the absence of nucleophile, see ref. 5, where it has been suggested that these extra absorptions may be due one each to two products corresponding to structures **4** and **5**. However, argument as to the structure of the product based on such observations cannot be conclusive.

In the present work evidence for the structures of σ-complexes formed in solution by the action of nucleophiles on 1-X-3,5-dinitrobenzenes (where X = —CN and —CF_3) has been obtained by n.m.r. spectroscopy. In corresponding systems where X = —I, —COOEt, and —NMe_2, no evidence of σ-complex formation was obtained. In no case was it found possible to isolate the solid salt.

§In these cases the peak intensities were too low to permit a definite assignment to be made.

n.m.r. spectrum shows the effectively instantaneous disappearance, at 33.5°, of the absorptions of the parent aromatic compound, an AB_2 spectrum of five lines centered at $\delta \simeq 9.10$, and the rapid formation of new absorptions. The relative intensities of the lines indicate that two species are present, the product in major abundance having doublets at $\delta = 8.08$ and $\delta = 7.35$ and a broader absorption at $\delta = 5.40$, whilst the product in lesser amount shows a very similar spectrum but with doublets at $\delta = 8.21$ and $\delta = 7.52$, and a broader absorption at $\delta \simeq 5.5$ (see Table I). All these observations are consistent with the formation of two products, **4** (X = —CN, Nu = —OMe) and **4** (X = —CN and Nu = —OH), the latter being formed by the attack of hydroxide ion derived from a small water impurity remaining in the DMSO.[1]

Reaction of 3,5-Dinitrobenzonitrile with Acetone and Triethylamine in DMSO

When 3,5-dinitrobenzonitrile is added to a solution of triethylamine and acetone in DMSO, an immediate red coloration is obtained which changes to blue after a few hours. Initially, the proton magnetic resonance (p.m.r.) spectrum shows only broad peaks which suggest that some exchange reaction with a free-radical species is occurring. However, after about 45 min at the probe temperature (33.5°) peaks become discernible and eventually become well resolved (Table I and Fig. 1). These absorptions are consistent with the formation of the ions **4** (X = —CN, Nu = —CH_2COMe) and **5** (X = —CN, Nu = —CH_2COMe). The relative intensities of the absorptions suggest that these ions are formed in the approximate ratio 2:1. Evidence for attack by the nucleophilic species $CH_3COCH_2^-$ in similar circumstances has been reported earlier. The assignment of the singlet at $\delta = 7.40$ to the protons H_β in **5** (X = —CN, Nu = —CH_2COMe), and the two doublets at $\delta = 8.05$ and $\delta = 7.17$ to the protons H_α, H_β respectively in **4** (X = —CN, Nu = —CH_2COMe), is consistent with the spin–spin splitting observed in the latter case, where these two protons are non-equivalent. The proton H_α between the two nitro groups in **4** (X = —CN, Nu = —CH_2COMe) would be expected to absorb at lower fields than H_β which lies between a nitro and a cyano group. In both ions the triplet splitting of H_γ is the result of spin–spin coupling with the methylene protons of the acetonyl group. Under very high resolution, the n.m.r. spectrum indicates that H_α is also weakly coupled with H_α in **4** (X = —CN, Nu = —CH_2COMe) and with H_β in **5** (X = —CN, Nu = —CH_2COMe) (in both cases $J \approx 0.8$ Hz). No coupling is observed between H_γ and H_β in **4** (X = —CN, Nu = —CH_2COMe).

Reaction of 3,5-Dinitrobenzonitrile with Acetone and Diethylamine in DMSO

Previously it had been shown that the ion **6** formed in acetone solutions containing 1,3,5-

[1]The authors are grateful to one of the referees for suggesting this possibility.

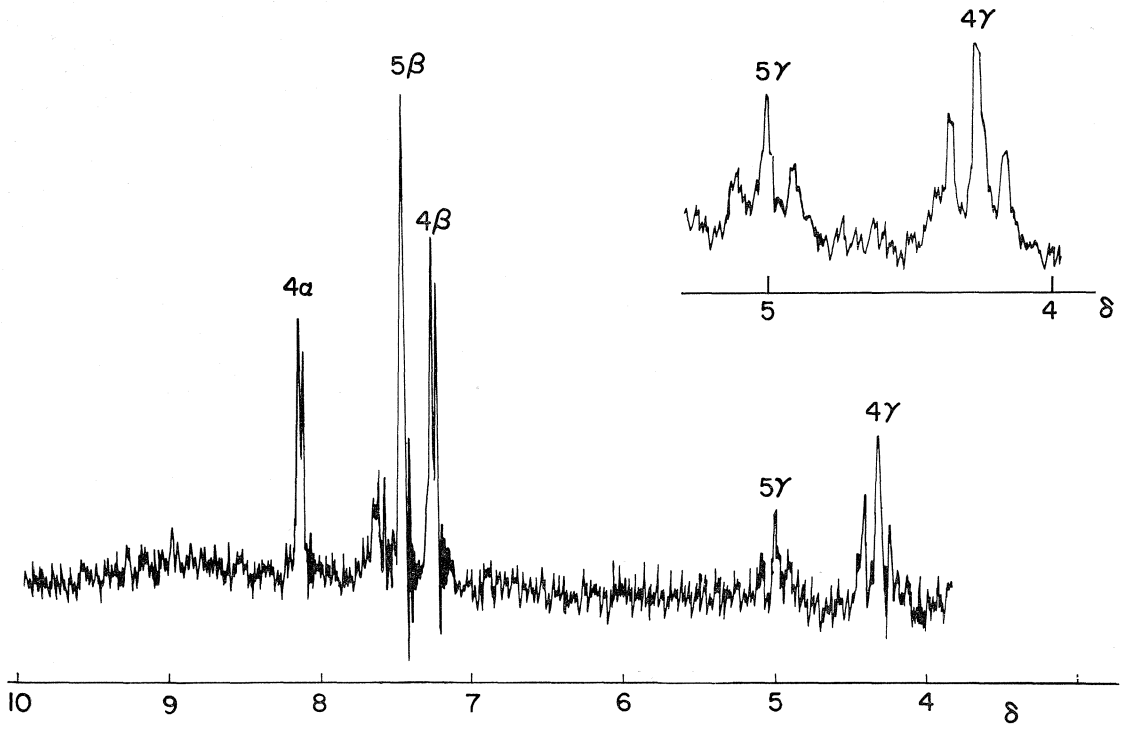

FIG. 1. Nuclear magnetic resonance spectrum below δ = 4.0 p.p.m. of the adducts **4** (X = —CN, Nu = —CH_2COMe) and **5** (X = —CN, Nu = —CH_2COMe) in DMSO solution at 33.5° (measured at 60.004 MHz).

trinitrobenzene and diethylamine reacts further with diethylamine in acetone to form *N*,*N*-diethyl-4-nitroaniline (6). It was thought that the ions **4** (X = —CN, Nu = —CH_2COMe) and **5** (X = —CN, Nu = —CH_2COMe) might undergo comparable reactions and thereby possibly yield information which would help to elucidate the mechanism of the reaction. However, addition of diethylamine to solutions containing these ions in acetone caused the collapse of the n.m.r. absorptions, presumably owing to free-radical formation.

Reaction of 3,5-Dinitrobenzonitrile with Diethyl Ketone and Triethylamine in DMSO

The behavior of this system is very similar to the reaction involving acetone. The deep red solution has a n.m.r. spectrum which is accounted for by the presence of the ions **4** (X = —CN, Nu = —CH(Me)COEt) and **5** (X = —CN, Nu = —CH(Me)COEt) (Table I). The intensities of the absorptions slowly change with time in favor of the former species.

Reaction of 3,5-Dinitrobenzotrifluoride with Sodium Methoxide in DMSO

The proton n.m.r. spectrum of the red solution formed by the addition of solid sodium methoxide to a solution of 3,5-dinitrobenzotrifluoride in DMSO shows a stronger set and a weaker set of absorptions which may be accounted for in terms of the ions **4** (X = —CF_3, Nu = —OMe) and **4** (X = —CF_3, Nu = —OH), the latter being the minor component (Table I). The parent compound in DMSO shows an AB_2 spectrum of seven lines centered at δ ≃ 9.00. The spectrum of the solution obtained by adding methoxide to 3,5-dinitrobenzotrifluoride shows free-radical broadening and collapses after a few minutes. The ^{19}F n.m.r. spectrum shows a similar broadening, which after a further lapse of time develops new maxima in the region of the original 3,5-dinitrobenzotrifluoride peak. It would therefore appear that although Meisenheimer-type complexes are formed at first, further reaction is more complicated. These changes are paralleled by the rapid decay of the initial visible spectrum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

which is characteristic of a Meisenheimer complex.

Reaction of 3,5-Dinitrobenzotrifluoride with Acetone and Triethylamine in DMSO

This reaction is analogous to the corresponding system involving 3,5-dinitrobenzonitrile. The absorptions correspond to the ions **4** (X = $-CF_3$, Nu = $-CH_3COMe$) and **5** (X = $-CF_3$, Nu = $-CH_2COMe$). Although there is some evidence for absorption at higher fields due to H_γ in **5** (X = $-CF_3$, Nu = $-CH_2COMe$) no positive identification has been made. With time these weaker absorptions disappear. These observations indicate that the ion **4** is more stable than the ion **5** in this case.

As in the case of the methoxide reaction the ^{19}F n.m.r. spectrum of the reaction mixture is complicated. However, an intense peak is observed 70 Hz upfield from the parent $-CF_3$ peak. This may be due to the species **4** (X = $-CF_3$, Nu = $-CH_2COMe$). From the relative intensities, a very much weaker absorption 55 Hz upfield from the parent $-CF_3$ peak may be accounted for by **5** (X = $-CF_3$, Nu = $-CH_2COMe$).

Experimental

Solutions of 3,5-dinitrobenzonitrile and 3,5-dinitrobenzotrifluoride (25% v/v in DMSO), were treated with equimolar amounts of the appropriate reagents. The nuclear magnetic resonance (n.m.r.) spectrum was then repeatedly scanned at intervals of a few minutes. Because of the high concentrations used, side-reactions occasionally gave rise to small absorptions in the n.m.r. spectra which could not be assigned in the above scheme.

In attempts to isolate solid products, the solutions in DMSO were treated with excess anhydrous ether. In every case an intractable, deep red, ether-insoluble oil was obtained. Addition of dilute aqueous acid to the oils regenerated the parent nitro compound in each case.

Where X = —I and X = —COOEt, both the addition of methoxide, and of acetone plus triethylamine produced deep red solutions. In the case of X = $-NMe_2$, a dark green solution was obtained with methoxide. In all these cases the n.m.r. absorptions collapsed. On long standing the absorptions due to the starting materials slowly reappeared. However, no peaks assignable to Meisenheimer complexes were observed. In the case of X = $-NMe_2$, addition of acetone plus triethylamine produced no color and the n.m.r. spectrum gave no evidence of reaction.

Materials

3,5-Dinitrobenzonitrile was prepared by the method of Bennett and Wain (7) recrystallized twice from ethanol, m.p. 127–128°. 3,5-Dinitrobenzotrifluoride was prepared by the method of Finger and Reed (8) recrystallized twice from ethanol, m.p. 49–50°. Dimethyl sulfoxide was dried by refluxing over calcium hydride and stored over 5A molecular sieve.

Nuclear Magnetic Resonance Spectra

^1H spectra were measured at 60.004 MHz and ^{19}F spectra at 56.462 MHz using a Perkin–Elmer R.10 spectrometer at 33.5°. All proton spectra are given as shifts in p.p.m. downfield from an internal tetramethylsilane reference ($\delta = 0$).

Le dimère de la *cis* dihydroxy-5,6 cyclohexène-2 dione-1,4

J. Y. Savoie et P. Brassard
Département de Chimie, Université Laval, Québec, Québec

Reçu le 15 août 1968

On reconnaît depuis longtemps que le produit d'oxydation de la *p*-benzoquinone par le chlorate de sodium en présence d'acide osmique est un dimère. Par le choix de conditions de plus en plus rigoureuses, il est possible d'en tirer trois acétates qui correspondent au dimère lui même et à ses produits de déshydratation et d'aromatisation. Ces substances ont été reconnues comme les tétra-acétates de la tétrahydroxy-1,2,6,7 dibenzo *p*-dioxinne (**2***a*), de l'oxo-2 tétrahydroxy-1,4*a* (*trans*), 6,7 tétrahydro-1,2,4*a*,10*a* dibenzo *cis* *p*-dioxinne (**3**) et du dimère monohémiacétal de la *cis* dihydroxy-5,6 cyclohexène-2 dione-1,4 (**4***b*). La structure du dimère à l'état solide et en solution y est discutée.

The osmic acid catalyzed oxidation of *p*-benzoquinone by sodium chlorate has long been recognized to yield a dimeric substance. By using progressively more vigorous conditions of acetylation, it has been possible to prepare from it three acetates corresponding to the dimer and to products of increasing degrees of dehydration and aromatization. The compounds have now been identified as the tetraacetates of 1,2,6,7-tetrahydroxydibenzo-*p*-dioxine (**2***a*), of 2-oxo-1,4*a* (*trans*),6,7-tetrahydroxy-1,2,4*a*,10*a*-tetrahydrodibenzo-*cis*-*p*-dioxinne (**3**) and of the monohemiacetal dimer of *cis*-5,6-dihydroxycyclohex-2-ene-1,4-dione (**4***b*). The structure of the dimer in the solid state and in solution is discussed.

Canadian Journal of Chemistry, **47**, 733 (1969)

L'oxydation de la *p*-benzoquinone par le chlorate de sodium en présence d'acide chlorhydrique et d'une quantité catalytique d'acide osmique donne une substance microcristalline insoluble dans les solvants organiques (1). On a alors cru que celle-ci était le produit dihydroxylé correspondant, mais on a suggéré depuis qu'il s'agissait bien du dimère de cette substance (2). Nous avons préparé la *cis* dihydroxy-5,6 cyclohexène-2 dione-1,4 (3) et vérifié qu'effectivement elle se transforme en un produit identique à celui déjà obtenu. L'étude des divers dérivés acétylés de ce dimère[1] nous a permis d'en préciser la structure.

Il est clair que l'acétate de p.f. 227–228° [litt. 217–218° (1)] obtenu dans des conditions rigoureuses ne peut être qu'une dibenzo *p*-dioxinne (**2***a*). Le spectre de masse indique un poids moléculaire de 416 et montre quatre groupes acétates. Le spectre de résonance magnétique nucléaire (r.m.n.) par ailleurs ne révèle que deux signaux pour ces acétates et un troisième singulet à 6.86 p.p.m. Après l'hydrolyse acide de cette substance en tétrahydroxy-1,2,6,7 dibenzo *p*-dioxinne (**2***b*), le signal correspondant aux protons aromatiques se présente comme un doublet dédoublé (J = 9.1 Hz). Ces données ne conviennent qu'à une structure très symétrique ayant deux paires identiques de protons vicinaux aromatiques.

Un deuxième acétate (**3**) de formule moléculaire $C_{20}H_{18}O_{11}$ obtenu par acétylation en présence d'une trace d'acide sulfurique se présente sous deux formes allotropiques (identiques aux points de vue analytiques et spectrales) de p.f. 140° et 182°. Il s'agit ici sans doute de l'"acétate d'apionol" et du composé $C_{24}H_{22}O_{13}$ décrits par Terry et Milas (1). L'authentique acétate d'apionol ne se forme qu'en présence de catalyseurs basiques.

Le spectre de masse de cette substance indique quatre fonctions acétates et un poids moléculaire de 434. Son spectre de r.m.n. révèle d'intéressantes analogies avec celui de la cétone de Pummerer (**1**) (6) et confirme sa formation à partir du dimère par perte d'une molécule d'eau et aromatisation d'un des cycles carbonés. En plus des quatre signaux dus aux acétates et du pic unique attribué aux deux protons aromatiques, ce spectre se compose de deux doublets et de deux doublets dédoublés correspondant à quatre protons. Les protons éthyléniques en 3 et 4 se reconnaissent aisément par leur déplacement chimique et leur constante de couplage. La valeur élevée (J = 2.6 Hz) de la constante de couplage à longue distance entre les protons en 4 et 10*a* ne laisse aucun doute sur la position

[1]Lors de la préparation de ce mémoire, Thompson et Anderson (4) ont également proposé pour ce dimère une structure tricyclique qui diffère au point de vue stéréochimique de celle que nous avons déjà communiquée (5).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

équatoriale de ce dernier (7), tandis que l'absence d'un tel couplage entre ceux en 1 et 3 et la configuration du monomère original font assigner au proton en 1 une position axiale. Il en résulte donc que la jonction des cycles en 4*a* et 10*a* ne peut être que *cis*, relation qui doit se retrouver dans le dimère.

Un troisième acétate de p.f. 196.0–196.5° fut obtenu à partir du même dimère par action de l'anhydride acétique à 90°, seul, ou mieux en présence d'une trace d'acide *p*-toluènesulfonique. Cette substance semble inédite et son analogie avec les α-hydroxy cétones (8) laisserait supposer qu'il s'agit du dioxanne tricyclique. En effet, son spectre de masse indique un poids moléculaire de 452 et la présence de quatre groupes acétates. Le spectre de r.m.n. par ailleurs permet de déceler les douze pics caractéristiques de l'arrangement des quatre protons en 1, 3, 4, et 10*a* du composé **3** superposés à un autre système de quatre protons couplés essentiellement de la même façon. Mais toute tentative d'interpréter ce spectre en fonction d'une structure tricyclique se heurte à des difficultés du fait de la faible différence de déplacements chimiques observée pour la seconde paire de protons éthyléniques et de l'absence d'un deuxième proton qui résonnerait vers 5 p.p.m.

Ces données concordent bien si l'on considère avoir affaire à un monohémiacétal (**4***b*). Une preuve supplémentaire à l'appui de cette proposition est tirée de la présence dans le spectre de masse de pics importants à *m/e* 322 (M — AcOH, CH_2CO, CO) et 321 (M — AcOH, CH_2CO, CHO) qui indiquent un mode de décomposition caractéristique des quinones (9). Le couplage à longue distance qui se manifeste entre deux protons de la partie cyclohexènedione de la molécule permet également de déterminer la conformation de ce cycle. En effet, le proton tertiaire le plus déblindé, celui en 6′ montre un dédoublement secondaire et doit en conséquence être équatorial; le proton en 5′ ne montre par contre aucune interaction de spin avec celui en 3′ et serait donc axial. La partie cyclohexènone doit avoir essentiellement la même conformation que dans l'acétate **3** puisqu'on n'observe que de faibles divergeances entre les déplacements chimiques et les constantes de couplage attribuées aux protons de chaque système.

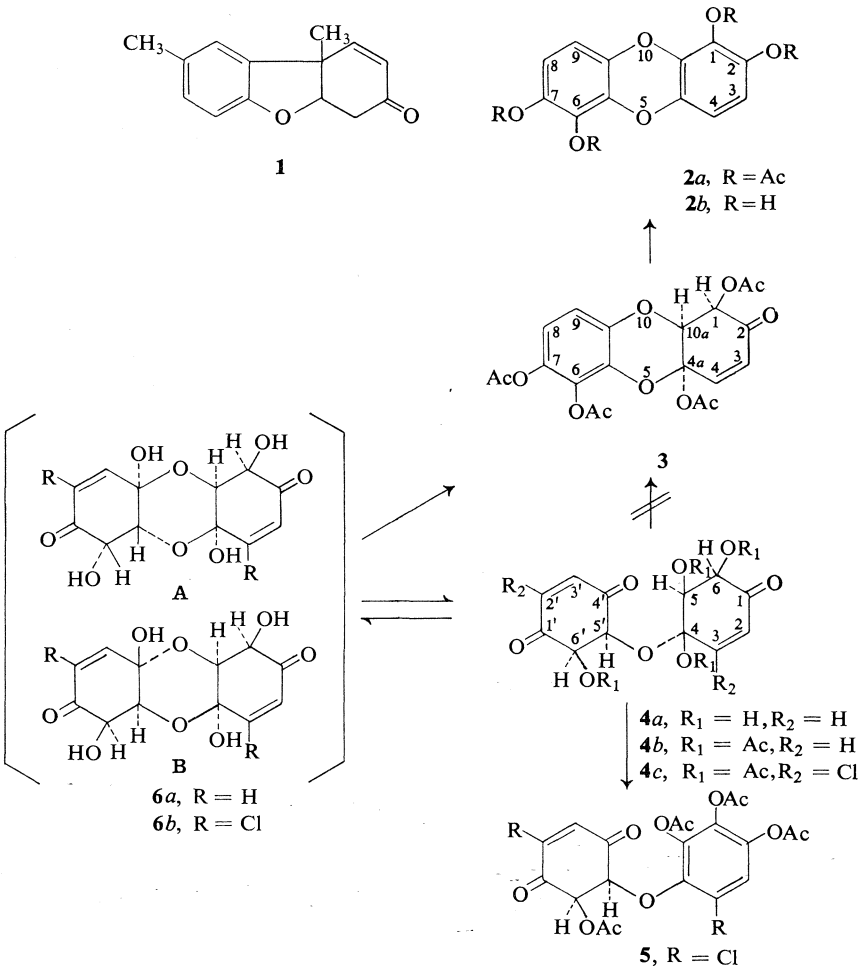
Nous avons de plus cherché à étayer ces preuves de structure par l'étude d'un dimère portant un plus petit nombre de protons. L'oxydation de la chlorohydroquinone n'a pas donné un produit homogène. Il est tout de même possible, suivant les conditions, d'obtenir deux acétates de ce mélange. La méthode employée pour la préparation du composé **4***b* produit un acétate (**4***c*) qui présente des caractéristiques (spectre infrarouge) comparables à celles de **4***b*. Son spectre de r.m.n. ne révèle aucun dédoublement secondaire et montre que les atomes de chlore sont en 3 et 2′. Il semble logique que, dans le monomère original, le groupe hydroxyle en 5 soit le plus nucléophile et réagisse de préférence avec le carbonyle voisin de l'halogène.

Dans des conditions plus rigoureuses, le dimère chloré fournit un autre acétate qui ne montre pas de ressemblance dans son spectre de r.m.n. avec le composé **3** quoique la substance s'avère partiellement aromatique. L'absence d'un proton qui résonne aux environs de 5 p.p.m. alors que les caractéristiques spectrales de la partie cyclohexènedione persistent, indique que l'aromatisation a suivi un autre cours pour aboutir à la structure **5**.

Les structures proposées pour ces différents acétates rendent également bien compte des propriétés et des réactions de ces composés. En effet, les conditions requises pour produire l'acétate **2***a* à partir du dimère **6***a* conduisent également à l'aromatisation du produit **3**. Par contre, il a été impossible de transformer la substance **4***b* en l'un ou l'autre des produits **3** et **2***a*.

Conformément aux données de Terry et Milas (1), plus tard niées par Baker et Munk (2), nous avons trouvé que le dimère original se dissoût lentement dans l'eau bouillante et y cristallise inchangé. Le spectre de r.m.n. de la substance (dans D_2O ou DMSO) indique clairement qu'elle existe en solution sous forme de monohémiacétal. Sous cette forme, le dimère est passablement soluble et la lenteur de la dissolution ne s'explique que si celle-ci est accompagnée d'une isomérisation. Il est d'ailleurs bien établi que les dimères des α-hydroxy cétones se dépolymérisent dans l'eau (10).

L'obtention facile de substances tricycliques à partir du dimère solide ne laisse pas de doute qu'il s'agit bien d'un di-hémiacétal. Un des produits de dégradation (**3**) indique qu'une des jonctions de cycles doit être *cis*, tandis que la



facilité de l'aromatisation partielle par perte d'une molécule d'eau laisse présumer que l'autre est *trans*. L'examen de modèles révèle que deux isomères *cis*, *trans* sont possibles (**6***a*; **A** ou **B**) sans qu'il soit possible dans l'état de nos connaissances actuelles de préciser davantage la structure tricyclique du dimère.

Partie expérimentale

Les points de fusion ont été déterminés en tube capillaire à l'aide d'un thermomètre calibré (appareil Thomas–Hoover). Les spectres infrarouges ont été réalisés sur un appareil Beckman, modèle IR-4. Les spectres ultraviolets ont été déterminés sur un appareil Beckman, modèle DK-1A. Les spectres de résonance magnétique nucléaire (r.m.n.) ont été enregistrés sur un appareil Varian A 60; les déplacements chimiques sont mesurés en δ par rapport au tétraméthyl silane (δ = 0) et ne sont pas corrigés. Les spectres de masse ont été déterminés sur un spectrographe Varian M 66.

Le dimère de la cis dihydroxy-5,6 cyclohexène-2 dione-1,4 (6a)

A une solution de chlorate de sodium (10.0 g) dans l'eau (50 ml) contenant de l'acide osmique (1.3 ml d'une solution aqueuse à 1%), on ajoute de l'acide chlorhydrique concentré (1 ml) puis de la *p*-benzoquinone (10.8 g; 0.1 mole) et on maintient le milieu réactionnel sous forte agitation pendant 48 h. Le dimère (3.0 g; 21%) obtenu par filtration est presque pur et peut être recristallisé en petites quantités dans l'eau ou encore mieux dans le diméthylsulfoxyde. Si l'on prolonge la durée de réaction à 8 jours ou si l'on ajoute de l'acétone (50 ml) au mélange 12 heures avant la fin de la préparation, les rendements s'élèvent à 43% (6.1 g) et à 50% (7.1 g) respectivement, p.f. 210–212° (décomp.) (chauffage rapide) (litt. p.f. 177–178°) (1).

Spectre infrarouge (KBr): bandes à 2.89, 3.07, 5.89 et 6.15 μ.

Spectre de résonance magnétique nucléaire (DMSO) (**4***a*): un triplet (doublet dédoublé) à 3.96 p.p.m., $J = 2.5$, 2.5 Hz (CH 5); un pic large à 4.44 p.p.m. qui rétrécit par deutériation (CH 6,5′,6′; OH); un doublet à 6.15 p.p.m., $J = 10.0$ Hz (CH 2); un quadruplet à 6.58 p.p.m., $J = 10.0$, 2.5 Hz (CH 3); un singulet correspondant à deux protons à 6.86 p.p.m. (CH 2′, 3′). Le spectre comprend en outre trois pics larges à 5.3, 6.0 et 7.4 p.p.m. qui disparaissent par deutériation et un signal à 6.90 p.p.m. dû à un produit de décomposition (son intensité est fonction de la durée de chauffage).

Anal. Calc. pour $C_{12}H_{12}O_8$: C, 50.71; H, 4.26. Trouvé: C, 50.37; H, 4.44.

Tétrahydroxy-1,2,3,4 benzène (apionol)

On chauffe au bain-marie pendant 20 min un mélange du dimère **6***a* (5.0 g) et de pyridine (40 ml). Après refroidissement on le verse dans 100 ml d'une solution d'acide chlorhydrique à 20%. Par extraction continue de la solution avec de l'éther on obtient de l'apionol (2.0 g; 40%) p.f. 158–160° (litt. 161° (11)). Cette substance est identique (spectre infrarouge) à celle obtenue par déméthylation ($AlCl_3$) du diméthoxy-1,2 dihydroxy-3,4 benzène (11).

*Tétra-acétoxy-1,2,6,7 dibenzo p-dioxinne (**2***a)*

A une suspension du dimère (**6***a*) de la *cis* dihydroxy-5,6 cyclohexène-2 dione-1,4 (5.0 g) dans de l'anhydride acétique (25 ml), on ajoute de l'acide sulfurique concentré (1 ml) et on chauffe le mélange au bain-marie pendant 15 min. Après l'hydrolyse de l'excès de l'anhydride, on obtient le tétra-acétate **2***a* (6.2 g; 85%) qui cristallise en aiguilles dans le benzène p.f. 227–228° (litt. p.f. 217–218° (1)). Ce composé s'obtient également à partir du tétra-acétate **3** dans les mêmes conditions, p.f. mixte 226–227°.

Spectre infrarouge (KBr): bandes à 5.60 μ et 6.71 μ.

Spectre ultraviolet (EtOH): bandes à 288 mμ, log ε = 3.41 et à 229 mμ, log ε = 4.53.

Spectre de résonance magnétique nucléaire (acétone-d_6): un singulet à 6.86 p.p.m. (CH aromatique).

Spectre de masse: pic moléculaire à *m/e* 416; pics à *m/e* 374, 332, 290 et 248.

Anal. Calc. pour $C_{20}H_{16}O_{10}$: C, 57.69; H, 3.87. Trouvé: C, 57.29; H, 4.01.

*Tétrahydroxy-1,2,6,7 dibenzo-p-dioxinne (**2***b)*

On porte à ébullition pendant 24 h un mélange du composé précédent (**2***a*) (6.0 g), de méthanol (50 ml) et d'acide chlorhydrique concentré (0.3 ml). Après dilution à froid avec du chloroforme (20 ml), le tétrahydroxy-1,2,6,7 dibenzo *p*-dioxine cristallise en aiguilles incolores (3.0 g; 84%), p.f. 335–337°.

Spectre d'infrarouge (KBr): bandes à 2.80, 3.07, 6.04, 6.20, 6.50 et 6.68 μ.

Spectre résonance magnétique nucléaire (acétone-d_6): centré à 6.46 p.p.m., un système AB, $J = 9.1$ Hz et $\Delta\nu = 0.05$ p.p.m.; un singulet disparaissant par deutériation.

Spectre de masse: pic moléculaire à *m/e* 248.

*Oxo-2 tétraacétoxy-1,4a(trans), 6,7, tétrahydro-1,2,4a, 10a dibenzo cis p-dioxinne (**3**)*

On chauffe au bain-marie pendant 30 min un mélange du dimère **6***a* (1.0 g), d'anhydride acétique (15 ml) et d'acide sulfurique concentré (1 goutte). Après l'hydrolyse de l'excès de l'anhydride et recristallisation dans l'acétate d'éthyle, on obtient 1.1 g du tétra-acétate **3** de p.f. 140–142°. Cette forme est métastable et se transforme en une autre de p.f. 182°. Les spectres infrarouges et de r.m.n. sont identiques.

Spectre infrarouge (KBr): 5.63, 5.70, 5.81 μ.

Spectre ultraviolet (EtOH): 275 mμ, log ε = 3.30; 217 mμ, log ε = 4.25.

Spectre de résonance magnétique nucléaire (acétone-d_6): quatre singulets à 2.20, 2.22, 2.25 et 2.27 p.p.m. ($OCOCH_3$); un quadruplet centré à 4.88 p.p.m., $J = 2.2$, 2.6 Hz (CH 10*a*); un doublet centré à 6.04 p.p.m., $J = 2.2$ Hz (CH 1); un doublet centré à 6.27 p.p.m., $J = 10.5$ Hz (CH 3); un singulet à 6.86 p.p.m. (CH 8, 9); un quadruplet centré à 7.33 p.p.m., $J = 10.5$, 2.6 (CH 4).

Spectre de masse: pic moléculaire à *m/e* 434; pics à *m/e* 392, 350, 308, 290, 266 et 248.

Anal. Calc. pour $C_{20}H_{18}O_{11}$: C, 55.30; H, 4.18. Trouvé: C, 55.45; H, 4.16.

*Tétra-acétate du dimère (hémiacétal) de la cis dihydroxy-5,6 cyclohexène-2 dione-1,4 (**4***b)*

On chauffe au bain-marie pendant 48 h un mélange du dimère (**6***a*) (1.0 g), d'acide *p*-toluènesulfonique (2 mg) et d'anhydride acétique (15 ml). Après hydrolyse de l'excès de l'anhydride et recristallisation du produit dans de l'éther anhydre, on obtient 0.9 g du tétra-acétate **4***b* de p.f. 196.0–196.5°.

Spectre infrarouge (KBr): 5.65, 5.77 et 6.08 μ.

Spectre ultraviolet (EtOH): 218 mμ, log ε = 4.24.

Spectre de résonance magnétique nucléaire (acétone-d_6): trois singulets à 2.06, 2.14 et 2.20 p.p.m. correspondant respectivement à 3,6 et 3 protons ($OCOCH_3$) un doublet dédoublé à 5.16 p.p.m., $J = 2.3$, 4.2 Hz (CH 5); un doublet à 5.76 p.p.m., $J = 2.8$ Hz (CH 5′); un doublet dédoublé à 5.91 p.p.m., $J = 2.1$, 2.8 Hz (CH 6′); un doublet à 6.11 p.p.m., $J = 4.1$ Hz (CH 6); un doublet à 6.23 p.p.m., $J = 10.4$ Hz (CH 2); un doublet à 6.31 p.p.m., $J = 10.2$ Hz (CH 3′); un doublet dédoublé à 6.56 p.p.m., $J = 2.1$, 10.2 Hz (CH 2′); un doublet dédoublé à 7.04 p.p.m., $J = 2.3$, 10.4 Hz (CH 3). La double irradiation de ce proton provoque la disparition du dédoublement secondaire du signal de CH 5.

Spectre de masse: pic moléculaire à *m/e* 452, pics à *m/e* 350, 322, 321, 308, 279, 266, 248.

Anal. Calc. pour $C_{20}H_{20}O_{12}$: C, 53.10; H, 4.46. Trouvé: C, 53.30; H, 4.32.

*Le dimère de la cis dihydroxy-5,6 chloro-2 cyclohexène-2 dione-1,4 (**6***b)*

On ajoute très lentement à 0° et sous forte agitation de la chlorohydroquinone (26 g) à un mélange de chlorate de sodium (37.5 g), d'acide chlorhydrique concentré (1 ml), d'acide osmique (3 ml d'une solution aqueuse à 1%), d'acétone (25 ml) et d'eau (75 ml). Après 5 jours, on recueille le dimère chloré (**6***b*) par filtration et on le lave successivement avec de l'eau, du méthanol et de l'acétone. La substance (1.3 g) se décompose à 172° et ne semble pas homogène.

*Le tétra-acétate du dimère (monohémiacétal) du cis dihydroxy-5,6 chloro-2 cyclohexène-2 dione-1,4 (**4***c)*

La substance se prépare de la même façon que le

tétra-acétate **4***b* si ce n'est que l'on élimine le dimère inchangé avant l'hydrolyse de l'excès du réactif. Elle cristallise dans l'acétate d'éthyle, p.f. 222.0–222.5°.

Spectre infrarouge (KBr): bandes à 5.63, 5.81 et 6.17 μ.

Spectre de résonance magnétique nucléaire (dioxanne): trois singulets à 2.07, 2.13 et 2.25 p.p.m. correspondant respectivement à 3,6 et 3 protons ($OCOCH_3$); un doublet à 5.17 p.p.m., $J = 4.0$ Hz (CH 5); un singulet à 5.84 p.p.m. (CH 5′,6′); un doublet à 6.18 p.p.m., $J = 4.0$ Hz (CH 6); deux singulets à 6.63 et 6.72 p.p.m. (CH 2′,3′). Dans le diméthylsulfoxyde les protons en 5 et 6 ne sont plus fortuitement équivalents: deux doublets à 6.12 et 6.29 p.p.m., $J = 2.8$ Hz.

Spectre de masse: pic moléculaire à *m/e* 520; pics à *m/e* 485, 418, 376, 341, 331, 316.

[Triacétoxy-2,3,4 chloro-6 phénoxy]-5 acétoxy-6 chloro-2 cyclohexène-2 dione-1,4 (5)

La préparation de ce composé à partir du dimère chloré (**6***b*) est analogue à celle du tétra-acétate **3**. Recristallisé dans l'acétate d'éthyle, ce tétra-acétate (**5**) fond à 186–187°.

Spectre infrarouge (KBr): 5.57, 5.64, 5.79, et 6.18 μ.

Spectre de résonance magnétique nucléaire (acétone-d_6): quatre singulets à 2.06, 2.25, 2.28 et 2.32 p.p.m. ($OCOCH_3$); un doublet à 5.77 p.p.m., $J = 2.9$ Hz (CH 5); un doublet à 6.07 p.p.m., $J = 2.9$ Hz, deux singulets à 6.73 et 7.15 p.p.m. (CH 3 et CH aromatique).

Spectre de masse: pic moléculaire à *m/e* 502, pics à *m/e* 460, 418, 376, 358, 334, 316, 282, 176, 160.

Reductions with sulfurated borohydrides. II. Reduction of typical aldehydes

J. M. LALANCETTE AND A. FRÊCHE
Department of Chemistry, Faculty of Sciences, University of Sherbrooke, Sherbrooke, Quebec

Received October 2, 1968

Aromatic and aliphatic aldehydes can be reduced by sulfurated sodium borohydride to the corresponding alcohols. The reduction gives a quantitative yield of alcohol, without secondary products, if the reaction is performed at 0–10 °C. At higher temperatures (60°), the reduction is accompanied by the formation of disulfide. A good selection of the two possible reactions is obtained by adjusting the operating temperature. A mechanism explaining the reduction and the formation of sulfurated product is presented.

Canadian Journal of Chemistry, 47, 739 (1969)

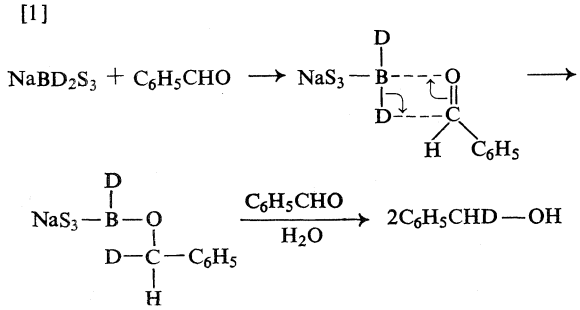
We have indicated in a previous article that the product obtained from the reaction of sodium borohydride with sulfur, $NaBH_2S_3$, behaves as a reducer towards many organic functions (1). We wish to report the reduction of typical aldehydes with this new reagent.

Like $NaBH_4$, where all hydrogen atoms are available for reduction, the two hydrogens carried by the boron atom in $NaBH_2S_3$ are capable of acting as reducer. This conclusion is confirmed by the yield of alcohol observed in the course of reduction of benzaldehyde at low temperature; with a 2:1 molar ratio of aldehyde and sulfurated hydride, an almost quantitative yield of benzyl alcohol is obtained. If a 100% excess of aldehyde is used, a 50% yield of alcohol is observed. The very high yield of intermediate borate, as it will be reported later, is also an indication that both hydrogens are available for reduction.

The reduction must take place through a hydride shift from the boron atom to the positive carbon of the carbonyl group, as it is the case with other borohydrides. This hypothesis has been confirmed by reduction of benzaldehyde with deuterated, sulfurated borohydride. This reaction gave the expected deuterated alcohol, eq. [1].

In this sequence of reaction, when both deuteride or hydride ions have been used up,

[1]



the intermediate ester must be a mixed orthothioborate : $NaS_3B—(O—CHD—C_6H_5)_2$ or $NaS_3B—(O—CH_2—C_6H_5)_2$. We have not been able to isolate this asymmetric boric ester but we have indirect evidence of the existence of a precursor to the symmetrical borate. The nuclear magnetic resonance (n.m.r.) measurement on a fresh reaction mixture, after the reduction of benzaldehyde by $NaBH_2S_3$, gave peaks that could not be related to any starting material or reaction products. Upon heating or simply keeping at room temperature, these peaks faded, as the expected peaks of the benzyl orthoborate appeared. This behavior is in accordance with the chemistry of the asymmetric orthoborates which are known to disproportionate spontaneously and very rapidly to symmetrical species rending their preparation impossible, except in the case of extreme steric hindrance (2). The disproportionation of an asymmetric borate is represented by eq. [2].

[2] $3\,RO—B—(OR')_2 \rightarrow (RO)_3—B + 2(R'O)_3—B$

The disproportionation should be eased greatly if B—S and B—O bonds are present on the same boron atom as it is the case with $NaS_3B(OCH_2C_6H_5)_2$. Following this spontaneous rearrangement, the orthoborate can be obtained in quantitative yield, by extraction of the crude reduction mixture with petroleum ether. This technique offers a very simple method of eliminating sulfur and inorganic residue from the organic substrate, since the sodium salt of the thioboric acid is completely insoluble in petroleum ether. Subsequent hydrolysis of the borate by water gives the expected alcohol, eq. [3].

[3] $3\,NaS_3—B—(OR)_2 \rightarrow Na_3S_9B\downarrow + 2B—(OR)_3$

$2\,B—(OR)_3 + 6\,H_2O \rightarrow 2\,H_3BO_3 + 6\,R—OH$

[4] 
$$C_6H_5CH_2O{-}B{-}(S_3^-)_2 + (C_6H_5CH_2O)_2{-}B{-}S_3^- \longrightarrow (C_6H_5CH_2O)_3{-}B + B{-}(S_3^-)_3$$

[5] 
The most appropriate experimental method of reduction with $NaBH_2S_3$ calls for short contact time and low temperature. Under these conditions, the percentage of reduction is always above 95%, the yield very high, and secondary product almost nonexistent. Cinnamaldehyde was reduced to cinnamyl alcohol, with a 95% yield; *p*-nitro- and *m*-nitrobenzaldehyde were reduced quantitatively to the corresponding alcohol without interference by, or attack on the nitro group. When an equimolar mixture of *meta* and *para* nitrobenzaldehyde was treated with half the required amount of $NaBH_2S_3$, for complete reduction, the resulting mixture of alcohols was 60% *para*- and 40% *meta*-nitrobenzyl alcohol. This competitive reaction, where relative steric factors were identical, indicates the preferred attack of the hydride ion on the more positive C-1 carbon of *para*-nitrobenzaldehyde. With simple aliphatic aldehydes the reaction led exclusively to the corresponding alcohols, even in the case of pivaldehyde, a somewhat hindered aldehyde.

Under more drastic experimental conditions such as reflux in tetrahydrofuran or a long period of contact, secondary reactions appear, leading to the production of sulfurated products and degradation of these products. With benzaldehyde, for example, a variable ratio of benzyl alcohol and benzyl disulfide can be obtained by adjusting the time of contact and the temperature of reaction. Yields as high as 50% of disulfide have been observed. When the crude mixture of reduction is distilled, after reflux at high temperature (80°) the disulfide is decomposed into olefin; for example, with benzyl disulfide, *trans*-stilbene is obtained. This production of sulfurated products was observed to be general with all aldehydes when high temperature was used. The critical stage of the reaction, as far as secondary products are concerned, must be at the level of the asymmetric orthoborate. The hydride shift must be the first step of the reaction, since in the case of benzaldehyde for instance, the benzyl group is found in either alcohol or sulfurated by-product as the sole constituent. On the other hand, the symmetric orthoborate cannot be the entity responsible for the production of sulfurated products. This has been verified by treating benzyl orthoborate with large excess of $NaBH_2S_3$ or B_2S_3 at reflux temperature in tetrahydrofuran. In all cases, the boric orthoester has been recovered unaffected by the treatment.

Different mechanisms for the disproportionation represented by eq. [3] must then prevail, depending on the temperature, to explain the presence, or absence, of product incorporating sulfur. We believe that at low temperature, the disproportionation must take place through intermolecular reaction. With such a mechanism, the asymmetric borate is transformed into a symmetric orthoester, all the sulfur being concentrated on the same boron atom, eq. [4].

But if the temperature is high enough, a pattern of reaction calling for an intramolecular rearrangement of the asymmetric borate explains the incorporation of sulfur in the reaction products, eq. [5].

The metaborate upon hydrolysis, yields the corresponding alcohol and the polysulfide can

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

rearrange to give the disulfide and the olefin. If this explanation is true, when the reaction is completely intramolecular, the yield of alcohol should be equal to the yield of sulfurated product. We have observed that as the temperature of reflux increases, the ratio of alcohol to secondary product decreases to reach a 50:50 value and then remains constant as expected from the proposed mechanism.

Conclusion

It can be seen, from these results that sulfurated sodium borohydride, at low temperature, behaves as a good reducer towards aldehydes, without any undesirable side reaction.

It is certainly surprising that such a sharp distinction can be made between pure reduction (intermolecular mechanism) and sulfuration (intramolecular mechanism) by a mere 50° increase in temperature. The rationale for such different reactions must be found in the thermodynamics of the system. An increase in reaction temperature, increasing the entropy of the system, should hamper an intermolecular reaction and at the same time favor intramolecular rearrangement of the transitory asymmetric thioborate.

Experimental

Nuclear magnetic resonance (n.m.r.) measurements were made with a Varian, A-60 apparatus. Infrared (i.r.) measurements were made with a Perkin–Elmer, model 137 spectrophotometer. Vapor-phase chromatography (v.p.c.) measurements were made with a Microteck, model GC2000R apparatus using an Se30, 4 ft column.

Optimal Conditions for Reduction

(1) Reduction of Benzaldehyde

To a suspension of 0.20 mole (26.4 g) of $NaBH_2S_3$ in tetrahydrofuran (125 ml), 0.40 mole (42.4 g) of benzaldehyde was added dropwise. The reaction mixture was stirred and kept at 5–10° for 1 h. This contact was followed by acid hydrolysis with 50 ml of 10% hydrochloric acid. The precipitated sulfur was filtered off and the filtrate extracted with chloroform. After drying over magnesium sulfate, the evaporation of chloroform gave a yield of 95% of benzyl alcohol. The i.r. and v.p.c. of this product, from comparison with authentic benzyl alcohol, indicated that the reduction was complete and that the alcohol was the sole product (99%) of the reaction.

Following the same procedure, a 50% yield of benzyl alcohol was obtained with a $\frac{1}{4}$ molar ratio of reducer and benzaldehyde.

(2) Reduction of Typical Aldehydes

Following the procedure cited in *(1)*, butyraldehyde, pivaldehyde, cinnamaldehyde, *p*-nitrobenzaldehyde, and *m*-nitrobenzaldehyde were reduced to the corresponding alcohols. The alcohols were identified by comparison with i.r. spectra of authentic samples. The absence (traces, less than 0.5%) of sulfurated product was shown by v.p.c. The yields were of the order of 95%. When a mixture of *p*-nitrobenzaldehyde (0.10 mole, 15.1 g) and *m*-nitrobenzaldehyde (0.10 mole, 15.1 g) was treated with 0.05 mole (6.60 g) of $NaBH_2S_3$, following the above procedure, a mixture of alcohols and unreduced aldehyde was obtained. From the relative intensity of the aldehydic hydrogens at 10.28 δ (*meta*) and 10.33 δ (*para*) observed with the reaction mixture, 1.5 mole of *p*-nitrobenzaldehyde was reduced for each mole of *m*-nitrobenzaldehyde.

(3) Identification of the Intermediate Orthoborate

In an experiment similar to *(1)*, 0.40 mole (42.4 g) of benzaldehyde was reduced by 0.20 mole (26.4 g) of $NaBH_2S_3$. The crude mixture given by the reduction, before hydrolysis, was evaporated to dryness under reduced pressure. The yellow lumps were then extracted by 200 ml of petroleum ether and the extract, after filtration, was evaporated, giving an oily liquid, benzyl orthoborate. The weight of the crude borate was 44 g (0.14 mole), a quantitative yield according to eq. [3]. The i.r., n.m.r., and v.p.c. of the borate were identical with the same measurements made on a pure sample of benzyl orthoborate prepared from benzyl alcohol and boric acid, by the azeotropic method.

(4) Indication of the Presence of an Asymmetric Borate in the Reaction Mixture

The crude reaction mixture (as in *(1)*) was examined by n.m.r. immediately after the reaction subsided. Three peaks were observed at 6.38, 6.68, and 6.92 δ. There was a weak singlet at 4.96 δ. Upon standing at room temperature, the peak at 4.96 δ increased and the other peaks decreased; after 18 h, all peaks, between 4.0 and 7.0 δ had disappeared except the singlet at 4.96 δ. The n.m.r. of the reaction mixture was then identical with the same measurement made on authentic benzyl orthoborate, in tetrahydrofuran.

(5) Reduction with Deuterated Hydride

The preparation of $NaBD_2S_3$ and the reduction procedure of benzaldehyde was identical with the procedure cited above, the reaction being carried on a 200 mg scale. The n.m.r. of the orthoborate $(C_6H_5CHDO)_3$—B was showing a rather wide singlet (or an ill defined multiplet) at 4.80 δ. The ratio of aromatic protons to aliphatic protons at 4.80 δ was 5.5:1, instead of the 5:2 ratio for $(C_6H_5CH_2O)_3$—B.

Production of Sulfurated Products

(a) Production of Benzyl Disulfide

The reaction was repeated as in *(1)* except that the initial mixture was kept at 60° for several hours, under a nitrogen atmosphere. After cooling, the reaction mixture was hydrolyzed with 3% HCl, at 5–10 °C. The crude mixture was extracted with chloroform and benzyl disulfide crystallized out upon evaporation of the solvent. Most of benzyl alcohol was eliminated by filtration and the disulfide was recrystallized from ethanol to give light rosy crystals, m.p. 70°; n.m.r. singlet at 3.53 δ, singlet at 7.20 δ.

Anal. Calcd. for $C_{14}H_{14}S_2$: C, 68.25; H, 5.75; S, 26.00. Found: C, 68.47; H, 6.00; S, 26.19.

The aqueous phase contained the expected benzyl

alcohol, extracted with chloroform and identified as in *(1)*. The reduction of carbonyl was complete (no trace of aldehyde left in the crude mixture, before hydrolysis, as shown by the infrared). The relative yield of alcohol to benzyl disulfide decreased, as time of contact was increased. After 20 h of contact, there was no significant increase in the yield of benzyl disulfide which remained in the 50% range. A higher temperature of reaction or a faster addition of aldehyde, as a rule, increased the percentage of sulfurated product which, in all cases levelled when a 1:1 ratio of benzyl disulfide to benzyl alcohol was reached.

The formation of disulfide was observed with all aldehydes under experimental conditions as in *(a)*.

(b) Production of Stilbene

If the crude mixture obtained after hydrolysis in *(a)* was extracted with chloroform, and distilled under vacuum, two fractions were obtained. The first one, b.p. 88°/0.8 mm, was benzyl alcohol. The second one, b.p. 180–190°/0.8 mm was stilbene (100% *trans* by n.m.r.).

(c) Stability of Various Intermediates

Benzyl orthoborate—Pure, redistilled benzyl orthoborate (5 g) was treated with 1.0 g of $NaBH_2S_3$ at 60 °C for 5 h. After removal of solid material by filtration, the residual material gave an i.r. identical with the same measurement made on the starting boric ester, indicating the absence of reaction.

A similar experiment, using boron sulfide, left the benzyl orthoborate unaffected.

Benzyl disulfide—Pure, recrystallized benzyl disulfide (0.500 g) was decomposed to stilbene, and another product by heating in a test tube for 15 min at 200°, under nitrogen atmosphere. The presence of stilbene (*trans*) was confirmed by the presence of the typical pattern for the *trans* isomer, in n.m.r. and by v.p.c.

Anisotropic effects on proton magnetic resonance frequencies of substituted barbituric acids[1]

GEORGE A. NEVILLE AND DENYS COOK
Research Laboratories, Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Canada
Received June 14, 1968

Several pharmacologically important barbituric acids were examined by proton magnetic resonance spectroscopy in trifluoroacetic acid, *p*-dioxane, and dimethyl sulfoxide-d_6. The data obtained greatly facilitate identifying and distinguishing barbiturates. Variations in chemical shift with alkyl substitution have been discussed, and the suggestion has been put forward that—the CH_3(Et) protons may be a sensitive probe for detecting changes in anisotropy (both ring and C=O) in a series of barbiturates. Evidence for the preferred configuration of C-5 phenyl, ethyl, and isopropyl substituents was obtained. Concentration studies by both proton magnetic resonance and infrared spectroscopy indicate that the barbiturates examined exist predominantly as solvated monomers rather than as dimers or oligomers.

Introduction

This proton magnetic resonance study of substituted barbituric acids was undertaken to obtain chemical shift and coupling data (*i*) to aid the identification of barbiturates that have very similar infrared spectra or melting points, (*ii*) to gain some insight into the possible existence of a partial ring current or localized anisotropic effects from a study of magnetic shielding and deshielding of ring substituents, and (*iii*) to determine if any tautomerism could be detected by proton magnetic resonance (p.m.r.) under normal conditions. When this work was begun, no comprehensive p.m.r. study of well-known barbiturates had been reported although some use of p.m.r. had been made in conjunction with the synthesis of new barbiturates (1). In the meantime, Rücker (2) published a qualitative analysis of barbituric acid derivatives by p.m.r. and noted the superiority of p.m.r. over other spectroscopic methods for distinguishing between barbiturates.

Results

Frequency data from p.m.r. studies are given in Tables I–III for several barbiturates in trifluoroacetic acid, *p*-dioxane, and dimethyl sulfoxide-d_6. Trifluoroacetic acid and *p*-dioxane solutions of 5-ethyl-5-phenylbarbituric acid (phenobarbital) and of 1-methyl-5-ethyl-5-phenylbarbituric acid (mephobarbital) have been examined by p.m.r. for a concentration effect while the same solutes have been examined by infrared (i.r.) spectroscopy in chloroform solution for a concentration effect.

[1]Presented in part at the Canadian Symposium on Applied Spectroscopy, Montreal, October 26, 1966.

Discussion

It is assumed that the barbiturate ring in the 5-substituted compounds discussed here is planar, as has been shown for 5,5-diethylbarbituric acid (**1**) (3) and its potassium salt (4). In **1** and **2** there is a barely perceptible fine structure in the CH_2(Et) and CH_3(Et) resonances which has been attributed to long range coupling ($J \sim 0.01$ p.p.m.). If, in fact, the fine structure is due to non-planarity of the ring, and therefore to non-equivalence of the two Et groups, then this small difference in chemical shift is barely significant when compared with chemical shift differences arising from substituent and solvent effects.

(a) Inductive and Anisotropy Effects

Effect of N-Substitution on CH_3(Et) and CH_2(Et) Chemical Shifts

Although the changes in chemical shift for the methyl protons, of the ethyl substituents, i.e. CH_3(Et), in the C-5 position of the barbiturate ring (Table I) amount to only a few (3–5) Hz with *N*-substitution, these changes appear to be real. The chemical shift (0.83 p.p.m., $CDCl_3$) for the CH_3(Et) of **2** shows weak shielding of these protons relative to the value (~0.90 p.p.m., $CDCl_3$) (5) for methyl protons in saturated hydrocarbons. When the latter value is corrected for the deshielding effect from β-substituents like CO_2H and CO_2Alkyl, which result in a shift of 0.25 p.p.m. (5) to lower frequencies, then the model chemical shift becomes 1.15 p.p.m., in close agreement with the observed chemical shifts for

the CH_3(Et) protons of *n*-propionamide (1.13 p.p.m., $CDCl_3$) (6) and *sym*-diethylurea (1.10 p.p.m., $CDCl_3$)[2]. Since any inductive electron withdrawal from the CH_3(Et) protons in the barbiturate ring is exerted as a γ-substituent effect, a much better model for comparison purposes is *N*,*N*′-dimethyl-α,α-diethyl malonamide. In this compound the CH_3(Et) protons absorb at 1.00 p.p.m. ($CDCl_3$); thus, the CH_3(Et) protons in **2** are shielded by 11 Hz relative to the same protons in the malonamide model. This is, perhaps, the best obtainable model for substituents at the C-5 position of the barbiturate ring since it represents both the inductive effects of γ-substitution and the anisotropy effects of the amide grouping also present in the barbiturate ring. In the barbiturate ring, however, delocalization of the π-electron system in the amide linkages is expected to generate a partial ring current (incomplete because of the C-5 methylene unit) which could induce diamagnetic shielding above and below the planar (3, 4) barbiturate ring. The CH_3(Et) protons in the C-5 position, therefore, might provide a sensitive probe for detecting changes in anisotropy (both ring and/or C=O) in a series of barbiturates. Comparison of the chemical shifts for the CH_3(Et) protons in Table I shows these protons to be shielded by 0.05–0.07 p.p.m. in 1-methyl-5,5-diethylbarbituric acid (**2**) relative to 5,5-diethylbarbituric acid (**1**), by 0.02–0.05 p.p.m. in 1-methyl-5-ethyl-5-phenylbarbituric acid (**4**) relative to 5-ethyl-5-phenylbarbituric acid (**3**), and by 0.03–0.07 p.p.m. in 5-ethyl-5-isopropylbarbituric acid (**5**) relative to 5,5-diethylbarbituric acid (**1**). This weak shielding in **2** and **4** is attributed to electron release by the 1-methyl substituents, assuming no conformational changes in the planar barbiturate. The crystal structures of the potassium salt of 5,5-diethylbarbituric acid (4) and of 5,5-diethylbarbituric acid (3) are known, and show that the methyl protons (Et), in their preferred configuration (**12**), are fully exposed to the shielding effects of the (nearly planar) ring π-electrons. The weak shielding effects observed above suggests that the same configuration, (**12**) for C-5 ethyl substituents exists in solution as in the solid state.

The chemical shift data in Table I for the methylene protons of the ethyl substituents, i.e. CH_2(Et), in the C-5 position show that no change occurs for the CH_2(Et) proton frequencies with methyl substitution at N-1 of the barbiturate ring. In the suggested preferred configuration (**12**) the CH_2(Et) protons are remotely exposed to the deshielding regions of the C-4 and C-6 carbonyl groups and little better oriented towards the deshielding region that might arise from a partial ring current in the planar ring. Any anisotropic effects arising from these carbonyl groups due to *N*-methylation might be expected to have little effect on the poorly oriented CH_2(Et) protons, particularly when the shielding effects observed for the more favorably oriented CH_3(Et) protons are so small.

Effects of an Isopropyl Substituent at C-5

When an isopropyl substituent is introduced at C-5 of the barbiturate ring as in **5**, the methyl protons of the isopropyl group, i.e. CH_3(*i*-Pr), are deshielded by 0.20 p.p.m. relative to the CH_3(Et) protons in the same molecule. While the barbiturate molecule appears to tolerate one methyl group hovering over its ring (~2.1 Å^3 between a CH_3 proton and the plane), the possibility of two methyl groups, as in the isopropyl substituent, over the ring appears to involve too much steric repulsion (~1.1 Å,[3] minimum distance between a CH_3 proton and the C-4 or C-6 carbonyl oxygen atom). Since the CH_3(*i*-Pr) protons are deshielded relative to the CH_3(Et) protons, it appears that the isopropyl methyl groups must be oriented away from the ring (i.e. *exo* conformation) such that the CH_3(*i*-Pr) protons are exposed to the deshielding regions of the C-4 and C-6 carbonyl groups and of the ring itself. In the *exo* conformation the minimum distance between the methyl (*i*-Pr) protons and the carbonyl oxygen atoms, and also between both types of protons, CH_3(Et) and CH_3(*i*-Pr), is approximately 1.7 Å^3.

It is also noteworthy that the 5-isopropyl substituent in **5** results in shielding of the CH_3(Et) protons of **5** equal to that produced by the 1-methyl substituent of **2**. This shielding in **5** relative to **1** is attributed to the greater electron release of an isopropyl group ($\sigma^* = -0.19$) to the C-5 carbon atom compared to that from an ethyl group ($\sigma^* = -0.10$) (7) which could then produce an increased anisotropy effect from the C-4 and C-6 carbonyl groups. The deshielding

[2]George A. Neville. Unpublished data.

[3]Distances estimated from Dreiding models.

of the methylene protons (Et) in **5** relative to **1** may be due in part to the above difference in inductive effects and in part to steric hindrance by the isopropyl group in the *exo*-conformation, proposed above, resulting in longer conformational lifetimes for the CH_2(Et) protons in the deshielding regions of the C-4 and C-6 carbonyl groups.

Effect of a Phenyl Substituent at C-5

Comparison of the chemical shift values for the CH_3(Et) and CH_2(Et) protons of **3** are deshielded by 0.47–0.49 p.p.m. and by 0.09–0.10 p.p.m. respectively relative to **1**. These shifts would appear to be due largely to the effect of the C-5 phenyl group being in the same plane as the C_{2v} mirror plane of the barbiturate ring. In this configuration the methylene and methyl protons are exposed to the deshielding region of the phenyl ring but this deshielding would be increased somewhat by inductive electron withdrawal by the phenyl ring ($\sigma^* = +0.60$) (7) from the C-4 and C-6 carbonyl groups. Also, in this configuration, the 1-methyl protons of **4** are exposed to the deshielding region of the phenyl ring; thus, the small downfield shift (0.01–0.05 p.p.m.) for these protons in **4** compared to **2** is supporting evidence for this configuration as the preferred one.

The introduction of a 1-methyl substituent in **4** results in shielding (relative to **3**) of 0.02–0.05 p.p.m. in the CH_3(Et) protons and this effect is due to the anisotropy of the C-4 and C-6 carbonyl groups as described above. It is interesting that the phenyl proton frequencies of **3** and of **7** (Table II) are identical whereas those of **4** show a slight shielding effect attributable to weak anisotropic shielding by the C-4 and C-6 carbonyl groups from introduction of the 1-methyl group.

The C-5 methyl protons of 5-methyl-5-phenylbarbituric acid (**7**) (Table II) are deshielded by 0.28–0.35 p.p.m. compared to those of 5-(1-cyclohexenyl)-1,5-dimethylbarbituric acid (**11**) (Table III). This shift is due mainly to the larger paramagnetic anisotropy from a benzene ring than from an isolated double bond having its plane in the C_{2v} mirror plane of the barbiturate ring.

(b) Concentration Effects

The effects of varying the concentration of an acid in solution were investigated by both proton magnetic resonance and infrared spectroscopy. In dilute alcohol-free chloroform solution (0.003 *M*) **3** and **4** gave infrared spectra in which the NH stretching frequency was at 3380 cm^{-1}, clearly not involved in hydrogen bonding, and therefore indicative of each acid being in its monomeric state. In the more concentrated solutions (up to 0.024 *M*, i.e., near saturation) a low intensity band developed near 3210 cm^{-1} showing the presence of a small amount of some more complicated species, possibly a dimer. The same infrared frequencies and behavior on dilution of mephobarbital, i.e. **4**, in chloroform (alcohol-free?) were recently reported by Kyogoku *et al.* (8). It is assumed, therefore, that the p.m.r. spectra of nearly saturated $CDCl_3$ solutions are those of predominantly monomeric molecules.

The effect of varying concentration on p.m.r. frequencies was examined with two representative barbiturates. 5-Ethyl-5-phenyl-barbituric acid and 1-methyl-5-ethyl-5-phenylbarbituric acid were chosen because the former can exist as long hydrogen bonded chains whereas the latter can only form dimers. The fact that no significant change occurs in the chemical shift values for either of these barbiturates with variation of concentration (from 160–10 mg/ml) in trifluoroacetic acid and in *p*-dioxane is taken as an indication that the solute is monomeric in the solvents over the concentration ranges examined. In the more dilute TFA samples (40 mg/ml and less) the NH peak was too broad to be seen. However, because of the sensitivity of the resonances of the

For personal use only.

methyl protons to changes in shielding caused by substituent and solvent effects, the frequencies of these protons provide a more reliable index to concentration effects. Since the chemical shifts for the barbiturates in dimethyl sulfoxide closely parallel those in *p*-dioxane, one may safely assume that the solutes are completely solvated as monomers in both these solvents. Trifluoroacetic acid *p*-dioxane and dimethyl sulfoxide, having relatively large dielectric constants, would be expected to break up any dimers or oligomers in solvating these barbiturates over the concentration range used.

(c) Solvent Effects

The CH_2(Et) protons of the C-5 ethyl substituents are more sensitive to solvent effects than the CH_3(Et) protons. Table I shows these shifts to be in the order, δ for TFA > $CDCl_3$ > DOX > DMS. These values would be in keeping with the solute–solvent interactions depicted in **13**, **14**, and **15**. In such hydrogen-bonded interactions the CH_2(Et) protons are expected to be less effected by anisotropy changes than the CH_3(Et) protons and more dependent on inductive effects than the CH_3(Et) protons.

Chloroform would form only a weak hydrogen bond to a carbonyl oxygen atom of the barbiturate ring (**13**) which would result in electron displacement away from the ring thus slightly deshielding the CH_2(Et) protons relative to the isolated molecule. DMS and dioxane would have the opposite effect (**14**) since they would enhance the tendency of the NH group to ionize. This would result in shielding of the CH_2(Et) protons. Since DMS is probably a little better donor than dioxane this accounts for the slightly smaller chemical shift values in DMS. In TFA the complex **15** is probably formed,[4] and the overall deshielding effect (relative to $CDCl_3$ solution) would be due to a balance between the good COOH proton donor and the rather weakly basic CO group in TFA.

Inductive effects due to solvent interactions would give rise to shifts in the CH_3(Et) resonances in the same direction as those induced by ring currents. The changes due to inductive effects are expected to be small because of the large number of bonds involved.

The *N*-methyl proton resonances can be analyzed in a similar manner. Inductive effects on these protons due to solvent interactions will be the same as just discussed for the CH_2(Et) and CH_3(Et) protons. Thus Table I shows the *N*—CH_3 resonances for **2** and **4** at about the same δ-value in DOX and DMS with both slightly upfield from $CDCl_3$, and downfield from $CDCl_3$ in TFA. These values are again quite consistent with the solvent interactions shown in **13**, **14**, and **15**. It is difficult to separate the inductive and ring current effects since they both operate in the same direction.

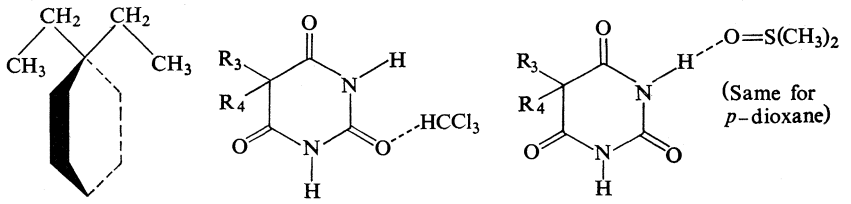
(d) Tautomerism

No indications of the presence of two tautomeric forms (lactam ⇌ lactim) could be seen in the p.m.r. spectra of the free barbituric acids listed in Tables I–III. A single, sometimes broad,[5] peak near 10 δ has been attributed to the NH proton. This, however, does not preclude the possibility of tautomerism because the concentration of tautomers in equilibrium in the solvents employed could be too small to be detected. However, peaks which we have attributed to NH protons have been found in the monosodium salts of 5,5-diethyl- and 5-ethyl-5-phenylbarbituric acids at 3.53 and 5.82 δ respectively in dimethyl sulfoxide-d_6. Although these anomalously high field absorptions occur in the same range (4.00–6.01 δ) as hydroxyl proton resonances in dimethyl sulfoxide (11) they do not necessarily indicate the existence of tautomerism since the negative charge in the salts would shift the resonance to higher field.

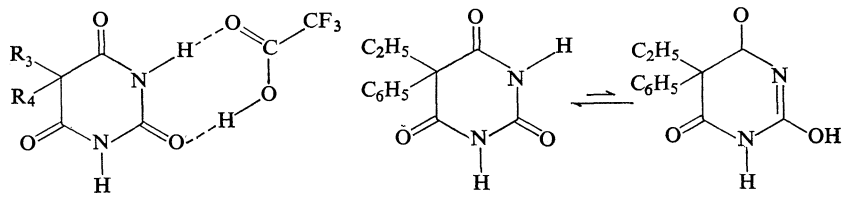
As a corollary to the concentration study, these results would reinforce the conclusion that no

[4]In glacial acetic acid (AcOH), **2** shows the same chemical shift value for the CH_3(Et) and N—CH_3 protons as in chloroform-*d* solution. Ma and Warnhoff (9) observed that the N—CH_3 signal of *N*-methyl amides was shifted downfield by nearly 0.2 p.p.m. in TFA relative to $CDCl_3$ with little or no change in AcOH relative to $CDCl_3$ solution whereas the *N*—CH_3 signal of aliphatic tertiary and secondary amines is shifted downfield by 0.6–0.8 and by 0.45–0.6 p.p.m. respectively in TFA. It would appear from this data that little protonation of amides occurs in TFA and that less protonation of barbiturates occurs than with amides. Hydrogen bonding between TFA and carboxylic acid esters has been reported (10). In the hydrogen bonded complex (**15**) a certain amount of proton transfer may occur but the extent of this cannot be deduced from the present measurements.

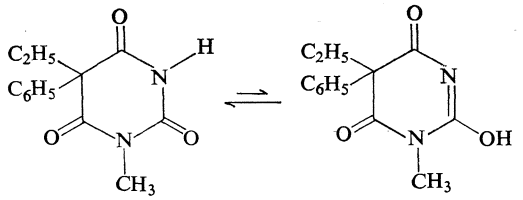
[5]The NH band is moderately sharp in both dimethyl sulfoxide and dioxane solution spectra relative to the broad band commonly seen for amides in chloroform solution. The band is broadened in trifluoroacetic acid solution spectra.



12 13 14



15 16



17

tautomerism, detectable by p.m.r., occurs in the barbiturates examined. If two tautomeric forms occurred (**16** and **17**) it might be expected that they would have different ring anisotropies which would be detected in the tautomeric proton resonances, and more particularly, in the CH_3(Et) proton frequencies. Tautomerism, however, could be masked in p.m.r. by rapid exchange of protons between the tautomers.

Experimental

Proton magnetic resonance spectra were obtained from a Varian A-60A spectrometer with ambient probe temperature at $40\pm2°$. Chemical shifts (δ) were measured downfield from tetramethylsilane (TMS), used as an internal reference, and are considered to be accurate to ±0.02 p.p.m. The NH chemical shift was taken as the center of the broad band, and is estimated to be accurate to ±0.05 p.p.m. Sweep width calibration was periodically checked against the 7.27 δ chloroform signal downfield from TMS. Concentrations of solutions were approximately 100 mg solute per ml solvent unless stated otherwise.

Infrared spectra were recorded on a Perkin–Elmer 621 grating spectrometer using 1.0 mm cells. The frequency counter was checked against established indene calibration frequencies. Alcohol-free chloroform was prepared from Mallinckrodt AR chloroform (containing ~0.75% ethanol) by (*i*) extraction with concentrated sulfuric acid, (*ii*) washing with distilled water until neutral, (*iii*) drying overnight over anhydrous magnesium sulfate, and (*iv*) distilling the dried solvent. The main fraction, b.r. 60.8–61.0°, was stored in the dark and used within two days after distillation.

All barbiturates except two were pharmaceutical grade having been obtained from various pharmaceutical manufacturers. All gave melting ranges in accordance with reported values, and were used without further purification. 1-Phenylbarbituric acid was obtained from the Aldrich Chemical Co., and was used without further purification. 1,3-Dimethylbarbituric acid (m.p. 122°) was prepared by the method of Biltz and Wittek (12).

N,N'-Dimethyl-α,α-diethylmalonamide was prepared by the method of Cohn (13) with modification. After 5,5-diethylbarbituric acid (0.0263 moles) had been heated under reflux for $3\frac{1}{2}$ h in aqueous sodium hydroxide solution (0.064 moles NaOH/40 ml water) with dimethyl sulfate (0.0640 moles), the crude product was ground up with concentrated hydrochloric acid. The acid insoluble solid was recrystallized from chloroform – petroleum ether mixed solvent to give the product m.p. 151–153°. Cohn reported a m.p. of 149°. The p.m.r. spectrum of the product showed a triplet (6H), a quartet (4H), a doublet (6H), and a broad band (2H) centered at 0.82, 1.92, 2.83, and 7.0 p.p.m. respectively downfield from TMS in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$CDCl_3$. The infrared spectrum ($CHCl_3$, 0.1 mm cell) showed a free (sharp) and an associated (broad) amide NH stretching band at 3470 and 3300 cm^{-1} respectively and a strong carbonyl band at 1665 cm^{-1} with a shoulder at 1630 cm^{-1}.

Acknowledgments

We are grateful to Mr. H. W. Avdovich for assistance with the preparative work; to Mr. Z. R. Regnier for recording the infrared spectra; and to Mr. P. Hanbury for some of the nuclear magnetic resonance spectra. We would like to acknowledge the kindness of many manufacturers in generously making samples available to us.

Etude de résonance magnétique nucléaire dans la série des pregnane et D-homopregnane

KRZYSZTOF JANKOWSKI ET CASIMIR BERSE
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 13 septembre 1968

L'influence d'environnement sur le déplacement chimique du méthyle-20 dans les spectres de résonance magnétique nucléaire (r.m.n.) a été étudiée pour la série des dérivés du prégnane. Les différences dans le déplacement chimique du méthyle-20 des produits examinés par rapport aux produits modèles ont été calculés. Le méthyle-20 a été transposé en le méthyle-17 ou -17*a* par la D-homoannulation et les spectres de r.m.n. de tous les isomères ont été interprétés.

Canadian Journal of Chemistry, **47**, 751 (1969)

Au cours de nos études précédentes (1),[1] nous avons fait quelques observations concernant l'influence des envrionnements chimiques sur le déplacement chimique du méthyle-20 des stéroides dans le spectre de résonance magnétique nucléaire (r.m.n.). Le déplacement chimique du méthyle-20 des stéroides différemment substitué réflète les changements dans leur structure parfois mieux que celles des méthyles-10 et -13.

Nous avons complété nos études et le Tableau I résume nos observations en donnant la position du méthyle-20, la correction $\Delta\delta$ due à la présence des substituants, la différence entre le méthyle-20 des acétyles-17 α ou β, la différence entre les déplacements chimiques des méthyles des acétyles et des cétales correspondantes. L'hydroxy-3β pregnène-5 one-20 (**1**) et son cétal (**2**) ont été utilisés comme produits de référence.

La différence entre le méthyle d'acétyl-17 α ou β varie entre 0.19–0.20 p.p.m. Le cétal correspondant donne la différence analogue entre 0.10–0.15 p.p.m.

La différence pour le méthyle-20 entre les paires des composés (cétal–acétyl, par exemple, **1–2**, **3–8** etc....) varie entre 0.67–0.89 p.p.m.

Nous voulons signaler que le déplacement chimique du méthyle-20 dans la série du prègnane même, donc un stéroide portant l'éthyle dans la position-17, réflète aussi le changement dans l'environnement.

Ensuite le méthyle-20 des certains stéroides (**3**, **6**) a été transformé en méthyle-17 ou -17*a* par la réaction de la D-homoannulation.

Les spectres de r.m.n. des D-homostéroides n'ont pas été étudiés.

Les seuls récents travaux qu'on peut citer sont des articles de Pivnitsky et Torgov (2), Trenner *et al.* (3) et Neudert et Röpke (4). Nos essais consistent à lier le déplacement chimique des méthyles-17 ou -17*a* avec leur position dans l'espace. Les données de r.m.n. des produits sont résumées dans le Tableau III.

Les stéroides hydroxy-17 acétyl-17 sont très sensibles en milieu basique ou en présence des acides de Lewis donnent les D-homo-17 ou -17*a* cétones. Ce réarrangement a été étudié par plusieurs auteurs (5^2–7) pour les différents stéroides. Nous avons effectué (voir le Tableau II) l'isomérisation des produits acétyl-17β hydroxy-17α (**3**) et acétyl-17α hydroxy-17β (**6**) en utilisant les bases classiques (KOH dans l'alcool) ou les acides de Lewis (BF_3, Al_2O_3 etc...).

Les quatre produits D-homo possibles dans les réactions ont été nommés **A**, **B**, **C** et **D**:

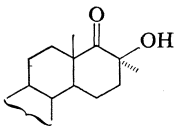
*La quantité de produit **D** a été évaluée d'après le spectre de résonance magnétique nucléaire.



D

A—le méthyl-17*aα* dihydroxy-3β, 17*aβ* D-homo-pregnène-5 one-17

B—le méthyl-17*aβ* dihydroxy-3β, 17*aα* D-homo-pregnène-5 one-17

C—le méthyl-17β dihydroxy-3β, 17α D-homo-pregnène-5 one-17*a*

D—le méthyl-17*a* dihydroxy-3β, 17β D-homo-pregnène-5 one-17*a*

Les produits **A** et **B** correspondant à la migration du lien C_{13}–C_{17}; produits **C** et **D** du lien C_{16}–C_{17}.

Le produit **D** n'a jamais été obtenu à l'état pur. Il faut souligner que le produit **D** est *a priori* le moins stable de tous les quatre isomères.

Nous avons isolé, par isomérisation du produit **3** avec les acides de Lewis, le composé **C** comme le principal et le composé **B**. Avec le KOH, le même produit **3** a donné les composés **A** et **D**. Par contre, l'isomérisation par les acides de Lewis ou la solution de KOH du produit **6** donne comme les principaux produits **A** ou **B** respectivement. Nos résultats sont soutenus par la littérature (5–8). Il n'y a aucune analogie entre la D-homoannulation faite par les acides de Lewis ou les bases avec ce réarrangement effectué à la façon thermique (les quantités équivalentes des produits, par exemple **A** et **C** sont les produits (9)).

Les quatre produits D-homo isolés dans les différentes réactions des deux séries montrent que le déplacement chimique (Tableau III) des protons du méthyle-10 se diffère très peu l'un à l'autre. On a observé pour les quatre produits que, si le groupement OH et cétonique sont du même côté du cycle, le déplacement chimique du méthyle-13 est légèrement déplacé vers le champ plus bas (1.016 par exemple) par rapport aux produits où la cétone et OH sont des côtés opposés.

Dans ce cas, une possibilité d'avoir la résolution des problèmes structuraux est une examination du déplacement chimique des méthyles-17 ou -17*a* provenant de la transformation du méthyle-20.

Le méthyle en question absorbe vers 1.46 p.p.m. pour le composé **A** et vers 1.43 p.p.m. pour le composé **C**. Pour la structure **B** son signal tombe

à 1.32 p.p.m. Par l'isomérisation avec le KOH, le produit **D** a été fait. Son déplacement chimique du méthyle-17 tombe vers 1.28 p.p.m. Ce produit a été obtenu en mélange avec le composé **A**.

Nous avons essayé d'interpréter l'isomérisation des produits **3** et **6** par les acides de Lewis ou par les bases. On observe généralement que le groupement cétonique formé reste de même côté que l'hydroxyle du produit de départ (rétention de la configuration de la fonction oxygénique) par rapport au cycle si on fait l'isomérisation à l'aide des acides de Lewis. Si on effectue l'isomérisation avec le KOH, il y a l'inversion de la fonction oxygénique par rapport au produit de départ.

Le produit **C** formé principalement par l'isomérisation du produit **3** possède le groupement OH α éloigné au maximum du carbonyle et du cycle **C** du stéroide donc dans la position du minimum d'énergie. Ce problème a été discuté par Elphimoff–Felkin (10)[3] et Wendler *et al.* (11).[4] Le réactif comme KOH produit le composé **A** qui est aussi stable (OH équatorial).

L'isomérisation du produit **6** par les acides de Lewis, fournit principalement le composé **A** qui est relativement stable. La formation du produit **B** à partir du même composé s'explique par l'attaque *trans*-coûplanaire de la part de base. Dans le cas du produit **3**, la présence des isomères **B** et **C** ensemble (isomérisation avec les acides de Lewis) et la présence des produits **A** et **D** ensemble (isomérisation avec des bases) ainsi que l'absence des mêmes paires d'isomères pour le composé **6** prouve notre suggestion. En plus on a observé que les différences dans le déplacement chimique du méthyle-17 et -17*a* pour les paires des isomères **A**–**B** et **C**–**D** restent constantes

pour les isomères **A**–**B** 0.14 p.p.m.
pour les isomères **C**–**D** 0.15 p.p.m.

Cette valeur est une mesure d'une différence énergétique entre la position α et β-axiale et équatoriale-du méthyle. L'approche de ces deux valeurs est une confirmation additionnelle d'exactitude de la structure **D** supposée. Les produits suivants: le méthyl-17*a*β dihydroxy-3β, 17*a*α D-homopregnène-5 (**19**) et le méthyl-17*a*α dihydroxy-3β, 17*a*β D-homopregnène-5 (**20**)—donc les composés ne contenant pas de carbonyle dans le noyau D—ont été examinés en vue de démontrer l'importance secondaire de l'effet électronique sur le déplacement chimique du méthyle-17*a*. Leur déplacement chimique tombe à 1.31 et 1.44 p.p.m. respectivement et la différence est de 0.13 p.p.m.

Les résultats obtenus pour les stéroides **19** et **20** ainsi que les stéroides nommés dans les références (4) démontrent que la présence du méthyle dans le plan du carbonyle (structure **B** et **D**) n'est pas une cause de la différence entre le déplacement chimique des paires des isomères **A**–**B** et **C**–**D**. L'avantage de notre méthode a aussi été démontrée pour la série de la décaline ou des autres stéroides; le déplacement chimique du diméthyl-9β,10 hydroxy-9α décalinène-4 one-3 (21) ou le méthyle 9β est équatoriale tombe à 1.33 p.p.m. (12).

Les mêmes corrélations entre les déplacements chimiques des méthyles ont été observées aussi pour quelques stéroides normales ayant le méthyle et l'hydroxyle dans les positions-3 ou -17 sur le même atome de carbone (4).

Cependant, la série des *tert*-butyl-méthylcyclohexanols—même que la rigidité du squelette est comparable à celle des stéroides—ne se subordonne pas à nos prévisions (13).

Partie expérimentale

Les points de fusion ne sont pas corrigés. Les spectres de résonance magnétique nucléaire (r.m.n.) ont été enregistrés à l'aide de spectrophotomètre Varian A-60 dans $CDCl_3$ (concentration environ 10%). L'éthynyl-17α dihydroxy-3β, 17β androstène-5 (**22**), l'hydroxy-3β pregnène-5 one-20 (**1**), le dihydroxy-3β, 17α pregnène-5 one-20 (**3**) ainsi que le *tert*-butylate d'aluminium ont été des produits commerciaux.

Les *N*-(oxo-20 dihydroxy-3β, 17α pregnène-5 yl)-16β glycinate d'éthyle (**5**) et son cétal (**10**), le trihydroxy-3β,-16β,17α pregnène-5 one-20 (**4**) et son cétal (**9**) ont été synthétisé par nous récemment (1).

Les cétales de l'hydroxy-3β pregnène-5 one-20 (**2**) (14) et dihydroxy-3β, 17α pregnène-5 one-20 (**8**) (15) ont été faites par la méthode habituelle à partir des cètones correspondants par l'action du glycol éthylénique dans le benzène en présence d'acide *p*-toluènesulfonique. L'estimation sur la quantité des produits isomériques **A**, **B**, **C** et **D** dans chaque préparation a été faite par l'examen des spectres des r.m.n. des mélanges réactionnels cristallisés en les comparant avec les spectres des produits purs. Les produits purs ont été obtenus par la chromatographie sur les couches minces préparatives.

D-Homoannulation du produit 6 à l'aide de l'alumine

Le produit **6** (100 mg, ~0.3 mmole) a été chromatographié sur une colonne d'alumine basique (act. II, 150 g). L'élution avec l'éthanol–benzène 1:99 (3000 ml) a

[3]Voir aussi la bibliographie de cet article.
[4]Voir aussi la bibliographie de ect article.

donné après avoir évaporé les solvants, les cristaux blancs des produits **A** et **D**.

*D-Homoannulation des produits **3** ou **6** par trifluorure de bore*

La suspension du produit (500 mg, 1.3 mmole) dans l'acide acétique (80 ml) a été mélangée avec l'anhydride acétique (3 ml) et le trifluorure de bore dans l'éther (4 ml). Le mélange a été agité pendant 24 h dans la température de la pièce. (Après 1 h environ, on observe la dissolution complète du produit cristallin). Ensuite l'eau (100 ml) a été ajouté. Environ la moitié des solvants a été évaporée *in vacuo* et le restant a été extrait trois fois à l'éther (500 ml). La solution éthérée a été lavée avec le bicarbonate de sodium à 5% (50 ml) et séchée avec le sulfate de magnésium. L'éther a été évaporé et le résidu a été chromatographié sur l'alumine acide. Après le contrôle sur les couches minces, les fractions de benzène–éther 9:1 (400 ml) et benzène–acétone 4:1 (500 ml) ont été combinés ensemble. Les solvants ont été évaporés *in vacuo* et le résidu a été traité avec l'hydroxyde de sodium à 10% dans l'éthanol (25 ml). La solution a été agitée dans la température de la pièce pendant 12 h, saturée avec le chlorure de sodium et extraite à l'éther. La phase éthérée a été séchée avec le sulfate de sodium anhydre, évaporée *in vacuo* et le résidu a été recristallisé de l'acétone.

*D-Homoannulation des produits **3** et **6** à l'aide de KOH*

La solution des produits **3** ou **6** (100 mg, ~0.3 mmole) a été portée à reflux avec l'hydroxyde de potassium à 5% dans le méthanol (ou éthanol) (25 ml) pendant 24 h. La solution a été traitée avec le carbonate de potassium à 5% (20 ml) et l'acide chlorhydrique à 5% (30 ml) et avec l'eau (50 ml); puis refroidi à 4° pendant 2 h. Les petites quantités des produits de la D-homoannulation ont été filtrées. La solution a été extraite deux fois à l'éther (50 ml), séchée avec le sulfate de magnésium, évaporée *in vacuo* et le résidu cristallin a été combiné ensemble avec les cristaux filtrés et recristallisés de l'acétone.

*D-Homoannulation des produits **3** et **6** à l'aide du butyle tertiaire d'aluminium*

La solution des produits **3** ou **6** (500 mg, 1.3 mmole) dans le toluène anhydre (40 ml) a été portée à reflux avec le butylate tertiaire d'aluminium (500 mg, 2 mmoles) pendant 6 h. Ensuite, la solution a été refroidie à 0° et neutralisée avec l'acide chlorhydrique à 5% (20 ml). Le matériel organique a été extrait à l'éther (200 ml), séché avec le sulfate de sodium anhydre et la solution a été évaporée *in vacuo*. Le résidu cristallise après refroidissement.

*D-Homoannulation des produits **3** et **6** à l'aide de $HgCl_2$*

La suspension des produits **3** ou **6** (1 g, 3 mmoles) et de chlorure de mercure (2 g) dans l'aniline (1 ml), l'eau (20 ml) et le benzène (70 ml) a été chauffée dans une bouteille à pression pendant 10 h à 100°. L'aniline et le benzène ont été séparés par l'entraînement à vapeur d'eau et le résidu aqueux a été traité avec le sulfure d'hydrogène gazeux. Le précipité noir a été filtré et séché à l'air, puis extrait à l'éther (250 ml) dans un appareil de Soxhlet. L'éther a été évaporé et le résidu a été filtré par une colonne de charbon activé. Après évaporation du solvant, le résidu cristallise.

Photo-additions of aromatic hydrocarbons—indene and naphthalene with acrylonitrile

JOHN J. MCCULLOUGH AND C. W. HUANG
Department of Chemistry, McMaster University, Hamilton, Ontario

Received September 23, 1968

The photolyses of indene and naphthalene with acrylonitrile have been studied, and the products characterized. Indene reacts with acrylonitrile when the hydrocarbon absorbs light, or when a triplet sensitizer (acetophenone) is absorbing. Photolysis under the former conditions in ethanol yields 2-(1-indenylpropionitrile) (70%), 2-(3-indenylpropionitrile) (10%), and 6-cyano-2,3-benzobicyclo[3,2,0]hept-2-ene (20%). Base-catalyzed isomerizations of the substituted indenes are reported. On sensitization, *cis*- and *trans*-isomers of 7-cyano-2,3-benzobicyclo[3,2,0]hept-2-ene are formed, with a minor amount of indene dimer. The former isomers can be equilibrated with strong base. Adducts of 1,1-dimethyl- and 1,1-diphenylindene with acrylonitrile are also described, and nuclear magnetic resonance data reported. Naphthalene adds acrylonitrile on photolysis in *t*-butyl alcohol (pyrex filter) to afford *trans*-8-cyano-2,3-benzobicyclo-[4,2,0]-octa-2,4-diene (90%) and 1- and 2-naphthyl-2-propionitrile (10%). Sensitization with acetophenone gave no detectable products. Irradiation of the major product at 253.7 mμ through Vycor gave naphthalene. The preparative value of these reactions is considered and possible mechanisms are proposed.

Canadian Journal of Chemistry, **47**, 757 (1969)

Introduction

Photocycloaddition reactions of aromatic hydrocarbons (1) constitute an important branch of organic chemistry. The dimerizations of anthracene (2), acenaphthylene (3), and indene (4) may be cited as examples. A number of interesting cross-additions leading to cyclic structures are also known. These include the additions of maleic anhydride and derivatives to benzene (5*a–c*), indene (5*d*), phenanthrene (6), and anthracene (7), and the reactions of benzene with alkenes (8), acrylonitrile (9), dienes (10), and acetylenes (11).

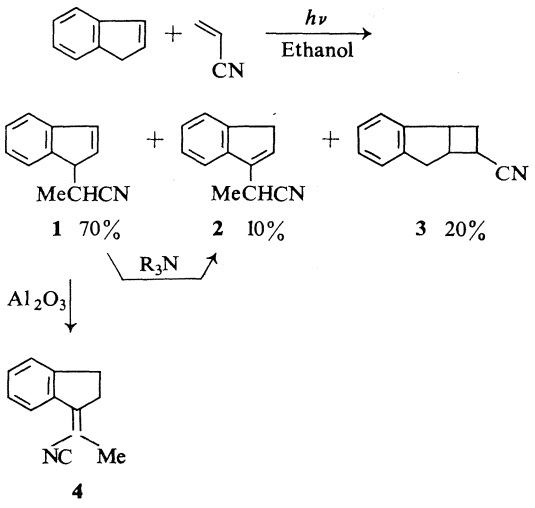
Cross additions of the bicyclic hydrocarbon naphthalene which have been reported are few in number. Naphthalene reportedly does not react with maleic anhydride on irradiation (12) but does form a photo-adduct with diphenylacetylene (13). Also, reactions have been observed on photolysis of naphthalene and dienes (14).

In our work in this area, initial experiments showed that indene and acrylonitrile react on irradiation, and subsequent work with naphthalene and acrylonitrile revealed similar reactions. We are reporting here the structures of the products of these reactions, and the evidence for our assignments.

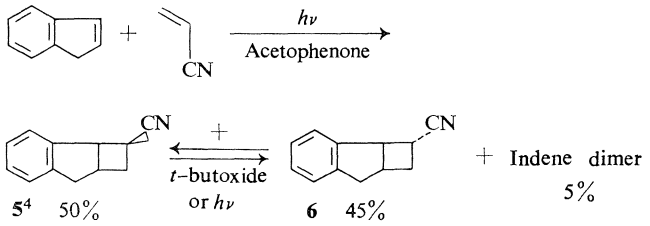
Acrylonitrile is a suitable ethylene derivative to use in trapping other excited molecules in a bimolecular reaction. First, it is transparent over much of the ultraviolet spectrum, having λ_{max} (EtOH) 215.5 mμ, log ε 1.69 (15), and therefore may be present in high concentration without restricting the choice of light-absorbing partner. Also, no charge–transfer absorption is observed in solutions containing acrylonitrile and benzene ((9) and references cited), naphthalene, or indene. No ambiguities regarding the excitation process should arise in future mechanistic work with the latter hydrocarbons, cf. maleic anhydride reactions (7, 16).

Results

Schemes I, II, and IV show that both indene and naphthalene form two kinds of adducts on



Scheme I



Scheme II

photoreaction with acrylonitrile. These are (*i*) cyanocyclobutane derivatives and (*ii*) cyanoethyl derivatives of the hydrocarbons, indene and naphthalene. The behavior of these two hydrocarbons will be described separately.

Indene and Acrylonitrile

Photolysis[1] of indene and acrylonitrile in ethanol, using a mercury lamp and a Vycor filter so that indene was the sole absorbing species, led to the formation of adducts which were detected and the ratio determined by gas–liquid chromatography. Analysis of aliquots (Column A, 175°)[1] revealed three major peaks of retention times 2.5, 3.3, and 3.8 min. If the mixture was allowed to stand, the 3.8 min peak increased at the expense of the major 2.5 min component, which eventually disappeared; the change was accelerated by heating or on adding triethylamine. Accordingly, vacuum distillation of the mixture allowed purification of the 3.8 min component, b.p. 100–115°/1 mm; these fractions crystallized, m.p. 80–82° from ethanol.

This product had infrared absorption at 2240 cm^{-1} (nitrile), and in the nuclear magnetic resonance (n.m.r.)[2] spectrum, resonances appeared at 1.56, doublet (J = 7.0) area 3, (methyl); at 3.26, broad peak, area 2, (methylene); quartet at 3.52 (J = 7.0) area 1, (methine); triplet at 6.44, area 1, (vinylic); the aromatic protons gave rise to a multiplet at 7.20, area 4. This n.m.r. spectrum is consistent with structure (**2**), but some doubt remained as to the location of the cyanoethyl substituent in the indene nucleus. Since it is known that protons at C-1 and C-3 of indene can be exchanged by treatment with deuterium oxide and triethylamine (17), while the C-2 proton is unaffected, this product was treated with triethylamine and deuterium oxide in dioxan at 20°. The doublet at 3.26 had disappeared in 27 h, but there was no change in the vinylic peak, hence the cyanoethyl group is at C-3 and structure (**2**) for the 3.8 min product was confirmed.

On alumina, (**2**) isomerized to a conjugated unsaturated nitrile, m.p. 114–115°, which had infrared absorption at 2201 cm^{-1}, and the ultraviolet spectrum[3] (18) had λ_{max} (EtOH) 274 mμ, log ε 4.20. The n.m.r. of this product is consistent with structure (**4**); the allylic protons of the methyl group gave a peak at 1.99, area 3, while the four methylene protons were included in a broad multiplet centered at 2.89, area 4. The downfield region is interesting because it showed one proton of the aromatic system as a doublet of doublets (J = 6.5 and 3.0) at 8.28, well downfield from the remaining three, which gave a multiplet centered at 7.27. The downfield shift of one proton has been reported (19) in compounds related to (**4**), and its observation here assures us of the *cis* relationship of the nitrile and phenyl groups.

Isolation of the 3.3 min and the major, labile 2.5 min components was achieved by careful chromatography on silica gel. These adducts were both liquids, which had the infrared nitrile band at 2240 cm^{-1}. The major 2.5 min product isomerized cleanly to (**2**) on treatment with water and triethylamine in dioxan (17), suggesting that it was the less stable tautomer, 2-(1-indenyl)-propionitrile (**1**). The n.m.r. of this major component was in agreement with structure (**1**), and showed a resonance at 1.10, doublet (J = 7.0), area 3 (methyl); one-proton multiplets at 3.0 and

3.6 (methines); one-proton multiplets at 6.35 and 6.88 (vinylic), and the aromatic protons gave multiplets at 7.25 and 7.59, total area 4.

The component of retention time 3.3 min was difficult to obtain pure, and the n.m.r. alone was not of great value in assigning the structure. It was possible to exclude the benzonorbornene system, as no resonances at high field (<2.0 p.p.m.) were observed (20). The n.m.r. did resemble[1] the spectra of the two adducts of the sensitized addition, although it was not identical with either of them; since the latter were subsequently shown to be cyclobutane derivatives we assign structure (**3**) to the 3.3 min adduct, but do not specify the stereochemistry of the cyano group.

Turning now to the products of the sensitized addition of indene and acrylonitrile, gas–liquid chromatography showed that three products, none of which was formed in the direct irradiation were produced, and these had retention times of 1.7, 2.0, and 8.0 min (Column A, 200°). Separation of the three components was readily achieved on a column of alumina; the 8.0 min product which was eluted first was identified as the product of sensitized dimerization of indene, m.p. 109–110°, lit. 109.5–111° (*4b*).

The two nitrilic adducts had m.p. 70° and m.p. 50°, and both showed a band in the infrared at 2240 cm^{-1}. They were interconverted by treatment with potassium *t*-butoxide in *t*-butyl alcohol, showing that they were epimers. The n.m.r. spectra (see Table I) were difficult to interpret, but were consistent with cyclobutane structures rather than benzonorbornenes (20). Their photochemical behavior also supports the cyclobutane structure for these adducts, and in addition, allows an assignment of the location of the nitrile group. Irradiation of either of the nitriles through Vycor resulted in formation of a mixture of the two. This reaction is interpreted by the mechanism shown in Scheme III. Excitation followed by uncoupling of the C_1—C_7 bond (numbering as shown), rotation about the C_6—C_7 bond, and closure to regenerate the four-membered ring seems to be a reasonable sequence. The photolytic isomerization would not occur by this

mechanism if the nitrile group were at C-6, and the reaction therefore allows us to place the substituent at C-7. Hence these products are the *cis*- and *trans*-isomers of 7-cyano-2,3-benzobicyclo[3,2,0]hept - 2 - ene. Prolonged irradiation caused other products to form, probably via decomposition of the cyclobutane derivative to indene and acrylonitrile (21, 22).

Related adducts were prepared by addition of 1,1-dimethylindene and 1,1-diphenylindene with acrylonitrile. The former were obtained either on sensitization or direct irradiation, the latter by direct irradiation. Some of their properties are summarized in Table I, in which data for the indene–acrylonitrile adducts is also given. Consideration of the n.m.r. data allows a tentative assignment of nitrile group stereochemistry in these derivatives.

First, the methine proton resonance at lowest field (close to 4.0 p.p.m.) was shown to be that of H-1, the benzylic methine. 3-Deuterio-1,1-diphenyl-indene was prepared[1] and in the n.m.r. of the adduct with acrylonitrile (B″) no signal was observed at 4.18 p.p.m. This shows that the 4.18 peak is due to H-1 in this adduct. In Table I it can be seen that adducts A and A′ have the H-1 resonance at somewhat lower field than the corresponding epimers, B and B′. This probably means that H-1 is *cis* to the cyano group in A and A′, since the deshielding effect of this group should be stronger for a vicinal proton on the same side of the four-membered ring.[5] Consistent with this argument is the fact that the H-1 signal in A′ is essentially a doublet (J = 6.5 c.p.s.), while B′ has this signal as a broad quintet. In the case where H-1 is *cis* to the cyano group, it will strongly couple to one other proton H-5, and J will be a vicinal *cis*- coupling constant.[6] Examination of models[7] shows that in this isomer the dihedral angle between the bonds to H-1 and H-7 is close to 90°, and should cause negligible coupling of these protons (25*a*).

On the other hand, the structure in which H-1 and the cyano group are *trans* will have H-1 *cis*-coupled to two vicinal protons H-5 and H-7, and the signal from H-1 should be more complex than a doublet. Hence on the basis of these features in the n.m.r. spectra, adducts B, B′, and B″ are assigned the *cis*-configuration of the five-membered ring and the cyano group.

It was considered that equilibration studies might help in assigning the stereochemistry, and adducts (A) and (B) were equilibrated with *t*-butoxide. The ratio of A:B was 30:70 at 25°, corresponding to a small free energy difference of 0.5 kcal/mole, and was of no help in settling the stereochemical problem.

Naphthalene and Acrylonitrile

The photo-additions of naphthalene and indene to acrylonitrile in which the hydrocarbon absorbs radiation are interesting in that analogous products are formed in the two reactions. Photolysis (Pyrex filter) of naphthalene and acrylonitrile in ethanol or *tert*-butyl alcohol gave two peaks when subjected to gas–liquid chromatography (Column A, 175°) of retention times 2.4 and 2.8 min. The ratio of the peak areas varied with conditions, but was approximately 1:9 for short photolysis times. The two components were separated by chromatography on silica gel. The component giving the 2.4 min peak appeared to be a mixture of 1-naphthyl- and 2-naphthyl-2-propionitrile, as the n.m.r. had two methyl signals (doublets), two methine resonances (quartets), and complicated signals in the aromatic region. 2-(1-Naphthyl)-propionitrile prepared by methylation of 2-(1-naphthyl)-acetonitrile with sodium amide (26) and methyl iodide had methyl, methine, and aromatic proton resonances corresponding to one set of peaks in the n.m.r. of the 2.4 min component. From the latter a crystalline compound, m.p. 64–66° from ethanol, was isolated which gave rise to the second set of n.m.r. peaks, and clearly is 2-(2-naphthyl)-propionitrile.

The component of retention time 2.8 min was obtained as a single compound m.p. 98–99°. This product had infrared absorption at 2235 cm^{-1}, and the mass spectrum showed a molecular ion of *m/e* 181. The ultraviolet spectrum had λ_{max} (EtOH) 269 mμ, log ε 3.91 with some absorption to longer wavelength than 300 mμ, suggesting that the aromatic ring was conjugated with a double bond.[8]

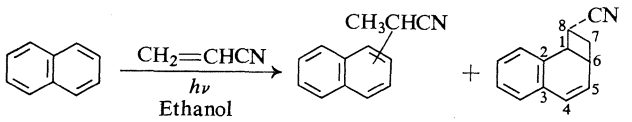
---

[5]In the nuclear magnetic resonance (23) of 2-methylacrylonitrile, the signals of the two vinyl protons are reported at 5.73 and 5.82 p.p.m., the latter is assigned to the proton *cis*- to the nitrile group.

[6]Steinmetz, Hartmann, and Schenck (24) give *cis* vicinal coupling constants ranging from 6.7–11.5 c.p.s. for a series of cyclobutane derivatives.

[7]Courtauld Atomic Models, available from Griffin and George Ltd., Wembley, Middlesex, England.

[8]The spectrum of 1,2-dihydronaphthalene has λ_{max} (EtOH) 259 mμ, log ε 3.98 (27).



8 and **9** **7**

Scheme IV

The n.m.r. spectrum ($CDCl_3$) at 100 Mc.p.s. showed a multiplet at 7.14, area 4, (aromatics), a multiplet at 3.54, area 3, (methines), and a multiplet at 2.65, area 2 (methylenes).

In the vinyl region, two doublets (J = 5 c.p.s.) appeared at 6.63 (area 1) and at 5.93 (area 1). The doublet at higher field showed some further splitting, and spin decoupling demonstrated that this was due to coupling with the protons of the methylene group. Thus, irradiation of the 2-proton multiplet at 2.65 caused the higher-field doublet to become much sharper. Structure (**7**) is consistent with the spectral data. The vinyl protons would be coupled with J_{cis} for ethylene, which is in the 6–14 c.p.s. range (25*b*). The higher-field doublet, assigned to the vinyl proton at C-5 might reasonably be expected to be coupled to a proton[9] at C-7, but not to protons at C-8. The spin-decoupling experiment therefore demonstrates that the methylene group is at C-7. This adduct is 8-cyano-2,3-benzobicyclo[4,2,0]-octa-2,4-diene (**7**) and one stereoisomer is formed, which has the *trans*-configuration, deduced from steric considerations of the unit cell packing (1*b*). Consistent with this conclusion is the observation that (**7**) could not be equilibrated with *t*-butoxide, in contrast to the cyanocyclobutanes from indene. This suggests the more stable, *trans*-structure for (**7**). Comparison of space-filling models[3] of *cis*-(**7**) and the *cis*-adduct of indene (**5**), shows that *cis*- (**7**) is the more strained due to steric interaction of the aromatic ring with the cyano group, and this could account for the difference in equilibrium position in the two systems.

Finally, it should be mentioned why the n.m.r. data point to the cyclobutane structure for (**7**) rather than an isomeric benzobicyclo[2,2,2]octadiene derivative. First, as stated above, the ultraviolet spectrum of (**7**) is very similar to 1,2-dihydronaphthalene (27). Second, it is difficult to see why a cyano-compound derived from benzobicyclo[2,2,2]octane would not isomerize on equilibration with strong base. Third, the n.m.r. spectrum is not consistent with the latter structure.[10]

The adduct (**7**) when irradiated at 253.7 mμ or with a Corex filter transmitting above 250 mμ, decomposed to naphthalene (and presumably, acrylonitrile).

No reaction was observed on attempted (acetophenone) sensitization of the naphthalene–acrylonitrile addition.

Discussion

We will consider first the preparative value of some of the reactions reported in the Results section. Scheme I shows two indene derivatives which are readily obtained by this photochemical route; they are (**2**) and (**4**). If the 3-substituted indene (**2**) is the desired product, the photolysis mixture is evaporated, then heated or treated with an amine to convert (**1**) to (**2**), and distilled. If the unsaturated nitrile (**4**) is required, the mixture after being heated is chromatographed slowly on alumina. The less stable indene derivative (**1**) and the cyclobutane (**3**) can also be obtained, but their isolation requires careful work or recovery is poor. It is to be noted that neither of the cyclobutane derivatives formed by sensitized addition were found in the direct photolysis.

The products of triplet sensitization (**5**) and (**6**) are efficiently produced by the reaction in Scheme II, and their separation is not troublesome. These comments also apply to the products of the addition of 1,1-dimethylindene and acrylonitrile, which are the same in the direct and sensitized reactions.

From the naphthalene–acrylonitrile reaction, the cyclobutane derivative (**7**) may be obtained by using a Pyrex filter in the photolysis. If excitation is by shorter wavelength light e.g. using a Corex

[9]Snyder and Franzus (28) report 4-bond coupling in 7-substituted norbornenes between the olefinic and *anti*-7 protons ($J \sim 0.8$ c.p.s.).

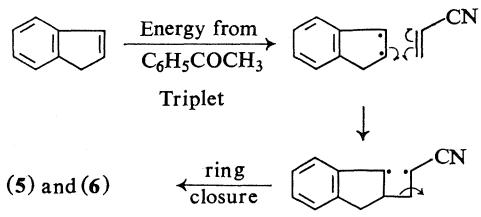
[10]For example, the bridgehead protons of benzobicyclo[2,2,2]octadiene are further downfield (3.91) than any methine resonance in this adduct. Also the splitting of the vinyl resonances is inconsistent with the bicyclo-[2,2,2]octane system (29).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

filter, the mixture of substituted naphthalenes (**8**) and (**9**) can be prepared.

No mechanistic studies of these photoreactions have been made so far, but such work will be reported in a future paper. However, we wish to make the following observations on the mechanistic aspects of the photo-additions described above.

The products of the triplet sensitized reaction of indene and acrylonitrile are in accord with other triplet state addition reactions such as the dimerization of indene (4) and additions of dienes and halogenated ethylenes (3). A reasonable biradical mechanism depicted in Scheme V



Scheme V

consists of energy transfer from the triplet state of the sensitizer (acetophenone) to the indene, followed by attack of indene triplet on acrylonitrile to produce the more stable biradical (30), which can close to a four-membered ring forming both epimers, as observed.

It seems likely that the sequence in the direct irradiation of indene (Scheme I) is initiated by a singlet excited state of the hydrocarbon.[11] In support of this is the observation that indene (and naphthalene) fluorescence is quenched efficiently by acrylonitrile (31) and the rate constant for the bimolecular quenching process (k_q) is similar to that reported by Hammond *et al.* (14) using dienes as quenchers, k_q being 10^8–10^9 l mole^{-1}s^{-1}. We may use this rate constant to estimate the rate of intersystem crossing for the indene singlet. Two of the processes competing for the latter in a steady state are (*i*) intersystem crossing and (*ii*) bimolecular capture by acrylonitrile. Since we do not observe the products of triplet addition in the direct irradiation, we will assume that they are formed in 1% yield, (this being an upper limit). Ignoring other processes such as fluorescence and radiationless decay of the triplet, the following equation holds to an approximation:

$$\frac{\text{Amount triplet products}}{\text{Amount singlet products}} \leqslant \frac{1}{100} = \frac{k_{ic}\ s^{-1}}{k_q[\text{Acrylonitrile}]s^{-1}}$$

where k_{ic} is the intersystem crossing rate constant for indene, k_q is the bimolecular quenching constant for indene singlet, and the acrylonitrile concentration is in square brackets. Setting $k_q = 10^8$ l mole^{-1} s^{-1}, and [Acrylonitrile] = 1 mole/l, this gives k_{ic} of 10^6 s^{-1}. This figure is of the same order as the estimated value for naphthalene, 1.5–4.4 × 10^6 s^{-1} (32). It appears then that the sluggish intersystem crossing and the high rate of singlet capture excludes the formation of products of triplet reaction.

The nature of later processes in the transformations leading to substituted indenes (and naphthalenes) is unknown. At first it was thought that the labile hydrogens of the indene methylene group might be involved, but since naphthalene undergoes a similar reaction, considerable doubt is thrown on this explanation. Mechanistic routes being considered as possibilities are concerted 1,3- and 1,5-hydrogen shifts, or such shifts in biradical intermediates, and intervention of the solvent acting as a proton donor.

Finally, it should be mentioned that the substituted indene derivatives may arise by photo-initiated, free radical chain reactions. This type of pathway seems unlikely, since none of the latter products are formed on heating indene and acrylonitrile with benzoyl peroxide, but a free radical mechanism cannot be rigorously excluded at present.

Experimental

The nuclear magnetic resonance spectra were obtained with a Varian HA-100 or A-60 spectrometer. The chemical shifts are δ values (p.p.m.) measured downfield from tetramethylsilane (δ = 0) as internal standard. Infrared spectra were run on a Beckman IR-5 or on a Perkin–Elmer 521 instrument and ultraviolet spectra were determined on a Cary model 14 spectrophotometer. Mass spectra were measured on a Hitachi Perkin–Elmer MRU 6 instrument. Gas–liquid chromatography was performed with a Varian 204B dual column instrument with 35 ml/min helium, using column A (5 ft × $\frac{1}{8}$ in. 5% SE-30 on Chromosorb W). Melting points were taken on a Kofler hot stage and are uncorrected.

[11]The ultraviolet absorption spectra of indene and naphthalene were unchanged by the addition of 0.47 *M* acrylonitrile. Although ground-state complexes are probably formed, cf. benzene and acrylonitrile, references cited in (9), the hydrocarbon is the absorbing species. We thank a referee for bringing the benzene–acrylonitrile case to our attention.

Nitrogen was Canadian Liquid Air certified grade and was further purified by successive passage through vanadous sulfate solution (33), concentrated sulfuric acid, and potassium hydroxide pellets.

Alumina used was Absorption, Fisher Alumina and the silica gel was Grace, 923 (100–200 mesh).

Unless specifically stated, all column chromatography was performed with a 2.5 × 90 cm column, slurry-packed in 10% benzene–hexane. Elution was begun with this mixture, and the benzene concentration was increased 5% for every additional liter of eluant; 250 ml fractions were collected.

Yields in photolysis reactions are not absolute yields, but are based on unrecovered hydrocarbon starting material.

Indene was J. T. Baker, Practical Grade, twice distilled, b.p. 65°/15 mm. Naphthalene (Fisher Reagent) was crystallized twice from benzene and had m.p. 79–80°. Acrylonitrile was Eastman Practical Grade, distilled four times, b.p. 75–76°. Acetophenone (Eastman Reagent) was distilled and had b.p. 87–90°/15 mm. Solvents were distilled before use.

Deuterium oxide was obtained from Columbia Organic Chemicals, Inc., and was specified at 99.7% D_2O. 1,1-Diphenylindene was prepared as described previously (34) and 3-deuterio-1,1-diphenylindene was obtained using sodium borodeuteride (Merck, Sharp and Dohme of Canada Ltd.) in the reduction of 3,3-diphenyl-1-indanone.

Microanalyses were by the Sprang Microanalytical Laboratory, Ann Arbor, Michigan.

Photo-condensation of Indene and Acrylonitrile

Indene (2.0 g; 0.0172 mole) and acrylonitrile (20.0 g; 0.377 mole) in 95% ethanol (400 ml) were stirred and purged with nitrogen for 30 min prior to and during the 2 h photolysis. The latter was carried out using a Hanovia type L 450W lamp in a conventional quartz immersion apparatus, which had an outlet for withdrawing aliquots. A Vycor sleeve was used. Gas–liquid chromatography of aliquots showed that three products were formed, having retention times (Column A, 175°) 2.5, 3.3 and 3.8 min, labelled **1**, **2**, and **3** respectively in the ratio 70:10:20 as measured from peak areas. After the 2 h photolysis, the mixture was filtered through silica gel to remove a small amount of polymer, and the solvent and residual indene were removed under vacuum at room temperature. The mixtures from nine such runs were combined and the three components were separated by chromatography on a 2.5 × 90 cm column of silica gel, slurry-packed in 10% benzene–hexane, using the gradient elution procedure described above. The fractions were monitored by gas–liquid chromatography. Fractions 1–6 contained indene (0.5 g); fractions 10–18 contained (**1**) 2.03 g; fractions 20–24 contained (**1**) and (**3**), 0.197 g; 25–29 were mixtures of (**2**) and (**3**), 1.297 g, and 30–37 contained (**2**) 0.807 g, m.p. 80.5–81.5° from ethanol.

Fractions 25–29 were combined and chromatographed on a 4.0 × 90 cm column of silica gel, slurry-packed in 50% benzene–hexane, and eluted with this solvent, 250 ml fractions being collected. Fractions 9–22 contained (**3**), 0.883 g, and 27–41 contained (**2**), 0.313 g. By this procedure (**1**) was obtained as an oil, 2.03 g; 21.6%, identified as 2-(1-indenyl)-propionitrile. Component (**2**) had m.p. 80.5–81.5°, 1.22 g; 13.0%, and was shown to be 2-(3-indenyl)-propionitrile as described in the Results section.

Anal. Calcd. for $C_{12}H_{11}N$: C, 85.17; H, 6.55; N, 8.28. Found: C, 85.35; H, 6.38; N, 8.35.

Compound (**3**) was also an oil, 1.08 g; 11.5%, which had a nitrile band at 2240 cm^{-1}, and the nuclear magnetic resonance (n.m.r.) spectrum (100 M c.p.s.) which had at 7.23, mult. area 4 (aromatics); 3.83, broad peak area 1 (benzylic methine) and at 2.00, mult. area 1 (alicyclic methylene). The remaining proton signals were superimposed in a complex multiplet from 2.50–3.50 p.p.m. This resembled the spectra of the sensitized reaction products. Also, the mass spectrum of (**3**) was almost identical with the spectra of the latter products, having a weak molecular ion, *m/e* 169, a base peak, *m/e* 116 (100) and a second strong peak, *m/e* 115 (35). From these comparisons, (**3**) is identified as 6-cyano-2,3-benzobicyclo[3,2,0]hept-2-ene.

*Isomerization of 2-(1-Indenyl)-propionitrile (**1**)*

Treatment of (**1**) (0.1 g; 0.0006 mole) with triethylamine (1.0 g) (17) in water (1.0 ml) and dioxane (5.0 ml) for 12 h was followed by the addition of water and ether, and separation of the ether layer, which was washed with saturated salt (NaCl) solution, and dried ($MgSO_4$). Evaporation of the solvent afforded 2-(3-indenyl)-propionitrile (**2**), 0.9 g (90%), m.p. 80.5–81.5° (from ethanol).

*Deuteration of (**2**)*

The procedure of Bergson (17) was followed. To a solution of (**2**) (50 mg) in dioxane (5.0 ml) was added 2 ml of a 1:1 mixture of deuterium oxide and triethylamine. The mixture was stirred at 25° for 27 h, when the reaction was poured into water, and immediately extracted with ether. The ether layer was washed with salt (NaCl) solution, and dried ($MgSO_4$). The n.m.r. of the residue on evaporating the ether showed a vinylic proton peak at 6.44 but the benzylic methylene peak 3.26 p.p.m. had disappeared, confirming the structure 2-(3-indenyl)-propionitrile for (**2**).

*Isolation of 2-(3-Indenyl)-propionitrile (**2**) by Distillation*

If (**2**) is the desired product in the above photolysis, the ethanol is distilled at atmospheric pressure, and the residue is then distilled at 2.0 mm. From 11.0 g of photolysis mixture, distillation gave 5.27 g of 2-(3-indenyl)-propionitrile, b.p. 100–115°/1 mm, m.p. 80–81°, from ethanol.

Isomerization of 2-(3-Indenyl)-propionitrile on Alumina

A solution of 2-(3-indenyl)-propionitrile (0.5 g) in benzene was left on a 2.5 × 30 cm column of alumina for one week. The column was eluted with 3 l of benzene to obtain 0.42 g (84%) of needles, m.p. 114.5–115° (from benzene–hexane). This was identified[12] as 2-(1-indanylidene)-propionitrile (**4**).

---

[12]C. K. Ingold and J. F. Thorpe (35) ioslated a compound by elimination of the carbethoxyl group from ethyl 2-(3-indenyl)-2-cyanopropionate, for which they reported m.p. 118°, and assigned it the structure 2-(3-indenyl)-propionitrile (**2**). We have repeated their experiments, and have found that their product is identical with the nitrile m.p. 114.5–115°, to which we assign structure (**4**).

Anal. Calcd. for $C_{12}H_{11}N$: C, 85.17; H, 6.55; N, 8.28. Found: C, 84.97; H, 6.58; N, 8.22.

Acetophenone Sensitized Photolysis of Indene and Acrylonitrile

Acetophenone (5.0 g; 0.0417 mole), indene (5.0 g; 0.0431 mole), and acrylonitrile (15 g; 0.283 mole) in ethanol (400 ml) were photolyzed as above, with a Corex filter. After the 3 h photolysis, the solvent and most of the residual starting materials were distilled. The residue was chromatographed on alumina by the above general procedure. Fractions 1–5 contained indene dimer (0.11 g), m.p. 109–110°, lit. (46) m.p. 109.5–111°. Fractions 7–14 contained (**6**), 0.90 g, m.p. 48.5–50° from benzene–hexane, identified as *trans*-7-cyano-2,3-benzobicyclo[3,2,0]hept-2-ene (A in Table I).

Anal. Calcd. for $C_{12}H_{11}N$: C, 85.17; H, 6.55; N, 8.28. Found: 85.08; H, 6.54; N, 8.22.

Fractions 19–26 contained (**5**), 0.44 g, m.p. 70.5–72° from benzene–hexane, identified as *cis*-7-cyano-2,3-benzobicyclo[3,2,0]hept-2-ene (**5**) (B in Table I).

Anal. Calcd. for $C_{12}H_{11}N$: C, 85.17; H, 6.55; N, 8.28. Found: C, 85.29; H, 6.60; N, 8.28.

Fractions 15–18 were mixtures of (**5**) and (**6**) total 0.475 g, which were separated by further chromatography on a 2.5 × 30 cm column of alumina, eluted with the usual benzene–hexane mixtures. Fractions 4–11 contained 0.115 g of (**6**), while 0.360 g of (**5**) was found in fractions 14–21.

The ratios reported in Scheme II were measured by gas–liquid chromatography (Column A, 200°) on the photolysis solution before work-up. Retention times were (**6**), 1.7 min; (**5**), 2.0 min and indene dimer 8.0 min.

*Base-catalyzed Epimerization of the 7-Cyano-2,3-benzobicyclo[3,2,0]hept-2-enes (**5** and **6**)*

Under a blanket of nitrogen, (**5**) (the *cis*-isomer) (0.8 g; 0.00473 mole) in tetrahydrofuran (10 ml) was added to potassium *t*-butoxide, from *tert*-butyl alcohol (30 ml) and potassium (1.0 g). The mixture was stirred at room temperature, and aliquots were withdrawn at 15 min intervals. These were added to dilute hydrochloric acid, and ether extracted. The ether solution was washed with salt (NaCl) solution, and dried ($MgSO_4$). This solution was monitored by gas–liquid chromatography (Column A, 200°). The same peaks as are obtained in the photolysis of retention times 1.7 and 2.0 min were observed, and an equilibrium was reached in 1 h. No change in ratio occurred in 48 h, and after this time the reaction was quenched with dilute HCl, and ether extracted. The mixture obtained on ether evaporation was chromatographed on alumina (2.5 × 30 cm column). The usual benzene–hexane mixtures were used as eluant; fractions 3–8 contained the *trans*-isomer (**6**), 0.23 g, m.p. 48–50°. The *cis*-isomer (**5**) was eluted in fractions 11–20, 0.56 g, m.p. 71–72°. The gas–liquid chromatographic *cis*:*trans* ratio at equilibrium was 70:30. An identical experiment was performed using pure (**6**), the *trans*-isomer, as starting material, and the same equilibrium mixture was obtained.

Photo-epimerization of the 7-Cyano-2,3-benzobicyclo-[3,2,0]hept-2-enes

A solution of the *cis*-compound, **5** (0.5 g, 0.003 mole) in ethanol (400 ml) was irradiated with the 450W Hanovia lamp, fitted with a Vycor sleeve. The progress of the reaction was followed by gas–liquid chromatography (g.l.c.) (Column A, 200°). In 9 h a photostationary state of *cis*/*trans* ratio 45/55 appeared to be reached. This ratio did not change on 12 h photolysis, but the g.l.c. showed slow decomposition of (**5**) and (**6**) resulting in the appearance of several other peaks.

An identical run, starting with 0.5 g, 0.003 mole of the *trans*-isomer (**6**) gave the same stationary state composition, measured by g.l.c., which was apparently reached more quickly (3 h) than with the *cis*-compound.

Photo-addition of 1,1-Dimethylindene and Acrylonitrile

1,1-Dimethylindene (2.0 g; 0.014 mole) (36) and acrylonitrile (3.7 g, 0.07 mole) in ethanol (400 ml) were irradiated (Vycor sleeve) in the usual apparatus for 6 h. The solvent was distilled and the products from five of these runs were combined and chromatographed on alumina. Fractions 7–18 contained A′ (Table I), 1.176 g, needles m.p. 70.5–72°, from benzene–hexane. This was assigned the structure *trans*-7-cyano-4,4-dimethyl-2,3-benzobicyclo[3,2,0]hept-2-ene.

Anal. Calcd. for $C_{14}H_{15}N$: C, 85.24; H, 7.66; N, 7.10. Found: C, 85.37; H, 7.79; N, 6.99.

Fractions 24–37 contained 1.16 g of B′, m.p. 58–59°, needles from benzene–hexane, identified as the *cis*-isomer, as described in the Results section.

Anal. Calcd. for $C_{14}H_{15}N$: C, 85.24; H, 7.66; N, 7.10. Found: C, 85.35; H, 7.76; N, 6.93.

Fractions 19–23 were mixtures of the two isomers, total 0.98 g which were further chromatographed on a 2.5 × 30 cm column of alumina to obtain 0.49 g of *cis*- and 0.49 g of *trans*-isomer.

The *cis*:*trans* ratio in the photolysis was measured by g.l.c. (Column A, 200°) and was approximately 40:60.

Acetophenone Sensitized Photo-addition of 1,1-Dimethylindene and Acrylonitrile

Acrylonitrile (3.7 g; 0.07 mole), 1,1-dimethylindene (2.0 g; 0.014 mole), and acetophenone (2.0 g; 0.0167 mole) in ethanol were photolyzed with the Hanovia lamp and a Corex filter for 5.5 h.

The solutions from five such reactions were combined, the solvent and residual starting materials distilled, and the mixture chromatographed on alumina as in the previous experiment to obtain 4.60 g of *cis*-adduct and 2.94 g of *trans*-compound, identical with the products of the direct photolysis by m.p. and n.m.r. and infrared spectra.

Photoaddition of 1,1-Diphenylindene and Acrylonitrile

Acrylonitrile (20.0 g; 0.377 mole) and 1,1-diphenylindene (1.349 g; 0.00503 mole) (34) in ethanol (400 ml) were photolyzed in the usual way (Vycor filter) for 2 h. After solvent evaporation, the mixture was chromatographed on a 4.0 × 90 cm column of alumina, slurry-packed in 10% benzene–hexane. The column was eluted with 2 l of 10%, 2 l of 20%, 2 l of 30% benzene–hexane and finally with 4 l of benzene, and 250 ml fractions were collected. Fractions 5–13 contained 1,1-diphenyl-indene 360 mg, m.p. 90–92° (from light petroleum, b.p. 80–110°).

Fractions 31–34 contained a nitrile adduct infrared band at 2420 cm^{-1}, 300 mg, m.p. 219–222° (from ethyl

acetate). This had a molecular ion of *m/e* 321, and is assigned the structure *cis*-7-cyano-4,4-diphenyl-2,3-benzobicyclo[3,2,0]hept-2-ene (B″) from the n.m.r. spectrum (Table I).

Anal. Calcd. for $C_{24}H_{19}N$: C, 89.68; H, 5.96. Found: C, 89.33; H, 6.11.

Preparation of 1-deuterio-B″

3-Deuterio-1,1-diphenylindene (1.45 g; 0.00542 mole) and acrylonitrile (20.0 g; 0.377 mole) in ethanol (400 ml) were photolyzed and chromatographed as above to afford 1-deuterio-B″ 137 mg, m.p. 220–222°. The quintet at 4.18 in the n.m.r. spectrum of B″ (Table I) was absent from the spectrum of 1-deuterio-B″, identifying the quintet as the resonance of H-1 in this adduct.

Photo-condensation of Naphthalene and Acrylonitrile

Acrylonitrile (2.0 g; 0.0377 mole) and naphthalene (0.1 g; 0.00078 mole) in *tert*-butyl alcohol (80 ml) (under nitrogen at 30°) were irradiated through Pyrex with the Hanovia 450W lamp for 40 min. Gas–liquid chromatography (Column A, 175°) showed two peaks at 2.4 and 2.8 min, in the ratio of 8:92 respectively. The mixtures from five such reactions were evaporated and combined, and the mixture was chromatographed on a 2.5 × 30 cm column of silica gel, slurry-packed in benzene. The column was eluted with benzene, and 250 ml fractions were collected. Fractions 1–3 contained naphthalene (0.286 g); fractions 4–20 contained 0.461 g of naphthalene and 3 mg of the 2.4 min product separated by sublimation. The latter was identical with the product from photolysis using a Corex filter or longer photolysis times and is described in the next experiment. Fractions 23–36 contained the 2.8 min product, 50 mg, m.p. 98–99° from ether. This is assigned the structure *trans*-8-cyano-2,3-benzobicyclo[4,2,0]octa-2,4-diene (**7**), from the data described in the Results.

Anal. Calcd. for $C_{13}H_{11}N$: C, 86.15; H, 6.12; N, 7.73. Found: C, 86.19; H, 6.14; N, 7.82.

Attempted Sensitization of the Naphthalene–Acrylonitrile Reaction with Acetophenone

Naphthalene (0.5 g; 0.00391 mole), acrylonitrile (10.0 g; 0.189 mole), and acetophenone (5.0 g; 0.0417 mole) were photolyzed through Pyrex for 4 h. Much polymer was formed, but no products were observed by g.l.c. (Column A, 175°).

Identification of the 2.4 Min Component

Photolysis of naphthalene (0.5 g; 0.00391 mole) and acrylonitrile (10 g; 0.189 mole) in ethanol (400 ml) with a Pyrex sleeve for 2.5 h (use of a Corex sleeve for 2 h gave similar results) gave a solution containing much polymer. This appeared after 40 min and was not observed in the previous small scale reactions. The polymer was removed by filtration (7.6 g), and the mixtures from ten reactions were combined and chromatographed on a 2.5 × 90 cm column of silica gel, slurry-packed in and eluted with benzene, 250 ml fractions being collected. Fractions 1–4 contained naphthalene 0.599 g, m.p. 79°. Fractions 6–19 were the 2.4 min component 0.239 g; 20–28 were a mixture of the 2.4 min component and (**7**), 0.616 g, while fractions 26–42 were pure (**7**), 1.743 g, m.p. 98°. Fractions 6–19 were combined, dissolved in the minimum volume of ethanol and kept in the refrigerator for several days. Crystals were deposited which were filtered and recrystallized from ethanol and had m.p. 64–66°. This compound had peaks at 7.58 p.p.m. mult., area 7 (aromatics); 3.92, quartet, area 1 (methine); 1.67, doublet, area 3 (methyl). This compound is assigned the structure 2-(2-naphthyl)-propionitrile from the n.m.r. spectrum and by its non-identity with authentic 2-(1-naphthyl)-propionitrile (26).

Anal. Calcd. for $C_{13}H_{11}N$: C, 86.15; H, 6.12; N, 7.73. Found: C, 86.00; H, 6.18; N, 7.59.

The mother liquors from the above crystallization were mainly 2-(1-naphthyl)-propionitrile, having peaks at 7.55, mult., area 7 (aromatic); 4.49, quartet, area 1 (methine), and at 1.72, doublet, area 3 (methyl). This n.m.r. was identical with that of an authentic sample, prepared by methylation of (1-naphthyl)-acetonitrile (26), which had b.p. 136–138/0.5 mm, lit. b.p. 125–127°/0.5 mm (26). The ratio of the 1- and 2-substituted naphthalenes formed in the photolysis was 2:1, estimated from the n.m.r. spectrum of the mixture.

Photolysis of trans-8-Cyano-2,3-benzobicyclo[4,2,0]-octa-2,4-diene (7)

A solution of the cyano compound (**7**) (80 mg, 4.42×10^{-4} mole) in ethanol (80 ml) was photolyzed for 10 min using a low-pressure Hanovia 87A-45 mercury lamp (Vycor envelope) giving 95% of the radiation at 253.7 mμ. On distillation of the solvent, and sublimation of the residue, 54 mg (95%) of naphthalene were obtained, m.p. and mixed melting point 78.5–79.5°.

Attempted Base-catalyzed Epimerization of trans-8-Cyano-2,3-benzobicyclo[4,2,0]octa-2,4-diene (7)

The adduct (**7**) (100 mg) in *tert*-butyl alcohol (10 ml) was added under nitrogen to potassium *t*-butoxide from potassium (1.0 g) and *tert*-butyl alcohol (20.0 ml). The mixture was stirred at 60° for 5 h, poured into cold acid (HCl), ether extracted, and the extracts dried ($MgSO_4$). Gas–liquid chromatography (Column A, 175°) did not show any peaks other than starting material. The solution was filtered through silica gel, and a quantitative recovery of starting material (**7**), m.p. 98–99° was obtained. A similar experiment was conducted as above, with a reflux time of 20 h. Gas–liquid chromatography showed no new peaks, but it was observed that the starting material gradually disappeared, and no identifiable material was isolated from the experiment.

Effects of Added Acrylonitrile on the Ultraviolet Absorptions of Indene and Naphthalene

The ultraviolet spectra of the following solutions were examined (1 mm path length) using the Cary 14 spectrometer.

(a) Naphthalene (0.125 g; 9.765×10^{-4} mole) in in ethanol, (to make 100 ml).

(b) Naphthalene (0.125 g; 9.765×10^{-4} mole), and acrylonitrile (2.5 g; 4.7×10^{-2} mole) in ethanol (to make 100 ml).

(c) Indene (0.05 g; 4.3×10^{-4} mole) in ethanol (to make 100 ml of solution).

(d) Indene (0.05 g; 4.3×10^{-4} mole) and acrylonitrile (0.5 g; 9.43×10^{-3} mole) in 100 ml ethanol solution.

The spectra of *(a)* and *(b)* were identical, as were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.29.10 on 08/31/12
For personal use only.

those of *(c)* and *(d)*, the absorption being measured from 200–800 mμ. No long wavelength band appeared on adding acrylonitrile to the hydrocarbon. Dilution of these solutions to allow measurement of the molar absorbance at the hydrocarbon λ_{max} showed that acrylonitrile had no effect on either of these properties.

Some metabolites of *Alternaria solani* [1,2]

A. STOESSL
Research Institute, Canada Department of Agriculture, London, Ontario
Received August 19, 1968

Pigments isolated from culture filtrates and mycelia of *Alternaria solani* were shown to be 5-hydroxy-7-methoxy-2-methylanthraquinone (**1**, 2-methylxanthopurpurin-7-methylether), 7-methoxy-2-methyl-3,4,5-trihydroxyanthraquinone (**2**), 3,5-dihydroxy-7-methoxy-2-methylanthraquinone (**3**, macrosporin), 7-methoxy-2-methyl-1,2,3,4,5-pentahydroxy-1,2,3,4-tetrahydroanthraquinone (**5**, altersolanol A) and 7-methoxy-2-methyl-1,2,3,4-tetrahydro-2,3,5-trihydroxyanthraquinone (**8**, altersolanol B). **3** has been described previously and may have chemotaxonomic significance. Compounds **5** and **8** represent a new type of naturally occurring, reduced anthraquinone.

Canadian Journal of Chemistry, **47**, 767 (1969)

Alternaria solani, a pathogen of solanaceous plants (2) which produces alternaric acid (3, 4), has been reported (3, 5) to yield also an antibiotically active substance, of unelucidated structure, together with some ill-defined pigments (5). Ergosterol and a dihydro-coenzyme Q have also been isolated (6), but little further knowledge of the mold's chemistry appears to be available. An interest in this Institute in phytotoxins led to the re-isolation of alternaric acid as a reference compound and thus gave an opportunity for a fresh examination of the culture filtrates and mycelia.

The antibiotic substance described earlier (5) could not be detected, possibly because a different strain of mold or different cultural conditions were employed, but five pigments were isolated and characterized (Table I). Two of them, altersolanol A and altersolanol B, represent a new type of naturally occurring, reduced anthraquinone while the three others are classical anthraquinones into which the altersolanols can be transformed. These interrelations in turn facilitated the structural studies on each. Thus all five compounds exhibit bands in their nuclear magnetic resonance (n.m.r.) spectra which can be assigned to an aromatic methoxyl group and a pair of *meta*-coupled aromatic protons, while the infrared spectra show absorption due to chelated phenol and both chelated and free quinone carbonyl groups. Since these bands account completely for the aromatic moiety of the altersolanols (see below), it is evident that all five compounds contain the same ring system (AB).

The simplest compound of the series is anthraquinone A, $C_{16}H_{12}O_4$. Its n.m.r. spectrum (Table II) shows signals, in addition to those already discussed, which can be assigned to one chelated phenol ($\tau -2.87$, subject to deuterium exchange) in (AB); and to three aromatic protons (in a 1,3,4 relation) and an aromatic *C*-methyl group arranged as in part structure (C). Evidence on hand from studies on anthraquinone B, indicates that fragment (C) is to be attached to (AB) in the sense implied by the numbering. Structure **1** for anthraquinone A follows and was confirmed by synthesis. Selective methylation at the 7-position of the readily accessible 2-methylxanthopurpurin (**1***a*) (7) gave **1** which was shown to be identical with anthraquinone A in every respect.

Anthraquinone B, $C_{16}H_{12}O_6$, has only one proton directly attached to the moiety (C) (Table II). This absorbs as a slightly broadened singlet (long-range coupling to the methyl group) at comparatively low field (deshielding by carbonyl). Three phenolic protons are manifested as a broad band at $\tau -2.5$ to -0.8 and can be attributed to system (D). As required by the catechol moiety present in this system, the pigment, alone of the five studied, gives an olive-brown color with ferric chloride. Anthraquinone B must therefore have structure **2**. This conclusion was verified when exhaustive methylation of the pigment gave a compound with the melting point and ultraviolet spectrum reported for 3,4,5,7-tetramethoxy-2-methylanthraquinone (**2***a*) (8).

Incomplete methylation of anthraquinone B led to the isolation of a small amount of the dimethyl ether (**2***b*), which shows three methoxyl groups in the n.m.r. spectrum (Table II) and a deuterium-exchangeable proton absorbing at

τ −3.4. Isolation of the same substance from a different precursor (see following communication (9)) allows placement of the phenolic hydroxyl at the 4-position rather than the 5-position. The melting point of **2***b* suggests that it is identical with the by-product, m.p. 220°, isolated by Briggs and regarded as a dihydroxydimethoxy compound (8).

Anthraquinone C, $C_{16}H_{12}O_5$, was too insoluble even in dimethyl sulfoxide to allow obtention of its n.m.r. spectrum. However, it furnished a soluble diacetate (**3***a*) which exhibits two broadened singlets which must be assigned to two weakly (i.e., *para*-) coupled protons on ring C. Since this ring must also accommodate one of the acetate groups and a *C*-methyl group, the pigment has structure **3**, already known as that of macrosporin (10*a–d*). Its identity with this compound was confirmed by the ultraviolet spectrum (10*a*) and by the preparation of the mono- and dimethylethers (**3***b* and *c* respectively) (10*b*). The pigment and its three derivatives were found to have melting points a few degrees higher than those reported, but all four compounds gave infrared spectra which match those published in the literature (10*a,b*).

Altersolanol A, which is optically active, has an ultraviolet spectrum resembling those of some naphthoquinones without oxygen substituents on the quinone double bond (e.g., 2-carbomethoxymethyl-3-methyl-5,7,8-trimethoxynaphthoquinone (11) and the quinone A methyl ether[3] obtained from protaphin (12)). Elemental analysis and integration of the n.m.r. spectrum gave its constitution as $(C_{16}H_{16}O_8)_n$. On acetylation in the presence of perchloric acid, it afforded a highly crystalline and chloroform-soluble pentaacetate which was shown to have the constitu-

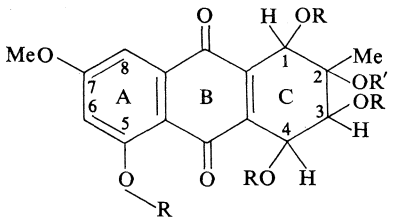
tion $C_{26}H_{26}O_{13}$ by elemental analysis and a molecular weight determination. Mild alkaline hydrolysis of this derivative regenerated appreciable amounts of altersolanol A of unchanged optical rotation; therefore, neither skeletal rearrangements nor disruption into two identical fragments had intervened and the parent compound must also be monomeric ($n = 1$).

The n.m.r. spectrum of altersolanol A (in hexadeuteriodimethyl sulfoxide) shows broadened signals from four alcoholic hydroxyl groups at τ 5.8 to 4.9 and a sharp singlet (1H, chelated phenol) at τ −2.17, which vanish on deuteration or acetylation. An aromatic methoxyl group (3H, singlet, τ 6.13) and a pair of *meta*-coupled aromatic protons (doublets, 1H each, J[4] 2.5 Hz, centered at 3.07 and 3.28) are accommodated by part structure (AB). A broadened singlet (1H, τ 5.62) and a pair of doublets (1H each, $J \sim 7$ Hz, centered at τ 5.46 and 6.32) are shifted downfield by acetylation; together with the only remaining signal, a singlet (3H, τ 8.69) corresponding to an aliphatic methyl group deshielded by a geminal oxygen atom, they require assignment as in part structure (E). All the atoms of the pigment are now accounted for. On heating *in vacuo* at moderate temperatures, altersolanol A was dehydrated to two anthraquinones. The major product, which was also obtained as a by-product of the deacetylation of the pentaacetate, is identical with anthraquinone B (**2**). The minor product could be characterized only by its spectroscopic properties (Table II and Experimental) but these left no doubt that it is 7-methoxy-2-methyl-1,3,5-trihydroxyanthraquinone (**4**). These facts establish that altersolanol A has structure **5**, which also accounts for the following observations.



(**5**, R = R′ = H)
(**5***a*, R = COMe, R′ = H)
(**5***b*, R = R′ = COMe)

Acetylation of altersolanol A in pyridine gave a tetraacetate (**5***a*),[5] further acetylable to the pentaacetate (**5***b*),[5] whose properties (exchangeable alcoholic proton at τ 7.12 not coupled to vicinal hydrogen) require the presence of a tertiary hydroxyl group. Oxidation of altersolanol A with

[4]J = apparent coupling constant = observed splitting throughout this paper.

[5]The nuclear magnetic resonance spectra of these compounds will be considered in detail in the following communication (9).

sodium periodate furnished almost one mole-equivalent each of formic and acetic acids. Attempted methylation with diazomethane led to several benzindazoles of which only one, **6** or an isomer, was obtained in substantial amounts. One of the minor products is the corresponding 4-desmethyl compound; the two others appear to be isomers of **6**.

The addition of diazomethane to naphthoquinones is well known (13) and, in the present instance, presumably is followed by an elimination of the type illustrated in Scheme I. This view is supported by the following observations. First, apart from the brightly colored indazoles, the reaction also yielded a colorless, intractable product which was very soluble in water and which furnished an equally unworkable mixture of precipitates on addition of 2,4-dinitrophenylhydrazine. Secondly, altersolanol A pentaacetate also reacted with diazomethane but gave only a single, colorless product. This compound is the adduct (**7** or equivalent structure) by elemental analysis and spectroscopic data (see Experimental). Acetylation has evidently blocked the dealdolization possible in altersolanol A itself. As required by this postulate, compound **7** reacted rapidly with dilute sodium hydroxide at

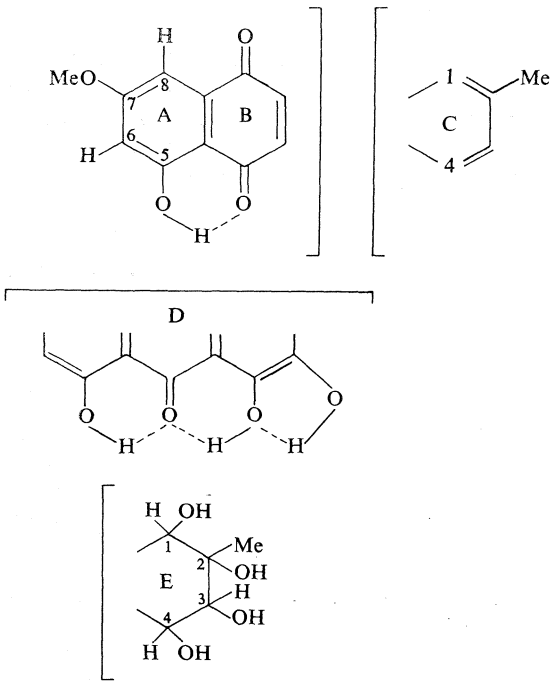
room temperature, to afford a mixture of yellow benzindazoles. These lacked *C*-methyl and acetoxyl groups and on methylation with diazomethane, gave the 4-desmethyl compound mentioned above, as major product.

The stereochemistry of altersolanol A, and further coincidental correlations with its cometabolites, will be discussed in the following communication (9).



Altersolanol B was found to have the constitution $C_{16}H_{16}O_6$, with two oxygen atoms fewer than altersolanol A, but resembles the latter in the ultraviolet spectrum. On aromatization with thionyl chloride in pyridine, it furnished anthraquinone A (**1**). Assignment of structure **8** to altersolanol B follows from the following further evidence: The n.m.r. spectrum (in hexadeuteriodimethyl sulfoxide), with bands at τ −2.12 (1H, s, exchangeable), 3.08 and 3.29 (1H each, d, *J* 2.75 Hz) and 6.12 (3H, s), and the infrared spectrum (KBr; 1679 (free CO), 1635 (chelated CO) and 1619 (aromatic) cm^{-1}) confirm the presence of part structure (AB). Other bands in the n.m.r. spectrum correspond to two alcoholic hydroxyl groups (τ 5.33 and 5.65, 1H each, broad, exchangeable), a deshielded *C*-methyl (τ 8.80, 3H, s) and —C*H*(OH)— (τ 6.75, 1H, m). The only remaining signal is a multiplet (4H?, partly submerged under solvent peak) at τ 7.27 to 7.62 which evidently represents two methylene groups in similar environments. Acetylation gave altersolanol B triacetate (**8***a*) which lacks protons readily exchangeable for deuterium. The n.m.r. spectrum of this compound, in deuteriochloroform, can be assigned as follows: τ 2.52 (1H, d, *J* 2.75 Hz; H-8), 3.22 (1H, d, *J* 2.75 Hz; H-6), 6.06 (3H, s; ArOMe), 7.59 (3H, s; ArOAc), 7.93 (3H, s; ROAc), 8.02 (3H, s; ROAc), and 8.42 (3H, s; C_2—Me). The essentially equivalent methylene groups at C-1 and C-4 again absorb as a complex multiplet in the relatively narrow range τ 6.67 to 7.33, while only the resonance of the proton assigned to C-3 has been moved downfield to τ 4.67 (1H, multiplet approximating a triplet).

As a by-product of the acetylation, there was isolated altersolanol B-2,3-diacetate (**8***b*) which was probably formed from **8***a* by facile hydrolysis of the reactive 5-acetoxyl during work-up. The free phenol at C-5, chelated to the carbonyl group, was easily detected in the ultraviolet and infrared spectra. Further hydrolysis, *via* a monoacetate which was not isolated, regenerated **8**.

Location of the secondary hydroxyl group in altersolanol B at C-4 rather than C-3 would have been more attractive on biogenetic considerations. Unfortunately, insufficient purified pigment was available to allow investigation of this point by degradative studies. However, the assignment to C-3 is strongly supported by a comparison of the relevant resonance positions in altersolanol A and B derivatives, as in Table III. Further confirmation of the vicinal diol system at C_2—C_3 in altersolanol B was obtained by the ready formation of an isopropylidene derivative (**9**) which, in analogy with altersolanol A acetonide (see following communication (9)) presumably has a dioxolane rather than dioxane structure. This also requires that the hydroxyl groups should be *cis* to one another. A complete analysis of the rather complex n.m.r. spectrum of this substance will be undertaken in the near future;[6] it is hoped that this will confirm the assigned structure and throw light on the possible conformations of altersolanol B and its derivatives.

[6]Dr. J. B. Stothers of the University of Western Ontario has kindly consented to undertake this analysis.

[a]As in Table II.
[b]Described in the following communication (9).
[c]Hexadeuteriodimethyl sulfoxide was used as solvent.

Macrosporin (**3**), earlier isolated from *A. porri* (10*a*), has recently also been obtained from cultures of *A. cucumerina* by Dr. A. N. Starratt of this Institute.[7] It may have chemotaxonomic significance since it does not appear to have been found in other fungal genera or plants. Pigments **2** and **1** do not appear to have been found in nature before, although the corresponding phenols, (**2***a*) and 2-methylxanthopurpurin (**1***a*) respectively, have been isolated but only from higher plants (7, 8). The altersolanols are clearly closely related to their co-metabolites since they have the same ring A and a *C*-methyl group in the biogenetic 2-position. It is indeed possible that **2** is formed from altersolanol A, and **1** from altersolanol B, by dehydration brought about enzymatically or by acid catalysis within the mold tissue.[8]

The question arises whether the altersolanols in turn could have been formed from anthraquinone precursors. While this may be the case, it is at least equally probable that **5** and **8** are on branches of the metabolic pathway leading to macrosporin. It is generally accepted (15) that fungal anthraquinones are biosynthesized from acetate and malonate but the detailed sequence of condensation, dehydration, and hydroxylation steps is not well known. For this reason, a thorough investigation of altersolanol biogenesis might be of general significance.

[7]Dr. A. N. Starratt. Private communication.
[8]The compounds are unlikely to be artifacts generated during work-up; extraction conditions, with temperatures not exceeding 80°, were too mild to dehydrate **5** and **8** which could be dried for several days at 100° without apparent damage.

*As in Table II.

Experimental

Analyses were by Dr. C. Daesslé, Montreal. Melting points were taken on the Köfler stage and infrared spectra with a Perkin–Elmer 21 spectrophotometer. Ultraviolet spectra, in 96% ethanol, were determined with a Beckman DK instrument. Nuclear magnetic resonance (n.m.r.) spectra (tetramethylsilane (TMS) as internal reference) were obtained on Varian A60 and A60A spectrometers with, where necessary, the use of a Varian C1024 computer. Compounds were deuterated, either by shaking their solution in deuteriochloroform with deuterium oxide, or by precipitation from hexadeuteriodimethyl sulfoxide with deuterium oxide. The latter method was convenient for compounds insoluble in chloroform but soluble in anhydrous dimethyl sulfoxide. Rotations were measured optically with a 1-dm path length. Petroleum ether was of b.p. 40–70°. Evaporations were done at the pressure of the water pump. Analytical and preparative thin-layer chromatography (t.l.c.) was on silica gel (Camag DMF) with methanol – chloroform – 90% formic acid (2:98:2) as the most useful irrigant; others are noted as required.

Growth and Harvesting of Alternaria solani

An alternaric acid producing strain of *A. solani* (P. W. Brian's strain No. 408 (3)) obtained from the American Type Culture Collection, Rockeville, Maryland, as ATCC No. 11078, has been maintained by Mr. C. H. Unwin in this Institute since 1962. It was used in the usual manner to inoculate 70 Roux bottles, each containing 150 ml of Brian's medium T (10% glucose, casein hydrolyzate and mineral salts (16)), which were then kept at 25° in the dark for 18 days. The mycelial mats were filtered off, squeezed dry, and washed twice by suspending in water and filtering. The compressed filtered cake was broken up and dried in air at 80° to give 206 g of product sufficiently dry to be ground to a coarse powder in a mortar.

Isolation of Pigments from Culture Filtrates

The culture filtrates and washings (pH ca. 5.6) obtained above were extracted continuously during 3 days with ethyl acetate distilling under reduced pressure from a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

suitably connected reservoir (2 l, bath temperature ca. 55°) in which the extracts were also collected. After concentration to approximately 1 l, the extracts were washed with sodium hydrogen carbonate solution (5%; 100 and 50 ml) and water (3 × 50 ml). The aqueous phases were reextracted in turn with several portions of ethyl acetate, the ethyl acetate layers were bulked and concentrated to about 300 ml. Essentially homogeneous altersolanol A (2.44 g) crystallized out. The mother liquors were evaporated to dryness and the residue (2.85 g) distributed between water (3 × 500 ml) and chloroform (3 × 500 ml). A little methanol was added to the first funnel to aid solution. The chloroform layers were combined, evaporated to dryness and the residue redistributed in a similar manner. The combined aqueous layers were concentrated to half-volume and extracted 5 times with equal volumes of ethyl acetate which gave another 1.02 g of essentially homogeneous altersolanol A on evaporation. The chloroform layers were concentrated and chromatographed on thin layers of silica gel (200 plates 20 × 20 cm) in the usual solvent. Well-separated bands corresponding, in order of decreasing R_f, to pigments **1** (about 10 mg), **2** (30 mg), and **3** (96 mg) were collected, moistened with dilute hydrochloric acid, and eluted with chloroform. The coalesced bands extending from the origin were similarly eluted and the product rechromatographed in methanol – chloroform – 90% formic acid (4:96:2) to give crude altersolanol B (148 mg) and at least 8 other incompletely resolved pigments (183 mg) which were not further examined.

When the culture filtrates were extracted by shaking with ethyl acetate at room temperature, essentially similar results were obtained but the yield of altersolanol A was reduced. When chloroform was used (3) instead of ethyl acetate, pigments **1**, **2**, **3**, and **8** were isolated but not altersolanol A. In contrast to the main experiment, these two runs yielded crystalline alternaric acid from the sodium hydrogen carbonate fraction.[9]

Isolation of Pigments from the Mycelium

The ground mycelium was extracted in a Soxhlet apparatus with petroleum ether during 5 days, to give an oil (18.4 g, ν_{max} (liquid) 1748 cm^{-1}), contaminated with only traces of pigments, which was not further examined. Extraction was continued for 10 days with ethyl acetate containing methanol (5–15%). The extracts (ca. 1 l) were filtered from precipitated solids which were refluxed with five successive portions (250 ml each) of methanol – ethyl acetate (1:4), to leave an olive-brown powder (4.8 g, not investigated). The combined ethyl acetate extracts were evaporated, the residue was suspended in petroleum ether, filtered off, and washed with more of the solvent. Filtrate and washings yielded an oil (35.7 g) essentially identical (infrared spectrum) with that obtained earlier. The solids (17.5 g) were Soxhlet-extracted for 5 days with benzene, the material which separated on cooling the extract was returned to the thimble, and extraction was continued for 3 days with chloroform (1.5 l, replaced by fresh solvent after 1 day with return of precipitated solids to the thimble). The residue in the thimble was combined with the solid which separated on cooling the second chloroform extract and was crystallized twice from pyridine to give pigment **3** (3.55 g) and mother liquor A.

The benzene extracts were evaporated to dryness, the residue was dissolved in chloroform (1.5 l) and stirred with basic magnesium carbonate (200 g). After filtration, chromatography of the material from the filtrates on silica gel (BDH; 100 g) gave pigment **1** (107 mg, eluted by benzene and chloroform–benzene (5:95) and further purified by preparative t.l.c.). The column was then stripped with acetone containing a little acetic acid, to give eluate A.

The chloroform Soxhlet extracts were treated with magnesium carbonate (several portions) as above. Evaporation of the filtrates gave **3** (1.10 g).

The filter cakes of magnesium carbonate from the preceding paragraphs were dissolved in a slight excess of 6 *N* hydrochloric acid. The precipitated pigments were combined with mother liquor A and eluate A, evaporated, and chromatographed on silica gel (BDH; 800 g). 0.5 l fractions were collected. Fractions 11–20 (benzene) contained pigment **1** (11 mg); benzene–chloroform (1:1) eluted **2** (0.685 g, fractions 32–46), a mixture A of **2** and **3** (fractions 47–55), and **3** (0.79 g, fractions 56–61). The column was then stripped with acetone containing a little acetic acid and methanol. On concentration, the eluate deposited **2** and **3** (mixture B). The mother liquors, on preparative t.l.c., gave more **2** (46 mg) and mixtures containing very small to trace amounts of **3** and at least eight other pigments. Analysis of mixtures A and B, by t.l.c. and spectrophotometry, showed that they contained 177 mg of **2** and 351 mg **3**.

Anthraquinone A (1)

Recrystallized from acetic acid, **1** had m.p. 184–185°; $\lambda\lambda_{max}$ 409, 279, 261, 252 and 226 mμ (log ε 3.71, 4.23, 4.23, 4.25 and 4.12); ν_{max} ($CHCl_3$) 3400–2400 (broad, chelated OH), 1676 (s, free CO), 1635 (vs, chelated CO) and 1610 (vs, aromatic) cm^{-1}.

Anal. Calcd. for $C_{16}H_{12}O_4$: C, 71.63; H, 4.51. Found: C, 71.58; H, 4.35.

Synthesis

2-Methylxanthopurpurin was prepared as in the literature (7) and further characterized by its n.m.r. spectrum (Table II). On methylation with diazomethane in ether–methanol (repeated addition of reagent until all starting material had been consumed), it gave **1**, identified by m.p., mixture m.p., t.l.c., infrared, and ultraviolet spectra.

Anthraquinone B (2)

Recrystallized from pyridine, the pigment had m.p. 267–268°; $\lambda\lambda_{max}$ 425, 312, 280, and 229 mμ (log ε 4.03, 4.00, 4.43, and 4.36); ν_{max} (KBr) 3480 (s), 1665 (m), and 1622 (vs) cm^{-1}.

Anal. Calcd. for $C_{16}H_{12}O_6$: C, 64.00; H, 4.03. Found: C, 63.67; H, 3.79.

The substance (100 mg) was methylated as described by Briggs (8) but reaction time was extended to 2.5 h, additional dimethyl sulfate (0.2 ml in 1 ml acetone) being added twice. The product (**2***a*) was extracted from water with ethyl acetate and crystallized on concentration. Recrystallized from chloroform–ethanol or acetic acid, it had m.p. 180–181.5°; $\lambda\lambda_{max}$ 367, 276, and 223 mμ (log ε 3.71, 4.36, and 4.34); ν_{max}(KBr) 1673 (s) and 1602 (vs)

[9]I thank Dr. G. A. White for informing me of this result.

For personal use only.

cm^{-1} (ref. (8) gives m.p. 181–182°; $\lambda\lambda_{max}$ 367, 278, and 225.5 mμ (log ε 3.80, 4.45, and 4.39)).

Anal. Calcd. for $C_{19}H_{18}O_6$: C, 66.85; H, 5.01. Found: C, 66.84; H, 5.04.

In methylation experiments in which literature conditions were followed precisely, a more complex product was obtained which was separated by preparative t.l.c. into **2***a* and a second major product (**2***b*). **2***b*, recrystallized from acetic acid, had m.p. 222–223°; $\lambda\lambda_{max}$ 418, 300 (sh), 274, and 226 mμ (log ε 4.04, 4.07, 4.49, and 4.54); ν_{max}(KBr) 1668 (m), 1632 (s), and 1600 (vs) cm^{-1}.

Anal. Calcd. for $C_{18}H_{16}O_6$: C, 65.84; H, 4.91. Found: C, 65.92; H, 4.81.

*Anthraquinone C (**3**)*

Recrystallized from pyridine, the substance had m.p. 308–316° (sealed capillary, decomp. with prior charring; lit. (10*a*) m.p. 300–302°); $\lambda\lambda_{max}$ 379, 305, 284, 251 (inf), and 225 mμ (log ε 3.74, 4.03, 4.45, 4.03, 4.00, and 4.23).

Anal. Calcd. for $C_{16}H_{12}O_5$: C, 67.60: H, 4.25; O, 28.14. Found: C, 67.30; H, 4.07; O, 28.37.

The pigment (30 mg) was acetylated overnight at 5° with acetic anhydride (2 ml) containing 70% perchloric acid (3 drops). The product (**3***a*) crystallized from chloroform–ethanol with m.p. 213–216° (lit. (10*a*), m.p. 209–210°) and $\lambda\lambda_{max}$ 331 and 270 mμ (log ε 3.71 and 4.67).

Anal. Calcd. for $C_{20}H_{16}O_7$ (mol. wt., 368.4): C, 65.21; H, 3.99. Found (mol. wt., (osmometer) 338): C, 64.90; H, 4.15.

Methylation with diazomethane in methanol–ether until reaction was complete, gave macrosporin monomethylether (**3***b*), crystallized from chloroform–ethanol; m.p. 211–214° (lit. (10*b*, *c*), m.p. 209–210°); $\lambda\lambda_{max}$ 410 (inf), 377, 308, 281, and 225 mμ (log ε 3.83, 4.12, 4.56, and 4.35).

Anal. Calcd. for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73. Found: C, 68.53; H, 4.63.

Methylation with dimethyl sulfate in acetone as described in the literature (9*a*) gave the dimethyl ether (**3***c*), m.p. 270–271° (lit., m.p. 260–261°).

Altersolanol A

The substance was obtained free of an impurity by recrystallization from dioxane. It had m.p. 218–218.5° (capillary; charring from 205°); $\lambda\lambda_{max}$ 422, 268, 240, and 219 mμ (log ε 3.65, 4.15, 3.96, and 4.57) and λ_{inf} 285 mμ (log ε 3.84); ν_{max}(KBr) 3650–3000, 1671 (m), 1635 (s), 1603 (vs) and 1595 (vs) cm^{-1}; $[\alpha]_D^{23°}$ −292° (*c*, 0.25 in pyridine).

Anal. Calcd. for $C_{16}H_{16}O_8$: C, 57.14; H, 4.80; O, 38.06; OCH_3, 9.23. Found: C, 56.70, 56.79; H, 4.85, 4.90; O, 38.41; OCH_3, 11.95.

Altersolanol A Pentaacetate

Altersolanol A (76 mg) was added to ice-cold acetic anhydride (5 ml) containing a few drops of 70% perchloric acid. After 2 h in the refrigerator, the solution was poured on ice, the product extracted into ethyl acetate and crystallized from ethanol. Recrystallized it had m.p. 169–173°; $\lambda\lambda_{max}$ 383, 268, and 210 mμ (log ε 3.41, 4.34, and 4.51); ν_{max}(CCl_4) 1750 (vs), 1669 (s) and 1603 (vs) cm^{-1}; $[\alpha]_D^{23°}$ −108° (*c*, 0.25 in chloroform).

Anal. Calcd. for $C_{26}H_{26}O_{13}$ (mol. wt., 546.5): C, 57.14; H, 4.80; O, 38.06. Found (mol. wt., 534 (Mechrolab osmometer; in chloroform, with benzil as reference)): C, 56.89; H, 4.57; O, 38.41.

A suspension of the pentaacetate (85 mg) in 0.05 *N* aqueous sodium hydroxide was stirred under nitrogen at room temperature until solution was complete (ca. 4 h) and then for a further 3 h. After addition of a slight excess of 0.05 *N* hydrochloric acid, the product was extracted, first with 2 portions of chloroform, then with ethyl acetate until the aqueous layer was almost colorless. The chloroform extracts (17 mg) were found by t.l.c. to contain some starting material and several colored products. A major component, corresponding to pigment **2** (2.6 mg), was isolated by preparative t.l.c. and identified by m.p. and mixture m.p. The combined ethyl acetate extracts contained altersolanol A (8.5 mg) which was isolated similarly and identified by m.p., mixture m.p., infrared, and ultraviolet spectra. Its specific rotation was identical with that of altersolanol A within the experimental error.

Altersolanol A Tetraacetate

Altersolanol A (67 mg) in ice-cold pyridine (3 ml) was treated with acetic anhydride (2 ml) and allowed to warm to room temperature. After 2 days, the solution was poured on ice and extracted with ethyl acetate. The major product, isolated by preparative t.l.c., was obtained microcrystalline by careful addition of petroleum ether to its solution in ether. It had m.p. 188–192° (capillary, prior charring); $\lambda\lambda_{max}$ 380, 266, and 210 mμ (log ε 3.44, 4.34, and 4.46); ν_{max}(CCl_4) 3600 (sharp), 3500 (broad), 1755, 1752 (vs), 1666 (s), and 1604 (vs) cm^{-1}; $[\alpha]_D^{23°}$ −84° (*c*, 0.25 in chloroform).

Anal. Calcd. for $C_{24}H_{24}O_{12}$: C, 57.14; H, 4.80. Found: C, 57.38; H, 4.82.

Periodate Degradation of Altersolanol A

The pigment (35.5 mg; 0.106 millimole) was shaken with 0.02 *M* aqueous sodium periodate (25 ml; 0.50 millimole) at room temperature for 48 h, when the solution was distilled to dryness *in vacuo* at room temperature. The distillate, collected at −70°, was rendered slightly alkaline with 0.10 *N* sodium hydroxide, concentrated to 4 ml, acidified (0.5 ml 1.0 *N* sulfuric acid) and distilled at atmospheric pressure and constant volume until no more acid passed over. The distillate was carefully neutralized (1.95 ml 0.100 *N* sodium hydroxide; 0.195 millimole) and evaporated to dryness. The n.m.r. spectrum of the product in deuterium oxide, with TMS as external reference, had bands only at τ 7.27 (singlet) and 3.48 (singlet) of relative area 3:1.07. The salts obtained by evaporating a mixture of 0.98 ml 0.100 *N* sodium formate and 0.98 ml 0.100 *N* sodium acetate gave singlets at 7.28 and 3.48 of relative area 3:1.04. The authentic mixture was indistinguishable from the degradation product by t.l.c. (cellulose; *n*-propanol – concentrated ammonium hydroxide 3:2; silver nitrate spray).

Sublimation of Altersolanol A

The pure pigment (42.6 mg) was sublimed in a high vacuum at 120–130° during 17 days, an almost black residue (17 mg) remaining. The orange sublimate was crystallized from pyridine to give **2** (12 mg), identified by m.p., mixture m.p., t.l.c., and infrared and ultraviolet spectra. The mother liquors, on preparative t.l.c., gave more of the substance (4 mg), material which remained at the origin, and a pigment ((**4**), ca. 2 mg crude yield) which,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

after recrystallization from petroleum ether, had m.p. 179–181°; $\lambda\lambda_{max}$ 428, 300 (sh), 275, 256, and 227 mμ (log ε 3.91, 3.91, 4.17, 4.19, and 4.39). The infrared spectrum ($CHCl_3$) exhibited a single band in the carbonyl region at 1612 cm^{-1} (shoulders at 1629 and 1597 cm^{-1}). In addition to the resonances listed (Table II), the time-averaged n.m.r. spectrum had sharp singlets (1 H each) at τ −3.00 and −2.93. The expected signal from a further phenolic hydroxyl group (at C-3) could not be observed, probably because of broadness.

Reaction of Altersolanol A with Diazomethane

Successive portions (10 ml at a time) of ethereal diazomethane were added to altersolanol A (200 mg) in methanol (10 ml) at room temperature until the starting material had been consumed (t.l.c.). After evaporation to dryness, the product was distributed between chloroform (10 ml, 5 ml) and water (3 × 5 ml). Evaporation of the aqueous layers furnished a brown lac (99 mg) which was treated with 2,4-dinitrophenylhydrazine in dilute hydrochloric acid. The precipitated solid was separated by t.l.c. into numerous components but none accrued in amounts sufficient for investigation.

The combined chloroform layers (140 mg) on preparative t.l.c. gave four yellow bands which furnished crystalline residues on elution and evaporation: A, 6.4 mg; B, 3.3 mg; C, 50.3 mg; D, 6.9 mg (in order of increasing polarity).

Indazole A, recrystallized from chloroform–ethanol, had m.p. 212–215°; $\lambda\lambda_{max}$ 416, 290 (sh), 266, 262, and 223 mμ (log ε 3.72, 4.01, 4.31, 4.30, and 4.45); ν_{max}(KBr) 1678 (s, free CO), 1634 (vs, chelated CO) and 1615 (sh, aromatic) cm^{-1}; n.m.r. data, Table IV. Methylation (dimethyl sulfate/potassium carbonate in refluxing acetone) gave indazole C, identified by t.l.c., m.p., and mixture melting point.

Indazole B, recrystallized from benzene, melted indistinctly above 190°; $\lambda\lambda_{max}$ 401, 270, and 215 mμ (E_{1cm}(1%) 157, 605, and 785); ν_{max}(KBr) 1665 (vs, 2 free CO) and 1600 (vs, aromatic) cm^{-1}; n.m.r. data, Table IV.

Indazole C was recrystallized from chloroform as orange needles, m.p. 214–215.5°; $\lambda\lambda_{max}$ 406 and 263 mμ (log ε 3.58 and 4.33); ν_{max}(KBr) 1671 (s, free CO), 1651 (s, free CO) and 1589 (vs, aromatic) cm^{-1}; n.m.r. data, Table IV.

Anal. Calcd. for $C_{14}H_{12}N_2O_4$: C, 61.76; H, 4.44; N, 10.29; two OCH_3, 22.81. Found: C, 61.99; H, 4.57; N, 10.07; OCH_3, 20.86.

The substance was recovered unchanged from acetic anhydride – perchloric acid.

Indazole D, recrystallized from aqueous acetic acid, sublimed without melting at 275–285°. It had $\lambda\lambda_{max}$ 391, 270, 255, and 220 mμ (log ε 3.63, 4.37, 4.26, and 4.29); ν_{max}(KBr)1683 (m, free CO), 1672 (s, free CO) and 1599 (vs, aromatic) cm^{-1}; n.m.r. data, Table IV.

Anal. Calcd. for $C_{14}H_{12}N_2O_4$: N, 10.29. Found: N, 10.07.

Reaction of Altersolanol A Pentaacetate with Diazomethane

To the pentaacetate (50 mg) in methanol (10 ml) was added an ethereal solution of diazomethane (10 ml) at room temperature. Reaction was complete after 15 min (t.l.c.). The homogeneous product crystallized on evaporation and trituration under ether and was recrystallized from methanol – ether – light petroleum ether, to give colorless needles, m.p. 145–156°; $[\alpha]_D^{23°}$ +200° (*c*, 0.25 in $CHCl_3$); $\lambda\lambda_{max}$ 322, 275 (sh), and 250 mμ (log ε 3.59, 4.02, and 4.38); ν_{max}($CHCl_3$) 1760 (vs, acetate), 1692 (s, free CO) and 1608 (vs, aromatic) cm^{-1}; τ 2.34 and 2.97 (lH each, d, *J* 2.5 Hz; H-8 and H-6 respectively), 3.03 (lH, s; H-1), 4.10 and 5.42 (lH each, d, *J* 18 Hz; —CH_2—N=N—), 4.26 and 5.28 (1H each, d, *J* 9.5 Hz; H-4 and H-3 respectively), 6.02 (3H, s; $ArOCH_3$), 7.68 (3H, s; $ArOCOCH_3$), 7.93, 7.95, and 7.96 (3H each, s; 3 $ROCOCH_3$), 8.26 (3H, s; shielded $ROCOCH_3$) and 8.48 (3H, s; C—CH_3).

Anal. Calcd. for $C_{27}H_{28}N_2O_{13}$: C, 55.10; H, 4.80; N, 4.76. Found: C, 55.22; H, 4.97; N, 4.97.

To a solution of the compound (10 mg) in ethanol (2 ml) was added sodium hydroxide (1 *N*; 2 ml) with the immediate appearance of a deep orange color. After 16 h (no noticeable change) the solution was acidified and extracted with ethyl acetate. The extracts were washed with water and evaporated. The n.m.r. spectrum of the yellow product showed absorption from aromatic protons and methoxyl but none attributable to acetate or *C*-methyl. The substance was dissolved in methanol – ethyl acetate (1:1, 4 ml) and treated with ethereal diazomethane (4 ml) for 10 min. Evaporation and isolation of the main product by preparative t.l.c. gave indazole A (2 mg), identified by m.p., mixture m.p., t.l.c., and infrared spectrum. One of the two minor products was indistinguishable from indazole C by chromatographic behavior.

Altersolanol B

The pigment crystallized from ethanol as lustrous red-brown plates, m.p. 228–230°; $\lambda\lambda_{max}$ 421, 285, 265, and 217 mμ (log ε 3.58, 3.97, 4.14, and 4.52); ν_{max} (KBr)3490, 3420, 1679 (m), 1635 (s), 1619 (s), and 1599 (m) cm^{-1}.

Anal. Calcd. for $C_{16}H_{16}O_6$: C, 63.15; H, 5.30; O, 31.55. Found: C, 63.12; H, 5.14; O, 32.01.

Acetylation of Altersolanol B

Altersolanol B (35 mg), suspended in acetic anhydride (2 ml) at ice temperature, was treated with 3 drops of 70% perchloric acid and kept overnight at 5°. The product was poured on ice, extracted with chloroform and separated by preparative t.l.c. into yellow and orange components (23 and 9 mg respectively).

The yellow substance was recrystallized from chloroform–ethanol to give altersolanol B triacetate; m.p. 182–185°; $\lambda\lambda_{max}$ 379, 348, and 265 mμ (log ε 3.39, 3.36, and 4.38); ν_{max}($CHCl_3$) 1768 (m), 1735 (vs), 1660 (vs) and 1605 (vs) cm^{-1}; $[\alpha]_D^{23°}$ −44° (*c*, 0.25 in $CHCl_3$).

Anal. Calcd. for $C_{22}H_{22}O_9$: C, 61.39; H, 5.15; O, 33.46. Found: C, 61.30; H, 5.05; O, 33.32.

The orange substance, on recrystallization from aqueous acetic acid, gave altersolanol B diacetate, m.p. 141–145°; $\lambda\lambda_{max}$ 423, 282, 267, and 217 mμ (log ε 3.62, 3.96, 4.15, and 4.54); ν_{max}($CHCl_3$) 3300–2600 (broad, chelated OH), 1734 (vs), 1660 (m), 1644 (s), and 1615 cm^{-1}.

Anal. Calcd. for $C_{20}H_{20}O_8$: C, 61.85; H, 5.19. Found: C, 61.92; H, 5.25.

Hydrolysis of Altersolanol B Triacetate

The triacetate (8 mg) was refluxed in a mixture of methanol (0.45 ml), chloroform (0.45 ml), and 6 *N* hydrochloric

acid (0.1 ml) for 20 h. Evaporation of the solution and recrystallization of the residue from ethanol gave altersolanol B, identified by m.p., mixture m.p. and infrared spectrum. Monitoring of the hydrolysis by t.l.c. indicated that it proceeded in the stages: triacetate → orange diacetate → a more polar compound, presumably the 3-monoacetate → altersolanol B.

Dehydration of Altersolanol B

The compound (10 mg) in ice-cold pyridine (1 ml) was treated with 3 drops of thionyl chloride, allowed to warm to room temperature and poured into water after a further hour. The product was extracted with chloroform and isolated from minor components by preparative t.l.c. After recrystallization, it was indistinguishable from pigment **1** by t.l.c., m.p., mixture m.p., ultraviolet, and infrared spectra.

Attempted dehydration by heating *in vacuo* at 145° gave only a trace of **1** (t.l.c.), most of the sublimate corresponding to starting material.

Altersolanol B Acetonide

A suspension of altersolanol B (30 mg) in dry acetone (3 ml) containing sulfuric acid (0.11 ml) was shaken until dissolved and for a further hour. The product was poured into dilute sodium hydrogen carbonate solution, extracted with ethyl acetate and separated from a little starting material by preparative t.l.c. Recrystallization from acetone–ethanol gave the acetonide, m.p. 133–134°; $\lambda\lambda_{max}$ 425, 287, 266, and 217 mμ (log ε 3.62, 3.90, 4.11, and 4.53); $\nu_{max}(CHCl_3)$ 2800–2300 (w, chelated OH), 1660 (sh, free CO), 1640 (s, chelated CO) and 1611 (vs, aromatic) cm^{-1}; τ −2.20 (1H, s; chelated phenol), 2.83 (1H, d, *J* 2.75 Hz; H-8), 3.48 (1H, d, *J* 2.75; H-6), 5.61 (1 H, m; H-3), 6.12 (3H, s; $ArOCH_3$), 6.33–7.92 (4H, several multiplets; H-1 and H-4), 8.57 (3 H, s (sharp); R—CH_3), 8.65 and 8.78 (2 × 3 H, s (broadened); *gem*-dimethyl); $[\alpha]_D^{23°}$ −16° (*c*, 0.25 in $CHCl_3$).

Anal. Calcd. for $C_{19}H_{20}O_6$: C, 66.27; H, 5.85. Found: C, 66.20; H, 6.04.

Acknowledgments

I thank the Director, Dr. E. Y. Spencer, for support of this work, Dr. G. A. White for providing culture filtrates for preliminary investigations, C. H. Unwin for growing the mold for large scale extraction, Mrs. M. H. H. Thomson for her patient assistance with tedious separations, and G. Rock for excellent experimental support throughout.

Relative stereochemistry of altersolanol A[1]

A. STOESSL
Research Institute, Canada Department of Agriculture, London, Ontario

Received August 19, 1968

Altersolanol A (**1**) forms a monoisopropylidene derivative which in turn yields a triacetate and a dimethylether monoacetate. Both of the latter compounds can be aromatized but the products indicate that either an acyl or a methyl migration has taken place. The former possibility is considered to be much more likely. This and other considerations lead to structure **2** for altersolanol A acetonide. Analysis of the nuclear magnetic resonance spectra of **1** and **2** and their derivatives allows assignments of their relative configurations and conformations as **7** and **8** respectively.

Canadian Journal of Chemistry, 47, 777 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Altersolanol A was shown in the preceding communication (1) to be represented by **1** but its stereochemistry remained unassigned. An approach to this problem was found in the preparation of an isopropylidene derivative whose structure must be considered in some detail.

The substance, altersolanol A acetonide (**2**), has the elemental composition corresponding to the addition of C_3H_4 to altersolanol A, and an ultraviolet spectrum essentially identical with that of the parent compound. It forms a triacetate (**2***a*) on acetylation in pyridine. The nuclear magnetic resonance (n.m.r.) spectrum (Fig. 1) shows signals from a chelated phenol (τ −2.00,s), two alcohols (τ 5.75–6.05,m) and those listed in Table I. Appropriate bands can be assigned unambiguously to the naphthoquinone moiety and the C_2—methyl group familiar from **1**, and to the *gem*-dimethyl group of an isopropylidene residue. The latter group must therefore be attached in ketal form to two of the oxygen atoms on ring C. The spectrum also indicates that carbon atom C-1 is the site of a free hydroxyl group because the signal from H-1 at τ 5.14 (doublet collapsing to a characteristic broadened singlet on deuteration) undergoes a pronounced downfield shift on acetylation. A similar situation prevails with respect to the signals at τ 4.80 (approximate quartet collapsing to approximate doublet on deuteration; downfield shift on acetylation), while those at τ 5.50 are unaffected. One of these two bands must represent H-3 and the other, H-4. Because it is adjacent to the quinone ring, it is reasonable to expect H-4 to be the more deshielded proton and therefore responsible for the absorption at τ 4.80. Similar assignments of resonance position have been made in the eleutherin series (e.g., (**3**)) and for derivatives (e.g., (**4**)) of the protoaphins (2). It then follows from the properties of the bands on deuteration and acetylation that H-4 is geminal to free hydroxyl, which must therefore be placed at C-4, while the other proton is attached to one terminus of the isopropylidene bridge at C-3. The second terminus is necessarily at C-2, since all other positions are accounted for. However, it remained conceivable that one of the oxygen functions in the vicinity[2] could deshield H-3 to a resonance position lower than that of H-4 so that the assignments would require reversal. Also, an inspection of Dreiding models suggested that neither steric repulsion nor steric strain would be present in an altersolanol-2,4-acetonide to a significantly greater extent than in a 2,3-acetonide.[3] Such effects therefore could not be invoked to clarify the position and it was necessary to confirm structure **2** by more extended studies.

Partial hydrolysis of the acetonide triacetate gave altersolanol A triacetate which has acetoxyl groups at C-1 and C-5 (ultraviolet and n.m.r. spectra) and at either C-3 or C-4. A ready reaction with periodate would have implied free hydroxyls at positions-2 and -3 but, when put to the test, the compound was not attacked by periodate in aqueous acetonitrile during 24 h at room temperature. More severe conditions

[1]Contribution No. 388 from the Research Institute.

[2]I am greatly indebted to Dr. J. B. Stothers for an informative discussion on this aspect.

[3]From numerous examples (3) from carbohydrate chemistry, it appears that six-membered ketal rings fused to a pyranose are obtained only when C-6 of the sugar, which is exocyclic to the pyranose ring, is a terminus. Six-membered cyclic ketals have also been considered (4) to be unobtainable from cyclitols for steric reasons which are not necessarily applicable in the present instance. On the other hand, at least one such compound has recently been reported (5) as a derivative of a 7,9-dihydroxyanthracyclinone.

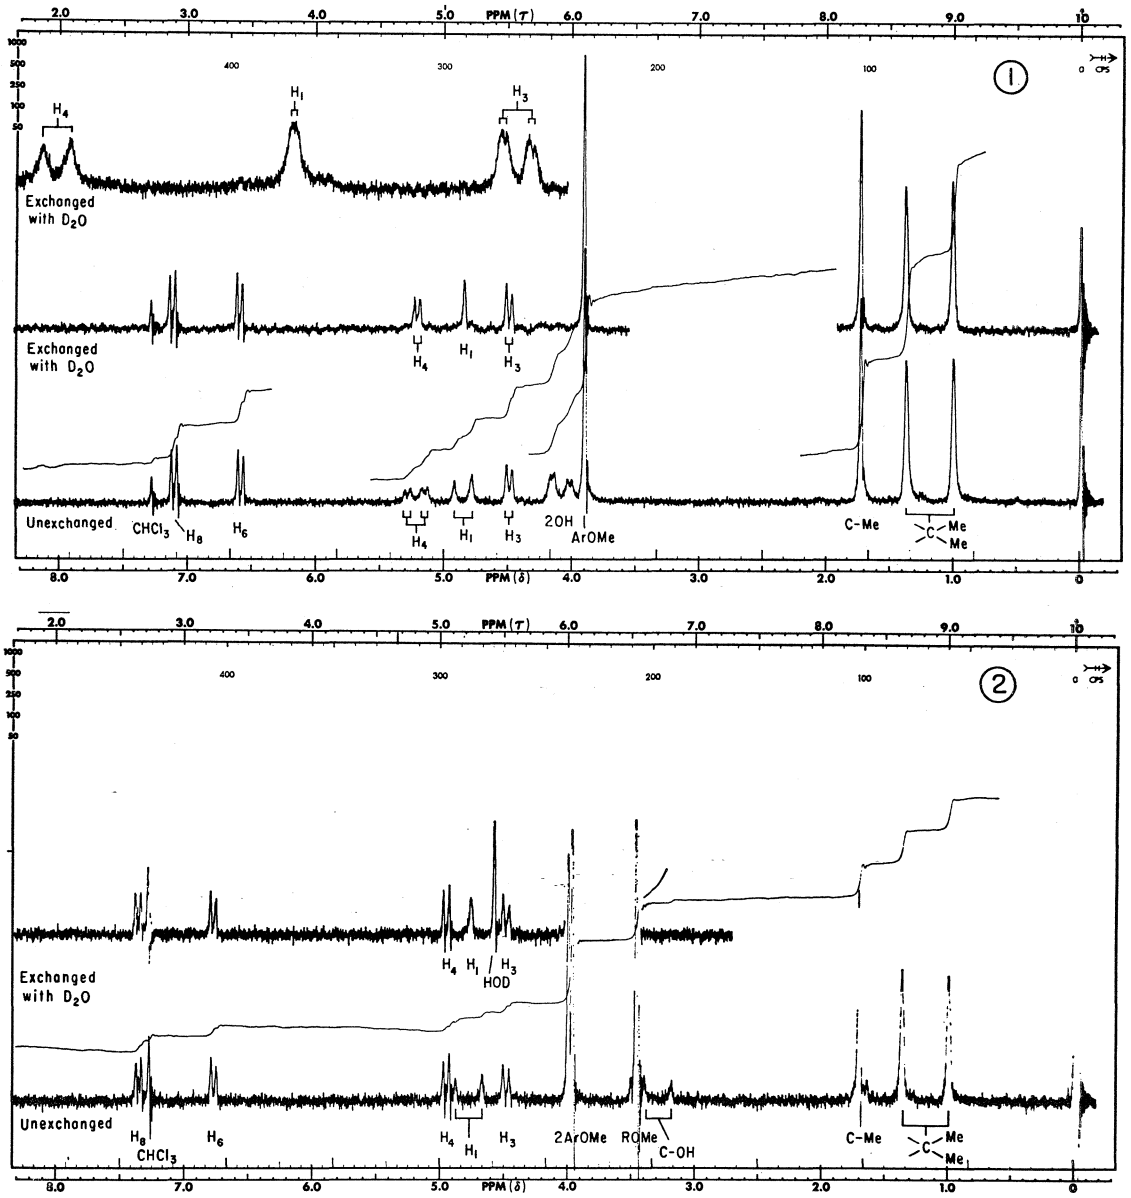

FIG. 1. The nuclear magnetic resonance spectrum of altersolanol A acetonide, obtained in deuteriochloroform with tetramethylsilane as internal reference. Expanded portions were determined with 100 Hz sweep-width and are off-set.
FIG. 2. The nuclear magnetic resonance spectrum of altersolanol A acetonide dimethylether.

seemed inadvisable and experimentation with the substance, which could not be obtained in satisfactory yields, was not continued. Similarly, in another experiment, the acetonide triacetate (**2***a*), on heating in pyridine at steam-bath temperature, deposited a substance which was readily characterized as 3-acetoxy-4,5-dihydroxy-7-methoxy-2-methylanthraquinone (**5***a*). At first sight, both these results appeared to require that the tentative assignment of band positions for H-3 and H-4 in the acetonide should indeed be reversed. However, the formation of **5***a* might have involved an acyl migration from the *peri*-position to C_3—O, while the failure of altersolanol A triacetate to be cleaved by periodate could possibly be ascribed to steric hindrance at C-2

and not to the lack of a vicinal glycol system. Thus, both results had to be regarded with suspicion.

A potentially more informative approach was sought in the preparation of a dihydro compound by reduction of the quinone double bond. Such hydrogenations have been realized in the case of juglone (6, 7) but, unfortunately, could not be accomplished in this instance. Altersolanol A pentaacetate (**1***a*), as a model substance, proved inert to hydrogenation in benzene in the presence of Wilkinson's catalyst (6). It reacted rapidly with zinc dust in ether – acetic acid or in ether – dilute sulfuric acid (7), but the only compound isolated under either set of conditions was the 5-acetate (**6***a*) of 7-*O*-methyl-2-methylxanthopurpurin (**6***b*), recognized by its n.m.r. spectrum and identical with a synthetic specimen. Obviously, the reaction which had occurred involved a succession of reduction–elimination steps and could not be usefully applied to the acetonide.

Attention was therefore turned to a derivative unlikely to rearrange under aromatization conditions. A dimethylether of altersolanol A acetonide was obtained by methylation over silver oxide in acetone; comparison of its n.m.r. spectrum (Fig. 2; Table I) with others shows that it is a di-*O*-methyl derivative with a free hydroxyl group at C-1 (τ 6.70, d, J[4] 13 Hz, exchangeable; H-1 before deuteration appearing as a doublet, J 13 Hz). Acetylation of the dimethylether gave the syrupy monoacetate (n.m.r. spectrum (Fig. 3)) which, on aromatization[5] by heating in pyridine at 105°, afforded two compounds. The major product was shown to be 3-hydroxy-2-methyl-4,5,7-trimethoxyanthraquinone (**5***b*) by analytical and spectroscopic data and by facile methylation with diazomethane to **5***c*. The minor product, on the basis of spectroscopic data, is a monodemethylation product of **5***b* (see Experimental; in order to conserve the small amount available, the compound was not submitted to elemental analysis). It gave the color reactions associated with the catechol system of **5** (1) and therefore can only be **5***d*. Methylation with diazomethane readily gave the 3-*O*-methyl derivative (**5***e*), the chelated phenol at C-4 remaining unattacked, which is identical with the dimethylation product obtained earlier (1) from **5**.

The two compounds which are directly relevant

[4]J = apparent coupling constant = observed splitting throughout this paper.

[5]The dimethylether (**2***b*) itself was not aromatized under these conditions but instead was transformed into a compound which retained both the acetonide grouping and optical activity. This product appeared to be pure, as judged from its chromatographic behavior and nuclear magnetic resonance spectrum, which suggested that it was a monoanhydro derivative. Nevertheless, despite repeated runs, the substance did not yield satisfactory elemental analyses and elucidation of its structure must be deferred until fresh supplies of starting material become available.

to this discussion are **5***a* and **5***b*. The formation of one of them must have involved a migration; either of acetyl from C_4—O to C_3—O or of methyl from C_3—O to C_4—O. To confirm the unlikelihood of a methyl migration, the trimethoxy compound (**5***e*) was treated with pyridine under the same conditions as the dimethylether acetate. It remained largely unattacked, yielding only negligible amounts of the monodemethylation product (**5***d*) and an unidentified, polar material. Only a minute trace, barely visible on thin-layer chromatograms, of a compound corresponding to **5***b* in R_f value and color, could be detected. Methyl migration, at any rate after aromatization, therefore cannot account for the substantial formation of **5***b* from the dimethylether acetate. On the other hand, the facility of acyl migration to suitably disposed hydroxyl groups is well attested (8). It is therefore almost certain that altersolanol A triacetate is **1***c*, while the acetonide dimethylether and its acetate must be **2***b* and **2***c* respectively. Thus, the original assignment of structures **2** and **2***a*, to altersolanol A acetonide and its triacetate respectively, can no longer be in serious doubt.

Examination of Dreiding models revealed the requirement for a *pseudo*-boat conformation for the acetonides (**2**, **2***a–c*) and, as expected (4), for a *cis*-configuration of the oxygen atoms at C-2 and C-3. The n.m.r. spectra indicate that one of the *gem*-dimethyl groups of the isopropylidene residue experiences considerable shielding which is clearly attributable to its position above the quinone double bond. This necessitates a diaxial disposition for the oxygen atoms at positions-2 and -3 in the acetonides. The apparent coupling constants associated with the interaction of the protons attached to C-3 and C-4, are about 2.6 Hz and are compatible with an equatorial – *pseudo*equatorial arrangement.

On the other hand, the apparent coupling constants for H-3, H-4 in altersolanol A and its acetates are 6.8 to 7.7 Hz. By analogy with eleutherin and related compounds (2), these values strongly suggest a *trans*-axial – *pseudo*-axial relation of these protons in **1**,**1***a–c*. Mild hydrolysis of **2** regenerated **1** which had the specific rotation of the natural substance. The change in coupling constants in the transformation (**1**) → (**2**) thus reflects a conformational rather than a more deep-seated rearrangement and all configurations must have remained unchanged. A further important fact is that the resonance position of H-1 in altersolanol A tetraacetate (**1***b*) (Fig. 4) at τ 3.82 was moved downfield by acetylation of the vicinal tertiary hydroxyl and appears at τ 2.83 in the pentaacetate (**1***a*) (Fig. 5). Analogous effects, previously observed in other compounds (9, 10), were studied quite recently in steroid derivatives (11) and correlated with those

FIG. 4. The nuclear magnetic resonance spectrum of altersolanol A tetraacetate.

situations, in which the deshielded protons were equatorial, and vicinal to axial tertiary acetoxyl groups.

Thus, in altersolanol A and its acetates, H-1 is *pseudo*equatorial, C_2—O axial and *cis* to C_3—O, and H_3,H_4 are *trans*-axial – *pseudo*axial. These conditions lead to only one stereochemical expression (**7** or mirror-image) for altersolanol A and its acetates. Similarly, only one representation (**8** or mirror-image) satisfies the properties of the acetonides.

Corroboration for these conclusions was obtained from some other observations. The acetoxyl groups attached to saturated carbon atoms in the acetonide triacetate are magnetically almost equivalent ($\Delta\tau = 0.02$) as expected of their di*pseudo*axial dispositions in **8**, (R = Ac). In altersolanol A pentaacetate (**7**, R = Ac), the

corresponding resonances range through $\Delta\tau = 0.17$, consistent with the presence of both equatorial and axial acetyl functions (12). However, this effect is less clearly evident in the tetraacetate ($\Delta\tau = 0.10$) and triacetate ($\Delta\tau = 0.07$). A comparison of the resonance positions of H-1 and H-4 is complicated by the need to consider neighboring group effects and was not attempted in detail; however, the values observed are compatible with the structural proposals (**7** and **8**). Finally, some moment can be attached to the smooth formation of the acetonide from altersolanol A. The sole by-product of this reaction accrued in less than 1% yield; it is thus improbable that more than one *cis*-glycol is available for acetonation.

One difficulty, however, remained. Cameron *et al.* (2) found that eleutherin and its analogues exhibit long-range coupling effects whose magni-

tudes vary with the character of the bonds. Thus, they could readily distinguish between *pseudo*-axial–*pseudo*equatorial ($J > 1.5$ Hz) and di*pseudo*-equatorial ($J < 1$ Hz) interactions through five bonds (H—C—C═C—C—H) in the non-aromatic ring. In altersolanol A derivatives, long-range interactions through both four and five bonds are discernible in the nuclear magnetic resonance spectra (see Figures) but all the effects are small (half-band widths of signals from H-4 < 1.2 Hz). If H-1, H-4 were always di*pseudo*-equatorial, then, irrespective of the configurations assigned to any center, acetonation would have to proceed without conformational rearrangement. This is clearly against all the evidence. Any differential long-range coupling effects in altersolanol A derivatives are therefore smaller than in eleutherin and thus eluded observation.

Experimental

General conditions were as described in the preceding paper (1).

Altersolanol A Acetonide

To a suspension of altersolanol A (40 mg) in dry acetone (4 ml) was added a cold solution of sulfuric acid (0.144 ml) in the same solvent (4 ml). After shaking at room temperature for 1.5 h, the solution was poured into dilute sodium hydrogen carbonate and extracted with ethyl acetate. The product crystallized on removal of the solvent and was recrystallized from methanol. It had m.p. 163–164°, with resetting and was recrystallized from methanol. It had m.p. 163–164°, with resetting and a second m.p. 180–183°; $\lambda\lambda_{max}$429, 285 (sh), 268 and 218 mμ (log ε 3.68, 3.75, 4.11, and 4.58; $\nu_{max}(CHCl_3)$ 3590 (sharp), 3310 (broad), 1662 (m), 1641 (s) and 1612 (vs) cm^{-1}; $[\alpha]_D^{23°}$ +32° (*c*, 0.25 in $CHCl_3$).

Anal. Calcd. for $C_{19}H_{20}O_8$: C, 60.63; H, 5.36. Found: C, 60.49; H, 5.28.

In a like experiment, the crude product from 2 mg altersolanol A was separated into its components by preparative thin-layer chromatography. The three colored bands obtained were eluted and the amounts estimated spectrophotometrically at 420 mμ. The ratio (altersolanol A acetonide: recovered altersolanol A: unidentified product) was (110:2:1).

The acetonide (10 mg) was refluxed for 18 h in ethanol (0.8 ml) containing hydrochloric acid (1 *N*; 0.2 ml). The solution was shaken with a slight excess of silver carbonate and filtered. Evaporation and recrystallization from ethyl acetate gave altersolanol A (t.l.c., m.p., and mixture m.p.) of unchanged specific rotation.

Altersolanol A Acetonide Triacetate

The acetonide (50 mg) was kept overnight in pyridine (1.2 ml) and acetic anhydride (0.9 ml). The product crystallized on removing the solvent and reevaporation from ethanol. Recrystallized from acetone–ethanol, it had m.p. 214–217°; $\lambda\lambda_{max}$ 384, 265, and 210 mμ (log ε 3.48, 4.31, and 4.49); $\nu_{max}(CHCl_3)$ 1743 (vs), 1666 (s) and 1605 (vs) cm^{-1}; $[\alpha]_D^{23°}$ +44° (*c*, 0.25 in $CHCl_3$).

Anal. Calcd. for $C_{25}H_{26}O_{11}$: C, 59.76; H, 5.22. Found: C, 59.10; H, 5.24.

Reaction of Altersolanol A Pentaacetate with Zinc Dust

The pentaacetate (35 mg) in ether (10 ml) was stirred with dilute sulfuric acid (5 ml) and zinc dust (Fisher Scientific, 300 mg) for 40 min. After dilution with ether, the organic phase was washed with water and evaporated. The product, recrystallized from ethyl acetate, had m.p. 171–173°; $\lambda\lambda_{max}$360, 328, and 267 mμ (log ε 3.55, 3.61, and 4.58); $\nu_{max}(CHCl_3)$ 1772 (s, ArOCOCH_3), 1673 (s, free CO), 1665 (sh), and 1606 (vs, aromatic) cm^{-1}; τ $CDCl_3$ 1.85 (1 H, d, *J* 8 Hz, H-4), 1.92 (1 H, s, H-1), 2.24 (1 H, d, *J* 2.5 Hz, H-8), 2.42 (1 H, broadened d, *J* 8 Hz, H-3), 3.08 (1 H, *J* 2.5 Hz, H-6), 6.00 (3 H, s, ArOCH_3), 7.47 (3 H, s, ArCH_3) and 7.51 (3H, s, ArOCOCH_3).

Anal. Calcd. for $C_{18}H_{14}O_5$: C, 69.67; H, 4.55. Found: C, 69.46; H, 4.51.

The same compound (m.p., mixture m.p., and t.l.c.) was also obtained when altersolanol A pentaacetate (25 mg) in ether (10 ml) containing acetic acid (0.5 ml) was stirred with zinc dust for 2 h. The substance was also identical by t.l.c., m.p., mixture m.p., ultraviolet, and infrared spectra with the product obtained by acetylation (acetic anhydride/perchloric acid) of the 7-methylether of 2-methylxanthopurpurin (1).

Altersolanol A Triacetate

Altersolanol A acetonide triacetate (120 mg) in acetonitrile (9 ml) and aqueous hydrochloric acid (3 *N*; 3 ml) was heated at 70° for 30 min. The solution was poured on ice and the product extracted with chloroform and washed with dilute sodium hydrogen carbonate solution and water. Preparative t.l.c. (methanol–chloroform – 90% formic acid; 10:90:2) gave starting material (ca. 60%) and crude triacetate (**1***c*) (R_f 0.49) which crystallized from isopropanol (14.5 mg, 16%). After repeated recrystallizations from the same solvent, it had m.p. 188–192°; $\lambda\lambda_{max}$384 and 267 mμ (log ε 3.43 and 4.31); $\nu_{max}(CHCl_3)$ 3520 (broad), 1755 (vs), 1671 (vs), and 1608 (vs) cm^{-1}.

Anal. Calcd. for $C_{22}H_{22}O_{11}$: C, 57.14; H, 4.80. Found: C, 57.28; H, 4.83.

The compound (2.2 mg) did not undergo a noticeable reaction (t.l.c.) when kept for 24 h at room temperature in acetonitrile (0.9 ml) containing sodium periodate solution (0.1 *M*; 0.1 ml).

Dehydration of Altersolanol A Acetonide Triacetate

A solution of the acetonide triacetate (34 mg) in pyridine (0.34 ml; stored over sodium hydroxide and distilled before use) was heated on the steam bath for 4 h. The crystalline product was filtered off, washed with hot pyridine, and recrystallized from the same solvent. It had m.p. 283–286°; $\lambda\lambda_{max}$ 428, 272 (broad), and 222 mμ (log ε 3.94, 4.15, and 4.33); ν_{max} (Nujol) 2800–2500 (w, chelated OH), 1754 (vs, acetate), 1675 (s, free CO), 1631 (vs, chelated CO), and 1608 (vs, aromatic) cm^{-1}; τ (saturated solution in $CDCl_3$, 81 accumulations) −2.33 (1 H, s, chelated phenol), −2.22 (1 H, s, chelated phenol), 2.32 (1 H, s, H-1), 2.64 (1 H, d, *J* 2.5 Hz, H-8),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

3.32 (1 H, d, J 2.5 Hz, H-6), 6.07 (3 H, s, ArOCH_3), 7.60 (3 H, s, ArCH_3), and 7.68 (3 H, s, ArOCOCH_3).

Anal. Calcd. for $C_{18}H_{14}O_7$: C, 63.16; H, 4.12. Found: C, 63.24; H, 4.21.

A solution of this product (0.7 mg) in sodium hydroxide (0.10 N; 1 ml) was acidified after 1 h. The resulting compound, extracted with ethyl acetate, was indistinguishable from 7-methoxy-2-methyl-3,4,5-trihydroxyanthraquinone (anthraquinone B) (1) by R_f and characteristic lake formation on t.l.c.

Altersolanol A Acetonide Dimethylether

Altersolanol A acetonide (120 mg) in dry acetone (12 ml) containing methyl iodide (0.18 ml) was shaken for 48 h at room temperature over silver oxide (420 mg). The suspension was filtered, the filter cake washed with acetone, the combined filtrates and washings concentrated, diluted with water, and extracted with ethyl acetate. The major band obtained on preparative t.l.c. of the product was crystallized from ether – light petroleum ether to give altersolanol A acetonide dimethylether (69 mg). After recrystallization from methanol, it had m.p. 173–175°; $\lambda\lambda_{max}$413, 267, and 217 mμ (log ε 3.61, 4.17, and 4.58); ν_{max}($CHCl_3$) 3470 (OH), 1659 (s, 2 free CO), and 1600 (s, aromatic) cm^{-1}; $[\alpha]_D^{23°}$ +40° (c, 0.25 in $CHCl_3$).

Anal. Calcd. for $C_{21}H_{24}O_8$: C, 62.37; H, 5.98. Found: C, 62.28; H, 6.34.

Aromatization of Altersolanol A Acetonide Dimethylether Acetate

The dimethylether (52 mg) was kept overnight at room temperature in pyridine (2.5 ml) containing acetic anhydride (1.5 ml). Evaporation in the usual manner and preparative t.l.c. gave altersolanol A acetonide dimethylether acetate as a syrup which was characterized by its nuclear magnetic resonance spectrum.

The substance was heated in pyridine (1 ml, dried over sodium hydroxide and distilled before use) at 105° until all the starting material had been consumed (48 h, no transient product revealed by t.l.c.). After removal of the solvent, the product, on preparative t.l.c., gave two major bands, yellow and orange respectively.

The yellow substance was recrystallized from chloroform–ether to give needles (16.5 mg), m.p. 226–235° (unchanged by recrystallization); $\lambda\lambda_{max}$374, 295 (inf), 280 and 226 mμ (log ε 3.96, 4.21, 4.52, and 4.46); ν_{max} ($CHCl_3$) 3470 and 3420 (OH), 1663 (s, 2 free CO) and 1590 (vs, aromatic) cm^{-1}; τ $CDCl_3$ 2.60 (1 H, d, J 2.5 Hz, H-8), 3.21 (1 H, s, exchangeable, non-chelated phenol), 3.24 (1 H, d, J 2.5 Hz, H-6), 5.96, 6.01 and 6.03 (3 × 3H, s, 3 ArOCH_3), and 7.62 (3 H, s, ArCH_3).

Anal. Calcd. for $C_{18}H_{16}O_6$: C, 65.84; H, 4.91. Found: C, 65.62; H, 4.79.

Ethereal diazomethane (2 ml) was added to ca. 2 mg of the substance in methanol (1 ml). Reaction was complete after 5 min. Recrystallization of the product from chloroform–ethanol gave 2-methyl-3,4,5,7-tetramethoxyanthraquinone, identical with an authentic specimen (1) by m.p., mixture m.p., and infrared spectrum.

The orange substance (11 mg), in chloroform–ethanol, was washed with dilute hydrochloric acid to remove inorganic material. Recrystallization from acetic acid (R_f and color unchanged throughout) gave the pure product, m.p. 266–267°; $\lambda\lambda_{max}$419, 302 (sh), 277, and 226 mμ (log ε 3.96, 4.05, 4.47, and 4.36); ν_{max} (Nujol) 3370 (bonded OH), 2700–2300 (w, chelated OH), 1655 (sh, free CO), 1636 (s, chelated CO) and 1593 (vs, aromatic) cm^{-1}; τ (saturated solution in $CDCl_3$, 16 accumulations) −3.40 (1 H, s, exchangeable, chelated phenol), 2.36 (1 H, s, H-1), 2.40 (1 H, d, J 2.5 Hz, H-8), 3.26 (1 H, d, J 2.5 Hz, H-6), 3.62 (1 H, broad, exchangeable, non-chelated phenol), 5.96 (3 H, s, ArOCH_3), 6.00 (3 H, s, ArOCH_3) and 7.62 (3 H, s, ArCH_3). The compound resembled 7-methoxy-2-methyl-3,4,5-trihydroxyanthraquinone (1) in giving an olive-brown color with alcoholic ferric chloride and in the reversible formation of purple lakes on thin layers of silica gel on evaporation of the acidic solvent.

The foregoing orange compound, in methanol – ethyl acetate (1:1), was methylated with ethereal diazomethane (2 ml) during 10 min. The product, recrystallized from chloroform–methanol, was identical with the dimethylether, m.p. 222–223°, obtained by partial methylation of anthraquinone B (1), by m.p., mixture m.p., nuclear magnetic resonance and infrared spectra.

The above methylation product (2 mg) in pyridine (0.15 ml) was heated at 105° for 48 h. Chromatograms of the product showed a very intense spot corresponding to starting material and three faint to very faint spots assigned as in the text.

Acknowledgments

I am grateful to Dr. J. B. Stothers for a stimulating discussion and for helpful comments on the manuscript; to Dr. E. Y. Spencer for encouraging this research; and to Mr. G. Rock for valuable experimental help.

Reaction of propionaldehyde with *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride. The dienone–imine intermediate in the Fischer indole synthesis and its conversion to the indole structure[1]

G. S. Bajwa and R. K. Brown
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received August 9, 1968

When *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride was condensed with propionaldehyde by azeotropic removal of water in refluxing benzene for 10–12 min, a solid mixture was obtained which contained no aromatic ring system but instead possessed features indicative of a dienone–imine structure. When this mixture, or the original combination of *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride and propionaldehyde, was heated in refluxing benzene for 20 h there was obtained 1,3,7-trimethylindole in 36 and 31% yield respectively. Evidence indicated that a substantial amount of 3,7-dimethylindole was also produced.

The results support the view that an intermediate dienone–imine is formed as one step in the Robinson mechanism of the Fischer indole synthesis.

In a recent communication from this laboratory (1) it was shown that the condensation of isobutyraldehyde with *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride, **1**, by azeotropic removal of water in refluxing dry benzene, led to the formation of an isolable dienone–imine, **4** (Scheme 1). The expected enamine, **2**, the product of the first step of the condensation, could not be obtained.

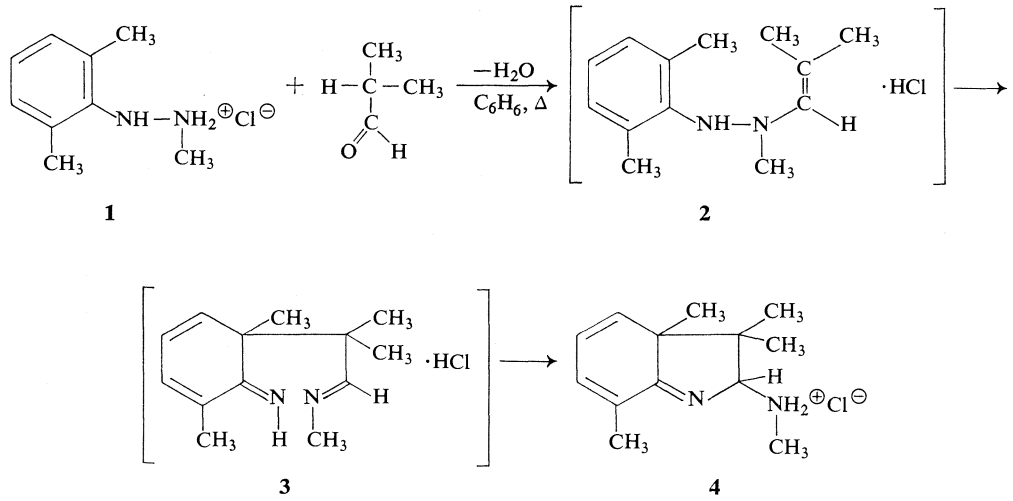
Elemental analysis, ultraviolet (u.v.), and infrared (i.r.) spectra supported either of the two dienone–imines, **3** and **4**, but the nuclear magnetic resonances (n.m.r.) spectrum clearly showed that **4** was the compound obtained. It was the presence of the methyl groups at the C-2 and C-6 positions of the aromatic ring of the hydrazine, and the two methyl groups on C-2 of the aldehyde which prevented final formation of the indole ring system and thus permitted isolation of this dienone–imine.

We have now condensed *propionaldehyde* with *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride by azeotropic removal of water in refluxing dry benzene. When this mixture was refluxed for 10–12 min, water collected in the trap and a solid appeared in the reaction flask. This was isolated and crystallized from alcohol–ether (m.p. 147–148°, 31% yield). The n.m.r. spectrum (Fig. 1) in D_2O showed the *absence* of aromatic proton signals expected in the region τ 2.0–3.3. Several features of this spectrum were similar to those found in the n.m.r. spectrum (Fig. 2) of the dienone–imine, **4**, previously described (1). These were, notably, (*a*) the signals for the olefinic protons of the former aromatic ring, between τ 3.3–4.2, (*b*) the high field signals for the aliphatic methyl protons between τ 8.5–9.4, (*c*) the signal for the protons of the methyl group attached to a C=C (~τ 8.0), (*d*) the signal for the protons of a methyl group attached to nitrogen (τ 7.0–7.3), and (*e*) the anomeric proton signal(s) in the region τ 4.8–5.2. The presence of *two* signals for N—CH_3 protons at τ 7.0–7.3 (Fig. 1) and the multiplicity of signals at τ 8.5–9.3 clearly showed that the solid contained more than one compound.[2] Attempts to purify the material by further crystallization or by chromatography were unsuccessful because of its susceptibility to decomposition. Because the material was impure, spin decoupling experiments were not carried out.

The u.v. spectrum in 95% ethanol showed a narrow band at λ_{max}, 204 mμ (ε = 3600) and a broad band at λ_{max}, 315 mμ (ε = 1200). This u.v.

[1]Taken from the Thesis of G. S. Bajwa presented to the Faculty of Graduate Studies, University of Alberta, Edmonton, Alberta, as part of the requirements for the Degree of Doctor of Philosophy.

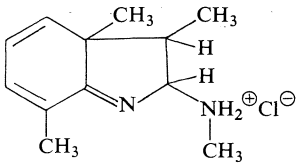
[2]Possible isomeric compounds, one or more of which might be present as impurities, are shown in Scheme 2. These are structures **6**, **7**, and **8**. The presence of a small amount of the dienone–imine hydrochloride, **6**, is indicated by the N—H absorption shown in the region 3100–3300 cm^{-1} of the i.r. spectrum. That compound **8** (shown in Fig. 1) might be a significant impurity is indicated by the fact that the chief product obtained upon prolonged heating of this material is 1,3,7-trimethylindole, which can arise only from a structure such as **8**.



SCHEME 1

spectrum is closely similar to that found for the dienone–imine, **4**, previously reported (1). The i.r. spectrum (in Nujol) showed weak absorption in the region 3100–3300 cm^{-1} (NH) and strong bands at 1580 and 2700 cm^{-1} ($NH_2^{\oplus}$) (2).

In addition to the above evidence, the elemental analysis also agreed with the dienone–imine structure indicated below (**5**), and thus the impurity present must have a closely similar if not identical elemental composition.[2]



5

When this impure dienone–imine hydrochloride was suspended in dry benzene and the mixture refluxed for 20 h, a precipitate was obtained. This was removed by filtration and dried. It melted at 299–320°. The n.m.r. spectrum of this crude material in D_2O showed only two signals—a singlet at τ 7.31 (NCH_3) and a singlet at τ 5.13 (DOH). These signals and their integrated areas, along with the melting point observed above, indicated that the precipitate was a mixture of ammonium chloride and methylammonium chloride in the molar ratio of 3:1.

Removal of the benzene from the filtrate above gave a dark yellowish oil whose i.r. spectrum showed a weak, though sharp band at 3490 cm^{-1} (NH for the indole molecule, ref. 2, p. 251). The n.m.r. spectrum in $CDCl_3$ (Fig. 3) showed that this oil was a mixture containing some of the dienone–imine (signals at τ 8.5–9.3, τ 8.0, τ 3.5–4.2) along with one or more compounds possessing aromatic protons as part of their structure (multiplet at τ 2.5–3.3). From this oil, after removal of the dienone–imine by aqueous acid wash, there was obtained by fractional crystallization, a solid melting at 46°. The yield, based on the dienone–imine hydrochloride, was 36%. This was assigned the structure 1,3,7-trimethylindole for the following reasons.

The elemental analysis agreed well with the proposed structure. The i.r. spectrum in CCl_4 showed no absorption in the N—H region. The u.v. spectrum in hexane showed two bands—a sharp band at λ_{max}, 226 mμ (ε = 39 200), and a broad band at λ_{max}, 281 mμ (ε = 6900). This u.v. spectrum was closely similar to that obtained for indole (3). The n.m.r. spectrum (Fig. 4) in $CDCl_3$ provided clear evidence that this was indeed 1,3,7-trimethylindole. The three signals at τ 6.08 (singlet, 3H), τ 7.29 (singlet, 3H) and τ 7.73 (narrow doublet, 3H) are readily assigned to the *N*-methyl, C-7 methyl, and C-3 methyl protons respectively. The three aromatic protons provide the multiplet at τ 2.5–3.2. The broad singlet at τ 3.32 is due to the C-2 proton. That C-2 rather than C-3 of the indole structure was unsubstituted, was corroborated by the large

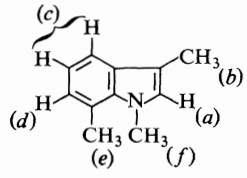
shift of the signal for this proton downfield to τ 3.05 ($\Delta\tau = 0.27$) when the more polar solvent dimethyl sulfoxide-d_6 was used. Such large signal shifts in the n.m.r. spectrum due to change in solvent are characteristic of the C-2 proton but not of the C-3 proton of the indole structure (4). Spin decoupling experiments supported the structure. Irradiation of the nucleus of H_a (τ 3.32) showed no effect on the signals of H_d (τ 2.5–2.7) but did cause a sharpening of the signal for the



methyl group *b* at τ 7.73. Irradiation of the methyl protons, *b*, at τ 7.73 changed the broad singlet ($w/2 \approx 3$ Hz) at τ 3.32 (H_a) to sharp singlet. This, along with the solvent shift of the signal for H_a when dimethyl sulfoxide-d_6 was used rather than $CDCl_3$ provides evidence that H_a and CH_3(*b*) give rise to the signals at τ 3.32 and 7.73 respectively. Irradiation at τ 7.29 (CH_3, *e*) changed the multiplet at τ 2.5–2.7 to two doublets centered at τ 2.98 and τ 2.91 ($J \approx 2$ Hz) which are believed to be due to H_d (1). As well, simplification occurred in the multiplet at τ 2.8–3.2 (protons *c*).

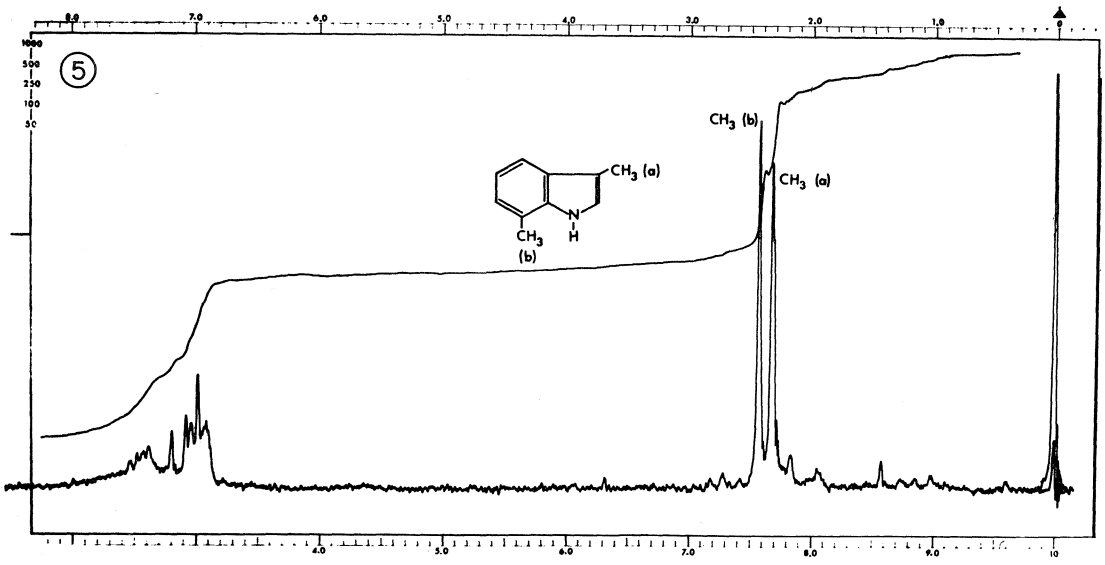
Authentic 1,3,7-trimethylindole was made by *N*-methylation of 3,7-dimethylindole. The synthesis of this latter compound has been reported previously (5–7). Our efforts to prepare 3,7-dimethylindole via cyclization of propionaldehyde *o*-tolylhydrazine by following the published directions (6, 7) have not been successful. The directions given by Marion and Oldfield (6) led to an oil boiling in the range reported (6).[3] However, the n.m.r. spectrum clearly showed that it was a mixture of substances. Of the several catalysts normally used to effect the cyclization of phenylhydrazones to indoles (9) we have found that boron trifluoride etherate in acetic acid was somewhat better, but this still gave a mixture. Both the procedures of Marion and Oldfield and that using the boron trifluoride etherate gave oils which showed absorption in the i.r. spectrum at 3490 cm^{-1} characteristic of the NH absorption of indoles (ref. 2, p. 251) thus showing that the 3,7-dimethylindole had been formed as one compound in the mixture of products, but our attempts to purify it by fractional distillation or chromatography have as yet been unsuccessful. However, a more fruitful route to 3,7-dimethylindole via Fischer cyclization was devised. This involved heating a mixture of *N'*-methyl-*o*-tolylhydrazine hydrochloride and propionaldehyde in refluxing, dry benzene, following the method described for the analogous reaction using *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride (1, 10). From this reaction there was obtained in 24% yield, an oil whose n.m.r. spectrum (Fig. 5) was consistent with that expected for 3,7-dimethylindole. But here also it was clear from this spectrum that small amounts of impurities were present. All attempts to eliminate these by fractional distillation or chromatography were unsuccessful. The elemental analysis clearly reflected the impure state.

Pure 3,7-dimethylindole was prepared by the method of Cornforth and Robinson (5) wherein 7-methylindole was heated in an autoclave at 215° with sodium methoxide in methanol. The material obtained was a solid, melting at 56–57°. That reported (5), melted at 56°. Its n.m.r. spectrum was practically identical with that shown in Fig. 5 but devoid of the slight impurities indicated by the very weak signals in the region τ 8.7 to τ 9.2.

N-Methylation of 3,7-dimethylindole by the published procedure (10) gave in very low yield authentic 1,3,7-trimethylindole identical in all respects (m.p., i.r., and n.m.r. spectra) with the compound obtained from the dienone–imine hydrochloride as described above.

We were particularly interested in preparing authentic 3,7-dimethylindole since the i.r. spectrum of the oil obtained from the benzene filtrate above (after removal of the ammonium chloride and methylammonium chloride from the mixture resulting from the 20-h heating of the dienone–imine hydrochloride in refluxing benzene) showed a band at 3490 cm^{-1}. This, along with the formation of a substantial proportion of methylammonium chloride, strongly indicated that the

[3]Marion and Oldfield report a melting point of 64° in Table I, page 2 of ref. 6. Their experimental details (page 5, ref. 6) of the preparation of 3,7-dimethylindole via the Fischer cyclization state that a boiling point of 80–95° at 0.5 mm was obtained for this compound. No melting point was reported in the Experimental and no indication was provided that a solid was obtained. Hence it is not clear where their figure of 64° was obtained.



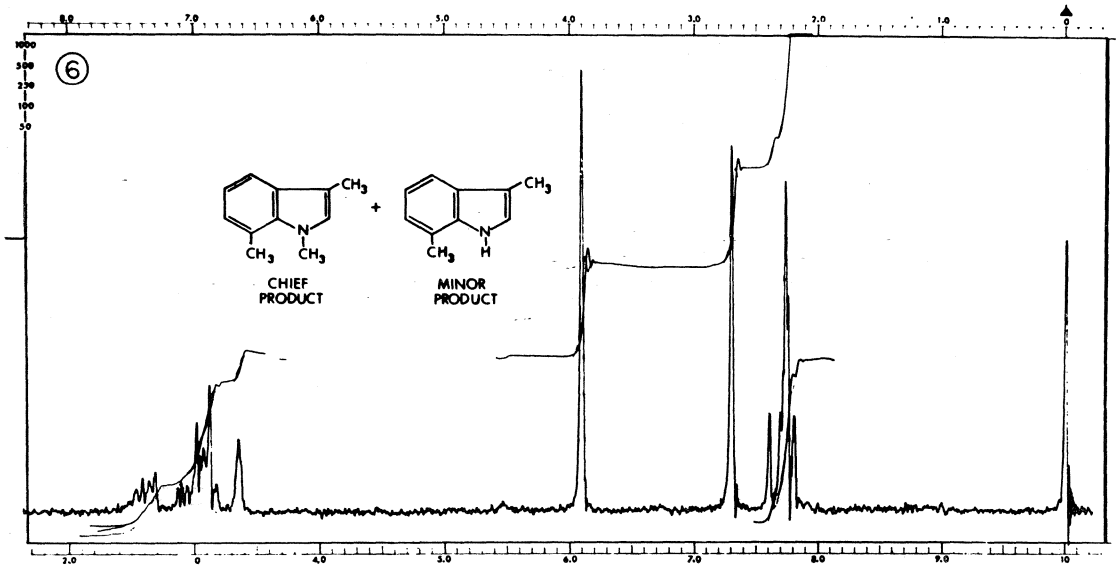


FIG. 5. The nuclear magnetic resonance spectrum (60 MHz in $CDCl_3$; reference, tetramethylsilane) of 3,7-dimethylindole prepared by the reaction of *N'*-methyl-*o*-tolylhydrazine hydrochloride with propionaldehyde in refluxing dry benzene.

FIG. 6. The nuclear magnetic resonance spectrum (60 MHz in $CDCl_3$; reference, tetramethylsilane) of the oil obtained from the 19 h reaction in refluxing benzene of the mixture of *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride and propionaldehyde.

other significant product formed by prolonged heating of this dienone–imine hydrochloride was 3,7-dimethylindole. The 3,7-dimethylindole synthesized above possessed characteristic signals in the n.m.r. spectrum which were clearly apparent (Fig. 5). In $CDCl_3$ these signals were at τ 7.57 (singlet, 3H) and τ 7.68 (narrow doublet, 3H) for the C-7 and C-3 methyl protons respectively. These were not obvious in the n.m.r. spectrum in $CDCl_3$ (Fig. 3) of the crude oil obtained when

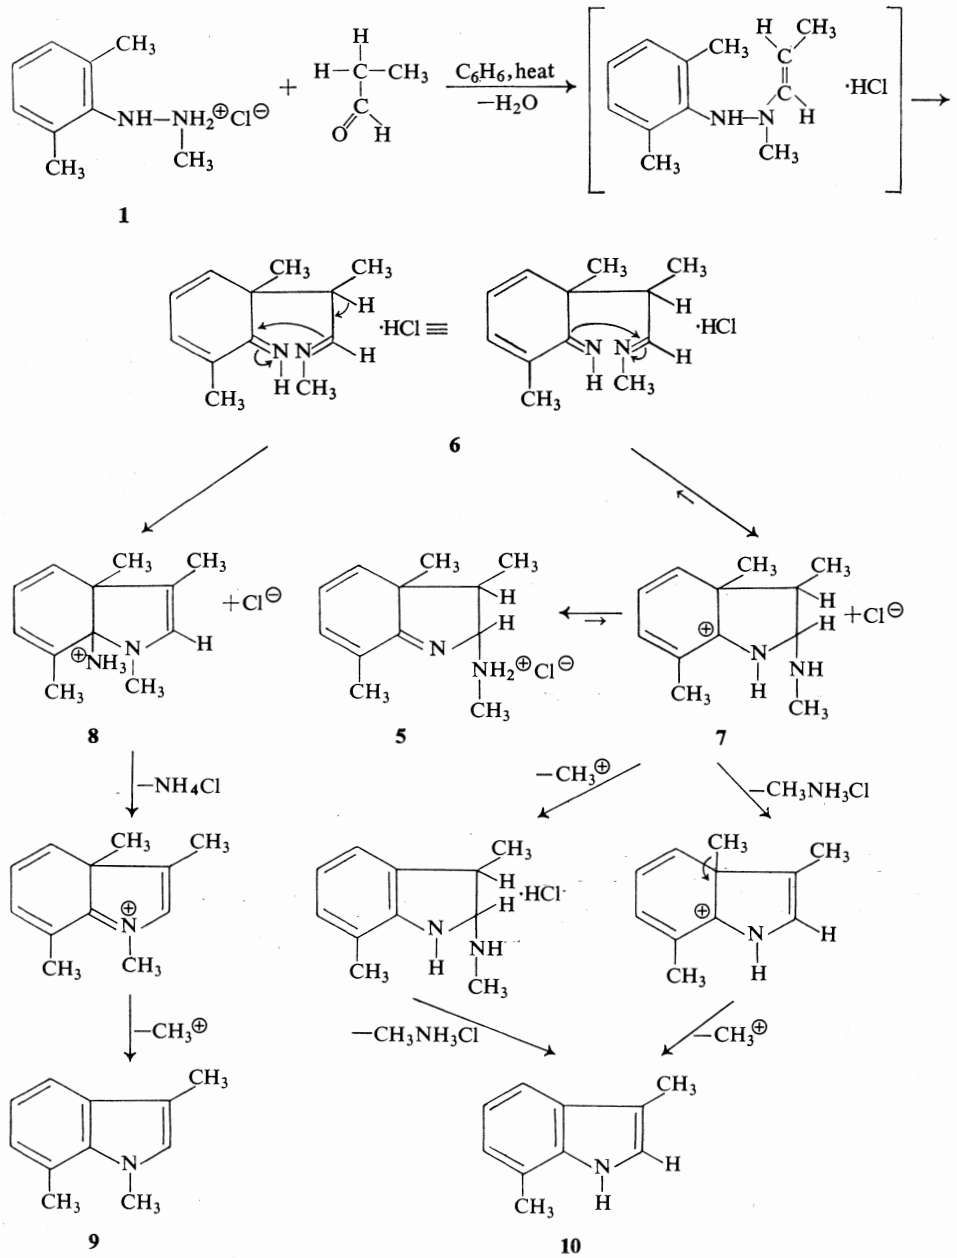
For personal use only.



SCHEME 2

the dienone–imine hydrochloride had been heated for 20 h. The small signals at τ 7.58 and 7.68 could be due to 3,7-dimethylindole. This is more clearly shown in the following work.

A mixture of *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride and excess propionaldehyde was heated for 19 h in refluxing dry benzene. Water was observed to collect in the trap. The mixture was then filtered and gave a gelatinous solid. This, when crystallized from ethanol–ether, gave a colorless solid which by its melting point characteristics and n.m.r. spectrum proved to be largely ammonium chloride contaminated with a small amount of methylammonium chloride.

For personal use only.

Apparently some of the latter compound had been lost during this crystallization due to its greater solubility. The benzene filtrate gave an oil which was distilled. The n.m.r. spectrum in $CDCl_3$ (Fig. 6) of the first fraction clearly showed that this was chiefly 1,3,7-trimethylindole (signals at τ 6.10, 7.30, and 7.74) containing a substantial quantity of 3,7-dimethylindole (signals at τ 7.60 and 7.69). The bulk of the trimethylindole was found in the second fraction. From both fractions, by crystallization, there was obtained a 31% yield of 1,3,7-trimethylindole (after accounting for some recovered unchanged *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride) identical with that obtained above. We were unable to isolate pure 3,7-dimethylindole from either of these fractions.

It is clear from the above work that *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride and propionaldehyde have reacted to produce first a non-aromatic intermediate (or intermediates) which in turn, upon further reaction, is converted into the indole structure. The reaction can be rationalized according to the Robinson mechanism (8, 9) as shown in Scheme 2, by routes similar to those utilized to explain the products reported in our previous communications (1, 10).

This scheme requires the loss of a methyl group from the aromatic ring under relatively mild conditions. However, such an elimination of a methyl group under similar conditions has been demonstrated previously for the reaction of *N'*-methyl-2,6-dimethylphenylhydrazine (or its hydrochloride) with cyclohexanone to produce 8,9-dimethyl-1,2,3,4-tetrahydrocarbazole (10). The fate of this lost methyl group is as yet unknown.

A significant point which must be considered with respect to Scheme 2, is the correlation between the structure of the dienone–imine, **5**, and the products actually obtained from its conversion to the indoles **9** and **10**. It was concluded that the mixture obtained from the 10–12 min condensation of propionaldehyde with *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride contains a predominance of the dienone–imine, **5**. Possible contaminating products are the compounds **6**, **7**, and/or **8**. Structure **5** should then give 3,7-dimethylindole as the main product. But as actually found, the product was a mixture containing 3,7-dimethylindole and 1,3,7-trimethylindole in the approximate proportion of 1:4 respectively. This suggests that in Scheme 2, there exists an equilibrium between compounds **5**–**8**. It is quite apparent that in structure **8**, there is much more strain than exists in any of the other structures (**5**–**7**). Models show that in **8** the C-7*a* substituent, $-NH_3^+Cl^\ominus$, is quite crowded. Hence, when heat is applied, structure **8** should lose ammonium chloride and subsequently $CH_3^\oplus$ to become 1,3,7-trimethylindole much more readily than structure **7** (or **5**) would lose methylammonium chloride to become 3,7-trimethylindole. This would explain the results obtained, and why the nitrogen atom adjacent to the aromatic ring of the hydrazine is lost in preference to that more remote from the ring (cf. ref. 9).

Experimental

Melting points and boiling points are uncorrected. Elemental analyses were made by Mrs. Darlene Mahlow of this Department.

Ultraviolet spectra of 1,3,7-trimethylindole were obtained with a JASCO model ORD/UV-5 spectrometer and of the dienone–imine hydrochloride with a Perkin–Elmer 202 ultraviolet–visible spectrometer. Infrared spectra were obtained with a Perkin–Elmer 421 grating spectrometer.

The 60 MHz n.m.r. spectra were made by Mr. R. Swindlehurst; the 100 MHz spectra and spin decoupling experiments were made by Mr. Glen Bigham of this Department. The instruments employed were the 60 MHz and 100 MHz Varian spectrometers.

Solvents were removed by rotary evaporator under vacuum unless otherwise stated.

Condensation of N'-Methyl-2,6-dimethylphenylhydrazine Hydrochloride with Propionaldehyde

(a) Limited Reaction—The Hydrochloride of the Dienone–imine Intermediate

A mixture of 1.5 g (0.008 mole) of *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride (1) and 0.9 g (0.016 mole) of propionaldehyde in 20 ml of dry benzene was refluxed for 10 min using a Dean–Stark water collection apparatus (11). To the solution was added a further quantity (1 g) of propionaldehyde and then refluxing was continued for 2 min longer. Water was observed in the Dean–Stark trap. The white insoluble precipitate was removed by filtration under vacuum and washed with ether. When air-dried, the crude material weighed 625 mg (36%) and melted at 143–145°. It was crystallized by solution in 95% ethyl alcohol followed by the addition of ether till a faint turbidity appeared. The white precipitate obtained weighed 520 mg (29%) and melted at 147–148°. A second crystallization was difficult because of the tendency for decomposition. But by using a minimum quantity of solvents and thorough cooling of the solution in a refrigerator for 2 days, crystals were obtained which melted at 147–148°.

Anal. Calcd. for $C_{12}H_{19}N_2Cl$: C, 63.58; H, 8.38; N, 12.36; Cl, 15.67. Found: C, 63.08; H, 8.37; N, 12.28; Cl, 16.17.

The n.m.r. spectrum in D_2O is shown in Fig. 1 and has been described in the discussion. The significant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

absorptions of the spectrum in 95% ethanol and the i.r. spectrum in Nujol have also been described in the discussion.

(b) Longer Reaction Time—1,3,7-Trimethylindole

A mixture of 10 g (0.054 mole) of *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride (1) and 3.1 g (0.054 mole) of propionaldehyde in 150 ml of dry benzene was refluxed for 19 h in the Dean–Stark apparatus (11). Water collected in the trap. The color of the reaction mixture became dark after 1 h of reflux. After the 19 h of reflux, the mixture was cooled and filtered free of a dark gelatinous material (~1 g). This was dissolved in 95% ethyl alcohol and diluted with ether to faint turbidity. A white water soluble solid (700 mg) was obtained melting at 290–320 °C. Its n.m.r. spectrum in D_2O showed only two signals, a small singlet at τ 7.4 (N—CH_3) and a large singlet at τ 5.4 (DOH). From the integrated areas and the above evidence it was certain that the solid was ammonium chloride contaminated with ~3% of methylammonium chloride.

The benzene filtrate was freed from solvent and the residual dark oil was treated with 150 ml of water. The aqueous material was extracted with ether (3 × 100 ml). The ether extracts were washed with 300 ml of 12% HCl in water and then with water (3 × 100 ml). The dried ether solution ($MgSO_4$, 2 h) was then freed from solvent. The resulting yellow oil was distilled to give two fractions. The first fraction boiled at 80–125 ° at 8 mm (1.6 g of yellow oil). Its n.m.r. spectrum (Fig. 6) indicated that it was chiefly 1,3,7-trimethylindole contaminated with 3,7-dimethylindole along with other very minor amounts of impurities. The second fraction boiled at 136–138° at 8 mm (2.5 g of viscous yellow oil). The latter fraction was twice crystallized from petroleum ether (b.p., 60–70°) and gave 1.8 g of *1,3,7-trimethylindole* melting at 46°. The first fraction (1.6 g) showed a sharp, weak band in the i.r. spectrum at 3490 cm^{-1} characteristic of the N—H stretching band found in indole (ref. 2, p. 251). Crystallization of this fraction from petroleum ether gave 300 mg of 1,3,7-trimethylindole. The total yield was 2.1 g, 31% based on the 8 g of *N'*-methyl-2,6-dimethylphenylhydrazine hydrochloride consumed (see below).

Anal. Calcd. for $C_{11}H_{13}N$: C, 83.02; H, 8.19; N, 8.80. Found: C, 83.10; H, 8.00; N, 8.66.

The i.r. spectrum in CCl_4 showed no absorption in the NH region (3100–3600 cm^{-1}). The u.v. spectrum in hexane, λ_{max}, 226 mμ (ε = 39 200), 281 mμ (ε = 6900) was nearly identical with that of indole (3). The 60 MHz n.m.r. spectrum in $CDCl_3$ (Fig. 4) and spin decoupling experiments are described in the discussion and support the structure as 1,3,7-trimethylindole.

The aqueous acidic solutions obtained from the ether extraction and water washes above were basified with aqueous sodium hydroxide and the mixture then extracted with ether (2 × 100 ml). The ether extract was washed with water (3 × 30 ml) and dried ($MgSO_4$) overnight while it was kept cold in a refrigerator. The drying agent was separated and the ether filtrate treated with dry hydrogen chloride. The resulting precipitate was crystallized from 95% ethyl alcohol, diluted with ether to faint turbidity, and gave 2.0 g of *N'-methyl-2,6-dimethylphenylhydrazine hydrochloride.*

Conversion of the Dienone–imine to 1,3,7-Trimethylindole

One gram of the above dienone–imine hydrochloride was heated in refluxing benzene for 20 h. The precipitate (113 mg) was removed (m.p. 299–320°) and found to be ammonium chloride contaminated with some methylammonium chloride (~3:1). The benzene filtrate was freed from solvent. The dark residue gave an n.m.r. spectrum in $CDCl_3$ (Fig. 3) which indicated that it was a mixture of 1,3,7-trimethylindole and some starting dienone–imine hydrochloride (see Discussion). The i.r. spectrum in CCl_4 showed a sharp, weak band at 3490 cm^{-1} indicative of the presence of an indole with a free NH group.

The dark oil was suspended in 50 ml of water and the mixture extracted with ether (2 × 50 ml). The ether solution was in turn washed with 20 ml of 10% aqueous HCl and then with water (3 × 20 ml). The ether solution was dried ($MgSO_4$, 2 h) and freed from the drying agent and then from the solvent. The residue deposited crystals (310 mg) melting at 38–42° which showed weak absorption at 3490 cm^{-1} in the i.r. spectrum. This solid was crystallized twice from petroleum ether (60–70°) and gave 250 mg of pure 1,3,7-trimethylindole, melting at 46°. The n.m.r. spectrum in $CDCl_3$ is shown in Fig. 4 and is described in the discussion. The i.r. spectrum in CCl_4 showed no absorption for N—H. The u.v. spectrum in hexane is very closely similar to that for indole itself (see Discussion).

Preparation of 3,7-Dimethylindole

To a solution of *o*-tolylhydrazine (58 g, 0.475 mole) in 150 ml of glacial acetic acid was added, over a period of 0.5 h, 21.4 g (0.476 mole) of formamide. The solution was stirred for 3 h at room temperature, and then diluted with 150 ml of water and allowed to stand for about 15 min. The solid which accumulated was removed and when air-dried weighed 40 g and melted at 115–118°. Two crystallizations from 95% ethanol gave 35 g of *N'-formyl-o-tolylhydrazine*, m.p. 120°; lit. m.p. 120° (12). The n.m.r. spectrum in $CDCl_3$ supported the structural assignment.

To a solution of *N'*-formyl-*o*-tolylhydrazine (35 g, 0.233 mole) in 150 ml of dimethyl sulfoxide was added, simultaneously in a dropwise fashion over a period of 0.5 h, equimolar quantities of dimethyl sulfate (29.5 g) and sodium hydroxide (9.3 g in 10 ml of water). The reaction mixture was stirred for 2.5 h and then diluted with 200 ml of water. The ether extract (3 × 100 ml) was washed with water and dried ($MgSO_4$, 1 h). The drying agent was separated and the solvent removed from the filtrate. The yellow oil so obtained darkened rapidly hence was not subjected to further purification or to elemental analysis. The i.r. spectrum (CCl_4) showed a band of medium strength at 3320 cm^{-1} (N—H) and a strong band at 1685 cm^{-1} (C=O). The n.m.r. spectrum in $CDCl_3$ clearly showed that *N*-methylation had occurred (singlet at τ 6.93 for N—CH_3). But the relative areas of the signal of the aromatic methyl group at τ 7.82 (singlet) and that for the N—CH_3 group at τ 6.93 were in the ratio 3:2, thus showing that methylation was incomplete. Hence this oil was approximately a 1:2 mixture of *N'-formyl-o-tolylhydrazine* and *N'-formyl-N'-methyl-o-tolylhydrazine.*

The mixture (14 g) was hydrolyzed by heating in 56 ml of a 1:1 solution (v/v) of concentrated hydrochloric acid and 95% ethanol under reflux for 6 h. The solution, when cooled and then allowed to stand in a refrigerator overnight, deposited a dark yellow solid (3 g) melting at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

130–140°. This was thrice crystallized by solution in 95% ethanol and addition of ether till a faint turbidity appeared. To avoid decomposition the crystallization had to be carried out quickly by effecting solution at room temperature and cooling in a refrigerator. In this manner 1.5 g of a solid hydrazine hydrochloride was obtained, melting at 144–146°. No elemental analysis was made because of the strong tendency of this material to decompose. The i.r. spectrum in Fluorolube showed two sharp bands at 3200 and 3300 cm^{-1} (N—H) and a broad band at 2700 (NH_2^+). The n.m.r. spectrum in D_2O showed a singlet at τ 7.02 (N—CH_3) and two closely spaced singlets at τ 7.80 and τ 7.82 (CH_3—C=C), as well as the DOH peak at τ 5.30 and the aromatic proton multiplet at τ 2.5–3.2. The relative area of the methyl proton signals at τ 7.02 and τ 7.80–7.82 was in the ratio 3:8 indicating that in the hydrolysis and crystallization there had been some loss of *N'*-methylated material, and that the material melting at 144–146° was a mixture primarily of two substances—*N'-methyl-o-tolylhydrazine hydrochloride* and *o-tolylhydrazine hydrochloride*. We were unable to separate these readily, hence proceeded to the cyclization.

A mixture of the above impure *N'*-methyl-*o*-tolylhydrazine hydrochloride (1 g, 0.0058 mole) and propionaldehyde (0.34 g, 0.0058 mole) was heated in refluxing dry benzene (50 ml) for 17 h in an apparatus equipped to collect the azeotropically distilled water. The dark solid which was formed was separated and thrice crystallized by solution in 95% ethanol followed by addition of ether to faint turbidity. There was obtained 52 mg of pure methylamine hydrochloride melting (with sublimation) at 225–230°. The n.m.r. spectrum in D_2O showed only two signals—a relatively large singlet at τ 7.34 (N—CH_3) and a small singlet at τ 5.18 (DOH).

The filtrate obtained after removal of the methylammonium chloride was freed from benzene and the residue was dissolved in 200 ml of ether. The ether solution was washed with 2% hydrochloric acid (15 × 100 ml), then with water (3 × 100 ml) and then dried ($MgSO_4$, 1 h). The $MgSO_4$ was separated and the ether removed from the filtrate to give 500 mg of a dark oil which, according to its n.m.r. spectrum, consisted of essentially 3,7-dimethylindole. The oil was distilled and gave 200 mg of *3,7-dimethylindole* boiling at 90–92°, 0.5 mm; lit. b.p., 85–95° (6) of what is now known to be a mixture containing some 3,7-dimethylindole. The i.r. spectrum in CCl_4 showed a sharp band at 3490 cm^{-1} (N—H). The n.m.r. spectrum in $CDCl_3$ (Fig. 5) showed signals at τ 7.68 (narrow doublet, $J \approx 1$ Hz, 3 H for CH_3 at C-3); τ 7.58 (singlet, 3 H for CH_3 at C-7); a narrow multiplet at τ 3.08 (1 H for H at C-2), and a multiplet for the aromatic protons and NH proton between τ 2.4–3.1. The spectrum showed evidence of the presence of impurities.

Anal. Calcd. for $C_{10}H_{11}N$: C, 82.75; H, 7.58; N, 9.66. Found: C, 79.84; 80.13; H, 10.25, 10.13; N, 9.52, 10.16.

Preparation of 1,3,7-Trimethylindole

The published procedure for *N*-methylation of 8-methyl-1,2,3,4-tetrahydrocarbazole (10) was followed for the *N*-methylation of 3,7-dimethylindole. However, the work-up procedure, following the addition of the concentrated ammonium hydroxide, was modified since the filtered solution failed to deposit any solid even when cooled in a refrigerator overnight. This ammoniacal filtrate was diluted with water and twice extracted with ether. The dried ether solution ($MgSO_4$) was freed from solid and ether.

From 0.5 g of 3,7-dimethylindole there was obtained 0.4 g of an oil whose n.m.r. spectrum in $CDCl_3$ showed it to be a mixture of 3,7-dimethylindole and 1,3,7-trimethylindole in the approximate proportion of 55:45. A petroleum ether (60–70°) solution of this mixture when cooled in a ice–salt bath for 6 h, deposited 44 mg of crystals melting at 43–46°. The n.m.r. spectrum showed that this was essentially 1,3,7-trimethylindole but contaminated with a small amount of 3,7-dimethylindole. The i.r. spectrum verified this contamination by the weak absorption band at 3490 cm^{-1}. A second crystallization from 1 ml of petroleum ether (cooled in a refrigerator overnight) gave 12 mg of pure 1,3,7-trimethylindole melting at 45–46°; mixture m.p. with that previously obtained was undepressed. The n.m.r. spectrum in $CDCl_3$ was identical to that in Fig. 4. No absorption for NH was evident in the i.r. spectrum (CCl_4).

Syntheses of 8-acetoxy-4-twistanone, twistane, 1-twistanol, 1-twistylamine, and 1-twistane carboxylic acid

A. BÉLANGER, Y. LAMBERT, AND P. DESLONGCHAMPS
Département de Chimie, Université de Sherbrooke, Sherbrooke, Québec

Received October 1, 1968

8-Acetoxy-4-twistanone (**8**) has been obtained in one-step from decalin dione **4** and a rigorous chemical proof has been obtained by chemical conversion of **8** into 4-twistanone (**6**). Twistane (**1**), 1-twistanol (**15**), 1-twistane carboxylic acid (**17**), and 1-twistylamine (**20**) have also been synthesized from compound **8** and chemical proofs are included.

The chemistry of tricyclo[$4\cdot4\cdot0\cdot0^{3,8}$]decane **1** (twistane), the twist boat isomer of adamantane, was started by Whitlock (1) who achieved an elegant and unambiguous synthesis of this hydrocarbon *via* the internal cyclization of the bicyclo[2·2·2]system **2** yielding 2-twistanone (**3**).

In order to study the chemistry of this new polycyclic system more thoroughly, it was necessary to develop complementary synthetic schemes which would afford twistane derivatives monofunctionalized at the other alternative positions of the twistane skeleton which are C-4 and the bridgehead.[1] Also shorter syntheses of twistane (**1**) itself were desirable and since its chemical structure was well established, more simple but *a priori* less trivial scheme could be theoretically conceived and tested in the laboratory.

Recently, we have reported (2) a seven-step synthesis of twistane (**1**) utilizing the readily available decalin dione **4**. The key step in this scheme was the internal cyclization of keto mesylate **5** yielding the previously unknown 4-twistanone (**6**).

The high yield obtained in the internal irreversible cyclization step (**5** → **6**) led us to suspect that in strong acidic medium, the decalin dione **4** might well be in equilibrium with the isomeric hydroxy tricyclic ketone **7**. We further anticipated that even if such isomer **7** could be present in small amount at equilibrium, one could take advantage of the presence of a hydroxyl group in **7** by trapping it in order to shift irreversibly the equilibrating system (**4** ⇌ **7**) toward the twistane compound **8**.

If such process can be realized, a twistane derivative would be obtained in one-step directly from the readily available decalin dione **4**. With its two functional groupings, such derivative **8** would permit the synthesis of a large variety of previously unknown twistane compounds.

In this paper, we wish to describe our successful investigation in this area.[2]

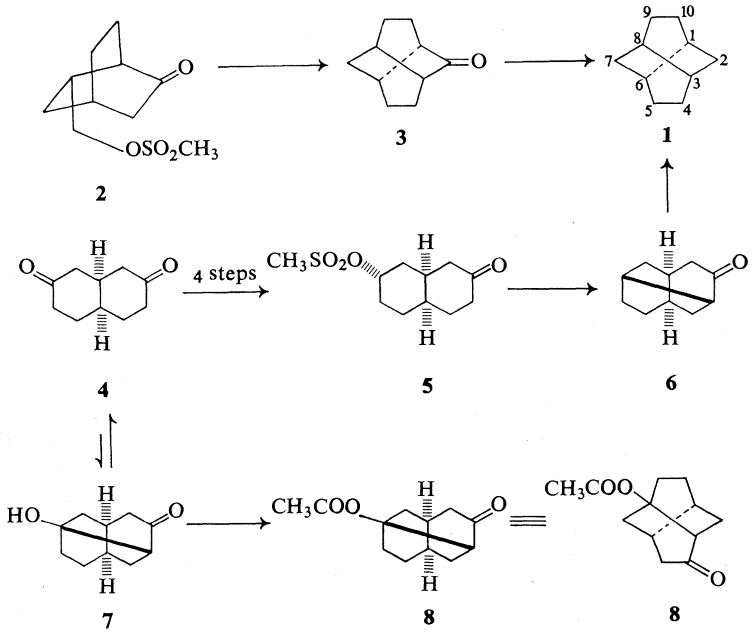
By treating decalin dione **4** with boron trifluoride ethereate in acetic acid containing acetic anhydride at room temperature and utilizing chromatography, the crystalline 8-acetoxy-4-twistanone (**8**) was obtained. Spectral as well as analytical data supported entirely structure **8**. In order to provide an unambiguous chemical proof, 8-acetoxy-4-twistanone (**8**) was converted into the known 4-twistanone (**6**).

Ketalization of 8-acetoxy-4-twistanone (**8**) in the usual manner with ethylene glycol, benzene, and *p*-toluenesulfonic acid gave the oily ketal acetate **9** which by reductive hydrolysis with lithium aluminium hydride in ether gave the expected ketal alcohol **10** in an almost quantitative yield.

Bromination of ketal alcohol **10** with thionyl bromide in pyridine (4) and chromatography gave bromoketal **11**. Hydrogenolysis of compound **11** with Raney nickel in methanol containing sodium hydroxide (4) yielded the corresponding ketal **12** which after acid hydrolysis gave a high yield of 4-twistanone (**6**) as shown by comparison with an authentic sample. This new six-step synthesis of 4-twistanone (**6**) is, however, inferior to our first synthesis (2) because of experimental difficulties encountered at the bromination step (**10** → **11**).

[1]In twistane, the bridgehead C-1, C-3, C-6, and C-8; C-2 and C-7; and C-4, C-5, C-9, and C-10 are all respectively equivalent.

[2]For a preliminary account on part of this work, see ref. 3.



It was of interest to find out if the intermediate hydroxy tricyclic ketone **7** (8-hydroxy-4-twistanone) could be isolated. We had in hand an ideal precursor, the ketal alcohol **10** which could possibly generate the intermediate **7** by a very mild acid hydrolysis.

Consequently, ketal alcohol was submitted to mild hydrolysis condition and was found to give two compounds as judged by thin-layer chromatography. One compound had an identical R_f value with the one of decalin dione **4**, the other compound had a lower R_f value which was a good indication for the presence of the intermediate **7**. This result was further supported by the infrared spectrum of the mixture which showed a strong absorption at 3450 cm^{-1}.

Therefore, an attempt was made to isolate these two compounds by preparative thin-layer chromatography with silica gel. A very neat separation of the two compounds was obtained on the preparative chromatogram and both compounds were isolated by the usual extraction procedure. As expected, the first compound (~25% yield) was found identical to authentic decalin dione **4** by comparison of R_f values (t.l.c.) and infrared spectra. Very surprisingly, the second compound (~75% yield) was also found to have an R_f value identical with the one of decalin dione **4** and its infrared spectra was also identical to an authentic spectra of decalin dione **4**.

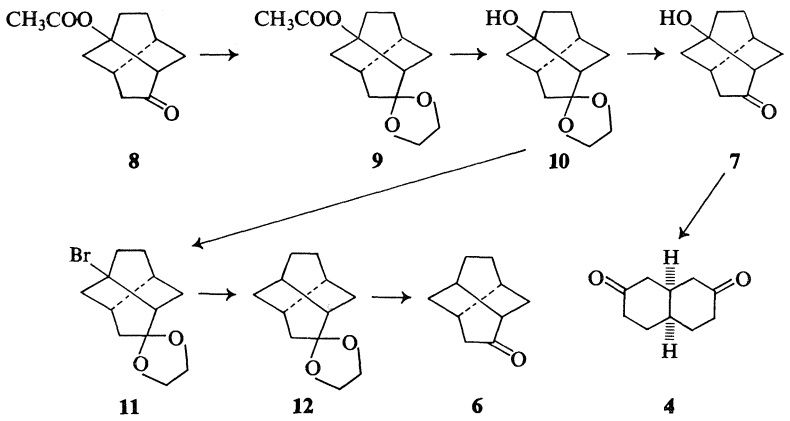
Consequently, a logical explanation for such result is that mild hydrolysis of ketal alcohol **10** gives decalin dione **4** and the isomeric hydroxy tricyclic ketone **7**. The tricyclic isomer **7** appears to survive during the elution on silica gel, but it is so sensitive that it is readily transformed into decaline dione **4** either by a prolonged contact with silica gel or during the extraction procedure.

With a rigorous structural proof in hand for 8-acetoxy-4-twistanone (**8**), the synthesis of twistane derivatives with functions at the bridgehead position was next investigated.

Reaction of 8-acetoxy-4-twistanone (**8**) with ethane dithiol and boron trifluoride in acetic acid at room temperature gave crude thioketal acetate **13** which could be obtained crystalline with petroleum ether. Desulfurization of crude thioketal **13** with a large excess of Raney nickel in boiling ethanol for two days gave the liquid 1-twistyl acetate (**14**). Reductive hydrolysis of compound **14** with lithium aluminium hydride in ether yielded the highly crystalline 1-twistanol (**15**).

Attempts to obtain directly 1-twistanol from 8-acetoxy-4-twistanone (**8**) by the tosylhydrazone – sodium borohydride method (5) followed by lithium aluminium hydride were not as success-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



ful. Yields of approximately 50% were obtained by this method while the thioketal route provided an overall yield of 80%. The Wolff–Kischener reduction procedure, although more esthetical, cannot be applied on 8-acetoxy-4-twistanone (**8**) since the removal of the acetoxy group either by hydroxide ion or hydrazine would destroy the twistane skeleton. Other alternative procedures were also not successful. Reductive hydrolysis of thioketal acetate **13** with lithium aluminium hydride gave the crystalline thioketal alcohol **13** ($CH_3CO{=}H$) which did not yield 1-twistanol (**15**) by desulfurization with Raney nickel or with sodium in liquid ammonia. Similarly, a Birch reduction on thioketal acetate **13** in order to obtain 1-twistanol (**15**) directly was also unsuccessful.

Treatment of 1-twistanol (**15**) with thionyl chloride at reflux temperature gave the crystalline 1-twistyl chloride (**16**) in 95% yield. Reduction of 1-twistyl chloride (**16**) by sodium in liquid ammonia and ether (6) gave a crystalline hydrocarbon which after one sublimation had its physical and spectral properties in complete agreement with those of authentic twistane (**1**). We consider this new six-step synthesis of twistane (**1**), the best practical route to produce the hydrocarbon (1, 2).

Reaction of 1-twistanol with formic acid in sulfuric acid, the Koch–Haaf carboxylation (7), proceeded with remarkable ease giving an excellent yield of a tricyclic tertiary carboxylic acid to which structure **17** was assigned. Because of a theoretically possible rearrangement of 1-twistanol into the adamantane skeleton during this reaction (8), compound **17** was compared and shown to be a different compound than 1-adamantane carboxylic acid. In order to eliminate any other possible structural isomers, a rigorous chemical proof for 1-twistane carboxylic acid (**17**) was necessary and it was achieved in the following manner. By reacting compound **17** with methyl lithium in ether, a quantitative yield of the corresponding methyl ketone **18** was obtained. Baeyer–Villiger oxidation of **18** with *m*-chloroperbenzoic acid in boiling chloroform gave in high yield a liquid identified as 1-twistyl acetate (**14**) which afforded after reductive hydrolysis the crystalline 1-twistanol (**15**) as shown by comparison with an authentic sample.

Similarly, the Ritter reaction proceeded with great facility. Treatment of 1-twistanol (**15**) with acetonitrile and sulfuric acid (9) at room temperature gave the highly crystalline 1-acetamidotwistane (**19**) with a 93% yield. Hydrolysis of compound **19** with diethylene glycol and sodium hydroxide (9) gave 1-twistylamine (**20**) which was obtained crystalline by sublimation. The crystalline hydrochloride salt **21** was obtained by treating an ethereal solution of 1-twistylamine (**20**) with dry hydrogen chloride.

Compounds **19**, **20**, and **21** were respectively compared with 1-acetamido-adamantane, 1-adamantylamine, and its hydrochloride salt.[3] They were shown to be different compounds on

[3]1-adamantylamine hydrochloride was obtained from Aldrich Chemical. 1-Acetamido-adamantane was produced by treating 1-adamantylamine with pyridine and acetic anhydride (m.p. 149–150 °C, reported m.p. 149 °C (9)).

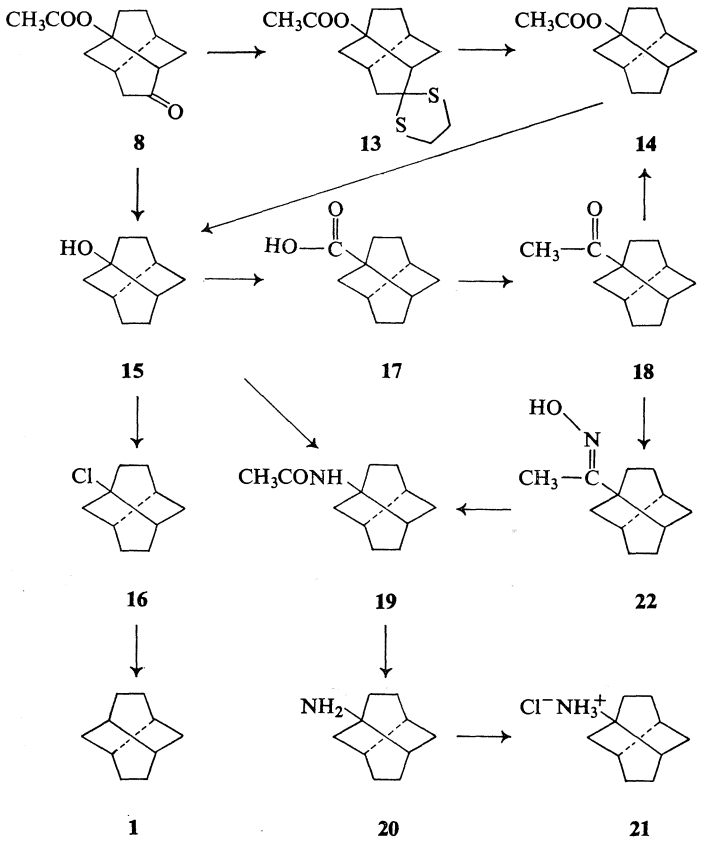
For personal use only.



the basis of their melting point and the finger print region of their respective infrared and nuclear magnetic resonance spectra. Furthermore, the spectral absorption (infrared and n.m.r.) of the functional groups of the adamantane derivatives (10) were found useful to confirm the presence of a primary acetamido group, a primary amino group and a primary ammonium group in compounds **19**, **20**, and **21** respectively.

Again, there remained a possibility that compound **19**, could belong to another tricyclic decane system isomeric with the twistane skeleton, consequently, a rigorous chemical proof was necessary.

Treatment of methyl twistyl ketone (**18**) with hydroxylamine gave the crystalline oxime **22** which was then transformed into the corresponding oxime mesylate (**22**, H=CH_3SO_2). The crude mesylate was heated at reflux in aqueous dioxane (11) and gave a high yield of an amide which was found completely identical to 1-acetamidotwistane (**19**), thus affording a rigorous chemical proof for 1-twistylamine (**20**) and its derivatives.

1-Twistylamine hydrochloride (**21**) is the only other possible skeletal isomer of the important antiviral agent, 1-adamantylamine hydrochloride (12) which possesses three six-membered rings. Biological results on 1-twistylamine and its derivatives will be reported elsewhere.

Experimental

Melting points are not corrected. Infrared spectra (ν_{max}) were recorded on Perkin–Elmer Infracord, model 137 spectrophotometer. Nuclear magnetic resonance spectra (n.m.r., τ values) were taken on a Varian A60 spectrometer with tetramethylsilane as an internal standard. Aluminium oxide G was used for thin-layer chromatography (t.l.c.) and the chromatograms were developed with iodine. Woelm alumina (neutral, grade II) was utilized for column chromatography unless otherwise stated. Anhydrous magnesium sulfate was used as the drying agent in working up reactions. Petroleum ether boiling point 30–60 °C was used.

8-Acetoxy-4-twistanone (8)

Decalin dione **4** (10 g, 63 mmoles) was added to a mixture of freshly distilled boron trifluoride ethereate (86 ml), acetic acid (150 ml), and acetic anhydride (80 ml). After 24 h at room temperature, water was added (700 ml) and the mixture was extracted with chloroform. The organic phase was washed twice with water, aqueous sodium carbonate solution (5%), and water. Evaporation of the dried organic phase yielded a reddish oil (12.79 g) which was purified by column chromatography. Elution with benzene – petroleum ether (15%) gave crystalline 8-acetoxy-4-twistanone **8** (7.54 g). Recrystallization with petroleum ether gave the analytical sample; m.p. 66–68 °C; t.l.c.: R_f value, 0.6, benzene–ether (1:3); mol. wt. (mass spectroscopy) 208; infrared: ν_{max} (CCl_4) 1725 and 1245 cm^{-1}; n.m.r.: τ ($CDCl_3$) 7.32 (1H, broad doublet, CHCO), and 8.05 (3H, singlet, CH_3COO).

Anal. Calcd. for $C_{12}H_{16}O$: C, 69.20; H, 7.74. Found: C, 69.44; H, 7.77.

The 2,4-dinitrophenylhydrazone had m.p. 184–185 °C.

Anal. Calcd. for $C_{18}H_{20}O_6N_4$: C, 55.66; H, 5.19; N, 14.42. Found: C, 55.53; H, 5.14; N, 14.44.

Ketal Acetate (9)

A mixture containing 8-acetoxy-4-twistanone **8** (5.93 g, 28.4 mmoles), ethylene glycol (9.31 g), and *p*-toluenesulfonic acid (210 mg) in benzene (225 ml) was heated at reflux for 24 h with continuous azeotropic removal of water and excess ethylene glycol by means of a Dean–Stark trap. The cooled mixture was washed with saturated aqueous sodium carbonate and water. The dried organic phase was evaporated *in vacuo* to give crude liquid ketal acetate (7.30 g). The analytical sample was obtained by distillation *in vacuo*; t.l.c.: R_f value, 0.9, benzene–ether (1:3); mol. wt. (mass spectroscopy) 252; infrared: ν_{max} (CCl_4) 1725 and 1245 cm^{-1}; n.m.r.: τ ($CDCl_3$) 6.14 (4H, multiplet, OCH_2CH_2O), and 8.03 (3H, singlet, CH_3COO).

Anal. Calcd. for $C_{14}H_{20}O_4$: C, 66.64; H, 8.00. Found: C, 66.53; H, 8.13.

Ketal Alcohol (10)

Crude ketal acetate **9** (6.62 g) was dissolved in ether (250 ml) and lithium aluminium hydride (4.95 g) was added. After a reflux of 3 h, the excess hydride was destroyed by careful addition of water. Magnesium sulfate was added and the inorganic insoluble material was removed by filtration. The organic phase was evaporated to dryness yielding the crude liquid ketal alcohol (4.65 g). The analytical sample was obtained by column chromatography (benzene as eluent) followed by microdistillation *in vacuo*; t.l.c.: R_f value, 0.8, benzene–ether (1:3); mol. wt. (mass spectroscopy) 210; infrared: ν_{max} (CCl_4) 3590 cm^{-1}; n.m.r.: τ($CDCl_3$) 5.96 (4H, multiplet, OCH_2CH_2O) and 7.90 (1H, singlet, OH).

Anal. Calcd. for $C_{12}H_{18}O_3$: C, 68.55; H, 8.63. Found: C, 68.72; H, 8.69.

Bromoketal (11)

A cooled solution (0 °C) of ketal alcohol **10** (750 mg, 3.5 mmoles) in pyridine (7 ml) was added dropwise to a cooled (0 °C) mixture of thionyl bromide (1.45 ml) in pyridine (7 ml) with magnetic stirring. The mixture was then heated (oil bath temperature 90–93 °C) for 90 min. The cooled mixture was mixed with dichloromethane (200 ml) and washed with saturated aqueous sodium carbonate solution and brine. The dried organic phase was evaporated to dryness yielding crude bromoketal (730 mg). Pure liquid bromoketal **11** (640 mg, 66% yield) was obtained by column chromatography with Fisher florisil (100–200 mesh) by elution with benzene. Distillation *in vacuo* gave the analytically pure sample; t.l.c.: R_f value, 0.9, benzene–ether (1:3); mol. wt. (mass spectroscopy) 272 and 274; infrared (CCl_4) no hydroxyl absorption; n.m.r.: τ (CCl_4) 6.08 (4H, multiplet, OCH_2CH_2O).

Anal. Calcd. for $C_{12}H_{17}O_2Br$: C, 52.76; H, 6.28. Found: C, 52.72; H, 6.37.

4-Twistanone (4)

Bromoketal **11** (771 mg, 2.82 mmoles) was hydrogenolyzed in methanol (20 ml) containing sodium hydroxide (124 mg) and Raney nickel (250 mg) under an atmosphere of hydrogen at 50 °C during 12 h. During this period, new portion of Raney nickel (~200 mg) was added twice. The catalyst was removed by filtration and the solvent evaporated *in vacuo*. Ether was added and the solution was washed with brine. The dried ethereal solution was evaporated to dryness to give crude ketal **12** (430 mg).

A solution of crude ketal (340 mg) in tetrahydrofuran (7 ml) was mixed with a hydrochloric acid solution (*N*, 35 ml) and left for 3 h at room temperature. Sodium chloride was added and the mixture was extracted with ether. The dried extract was evaporated to dryness yielding crude 4-twistanone (**6**). This crude product was purified by column chromatography. Elution with benzene gave pure 4-twistanone **6** (160 mg) which after one sublimation was found identical (mixed melting point, t.l.c., infrared, and n.m.r. spectra) with an authentic sample (2).

Acid Hydrolysis of Ketal Alcohol (10)

p-Toluenesulfonic acid (9 mg) and water (5 drops) were added to an ethereal solution (10 ml) of ketal alcohol **10** (80 mg, 0.38 mmole). The mixture was magnetically stirred at room temperature. The reaction was followed by thin-layer chromatography analyses and after 12 h, ketal alcohol **10** was completely hydrolyzed. The reaction mixture was washed with an aqueous solution of sodium bicarbonate (0.5 *N*). The dried organic phase was evaporated to dryness at room temperature to give a mixture of two compounds (70 mg). This mixture was separated by preparative thin-layer chromatography with Silica Gel G as adsorbent and benzene–ether (1:3).

The compound having an R_f value of 0.6 was extracted with ether. Evaporation of the solvent gave a compound (12 mg) which was found completely identical with authentic diketone **4** by comparison of their R_f value (t.l.c.), infrared, and n.m.r. spectra.

The product having an R_f value of 0.5 was extracted with ether. Evaporation of the solvent gave a product (33 mg) which had an identical R_f value with the one of diketone **4**. The infrared spectrum was almost completely identical to the infrared spectrum of diketone **4**. This material was submitted again to preparative thin-layer chromatography and yielded a product having an

For personal use only.

infrared spectrum which was completely identical to the one of authentic diketone **4**.

*Thioketal Acetate (**13**)*

Boron trifluoride ethearate (12 ml) and ethane dithiol (10 ml) was added to a solution of 8-acetoxy-4-twistanone **8** (10 g, 48 mmoles) in acetic acid (600 ml). After 17 h at room temperature, water (5 l) was added and the mixture was extracted with ether. The ethereal extract was washed with a saturated solution of sodium carbonate and the dried organic phase was evaporated to dryness. This material (17.7 g) was heated (oil bath temperature, 100 °C) *in vacuo* (0.5 mm) during 3 h to remove excess of ethane dithiol. The crude oily material (14.4 g) was suitable for the next reaction. Pure crystalline thioketal acetate **13** was obtained by crystallization with petroleum ether; m.p. 71–72 °C; t.l.c.: R_f value, 0.4, petroleum ether – benzene (1:1); mol. wt. (mass spectroscopy) 284; infrared: ν_{max} (CCl_4) 1735 cm^{-1}; n.m.r.: τ (CCl_4) 6.60 (4H, multiplet, SCH_2CH_2S) and 8.02 (3H, singlet, CH_3COO).

Anal. Calcd. for $C_{14}H_{20}O_2S_2$: C, 59.15; H, 7.04; S. 22.54. Found: C, 59.15; H, 7.17; S, 22.83.

*Thioketal Alcohol (**13**, $CH_3CO{=}H$)*

Lithium aluminium hydride (1.1 g) was added to a solution of crude thioketal acetate (900 mg) in ether (150 ml) and the mixture was refluxed during 4 h. The excess hydride was destroyed by careful addition of water, magnesium sulfate was added, and the insoluble material was removed by filtration. The ethereal solution was evaporated to dryness yielding a crude product (860 mg) which was purified by column chromatography. Elution with benzene – petroleum ether (10%) gave unidentified material. Elution with mixtures of benzene – petroleum ether (25% and 50%) gave crystalline thioketal alcohol **13** (450 mg). Recrystallization with petroleum ether gave the analytical sample; m.p. 111–112 °C; t.l.c.: R_f value, 0.5, benzene; infrared: ν_{max} (CCl_4) 3480 cm^{-1}; n.m.r.: τ ($CDCl_3$) 6.65 (4H, complex multiplet, SCH_2CH_2S).

Anal. Calcd. for $C_{12}H_{18}OS_2$: C, 59.49; H, 7.48; S, 26.41. Found: C, 59.37; H, 7.67; S, 26.19.

*1-Twistyl Acetate (**14**)*

*(a) from Thioketal Acetate (**13**)*

Crude thioketal acetate **13** (14.4 g) was dissolved in absolute ethanol (1.5 l), Raney nickel (225 g) was added and the mixture was mechanically stirred and refluxed for 24 h. The catalyst was removed by filtration and a new portion of catalyst (150 g) was added and the mixture was refluxed for 24 h. After removal of the Raney nickel by filtration, the ethanol was evaporated *in vacuo* yielding pure 1-twistyl acetate **14** (7.3 g, 80% overall yield from 8-acetoxy-4-twistanone). The analytical sample was obtained by distillation *in vacuo* (80 °C, 0.5 mm). t.l.c.: R_f value, 0.6, petroleum ether – benzene (1:1); infrared: ν_{max} (film) 1735 cm^{-1}; n.m.r.: τ (CCl_4) 8.11 (3H, singlet, CH_3COO).

Anal. Calcd. for $C_{12}H_{18}O_2$: C, 74.23; H, 9.28. Found: C, 74.48; H, 9.62.

*(b) from Methyl Twistyl Ketone (**22**)*

Methyl twistyl ketone **22** (192 mg, 1.08 mmoles) was dissolved in dichloromethane (20 ml) containing *m*-chloroperbenzoic acid (400 mg) and the mixture was refluxed for seven days. An aqueous sodium hydroxide solution (0.5 *N*) was added and the organic phase was separated, washed with water, and dried. The solvent was evaporated *in vacuo* to give a crude liquid (200 mg) which showed one spot on thin-layer chromatography having a R_f value corresponding to 1-twistyl acetate. A small quantity (40 mg) was purified by column chromatography using a mixture of petroleum ether – dichloromethane (1:1) and was shown to be identical to authentic 1-twistyl acetate (**14**) by comparison of infrared and n.m.r. spectra. Crude 1-twistyl acetate **14** (200 mg) was hydrolyzed with lithium aluminium hydride in ether and after the usual work-up gave crude crystalline 1-twistanol (120 mg). This product was recrystallized in petroleum ether (m.p. 216–217 °C) and was shown to be identical with authentic 1-twistanol by mixed melting point determination and by comparison of infrared and nuclear magnetic resonance spectra.

*1-Twistanol (**15**)*

*(a) from 1-Twistyl Acetate (**14**)*

Lithium aluminium hydride (15 g) was added to an ethereal solution (2 l) of 1-twistyl acetate (14.5 g, 75 mmoles) and the mixture was refluxed for 12 h. The excess hydride was carefully destroyed by addition of moist ether and a hydrochloric acid solution (*N*) was added. The organic phase was separated, dried, and evaporated to dryness to give quantitatively 1-twistanol **15** (11.4 g). Recrystallization with petroleum ether gave the analytical sample; m.p. 215–216 °C; t.l.c.: R_f value, 0.7, ether; infrared: ν_{max} (CCl_4) 3600 and 3400 cm^{-1}.

Anal. Calcd. for $C_{10}H_{16}O$: C, 78.95; H, 10.53. Found: C, 78.75; H, 10.81.

*(b) from 8-Acetoxy-twistanone (**8**)*

p-Toluenesulfonylhydrazine (559 mg, 3 mmoles) was added to methanol (50 ml) containing 8-acetoxy-4-twistanone (500 mg, 2.4 mmoles) and the mixture was refluxed for 20 h. Most of the solvent was removed and the residue was recrystallized with methanol (750 mg, 83% yield). The *p*-toluenesulfonylhydrazone derivative was recrystallized with methanol to give the analytical sample; m.p. 165.5–167.5 °C.

Anal. Calcd. for $C_{19}H_{24}N_2O_4S$: C, 60.64; H, 6.38; N, 7.45. Found: C, 60.32; H, 6.88; N, 7.88.

The crude *p*-toluenesulfonylhydrazone derivative (1.26 g) obtained from 8-acetoxy-4-twistanone (1.15 g, 2.76 mmoles) was dissolved in dry dioxane (50 ml), sodium borohydride (786 mg, 20.7 mmoles) was added, and the mixture was refluxed for 10 h. Excess lithium aluminium hydride was added and the mixture was heated at reflux during 12 h. The excess hydride was destroyed by addition of acetone and water. The insoluble material was filtered, dissolved in hydrochloric acid solution (*N*, 10 ml), and extracted with ether. The dried dioxane filtrate was evaporated to dryness and combined with the ethereal extract which was evaporated to dryness (638 mg). This crude material was distilled *in vacuo* to yield an oil (480 mg) which was purified by column chromatography. Elution with petroleum ether and benzene gave no desired product. Elution with ether–benzene (2%) gave pure crystalline 1-twistanol **15** (207 mg, 52% yield from **8**) which was found to be identical with an authentic sample by comparison of their infrared spectra.

*1-Twistyl Chloride (**16**)*

1-Twistanol **15** (1.6 g, 10.5 mmoles) was slowly added to freshly distilled thionyl chloride (35 ml) with an efficient stirring. When the solution was homogeneous, it was refluxed for 2 h. The solution was evaporated to dryness giving a yellow oil which was dissolved in pentane (500 ml), washed with water, and saturated sodium carbonate solution. The dried pentane solution was evaporated to dryness yielding a slightly yellow crystalline residue (1.75 g). This material was purified by column chromatography using pentane – petroleum ether (1:1). The analytical sample was obtained by sublimation, m.p. 147–148 °C.

Anal. Calcd. for $C_{10}H_{15}Cl$: C, 70.38; H, 8.80. Found: C, 69.31; H, 8.90.

*Twistane (**1**)*

An ethereal solution (350 ml) of 1-twistyl chloride **16** (5.16 g, 30.3 mmoles) was mixed with liquid ammonia (750 ml) and sodium (2.7 g) was added in small pieces over a period of 4 h. Ethanol was added to destroy the excess of sodium and the ammonia was allowed to evaporate at room temperature. A solution of hydrochloric acid (*N*) was added to the residue and extracted with pentane. The pentane solution was washed with water, dried, and distilled at atmospheric pressure giving semi-crystalline residue. One sublimation (120–124 °C, 12 mm) gave pure twistane (3.46 g, 85% yield) which was found to be identical (t.l.c., infrared, and n.m.r.) with an authentic sample (1, 2).

*1-Twistane Carboxylic Acid (**17**)*

A mixture of 1-twistanol **15** (2.18 g, 182 mmoles) and formic acid (97%+, 4.7 ml) in hexane (47 ml) cooled at 0 °C was slowly added during a period of 1 h in cold sulfuric acid (0 °C). Vigourous stirring was maintained during the addition and for a period of 3 h at room temperature. The mixture was poured on ice, sodium chloride was added, and the mixture was extracted with ether. The organic phase was extracted with an aqueous sodium hydroxide solution (*N*). The basic aqueous phase was acidified with hydrochloric acid solution (3 *N*) and extracted with ether. The dried organic phase was evaporated to dryness yielding a semi-crystalline product (2.2 g, 80% yield) which was shown homogeneous by thin-layer chromatography. This product was obtained crystalline with methanol–water. Recrystallization and sublimation *in vacuo* gave the analytical sample, m.p. 85–87 °C; t.l.c. (silicagel G): R_f value, 0.5, methanol–ether (10%); infrared: ν_{max} (CCl_4) 1710 cm^{-1}; n.m.r.: τ ($CDCl_3$) −1.34 (1H, broad singlet, COOH).

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.26; H, 8.94. Found: C, 73.02; H, 9.12.

*Methyl Twistyl Ketone (**18**)*

An ethereal solution of methyl lithium (60 ml, 0.6 *N*) was added to 1-twistane carboxylic acid **17** (2.0 g, 11.1 mmoles) dissolved in dry ether (80 ml). This mixture was refluxed for 3 h, the excess methyl lithium was destroyed by addition of moist ether and brine was added. The dried ethereal phase was evaporated *in vacuo* to give a liquid (1.96 g, 100% yield) which was shown homogeneous by thin-layer chromatography. A pure sample was obtained by microdistillation *in vacuo*; t.l.c.: R_f value, 0.6, benzene; infrared: ν_{max} (CCl_4) 1700 cm^{-1}; n.m.r.: τ (CCl_4) 8.01 (3H, singlet, CH_3CO) 2,4-dinitrophenylhydrazone, m.p. 175–177 °C.

Anal. Calcd. for $C_{18}H_{22}N_4O_4$: C, 60.30; H, 6.20; N, 15.65. Found: C, 60.01; H, 6.52; N, 15.89.

*Methyl Twistyl Ketone Oxime (**23**)*

Hydroxylamine hydrochloride (10.24 g), sodium acetate (15.35 g), and methyl twistyl ketone **18** (1.454 g, 8.2 mmoles) was dissolved in methanol (150 ml) and the mixture was refluxed for 5 h. A part of the methanol was evaporated *in vacuo*, water was added, and the mixture was extracted with ether. The dried organic phase was evaporated to dryness yielding a crystalline product (1.734 g). Recrystallization with petroleum ether gave the analytical sample; m.p. 150–151 °C; t.l.c.: R_f value, 0.6, benzene; infrared: ν_{max} (CCl_4) 3250 and 1660 (weak) cm^{-1}; n.m.r. τ (CCl_4) 8.23 (3H, singlet, CH_3).

Anal. Calcd. for $C_{12}H_{19}OH$: C, 74.57; H, 9.90; N, 7.24. Found: C, 74.37; H, 10.13; N, 7.43.

*1-Acetamidotwistane (**19**)*

*(a) from 1-Twistanol (**15**)*

Concentrated sulfuric acid (3.8 ml) was slowly added to cold acetonitrile (10 ml, ice-bath) and this solution was added drop-by-drop (30 min) to a solution of 1-twistanol **15** (579 mg, 3.8 mmoles) in acetonitrile (10 ml) while magnetically stirred and cooled with an ice-bath. The reaction mixture was left at room temperature for 12 h. The mixture was then cooled with an ice–bath and a solution of sodium hydroxide (6 g) in water (20 ml) was slowly added. The mixture was extracted with ether and the organic extract was washed once with brine. The dried organic phase was evaporated *in vacuo* to give a crystalline product **19** (741 mg; 100% yield). 1-Acetamidotwistane **19** was recrystallized with ether – petroleum ether to give the analytical sample (686 mg, 93% yield); m.p. 129–131 °C, t.l.c.: R_f value, 0.5, ether; mol. wt. (mass spectroscopy) 193; infrared: ν_{max} (CCl_4) 3230 and 1670 cm^{-1}; n.m.r.: τ (CCl_4) 3.55 (1H, broad singlet, CONH) and 8.18 (3H, singlet, CH_3CO).

Anal. Calcd. for $C_{12}H_{19}NO$: C, 74.57; H, 9.91; N, 7.25. Found: C, 74.22; H, 9.76; N, 7.16.

*(b) from Methyl Twistyl Ketone Oxime (**22**)*

A cold solution of methyl twistyl ketone oxime **22** (68 mg, 0.35 mmole) in dichloromethane (0.6 ml) was added to a cold mixture of methanesulfonyl chloride (68 mg), pyridine (0.2 ml), and dichloromethane (2 ml). After 36 h in the cold, dichloromethane was added, the mixture was washed twice with saturated aqueous sodium carbonate, and with water. The dried organic phase was evaporated to dryness yielding the crude methyl twistyl ketone oxime mesylate (75 mg). This crude product (70 mg) was dissolved in a mixture of dioxane (4 ml) and water (3 ml) and heated at reflux for 4 h. Brine was added and the mixture was extracted with ether. The dried organic phase was evaporated to dryness to give crude crystalline 1-acetamido twistane (52 mg). This product was further purified by column chromatography and recrystallized with ether–petroleum ether to give a compound which was found identical (m.p., t.l.c., infrared, and n.m.r. spectra) to 1-acetamido twistane **19** obtained from procedure *a*.

*1-Twistylamine (**20**) and its Hydrochloride Salt (**21**)*

1-Acetamidotwistane **19** (522 mg, 2.7 mmoles) was dissolved by heating in diethylene glycol (10 ml) and then cooled at room temperature. Sodium hydroxide (1 g) was added and the mixture was heated (oil bath temperature 240–250 °C) under a nitrogen atmosphere during 4 h. The reaction mixture was cooled at room temperature, brine (40 ml) was added and the mixture was extracted with ether. The dried extract was evaporated to dryness to give crude 1-twistyl amine (560 mg) which slowly solidified on standing. Pure 1-twistylamine **20** was obtained by sublimation; m.p. 184–185 °C; t.l.c.: R_f value 0.25, methanol–ether (7%); infrared: ν_{max} (NaCl) 3300 (broad) and 1600 (broad) cm^{-1}; n.m.r. τ (CCl_4) 9.02 (2H, singlet, NH_2).

Crude 1-twistylamine (560 mg) was dissolved in dry ether and dry hydrogen chloride gas was passed through the solution until the precipitation of 1-twistylamine hydrochloride **21** was completed (392 mg, 80% yield). Recrystallization with methanol–ether gave the analytical sample; m.p. above 360 °C; mol. wt. (mass spectroscopy) 151 (M^+-HCl); n.m.r.: τ ($CDCl_3$), 1.65 (3H, broad singlet, NH_3^+).

Anal. Calcd. for $C_{10}H_{18}NCl$: C, 64.34; H, 9.65; N, 7.50. Found: C, 64.03; H, 9.62; N, 7.48.

Nuclear magnetic resonance study of intramolecular electronic effects in diphenyl sulfides, sulfoxides, and sulfones[1]

J. B. Hyne and J. W. Greidanus

Fundamental Sulphur Research Group, Alberta Sulphur Research Ltd., and Department of Chemistry, University of Calgary, Calgary, Alberta

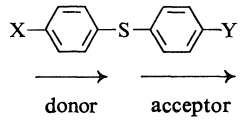
Received August 13, 1968

A nuclear magnetic resonance (n.m.r.) method has been applied to the study of variations in electron density in the aromatic rings of *para*-disubstituted diphenyl sulfides, sulfoxides and sulfones. The n.m.r. response of the aromatic ring protons has been determined as a function of the nature of the *para* substituents and particularly as a function of the nature of the bridging group between the rings. Certain diphenyl ethers and diphenyl methanes have been investigated for comparison purposes. The results establish that a transmission mechanism is operative through sulfur in diphenyl sulfides that is not effective when the bridging function is sulfoxide or sulfone. The extent to which transmission is operative even in the sulfides is dependent on the precise nature of the *para* substituents, in particular whether they are donors or acceptors and the manner in which they interact with the remainder of the molecule.

Canadian Journal of Chemistry, **47** 803 (1969)

Introduction

Many experimental techniques have been applied to the study of transmission of electronic effects through a sulfur bridge. In any bridged system we may expect σ-conduction which rapidly diminishes with distance. The potentially much stronger transmission of effects through a system of delocalized π-bonds in particular has attracted much attention; for instance the question of whether a bridging sulfur atom linking two π-bonded systems, one a potential electron donor, the other a potential acceptor, permits "leakage" of electron density from one ring to the other:



In general the state of hybridization of the bridging atom is fundamental to the question of transmission across a bridging atom or group located between potential donor and acceptor functions in a molecule. When the energy differences between the various possible states of hybridization of the bridging function become small, as is the case in sulfur compared with oxygen, it also becomes increasingly difficult to establish whether there exists sufficient "incentive" for the molecule to promote electrons from lower lying orbital energy levels to slightly higher ones, i.e. undergo rehybridization. The possibility of expansion of the sulfur valence shell has been discussed by many workers and reviews covering this topic up to a recent date have been published (2, 3).

Mangini and co-workers, studying the ultraviolet spectra of a large variety of aromatic sulfides found no evidence for transmission of electronic effects (4–6). Szmant and McIntosh (7) have, on the basis of similar studies, come to the conclusion that there was indeed evidence for this type of transmission when there was sufficient driving force in the form of both a powerful electron donating and an electron accepting potential within the molecule. The conclusion that interaction through the sulfur atom in various diphenyl sulfides was very limited was reached by other workers as a result of infrared and polarographic studies (8, 9). The effect of various ring substituents on the acid strengths of β-phenylthio, β-phenylsulfinyl, and β-phenylsulfonyl acrylic acids led Hogeveen (10) to the conclusion that the effects were more efficiently transmitted through the sulfide *S*-bridge than through the sulfinyl or sulfonyl bridges. Litvinenko and co-workers (11–14) studied the reactivity of the primary amino group in di-*para*-substituted compounds of the type $Y—C_6H_4—X—C_6H_4—NH_2$, where X = S, Se or NH. These authors suggested that the ability to transmit electronic effects decreases in the order —NH—>—S—>—Se—>—O—.

In any experimental investigation of the possible transmission of electronic effects through a bridging sulfur atom the question as to whether

[1]Preliminary results were presented at the Princeton University Conference on "The Chemistry of Sulfides", June 1966 (1).

TABLE I

Average chemical shift* of the aromatic protons† of some diphenyl compounds ("whole molecules") and of the corresponding *para*-substituted "half molecules"‡

Z = SO_2	Half molecule	455.3	Half molecule	497.5
	Whole molecule	456.1	Whole molecule	493.8
	Change§	−0.8	Change	+3.7

*All figures in c.p.s. from tetramethylsilane internal standard in $CDCl_3$, calibrated on singlet peak of residual $CHCl_3$ at 435 c.p.s.
†The shift of the center of the aromatic multiplet was taken.
‡For explanation see text.
§A negative change indicates a downfield shift, the protons being less shielded in the diphenyl compound.

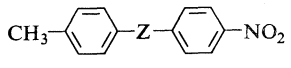
excited states are involved in the study must be clearly established. Transmission mechanisms operative in excited states may not be important in the ground state. Any evidence obtained from the study of ultraviolet spectra and reactivity differences must be considered to be in a different class from that obtained in studies where ground states are involved, such as dipole moment, infrared, and nuclear magnetic resonance studies. In a recent paper Wehry (15) discussed the results of his measurement of acid dissociation constants of various phenols with sulfur-containing substituents in the ground state, the lowest triplet and the first excited singlet state. He obtained good evidence for both $3p_\pi$ donor and $3d_\pi$ acceptor conjugation of sulfide sulfur in the ground state.

Because the nature of the transmission process is subtle and may be energetically of minor magnitude, the proper choice of the experimental tool to be applied would seem to be important. It is therefore not surprising that in recent times nuclear magnetic resonance techniques have been increasingly used in studies of sulfur bonding (6, 16–18). We also chose to use this tool to study the transmission of electronic effects in di-*para*-substituted diphenyl compounds of the sulfide, sulfoxide, sulfone, ether and methylene types.

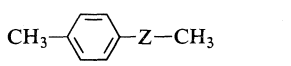
Methods and Results

The specific aim of our study was to investigate changes in the electron density of the aromatic rings of disubstituted diphenyl systems by measuring the chemical shifts associated with the protons of each aromatic ring. Almost all compounds contained unsymmetrically *para*-disubstituted rings only and the splitting pattern associated with the n.m.r. response of each set of four ring protons, although strictly of the A_2B_2 type, may be considered as two superimposed identical AB patterns, yielding a typical AB quartet. The average n.m.r. shift associated with the four ring protons was obtained by measuring the position of the center of the multiplet. The value of this shift was then taken as a measure of the relative electron density in each aromatic ring in the various compounds studied. The further approach chosen to find an answer to the basic question of whether a bridging function Z acts as an insulator or a transmitter of electronic effects will be illustrated by reference to a specific set of compounds.

The average n.m.r. shifts observed for the aromatic protons in the "whole molecule" were compared with those of the corresponding "half molecules", where Z = S, SO, or SO_2:



"whole molecule"



"half molecules"

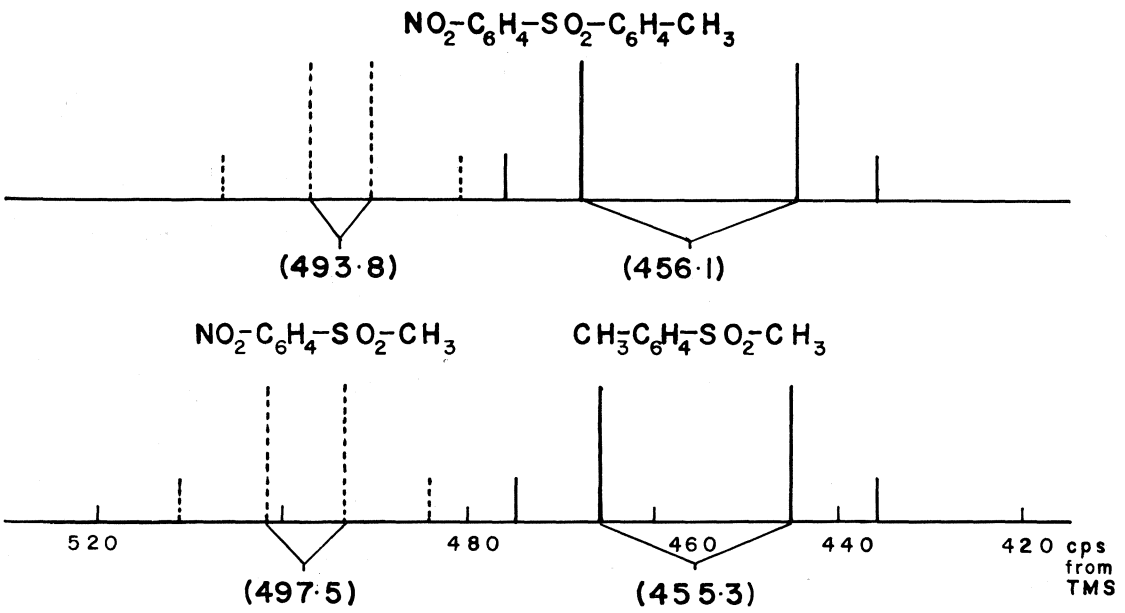

FIG. 1. Diagrammatic representation of the nuclear magnetic resonance spectra for 4-(*p*-nitrophenylsulfonyl)-toluene.

If the sum of the n.m.r. ring spectra of the "half molecules" shows no significant difference from that of the "whole molecule", it must be concluded that the Z-function bridge acts as an insulator between the two phenyl rings. Even if there is no transmission across the Z-function, it is to be expected that strict additivity will not be observed, since replacing the terminal methyl group in the "half molecules" by a substituted phenyl ring, as in the "whole molecule", must lead to minor changes in electron density due to inductive effects (σ-conduction). The shifts observed for the three sets of compounds under consideration are presented in Table I. The sign convention used for the differences is indicated in this Table.

In these three systems it was found that in the sulfone and sulfoxide cases (Z = SO_2 or SO) there was little difference between the ring proton shifts in the "half molecules" compared with the "whole molecule" as manifest in the small value of the "change". Such was not the case where Z = S (Figs. 1, 2, and 3). In the diphenyl sulfide (Z = S) the electron density of the methyl-carrying ring was significantly decreased, while that of the nitro-substituted ring was increased when compared with the n.m.r. data obtained for the "half molecules".

Based on the initial analysis described above the study was extended to cover a wider range of *para*-substituents and the corresponding oxygen- and methylene-bridged compounds. The complete n.m.r. data are presented in Tables II and III. In Table IV the differences in chemical shifts for the aromatic protons, calculated in exactly the same way as the "change" entry in Table I, are tabulated.

Discussion

The n.m.r. results for 4-(*p*-nitrophenylthio)-toluene (Table I, Z = S) are in agreement with transmission through the sulfur bridge, the electron density in the methyl-substituted ring having decreased, that in the nitro-substituted ring having increased in the "whole molecule" compared with two "half molecules". This can only arise if the molecule is polarized along its entire length, permitting electron density to leak from the donor ring to the acceptor ring. In the case of the corresponding sulfoxide and sulfone (Table I, Z = SO or SO_2) the changes in shift are comparatively minor and may be due to inductive effects. These results clearly established the fact that a transmission effect is operative in the sulfide that is not operative in the sulfoxide or sulfone. This trend is also evident from the data

collected for the three other diphenyl sulfides whose sulfoxides and sulfones were used in this study together with their corresponding ethers and methylenes (see Table IV, first four lines). There are some notable exceptions, however.

In general the changes in the shifts are largest for the sulfide-bridged molecules with the exception of the 4-methoxy-4′-methyl-disubstituted sulfide; here the behavior is more comparable with the shift changes observed for the sulfoxides and sulfones. This may be a reflection of the fact that both substituents are electron donors, working against each other. The necessary "incentive" for the bridging sulfur to transmit may therefore be missing in this case, as was suggested by Szmant and McIntosh (7) in their study of the ultraviolet spectra of some other diphenyl sulfides.

The methylene-bridged compounds were included in this study because it was not expected that they would transmit by other than an inductive mechanism, and therefore would serve as a useful reference. Indeed, all changes in the shifts for both rings in the substituted diphenylmethane compounds are positive. This strongly suggests that these changes arise from a diamagnetic anisotropy effect resulting from the replacement of the terminal methyl group in the "half molecule" by the aromatic ring in the "whole molecule". Since this shift effect is extraneous to the transmission effect, these data serve to establish the fact that changes in shift of the order of 2 c.p.s. can not be considered as meaningful as far as the study of transmission is concerned. This would conveniently account for many of the minor shift variations listed in Table IV but it does not account for the very sizeable negative variations (decreased electron density) in the shifts observed in the X-substituted ring of the oxygen-bridged compounds (see Table IV). There is no corresponding positive variation

(increase in electron density) observed in the Y-substituted ring as is the case in the sulfides.

At first sight it is hardly conceivable that the flow of electron density from the donor ring of the oxygen-bridged compounds would find its way on to the oxygen without being subsequently transmitted to the acceptor ring by some mechanism. The findings of Marcus *et al.* (18) are of interest in this regard. These authors concluded on the basis of results of their own n.m.r. study as well as of the work of others that in conjugative roles sulfur is a better transmitter than oxygen when acting as an acceptor or acceptor–donor of negative charge, but that the situation is reversed when only conjugative donation by the bridging atom is called for. When this conclusion is accepted it is clear that the relative order of the sulfur and oxygen bridge-effects may depend to a great extent on the role these atoms are called upon to play by the specific relative nature of the two *para*-substituents on the aromatic rings. Indeed, it is possible using these conclusions by Marcus *et al.* to account qualitatively for the marked differences in the shift changes (Table IV) obtained for sulfur and oxygen-bridged compounds where strong donor and acceptor groups are present as substituents, i.e. in the case of the combinations of CH_3O— with NO_2—, and of NH_2— with NO_2—. In the other two cases where comparison is possible between O and S as a bridging atom, i.e. in the case of the combinations of CH_3— with NO_2—, and of CH_3O— with CH_3— as *para*-substituents, the predictions on the basis of the same conclusions of Marcus *et al.* (18) do not always agree with the changes in the shift.

There are probably many interesting facts relevant to the problem hidden within the many minor changes in shift as tabulated in Table IV. However, there are also a number of minor perturbing factors at work which are not directly related to the transmission problem. We are obliged therefore to restrict our attention to *the more salient features of the data* and accordingly limit our conclusion to the fact that there is evidence for the existence of a transmission mechanism across the sulfide bridge that is absent in the cases of the sulfoxide, sulfone and methylene bridges. There does not appear to be a similar transmission mechanism operative in the oxygen bridge but some type of deshielding of the donor ring protons takes place when oxygen is flanked by two π-electron systems.

In the case of the sulfides, where transmission appears to be operative, the study was extended to cover a wider range of substituents (see Table IV). In all but one of these compounds the donor ring is deshielded and the acceptor ring shows increased shielding. The exception is the case where CH_3— and H— are the substituents; conjugative interaction would be expected to be weaker.

The deshielding of the donor ring in the *p*-nitro-substituted diphenyl sulfide coupled with the increase in shielding in the nitro-substituted acceptor ring provides evidence for a transmission process and is in contrast with the conclusion reached by Szmant and McIntosh (7). On the basis of their ultraviolet studies, there is no evidence for involvement of the resonance structure:

Wehry (15) found that when donor–acceptor type conjugation is present in the ground state of sulfides it must be expected to increase upon excitation, unless electron releasing p_π conjugation is sterically inhibited.

The data obtained for the 4-chloro-4′-nitro-substituted diphenyl sulfide (see Table IV) indicate that in the presence of the powerful electron withdrawing nitro group the chloro substituent is also forced to act as a donor.

Conclusion

The n.m.r. evidence presented supports the conclusion that intramolecular transmission of electronic effects between a donor and acceptor moiety occurs more readily across a sulfide bridge than across sulfoxide, sulfone, ether or methylene bridges. The extent to which such transmission occurs, however, is strongly dependent upon the nature of the donor and acceptor functions and the availability of a mechanism for establishing a sufficient degree of polarization across the bridging function to provide sufficient "incentive" for the bridging function to act as a conductor as opposed to an insulator.

Experimental

Nuclear magnetic resonance spectra were recorded on a Varian A-60 spectrometer. The concentration of the solutions was 2.5% (W/W) in $CDCl_3$, with tetramethylsilane as an internal reference. All spectra were run at a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

sweep width of 500 c.p.s., but the aromatic multiplets were always re-run at sweep widths of 100 or 50 c.p.s. In this region the residual $CHCl_3$ in the solvent served as a convenient standard for calibration (at 435 c.p.s. from tetramethylsilane).

Microanalyses were carried out by Mrs. S. Bagley, and the nuclear magnetic resonance spectra were recorded by Mrs. V. Boon, both of the Department of Chemistry, The University of Calgary.

Most of the compounds used in this study had been reported previously and several were commercially available. The data for those prepared follow. Melting points are not corrected. Numbers given to compounds refer to the listing in Tables II and III.

Preparation of Sulfides

(a) Methyl Phenyl Sulfides

Most of the methyl phenyl sulfides were prepared by methylation of the corresponding thiols, using the procedure of Gilman and Beaber (19): 1-bromo-4-(methylthio)benzene (**33**), m.p. 38–39° from aqueous methanol (lit. m.p. 38° (20)); 1-chloro-4-(methylthio)-benzene (**34**), b.p. 87° at 5 mm (lit. b.p. 170° (21)); 4-(methylthio)toluene (**27**), b.p. 82° at 6 mm (lit. 104–105° at 20 mm (19)); 1-(methylthio)-4-nitrobenzene (**30**), m.p. 71–72° from methanol (lit. m.p. 72° (22)); 4-(methylthio)-anisole (**28**), b.p. 100° at 5 mm (lit. b.p. 99° at 4 mm (23)); *N,N*-dimethyl-4-(methylthio)aniline (**32**), b.p. 74–77° at 0.13–0.20 mm (lit. b.p. 140° at 3 mm (5)).

4-(Methylthio)aniline (**29**) was prepared as reported (24), b.p. 74° at 0.15 mm (lit. b.p. 155° at 23 mm (24)).

(b) Diphenyl Sulfides

The procedure given by Gilman and Broadbent (25) was used for the preparation of the following sufides: 4-(*p*-nitrophenylthio)anisole (**1**), m.p. 67–68° from ethanol (lit. m.p. 67–68° (26)); 4-(*p*-nitrophenylthio)-toluene (**4**), m.p. 80–82° from ethanol (lit. m.p. 80–81° (25)); (*p*-nitrophenylthio)benzene (**6**), m.p. 55–56° from ethanol (lit. m.p. 55° (25)); *N,N*-dimethyl-4-(*p*-nitrophenylthio)aniline (**7**), m.p. 181.5–183° from ethanol–chloroform (lit. m.p. 181° (4)); 1-chloro-4-(*p*-nitrophenylthio)benzene (**9**), m.p. 85–87° from ethanol (lit. m.p. 83–84° (25), 88° (27)).

Diazotization of *p*-anisidine, *p*-bromoaniline, and *p*-chloraniline, followed by reaction with a solution of the appropriate sodium thiolate (28, 29) gave the following sulfides respectively: 4-(*p*-tolylthio)anisole (**3**), b.p. 145–149° at 0.8 mm, m.p. 43–45° from 95% ethanol (lit. b.p. 181–182° at 4 mm, m.p. 45–46° (28)); 4-(*p*-bromophenylthio)toluene (**10**), m.p. 82.5–83.5° from methanol (lit. m.p. 82.5° (30)); 4-(*p*-chlorophenylthio)toluene (**11**), m.p. 72–74° from methanol (lit. m.p. 72–73° (31)).

The method described by Campbell (32) was used for the preparation of *p*-(phenylthio)toluene (**5**), b.p. 137–140° at 3.2 mm (lit. 169° at 13 mm (29)).

4-(*p*-Nitrophenylthio)aniline (**2**) was prepared from *p*-chloronitrobenzene (33), m.p. 144–145.5° from ethanol (lit. m.p. 145° (33)). Acetylation of this amine gave 4′-(*p*-nitrophenylthio)acetanilide, m.p. 196.5–198° from methanol (lit. m.p. 198° (33)).

4-(*p*-Tolylthio)aniline (**8**) was prepared by reduction of the corresponding nitro compound with stannous chloride (34), m.p. 72.5–73.5° from 50% ethanol, as reported (35).

Preparation of Sulfoxides

A variety of oxidation methods was used for the preparation from the corresponding sulfides.

(a) Methyl Phenyl Sulfoxides

4-(Methylsulfinyl)toluene (**35**) was prepared by oxidation with sodium periodate (36), m.p. 42–44° (lit. m.p. 42–43° (37)). 1-(Methylsulfinyl)-4-nitrobenzene (**38**) was prepared by oxidation with H_2O_2 in glacial acetic acid (38), m.p. 147–149° after repeated crystallizations from benzene (lit. m.p. 151–152° from benzene (38)).

4-(Methylsulfinyl)anisole (**36**) was prepared by oxidation with H_2O_2 in acetone as described by Ghersetti and Palotti (39), b.p. 110–115° at 0.1 mm, m.p. 44–45° from low-boiling petroleum ether (lit. m.p. 43°, b.p. 153–154° at 5 mm (37)). This oxidation method was also used for the preparation of 4-(methylsulfinyl)aniline (**37**). In this case it was found to be advantageous to keep the reaction mixture in the dark for 2–4 days. It was necessary to purify the crude sulfoxide by chromatography on an alumina column as described by Ghersetti and Palotti (39) for some other sulfoxides. Using the eluents benzene, benzene–chloroform (1:1), chloroform and finally ethanol, the sulfoxide was isolated from the ethanol fraction, m.p. 96–96.5° from chloroform – petroleum ether (1:1); lit. m.p. 95–96° (39).

(b) Diphenyl Sulfoxides

Most required diphenyl sulfoxides were prepared using the same procedure: the sulfide and the theoretically required quantity of hydrogen peroxide (30% aqueous solution) were mixed, and glacial acetic acid was added until the mixture had become homogeneous after thorough mixing. The mixture was left standing for 4–7 days at about 20°. Water was added and the mixture was extracted with chloroform, from which the sulfoxide was isolated. The following sulfoxides were prepared by this method.

4-(*p*-Nitrophenylsulfinyl)toluene (**15**), m.p. 125.5–126.5° after crystallization from methanol (2 times) and petroleum ether.

Anal. Calcd. for $C_{13}H_{11}NO_3S$: C, 59.76; H, 4.24; N, 5.36. Found: C, 59.92; H, 3.93; N, 5.05.

4-(*p*-Tolylsulfinyl)anisole (**14**), m.p. 69–70° after crystallization from aqueous methanol and petroleum ether.

Anal. Calcd. for $C_{14}H_{14}O_2S$: C, 68.26; H, 5.73. Found: C, 67.98; H, 5.69.

4-(*p*-Nitrophenylsulfinyl)anisole (**12**), m.p. 122° from petroleum ether.

Anal. Calcd. for $C_{13}H_{11}NO_4S$: C, 56.31; H, 4.00; N, 5.05. Found: C, 56.01; H, 3.90; N, 4.93.

Deacetylation of crude 4′-(*p*-nitrophenylsulfinyl)-acetanilide with m.p. 194–196°, prepared according to Gabel and Grinberg (40), gave 4-(*p*-nitrophenylsulfinyl)-aniline (**13**), m.p. 130–131° from water, as reported (7).

Preparation of Sulfones

All sulfones, except where indicated, were prepared by oxidation of the corresponding sulfides with hydrogen peroxide in refluxing glacial acetic acid.

(a) Methyl Phenyl Sulfones

4-(Methylsulfonyl)toluene (**39**), m.p. 88–89° from ethanol, as reported (41); 4-(methylsulfonyl)anisole

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(**40**), m.p. 120–121° from water (lit. m.p. 121° (42)); 1-(methylsulfonyl)-4-nitrobenzene (**42**), m.p. 142–143° from methanol (lit. m.p. 142.5° (43)). Low pressure hydrogenation of the latter compound using Raney nickel catalyst as described by Gilman and Broadbent (25) gave an 80% yield of 4-(methylsulfonyl)aniline (**41**), m.p. 136.5–137.5° from water (lit. m.p. 134–135° (44)).

(b) Diphenyl Sulfones

4-(*p*-Nitrophenylsulfonyl)toluene (**19**), m.p. 171–172.5° from ethanol, as reported (25); 4-(*p*-tolylsulfonyl)-anisole (**18**), m.p. 102.5–104° from petroleum ether containing 5% *p*-dioxane (lit. m.p. 103–104.5° (45)); 4′-(*p*-nitrophenylsulfonyl)acetanilide, m.p. 227–229° from tetrahydrofuran (lit. m.p. 229–230° (33)). Deacetylation of this compound (46) gave 4-(*p*-nitrophenylsulfonyl)-aniline (**17**), m.p. 170–171° from methanol (lit. m.p. 168–169° (46)).

4-(*p*-Nitrophenylsulfonyl)anisole (**16**), a compound not yet reported to our knowledge, was also prepared by oxidation of the corresponding sulfide. After crystallization from ethanol m.p. 162–163.5°.

Anal. Calcd. for $C_{13}H_{11}NO_5S$: C, 54.16; H, 3.85; N, 4.86. Found: C, 53.93; H, 4.01; N, 4.84.

Preparation of Diphenyl Ethers

4-(*p*-Nitrophenoxy)aniline (**21**) was prepared from 4′-hydroxyacetanilide and 1-bromo-4-nitrobenzene according to Ikawa (47), m.p. 134° from ethanol (lit. m.p. 133° (47)). The same method was used for the preparation of 1-methoxy-4-(*p*-nitrophenoxy)benzene (**20**), m.p. 111° from methanol, as reported (48), and for the preparation of 1-methoxy-4-(*p*-tolyloxy)benzene (**22**). Even after many recrystallizations the m.p. 52–53° reported by Tomita and Ikawa (49) for the last compound could not be duplicated, but remained at 46–47° (from petroleum ether), in agreement with the m.p. 47–48° reported by Harrington (50). 4-(*p*-Nitrophenoxy)toluene (**23**) was prepared as reported (51), m.p. 67° (sharp) from petroleum ether. Tomita and Ikawa (52) report a m.p. 82°. This could not be duplicated, but our m.p. is in better agreement with another reported value, m.p. 69° (53).

Preparation of Diphenyl Methanes

α-(*p*-Nitrophenyl)*p*-toluidine (**25**) was prepared by nitration of *p*-benzylaniline (54, 55), m.p. 98–99° from ethanol (lit. 97.5–98.5° (54)). The required *p*-benzylaniline was prepared by reduction of the corresponding nitro compound with iron powder in aqueous acetic acid (56) and isolated as its *N*-acetyl derivative, m.p. 120° for the crude product (lit. m.p. 125–126° (57)). 4-(*p*-Methylbenzyl)anisole (**26**), prepared as reported by Pratt *et al.* (58) was found to be impure and contaminated with what seemed to be 2-(*p*-methylbenzyl)anisole, on the basis of the n.m.r. spectrum of the distilled product. An attempt to separate the two isomers on an alumina column failed. The compound was finally prepared by a method described by Houston (59). In this preparation a mixture of the two isomers was obtained again, but the pure *para* isomer could be obtained after careful distillation:

To a well stirred mixture of 30.5 g (0.25 mole) of *p*-methylbenzyl alcohol, and 39 g (0.36 mole) of anisole in 100 ml of low-boiling petroleum ether were added 18.8 g (0.14 mole) of aluminium trichloride in small portions over a period of 30 min. The temperature was kept at 15–25°. After standing overnight, ice, water and hydrochloric acid were added, as well as ether. After work-up and distillation of the products (a fore-run of anisole was collected) two main fractions were collected. The first fraction, weighing 19.75 g, collected at 99–101° (0.13–0.15 mm), n_D^{25} 1.5696 contained again a mixture of the *ortho* and *para* isomers. The second fraction, weighing 5.80 g, distilling at 103–109° (0.08–0.15 mm), n_D^{25} 1.5691, was the desired 4-(*p*-methylbenzyl)anisole (lit. b.p. 140–145° at 2.7 mm, n_D^{25} 1.5671 (58)).

4-(*p*-Nitrobenzyl)anisole (**24**) was prepared according to Blackwell and Hickinbottom (60). The crude product, a yellow oil, was purified by chromatography on aluminium oxide, and the compound was isolated from the first eluent fraction (petroleum ether – benzene 5:1). After recrystallization from methanol m.p. 70–71° (lit. m.p. 61° (60)).

Acknowledgment

The authors wish to acknowledge the capable technical assistance of Mrs. D. J. Bird who did most of the preparative work.

Tetrazolylacetic acids

R. RAAP AND J. HOWARD[1]
R. and L. Molecular Research Limited, 8045 Argyll Road, Edmonton 82, Alberta
Received June 3, 1968

The syntheses of several 1-,2- and 5-tetrazolylacetic acids are described. Isomeric tetrazolylacetic esters can be separated by fractional distillation or crystallization. 5-Hydroxytetrazole reacts with ethyl bromoacetate in the presence of triethylamine to give 1,4-dicarbethoxymethyl-5-tetrazolone. The use of nuclear magnetic resonance spectroscopy for the assignment of structural isomers is discussed.

Canadian Journal of Chemistry, **47**, 813 (1969)

In our search for precursors for arylmethylpenicillins (1) we recently prepared several 1-, 2-, and 5-tetrazolylacetic acids. This report describes the syntheses and some of the properties of these acids.

Alkylation of the triethylammonium salt of the tetrazole **1** with either ethyl bromoacetate or methyl chloroacetate generally provided a mixture of the 1- and 2-tetrazolylacetic esters **2** and **3**. Separation of the isomers was effected by fractional crystallization (the 2-isomers were more soluble in organic solvents than the corresponding 1-isomers) or by fractional distillation. The boiling points of the 2-isomers were considerably below those of the corresponding 1-isomers, a behavior which had been noted before in similar instances (2, 3). The predominance of the 1- or 2-isomer depended strongly on the 5-substituent R. Whereas from 5-methyltetrazole and ethyl bromoacetate more than twice as much ethyl 5-methyl-1-tetrazolylacetate than ethyl 5-methyl-2-tetrazolylacetate was obtained, 5-chlorotetrazole gave under the same conditions at least seven times as much 2-isomer than 1-isomer. This effect has been observed before (3–5) and is probably a result of electrostatic interactions giving rise to localization of the negative charge of the tetrazole anion in the 1- or 2-position, depending on the electropositive or electronegative character of the 5-substituent.

Alkylation of the triethylammonium salt of methyl 5-tetrazolylacetate with an alkyl halide provided a mixture of the isomeric 5-tetrazolylacetic esters **4** and **5**, which again could be separated by fractional distillation. Whereas the reaction with methyl iodide gave a 1:1 mixture of the 1- and 2-isomer, with isopropyl bromide this ratio was 3:1 in favor of the 2-isomer, indicating that not only electronic factors control the isomer distribution, but that steric factors can also play an important role.

The reaction of 5-hydroxytetrazole and ethyl bromoacetate in the presence of triethylamine

*5-Tetrazolylacetic acid was recrystallized from aqueous acetic acid; all other acids were recrystallized from benzene – *n*-hexane mixtures.

unequivocal synthesis. *t*-Butyl 1-tetrazolylacetate was prepared from *t*-butyl isocyanoacetate and hydrazoic acid. The acid obtained from this ester was identical with the one prepared from the highest boiling ethyl tetrazolylacetate. This latter ester in turn was also obtained by reductive deamination of the ethyl 5-aminotetrazolylacetate isomer which was least soluble in organic solvents. Methyl 5-trifluoromethyl-1-tetrazolylacetate was prepared from trifluoroacetonitrile and methyl azidoacetate under the conditions given by Carpenter (9). The reaction between sodium 5-trifluoromethyltetrazole and ethyl bromoacetate gives rise to only one of the isomers of ethyl 5-trifluoromethyltetrazolylacetate. The acids and amides prepared from these esters were different, indicating that in the latter reaction the 2-isomer was produced. The reaction of methyl (methoxy-*N*-ethylcarbimino)-acetate (**7**) (10) with sodium azide in glacial acetic acid, conditions described by Hagedorn and Winkelmann (11), provided methyl 1-ethyl-5-tetrazolylacetate (**8**), identical with the higher boiling isomer obtained from methyl 5-tetrazolylacetate and ethyl bromide.

Nuclear magnetic resonance spectroscopy represents an excellent tool for assigning structural isomers in the tetrazole series. It has already been shown that 1- and 2-methyltetrazoles can readily be distinguished from one another as the signal of the 1-methyl group appears at a higher field than the 2-methyl group in the corresponding isomer (except in the 1- and 2-methyl-5-tetrazolylhydrazones where the signals coincide) (12–16). The 5-methyl group experiences approximately the same chemical shift in dimethyltetrazoles (12), the 5-proton in 1- and 2-alkyltetrazoles is however distinctively more shielded in the 2-isomer than in the corresponding 1-isomer (13, 17). The chemical shifts of some representative tetrazolylacetic acids and esters are listed in Table IV and similar trends as the above-mentioned ones are clearly noticeable. The carboxymethylene signals for the 1- and 2-tetrazolylacetic acids and esters appear at τ 4.60–4.95 and τ 4.29–4.67 respectively (for isomer pairs: $\Delta\tau$ = 0.23–0.33). Also interesting to note is the comparatively large difference in the degree of shielding of the 5-hydrogen, 5-carboxymethylene and 5-amino between corresponding 1- and 2-substituted isomers ($\Delta\tau$ = 0.30, 0.13–0.23, and 0.73 respectively) whereas this difference is small for the 5-methyl and the 5-methylthio group ($\Delta\tau$ = 0.05 and 0.10 respectively).

* 
†The 1-isomer could not always be distilled; the yield in these instances refers to the amount of crude isomer.
‡Acetone was used as solvent except when indicated.
§m.p. 49–52°; reported b.p. 83.5–84°; m.p. 51–52° (26).
‖Reported m.p. 73–74° (27); the 1-isomer crystallized from the isomer mixture by the addition of ether.
¶The product mixture (b.p. 120–130° (0.4 mm)), the n.m.r. spectrum indicated a 3:5 ratio of 1- and 2-isomer, could be only separated by careful fractional distillation using a spinning band column but much material was lost due to decomposition. A mixture of the acids however could be separated on basis of the different solubilities of the acids in ethyl acetate. Whereas 5-methylthio-2-tetrazolylacetic acid is very soluble in this solvent at room temperature, the 1-isomer is almost completely insoluble. The n.m.r. spectra of the esters are given in Table IV.
**The crude product mixture (the n.m.r. spectrum showed the predominance of the 2-isomer by at least a factor of six) was recrystallized from a benzene – *n*-hexane (5:2) mixture to give the 2-isomer as long white needles. This same product was also obtained by hydrogen peroxide oxidation of ethyl 5-methylthio-2-tetrazolylacetate. The n.m.r. spectrum is given in Table IV.
††The compound decomposed extensively upon distillation.

Experimental

The nuclear magnetic resonance (n.m.r.) spectra were recorded on a Varian Associates model A-60 Spectrometer, with tetramethylsilane as a reference. Melting and boiling points are uncorrected. The elemental analyses were performed by Dr. G. Weiler and Dr. F. B. Strauss, Micro-analytical Laboratory, Oxford, England. Elemental analyses were only obtained on the acetic acids (Tables I–III) or, in those instances where the acid was either not crystalline or difficult to purify, on a derivative.

Starting Materials

Most of the tetrazoles were prepared by standard procedures. The reaction of a nitrile with ammonium azide according to the procedure of Finnegan, Henry, and Lofquist (18) provided: 5-ethyltetrazole (m.p. 90–91°), 5-*n*-propyltetrazole, 5-phenyltetrazole, 5-methylthiotetrazole and 5-carbomethoxymethyltetrazole (m.p. 152–155°). 5-Methyltetrazole (12) and sodium 5-trifluoromethyltetrazole (3) were prepared by reaction of acetonitrile and trifluoroacetonitrile with sodium azide. From 5-aminotetrazole (19) were prepared: tetrazole by reductive deamination (2, 20) and 5-chloro- and 5-bromotetrazole by a Sandmeyer reaction (21).

5-Methylsulfonyltetrazole

A mixture of 5-methylthiotetrazole (10.0 g, 0.086 mole), 30% aqueous hydrogen peroxide (22.7 ml, 0.20 mole) and glacial acetic acid (150 ml) was allowed to react at room temperature for three days. The solvent was removed under reduced pressure and the residue recrystallized from an ethyl acetate – *n*-hexane (1:1) mixture to give 11.4 g (90%) of white crystals, m.p. 127–128° (decomp.). Reported m.p. 110–120° (22).

Tetrazolylacetic Esters (General Procedure)

A solution of alkyl halide (0.1 mole) in 50 ml of acetone was added to a mixture of the tetrazole (0.1 mole) and triethylamine (0.1 mole) in 50 ml of acetone. When the reaction was completed the triethylammonium hydrochloride was filtered off and the acetone removed from the filtrate. The residue was dissolved in 100 ml of methylene chloride and this solution washed with an aqueous sodium carbonate solution. The residue obtained after drying and removal of the methylene chloride was generally fractionally distilled *in vacuo*. Table V lists some of the esters prepared by this procedure, together with the reaction conditions employed. The products for which the work-up differed or that were prepared by a different method are described separately.

t-Butyl 1-Tetrazolylacetate

To *t*-butyl isocyanoacetate (2.7 g, 0.019 mole) (23) were added 46 ml of a 1.16 *M* solution of hydrazoic acid (0.053 mole) in benzene. The mixture was heated under reflux for 24 h. The residue obtained after removal of the solvent, solidified and was recrystallized from *n*-hexane – ethyl acetate to give 2.4 g (68%) of product, m.p. 82–84°.

1-Tetrazolylacetic Acid

t-Butyl 1-tetrazolylacetate (10.0 g, 0.054 mole) was dissolved in 100 ml of acetic acid and heated under reflux for 4 h. The residue obtained after removal of the acetic acid was recrystallized from ethyl acetate to give 4.4 g (64%) of acid, m.p. 127–129°, identical with the acid prepared from ethyl 1-tetrazolylacetate (mixture m.p. 127–129°, the infrared spectra were superimposable). The elemental analyses are reported in Table I.

t-Butyl 5-N,N-Dimethylaminomethyl-1-tetrazolylacetate

To a suspension of dimethylamine hydrochloride (3.25 g, 0.040 mole) in 40 ml of acetone, cooled in an ice–salt bath, was added successively 3.0 ml of 40% aqueous formaldehyde (0.040 mole), a solution of sodium azide (2.6 g, 0.040 mole) in 10 ml of water, and *t*-butyl isocyanoacetate (5.5 g, 0.040 mole) (23). The reaction mixture was stirred for 45 min at −10°, then for 3 h at room temperature. After the addition of 150 ml of water the mixture was cooled. The product precipitated as fine white needles which were filtered off; yield: 6.2 g (65%); m.p. 50–52°. Two recrystallizations from ether – *n*-hexane raised the melting point to 53–54°.

5-N,N-Dimethylaminomethyl-1-tetrazolylacetic Acid

The *t*-butyl ester (6.1 g, 0.025 mole) was dissolved in 60 ml of acetic acid and this mixture was heated under reflux for 45 min. The solvent was removed and the residue recrystallized from ethanol–ether to give 4.3 g (93%) of the acid, m.p. 187–189° (decomp.). The elemental analyses are reported in Table I.

5-Phenyl-1-tetrazolylacetic Acid and 5-Phenyl-2-tetrazolylacetic Acid

To a mixture of the two isomeric esters, prepared from 5-phenyltetrazole (14.6 g, 0.1 mole), triethylamine (10.8 g, 0.105 mole) and ethyl bromoacetate (16.7 g, 0.1 mole), were added 50 ml of 3 *N* methanolic sodium hydroxide. After the reaction mixture was left at room temperature for 2 h, the methanol was removed and the salt mixture dissolved in 300 ml of water. Upon acidification, 5-phenyl-2-tetrazolylacetic acid (14 g, 69%), m.p. 176–181° (decomp.) crystallized. An analytical sample, m.p. 182–184° (decomp.), was obtained after one recrystallization from ethyl acetate – *n*-hexane. The aqueous filtrate was extracted with two 100-ml portions of ether. After drying, the ethereal solution was treated with cyclohexylamine (7 ml). The precipitated cyclohexylamine salt was recrystallized from methanol–ether to give 1.7 g of cyclohexylammonium 5-phenyl-1-tetrazolylacetate, m.p. 157–159° (decomp.). A solution of the salt in hot water was acidified. Upon cooling pure 5-phenyl-1-tetrazolylacetic acid (1.0 g, m.p. 148–150° (decomp.)) precipitated. Both acids had the correct neutralization equivalent. The analytical results are recorded in Tables I and II.

Ethyl 5-Amino-1-tetrazolylacetate and Ethyl 5-Amino-2-tetrazolylacetate

A solution of ethyl bromoacetate (20.0 g, 0.12 mole) in 50 ml of acetone was added to a mixture of 5-aminotetrazole monohydrate (12.4 g, 0.12 mole), triethylamine 12.1 g, 0.12 mole) and 50 ml of acetone. Upon shaking, the mixture rapidly became homogeneous and the exothermic reaction necessitated cooling with water. When the reaction subdued the reaction mixture was left at room temperature for an additional 3 h. The isomer mixture, obtained after filtering off the triethylamine hydrobromide and removal of the acetone from the filtrate, was dissolved in 250 ml of warm ethyl acetate. The warm ethyl acetate solution, after washing with small amounts of water and aqueous bicarbonate, was dried, then concentrated to a volume of approximately 100 ml. Chloroform (75 ml) was added and the mixture was kept under refrigeration overnight. The solid (10.0 g) was filtered off and recrystallized from ethyl acetate to give 7.4 g (36%) of ethyl 5-amino-1-tetrazolylacetate, m.p. 145–148°. The filtrate was concentrated to dryness and the solid residue (4.0 g) was heated with 50 ml of chloroform. Some insoluble material (1-isomer) was filtered off and 75 ml of carbon tetrachloride was added to the filtrate. Upon cooling, 2.8 g (14%) of white crystalline ethyl 5-amino-2-tetrazolylacetate, m.p. 96–103° (could be raised to 105–107° by an additional recrystallization from carbon tetrachloride) was obtained. Ethyl 5-amino-1-tetrazolylacetate upon treatment with methanolic ammonia could readily be converted to 5-amino-1-tetrazolylacetamide, m.p. 211–212° (decomp.). Treatment of a solution of ethyl 5-amino-1-tetrazolylacetate in dilute hypophosphorous acid with a sodium nitrite solution at room temperature gave rise to the formation of ethyl 1-tetrazolylacetate (characterized as the amide, m.p. 150–152° (decomp.)).

Methyl 5-Amino-1-tetrazolylacetate

Methyl chloroacetate (27.1 g, 0.25 mole) was added to a mixture of 5-aminotetrazole monohydrate (25.7 g, 0.25 mole), triethylamine (25.3 g, 0.25 mole), and 150 ml of acetone. The resulting mixture was refluxed for 1 h, then left at room temperature overnight. After cooling the solid precipitate was collected, followed by concentration of the solution to a volume of approximately 75 ml. Upon cooling some more solid precipitated. The combined solids were twice recrystallized from 200 ml of water to give 13.9 (36%) of white plates, m.p. 179–181°.

Methyl 5-Trifluoromethyl-1-tetrazolylacetate

A mixture of methyl azidoacetate (4.9 g, 0.043 mole; prepared by the procedure of Forster and Fierz (24) for the ethyl ester) and trifluoroacetonitrile (approximately 5 ml at −70°) (25) in a 250 ml autoclave was heated at 140–150° for 20 h. The product was distilled *in vacuo* to give 7.0 g (78%) of colorless liquid, b.p. 72–73° (0.5 mm); n.m.r. ($CDCl_3$): τ 4.63 (s, 2H), 6.14 (s, 3H.)

Methyl 1-Ethyl-5-tetrazolylacetate

A mixture of methyl (methoxy-*N*-ethylcarbimino)-acetate (8.0 g, 0.050 mole) (10), sodium azide (16.2 g, 0.25 mole) and glacial acetic acid (100 ml) was heated at 45° for 18 h. The reaction mixture was poured into 200 ml of ice-water and the product extracted with ether (2 × 100 ml). The ether extracts were dried, the solvent removed, and the residue distilled *in vacuo* to give 2.5 g (29%) of the desired product, b.p. 152–153° (1.0 mm). The infrared spectrum was superimposable with that of the high boiling fraction obtained from the reaction of methyl 5-tetrazolylacetate with ethyl bromide in the presence of triethylamine (Table V).

General Procedure for the Preparation of Tetrazolylacetic Acids from Tetrazolylacetic Esters

Tetrazolylacetic ester (0.010 mole) was dissolved in approximately 5 ml of methanol, followed by the addition of 4 ml of a 3 *N* methanolic sodium hydroxide solution. In most instances the sodium salt precipitated. The mixture was left at room temperature for 1 h, whereafter the methanol was removed. The sodium salt was converted to the acid by method *a*, *b*, or *c* (see Tables I–III): *a*.) An aqueous solution of the salt was passed through a column of DOWEX 50W-X8 H^+ form ion exchange resin, followed by removal of the water of the eluate under reduced pressure. *b*.) The sodium salt was dissolved in a small amount of water and this solution was acidified. The acid was extracted with ethyl acetate. *c*.) A solution of the sodium salt in a small amount of water was acidified. The precipitated acid was collected by filtration.

The acids prepared in this manner are listed in Tables I–III. The experimental neutralization equivalents were all within 5% of the theoretical value.

5-Tetrazolone-1,4-diacetic Acid

To a mixture of 5-hydroxytetrazole (3.0 g, 0.035 mole) (8), triethylamine (7.05 g, 0.070 mole) and 20 ml of acetone, cooled in ice, was added a solution of ethyl bromoacetate (11.7 g, 0.070 mole) in 20 ml of acetone. The reaction mixture was left at room temperature overnight, followed by the usual work-up. There were obtained 6.8 g (76%) of crystalline material, m.p. 87–89° (after recrystallization from carbon tetrachloride). The same product was obtained when equimolar amounts of reactants were employed. The infrared spectrum did not show any absorption in the 3600–3000 cm^{-1} range, indicating the absence of OH, but showed strong absorption in the 1720–1750 cm^{-1} region. The n.m.r. spectrum ($CDCl_3$) showed a singlet at τ 5.17, a quartet at τ 5.65, and a triplet at τ 8.68, with an integrated area ratio of 2:2:3. The ester, 1,4-dicarbethoxymethyl-5-tetrazolone, was converted in 90% yield to the diacid by following the general procedure outlined above (method *a*). The diacid, m.p. 213–215°, could be recrystallized from ethyl acetate and was found to have a neutralization equivalent of 102 (calcd. 101).

Anal. Calcd. for $C_5H_6N_4O_5$: C, 29.71; H, 2.99; N, 27.72. Found: C, 29.78; H, 3.09; N, 27.85.

Structure of crotonic acid dimers and higher polymers with partial stereochemistry of the dimers[1]

MARTIN B. HOCKING
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received June 5, 1968

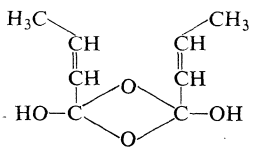
Heating *trans*-crotonic acid (CH_3—CH=CH—CO_2H) yields labile high boiling compounds which have received some attention in the past. These have now been conclusively characterized as the two geometric isomers of a dimer of crotonic acid. In addition trimers and tetramers discovered in the thermally polymerized crotonic acid were isolated as their methyl esters and positively identified.

Canadian Journal of Chemistry, 47, 821 (1969)

Introduction

Partial dimerization by heat of crotonic acid has been given the attention of a number of early workers (1–3) who have attributed at least two possible structures, **1** and **2**, to the compound obtained.

In the most recent publication on the subject, Skau and Saxton (4) conduct a critical reappraisal of earlier results with consideration of new data of their own and reservedly suggest that structure **2** fits the compound best. We confirm with new evidence the latter authors' structural assignment and have also determined the orientations of two geometrical isomers of this dimer. In addition we have obtained conclusive evidence of some higher polymers of crotonic acid.



1

2

Results and Discussion

The primary difficulty encountered with the dimer of crotonic acid has been its isolation. To bring about its formation, a quantity of *trans*-crotonic acid is heated at around 150° for a few days. Most of the unchanged *trans* isomer is separated from the dimer by allowing the mixture to cool to ambient and then draining the dimer, as an oil, from the crystallized *trans* compound. It is the remainder of the dissolved *trans* acid, together with some *cis*-crotonic acid also present, that is very difficult to remove from this oil. At distillation pressures low enough to avoid cracking of the dimer (around 0.01 mm), the *trans*-crotonic acid still present in the crude mixture undergoes ready sublimation, fouling and blocking distillation passages. Clean distillation of *trans*-crotonic acid from the dimer can be accomplished at 40 mm, but this makes pot temperatures severe enough to cause simultaneous cracking of the dimer.

This difficulty was initially circumvented by esterifying all of the mixture. Vacuum distillation of this mixture of methyl esters then cleanly separated them. Characterization of the methyl-(*trans*-crotonate)-3-hydroxybutyrate (**2***a*, methyl ester) by infrared (i.r.), nuclear magnetic resonance (n.m.r.), elemental analysis, and molecular weight confirmed its structure. The geometry of the still unsaturated portion of the molecule was

†Could not determine accurately due to interfering δ_c resonance merging with this.

‡Due to two quartets the proximate two peaks of each which have merged. A more complex spin–spin coupling due to the adjacent non-equivalent methylene protons has not been resolved because their respective coupling constants are too similar, and too close to that of the saturate methyl.

§Shift difference between the diastereomeric non-equivalent hydrogens ($\delta_{H1} - \delta_{H2}$), taken from the calculated centers of gravity of each of the two pairs of doublets (5), was found to be 7.8 c.p.s. Calculation of the relative intensities of the inner and outer peaks of this multiplet, using this shift difference, gave ratios of 1:18.9 (5*a*) and 1:18.4 (5*b*) which confirmed the interpretation. Geminal diastereomeric hydrogen calculated shift differences of the magnitude observed here are common (6).

expected to be *trans*, due to the preponderant presence of this monomer, and indeed the chemical shifts in the n.m.r. of appropriate protons were virtually the same as those found for the analogous protons in methyl *trans*-crotonate (Tables I and II).

After isolation of the ester, attention turned again to isolation of the dimer free acid since a differential hydrolysis of the methyl over the 3-hydroxybutyric acid ester group was not an attractive proposition. At least isolation and identification of the ester first made it much easier to determine whether or not procedures used to isolate the free acid were being applied successfully. Several careful aqueous acetone titrations of the crude mixtures were tried. Unfortunately, only one plateau at pH 4.9 was evident (p*K*a of *trans*-crotonic acid is 4.60; (9))

indicating that **2** and monomeric *trans* acid were being neutralized together.

Pure dimer **2** was eventually obtained on a relatively large scale by taking advantage of the ready sublimation of the *trans* acid. First, *trans*-crotonic acid (plus a small amount of the *cis* isomer) was sublimed and distilled from the crude oil under moderate conditions in a rotary evaporator until no further sublimation occurred. The vacuum was then improved and the temperature was raised just sufficiently to allow the dimer to distil. Titration of the material obtained by this method gave an acid equivalence of 0.515, an improvement on the best material obtained by Skau and Saxton (4), which gave an acid equivalence of 0.535. Bromination and catalytic hydrogenation established chemically the presence of one double bond per molecule. Physical data on the compound confirmed its identity as compound **2** (not its structural isomer **3**: CH_3—CH=CH—CO_2—$CH(CH_2$—$CH_3)CO_2H$) and verified its purity. The molecular weight of **2** determined in acetone was 190 (near the theoretical 172). In benzene a value of 377 was obtained, twice that observed in the polar solvent. This doubling of molecular weight of carboxylic acids in solutions of nonpolar solvents is a demonstration of the strong intermolecular hydrogen bonding (10).

Earlier papers by others (11) deal with the formation of *cis*-crotonic acid on heating the *trans*, so it was not surprising when it was found that the unsaturated portion of dimer **2** was in fact a mixture of *trans*- (**2***a*) and *cis*- (**2***b*) crotonate moieties. The percent of *cis*-crotonate in the mixture ranged between 15 and 19, which was about the same as the ratio of *cis* to *trans* monomeric acids present in the thermally equilibrated mixtures (7). As in the case of the methyl ester of **2** the identities and reasonably accurate proportions of the two isomeric free acids were readily confirmed and determined by n.m.r. by comparison of the appropriate shifts with those of the respective monomeric free acids (see Tables I and II). That the n.m.r. evidence for the presence of **2***b* was not due to this amount of dissolved *cis*-crotonic acid coming through the isolation procedure was confirmed by several vigorous water (in which both monomers are very soluble (12)) washes which caused negligible change in the n.m.r. but did improve the acid equivalence to a figure of 0.504. The absence of *cis* ester in the methyl ester of **2** was probably due to the shorter heating time for the starting *trans* acid (giving less time for *cis* equilibration).

Degradative experiments helped to confirm the identity of **2**. Cracking the mixture of dimers **2***a* and **2***b* by heat was expected to yield *trans*-crotonic acid **4***a* plus a little *cis* **4***b* resulting from the crotonate moiety of **2***b*. From the butyric portion of **2***a* and **2***b*, appreciable further proportions of *cis*-crotonic acid and at least detectable amounts of vinylacetic acid **5** were also anticipated, based on the statistical distribution of protons available for a leaving crotonate

	92.9	7.1 (8.2)	0.0

*Calculations are assuming butyrate portion of dimer goes entirely to *trans*-crotonic acid.
†The percent of the dimer butyrate converted to *cis*-crotonic acid, taking into account the *cis* unsaturated half present in **2***b*, is given in parentheses.

moiety. Early tautomeric studies gave analogy for the anticipated formation of vinylacetic acid in at least strongly basic systems (13).

Initially the mixture of dimers **2***a* and **2***b* was cracked under reduced pressure to decrease the tendency of *cis* to isomerize to *trans* or vice versa, and to approximate the cracking temperatures existing during the formation of the dimer. The distillate contained 11.8% *cis*-crotonic, and 1.5% vinylacetic acid (by n.m.r.) in addition to the expected *trans*. This represents conversion of 7.6% of the saturated half of dimer **2** to *cis*-crotonic and about 3% to vinylacetic acids (Table III).

However, one other consequence of the lower temperature cracking under reduced pressure should be the favoring of initial formation of the thermodynamically more stable product, *trans*-crotonic acid, over a statistical product distribution. This would act in opposition to the slower *cis* to *trans* isomerization expected at lower temperatures and may in fact give less *cis* compound than would higher temperature cracking. To test this theory a further sample of a mixture of dimers **2***a* and **2***b* was cracked at atmospheric pressure. A small amount of unchanged dimer came over, but correcting for this, 12.8% *cis*-crotonic and 1.2% vinylacetic acid were obtained. The changes detected in product ratios were insufficient to permit any conclusions to be drawn.

For clarification of the degradative experiments an effort was made to obtain pure dimer **2***a* so that none of the *cis*-crotonate moiety would be present in the dimer to contribute to the *cis*-crotonic acid arising from the saturated portion of the dimer on cracking it. Preliminary thin-layer chromatographic experiments to establish whether or not column chromatography was likely to be successful in physically separating **2***a* from **2***b* were not promising. Using dimerization conditions such that dimer **2***a* should form exclusively, an increase in the concentration of **2***a* from 84 to 94% was obtained. Cracking this mixture yielded about the same proportion of *cis*-crotonic acid via the butyrate as did the 84% pure **2***a* (Table III), but surprisingly no vinylacetic acid. This may be an indication, as suggested earlier, that the vinylacetic acid is largely arising via tautomerization of *cis*-crotonic acid (7) and not directly from the saturated portion of the dimers.

An attempt to crack the methyl esters of a mixture of dimers **2***a* and **2***b* by distillation up a column at atmospheric pressure was unsuccessful.

Saponification of the dimer **2**, which has been carried out previously (1) but details of which are inaccessible, in our hands yielded a good material balance of nearly equivalent amounts of the component monomeric acids present, *cis*- and *trans*-crotonic acids and β-hydroxybutyric acid. The identity of the latter was confirmed by comparison of its physical properties with those of an authentic sample. Many of the interesting features of the n.m.r. of β-hydroxybutyric acid are relevant to, and help confirm the n.m.r. interpretations of dimers **2***a* and **2***b*.

Trimers and Tetramers of Crotonic Acid

The n.m.r. spectra of the crude oils obtained from some of the longer duration or higher temperature dimer preparations showed 4–6 additional bands at the approximate chemical shift of the doublet due to the saturated methyl (*e*) of the dimer, four additional bands at the

shift of the methylene protons (f) of the dimer, and broadening with fine structure of the bands which appeared in the region of the methine (d) of the dimer. On the basis of this n.m.r. evidence, i.e. no additional n.m.r. resonances other than those easily attributable to repetition of the unit —$CH(CH_3)—CH_2—CO_2$— above, and the i.r. band at 1745 cm^{-1} (saturated ester carbonyl) which was relatively stronger in partially enriched material than the band at 1720 cm^{-1} (saturated acid and unsaturated ester carbonyls), it was suspected that simple higher polymers were being obtained.

After early attempts to isolate the free acids of these materials were unsuccessful, the ester route was satisfactorily employed for isolation of the suspected higher polymers. Distillation of the mixture of polymer esters thus obtained, initially gave fractions of dimer methyl ester, followed by trimer and tetramer esters with about 50° increments in the boiling points with each crotonyl unit. Characterization of these materials was by elemental analyses and molecular weights (Table IV), mass spectral analyses, i.r., n.m.r., and chemically by catalytic hydrogenation.

Mass spectral analyses gave small signals for the mass numbers corresponding to the molecular weights of the parent ions of the dimer, trimer, and tetramer methyl esters (Tables V and VI). Fragmentation was quite severe for the telomers however, as is evident by the much larger relative abundance of the parent ion of methyl crotonate than those of the polymer parent ions.

Nuclear magnetic resonance confirmed in two ways the structures of the trimer and tetramer. The first was by the absence in these spectra of any bands with a large shift difference from any already present in spectra of the dimers' methyl esters. Any structural isomer of the trimer or tetramer different from that shown, for example such as the orientation of dimer **3**, would be expected to lead to spectra with at least two multiplet groups at shifts quite different from those of the dimers' methyl esters. The change most clearly evident was an increase in the apparent multiplicity of the resonance due to the butyric type methyl, details of which are given in the Experimental. Integration reaffirmed the other n.m.r. interpretations. Table VII shows how well the proton integral ratios of ester methyl and crotonate moieties to butyrate moieties in the polymers agree with the structures suggested for the crotonic acid polymers.

Catalytic hydrogenation of the polymer esters established, by the equimolar consumption of hydrogen (Table VIII), the presence of one olefinic double bond per molecule. The answers obtained for the dimer ester are slightly lower than could be explained on the basis of experimental error, but this could perhaps have been caused by the presence of traces of trimer ester.

Experimental

trans-Crotonic acid used was practical grade material purchased from Matheson, Coleman, and Bell. Melting points and boiling points are not corrected. Microanalyses and molecular weights are by A. B. Gygli, Toronto, Ontario, and L. E. Swim, The Dow Chemical Company, Midland, Michigan.

Infrared spectra were recorded on Beckman IR-9 and Perkin–Elmer 337 spectrophotometers and are quoted in reciprocal centimeters. Ultraviolet (u.v.) data were obtained on a Beckman DK-2 Ratio Recording Spectrophotometer. A Varian A60 nuclear magnetic resonance

(n.m.r.) spectrometer fitted with a phase detector integrator, and with a Hewlett–Packard oscillator and electronic counter (models 200CD and 5212A respectively) for sweep width calibration was used to measure the n.m.r. data. The latter were recorded at room temperature in deuteriochloroform. Shifts are those of the centers of multiplets given in p.p.m. downfield from internal tetramethylsilane and coupling constants, which were measured on spectra expanded to 50 or 100 cycle sweep width, are quoted in c.p.s. Mass spectra of the methyl esters of *trans*-crotonic acid, and its dimer and trimer were run on a Westinghouse 90° sector machine, and that of the tetramer on a Consolidated Electrodynamics 21-110B high resolution instrument all at 70 eV.

Separation of Ester Mixture

trans-Crotonic acid (250 g) was heated in a thermostatted bath at 180° for 28 h; crystallization from hexane (250 ml) recovered 112 g of unchanged *trans* acid. Evaporation of the solvent from the filtrate left 116 g of brown oil, a mixture of dimer **2***a*, polymers **6**, and *cis*- and *trans*-crotonic acids (by n.m.r. approximate weight percentages: 47, 10, 10, and 33 respectively). This oil was dissolved in ammonium hydroxide (640 ml of 2 *N*) with cooling in an ice bath. In subdued light aqueous

*Free space equivalent, or the mmole equivalent for the volume of hydrogen displaced by olefin and borohydride addition. Determination: (ml olefin + ml borohydride) × 0.04.

silver nitrate (1.29 l of 1.1 *N*) was then added with stirring to the solution of ammonium salts, and the precipitated silver salts then filtered off and washed with water. These salts were dried in the dark azeotropically with benzene (1500 ml) using a Dean and Stark apparatus and occasional agitation. When dry, methyl iodide (60 ml plus 40 ml after 1 h) was added and boiling under reflux continued for 1½ h. The reaction mixture was filtered and the benzene removed up a 40 cm Vigreux column under slightly reduced pressure leaving 110 g of brown oil. This was distilled up a Todd column (90 × 2.5 cm, 10:1 reflux ratio) packed with ⅛ in. glass helices. After a forerun (about 30 ml), taken off at about 100 mm pressure consisting of a mixture of benzene and the *cis*- and *trans*-crotonates, methyl-(*trans*-crotonate)-3-hydroxybutyrate (**2***a*, methyl ester; 45 g, b.p. 70°/0.03 mm) was obtained. On a stainless steel gas chromatographic column (6 ft × ⅛ in.) packed with 5% FFAP (mono-ester of 2-nitroterephthallic acid with 20 000 mol. wt. polyethylene glycol) on 90–100 mesh Anachrome ABS support, at 250° with 1 cm^3/min nitrogen flow, a single peak of retention time 1½ min was observed for this compound.

Anal. Calcd. for $C_9H_{14}O_4$ (mol. wt., 186.2): C, 58.05; H, 7.58. Found (mol. wt., ebulliometric in $CHCl_3$, 214): C, 58.1, 57.9; H, 7.38, 7.41.

Spectroscopic examination of a thin film in the i.r. showed for aliphatic C—H a broad weak multiplet 2850 to 3050, saturated and unsaturated ester C=O strong bands at 1750 and 1725 and olefinic C=C stretch at 1665 cm^{-1}. The u.v. spectrum in ethanol showed no maximum above 212 mμ and the complete unambiguous structural correlation of the n.m.r. spectrum is given in Table I.

Separation of Mixtures of trans-Crotonic Acid and Dimers

(a) By Titration

Solutions of mixtures of dimers **2***a* and **2***b* with about 17% of *trans*-crotonic acid present, in acetone–water (30:70, v/v), were titrated with 0.100 *N* sodium hydroxide. Using a pH meter to observe the progress only one plateau with mid-point at pH 5.25 was observed. There was a reproducible marginal point of inflection in this plateau about ⅕ from the low pH end (pH 4.8) which may have been caused by complete formation of monomer sodium salt and the beginning of the neutralization of the dimer acid. This was too slight a difference to be useful in separating mixtures of the two. However, after successful separation of the dimer from monomer by the method immediately following pH determinations confirmed this interpretation of the titrations. Solutions of the dimer **2***a* (0.0098 *M*) and *trans*-crotonic acid (0.01008 *M*) in water at 26.2° gave pH readings of 3.18 and 3.40 respectively (Radiometer type PHM 28 instrument). In acetone–water (30:70, v/v) pH readings of 2.40 and 2.65 respectively were obtained for 1.000 *M* solutions at 26.6°.

(b) By Rotary Evaporation

About 500 g of a crude mixture of dimers **2***a* and **2***b* (together about $\frac{1}{3}$ of total, by n.m.r.) and *cis*- and *trans*-crotonic acids, obtained from 2 kg of *trans*-crotonic acid heated at 180 °C for 7 days, was distilled under reduced pressure. Using a 1 m × 2 cm vacuum jacketed column packed with $\frac{1}{8}$ in. glass helices, and a 4:1 reflux ratio, a total of 300 g of a mixture of monomeric acids (b.p. 80°/10 mm to 93°/0.5 mm at pot temperatures of 118–168°) were obtained in the distillate. The residue (140 g) contained less than 10% of the monomeric acids (by n.m.r.) and was predominantly dimer **2** with a higher polymer content than the starting mixture. Distillation of this residue without a column (100–115°/0.1–0.2 mm; pot 120–165°) under conditions such that the vapor temperature was kept as close as possible to that of the distilland yielded only a distillate (114 g in six fractions) comprised largely of the cracking products of dimer **2** and there was no sign of higher polymers in either the distillate or residue. The last four fractions (70 g), containing the largest proportion of dimer, were then combined and worked up using a Büchi vacuum rotary evaporator. The monomeric acids (52 g oily crystals) were first sublimed and distilled out by heating with a boiling water bath (5–0.1 mm Hg). When no further sublimate could be obtained under these conditions, the vacuum was improved to 0.01 mm and the temperature of an oil bath heat source was very gradually raised. At 135° dimer began to come over and 15 g were collected as a colorless oil at 135–140°. No impurities were detectable by n.m.r. Later preparations using rotary evaporation immediately after the initial rough removal of the monomeric acid by distillation gave recoveries of 100–120 g of the dimers **2** from 500 g of the crude oil.

Anal. Calcd. for $C_8H_{12}O_4$ (mol. wt., 172.2): C, 55.8; H, 7.0. Found (mol. wt., ebullioscopic; in acetone 189, 191; in benzene, 377): C, 55.3, 55.7; H, 6.9, 7.0.

The i.r. spectrum of a thin film showed OH stretch at 3500, 3150, and 2650, CH stretch at 2925 and 2975, C=O stretch at 1720 and 1745, and C=C stretch at 1655. The portion of the n.m.r. spectrum of the mixture of *cis* and *trans* dimers attributed to the *trans* (**2***a*), correlated with that of the *trans* monomer methyl ester, and no higher polymer was present (see Table I).

Bromination of the dimer acid at room temperature in CCl_4 failed to reach completion in 8 days. However, in glacial acetic acid (5 ml) at room temperature over 6 days bromine (0.10 g; 0.625 mmoles) was decolorized by 0.125 g (0.728 mmoles) of dimer, and was not decolorized by 0.090 g (0.525 mmoles) of dimer.

A methylene chloride solution of the dimers **2** (17.2 g) as obtained above was washed with water (2 × 10 ml). On drying ($MgSO_4$) and evaporation of the solvent the dimers **2** (15.7 g) were obtained free of monomeric acids. Confirmation of the purity improvement was obtained by titration for acid equivalence. Values of 0.519 and 0.504 (theory = 0.500; crotonic acid = 1) were obtained before and after washing. The only apparent indication by n.m.r. was slight net loss, from 15.9 to 14.7, in the percentage of dimer **2***b* present.

Thermal Cracking of Mixtures of Dimers 2a and 2b

(a) At 250 mm

Dimer mixture (containing 16% **2***b*; 3.8 g) was placed in a short-path micro distillation apparatus, the pressure in the system reduced to 250 mm and heat applied with a mantle at such a rate that distillation was complete in 15 min. The distillate (3.3 g; vapor temperature 157–162°, pot temperature 180–204°) consisted of these acids: *trans*-crotonic, 86.7%; *cis*-crotonic, 11.8%; vinylacetic, 1.5% (by n.m.r). The pot residue (0.4 g) was dimer mixture plus a small amount of *trans*-crotonic acid.

(b) At Atmospheric Pressure

Dimer mixture (as in (*a*); 4 g) was cracked in the same apparatus and at the same rate as in (*a*). The distillate (3.5 g; vapor temperature 182–218°, pot temperature 220–258°) consisted of the following monomeric acids; *trans*-crotonic 81.5%, *cis*-crotonic 12.1%, vinylacetic 1.2%, and in addition 5.2% (by weight) of unchanged dimer. Recalculation of these results correcting for the dimer still present gave the figures quoted in Table III.

(c) Control Experiment

Recrystallized *trans*-crotonic acid (4.6 g) was distilled over the same time in the same apparatus as in (*a*) and (*b*) above, except that the condenser was only air cooled and the receiving flask was cooled in an ice–water bath. The distillate (4.1 g; vapor temperature 179–190°, pot temperature 182–200°) contained no vinylacetic acid and only a trace (0.5% or less) of *cis*-crotonic acid.

Attempted Thermal Cracking of 2a, Methyl Ester

Methyl-(3-*trans*-crotonate)-butyrate (**2***a*, methyl ester; 2.1 g) in the same apparatus as the preceding cracking experiments was distilled over in 10 min (vapor temperature 224–230°, pot temperature 228–240°). The distillate (2 g) consisted entirely of unchanged starting material.

Saponification of Mixture of 2a and 2b

The mixture of dimers (containing 16% **2***b*; 22 g) was boiled in 10% aqueous caustic (120 ml) for $1\frac{1}{2}$ h, and acidified to pH 4 with concentrated hydrochloric acid while cooling in an ice bath, then saturated with sodium chloride. Crystals of *trans*-crotonic acid (6.2 g, m.p. 66–70°) came out of the brine solution, which when recrystallized from hexane melted at 70–72°. The brine solution was then extracted with ether (1 × 50 + 3 × 30 ml) which when dried (Na_2SO_4) and concentrated under reduced pressure, yielded 10.9 g of pale-yellow oil. Distillation of this oil yielded crotonic acid (some *cis*, 2 g, b.p. 99°/16 mm) and, after a middle fraction consisting of a mixture of the crotonic and butyric acids (0.2 g, b.p. 94–149/10 mm), 1.2 g of 3-hydroxybutyric acid (b.p. 149–149.5°/10 mm; lit. b.p. 130°/12–14 mm (9)) was obtained.

Anal. Calcd. for $C_4H_8O_3$: C, 46.15; H, 7.75. Found: C, 46.0, 45.9; H, 8.21, 7.90.

Its identity was confirmed by comparison of its n.m.r. (*vide infra*) and i.r. spectra with those of a redistilled sample of authentic material.[2] The water was then carefully removed from the brine solution on a steam bath under reduced pressure; no crotonic or butyric acid came off with the water (determined by i.r.). The residual oily crystals were washed with ether (3 × 20 ml) and filtered. Drying and evaporation of the ether from the filtrate gave a further 6.7 g of 3-hydroxybutyric acid (as determined by n.m.r.). Total crude yields obtained were 8.3 g (76%) and 8.0 g (61%) of the crotonic acids and 3-hydroxybutyric acid respectively.

The n.m.r. spectrum of 3-hydroxybutyric acid showed: for the methyl protons, a doublet at 1.25 p.p.m., $J = 6.0$ c.p.s.; for the methine proton, a sextet (footnote‡, Table I) at 4.27 p.p.m., $J = 6.0$ c.p.s.; for the methylene protons, a doublet at 2.51 p.p.m., $J = 6.0$ c.p.s.; and for the hydroxyl and carboxyl, a singlet at 7.57 p.p.m. The less complex spin–spin splitting pattern observed here, over that of protons *f* in dimer (Table I), has two possible explanations. Either the diastereomeric methylene hydrogens are equivalent in this special case, or more complex positive and negative coupling constants operate (14). This net effect has invariably been observed where a diastereomeric methylene is adjacent to an optically active R—CHOH-group (6).

Separation of Dimers **2***a and* **2***b*

(a) Thin-Layer Chromatography

A mixture of the dimers **2***a* and **2***b* containing about 15% **2***b* was duplicate spotted on Kodak prepared silica gel plates. They were developed using various appropriate solvent systems (15) with aqueous $KMnO_4$ as the visualizing agent. The R_f values for **2***a* and **2***b* were the same for the solvent systems chloroform with 4 volume % acetic acid, benzene – methanol – acetic acid 45:8:4 by volume, and ethyl acetate – hexane – acetic acid 50:50:1 by volume and were found to be 0.47, 0.78, and 0.65 respectively. Only the system ethanol – water – concentrated ammonium hydroxide (100:12:16 by volume) showed any promise by yielding R_f values of 0.77 for **2***a* and 0.63 for **2***b* (values for ammonium salts). The difficulties expected in scaling this up for elution chromatography to obtain sufficient for one or two cracking experiments made us discontinue this approach.

(b) Preparation of Dimer **2***a Alone*

trans-Crotonic acid was dimerized under conditions such that an insignificant amount of *cis*-crotonic acid would be present (7) and hence avoid even the formation of **2***b* as the dimer was made. *trans*-Crotonic acid (3.5 kg) was heated at 116–119° for 21 days. Generally during this interval the *cis* monomer concentration in the pot was kept below 2% though on two occasions it rose to 5% for a few hours. After cooling, the dimer oil (1300 ml) was decanted from the crystallized *trans*-crotonic acid. This brown oil was diluted with methylene chloride (800 ml) and vigorously washed with cold water (6 × 600 ml), dried, and the solvent removed on a boiling water bath under reduced pressure leaving 1220 g of brown oil. Rotary evaporation of this oil (100–110° oil bath; 0.1 mm) removed 335 g of *trans*-crotonic acid. Continuation of rotary evaporation (130–150° oil bath, 0.05 mm) yielded 526 g of the dimers **2***a* and **2***b* (5.75% of the latter) as a very pale-yellow viscous oil, and a residue of 338 g of viscous brown oil which consisted almost entirely of higher polymers of crotonic acid.

*Preparation of Methyl Esters of Trimer and Tetramer (***6***)*

After a successful dummy run using methanol/sulfuric acid to esterify the dimer, this procedure was used with a portion of the 338 g of higher polymer obtained in the preparation of *trans*-dimer (**2***a*).

Polymer mixture (25.5 g), methanol (64 g), and concentrated sulfuric acid (1 ml) were boiled together under reflux for 6 h. At the end of this time it was allowed to cool and diluted with methylene chloride (30 ml). This solution was washed with dilute brine (2 × 400 ml), saturated aqueous sodium bicarbonate (2 × 100 ml), and water (1 × 100 ml), and then dried ($MgSO_4$), and solvent removed. About 13 g of pale-brown oil remained which was distilled at 0.01 mm pressure using a short path apparatus. Six fractions of the esters were taken: fractions 1 and 2, b.p. 82–95°, 2.8 ml of colorless oil consisting largely of dimer; fraction 3, b.p. 95–128°, 0.7 ml of colorless oil, mixture of dimer and trimer; fraction 4, b.p. 128–136°, 3.9 ml of colorless oil which was trimer (93%, 7% dimer); fraction 5, b.p. 136–175°, 1.5 ml of pale-yellow oil consisting of trimer (38%) and tetramer (62%); fraction 6, b.p. 175–202°, 2.0 ml tetramer pale-yellow oil. The compositions reported above were obtained by gas–liquid chromatography using the same conditions reported under the analysis of the pure dimer ester, except that carrier gas flow rate was 17 cm^3/min here. Trimer methyl ester retention time was 2 min, tetramer 8 min. The elemental analyses, molecular weights, mass spectra, and n.m.r. data on these methyl esters are given in Tables IV, V, and VI. The distinguishing feature noticed in n.m.r. spectra of the methyl esters of the trimer and tetramer over those of the dimer was an increase in the multiplicity of the resonance ascribed to a butyric type methyl. Whereas the dimer yielded a doublet attributable to this moiety, the trimer apparently gave rise to three doublets, each with the same splitting as the dimer doublet, but with the first pair shifted about one cycle downfield and the second, a further cycle downfield. The tetramer additionally gave a further doublet one cycle downfield of the lowest field pair of the trimer.

Unsaturation in Crotonate Polymers by Quantitative Catalytic Hydrogenation

Using a published (16) method the methyl esters of the crotonate dimer, trimer, and tetramer were quantitatively hydrogenated. An unsupported platinum catalyst was prepared *in situ* by treating 10% aqueous chloroplatinic acid (2 ml) in ethanol (40 ml), which in a special borohydride hydrogenation flask had been previously purged with nitrogen, with a 1 *M* stabilized solution of sodium borohydride (10 ml). Excess 6 *N* hydrochloric acid (8 ml) was then added to the flask, followed shortly after by the injection of the olefin, neat. The hydrogenation then proceeded rapidly by the action of the acid present on the standardized sodium borohydride solution as it was added. The rate of borohydride addition was automatically regulated by the hydrogen uptake. Standardization of the borohydride solutions used was by duplicate runs against octene-1 and ethyl crotonate. The average of the four results, which agreed to within 2%, was taken as the molarity.

Acknowledgments

The author thanks Mr. H. D. Mak for obtaining the n.m.r. spectra required for this work and Dr. L. A. Shadoff for the mass spectra. He is also indebted to Dr. J. G. Smith for carrying out the thin-layer chromatography experiments.

Total synthesis of (±)-aristolone[1]

EDWARD PIERS, RONALD W. BRITTON, AND WILLIAM DE WAAL
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received August 28, 1968

A novel and efficient total synthesis of the racemic form of the sesquiterpene (−)-aristolone (**1**) is presented. The key step involves the cupric sulfate catalyzed intramolecular cyclization of the diazoketone **27**, which produces a mixture of products, the major component of which is (±)-aristolone.

Canadian Journal of Chemistry, **47**, 831 (1969)

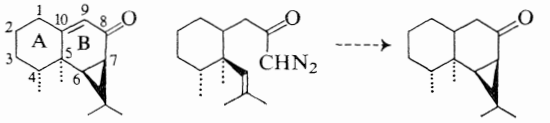
The sesquiterpene (−)-aristolone was initially isolated from *Aristolochia debilis* Sieb. *et* Zucc. in 1955 (1). The structure determination of this interesting natural product was reported (2) some six years later and, in 1962, Büchi and co-workers (3), on the basis of an indirect correlation with maaliol (4), of known absolute configuration, established the absolute configuration of (−)-aristolone as depicted in **1**. We previously carried out, and reported in preliminary form (5), a model study involving the synthesis of (±)-4-demethylaristolone. In this paper we describe the total synthesis of (±)-aristolone.

In any consideration of possible approaches to the total synthesis of (±)-aristolone, it is obvious that the most difficult and complex part of the synthesis would involve the construction of ring B, containing the olefinic double bond and the *gem* dimethylcyclopropyl moiety conjugated to the carbonyl. Of the number of possible routes which might be employed in the construction of these functionalities, we chose the scheme which can be illustrated, in general terms, by the hypothetical conversion of **2** into **3**. This conversion, involving an intramolecular cyclization of an olefinic diazoketone, appeared at first sight to be a potentially efficient method for the synthesis of the required substituted bicyclo[4·1·0]heptanone system. The use of olefinic diazoketones in intramolecular cyclizations was already well documented (6), and success of the above proposed conversion (**2** into **3**) appeared, in our opinion, quite likely.

The starting material which was chosen for the synthesis of the required crucial intermediate of type **2** was the readily available 2,3-dimethylcyclohexanone (7). Conversion of the latter into its 6-*n*-butylthiomethylene derivative **5**, *via* the corresponding hydroxymethylene compound **4**, was readily accomplished by standard procedures (8). Alkylation of **5** with methallyl chloride in *t*-butyl alcohol in the presence of potassium *t*-butoxide (8) gave, in 87% yield, a mixture of the corresponding alkylated products (**6**). Removal of the *n*-butylthiomethylene blocking group by treatment of **6** with potassium hydroxide in refluxing aqueous diethylene glycol (8) provided, in 90% yield, a mixture of *cis*-(**7**) and *trans*-2,3-dimethyl-2-methallylcyclohexanone (**8**). Analysis of this mixture by gas–liquid chromatography (g.l.c.) indicated that these two compounds were present in a ratio of approximately 4:1, respectively. An analytical sample of each epimer was obtained by preparative g.l.c. and each exhibited spectral data which were fully in accord with the assigned structure.

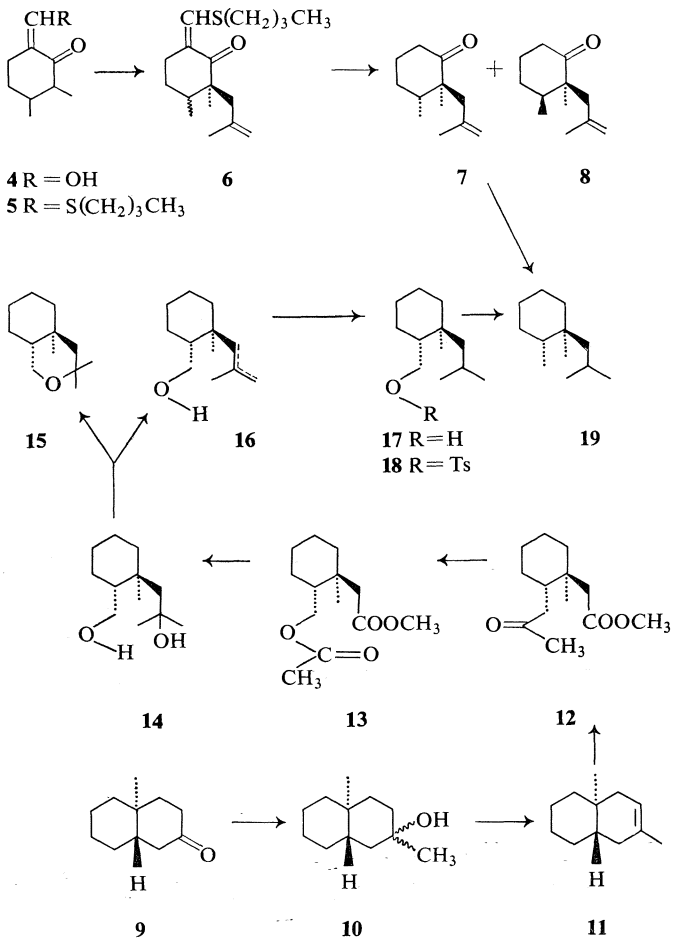


1 **2** **3**

Since the factors which affect the stereochemical outcome of the alkylation of cyclohexanone derivatives are not well understood in detail and were, in fact, the subject of very recent discussion (9), it was rather difficult to predict with certainty the stereochemistry of the alkylation products **7** and **8**. We therefore felt it necessary to obtain unambiguous proof concerning this point and showed that the major alkylation product was, in fact, the desired *cis* compound **7**.

Reaction of the well known and readily available (10) *trans*-10-methyl-2-decalone (**9**) with excess methyllithium in refluxing ether provided a high yield of a semicrystalline material,

[1]Presented at the 51st Annual Conference and Exhibition of the Chemical Institute of Canada, Vancouver, British Columbia, June 3–6, 1968.



consisting of a mixture of the epimeric tertiary alcohols **10**. Dehydration of this material with a catalytic amount of *p*-toluenesulfonic acid in refluxing benzene produced 2,10-dimethyl-*trans*-2-octalin (**11**) (see ref. 11). The latter was obtained as a clear, colorless oil and was shown by g.l.c. analysis to be greater than 95% pure. Furthermore, the nuclear magnetic resonance (n.m.r.) spectrum exhibited only one olefinic proton signal, an unresolved multiplet at τ 4.72, with a half-height width of 8 Hz. This was clearly in accord with the octalin structure having the olefinic double bond at the 2-position.

The octalin **11** was subjected to a modified ozonolysis reaction (12) and the resulting crude keto-aldehyde was immediately oxidized with Jones reagent (13). The keto-acid thus obtained was esterified with ethereal diazomethane, affording an overall 68% yield (from the octalin **11**) of the keto ester **12**.

In order to obtain, from the keto-ester **12**, a compound suitable for appropriate comparison with the alkylation products (**7** and/or **8**), it can readily be seen that the acetic ester side chain of **12** required conversion to an *iso*butyl-type group, while the keto containing side chain required degradation to a methyl group. This was accomplished as follows.

Baeyer–Villiger oxidation of the keto-ester **12** with trifluoroperacetic acid in dichloromethane in the presence of disodium hydrogen phosphate (see ref. 14) gave, in 83% yield, the diester **13**. Interestingly, the n.m.r. spectrum of this compound exhibited, in addition to the expected signals, a pair of quartets (AB of ABX system) between τ 5.65 and τ 6.32, readily attributable to

the methylene protons on the carbon bearing the acetate group. However, the magnetic non-equivalence of methylene protons found in an asymmetric environment is a well-established phenomenon (15), and this therefore deserves no further comment.

Reaction of the diester **13** with excess refluxing ethereal methyllithium afforded the diol **14** in 97% yield. Treatment of the latter with a catalytic amount of *p*-toluenesulfonic acid in refluxing benzene, followed by careful distillation of the crude product, gave, in addition to the cyclic ether **15** (44%, b.p. 64–66° at 0.1 mm), a mixture of the olefinic alcohols **16** (46%, b.p. 104–108° at 0.1 mm). Hydrogenation of the latter over Adam's catalyst in ethanol at room temperature and atmospheric pressure provided the primary alcohol **17**. This material was converted, by treatment with *p*-toluenesulfonyl chloride in pyridine at 0°, into the corresponding tosylate (**18**) and the crude material thus obtained was subjected to lithium aluminium hydride reduction in refluxing tetrahydrofuran. The product, *cis*-1,2-dimethyl-1-*iso*butylcyclohexane (**19**) was obtained in 66% overall yield from the alcohol **17**.

When the major alkylation product (**7**) was subjected to successive catalytic hydrogenation (ethanol, Adam's catalyst) and Huang–Minlon reduction (16), the corresponding hydrocarbon was obtained in high yield. The latter was shown to be identical (refractive index, infrared and n.m.r. spectra, g.l.c. retention time) with *cis*-1,2-dimethyl-1-*iso*butylcyclohexane (**19**) obtained from alcohol **17** as described above. This comparison unambiguously proved that the major alkylation product was, in fact, the desired *cis*-2,3-dimethyl-2-methallylcyclohexanone (**7**).

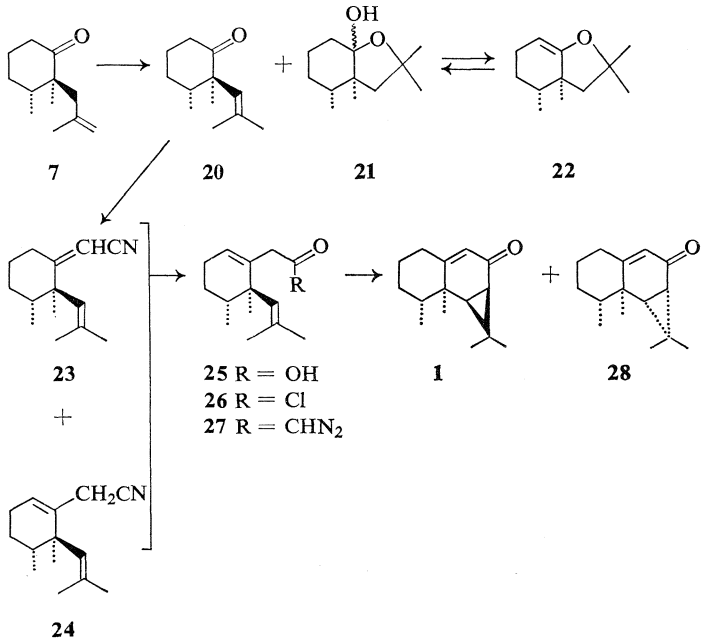
Having obtained a suitable synthetic intermediate with appropriate stereochemistry, it became necessary at this point, bearing in mind the initially proposed synthetic approach, to convert the methallyl group of **7** into the methylpropenyl moiety. In this connection, we had found in a model study (5) that 2-methyl-2-methallylcyclohexanone was smoothly converted, by treatment with *p*-toluenesulfonic acid in refluxing benzene, into a mixture consisting mainly of the starting material and 2-methyl-2-methylpropenylcyclohexanone in a ratio of approximately 1:3, respectively. This procedure was therefore adopted in the present work.

A solution of compound **7** in benzene containing *p*-toluenesulfonic acid was refluxed for three days and the reaction mixture was then subjected to aqueous work-up. Gas–liquid chromatographic analysis of the crude product showed that it consisted of a mixture, containing the starting material **7** (approximately 12%), the desired cyclohexanone derivative **20** (46%), the cyclic hemiketal **21** (37%) and an unidentified compound (5%). Distillation of this material (b.p. 66–68° at 2.8 mm) allowed the isolation (see Experimental) of a small amount of the crystalline hemiketal **21**, m.p. 74–74.5°. The spectral data of this compound was in full accord with the assigned structure. It should be noted that the hemiketal **21**, when heated at temperatures greater than 120° readily dihydrated to afford the corresponding cyclic enol-ether **22** (see below).

When the bulk of the material obtained from the above distillation was redistilled, at 53 mm pressure, through a spinning band column, the initial fractions consisted of a mixture of water and the enol ether **22** (the dehydration product of hemiketal **21**). The structure assigned to compound **22**, b.p. 128° at 53 mm, was fully substantiated by spectral data. It should be noted that this compound was extremely sensitive to moisture and, even upon exposure to the atmosphere, readily hydrated to re-form the crystalline hemiketal **21**.

A later fraction from the above spinning-band distillation consisted of nearly pure desired *cis*-2,-3-dimethyl-2-methylpropenylcyclohexanone **20**, b.p. 143–144° at 53 mm. The isolated yield of this compound was approximately 22% and thus, in contrast to the equivalent reaction in the model study (5), the direct acid-catalyzed conversion of compound **7** into compound **20** was not particularly efficient.[2] The n.m.r. spectrum of compound **20**, particularly when compared with that of the starting material **7**, clearly showed that the carbon–carbon double bond had undergone the desired migration. Thus, while **7**

[2]We were subsequently able to show (E. Piers and W. de Waal, unpublished results) that the conversion of **7** into **20** could be carried out more efficiently by use of a modified sequence in which the keto group of **7** was first protected by formation of the corresponding ethylene ketal. Subsequent acid-catalyzed isomerization of the carbon–carbon double bond, followed by removal of the ketal protecting group (*p*-toluenesulfonic acid in refluxing dry acetone) and separation of isomers allowed the isolation of cyclohexanone **20** in 50% overall yield (from **7**).



exhibited signals for two olefinic protons (τ 5.17 and τ 5.27) and one vinyl methyl group (τ 8.38), the isomerized material **20** showed signals for only one olefinic proton (τ 4.59) and two vinyl methyl groups (τ 8.27 and τ 8.57).

Having obtained in sufficient quantity a cyclohexanone derivative with the desired functionality and stereochemistry, we planned to use the keto group of **20** as a "handle" for the introduction of the required diazoketone-containing side chain. We initially considered for this purpose the reaction of **20** with the modified Wittig reagent, triethyl phosphonoacetate (17). However, this reaction proved very sluggish and even when carried out at elevated temperatures, produced no useful result. Since we felt that the failure of this reaction was due, at least in part, to the sterically hindered nature of the carbonyl group in **20**, we decided to attempt the use of a reagent which was sterically less demanding, namely, diethyl cyanomethylphosphonate (17). This approach proved successful. Thus, reaction of cyclohexanone **20** with diethyl cyanomethylphosphonate in the presence of methylsulfinyl carbanion in dimethyl sulfoxide (18) at 100° for 1 h, produced, in 87% yield, a mixture of the α,β-unsaturated nitrile **23** and the β,γ-unsaturated nitrile **24**, in a ratio of approximately 2:1, respectively.[3] The fact that these compounds were isomeric was clearly shown by the spectral data. The α,β-unsaturated isomer **23** exhibited a strong ultraviolet absorption at 220.5 mμ (ε = 12 300) and, in the n.m.r. spectrum, showed a one-proton singlet at τ 4.75 (=CHCN). The β,γ-unsaturated isomer **24**, on the other hand, gave no strong ultraviolet absorption and, in the n.m.r. spectrum, exhibited a broad one-proton signal at τ 4.07 (γ-vinyl H) and a two-proton multiplet at τ 7.01 (—CH_2CN).

Hydrolysis of the mixture of nitriles (**23** and **24**) with potassium hydroxide in refluxing aqueous ethanol afforded, in 82% yield, the β,γ-unsaturated carboxylic acid **25**. That the double bond had now completely isomerized into the β,γ-position was again clearly shown by the lack of an appropriate absorption in the ultraviolet and by the n.m.r. spectrum which showed, in addition to a two-proton multiplet at τ 7.07 (—CH_2COOH), the γ-vinyl proton as a poorly resolved triplet at τ 4.35. Although the

[3]The relative amounts of these two isomers in the product depended somewhat on the reaction conditions and reaction time.

base-promoted equilibration of α,β- and β,γ-unsaturated carboxylic acids is a well-known process (19), it is interesting that in the present case the equilibrium lies completely on the side of the β,γ-unsaturated isomer. One of the major factors contributing to this phenomenon may well be the $A^{(1,3)}$ strain (20) which would be associated with the exocyclic double bond in the α,β-unsaturated isomer.

The carboxylic acid **25** was converted into its sodium salt and the latter was reacted with oxalyl chloride in benzene at 0°. The crude acid chloride **26** (λ_{max} 5.62 μ) thus obtained was, due to its instability, immediately converted, by reaction with dry ethereal diazomethane, into the corresponding diazoketone **27** (λ_{max} 4.79, 6.15 μ). The n.m.r. spectrum of the crude diazoketone indicated that during the sequence **25** → **26** → **27**, the olefinic double bond had remained in the β,γ-position with respect to the carbonyl group. This was of some importance since any migration of the double bond into conjugation with the carbonyl would undoubtedly have resulted in a large predominance of the geometric isomer having the diazoketone moiety *trans* to the ring carbon bearing the methylpropenyl substituent, thus making the subsequent intramolecular cyclization (see below) of the diazoketone impossible.

When the crude diazoketone **27** was refluxed in cyclohexane in the presence of cupric sulfate (6) and the crude product distilled under reduced pressure, a clear oil (70%, based on the carboxylic acid **25**) was obtained. This material was shown by g.l.c. analysis to consist of approximately 42% (±)-aristolone (**1**), 20% (±)-6,7-epi-aristolone (**28**) and a number of minor unidentified components. Purification of this mixture by a combination of preparative thin-layer chromatography and preparative g.l.c. allowed the isolation of both of the major products. Thus, (±)-aristolone (**1**) was obtained as a crystalline solid which, upon recrystallization from petroleum ether, exhibited m.p. 62–63°. This material was shown to be identical (m.p., mixed m.p., infrared, and n.m.r.[4] spectra) with a recrystallized (petroleum ether) 1:1 mixture of (−)-aristolone and α-ferulone [(+)-aristolone] (22).

(±)-6,7-Epi-aristolone (**28**) was obtained as an oil. It was shown to be isomeric with (±)-aristolone by high resolution mass spectrometry, and gave spectral data in complete accord with the assigned structure.

It should be noted that very recently another synthesis of (±)-aristolone by a sequence completely different from that described above, was reported (23).

Experimental

Melting points, which were determined on a Kofler block, and boiling points are uncorrected. Ultraviolet spectra were, unless otherwise noted, measured in methanol solution on either a Cary, model 14, or a Unicam, model SP. 800, spectrophotometer. Routine infrared spectra were recorded on a Perkin–Elmer Infracord model 137 spectrophotometer, while all comparison spectra were recorded on a Perkin–Elmer model 421 spectrophotometer. Nuclear magnetic resonance spectra were taken in dueteriochloroform solution on Varian Associates spectrometers, model A-60 and/or model HA-100. Line positions are given in the Tiers τ scale, with tetramethylsilane as an internal standard; the multiplicity, integrated peak areas, and proton assignments are indicated in parentheses. Gas–liquid chromatography (g.l.c.) was carried out on an Aerograph Autoprep, model 700. The following columns (10 ft × 1/4 in., unless otherwise noted) were employed, with the inert, supporting material being 60/80 mesh Chromosorb W in each case: column A, 20% FFAP; column B (10 ft × 3/8 in.), 30% FFAP; column C, 15% QF-1; column D, 3% SE-30; column E, 20% SE-30; column F (10 ft × 3/8 in.), 30% Apiezon J; column G, 10% Apiezon J; column H, 10% FFAP; column I (20 ft × 3/8 in.), 30% SE-30. The specific column used, along with column temperature and carrier gas (helium) flow-rate (in ml/min), are indicated in parentheses. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver.

*6-Hydroxymethylene-2,3-dimethylcyclohexanone (**4**)*

To an ice-cooled, stirred suspension of powdered sodium methoxide 78 g, 1.44 moles) in 800 ml of dry benzene, kept under an atmosphere of dry nitrogen, was added 71 g (0.564 mole) of 2,3-dimethylcyclohexanone. The resulting mixture was stirred for 10 min, and then 70 g (0.945 mole) of ethyl formate was added. The mixture was warmed to room temperature and allowed to stand overnight. Water was added, the mixture was thoroughly shaken, and the layers separated. The organic layer was extracted with two portions of 10% aqueous sodium hydroxide. The combined aqueous layer and alkaline extracts were cooled, acidified with 6 *N* hydrochloric acid, and thoroughly extracted with ether. The combined extracts were washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residual oil under reduced pressure, gave 77.5 g (90%) of the hydroxymethylene derivative **4** as a pale-yellow oil, b.p. 60–63° at 2 mm,

[4]For an analysis of the n.m.r. spectrum of (−)-aristolone, see ref. 21.

n_D^{20} 1.5135. Ultraviolet, λ_{max} 281 mμ, λ_{max} (NaOH added) 316 mμ; infrared (film), λ_{max} 6.05, 6.25 μ. The instability of this compound precluded the acquisition of satisfactory analytical data.

6-n-Butylthiomethylene-2,3-dimethylcyclohexanone (5)

A solution of the hydroxymethylene derivative (**4**) (77.5 g, 0.504 mole), *n*-butyl mercaptan (55.5 g, 0.615 mole), and *p*-toluenesulfonic acid (50 mg) in 500 ml of dry benzene was refluxed in a nitrogen atmosphere under a Dean–Stark water separator for 6 h, at which time 6 ml of water had been collected. The cooled solution was washed with saturated aqueous sodium bicarbonate, then with water and finally dried over anhydrous magnesium sulfate. Removal of the solvent gave an oil which, upon distillation under reduced pressure, afforded 99.4 g (87%) of the *n*-butylthiomethylene derivative (**5**), b.p. 116–118° at 0.3 mm, n_D^{20} 1.5368; ultraviolet, λ_{max} 309 mμ (ε = 15 400); infrared (film), λ_{max} 6.01, 6.48 μ.

Anal. Calcd. for $C_{13}H_{22}OS$: C, 68.97; H, 9.79. Found: C, 68.59; H, 9.71.

2,3-Dimethyl-2-methallyl-6-n-butylthiomethylenecyclohexanone (6)

The *n*-butylthiomethylene derivative **5** (99.4 g, 0.440 mole) was added to 1800 ml of dry *t*-butanol containing 144 g (1.40 moles) potassium *t*-butoxide and the resulting solution was stirred at room temperature for 10 min and then cooled to 0°. Freshly distilled methallyl chloride (255 g, 2.82 moles) was added slowly and the reaction mixture was refluxed under an atmosphere of dry nitrogen for 2 h. Most of the solvent was removed under reduced pressure and the residue was diluted with water. The resulting mixture was extracted thrice with ether. The combined ether extracts were washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent gave an oil which, upon distillation under reduced pressure, afforded 107 g (87%) of 2,3-dimethyl-2-methallyl-6-*n*-butylthiomethylenecyclohexanone (**6**) (mixture of epimers), b.p. 106–109° at 0.25 mm, n_D^{20} 1.5043; ultraviolet, λ_{max} 281 mμ (ε = 14 700); infrared (film), λ_{max} 6.00, 6.32, 11.10 μ.

Anal. Calcd. for $C_{17}H_{28}OS$: C, 72.80; H, 10.06. Found: C, 73.09; H, 10.11.

cis- and trans-2,3-Dimethyl-2-methallylcyclohexanone (7 and 8)

To a solution of the above alkylated material (**6**) (107 g) in 700 ml of diethylene glycol was added 650 ml of 25% aqueous potassium hydroxide and the resulting solution was refluxed under nitrogen for 18 h. The reaction mixture was steam distilled until the distillate was clear. The distillate was saturated with salt and extracted thrice with ether. The combined ether extracts were washed with water, dried (anhydrous magnesium sulfate), and evaporated. The residual oil, upon distillation under reduced pressure, gave 66 g (96%) of a mixture of *cis*- and *trans*-2,3-dimethyl-2-methallyl cyclohexanone, (**7** and **8**), b.p. 76–80° at 3.6 mm. Analysis of this mixture by g.l.c. (column A, 140°, 85) indicated that the ratio of the *cis* compound (**7**) to the *trans* compound (**8**) was approximately 4:1. An analytical sample of each epimer was obtained by preparative g.l.c. (column B, 250°, 120). The desired *cis* epimer **7** exhibited n_D^{20} 1.4809. Infrared (film), λ_{max} 5.89, 6.13, 11.25 mμ; n.m.r., τ 5.17, 5.27 (unresolved multiplets, 2H, $=CH_2$), 7.33, 7.84 (broadened AB-type pair of doublets, 2H, vinyl $—CH_2$, J = 14 Hz), 8.38 (broad singlet, 3H, vinyl methyl), 9.13 (singlet, 3H, tertiary methyl), 9.28 (doublet, 3H, secondary methyl, J = 6.5 Hz).

Anal. Calcd. for $C_{12}H_{20}O$: C, 80.01; H, 11.11. Found: C, 79.78; H, 11.31.

The *trans* epimer (**8**) exhibited n_D^{20} 1.4812; infrared (film), λ_{max} 5.88, 6.11, 11.28 μ; n.m.r., τ 5.22, 5.32 (unresolved multiplets, 2H $=CH_2$), 7.62, 8.04 (broadened AB-type pair of doublets, 2H, vinyl $—CH_2$, J = 14 Hz), 8.42 (broad singlet, 3H, vinyl methyl), 8.84 (singlet, 3H, tertiary methyl), 9.27 (doublet, 3H, secondary methyl, J = 5.8 Hz).

Anal. Calcd. for $C_{12}H_{20}O$: C, 80.01; H, 11.11. Found: C, 79.78; H, 11.27.

2,10-Dimethyl-trans-2-octalin (11)

To a solution of *trans*-10-methyl-2-decalone (10) (**9**, 44.5 g, 0.236 mole) in 1 l of dry ether was added 9 g (0.41 mole) of methyllithium in 200 ml of ether. The solution was refluxed for 8 h, cooled, and the excess methyllithium was destroyed by careful addition of dilute hydrochloric acid. The ether layer was washed with water, dried (anhydrous magnesium sulfate), and evaporated. Distillation of the residual material under reduced pressure gave 42.7 g (88%) of a mixture of epimeric alcohols (**10**) as a semi-crystalline mass, b.p. 62–67° at 0.2 mm. This material was not further purified, but was used directly for the next step.

A solution of the above mixture of alcohols (**10**) (2.0 g) and *p*-toluenesulfonic acid (25 mg) in 25 ml of dry benzene was refluxed under a Dean–Stark water separator until the required amount of water had been collected. The solution was cooled, washed with dilute aqueous sodium hydroxide, and evaporated. Distillation of the residual oil afforded 1.15 g (70%) of 2,10-dimethyl-*trans*-2-octalin (**11**) as a clear colorless oil, b.p. 91–93° at 11 mm. Gas–liquid chromatographic analysis (column C, 170°, 85) indicated that this material was greater than 95% pure. An analytical sample, collected by preparative g.l.c. (column C, 150°, 85) exhibited n_D^{20} 1.4873. Infrared (film), λ_{max} 6.94, 7.33, 12.73 μ; n.m.r., τ 4.72 (unresolved multiplet, 1H, olefinic proton, width at half-height = 8 Hz), 8.37 (broad singlet, 3H, vinyl methyl), 9.23 (singlet, 3H, tertiary methyl).

Anal. Calcd. for $C_{12}H_{20}$: C, 87.73; H, 12.27. Found: C, 87.58; H, 12.40.

Preparation of Keto-ester 12

A solution of the octalin **11** (19.6 g, 0.12 mole) in 1 l of dry methanol was cooled by means of a dry ice – acetone bath. Ozone was bubbled through the solution until a permanent blue color persisted, and then continued for an additional 15 min. Dimethyl sulfide (11.9 ml, 0.162 mole) was added and the solution was allowed to warm to room temperature. The methanol and excess dimethyl sulfide were removed under reduced pressure and the residue was taken up in ether. The ether solution was washed with water, dried (anhydrous magnesium sulfate), and evaporated. The residual crude keto-aldehyde was immediately oxidized with Jones reagent (13) (30 ml) and, after

the normal work-up, afforded 22.7 g of the corresponding keto-acid. Treatment of the latter crude material with excess ethereal diazomethane, followed by removal of the ether and distillation of the residual oil, gave 18.2 g (68%) of the desired keto-ester (**12**), b.p. 85–85.5° at 0.1 mm. An analytical sample isolated by preparative g.l.c. (column D, 160°, 80), showed n_D^{20} 1.4712. Infrared (film), λ_{max} 5.83, 6.97, 9.83 μ; n.m.r., τ 6.34 (singlet, 3H, —$COOCH_3$), 7.73 (singlet, 2H, —CH_2COOCH_3), 7.85 (singlet, 3H, —$COCH_3$), 9.07 (singlet, 3H, tertiary methyl).

The 2,4-dinitrophenylhydrazone derivative of the keto-ester **12** exhibited m.p. 111–112°.

Anal. Calcd. for $C_{19}H_{26}N_4O_6$: C, 56.15; H, 6.44; N, 13.78. Found: C, 55.85; H, 6.65; N, 13.61.

*Preparation of Diester **13***

To a solution of the keto-ester **12** (18.2 g, 85 mmoles) in 1.7 l of dichloromethane was added 220 g of anhydrous disodium hydrogen phosphate. The resulting mixture was stirred vigorously and a solution of trifluoroperacetic acid (prepared by adding 13.5 ml of 90% hydrogen peroxide to 86.5 ml of trifluoroacetic anhydride in 42 ml of dichloromethane) was added. The mixture was stirred at room temperature for 1.5 h and then at reflux for 3.5 h. Ethyl acetate (500 ml) was added and the mixture was washed with saturated aqueous sodium bicarbonate, water, saturated brine, and then dried over anhydrous magnesium sulfate. Removal of the solvents, followed by distillation of the residual oil afforded 16.2 g (83%) of the diester **13**, b.p. 96–102° at 0.1 mm. An analytical sample, collected by preparative g.l.c. (column D, 190°, 90), exhibited n_D^{20} 1.4658; infrared (film), λ_{max} 5.77, 6.97, 9.71 μ; n.m.r., τ 5.65–6.32 (pair of quartets, 2H, —CH_2—OAc, AB of ABX system), 6.35 (singlet, 3H, —$COOCH_3$), 7.64 (singlet, 2H, CH_2COOCH_3), 7.96 (singlet, 3H, —$OCOCH_3$), 9.03 (singlet, 3H, tertiary methyl).

Anal. Calcd. for $C_{13}H_{22}O_4$: C, 64.43; H, 9.14. Found: C, 64.28; H, 9.23.

*Preparation of Diol **14***

To a solution of the diester **13** (15.8 g, 65.5 mmoles) in 250 ml of dry ether was added 300 ml of 1.7 *M* methyllithium in ether. The solution was refluxed overnight, cooled, and quenched by careful addition of water. The ether solution was dried over anhydrous magnesium sulfate. Removal of the ether and distillation of the residual oil provided 12.6 g (97%) of the diol **14**, b.p. 109–110° at 0.15 mm; infrared (film), λ_{max} 3.08, 6.89, 9.80 μ; n.m.r., τ 6.17–6.83 (pair of quartets, 2H, —CH_2OH, AB of ABX system), 6.65 (singlet, 2H, OH | 2—O—H), 8.15, 8.54 (doublets, 2H, —CH_2—$C(CH_3)_2$, AB system, J = 15 Hz), 8.64, 8.76 (singlets, 6H, OH | —$C(CH_3)_2$), 9.12 (singlet, 3H, tertiary methyl). Due to the ease with which this compound dehydrated, it was virtually impossible to obtain pure diol which was not contaminated with small amounts of its dehydration products. Satisfactory analytical data was therefore not obtained.

*Dehydration of Diol **14***

A solution of the diol **14** (5.0 g) in 250 ml of dry benzene containing 50 mg of *p*-toluenesulfonic acid was refluxed under a Dean–Stark water separator for 4 h, at which time the required amount of water had been collected. The solution was cooled, washed with dilute aqueous sodium bicarbonate, and dried over anhydrous magnesium sulfate. Removal of the benzene gave an oil, which, upon distillation gave two distinct fractions. The first fraction (2.0 g, 44%, b.p. 64–66° at 0.1 mm) was shown by g.l.c. analysis (column E, 135°, 100) to consist of nearly pure cyclic ether **15**. An analytical sample was collected by preparative g.l.c. (column F, 230°, 150), and exhibited n_D^{20} 1.4747; infrared (film), λ_{max} 6.97, 7.30, 9.40, 9.57 μ; n.m.r., τ 6.25–6.80 (diffuse, 2H, —CH_2—O—, overlapped AB of ABX system), 8.71, 8.81, 8.97 (singlets, 9H, tertiary methyls).

Anal. Calcd. for $C_{12}H_{22}O$: C, 79.07; H, 12.15. Found: C, 79.19; H, 12.17.

The second fraction (2.1 g, 46%) was a mixture of the two olefinic alcohols **16**, b.p. 104–108° at 0.1 mm, n_D^{20} 1.4919; infrared (film), λ_{max} 3.05, 6.12, 6.98, 9.80, 10.19, 11.28 μ.

Anal. Calcd. for $C_{12}H_{22}O$: C, 79.07; H, 12.15. Found: C, 79.17; H, 12.35.

*Preparation of Alcohol **17***

The hydrogenation of the mixture of the olefinic alcohols **16** was carried out in ethanol at room temperature and atmospheric pressure using platinum as the catalyst. From 1.85 g of **16** there was obtained 1.23 g (71%) of pure saturated alcohol **17**, b.p. 110–115° (bath temperature) at 0.15 mm, n_D^{20} 1.4749. Infrared (film), λ_{max} 6.04, 6.90, 9.83 μ; n.m.r., τ 6.12–6.88 (pair of quartets, 2H, —CH_2OH, AB of ABX system), 9.07 (doublet, 6H, —$CH(CH_3)_2$, J = 6.2 Hz), 9.22 (singlet, 3H, tertiary methyl).

Anal. Calcd. for $C_{12}H_{24}O$: C, 78.19; H, 13.12. Found: C, 78.33; H, 13.20.

*cis-1,2-Dimethyl-1-isobutylcyclohexane (**19**)*

*(a) From Alcohol **17***

A solution of alcohol **17** (1 g, 5.4 mmoles) in 5 ml of dry pyridine was cooled to 0° and 1.09 g (5.75 mmoles) of *p*-toluenesulfonyl chloride was added. The solution was stirred at 0° for 1.5 h and then diluted with ice-cold water. The mixture was extracted with ether and the ether solution was washed with saturated aqueous sodium bicarbonate, water, saturated brine, and then dried over anhydrous magnesium sulfate. Removal of the ether gave 1.77 g of the crude tosylate **18** as a pale-yellow oil. The latter was dissolved in 32 ml of dry tetrahydrofuran and 380 mg (10 mmoles) of lithium aluminium hydride was added. The mixture was refluxed, with stirring, for 22 h, cooled, and the excess hydride was destroyed by careful addition of ice-cold water. Ether was added and the organic layer was separated and dried over anhydrous magnesium sulfate. Removal of the solvents, followed by distillation of the residual oil, afforded 500 mg (66%) of *cis*-1,2-dimethyl-1-*iso*butylcyclohexane (**19**), b.p. 110° at 10 mm. An analytical sample was collected by preparative g.l.c. (column G, 165°, 85) and exhibited n_D^{20} 1.4544. The n.m.r. spectrum of this compound showed signals only in the expected region, between τ 8.0 and τ 9.3.

(b) From cis-2,3-Dimethyl-2-methallylcyclohexanone (7)

Hydrogenation of 202 mg of *cis*-2,3-dimethyl-2-methallylcyclohexanone (**7**) in ethanol at room temperature and atmospheric pressure, using platinum as the catalyst, gave 195 mg of undistilled *cis*-2,3-dimethyl-2-*iso*butylcyclohexanone, which exhibited one component by g.l.c. (column G, 200°, 80). The latter was not further purified, but was directly subjected to Huang–Minlon reduction (16). Thus, a solution of the cyclohexanone (190 mg) in diethylene glycol (1.5 ml) containing 0.5 g of potassium hydroxide and 0.2 ml of hydrazine hydrate was refluxed for 2 h. The reflux condensor was removed and replaced by a distillation head, and the temperature of the reaction mixture was slowly raised to 195° and kept at this temperature for 1 h. The distillate and the cooled reaction mixture were combined, diluted with water, and thoroughly extracted with ether. The combined ether extracts were washed with dilute hydrochloric acid, water, saturated brine, and dried over anhydrous magnesium sulfate. Careful removal of the ether afforded 176 mg (94%) of a pale-yellow oil which exhibited one component by g.l.c. (column G, 155°, 80). An analytical sample, collected by preparative g.l.c. (column G, 155°, 80), exhibited refractive index, infrared and n.m.r. spectra, and g.l.c. retention time identical with those of *cis*-1,2-dimethyl-1-*iso*butylcyclohexanone (**19**) obtained from the alcohol **17**, as described above.

Acid-catalyzed Isomerization of cis-2,3-Dimethyl-2-methallylcyclohexanone (7)

A solution of compound **7** (62 g, containing approximately 5% of its epimer **8**) in 1 l of dry benzene containing 1 g of *p*-toluenesulfonic acid was refluxed under an atmosphere of nitrogen for 3 days. The cooled solution was extracted twice with saturated aqueous sodium bicarbonate, then with water, and finally with saturated brine. After drying (anhydrous magnesium sulfate) the benzene was removed, yielding a yellow oil, which was shown by g.l.c. analysis (column H, 140°, 85) to consist of approximately 46% of the desired cyclohexanone **20**, 12% of the starting material, 37% of the cyclic hemiketal **21**,[5] and 5% of an unidentified compound. Distillation of the oil under reduced pressure (2.8 mm) gave the following fractions: fraction 1, b.p. 66–66.5°, 7 g; fraction 2, b.p. 66.5°, 7 g; fraction 3, b.p. 66.5–67.5°, 37.5 g; fraction 4, b.p. 67.5–68°, 3.5 g. Fraction 3 contained a small amount of crystalline material, while fraction 4 was nearly entirely crystalline. Isolation of this material, followed by recrystallization from petroleum ether (b.p. 60–80°) gave pure hemiketal **21** (3.2 g), m.p. 74–74.5°. Infrared (Nujol), λ_{max} 2.92, 6.92, 7.28, 9.16, 9.85, 10.08 μ; n.m.r., τ 7.69 (broad singlet, 1H, —O—H, D_2O exchange), 8.14 (singlet, 2H, —C—CH_2—C—), 8.58, 8.65, 9.06 (singlets, 9H, 3 tertiary methyls), 9.13 (doublet, 3H, secondary methyl J = 6.2 Hz).

Anal. Calcd. for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18. Found: C, 73.00; H, 11.00.

Fraction 2 and the oil of fraction 3 from the above distillation were combined and subjected to careful fractional distillation through a spinning band column (stainless steel, 8 mm × 24 in.). The distillation was carried out at a pressure of 53 mm, and the various fractions were subjected to g.l.c. analysis (column H, 140°, 85). The initial three fractions (5.5 g) consisted mainly of a mixture of the cyclic enol-ether **22** and water (due to dehydration of the hemiketal **21**). Fraction 4 (11.1 g, b.p. 128°) was nearly pure enol-ether **22**, fraction 7 (13.7 g, b.p. 143–144°) was shown to be greater than 90% pure ketone **20**, while fractions 5 and 6 (6.4 g, b.p. 128–143°) consisted of a mixture of compounds **20** and **22**. Fractions 8 and 9 (5 g, b.p. 144–147°) contained ketone **20** and starting material **7** in a ratio of approximately 5:2, respectively.

An analytical sample of the cyclic enol ether **22** was obtained from fraction 4 by preparative g.l.c. (column B, 200°, 110). This compound was extremely sensitive to moisture and, even upon exposure to the atmosphere, readily hydrated to afford the crystalline hemiketal **21**. The pure enol-ether exhibited n_D^{20} 1.4760. Ultraviolet (cyclohexane) λ_{max} 200 mμ (ε = 8 760); infrared (film), λ_{max} 5.92 μ; n.m.r., τ 5.36 (triplet, 1H, olefinic H, J = 3.5 Hz), 8.57, 8.74, 8.90 (singlets, 9H, tertiary methyls), 9.10 (doublet, 3H, secondary methyl, J = 6 Hz).

Anal. Calcd. for $C_{12}H_{20}O$: C, 80.01; H, 11.11. Found: C, 80.19; H, 11.10.

An analytical sample of *cis*-2,3-dimethyl-2-methylpropenylcyclohexanone (**20**) was obtained from fraction 7 by preparative g.l.c. (column B, 200°, 110) and exhibited n_D^{20} 1.4822. Infrared (film), λ_{max} 5.85 μ; n.m.r., τ 4.59 (multiplet, 1H, vinyl H), 8.27, 8.57 (doublets, 6H, vinyl methyls, J = 1.5, 1.3 Hz, respectively), 8.91 (singlet, 3H, tertiary methyl), 9.17 (doublet, 3H, secondary methyl, J = 7 Hz).

Anal. Calcd. for $C_{12}H_{20}O$: C, 80.01; H, 11.11. Found: C, 80.08; H, 11.02.

Reaction of Ketone 20 with Diethyl Cyanomethylphosphonate

A stirred suspension of sodium hydride (9.3 g, 0.387 mole) in dry dimethyl sulfoxide (200 ml) was slowly heated under an atmosphere of nitrogen, to 75° and kept at this temperature until frothing had ceased (approximately 45 min). The solution was cooled to room temperature and a solution of diethyl cyanomethylphosphonate (72.6 g, 0.387 mole) in 125 ml of dimethyl sulfoxide was added. The solution was stirred for 10 min and then a solution of compound **20** (13 g, 64.2 mmoles) in 125 ml of dimethyl sulfoxide was added. The reaction mixture was heated at 100° for 1 h, cooled, diluted with water, and then thoroughly extracted with petroleum ether (b.p. 30–60°). The combined extracts were washed twice with water, once with saturated brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residual oil under reduced

[5]It should be noted that the hemiketal **21** was not stable to the high temperatures used in the g.l.c. analysis, but, in fact, dehydrated to the enol-ether **22**. Thus, both authentic hemiketal and enol-ether exhibited identical g.l.c. retention times. However, distillation of the crude reaction product under reduced pressure at a relatively low temperature clearly showed that none of the relatively low boiling enol-ether was present in the initially obtained mixture.

pressure yielded 12.7 g (89%) of a pale-yellow oil, b.p. 86–91° at 0.25 mm. This material was shown, by g.l.c. analysis (column C, 190°, 100), to consist of a mixture of the α,β-unsaturated nitrile **23** and the β,γ-unsaturated nitrile **24**, in a ratio of approximately 2:1, respectively. An analytical sample of each of these compounds was isolated by preparative g.l.c. (column F, 230°, 120). The α,β-unsaturated nitrile **23** exhibited n_D^{20} 1.5109. Ultraviolet, λ_{max} 220.5 mμ (ε = 12 300); infrared (film), λ_{max} 4.53, 6.20 μ; n.m.r., τ 4.75 (singlet, 1H, =CHCN), 4.82 (unresolved multiplet, 1H, vinyl H), 8.25, 8.44 (doublets, 6H, vinyl methyls, J = 1.4, 1.6 Hz, respectively), 8.84 (singlet, 3H, tertiary methyl), 9.13 (doublet, 3H, secondary methyl, J = 6.5 Hz).

Anal. Calcd. for $C_{14}H_{21}N$: C, 82.70; H, 10.41. Found: C, 82.85; H, 10.25.

The β,γ-unsaturated nitrile **24** exhibited n_D^{20} 1.4981. Infrared (film), λ_{max} 4.48, 6.06 μ; n.m.r., τ 4.07 (unresolved multiplet, 1H, γ-vinyl H), 4.94 (unresolved multiplet, 1H, vinyl H), 7.01 (unresolved multiplet, 2H, —CH_2CN) 8.31, 8.40 (doublets, 6H, vinyl methyls, J = 1.5, 1.7 Hz respectively), 9.00 (singlet, 3H, tertiary methyl), 9.11 (doublet, 3H, secondary methyl).

Anal. Calcd. for $C_{14}H_{21}N$: C, 82.70; H, 10.41. Found: C, 82.71; H, 10.45.

Preparation of Carboxylic Acid ***25***

Potassium hydroxide (77 g) was dissolved in a mixture of ethanol (380 ml) and water (20 ml), and a mixture of the two nitriles (**23** and **24**) (13.2 g) was added. The solution was refluxed under an atmosphere of nitrogen for 3 days and then most of the solvent was removed under reduced pressure. The residual material was diluted with water and the resulting solution was washed with ether. The aqueous layer was acidified with 6 *N* hydrochloric acid and extracted thoroughly with ether. The combined extracts were washed with water, saturated brine, and then dried over anhydrous sodium sulfate. Removal of the solvent gave a viscous yellow oil which, upon distillation under reduced pressure, yielded 12 g (82%) of the β,γ-unsaturated carboxylic acid **25** as a clear viscous oil, b.p. 130–134° at 0.25 mm, n_D^{20} 1.5040; infrared ($CHCl_3$), λ_{max} 2.9–4.2 (broad), 5.88 μ; n.m.r., τ 4.35 (poorly resolved triplet, 1H, γ-vinyl H), 4.93 (unresolved multiplet, 1H, vinyl H), 7.07 (unresolved multiplet, 2H,—CH_2C-OOH), 8.32, 8.38 (doublets, 6H, vinyl methyls, J = 1.5, 1.3 Hz, respectively), 8.99 (singlet, 3H, tertiary methyl), 9.11 (doublet, 3H, secondary methyl, J = 6.5 Hz).

Anal. Calcd. for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97. Found: C, 75.61; H, 10.00.

*(±)-Aristolone (**1**) and (±)-6,7-Epi-aristolone (**28**)*

The β,γ-unsaturated carboxylic acid **25** (5.0 g, 22.4 mmoles) was dissolved in aqueous sodium hydroxide (25.0 mmoles), the water was evaporated under reduced pressure, and the residue was dried in a vacuum oven at 70°. A stirred suspension of the resulting dry sodium salt in 140 ml of dry benzene containing 0.5 ml of pyridine was cooled to 0° and 56 g (0.44 mole) of oxalyl chloride was added. The reaction mixture was stirred at 0° for 15 min, filtered, and evaporated under reduced pressure (vacuum pump). The solution was kept at 0° during this process. The crude acid chloride **26** [infrared (film), λ_{max} 5.62 μ; n.m.r., very similar to that of the carboxylic acid] thus obtained was taken up in 250 ml of dry ether and the resulting solution was added to excess alcohol free ethereal diazomethane which had been dried over potassium hydroxide. The solution was stirred for 15 min and evaporated under reduced pressure affording the crude diazoketone **27**. Infrared (film), λ_{max} 4.79, 6.15 μ. The crude diazoketone **27** was dissolved in 600 ml of cyclohexane and cupric sulfate (15 g) was added. The resulting suspension was refluxed, with stirring, until the infrared absorption at 4.79 μ had disappeared (approximately 4 h). The cooled mixture was filtered and the filtrate was washed with saturated aqueous sodium bicarbonate, water, saturated brine, and then dried over anhydrous sodium sulfate. Removal of the solvent, followed by distillation of the residual material under reduced pressure, yielded 3.5 g (approximately 70%, based on the acid **25**) of a clear oil, b.p. 100–110° (bath temperature) at 0.1 mm. This material was shown by g.l.c. analysis (column G, 220°, 110) to consist of approximately 42% of (±)-aristolone (**1**), 20% of (±)-6,7-epi-aristolone (**28**) and a number of minor unidentified components. This mixture was partially purified by preparative thin-layer chromatography. Neutral alumina plates (20 × 60 cm, 0.5 mm thick) were used, with 3:2 *n*-hexane – ether being employed as developing solvent. Approximately 150 mg of the distilled material was applied per plate and the appropriate band of each plate, containing (±)-aristolone (**1**) and its isomer **28**, was eluted with ether. From 3.5 g of distilled material there was thus obtained 2.1 g of a clear oil which consisted mainly of (±)-aristolone (**1**) and its isomer **28**, in a ratio of approximately 2.4:1, respectively. Final purification was effected by preparative g.l.c. (column I, 240°, 110). Crystalline (±)-aristolone (**1**), thus obtained was recrystallized from petroleum ether (b.p. 60–80°), and exhibited m.p. 62–63°. Ultraviolet, λ_{max} 236 mμ (ε = 10 300); infrared ($CHCl_3$), λ_{max} 6.09 μ; n.m.r., τ 4.28 (unresolved multiplet, 1H, —C^9H, width at half-height = 3.5 Hz), 8.28 (pair of doublets, 1H, —C^7H, J = 8 and 1.2 Hz), 8.61 (doublet, 1H, —C^6H, J = 8 Hz), 8.74, 8.80, 8.81 (singlets, 9H, tertiary methyls), 8.93 (doublet, 3H, secondary methyl, J = 6.5 Hz). This material was found to be identical (m.p., mixed m.p., infrared, n.m.r., g.l.c. retention time) with authentic (±)-aristolone, prepared by recrystallizing, from petroleum ether (b.p. 60–80°), a 1:1 mixture of (−)-aristolone and α-ferulone [(+)-aristolone] (23).

Mol. Wt. Calcd. for $C_{15}H_{22}O$: 218.167. Found (high resolution mass spectrometry): 218.166.

Pure (±)-6,7-epi-aristolone (**28**) was obtained as a colorless oil. Ultraviolet, λ_{max} 233 (ε = 10 000); infrared ($CHCl_3$), λ_{max} 6.08 μ; n.m.r., τ 4.24 (unresolved multiplet, 1H, —C^9H, width at half-height = 2.5 Hz), 8.38 (pair of doublets, 1H, —C^7H, J = 8 and 1.1 Hz), 8.45 (doublet, 1H, —C^6H, J = 8 Hz), 8.80, 8.81, 8.84 (singlets, 9H, tertiary methyls), 9.02 (doublet, 3H, secondary methyl, J = 6.0 Hz).

Mol. Wt. Calcd. for $C_{15}H_{22}O$: 218.167. Found (high resolution mass spectrometry): 218.167.

Acknowledgments

We are very grateful to Professor A. Marsili for generous samples of (−)-aristolone and

α-ferulone, and to Professor F. Sorm for a generous quantity of (−)-aristolone. Financial support from the National Research Council of Canada, and a National Research Council of Canada Studentship (to W. de W.) are gratefully acknowledged.

Enzymic deacylation of esterified mono- and disaccharides.[1] 2. The chemical synthesis of 2,3-di-*O*-acetyl-D-glucopyranose

A. L. FINK[2] AND G. W. HAY[3]
Department of Chemistry, Queen's University, Kingston, Ontario
Received July 9, 1968

2,3-Di-*O*-acetyl-D-glucopyranose was synthesized by catalytic (paladium on carbon) hydrogenation of benzyl 2,3-di-*O*-acetyl-4,6-*O*-benzylidene-β-D-glucoside.

Canadian Journal of Chemistry, **47**, 841 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The synthesis of 2,3-di-*O*-acetyl-D-glucopyranose (**1**) was prompted by the need for a partially acetylated glucose derivative for use in assessing the suitability of methods for identifying partially acetylated sugars (1). Benzyl 2,3-di-*O*-acetyl-4,6-*O*-benzylidene-β-D-glucoside (**2**) was prepared from glucose by the route shown in Scheme 1, using standard procedures. Hydrogenation of **2**, performed using a suspension in ethyl ether (methanol, chloroform, or methanol–acetic acid, proved to be unsatisfactory) at room temperature under a small positive pressure, removed the benzylidene and/or benzyl groups to give **1** and 2,3-di-*O*-acetyl-4,6-*O*-benzylidene-β-D-glucose (**3**). Careful preparation of the catalyst, palladium on carbon, by hydrogenation of the chloride salt, was essential and uniformity of reactivity with different batches of catalyst was difficult to attain. The hydrogenation was conducted under strictly anhydrous, neutral conditions to minimize the possibility of any acetyl migration. The progress of the reaction was followed conveniently by thin-layer chromatography of the reaction mixture, and by gas–liquid partition chromatography of trimethylsilyl ether derivatives of aliquots (Table I).

A rapid initial consumption of hydrogen occurred until approximately 40% of the theoretical amount of hydrogen had been incorporated, whereupon the rate diminished to a lower value for a brief period of time. This lull was most pronounced with less active batches of catalyst. Evaporation of the filtrate of the reaction mixture at that point afforded a crystalline product which, upon recrystallization from ethyl ether, had a nuclear magnetic resonance (n.m.r.) spectrum and an elemental analysis consistent with structure **3**.

TABLE I

Retention times for acetyl trimethylsilyl and methyl derivatives of glucose

Derivative of D-glucoside	Relative retention time
Trimethylsilyl 2,3,4,6-tetrakis-*O*-trimethylsilyl-β-	1.5
Trimethylsilyl 2-*O*-acetyl-3,4,6-tris-*O*-trimethylsilyl-β-	2.7
Trimethylsilyl 2,3-di-*O*-acetyl-4,6-bis-*O*-trimethylsilyl-β-	3.8
Methyl 2,3,4,6-tetra-*O*-methyl-α-	0.14
Methyl 2,3,4,6-tetra-*O*-methyl-β-	0.10
Methyl 3,4,6-tri-*O*-acetyl-2-*O*-methyl-α-	1.71
Methyl 3,4,6-tri-*O*-acetyl-2-*O*-methyl-β-	2.60
Methyl 4,6-di-*O*-acetyl-2,3-di-*O*-methyl-α-	1.00
Methyl 4,6-di-*O*-acetyl-2,3-di-*O*-methyl-β-	0.77

NOTE: Column *a*; 180 °C; 100 ml per min. Retention times relative to trimethylsilyl tetrakis-*O*-trimethylsilyl-α-D-glucopyranoside for the trimethylsilyl derivatives, and methyl 4,6-di-*O*-acetyl-2,3-di-*O*-methyl-α-D-glucopyranoside for the methyl derivatives.

The continuation of hydrogenation after the initial lull in the rate of hydrogen uptake resulted in a gradual decrease until the uptake was almost negligible. Further hydrogenation caused an increase in the rate of hydrogen uptake which thereafter slowly diminished to zero. The total consumption at that point was greater than the theoretical amount. Evaporation of the filtrate obtained when the hydrogenation rate first became negligible (ca. 100% of theoretical) gave a white, amorphous powder. Attempts to crystallize the compound failed. On the basis of the n.m.r. spectrum, elemental analysis, thin-layer chromatographic behavior, and the gas–liquid chromatographic analysis of the trimethylsilyl derivative, the compound was assigned structure **1**.

[1]This project was supported by the National Research Council of Canada, Operating Grant A1921. Abstracted from the Ph.D. Thesis of A. L. Fink, Queen's University, Kingston, Ontario, December, 1967.

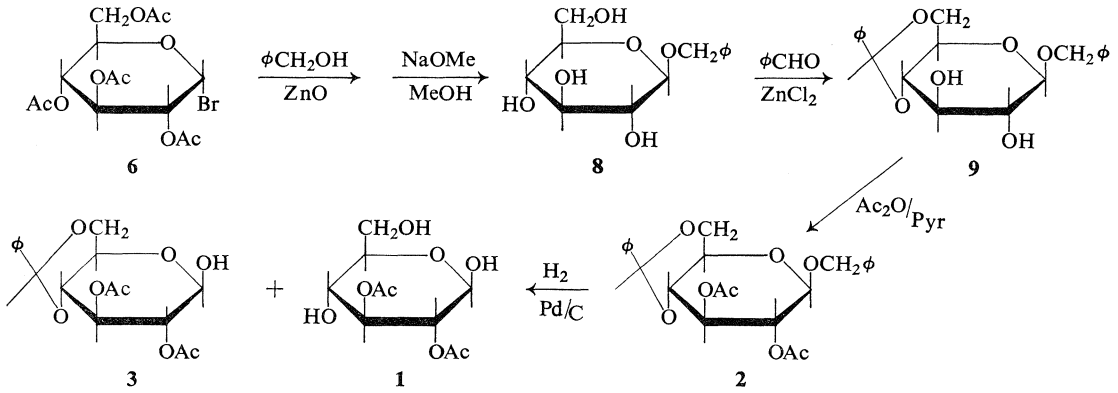
[3]To whom enquiries should be addressed.



SCHEME 1. The reaction sequence for the synthesis of 2,3-di-*O*-acetyl-D-glucopyranose.

In the amorphous state, **1** underwent spontaneous decomposition into 2-*O*-acetyl-D-glucopyranose (**4**) and D-glucose (**5**), even at −1 °C. This chemical lability greatly hindered the unequivocal establishment of the identity of **1**. Compound **1** was very sensitive to alcoholysis. Thus, if the catalyst was washed with methanol or ethanol during the work-up following hydrogenation the amount of decomposition of **1** into **4** and **5** greatly increased. Furthermore, elution with methanol during preparative thin-layer chromatography resulted in complete deacetylation of **1**. Methanol also has been found to cause deacetylation during the hydrogenation of benzyl 2-*O*-acetyl-4-*O*-methyl-β-D-xyloside (2).

Preparative thin-layer or paper partition chromatography could be used to purify **1** and **3**. Freshly prepared **1** was homogeneous by thin-layer chromatography. An aged sample afforded three closely adjacent compounds in the region of the chromatogram where diacetates were expected. This observation, and the finding that a random mixture of glucose acetates was resolved by thin-layer chromatography into groups of components in the vicinity of each product from the enzymic deacetylation of glucose pentaacetate, inferred that the technique was capable of distinguishing some, if not all, of the isomeric acetate derivatives.

Gas–liquid partition chromatographic analysis of the trimethylsilyl derivative from **1** revealed one major and two minor products. Only the major product had a retention time consistent with a di-*O*-acetyl derivative. The retention times of the minor products corresponded to those of the trimethylsilyl derivatives of **4** and **5**. Thus, whereas trimethylsilylation may have caused some deacetylation no evidence of acetyl group migration was obtained.

Paper partition chromatographic analysis of the hydrogenation product from **2** disclosed only three products with migration rates corresponding to those of **1**, **2**, and **3**.

The detection of **1** and **3** but not glucose pentaacetate by *p*-anisidine spray reagent was taken as presumptive evidence for the absence of substitution at C-1 in **1** and **3**.

These chromatographic data argue for the ability of the methods to discriminate between similar or isomeric acetyl derivatives, and aver either that no acetyl group migration occurred or that a quantitative, selective migration of acetyl groups occurred to yield only one of the potentially numerous isomers.

The n.m.r. spectrum of **1** in dimethyl sulfoxide (DMSO)-d_6 revealed the ratio of acetoxy protons (8.05 τ) to ring protons to be 6:10. The resonance at 3.3 τ was assigned to O_1H (3.5 τ in β-D-glucopyranose), that at 5.6 τ to C_1H (5.7 τ in β-D-glucopyranose), and that at 5.54 τ to O_6H (5.58 τ in β-D-glucopyranose). The same ratio of acetoxy to ring protons was obtained in acetone-d_6(acetoxy protons 8.22 τ). In D_2O the acetoxy resonance occurred at 7.94 τ. The chemical shifts for acetoxy resonance are in accord with equatorial acetoxy groups (3) and bear the correct ratio with ring protons for a hexose diacetate. The chemical shifts for O_1H and O_6H in DMSO-d_6 are consistent with the β configuration, but are too low for the α anomer (3).

Elemental analysis of **1** was consistent with a di-*O*-acetylhexose.

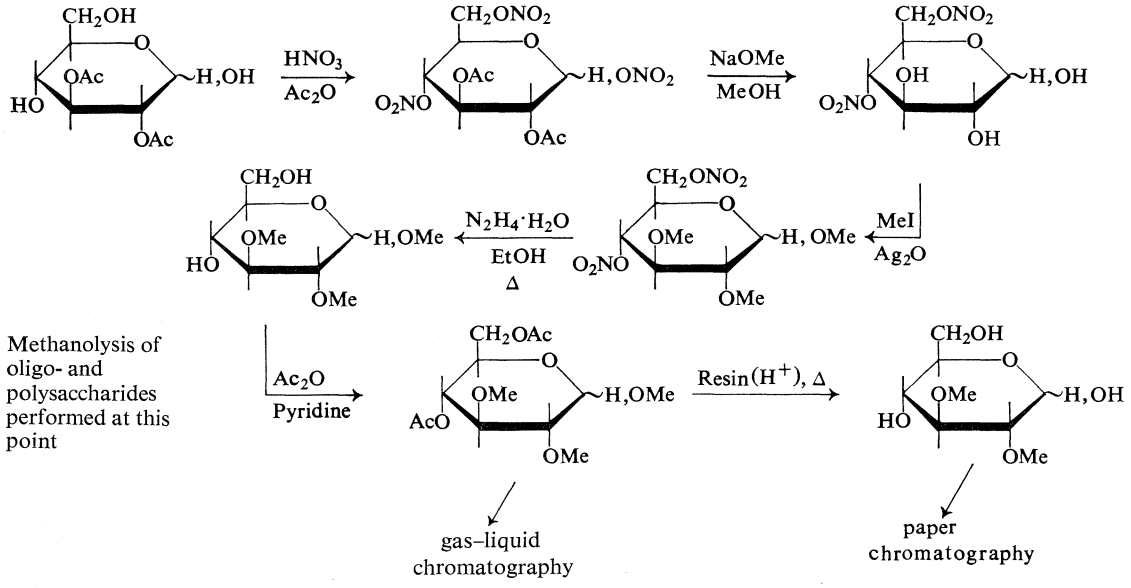

SCHEME 2. Reaction sequence for the location of acetyl groups in partially acetylated sugars.

Compound **1** was subjected to a sequence of reactions designed to locate the positions of acetate esters in carbohydrates (1). The major product was identified as methyl 4,6-di-*O*-acetyl-2,3-di-*O*-methyl-D-glucoside which is in agreement with the structure proposed for **1** (Scheme 2). The literature (4, 5) indicates that nitrate esters and methyl ethers do not migrate under the conditions utilized in Scheme 2. Consequently only acetyl migration prior to nitration is to be expected. However, to obtain the 2,3-di-*O*-methyl derivative, either a migration of nitrate esters in the direction opposite to that observed with acetate groups must have occurred, or deacetylation must have caused a concurrent loss of certain nitrate esters and methylation must have been almost quantitatively ineffective at C-4 and/or C-6 while being quantitatively effective at C-2 and C-3.

Experimental

Unless stated otherwise the chemicals used were reagent grade products. Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Optical rotations were measured with a Bendix automatic polarimeter (sodium lamp) at 25 ± 1 °C. Nuclear magnetic resonance (n.m.r.) spectra were obtained with a Varian A-60 spectrometer using tetramethylsilane as external standard. Paper partition chromatography was performed by the descending technique using butanone-water azeotrope on Whatman No. 1 paper. Thin-layer chromatography was performed on Silica Gel G or Silica Gel HF254 (preparative) irrigated with methanol:benzene 1:9 (v/v). Gas–liquid partition chromatography was carried out with an F and M model 402 chromatograph with hydrogen flame detector. Compounds were identified by co-chromatography with authentic specimens or by comparison of retention times. The columns (6 ft × 1/8 in. I.D., U-shaped) used were 5% (Column *a*) and 10% (w/w) LAC-4R-886 on Chromosorb W, 100–120 mesh.

Tetra-O-acetyl-1-bromo-1-deoxy-α-D-glucopyranose (6)

Compound **6** was prepared by the method of Scheurer and Smith (6); m.p. 88–89 °C (lit. 88–89 °C); yield, 67%.

Benzyl Tetra-O-acetyl-β-D-glucopyranoside (7)

Compound **7** was prepared from **6** by the method of Helferich and Wedemeyer (7); m.p. 95–97 °C (lit. 95–101 °C); yield, 54%.

Benzyl β-D-glucopyranoside (8)

Compound **8** was prepared from **7** by deacetylation with sodium methoxide – methanol; m.p. 121–122 °C (lit. (8) 123–125 °C); yield, 88%.

Benzyl 4,6-O-Benzylidene-β-D-glucoside (9)

Compound **9** was prepared from **8** by the method of Klemer (9); m.p. 158–159 °C (lit. 159–160 °C); yield, 75%.

Benzyl 2,3-Di-O-acetyl-4,6-O-benzylidene-β-D-glucoside (2)

Compound **9** (7.0 g) was dissolved in 45 ml dry pyridine, 35 ml acetic anhydride added, and the solution allowed to stand at room temperature for 24 h. A white precipitate formed after a few hours. The reaction mixture was filtered, the residue washed with ice-water, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

recrystallized from ethyl acetate to give **2**, m.p. 211–212 °C (lit. (10) 208–209 °C); yield, 66%.

Anal. Calcd. for $C_{24}H_{26}O_8$: C, 65.0; H, 5.9. Found: C, 64.7; H, 6.0.

The n.m.r. spectrum of **2** showed acetoxy resonance at 8.15 τ in acetone-d_6, and at 7.98 τ and 8.02 τ in deuteriochloroform.

2,3-Di-O-acetyl-4,6-O-benzylidene-β-D-glucose (3)

Palladium on carbon catalyst was prepared from palladium chloride on carbon (11) (0.5 g), by slurrying in methanol, and hydrogenating until the uptake of hydrogen ceased. The catalyst was washed 10 times with methanol, 5 times with glacial acetic acid, and 10 times with ethyl ether on a sintered glass funnel. The catalyst was added to 125 mg **2** as a slurry in ethyl ether and hydrogenation carried out until a lull in the rate of hydrogen uptake occurred (ca. 40% of theoretical). The mixture was filtered through a sintered glass funnel and the filtrate evaporated to dryness under reduced pressure at room temperature. The resulting syrup was crystallized from ethyl ether as fine white needles, m.p. 162–163 °C, $[\alpha]_D^{25}$ −7.0° (*c*, 1.0 in acetone). The compound was insoluble in water, sparingly soluble in ethyl ether, and soluble in acetone or DMSO. Thin-layer chromatography detected only one component, which was identified as a reducing sugar by its reaction with *p*-anisidine (12). Analysis by n.m.r., in acetone-d_6 detected the presence of resonance at 2.20 τ (aromatic ring protons), at 8.14 τ (acetoxy protons), as well as that due to protons on the sugar ring. Integration indicated a ratio of 5:6:9, respectively, which is in accord with the proposed structure, **3**. The elemental analysis was consistent with this conclusion.

Anal. Calcd. for $C_{17}H_{20}O_8$: C, 58.1; H, 5.7. Found: C, 58.3; H, 5.9.

2,3-Di-O-acetyl-β-D-glucopyranose (1)

If hydrogenation of **2** was continued until the rate of hydrogen uptake became negligible (ca. 100% of theoretical), or if **3** was subjected to similar hydrogenation conditions and work-up, an amorphous, white compound, (yield: 82%, $[\alpha]_D$ +10.9° (*c*, 2.2 in H_2O)), was isolated which could not be crystallized. The compound was soluble in water and in acetone. Thin-layer chromatographic analysis of the compound detected only one compound, R_3 0.16. This compound (**1**) was visualizable with *p*-anisidine spray reagent. Gas–liquid chromatography of the trimethylsilyl ether of **1** revealed only one major component with a retention time relative to that of pentakis-*O*-trimethylsilyl-α-D-glucopyranose (R_T) of 3.2, and two minor components with R_T 2.7 and 1.5, respectively. The elemental analysis was as follows:

Anal. Calcd. for $C_{10}H_{16}O_8$: C, 45.5; H, 6.1. Found: C, 45.75; H, 6.5.

Products Obtained from Compound 1 via Scheme 2

Compound **1** was subjected to the sequence of reactions outlined in Scheme 2 (1). Gas–liquid partition chromatographic analysis (Column *a*; 180 °C; 100 ml/min) of the products (1) revealed that the major product was a mixture of methyl 4,6-di-*O*-acetyl-2,3-di-*O*-methyl-α- and β-D-glucosides with retention times of 1.00 and 0.77 respectively, relative to an authentic sample of the α-anomer. Either peak could be exclusively augmented by co-chromatography with an authentic sample.

Enzymic deacylation of esterified mono- and disaccharides.[1] 3. The location of acetylated positions in partially acetylated sugars[2]

A. L. FINK[3] AND G. W. HAY[4]
Department of Chemistry, Queen's University, Kingston, Ontario

Received July 9, 1968

The nitrate ester, formed by reaction with fuming nitric acid in acetic anhydride at 0 °C, was suitable to block free hydroxyl groups in partially acetylated sugars without acetyl migration. This allowed the acetylated positions in partially acetylated mono- and disaccharides to be located by the reaction sequence: nitration, deacetylation, methylation, de-nitration, disaccharide hydrolysis and methyl glycosylation (initial product identification by paper partition chromatography), acetylation, and analysis of the products by gas–liquid partition chromatography. D-Glucose, penta-*O*-acetyl-D-glucopyranose, and 2,3-di-*O*-acetyl-β-D-glucopyranose were used as test compounds in the evaluation of this scheme.

Introduction

In connection with studies on the enzymic deacylation of some esterified sugars (1), it became necessary to identify partially acylated sugar derivatives, particularly the partially acetylated derivatives of glucose and disaccharides of glucose. Techniques to locate the acetylated positions in such compounds are complicated by the mobility and lability of the acetyl group. The results of various investigations of means of locating the acetylated positions are reported herein.

Results and Discussion

The facile migrations of acyl groups in partially acylated polyhydroxylic compounds first noted by Fischer (2), have been observed under neutral, basic, and acidic conditions, and have been reported to originate at all positions except C-6 in the hexose series (3, 4). As a consequence, the number of reactions that may be carried out in the partially acetylated sugars without affecting the acetylated positions is severely limited.

With the exception of the methylation of acidic hydroxyls by diazomethane, all the procedures currently used in carbohydrate chemistry for methylation involve basic conditions (5) which could lead to hydrolysis or migration of the acetyl groups (4, 6). Indeed, the migration of acetyl groups during methylation has been used advantageously in some syntheses (7). Attempts to permethylate sugars using the diazomethane – boron trifluoride reagent resulted in incomplete methylation (8) and although methyl glycosides have been prepared by such a method the yields were low. Recently the methylation of some tetra-*O*-acetylhexopyranosides and a hepta-*O*-acetylmaltose with diazomethane and boron trifluoride etherate has been reported (9, 10). No migration or hydrolysis of acetate was observed.

As an initial test, the diazomethane – boron trifluoride etherate methylation method was applied to D-glucose (**1**) and to penta-*O*-acetyl-β-D-glucopyranose (**2**). Some replacement of acetyl by methyl occurred as a result of the boron trifluoride – catalyzed hydrolysis of some acetate groups of **2**, and no conditions were found under which **1** was fully methylated.

The sodium *t*-butoxide-catalyzed deacetylation of **2** was very slow. Methylation by the use of methyl iodide and sodium *t*-butoxide in dimethyl sulfoxide permethylated **1** rapidly, but afforded methyl tetra-*O*-methyl-α- and β-D-glycopyranosides as the major products from **2**. Presumably the sodium *t*-butoxide reacted with dimethyl sulfoxide to form methylsulfinylcarbanion (11) which can cause deacetylation (12).

The general reaction sequence whereby acetate groups can be located in carbohydrates is shown in Scheme 1*a*. Model compounds were used to determine the suitability of potential protective groups. A partial list of the various protective

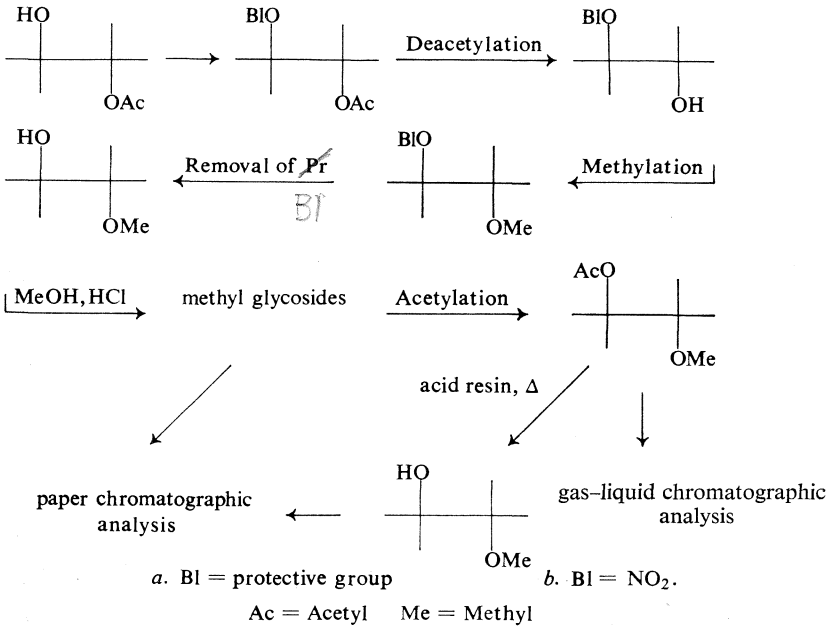
[4]To whom enquiries should be addressed.



SCHEME 1. The reaction sequence used to locate the acetylated positions in partially acetylated glucoses or disaccharides of glucose.

groups considered follows; the stage in the reaction series at which the protective group was considered unsuitable is given in parentheses: alkyl, aryl, allyl (13), vinyl (14), and alkoxy–alkyl ethers (15) (formation); carbonate, thiocarbonate (16), formyl, trifluoroacetyl, and benzoyl esters (17) (formation, deacetylation); 2,4-dinitrobenzenesulfinyl esters (18) (deacetylation, methylation); sulfonates and sulfates (19) (deacetylation, removal); and alkylhalogenomethyl ethers (20) and phenylcarbanilates (21) (methylation).

Trimethylsilyl ethers of sugars may be formed rapidly and quantitatively (22) and have found much use in gas–liquid partition chromatographic analysis. The trimethylsilyl ethers are susceptible to alcoholysis except in neutral solvents, and are sensitive to acid- and base-catalyzed hydrolysis. Methanolysis has been found to occur much more rapidly at C-6 than at the secondary hydroxyl positions in **4** (23). Consequently, whereas sodium methoxide – catalyzed deacetylation would affect the trimethylsilyl groups at C-6, other methods of deacetylation such as reduction, acid hydrolysis, and reaction with Grignard reagents were precluded since they would cause general cleavage of the oxygen–silicon bond (24).

1 could be completely trimethylsilylated in a few minutes at 0 °C (22), and **2** could be recovered unaltered after the reaction. However, with 2,3-di-*O*-acetyl-β-D-glucopyranose (**3**) trimethylsilylation in this fashion caused some replacement of acetyl by trimethylsilyl groups as revealed by the formation of some trimethylsilyl 2-*O*-acetyl-3,4,6-tris-*O*-trimethylsilyl- and 2,3,4,6-tetrakis-*O*-trimethylsilyl-β-D-glucopyranosides. Trimethylsilylation of the products from the enzymic deacetylation of penta-*O*-acetyl-α and β-D-glucopyranoses with a purified esterase from wheat germ lipase (1) gave 12 well-resolved peaks on gas–liquid partition chromatographic analysis. These *O*-acetyl-*O*-trimethylsilyl derivatives tentatively were assigned identities from their relative retention times (Table I).

The conditions used for the synthesis of **5** were very similar to those of deacetylation (25). The effects of sodium methoxide/methanol on **2** and **6** at various temperatures and catalyst concentrations were followed conveniently by thin-layer chromatography. At temperatures above 15 °C hydrolysis of trimethylsilyl ethers proceeded faster than deacetylation, whereas below 15 °C the order was reversed. The effect of catalyst concentration was similar in both reactions.

NOTE: Column 5% LAC-4R-886, 180° C, 100 ml/min.

Dissolving the substrate in acetone prior to the addition of methanol – sodium methoxide decreased the rate of deacetylation. Replacement of sodium methoxide by sodium *t*-butoxide or sodium isopropoxide resulted in much slower reactions and, at temperatures resulting in complete deacetylation within a reasonable time, detrimethylsilylation proceeded faster than deacetylation.

7 R = R_1 = TMS R_2 = H
8 R = Me $R_1 = R_2$ = H
TMS = Trimethylsilyl
Me = Methyl

The use of methanolic piperidine solutions (26) caused deacetylation of **2** and detrimethylsilylation of **6**. The optimum conditions for complete deacetylation of **2** and minimum loss of trimethylsilyl groups from **6** required 10–20% methanol in piperidine at 70 °C. However, even these conditions gave starting material and **7** as the major products from **6**. The deacetylation of **2** by reduction with diborane or by sodium methoxide/chloroform (conditions which had no effect on **6**) failed.

Although the phenylcarbamoyl group has been used as a protective agent for locating the position of acetyl groups in partially acetylated (1 → 4)-linked polysaccharides (21, 27, 28), the method is unsuitable if the C-4 hydroxyl is not blocked because migration of the phenylcarbamoyl group may occur during methylation (21). The benzylthiocarbonyl group (29) was not investigated but might be suitable if not liable to migration.

Dihydropyran forms ethers of tetrahydropyran by acid-catalyzed condensation with alcohols. The products are sensitive to acid but stable to base (30). The reaction has been used to block free positions in some partially acetylated carbohydrates (31–33) although the yields were not quantitative. None of the reports specifically mentioned any replacement of acetyl by tetrahydropyranyl groups. The effect of the reaction on **1** and **2** was followed conveniently by infrared spectroscopy. Experiments with various catalysts, and various catalyst concentrations showed that the rate of tetrahydropyranyl ether formation increased with increasing catalyst concentration, that sufficient catalyst for complete substitution of **1** resulted in some replacement of acetyl by tetrahydropyranyl groups in **2**, and that *p*-toluenesulfonic acid catalysis appeared to cause the least replacement of acetyl groups. No conditions were found in which both complete etherification of the free hydroxyl groups of **1**, and complete retention of acetyl groups of **2** were achieved. Evidence of deacetylation upon the addition of trifluoroacetic acid alone was observed by infrared spectroscopy.

Both dimethyl sulfoxide and dimethylformamide reacted with **6**, but Purdie methylation conditions (5) had no effect. However, the Purdie methylation of the products obtained by subjecting **6** to the optimum deacetylation conditions (sodium methoxide/methanol, −15 °C) gave methyl tetra-*O*-methyl-α- and β-D-glucopyranosides as major products.

Of the several procedures used to prepare nitrate esters of carbohydrates (34) the mildest, fuming nitric acid in acetic anhydride at or below 0 °C, has been shown to have no effect on acetyl groups (35). Neither fuming nitric acid/acetic

anhydride nor dinitrogen pentoxide/chloroform (36) had any effect on **2**. Reaction of **1** and **8** with fuming nitric acid/acetic anhydride yielded penta-*O*-nitro-D-glucopyranose (**9**) and methyl penta-*O*-nitro-D-glucopyranoside (**10**), respectively. The infrared spectra of **9** and **10** exhibited the characteristic strong absorptions of the nitrate bands I, II, and III (37), and detected no free hydroxyl groups. Thus, nitration under these conditions did not affect acetylated positions and reacted quantitatively with free hydroxyl groups. Mildly basic conditions cause hydrolysis of the nitrate group on C-1. Accordingly, treatment of **9** with sodium methoxide/methanol, followed by methylation gave a product with an infrared spectrum indistinguishable from that of **10**. However, nitrate groups can be removed quantitatively and conveniently by refluxing with ethanolic hydrazine hydrate, a reagent which has no effect on methyl groups (38). Other substituents on the sugar ring may exert a strong influence on the ease of formation and removal of nitrate esters, and *vice-versa* (39–41).

When **1** was subjected to the reaction sequence: nitration, deacetylation, methylation, de-nitration, and acetylation, product analysis by gas–liquid partition and thin-layer chromatography revealed only methyl tetra-*O*-acetyl-α- and β-D-glucopyranosides. This suggested that nitration of **1** proceeded quantitatively, the deacetylation conditions caused removal of the nitrate group only on C-1, and that the methylation of free hydroxyl groups and the hydrazine denitration proceeded quantitatively. When **2** was put through the reaction sequence the only products were the anticipated methyl tetra-*O*-methyl-α- and β-D-glucopyranosides.

Compound **3** (42), which affords opportunities for both acetyl migration and hydrolysis, was put through the reaction sequence as a further test. **3** was rather unstable and underwent spontaneous deacetylation to give a mono-acetyl derivative, and **1** (42). Consequently, in spite of purification by preparative thin-layer chromatography, the starting sample probably was contaminated with some decomposition products. The products of the above reaction sequence and subsequent acetylation were identified as methyl 4,6-di-*O*-acetyl-2,3-di-*O*-methyl-α- and β-D-glucopyranosides, with traces of the tri-*O*-acetyl-2-*O*-methyl and tetra-*O*-acetyl derivatives. These results suggested that the starting compound was **3**, which contained traces of 2-*O*-acetyl-β-D-glucopyranose and **1**, resulting from deacetylation prior to nitration.

On the basis of these results, the reliability of the reaction sequence outlined in Scheme 1*b* was judged satisfactory for locating the acetylated position in partially acetylated glucoses and disaccharides of glucose. The reaction sequence is not capable of locating acetyl groups on C-1 at the reducing end of the sugar. However, the presence of a reducing sugar may be determined independently by other methods. Thus, the use of maltose-1-^{14}C permits the reducing and non-reducing glucose moieties to be distinguished readily. The method has been used to identify the partially acetylated products from the enzymic and solvolytic deacetylation of some per-acetylated disaccharides and per-acetylated glucose (1).

Experimental

Several Methods

Unless otherwise stated, materials were commercially available reagent grade products. Melting points were measured with a Fisher–Johns apparatus and are uncorrected. Optical rotations were measured with a Bendix automatic polarimeter at 25 ± 1 °C. All solutions were concentrated under reduced pressure at or below 40 °C. Infrared spectra were recorded using a Perkin–Elmer model 21 or Beckman model IR-5A instrument. Samples were analyzed in 5–10% (w/v) solutions. Paper partition chromatograms were developed by the descending technique using Whatman #1 paper and butanone–water azeotrope, or 1-butanol:acetic acid:water 4:1:5 (v/v). The spray reagent used was *p*-anisidine (43). Thin-layer chromatography was done on Silica Gel G using methanol–benzene (1:9 v/v). A 5% solution of sulfuric acid in ethanol and/or *p*-anisidine was used to detect compounds. Gas–liquid partition chromatography was performed with an F and M model 402 chromatograph equipped with a hydrogen flame detector. Compounds were identified with the aid of authentic specimens either by simultaneous injection, or by comparison of retention times (44). Six-foot, 4 mm I.D. glass columns of LAC-4R-886 (Column *a*, 5%; Column *b*, 10%) on Chromosorb W, 100–120 mesh, were used at various isothermal temperatures between 150 °C and 200 °C, and programmed between 150 °C and 200 °C. Standard procedures were employed for nitration (35), hydrolysis of nitrate esters (38), methylation (9, 45, 46), trimethylsilylation (22) and acetylation (47, 48), unless otherwise stated. 2,3-Di-*O*-acetyl-D-glucopyranose was prepared by the method of Fink and Hay (42).

Formation of Tetrahydropyranyl (THP) Ethers

A sample (100 mg) was dissolved in dichloromethane (2 ml) or in dimethyl sulfoxide or 1,4-dioxane, and dihydropyran (distilled from sodium hydroxide pellets) (10 ml) was added. Alternatively, dihydropyran was used as solvent in some reactions. Catalyst (0.02 to 0.2 ml) was

TABLE II

*DCM, dichloromethane.
†DMSO, dimethyl sulfoxide.
‡DHP, dihydropyran.
§*p*TsOH, *p*-toluenesulfonic acid.
‖TFA, trifluoroacetic acid.

added, and the solution was stirred at 25 °C in a water bath. When etherification was complete, anhydrous potassium carbonate (1 g) was added. After 15 min the mixture was filtered and evaporated to dryness under reduced pressure. The residue was extracted with chloroform and dried over anhydrous potassium carbonate.

Catalysts used were concentrated hydrochloric acid, trifluoroacetic acid, *p*-toluenesulfonic acid, phosphorus oxychloride, and anhydrous HCl/dioxane (5 *N*). The reaction was followed by changes observed in the infrared spectrum at wavelengths at which absorption was absent or negligible except in the compounds of interest:

2.8–3.0 μ (OH)	Decreasing presence of **1**
3.5 μ (C—H)	THP ether formation
8.9, 9.8, 10.3 μ	THP ether formation
5.7 μ	Presence of **2**
6.1, 12.0 μ	Presence of dihydropyran

The decrement in the ratio of absorbance at 2.8 μ relative to that at 3.5 μ was used as an estimation of the proportion of THP ether formed from **1**, whereas the ratio of intensities at 3.5 and 5.7 μ was used as a measure of the replacement of acetyl by THP groups in **2**. Figure 1 shows the results of a typical experiment plotted in such a manner.

The use of this assay revealed that a 4-fold increase in *p*-toluenesulfonic acid concentration caused a small but significant increase in the rate of both THP ether formation and of substitution of acetyl by THP groups. This replacement was confirmed by thin-layer chromatographic analysis of the product after deacetylation. A series of components having mobilities relative to **2** (R_2) of 0.0 (**1**) – 1.4 were detected.

The effect of catalyst was studied by treating 100 mg **2** with 5.0 ml 0.025 *M* trifluoroacetic acid in dichloromethane. The infrared spectrum showed no change after 4.5 h, but revealed variations in the relative intensities of absorption at 2.8, 3.5, and 5.7 μ after 24 h which indicated that some deacetylation had occurred.

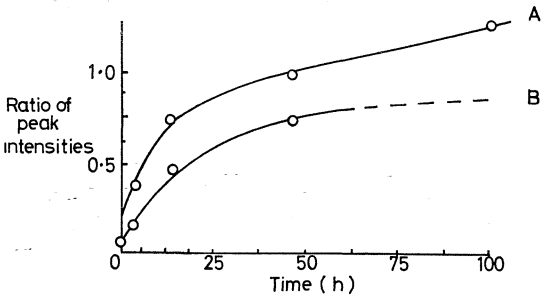

FIG. 1. The ratios of the intensities of infrared absorption at 3.5 μ relative to 3.0 μ (A), and at 3.5 μ relative to 5.7 μ (B), during the reaction of dihydropyran with **1** (A) and **2** (B), respectively. The catalyst used was 0.03 *M* *p*-toluenesulfonic acid.

The conditions under which substitution of acetyl by THP groups in **2** occurred prior to complete etherification of **1** are summarized in Table II. In each case 100 mg substrate was dissolved in 4:1 (v/w) solvent:dihydropyran. The volume was such that the weight ratio of dihydropyran:substrate was 5:1.

Deacetylation

Sodium methoxide-catalyzed deacetylation (Zemplen procedure) was used (49). Similar procedures were utilized with sodium isopropoxide and *t*-butoxide except for substitution of the appropriate alkoxide/alcohol mixture.

The reactions were monitored by thin-layer chromatography.

With piperidine as catalyst, the sugar acetate (25 mg) was dissolved in dry methanol (1.0 ml). Dry, redistilled piperidine (10.0 ml) and a few grains of crushed Drierite were added, and the mixture heated at 65 °C for 5 h. The reaction mixture was filtered through a layer of activated carbon, and evaporated to dryness.

Deacetylation of D-*Glucose Pentaacetate with Sodium Methoxide/Chloroform*

To 10 g **2** was added 1.0 ml $CHCl_3$ solution containing 0.2 mg NaOMe and 0.02 MeOH per ml. The solution was allowed to stand at room temperature and was analyzed at intervals by thin-layer chromatography. After 6 h the chromatogram revealed compounds having R_2 1.0, 0.5, 0.36, 0.18, 0.05, and 0.0. Reference standards of **1** and **2** had R_2 0.0 and 1.0 respectively. A control experiment using MeOH in place of $CHCl_3$ gave only **1** (R_2 0.0) after 0.5 h.

*The Attempted Reduction of Penta-O-acetyl-*β-D-*glucose by Diborane*

Compound **2** (25 mg) was dissolved in 2.0 ml tetrahydrofuran (THF) in a magnetically stirred flask thermostatted at 25 °C. The system was purged with dry nitrogen, 1.2 ml 0.5 *M* B_2H_6 in THF was added, and the solution stirred for 2 h. Excess diborane was removed by reaction with ethylene glycol, water was added, and the solution evaporated to dryness. Thin-layer chromatographic analysis revealed a series of compounds with R_2: 0.24, 0.10, and 0.0.

Methylation

Sodium *t*-butoxide – dimethyl sulfoxide – methyl iodide: The sample (50 mg) was dissolved in dry dimethyl sulfoxide (1.0 ml). Methyl iodide (5.0 ml) and a few grains of crushed Drierite were added, and the mixture was stirred at 25 °C. Dry sodium *t*-butoxide was added at a rate sufficient to maintain an excess of sodium *t*-butoxide. The reaction was followed by thin-layer chromatography, and worked up by the usual procedures (50).

*The Effect of Various Methylating Reagents on Penta-bis-O-trimethylsilyl-*α-D-*glucopyranose*

Compound **6** was prepared from **1** by the method of Sweeley *et al.* (22). A chloroform solution of **6** was placed in several nitrogen-filled vials. Methylation reagents were added and the solutions allowed to stand at room temperature. Contents were analyzed by gas–liquid partition chromatography (Column *a*, 180 °C, 100 ml/min). The results have been summarized in Table III.

Disaccharide Hydrolysis and Methyl Glycosylation

A solution of 1.5% HCl in methanol (15 ml) was added to the sample (100 mg) and refluxed overnight. The solution was neutralized by the addition of Duolite 101D resin (OH form), filtered, the resin washed with methanol, and combined filtrate and washings evaporated to dryness under reduced pressure.

Hydrolysis of Methyl O-Acetyl-O-methylglucosides

The sample was heated in a sealed glass vial with Duolite C20 resin. The combined solutions were evaporated to dryness under reduced pressure.

*Retention time relative to compound **6**.

Reaction Sequence to Locate Acetylated Positions

The dry sample was subjected to the following series of reactions: (1) nitration; (2) deacetylation (sodium methoxide – methanol); (3) methylation (method *a*); (4) denitration; (5) disaccharide hydrolysis and methyl glycosylation (in the case of disaccharide derivatives); (6) acetylation, analysis by gas–liquid partition chromatography; (7) hydrolysis of the acetyl groups and analysis by paper partition chromatography (alternatively the analysis could have been done at step (5) (Scheme 1*b*).)

*Identification of the Products from Esterase-catalyzed Deacetylation of Penta-O-acetyl-*β-D-*glucopyranose*

A solution containing approximately 100 mg of a mixture of glucose acetates was lyophilized and cooled in an ice-brine bath at $\leqslant 5$ °C. Colorless, fuming nitric acid, and acetic anhydride were cooled to < -5 °C and 2.0 ml of the acid were added to 5.0 ml of acetic anhydride to form the nitrating reagent, which was held at -5 °C. Cold acetic anhydride (2.0 ml) and 0.5 ml nitrating reagent were added in sequence to the glucose acetate mixture and the solution stirred 1 h at $\leqslant 5$ °C. The reaction solution was added to a large excess of ice-water and extracted with chloroform. The chloroform extract was washed free of acid and dried over anhydrous magnesium sulfate in the usual manner. The chloroform was evaporated and the residue dissolved in 5.0 ml anhydrous methanol. A 0.2 *M* solution (0.2 ml) of sodium methoxide in methanol was added and stirred at room temperature for 1 h. Sodium ions were removed by treatment with Rexyn 101 (H-form) cation exchange resin. The solvent was evaporated and the residue methylated three times by the modified Purdie technique (45, 46) using small amounts of powdered Drierite to maintain anhydrous conditions in the reaction solution. The product was dissolved in 10 ml ethanol, 1.5 ml 64% aqueous hydrazine was added, and the solution refluxed for 2 h. Excess hydrazine was decomposed by boiling the solution with Raney nickel for 15 min. The catalyst was filtered, washed with ethanol, and the combined filtrate and wash solutions evaporated to dryness. Cold (0 °C) pyridine (2.5 ml) and 0.5 ml acetic anhydride were added to the residue and allowed to react at room temperature for 18 h prior to warming to 60–70 °C for 1 h. The solution was poured into ice-water and the products isolated by chloroform extraction in the usual manner. The product was con-

TABLE IV

Retention times of *O*-acetyl and/or *O*-methyl derivatives of methyl D-glucoside

Derivative of methyl D-glucoside	Column *a*	Column *b*	Relative peak area
2,3,4,6-Tetra-*O*-methyl-β-	0.11	0.10	96
-α-	0.14	0.16	10

centrated to a syrup and examined by gas–liquid partition chromatography. The mixture was resolved into components which were identified by co-chromatography with authentic samples or by comparison of retention times. Column *a* was used at 180 °C and Column *b* at 195 °C, both with a flow rate of 100 ml/min. The retention times relative to that of methyl 4,6-di-*O*-acetyl-2,3-di-*O*-methyl-α-D-glucoside, and the identities of the methyl D-glucosides are given in Table IV.

Products Obtained from Scheme 1b Sequence with 2,3-Di-O-acetyl-β-D-glucopyranose

A sample of **3** (42) was subjected to the reaction sequence of Scheme 1*b*. Analysis of the product by gas–liquid partition chromatography gave peaks with the following retention times relative to methyl 4,6-di-*O*-acetyl-2,3-di-*O*-methyl-α-D-glucoside:

Column *a*: 0.77, 1.00, 1.61, 1.70, 3.20, 4.05;

Column *b*: 0.72, 1.00, 1.67, 2.30, 2.85, 3.60,

corresponding to the anomers of methyl 4,6-di-*O*-acetyl-2,3-di-*O*-methyl-D-glucoside, methyl 3,4,6-tri-*O*-acetyl-2-*O*-methyl-D-glucoside, and methyl 2,3,4,6-tetra-*O*-acetyl-D-glucoside, respectively.

Monomolecular films of compounds with potential dermophilic and prophylactic properties. Esters of dihydroxyacetone

RONALD P. QUINTANA, LORRIN R. GARSON, AND ANDREW LASSLO
Department of Medicinal Chemistry, College of Pharmacy, University of Tennessee Medical Units, Memphis, Tennessee 38103

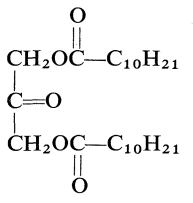
Received August 30, 1968

The synthesis of 1,3-diundecanoyloxyacetone (**1**) and 1-undecanoyloxy-3-hydroxyacetone (**2**) is reported. The properties of **1**, spread as a pure monomolecular film and in mixed films with stearic acid, were determined and evaluated. Compound **2** did not form films. The compounds were designed to exert, potentially, long-lasting insect-repellent activity subsequent to anchoring to the skin.

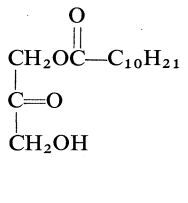
Canadian Journal of Chemistry, **47**, 853 (1969)

During the past few years, we have been concerned with the development of agents exerting *perdurable* insect-repellent and other types of prophylactic activity subsequent to topical or systemic administration (1–6). Currently, our efforts are focused on compounds designed to provide long-lasting prophylactic efficacy by means of the *gradual* release of an active component from a precursor-type molecule anchored to the epidermal surface (3). Figure 1 illustrates this concept schematically.

In this communication, we report the synthesis of two novel precursor-type molecules (**1** and **2**), and their effects upon monolayers of stearic acid, a known dermal constituent (7). Their molecular structures incorporate undecanoic acid and



1



2

dihydroxyacetone; undecanoic acid is a proven insect-repellent (8), and the ability of dihydroxyacetone, and of some structurally related entities, to interact with skin is well established (9–12).

Experimental

Melting points are corrected; they were determined with a Büchi melting point apparatus. Infrared (i.r.) spectra were obtained with a Perkin–Elmer model 137B spectrophotometer. Mass-spectral analyses were carried out by the Morgan–Schaffer Corporation of Montreal, Canada, employing a Hitachi Perkin–Elmer RMU-GD mass spectrometer. Combustion analyses were performed by Drs. G. Weiler and F. B. Strauss, Oxford, England.

Synthetic Work

*1,3-Diundecanoyloxyacetone (**1**)*

To a stirred solution of 25.0 g (0.277 mole) of dry 1,3-dihydroxyacetone in 250 ml of dry freshly distilled pyridine, 56.7 g (0.277 mole) of undecanoyl chloride was added dropwise over a period of 1.5 h. After standing at room temperature for 22 h, the reaction mixture was poured into 600 ml of cold 6 *N* sulfuric acid, precipitating a white solid which was collected by filtration and washed with water. The product was recrystallized three times from hexane and once from 95% ethanol, affording 35.3 g (59.7%) of pure **1**, m.p. 67.4–68.0°, $\nu_{max}(CHCl_3)$ 1750 cm^{-1} (ester carbonyl).

Anal. Calcd. for $C_{25}H_{46}O_5$: C, 70.38; H, 10.87. Found: C, 70.62; H, 10.81.

The method described by Schlenk, Lamp, and DeHaas (13) for the preparation of a similar compound, was employed in the synthesis of compound **2**.

*Undecanoyloxyacetic Acid (**3**)*

This was prepared employing the procedure described for the preparation of **1**. A solution of 25.0 g (0.329 mole) of glycolic acid in 250 ml of pyridine was allowed to react with 67.2 g (0.328 mole) of undecanoyl chloride, affording 83.5 g of product. Four recrystallizations of a 10 g sample from hexane yielded 8.4 g of pure **3**, m.p. 71.2–71.9°, $\nu_{max}(CHCl_3)$ 1748 cm^{-1} (ester and carboxylic acid carbonyl).

Anal. Calcd. for $C_{13}H_{24}O_4$: C, 63.91; H, 9.90. Found: C, 63.78; H, 9.81.

*1-Undecanoyloxy-3-diazoacetone (**4**)*

A mixture of 24.4 g (0.100 mole) of **3** (recrystallized once from hexane; m.p. 71.4–71.9°), 50.8 g (0.400 mole) of oxalyl chloride, and 100 ml of dry benzene was refluxed for 2 h. The solvent and excess oxalyl chloride were removed by distillation *in vacuo* affording brown, liquid undecanoyloxyacetyl chloride. After drying *in vacuo* for 2 h, the acid chloride was dissolved in 150 ml of anhydrous ether, the solution was cooled to −3°, and 0.256 mole of dry, alcohol-free diazomethane in 950 ml of ether was added over a period of 1.2 h. After standing at −2° for an additional 1.5 h, the ether solution was concentrated *in vacuo* to 300 ml, dried over anhydrous magnesium sulfate, and filtered. The filtrate was evaporated *in vacuo* yielding a mobile, oily liquid which solidified upon storage in a refrigerator (24 h). The solid was recrystallized once from hexane affording 19.2 g

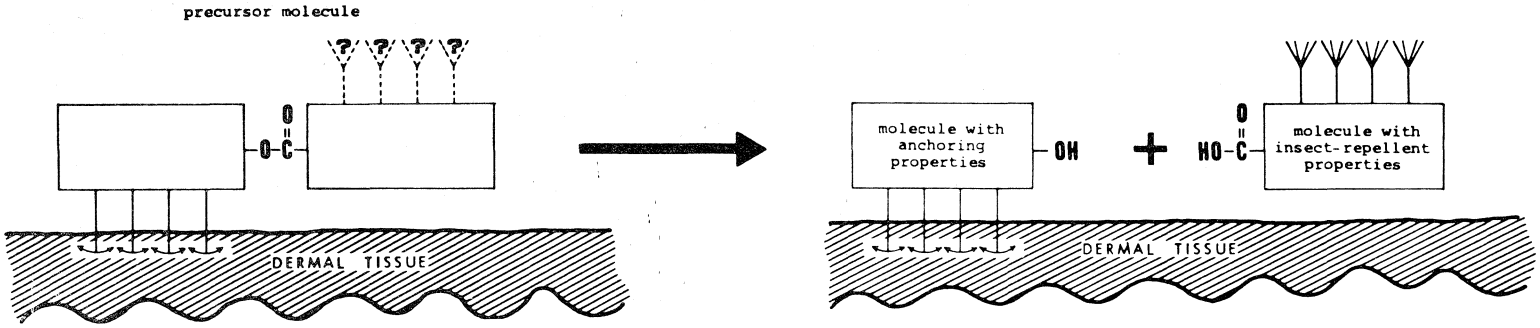

FIG. 1. In the schematic illustration, the precursor molecule itself, anchored to dermal tissue, may or may not have repellent activity; this is indicated by the broken-line symbol for repellency and by the question marks. The release is effected by moisture, pH, esterases or other enzymes, and bacterial flora on and in the epidermal structure.

(71%) of **4**, m.p. 29.2–31.7°, $\nu_{max}(CHCl_3)$ 2128 (diazo group), 1754 (ester carbonyl), 1653 cm^{-1} (ketone carbonyl). The product was employed, without further purification, in the preparation of **2**.

1-Undecanoyloxy-3-hydroxyacetone (2)

To a hot (80°) solution of 15.0 g (0.056 mole) of **4** in 100 ml of *p*-dioxane, a solution containing 75 ml of water and 15.0 g of 75% aqueous perchloric acid, also heated to 80°, was added. The resulting solution was heated at 80–85° for 2 min, during which time evolution of nitrogen occurred and then ceased. The reaction mixture was rapidly chilled to 5°, poured into cold (0°) water, and was extracted with benzene. The benzene extracts were evaporated *in vacuo* to yield a yellow, viscous liquid. After standing for 10 weeks, the desired product was purified by three recrystallizations from hexane, affording 715 mg (4.9%) of pure **2**, m.p. 81.4–82.3° (sealed capillary), $\nu_{max}(CHCl_3)$ 3546 (O—H stretching), 1736 cm^{-1} (ester and ketone carbonyl).

Anal. Calcd. for $C_{14}H_{26}O_4$: C, 65.09; H, 10.14. Found: C, 65.07; H, 10.09.

Monolayer Studies

Specific details of the film balance, ancillary equipment, and general methods employed in our monolayer studies have already been described (2, 4–6).

In the currently reported work, spectrograde chloroform was utilized as the spreading solvent; solutions of the individual compounds (0.070 μmole/0.02 ml) and of the mixtures (0.070 μmole of each component/0.02 ml) were prepared immediately before they were deposited on the aqueous subphase surface. The compression procedure previously reported (5, 6) was employed. At low pressures the compression barrier was moved in 2 mm decrements, while at higher pressures 1 mm decrements were used; one-minute intervals were employed between each decrement. The subphase temperature was 25.5 ± 1.4°. At least three independent determinations were used to determine average pressure–area curves. The experimental curves deviated from the average curves normally by no more than 0.5 $Å^2$ per molecule, at a given surface pressure.

Results and Discussion

The structure assignments made for compounds **1** and **2** were based upon their combustion analyses and their infrared (i.r.) and mass spectra. The molecular weight of 426 for 1,3-diundecanoyloxyacetone (**1**) was confirmed by the appearance of the molecular ion at *m/e* 426. The fragmentation pattern obtained for this compound was also consistent with the proposed structure. The findings of Schlenk, Lamp, and DeHaas (13), in their work with 1-palmitoxy-3-hydroxyacetone, imply the possibility that we could have obtained 1-undecanoyloxy-3-hydroxyacetone (**2**) in a dimeric form. Further work on the nature of monomer and dimer formation is currently in progress and will be reported later.

Experimentally derived pressure–area isotherms for compound **1**, stearic acid, and an equimolar mixture[1] of **1** and stearic acid are illustrated in Fig. 2 along with the calculated average obtained by assuming additivity of the curves for **1** and for stearic acid.

The isotherm for **1** indicates that the film is expanded; this, along with the relatively low collapse pressure (14.5 dynes/cm), is consistent with curves obtained for some triglycerides with alkyl chains of intermediate length (14, pp. 245–249). Considering that **1** has only two such chains, the observed limiting area per molecule (62.5 $Å^3$) appears also to be compatible with published data (14, pp. 245–249). Examination of accurate, space-filling molecular models[2] supports the view that molecules of **1**, at pressures close to collapse, are anchored to the aqueous subphase surface by their polar ketonic and ester oxygen atoms; the ester alkyl groups project upwards but in a somewhat tilted manner.

In the mixed film containing compound **1** and stearic acid, **1** controls the properties of the film at low pressures (up to 15 dynes/cm), while stearic acid exerts prominent influence at higher pressures.[3] At low pressures, the experimentally derived isotherm for the mixture is shifted toward slightly higher area-per-molecule values, compared with the calculated-average curve; although the displacement is quite limited, it reflects non-additive behavior. Molecules of **1** are ejected from area-determining positions in the film during the plateau portion of the curve. In the latter region, the congruence of the calculated and experimental curves may be indicative of phase separation (14, p. 285). The difference (i.e., 10.6 dynes/cm) between the collapse pressure of pure stearic acid and the high-pressure region of the mixed film suggests that **1** has a pronounced influence upon the collapse process.[4]

---

[1]Area-per-molecule values for the mixture were obtained by dividing the area occupied by the film by the total number of molecules in the film.

[2]Godfrey molecular models; cf. ref. 5.

[3]The compressibility (15) of **1** (0.0168) was virtually identical with that of the mixed-film curve (0.0173), at pressures up to 15 dynes/cm; similarly, the compressibility of stearic acid (0.0023) was essentially the same as that for the high-pressure portion of the mixed-film isotherm (0.0026).

[4]In addition to the quintuplicate determination for the pressure–area curve of pure stearic acid (Fig. 2), the behavior of the latter was determined under kinetic conditions paralleling those of stearic acid in the mixed film. Two sets of duplicate control experiments with *pure* stearic acid, with the same rate of compression as in the *mixed* film, indicated unequivocally that the collapse pressure of stearic acid *per se* was not affected by the rates of compression employed in the experiments reported here.

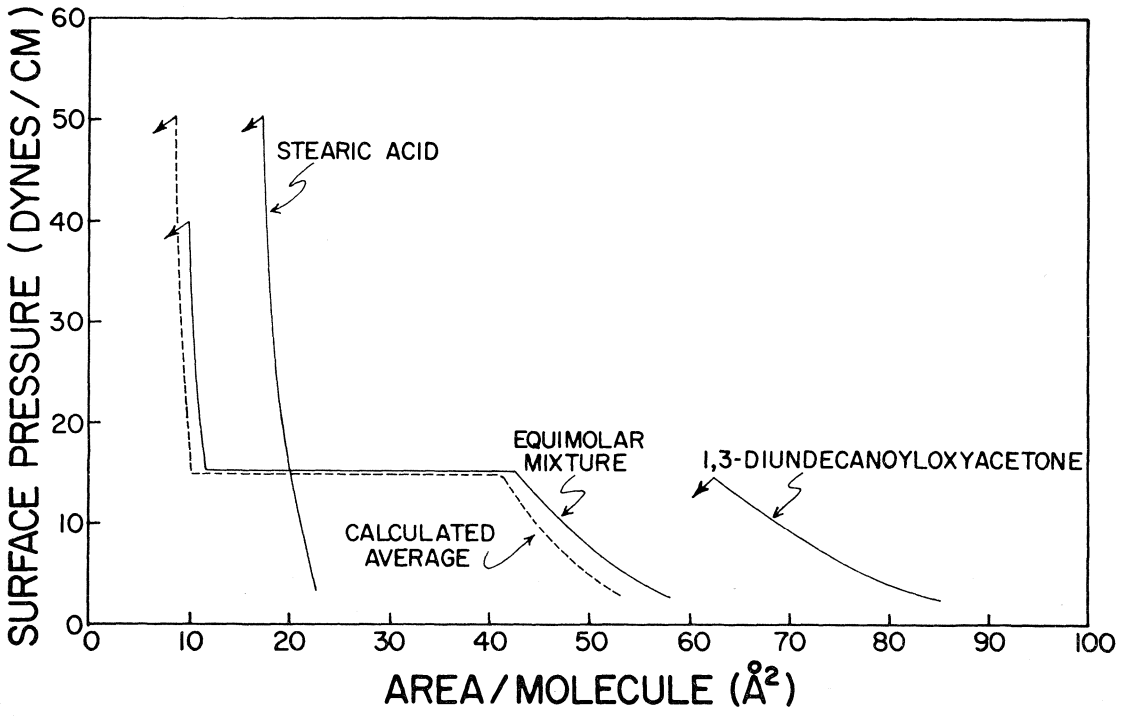

FIG. 2. Pressure–area isotherms for 1,3-diundecanoyloxyacetone (**1**), stearic acid, an equimolar mixture, and the calculated average for the mixture.

While the physicochemical properties of **2** are consistent with all desired characteristics for a precursor molecule, the compound's polarity did not lend itself to evaluation within the system suited for the study of the first compound (**1**) of this series. Attempts to evaluate pure and mixed films of **2** revealed, in two sets of independent determinations, that this compound did not form a monolayer. It was not retained in area-determining positions when mixed films (1:1) with stearic acid were spread; the pressure–area curve was identical, in all respects, with that of stearic acid. The comparative potentialities for anchoring affinity of the two compounds, with particular reference to the effect of one free hydroxyl function, will be investigated in the near future.

Acknowledgments

This investigation was supported by the United States Army Medical Research and Development Command, Washington, D.C., through Research Contract No. DA-49-193-MD-2636.

The authors gratefully acknowledge the assistance of Mrs. P. L. Sanders in determining the pressure–area isotherms reported in this communication.

One-step conversion of isatins to oxindoles and phthalonimides to homophthalimides

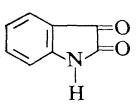
J. M. MUCHOWSKI
Bristol Laboratories of Canada Ltd., Candiac, Quebec

Received October 7, 1968

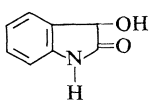
The palladium-catalyzed hydrogenation of isatins and phthalonimides in acetic acid containing perchloric acid produced oxindoles and homophthalimides directly.
A general, one-step synthesis of phthalonimides from isocarbostyrils is described.

Canadian Journal of Chemistry, **47**, 857 (1969)

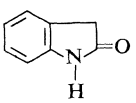
The conversion of isatin to oxindole was first effected by von Baeyer and Knop (1) in 1866 in connection with studies which culminated in the first rational synthesis (2) of the important dyestuff indigo. The transformation was achieved by the reduction of isatin (**1**) with sodium amalgam in water to dioxindole (**2**), which, without isolation, could be further reduced to oxindole (**3**) with the same reagent in aqueous acidic medium. Since von Baeyer's original work, numerous methods have been developed[1] for the preparation of **3** from **1**, but to date, only one of these has not involved a two-step process,[2] i.e. in 1942 Sakurai (4) showed that electrolysis of isatin in aqueous sodium sulfate at a mercury cathode gave a mixture which was comprised of oxindole, dioxindole, and isatide (3,3′-dihydroxy-3,3′-*bi*-oxindole).



1



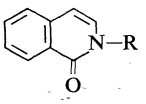
2



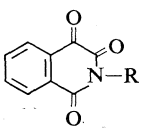
3

We have found that oxindole can be prepared in one step by the palladium-catalyzed hydrogenation (at 60°) of isatin in glacial acetic acid containing approximately two equivalents of perchloric acid. The reduction evidently proceeds in two stages, since the first equivalent of hydrogen is absorbed rapidly and the second slowly. The reduction is also applicable to the synthesis of *N*-methyloxindole (see Table I) and presumably could be used for the preparation of other oxindoles bearing substituents stable to the reaction conditions.

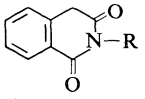
Under somewhat milder conditions (see Table I) the reaction can be utilized for the synthesis of homophthalimides (**6**) from the corresponding readily available (see below) phthalonimides (**5**),



4



5



6

but this method will probably not be extensively applied to simple homophthalimides inasmuch as these are easily prepared from homophthalic acid and ammonia or primary amines (for example see refs. 5 and 6). On the other hand, it should find use in the synthesis of homophthalimides substituted in the benzene ring since the requisite homophthalic acids are relatively difficult to obtain.

Phthalonimides, a long known but comparatively rare class of compounds, have heretofore been synthesized by the chromic acid oxidation of tetrahydroisoquinolines (7), the nitric acid oxidation of 4-hydroxyisocarbostyrils (8, 9), and recently, by the selenium dioxide oxidation of homophthalimides (5). We have found that phthalonimides are generally available by the oxidation of isocarbostyrils (**4**) with chromic acid in acetic acid at room temperature. A number of examples of this oxidation are shown in Table II.

Several synthetic consequences of the results

[1]For a summary of these methods through 1952, see ref. 3.

[2]*Note added in proof:*—After this manuscript was accepted for publication, Beckett, Daisley, and Walker (12) described the palladium-catalyzed hydrogenation, at atmospheric pressure, of isatin to oxindole, and Foglia and Swern (13) showed that zinc–copper couple in refluxing acetic acid converted isatins to oxindoles.

described herein will be submitted for publication in due course.

Experimental

The melting points were determined in a Gallenkamp melting point apparatus and are not corrected.

Oxindole

The following method was typical for the reduction of isatins.

A mixture consisting of isatin (5.98 g, 40 mmoles), glacial acetic acid (192 ml), 60–62% perchloric acid (8 ml), and 600 mg of 10% palladium on charcoal was hydrogenated in a Parr apparatus at 60° and an initial hydrogen pressure of 60 p.s.i.g. The theoretical amount of hydrogen was absorbed in 16 h. The cooled mixture was filtered through Celite, and the filtrate was concentrated to a small volume *in vacuo* at 40°. The residue was diluted with 300 ml of water and then extracted with ethyl acetate. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The solid thus obtained was boiled with 200 ml of cyclohexane to give an insoluble residue which was collected by filtration and dried. It weighed 1.669 g and had m.p. 124–126°; mixture m.p. with oxindole was undepressed. The cyclohexane solution on cooling deposited 1.681 g of a cream-colored solid, m.p. 122.5–124°; mixture m.p. with oxindole, 123–126°. The total yield of oxindole was 3.35 g or 63%.

N-Methylhomophthalimide

The following procedure was typical for the reduction of phthalonimides.

A mixture of *N*-methylphthalonimide (7.57 g, 40 mmoles), glacial acetic acid (192 ml), 60–62% perchloric acid (8 ml), and 760 mg of 10% palladium on charcoal was hydrogenated at room temperature and an initial hydrogen pressure of 60 p.s.i.g. After 5 h, the catalyst was removed by filtration through Celite, and the filtrate was evaporated to a volume of ca. 10 ml *in vacuo* at 40°. The solution was carefully diluted with 300 ml of water with swirling, whereupon a white, crystalline solid separated from solution. After being cooled in ice, the product was collected by filtration, washed well with ice-cold water, and dried *in vacuo*. The product weighed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

5.68 g (81%) and had m.p. 120–121°. A mixture melting point with an authentic specimen of *N*-methylhomophthalimide was undepressed.

N-Methylphthalonimide

The following procedure was typical for the oxidation of isocarbostyrils.

A magnetically stirred solution of *N*-methylisocarbostyril (20.0 g, 125.8 mmoles) in 200 ml of glacial acetic acid was titrated with 0.649 *M* sodium dichromate in 2.5 *M* sulfuric acid (194 ml, 377.7 m eq.) at a rate such that the reaction temperature did not exceed 30°. When the addition was completed the mixture was stirred for an additional ½ h at room temperature, and then it was poured with stirring into ca. 1.5 l of ice-cold water. The precipitated yellow solid was collected by filtration, washed well with ice-cold water, and dried *in vacuo*. The yellow solid obtained in this way had m.p. 185–186° (lit. (7), m.p. 186–187°), and weighed 19.2 g (81%).

Facile preparation of thioacetals in neutral medium starting from sodium borohydride

J. M. LALANCETTE AND A. LACHANCE
Department of Chemistry, Faculty of Sciences, University of Sherbrooke, Sherbrooke, Quebec

Received October 23, 1968

Sodium borohydride can be sulfurated to give $NaBH_2S_3$. The sulfurated hydride, when treated with a mercaptan, gives an orthothioborate: $(RS)_3B$. The orthoborates react with aldehydes and ketones to give the corresponding thioacetals with quantitative yields, in neutral medium.

Canadian Journal of Chemistry, **47**, 859 (1969)

We have reported (1) the preparation of thioacetals in neutral media (benzene or petroleum ether) using alkyl orthothioborates (eq. [1]).

[1] $2(RS)_3B + 3R'COR'' \rightarrow$  $+ \quad B_2O_3$

The orthothioesters can be prepared from boron sulfide (2) or boron halides (3) but in both cases, these preparations are somewhat tedious. Recently, we have reported the partial sulfuration of sodium borohydride to give a sulfurated borohydride formulated as $NaBH_2S_3$ (4).

This sulfurated borohydride reacts very easily with mercaptans to give the corresponding orthothioborates, according to eq. [2]:

[2] $NaBH_2S_3 + RSH \rightarrow (RS)_3B + H_2 + RSSR + NaS_3H$

The sulfuration of the borohydride is an extremely simple reaction; a mixture of $NaBH_4$ (1 mole) and sulfur (3 moles) is treated by anhydrous tetrahydrofuran and the solvent is evaporated under vacuum after a short contact. This sulfurated hydride is then treated with an excess of the selected mercaptan in petroleum ether. The use of a stoichiometric amount of mercaptan gives rather low yields of orthothioborate (10–20%) but a 100% excess of mercaptan brings the yield in the 50–60% range. In petroleum ether the sodium polysulfide is insoluble and the organic fraction can be filtered off. Due care must be exercized in the course of this filtration since orthothioborates are very hygroscopic. The orthothioborate is then separated from the disulfide by distillation and can be used for the preparation of the thioacetal.

This sequence of reactions besides giving a new

preparative method of orthothioborates, offers a new, simple and rapid technique of preparation of thioacetals, under neutral conditions. The side reactions resulting from acid catalysis, as required by the standard methods of preparation of thioacetals, can be avoided with this new procedure.

Experimental

In a dry 500 ml flask, a mixture of 7.6 g (0.2 mole) of sodium borohydride and 19.2 g (0.6 mole) of sulfur was stirred with 50 ml of anhydrous tetrahydrofuran (slow addition). After the initial reflux had subsided, heat was applied, for a total reflux time of 1½ h. The tetrahydrofuran was then evaporated under vacuum at room temperature and 200 ml of dry petroleum ether, b.p. 30–60° was added to the hydride, with 137 g (1.8 mole) of 1-propanethiol. The reaction mixture was then refluxed overnight.

The crude mixture was then filtered on a carefully dried sintered glass filter (medium porosity). It is advantageous to keep the system dry during the filtration, using a stream of dry nitrogen flowing through an inverted funnel over the filter. After evaporation of the solvent at atmospheric pressure under dry nitrogen, the residue (56.0 g) was then fractionated under vacuum. The first fraction was di-*n*-propyl disulfide, 20.3 g, b.p. 44°/0.5 mm, n_D^{29} 1.4980. Reported for di-*n*-propyl disulfide, b.p. 193.5°/750 mm, n_D^{20} 1.4981. The second fraction, 25.8 g (55% yield based on $NaBH_4$) was *n*-propyl orthothioborate, b.p. 110–118° /0.6 mm, n_D^{29} 1.5341. Reported (5) for *n*-propyl orthothioborate, b.p. 110°/0.6 mm, n_D^{25} 1.5346. This second fraction had an infrared spectrum showing the typical B—S bands at 910 cm^{-1}.

In a dry 250 ml flask, 6.7 g (0.93 mole) of butanone were mixed with 16.1 g (0.82 mole) of ethyl orthoborate. Upon warming, the mixture assumed a gel-like appearance. After a 1h- contact, the mass was extracted with petroleum ether. The boric anhydride was filtered off, the solvent evaporated, and the crude thioacetal distilled. The main fraction was the ethyl thioacetal of butanone, b.p. 73°/0.15 mm, n_D^{28} 1.4959. Reported (2), b.p. 205–208°/750 mm, n_D^{25} 1.4955. The yield of thioacetal was 86%. The reaction could be reproduced with other simple orthothioborates, such as propyl, butyl, and pentyl, with similar yields.

α-Metallation and subsequent alkylation of alkyl alkanesulfonates

W. E. Truce and D. J. Vrencur
Purdue University, Lafayette, Indiana 47907

Received October 3, 1968

Strong bases affect α-metallation of alkyl alkanesulfonates; subsequent alkylation offers a useful approach to esters of the higher sulfonic acids.

Canadian Journal of Chemistry, **47**, 860 (1969)

In further pursuing the synthesis utility of sulfur group-stabilized carbanions as in alkylations (1), acylations (2), halogenations (3), nitrations (4), and sulfonylations,[1] it has been found that alkyl alkanesulfonates can be metallated and subsequently alkylated in fair to excellent yields.[2,3]

Interest in this area was cultivated by the discovery in this laboratory (6) that the azasultone **1** could be alkylated to yield two different products depending on the conditions employed. Also, the related 1,3-diphenyl-1,4-butanesultone was methylated under the first set of conditions (6).

Following this, attention was turned to a series of neopentyl alkanesulfonates (**2**–**4** in Table I), the neopentyl group being used initially to preclude the possibility of such undesirable side reactions on the alkyl unit as elimination and displacement. With neopentyl α-toluenesulfonate (**2**), where a benzylic carbanion is formed, *n*-

butyllithium in hexane was found to be a satisfactory metallating agent. Subsequent reaction of the α-metallated species with methyl or isopropyl iodide led to alkylation product in excellent yield.

With neopentyl methanesulfonate (**3**) or neopentyl ethanesulfonate (**4**), where the α-position being metallated is not benzylic, best yields were obtained with potassium hydride in tetrahydrofuran or *n*-butyllithium complexed with *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) (7–9) as metallating agent.

Most recently,[4] ethyl-α-toluenesulfonate (**5**) has been prepared, and shows, by its conversion to its α-methyl derivative in high yield, that the presence of the neopentyl "protective group" is not necessary to obtain high yields when a benzylic position is being alkylated. That is, α-metallation is preferred over elimination or displacement in these systems.

[4]Recently, we extended the use of α-metallated sulfonate esters to the preparation of cyclopropanesulfonates from γ-chloropropanesulfonates by internal alkylation, e.g., neopentyl cyclopropanesulfonate from γ-chloropropanesulfonate, see ref. 10.

Experimental

All reactions described herein were carried out in thoroughly dried apparatus under an atmosphere of nitrogen. *n*-Butyllithium in hexane was purchased from the Foote Mineral Co., and potassium hydride, as a 50% suspension in mineral oil, from Alfa Inorganics. Starting sulfonates were prepared by the reaction of the appropriate sulfonyl chloride and alcohol in the presence of triethylamine in benzene or diethyl ether solvent. These consisted of: neopentyl α-toluenesulfonate, m.p. 71–73°; neopentyl methanesulfonate, b.p. 94–96°/10 mm; neopentyl ethanesulfonate, b.p. 58–60°/0.15 mm; and ethyl α-toluenesulfonate, b.p. 129–130°/0.04 mm. Infrared (i.r.) spectra were recorded on an Infracord spectrophotometer and nuclear magnetic resonance (n.m.r.) spectra on a Varian Associates A-60A spectrophotometer. Microanalyses were carried out by Dr. C. S. Yeh and staff.

Neopentyl 1-Phenylethanesulfonate

A solution of 7.27 g (0.030 mole) of neopentyl α-toluenesulfonate dissolved in 40 ml of tetrahydrofuran was added dropwise to 20.7 ml of a 1.6 *M* solution (0.033 mole) of *n*-butyllithium in hexane at −65 °C over a 35 min period. As soon as the addition was complete, 4.69 g (0.033 mole) of methyl iodide were added portionwise resulting in the precipitation of finely divided lithium iodide. After 15 min stirring at −65°, the reaction mixture was allowed to warm to room temperature, was quenched with 100 ml of H_2O, and the resulting suspension was extracted with chloroform. The chloroform

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

extracts were combined, dried, and evaporated *in vacuo* yielding a yellow oil which was chromatographed on a 3 × 25 cm column of alumina with chloroform as eluent. The neopentyl 1-phenylethanesulfonate thus obtained was distilled yielding 5.62 g (73.1%) of pure material, b.p. 110–113°/0.25 mm; i.r. (neat): 2950 (s), 1470 (s), 1360 (s), 1175 (s), 980 (b), 840 (b), and 700 cm^{-1} (s); n.m.r. ($CDCl_3$): δ 0.84 (s, 9H, $C(CH_3)_3$), 1.77 (d, 3H, $CH—CH_3$) J = 7 c.p.s., 3.62 (sym m, 2H, $O—CH_2C(CH_3)_3$), 4.37 (quartet, 1H, $CHCH_3$) J = 7 c.p.s., and 7.35 (m, 5H, ArH).

Anal. Calcd. for $C_{10}H_{14}O_3S$: C, 60.90; H, 7.86; S, 12.51. Found: C, 61.10; H, 8.14; S, 12.52.

Neopentyl 2-Methyl-1-phenylpropanesulfonate

In a manner completely analogous to that above, the title compound was prepared from neopentyl α-toluenesulfonate and isopropyl iodide in 86% yield, b.p. 112–115°/0.25 mm; i.r. (neat): 3000 (s), 1460 (s), 1180 (s), 975 (b), and 704 cm^{-1} (s); n.m.r. ($CDCl_3$): δ 0.75 (s, 9H, $C(CH_3)_3$), 0.98 (d, 3H), and 1.22 (d, 3H), the two non-equivalent methyl groups of the isopropyl group, δ 2.62 (m, 1H, $CH(CH_3)_2$), 3.51 (sym m, 2H, $OCH_2C(CH_3)_3$), 3.98 (d, 1H, C_6H_5CH), and 7.35 (s, 5H, C_6H_5).

Anal. Calcd. for $C_{15}H_{24}O_3S$: C, 63.34; H, 8.51; S, 11.28. Found: C, 63.55; H, 8.81; S, 11.64.

Neopentyl 2-p-Tolylethanesulfonate

To 0.050 mole of the *n*-butyllithium – TMEDA complex prepared as described by Peterson (9), were added 8.31 g (0.050 mole) of neopentyl methanesulfonate. After 2.25 h stirring, a solution of 9.25 g (0.050 mole) of *p*-methylbenzylbromide in 30 ml of tetrahydrofuran was added. After 1.5 h additional stirring, the reaction was quenched with 100 ml of H_2O and extracted with chloroform. The chloroform extracts were combined, dried, and evaporated *in vacuo* yielding a yellow oil. The oil was dissolved in a small amount of 95% ethanol, and the solution cooled to −78°. The white solid that separated was recrystallized from isopropanol–water yielding 2.05 g (15.1%) of the title compound, m.p. 51–52°; i.r. (solid film): 3000 (s), 1530 (s), 1370 (s), 1170 (s), and 970 cm^{-1} (b); n.m.r. ($CDCl_3$): δ 0.98 (s, 9H, $C(CH_3)_3$), 2.28 (s, 3H, $ArCH_3$), 3.20 (sym m, 4H, CH_2CH_2), 3.82 (s, 2H, OCH_2), and 7.08 (s, 4H, ArH).

Neopentyl 2-Phenylethanesulfonate

A solution of 7.07 g (0.0425 mole) of neopentyl methanesulfonate dissolved in 20 ml of tetrahydrofuran was added to a suspension of 0.0425 mole of potassium hydride in 30 ml of tetrahydrofuran. The reaction mixture was stirred at room temperature for 5.5 h, and then heated to 60° until hydrogen evolution ceased. The reaction mixture was then cooled to 0°, and 5.37 g (0.0425 mole) of benzyl chloride were added dropwise. After 12 h stirring, 200 ml of water were added, and the resulting suspension was extracted with chloroform. The chloroform extracts were combined, dried, and evaporated *in vacuo* yielding a light oil. Upon distillation, 4.0 g (38%) of the title compound, contaminated with a small amount of mineral oil was obtained, b.p. 131–137°/0.45 mm; i.r. (neat): 2950 (s), 1360 (s), 1175 (s), 970 (b), and 700 cm^{-1} (s); n.m.r. ($CDCl_3$): δ 0.94 (s, 9H, $C(CH_3)_3$), 3.19 (sym m, 4H, CH_2CH_2), 3.78 (s, 2H, OCH_2), and 7.21 (s, 5H, ArH).

Neopentyl 2-Propanesulfonate

To 0.105 mole of potassium hydride suspended in tetrahydrofuran were added 9.5 g (0.052 mole) of neopentyl ethanesulfonate, and the reaction mixture was stirred for 48 h. After this time, 15 g of methyl iodide (0.105 mole) were added and stirring continued for 24 h before the reaction mixture was quenched with 100 ml of water and extracted with chloroform. The chloroform extracts were combined, dried, and evaporated *in vacuo* leaving a light oil that was chromatographed on acid-washed alumina with chloroform as eluent. The product obtained was distilled under vacuum yielding 4.72 g (46.2%) of neopentyl 2-propanesulfonate, b.p. 51–52°/0.20 mm; i.r. (neat): 3020 (s), 1370 (s), 1190 (s), 1170 (s), 975 (b), and 835 cm^{-1} (b); n.m.r. ($CDCl_3$): δ 0.98 (s, 9H, $C(CH_3)_3$), 1.43 (d, 6H, $(CH_3)_2CH$), 3.37 (septet, 1H, $(CH_3)_2CH$), and 3.89 (s, 2H, OCH_2).

Ethyl 1-Phenylethanesulfonate

In a manner completely analogous to that used for the preparation of neopentyl 1-phenylethanesulfonate, the title compound was prepared in 79% yield from ethyl α-toluenesulfonate and methyl iodide with *n*-butyllithium as metallating agent, b.p. 99–101°/0.20 mm; i.r. (neat): 3000 (w), 1350 (s), 1175 (s), 1005 (s), 920 (b), and 700 cm^{-1} (s); n.m.r. ($CDCl_3$): δ 1.17 (t, 3H, CH_2CH_3), 1.76 (d, 3H, $CHCH_3$), 3.98 (m, 2H, CH_2CH_3), 4.33 (m, 1H, $CHCH_3$), and 7.37 (m, 5H, ArH).

Anal. Calcd. for $C_{10}H_{14}O_3S$: C, 56.05; H, 6.58; S, 14.97. Found: C, 55.77; H, 6.54; S, 15.12.

Ultraviolet absorption maxima, both calculated and observed, for some α-benzoyl-*trans*-benzalacetones, ethyl α-benzoyl-*trans*-cinnamates, and some α-cyano-*trans*-benzalacetophenones

D. J. Currie and H. L. Holmes
The Chemistry Section, Defence Research Establishment Suffield, Ralston, Alberta

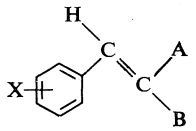
Received September 9, 1968

The equation for the calculation of absorption maxima for conjugated heteroenoid compounds has been extended to include a number of α-benzoyl-*trans*-benzalacetones and ethyl α-benzoyl-*trans*-cinnamates and has been used to assign configuration to the α-cyano-*trans*-benzalacetophenones. The method for calculating the substituent constant, *D*, has been refined to give more accurate values.

Canadian Journal of Chemistry, 47, 863 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

A method for calculating the long wavelength absorption maxima for conjugated heteroenoid compounds with the generalized formula **1** has already been presented (1) and eq. [1] has now



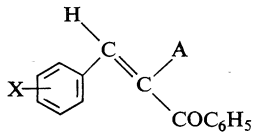
1

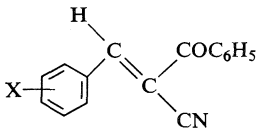
been extended and refined to calculate the long wavelength maxima, λ(mμ), of the title compounds.

$$[1]\quad \lambda\left(\mathrm{X{-}C_6H_4{-}CH{=}C(A)(B)}\right) = \lambda(\mathrm{C_6H_5{-}CH{=}CH_2}) + \Delta\lambda_A + \Delta\lambda_B{}^1 + \Sigma\Delta\lambda^{11} + D$$

where $\Delta\lambda_A$ is the conjugative effect (mμ) of the A group, $\Delta\lambda_B{}^1$ is the inductive effect (mμ) of the B group, $\Delta\lambda^{11}$ is the sum of the steric effects (mμ) of the A, B, and phenyl groups, and *D* is the increment (mμ) for the X substituent.

The values for the inductive and steric effects of the benzoyl group presented earlier (1) are based upon an estimated value for the inductive effect of this group in 2-benzal-1,3-diphenyl-1,3-propanedione. The long wavelength ultraviolet absorption maxima for a series of α-benzoyl-*trans*-benzalacetones, **2***a* (Table I),[1] ethyl α-benzoyl-*trans*-cinnamates, **2***b* (Table I), and α-cyano-*trans*-benzalacetophenones, **3** (Table I), have provided new values for these two effects.





2*a*, A = $COCH_3$
2*b*, A = $CO_2C_2H_5$
2*c*, A = CN

3

Absence of an upfield shift for the CH_3 protons in A of C_2-substituted **2***a* compounds and for the CH_2 and CH_3 protons in A of the C_2-substituted **2***b* compounds assigns the configurations of **2***a* and **2***b* to these compounds (2). Inductive and steric effects of +52 mμ and −30 mμ respectively for the *cis*-benzoyl group provide satisfactory long wavelength absorption maxima for the **2***a* and **2***b* compounds and for 2-benzal-1,3-diphenyl-1,3-propanedione (λ_{obs} = 295 mμ).

The calculated absorption maximum for **3**, X = H (317 mμ) while not good, agrees much better with the observed value (310 mμ) than does that for the alternate **2***c* configuration. In fact this difference is quite constant for substituted derivatives of **3** and may be accounted for by the additional steric effect resulting from interaction of the *trans*-benzoyl group with the ethylenic hydrogen atom. Models indicate that steric factors in 2-benzal-1,3-diphenyl-1,3-propanedione preclude the conformation where such interference can become operative and so the agreement between λ_{obs} and λ_{calcd} is good. This could account for the similar deviation in benzalcyanoacetanilide and its absence in benzalacetoacetanilide (2).

The contribution of an electron donating X

[1]A photocopy of Table I may be obtained, upon request, from The Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada.

group at C-4 to the resonance system of this general class of compounds will depend upon the polarization of the rest of the conjugated system which in turn is reflected in the long wavelength absorption maximum of the parent compound. Hence a more accurate estimation of the *D* values for electron donating groups at C-4 is given by the equation

$$D^1 = \frac{\lambda^1 \text{ parent}}{\lambda \text{ parent}} \times D$$

where λ^1 parent is the absorption maximum of the unsubstituted compound in the given series and λ parent is that from which the *D* value was derived. The *D* value for the 4-acetamido group is a case in point (Table I). Using the 4-acetamidobenzalmalononitrile as reference, the D^1 values so obtained for the C_4-acetamido group provides an absorption maximum in agreement with the observed value for 4-acetamido-3-benzal-2,4-pentanedione while that calculated for 4-acetamido-α-cyano-*trans*-benzalacetophenone is 8.5 mμ too high.

The spectra of the ethanolic solutions of these compounds were recorded on a model 15 Cary spectrophotometer. Calculated and observed maxima, and extinction coefficients are listed in Table I.

All of these compounds were prepared by the method of Horning *et al.* (4) with the exception of 4-acetamidobenzalmalononitrile which was prepared by the method of Corson and Stoughton (5) and the α-cyano-*trans*-benzalacetophenones which were prepared by the method of Kauffmann (3). Melting and boiling points and analytical figures for these compounds are listed in Table I.

Reaction of 6,7-dimethoxy-3-isochromanone with hydrazine

Gerald Rosen and Frank D. Popp
Department of Chemistry, Clarkson College of Technology, Potsdam, New York 13676

Received September 19, 1968

The reaction of the title compound with hydrazine resulted in the formation of the hydroxy hydrazide **5**. Alkylation of **5** took place on both oxygen and nitrogen. Compound **5** can be reconverted to the title compound or to the corresponding isoquinolone.

Canadian Journal of Chemistry, **47**, 864 (1969)

Recently Finkelstein and Brossi (1) reported the synthesis of 6,7-dimethoxy-3-isochromanone (**1**). In view of the reported[1] conversion of compounds of the types **2** and **3** to diazepines on reaction with hydrazine, it was felt that **1** might be an attractive intermediate for the synthesis of 2,3-benzodiazepines of the type **4**.

Reaction of **1** with hydrazine in ethanol gave a compound, $C_{11}H_{16}N_2O_4$, whose analysis would suggest the formation of a hydrate of the desired

6, R = alkyl

7

8

diazepine **4**. Examination of the infrared (i.r.) and nuclear magnetic resonance (n.m.r.) spectra and reactions of this product, however, indicates that rather it is the hydroxy hydrazide **5**. This type of product is similar to those observed (1) from the reaction of **1** with amines. When the reaction with hydrazine was carried out in ethanol containing a trace of acetic acid, **5** was still the major product; however, the reaction of **1** with hydrazine in acetic acid (hot or cold) gave only **1**. It was noted that **5** can be converted to **1** on heating in glacial acetic acid.

Alkylation of **5**, with alkyl halides and sodium hydride in dimethyl formamide, occurred both at nitrogen and oxygen to give compounds of the type **6** as indicated in Table I. Treatment of **5** with 10% hydrochloric acid gave a 76% yield of 6,7-dimethoxy-1,4-dihydro-3(2*H*)isoquinolone (**7**) together with 5% of **1**; with formic acid, **1** was the major product, and as noted above with acetic acid, **1** was the exclusive product.

In a further attempt to convert **1** to **4**, compound **1** was converted to **8** (1) and without isolation the crude **8** was reacted with hydrazine. This reaction gave **7** as the only pure product isolated.

Experimental

Reaction of 6,7-Dimethoxy-3-isochromanone with Hydrazine

To 1 g (0.0048 mole) of **1** dissolved in 20 ml of ethanol was added, slowly, 0.154 g (0.0048 mole) of hydrazine. After 6 h of reflux, the mixture was evaporated to one-half volume and cooled to give 0.945 g (82%) of a white solid (**5**), m.p. 163–165° from ethanol. Infrared (KBr): 3300, 3100, 3000, 1680, 1610 cm^{-1}.

Anal. Calcd. for $C_{11}H_{16}N_2O_4$: C, 54.99; H, 6.71; N, 11.66. Found: C, 54.71; H, 6.64; N, 11.66.

Addition of a trace of acetic acid to the ethanol in the above sequence gave a 68% yield of **5**. Replacement of the ethanol by glacial acetic acid in the above sequence gave a 74% recovery of **1** when the reaction was run in the cold and a 78% recovery of **1** when the reaction was run on the steam bath (in these cases the reaction mixture was poured on ice and the product extracted with methylene chloride).

*Preparation of **6** by Alkylation of **5***

To 0.75 g (0.00312 mole) of **5** dissolved in 15 ml of dimethyl formamide was added at room temperature with stirring 0.25 g (0.00312 mole) of 30% sodium hydride. To the resulting yellow solution was added an excess of the alkyl iodide (or benzyl chloride). After stirring for 1 h, the solution was poured on ice and extracted with chloroform. Evaporation of the dried ($MgSO_4$) extract gave an oil, infrared: 1650 cm^{-1}, which was converted to the picrate as recorded in Table I. (The benzyl product was obtained as a solid.)

*Reaction of **5** with Acid*

To 1 g (0.00415 mole) of **5** were added 20 ml of 10% hydrochloric acid and the solution was refluxed for 2 h. Upon cooling and the addition of water, 0.65 g (76%) of **7**, m.p. 227–228° (from ethanol), was obtained. Infrared (KBr): 3400 and 1660 cm^{-1}; n.m.r. (DMSO-d_6): 2.7 (Ar), 4.9 (NH), 5.9 (CH_3O), 6.45 (CH_2), and 7.8 τ (CH_2).

Anal. Calcd. for $C_{11}H_{13}NO_3$: C, 63.75; H, 6.32; N, 6.76. Found: C, 63.53; H, 5.96; N, 6.62.

Extraction of the remaining solution with methylene chloride gave a 5% yield of **1**.

cis-Crotonaldehyde and related compounds

D. E. MCGREER AND B. D. PAGE
Department of Chemistry, The University of British Columbia, Vancouver, British Columbia

Received September 23, 1968

cis-Crotonaldehyde (**1**) has been prepared as a mixture with *trans*-crotonaldehyde (**2**) by irradiation of **2** with 3000 Å light. The thermodynamic equilibrium value for **1** to **2** was determined to be 1:50. Conditions for attaining this equilibrium and the structural factors contributing to its position are discussed.

Canadian Journal of Chemistry, **47**, 866 (1969)

In one reported attempt to prepare *cis*-crotonaldehyde (**1**) by irradiation of an acid solution of *trans*-crotonaldehyde (**2**) no evidence could be found for the formation of **1** (1). The photodecomposition (2–6) and photooxidation (7) of **2** has been studied without reports of the formation of **1**. On the other hand irradiation of *trans*-α,β-unsaturated ketones readily leads to the *cis*-isomers (5, 8, 9). As part of a general study on the chemistry of α,β-unsaturated carbonyl compounds we have investigated the conversion of **2** to **1**.

Irradiation at room temperature of **2** sealed in a 4 mm tube in a Rayonet Srinivasan-Griffin reactor using 16 RPR-3000 Å lamps gave after 4 days a mixture of **1** and **2** in the ratio of 29:71. Further irradiation did not increase the proportion of **1**. Detection of **1** in **2** was possible by nuclear magnetic resonance (n.m.r.) and the spectra of **1** and **2** are given in Table I.[1]

cis-Crotonaldehyde (**1**) was found to be particularly sensitive to acids being converted rapidly with a trace of acid to **2**. The separation of **1** from **2** has as yet been unsuccessful by distillation or vapor-phase chromatography with a variety of columns including DIDP, DNP, Ucon P, silver nitrate-glycerol, DEGS and Poropak Q. Samples collected from the chromatograph (Varian Aerograph A-90P) remained unchanged. Heating samples of **1** and **2** indicated **1** to be also thermally labile with half-life of 2 h at 160°. This value however is a minimum due to the sensitivity of **1** to acid.

The thermodynamic equilibrium of **1** and **2**, attained at room temperature with a trace of dry hydrochloric acid or by heating mixtures to 200 °C for 5 h, contains 2.0% of **1**. No evidence was found for the presence of 3-butenal which would be expected to be less than 0.5% based on the results of Sifniades (11) who found 0.35% of 3-butenal in equilibrium with crotonaldehyde when **1** was heated in the gas phase at 150° and 1% at 210°. For comparison we have determined the acid-catalyzed equilibrium of angelaldehyde with tiglaldehyde to be 1:100 and of *cis*-3-methyl-3-penten-2-one with *trans*-3-methyl-3-pentene-2-one to be 1.5:100.

The marked stability of the *trans*-conjugated forms of these compounds implies a high resonance stabilization in this form. This stabilization apparently is reduced in the *cis* form by distortion from planarity of the carbonyl group of the conjugated system. The importance of this destabilizing interaction is emphasized in angelaldehyde and *cis*-3-methyl-3-pentenoate where the stable isomer involves a *cis* arrangement of two methyl groups rather than a *cis* arrangement of a methyl and the smaller formyl or acetyl groups (the conformational free energy difference $-\Delta G$ for the formyl group on a cyclohexane ring is 1.35 (12) compared to 1.7 for methyl (13)).

The conjugative stabilization in esters is expected to be less than that for ketones and aldehydes and this is supported by the fact that the

[1]The spectrum of **2** is reported in ref. 10.

Replacement of the hydrochloric acid by acetic acid gave a 74.5% yield of **1** and no **7**, while replacement of the hydrochloric acid by formic acid gave a 67% yield of **1** and a 5% yield of **7**.

[1]The spectrum of **2** is reported in ref. 10.

TABLE I

The nuclear magnetic resonance spectra of **1** and **2** neat with internal tetramethylsilane reference

	β-CH_3	β-H	α-H	—CHO
1	7.90 τ *J* 7.6, 1.8 Hz	3.36 τ 11.4, 7.6 Hz	4.19 τ 11.4, 8.0, 1.8 Hz	−0.04 τ 8.0 Hz
2	8.07 τ *J* 6.7, 1.5 Hz	3.15 τ 15.4, 6.7 Hz	4.01 τ 15.4, 7.6, 1.5 Hz	0.60 τ 7.6 Hz

equilibrium achieved from the crotonates is 83:12:5 for *trans*:*cis*:β, γ at 300° (14).

The formation of *cis*-crotonaldehyde from the *trans*-isomer may be a key step in the photoisomerization of crotonaldehyde to 3-butenal, which is an important step in the photochemical breakdown of this 4 carbon unit (6). The deconjugated isomer is expected to be formed photochemically from the *cis*-isomer rather than from the *trans*-isomer for precedent is available for this preference in the ketone series (8). The ready isomerization of **1** in acid accounts for its absence in normal methods for preparation of crotonaldehyde (15) and for the lack of detection by Blacet *et al.* (1). By extrapolation citral and other naturally occurring α,β-unsaturated aldehydes can be expected to isomerize thermally and with acid. An equilibrium of citral *a* to citral *b* of 61:39 is in fact achieved at 140°.

Reaction of diphenylphosphine and 1,2-dichlorotetrafluorocyclobutene

Richard F. Stockel

Research and Development, Organic Chemicals Division, American Cyanamid Company, Bound Brook, New Jersey 08805

Received September 27, 1968

Diphenylphosphine and 1,2-dichlorohexafluorocyclobutene react in a solvent medium of dimethyl formamide to give both the mono (**3**) and 1,2-disubstituted (**2**) derivatives as products. In contrast, these same reactants give entirely different products when the reaction is conducted in the absence of a solvent.

Analytical and spectroscopic data are presented for the proposed structures.

Canadian Journal of Chemistry, **47**, 867 (1969)

The reactions of secondary phosphines and perhalocyclobutene have been investigated recently (1). While diethylphosphine reacts with either perfluorocyclobutene or 1,2-dichlorotetrafluorocyclobutene to give the monosubstituted tertiary phosphine **1**, diphenylphosphine reacts with perfluorocyclobutene to give only the disubstituted tertiary phosphine **2**. Interestingly, diphenylphosphine did not give an analogous product with 1,2-dichlorotetrafluorocyclobutene,

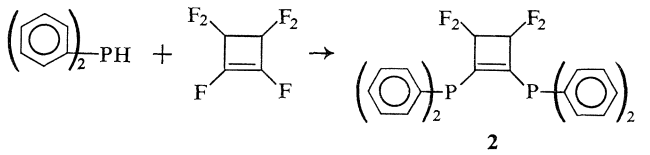
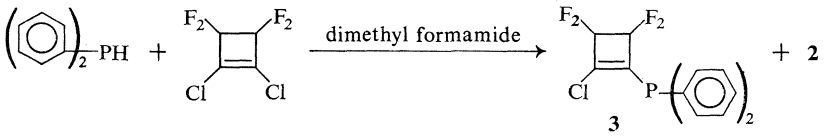
1

where X = Cl or F



2



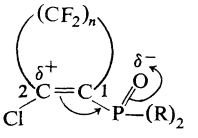
3

but instead hydrogen chloride, trifluorodiphenylphosphorane, and diphenylphosphinic fluoride were found. All of these experiments were carried out in the absence of solvent (neat). The reaction of 1,2-dichlorotetrafluorocyclobutene and diphenylphosphine was of particular interest in view of some recent work which this laboratory has just published (2).

The effect of the reaction medium, in which similar type nucleophilic reactions have been carried out (3), indicates that the judicious choice of a solvent can play a dominant role in product(s) formation. The reason for this is that the chemical potential of the various species involved in the reaction can be altered by the dipolar aprotic solvent (4).

With dimethyl formamide as the solvent, diphenylphosphine and 1,2-dichlorotetrafluorocyclobutene gave both **3** (46.3%) and **2** (20.0%). This result is in contrast to the work of Cullen *et al.* (1), where the reaction was run in the absence of a solvent.

Based on the reactions of phosphites and 1,2-dichlorohexafluorocyclopentene (5), the formation of **2** might not have been predicted. With phosphites as the nucleophile, the 1,2-disubstituted products are exclusively found due to a conjugative effect by the phosphonate group which renders C-2 susceptible to further nucleophilic attack (**4**). Although this electronic effect is not possible with **3**, a 1,2-disubstituted product is still found.



$n = 3$

4

Recent studies involving cyclic perhaloolefins and alkoxides (6, 7) suggest that the products can be predicted on the basis of the stability of the intermediate carbanions formed. Undoubtedly, as illustrated in this and other studies (1, 2, 6–8) the actual product distribution must definitely depend on other factors like ring size, nucleophilicity of the reactant, steric hindrance, polarity of the reaction medium, as well as electronic effects. Much more work is needed before the role of each variable can be deduced, and its role in the mechanistic pathway be understood.

Experimental

The infrared (i.r.) spectra were determined as mineral oil mulls on a Perkin–Elmer model 317 spectrophotometer. Phosphorus nuclear magnetic resonance (n.m.r.) spectra were measured as 10% solutions using triethylphosphate as the reference on a Varian HR-60 instrument.

Preparation of **3** *(2-Chloro-3,3,4,4-tetrafluoro-1-cyclobuten-1-yl)diphenylphosphine and* **2** *(3,3,4,4-Tetrafluorocyclobuten-1,2-ylene)bisdiphenylphosphine*

A solution of 19.5 g (0.1 mole) of 1,2-dichlorotetrafluorocyclobutene and 18.6 g (0.1 mole) of diphenylphosphine (9) in 100 ml of dimethyl formamide was stirred at 65 °C for 10 h, then poured into 300 ml water. The organic materials were extracted twice with 100 ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ether and the combined ethereal extracts were washed three times with 50 ml portions of water. The ether solution was dried over anhydrous $MgSO_4$ and concentrated to dryness. The crude consisted of solid and an oil. Approximately 10 g of solid (**2**) were filtered off and 16 g of oil (**3**) remained. The oil was distilled at 114–116 °C/0.1 mm and the solid was recrystallized from ethanol and had m.p. 127–127.5 °C (lit. (1), m.p. 129.5–130.5°). A vapor-phase chromatography analysis employing an F and M model 810 equipped with a 3 ft silicon gum rubber column indicated that the crude mixture had at least two other minor components representing less than 5% of the total besides **2** and **3**.

Anal. Calcd. for **3**, $C_{16}H_{10}ClF_4P$: C, 55.76; H, 2.90; Cl, 10.28; P, 8.99. Found: C, 55.36; H, 3.14; Cl, 10.41; P, 8.78.

Infrared spectrum (neat): some of the more significant peaks are 3060w, 1575m, 1480m, 1320s, 1120vs, 1070w, 1030w, 1000m, 860s, 835s, 745s, 693s. Nuclear magnetic resonance: the phosphorus spectrum shows only one peak at +25.1 p.p.m., which is in agreement for a tertiary phosphine (10).

Anal. Calcd. for **2**, $C_{28}H_{20}P_2F_4$: C, 68.03; H, 4.04; P, 12.54. Found: C, 68.29; H, 4.38; P, 12.71.

Infrared spectrum (mull): some of the more significant peaks are 1595w, 1435m, 1375w, 1295s, 1220s, 1155s, 1085s, 1065w, 1025w, 1000w, 830m, 822m, 758m, 740s, 730w, 725m, 694s. Nuclear magnetic resonance: the phosphorus spectrum shows only one peak at 22.7 p.p.m. which is in agreement for a tertiary phosphine (10). A sample of **2** was obtained from Professor W. R. Cullen (1) and it was shown by i.r., ^{31}P n.m.r., and a mixture melting point, to be identical to that obtained in this work.

Acknowledgments

The author wishes to acknowledge the assistance of Dr. J. E. Lancaster and Mrs. M. Neglia of the American Cyanamid Company's Central Research Laboratories for the phosphorus nuclear magnetic resonance spectra.

I would also like to thank Professor W. R. Cullen of the University of British Columbia for a generous sample of (3,3,4,4-tetrafluorocyclobuten-1,2-ylene)bisdiphenylphosphine.

7-*O*-β-D-Glucosyl-3′,4′,5-trihydroxy-6-methyl flavanone—a new *C*-methyl flavanone glycoside from Douglas-fir [*Pseudotsuga menziesii* (Mirb.) Franco] roots

G. M. Barton

Forest Products Laboratory, Forestry Branch, Department of Fisheries and Forestry, Vancouver, British Columbia

Received September 13, 1968

A new *C*-methyl flavanone, 7-*O*-β-D-glucosyl-3′,4′,5-trihydroxy-6-methyl flavanone, has been obtained from healthy Douglas-fir [*Pseudotsuga menziesii* (Mirb.) Franco] root bark in a high yield of 2.6%. Its structure was elucidated by high resolution and mass spectrometry together with a variety of chemical and physical tests and confirmed by synthesis of its methylated aglycone. Pathological testing of this new glucoside against *Poria weirii* Murr. is being undertaken.

Canadian Journal of Chemistry, **47**, 869 (1969)

The first new *C*-methyl flavanone, poriol, to be discovered in Douglas-fir [*Pseudotsuga menziesii* (Mirb.) Franco] roots has been described in a previous paper (1). In contrast to poriol, which was obtained in low yield (0.2%) from diseased (*Poria weirii* Murr.) Douglas-fir root bark, the new *C*-methyl flavanone glucoside (**1**) was obtained in high yield (2.6%) from healthy Douglas-fir root bark. The structure of this new *C*-methyl flavanone glucoside (**1**) is proposed as 7-*O*-β-D-glucosyl-3′,4′,5-trihydroxy-6-methyl flavanone.

Flavanone glucoside (**1**) crystallized from an ethyl acetate extract of healthy Douglas-fir root bark. This bark had been previously extracted

ether and the combined ethereal extracts were washed three times with 50 ml portions of water. The ether solution was dried over anhydrous $MgSO_4$ and concentrated to dryness. The crude consisted of solid and an oil. Approximately 10 g of solid (**2**) were filtered off and 16 g of oil (**3**) remained. The oil was distilled at 114–116 °C/0.1 mm and the solid was recrystallized from ethanol and had m.p. 127–127.5 °C (lit. (1), m.p. 129.5–130.5°). A vapor-phase chromatography analysis employing an F and M model 810 equipped with a 3 ft silicon gum rubber column indicated that the crude mixture had at least two other minor components representing less than 5% of the total besides **2** and **3**.

Anal. Calcd. for **3**, $C_{16}H_{10}ClF_4P$: C, 55.76; H, 2.90; Cl, 10.28; P, 8.99. Found: C, 55.36; H, 3.14; Cl, 10.41; P, 8.78.

Infrared spectrum (neat): some of the more significant peaks are 3060w, 1575m, 1480m, 1320s, 1120vs, 1070w, 1030w, 1000m, 860s, 835s, 745s, 693s. Nuclear magnetic resonance: the phosphorus spectrum shows only one peak at +25.1 p.p.m., which is in agreement for a tertiary phosphine (10).

Anal. Calcd. for **2**, $C_{28}H_{20}P_2F_4$: C, 68.03; H, 4.04; P, 12.54. Found: C, 68.29; H, 4.38; P, 12.71.

Infrared spectrum (mull): some of the more significant peaks are 1595w, 1435m, 1375w, 1295s, 1220s, 1155s, 1085s, 1065w, 1025w, 1000w, 830m, 822m, 758m, 740s, 730w, 725m, 694s. Nuclear magnetic resonance: the phosphorus spectrum shows only one peak at 22.7 p.p.m. which is in agreement for a tertiary phosphine (10). A sample of **2** was obtained from Professor W. R. Cullen (1) and it was shown by i.r., ^{31}P n.m.r., and a mixture melting point, to be identical to that obtained in this work.

Acknowledgments

The author wishes to acknowledge the assistance of Dr. J. E. Lancaster and Mrs. M. Neglia of the American Cyanamid Company's Central Research Laboratories for the phosphorus nuclear magnetic resonance spectra.

I would also like to thank Professor W. R. Cullen of the University of British Columbia for a generous sample of (3,3,4,4-tetrafluorocyclobuten-1,2-ylene)bisdiphenylphosphine.

7-*O*-β-D-Glucosyl-3′,4′,5-trihydroxy-6-methyl flavanone—a new *C*-methyl flavanone glycoside from Douglas-fir [*Pseudotsuga menziesii* (Mirb.) Franco] roots

G. M. Barton

Forest Products Laboratory, Forestry Branch, Department of Fisheries and Forestry, Vancouver, British Columbia

Received September 13, 1968

A new *C*-methyl flavanone, 7-*O*-β-D-glucosyl-3′,4′,5-trihydroxy-6-methyl flavanone, has been obtained from healthy Douglas-fir [*Pseudotsuga menziesii* (Mirb.) Franco] root bark in a high yield of 2.6%. Its structure was elucidated by high resolution and mass spectrometry together with a variety of chemical and physical tests and confirmed by synthesis of its methylated aglycone. Pathological testing of this new glucoside against *Poria weirii* Murr. is being undertaken.

Canadian Journal of Chemistry, **47**, 869 (1969)

The first new *C*-methyl flavanone, poriol, to be discovered in Douglas-fir [*Pseudotsuga menziesii* (Mirb.) Franco] roots has been described in a previous paper (1). In contrast to poriol, which was obtained in low yield (0.2%) from diseased (*Poria weirii* Murr.) Douglas-fir root bark, the new *C*-methyl flavanone glucoside (**1**) was obtained in high yield (2.6%) from healthy Douglas-fir root bark. The structure of this new *C*-methyl flavanone glucoside (**1**) is proposed as 7-*O*-β-D-glucosyl-3′,4′,5-trihydroxy-6-methyl flavanone.

Flavanone glucoside (**1**) crystallized from an ethyl acetate extract of healthy Douglas-fir root bark. This bark had been previously extracted

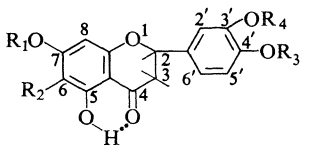
(soxhlet) with chloroform to remove interfering substances. White crystals were obtained, melting at 228.5 °C (Mettler FP 1). After recrystallization from aqueous methanol, the melting point was raised to 255.1 °C.

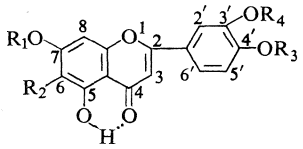
Flavanone glucoside (**1**) gave positive phenolic tests with Barton's reagent (2) (blue) and diazotized sulfanilic acid (3) (yellow). The 3-hydroxy flavanone test (4) developed for thin-layer chromatography (t.l.c.) proved negative, but the Shinoda test (5) was positive (violet). Its infrared (i.r.) spectrum was similar to flavanone glucosides such as hesperedin. Principal absorption peaks were ν(KBr) 530 (w), 545 (w), 565 (w), 615 (w), 625 (w), 690 (m), 720 (m), 740 (m), 760 (m), 785 (w), 815 (s), 865 (m), 880 (m), 890 (m), 915 (s), 960 (s), 1030 (m), 1070 (m), 1080 (m), 1130 (m), 1170 (s), 1190 (m), 1240 (m), 1290 (s), 1320–1350 (br, m), 1435 (m), 1450 (m), 1490 (m), 1540 (m), 1580 (m), 1605 (w), 1635 (s), 2920 (m), 2940 (m), 2960 (w), 3000–3560 (br, s).

Its ultraviolet (u.v.) spectrum was typical of a substituted flavanone λ_{max} 288 (log ε 4.31) λ_{min} 251 mμ (isopropanol).

The 100 Mc.p.s. nuclear magnetic resonance (n.m.r.) spectrum of its acetate (**2**) in deuteriochloroform showed clearly that it was a monoglucoside with 4 free aromatic protons. The AB part of the expected ABX absorption pattern of ring C protons was easily discernable, centered at 7.2 τ. Mold hydrolysis of **1** (300 mg) with a mixture of hydrochloric – acetic acid (0.2 ml concentrated hydrochloric acid, 5 ml of glacial acetic acid) for 30 min at 100 °C gave two main fragments, glucose and aglycone (**3**) which were identified by t.l.c. The first preparations of the glycosides (**1**) after hydrolysis gave, in addition to glucose, a small quantity of rhamnose. Recrystallization of the glucoside (**1**) from ethanol (trace of water) resulted in only glucose and aglycone (**4**) being formed. It has not been determined whether the rhamnose was present as a free sugar impurity or whether a small quantity of rhamnoside co-crystallized with the glucoside. Lack of an extra methyl group (required for the C-6 position of rhamnose) in the n.m.r. spectrum of the glycoside acetate (**2**) precluded the possibility of a rutinoside. High-resolution nuclear magnetic resonance of the methylated aglycone (**4**) enabled probable assignments to be made as follows: τ (deuteriochloroform): 2.06 (1H, singlet, hindered hydroxyl group C-5), 3.10 (3H, multiplet, aromatic protons ring B), 3.95 (1H, singlet, aromatic proton C-8), 4.60, 4.73 (1H, doublets, X part of ABX, J_{BX} = 3.5 c.p.s. proton C-2), 6.10 (3H, singlet, methoxyl C-3′ or C-4′), 6.13 (3H, singlet, methoxyl C-3′ or C-4′), 6.20 (3H, singlet, methoxyl C-7), 7.07 (2H, mulitplet, AB part of ABX, J_{AB} = 17.5 c.p.s., J_{AX} = 12.5 c.p.s., C-3), 8.01 (3H, singlet, methyl, C-6).



1 R_1 = glucose, R_2 = CH_3, R_3 = R_4 = H
2 R_1 = glucose acetate, R_2 = CH_3, R_3 = R_4 = acetate
3 R_1 = R_3 = R_4 = H, R_2 = CH_3
4 R_1 = R_2 = R_3 = R_4 = CH_3
6 R_1 = R_2 = R_3 = H, R_4 = CH_3



5 R_1 = R_2 = R_3 = R_4 = CH_3

The high value (12.5 c.p.s.) for the coupling constant J_{AX} is indicative of an axial–axial coupling only. Therefore, the C-2 hydrogen is axial and ring B is equatorial (6).

The mass spectrum of **4** showed a strong parent ion peak at *m/e* 330 (100) and 3 main fragments at *m/e* 164 (99), 151 (86), and 133 (43). The abundance of the 164 fragment indicates great stability of 3,4-dimethoxystyrene arising from the expected cleavage between C-1 and the heterocyclic oxygen and between C-3 and C-4. The fragments are consistent with structure **4**.

Since the n.m.r. spectrum of **4** had shown the presence of three methoxyl groups and color tests (7) indicated that compound **1** had vicinal phenolic hydroxyl groups, it must be concluded that the glucoside was formed at the non-vicinal hydroxyl group. Subsequent experiments showed that this hydroxyl group was on C-7 and hence the sugar moiety was associated with ring A at C-7. The successful hydrolysis of compound **1** by emulsin showed that it was a β-glucoside.

Final proof of structure was obtained in two ways. It was shown that dehydrogenation of the methylated aglycone (**4**) with iodine and glacial

acetic acid (30 mg of **4** was refluxed for 2 h with 30 mg of iodine in 5 ml of glacial acetic acid) followed by purification on t.l.c. (silica gel, carbon tetrachloride – methanol (7:1) R_f 0.61) resulted in the known compound 6-methyl-luteolin, 7,3′,4′-trimethylether (**5**) melting at 197.6 °C. It was also shown that nuclear methylation of hesperetin (**6**) at C-6 with methyl iodide and sodium methoxide (8) resulted in the methylated aglycone (**4**). This result was confirmed by quantitative i.r. comparison and mixture melting point 176.8 °C. Thus the structure of the new *C*-methyl flavanone glucoside is 7-*O*-β-D-glucosyl-3′,4′,5-trihydroxy-6-methyl flavanone. Pathological testing of this glucoside (**1**) against *Poria weirii* is currently being undertaken by Dr. G. W. Wallis at the Forest Research Laboratory, Victoria, British Columbia.

Acknowledgments

The author thanks Dr. Wallis and his staff for the collection of the Douglas-fir roots. Technical assistance by Mr. C. R. Daniels of the Wood Chemistry Section, Forest Products Laboratory, is gratefully acknowledged.

Nucleophilic decomposition of α-disulfones

PAUL ALLEN, JR. AND PATRICK J. CONWAY

The Department of Chemistry and Chemical Engineering, Stevens Institute of Technology, Hoboken, New Jersey 07030

Received June 18, 1968

The sulfur–sulfur bond of α-disulfones is attacked by hydroxide ion in alcohol to yield sulfinate and sulfonate ion by a second-order reaction, first order in each of the reactants. With aromatic disulfones the ρ value of the Hammett equation is 0.2. The Arrhenius activation energy of the reaction of *p*-tolyl disulfone is 7.95 kcal/mole.

Canadian Journal of Chemistry, **47**, 873 (1969)

Although α-disulfones are very stable towards acids, they readily undergo nucleophilic attack. *p*-Tolyl α-disulfone reacts with potassium hydroxide (2) according to eq. [1].

[1] $$C_7H_7SO_2\cdot SO_2C_7H_7 + 2KOH \rightarrow C_7H_7SO_2K + C_7H_7SO_3K + H_2O$$

and with piperidine (3) to give *p*-tolylsulfopiperidide and piperidinium *p*-toluene-sulfinate.

The kinetics and mechanism of this reaction have not been investigated.

Kharasch and Parker (4), Kice (5), and others have studied the nucleophilic fission of the sulfur–sulfur bond in disulfides, sulfinyl sulfones, and other sulfur compounds and found that it takes place by a second-order reaction.

The reaction of one aliphatic and several aromatic disulfones with sodium hydroxide in alcohol has now been studied and shown to be second order, first order in disulfone and first order in hydroxide ion. The initial reaction is, therefore

[2] $$(RSO_2)_2 + OH^- \rightarrow RSO_2^- + RSO_3H$$

followed immediately by neutralization of the sulfonic acid.

Ultraviolet absorption afforded a suitable method of analysis since aromatic α-disulfones, in most cases, have strong and characteristic absorptions, different from those of the corresponding sulfinates and sulfonates, see Table I. All the substances obey the Beer–Lambert law.

*As sodium salt.

The disulfones were made by cobalt(III) oxidation of sulfinic acid (6).

The reaction was followed by measuring the absorbance of the solution at suitable time intervals at the λ_{max} of the disulfone and at the λ_{max} of the sulfinate ion, with an allowance for the very small absorption of the sulfonate ion at these wavelengths. Three disulfones and the corresponding sulfinate ions had absorption maxima so close to each other that they could not be analyzed by this method. With these, using others as a check, and with *n*-dodecyl disulfone, the concentration of sulfinate was determined at intervals by permanganimetry. The permanganate and absorption methods gave essentially the same second-order rate constants, see Tables II and III.

To determine the activation energy, the rate of reaction of hydroxide ion and *p*-tolyl α-disulfone was measured at several temperatures, see Table IV. A plot of $\log k_2$ vs. $1/T$ gives an excellent straight line. Calculation by least-squares gives an Arrhenius activation energy of 7.95 kcal/mole. According to the formula $\Delta S^{\ddagger}/4.576 = \log k - 10.753 - \log T + E_a/4.576T$ (see ref. 7), the entropy of activation is about −30 e.u.

Hammett Function

The logarithms of the rate constants of the substituted disulfones, $(XC_6H_4SO_2)_2$, were plotted against the Hammett substituent constants σ of the groups X, using the rate constants determined by permanganimetry, except for the tolyl disulfone. If the meta and para $—CO_2^-$ groups are omitted, the points are fairly close to a straight line of which the slope, ρ, is 0.2. (If the two $—CO_2^-$ groups are included, the slope by the least-squares method becomes 1.23, but it seems advisable to omit these groups.)

It is of interest to compare these results with those for the ionization of sulfinic acids. Unfortunately, there is considerable disagreement between the published values. Burkhard *et al.* (8) determined the pK_a of a few aromatic sulfinic acids taking great care to avoid oxidation to the stronger sulfonic acids. They gave two figures for the pK_a of benzene sulfinic acid, 1.84 and 2.16; for the pK_a of *p*-toluene sulfinic acid they gave 1.99. Other workers have found that the benzene is stronger than the toluene acid. Ritchie, Saltiel, and Lewis (9) found pK_a's considerably lower than those published by Burkhard; their data agreed with fair precision with the equation $\log K_a = 0.976\sigma - 1.23$. A plot of Burkhard's results vs. σ, excluding the pK_a of benzene sulfinic acid, gives a moderately good line with a slope of about 0.15; according to this line the pK_a of benzenesulfinic acid should be 1.94. In the plot of our rate constants, if solvent or other effects make the σ values of the $—CO_2^-$ groups sufficiently uncertain for them to be left out, the slope of the line σ vs. $\log k_2$, about 0.2, is quite like that of σ vs. $\log K_a$ of Burkhard's data. These figures indicate that substituents on the aromatic ring do not greatly affect the sulfur atom in these reactions. However, one would expect more

299.7	7.644	333.1	27.248

effect when the sulfur is directly attacked, as in the reaction between OH^- and disulfones, than when the reaction is removed from the sulfur, as in ionization of sulfinic acids. On the other hand, Kice (ref. 5, p. 62) found that substituents on the ring had a large effect in both the spontaneous and acid-catalyzed hydrolysis of sulfinyl sulfones.

Mechanism

The data indicate that the hydroxide ion attacks one of the sulfur atoms, displacing a sulfinate ion by scission of the sulfur–sulfur bond,

$$[3]\quad HO^- + \underset{\underset{R}{|}}{SO_2}\text{—}SO_2R \rightarrow [HO\cdots \underset{\underset{R}{|}}{SO_2} \cdots SO_2R]^- \rightarrow RSO_3H + RSO_2^-$$

As expected, the rate of reaction increases as the sulfur of the disulfone is made more positive by introduction of electron attracting groups into the aromatic ring.

Experimental Section

Sulfinic Acids

Benzene- and *p*-toluene-sulfinic and sulfonic acid sodium salts were Eastman products. *m*-Bromobenzenesulfinic acid was made by diazotizing *m*-bromoaniline and adding sulfur dioxide in the presence of copper. The other sulfinic acids were prepared by reducing the sulfonyl chlorides with sodium sulfite.

Sulfonic Acids

When not available from other sources, these were made by peroxide oxidation of sulfinic acids in dilute hydrochloric acid.

α-Disulfones

Sulfinic acids or their sodium salts were oxidized by cobaltic(III) sulfate directly to disulfones (6).

The disulfones were very slightly soluble in ethanol, sparingly soluble in cold, but soluble in hot carbon tetrachloride, benzene, and benzene–xylene, soluble in dioxane and in acetonitrile. Constancy of melting point, analyses, and spectral data confirmed the purity and structure of the compounds.

Ultraviolet Absorption

A recording DK 2A Beckman spectrophotometer was used. The absorbances of α-disulfones, sodium sulfinates, and sodium sulfonates were determined in absolute alcohol at various concentrations. From the absorbance curves the values of the extinction coefficients were calculated by the method of least squares. In all cases the Beer–Lambert law was obeyed.

Temperature

For the calculation of the activation energy of the reaction of *p*-tolyl disulfone the temperatures were controlled within 0.03°. In all other runs the temperature was kept at 23.00 ± 0.05 °C.

Determination by u.v. Absorbance

Solutions of known strength of sodium hydroxide and of disulfone in absolute ethanol at 23 °C were mixed in a silica absorption cell. At intervals, timed by a stopwatch, absorption curves were recorded from 200–360 mμ. The intervals varied from 1–5 min. Calculations of disulfone concentration were made from the absorbances at two wavelengths, the λ_{max} of the disulfone and that of the sodium sulfinate, and the extinction coefficients of the disulfone, sulfinate, and sulfonate at these wavelengths. The sodium sulfonates showed little absorption; nevertheless their small absorbances were included. At the initial concentrations given in Table II, the reactions were 75% complete in about 25 min. For each run, 10–12 absorption curves were taken; second-order rate constants were calculated according to eq. [2] and gave excellent straight lines.

Determination by Permanganimetry in Alkaline Solution (10)

Solutions of known strength of base and of disulfone in absolute alcohol at 23° were mixed in a flask at 23° and kept at this temperature. At known intervals, 2–5 min, 100 cc samples were pipetted into water containing a few drops of sodium hydroxide. Standard 0.01 *N* permanganate was added from a microburette to a potentiometric end point shown on a pH meter with an expanded scale, using a platinum and a calomel electrode. The method of titration was checked against purified Eastman sodium benzenesulfinate. Tests showed that the reaction of disulfone and base stopped completely when the alcoholic solution was added to water. Seven or eight samples were withdrawn for titration in each run and second-order rate constants calculated. Second-order plots gave excellent straight lines. At the initial concentrations listed in Table II, the reactions of aromatic disulfones were 50% complete in 15–20 min. The reaction of dodecyl disulfone was 50% complete in 5 min and 90% in 20 min, but the concentration of base was relatively larger than in the reaction of the aromatic disulfones.

Low temperature Raman spectrum of rhombic sulfur

A. Anderson and Y. T. Loh
Department of Physics, University of Waterloo, Waterloo, Ontario

Received October 2, 1968

Raman spectra of polycrystalline samples of rhombic sulfur have been recorded at 100 and 300 °K, with excitation by the 5145 Å line of an argon ion laser. Spectra of sulfur solutions in carbon disulfide and bromoform were also obtained to aid in assignments. Experimental confirmation is presented of the frequencies of two intramolecular fundamental vibrations, suggested from normal coordinate analysis (one at very low frequency, the other inactive in both Raman and infrared for the free molecule). The spectra are analyzed in terms of the static and correlation crystal field perturbations, and for all except the weakest bands, substantial agreement is obtained. It is concluded that the effects of the two types of interaction are comparable in magnitude, and that a correct analysis must take account of the full symmetry of the unit cell.

Introduction

Infrared and Raman spectra of rhombic sulfur have been reported previously. The results are conveniently summarized in a recent monograph (1). Only recently, however, have experimental techniques become adequate to obtain high resolution results, such as might reveal the crystal field splittings. All the 11 fundamental vibrations of the S_8 molecule have frequencies below 500 cm^{-1}. In the infrared, this is a region where low energy and insensitive detectors make high resolution studies difficult by conventional techniques. The difficulties are compounded in this case as crystalline sulfur absorbs very strongly. Some evidence of splitting in two of the fundamentals was, however, reported recently with the use of interferometric methods (2), but no specific conclusions were possible.

For Raman spectra, measurements near the exciting line have also presented problems because of excessive Rayleigh scattering. The advent of the laser as exciting source, and the use of double monochromators (3) have largely overcome these difficulties. In a recent paper, Ward (4) presented high resolution Raman results on rhombic sulfur using a helium–neon laser, and observed certain splittings. The research described here covers the same ground, but differs in three important respects. (*a*) The more powerful argon ion laser was used, giving greater scattering intensity, and allowing additional weak features to be recorded. (*b*) The sulfur was cooled to liquid nitrogen temperature, resulting in considerable sharpening of the observed bands, and permitting additional splittings to be detected. (*c*) Discussion of these splittings is in terms of both the static field effect, responsible for the removal of degeneracy of certain vibrations because of the lower site symmetry, and the correlation field effect, which results from coupling of vibrating molecules within the same unit cell.

Experimental

Raman spectra were excited by the Spectra-Physics Argon Ion Laser, model 140, using the 5145 Å line which has a power level of about 900 mW. A Spex Double Monochromator, model 1400, fitted with Bausch and Lomb 1200 lines/mm gratings, and a photomultiplier (model FW 130, manufactured by IT and T Co.) cooled by a flow of cold nitrogen gas, were used to measure the scattered radiation. The signal was recorded by the photon counting technique, and processed in a 400 Channel Analyzer (Nuclear Chicago Co.) with output through a rate-meter and chart recorder.

Because of difficulties in growing good quality single crystals of rhombic sulfur and their fragility, particularly with respect to thermal shock, pressed discs of powdered sulfur (Fisher, U.S.P. grade) were used. These were 1 cm in diameter and about 0.5 mm thick. In the absence of a perfect crystal suitable for a complete polarization analysis, a powdered sample has the advantage of a completely random orientation of crystallites, so that spurious intensity dependence from a partially oriented sample is avoided.

The sulfur pellet was positioned at an angle of 30° to the vertical in a brass sample holder which was connected through a Kovar–Pyrex seal to the reservoir of liquid nitrogen in a simple cylindrical glass cryostat with plate glass end disc. A thin layer of vacuum grease between the back surface of the sample and the holder improved thermal contact. The temperature, as measured by a copper–constantan thermocouple soldered on the holding ring, was 85 °K, rising to 90 °K in the laser beam. Local heating of the sample by the laser undoubtedly occurred, but was not appreciable, since the sulfur loses its characteristic yellow color at low temperatures and absorption is correspondingly small. The appreciable sharpening of the bands in the liquid nitrogen experiments confirmed that the sample was, in fact, cold, and its temperature is estimated at approximately 100 °K.

The unfocused laser beams entered the cryostat vertically upwards, and the main reflected beam emerged at

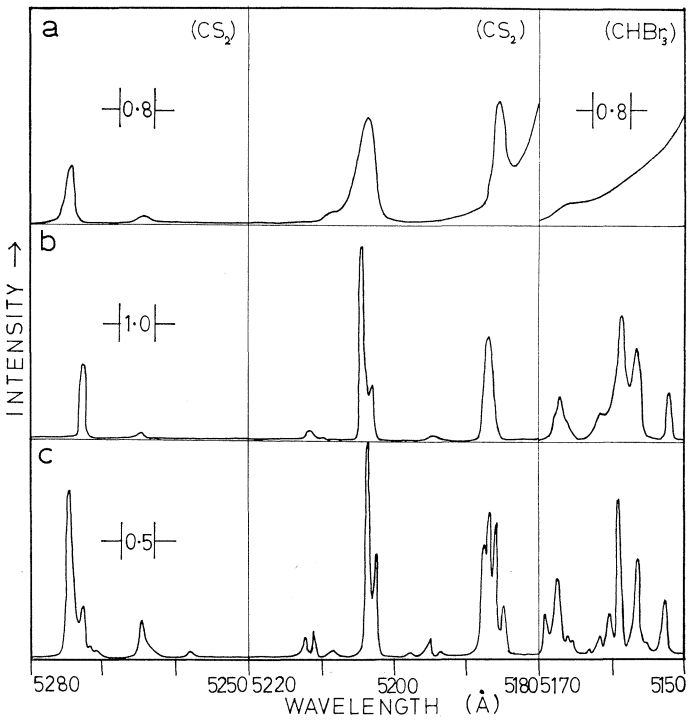

FIG. 1. Raman spectra of sulfur excited by 5145 Å argon line. (*a*) Solution in CS_2 and $CHBr_3$, (*b*) crystal at 300 °K, (*c*) crystal at 100 °K.

60° to the vertical. Scattered radiation was observed horizontally through a standard optical system mounted in front of the entrance slit of the monochromator.

Several solution spectra were also recorded. Saturated solutions of sulfur in CS_2 and $CHBr_3$ were placed in flat-ended Pyrex tubes. As sample warming was no problem here, the laser beam was focused in the solution at the focal point of the entrance optics, and horizontal scattering again observed.

Calibration was effected by noting the positions of non-lasing argon lines of known wavelength, when a small fraction of the beam was scattered directly into the monochromator. This also revealed the presence of two grating ghosts near the exciting line ($\Delta\nu$ = 13 and 23 cm^{-1}), similar to those reported by Ward (4). The resolution of the instrument as a function of slit widths was also checked using these sharp argon lines.

Results

In Fig. 1 are shown the spectra recorded from (*a*) room temperature saturated solutions of sulfur in CS_2 and $CHBr_3$, (*b*) the solid at room temperature, and (*c*) the solid at liquid nitrogen temperature. The bromoform spectrum is included only for the low temperature region, where the Rayleigh wing of carbon disulfide is very intense. In other regions, there is overlap between most of the sulfur peaks and those from $CHBr_3$.

The numbers inside slit symbols indicate the instrumental resolution in wavenumbers used for the different spectra. The frequencies of scattering intensity maxima are collected in Table I, and are estimated to be accurate to within ± 2 cm^{-1}. Results from other workers (refs. 4 and 5) are also included. The assignments and symmetry classifications of the normal vibrations of the isolated molecule are those of Scott, McCullough, and Kruse (5).

Additional spectra, not reproduced here, showed that (*a*) raising the temperature of the bromoform to just below its boiling point ($\sim$ 150 °C) and adding more sulfur to obtain a near saturated solution, increased the intensity of the band present as a shoulder in the room temperature experiment, thus confirming this as a fundamental of the isolated sulfur molecule; (*b*) room temperature experiments of the sulfur in solution and as a pressed disc, run under identical slit conditions, confirmed that none of the splittings

observed in the crystal spectra were present in solution, thus eliminating isotopic species as a possible cause.

Discussion

(a) General

The molecular and crystal structures of sulfur in the orthorhombic modification are well known (6, 7). There are 16 S_8 puckered octagon molecules in the face-centered orthorhombic unit cell with space group D_{2h}^{24} (*Fddd*). However, in the primitive unit cell (the smallest volume from which the entire lattice can be generated by translations alone), this is reduced to 4 molecules. The only sites available with this occupancy number are C_2 and C_i, and the latter is excluded because it is not a sub-group of the molecular symmetry, D_{4d}. The two-fold axis is along the crystalline z axis, which lies in the nodal planes of the molecules, and thus does not correspond to the principal four-fold molecular axis. Hence, in the discussion which follows, the site symmetry is taken as C_2'. The distinction is important when the correlation table is constructed, as different predictions of infrared and Raman activity can result (8). Ward's assumption that there are only two types of molecule in the unit cell is incorrect (4). In any case, his analysis in terms of site symmetry only should be independent of the number of non-equivalent molecules present. The activities of the normal modes of the unit cell may be found by standard methods (9, 10). The correlation table relating the representations of the molecular, site, and unit cell symmetries is obtained by a comparison of their character tables, or more directly by using the standard compilations of

Wilson, Decius, and Cross (11). The result is shown in Fig. 2, which also includes the classification of the 11 internal and 4 external modes of S_8, and their optical activities. For convenience, the numbers of infrared and Raman components predicted for all the fundamental molecular and lattice vibrations are summarized in Table II, with the final column listing the Raman components actually observed in this study.

As indicated, group theory predicts 48 Raman and 33 infrared bands for vibrations within the unit cell. Together with 12 inactive components, these total 93, all non-degenerate. This agrees with the formula $3nN - 3$ where $n = 8$, the number of atoms per molecule, and $N = 4$, the number of molecules per unit cell. The 3 zero frequency modes, corresponding to translations of the entire lattice, are subtracted. Usually, many of these 48 components will be either too weak to be observed, or too close to other bands to be resolved. However, one would at least hope to observe the splitting of those bands which are strongly Raman active in the isolated molecule, and the appearance of weak bands corresponding to those modes which are active only under the crystal symmetry selection rules. As indicated by Ward (4), the degree of perturbation on the spectrum of the isolated molecule is governed by the relative strength of the intermolecular van der Waals forces compared to the covalent intramolecular sulfur bonds.

In fact a total of 29 peaks were observed. These will now be classified, using as basis the assignments of the isolated molecule by Scott *et al.* (5).

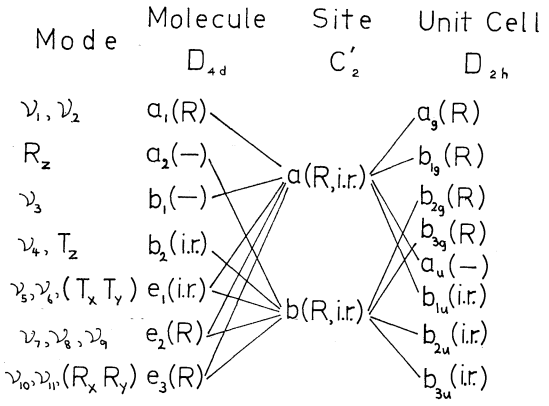

FIG. 2. Correlation between the molecular, site, and unit cell symmetries of orthorhombic sulfur. R, Raman active; i.r., infrared active; —, inactive.

The convention suggested by Herzberg (12) will be adopted: the modes are numbered with suffices from 1 to 11 in order of decreasing symmetry, and, for those having the same representation (e.g. e_2), in order of decreasing frequency. There is an initial problem of separating lattice from intramolecular modes. It is known from normal coordinate analysis (5), that there is a very low frequency molecular mode of e_2 species, ν_9, its most likely position, for consistency with vapor pressure data, being 56 cm^{-1}. The only experimental evidence for this vibration appears to be from the work of Gerding and Westrik (13), who observed a band at 86 cm^{-1} from a solution of sulfur in naphthalene at 110 °C and at 92 cm^{-1} from liquid sulfur at 120 °C. Because of the strong

For personal use only.

scattering from the wing of the Rayleigh peak of CS_2, the band could not be detected in this solvent. However, the peak observed at 80 cm^{-1} from sulfur in bromoform at room temperature in this work puts the assignment of ν_9 on a more substantial basis as there is some evidence of breakage of the puckered rings of S_8 at elevated temperatures (6). The frequency is expected to increase with the extent of perturbation (5), and so the multiplet centered at 85 cm^{-1} in the low temperature crystal spectrum is assigned to ν_9 and all peaks below 75 cm^{-1} are assigned to lattice vibrations.

(b) Non-degenerate Vibrations

There are two totally symmetric vibrations, ν_1 (stretch) and ν_2 (bend). Both of these are split into well-resolved doublets as predicted. The splittings at 100 °K are 7 and 4 cm^{-1}, respectively. The strong component of each doublet is presumably the a_g mode and occurs at the higher frequency in each case. The b_1 mode, ν_3, which is completely inactive in the isolated molecule, should have two Raman components in the crystal. Normal coordinate analysis (5) predicts this frequency to be near 412 cm^{-1}, but experimental confirmation is indirect, relying on a combination band in the infrared (14). A weak band is observed in this work at 417 cm^{-1}, which may be the first direct sighting of ν_3. The b_2 mode, ν_4, is also Raman inactive in the molecule but has been observed in the infrared at 239 cm^{-1} (2). The weak band observed here at 236 cm^{-1} is probably the unresolved doublet predicted from the correlation table.

(c) Degenerate Vibrations

The two e_1 modes, ν_5 and ν_6, are also Raman active only through violation of the selection rules for the free molecule. A weak doublet is observed on the low frequency side of ν_1 which is close to the value observed for ν_5 in the infrared spectrum of the crystal at low temperature (15). However, the situation is complicated by an accidental degeneracy between ν_1 and ν_7 (e_2). Since ν_7 is nominally active for the free molecule, it is perhaps more likely that the weak doublet is really the unresolved quartet predicted for this mode. Three peaks are observed in the 180–200 cm^{-1} region, which is where ν_6 is observed in the far infrared (2). The strongest of these appears asymmetric on the high frequency side, and probably conceals a weak fourth component, so that again the agreement with theory is close.

There are three e_2 vibrations, one of which, ν_7, has been discussed above. At 100 °K, ν_8 is beautifully resolved into the four predicted components, the separations being of the order of 3 cm^{-1}. The low lying vibration, ν_9, is also well resolved into four components at low temperature, but here the assignment is not quite so clear-cut because of possible overlap with lattice modes. The splittings here range from 3 to 6 cm^{-1}.

The two e_3 modes appear only weakly in the solution spectra, and are not resolved into the predicted quartets in the crystal: ν_{10} is the rather broad band at 441 cm^{-1} with a low frequency tail; ν_{11} is observed as a doublet near 250 cm^{-1}, the splitting being 4 cm^{-1}. For this mode, it appears that either the static or correlation field is dominant, but as has been seen from the above analysis, in general the two effects give comparable splittings.

(d) Lattice Vibrations

Analysis of the lattice region is complicated by four factors. (*a*) The predicted Raman spectrum is rich, with 12 peaks lying in a narrow frequency region (between 10 and 75 cm^{-1}). (*b*) Strong grating ghosts may obscure certain very low frequency peaks. (*c*) There is a strong possibility of mixing between translational and torsional modes of like symmetry and similar frequency. (*d*) No normal coordinate analysis is available to aid in assignments.

Certain theoretical factors which should help in the analysis will first be considered. Of the six torsional modes, the two originating from motions about the principal molecular axis (R_z) are expected to be at low frequencies. Not only is the moment of inertia larger ($I_z:I_{xy} = 1.8:1$), but the restoring force about this axis should be weak (4). The other four torsional modes may be expected to be relatively strong, since the degenerate rotation from which they originate (R_xR_y) is formally Raman active for the free molecule. In particular, the in-phase totally symmetric component (a_g) should be more intense than the others.

A recent paper by Walmsley (16) suggests an approximate method for calculating the optically active translational frequencies of molecular crystals in terms of the intermolecular distance, static lattice energy at 0 °K, and molecular weight. Although strictly applicable only to face-centered cubic lattices, extension to crystals where neighboring molecules are almost equidistant is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

possible. From the crystallographic data, the mean nearest neighbor intermolecular distance of rhombic sulfur is calculated to be 6.8 Å. The static lattice energy at 0 °K is the sum of the heat of sublimation at 0 °K and the zero-point energy. These quantities can be calculated using standard thermodynamic formulae (17) and the experimental data of Nernst (18), Norris (19), and Bradley (20). In this way, values of the two translational modes are estimated to be 35 and 52 cm^{-1}. For sulfur, there are in total eight optically active translational modes, and so the above frequencies serve merely as a guide to the general position of these bands and precise agreement is not expected. It is known that orthorhombic crystals of S_8 cleave readily across the 001 face (6). This suggests that translations in the crystallographic z direction (which corresponds to components of the molecular translation, T_xT_y) experience weak restoring forces and hence have low frequencies of vibration. Since no translational modes of the free molecule are Raman active, only weak bands in the crystal are probable. Similar to the torsions, however, the a_g component, originating from T_xT_y, might be more intense than the others.

With these factors in mind, the most plausible assignment of the seven observed lattice peaks appears to be as follows: R_z, 29 cm^{-1}; R_xR_y, 53, 59, 63, 68 cm^{-1}; T_z, $\sim$ 52 cm^{-1} (obscured by R_xR_y); T_xT_y, 39, 44 cm^{-1}. It is recognized that this is at best tentative. Further experiments such as polarization studies on a single crystal (Raman and infrared) would resolve some of the ambiguities, but probably not the basic problem of separating translational and torsional modes, since, as mentioned earlier, these have like symmetries.

Conclusions

The Raman spectrum of rhombic sulfur at 100 °K has been observed, and analyzed in terms of the normal modes of the unit cell. All except one of the intramolecular fundamentals are observed directly[1]. General confirmation of the assignments of Scott *et al.* (5) is obtained. In particular, there is new experimental verification of the frequencies of two modes (ν_3 and ν_9) deduced from their normal coordinate analysis. The splittings observed for the strongly Raman active fundamentals are entirely consistent with the group theoretical analysis in terms of the static and correlation crystal fields. The observed bands are never more than predicted, and the indications are that under ideal conditions of intensity, instrumental resolution, and sharp non-overlapping bands, the agreement would be complete. In general, the effects from the two types of field appear comparable, and a correct analysis must take account of both.

[1]At the suggestion of a referee, who pointed out that several weak spectral features may be caused by long chain molecules of sulfur stabilized by small amounts of impurity, the experiments were repeated with Gallard–Schlesinger sulfur stated to be 99.9999% pure. Identical spectra were obtained. The co-existence of S_8 rings and S_n chains is discussed in a recent paper (21). We are grateful to the referee for his advice, and to Mr. T. S. Sun for help with these later experiments.

The effect of pressure on the radiation-induced conductance of liquid hydrocarbons

D. W. Brazier and G. R. Freeman
Chemistry Department, University of Alberta, Edmonton, Alberta

Received September 26, 1968

An attempt was made to test the cavity model of electron localization in liquid hydrocarbons by measuring the effect of pressures up to 4000 bars on the radiation induced conductance of *n*-pentane, *n*-hexane, *n*-octane, cyclopentane, methylcyclohexane, and 2,2-dimethylbutane at 30°. Measurements at 3 and 56° were also made on *n*-hexane and *n*-octane. The relative induced conductance, i.e. the ratio of the induced conductance at pressure *p* to that at 1 bar, decreased with increasing pressure. The amount of decrease was slightly greater at low than at high temperatures. The behavior of 2,2-dimethylbutane was complex and is not understood. For the other liquids, it was concluded that the free ion yields remained constant or decreased somewhat with increasing pressure. An appreciable increase in the free ion yields, which is a possible implication of the cavity model of electron localization, did not occur. Therefore, either (*a*) the cavity model of electron localization in hydrocarbons is wrong, or (*b*) application of pressures up to 4000 bars did not appreciably alter the cavity concentrations in the liquids. Perhaps the cavity concentration is greatly reduced only by pressures great enough to cause a solid phase (glass or crystal) to form.

Canadian Journal of Chemistry, **47**, 885 (1969)

Introduction

The cavity model for the structure of solvated electrons in liquid hydrocarbons (1) is useful in the interpretation of various effects that indicate that extra electrons are localized in these liquids (2). One of the implications of the model is that the range of a low energy secondary electron might be significantly dependent on the concentration of cavities in the liquid, i.e. the range might increase as the concentration of cavities decreases. An increasing range would result in an increasing free ion yield (2*b*).

It was thought that the application of several thousands of atmospheres pressure to a liquid might reduce the cavity concentration. For this reason, the effect of pressure on the radiation-induced conductance of several hydrocarbons was measured. Increasing the pressure on a hydrocarbon also increases the density, dielectric constant, and viscosity of the liquid. The first two of these factors affect the induced conductance through the free ion yield, and the third affects it through the ion mobilities. The influence of pressure on the cavity concentration must be sorted out from the other factors.

The hydrocarbons used in the present work were *n*-pentane, *n*-hexane, *n*-octane, cyclopentane, methylcyclohexane, and 2,2-dimethylbutane. The pressure dependences of the density, dielectric constant, and viscosity of these liquids were also measured and the results are reported in the following paper (3).

Experimental

High Pressure System

Full details of the high pressure system are given elsewhere (4). The pressure in the system was measured with a 14 in. dial Heise gauge that was calibrated in 100 p.s.i. divisions; 1 bar = 14.504 p.s.i. The temperature of the thermostated pressure vessel was controllable to within ±0.5 °C.

Three electrical connections to the pressure vessel interior were passed through the closure plunger. The connectors, obtained from American Instrument Co., were of the self-sealing cone design.

High Pressure Conductance Cells

Glass-to-metal seals made from all combinations of tungsten, platinum, and Kovar, with Pyrex, soda, and uranium glasses usually failed when the pressure was released, so glass cells were unsatisfactory.

The bellows cell employed is illustrated in Figs. 1 and 2. The cell electrodes (Fig. 1) were 16 mm in diameter and were made from stainless steel. The electrodes were separated (2–10 mm) by an interchangeable spacer made of Supramica 500 Ceramoplastic (Mycalex Corp.). The

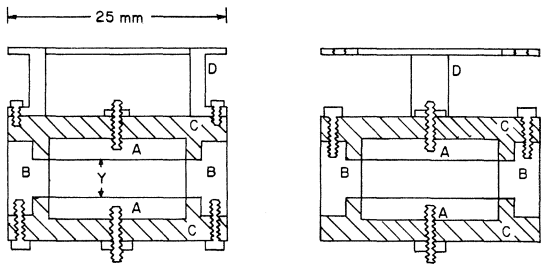

Fig. 1. Conductance cell (two sections at 90°). A, electrodes (2 mm thick); B, Supramica Ceramoplastic spacer; C, Supramica electrode holder; D, support post; Y, the interelectrode separation, varied from 2 to 10 mm.

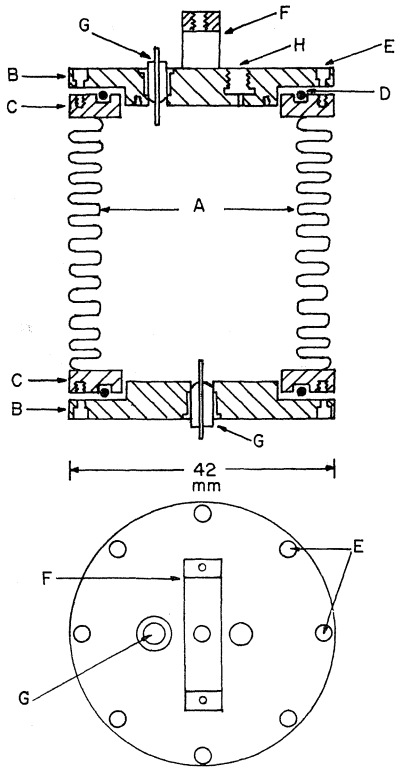

FIG. 2. Bellows assembly. A, stainless steel bellows; B, stainless steel closure cap; C, "O" ring seat; D, "O" ring; E, compression bolts; F, bracket to attach bellows to pressure vessel piston; G, terminal seal; H, filling aperture.

cell was enclosed in a bellows (Robertshaw Controls Ltd.) that was closed at each end as shown in Fig. 2. The "O" ring seats were silver soldered to the bellows.

Electrical connections into the bellows were made through Latronics Corp. metal-to-ceramic terminal seals. The conductance cell was rigidly attached to the lower surface of the top cap of the bellows. The filling aperture was closed by a needle valve type of screw.

Prior to assembly of the cell, all components were washed in a large Soxhlet apparatus for several days. Either hexane or the hydrocarbon under investigation was used for washing.

Materials

The hydrocarbons used for conductance measurements were Phillips Research Grade. Olefinic impurities were removed by concentrated sulfuric acid. The hydrocarbon was then washed with 5% sodium hydroxide and with doubly distilled water. After preliminary drying over anhydrous magnesium sulfate, the liquid was distilled from lithium aluminium hydride.

Radiation Sources and Dosimetry

A 5500 Ci ^{60}Co γ source could be reproducibly positioned near the pressure vessel. The dose rate within the vessel was 10^{14}–10^{15} eV/cm^3 s, determined using the Fricke dosimeter. The dose rate was very dependent on the position of the sample within the vessel, because of the variable path length of the radiation through the steel vessel wall.

Conductance Measurements

Currents were measured with an E. H. Laboratories Model 240 micromicroammeter. The meter was calibrated by applying known voltages across Victoreen precision resistors.

An extra (dummy) cable was used on the current measuring side of the circuit to check whether currents that did not originate in the conductance cell were negligible. The extra cable paralleled the actual measuring cable and passed into the interior of the pressure vessel, but terminated just prior to the conductance cell electrode.

The method of shielding the connections at the pressure vessel head, to reduce the amount of ion collection from the surrounding ionized air, is shown in Fig. 3. In this way the current that passed through the ionized air was reduced to a negligible level.

Electrical connections were spot welded, when possible.

Cell Filling and Experimental Procedure

The cleaned and assembled bellows cell was connected to a vacuum manifold, using a Kovar seal and a special hollow screw which fitted into the needle valve closure of the bellows cap.

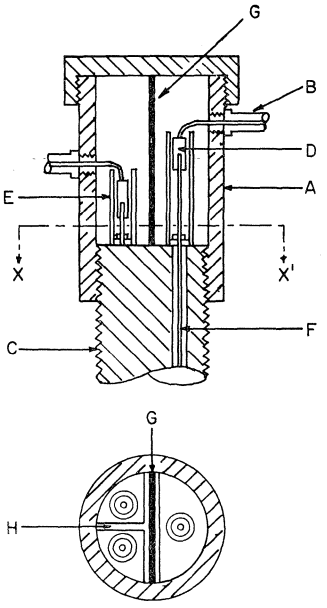

FIG. 3. Shielding of cables at pressure vessel head. A, brass cap; B, BNC coaxial cable connector; C, pressure vessel closure piston; D, brass sleeve; E, polyethylene tubing; F, electrical connection through closure piston; G, grounded copper plate; H, rubber sheet.

The chemically purified and degassed hydrocarbon was electrolyzed for several hours between platinum electrodes, with fields up to 5 kV/cm. The liquid was then transferred to the radiolysis cell; if its conductance was greater than 10^{-14} mho at 200 V/cm, it was transferred back to the electrolysis cell for further purification. The liquid was transferred back and forth between the electrolysis and radiolysis cells by a special device (4), to prevent contamination. When the sample in the radiolysis cell had a sufficiently low intrinsic conductance, an atmosphere of dry argon was allowed into the vacuum manifold. The cell was removed and the needle valve screw closure inserted whilst maintaining an argon atmosphere around the cell.

The cell current, in the presence and absence of radiation, was measured as a function of voltage up to a maximum of 500 V. The pressure was then changed to a new value and the system was allowed to sit for at least 20 min before taking the new conductance measurements.

Measurements were made during both the pressure increasing and the pressure decreasing parts of the cycle. If the conductance values obtained at atmospheric pressure were different before and after the pressure cycle, the cycle was repeated. The "before" and "after" readings were different if there had been a shift in the position of the closure piston before it became tightly seated.

Results

At all pressures and temperatures employed in the present work, a linear relationship was found between the cell current and the applied voltage. Typical results are shown in Fig. 4. The plots exhibited voltage intercepts that varied in a non-reproducible manner between 0.5 and 10 V. The non-zero intercepts were probably due to induced currents in the cables and to contact potentials, and had been noted earlier (5, 6). The conductance of the sample was taken from the slope of the current–voltage plot. The radiation induced conductance was assumed to be equal to the difference between the conductances measured in the presence and absence of radiation.

In general, the induced conductance decreased with increasing pressure. A typical plot is shown in Fig. 5.

In order to correlate the results obtained under different conditions, the relative conductance is used: the relative conductance is the ratio of the conductance at pressure p to that at 1 bar, at the same temperature.

Within the $\pm 3\%$ experimental error, the relative conductance was independent of electrode separation (2–10 mm) and of dose rate (1–6 $\times$ 10^{14} eV/cm^3 s) for all the hydrocarbons studied.

The induced conductances of all the hydrocarbons except 2,2-dimethylbutane were independent of the absorbed dose. The induced conductance of 2,2-dimethylbutane varied in a peculiar fashion with absorbed dose (Fig. 6).

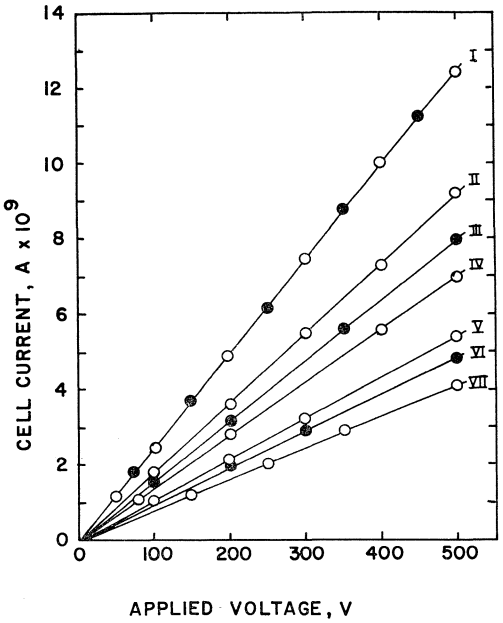

FIG. 4. Cell current vs. applied voltage in hexane at 30 °C. Electrode spacing 3.2 mm; dose rate 4.3 $\times$ 10^{14} eV/cm^3 s. I–VII results at pressures of 1, 747, 1140, 1600, 2690, 3450, and 4068 bars, respectively. Open points, pressure increasing cycle; closed points, pressure decreasing cycle.

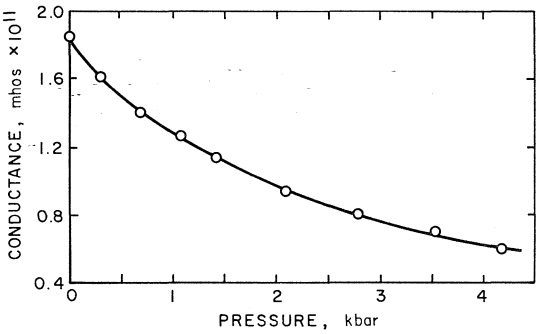

FIG. 5. Conductance vs. pressure in hexane at 30 °C. Electrode spacing 2 mm; dose rate 1.5 $\times$ 10^{14} eV/cm^3 s.

The relative induced conductances of n-hexane and n-octane were measured up to 4000 bars at each of the temperatures 3, 30, and 56°, and the results are recorded in Table I. Each number in the Table is the average of several results obtained with different electrode spacings and at different

TABLE I

Relative induced conductances of *n*-hexane and *n*-octane at 3, 30, and 56 °C

*Freezes above 2500 bars.

dose rates. The relative conductances are essentially independent of temperature. The value for *n*-octane decreases slightly more rapidly with pressure than does that for *n*-hexane.

The relative induced conductances of *n*-pentane, cyclopentane, methylcyclohexane, and 2,2-dimethylbutane up to 4000 bars at 30° are given in Table II. The tabulated values are the averages obtained from several experiments. Methylcyclohexane shows a greater pressure effect than does either *n*-pentane or cyclopentane. The conductance of 2,2-dimethylbutane was dose dependent at doses below 2×10^{19} eV/cm^3 (Fig. 6), so two sets of values are included for this compound in Table II. The first set corresponds to the average of the values obtained during the pressure increasing and pressure decreasing parts of a cycle, starting with a fresh sample. During this experiment the sample received a dose of about 1.4×10^{18} eV/cm^3. The second set was obtained from a sample that had previously been irradiated to 3.8×10^{19} eV/cm^3, and the conductance had become independent of the dose (see Fig. 6). The pressure effect was somewhat greater for the high than for the low dose sample (Table II).

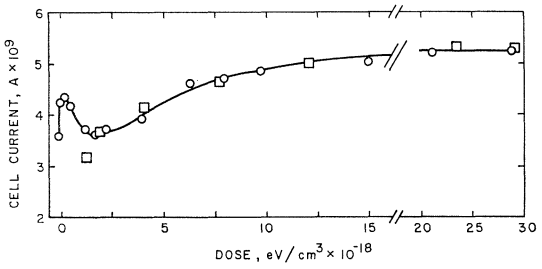

FIG. 6. Dose dependence of current in 2,2-dimethylbutane at 30 °C: dose rate, 4.2×10^{14} eV/cm^3 s; field strength, 260 V/cm; ○, fresh sample; □, after 1.4×10^{18} eV/cm^3 irradiation during a pressure cycle up to 4000 bars.

Discussion

The free ion yield G_{fi} in a liquid under irradiation is related to the induced conductance κ by the following equation (5, 7).

$$[1] \qquad G_{fi} = \frac{100k\kappa^2}{Ru^2}$$

where k is the ion neutralization rate constant (cm^3/ion s), R is the absorbed radiation dose rate (eV/cm^3 s), and u is the sum of the positive and negative ion mobilities (cm^2/V s). The appropriate units for κ in eq. [1] are ion/cm V s.

One can show from equations presented earlier (5, 7) that, theoretically,

$$[2] \qquad k/u = 1.81 \times 10^{-6}/\varepsilon \quad \text{V/cm}$$

where ε is the dielectric constant of the liquid. Hence,

$$[3] \qquad G_{fi} = \frac{1.81 \times 10^{-4}\kappa^2}{Ru\varepsilon}$$

The yield of free ions at pressure p, $G_{fi}{}^p$, is related to the yield at 1 bar, $G_{fi}{}^1$, by eq. [4].

$$[4] \qquad \frac{G_{fi}{}^p}{G_{fi}{}^1} = \frac{R_1u_1\varepsilon_1}{R_pu_p\varepsilon_p}\left(\frac{\kappa_p}{\kappa_1}\right)^2$$

*Fresh sample.
†High dose sample (see text).

However, the dose rate is directly proportional to the density ρ of the liquid, so one may write

$$[5] \qquad \frac{G_{fi}{}^{p}}{G_{fi}{}^{1}} = \frac{\rho_1 u_1 \varepsilon_1}{\rho_p u_p \varepsilon_p}\left(\frac{\kappa_p}{\kappa_1}\right)^2$$

The pressure dependences of the densities and dielectric constants of the liquids used in the present work are reported elsewhere (3).

The pressure dependences of the radiolytic ion mobilities are not known, and there is conflicting evidence about the relationship between the ion mobilities and the liquid viscosity η at atmospheric pressure (8, 9). Therefore, two sets of calculations were done to answer the following questions: (*a*) if the ion mobilities obey the Stokes–Walden relationship,

$$[6] \qquad u_1/u_p = \eta_p/\eta_1$$

how does the value of G_{fi} change with pressure; (*b*) if G_{fi} is independent of pressure, how do the ion mobilities vary with pressure?

(a) Assume that the Stokes–Walden Relationship is Obeyed

Then,

$$[7] \qquad \frac{G_{fi}{}^{p}}{G_{fi}{}^{1}} = \frac{\rho_1 \eta_p \varepsilon_1}{\rho_p \eta_1 \varepsilon_p}\left(\frac{\kappa_p}{\kappa_1}\right)^2$$

The pressure dependence of η is reported elsewhere (3), along with those of ρ and ε.

The dependence of G_{fi} on pressure, as calculated from eq. [7], is illustrated in Fig. 7 for all the hydrocarbons studied except 2,2-dimethylbutane. In every instance, G_{fi} decreases with increasing pressure. The decrease at 4000 bars amounts to 33% for *n*-pentane and *n*-hexane, 30% for *n*-octane, and about 20% for the two cyclic hydrocarbons, all at 30°. The curves of $G_{fi}{}^{p}/G_{fi}{}^{1}$ for *n*-hexane at 3 and 56° are also shown in Fig. 7. The variation with temperature is small.

The induced conductance of 2,2-dimethylbutane was dose dependent at low doses, but became independent of dose above about 2×10^{19} eV/cm^3 (Fig. 6). In a low dose sample, the apparent value of $G_{fi}{}^{p}/G_{fi}{}^{1}$ increased at first with increasing pressure, then went through a maximum (Fig. 8). This behavior is probably associated with the dose dependence of the conductance. In a high dose sample (3.8×10^{19} eV/cm^3), the apparent value of $G_{fi}{}^{p}/G_{fi}{}^{1}$ decreased at first with increasing pressure and passed through a minimum at 2500 bars. The viscosity of this liquid increased abnormally rapidly with pressure (3), so the complex behavior displayed by the high dose curve in Fig. 8 may represent changes in the liquid structure.

(b) Assume that G_{fi} is Independent of Pressure

The mobilities of positive and negative radiolytic ions have been measured at atmospheric pressure in many hydrocarbon liquids with widely different viscosities (8, 9). The viscosity dependences of the mobilities were expressed in the form

$$[8] \qquad u_+ = a_+ \eta^{-b_+}$$

$$[9] \qquad u_- = a_- \eta^{-b_-}$$

where a_+, a_-, b_+, and b_- are constants. The Stokes–Walden relationship corresponds to $b_+ = b_- = 1.0$. The reported values of b_+ lie between 1.5 (8) and 0.94 (10), whereas those of b_- are between 1.00 (8) and 0.83 (9). Thus, in the

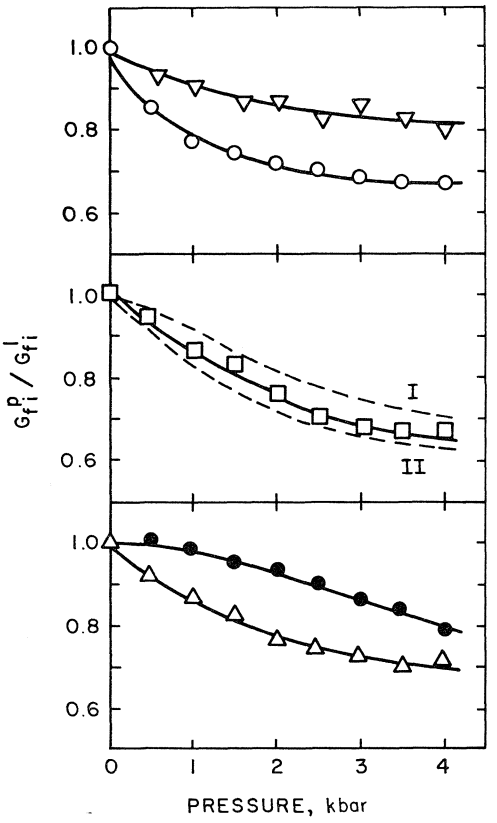

FIG. 7. $G_{fi}{}^{p}/G_{fi}{}^{1}$ vs. pressure. Temperature 30° unless otherwise specified: ○, *n*-pentane; ▽, methylcyclohexane; □, *n*-hexane (line I, 3°; line II, 56°); ●, cyclopentane; △, *n*-octane. Dose rate range 1–6 × 10^{14} eV/cm^3 s.

majority of cases the Stokes–Walden rule does not accurately correlate the mobilities of radiolytic ions in different liquids at atmospheric pressure.

We now assume that

$$[10] \qquad u = u_+ + u_- = a\eta^{-b}$$

then assume that G_{fi} is independent of pressure and calculate the value of b that is required to fit the results at different pressures. The relationship used is

$$[11] \qquad \left(\frac{\eta_p}{\eta_1}\right)^b = \frac{\rho_p\varepsilon_p}{\rho_1\varepsilon_1}\left(\frac{\kappa_1}{\kappa_p}\right)^2$$

and the values of η, ρ, and ε are taken from ref. 3. The pressure dependences of the power b for all the hydrocarbons used except 2,2-dimethylbutane are shown in Fig. 9. The value of b is 1.2 at all pressures above 1 kbar in *n*-hexane and *n*-octane. In *n*-pentane b decreases from 1.4 at 0.5 kbar to 1.2 at 4 kbar; in cyclopentane b increases from 1.0 to 1.1, while in methylcyclohexane it decreases from 1.2 to 1.1 over this pressure range.

The variation of b with pressure in 2,2-dimethylbutane, assuming G_{fi} to be independent of pressure, is shown in Fig. 10. For the low dose sample, b appeared to vary between 0.8 and 1.0, whereas for the high dose sample b varied between 1.2 and 1.5 with a maximum at about 2 kbar.

In all the compounds studied, the values of b are within the range of values previously obtained from measurements at atmospheric pressure. Although it is not necessary that the value of b obtained by varying the pressure on a given liquid would be the same as that obtained from a series of compounds with different viscosities at atmospheric pressure, it appears that G_{fi} in liquid hydrocarbons is not greatly dependent on the pressure, up to 4000 bars.

(c) Nonhomogeneous Kinetics Model Calculations

By assuming that the electron ranges in a liquid at different pressures are simply inversely proportional to the liquid density, one can calculate the variation of G_{fi} with pressure that is predicted by our nonhomogeneous kinetics model (2*b*, 11). The required values of the densities and dielectric constants are given in ref. 3.

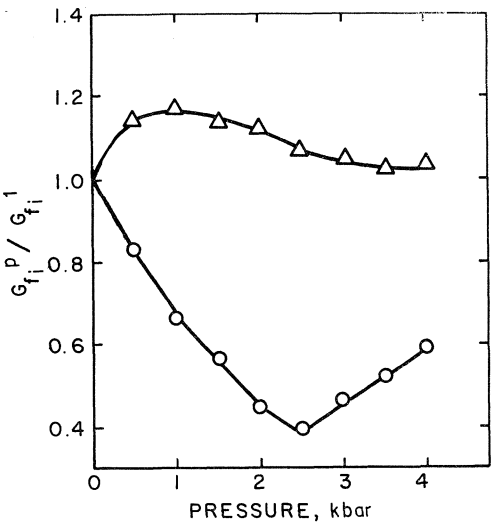

FIG. 8. $G_{fi}{}^{p}/G_{fi}{}^{1}$ vs. pressure in 2,2-dimethylbutane at 30 °C: electrode spacing, 3.9 mm; dose rate, 4.2 × 10^{14} eV/cm^3 s; △, low dose sample; ○, high dose sample (see text).

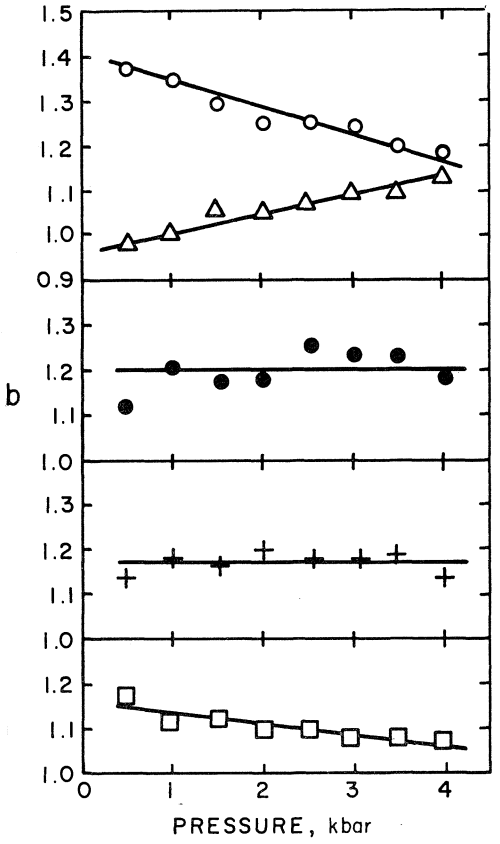

FIG. 9. Power b vs. pressure at 30 °C: ○, n-pentane; △, cyclopentane; ●, n-hexane; +, n-octane; □, methylcyclohexane.

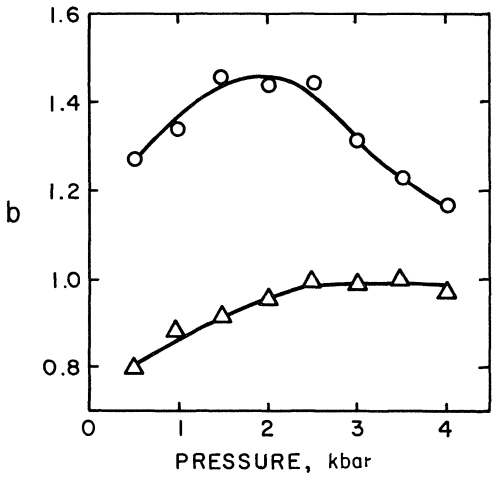

FIG. 10. Pressure dependence of b in 2,2-dimethylbutane at 30 °C. △, low dose sample; ○, high dose sample.

The model calculations for n-hexane give the result that G_{fi} at 4000 bars is 6% smaller than at 1 bar. The estimated variation of G_{fi} is small because the effect of the increasing density, and hence the decreasing electron range, is nearly cancelled by the effect of the increasing dielectric constant. The same is true of the other hydrocarbons.

Comments and Conclusions

1. The free ion yield in liquid hydrocarbons may remain constant or it may decrease somewhat as the pressure is increased from 1 to 4000 bars. An appreciable *increase* in the yield, which is a possible implication of the cavity model of electron localization, does not occur.

2. Either (*a*) the cavity model of electron localization is wrong, or (*b*) compression of the liquids by a pressure of 4000 bars did not appreciably alter the cavity concentrations. The molar volumes of the hydrocarbons at 4000 bars are about 20% smaller than those at 1 bar (3), and most of this contraction should correspond to a decrease in the "free volume" of the liquids. Thus the sizes of the cavities should be smaller at 4000 bars than those at 1 bar, but the decrease in size may not have been great enough to affect the electron capture cross sections of the cavities beyond the present limits of detection. Furthermore, if the compressibility of the cavities is about the same as that of the average free volume, the cavity concentration would not be greatly reduced by pressure until the pressure was great enough to cause a change of phase, i.e. to cause glass formation or crystallization. Unfortunately, the present conductance technique is not applicable to solid phase samples, because the ion mobilities are too low in solids.

3. The complex behavior of 2,2-dimethylbutane is not understood.

The effects of pressure on the density, dielectric constant, and viscosity of several hydrocarbons and other organic liquids

D. W. Brazier and G. R. Freeman
Chemistry Department, University of Alberta, Edmonton, Alberta
Received September 26, 1968

The effects of pressures up to 4 kbar on the density, dielectric constant, and viscosity of *n*-pentane, *n*-hexane, *n*-octane, cyclopentane, methylcyclohexane, and 2,2-dimethylbutane (DMB) were measured at 30 °C. The pressure effects on the viscosities of *n*-hexane and *n*-octane were also determined at 0 and 60°. The densities of diethyl ether and cyclopentanone and the dielectric constant of carbon tetrachloride at high pressures are also recorded. The densities of the hydrocarbons increased by 20–30% and the dielectric constants increased by 11–16% as the pressure was increased from 1 to 4000 bars at 30°, but the viscosities increased by 695–2352% over the same pressure range. Carbon tetrachloride froze at 1500 bars at 30°, and cyclopentanone froze at 3500 bars at about 20°. In agreement with earlier work on other liquids, the value of the Clausius–Mosotti function $(\varepsilon - 1)V/(\varepsilon + 2)$ for the present compounds decreased slightly with increasing pressure. The viscosity at a given pressure decreased slightly with increasing temperature, and temperature effect increased with increasing pressure. In general, the smaller the compressibility of the liquid, the greater was the effect of pressure on the viscosity; DMB was an exception because its viscosity increased abnormally rapidly with pressure. Molecular structure and liquid structure have greater influences on the pressure dependence of viscosity than on that of density or dielectric constant.

Introduction

As part of an investigation of the effect of pressure on the radiation induced conductance of liquid hydrocarbons (1), it was necessary to measure the variation of the density, dielectric constant, and viscosity of the liquids. The hydrocarbons used in the conductance study were *n*-pentane, *n*-hexane, *n*-octane, cyclopentane, methylcyclohexane, and 2,2-dimethylbutane. These and several other compounds were used in the present work. Values of pressure coefficients of physical properties of many liquids have been reported earlier (2–9).

Experimental

High Pressure System

The high pressure system is described briefly in ref. 1 and in detail in ref. 10. The pressure vessel temperature was controlled to within ±0.5° over the range 0–60 °C.

Materials

The *n*-pentane, *n*-hexane, *n*-heptane, *n*-octane, *n*-decane, cyclopentane, methylcyclohexane, and 2,2-dimethylbutane were Phillips Research Grade and were purified as described earlier (1). Phillips Research Grade benzene was purified by repeated partial recrystallization. Eastman Spectroscopic Grade carbon tetrachloride and diethyl ether were used as supplied. Dodecane, tetradecane (both from Eastman Organic Chemicals), and octadecane (Matheson, Coleman and Bell) were also used as supplied. Eastman White Label cyclopentanone was distilled twice through a 45 cm column packed with glass helices, retaining the middle 50% each time.

A series of viscometric standard oils, which were mixtures of high boiling straight chain hydrocarbons, were obtained from the Cannon Instrument Co. This company also supplied the precalibrated Ubbelohde viscometers. Silicone oils from Dow Corning Co. were also used during the calibration of the rolling ball viscometer. The viscosities of the silicone oils were measured with the Ubbelohde viscometers.

Density Measurements

The change of liquid volume with pressure was measured using a bellows dilatometer (3, 11). A detailed description of the apparatus is given elsewhere (10). The internal volume of the dilatometer was 20 ml. The change of volume of the bellows was measured with a slide wire, using the potential ratio technique (11). The dilatometer operation was calibrated at atmospheric pressure, using a special apparatus (10).

Dielectric Constant Measurements

The dielectric constants of the hydrocarbons were measured at pressures up to 4 kbar in the cell shown in Fig. 1. Pressure was transmitted to the cell interior by a teflon piston and cylinder of the type described by Jamieson (12). The leads from the cylindrical platinum electrodes through the Supramica plug (Fig. 1) were cemented with Armstrong Epoxy Resin cement. Samples of the latter cement, cured for 4 days at 80°, were placed in contact with the hydrocarbon liquids for 4 months and no change in the dielectric constants of the liquids was observed.

Capacitance measurements were made with a General Radio Impedence Bridge, Model 1608-A. The bridge was calibrated with an accuracy of ±0.02 pF. The capacitance measurements were conducted at 1 kc. The total system capacitance at 30° and atmospheric pressure was determined with a series of standard dielectrics between the cell plates. The standards used were air ($\varepsilon = 1.0005$),

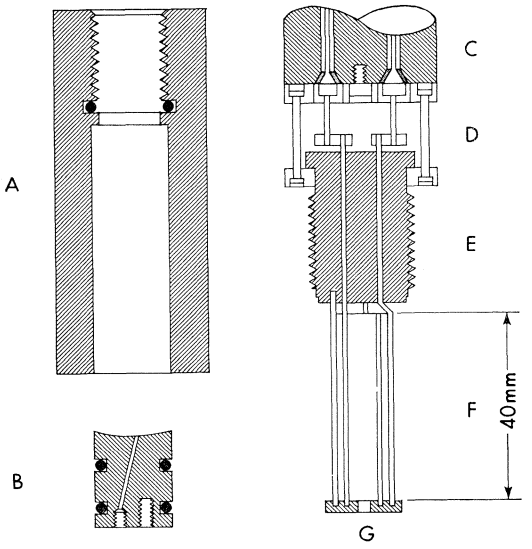

FIG. 1. Dielectric constant cell (not to scale): A, teflon cylindrical cell walls; B, teflon piston with "O" ring seals; C, pressure vessel closure piston; D, stainless steel and teflon cell holder; E, Supramica Ceramoplastic plug; F, cylindrical platinum electrodes (0.25 mm thick); G, teflon cap.

cyclohexane ($\varepsilon = 2.023$), carbon tetrachloride ($\varepsilon = 2.239$), benzene ($\varepsilon = 2.274$), and diethyl ether ($\varepsilon = 4.335$). The total capacitances at atmospheric pressure ranged from 40 to 70 pF. A calibration graph was plotted of total capacitance vs. dielectric constant of the liquid in the cell.

Viscosity Measurement

A rolling ball viscometer (13, 14) was used to measure the viscosities of the liquids at pressures up to 4 kbar. The principle of operation was to measure the amount of time required for a ball to roll a given distance down a tilted tube full of liquid. A steel ball, 6.35 mm diameter, and a precision bore quartz tube, 7.99 ± 0.01 mm internal diameter, were used. The roll tube with ball-detector coils is illustrated in Fig. 2. The roll tube was inserted in a tiltable pressure vessel.

Full details of the viscometer construction and operation are given elsewhere (10). Briefly, the roll tube and detector device were placed within a cylindrical stainless steel holder that contained a bellows section for the transmission of pressure. Electrical connections to the interior of the holder, through end plate H (Fig. 2), were made with Latronics Corp. metal to ceramic terminal seals. The detector coils, in slots E, were each 100 turns of 30 gauge magnet wire (Belden Wire Co.). The coils were wound in series.

The electrical circuit and timing device used in conjunction with the detector coils are described in ref. 10. The time required for the ball to roll between the two detector coils was measurable with a precision of ±0.3%.

All the components of the viscometer and holder were cleaned in a Soxhlet extractor before being assembled. The solvent used was either hexane or the hydrocarbon to be investigated. Soldered components underwent a preliminary extraction with water.

The assembled viscometer and holder were tested for leaks on a vacuum line, then filled by a technique similar to that used for the filling of the conductance cells (10).

The viscometer was calibrated with a series of liquids of known viscosity. The calibration plot for 30 °C is shown in Fig. 3. The variables of the system were correlated with the expression (14)

$$[1] \qquad \eta = \kappa(\rho_S - \rho_L)t$$

where η is the viscosity, κ is the viscometer coefficient, ρ_S and ρ_L are the densities of the ball and the liquid, respectively, and t is the roll time. The variation of ρ_S with

4000	0.778	0.803	0.813	0.827	0.815	0.836	0.802
4500	0.767	0.796	—	—	0.807	0.828	—
Molar volume (cm^3) at 1 bar	117.03	132.46	148.38	164.53	95.32	129.08	134.9
Density (g/cm^3) at 1 bar	0.6165	0.6505	0.6753	0.6942	0.7357	0.7606	0.639

*Estimated from data in ref. 3.

pressure and temperature was negligible; $\rho_S = 7.78 \pm 0.02$ g/cm³ under all conditions used. Values of ρ_L were taken from Table I.

The variation of $(\rho_S - \rho_L)t$ with η was determined at several temperatures in the range 0–60 °C for each of the two angles of inclination. The values of $(\rho_S - \rho_L)t$ plotted in Fig. 3 were obtained for 30 °C by graphical interpolation. Similar plots were made for 0 and 60 °C. The values of η were taken from ref. 15 or were measured with an Ubbelohde viscometer. All of the standards used, except the two cyclic hydrocarbons, fell on a smooth curve at each temperature (Fig. 3). The cause of the deviation of the cyclic compounds is unknown, but it may have to do with an effect of liquid structure on eddy currents. The flow of liquid past the ball in the tube was probably turbulent, indicated by the fact that the value of κ was viscosity dependent under the present conditions (see ref. 14).

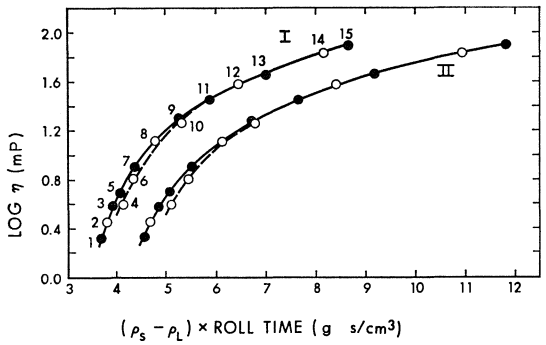

FIG. 3. Viscometer calibration plot, 30 °C: I, 30° angle of inclination; II, 20° angle. The liquids used were: *1*, *n*-pentane; *2*, *n*-hexane; *3*, 2,2-dimethylbutane; *4*, cyclopentane; *5*, *n*-octane; *6*, methylcyclohexane; *7*, *n*-decane; *8*, *n*-dodecane; *9*, *n*-tetradecane; *10*, Dow silicone oil (2 cts); *11*, Cannon standard oil S3; *12*, *n*-octadecane; *13*, Dow silicone oil (5 cts); *14*, Cannon standard oil S6; *15*, Dow silicone oil (10 cts).

The viscosities of the hydrocarbons under pressure at 30 °C were obtained by evaluating $(\rho_S - \rho_L)t$ and reading the corresponding values of log η from Fig. 3. It was assumed that the calibration plot obtained at atmospheric pressure was valid at higher pressures, the change in the roll time arising only from the increased viscosity. This assumption is reasonable because the dimensions of the ball and of the roll tube were reduced by only 0.1 and 0.3%, respectively, at 4.5 kbar.

Results and Discussion

Pressure Dependence of Density

The pressure–volume relationships were determined for *n*-pentane, *n*-hexane, *n*-heptane, *n*-octane, cyclopentane, and methylcyclohexane at 30° and pressures up to 4.5 kbar. The results are reported as relative volumes, i.e. the ratio of the volume at pressure p to that at 1 bar, and are listed in Table I. The absolute densities and molar volumes at 1 bar are also given.

There was no hysteresis in the measurements. The value of the potential ratio obtained from the dilatometer at atmospheric pressure after a pressure cycle agreed with the value obtained before the pressure was applied, to within 0.1%. At least two runs were done for each compound, and the results were averaged. The reproducibility of the relative volumes measured from one experiment to the next was ±0.25% at 4000 bars, and was better at lower pressures.

Molar volume (cm^3) at 1 bar	105.61	89.2
Density (g/cm^3) at 1 bar	0.7018	0.943

Pressure–volume measurements on 2,2-dimethylbutane were not done. The relative volumes of this compound at 30° at different pressures were estimated graphically from Bridgman's data (3), and are listed in Table I.

Table II lists the relative volumes measured for diethyl ether at 30° and cyclopentanone at 25°. These measurements are related to other studies in this laboratory. It was also noted that if the temperature of cyclopentanone at 3500 bars was lowered to 20°, the sample froze. This tends to support the interpretation (16) that the rapid decrease in the radiation yield of isomerization of cyclopentanone to 4-pentenal, as the pressure was increased from 3000 to 5000 bars at about 25°, was due to the solidification of the sample.

Where comparison with other literature values is possible (3, 5, 6), the present results agree with them to within 0.2%. The only exception was *n*-pentane, for which the present result at 4 kbar was 1% higher than that estimated graphically from Bridgman's data at 0, 50, and 95° (3).

Pressure Dependence of Dielectric Constant

The total capacitance of the system was determined as a function of pressure with a given liquid in the cell, and the dielectric constant was read directly from the calibration graph. The sensitivity of the system was approximately 10 pF per unit change in dielectric constant. The agreement between the total capacitance values before and after a pressure cycle was usually within 0.5%, unless a phase change had occurred. The cell became distorted if the sample froze in it. The change in cell capacitance caused by the decrease in the electrode dimensions with increasing pressure amounted to an error of 0.06% in the measured capacitance at 4 kbar. This was calculated using the volume compressibility of platinum, which is (2)

$$[2] \qquad \beta = 3.6 \times 10^{-7} - 3.6 \times 10^{-12} p$$

where p is the pressure in kg/cm^2 (1 bar = 1.02 kg/cm^2).

Values of the relative dielectric constant, i.e. the

ratio of the dielectric constant at pressure p to that at 1 bar, are listed for *n*-pentane, *n*-hexane, *n*-octane, cyclopentane, methylcyclohexane, 2,2-dimethylbutane, and carbon tetrachloride at 30° in Table III. The absolute values of the dielectric constant at atmospheric pressure are also given.

The present results for *n*-pentane and *n*-hexane agree with those of earlier workers (8, 9). Our values of the relative dielectric constant at 30° and 2 kbar for *n*-pentane and *n*-hexane are 1.114 and 1.094, respectively, whereas those estimated from the literature are 1.113 (8) and 1.096 (9), respectively.

The Clausius–Mosotti (C.M.) function is

$$[3] \qquad \frac{\varepsilon - 1}{\varepsilon + 2} V = \frac{4}{3}\pi N\alpha$$

where ε is the dielectric constant, V is the molar volume of the liquid, N is Avogadro's number, and α is the molecular polarizability. This function is frequently used to describe the relationship between the molar volume, or density, and the dielectric constant of a medium. It is usually assumed that the C.M. function is independent of the density of the medium, but plots of the left-hand side of eq. [3] against the densities of liquids at high pressures have slightly negative slopes (see Fig. 4 and refs. 2, 7–9). Two possible explanations of the negative slope are (*a*) that the form of the C.M. function is incorrect at high densities (17), and (*b*) that the molecular polarizabilities decrease with increasing pressure (18, 19). Both (*a*) and (*b*) may contribute to the observed effect.

Pressure Dependence of Viscosity

The relative viscosities, i.e. values of the ratio of the viscosity at pressure p to that at 1 bar at the same temperature, of *n*-hexane and *n*-octane at 0, 30, and 60 °C are listed in Table IV. The relative viscosity increased greatly as the pressure was

4000	6.95	8.10	18.41	23.52
η(cP) at 1 bar	0.216	0.390	0.641	0.330

increased from 1–4000 bars; it decreased slightly as the temperature was increased from 0–60°. The temperature effect increased with increasing pressure.

The absolute values of the viscosities at 1 bar are given at the bottom of Table IV.

The relative viscosities of *n*-pentane, cyclopentane, methylcyclohexane, and 2,2-dimethylbutane at 30° and pressures up to 4000 bars are listed in Table V. The absolute viscosities at 1 bar are also given.

The present 30° data for *n*-pentane, *n*-hexane, *n*-octane, and methylcyclohexane may be compared with results of Bridgman (2). The present results for hexane and octane are 6% lower than Bridgman's at 4000 bars, but the discrepancy decreases with decreasing pressure. The cause of the difference is not known. The present result for pentane is 1% lower and that for methylcyclohexane is 2% lower than Bridgman's at 4000 bars.

Although the relative volumes of similar organic compounds are similar at a given pressure, the relative viscosities of the compounds at a pressure of several thousand bars vary over a wide range (2). In the current work the relative volumes of the hydrocarbons at 4000 bars were all in the range from 0.836 to 0.778, whereas the relative viscosities at this pressure varied from 6.95 to 23.5. With the exception of 2,2-dimethylbutane, which has been exceptional throughout this work (1), the relative viscosity at 4000 bars increases with the relative volume at that pressure (Fig. 5). A "large" value of the relative volume at a high pressure implies a small compressibility of the liquid. Thus, when comparing several similar liquids, a large relative viscosity is linked to a small compressibility; both of these properties are probably linked to a close molecular packing in the liquid.

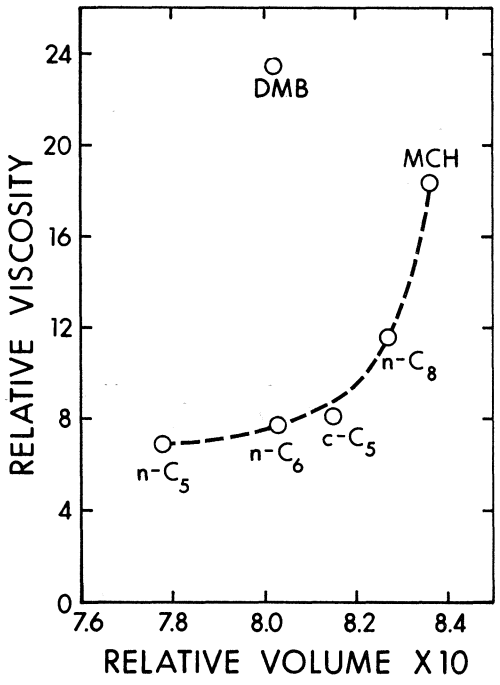

FIG. 5. Relative viscosity vs. relative volume for several hydrocarbons at 4000 bars and 30 °C. DMB is 2,2-dimethylbutane and MCH is methylcyclohexane.

The abnormally high value of the relative viscosity of 2,2-dimethylbutane (Fig. 5) supports the observation of Bridgman (2) that the vis-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

cosity–pressure effects are largest for those liquids with the most complicated molecules. For example, isocompounds showed larger viscosity increases than did the isomeric normal compounds (2). It is clear that molecular structure and liquid structure have great influences on the magnitude of the effect of pressure on viscosity.

The free volume theory of liquids adequately describes the pressure and temperature dependences of the viscosities of the liquids *n*-pentane, *n*-hexane, and *n*-octane, provided one assumes that the "limiting specific volume" increases with increasing temperature and decreases with increasing pressure in ways similar to the changes in the specific volume of a solid (20). The theory was applied only to liquids whose viscosities were not described by the Arrhenius equation (20). The theory utilizes empirical constants which cannot be evaluated for the other hydrocarbons used in the current work, due to lack of appropriate data. It would be especially interesting to attempt to apply the theory to 2,2-dimethylbutane.

Infrared studies on rotational isomerism. III. 2-Chloro- and 2-bromo-ethanol

PAUL BUCKLEY, PAUL A. GIGUÈRE, AND MICHEL SCHNEIDER
Département de Chimie, Université Laval, Québec, Québec

Received August 19, 1968

The relative intensities of the C—X stretching bands of the *gauche* and *trans* isomers in the vapor were measured as a function of temperature up to 165 °C for 2-chloroethanol, and up to 130 °C for 2-bromoethanol. From these the enthalpy differences between the two isomers were found to be 1.20 and 1.45 ± 0.1 kcal mole^{-1} respectively for the two halogenated ethanols. Similar measurements on the O—H stretching bands gave values higher than the above by 0.45 kcal mole^{-1} for both compounds. This apparent discrepancy is interpreted as due to a second *gauche* isomer, the OH group of which is not engaged in intramolecular hydrogen bonding, and which is less stable than the *trans* isomer.

A study of the isotopic molecule $ClCH_2$—CH_2OD has led to unambiguous assignment of the OH bending and torsional frequencies. The spectra of the solid show that 2-chloroethanol can exist in two different crystalline phases: a stable one consisting of *gauche* molecules only, and a metastable one containing both isomers.

L'intensité relative des bandes de valence C—X dans le spectre infrarouge de la vapeur a été mesurée en fonction de la température jusqu'à 165 °C pour le 2-chloroéthanol et jusqu'à 130 °C pour le 2-bromoéthanol. De ces mesures on tire les valeurs 1.20 et 1.45 ± 0.1 kcal mole^{-1} respectivement pour les différences d'enthalpie entre les isomères *gauche* et *trans*. Par contre des mesures semblables faites sur les bandes de valence O—H conduisent à des valeurs de ΔH plus élevées d'environ 0.45 kcal mole^{-1} pour les deux composés. Ce désaccord est probablement dû à la présence d'un troisième isomère, de configuration *gauche*, mais sans liaison hydrogène intramoléculaire.

Une étude de la molécule isotopique $ClCH_2$—CH_2OD a permis d'identifier sans ambiguité les bandes de déformation OH. Les spectres du 2-chloroéthanol à l'état solide ont révélé deux phases cristallines distinctes: l'une stable, ne contenant que l'isomère *gauche*, l'autre métastable, faite d'un mélange des deux isomères.

Introduction

The question of rotational isomerism in 2-chloro- and 2-bromo-ethanol (also called ethylene chloro- and bromo-hydrin) was settled much sooner, at least qualitatively, than in the case of ethylene glycol discussed in Part I of this series (1). Indeed, the very first spectroscopic studies revealed the presence of more than one conformer in the liquid (2, 3) and the vapor as well (4, 5). Further studies have led to the correct structure for the *gauche* and the *trans* isomers, the former being the most abundant owing to its stabilization by internal hydrogen bonding. Quantitatively, however, there remains some uncertainty as to the energy difference ΔH between the two conformers. Zumwalt and Badger (5) found this to be 2 kcal mole^{-1} for 2-chloroethanol based on the temperature dependence of the relative intensities of the second overtone O—H bands, whereas similar measurements by Mizushima *et al.* (6), but on the fundamental C—Cl stretching bands, led to a value only half as large. Still a third value, 1.20 ± 0.09 kcal mole^{-1}, has been reported by Krueger and Mettee (7) from high resolution studies of the fundamental O—H bands in dilute solutions in carbon tetrachloride.

2-Bromoethanol has not received nearly as much attention as 2-chloroethanol. The last named authors found its enthalpy of isomerization to be about the same as that for 2-chloroethanol within the accuracy of their measurements. In contrast Kuhn *et al.* (8) estimated it to be practically zero. At the time the present work was carried out no infrared spectra of the pure compound had been published. A recent paper on the four 2-haloethanols (9) has just come to our attention.

In view of the above, and considering that the low-frequency vibrations of these molecules are strongly affected by rotational isomerism, it seemed to us that a systematic study extending into the far infrared, and covering the three physical states was desirable. This is reported here except for crystalline 2-bromoethanol which could not be obtained despite numerous attempts.

Experimental

The experimental conditions were essentially the same as before (1). For the intensity measurements special care

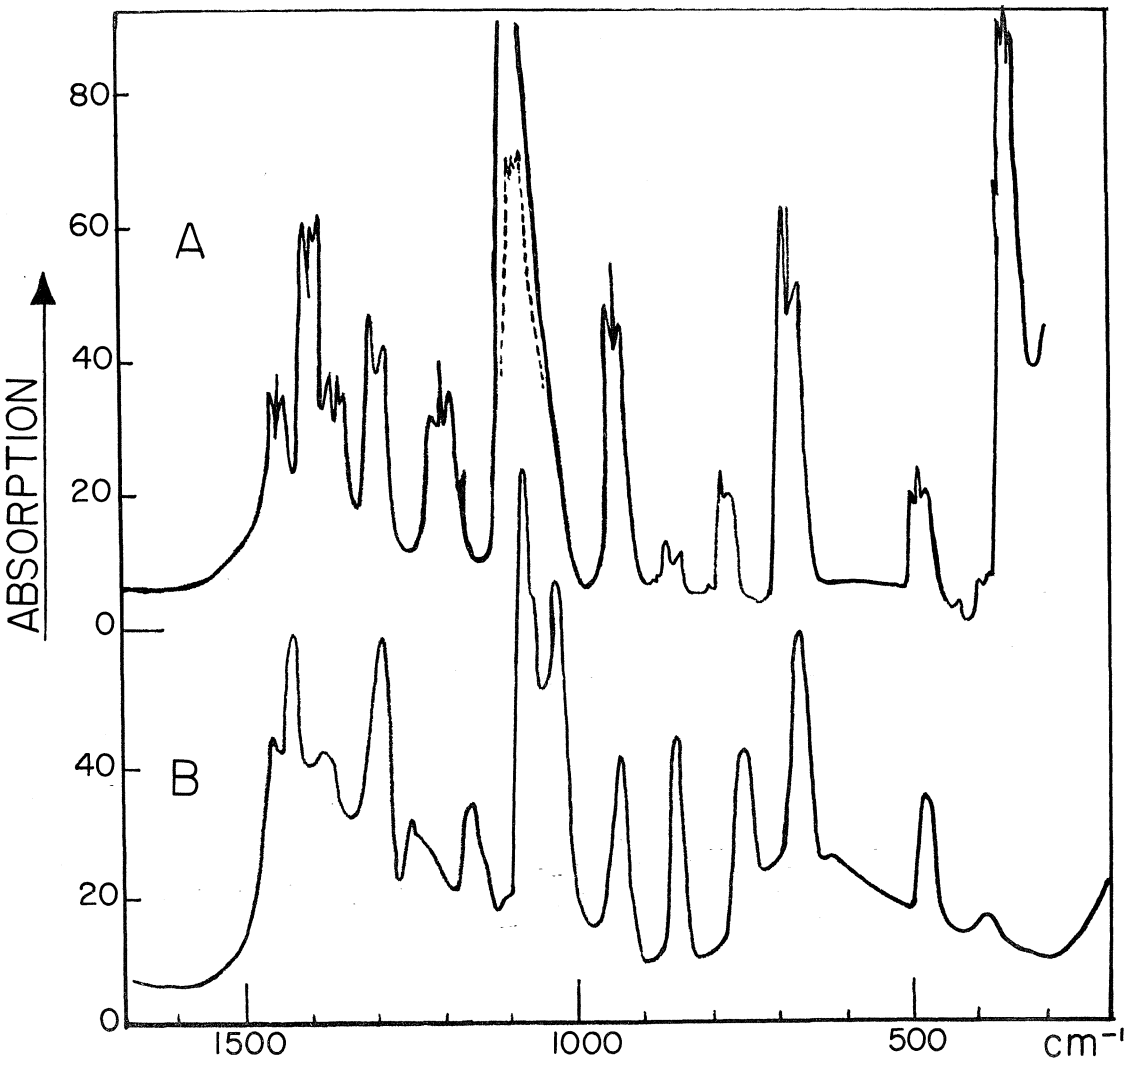

FIG. 1. Infrared spectra of 2-chloroethanol in the vapor (A) and liquid (B) at room temperature.

was exercised to insure that the temperature of the absorption cells was uniform throughout. Calibrated copper–constantan thermocouples and a precision potentiometer gave readings of more than sufficient accuracy. A short absorption cell 10 cm long made of brass was used for 2-chloroethanol. The cell and the liquid sample in a side tube were placed in an oven at 65 °C for about 1 h to reach equilibrium. Thereafter only the temperature of the cell was raised. A multiple reflection cell of 2.5 m total path was also used. With 2-chloroethanol the evacuated cell was briefly put in contact with the liquid at room temperature (vapor pressure of about 6 mm Hg). This operation had to be repeated periodically for over 1 h as appreciable absorption took place on the walls of the cell. For 2-bromoethanol, which is less volatile, a flow system with nitrogen as carrier gas was needed to reach equilibrium within reasonable time. Decomposition was noticeable at the higher temperatures after a while, as shown by weak absorption bands at 1760, 1135, and 860 cm^{-1} (aldehydes and ketones). However, these did not interfere with intensity measurements. The commercial samples of 2-chloroethanol (Eastman Organic Chemicals) and 2-bromoethanol (Matheson, Coleman and Bell) were vacuum distilled, the latter three times to remove all traces of impurities from the spectra. The sample of OD substituted 2-chloroethanol was prepared through synthesis of the borate ester (10) followed by hydrolysis with 99.6% pure D_2O. The operations were

carried out under controlled atmosphere to exclude moisture. From the intensity of the residual OH bands the extent of deuteration was of the order of 90%.

Results

The absorption spectra at room temperature of the two compounds between 1500 and 200 cm^{-1} are shown in Figs. 1 and 2 for both vapor and liquid. The 3 μ region is shown separately in Fig. 3.

Vibrational Spectra

Detailed assignment of the bands to normal modes of these two molecules is not feasible in all cases because of strong coupling or near coincidence of certain bands. At any rate the assignments given in Table I seem straightforward and need not be discussed further except in connection with rotational isomerism. For that purpose the O—H and the C—X stretching modes are the most useful. Both give rise to two distinct bands with temperature dependent relative intensities. Approximate calculations of the P–R branch maximum separation (Table II) based on moments of inertia from microwave spectra (11)

confirm that the high- and the low-frequency components of the C—X pairs of bands must be assigned to the *trans* and the *gauche* conformers respectively, in agreement with previous inferences.

In the spectra of the deuterated chloroalcohol the band at 1352 cm^{-1} has disappeared and is replaced by a weak pair at 985–1005 cm^{-1}, which confirms our assignment to the OH bending mode of the *gauche* isomer. The corresponding bands of the *trans* conformer are not so readily identified owing to their relative weakness. However, an appreciable decrease in intensity of the band at 1200 cm^{-1} upon deuteration indicates some contribution from an OH vibration. Normally this should be shifted to about 900 cm^{-1} in the OD compound, which coincides with a strong, slightly displaced CH_2 rocking band. As for the OH torsion, the strong peak at 340 cm^{-1} has now vanished almost completely, whereas absorption in the 220 to 250 cm^{-1} region has increased markedly.

Intensity Measurements

The band intensities were compared by the two methods of optical density at the maximum and integrated absorption intensities (Figs. 4, 5). Besides the well-known limitations of these methods, the method of optical density of the C—Br stretching bands in the *gauche* isomer presented further difficulty because of the irregular contour near the maximum. This may be due to an isotope effect, although it is not clear why

the *trans* band is not similarly affected. At any rate the optical density measured at 570 cm^{-1}, corresponding roughly to the R branch maximum of one of the presumed isotope bands, gives roughly the same slope of the ln D_t/D_g curve (Fig. 5) as that from integrated intensity measurements. Treatment of the data by the least squares method led to the values of ΔH shown in Table II along with those of previous workers. The entropy differences were evaluated by the method of Mizushima (12) using the optical density measurements, and as standard, or reference band, one of the C—H stretching at 2890 cm^{-1}. The possible effect of some slight decomposition of the vapor at the higher temperatures is exaggerated in the plotting of Fig. 6.

Spectra of the Solid

The first few spectra of 2-chloroethanol in the solid state were obtained by the usual technique of deposition from the vapor on a salt plate cooled to about −170°. This invariably yielded a glassy transparent solid with roughly the same absorption spectrum as the liquid. Annealing by controlled warming induced crystallization, as did also a fast deposition rate. The spectra of these crystals (I, in Fig. 7) show quite conspicuously the disappearance of the characteristic bands of the *trans* isomer in the liquid as observed previously in Raman effect (3). Then, on one occasion, while warming very slowly a sample deposited on a polyethylene disc for the far infrared spectra, a new crystalline form (crystal II) was obtained accidentally which exhibited four absorption bands, instead of only two, below 300 cm^{-1}. Duplication of this phenomenon on a salt disc

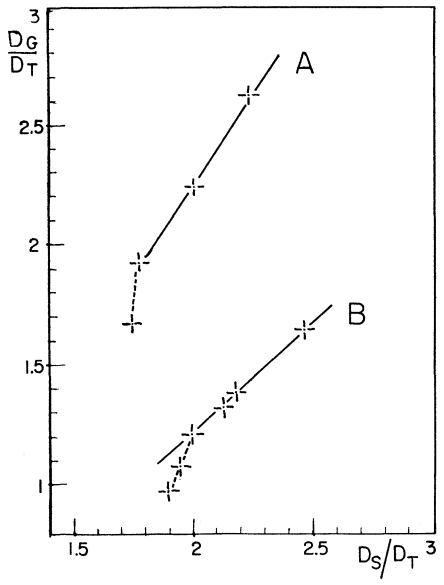

FIG. 6. Entropy relationships for 2-chloroethanol (A) and 2-bromoethanol isomers (B).

(CsBr) turned out to be extremely difficult. This may be due partly to the strongly polar nature of the ionic crystal, as opposed to a molecular solid, and also partly to the greater thermal conductivity of the salt plate. With a poor heat conductor like polyethylene a temperature gradient could develop between the center and the rim of the support, which seemed to favor formation of the metastable phase. Eventually another method was found for preparing crystal II by very slow cooling of crystal I below −90°. As far as could be judged from visual observation (crystal II has a powdery aspect), the transition occurred through melting, somewhere around −120°. On warming up, crystal II changed into an amorphous translucent solid in the neighborhood of −100° well before melting for the second time. The complex nature of the new crystalline phase is confirmed by the reappearance of the strong bands of the *trans* isomer (Table III).

As for 2-bromoethanol, as previously experienced (13), it could not be crystallized in spite of numerous attempts, for instance by quick quenching in liquid nitrogen, rubbing and shearing of a film of the supercooled liquid (around −100°), application of ultrasonics, etc. This is all the more surprising as the three other 2-haloethanols can be crystallized without difficulty.

Discussion

Our knowledge of the problem of rotational isomerism in the 2-haloethanols rests mainly on spectroscopic evidence (14) as the other methods have not provided complete or unambiguous evidence. For instance, an electron diffraction study (15) has established the structure of the *gauche* isomer with an intramolecular hydrogen bond, but the results were interpreted in terms of that isomer only. An independent reinvestigation (16) has led to essentially the same conclusions. It would seem that the method is not sensitive enough to detect the less abundant conformer. One fundamental difficulty here is the uncertainty as to temperature of the vapor at the moment of diffraction (17).

It is interesting to compare the frequency

difference between the "free" and the "bonded" O—H stretching fundamentals for the chloro (40 cm^{-1}) and the bromo compound (50 cm^{-1}) with that for ethylene glycol (33 cm^{-1}). As explained before, these relatively small shifts are due to the non-linearity of the intramolecular hydrogen bond. By contrast the OH bending frequencies are strongly shifted. As for the OH torsional frequency in the *gauche* conformer, it shows surprisingly little correlation with the strength of the hydrogen bond, by comparison with the values in ethylene glycol, 375 cm^{-1}, and in 2-fluoroethanol, 343 cm^{-1} (18). On that basis the barrier to free rotation of the hydroxyl in the *gauche* conformer would have roughly the same height, 3–4 kcal $mole^{-1}$ in these four molecules.

Regarding our intensity measurements the following points are noteworthy. (*a*) Both the data from O—H and C—X stretching bands give a higher ΔH for the bromo than for the chloro alcohol. The difference seems real as it lies outside the uncertainty of our measurements. This is in agreement with the magnitude of the *gauche*-to-*trans* shifts of the O—H stretching frequencies (40 cm^{-1} in the chloro vs. 50 cm^{-1} in the bromo alcohol). Presumably, this could be due to the larger size of the Br atom, which brings it closer to the proton in a strained intramolecular hydrogen bond, and (or) to the greater mass of Br (more than double that of Cl) which changes the force constants throughout the whole molecule. In that connection it is interesting that both 2-haloethanols have been found recently by microwave spectroscopy (11) to have the same azimuthal angle in the *gauche* configuration, 64 $\pm$ 2°. This is appreciably smaller than first believed, 74°, from electron diffraction data (15, 16). Intuitively one would expect that angle to be a bit smaller than in 1,2-dichloroethane, 71°.

(*b*) Our results show definitely that the ΔH based on the O—H stretching bands are greater than those from the C—X bands for both haloethanols. (The discrepancy between our value for 2-chloroethanol and that of Zumwalt and Badger (5) is understandable considering the vagaries of the photometric method.) The explanation suggested before (6) of a third isomer, that is *gauche* but without intramolecular hydrogen bond, in the vapor seems the most plausible. In fact other experimental evidence points to the possibility of more than two orientations for the OH group in these molecules. For instance three distinct O—H stretching bands have been reported in the second and third overtones for the vapor (4, 5) as well as in the first overtone for dilute solutions (19). This multiplet structure seems to be a common occurrence, as found long ago (20), in saturated primary alcohols. Pending more complete data on this non-hydrogen-bonded *gauche* conformer, its relative energy may be taken as about 1 kcal $mole^{-1}$ above that of the *trans* by analogy with 1,2-dichloroethane. Based on our optical density data the relative populations of the three species are estimated to be as shown in Table II.

Lastly the existence of two distinct crystalline phases in 2-chloroethanol, and the transition into an amorphous, or plastic state prior to melting are rather surprising. Such behavior has been observed so far only in the so-called globular molecules, i.e. molecules which describe a symmetrical figure of revolution in space, such as a spheroid, e.g. CH_4, or an ellipsoid, e.g. $(CH_2CN)_2$. Now, 2-chloroethanol is not a globular molecule in either conformation. It may be that in condensed phases the *gauche* and the *trans* conformers have nearly equal energy due to stabilization by intermolecular hydrogen bonding. This would make orientation into the most stable crystalline arrangement rather sluggish, and a metastable phase could ensue under certain conditions. The same explanation may account for the observation that the relative intensity of the *gauche* and *trans* C—Cl stretching bands changes very little with temperature (21). In conclusion, this phenomenon certainly deserves further investigation by other physical methods such as calorimetry and X-ray diffraction.

The Wallach rearrangement. Part V.[1] Acid catalyzed hydrolysis of azobenzene-4-hydrogen sulfate[2]

E. BUNCEL AND W. M. J. STRACHAN
Department of Chemistry, Queen's University, Kingston, Ontario

Received September 18, 1968

In relation to the intermediacy of azobenzene-4-hydrogen sulfate in the Wallach rearrangement of azoxybenzene, the potassium salt has been characterized and subjected to examination under acidic conditions. A pK_a value of -2.14 has been obtained, for N-protonation. The sulfate salt hydrolyzes to *p*-hydroxyazobenzene in acid media and the rate of the reaction has been measured over the region 22–42% H_2SO_4 at 25° spectrophotometrically. A correlation between rate and acidity function indicates that a two-proton process is involved; a reactive species is proposed having a nitrogen and the phenolic oxygen protonated. The relevance of these findings to Wallach rearrangement studies is discussed.

Canadian Journal of Chemistry, **47**, 911 (1969)

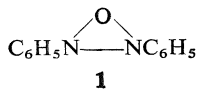
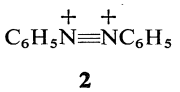
The mechanism of the acid-catalyzed Wallach rearrangement, the conversion of azoxybenzene and its derivatives into *p*-hydroxyazobenzenes in strong sulfuric acid solutions, has received considerable attention recently (1–10). Discussion has centered mainly on the intermediacy of an N,N-oxide intermediate **1**, or its protonated forms (5), as opposed to a dicationic intermediate **2** (4, 9). Some authors have proposed mechanisms which involve both **1** and **2** in the reaction schemes (3, 6). Of direct consequence to the reaction mechanism was the observation of a two-proton process in a kinetic study of the rearrangement of azoxybenzene (10), which was subsequently confirmed and extended to substituted azoxybenzenes (2, 3).



1



2

There appears to be general agreement that in the product-forming step the reaction intermediate(s) reacts with a nucleophile derived from the solvent. However, opinions on the nature of the nucleophile are divided: some authors consider solvent water to act as the nucleophilic species (4, 6), others consider bisulfate ion to be the effective nucleophile (2, 3, 9), while still others do not differentiate between these (5). In one recent study (3) bisulfate ion was ascribed a specific role in hydrogen-bond formation when attached to an ortho position of the protonated N,N-oxide intermediate, in the "abnormal" cases when the Wallach rearrangement leads to *o*-hydroxyazo product. Since an arylazo hydrogen sulfate has never been isolated in a Wallach rearrangement reaction, it has generally been assumed (2, 3, 8, 9) that the postulated hydrogen sulfate becomes hydrolyzed to the hydroxyazo product in the reaction medium or during isolation. There has only been one report of an indirect observation of an azoaryl hydrogen sulfate: cryoscopic, conductivity, and spectral evidence was given that in the rearrangement of azoxybenzene in $\geqslant$ 100% H_2SO_4 the first product formed was the hydrogen sulfate (2).

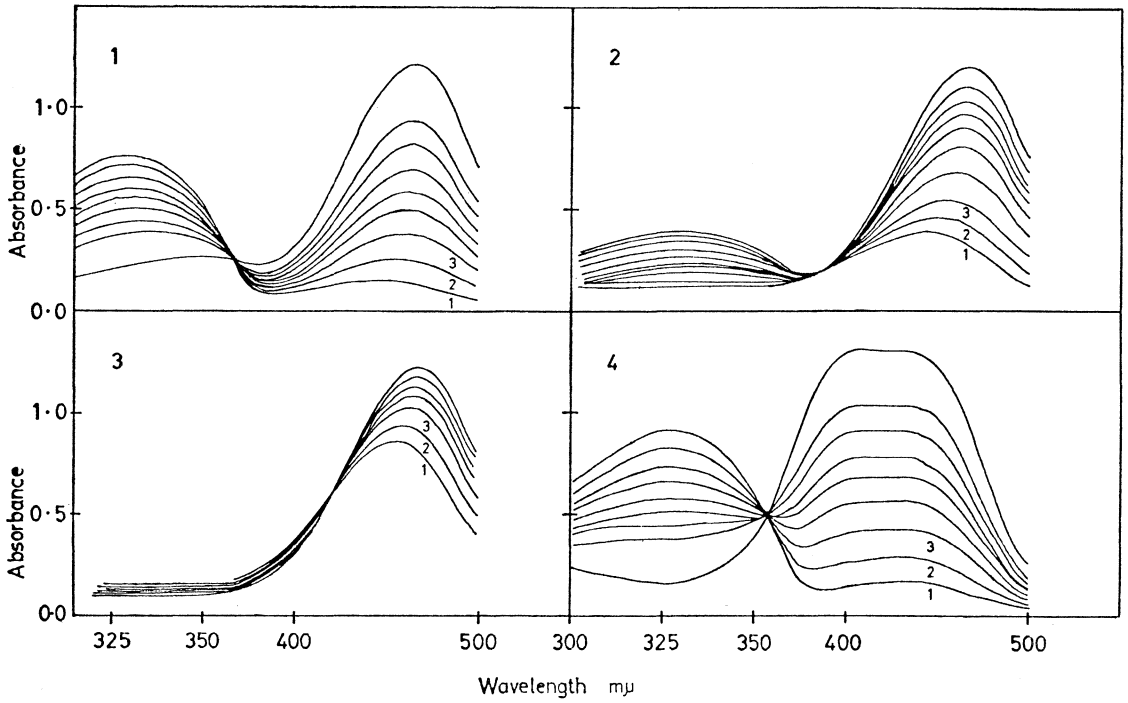
Previously we suggested (4) the possibility that the dication **2** might become stabilized in anhydrous acids where water as nucleophile is not available. In order to obtain further information on the intermediacy of azobenzene-4-hydrogen sulfate for azoxybenzene rearragement in sulfuric acid we have now prepared this material, as the stable potassium salt, and subjected it to examination under acidic conditions. We report here the spectral characterization of this compound, its protonation behavior, and the kinetics of its hydrolysis to *p*-hydroxyazobenzene in aqueous sulfuric acid solutions.

Results and Discussion

Spectral Characterization

Azobenzene-4-hydrogen sulfate was prepared by sulfonation of *p*-hydroxyazobenzene and was isolated as the potassium salt, as described in the Experimental section. The ultraviolet–visible spectrum of this compound in 95% ethanol is similar to that of *p*-hydroxyazobenzene, but in basic medium the spectra are widely different.

[1]Part IV: Tetrahedron, **24**, 6671 (1968).
[2]A more systematic name for the title compound would be 4-phenylazophenyl hydrogen sulfate.



FIGS. 1–4. Sample kinetic runs for the acid hydrolysis of azobenzene-4-sulfate at 25 °C.

Figure 1, reaction medium, 24.0% H_2SO_4; substrate concentration, 38.8×10^{-5} *M*; followed in situ in 0.100 cm cell. Scan times noted are: 1–5 min, 2–26 min, 3–55 min, final scan 22 h. Figure 2, reaction medium, 34.3% H_2SO_4; substrate concentration, 3.22×10^{-5} *M*; followed in situ in 1.00 cm cell. Scan times noted are: 1–1 min, 2–2.5 min, 3–4.5 min, final scan 4.5 h. Figure 3, reaction medium, 41.1% H_2SO_4; substrate concentration, 3.22×10^{-5} *M*; followed in situ in 1.00 cm cell. Scan times noted are: 1–1.2 min, 2–2 min, 3–3 min, final scan 23 min. Figure 4, reaction medium, 24.0% H_2SO_4; substrate concentration, 38.8×10^{-5} *M*; base-quenched and followed in 4.00 cm cell (1.55×10^{-5} *M*). Scan times noted are: 1–6 min, 2–27 min, 3–56 min, final scan 22 h.

The respective absorption maxima and molar extinctions are given in Table I. The shift in absorption maximum for *p*-hydroxyazobenzene which accompanies basification is due to formation of the azophenolate anion, which is structurally not possible with the hydrogen sulfate derivative.

TABLE I

Spectral characteristics of azobenzene-4-sulfate and of *p*-hydroxyazobenzene in neutral and basic solution

	Spectral characteristics in			
	95% Ethanol		1 *N* aq. KOH	
Compound	λ_{max} (mμ)	$\varepsilon \times 10^4$	λ_{max} (mμ)	$\varepsilon \times 10^4$
Azobenzene-4-sulfate	329	2.08	325	1.46
p-Hydroxyazobenzene	348	2.50	400	2.19[a]
			440	2.17[a]

[a]In 1 *N* aqueous KOH, *p*-hydroxyazobenzene exhibits a broad absorption covering the range 400–440 mμ over which the extinction is practically invariant (see also Fig. 4).

Kinetic Measurements

The acid hydrolysis of azobenzene-4-hydrogen sulfate is characterized by certain spectral changes, dependent on the acid concentration. This is illustrated in the following kinetic runs at 25° which were followed by periodic scanning of the visible spectrum. (*i*) 24.0% H_2SO_4 (Fig. 1). In this medium protonation of reactant (on azo function, *vide infra*) is only slight and the initial absorption is mainly in the 325 mμ region. Reaction leads to a gradual decrease in the 325 mμ absorption and an increase in absorption in the 460 mμ region, due to *p*-hydroxyazobenzene formation (extensively protonated in this medium). (*ii*) 34.3% H_2SO_4 (Fig. 2). Protonation of substrate in this medium is appreciable and the initial spectrum now shows roughly equal absorption in the 325 and 440 mμ regions, of which the latter is characteristic of protonated substrate. The reaction is accompanied by an increase in the 460 mμ absorption, as previously

mentioned. (*iii*) 41.1% H_2SO_4 (Fig. 3). The substrate now exists largely as the protonated form, so that the initial absorption is largely shifted to the 440 mμ region. A sharp isosbestic point defines the rate process for the conversion between the two absorbing species and was observed in every kinetic run with this compound. The spectral data obtained in the above runs readily lend themselves to analysis by the Guggenheim method. The first order rate constants for formation of the spectral absorptions at 460 mμ due to *p*-hydroxyazobenzene are 7.91×10^{-5}, 126×10^{-5}, and 656×10^{-5} s^{-1}, in 24.0, 34.3, and 41.1% H_2SO_4 respectively.

As an alternative to the above kinetic method the reaction may be followed by quenching of aliquots of the reaction solution in base, thus taking advantage of the considerably different spectral absorptions of reactant and product in basic medium. An illustrative run is shown in Fig. 4, for 24.0% H_2SO_4. The rate constant for the appearance of the azophenolate ion absorption at 440 mμ is found to be 8.25×10^{-5} s^{-1} by the Guggenheim method. The more usual $\log (A_\infty - A_t)$ vs. time plot, where A_∞ is the theoretical expected absorbance based on *p*-hydroxyazobenzene, gave 8.28×10^{-5} s^{-1} for the rate constant. Hence the rate constants obtained by the alkaline quenching procedure are in satisfactory agreement with those obtained when the reaction is followed directly in the acid medium, and confirm the validity of that method. The total kinetic data obtained by the various methods are listed in Table II.

pK Determination

In order to evaluate quantitatively the extent of protonation of azobenzene-4-hydrogen sulfate in the various acid media, "zero time" spectra were obtained by extrapolation of the spectral sweeps for the various kinetic runs. The family of curves so obtained passes through a fairly sharp

For personal use only.

isosbestic point and shows absorption maxima at 326 and 440 mμ, due to the neutral and protonated forms of substrate. The zero time extrapolated absorbances at these wavelengths are given in Table III. Plots of A^{326} vs. H_0 and A^{440} vs. H_0 (11) are sigmoid, with some scatter of the points. An approximate value of -2.1 is obtained for the pK_a, corresponding to the H_0 value at the inflexion point of each curve. Treatment of the data at 440 mμ, which fell more closely on the absorbance vs. H_0 curve, by the convergence method of Arnett and Wu (12) yields a value of -2.14 for the pK_a of azobenzene-4-sulfate. The pK_a of *p*-hydroxyazobenzene itself is -0.93 (13).

There seems little doubt that the basic center in the equilibrium protonation measured here is the azo function, rather than the negatively charged oxygen of the sulfate moiety. It is likely that the sulfate salt remains completely dissociated throughout the acid region covered in Table III. The dissociation constant of an aryl hydrogen sulfate should not be vastly different from the first dissociation constant of sulfuric acid itself, which is known to be very large, though estimates of its actual magnitude vary (14, 15). Further evidence for nitrogen protonation in the present system is derived from the shift in λ_{max} on protonation, which is very similar to corresponding shifts observed with other azobenzene derivatives (13, 16–18). The azobenzene sulfate ion is a weaker base than *p*-hydroxyazobenzene due to the electron withdrawing character of the SO_3^- group (14, 19). Azobenzene-4-sulfonate has a pK of -3.13 (18). The probable site of protonation is the nitrogen furthest removed from the OSO_3^- substituent, by analogy with considerations applied previously to related azo derivatives (13, 20).

TABLE III

Protonation behavior of azobenzene-4-sulfate

Weight %H_2SO_4	H_0	$\varepsilon^{326} \times 10^4$	$\varepsilon^{440} \times 10^4$
2.0[a]	0.49	2.06	0.17
4.8[a]	0.11	2.07	0.14
13.0[a]	−0.52	2.08	0.23

27.2	−1.54	1.63	0.63
29.8	−1.72	1.52	0.69
32.0	−1.86	1.47	0.85
34.3	−2.02	1.37	0.98
35.4	−2.10	1.31	1.18
36.3[a]	−2.16	1.38	1.30
37.2	−2.22	1.20	1.44
41.1	−2.53	(0.56)[b]	(2.06)[b]
42.1	−2.60	(0.47)[b]	(1.90)[b]

[a]Except for these determinations which were obtained by spectral measurement on individually prepared solutions, all of the above data were obtained by using a stock solution as described in the Experimental section.

[b]These values are dubious due to the very fast hydrolysis of the substrate and the accompanying uncertainty in extrapolation, and hence were not employed in the pK_a determination.

Mechanism of Hydrolysis

Several possible modes of hydrolysis of azobenzene sulfate ion need to be considered. First there is the mechanism described by eqs. [1] and [2], which is essentially similar to the mechanism proposed by Kice and Anderson (19) for the hydrolysis of sodium phenyl sulfate. Among the evidence presented by these authors for the formation of a reactive species by aryl-oxygen protonation was the solvent isotope effect ($k_{D_2O}/k_{H_2O} = 2.43$), an increase in rate with decreased dielectric constant, and the unit slope in the log $k - H_0$ plot. In the present case, an equilibrium protonation on the phenolic oxygen yields the reactive zwitterion SH'^+, which decomposes to products by a unimolecular (A-1) mechanism. The concentration of SH'^+ would be very small over the range of acid concentration studied, so that the N-protonated substrate (eq. [3]) would represent a storage of material in an unreactive form.

[1] $$PhN{=}N.C_6H_4.OSO_3^- + H^+ \underset{K_{SH'^+}}{\overset{\text{fast}}{\rightleftharpoons}} PhN{=}N.C_6H_4.\overset{\overset{H}{|}}{\underset{+}{O}}{-}SO_3^- \ (SH'^+)$$

[2] $$PhN{=}N.C_6H_4.\overset{\overset{H}{|}}{\underset{+}{O}}{-}SO_3^- \xrightarrow[k]{\text{slow}} PhN{=}N.C_6H_4.OH + SO_3$$

The second mechanism involves an initial protonation on nitrogen, to give the species SH^+, followed by a second equilibrium protonation on phenolic oxygen to give the reactive species SH_2^{2+} which decomposes unimolecularly; this is shown in eqs. [3] – [5].

[3] $$PhN{=}N.C_6H_4.OSO_3^- + H^+ \underset{K_{SH^+}}{\overset{\text{fast}}{\rightleftharpoons}} \underset{+}{\overset{H}{\overset{|}{PhN}}}{=}N.C_6H_4.OSO_3^- \ (SH^+)$$

[4] $$\underset{+}{\overset{H}{\overset{|}{PhN}}}{=}N.C_6H_4.OSO_3^- + H^+ \underset{K_{SH_2{}^{2+}}}{\overset{\text{fast}}{\rightleftharpoons}} \underset{+}{\overset{H}{\overset{|}{PhN}}}{=}N.C_6H_4.\underset{+}{\overset{H}{\overset{|}{O}}}{-}SO_3^- \ (SH_2^{2+})$$

[5] $$\underset{+}{\overset{H}{\overset{|}{PhN}}}{=}N.C_6H_4.\underset{+}{\overset{H}{\overset{|}{O}}}{-}SO_3^- \xrightarrow[k']{\text{slow}} Ph{-}\underset{+}{\overset{H}{\overset{|}{N}}}{=}N.C_6H_4.OH + SO_3$$

Thirdly, there is the possibility that the reaction involves C—O bond fission, rather than S—O bond fission as depicted in the above two mechanisms. The last proposal, which would presumably involve nucleophilic attack by H_2O on aromatic carbon, would normally be considered unlikely but cannot be ruled out since the acid catalyzed hydrolysis of certain azoaryl ethers was in fact shown to involve aryl–oxygen bond cleavage (17, 21). In the absence of further evidence, such as from isotopic tracer studies, the last possibility will not be considered further at this time.

The mechanisms of eqs. [1], [2], and [3] – [5] can be tested by means of acidity function correlations (22–25). The rate expression given by eq. [6] can readily be derived (23) for the mechanism of eqs. [1] and [2]. In eq. [6], k_{obs} is the measured pseudo first order rate constant, $c_S/(c_S + c_{SH^+})$ represents the fraction of substrate present in the unprotonated form in a given reaction medium, f_S and $f_{\neq}$ refer to the activity coefficients of neutral substrate and of the activated complex, while f_B and f_{BH^+} refer to the activity coefficients of the standard amine base used to define H_0. The activity coefficient term in eq. [6] is assumed to be zero (22, 23) so that one would expect a plot of the two left hand terms against $-H_0$ to be linear of unit slope.

[6] $$\log k_{obs} - \log \frac{c_S}{c_S + c_{SH^+}} = -H_0 + \log \frac{k}{K_{SH'^+}} + \log \frac{f_S f_{BH^+}}{f_{\neq} f_B}$$

The mechanism of eqs. [3] – [5] is reminiscent of the two-proton process previously considered for the rearrangement of azoxybenzene (4), and analogous rate expressions (eqs. [7] and [8]) can be derived. In eqs. [7] and [8], H_+ is the acidity function applicable to the protonation of a positively charged base, C^+. The available evidence indicates that H_0 and H_+ are parallel functions (26, 27) so that one would expect a plot of the two left hand terms of eq. [7] against H_0 to be linear of unit slope, while the two left hand terms of eq. [8] plotted against $-H_0$ should give a slope of +2, assuming that the activity coefficient terms cancel as is probable at least in eq. [7].

[7] $$\log k_{obs} - \log \frac{c_{SH^+}}{c_S + c_{SH^+}} = -H_+ + \log \frac{k'}{K_{SH_2{}^{2+}}} + \log \frac{f_{SH^+} f_{CH^{2+}}}{f_{\neq}' f_{C^+}}$$

[8] $$\log k_{obs} - \log \frac{c_S}{c_S + c_{SH^+}} = -H_0 - H_+ + \log \frac{k'}{K_{SH^+} K_{SH_2{}^{2+}}} + \log \frac{f_S f_{BH^+} f_{CH^{2+}}}{f_{\neq}' f_B f_{C^+}}$$

The relevant plots are presented in Fig. 5. It is seen that $\log k_{obs} - \log c_S/(c_S + c_{SH^+})$ vs. $-H_0$ gives a linear plot with a slope of 1.97, while $\log k_{obs} - \log c_{SH^+}/(c_S + c_{SH^+})$ vs. $-H_0$ is linear with a slope of 0.97. These results are not consistent with the mechanism of eqs. [1] and [2] but are in good accordance with the predicted values on the basis of eqs. [3] – [5]. Furthermore, examination of eqs. [7] and [8] shows that one should be able to calculate K_{SH^+} by combining the intercepts of the two plots, provided the activity coefficient terms are zero. The value obtained for

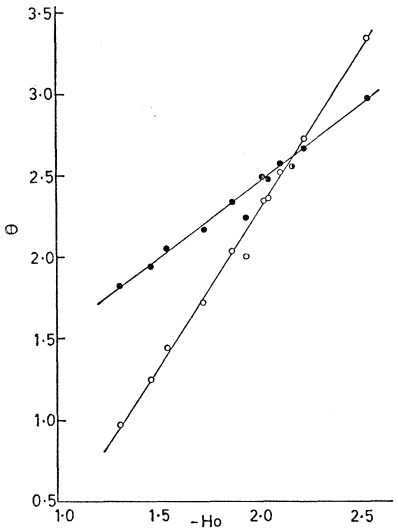

FIG. 5. Correlation between acidity function and rate for the acid hydrolysis of azobenzene-4-sulfate. ○, $\theta = 5 + \log k_{obs} - \log c_S/(c_S + c_{SH^+})$; ●, $\theta = 5 + \log k_{obs} - \log c_{SH^+}/(c_S + c_{SH^+})$.

K_{SH^+} in this manner is 133 which agrees satisfactorily with the experimentally determined value of 138 ($pK_a = -2.14$).

Azobenzene-4-hydrogen Sulfate as an Intermediate in the Wallach Rearrangement

The question of the intermediacy of azobenzene-4-hydrogen sulfate in the Wallach rearrangement of azoxybenzene has to be considered in the light of the present study. This has shown that hydrolysis of the sulfate salt proceeds readily over the region 22–42% H_2SO_4, with the half-life in the upper acid region being about 2 min. If the dependence of rate on acidity continued to obey the same function of H_0 then the estimated half-life for reaction in 90% H_2SO_4 would be of the order of 10^{-4} s. It is of course conceivable that a discontinuity between rate and acidity can arise over such a large extrapolation. A few exploratory experiments were performed to test this possibility. Spectra were taken of solutions of the sulfate salt in 56.1, 75.3, and 89.3% H_2SO_4 within minutes of their preparation: the spectra were virtually identical with the *p*-hydroxyazobenzene spectrum in these media.

Despite the above considerations one may not conclude that azobenzene hydrogen sulfate is not initially formed in the Wallach rearrangement. In strong sulfuric acid solutions the nucleophilic species present predominantly is the bisulfate ion. According to the calculations of Robertson and Dunford (28), when hydration of the hydrogen ion is taken into account, the bisulfate ion concentration exceeds that of the available water above 40% H_2SO_4. The water activity diminishes by about 10^4 on going from 40 to 95% H_2SO_4 but the bisulfate ion concentration remains within a factor of 10 over the same acid range (28). It would seem probable that unless there was a dramatic reversal in the relative reactivities of the two nucleophiles, then bisulfate ion would be the actual nucleophilic species in Wallach rearrangement studies, generally carried out in 65–95% H_2SO_4. However, the azobenzene hydrogen sulfate initially formed would, under these conditions, become rapidly hydrolyzed to *p*-hydroxyazobenzene which would then be the observed product.

Experimental

Materials

The potassium salt of azobenzene-4-hydrogen sulfate was prepared by a modification of the method described by Burkhardt and Lapworth (29). Pyridine – sulfur trioxide adduct was prepared from pyridine (3.33 g) and stabilized SO_3 (2.78 g) under nitrogen at 0°. The white solid was suspended in 20 ml benzene and after heating till reflux, *p*-hydroxyazobenzene (4.95 g) was added as a suspension in 15 ml benzene. After 4 h refluxing, the suspension of yellow-orange precipitate which had formed was poured into an excess (40 ml) of 1 *N* KOH. After stirring for 2 h the solid was filtered, washed extensively with absolute ethanol, followed by ether, and then dried over P_2O_5 at 0.1 mm/25°. The bright-yellow powder decomposed over the temperature range 200–235°.

Anal. Calcd. for $C_{12}H_9N_2O_4SK$: C, 45.56; H, 2.85; N, 8.85; S, 10.13. Found: C, 45.22; H, 2.63; N, 8.73; S, 9.80.

p-Hydroxyazobenzene (Eastman) was recrystallized from 40% ethanol, m.p. 154.5–155.5° (lit. (30) 155–156°). Sulfuric acid solutions were made up by dilution of Reagent grade acid and standardized by titration with sodium hydroxide.

Kinetic Procedures

Rate data were generally obtained by spectral examination of the reaction solutions contained in a thermostatted cell (25.00 ± 0.03°) mounted in a Unicam SP800B ultraviolet–visible spectrophotometer. These kinetics were conducted by two main methods. In the first method a 1.00 ml sample of a 1.61×10^{-3} *M* aqueous solution of azobenzene-4-sulfate was placed in a 50 ml volumetric flask in a thermostatted bath and made up with pre-thermostatted sulfuric acid, the resulting acid concentration being determined by titration at the end of the kinetic run. This reaction solution was placed in the thermostatted cell and spectra were recorded periodically

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

over the region 300–500 mμ. In the second method the reaction solution was prepared by direct addition of a weighed quantity of the potassium salt to a given sulfuric acid medium and then transferred to the cell. Most of the kinetic runs were carried out in 1.00 cm cells but in a few runs 0.100 cm cells were used, in order to compare directly (at the given concentration of acid and substrate) the rate constant obtained by the above method with the value obtained by the base-dilution method described below.

The base-dilution procedure was similar to that employed previously (4). In a typical run, 1.227 mg of azobenzene-4-sulfate was dissolved in 10.0 ml of 24.0% H_2SO_4 at 25°, to give a 3.88×10^{-4} *M* solution of substrate. This reaction solution, contained in a flask in the thermostatted bath, was sampled periodically and the aliquots (1.00 ml) quenched by adding to precooled 1 *N* KOH solution which was subsequently made up to 25 ml with the aqueous base. The spectra of these quenched solutions were recorded in 4.00 cm cells over the range 300–500 mμ.

Rate constants were calculated either by the Guggenheim method or from $(A_\infty - A_t)$ vs. time plots. In the case of runs monitored *in situ* the absorbance changes at 460 mμ were used, while in the case of the base-quenched runs the absorbance changes at 440 mμ were so treated; these wavelengths correspond to λ_{max} for *p*-hydroxyazobenzene in acidic and basic medium (see footnote in Table I), respectively.

Examination of Azobenzene-4-sulfate in Intermediate Acid Concentrations

The stability of the above potassium salt was examined spectrally in the media 56.1, 75.3, and 89.3% H_2SO_4, at 25°, within minutes of preparation of the reaction solutions. For the last acid concentration, in addition to recording the spectrum in the acid medium, the reaction solution was diluted with base (1.00 ml of 4.18×10^{-4} *M* reaction solution made up to 50 ml with 1 *N* KOH and run in a 4.00 cm cell) and the basic spectrum taken. The above spectra were compared with corresponding spectra of *p*-hydroxyazobenzene over this acid region and were found to be identical within experimental error. The spectral absorptions in the acid media all fell in the range λ_{max} 460 ± 1 mμ, ε 3.87 ± 0.09 × 10^4. The base-quenched solution of azobenzene-4-sulfate after exposure to 89.3% H_2SO_4 showed λ_{max} 400 mμ, ε 2.22 × 10^4; and λ_{max} 440 mμ, ε 2.19 × 10^4 (cf. Table I).

Mass spectrometry of ozonides

J. CASTONGUAY, M. BERTRAND[1], J. CARLES, S. FLISZÁR, AND Y. ROUSSEAU[2]
Département de Chimie, Université de Montréal, Montréal, Québec

Received August 9, 1968

The mass spectra of some ozonides are reported, and the modes of formation of the major fragment ions tentatively described. The use of ^{18}O-labelled compounds has proven to be useful in establishing fragmentation patterns. It is concluded that these follow a characteristic path, which is common to all the ozonides studied and permits mass spectrometric identification.

Les spectres de masse d'une série d'ozonides sont rapportés ainsi qu'une rationalisation des modes de fragmentation conduisant aux principaux ions. Dans certains cas, des ozonides marqués avec ^{18}O ont servi à établir plus fermement les divers modes de fragmentation. Il s'avère que tous les produits étudiés se décomposent par impact électronique, selon un mode qui leur est caractéristique et qui permet leur identification par spectrométrie de masse.

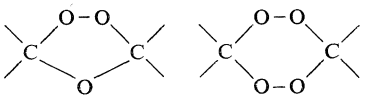
We have recently reported on the general behavior of cyclic organic peroxides (**B**), when submitted to electron impact (1), and the present communication reports an analogous study on some selected ozonides (**A**).



(A) (B)

The behavior of a number of ozonides towards electron impact and the characteristics of the fragmentation patterns are of considerable interest both for comparative purposes, for example, with peroxides containing ring (**B**), and for mass spectral identification. The identification of the fragment ions in the mass spectra of the ozonides, in particular of those suitably labelled with ^{18}O, provides additional evidence as to the position of incorporation of the aldehydic oxygen in the ozonide molecule [1]. This evidence may be used as suitable support for the mechanism of ozonolysis now under consideration (2). The compounds listed in Table I and referred to as compounds **1** to **8**, were selected for study, as suitable substituents are attached to the ozonide ring. The effect of these substituents on the fragmentation patterns will indicate the possibility of aromatic stabilization and the path of any bond cleavage.

The fact that the compounds chosen are unstable is a serious disadvantage for mass spectrometric study. In fact, there is a possibility that the recorded spectra may arise from the decomposition products of the ozonides and not from the ozonides. Two observations, however, verified that the recorded spectra were those of the ozonides. First, the spectra of the compounds did not differ when the same sample was subjected to a number of consecutive analyses. If decomposition did occur, the spectra would be expected to change due to the formation of ions of the more stable products. Second, stilbene ozonide was intentionally pyrolyzed in the mass spectrometer by using the standard metal inlet system. In these experiments, the temperature of the sample was raised slowly and consecutive spectra were taken. They showed a completely different pattern when compared to the spectrum of the stilbene ozonide. The ions at *m/e* 196 and 122 disappeared, and peaks at *m/e* 18, 28, 44, 78, and 106, showing the presence of H_2O^+, CO^+, CO_2^+, $C_6H_6^+$, and $PhCHO^+$, were very intense. The pattern from one spectrum to the other was found to vary in favor of these ions. Furthermore, since the spectrum of styrene ozonide was reproducible and had ions at *m/e* 122 (8.2% Σ) and at the right molecular weight (this compound having the lowest thermal stability of all) it supports the conclusion that decomposition by means other than electron impact could not play a significant role in the present conditions.

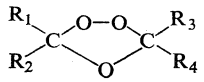
TABLE I

List of compounds studied



Compound number	Nature of substituents	Name
1	$R_1=R_3=R_4=H$, $R_2=Ph$	Styrene ozonide
2	$R_1=R_3=H$, $R_4=CH_3$, $R_2=Ph$	β-Methylstyrene ozonide (*cis–trans*-mixture)
3	$R_1=R_3=H$, $R_2=R_4=Ph$	Stilbene ozonide (*cis–trans*-mixture)
4	$R_2=R_3=R_4=Ph$, $R_1=H$	Triphenylethylene ozonide
5	$R_1=R_3=H$, $R_2=R_4=n\text{-}C_3H_7$-	4-Octene ozonide (*cis–trans*-mixture)
6	$R_1=R_3=H$, $R_2=R_4=Ph\text{-}CH_2$-	1,4-Diphenyl-2-butene ozonide (*cis–trans*-mixture)
7	$R_1=R_3=H$, $R_2=R_4=Cl\text{-}CH_2$	1,4-Dichloro-2-butene ozonide (*cis–trans*-mixture)
8		1-Phenyl-cyclopentene ozonide

Experimental

All spectra were obtained by using a single focussing Hitachi RMU-6D mass spectrometer with the MG-150 direct introducing system. The compounds have sufficiently high vapor pressures to eliminate the need for external heat on the sample holder. The ionization chamber was maintained between 150 and 170 °C and the ionizing electrons were accelerated by a 70 V potential.

Compounds **1**, **3**, **5**, **6**, and **7** were prepared and purified according to literature (3–5).

Styrene Ozonide

Five mmoles of styrene dissolved in 25 ml of CCl_4 were ozonized at room temperature with 80% of the theoretical amount of ozone. Isolation of the styrene and the stilbene ozonides was performed by column chromatography, using Baker silica gel. The unreacted olefin was collected in the CCl_4 fraction. With a benzene–hexane (9:10) mixture, the stilbene ozonide (m.p. 74 °C) was collected initially and then the styrene ozonide, m.p. −12 °C (lit. (5) −15 °C), n_D^{25} 1.4482 (lit. (5) n_D^{20} 1.4511).

Stilbene Ozonide

Five mmoles of *cis*- or *trans*-stilbene dissolved in 25 ml of CCl_4 were ozonized at room temperature with 80% of the theoretical amount of ozone. After evaporation of the solvent, the product was crystallized several times in hot methanol. Fine needles of the ozonide (m.p. 74 °C, lit. (5) 74 °C) were obtained and the nuclear magnetic resonance (n.m.r.) spectrum of this product showed a multiplet at 2.7 and two signals at 3.79 and 3.83 (methine protons), which are attributed (2) to the *cis*-ozonide and *trans*-ozonide, respectively. On the 100 c.p.s. scale, the signals for the *cis*- and the *trans*-ozonides can be integrated separately. Measurements made with *cis–trans* mixtures in known proportions prepared from the pure isomers (2) confirm that the ozonide (m.p. 74 °C) is a 1:1 *cis–trans*-ozonide mixture. The stilbene ozonide, obtained as cross ozonide during the ozonization of styrene, has been shown to be identical with the product, m.p. 74 °C.

β-Methylstyrene Ozonide

Five mmoles of *trans*-β-methylstyrene in 25 ml of CCl_4 or pentane were ozonized at room temperature with 80% of the theoretical amount of ozone. For experiments at −78 °C, pentane was used as solvent. The initial separation of the unreacted olefin in the CCl_4 fraction was effected by column chromatography, using Baker silical gel. From a *n*-hexane–benzene mixture (1:1), the stilbene ozonide which can be purified by recrystallization in methanol (m.p. 74 °C) was first obtained. The subsequent fraction contained the β-methylstyrene ozonide, which can be purified further by repeating the chromatography.

Anal. Calcd. for $C_9H_{10}O_3$ (m.p. 19 °C): C, 65.05; H, 6.07. Found: C, 65.4; H, 6.25, 6.00.

The n.m.r. spectrum showed the following signals: 9.48 (d), 4.52 (q), and 2.6 (m). The two signals at 4.04 and 4.00 (methine protons) indicated that this ozonide was a *cis–trans* mixture. By comparison with similar systems (2, 7), it is reasonable to assign the 4.04 signal to the *trans*-ozonide and the 4.00 signal to the *cis*-ozonide.

Triphenylethylene Ozonide

Five mmoles of triphenylethylene in 25 ml of CCl_4 or pentane were ozonized at room temperature with 80% of the theoretical amount of ozone. The unreacted olefin was recovered in column chromatography, using Baker silica gel, in the CCl_4 fraction. The ozonide was recovered in the benzene–hexane (1:1) fraction. After evaporation of the solvent, the triphenylethylene ozonide was recrystallized in methanol. The colorless crystals obtained had a m.p. of 95 °C.

Anal. Calcd. for $C_{20}H_{16}O_3$: C, 78.95; H, 5.33. Found: C, 79.11; H, 5.45.

The n.m.r. spectrum shows a multiplet at 2.7 and a singlet (methine proton) at 3.72.

1-Phenyl-cyclopentene Ozonide

A solution of 1.0 mmole of 1-phenyl-cyclopentene in 10 ml of CCl_4 was ozonized with the theoretical amount of ozone at room temperature. After evaporation of the solvent, the ozonide was recovered in almost quantitative yield. For purification, the cyclic compound was dissolved in a 1:1 mixture of benzene–hexane and passed through a Baker silica gel column. The waxy crystalline compound obtained after removal of the solvent under vacuum, had a m.p. of 34 °C.

Anal. Calcd. for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29. Found: C, 68.74; H, 6.42.

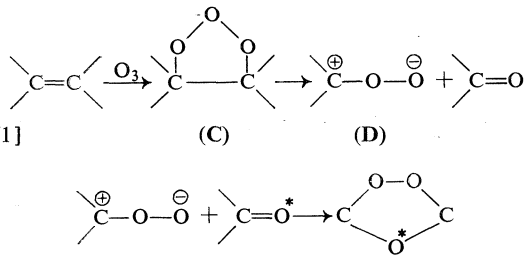
Benzaldehyde ^{18}O

This aldehyde, which was used to label the ozonides **1** to **4**, was prepared by an exchange reaction (6).

In a nitrogen atmosphere, 2.0 g of $H_2{}^{18}O$ (67.17% ^{18}O), 5.3 g of freshly distilled benzaldehyde, and a trace of *p*-toluenesulfonic acid were stirred together at room temperature. After 12 h, the organic layer, together with the ether extract of the water, was distilled at 15 Torr. The aldehyde obtained (5 g) contained 44.6% ^{18}O.

Ozonides Labelled with ^{18}O

If the formation of ozonides proceeds via the Criegee mechanism (8), the ^{18}O atom of the benzaldehyde will be located only in the ether position of the ozonide:



[1] (C) (D)

The key zwitterion intermediate (**D**) formed during the cleavage of the molozonide (**C**) can react equally well with the ^{18}O-labelled PhCHO or with the carbonyl compound formed during the cleavage of (**C**).

The present results indicate that all of the ^{18}O incorporation is located in the ether position of the ozonides. It must be stressed, however, that this does not prove that the Criegee mechanism is necessarily the correct one, since other pathways (2) would also yield the same labelled molecule[3]. Owing to the instability of the molozonides, even at very low temperatures, it is reasonable to assume that no molozonide–aldehyde mechanism will compete with the Criegee mechanism at room temperature.

The labelled ozonides were obtained by ozonizing 25 ml of 0.2 *M* olefin in the presence of 0.2 *M* $PhCH^{18}O$ (44.6% ^{18}O) at room temperature. The solvents used were CCl_4 and pentane, and no difference in incorporation was detected between the solvents. The amounts of ozone used were limited to 80% of the theoretical amount to prevent the formation of peracids due to the autoxidation of the aldehydes, the probability of this being enhanced by the presence of ozone. The isolation of the ozonides by the column chromatography work-up procedure was described previously for the nonlabelled compounds.

Results and Discussion

The spectra[4] of compounds **1** to **8** are shown in Figs. 1–8. In many cases the sample introduced into the mass spectrometer contained a mixture of *cis*- and *trans*-ozonide. However, examination of the spectra of pure *cis*- and pure *trans*-stilbene enriched in ^{18}O (5%), from Fig. 9, shows that the cracking patterns are very similar for the two isomers. This is not unreasonable since both of these compounds give the same ion on primary fragmentation.

A general fragmentation scheme (Scheme 1) is proposed to explain the spectra obtained with ozonides **1** to **7**. Compound **8**, which has a different structure, will be discussed separately and will permit comparisons to be made. Although in specific cases the substituent groups affect the intensity of certain fragments, it can be seen that fragmentation of the molecular ion occurs by two distinct paths, both of which involve a rupture of the heterocycle. The first involves the cleavages of an O—O and a C—O bond, whereas the second, which occurs less frequently, proceeds by the rupture of two C—O bonds. These differences are also clearly illustrated by the spectra of the labelled compounds, which will be discussed later. These two major modes of fragmentation are depicted in Scheme 1. The ions reported in that figure account for most of the ionic current recorded. In some cases the elimination of a radical (R_1, R_2, R_3, or R_4) from the molecular ion was detected but this process gave rise to peaks of very low intensity.

With the exception of the $[M - 32]^+$ peak, processes 1 and 2 of Scheme 1 give rise to ions having the same *m/e* ratio. Nevertheless, the spectra of ^{18}O-labelled ozonides show clearly

[3]A detailed study of the mechanism of ozonolysis, including the formation of *cis*- or *trans*-ozonides and the stereospecifical dependence of the ozonides *cis*/*trans* ratio on the olefin geometry, is now being conducted in one of our laboratories (S. Fliszár).

[4]In many cases low intensity peaks (<0.5% Σ) have been omitted in the figures.

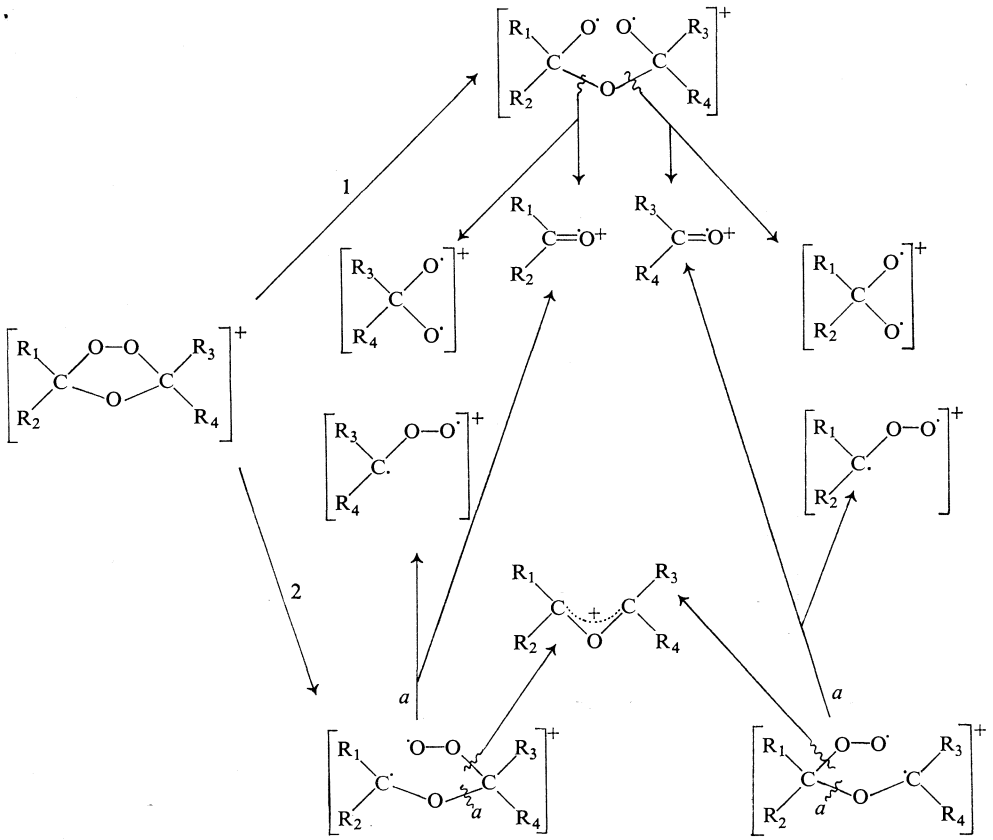
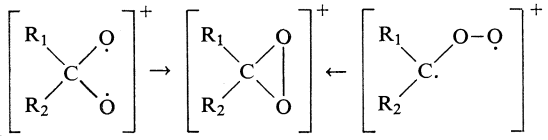
*Not only due to above ion.



SCHEME 1. General fragmentation pattern for the ozonides **1–7**

that there are two different ions, i.e. (**E**) and (**G**) of the same *m/e* ratio:

[2]



(**E**) (**F**) (**G**)

Structures (**E**) and (**G**) are shown to indicate the original ions produced by ruptures 1 or 2 of Scheme 1. It is possible that one or both of these ions can exist in the (**F**) form, although no definite indication of this has been obtained.

Further fragmentation of the carbonyl fragments usually occurs by the well-established mechanism (9)

[3] 
The decomposition of the $[M - 32]^+$ and the $[RR'CO_2]^+$ ions[5] depends on the R substituents and this decomposition will be specified in particular cases. For compounds **1** to **7**, the major ions produced by the general fragmentation scheme are given in Table II.

The spectra of compounds **1–4** (Figs. 1–4) exhibit breakdown patterns found to be in agreement with the general mechanism of Scheme 1. Whenever a phenyl radical is substituted directly onto the ozonide ring, the most intense peak is at *m/e* 105. The ionic intensity distribution reflects the relative stability of the secondary ions. On the basis of a unimolecular fragmentation pattern, the relative abundance of the major ions can be qualitatively estimated by considering the charge stabilization effect of the substituents. From Table II, the intensity ratio $R_3R_4CO^+/PhCHO^+$

[5] $RR'CO_2^+$ through the text stands for $R_1R_2CO_2^+$ and $R_3R_4CO_2^+$.

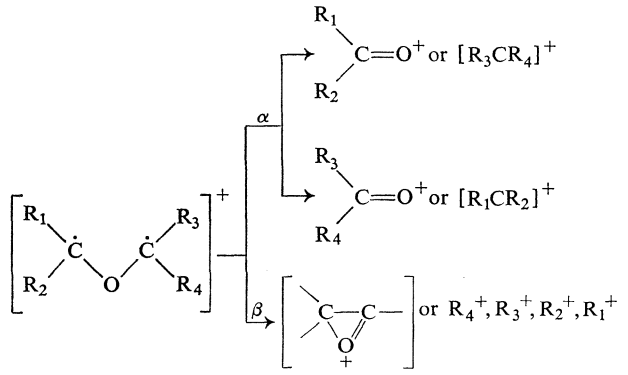
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

for compounds **1**, **2**, and **4** is, respectively, 0.3, 0.5, and 2. Therefore, it is possible to classify the following ions by order of their increasing ease of formation from the molecular ion

[4] $H_2CO^+ < CH_3CHO^+ < PhCHO^+ < Ph_2CO^+$

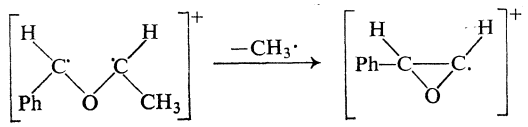
In all four spectra, the presence of a fragment ion at $[M - 32]^+$ which results from the elimination of O_2 from the molecular ion, can be seen. This elimination is believed to occur in a way similar to that observed for the peroxides (1) in that this elimination of O_2 is from the peroxidic bridge of the ozonide ring. However, in the present study, molecular elimination of O_2 is not indicated by the presence of ions of *m/e* 32, unlike in the case of the peroxides (1). Further decomposition of the $[M - 32]^+$ occurs most probably as in ethers (10) by α or β cleavages

[5]



Process α gives rise to ions of low intensity at *m/e* 90, $[Ph—CH]^+$, for compounds **1**–**4** and to an ion at *m/e* 166, $[Ph—C—Ph]^+$, for compound **4**. Process β is responsible for ions at *m/e* 119 for compound **2**

[6]



m/e 134 *m/e* 119

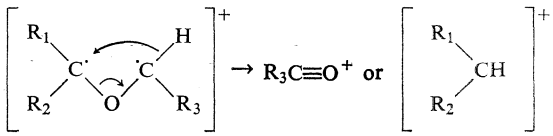
This β cleavage is also responsible for the presence of an $[M - 33]^+$ ion in the spectrum of compounds **1**–**4**. The transition

[7] $$[M - 32]^+ \xrightarrow{-H\cdot} [M - 33]^+$$

is characterized by metastable peaks at *m/e* 270 ($272^+ \rightarrow 271^+$) and at *m/e* 194 ($196^+ \rightarrow 195^+$) for compounds **4** and **3**, respectively. The $[M - 33]^+/[M - 32]^+$ intensity ratio depends on the compounds and is found to be 0.97, 1.6, 0.15, and 0.43 for compounds **1**–**4**, respectively.

In competition with the above processes it is possible to detect a β cleavage coupled with a hydrogen atom transfer, as shown below:

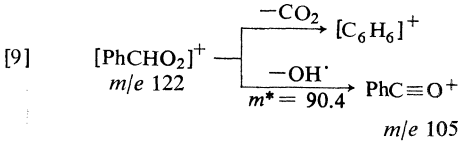
[8]



This rearrangement is indicated by the presence of ions at *m/e* 91 in compounds **1** to **4** and *m/e* 167 $[R_3R_4CH]^+$ in compound **4**.

It has been established that the base peak[6] in the spectrum of benzoic acid is at *m/e* 105 (11). This ion was found to result from an OH· elimination from the molecular ion at *m/e* 122 (12). Fragments ions at *m/e* 122 from the ozonides also undergo hydroxyl elimination, as indicated by a metastable peak (*m**) at 90.4

[9]



[6]Throughout the text the term "base peak" is used to designate the most intense peak.

*A and B represent two labelled ozonides, differently synthesized.
†Corrected to represent the intensity of the $[R_3R_4CO_2]^+$ ion exclusively.

Furthermore, these *m/e* 122 ions also undergo rearrangement to give the phenol ion at *m/e* 94. This transition has been characterized previously (1, 11).

Isotopic Labelling

A minimum of two differently synthesized labelled ozonides were studied for each of the compounds **1**–**4**. The labelled ozonides studied were found to contain only one labelled oxygen atom, as the $(M + 4)^+$ ion was accounted for entirely with the natural isotopic abundance. Table IV reports the percentages of incorporation calculated as follows from Table III

$$[10] \qquad \% = \frac{H_{(M+2)}}{H_{(M)} + H_{(M+2)}} \times 100$$

where $H_{(M)}$ and $H_{(M+2)}$ represent the peak heights of the ^{16}O and ^{18}O containing ions, respectively. The ^{18}O isotope was found to appear exclusively in the ether position of the ozonide ring. For compounds **1** and **2** this conclusion is readily verified, since the percentages of ^{18}O incorporation for the $[M]^+$, $[M - 32]^+$, and/or $[M - 33]^+$ ions are the same within experimental error. For compounds **3** and **4**, it can be seen that the sum of incorporation for the $RR'CO^+$ and $R''R'''CO_2^+$ fragment ions, i.e. % enrichment in $R_1R_2CO^+$ + % enrichment in $R_3R_4CO_2^+$, or % enrichment in $R_3R_4CO^+$ + % enrichment in $R_1R_2CO_2^+$, is equal to the % enrichment in ^{18}O for the $[M - 32]^+$ ion. It is evident that the sum of the ^{18}O incorporation of the two sets of fragments given above must represent the total percentage of ^{18}O incorporation. It can, therefore, be concluded that the ^{18}O incorporation took place exclusively at the ether position of the ozonide ring. A study which will be published shortly, of the reaction of these labelled ozonides with triphenylphosphine, indicates that the carbonyl compounds formed on reduction retain all the ^{18}O and that the triphenylphosphine oxide formed does not retain ^{18}O. These results thus indicate that only the peroxidic oxygens of the ozonides are attacked by the triphenylphosphine and further confirm that only the ether oxygen of the ozonide is labelled by ^{18}O.

The incorporation in the $[M - 32]^+$ ion can be verified by using the $[M - 33]^+$ peak, which, as shown earlier in reaction [7], contains the ether oxygen. This proved to be useful also for compound **1** where the labelled counterpart of the $[M - 32]^+$ ion is at *m/e* 122, the same *m/e* value as $PhHCO_2^+$. In that particular case, the incorporation was calculated by using the $[M - 33]^+$ ion.

The observation that the enrichment in ^{18}O

*Not computable because of interference from other ions.

occurs exclusively at the ether position of the ozonide ring supports what has been previously stated regarding the structure and decomposition of the $[RR'CO_2]^+$ fragments. It is apparent that if these ions were all of type (**E**), then the incorporation at the *m/e* 122 peak should be the same as that of the molecular ion, because it would be formed exclusively with the ether oxygen. From Table V, which is computed from data of Table IV, it can be readily observed that the incorporation of the $[RR'CO_2]^+$ ion is always less than that of $[M]^+$. This supports the presence of *m/e* 122 ions of the form (**G**), i.e., $[RR'C^{\cdot}—OO^{\cdot}]^+$, which has no ^{18}O incorporation. The ^{18}O spectra confirm that for the $[PhHCO_2]^+$ fragments at *m/e* 122, the (**E**) form eliminates an $OH^{\cdot}$ radical; metastable peaks are recorded for the following transitions

[11] 
Furthermore, the ^{18}O incorporation, calculated for the phenol ion, is about 20% of that calculated at *m/e* 122. This indicates that, although the (**E**) form rearranges to give the phenol ion, the (**G**) form undergoes the same rearrangement to a much greater extent. Since the $PhCHO^+$ and $PhCO_2^+$ ions are common to spectra of compounds **1** to **4**, the amount of incorporation of ^{18}O given in Table IV can be used to calculate the relative intensities of ions given in Table V. It can be seen that the aldehydic ion $PhCHO^+$ usually includes an oxygen from the peroxidic bridge. This implies rupture of a C—O and an O—O bond as in process (1) of Scheme 1. This process is most probable for compounds **1**–**4** inclusively. The $PhCHO^+$ ion formed with the ether oxygen implies rupture of two C—O bonds and this process seems to be less frequent for all ozonides **1**–**4**. Nevertheless this process appears to be more probable for compound **4** than for the other three. Now, for the $[PhCHO_2]^+$ ion, it can be seen, also from Table V, that the (**E**) form is predominant, thus confirming the possibility of process (1) rather than (2) (Scheme 1).

From these data, it thus appears that even

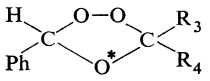
TABLE V

Relative intensities of ions from compound

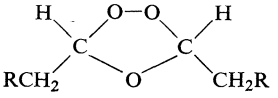


Compounds	Relative intensity of the fragmentation			
				$R_3=R_4=H$	14	86	85	15
$R_4=CH_3$, $R_3=H$	20	80	79	21
$R_4=Ph$, $R_3=H$	17	83	83	17
$R_3=Ph$, $R_4=Ph$	36	64	88	12

NOTE: O* to differentiate the ether oxygen from the other two.

though the substituents influence the relative intensities of the major ions, they have little influence on the primary fragmentation processes of the ozonide ring for compounds **1** to **4**. Every time, the rupture implying the more vulnerable O—O bond occurs predominantly.

Although compounds **5** to **7** fall under the common structural formula given in Table I, they can also be visualized in terms of substituents as



where R is C_2H_5, Ph, and Cl for compounds **5**, **6**, and **7**, respectively. In other words, it is considered that the heterocycle is directly substituted by two methylene groups and the effects of the R group can be studied as a function of intensity distribution. An interesting feature of these compounds is that, even though their spectra can be interpreted according to the general scheme proposed in Scheme 1, most of the ionic current recorded is due to ions of lower *m/e* ratio. In this series, the only molecular ion recorded is that of compound **5** (0.26% Σ at *m/e* 160). The $[M-32]^+$ ion is not seen in any of these spectra, but further fragmentation indicates that it is present as an intermediate. The $[RR'CO_2]^+$ fragment is only recorded in the spectrum of compound **5** (0.5% Σ at *m/e* 88). The only ion that appears in all three spectra is the aldehydic fragment, which is unique when the symmetry of the substituents is considered. It therefore appears that these structures exhibit a lack of charge stabilization on the major ions issued from Scheme 1, when these are compared to the ions from compounds **1** to **4**, where aromatic stabilization was strongly indicated. Even in these cases where the intensities of the ions of higher masses are very low, the general fragmentation scheme can be used to explain the obtained spectra. These explanations are based on the presence of the aldehydic fragments in the spectra and on the prescence of the $[RR'CO_2]^+$ type ion in the spectra of compound **5**. In fact, the absence of the $[RR'CO_2]^+$ ion in compounds **6** and **7** can be interpreted in terms of substituents effects. For compound **6**, where the *m/e* 91 ion is 25.8% Σ, it is expected that transition [12] would be preferred.

[12] 
m/e 136 *m/e* 91

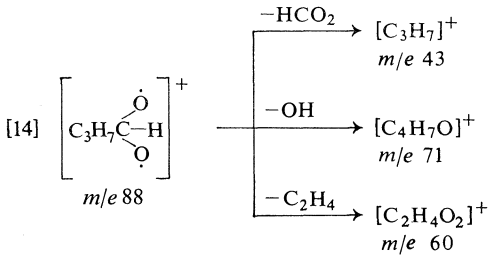
With compound **7**, the intensity of $[CH_3 — Cl]^+$ is 24.7% Σ at *m/e* 50 and it is proposed that a similar mechanism for the fast decomposition of the $RR'CO_2{}^+$ occurs

[13] 
m/e 94, 96 *m/e* 50, 52

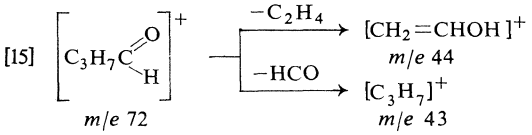
In fact, comparison of this ion (*m/e* 94, 96) with the monochloroacetic acid molecular ion (13) indicates that both have the *m/e* 50 ion as the most intense peak. As for the $[C_4H_8O_2]^+$ ion, it is

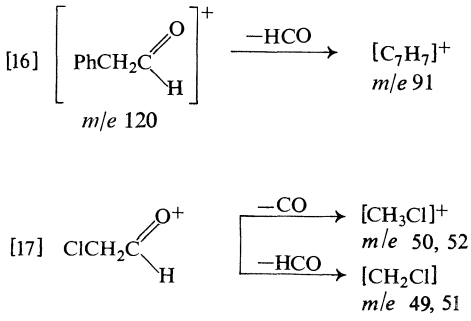
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

proposed that it decomposes in a way similar to the corresponding acid

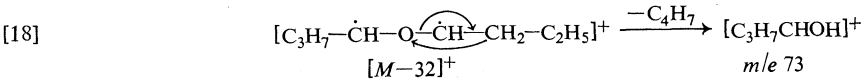


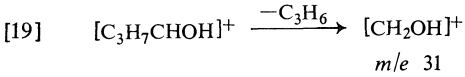
The high intensities of the ion at *m/e* 44 (11.2% Σ) is explained by decomposition of aldehydic fragments:





The $[M-32]^+$ ion, not recorded in these spectra, can be identified by its decomposition fragments: the spectrum of compound **5**, for example, exhibits peaks at *m/e* 73 and 31 which most probably evolve by the following sequence

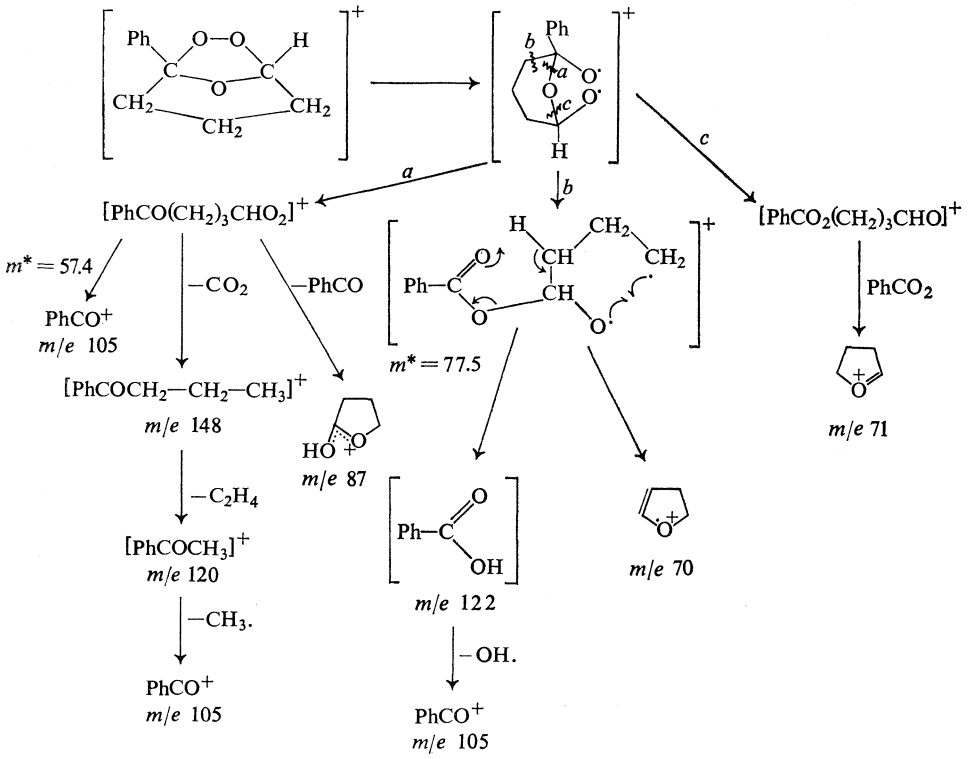




These processes are similar to those reported for ethers (10). Process [18] also gives rise to ions at *m/e* 121 and 79 for compounds **6** and **7**, respectively. However, for these ozonides (**6** and **7**), reaction [19] is not detected, as these lack a β hydrogen necessary for this process to occur. The $[R_1R_2CH]^+$ ions are recorded at *m/e* 57 and 105 for compounds **5** and **6**, and the $[R_1R_2C]^+$ ions at *m/e* 56, 104, and 62 for compounds **5**, **6**, and **7**. All these ions occur from decomposition of the $[M-32]^+$ ions as shown previously for compounds **1–4**. Therefore, the general scheme appears to be valid for ozonides **1** to **7** as the effect of substituents is reflected mainly in the ionic distribution.

Compound **8**, which can be represented as indicated in Table I, cannot be included in the general formula since the aliphatic bridging between the two carbon atoms on the ring is not comparable with the structures of compounds **1–7**. It is of interest, however, to determine if fragmentation of compound **8** will occur in a similar manner to the one observed for compounds **1** to **7**, or if its particular structure will favor a competitive process. Spectrum 8 (Fig. 8) shows ions at *m/e* 160, 148, 122, 120, 105, 87, 77, and 71. The ions at lower *m/e* ratio are decomposition fragments of the above ions. The $[M-32]^+$ ion is seen at *m/e* 160, but with a very low intensity (0.1% Σ). As shown in Scheme 2, the opening of the ozonide ring proceeds in a similar fashion to that found for compounds **1** to **7** (Scheme 2, ruptures *a* and *c*), but there is a competitive process (*b*) which involves a C—C cleavage to give the ion at *m/e* 122 (5.7% Σ). This cleavage initiates a process involving a six-membered ring intermediate, characterized by a metastable peak at *m/e* 77.5. Ions at *m/e* 87, 71, and 70 are believed to be cyclic because of their high intensity (11.8% Σ at *m/e* 71). In fact, the cyclic structure has been found to be more stable (14) than the biradical equivalent. Charge stabilization in the cyclic structure is enhanced by resonance with the oxygen, whereas the biradical form would readily eliminate a neutral fragment. Thus, it is apparent that the different structure of compound **8** favors a fragmentation pattern which differs from that of Scheme 1. Process (*b*), Scheme 2, must be of some importance if the relative height of the *m/e* 122 peak is considered.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



SCHEME 2. Fragmentation pattern of compound **8**

However, the spectrum still indicates that the primary cleavage predominantly involves rupture of the O—O bond, although further decomposition differs as a result of aliphatic bridging which does not permit fragmentation via simple carbonyl or $RR'CO_2$ type fragments, as in the case of compounds **1** to **7**.

Conclusions

The mass spectra recorded for compounds **1** to **7** were found to include ions such as $[M - 32]^+$, $[RR'CO_2]^+$, and the carbonyl ions, that are characteristic of these ozonides. A comparison of the spectra of compounds **1** to **4** with those of compounds **5** to **7** shows that there is a net effect on the charge stabilization, due to the substituents, which is reflected in the ionic current distribution. For compounds **1** to **4**, which have aromatic stabilization, most of the ionic current is due to the carbonyl fragments, whereas for compounds **5** to **7**, the carbonyl fragment ions are less intense and more ions due to secondary decomposition are observed. The fact that the $[M - 32]^+$ ion is present in the spectra of compounds **1** to **4** and not in those of compounds **5** to **7** indicates that aromatic substituents have a large influence on the intensity of this ion. The molecular ion is present only in the spectra of compounds **1** and **2**, which have only one phenyl group as substituent on either side of the ring. This observation indicates that carbonyl fragments containing phenyl groups are of sufficient stability so that decomposition through them is favored.

In compounds **5**, **6**, and **7**, where substituents are in the β position, the substituent effects are inferred by the non-appearance of the $[M - 32]^+$ ion in their spectra, and also by the non-appearance of the $[M]^+$ and $[RR'CO_2]^+$ ions in the spectra of compounds **6** and **7**. It is also seen for compounds **6** and **7** that the phenyl group favors the formation of the tropylium ion whereas the presence of chlorine atoms in the molecule favors the formation of $[CH_3Cl]^+$ ion.

In all of these compounds (**1**–**7**), the mode of fragmentation is similar, as indicated by ^{18}O

isotopic labelling. Rupture of the ozonide ring proceeds predominantly by an O—O and a C—O bond split. The influence of molecular structure on the fragmentation pattern of the ozonides is clearly indicated by comparison of the spectrum of compound **8** with the spectra of compounds **1**–**7**. However, even for compound **8**, the O—O bond appears to be the most easily opened by electron impact. It is also concluded that the ^{18}O incorporation in the ozonide molecules studied occurs exclusively at the ether position of the ring.

On the in-plane vibration frequencies of the vinylidene, d_1-, and d_2-vinylidene halides. I. Force fields and normal modes. II. Characteristic group vibrations

J. M. FREEMAN AND T. HENSHALL
Department of Chemistry and Applied Chemistry, University of Salford, Salford 5, Lancashire, England
Received October 15, 1968

An investigation has been undertaken of the characteristic in-plane group vibrations of the vinylidene and d_2-vinylidene groups from the viewpoints both of approximation methods of the vibrational analysis of, and aids to assignments in, molecules containing such groups.

The need in these studies for reliable force fields for the vinylidene halides has caused us to undertake a normal coordinate analysis of the in-plane vibrations of these molecules using a modified valence force field, and including all the available information from the hydrogen and deuterium isotopically substituted species.

I. Force Fields and Normal Modes

In continuation of our investigations of characteristic group frequencies from the viewpoint both of approximation methods of vibrational analysis and as aids to frequency assignments (1), we have undertaken a study of the vinylidene group.

However, for the approximation methods we required reliable force fields for the vinylidene halides, but surprisingly little work has been published on them. These include an early determination of a symmetry force field by Manneback and Rahman (2), calculations of a Urey–Bradley potential by Scherer and Overend (3), and by Enomoto and Ichinohe (4), but no valence force constants have so far been reported. Accordingly we have also undertaken a normal coordinate analysis of the in-plane vibrations of the vinylidene halides using a modified valence force field, and including all the available information from the hydrogen and deuterium isotopically substituted species.

The internal coordinates used are shown in Fig. 1. The symmetry coordinates for in-plane vibrations of CH_2CX_2 and CD_2CX_2 under the covering operations of the C_{2v} point group are listed in Table I, which also includes the coordinates for the isotopic species $CHDCX_2$ under C_s.

The molecular geometries were taken mainly from ref. 5 but with some minor modifications, and are presented in Table II. The **G** matrices for the complete solutions for CH_2CX_2, $CHDCX_2$, and CD_2CX_2 (X = F, Cl, Br) were calculated on an English-Electric KDF-9 computer using the program described in ref. 6. The valence force field of Table III was chosen on the basis of calculations on the "standard vinylidene molecule" of Part II. Those force constants in parentheses, viz. $f_{r\alpha}$ and $f_{d\alpha}$, were included in an attempt to fit the observed frequencies for the fluoro compounds; they were not used for the bromides and chlorides. The corresponding symmetry force field for CH_2CX_2, CD_2CX_2 is given in Table IV, from which that for $CHDCX_2$ is easily constructed by combining the elements in the A_1 and B_2 species, with due regard for the renumbering of the coordinates in Table I.

The observed frequencies of the fluorides and bromides were taken from refs. 7, 8, and 9 respectively, but with some slight amendments suggested by Scherer and Overend (3); the assignments quoted in Tables V–VII were made on the basis of their approximate potential energy distributions (p.e.d.) derived from a Urey–Bradley potential. In our calculations, the force constants of Table IX were determined by an iterative procedure (10), so that a force field could be obtained corresponding to a chosen assignment.

In the case of the vinylidene chlorides, no observed frequencies are available for the monodeuterated species $CHDCCl_2$. The results are, therefore, confined to the symmetrically substituted molecules. But even for CD_2CCl_2 the assignment is incomplete; the unknown frequencies were therefore accorded zero weight in the iteration process. The first estimate of the valence force constants was made by interpolation of the values for vinylidene fluoride and bromide, and the results of this zero-order calculation came surprisingly close to the observed frequencies apart from the bands at 980 cm^{-1} in the A_1 species and 815 cm^{-1} in the B_2 species of CD_2CCl_2, for which the calculated values were 1035 and 960 cm^{-1} respectively.

These bands correspond respectively to δ(DCD) and δ(DCC). Their values in the fluoride are 1076 and 807 cm^{-1}, and are 1019 and 932 cm^{-1} in the bromide. It is perhaps indicative of an error in assignment in the chloride, that while the observed frequency of 980 cm^{-1} for the deuterated molecule does not lie between those of

	S_9				H_γ	

the fluoride and bromide, the calculated frequency of 1035 cm^{-1} does! Some doubt on the accuracy of this observed frequency is also expressed in ref. 3, where it is estimated that such a low frequency for the bending mode excludes any contributions from the force constants of the CX_2 group. The components of δ(DCD) in d_2-vinylidene chloride are shown by the zero-order calculation to be almost identical to those in d_2-vinylidene bromide, and it is, therefore, unlikely that any change in the force constants can remove the contributions (of S_2 and S_5) from the CX_2 group, since the transition from the force field of the bromide to that of the chloride has had but little effect on them. However, no such correlation is possible for the band at 815 cm^{-1} in the B_2 species because of the complex nature of this frequency. The high value of 932 cm^{-1} in the d_2-vinylidene bromide arises from a measure of coupling with the frequency at 625 cm^{-1}, whereas little vibrational coupling of this kind occurs in the fluoride. Thus a large degree of coupling in the chloride would be expected to raise the DĈC deformation frequency in the B_2 species; indeed the calculation revealed a very strong degree of coupling between those frequencies at 680 and 960 cm^{-1}. It seemed reasonable, therefore, to question the validity of the observed frequency of 815 cm^{-1} in CD_2CCl_2, which is at 117 cm^{-1} less than the corresponding frequency in CD_2CBr_2. Accordingly, two iterative calculations were made, one in which the observed frequency of 815 cm^{-1} in CD_2CCl_2 was included in the data, and given normal weighting (I), and another in which it was assigned a zero weight (II). Examination of the results in Table VI reveals a considerable improvement in the agreement of the remaining calculated and observed frequencies in the latter case. This provides a further indication of a possible error in the assignment of the frequency at 815 cm^{-1}. Since there is still a discrepancy of 63 cm^{-1} in the frequency at 980 cm^{-1} in the A_1 species of CD_2CCl_2, the doubt expressed above on the reliability of this frequency is re-emphasized. Finally, in view of the lack of a complete vibrational assignment for the deuterated compounds it was considered to be unprofitable to attempt any further refinement of the force field.

Discussion

The vinylidene halides are so vibrationally dissimilar that it is more convenient to discuss them separately.

(i) Vinylidene Fluoride

The observed and calculated frequencies for CH_2CF_2, $CHDCF_2$, and CD_2CF_2 are presented in Table V. The assignments of the bands at 1359 and 1076 cm^{-1} to δ(HCH) and δ(DCD) respectively have been taken from ref. 3, and were made on the basis of a close agreement with calculated values when the frequencies were accorded a zero weight. Our calculations, however, give values of 1374 and 1050 cm^{-1} for these modes, which are closer to the original assignments of 1380 and 1060 cm^{-1} by Edgell and

Ultee (7), but although this agreement may be considered as supporting evidence for this latter assignment, the results are not really sufficiently conclusive.

The most interesting feature of the approximate p.e.d. of Table V is the purity of δ(HCH) in CH_2CF_2. This is due to the much wider separation of δ(HCH) and ν(C═C) in this molecule than in the other vinylidene halides; the contribution from ν(C═C) is considerable in the bromide, though less marked in the chloride. Hence δ(HCH) can be considered as a true group frequency only in vinylidene fluoride. No such purity is apparent in the C═C stretching frequencies to which the symmetric C—X stretching vibration contributes 30% in CH_2CF_2, 8% in CH_2CCl_2, and only 4% in CH_2CBr_2. As the mass of atom X increases through F to Br, the contributions to ν(C═C) from the coordinate S_4 are gradually replaced by those from S_2.

In CD_2CF_2, the DĈD bending mode is highly complex in contrast to CD_2CCl_2 and CD_2CBr_2 where the mode is relatively pure. The composition of ν(C═C) in CD_2CF_2 is similar to that in CH_2CF_2, whilst in the vibrations of species B_2 considerable mixing occurs between ν(C—F) (a) and δ(HCC) or δ(DCC), but replacement of H by D does lead to slightly purer δ(DCC) and ν(C—F) (a) vibrational modes.

TABLE VIII

Valence force constants for the vinylidene halides*

Force constants	Values in F	Cl I	Cl II	Br
F_r	5.252	5.170	5.168	5.131
F_R	8.509	8.397	8.396	7.622
H_α	0.524	0.470	0.509	0.507
F_d	7.175	3.613	3.716	3.098
H_γ	0.707	0.726	0.812	0.745
H_β	0.367	0.381	0.384	0.382
H_θ	1.552	1.257	1.252	1.192
f_{rr}	0.032	0.016	0.017	0.029
f_{dd}	0.992	0.232	0.133	−0.039
$f_{d\gamma}$	0.646	0.829	0.633	0.651
$f_{R\alpha}$	0.362	0.254	0.236	0.121
$f_{d\theta}$	0.435	0.346	0.340	0.244
$f_{R\gamma}$	0.371	0.106	0.110	−0.104
$(f_{r\alpha})$	−0.008	—	—	—
$(f_{d\alpha})$	−0.012	—	—	—

*Stretching force constants, e.g. F_r, are in mdyn Å^{-1}; bending force constants, e.g. H_γ, are in mdyn Å rad^{-2}; stretch–stretch interaction constants, e.g. f_{rr}, are in mdyn Å^{-1}; stretch–bend interaction constants, e.g. $f_{d\gamma}$, are in mdyn rad^{-1}.

An estimate provided by the iterative program of the relative importance of the constants in the valence force field indicates that $f_{r\alpha}$ and $f_{d\alpha}$ make very little contribution to the determination of the frequencies. The reason lies in the very small values for these constants (Table VIII), and there is no indication that these values are only weakly determined by the data. These constants were only included in an attempt to obtain agreement between observed and calculated values of ν(C—H) and ν(C—D), and the failure of this attempt may serve to indicate that the discrepancies are more probably due to the effects of anharmonicity in the vibrations, which will clearly be more important for ν(C—H) than for ν(C—D).

The interaction constant $f_{R\gamma}$ has a relatively large effect on the calculated frequencies, but the value of the expression (10),

$$Q = (\Sigma_{q=1}(JZ)^*P(JZ))_{ii}$$

for this constant indicates that it is only weakly determined.

The values of F_r and F_R, the force constants for the C—H and C═C stretching vibrations compare favorably with those reported in ref. 3, but our value for F_d, the constant for the CF stretching vibration of 7.175 mdyn Å^{-1}, does not compare favorably with their value of 4.660 mdyn Å^{-1}. The reasons for this discrepancy may lie in the different types of force field used, with the resultant arbitrary allocations of neglected force constants amongst those remaining, and in the large uncertainty of 0.63 mdyn Å^{-1} reported (3) for the F—F interaction constant.

However, our values of F_d and f_{dd} appear to be well determined, the former having the largest relative importance of all the constants in the valence force field, although such considerations should strictly be applied only to interaction constants. The reliabilities of F_d and f_{dd} are also indicated by the fact that, during the iteration process, F_d remained sensibly constant, whilst f_{dd} oscillated only very slightly.

(ii) Vinylidene Chloride

Due to the paucity of experimental data for the chlorides, the results of the calculations on these compounds are not as reliable as those for the fluorides and bromides. This is emphasized by the smaller values of Q for the interaction constants f_{dd}, $f_{d\theta}$, and $f_{R\gamma}$ compared with the

values obtained for the fluorides and bromides, which indicates that these force constants are only weakly determined in this case by the experimental data.

Scherer and Overend (3) point to the close correspondence of the frequencies for ν(C═C) and δ(HCH) in both vinylidene chloride and bromide, and suggest that in consequence these modes will be considerably mixed in both cases. However, our calculations only partly confirm this suggestion; the p.e.d. in Tables VI and VII indicate that the amounts of vibrational coupling are less for the chlorides than the bromides.

For the B_2 species of CD_2CCl_2, the force constants under I and II (Table VIII) correspond to different assignments of δ(DCC) and ν(C—Cl) (a), and calculation II is really contrary to the chosen assignment. However, the extent of vibrational mixing is so great that it is questionable whether any such assignment should be made.

Little evidence is available to enable a choice to be made between the results of the calculations in I and II, but the force constants from II do lead to closer agreement between calculated and observed frequencies, and the values of H_α and $f_{d\gamma}$ from II are more consistent with those for the fluorides and bromides than are those from I. For these reasons we chose to use the force constants under II in our considerations of group frequencies in Part II.

(iii) Vinylidene Bromide

The observed and calculated frequencies of vinylidene and d_2-vinylidene bromides are compared in Table VII; the agreement is satisfactory in all cases, with a maximum error of 1.46% for the band at 476 cm^{-1} in the A_1 species of CH_2CBr_2. The calculations show that the interaction constant $f_{R\gamma}$ is of little importance in determining the calculated frequencies, even though its value is -0.103 mdyn $Å^{-1}$; the conclusion, therefore, is that this value is unreliable.

The **L** matrices indicate a considerable degree of mixing between the coordinates S_2 and S_3 in both CH_2CBr_2 and CD_2CBr_2, but the marked vibrational coupling between S_7 and S_8 in the latter molecule is not so pronounced in the former. Similar conclusions may be drawn from the p.e.d. of Table VII. This vibrational coupling of S_7 and S_8 as noted above is the reason for the high values of the δ(HCC) and δ(DCC) modes in the B_2 species.

The use by Scherer and Overend (3) of a Urey–Bradley potential makes a comparison of the force constants difficult. However, similar values are obtained for the C—H and C═C stretching force constants, but their value is 2.225 mdyn $Å^{-1}$ for F_d against 3.098 mdyn $Å^{-1}$ in this study. Again the discrepancy may lie in the very different character of the force fields, and in the extremely large uncertainty of 2.4 mdyn $Å^{-1}$ reported (3) for the Br—Br interaction constant.

Both F_d and F_{dd} appear to be well determined in our calculations. Their values were decreasing only very slowly in the last stages of the iteration process, which indicates that the convergence was almost complete. The final value of 3.098 mdyn $Å^{-1}$ for F_d is, however, considerably lower than the value 3.54 mdyn $Å^{-1}$ reported by Manneback and Rahman (2), and the small value, -0.039 mdyn $Å^{-1}$, for f_{dd} implies that its inclusion in the force field will have little effect on the calculated frequencies.

II. Characteristic Group Vibrations

The vinylidene halides are reported (11) to exhibit four in-plane group vibrations: two ν(C—H), a δ(HCH), and a ν(C═C). The shifts in δ(HCH) and ν(C═C) with changes in molecular structure have been discussed by many authors (11) in terms of inductive and mesomeric effects within the molecule. However, on the basis of a normal coordinate analysis using a Urey–Bradley potential, Scherer and Overend (3) have shown that the use of ν(C═C) in such attempted correlations can lead to erroneous conclusions regarding the relative strengths of C═C bonds. The reason lies in a strong and variable degree of vibrational coupling between the nearly degenerate C═C stretching and HĈH bending modes in some molecules containing vinylidene groups. This coupling is most pronounced in vinylidene bromide, but almost absent from the corresponding fluoride. Its occurrence precludes the applications both of a first-order perturbation treatment of these "group frequencies" (12), and the method of Wilson *et al.* (13) for the reduction in the order of the vibrational secular determinants for the vinylidene halides by factorization of these frequencies from them.

However, Needham and Overend (14) have discussed the application to the vinylidene halides of a first-order perturbation theory for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the nearly degenerate case, and their method has been combined with that of King and Crawford (12) in an investigation of group frequencies in vinylidene and d_2-vinylidene halides.

The starting point for the calculations was the "standard molecule" defined in Fig. 1, in which angles of 120° were assumed, and with the following bond lengths (5): r(C—H) = r(C—D) = 1.07 Å; r(C=C) = 1.31 Å; r(C—X) = 1.50 Å, as for a C—C bond in a similar environment. The symmetry coordinates under the operations of C_{2v} point group symmetry are listed in Table I; they are orthogonal to the redundant coordinate, and conform to the convention proposed by Cyvin *et al.* (15).

The force field for the standard molecule (Table IX) was constructed from that for vinylidene bromide (3), but in which the force constants in the $=CX_2$ group were replaced by values representative of the group $=C—C_2$, in view of the possible application of the group frequency factorization procedure to organic molecules to which the vinylidene group is so attached.

The secular equations for the standard molecules derived both from the vinylidene and d_2-vinylidene groups were solved on an English-Electric KDF-9 computer. The resulting **L** matrices and calculated frequencies are given in Table X, and the corresponding inverse **L** matrices in Table XI. Both the **L** and $\mathbf{L}^{-1}$ matrices indicate that ν(C—H), 3100 and 3020 cm^{-1} and ν(C—D), 2328 and 2209 cm^{-1} are characteristic of the vinylidene and d_2-vinylidene groups, respectively, but that ν(C=C), 1602 and 1564 cm^{-1}; δ(HCH), 1398 cm^{-1}; and δ(DCD), 1041 cm^{-1} are expressions of considerably mixed

vibrations, the first being the more highly contaminated with contributions from the skeletal modes, and the latter two contaminated to a lesser degree with the XĈX bending mode.

However, despite the unfavorable degree of vibrational coupling, an attempt was made to factorize the ν(CH) or ν(CD), ν(C═C) and δ(HCH) or δ(DCD) frequencies from the secular determinant for the A_1 vibrational species by the method of King and Crawford (12). As expected, large corrections were required to the inverse masses and force constants for the skeletal modes, and this is usually considered to be a possible source of difficulty, even of failure, in an application of the method. However, satisfactory results were obtained for vinylidene and d_2-vinylidene bromides, but not so for the corresponding fluorides in which the degree of vibrational coupling was relatively small, and which did not therefore so closely resemble the conditions in the "standard molecule".

A second approach was suggested by the more pronounced vinylidene and d_2-vinylidene group character of δ(HCH) and δ(DCD) than of ν(C═C). This involved the inclusion of ν(C═C) in the skeletal modes and of ν(CH), δ(HCH), and their deuterium counterparts in the group vibrations in the factorization procedure.

The **A** matrices of the orthogonal transformation (12) are presented in Table XII for both the A_1 and B_2 vibrational species, and were calculated from $\mathbf{L}^{-1}$ matrices of Table XI. It is noteworthy that in the construction of $\mathbf{A}(A_1)$ an unusual situation arises in that ν(CH) and δ(HCH) are not the two highest frequencies, so that in this case it is the first and third rows of $\mathbf{L}^{-1}(A_1)$ that are used. Examination of the $\mathbf{A}(A_1)$ matrices reveals that the only potential source of difficulty in the application of the group frequency factorization method lies in the relatively large matrix elements which couple the coordinate S_2 with ν(C═C) in D_3, and with ν(C—X) in D_4. No such difficulty was anticipated for the B_2 vibrations, since there are no abnormally large elements coupling group and framework coordinates in this species.

The effective inverse mass matrices for atoms C_3 and C_4 (Fig. 1) are presented in Table XIII and the corrections, $\mathbf{\Phi}_{ff}$, to the force constants for the framework vibrations in Table XIV. Although some of the elements in $\mathbf{\Phi}_{ff}(A_1)$ are larger than is desirable in the method, they are nonetheless far smaller than those arising in the first calculations in which ν(C═C) was included in the group vibrations, and the corrections, $\mathbf{\Phi}_{ff}(B_2)$, are so small as to be negligible.

Since the skeletal vibrations involve only the system C═CX$_2$, it is unnecessary to define effective inverse hydrogen or deuterium masses for the A_1 species. The derivation of the reduced **G** matrices ($\mathbf{G}_{ff}{}^{+}$) is therefore particularly simple here, and the results for bond angles of 120° are quoted in Table XV. However, care should be taken in calculations not to confuse the two effective inverse carbon masses; viz. $\mu^{+}{}_{C_3(y)}$, $\mu^{+}{}_{C_4(y)}$ refer respectively to the motions of C_3 and C_4 in the y direction. On the other hand, the derivations of the reduced secular equations for the B_2 species do strictly require the definition of inverse hydrogen and deuterium masses, but the corrections are so small as to be negligible.

The construction of the approximate group frequency equations for ν(C—H) and ν(C—D) is straightforward, but the inclusion of several

elements of ΔG_{ij} is necessary to achieve a satisfactory degree of accuracy when the equations are applied to molecules with bond angles differing from 120°. The following equations contain all the significant terms in the first-order perturbation treatment (12):

vinylidene group

$$\lambda_1 = 5.3713 + 1.0312\Delta F_{11} + 0.0250\Delta F_{22} + 5.1113\Delta G_{11} - 0.0988\Delta G_{12}$$

$$\lambda_6 = 5.6621 + 1.1160\Delta F_{66} + 5.0073\Delta G_{66}$$

d_2-vinylidene group

$$\lambda_1 = 5.3713 + 1.0312\,\Delta F_{11} + 0.0250\,\Delta F_{22} + 5.1113\,\Delta G_{11} - 0.0988\,\Delta G_{12}$$

$$\lambda_6 = 5.6621 + 1.1160\,\Delta F_{66} + 5.0073\,\Delta G_{66}$$

$$\lambda_1 = 2.8757 + 0.5211\Delta F_{11} + 0.0656\Delta F_{22} + 0.0221\Delta F_{33} + 0.0761\Delta F_{23} + 4.8257\Delta G_{11} - 0.1990\Delta G_{12}$$

$$\lambda_6 = 3.1931 + 0.6187\Delta F_{66} + 4.9224\Delta G_{66}$$

$$(\Delta F_{ij} = F_{ij} - F_{ij}^{\circ} \qquad \Delta G_{ij} = G_{ij} - G_{ij}^{\circ})$$

where superscript 0 refers to the standard molecule.

The C=C stretching and HĈH (DĈD) bending frequencies were then treated by the method of ref. 14. This method is applicable to two or more frequencies which, although they may involve some mixing among themselves, are relatively independent of the other vibrations of the same symmetry species. Thus, if the subscript 0 refers to the standard molecule, then for a perturbed system

$$\mathbf{G} = \mathbf{G}_0 + \Delta\mathbf{G} \qquad \mathbf{F} = \mathbf{F}_0 + \Delta\mathbf{F}$$

and to first-order,

$$\mathbf{H} = \mathbf{GF} = \mathbf{G}_0\mathbf{F}_0 + \mathbf{G}_0\Delta\mathbf{F} + \Delta\mathbf{G}\mathbf{F}_0$$

$$= \mathbf{H}_0 + \Delta\mathbf{H}$$

S_7	$\{\frac{1}{2}[2/R + 1/r]^2\mu^+{}_{C_3(x)} + 2\mu^+{}_{C_4(x)}/R^2 + \mu_{H(D)}/r^2\}$	$[3\mu^+{}_{C_4(x)}/r]$	$\{-[(2/R + 1/r)\mu^+{}_{C_3(x)} + (2/R + 1/d)\mu^+{}_{C_4(x)}]/R\}$
S_8		$[3\mu^+{}_{C_4(x)}/2 + \mu_X]$	$[-\sqrt{3}(2/R + 1/d)\mu^+{}_{C_4(x)}/2]$
S_9	(symmetrical)		$[2\mu^+{}_{C_3(x)}/R^2 + (2/R + 1/d)^2\mu^+{}_{C_4(x)}/2 + \mu_X/d^2]$

Then on transforming **H** into the representation in which $\mathbf{H}_0$ is diagonal there results:

$$\mathscr{H} = \mathbf{L}_0{}^{-1}\mathbf{H}\mathbf{L}_0 = \mathbf{\Lambda}_0 + \mathbf{L}_0{}^*\Delta\mathbf{F}\mathbf{L}_0 + \mathbf{L}_0{}^{-1}\Delta\mathbf{G}(\mathbf{L}^{-1})^*\mathbf{\Lambda}_0$$
$$= \mathbf{\Lambda}_0 + \Delta\mathscr{H}$$

wherein the asterisk denotes the transpose.

The matrix elements of $\Delta\mathscr{H}$ for the required frequencies are thus determined from the eigenvectors of the zero-order problem, in this case the standard molecule, and from the perturbed **G** and **F** matrices. The diagonal elements of $\mathscr{H}$ are the frequency parameters obtained from first-order perturbation theory, and the off-diagonal elements usually contribute to the next higher order of approximation. In those cases for which $|\Delta\mathscr{H}_{ij}| \sim |\mathscr{H}_{ii} - \mathscr{H}_{jj}|$, the off-diagonal elements are important, and the submatrix $\mathscr{H}$ must be diagonalized to obtain the frequency parameters of the perturbed system. The application of the method to ν(C═C) and δ(HCH) or δ(DCD) leads to a second-order secular determinant involving the corresponding eigenvectors from the standard molecule. Since ν(C═C) is obtained from the treatment of both the skeletal and group vibrations, a convenient internal check for self-consistency is available, and a close agreement between the results from the two methods of calculation is an indication that the values so obtained are satisfactory. The results of the calculations by this, and by the other methods described above are collected in Tables V–VII. It is apparent that a simple first-order perturbation treatment gives excellent results for all those frequencies for which it is strictly applicable, i.e. in the absence of near degeneracy, and the values obtained for ν(C═C) and δ(HCH) or δ(DCD) in $CH_2{=}CF_2$, $CD_2{=}CF_2$, and $CH_2{=}CBr_2$ are expectedly in poor agreement with the observed frequencies due to the very complex nature of the vibrational modes in these compounds.

However, the first-order perturbation method for the degenerate case gives excellent agreement for ν(C═C) and δ(HCH) or δ(DCD) in all the molecules studied, with the exceptions of CH_2CF_2 where there is a difference of 37 cm^{-1} in ν(C═C), and of CD_2CF_2 where the calculated values of ν(C═C) and δ(DCD) are in error by 38 and 28 cm^{-1}, respectively. These discrepancies arise from a very high degree of participation of the symmetric C—F stretching vibration in these modes, which is not expected to occur to such a marked extent in compounds containing the groups $CH_2{=}CC_2$ and $CD_2{=}CC_2$. Even so, the results obtained by this method are an improvement on those from the simple first-order theory except for δ(DCD) in $CD_2{=}CF_2$, but it should be noted that the solutions of the reduced secular equations for the fluorides give reliable values for the C═C stretching frequencies.

Although the approximation methods described above have not proved completely successful in the vibrational analysis of the vinylidene halides, nevertheless the results do suggest criteria for the choice of method suitable for the treatment of individual cases. Thus the results obtained for the bromide and chloride indicate that for those molecules in which δ(HCH) or δ(DCD) and symmetric ν(C—X) are widely separated, the solution of the reduced equation in the method of King and Crawford (12) will give reliable results for all frequencies except ν(C═C), and that the first-order perturbation method for the case of near degeneracy will then give accurate values for this frequency and for δ(HCH) or δ(DCD).

On the other hand, the results for the fluoride suggest that for those molecules having a high value for the C—X stretching force constant so that δ(HCH) or δ(DCD) and symmetric ν(C—X) are very close, then it is the solution of the reduced secular equation which gives the more reliable value for ν(C=C). In such cases first-order perturbation theory for the degenerate case also provides accurate values for δ(HCH) in $CH_2{=}CF_2$, but gives only moderate agreement for δ(DCD) in $CD_2{=}CF_2$.

However, simple first-order perturbation theory provides satisfactory results for ν(C—H) and ν(C—D) in all cases, provided only that account is taken of changes in molecular geometry.

Finally, we consider the calculation of the skeletal frequencies for CH_2CX_2 and CD_2CX_2 by solution of the reduced secular determinant $|\mathbf{G}_{ff}{}^{+}\mathbf{F}_{ff}{}^{+} - \lambda\mathbf{E}_{ff}| = 0$ (12) wherein $\mathbf{F}_{ff}{}^{+} = \mathbf{F}_{ff} + \mathbf{\Phi}_{ff}$, with $\mathbf{F}_{ff}$ the force constants in Table VIII, and $\mathbf{\Phi}_{ff}$, the "corrections" of Table XIV. For convenience, the $\mathbf{G}_{ff}{}^{+}$ matrices were calculated on the computer using the program in ref. 6, since the analytical expressions of Table XV apply only to the simplified geometry with bond angles of 120°.

The determinants for the reduced problem were solved on the computer. The results of the calculations are presented in Tables V–VII, and inspection of Table VII for CH_2CBr_2 and CD_2CBr_2 reveals that the only significant error in the frequencies of the framework vibrations obtained by the approximation method lies in ν(C=C). This applies to both "light" and "heavy" isotopic molecules, but the results are slightly better in the former. The approximate value of ν(C=C) is about 70 cm^{-1} too low in both molecules, and as indicated by the **L** matrix, is most probably due to an unusually large contribution from δ(HCH) and δ(DCD). But reliable values for ν(C=C) are available from the other approximation methods described above.

A similar situation occurs in the chlorides, but the contributions to ν(C=C) from δ(HCH) and δ(DCD) are much smaller, with consequent reduction in the errors of ν(C=C) to 35 cm^{-1}. Both of the first-order perturbation calculations again give reliable results for ν(C=C).

However, the results of the approximation methods for the fluorides are quite different. Here, only skeletal modes contribute to ν(C=C), and the values obtained for this frequency in both "light" and "heavy" isotopic molecules are satisfactory. The remaining framework frequencies for the "light" molecule are generally satisfactory, the only significant error being one of 20 cm^{-1} in ν(C—F) (s). The discrepancy in this frequency in the "heavy" molecule is 56 cm^{-1}, and arises from a 28% contribution for δ(DCD). However, it is not expected that an application of the approximation method to molecules containing the groups $Y_2C{=}C(C_2)$ (Y = H, D) would encounter this difficulty, since ν(C=C) and δ(YCY) (Y = H, D) are more widely separated in these cases; for the effect is due mainly to the high value, 7.175 mdyn $Å^{-1}$, for F_d, and not to the mass of the fluorine atom.

Circular dichroism of some bis(halogenoacetato)bis(ethylenediamine)cobalt(III) complexes

ROLAND A. HAINES AND EDWARD B. KIPP
Department of Chemistry, University of Western Ontario, London, Ontario

Received August 22, 1968

Compounds of the general type *cis*-bis(halogenoacetato)bis(ethylenediamine)cobalt(III) are discussed for the cases where the halogenoacetate ion is monochloroacetate, dichloroacetate, trichloroacetate, or dibromoacetate. For the first time these complexes have been resolved into their optical isomers and a study has been made of the circular dichroism data obtained.

The positions of circular dichroism and absorption bands have been interpreted by calculating relative values of the σ and π interactions for the halogenoacetate ligands.

Canadian Journal of Chemistry, **47**, 949 (1969)

Introduction

Both *cis*- and *trans*-isomers of the type $[Co(en)_2(halac)_2]^+$ (where en is ethylenediamine and halac is the anion of a halogenoacetic acid) have been reported in the literature (1–5).Their absorption spectra have been given and from the shifts in absorption maxima, the various acids have been arranged into a spectrochemical series.

Although these compounds are of the general type $[Co(en)_2X_2]^{n+}$, for which many examples are known, very significant differences are present which justify a detailed study. For most compounds of this type the X groups can vary over a wide range of size, charge, coordinating atom, π-bonding properties, etc.; in fact, generally the X groups have little in common for any given series. However, when halogenoacetate ions are the X groups, greater similarities are present since all involve the carboxylate grouping as the common coordinating species. The sole changes are due to the degree of halogen substitution on the acetic acid, resulting in changes of basicity of the carboxylate anion. Scale molecular models indicate that the halogen substituted groups do not interfere with each other and thus effects due to interaction of these groups will not be significant. Hence it should be possible to study the effect of *small* changes in the donor properties of the ligand on the various spectral properties of the complex.

For the *cis*-compounds two d–d absorption bands have been reported (2) and small differences are observed in the absorption maxima. However, it is well known that in complexes such as these, with C_2 symmetry, splitting of the various energy levels should occur. Such splitting is usually not apparent from absorption spectra but circular dichroism (c.d.) spectra have frequently been able to show the features. Thus it should be possible to obtain more information regarding these ligands if the c.d. spectra could be obtained.

In this paper we report the resolution of several of the *cis*-complexes into their optical isomers and discuss the results derived from the c.d. curves.

Experimental

Racemic complexes with the general formula *cis*-$[Co(en)_2(halac)_2]^+$ (where halac is monochloroacetate, dichloroacetate, trichloroacetate, and dibromoacetate) were prepared by previous methods (1, 3). Optically active sodium arsenyl tartrate was prepared by the method of Henderson and Ewing (6). Starting chemicals were obtained from Fisher Scientific Co., with the exception of dibromoacetic acid which was purchased from K and K Laboratories.

Ultraviolet and visible absorption spectra were obtained from a Beckman DK-1 recording spectrophotometer, while optical rotatory dispersion (o.r.d.) and circular dichroism data were measured on a Durrum-Jasco ORD/UV/5 spectropolarimeter. Microanalyses were performed by Alfred Bernhardt, West Germany, or A. Gygli, Toronto.

Resolution of the cis-$[Co(en)_2(CH_2ClCO_2)_2]^+$ Ion

cis-$[Co(en)_2(CH_2ClCO_2)_2]I$ (8.0 g) in 40 ml of water at 60 °C was converted to the acetate by stirring for 10 min with 2.68 g of silver acetate. The silver salts were filtered and washed with 20 ml of warm water. Three drops of glacial acetic acid were added to the filtrate, followed by 4.84 g of $(+)_{589}$-$NaAsOC_4H_4O_6.2H_2O$, then 30 ml of ethanol. The solution was allowed to stand 1 h in an ice bath, then was placed in a freezer for 20 min, and finally was allowed to stand at 0 °C overnight, after the beaker was scratched vigorously with a glass rod. The pink crystals of the diastereoisomer $(-)_{589}$-$[Co(en)_2(CH_2ClCO_2)_2][(+)_{589}$-$AsOC_4H_4O_6].2\frac{1}{2}H_2O$ were filtered, washed with small amounts of ethanol and ether, and air dried. Yield: 2.72 g. $[\alpha]_{546} = -331°$.

Anal. Calcd. for $[Co(en)_2(CH_2ClCO_2)_2][AsOC_4H_4O_6]$: C, 23.82; H, 4.00; N, 9.26; Cl, 11.72; As, 12.52.

Found: C, 23.65; H, 4.08; N, 9.14; Cl, 11.75; As, 12.52.

To a solution of 2.35 g of $(-)_{589}$-$[Co(en)_2(CH_2ClCO_2)_2][(+)_{589}$-$AsOC_4H_4O_6].2\frac{1}{2}H_2O$ in 140 ml of water was added a solution of 1.35 g of $NaB(C_6H_5)_4$ in 40 ml of water. Acetone (2 ml) was added slowly and the solution was stirred for a few minutes. The pink precipitate of $(-)_{589}$-$[Co(en)_2(CH_2ClCO_2)_2]B(C_6H_5)_4.H_2O$ was filtered, washed with water, sucked dry, and dried in a vacuum desiccator. Yield: 1.76 g. $[\alpha]_{546} = -278°$.

Recrystallization was accomplished by *partially* dissolving 1.20 g of crude material in a minimum amount of methanol. The clear red solution was separated from the undissolved solid. To the solution, water was added dropwise with stirring until a permanent cloudiness remained on mixing. The solution was poured into another beaker, and the major part of the complex precipitated by adding water quickly. The pink crystals of the $(-)_{589}$-isomer were filtered, washed with water, sucked dry, and dried in a vacuum desiccator. Yield: 0.73 g. $[\alpha]_{546} = -278°$.

Anal. Calcd. for $[Co(en)_2(CH_2ClCO_2)_2]B(C_6H_5)_4$: C, 56.08; H, 5.88; N, 8.18; Cl, 10.35. Found: C, 56.27; H, 6.12; N, 8.23; Cl, 10.18.

Resolution of the cis-$[Co(en)_2(CHCl_2CO_2)_2]^+$ Ion

cis-$[Co(en)_2(CHCl_2CO_2)_2]I$ (4.0 g) in 65 ml of water at 60 °C was converted to the acetate by stirring for 10 min with 1.19 g of silver acetate. The silver salts were filtered and washed with 12 ml of warm water. Three drops of glacial acetic acid were added to the filtrate, followed by 2.12 g of $(+)_{589}$-$NaAsOC_4H_4O_6.2H_2O$, then 30 ml of ethanol. The solution was allowed to stand in an ice–salt–water bath at −7 °C for $1\frac{1}{4}$ h. The pink crystals of the diastereoisomer $(+)_{589}$-$[Co(en)_2(CHCl_2CO_2)_2][(+)_{589}$-$AsOC_4H_4O_6].H_2O$ were filtered, sucked dry, washed with ethanol, then ether[1], and dried in a desiccator. Yield: 0.80 g. $[\alpha]_{546} = +53.4°$.

Anal. Calcd. for $[Co(en)_2(CHCl_2CO_2)_2][AsOC_4H_4O_6]$: C, 21.39; H, 3.29; N, 8.31; Cl, 21.04; As, 11.12. Found: C, 21.54; H, 3.10; N, 8.25; Cl, 21.02; As, 11.36.

To a filtered solution of 0.76 g of the diastereoisomer $(+)_{589}$-$[Co(en)_2(CHCl_2CO_2)_2][(+)_{589}$-$AsOC_4H_4O_6].H_2O$ in 40 ml of water was added a solution of 0.38 g of $NaB(C_6H_5)_4$ in 10 ml of water. Acetone ($\frac{1}{2}$ ml) was added slowly with stirring and the solution was allowed to stand $\frac{1}{2}$ h. The pink crystals of $(+)_{589}$-$[Co(en)_2(CHCl_2CO_2)_2]B(C_6H_5)_4.H_2O$ were filtered, washed with water, sucked dry, and dried in a vacuum desiccator. Yield: 0.69 g.

The crude material (0.35 g) was dissolved in the minimum amount of methanol. The solution was filtered, and the complex crystallized by adding water slowly to the filtrate with stirring. The pink crystals of the $(+)_{589}$-isomer were filtered, washed with water, sucked dry, and dried in a vacuum desiccator. Yield: 0.20 g. $[\alpha]_{546} = +46.4°$.

Anal. Calcd. for $[Co(en)_2(CHCl_2CO_2)_2]B(C_6H_5)_4$: C, 50.96; H, 5.08; N, 7.43; Cl, 18.80. Found: C, 51.30; H, 5.12; N, 7.29; Cl, 18.77.

[1]During washing with ethanol and ether, some of the diastereoisomer may change into a sticky residue and the crystalline material remaining must be manually separated.

Resolution of the cis-$[Co(en)_2(CCl_3CO_2)_2]^+$ Ion

cis-$[Co(en)_2(CCl_3CO_2)_2]Cl$ (4.0 g) in 200 ml of water at 60 °C was converted to the acetate by stirring for 10 min with 1.38 g of silver acetate. The silver salts were filtered and washed with 10 ml of warm water. Four drops of glacial acetic acid were added to the filtrate, followed by 2.21 g of $(+)_{589}$-$NaAsOC_4H_4O_6.2H_2O$ and 80 ml of ethanol. The solution was allowed to stand in an ice–salt–water bath at −5 °C for $1\frac{1}{4}$ h. The pink crystals of the diastereoisomer $(-)_{589}$-$[Co(en)_2(CCl_3CO_2)_2][(+)_{589}$-$AsOC_4H_4O_6]$ were filtered, washed with ethanol and ether, and dried in a desiccator. Yield: 0.80 g. $[\alpha]_{546} = -228°$.

A second fraction of the $(-)_{589}$-diastereoisomer was obtained by taking the filtrate from the first fraction and cooling it for 1–$1\frac{1}{2}$ h in a freezer. When a precipitate began to form, the solution was allowed to stand at 0 °C overnight. The diastereoisomer was filtered, washed with ethanol and ether, and dried in a desiccator. Yield: 0.50 g. $[\alpha]_{546} = -236°$.

Anal. Calcd. for $[Co(en)_2(CCl_3CO_2)_2][AsOC_4H_4O_6]$: C, 19.40; H, 2.71; N, 7.54; Cl, 28.63; As, 10.08. Found: C, 19.60; H, 2.85; N, 7.43; Cl, 28.46; As, 10.16.

To a filtered solution of 0.92 g of the diastereoisomer $(-)_{589}$-$[Co(en)_2(CCl_3CO_2)_2][(+)_{589}$-$AsOC_4H_4O_6]$ in 550 ml of water was added a solution of 0.50 g of $NaB(C_6H_5)_4$ in 20 ml of water. Acetone (2 ml) was added slowly with stirring and the solution was allowed to stand $\frac{1}{2}$ h. The pink crystals of $(-)_{589}$-$[Co(en)_2(CCl_3CO_2)_2]B(C_6H_5)_4$ were filtered, washed with water, sucked dry, and dried in a vacuum desiccator. Yield: 0.82 g.

The crude material (0.65 g) was dissolved in the minimum amount of methanol. The solution was filtered, and the complex caused to crystallize by adding water slowly to the solution with stirring. The pink crystals of the $(-)_{589}$-isomer were filtered, washed with water, sucked dry, and dried in a vacuum desiccator. Yield: 0.20 g. $[\alpha]_{546} = -240°$.

Anal. Calcd. for $[Co(en)_2(CCl_3CO_2)_2]B(C_6H_5)_4$: C, 46.70; H, 4.41; N, 6.81; Cl, 25.81. Found: C, 47.04; H, 4.56; N, 6.79; Cl, 25.72.

Resolution of the cis-$[Co(en)_2(CHBr_2CO_2)_2]^+$ Ion

cis-$[Co(en)_2(CHBr_2CO_2)_2]I$ (4.0 g) in 120 ml of water at 60 °C was converted to the acetate by stirring for 10 min with 0.92 g of silver acetate. The silver salts were filtered off and washed with 10 ml of warm water. Three drops of glacial acetic acid were added to the filtrate, followed by 1.62 g of $(+)_{589}$-$NaAsOC_4H_4O_6.2H_2O$, then 30 ml of ethanol. The solution was allowed to stand in an ice–salt–water bath at −7 °C for $1\frac{1}{4}$ h. The pink crystals of the diastereoisomer $(+)_{589}$-$[Co(en)_2(CHBr_2CO_2)_2][(+)_{589}$-$AsOC_4H_4O_6]$ were filtered, washed with ethanol and ether, and dried in a desiccator. Yield: 1.10 g. $[\alpha]_{546} = +39.7°$.

Anal. Calcd. for $[Co(en)_2(CHBr_2CO_2)_2][AsOC_4H_4O_6]$: C, 16.92; H, 2.60; N, 6.58; Br, 37.52; As, 8.79. Found: C, 16.85; H, 2.56; N, 6.45; Br, 37.52; As, 9.01.

To a filtered solution of 0.94 g of the diastereoisomer $(+)_{589}$-$[Co(en)_2(CHBr_2CO_2)_2][(+)_{589}$-$AsOC_4H_4O_6]$ in 100 ml of water was added a solution of 0.39 g of $NaB(C_6H_5)_4$ in 20 ml of water. Acetone ($\frac{1}{2}$ ml) was added slowly with stirring and the solution was allowed to

The crude material (0.70 g) was dissolved in the minimum amount of methanol. The solution was filtered, and the complex caused to crystallize by adding water slowly with stirring. The pink crystals of the $(+)_{589}$-isomer were filtered, washed with water, sucked dry, and dried in a vacuum desiccator. Yield: 0.56 g. $[\alpha]_{546} = +28.0°$.

Anal. Calcd. for $[Co(en)_2(CHBr_2CO_2)_2]B(C_6H_5)_4$: C, 41.24; H, 4.11; N, 6.01; Br, 34.29. Found: C, 40.96; H, 4.19; N, 5.95; Br, 34.37.

For all complexes the optical isomer of opposite configuration was obtained by using $(-)_{589}$-$NaAsOC_4H_4O_6$ as the resolving agent.

All measurements were made on methanol solutions of the resolved complex.

Results and Discussion

The absorption spectra, o.r.d., and c.d. curves for each of the compounds studied are shown in Figs. 1–4 and a comparison of the absorption and circular dichroism data is given in Table I. Previous workers (2) have examined the absorption spectra of these complexes and have arranged the various acids into a spectrochemical series on the basis of shifts in absorption maxima. The relative ordering of the ligands was $CH_2ClCO_2^- < CHCl_2CO_2^- \sim CHBr_2CO_2^- < CCl_3CO_2^-$ and was the reverse of that expected on purely electrostatic grounds, thus suggesting that other effects were more predominant. An examination of the c.d. results presented below provides additional information on the matter.

To begin our discussion it is necessary to recall both the interrelationship of c.d. and absorption spectra and the splitting of absorption bands in complexes of low symmetry. For each electronic transition which is magnetic dipole allowed, strong circular dichroism will be observed and since c.d. is only a difference in absorbance of left and right

circularly polarized light at any particular wavelength, the position of the c.d. and absorption maxima should be identical. Octahedral cobalt(III) complexes have two d–d absorption bands, corresponding to the $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$ transitions, and theory predicts that in complexes of lower symmetry these bands become split. Thus two components are predicted for each band in complexes of D_3 symmetry, while three are expected for complexes of C_2 and C_{2v} symmetry. However, in many cases these component bands are not seen since the energy differences are rather small. Hence only the envelope of the combined absorption bands is observed and these results have suggested that the symmetry could be regarded as O_h to a first approximation.

The use of c.d. spectra has permitted some of the component bands to be located in certain compounds, this being largely due to the fact that c.d. bands are narrower than absorption bands and also may be of different sign. Thus in $[Co(en)_3]^{3+}$, which has D_3 symmetry, two c.d. bands of opposite sign are observed in the region of the low energy absorption band. For com-

plexes of C_2 or C_{2v} symmetry three c.d. bands are predicted in this region but only for $[Co(en)(mal)_2]^-$ (mal = malonate ion) are all three clearly defined (8), and the number observed in other compounds is strongly dependent on the ligands.

The two low energy c.d. bands observed for the $[Co(en)_3]^{3+}$ complex correspond to transitions to a doubly degenerate E level and to one with A_2 symmetry. In the C_2 complexes one transition has A symmetry while the remaining two have B symmetry. One of the B components derives from the A_2 transition in the corresponding $[Co(en)_3]^{3+}$ compound, while the other B component and the one with A symmetry result from the breakdown of the E level in that complex (7).

The octahedral T_{2g} level is also broken down for $[Co(en)_3]^{3+}$ and a symmetry forbidden A_1 state which shows no c.d. and a double degenerate E level are produced. The degeneracy of the latter becomes further broken down into two components with A and B symmetry in C_2 complexes.

The compounds reported here are all of the type $[Co(en)_2XX]^{n+}$ and possess C_2 symmetry. Two c.d. bands of opposite sign are found in the region of the low energy absorption band and this is similar to that often observed when X is a monodentate ligand. The band of lower energy corresponds to the B component derived from A_2 in $[Co(en)_3]^{3+}$, while the other is a combination of the A and B transitions which are obtained from the E band in that complex and are very similar in energy (7, 9). For most complexes of this general type the shifts of these bands upon changing the X group parallel the shifts in absorption maxima, but for the series of halogenoacetic acids such was not found to be the case. This may be due to the fact that most ligands in the spectrochemical series differ quite markedly from one another and hence any changes observed on substitution of ligands are quite distinct. This is not the situation for the halogenoacetate ligands which all bear a strong similarity to one another and hence present much smaller changes at the coordination site. All are uninegative, unidentate, and possess the same carboxylate grouping, thus eliminating some of the problems encountered in comparing ligands. Hence the differences observed should be related directly to properties of the particular halogenoacetate ion.

Yamatera (9) has predicted the relative magnitudes of splitting in absorption bands as the symmetry is lowered from O_h. Accordingly each shift can be attributed to some combination of σ and π interactions in complexes of the type *cis*-$[Coa_4b_2]$ of C_{2v} symmetry, and the arguments are readily extended to similar complexes with C_2 symmetry. From his arguments it can be seen that in the low energy region the net shift of the B component should be twice that of the combined A and B transition. Other equations apply to the shifts observed in the region of the higher energy absorption band. The positions of our c.d. maxima were considered as shifts relative to the absorption maxima of $[Co(en)_3]^{3+}$, which has O_h point symmetry and D_3 overall symmetry. The equations presented in Table II of Yamatera's paper were then employed and two quantities, δ_σ and δ_π, were calculated for each of the complexes. These two terms are measures of the effect of changes in σ and π interactions respectively on the spectral band shifts. Since the c.d. data is derived from overlapping Gaussian curves, probably not too much significance should be attached to the actual numerical values. However, the trends should give indications of the relative importance of each term to the observed shifts. It can be seen from Table II presented below that δ_σ and δ_π individually have different trends but their sum produces the observed variations in c.d. maxima.

The δ_σ term becomes more negative as chlorine substitution on the acid is increased, while the dibromoacetate compound has a δ_σ value which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

is less than that of the dichloroacetate species. This term is an indication of the shift produced if only σ interactions are involved and a possible explanation can be put forward using an electrostatic argument. The relative acid strengths of the free acids follow the order $CH_2ClCO_2H < CHCl_2COOH \sim CHBr_2CO_2H < CCl_3CO_2H$. Thus the trichloroacetate ion is the poorest Lewis base and will present the weakest field to the metal ion. Hence a shift to the lowest energies (or most negative δ_σ values) should occur for this ligand. The remaining acid anions should cause a smaller shift toward lower energies in proportion to their basicity and such is found to be the case.

The δ_π term, which indicates the contributions from π bonding effects, follows a trend toward more positive values as the chlorine substitution on the ligand is increased, while the dibromoacetate compound has a value which is similar to that for the dichloroacetate complex. According to Yamatera (9) the δ_π term should become more positive as π bonding is increased, and hence the metal–ligand π bonding would be greatest in the trichloroacetate compound and least in the monochloroacetate. The dichloroacetate and dibromoacetate compounds have values which are similar to each other and indicate π bonding which is intermediate between the two extremes. Thus the trend is the reverse of that for δ_σ and it is possible that the σ effects produced by increasing halogen substitution render the carboxylate group a better π acceptor of electron density from the metal. This seems logical if simple ligand field theory is applied. As the field presented by the ligand becomes weaker, the donor atom may approach the metal more closely and hence better overlap is possible in the π system.

The positions of either absorption or c.d. spectra depend on the relative importance of each term. As predicted (9), the δ_σ term is always predominant but as δ_π changes the combination can produce different trends which are reflected in positions of the c.d. maxima. The absorption spectra show an average effect due to band overlap (of the same sign) and the location of the band maximum depends on the actual energy separation of the components. For this series these vary only by small amounts and produce small changes in absorption maxima. A more meaningful picture can be obtained by considering the interrelationship of all the component bands as located by c.d. spectra.

The intensities of the c.d. spectra vary considerably and detailed calculations are needed before a satisfactory argument can be put forward. Two major problems contribute to the observed c.d. intensity in these complexes, (*a*) band overlap and (*b*) mixing of transitions with the same symmetry. It has been shown previously (10) that in $[Co(en)_3]^{3+}$ the bands cancel each other to within 5%. Such cancellation would obtain for these complexes also, since the energy separation is almost the same or in some cases even less than that in $[Co(en)_3]^{3+}$. Thus the intensity could vary considerably, depending on the energy separation.

An even more important contribution could be due to configuration interaction which occurs between transitions of the same symmetry. Thus in the region of the low energy absorption band the two *B* components should have rotational strengths which are a combination of the two "pure" *B* rotational strengths. Although limits have been set on the extent of such mixing (7), for any given compound it has remained an unknown quantity. Examination of the equations describing the interaction shows that the resultants vary widely in both sign and magnitude for small changes in mixing coefficients, and thus casual examination of the relative c.d. intensities may not be too useful.

All of these complexes may be assigned an absolute configuration on the basis of their c.d. curves. It has been shown (7) that for complexes of this type the predominant c.d. band is the *A* component, and hence may be related to the *E* band of the compound $[Co(en)_3]^{3+}$ for which an absolute configuration is known (11). On this basis, all complexes of $[Co(en)_2(halac)_2]^+$ which have a positive *A* component of c.d. may be assigned the *D* or Λ configuration which is related directly to the *D* or Λ isomer of $[Co(en)_3]^{3+}$, as shown in Fig. 5.

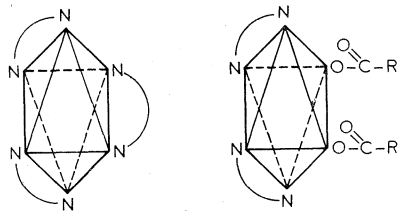

FIG. 5. Configuration of the *D* or Λ isomers of $[Co(en)_3]^{3+}$ and $[Co(en)_2(halac)_2]^+$.

This study emphasizes the fact that absorption spectra frequently do not give detailed information concerning metal complexes but rather present an average effect. Although in many cases this is sufficient, for this particular series with very similar ligands it is not. We have shown how c.d. spectra can be used to gain information concerning the metal–ligand interactions.

Ion–molecule reactions in vinyl fluoride

J. A. HERMAN[1] AND A. G. HARRISON
Department of Chemistry, University of Toronto, Toronto 5, Ontario

Received June 24, 1968

The ion–molecule reactions in vinyl fluoride have been studied as a function of pressure and electron energy. The $C_2H_2^+$ and C_2HF^+ fragment ions react predominantly by charge transfer while $C_2H_3^+$ produces $C_2H_4F^+$ and $C_4H_5^+$. The $C_2H_2F^+$ fragment forms $C_2H_4F^+$, CHF_2^+, $C_2H_3F_2^+$, $C_4H_4F^+$, and probably $C_2H_3^+$. The rate constants for the individual reactions have been measured. The $C_2H_3F^+$ ion reacts to form $C_3H_5^+$, $C_3H_4F^+$, $C_3H_3F_2^+$, and $C_4H_5F^+$ (in minor yield), both by a second order and by a third order reaction. The rate constants and product distributions from the individual reactions have been evaluated. A number of consecutive reactions have been identified and shown to be third order processes.

Canadian Journal of Chemistry, 47, 957 (1969)

Introduction

The ion–molecule reactions in vinyl chloride have been studied recently both by ion cyclotron resonance spectrometry (1) and by conventional mass spectrometric techniques (2). The reaction of $C_2H_3Cl^+$ leads to $C_3H_4Cl^+$, $C_4H_5Cl^+$, and $C_4H_6Cl^+$. The $C_3H_4Cl^+$ and $C_4H_6Cl^+$ products are analogous to the $C_3H_5^+$ and $C_4H_7^+$ products observed from reaction of $C_2H_4^+$ in ethylene (3), while the $C_4H_5Cl^+$ product is distinctive. The vinyl chloride system is also distinctive in that the bimolecular reaction of $C_2H_3Cl^+$ is very slow, the majority of those $C_2H_3Cl^+$ ions which react disappearing by a reaction which is second order in neutral vinyl chloride. A similar third order reaction has been observed in vinyl bromide (2). In view of the large effect which substitution of chlorine or bromine has on the reaction course and rates, it appeared of interest to study the ionic reactions in vinyl fluoride. The present work reports the results we have obtained in such a study.

Experimental

The experimental work was carried out on the medium pressure instrument recently described (4). The pertinent operating conditions were a source temperature of approximately 100 °C, a primary ion travel distance of 0.54 cm, and a repeller field corresponding to 2.4 eV ion exit energy. The ionizing electron beam was pulsed and primary ion residence times were measured by the deflection technique previously described (4). The source pressures were measured directly using an MKS Baratron capacitance micromanometer.

The vinyl fluoride was obtained from Matheson and Co. and was purified by bulb-to-bulb distillation in vacuo before use. No impurities were detected in the mass spectrum.

Results and Discussion

Figure 1 shows the dependence of the primary ion intensities (% total ionization) on the ion source pressure for impact of 50 eV electrons at 2.4 eV ion exit energy. The $C_2H_2F^+$, C_2HF^+, and $C_2H_2^+$ primary ion intensities decrease with

increasing pressure in the exponential manner expected of reactive primary ions. On the other hand, the $C_2H_3^+$ and $C_2H_3F^+$ intensities show an initial increase followed by a decrease at higher pressures, indicating that these ions are products of ion–molecule reactions as well as being reactive ions.

Figure 2 shows the product ion intensities as a function of pressure. The products $C_2H_4F^+$, CHF_2^+, $C_2H_3F_2^+$, $C_4H_5^+$, and $C_4H_4F^+$ show an increase in intensity with pressure which is characteristic of the products of bimolecular reactions. On the other hand, the curves for $C_3H_5^+$, $C_3H_4F^+$, and $C_3H_3F_2^+$ suggest that they are formed predominantly, if not exclusively, by third order reactions. The curve for $C_4H_6F^+$ also shows a pronounced upward curvature, indicating a high kinetic order for the reaction producing this ion. In addition to the products shown in Fig. 2 very small intensities were observed for $C_3H_3^+$ and $C_4H_5F^+$. From observations of the ion intensities as a function of electron energy and from ratio plot (5) studies, the reaction identifications summarized in Table I were obtained. The reactions of the individual primary ions are considered in detail in the following.

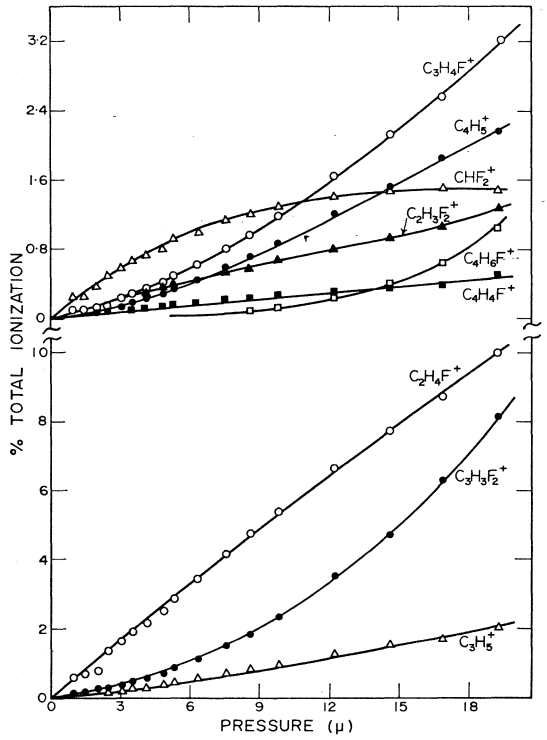

FIG. 2. Pressure plot for product ion, conditions as for Fig. 1.

TABLE I

Reaction identification in vinyl fluoride

Reactant	Products
$C_2H_2^+$	$C_3H_3^+$, $C_2H_3F^+$
$C_2H_3^+$	$C_2H_4F^+$, $C_4H_5^+$
C_2HF^+	$C_2H_3F^+$
$C_2H_2F^+$	$C_2H_4F^+$, CHF_2^+, $C_2H_3F_2^+$, $C_4H_4F^+$
$C_2H_3F^+$	$C_3H_5^+$, $C_3H_4F^+$, $C_4H_5F^+$, $C_3H_3F_2^+$

$C_2H_2^+$

A typical log plot of the normalized $C_2H_2^+$ intensity versus pressure is shown in Fig. 3. Several such plots gave an average total rate constant for the disappearance of $C_2H_2^+$ of $(19.5 \pm 0.3) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}. The $C_3H_3^+$ ion was found to originate from reaction of $C_2H_2^+$ (reaction [1]), the rate constant being 0.5×10^{-10} cm^3 molecule^{-1} s^{-1}. No other products were observed and we conclude that the majority of the $C_2H_2^+$ ions charge transfer to vinyl fluoride (reaction [2]). Since $I(C_2H_2) = 11.42$ eV (6) and $I(C_2H_3F) = 10.37$ eV (7), the reaction is exothermic. A similar rapid charge transfer reaction of $C_2H_2^+$ has been observed in the vinyl chloride system (2)

$$[1] \quad C_2H_2^+ + C_2H_3F \rightarrow C_3H_3^+ + CH_2F \qquad k = 0.5 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

$$[2] \quad C_2H_2^+ + C_2H_3F \rightarrow C_2H_3F^+ + C_2H_2 \qquad k = 19.0 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

$C_2H_3^+$

No total rate constants for the disappearance of $C_2H_3^+$ could be obtained since this ion appears to be produced in an ion–molecule reaction. Ratio plots showed that both $C_2H_3^+$ and $C_2H_2F^+$ reacted to form $C_2H_4F^+$. A typical ratio plot obtained over the electron energy range 13 to 18.8 eV nominal is shown in Fig. 3. The non-zero slope and intercept clearly indicate the occurrence of both reactions [3] and [4] with the average rate constants indicated.

$$[3] \quad C_2H_3^+ + C_2H_3F \rightarrow C_2H_4F^+ + C_2H_2 \qquad k = (3.0 \pm 0.5) \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

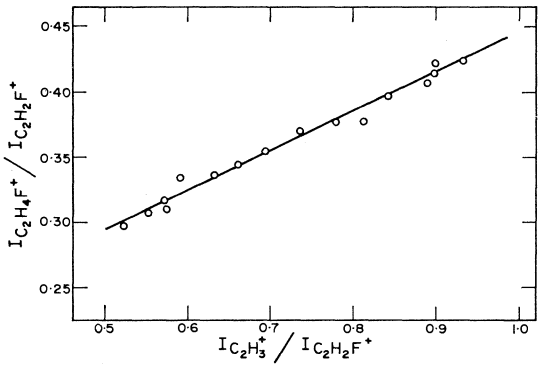

FIG. 3. Ratio plot for formation of $C_2H_4F^+$ [M] = 2.66×10^{14} molecules cm^{-3}.

[4] $C_2H_2F^+ + C_2H_3F \rightarrow C_2H_4F^+ + C_2HF$

$k = (1.7 \pm 0.2) \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1}

The $C_2H_3^+$ ion also reacts to form $C_4H_5^+$. However, the ratio $I_{C_4H_5^+}/\sum I_{C_2H_3^+}$ was not linear with pressure as expected but showed an upward curvature. It is not known whether another reaction of higher order also produces $C_4H_5^+$ or whether the $C_2H_3^+$ ions produced by ion–molecule reaction react at a faster rate than those produced by dissociative ionization. No rate constant could be evaluated for reaction [5].

[5] $C_2H_3^+ + C_2H_3F \rightarrow C_4H_5^+ + HF$

C_2HF^+

No products of the reaction of this ion were observed and we conclude that it reacts exclusively by charge transfer to vinyl fluoride (reaction [6]). A typical log plot is shown in Fig. 4 and leads to $k_6 = 19.5 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1}.

[6] $C_2HF^+ + C_2H_3F \rightarrow C_2H_3F^+ + C_2HF$

$C_2H_2F^+$

The following reactions of $C_2H_2F^+$ were observed (all rate constants in cm^3 $molecule^{-1}$ s^{-1}).

[4] $C_2H_2F^+ + C_2H_3F \rightarrow C_2H_4F^+ + C_2HF$

$k = (1.7 \pm 0.2) \times 10^{-10}$

[7] $C_2H_2F^+ + C_2H_3F \rightarrow CHF_2^+ + C_3H_4$

$k = (1.1 \pm 0.1) \times 10^{-10}$

[8] $C_2H_2F^+ + C_2H_3F \rightarrow C_2H_3F_2^+ + C_2H_2$

$k = (0.50 \pm 0.1) \times 10^{-10}$

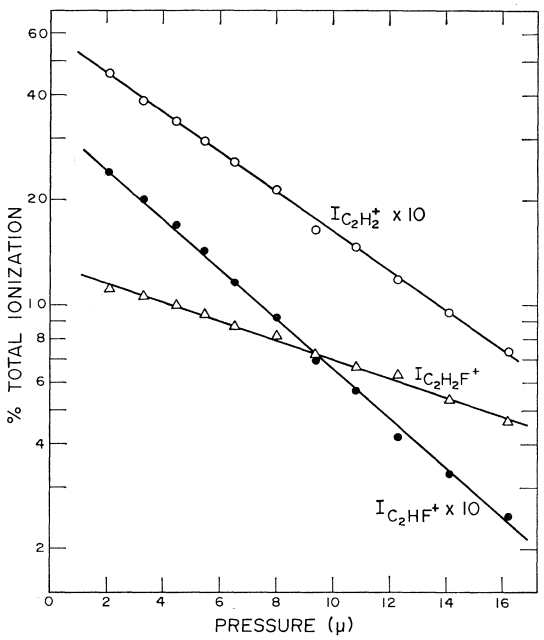

FIG. 4. log (I_{X^+}/Σ) versus pressure.

[9] $C_2H_2F^+ + C_2H_3F \rightarrow C_4H_4F^+ + HF$

$k = (0.20 \pm 0.1) \times 10^{-10}$

The total rate constant for the disappearance of $C_2H_2F^+$ (see typical log plot in Fig. 4) was found to be $(7.5 \pm 0.3) \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1} while the sum of the rate constants for the above four reactions is only $\sim 3.5 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1}, indicating a further undetected reaction. It is probable that this is reaction [10], leading to formation of $C_2H_3^+$, with a rate constant of approximately 4×10^{-10} cm^3 $molecule^{-1}$ s^{-1}.

[10] $C_2H_2F^+ + C_2H_3F \rightarrow C_2H_3^+ + C_2H_2F_2$

$C_2H_3F^+$

In addition to being formed in reactions [1] and [6] $C_2H_3F^+$ reacts to produce $C_3H_3F_2^+$, $C_3H_4F^+$, $C_3H_5^+$, and $C_4H_5F^+$ in order of decreasing yield. The data in Fig. 2 suggest that the first three are formed predominantly by third-order reactions, although the partial secondary character of the $C_2H_3F^+$ makes this interpretation uncertain. Figure 5 shows a pressure plot obtained at 10.4 eV nominal electron energy where $C_2H_3F^+$ is the only significant primary ion. In addition to the expected products, $C_5H_7^+$,

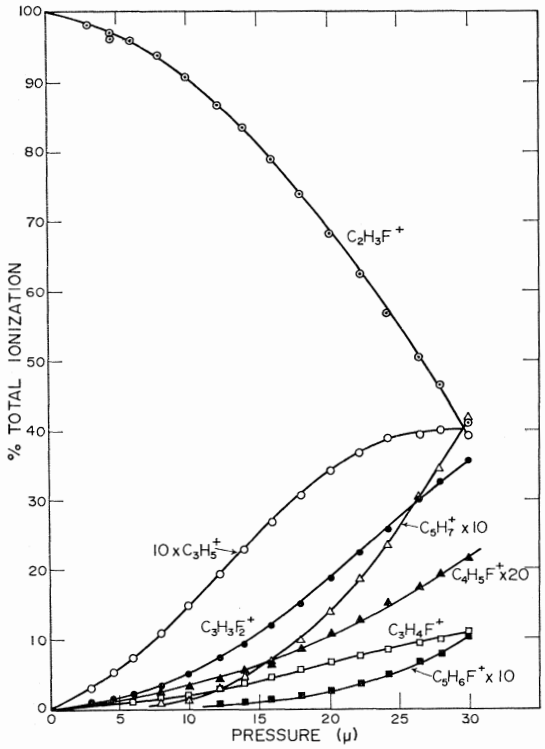

FIG. 5. Pressure plot 10.4 eV electron energy, 2.4 eV ion exit energy.

$C_5H_6F^+$, and, in minor yield, $C_4H_3F_3^+$ (not shown on graph) are found at high pressures, presumably as a result of the following consecutive reactions.

$$C_2H_3F^+ \rightarrow C_3H_5^+ \rightarrow C_5H_7^+$$
$$C_2H_3F^+ \rightarrow C_3H_4F^+ \rightarrow C_5H_6F^+$$
$$C_2H_3F^+ \rightarrow C_3H_3F_2^+ \rightarrow C_4H_3F_3^+$$

Both the shape of the curve for the reactant $C_2H_3F^+$ and the shapes of the curves for the product ions indicate that the major part of the reaction of $C_2H_3F^+$ is second order in concentration of the neutral reactant. The order of the reaction is shown more clearly by the data in Fig. 6, which cover a smaller range of pressure with the result that the consecutive reactions are unimportant. At higher pressures both the reactant ion intensity and the product ion intensities are linear functions of the square of the source pressure, indicating a predominant third-order reaction. The curvature in the initial region for the product ions indicates a small contribution from a second-order reaction.

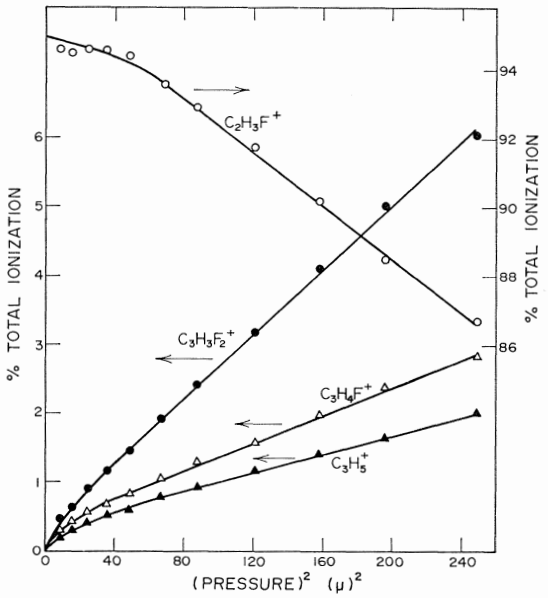

FIG. 6. Ion intensities versus P^2.

For the concurrent second-order and third-order reactions, [11] and [12] respectively,

[11] $C_2H_3F^+ + C_2H_3F \rightarrow C_3H_5^+ + CHF_2$
$\rightarrow C_3H_4F^+ + CH_2F$
$\rightarrow C_3H_3F_2^+ + CH_3$

[12] $C_2H_3F^+ + 2C_2H_3F \rightarrow C_3H_5^+ + ?$
$\rightarrow C_3H_4F^+ + ?$
$\rightarrow C_3H_3F_2^+ + ?$

we may write for each product ion at low total conversions

$$[13] \qquad \frac{I_{X^+}}{\sum I_{p^+} \cdot P} = k_{11_x} tK + k_{12_x} tK^2 P$$

where I_{X^+} is the ion current for product X^+, $\sum I_{p^+}$ is the sum of reactant and product ion currents, t is the reaction time, P is the ion source pressure, and K is the proportionality constant relating the source pressure to the source concentration in molecules cm^{-3}. Figure 7 shows the data of Fig. 6 plotted in the manner indicated by eq. [13]; satisfactory straight lines are obtained[2]. From the slopes and intercepts of such plots we have obtained the rate constants for formation of

[2]The $C_4H_5F^+$ product has been omitted from this analysis because of its low intensity (<1% of total product).

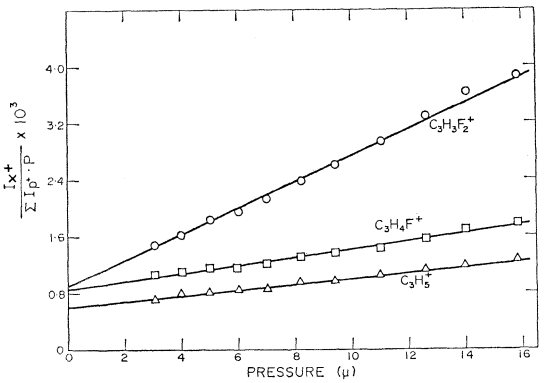

FIG. 7. $I_{X^+}/\Sigma I_{p^+} \cdot P$ versus P.

each product by both reaction [11] and reaction [12]. The results are summarized in Table II as total reaction rate constants and product distributions[3].

The bimolecular rate constant $k_{11} = 2.6 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} is approximately a factor of 20 lower than that measured (3) for the analogous reaction [14] in ethylene

[14] $\quad C_2H_4^+ + C_2H_4 \rightarrow C_3H_5^+ + CH_3$

The bimolecular rate constant for vinyl fluoride is only slightly larger than that observed (2) for vinyl chloride ($\sim 1 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}), although the product distribution is different. For vinyl chloride the only C_3 ion observed was $C_3H_4Cl^+$ ($\sim$85% of total), the remaining product being $C_4H_6Cl^+$. In addition, in vinyl chloride both the product distribution and the bimolecular rate constant appeared to be dependent on the ionizing electron energy. No such trend is evident in the vinyl fluoride system.

The apparent third order rate constant $k_{12} = 1.2 \times 10^{-25}$ cm^6 molecule^{-2} s^{-1} is approximately the same as the third order rate constant in vinyl chloride. The product distribution is distinctly different, the third-order reaction in vinyl chloride leading to $C_3H_4Cl^+$ ($\sim$36%), $C_4H_5Cl^+$ (49%), and $C_4H_6Cl^+$ (15%) with no $C_3H_5^+$ or $C_3H_3Cl_2^+$ being observed.

The reasons for the slow bimolecular reaction and the mechanism of the third-order reaction are not known with certainty; however, a reaction scheme similar to that proposed (8) for the vinyl chloride system can explain the results. Reactions [15] to [19] outline this scheme as modified in the light of our results (2) for the vinyl chloride system.

[15] $\quad C_2H_3F + e \rightarrow C_2H_3F^{+*} + 2e$

[16] $\quad C_2H_3F^{+*} + C_2H_3F \rightarrow (C_2H_3F)_2^{+*}$

[17a] $\quad (C_2H_3F)_2^{+*} \rightarrow$ Products

[17b] $\quad \rightarrow C_2H_3F^+\dagger + C_2H_3F$

[18] $\quad C_2H_3F^+\dagger + C_2H_3F \rightarrow (C_2H_3F)_2^+\dagger$

[19a] $\quad (C_2H_3F)_2^+\dagger \rightarrow$ Products

[19b] $\quad \rightarrow C_2H_3F^+\dagger + C_2H_3F$

The collision complex formed in reaction [16] produces the observed products with low efficiency ($\sim$1%), the majority of the complexes taking part in the charge transfer reaction [17b]. The analogous charge transfer reaction is known (8) to occur rapidly in vinyl chloride, and it has been shown (2) that it must occur through complex formation. The broadening of the withdrawal curves for the $C_2H_3F^+$ ion indicates a similar charge transfer in vinyl fluoride. The product of the charge transfer reaction, $C_2H_3F^+\dagger$, undergoes reactions [18] and [19] to form the observed products with an efficiency of $\sim$10%, somewhat

[3]It might be noted that the product distributions do not correspond to random loss of H and F from the $C_4H_6F_2^+$ intermediate. Such a statistical loss would predict 10.7% $C_3H_5^+$, 53.6% $C_3H_4F^+$, and 35.7% $C_3H_3F_2^+$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

higher than for the ions produced directly by electron impact.

For the vinyl chloride system it has been suggested (8) that the overall efficiency of the condensation reaction and the distribution of products therefrom depend on the internal excitation of the collision complex, and that the complex formed in reaction [16] has a greater internal energy than that formed in reaction [18], presumably because $C_2H_3X^+$* is more highly excited than $C_2H_3X^+$†. As pointed out in the previous paper (2) the effect of ionizing electron energy on the second order rate constant and product distribution does not entirely support the suggestion. The present results do not either. If the internal energy of the complex is important in determining the rate and product distribution, one would expect both to vary as the ionizing electron energy is changed, whereas, in fact, both are independent of electron energy in the vinyl fluoride system. This is in contrast to the vinyl chloride system where a variation with electron energy was observed, but in a direction opposite to that predicted if vibrational excitation of the reactant ion plays an important role. The reasons for the low efficiencies of the second-order reactions in the vinyl halides and for the differences in the two vinyl halide systems are not readily apparent. Our results would certainly indicate that excess vibrational energy of the reactant ion is not an important factor in determining the fate of the collision complex; however, they do not preclude the possibility that excited electronic states may play an important role.

Consecutive Reactions in Vinyl Fluoride

In addition to the primary reactions discussed above, the following reactions of product ions have been observed in the vinyl fluoride system

[20] $C_2H_4F^+ + 2C_2H_3F \rightarrow C_4H_6F^+ + ?$

[21] $C_3H_5^+ + 2C_2H_3F \rightarrow C_5H_7^+ + ?$

[22] $C_3H_4F^+ + 2C_2H_3F \rightarrow C_5H_6F^+ + ?$

In each case the reaction corresponds formally to the type $A^+ + C_2H_3F \rightarrow AC_2H_2^+ + HF$, a reaction type whose importance was first pointed out by Baldeschwieler *et al.* (1); however, for all three reactions we find that the rate is second order in neutral vinyl fluoride pressure. The relevant plots are shown in Figs. 8 to 10 where in each case a good linear plot versus P^2 is obtained. For reactions [20] and [22] the extent of reaction

is low and we have plotted I(product)/(I(reactant) + I(product)) as a function of pressure. For reaction [21] the extent of reaction is large and a logarithmic plot is necessary. Since the reactant ions are themselves produced by ion–molecule reactions, their residence times in the ion source cannot be determined accurately and therefore accurate third order rate constants cannot be evaluated. If we estimate the reaction times to be a few microseconds (compare 3 μs for the withdrawal time of $C_2H_3F^+$), we calculate third order rate constants in the region 10^{-25} to 10^{-24} cm^6 molecule^{-2} s^{-1}. While the third-order reaction of $C_2H_3F^+$ can readily be accommodated by the mechanism outlined above, no simple rationale can be advanced for the third-order reactions [20] to [22]. It appears that the collision complex in each case must be collisionally stabilized before decomposition to the observed products occurs.

Comparison of Ionic Reactions of Vinylic Compounds

The ion–molecule reactions in C_2H_4, C_2H_3Cl, C_2H_3F, C_2H_3Br, and C_2F_4 have now been studied and it is of interest to compare the reactions which occur in these various vinylic systems. The comparisons for the reactions of the $C_2X_2^+$, $C_2X_3^+$, and $C_2X_4^+$ ions (X = H or halogen) are summarized in Tables III to V. The $C_2X_2^+$ ion reacts chiefly by reactions [23] and [24],

$$[23] \quad C_2X_2^+ + C_2X_4 \rightarrow C_2X_4^+ + C_2X_2$$

$$[24] \quad \rightarrow C_3X_3^+ + CX_3$$

although in ethylene a third reaction yielding $C_4H_5^+$ has been reported (9). The summary in Table III shows that the charge transfer reaction [23] is the most important in all systems and, indeed, is the only reaction observed for $C_2H_2^+$ in vinyl chloride and C_2HF^+ in vinyl fluoride. For both vinyl fluoride and chloride the reaction of $C_2X_2^+$ has a rate constant comparable to the Langevin prediction, although for ethylene the reaction is slower. The $C_2F_2^+$ ion intensity in C_2F_4 is low and only the $C_3F_3^+$ product has been definitely identified (10); however, the charge transfer reaction is exothermic and probably occurs.

The reaction of $C_2X_3^+$ with C_2X_4 forms two products by reactions [25] and [26].

$$[25] \quad C_2X_3 + C_2X_4 \rightarrow C_2X_5^+ + C_2X_2$$

$$[26] \quad \rightarrow C_4X_5^+ + X_2$$

In all cases (see Table IV) reaction [25] is the most important with reaction [26] being of minor

TABLE V
Products of reaction $C_2X_4^+ + C_2X_4$

Reactant		Product %			
Ion	Neutral	$C_3X_5^+$	$C_4X_7^+$	$C_4X_6^+$	Reference
$C_2H_4^+$	C_2H_4	84	10	0.04	9
$C_2H_3Cl^+$	C_2H_3Cl	36–85 ($C_3H_4Cl^+$)	15–18 ($C_4H_6Cl^+$)	0–49 ($C_4H_5Cl^+$)	2
$C_2H_3F^+$	C_2H_3F	~99 ($C_3H_5^+$, $C_3H_4F^+$, $C_3H_3F_2^+$)		~1 ($C_4H_5F^+$)	This work
$C_2H_3Br^+$	C_2H_3Br		100 ($C_4H_6Br^+$)		2
$C_2F_4^+$	C_2F_4	~99	~1		10

importance. Reaction [25] involves H^+ transfer except for $C_2H_2F^+$ as a reactant in the vinyl fluoride system where both $C_2H_4F^+$ and $C_2H_3F_2^+$ are observed as products. Reaction [26] proceeds in all the vinyl halides with formation of the corresponding hydrogen halide as the X_2 neutral fragment. A number of other minor products are observed in the ethylene, tetrafluoroethylene, and vinyl fluoride systems. In the latter system the most important extra reaction is

[10] $C_2H_2F^+ + C_2H_3F \rightarrow C_2H_3^+ + C_2H_2F_2^+$

and it is interesting to note that the analogous reaction in ethylene, reaction [27], has been reported recently (9).

[27] $C_2H_3^+ + C_2D_4 \rightarrow C_2H_3D + C_2D_3^+$

Three different reactions, [28] to [30], have been observed for the $C_2X_4^+$ molecule-ion

[28] $C_2X_4^+ + C_2X_4 \rightarrow C_3X_5^+ + CX_3$

[29] $C_2X_4^+ + C_2X_4 \rightarrow C_4X_7^+ + X$

[30] $\rightarrow C_4X_6^+ + X_2$

As shown in Table V, reaction [28] is the major reaction in all cases except vinyl bromide where only $C_4H_6Br^+$ (reaction [29]) is observed. Reaction [30] is significant in vinyl chloride and of minor importance in vinyl fluoride. The reaction $C_2H_3F^+ + C_2H_3F$ produces the full range of possible $C_3X_5^+$ ions consistent with extensive, but not complete, scrambling of the hydrogens and fluorines. In all other reactions of the vinyl halide molecule-ions, one halogen atom is found in the ionic product and one in the neutral product.

From the above comparisons it is evident that the major features of the ionic reactions in ethylene and in the halogen-substituted ethylenes are very similar. The most noticeable difference lies in the low efficiency of the second-order reaction of the molecule-ion in the vinyl halides. It might be noted that in C_2F_4 it has been suggested (10) that the $C_3F_5^+$ and $C_4F_7^+$ products are also produced by higher order reactions involving the molecule-ion.

Acknowledgments

The authors are indebted to the National Research Council of Canada for financial support of this work. The authors are deeply indebted to Dr. T. O. Tiernan for communication of results prior to publication and for illuminating discussions concerning ion–molecule reaction mechanisms, and to a referee for helpful suggestions.

Electromotive force studies of liquid uranium–zinc alloys

Y. HOSHINO[1] AND J. A. PLAMBECK
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received September 3, 1968

The electromotive force of cells of the type U(s)/LiCl–KCl (eutectic) + UCl_3/(U + Zn) (liquid alloy) have been measured over the temperature range 450–550 °C, in the zinc-rich region of alloy composition. Thermodynamic functions for the limiting uranium–zinc intermetallic compound existing in this region are: ΔG_f^0, −23.0 kcal/mole; ΔS_f^0, −37.1 cal/deg mole; ΔH_f^0, −52.9 kcal/mole at 535 °C. These values are compared with those previously reported by other workers.

Introduction

The processing of spent nuclear reactor fuel is one of the most important problems in nuclear technology. Although aqueous processes are currently used, there has been considerable recent interest in pyrometallurgical processes and reviews of this work are available (1–6). In some of these processes, spent fuel is first dissolved in liquid bismuth or zinc metal at high temperatures. This liquid metal is then contacted with a fused salt; the fission products distribute themselves between the salt and metal phases. Although this process has generally been considered (5, 6, 11, 12, 14) from the point of view of distribution equilibria, the material in the salt phase (metal ions) is related to that in the metal phase (metal alloys) through electrochemical as well as distributive equilibria. The use of electrochemical cells could well lead to improvements in the effectiveness and/or selectivity of these separations. The electrochemical properties of metal ions in fused salts have been extensively studied (7, and references cited therein). The electrochemical and thermodynamic properties of the alloys have been studied less extensively, but it is clear that they cannot, in general, be treated as merely ideal solutions of one metal in another. In view of the obvious central importance of the U–Zn system and the existence of prior studies of it, the zinc-rich portion of this system was chosen for initial investigation.

The phase diagram of the zinc-rich region of the U–Zn binary system (8) has a liquidus line rising sharply near the melting point of zinc. The stoichiometry of the solid phase existing in equilibrium with dilute liquid U–Zn alloy has been the subject of considerable recent controversy; this has been reviewed by Pascal (9). For the purpose of this paper, we will consider the stoichiometry of the limiting U–Zn compound to be $UZn_{8.5}$; our data are given in a form which permits recalculation in terms of other stoichiometric compositions.

The thermodynamic behavior of U–Zn alloys in the zinc-rich portion of the phase diagram has previously been studied by United States Atomic Energy Commission workers. Chiotti and co-workers (10–14) have used vapor pressure and electromotive force (e.m.f.) measurements, and Johnson and co-workers (15, 16) have used e.m.f. measurements to obtain thermodynamic data on the $UZn_{8.5}$ phase in general agreement with our own. The study of solutions in the more dilute range is less extensive (16). Carbide and oxycarbide formation have also been studied in this system by e.m.f. methods (17, 18).

Experimental

Materials

The fused LiCl–KCl eutectic was prepared by the method of Laitinen *et al.* (19) and ampuled under argon for future use. Reagent grade zinc shot (Allied Chemical, New York) was cast into a small ingot under fused zinc chloride for future use. Uranium wire (0.1 in. diameter, 99.9%, A. D. MacKay Inc., New York) was cut into small pieces which were weighed and stored in small zinc wire capsules for ease in handling. Argon gas was purified by passage over hot copper wires followed by a magnesium perchlorate drying tube.

Instruments

All potential measurements were made with a K-3 potentiometer (Leeds and Northrup Co., Philadelphia, Pennsylvania). The entire cell envelope was contained in a 3 in. internal diameter vertical tube furnace equipped with an indicating temperature controller (Models 54231A, 59344; Lindberg-Hevi-Duty Heating Equipment Co., Watertown, Wisconsin). The temperature within the

[1]Present address: Department of Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo, Japan.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

cell was monitored by a calibrated chromel–alumel thermocouple in a Pyrex sheath immersed in the melt; its output was read on a Model 3440A digital voltmeter (Hewlett–Packard, Palo Alto, California) or the K-3 potentiometer. Coulometric oxidations were carried out with a Model IV current source (E. H. Sargent and Co., Chicago, Illinois).

Cell and Electrodes

All parts of the cell and associated apparatus were of Pyrex glass unless otherwise specified. The cell proper consisted of a high-wall crucible with a central bottom depression to hold the U–Zn pool; this contained the LiCl–KCl melt. Contact with the pool was made by a tungsten lead sealed in a Pyrex tube to insulate it from other leads. Other electrodes were suspended in the melt from the outer glass envelope cap.

The outer glass envelope consisted of a closed-end tube with a 60/50 male standard taper joint at the top, which extended above the furnace. The cell crucible rested on Pyrex wool at the bottom of the outer envelope. The envelope was capped with a female standard taper joint, closed off, into which were blown one 10/30 and four 14/20 standard taper female joints to permit insertion of electrodes, gas inlets, or other apparatus. The outer glass envelope was airtight and was maintained at a slight positive pressure of argon during experiments, to prevent entry of air.

In addition to the zinc pool electrode, the cell always contained a uranium rod electrode. This rod (0.1 in. diameter) was attached to a flexible copper lead well above the melt level. It could be raised and lowered into the melt by rotating a horizontal Pyrex rod around which the wire was wound. The Pyrex rod entered through a standard taper joint, and electrical contact was made through a Kovar seal to ensure airtight operation. A counter electrode and auxiliary reference electrode were sometimes required as well as the uranium rod. These consisted of tungsten or silver wires, respectively, held in isolation compartments made from 10 mm sealing tubes (D porosity, Ace Glass Co., Vineland, New Jersey) and allowed to fill with melt before addition of uranium or zinc. The silver reference wire was anodized to produce a solution of about 0.1 *M* Ag^+ within the compartment; this reference electrode has been discussed (20).

The small zinc capsules containing uranium were lined up in a horizontal sealed side tube with a small piece of iron behind them. To add a capsule to the U–Zn pool, an external magnet was used to move the iron so that the leading capsule was pushed out of the side tube. It then fell through a vertical Pyrex guide tube ending just above the melt, and through the melt into the pool. This method permitted successive additions of uranium without exposure of the melt to air.

Procedure

An ampul of the previously prepared eutectic was taken, melted, subjected to HCl for 1 h, purged with argon, and evacuated. Argon was then introduced and a positive pressure maintained throughout each experiment. If changes in the electrodes necessitated opening the cell for a few moments, the cell was evacuated and argon re-introduced before continuing with the experiment.

Uranium trichloride solutions were prepared by anodization of the uranium rod at 20 mA to the extent of 200 mC against an isolated counter electrode. The e.m.f. of the cell was, as expected, independent of the concentration of U(III) so produced, provided that a reasonable concentration was generated; all experimental runs used approximately 0.012 *M* U(III) solutions. The activity of U(III) was also checked against the auxiliary Ag/Ag(I) reference to ensure that approximately 100% current efficiency had been attained. The melt was stirred with argon bubbling to destroy the electrolytic concentration gradient before any potential measurements were made.

The U–Zn pool was made by adding individual weighed zinc capsules containing weighed uranium metal, through the addition apparatus described above, to a pool made from a weighed small zinc ingot. Previous attempts to prepare the alloys by coulometric deposition of uranium were successful but potentials were not reproducible, the current efficiency being less than 100% for the deposition, and hence this method was discarded. Several hours were generally required to reach equilibrium (e.m.f. change less than 0.1 mV in 30 min). Several composition values were obtained in each run by addition of successive zinc capsules.

In the measurements of e.m.f. as a function of temperature, values were taken both with increasing and with decreasing temperature. The time required to return to equilibrium after a temperature change was several times longer when cooling than when heating, although the equilibrium e.m.f. was the same; this indicates that the dissolution of the solid U–Zn phase is more rapid than its formation.

Results and Discussion

Typical results of the e.m.f. measurements of the cell U(s)/LiCl–KCl (eutectic) + UCl_3/U in Zn(I) at 808 °K are shown in Fig. 1. The break point in this curve is considered to be the point at which the solid compound $UZn_{8.5}$ begins to precipitate from the liquid U–Zn alloy, and occurs at 2.2×10^{-2} mole % uranium. This does not agree with corresponding value of 8.1×10^{-2}

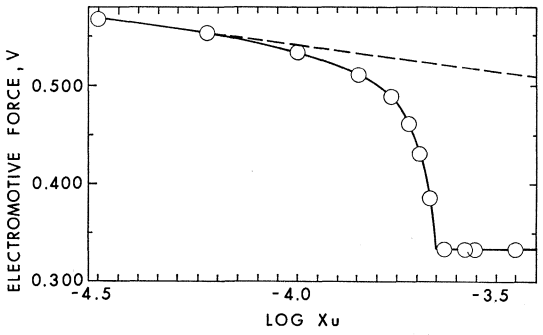

FIG. 1. Cell e.m.f. as a function of the mole fraction uranium in the alloy. Dashed line indicates Henrian behavior, horizontal region formation of solid compound.

mole % we calculate from early solubility data of Chiotti *et al.* (21), but is in considerably better agreement with the value of 1.2×10^{-2} mole % we calculate from the more recent direct solubility measurements analyzed by Johnson and Dillon (22).

The thermodynamics of the region preceding the break point (unsaturated region) and following it (saturated region) must be treated separately. In the unsaturated region, the excess partial molal free energy of uranium (excess chemical potential) is related to the e.m.f. of the cell studied through the well-known thermodynamic equation

$$\Delta\bar{G}_U^{XS} = -nFE - RT\mathrm{d}\ln X_U$$

Values of $\Delta\bar{G}_U^{XS}$ are calculated in Table I, and their relation to Henry's law is shown in Fig. 1. It is clear that positive deviations from Henry's law exist for all solutions of uranium in zinc more concentrated than 1×10^{-2} mole %. Large negative deviations from Raoult's law are always observed, as expected. The data reported here do not agree with the report of Johnson and Feder (15) that the excess partial molal free energy of uranium was independent of uranium concentration in the unsaturated region at 450 °C; it is probable that these workers did not take experimental data in the comparatively small region where Henry's law is not obeyed.

†Data from run 1; all other data from run 2.

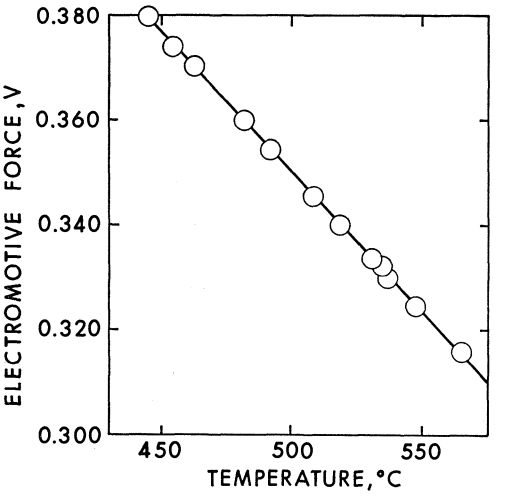

FIG. 2. Behavior of cell e.m.f. in saturated region as a function of temperature. Points taken randomly with increasing and decreasing temperature.

The excess chemical potential of zinc can be calculated from that of uranium by use of the Gibbs–Duhem equation, and is found from our data to be 2.5 cal/mole at $X_U = 2.2 \times 10^{-4}$, which is negligible. We can therefore assume ideal (Raoultian) behavior for zinc.

The thermodynamics of the saturated region are quite different since we are now concerned with the solid alloy $UZn_{8.5}$. A typical e.m.f. – temperature plot for this region is shown in Fig. 2. A least squares analysis of the results of several such runs gives the equation:

$$E = 0.7646 - 5.36 \times 10^{-4}\,T$$

where E is the e.m.f. (V) and T the temperature (°K); the standard deviation is 0.0011 V.

Since the cell reaction corresponding to this potential is $U(s) + 8.5\,Zn(l, alloy) \rightarrow UZn_{8.5}(s)$, the standard free energy of formation of the compound $UZn_{8.5}(s)$ will be given by

$$\Delta G_f^0 = \Delta G + 8.5RT \ln a_{Zn}$$

where ΔG is the free energy change of the cell and a_{Zn} is the activity of zinc metal in the alloy. Standard states are taken as pure (solid) uranium, pure (liquid) zinc, pure (solid) $UZn_{8.5}$. Using the Gibbs–Duhem equation discussed above for a_{Zn}, the term $8.5\,RT \ln a_{Zn}$ is found to be only −6.3 cal/mole so that we may neglect it and

TABLE II

use $\Delta G_f^0 = \Delta G$. The least-squares equation then becomes

$$\Delta G_f^0{}_{UZn_{8.5}} = -52.90 + 37.08 \times 10^{-3} T\ (°K) \text{ kcal/mole}$$

over the temperature range 450–550 °C, standard deviation 0.076 kcal/mole. The values given by this equation are compared to those given by previous authors (10, 15, 18) in Table II. Values calculated beyond the actual temperature range of the author's experiments are indicated by asterisks. Our work confirms that of Johnson (15, 16) but differs more from that of Chiotti and Kilp (10) even using the recalculated values of Chiotti *et al.* (18). Chiotti *et al.* (18), in discussing Johnson's work, suggested that the contamination of the uranium electrode surface by impurities might explain the discrepancy. We cannot accept this criticism, however, since the potential of the U–Zn pool against a uranium electrode which had been in the melt for several days was the same as its potential against a freshly prepared uranium electrode.

The standard entropy and enthalpy of the formation of $UZn_{8.5}$ were calculated from the temperature dependence of the potential given above; their values are $\Delta S_f^0 = -37.1$ cal/deg mole, $\Delta H_f^0 = -52.9$ kcal/mole. These are in good agreement with the values we calculate from the work of Johnson (15, 16), −38.2 cal/deg mole and −54.2 kcal/mole respectively. The vapor pressure data of Chiotti and Kilp (10) gives, for ΔH_f^0, −54.6 kcal/mole at 450 °C and −55.9 kcal/mole at 500°, and −35.6 cal/deg mole and −37.3 cal/deg mole for ΔS_f^0 at the same temperatures.

Since completion of this study, Volkovich *et al.* (23) have published a study at 700–950 °C in fused NaCl–KCl from which we calculate

$$\Delta G_f^0{}_{UZn_{8.5}} = -53.43 + 37.4 \times 10^{-3} T\ (°K) \pm 0.035 \text{ kcal/mole}$$

This, extrapolated to our lower temperature range, is in agreement with the results of the present study.

Conclusion

Uranium in liquid zinc is a solute which retains ideal Henrian behavior only up to 1×10^{-2} mole % U at 808 °K. Positive deviations then occur up to 2.2×10^{-2} mole % U at which point a solid U–Zn phase precipitates. The thermodynamic properties of the liquid and solid phases have been measured and these measurements compared with those of other workers.

Pyrochlores. V. Thermoanalytic, X-ray, neutron, infrared, and dielectric studies of $A_2Ti_2O_7$ titanates[1]

OSVALD KNOP AND FRANÇOIS BRISSE[2]
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

AND

LOTTE CASTELLIZ
Department of Chemical Engineering, Nova Scotia Technical College, Halifax, Nova Scotia

Received August 14, 1968

A number of compositions $A_2^{3+}Ti_2^{4+}O_7$ and of related mixed phases were prepared and investigated. For the trivalent lanthanons from Sm to Lu, and for Y, the homogeneous $A_2Ti_2O_7$ phases were of the cubic pyrochlore type. Their lattice parameters gave a very good linear relationship when plotted against the Templeton–Dauben radii of A^{3+}. The room-temperature stability region of the pyrochlore titanates at ordinary pressures extends from an Ahrens radius ratio, $r(A^{3+}):r(Ti^{4+})$, of about 1.22 to about 1.50, taking into account homogeneous mixed phases. The compositions $Bi_2Ti_2O_7$, $In_2Ti_2O_7$, and $Cr_2Ti_2O_7$ were not cubic pyrochlores; the results of an X-ray and neutron examination of $Sc_2Ti_2O_7$ indicate that further work is needed to clarify its structural properties.

The structures of Lu, Y, Gd, and Sm titanates were refined from X-ray powder data and that of $Y_2(Ti_{0.64}Zr_{0.36})_2O_7$, from neutron powder data. The structure of $Er_2Ti_2O_7$ was re-refined from previously published data without significant improvement. The positional parameter of the majority oxygen atom, $x(O_2)$, in $A_2B_2O_7$ pyrochlores has been found to increase, and the distortion of the BO_6 octahedra to decrease, with the increasing $r(A^{3+}):r(B^{4+})$ ratio. This is in agreement with a similar result obtained earlier from Mössbauer spectra for A_2FeSbO_7 pyrochlores.

The variation of the frequencies of the principal absorption bands in the infrared spectra of the titanates has been correlated with $r(A^{3+})$. No evidence of ferroelectricity was found in Sm and Er titanates between room temperature and 4.2 °K.

The Templeton–Dauben set of empirical crystal radii for trivalent lanthanons has been supplemented by values for Sc, In, Tl, and Bi derived from the *C*-type sesquioxides and the pyrochlores. The self-consistency and applicability of the expanded set have been tested on several series of isostructural compounds.

Canadian Journal of Chemistry, 47, 971 (1969)

In a previous paper (1) it was established that $Er_2Ti_2O_7$, which is a typical representative of the cubic $A_2^{3+}B_2^{4+}O_7$ phases, is isostructural with pyrochlore, (NaCa)(NbTa)O_6F. The crystal structures of another 4 members of the $A_2Ti_2O_7$ series (A = Y, Lu, Gd, and Sm) have now been refined from X-ray powder diffractometer data, and the systematic study (2) of the cubic pyrochlore stannates, $A_2Sn_2O_7$, has been extended to the titanate series. For reasons similar to those stated in ref. 2, a mixed phase, $Y_2(Ti_{0.64}Zr_{0.36})_2O_7$, was also prepared and investigated by neutron powder diffraction.

The main points of interest, as with the stannates, have been the variation of the positional parameter $x(O_2)$ of the majority oxygen atom (and thus the distortion of the TiO_6 octahedra) with the size of A^{3+}, and the limits of existence of the cubic pyrochlore structure. Results of preliminary work on the latter problem were reported earlier (3).

Experimental

The origin and purity of the starting materials have been described in ref. 2. In addition, MnO_2 (Fisher Certified Reagent), Ga_2O_3 (4 *N*) and ZrO_2 (3 *N*) (Koch–Light Laboratories Limited), GeO_2 (K & K Laboratories, Inc.), and $ZrO(NO_3)_2$ (Tizon Chemical Corporation; stated to contain less than 100 p.p.m. Si) were used. Solutions of titanyl oxalate were prepared from $TiCl_4$ that had been purified by the method described in ref. 4.

Titanates of series D (dry-mixed) were prepared as in ref. 1. The individual firing schedules are listed in Table I. The progress of the solid-state reaction was followed by powder photography. In series C (coprecipitated, or totally precipitated) the hydroxides were precipitated with NH_4OH from mixed solutions of the A nitrate and titanyl oxalate of correct stoichiometries. The resulting slurry was dried at 120°, calcined at 900° for 1 h, ground to pass 400 mesh, and calcined at 1100° for 10 h. The calcine was pressed to pellets and fired at 1300° for 2 h, ground, pressed again, and fired at 1400° for 2 h. When the heat treatment differed from the standard procedure details are given in Table I (La, Y, Sc).

*1000/24 stands for 1000°/24 h. Reference 3: 1000/16, 1000–1400/5, 1400/2, cooled in the furnace; the temperature dropped from 1400 to 1060° during the first hour. Reference 17: 1200–1350/10–14.
†C, this work, coprecipitated; D, this work, dry-mixed.
‡Converted to present λ (Cu Kα) (cf. ref. 2).
§$Y_2Ti_2O_7$ fired at 1420/20 is reported to be weberite + ? (34).

Not listed in Table I are the following firing schedules: Ln_2O_3 + 2TiO_2 (Ln = Pr, Nd); Bi_2O_3 + 2TiO_2 (950/6, 1000/12, 1000/12)[3]; Cr_2O_3 + 2TiO_2 (950/12, 1200/3, 1300/8, 1400/2); Y_2O_3 + 2GeO_2 (1000/24, 1100/24, 1350/24, 1350/24); and Er_2O_3 + 2GeO_2 (1000/12, 1200/4, 1300/4, 1400/8). Preparative firing was not carried out for MnO_2 + TiO_2 (only thermogravimetric analysis (t.g.a.) up to 1310° at 6°/min)[4] and In_2O_3 + 2TiO_2 (only differential thermal analysis (d.t.a.) up to 1600° at 20°/min).

Terbium presented a complication in that the commercial brown oxide is not Tb_2O_3 but a phase of uncertain composition usually referred to as Tb_4O_7. To determine the actual Tb content a sample of the oxide was heated in a thermobalance in stagnant air (for details see ref. 1). The t.g.a. curve showed an intermediate plateau between 600 and 940°. When the final plateau (above 1130°) is taken to correspond to Tb_2O_3, the composition of the intermediate oxide would be $TbO_{1.692}$, i.e. almost Tb_7O_{12}, and the initial composition would be $TbO_{1.790}$, i.e. almost Tb_5O_9. The endothermic peaks in the d.t.a. curve corresponded with the plateaus of the t.g.a. curve. The final product, Tb_2O_3, could be reoxidized almost reversibly. When the heating was carried out in a stream of oxygen, the positions of the t.g.a. plateaus shifted toward higher temperatures (Fig. 1, Table II).

A similar investigation was carried out on the commercial black Pr_6O_{11}. The t.g.a. and d.t.a. curves were more complicated than for TbO_x (Fig. 1, Table II). Pr_2O_3 appears to be stable in atmospheric air above 1360°.

[3]950/6 stands for 950° for 6 h, etc.
[4]MnO_2 goes over to Mn_2O_3 between 880 and 960°. The sesquioxide, which exists above 1085°, is stable on further heating in stagnant air (6°/min) to at least 1320°.

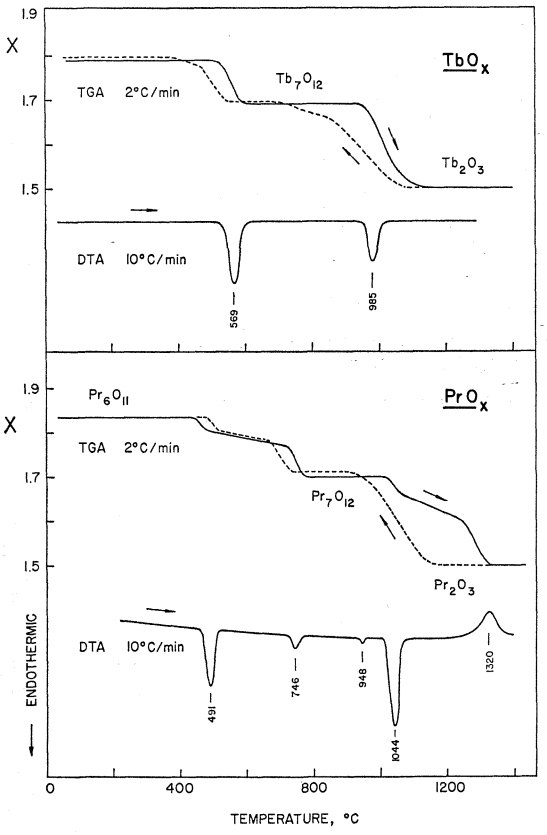

FIG. 1. Differential thermal analysis and thermogravimetric analysis curves of TbO_x and PrO_x in stagnant air. The formulae Tb_7O_{12} and Pr_7O_{12} are only approximations (see text).

The information from t.g.a. and d.t.a. was used merely to ensure that correct amounts of Tb and Pr were introduced to yield products of the intended compositions. However, the analyses were done with care, and the results concerning the intermediate stability levels can be used to verify the findings on the systems Tb–O and Pr–O reported by other authors (5–7).

The process of formation of some of the titanates was followed by thermogravimetry as well as by d.t.a. There was no loss of weight on heating intimate mixtures of $Ln_2O_3 + 2TiO_2$ (Ln = La, Nd, Sm, Er) to 1400° in air. For $TbO_x + TiO_2$ and $PrO_{1.833} + TiO_2$ the total weight decreased with increasing temperature till the sesquioxides formed, but there was no further loss on continued heating and no gain on cooling. This was confirmed for $TbO_x + TiO_2$ by d.t.a.

Differential Thermal Analysis

A Deltatherm Model 2000-16 differential thermal analyzer (Technical Equipment Corporation, Denver, Colorado) was capable of reaching 1600° in non-reducing atmospheres. The heating rate could be varied in steps from 2 to 20°/min. The Pt–Rh sample block was designed to accommodate 4 samples plus 4 alumina references. Some of the d.t.a. experiments were carried out with a home-made differential thermal analyzer of the Mineral Sciences Division, Department of Energy, Mines and Resources, in Ottawa, Canada.

Infrared Spectra

Infrared spectra were recorded from 4000 to 250 cm^{-1} on a Perkin–Elmer model 521 spectrophotometer using KBr pellets (1 mg sample/200 mg KBr) with a KBr reference.

Permittivity Measurements

These were performed by Y. S. Lim of the Physics Department, Dalhousie University, Halifax, Nova Scotia. For details see ref. 2.

X-ray and Neutron Diffraction

Details will be found in refs. 1, 2, and 8. No foreign

lines were visible in well-exposed powder photographs of the pyrochlore titanates. Films of Gd, Sm, Nd, and Eu titanates taken with Ni-filtered CuK radiation had exceptionally dark backgrounds. A Rigaku–Denki high-temperature X-ray camera was used in the examination of $La_2Ti_2O_7$.

For details of the least-squares refinement, ref. 2 may be consulted. Neutral and ionic scattering factors and dispersion corrections were taken from the following sources:

Y, Sm, Gd, Er, Lu (neutral and 3+), and Ti^{4+}: *f*, ref. 9; dispersion corrections, ref. 10.

O, Ti, and Ti^{3+}: *f* and dispersion corrections, ref. 11.

O^{2-}: *f*, ref. 12.

Results and Discussion

In agreement with previous reports (3, 13–20) the lanthanons from Lu to Sm as well as Y were found to form cubic $A_2Ti_2O_7$ pyrochlores (Table I), whereas Nd, Pr, and La gave X-ray powder patterns of a different type. A notable exception is the finding of Padurow and Schusterius (21), who stated that $La_2Ti_2O_7$ had a cubic pyrochlore structure with $a = 10.60$ Å. We have been unable to confirm this result. All attempts to prepare a cubic $La_2Ti_2O_7$ pyrochlore failed, be it by solid-state reaction or by firing the coprecipitated hydroxides. The possibility of a phase transformation was examined with a high-temperature X-ray camera. There was no significant change in the powder pattern of $La_2Ti_2O_7$ (coprecipitated and fired at 1400°) as the temperature was continuously raised from room temperature to 1490°. $(Sm_{1-x}La_x)_2Ti_2O_7$ compositions gave patterns of the same type as $La_2Ti_2O_7$. Moreover, compared with the a_0 values obtained for $La_2Ti_2O_7$ by extrapolating the lattice parameters of the cubic pyrochlores (Fig. 2), the value of 10.60 Å is about 0.19 Å too high and thus improbable, quite apart from the impurities in Padurow and Schusterius's La_2O_3 which would tend to lower the a_0 of the cubic phase.

All the reflections observed in the powder pattern of $Sc_2Ti_2O_7$ could be indexed on a fluorite unit cell. Because of the similarity of the atomic scattering factors of Sc^{3+} and Ti^{4+}, it was not possible to decide whether the product had the pyrochlore or the disordered fluorite-type structure[5]. With $b(Sc) = 1.18$, $b(Ti) = -0.34$,

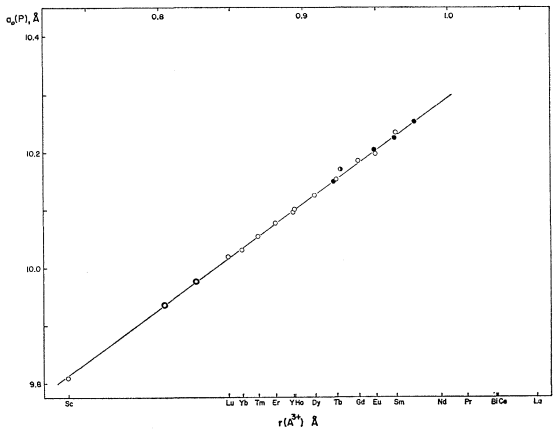

FIG. 2. Dependence of $a_0(A_2Ti_2O_7)$ on the radius of A^{3+}. Full circles, $(Y_{1-x}Bi_x)_2Ti_2O_7$; double circles, $(Lu_{1-x}Sc_x)_2Ti_2O_7$; half-full circle, $YbNdTi_2O_7$. The value for Sc is $2a_0$ of the fluorite pattern.

and $b(O) = 0.577$ (all in 10^{-12} cm (22)), neutron diffraction ought to make the distinction possible.

To this end a large batch of $Sc_2Ti_2O_7$ was prepared by coprecipitation (1000/24, 1200/24, 1400/24, 1400/24, 950/2 days, cooled with the furnace). The neutron diffraction pattern of the product was neither that of pyrochlore nor that of fluorite, but X-ray powder photographs taken before and after the neutron diffraction experiment contained only lines of a fluorite-type pattern. The films were of very good quality, with sharp diffraction lines.

These results are at variance with what would be expected from the investigation of the system Sc_2O_3–TiO_2 by Komissarova *et al.* (23). These authors concluded that there is no phase of the composition $Sc_2O_3 \cdot 2TiO_2$. The phase closest to TiO_2 is the δ phase $2Sc_2O_3 \cdot 3TiO_2$, which is rhombohedral ($a_{rh} = 7.742 \pm 5$ Å, $\alpha_{rh} = 71.94 \pm 0.10°$) below $1150 \pm 50°$, and of the defect fluorite type above this temperature. The composition $Sc_2O_3 \cdot 2TiO_2$ should thus correspond to a mixture of $\delta(Sc_2O_3$–$TiO_2)$ and rutile if cooled slowly or annealed below 1150°, or to a single phase of the fluorite type if quenched from temperatures above 1150°.

The conflicting evidence from the X-ray and neutron diffraction patterns of our sample fitted neither case. A possible explanation might be that the high-temperature disordered fluorite phase did not transform, under the above annealing conditions, into a mixture of δ and TiO_2 but had

[5]Brixner (17), who had prepared $Sc_2Ti_2O_7$ earlier, listed it with the cubic pyrochlore titanates and quoted an a_0 that corresponds to a double fluorite cell (Table I).

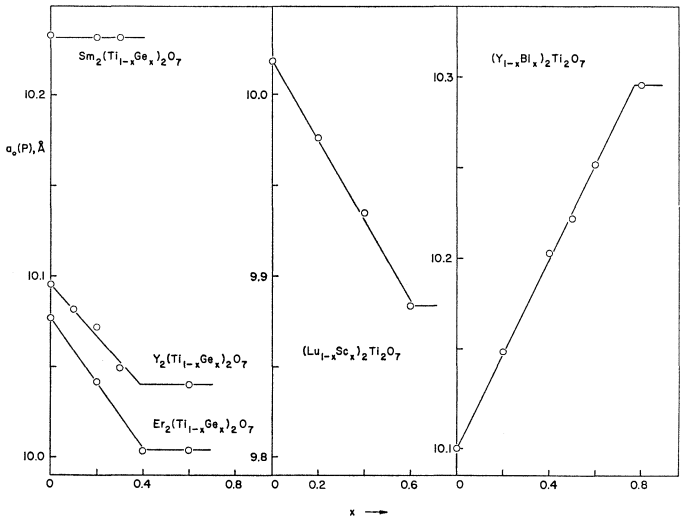

FIG. 3. Lattice parameter $a_0(P)$ vs. composition. *Left*, $A_2(Ti_{1-x}Ge_x)_2O_7$ (A = Sm, Y, Er); *center*, $(Lu_{1-x}Sc_x)_2Ti_2O_7$; *right*, $(Y_{1-x}Bi_x)_2Ti_2O_7$.

nevertheless attained a considerable degree of short-range order. This, as well as vacancy ordering in the anion sublattice, might give rise to extra neutron diffraction maxima but not necessarily to additional X-ray reflections. A situation of this kind has recently been described for the phase $Y_2O_3 \cdot 2CeO_2$ by Barker and Wilson (25). Further work to clarify the discrepancy is underway, but even on the evidence available at present it is clear that the $Sc_2Ti_2O_7$ sample was not a cubic pyrochlore.

Chromium and indium titanates apparently had formed (cf. Fig. 5) but they did not have the pyrochlore structure[6]. The In compound was greyish, the Cr compound was dark brown. No compound appeared to form on firing $InAlO_3$ (*C*-type, $a_0 = 10.1070 \pm 9$ Å) + $2TiO_2$ at 1400° for 12 h. $MnTiO_3$ with the ilmenite structure rather than $Mn_2Ti_2O_7$ was obtained by firing $MnO_2 + TiO_2$ or $Mn_2O_3 + 2TiO_2$ in air; this result was confirmed by t.g.a.

The structure of Bi titanate appeared to be related to that of pyrochlore (cf. $Bi_2Sn_2O_7$, refs. 15 and 2). The extra lines present in the X-ray powder pattern could not be accounted for on a cubic pyrochlore cell. However, mixed phases $(Y_{1-x}Bi_x)_2Ti_2O_7$ that contained up to $x = 0.75$ bismuth were prepared as cubic pyrochlores (Table I, Fig. 3).

The $(Lu_{1-x}Sc_x)_2Ti_2O_7$ system was investigated to determine the lower limit of existence of the pyrochlore phase. The limit is approximately at $x = 0.55$ (Table I, Fig. 3), which corresponds to an average Ahrens ionic radius of about 0.83 Å.

Although Cr^{3+} is too small to form a pyrochlore phase in its own right, the slight lowering of $a_0(P)$ of $Y_2Ti_2O_7$ on introducing chromium (Table I) would seem to indicate that a small amount of Cr had entered the pyrochlore structure. A similar observation was made with gallium. In spite of the similarity of the Ahrens ionic radii of In and Sc, a mixed Y–In pyrochlore titanate did not appear to form.

The two mixed titanates $HoYTi_2O_7$ and $YbNdTi_2O_7$ were pyrochlores, as expected.

Mixed Phases $A_2(Ti_{1-x}M_x)_2O_7$ (M = Ge, Zr)

No pyrochlore pattern was obtained for pure $Y_2Ge_2O_7$, $Er_2Ge_2O_7$, or $Sc_2Ge_2O_7$,[7] but it was possible to estimate the extent to which Ge could

[6]Roth (15) did not obtain a compound on firing $In_2O_3 + 2TiO_2$ at 1550° for 3 h. Hamelin (24) stated $Cr_2Ti_2O_7$ to form by firing the dry-mixed oxides at 1440° in air for 10 min as well as under other firing conditions. She reported the *d* spacings of the phase but made no attempt at indexing.

[7]Recently Shannon and Sleight (26) prepared high-pressure cubic $A_2Ge_2O_7$ pyrochlores (A = Gd, Dy, Ho, Tl, Er, Tm, Yb, Lu, Y, In, and Sc); a corresponding Sm phase did not form. The lattice parameters of $Y_2Ge_2O_7$ (9.897 ± 2 Å) and $Er_2Ge_2O_7$ (9.864 ± 2 Å) would fall 0.03–0.05 Å below the points obtained for the corresponding $A_2(Ti_{1-x}Ge_x)_2O_7$ phases by extrapolating the $a_0(P)$ vs. x straight lines of Fig. 3 to $x = 1$.

be accommodated in Er, Y, and Sm titanates as host structures (Table I, Fig. 3):

Very little Ge was present in the homogeneous Sm phase at the saturation limit. Assuming that the stability of the pyrochlore structure in $A_2Ti_2O_7$ is determined primarily by the radius ratio $r(A^{3+}):r(B^{4+})$, the upper limit of the ratio can be estimated from $Sm_2(Ti_{0.92}Ge_{0.08})_2O_7$ as 1.50 (Ahrens). The largest value of $r(A^{3+})$ in combination with $r(Ge^{4+}) = 0.53$ Å would then be $1.50 \times r(Ge^{4+}) = 0.80$ Å, which is smaller than $r(Lu^{3+})$. The lanthanons and scandium would thus not be expected to form pyrochlores with Ge. In a similar manner one can estimate the average maximum values of $r(B^{4+})_{calcd} = r(A^{3+})/1.50$ appropriate to Y and Er in the mixed germanates. As Table III shows, the estimates,

TABLE III

A	x (limit)	$\bar{r}(B^{4+})$, Å: limit	$\bar{r}(B^{4+})$, Å: calcd.	$r(A^{3+}):r(B^{4+})$ (limit)
		Ahrens radii		
Sm	0.08	0.668	0.668	1.50
Y	0.36	0.626	0.613	1.45
Er	0.40	0.620	0.593	1.44
		"Improved" radii		
Sm	0.08	0.616	0.616	1.56
Y	0.36	0.602	0.571	1.48
Er	0.40	0.600	0.565	1.47

though lower, are reasonably close to the average radii $\bar{r}(B^{4+})_{limit}$ calculated from the experimental saturation limits.

When "improved" radii are used, the upper limit of the radius ratio becomes 1.56 and the largest value of $r(A^{3+})$, 0.89 Å[8]. This value falls between $r(Er^{3+})$ and $r(Y^{3+})$ (cf. ref. 2), which would suggest that a cubic $Er_2Ge_2O_7$ ought to exist. Since neither Y nor Er form pure germanate pyrochlores at ordinary pressures, the implication is that the effective size of the oxygen ion exerts a controlling influence on the upper stability limit of the pyrochlore structure even when the radius ratio is favorable, similar to the way in which it controls the lower limit (8), and prevents the germanates from existing as pyrochlores. In other words, the value of the upper limit of the radius ratio decreases with decreasing $r(A^{3+})$ and $r(B^{4+})$, which is the reason for $\bar{r}(B^{4+})_{calcd}$ being increasingly lower than $\bar{r}(B^{4+})_{limit}$ (cf. Table III). The same is of course true of the Ahrens radii, even disregarding the fact that the Ahrens radius of Sc^{3+}, 0.81 Å, is much too large (cf. next section). The upper limit can, however, be extended to include the pure germanates by application of high pressure (cf. footnote 7).

The three $Y_2(Ti_{1-x}Zr_x)_2O_7$ phases ($x = 0.36$, 0.5, and 0.64) were pyrochlores (Table I).

Other Compositions

An attempt was made to prepare, by firing the dry-mixed oxides, mixed titanate pyrochlores of the type $M^{2+}N^{4+}Ti_2O_7$. The combinations tried were CaGe (1200°), SrGe (1200°), CaSn (1500°), CaZr (1400°), SrZr (1400°), CaCe (1400°), and SrCe (1400°). The average ionic size of the combination CaSn is about the same as $r(Lu^{3+})$, and CaZr would correspond to Er^{3+}. SrZr, CaCe, and SrCe are still within the size range of the trivalent lanthanons (Ahrens radii), and compounds are known in which $Ca^{2+}Sn^{4+}$ or $Ca^{2+}Zr^{4+}$ substitute for a trivalent ion of similar size. Examples are $CaSn(BO_3)_2$ (nordenskiöldite) and $La(Ca_{0.5}Zr_{0.5})O_3$, though $CaZrTi_2O_7$ has previously been reported to have a symmetry lower than cubic (28), in fact tetragonal (calzirtite, ref. 29).

None of the products gave a pyrochlore pattern.

Lattice Parameters

The agreement with the literature values was on the whole good (Table I). The differences between corresponding $a_0(P)$ values in series C and D were within 3σ, with the exception of $Er_2Ti_2O_7$ and $Lu_2Ti_2O_7$. The final a_0 is probably affected by the method of preparation and the firing cycle.

The overall agreement of the lattice parameters reported in refs. 15, 2, and 17 with those of series D was compared by regressing the a_0 sets on each other. Very high correlation coefficients were obtained, the highest one being that for series D and the a_0 values of ref. 3 (Table IV). Regression of series D on $a_0(A_2Sn_2O_7)$ (2) also gave a very high correlation coefficient, the slopes of the regression and reverse regression lines being very nearly unity. As with the stannates (2), the relationship between the lattice parameters of the titanates and $r(A^{3+})$ was linear (Table IV, Fig. 2). For the D series least squares gave the equations

[8]A set of empirical $r(B^{4+})$ for six-coordination has been derived from the lattice parameters and stability limits of cubic $A_2^{3+}B_2^{4+}O_7$ pyrochlores and BO_2 rutiles that leads to a more satisfactory description of the crystal chemistry of such compounds (27). Provisional values for Ge and Ti are 0.57 and 0.62 Å respectively. These values together with the $r(A^{3+})$ of Templeton and Dauben (cf. ref. 2) constitute the above "improved" radii.

TABLE IV

Standard deviations and correlation coefficients of a_0 and $r(A^{3+})$ regressions*

*Templeton–Dauben radii (cf. ref. 2).
†Converted to present λ(Cu Kα) (cf. ref. 2).

$$a_0(P) = 8.45913 + 1.8344r(A^{3+})$$

$$r(A^{3+}) = -4.5910 + 0.54312a_0(P)$$

with standard deviations of the same order as were obtained for the stannates (2).

When the lattice parameters of the homogeneous $(Lu_{1-x}Sc_x)_2Ti_2O_7$ phases ($x = 0.2, 0.4$) are substituted in the last equation, effective crystal radii of the "$(Lu_{1-x}Sc_x)^{3+}$" ion are obtained, from which an average value of $r(Sc^{3+})$, 0.742 ± 2 Å, can be calculated. Extrapolating the correlation of $a_0(C)$ and the Templeton–Dauben radii (2) to Sc_2O_3 ($a_0 = 9.8455$ Å (30)) gave $r(Sc^{3+}) = 0.733$ Å.

The accuracy of these linear extrapolations may be questioned and the radius obtained from the mixed Lu–Sc titanates may be too high. Lu, as the larger ion of the two, may tend to dominate the lattice parameters in a situation which is marginal with respect to the stability of the pyrochlore phase. But there can be little doubt that the effective radius of Sc^{3+} in six or near-six coordination is much smaller than the value of 0.81 Å ascribed to it by Ahrens. We have adopted the average of the above two values, 0.737 ± 7 Å, as a provisional working value to be used in the pyrochlore chemistry.

In a similar manner a value can be obtained for the radius of Bi(III) from homogeneous $(Y_{1-x}Bi_x)_2Ti_2O_7$ phases ($x = 0.2, 0.4, 0.5, 0.6$; Table I). The average for the four compositions, 1.033 ± 3 Å, is again quite different from the "ionic" radius listed for trivalent bismuth by Ahrens, 0.93 Å, but the straight-line fit of Fig. 3 justifies accepting this figure as a provisional working value for $r(Bi(III))$ in pyrochlores. The extrapolated lattice parameter of $Bi_2Ti_2O_7$ would be 10.354 Å. Similarly, extrapolating for $Bi_2Sn_2O_7$ (cf. ref. 2) would yield 10.642 Å, which is not too far from the dimension of the cubic pseudocell quoted for the stannate by Roth (15), 10.68 Å.

It should be noted that these radii are for six-coordination, since they have been arrived at from the linear relationship of $a_0(P)$ and the $r(A^{3+})$ of Templeton and Dauben, but the actual coordination of A in the pyrochlore structure is 2 + 6.

Mechanism of Formation of the Pyrochlore Phase

Differential thermal analysis experiments with dry-mixed $A_2O_3 + 2TiO_2$ at heating rates of 10 and 20°/min in stagnant air revealed two exothermic peaks of roughly equal intensity (Fig. 4, curve 1). While the position of the first peak varied little with A, the temperature corresponding to the second peak maximum depended markedly on A and passed through a minimum at Gd or Sm (Fig. 5).

The presence of two exothermic peaks indicates that the formation of the final product, $A_2Ti_2O_7$, proceeds in two or more steps. A likely possibility is the formation of A_2TiO_5 as the precursory phase. To test this hypothesis d.t.a. curves of dry-mixed $Gd_2O_3 + TiO_2$ (Fig. 4, curve 2) and $Gd_2TiO_5 + TiO_2$ (Fig. 4, curve 3) were recorded under similar conditions[9]. The curve for $Gd_2O_3 + TiO_2$ contained a single broad exothermic peak with a maximum at *ca.* 1152°. Similarly, only one broad exothermic peak was observed in the curve for $Gd_2TiO_5 + TiO_2$, with a maximum at *ca.*

[9]Gd_2TiO_5 was prepared by firing $Gd_2O_3 + TiO_2$ at 1350° for 24 h. The powder pattern of the product was different from those of rutile, Gd_2O_3 and $Gd_2Ti_2O_7$ (cf. refs. 19, 31, and 32).

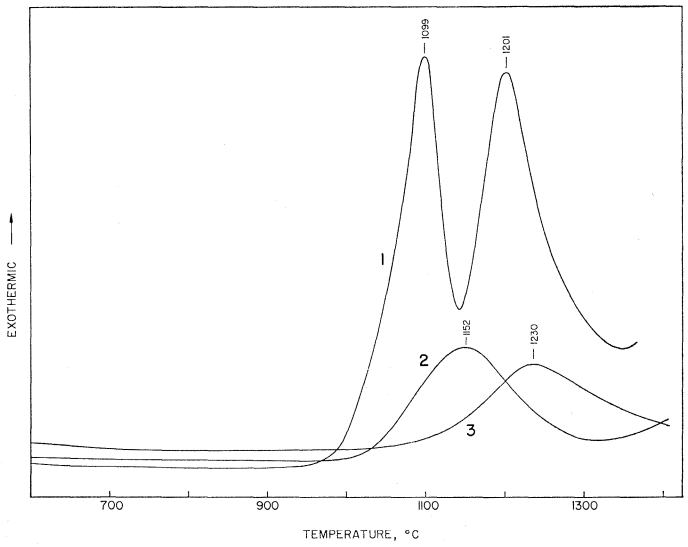

FIG. 4. Differential thermal analysis curves of dry-mixed $Gd_2O_3 + 2TiO_2$ (*1*), $Gd_2O_3 + TiO_2$ (*2*), and $Gd_2TiO_5 + TiO_2$ (*3*) in stagnant air. Rate of heating, 20°/min.

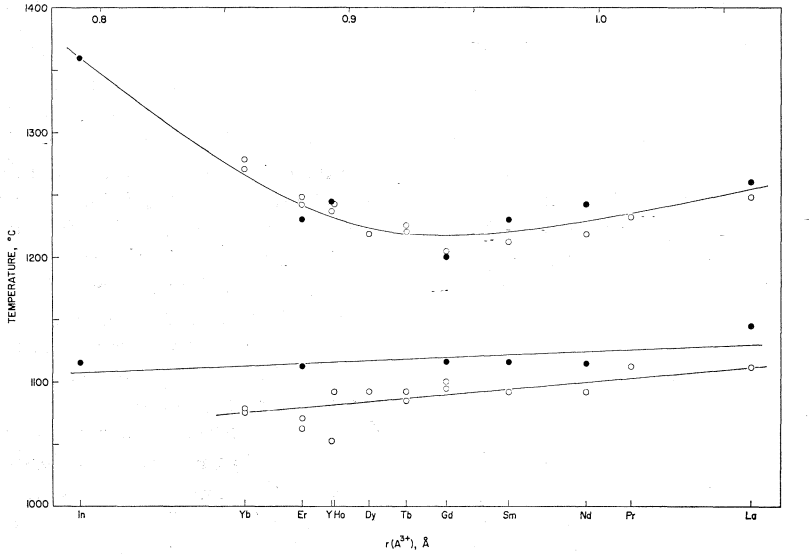

FIG. 5. Temperatures of the d.t.a. maxima of curve *1* (Fig. 4) plotted against the radius of A^{3+}. Heating rates in stagnant air: open circles, 10°/min; full circles, 20°/min.

1230°. When allowance is made for the difficulties in attempting to reproduce d.t.a. conditions with sufficient accuracy from one sample to another, and for the different solid state reactivities of the three mixtures (different reacting species, particle size, extent of surface contact, thermal conductivity), it may be concluded that the 1152° peak corresponds to the 1099° peak of curve 1 and thus to the formation of the 1:1 compound, Gd_2TiO_5, while the 1230° peak corresponds to the 1201° peak of curve 1 and to the formation of the 1:2 compound, $Gd_2Ti_2O_7$. The latter in turn is of course the 1:1 product of the reaction $Gd_2TiO_5 + TiO_2$.

The appreciable overlap of the two maxima of curve 1 indicates that the two stages were not clearly separated and that some $Gd_2Ti_2O_7$ had formed already at temperatures within the first peak. That the two-stage process of formation of $Ln_2Ti_2O_7$ in d.t.a. experiments is essentially dynamic in character was demonstrated from an X-ray photograph of the product obtained by firing a mixture of $Er_2O_3 + 2TiO_2$ at 1100° for 10 h. This temperature corresponds to the minimum between the two peaks in the d.t.a. curve of $Er_2O_3 + 2TiO_2$; the firing was an isothermal subsolidus process. There was no evidence of Er_2TiO_5. All the lines of the composite pattern could be accounted for by $Er_2Ti_2O_7$, Er_2O_3, and TiO_2.

The appearance of the two exothermic peaks in the d.t.a. curve of $In_2O_3 + 2TiO_2$ is additional evidence of compound formation in this system. The dry-mixed oxides in Roth's experiment (15) may have been brought to too high a temperature too quickly for a reaction to begin before the In_2O_3 volatilized.

The d.t.a. curve of $TbO_{1.79} + TiO_2$ showed that $Tb_2Ti_2O_7$ formed after the higher oxide had decomposed to Tb_2O_3.

Least-Squares Refinement

The structures of Lu, Gd, Sm, and Y titanates were refined from X-ray powder diffractometer data (Cu Kα) using (I) individual isotropic temperature factors and a block-diagonal approximation F-program written for IBM 1620/40K (cf. ref. 1); (II) individual isotropic temperature factors and an *ad hoc* full-matrix F-program written for IBM 360/50; and (III) an overall temperature factor and program II. The weighting scheme was W3 of ref. 35. One set of initial parameter values was employed in all the refinements: $K = 1.000$, $x(O_2) = 0.4200$, B(A) = 0.15 Å^2, B(Ti) = 0.60 Å^2, $B(O_1) = B(O_2) = 1.50$ Å^2, and B(overall) = 0.50 Å^2. In addition the structure of $Er_2Ti_2O_7$ (1) was re-refined to see the effect of a different weighting scheme and a different set of scattering factors.

The refinement was relatively insensitive to the choice of weighting scheme and, for each of the three programs, to the assumed degree of ionicity of the constituent atoms. On Hamilton's $\mathcal{R}$ criterion (36) there was no significant difference between the results obtained with f's for neutral atoms, for (A^{3+}, Ti^{3+}, O^{2-}), and for (A^{3+}, Ti^{4+}, O^{2-}). However, program I gave consistently lower $x(O_2)$ values than II or III (Fig. 6), with large e.s.d.'s of $B(O_1)$ and $B(O_2)$, while some of the $B(O_1)$ obtained with II were (positive or negative) indefinite (Table V). The overall temperature factors obtained with III were always physically reasonable and the $x(O_2)$ values were closely similar to those obtained with II, in fact always within 1σ (Table V and Fig. 6). On the whole, the ionic model with Ti^{4+} yielded the lowest-correlated parameters.

As for $Er_2Ti_2O_7$, there were small differences

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

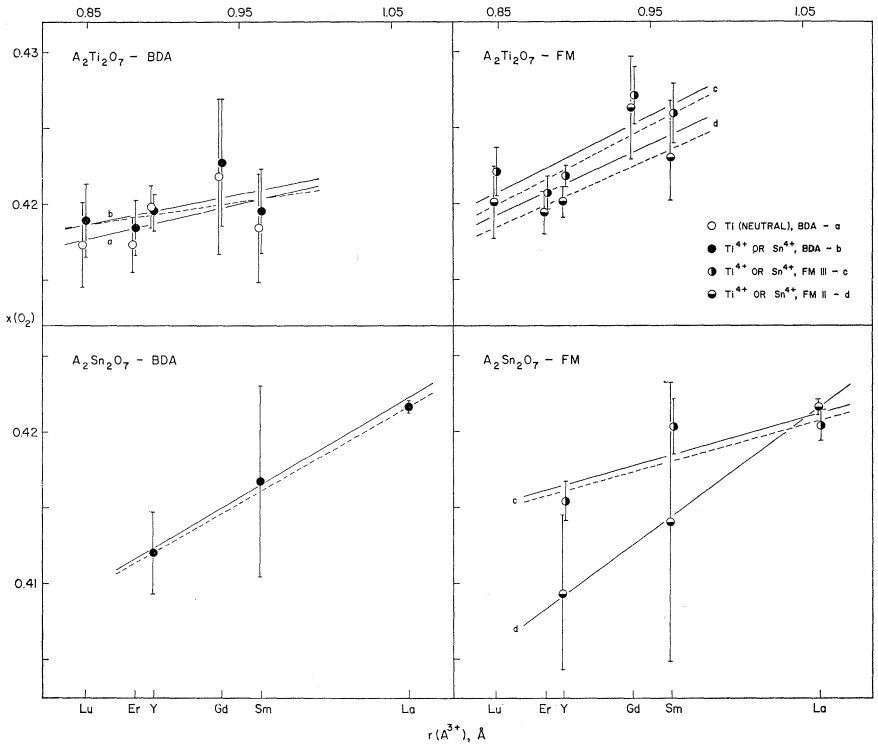

FIG. 6. Variation of the positional parameter $x(O_2)$ with $r(A^{3+})$. BDA, block-diagonal approximation (refinement I); FM II and FM III, full-matrix refinements II and III. The points are slightly displaced to facilitate plotting.

in the final values of the temperature factors, but the $x(O_2)$ values obtained with $f(Er^{3+}, Ti^{4+}, O^{2-})$ from all three programs were the same within 1σ of the individual values. The refinement results quoted in ref. 1 were not different within 2σ, and mostly within 1σ, from those obtained with refinement I in the present work.

The similarity of the $x(O_2)$ values obtained from II and III indicated that the success of refining with program II, which is physically more reasonable than III, was not prejudiced by the relatively small number of $|F_o|$ used in the refinement. The final R(II) values were slightly lower than R(III), and the slopes of the best $x(O_2)$ vs. $r(A^{3+})$ lines were practically the same for II and III, and similar to the corresponding lines for the stannates (2) (Fig. 6)[10]. The final $x(O_2)$ values from II (Table V) have therefore been adopted as the best set. The observed and calculated structure factors based on II are compared in Table VI.

When the $x(O_2)$ values are plotted against $r(A^{3+})$ there is an appreciable scatter, but the increase of $x(O_2)$ with the size of A^{3+} is reasonably evident. While it is true that the trend disappears when the uncertainty intervals are increased to $3\sigma(x)$, corresponding plots for the stannates (Fig. 6) and for two hafnates (27) show similar behavior. One may conclude that $x(O_2)$ increases with $r(A^{3+})$ in both the titanate and the stannate series, even though the accuracy of the refinements is perhaps not quite high enough to demonstrate this unambiguously. Thus the larger A^{3+} the smaller the distortion of the BO_6 octahedron for a particular B^{4+}, and the larger the B^{4+} ion, for a particular A^{3+}, the greater the distortion. In other words, the greater the $r(A^{3+}):r(B^{4+})$ ratio, the less distorted is the BO_6

[10]For comparison, the refinements of the three stannates (2) were repeated with II and III. For II the final $x(O_2)$, B(A), B(Ti), $B(O_1)$, $B(O_2)$, R, and e.s.d.(w) values respectively were: Y, 0.4093 ± 52, 0.85 ± 31, 0.12 ± 18, −0.68 ± 129, 2.75 ± 123, 0.85%, 2.215; Sm, 0.4140 ± 92, 0.63 ± 73, 0.80 ± 91, 0.63 ± 213, 3.25 ± 227, 0.81%, 3.536; La, 0.4216 ± 5, 1.32 ± 32, −0.22 ± 31, 4.17 ± 71, −0.21 ± 21, 0.71%, 0.170. For III the final $x(O_2)$, B(overall), R and e.s.d.(w) values respectively were: Y, 0.4154 ± 13, 0.40 ± 3, 1.03%, 2.467; Sm, 0.4203 ± 18, 0.71 ± 3, 1.17%, 3.661; La, 0.4204 ± 10, 0.77 ± 22, 1.92%, 0.391.

octahedron. An independent and striking confirmation of the decrease of the distortion of BO_6 with increasing $r(A^{3+})$ in the A_2FeSbO_7 pyrochlore series has been obtained from the Mössbauer spectra of these phases at room temperature (37). The quadrupole splitting at the Fe^{57} nucleus decreases with increasing $r(A^{3+})$, thus indicating a progressively smaller distortion of the FeO_6 octahedron.

Compared with the other titanates, the values of $x(O_2)$ for $Gd_2Ti_2O_7$ and $Sm_2Ti_2O_7$ are less reliable because of the exceptionally high backgrounds and low peak-to-background ratios of most reflections in the diffractometer patterns of these two phases, and also because of the large and probably uncertain dispersion corrections for f(Gd) for Cu Kα radiation.

The powder intensity data for the five titanates have been submitted to the American Society for Testing and Materials (ASTM) powder diffraction file.

Refinement of $Y_2(Ti_{0.64}Zr_{0.36})_2O_7$ from Neutron Data

Twelve $|F_o|$ were extracted from the neutron powder pattern (Fig. 7) by Gaussian analysis (cf. ref. 2) and utilized in refinements I, II, and III. The initial parameter values were the same as for the refinements from X-ray data except for B(overall), which was 0.70 Å^2. The neutron scattering amplitudes were taken as b(Ti) = −0.34, b(Zr) = 0.62, b(O) = 0.577, and b(Y) = 0.80 (all in 10^{-12} cm) (22).

None of the refinements was completely satisfactory. Some of the temperature factors were (positive or negative) indefinite or even negative. No significant difference resulted on using $b(Y) = 0.788 \times 10^{-12}$ cm (38).

The best $x(O_2)$ value was that from III, 0.4177 ± 21. It was identical with that from II, while the value obtained in refinement I was considerably lower. The final R values were in the range 6–9%.

Interatomic Distances and Bond Angles

The apparent interatomic distances and bond angles (not corrected for thermal motion) are listed in Table VII. They have been calculated from the final $x(O_2)$ (II). The uncertainty limits are based on $3\sigma(x)$, and on $4\sigma(a_0)$ for distances independent of $x(O_2)$.

The shortest Ti–O distances in the five titanates

For personal use only.

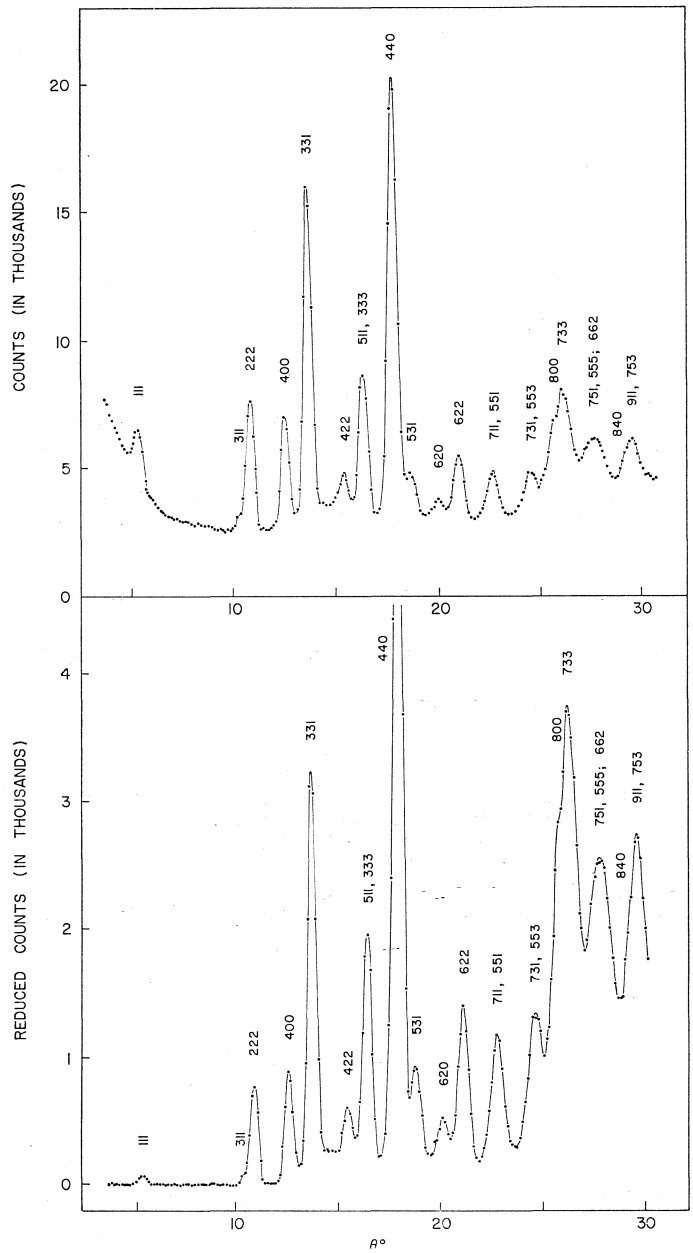

FIG. 7. Raw (*top*) and reduced (*bottom*) neutron diffraction patterns of $Y_2(Ti_{0.64}Zr_{0.36})_2O_7$ (monochromator, Al(111); $\lambda = 1.10$ Å; counting time per point, 10 min).

all fall between the two Ti–O distances reported by Baur for rutile, 1.944 ± 4 and 1.988 ± 6 Å (cf. ref. 1), and they are all within the range known from TiO_6 octahedra in other compounds (Table VIII and ref. 1).

Comparison of the A–O distances is more difficult to make. The $A–O_1$ distance depends only on a_0. It is thus shorter in the titanate than in the stannate pyrochlores. For example, the $Y–O_1$ distance in the stannate is 2.2457 ± 10 Å (2), while in the titanate it is 2.1856 ± 6 Å, which is one of the shortest Y–O distances reported (Table VIII, and Table V of ref. 2). The $A–O_1$ distances are on the whole rather short, as might

$ThTi_2O_6$	1O+1O+2O+1O+1O	1.83±5; 1.84±4; 1.94±7; 2.06±4; 2.20±7	46
$NaTi_2Al_5O_{12}$	1O+2O+2O+1O	1.843±16; 1.952±18; 1.973±17; 2.167±19	47

*For Sm–O distances see ref. 2. For additional values of Er–O, Y–O, and Ti(IV)–O distances see refs. 1 and 2.

be expected from the tetrahedral coordination of the O_1 atom, and hence not typical. Subtracting $r(A^{3+})$ for six-coordination from the $A–O_1$ distances gives values from 1.321 Å (Lu) to 1.252 Å (Sm) for the radius of the oxygen atom; in view of the quite small uncertainties in the $A–O_1$ distances these differences must be considered as meaningful. By contrast, subtracting $r(A^{3+})$ from the $A–O_2$ distances leaves residues that do not significantly differ within the 3σ, and in fact within the 2σ limits, the average value of the "oxygen radius" being about 1.59 Å.

The $A–O_2$ distances increase progressively from Lu to Sm. As in the stannates, they are longer than the corresponding distances reported for six-coordinated A, but within the range for higher coordination. In the two cases where they are known for both series, they are not signif-

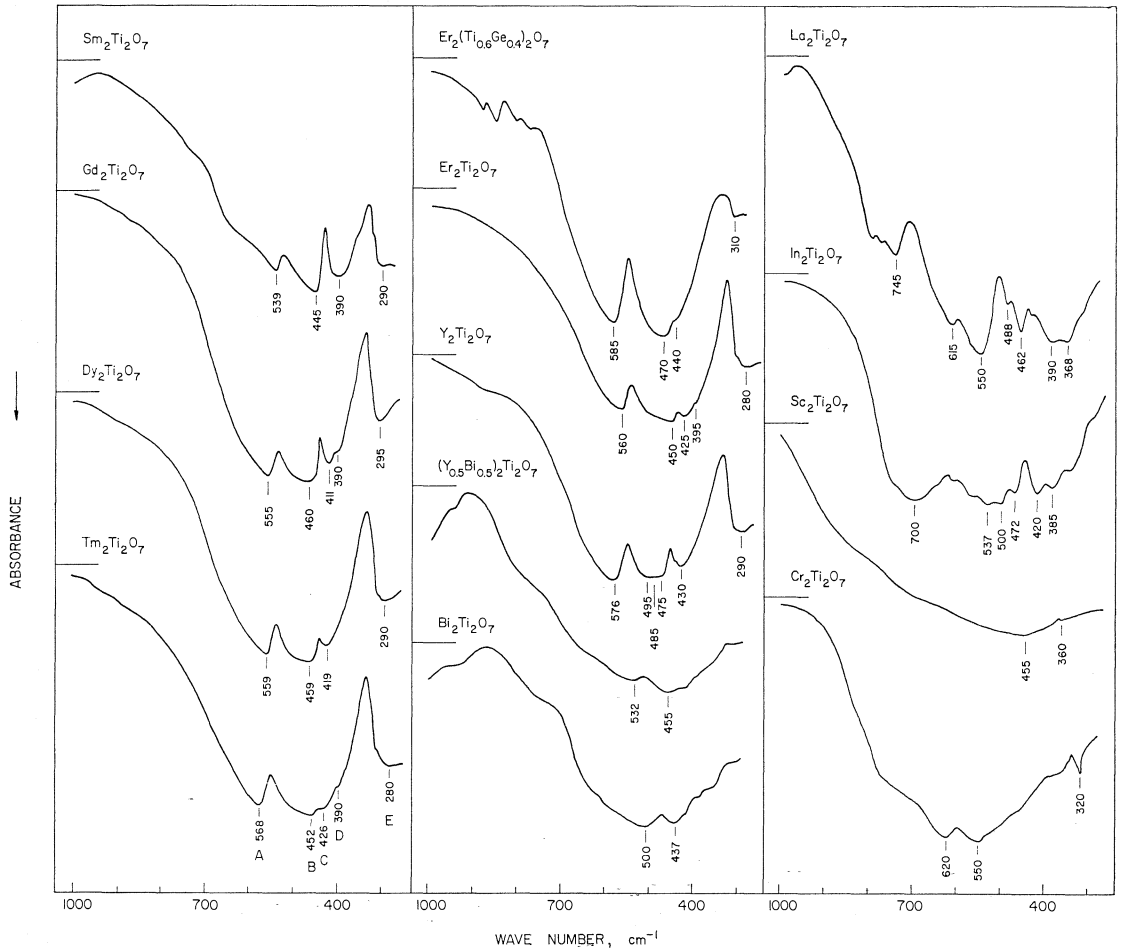

FIG. 8. Infrared transmission spectra of representative pyrochlore titanates and related compounds.

icantly different within 3σ (Sm) or even within 2σ (Y). This seems to indicate that the O_1 atom, for which the A–O distance varies with B^{4+}, is under constraint in a "forced" coordination, and the $A–O_1$ distance is not free to adjust in the same way as the $A–O_2$ distance does through change in $x(O_2)$. As a consequence the O_1 atom will be polarized by the same nearest neighbor A to an extent that will depend on the size of B^{4+}.

The difference between $A–O_1$ and $A–O_2$ introduces an ambiguity into attempts to assign an "effective radius" to A^{3+} in the 2 + 6 coordination. The standard radii for six-coordination leave O_1 undersized and O_2 too large, thus leading to the conclusion that the effective "shape" of the A atom in this coordination is an oblate spheroid.

Infrared Spectra

Compared with the spectra of the pyrochlore stannates in the 1600–250 cm^{-1} region (2), the features of the corresponding titanate spectra were not nearly as well defined. This applies also to the spectrum of $BaTiO_3$ (1) compared with $BaSnO_3$ (2), and to rutile compared with SnO_2. The main feature of the titanate spectra in this region is a very strong band with a wide, flat maximum exhibiting shallow fine structure peaks at 540–575 (*A*), 440–460 (*B*), 390–440 (*C*), and about 390 cm^{-1} (*D*) (Fig. 8). Another band was sometimes observed at 280–295 cm^{-1}, but its position could not be determined accurately because it was too close to the limit of the instrument range.

When the trivalent cation in the titanate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

changes, the frequency of the *B* band does not appear to change, but the frequencies of *A* and *C* are shifted (Fig. 9). The *A* and *B* frequencies of $Y_2Ti_2O_7$ are noticeably above the corresponding frequencies of the lanthanon titanates. This is in contrast with the stannate series (2), where the peak frequencies of the yttrium member were indistinguishable from those of Ho and Er stannates. The assumption that was made for the stannates does not seem to hold for the titanates. That is, the Ti atom is not sufficiently heavy to provide, together with Y, a quasi-stationary framework for the oxygen atoms. Consequently the effect of approximately halving the mass of the lanthanon atoms makes itself felt in the increased frequencies of $Y_2Ti_2O_7$, even though the increase may not be as much as would appear from Fig. 9 because of the spread of the points about the least-squares straight lines.

Changes of frequency of the absorption bands in the expected direction were observed on replacing Ti in $Er_2Ti_2O_7$ partially with Ge, and Y in $Y_2Ti_2O_7$ with Bi. The mass average of

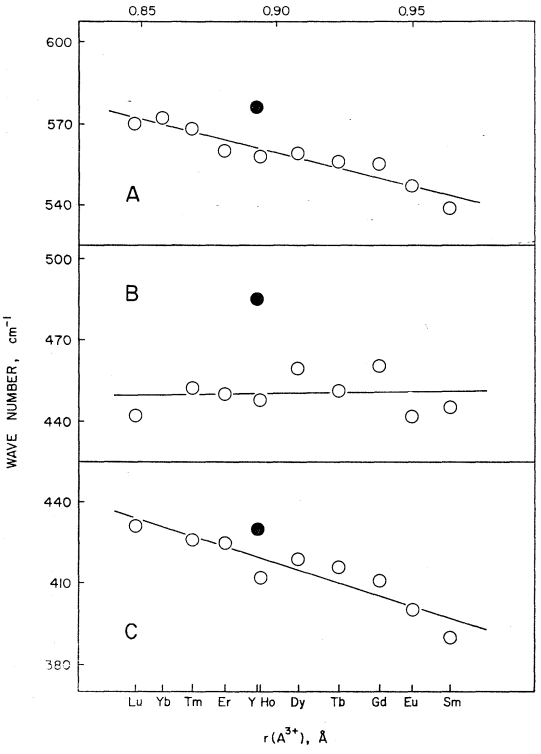

FIG. 9. Variation of the frequencies of the *A*, *B*, and *C* absorption maxima with $r(A^{3+})$. Full circles, $Y_2Ti_2O_7$.

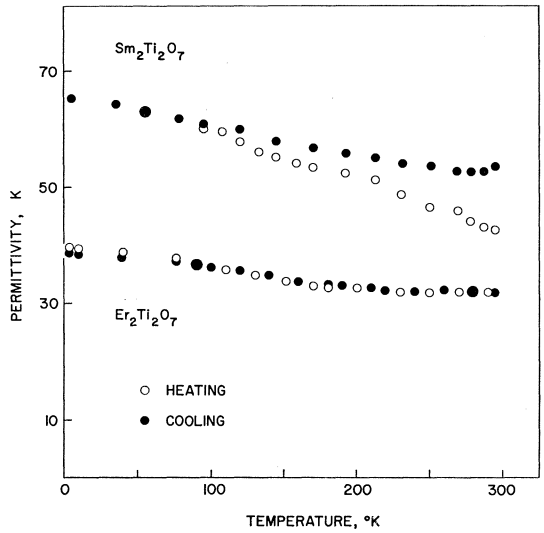

FIG. 10. Permittivity vs. temperature relationships for $Sm_2Ti_2O_7$ and $Er_2Ti_2O_7$.

$Y_{0.5}Bi_{0.5}$ is very close to the mass of Sm, but the general features of the spectrum of the mixed phase resemble more those of $Bi_2Ti_2O_7$ (which is not a cubic pyrochlore) than those of $Sm_2Ti_2O_7$. The spectrum of $La_2Ti_2O_7$ may be viewed as derived from the spectrum of $Sm_2Ti_2O_7$ by splitting of the main absorption bands and an appreciable increase in the intensity of the shoulder between 700 and 800 cm^{-1}; a detailed correlation cannot be offered at present.

The spectra of the In and Cr phases, which are believed to be homogeneous phases, are also shown in Fig. 8. The $Sc_2Ti_2O_7$ phase which gave a fluorite-type pattern had a spectrum with no distinct features but resembling, in a general way, the spectrum of $Sc_4Sn_3O_{12}$ (2).

Dielectric Properties

Permittivity measurements on two pyrochlore titanates, $Sm_2Ti_2O_7$ and $Er_2Ti_2O_7$, from room temperature to 4.2 °K gave no indication of ferroelectric transitions (Fig. 10).

Conclusions

(1) The linear relationship, which exists between a_0 of the pyrochlore titanates and the Templeton–Dauben radii of A^{3+}, makes it possible to derive provisional values of the crystal radii of Sc^{3+} and Bi(III) for six-coordination. Similarly, linear extrapolation for *C*-type sesquioxides (2) provides a check on the compatibility,

†Templeton and Dauben (cf. ref. 2).
‡The lattice parameters of the *C*-type oxides used in the calculation were: Tl, 10.543 (50); In, 10.117±1 (51); β-Fe_2O_3, 9.40 (52); Am, 11.03±1 (53); Pu, 11.04±2 (54); Cm, 11.01±2 (55); Pm, 10.99 (56); and Bk, 10.8865 (49) (all in Å). For Cf the *B*-type sesquioxide was used (57); its exact stoichiometry was, however, not known.

with the Templeton–Dauben set, of the values quoted for the crystal radii of some other six-coordinated trivalent ions. Comparing the radii derived in this way for Tl^{3+}, In^{3+}, and Fe^{3+} (Table IX) with the corresponding Ahrens values reveals a major discrepancy for $r(Tl^{3+})$, but only a small difference for In^{3+}; the values for Fe^{3+} are identical[11].

Linear extrapolation using the same relationship leads to crystal radii for six-coordinated trivalent Pu, Am, Cm, and Bk which differ only insignificantly, or not at all, from the values listed recently by Peterson and Cunningham (49). It also shows that Espinosa's a_0 of Pr_2O_3 (*C*-type), 11.152 ± 3 Å (66), though higher than the 11.140 ± 2 Å quoted by Eyring and Baenziger (69), is still below the calculated value, 11.165 ± 5 Å. The lattice parameter reported by Sastry *et al.* (70), 11.160 ± 6 Å, is however in close agreement.

Whatever the precise significance and applicability of empirical crystal radii, if a consistent set for a particular coordination is available, it can serve for correlation, verification, and prediction of various metric properties of crystal structures. The usefulness and self-consistency of the Templeton–Dauben set, augmented by Geller's value for Y^{3+}, has been demonstrated earlier (2). The enlarged set of Table IX has been tested on several isostructural series of compounds (Fig. 11)[12]. The straight-line fits are seen to be very satisfactory for coordination numbers from 6 to 8 and for structure types as different as CrB and the

[11]Shannon (71) has suggested that the effective radius of Tl^{3+} in the 3–3 perovskites is considerably smaller than the Ahrens value, and probably less than 0.85 Å; for Sc^{3+} he uses a value of 0.73 Å and for In^{3+}, 0.77 Å (estimated from his Fig. 2). Shannon's values thus corroborate the validity of the effective crystal radii in six-coordination deduced for the three ions in the present work.

[12]The unit-cell dimensions of the compounds shown in Fig. 11 were taken mostly from ref. 58. In addition the following references were used: A_2O_3 (*B*-type), 56, 57, 61, 62; A_2O_3 (high-pressure corundum), 63; AUO_4, 64; $A_2Ge_2O_7$ (high-pressure pyrochlore), 26; Fe and Ga garnets, 65, 66; $Ca_3Al_2Si_3O_{12}$, 59, 60; Sr hydrogarnets, 59; AGa, 67, 68.

garnets. It is probably true, however, that these radii will in general give best linear correlations for oxygen compounds with structures of high symmetries, in which variations of the positional parameters from one member of an isostructural series to next are relatively insignificant compared with the variations of the unit-cell volume. Where appreciable covalency and pronounced asymmetric orbital occupancies are involved, the radii lose their universality. An example is Bi. When occupying sites of highly regular coordination at random, such as in mixed phases of the pyrochlore or fluorite type (Fig. 11), Bi(III) falls in the $r(A^{3+})$ sequence just below Ce^{3+}. In other structures, where the coordination is less regular and the degree of covalency higher, the apparent size of the Bi atom decreases, approaching perhaps that of Pr^{3+} or even Nd^{3+}. This is evident in Fig. 11. Although there may be some doubt about the exact composition of at least one of the two forms of $BiPO_4$ referred to in the drawing, BiOCl illustrates this point adequately. A similar tendency may exist for Tl.

Successful correlation of the Templeton–Dauben radii with the empirical crystal radii of the smaller trivalent ions (Al, Ga, Ti, V, Cr, Mn, Co, Rh) is handicapped by the paucity of suitable isostructural series that would include compounds of Sc and In and at least a few of the smaller lanthanons; the spin configurations of the *d* electrons may also have to be taken into consideration in some cases.

(2) The stability region of the pyrochlore titanates extends from an Ahrens radius ratio, $r(A^{3+}):r(B^{4+})$, of about 1.22 (in mixed Lu–Sc phases) to about 1.47 ($Sm_2Ti_2O_7$); or, using the "improved" radii, from about 1.27 to about 1.55. The upper limit is slightly extended in Sm titanate–germanate phases to 1.50 (Ahrens) or 1.56 ("improved").

Although $Bi_2Ti_2O_7$ is not a cubic pyrochlore, in mixed Y–Bi titanates the pyrochlore phase extends to about $Y_{0.5}Bi_{1.5}Ti_2O_7$, i.e. to a radius ratio of *ca.* 1.36 (Ahrens) or 1.61 ("improved"). The corresponding values for a pure Bi pyrochlore would be 1.37 and 1.67.

If the present value proposed for r(Bi(III)), 1.033 Å, is accepted, the upper limit in the Y–Bi titanates is higher than in the Ln compounds, though pure Bi titanate should be, on the radius-ratio criterion, outside the pyrochlore field, as is in fact the case. However, $Bi_2Sn_2O_7$, which is not a pyrochlore either, has a radius ratio of 1.31 (Ahrens) or 1.44 ("improved"), and is thus inside the upper ratio limit for the pyrochlore stannates, 1.61 (Ahrens) or 1.48 ("improved") (in $La_2Sn_2O_7$).

These observations again demonstrate the exceptional behavior of bismuth as a potential pyrochlore former.

(3) The positional parameter $x(O_2)$ in the titanates increases with $r(A^{3+})$ and has larger values than in the corresponding stannates. Consequently the distortion of the BO_6 octahedra decreases with the increasing $r(A^{3+}):r(B^{4+})$ ratio.

(4) No evidence of ferroelectric transitions in Sm and Er titanates was found by permittivity measurements between room temperature and 4.2 °K.

(5) Unlike in $Y_2Sn_2O_7$, in $Y_2Ti_2O_7$ the atoms of the two metals are not sufficiently heavy for their sublattices to behave like a stationary framework with respect to the oxygen atoms. Some of the absorption maxima of $Y_2Ti_2O_7$ in the 600–300 cm^{-1} region have therefore frequencies significantly higher than those of the corresponding maxima of Er and Ho titanates.

Acknowledgments

We should like to express our gratitude to the following individuals and agencies:

The staff of the Neutron Physics Branch, Atomic Energy of Canada Limited, for permission to use their neutron diffraction facilities; Dr. F. R. Ahmed, for making available to us the least-squares program of ref. 1; Dr. M. Falk, for placing at our disposal the infrared spectrometer; Mr. Y. S. Lim, for carrying out the dielectric measurements; Dr. M. H. Jericho, for making possible the dielectric study at low temperatures; Dr. N. F. H. Bright and Mr. R. H. Lake, for the differential thermal analysis of the $Gd_2O_3 + TiO_2$ mixtures; Drs. R. D. Shannon and W. W. Barker, for seeing the manuscripts of their papers (refs. 26 and 25) before publication; Dr. V. Seidl and Mr. C. Ayasse, for assistance with some of the computations; and Drs. B. I. Pokrovskiĭ and F. M. Spiridonov of the Moscow State University, for encouraging us to investigate $Sc_2Ti_2O_7$ in detail and for a generous gift of high-purity scandium oxide.

Financial support of this investigation by the Defence Research Board and the National Research Council of Canada through grants to the first-named author is hereby acknowledged. Some of the preparative work and a part of the

X-ray study were carried out under Defence Research Board contract No. 800107/200024 and are reported in the present form with the permission of the Board.

Last but not least we should like to thank the staff of the Dalhousie Computing Centre for their unfailing assistance with machine computation.

Determination of the bond dissociation energy, $D(CH_3Hg—CH_3)$, by the toluene carrier method

R. J. KOMINAR[1] AND S. J. PRICE
Department of Chemistry, University of Windsor, Windsor, Ontario
Received October 11, 1968

The thermal decomposition of $Hg(CH_3)_2$ has been studied in a toluene carrier flow system over the pressure range 4.5 to 323 mm at temperatures of 422 to 527 °C. The Arrhenius equation for the pressure independent region,

$$k = 5.5 \times 10^{15} \exp(-57\,500/RT)\ s^{-1}$$

is in excellent agreement with earlier work on the fully inhibited decomposition at lower temperatures. The region of fall off of the unimolecular rate constant is in agreement with a classical Kassel calculation using $s = 16$–18, but the rate of fall off requires the use of a curve with $s = 3$, displaced five log units to the left. This is consistent with the previous results for the dissociation of ethane into two methyl radicals and is further evidence of the inability of the classical Kassel equation to represent the behavior of systems with high pre-exponential factors.

Introduction

The available high pressure Arrhenius parameters for the pyrolysis of dimethylmercury in the presence of suitable inhibitors are in reasonable agreement (1–4). The results of Russell and Bernstein (1), $k = 5.0 \times 10^{15} \exp(-57\,900/RT)\ s^{-1}$, and of Kallend and Purnell (2), $k = 5.0 \times 10^{15} \exp(-57\,600/RT)\ s^{-1}$ are in excellent agreement. However, Weston and Seltzer (3) report $k = 7.0 \times 10^{16} \exp(-61\,200/RT)\ s^{-1}$ and a previous benzene carrier study from this laboratory (4) gave $k = 6.3 \times 10^{14} \exp(-53\,700/RT)\ s^{-1}$. The results of Weston and Seltzer cover approximately the same temperature range as those of Russell and Bernstein and the actual rate constants, particularly at higher decompositions, are in good agreement. The benzene carrier work represented an attempt to extend the data on the fully inhibited high pressure decomposition to considerably higher temperatures. An extrapolation of the Arrhenius plot obtained by combining the results of Russell and Bernstein and of Kallend and Purnell indicated that the benzene carrier results are in excellent agreement with those studies at high decomposition, but become progressively poorer with decreasing conversion. This may indicate that benzene was not a sufficiently effective scavenger. A reinvestigation using toluene as carrier has therefore been carried out.

[1]Present address: Division of Pure Chemistry, National Research Council, Ottawa, Canada.

Experimental

Materials

(*a*) Dimethylmercury was prepared by adding methyl magnesium iodide to an ether slurry of mercuric chloride (4).

(*b*) Toluene from sulfonic acid (Eastman Organic X325) was prepared for use by refluxing over sodium under vacuum for 24 h and then degassing twice by bulb-to-bulb distillation.

Apparatus and Procedure

The experiments were carried out using the same system previously used in studying the decomposition of dimethylmercury in a benzene carrier (4). The gaseous products were analyzed using a Perkin–Elmer 154 gas chromatograph equipped with a $\frac{1}{4}$ in. × 6 in. silica gel column. The column was maintained at 80 °C and a helium flow rate of 20 cc/min was used.

The liquid products condensed along with the toluene in an acetone–dry ice trap were analyzed using a P.E. model 800 gas chromatograph equipped with a 150 ft × 0.02 in. inside diameter Golay Column coated with poly(propylene glycol) (isothermal operation at 50 °C, inlet pressure of N_2 carrier is 7 lb).

Results and Discussion

The thermal decomposition of $Hg(CH_3)_2$ has been studied over the temperature range 422–554 °C at pressures of 111–318 mm, and 507–580 °C at 4.5 mm.

The major processes occurring in the thermal decomposition of dimethylmercury in a toluene carrier system may be represented by the following mechanism

[1] $$Hg(CH_3)_2 \rightarrow CH_3^{\cdot} + HgCH_3^{\cdot}$$

[2] $$HgCH_3^{\cdot} \rightarrow Hg + CH_3^{\cdot}$$

*Prerun, duration of alkyl flow, post run.
†C_2H_4 and C_3H_8 negligible in all runs.
‡Ethyl toluenes, propyl benzenes, and styrene negligible in all runs.

[3] $CH_3^{\cdot} + C_6H_5CH_3 \rightarrow CH_4 + C_6H_5CH_2^{\cdot}$

[4] $2CH_3^{\cdot} \rightarrow C_2H_6$

[5] $2C_6H_5CH_2^{\cdot} \rightarrow$ dibenzyl

[6] $CH_3^{\cdot} + C_6H_5CH_2^{\cdot} \rightarrow C_6H_5C_2H_5$

plus other minor reactions including

[7] $CH_3^{\cdot} + C_2H_6 \rightarrow CH_4 + C_2H_5^{\cdot}$

[8] $C_2H_5^{\cdot} \rightarrow C_2H_4 + H^{\cdot}$

[9] $CH_3^{\cdot} + C_2H_5^{\cdot} \rightarrow C_3H_8$

[10] $C_6H_5CH_2^{\cdot} + C_2H_5^{\cdot} \rightarrow C_6H_5CH_2CH_2CH_3$

and reactions analogous to reactions [3], [5], [6], and [10] resulting from ring abstraction.

The results obtained above 100 mm are shown in Table I. Rate coefficients were calculated from the usual first order equation, $k = 2.3/t_c \log (a/a - x)$. Under the experimental conditions used, the only minor reactions of any importance are those leading to the formation of xylenes. The extent of decomposition was therefore calculated from

$$\text{fraction decomposed} = \frac{\frac{1}{2}\,\text{moles}\,(CH_4 + C_6H_5C_2H_5 + \text{xylenes}) + \text{moles}\ C_2H_6}{\text{moles}\ Hg(CH_3)_2}$$

The first-order rate coefficients are approximately independent of pressure above 100 mm. At any given temperature the values at 318, 206, and 111 mm agree within ±8%. The least mean squares equation obtained using the rate data at these three pressures is $k = 5.5 \times 10^{15}$ exp

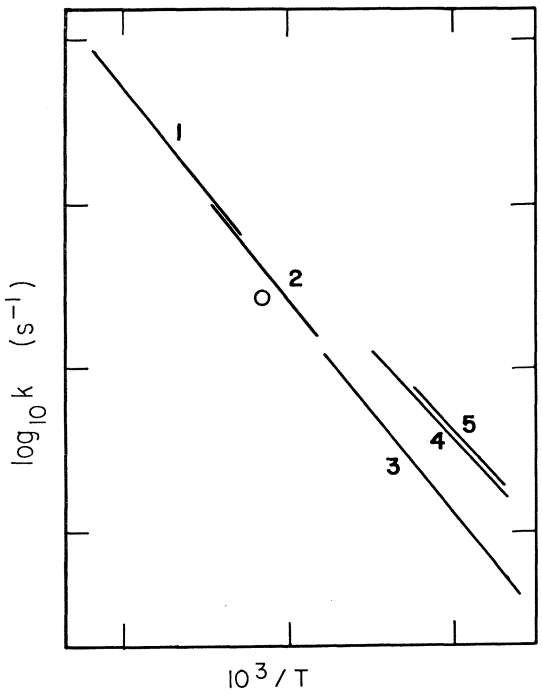

FIG. 1. Arrhenius plots for the decomposition of dimethylmercury. All rate constants are at or near the high pressure limit. If a radical scavenger has been used it is shown in brackets: 1, this work (toluene); 2, Kallend and Purnell (propylene); 3, Russell and Bernstein (cyclopentane); 4, Russell and Bernstein; 5, Laurie and Long; O, point calculated from steady state equation of Kallend and Purnell.

$(-57\,500/RT)\,s^{-1}$ (422–527 °C). This result should represent the fully inhibited decomposition and should be a good approximation to k_∞, the rate constant at infinite pressure.

It is compared with previous work in Fig. 1. The agreement with the work of Russell and Bernstein and of Kallend and Purnell is excellent.

Curves 4 (1) and 5 (5) in Fig. 1 represent studies on the decomposition of $Hg(CH_3)_2$ in uninhibited systems. The uninhibited decomposition is faster than the fully inhibited decomposition by a factor of 5 to 15. Russell and Bernstein (1) propose short chain processes, while work by Laurie and Long (5, 6) and Cattanach and Long (7) seems to contradict this. At the present time, no mechanism has been proposed for the uninhibited decomposition that can explain all the observed facts. It is possible that surface reactions either chain, nonchain, or a mixture of both, play a significant role.

Taking $\Delta H_f^\circ{}_{298}(CH_3,g) = 33.2$ kcal mole^{-1} (8), $\Delta H_f^\circ{}_{298}(Hg,g) = 14.7$ kcal mole^{-1} (9), and $\Delta H_f^\circ{}_{298}(Hg(CH_3)_2,g) = 22.4$ kcal mole^{-1} (10) gives for the reaction

$$Hg(CH_3)_2,g \rightarrow Hg,g + 2CH_3,g$$

a value of $\Delta H^\circ{}_{298} = 58.6$ kcal mole^{-1}. If this is a sufficient approximation to ΔH_0° then

$$D(CH_3Hg - CH_3) + D(Hg - CH_3) = 58.6 \text{ kcal mole}^{-1}$$

The observed Arrhenius activation energy for reaction [1] in the fully inhibited system at the high pressure limit, $E_1 = 57.5$ kcal mole^{-1}, should be within the limits $D_1 \leqslant E_1 \leqslant D_1 + 1.5$ kcal mole^{-1} (assuming E_1 contains no experimental error). This would yield $D_2 = 1.1$ to 2.6 kcal mole^{-1}. However, a conservative estimate of the accumulated experimental error in D_2 would be ± 2 kcal mole^{-1} so that although D_2 may have a small finite value, the value $D_2 = 0$ is a possibility.

The work at 4.5 mm is not primarily concerned with the pyrolysis of $Hg(CH_3)_2$ and is therefore not reported in detail here. It will appear shortly in conjunction with another study. However, some pertinent features should be noted. At the toluene/alkyl ratios used, approximately 10/1, all the minor reactions previously proposed play a significant role as well as limited pyrolysis of the ethylbenzene formed in reaction [6]. In the temperature range 507–589 °C the Arrhenius equation for the decomposition is

$$\log k = 13.6 - 51\,800/2.3RT$$

If the equation is extrapolated to 360 °C, $k = 5 \times 10^{-5}\,s^{-1}$. This is in close agreement with the results of Russell and Bernstein (1) under fully inhibited conditions, $4.5 \times 10^{-5}\,s^{-1}$, indicating that the present equation is a good approximation to that representing the fully inhibited decomposition at this pressure.

The present results for the region of fall-off of the first-order rate constant agree reasonably well with Kassel theory predictions if 17 ± 1 effective oscillators are assumed. However, the fall-off is much faster than predicted by Kassel theory with $s = 17$, due to the inadequacy of the classical theory for reactions with high frequency factors. For ethane the Rice, Ramsperger, Kassel, Marcus theory shows that the experimental data should in fact fit a classical Kassel curve with $s = 3$ when this curve is shifted 5.6 logarithmic units to the left (11). The pre-exponential factor for the

$Hg(CH_3)_2$ decomposition is of the same order of magnitude as that for the dissociation of ethane into two methyl radicals, $5.5 \times 10^{15}\ s^{-1}$ vs. $2 \times 10^{16}\ s^{-1}$ (11), and the best fit for the present data would also be obtained using classical Kassel theory if the curve for $s = 3$ shifted approximately 5 logarithmic units to the left was used.

Dimethyl and diphenyl formamide complexes of lanthanide perchlorates

S. S. KRISHNAMURTHY AND S. SOUNDARARAJAN
Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 12, India

Received September 9, 1968

N,N-Dimethyl formamide (DMF) and N,N-diphenyl formamide (DPF) complexes of six lanthanide perchlorates of the composition $M(DMF)_8(ClO_4)_3$ and $M(DPF)_6(ClO_4)_3$ where M = La, Ce, Pr, Nd, Sm, or Y have been prepared and characterized. The infrared spectra show that the amide is bonded to the metal through oxygen. Conductivity, molecular weight, and spectral studies indicate coordination numbers of eight and six for DMF and DPF complexes respectively, with the perchlorate groups remaining ionic.

Introduction

The ligating properties of N,N-disubstituted tertiary amides have been well investigated in recent years (1–6). We had previously described the preparation and the properties of lanthanide nitrate complexes with N,N-dimethyl formamide (DMF) and inferred that the nitrato groups are covalently bound to the metal (6). It is to be expected that if the nitrate is replaced by an ion having low coordinating tendencies such as the perchlorate, the metal atom would tend to add on to itself the maximum number of organic ligands. Consequently a study of the lanthanide perchlorate complexes with DMF was undertaken. The study was extended to cover diphenyl formamide (DPF) in order to investigate the electronic and steric effects (if any) of the phenyl groups on the coordination behavior of the lanthanides.

Experimental

Materials

Dimethylformamide (E. Merck L. R. Grade), nitromethane, and nitrobenzene (both B.D.H. L. R. grade) were purified by standard methods (7).

Diphenyl formamide was prepared by formylating diphenylamine with 99% formic acid (8) (E. Merck) and recrystallizing the product from hot petroleum ether (boiling range 50–60°), m.p. 73 °C (lit. 73–74 °C (8)).

The starting materials for the rare earth complexes were the oxides (99.9% pure) obtained from Lindsay Chem. Co., U.S.A. Cerous chloride (A. R.), used for preparing Ce(III) perchlorate, was obtained from Atomic Energy Commission, India.

Preparation of the Complexes

Except for that of cerium, the rare earth perchlorates were prepared by dissolving the oxides in 60% perchloric acid (E. Merck "proanalyze" grade) and crystallizing them from water. Cerium(III) perchlorate was prepared by dissolving freshly precipitated Ce(III) hydroxide in perchloric acid in the presence of small quantities of hydrogen peroxide to reduce any Ce(IV) formed by atmospheric oxidation.

DMF Complexes

About 2–3 g of rare earth perchlorate were dissolved in 5 ml of DMF, and the excess DMF was pumped off, avoiding contamination with moisture. The complexes were left behind as glistening hygroscopic crystals. The complexes were soluble in polar solvents such as nitromethane, nitrobenzene, and acetone.

DPF Complexes

A solution of rare earth perchlorate (1 g) in A. R. acetone (3 ml) was added dropwise to a solution of 3.2 g of DPF in 5 ml acetone. The mixture was warmed to 50 °C and then cooled at 0 °C for 12 h. Since no precipitate was obtained, the solvent was pumped off and the residue dried over P_2O_5 under vacuum. The solid residue was washed 3 or 4 times with 10 ml portions of petroleum ether and then thrice with 10 ml portions of CCl_4, in order to remove the excess ligand. The complex was finally dried over P_2O_5 and analyzed.

Unlike the parent perchlorates the complexes were not hygroscopic. It was, however, found that the ligand and the complexes, when exposed to direct sunlight, were photoactive and turned green. When light exposure was minimized the complexes could be preserved without any apparent change.

Analyses

The metal content of the complexes was estimated by precipitation as oxalate and subsequent ignition to the oxide. The perchlorate determination was carried out by Kurtz's method (9). The DMF content was determined as described in an earlier publication (6). In the case of DPF complexes the carbon content in a few representative cases was determined by using a conventional semimicro combustion apparatus. The analytical data are summarized in Table I.

Conductivity Measurements

The molar conductance of the complexes in DMF, nitromethane, and nitrobenzene solutions was determined in a Siemen's conductivity bridge at 30 °C, using an immersion cell (Type LTA) previously calibrated with standard KCl solutions. The data are presented in Table II.

Molecular Weight Measurements

The molecular weights of the DMF complexes in water and nitrobenzene and those of DPF complexes in nitrobenzene were determined by the freezing point method.

TABLE I

Analytical data for Ln perchlorate complexes with DMF and DPF

Compound	Found (%)			Calculated (%)		
	Metal	Perchlorate	DMF	Metal	Perchlorate	DMF
$La(DMF)_8(ClO_4)_3$	13.85	29.70	57.71	13.60	29.2	57.23
$Ce(DMF)_8(ClO_4)_3$	14.05	29.60	57.00	13.70	29.18	57.10
$Pr(DMF)_8(ClO_4)_3$	13.71	28.91	56.30	13.76	29.14	57.10
$Nd(DMF)_8(ClO_4)_3$	14.09	29.38	55.90	14.05	29.05	56.90
$Sm(DMF)_8(ClO_4)_3$	14.50	28.77	55.80	14.54	28.85	56.70
$Y(DMF)_8(ClO_4)_3$	9.23	30.30	59.60	9.15	30.70	60.15
$La(DPF)_6(ClO_4)_3$	8.73	19.00	57.3*	8.57	18.41	57.80*
$Ce(DPF)_6(ClO_4)_3$	8.50	18.38	—	8.65	18.40	—
$Pr(DPF)_6(ClO_4)_3$	8.58	18.60	—	8.71	18.38	—
$Nd(DPF)_6(ClO_4)_3$	9.00	18.71	—	8.88	18.35	—
$Sm(DPF)_6(ClO_4)_3$	9.03	18.01	—	9.22	18.28	—
$Y(DPF)_6(ClO_4)_3$	5.60	18.72	59.10*	5.66	19.00	59.63*

*The values refer to the percentage of carbon.

While using nitrobenzene as the solvent, a mercury seal stirrer was employed to exclude moisture. The data are tabulated in Table II.

Infrared Spectra

The infrared (i.r.) spectra of the complexes were recorded in Nujol mulls and KCl pellets employing a Carl–Zeiss UR-10 automatic infrared spectrophotometer. Some of the spectra were also recorded on a Perkin–Elmer Infracord. The principal absorption peaks and their assignments are shown in Table III.

Results and Discussion

The analytical data show that the DMF complexes have the formula $M(DMF)_8(ClO_4)_3$ where M = La, Ce, Pr, Nd, Sm, or Y. The corresponding DPF complexes analyze for the composition $M(DPF)_6(ClO_4)_3$ (Table I).

The conductivities of all the complexes in DMF, nitromethene, and nitrobenzene lie in the range expected for 1:3 electrolytes (Table II). This suggests that the perchlorate groups are not covalently bound to the metal. In nitrobenzene the complexes are dissociated into 4 species as shown by molecular weight data (Table II), confirming the ionic nature of the perchlorate. The molecular weight data for DMF complexes in water reveal the presence of 12 species (Table II) implying that the complex breaks down into its components in water.

The i.r. spectra of the complexes with the same ligand are very similar, exhibiting no significant dependence on the nature of the metal. The highest frequencies at 1650 and 1645 cm^{-1} in the spectra of DMF and DPF complexes respectively are attributed to carbonyl stretching vibrations. These are about 30 and 35 cm^{-1} lower than the carbonyl frequencies in the free amides (Table III). The decrease in carbonyl frequency suggests coordination through oxygen (2, 6).

There is considerable confusion in the literature regarding the assignment of ν(C—N) frequency in DMF and its complexes (14). While Randall *et al.* (14) opine that either 1389 or 1255 cm^{-1} band is to be attributed to ν(C—N), a recent normal coordinate treatment (15) shows that the 1499 band must be ν(C—N). Randall *et al.* (14) have also pointed out that in DMF complexes, shifts of ν(C=O) to lower frequencies are accompanied by shifts to lower frequencies of the two bands 1389 and 1255 cm^{-1}, one of which must be ν(C—N). Perhaps the group frequency approximation is inadmissible here due to some coupling of ν(C—N) and ν′(C—N) with ν(C=O) (14). However, the 1680 cm^{-1} band has been shown to be essentially due to C=O stretching vibration with very little contribution from C—N stretch (15). Table III shows the best possible assignment in the light of available literature data on the spectra of tertiary amides and their complexes.

The shifts in the case of DPF complexes compared with the free ligand are slightly greater than the corresponding shifts in the spectra of DMF complexes. This suggests that the phenyl groups on the nitrogen increase the basicity of the carbonyl. It is likely that the larger shifts observed in DPF complexes are due to the greater extent of delocalization of the positive charge on nitrogen arising from the flow of the electrons from the carbonyl to the metal. This is

†In nitromethane, 1:1 electrolytes have a molar conductance in the range 80–100 Ω^{-1} cm^2 mole^{-1} (10, 11); 2:1 electrolytes have λ_m in the range 140–160 (11). It can be expected that 3:1 electrolytes will show a molar conductance around 210 in $MeNO_2$.

‡In DMF, the molar conductance of 1:1, 2:1, and 3:1 electrolytes are 85–100, 140–170, and 200–260 Ω^{-1} cm^2 mole^{-1}, respectively (12).

§In nitrobenzene, 1:1 electrolytes exhibit λ_m values in the range 25–35 and 2:1 electrolytes around 45–60. From these values it is reasonable to anticipate a value around 80 for 3:1 electrolytes (13).

borne out by the perturbations of the aromatic ring vibrations. The phenyl band at 1602 cm^{-1} in the free amide, shifts to 1590 cm^{-1} in the complexes with enhanced intensity. An increased resonance involving electrons of the carbonyl and phenyl groups can account for this behavior (16). Further as in the case of the N,N-diphenylacetamide (DPA) complex with BCl_3 (17), the C—H out of plane deformations appear as doublets at 766 and 758 cm^{-1} (free DPF) and at 764 and 749 cm^{-1} (complex). This has been interpreted as implying double bond character in the C—N bond of (—CO.N<) in both the amide and the complex, and would thus be consistent with oxygen coordination.

The i.r. spectra also throw light on the nature of the perchlorate groups in the complexes. In the DPF complexes the ν_3 and the ν_4 bands of the perchlorate ion (18) at 1100 and 625 cm^{-1} respectively, are sharp and unsplit indicating retention of the T_d symmetry for the ion.

In the case of DMF complexes, however, the ν_3 band at 1096 cm^{-1} undergoes splitting. There seems to be a strong interaction between this perchlorate mode and the ligand vibration appearing around 1120 cm^{-1}. Actually a triplet is observed in this region (Table III). The ν_4 band is also split except in the case of Ce complex. The splitting of both ν_3 and ν_4 bands definitely indicates the loss of T_d symmetry of the perchlorate ion. The possible causes (19) for such a lowering of symmetry are (*a*) a covalent bonding of the perchlorate ion to the metal through one or two of its oxygen atoms, (*b*) a non-uniform field due to the ligand molecules round the cation, and (*c*) distortion of the perchlorate tetrahedron in the crystal lattice. If the observed splittings were the result of covalent bonding of the perchlorate, then both ν_1 and ν_2 must become i.r. active. These frequencies are not observed in the spectra except for a weak kink at 930 cm^{-1} attributable to ν_1 mode. Hathaway and Underhill (18) have shown that ν_1 at 930 cm^{-1} can appear for complexes with ionic perchlorate due to distortion of the ion by the crystal lattice. Also, Moeller and Vicentini (25) reported a splitting of the ν_3 band for the N,N-DMA complexes of lanthanide perchlorates in KBr pellets. Further, the known instability of the covalent perchlorate complexes (20), the very few instances of their occurrence (21, 22), and the completely altered spectrum of the covalent perchlorates (22) rule out the possibility of covalent bonding of the perchlorate in DMF complexes of the present study. While the effect of coordination of the perchlorate must be to bring about major differences in the i.r. spectra, minor shifts or splittings such as those observed may result from the other two causes listed above. The i.r. spectra thus confirm the non-coordinating nature of the perchlorate groups in the complexes.

With the perchlorate groups remaining ionic, it emerges that the coordination number of the rare earth ion is eight and six in DMF and DPF complexes respectively. The difference in behavior is attributable to steric considerations. The bulkier phenyl groups in DPF preclude the close approach of more than six ligand molecules

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

to the metal. The effect of ligand size in lowering the coordination number of rare earths is also reflected in the decrease of coordination number from eight in DMSO complexes (23) to six in analogous diphenyl sulfoxide complexes (24).

Theoretical considerations bearing on the evaluation and interpretation of the dielectric behavior of physically adsorbed polar gases[1]

T. McMullen[2] and R. McIntosh
Department of Chemistry, Queen's University, Kingston, Ontario
Received May 22, 1968

This paper consists of Part I and Part II. Part I contains a discussion of the evaluation of the dielectric constant of an adsorbed phase for a system which contains a small volume fraction of adsorbing solid. The method is similar to one employed earlier, but treats the case of spherical particles rather than spherical voids and employs the volume average macroscopic field of a phase rather than the volume average internal field. Part II contains the application of the correlation function method of Kubo to the assignment of the macroscopic dielectric properties of the adsorbed phase. The correlation function is developed for a system of rigid harmonic oscillators and used to establish the formulae for the static polarization and the resonance behavior of such a system. The results agree with earlier derivations by Kurbatov, by Benson, Channen, and McIntosh, and by Fröhlich.

Introduction

Many authors have reported the results of measurements of dielectric constant and loss of adsorbent–adsorbate systems (1). These measurements should provide a good deal of information about the structure of the adsorbed layer, since the dielectric behavior depends upon the interactions of an adsorbed molecule with its neighbors, and with the surface on which it lies. Unfortunately, the heterogeneous dielectric composed of the solid, adsorbed phase, and gas phase, is not easily treated theoretically, so that although the dielectric behavior of liquids and solids is in principle well understood, the same cannot be said for adsorbent–adsorbate systems. Consequently, many investigators have restricted themselves to qualitative interpretations of dielectric isotherms, and have emphasized features such as changes in the rate of increase of the dielectric constant of the overall system with amount adsorbed between points on a single isotherm, and the temperature coefficients of these slopes. Other investigators have used other methods of comparing dielectric isotherms of different adsorbates. A recent and interesting approach is discussed by Gröbner (2).

Any attempt at comparison of different adsorbates must encounter the obstacle which prevents proper interpretation of the dielectric behavior of any particular adsorbent–adsorbate system. The polarization of an adsorbed molecule depends on two factors: its net polarizability at the appropriate frequency, and the electric field at its location in the sample. This field is not generally the same as the external applied field. The experimentally measured quantity is essentially the total polarization of the sample, or more precisely the ratio of this quantity to the magnitude of the applied field. One wishes to obtain from this measurement the polarizability of an adsorbate molecule, which contains the useful information about the structure of the adsorbed layer. In the case of a homogeneous sample of solid or liquid, a model is assumed, and the macroscopic response of the system to the applied field is calculated in terms of molecular properties. However, a similar approach to heterogeneous dielectrics of the type at present employed in adsorption studies is considerably more difficult, and has not yet been attempted.

Several methods to establish approximate solutions have been tried, and these are reviewed by McIntosh (1). One which has been reasonably successful, and has some theoretical basis, is the extension of the Böttcher powder treatment (3, 4) by McIntosh and his associates (5, 6). These authors assume that a dielectric constant can be assigned to the adsorbed phase, and in the case of porous adsorbents, they obtain values for the adsorbates which appear reasonable when compared with liquid state values. However, there is reason to believe that their model is not applicable to powdered adsorbents of low packing fraction, since their method has been found to assign negative dielectric constants to the adsorbed phase

[1]Based on a thesis by T. McMullen which was presented in partial fulfilment of the requirements of the Ph.D. degree.

[2]Present address: H. H. Wills Laboratory, Department of Physics, Bristol University, Bristol, England.

when applied to the results of some recent measurements employing hydrogen and ethyl chlorides adsorbed on nonporous sodium chloride (7).

Because of the complexity of the problem, the retention of the assumption that a dielectric constant can be assigned to the adsorbed phase is attractive. This permits separation into two independent problems: the evaluation of this dielectric constant from experimental data, and, also, the interpretation of its behavior in terms of molecular properties. Consequently, in the first part of the present paper, we describe a modification of the extended Böttcher powder treatment which does appear to be applicable to powder samples with a low volume fraction of solid. In the second part, we show how the approach of Cole (8) can be modified in order to interpret the dielectric constant of the adsorbed phase which, by the above assumption, may now be considered to be a "two-dimensional" liquid (or gas) in an external potential which is chosen to represent the effect of the solid surface. No other property of the actual sample, such as its geometry, need be included. The "rotational oscillator model" of Kurbatov (9) and of Benson, Channen, and McIntosh (10) is considered explicitly, and the results of these authors are rederived by the correlation function method, which permits somewhat easier physical interpretation. In addition, the relaxation behavior of the model is discussed.

Part I
The Extended Böttcher Powder Treatment

Consider a sample of dielectric containing several distinct phases, each denoted by an index k. The polarization of this sample is

$$[1] \qquad \boldsymbol{P} = \boldsymbol{M}/V$$

with $\boldsymbol{M}$ the total moment, and V the volume. Because of the inhomogeneity of the sample, the polarization at any point is not a constant throughout, but may nevertheless be defined as

$$[2] \qquad \boldsymbol{P}(\boldsymbol{x}) = \Delta\boldsymbol{M}(\boldsymbol{x})/\Delta V(\boldsymbol{x})$$

where $\Delta\boldsymbol{M}(\boldsymbol{x})$ is the moment of a microscopically large, macroscopically small volume ΔV not including a phase boundary situated around a position defined by the position vector $\boldsymbol{x}$. With this definition, $\boldsymbol{P}(\boldsymbol{x})$ is continuous within a phase. Furthermore, we have

$$[3] \qquad \boldsymbol{P} = \frac{1}{V}\int_V \mathrm{d}^3x\, \boldsymbol{P}(\boldsymbol{x}) = \sum_k \frac{V_k}{V}\cdot\frac{1}{V_k}\cdot\int_{V_k} \mathrm{d}^3x\, \boldsymbol{P}(\boldsymbol{x})$$

which may be rewritten as

$$[4] \qquad \langle\boldsymbol{P}\rangle = \sum_k \delta_k\langle\boldsymbol{P}\rangle_k$$

where δ_k is the volume fraction of the kth phase, $\langle\rangle_k$ represents a volume average over the kth phase, and $\langle\rangle$, a volume average over the entire sample.

The macroscopic electric field may also be written as a volume average

$$[5] \qquad \boldsymbol{E}(\boldsymbol{x}) = 1/\Delta V\int_{\Delta V} \mathrm{d}^3x'\, \boldsymbol{F}(\boldsymbol{x}')$$

where $\boldsymbol{F}(\boldsymbol{x}')$ is the internal, or microscopic, field at the point $\boldsymbol{x}'$. In the same way, then

$$[6] \qquad \langle\boldsymbol{E}\rangle = \sum_k \delta_k\langle\boldsymbol{E}\rangle_k$$

which, from [5], is identical to

$$[7] \qquad \langle\boldsymbol{F}\rangle = \sum_k \delta_k\langle\boldsymbol{F}\rangle_k$$

McIntosh and co-workers (5, 6) consider a medium, the adsorbent, which contain spherical inclusions, and adsorption occurs on the walls of these interstices. For powder samples of low packing fraction, however, a model in which the solid is considered to be composed of spherical particles, seems preferable. (This may, for convenience, be called the "spherical particle model", and the former the "spherical void model".) The reason for this is that in the development, it is necessary to assume that the volume average field in the non-spherical region (whether it is the gas or the solid phase) remains constant on adsorption, and this is probably more nearly true for the phase occupying the largest volume.

Let the solid, adsorbed phase, and gas phase be denoted by the subscripts 1, 2, and 3 respectively. The average polarization is then written in terms of an average or overall dielectric constant ε found from the experimental data, so that [4] becomes

$$[8] \qquad \frac{\varepsilon - 1}{4\pi}\langle\boldsymbol{E}\rangle = \sum_k \delta_k\langle\boldsymbol{P}\rangle_k$$

Previous authors have used [7] as a second relation, and expressed the internal fields in terms of the macroscopic fields by the Lorentz relation. The same result is obtained for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

spherical particle model if [6] is employed instead of [7]; this makes it unnecessary to assume the Lorentz field.

If the polarization of the kth phase is written

$$[9] \qquad \langle \boldsymbol{P} \rangle_k = \chi_k \langle \boldsymbol{E} \rangle_k = \frac{\varepsilon_k - 1}{4\pi} \langle \boldsymbol{E} \rangle_k$$

we have, in the case of no adsorption:

$$[10] \qquad \frac{\varepsilon_0 - 1}{4\pi} \langle \boldsymbol{E} \rangle = \delta_1 \chi_1 \langle \boldsymbol{E} \rangle_1{}^0$$

$$[11] \qquad \langle \boldsymbol{E} \rangle = \delta_1 \langle \boldsymbol{E} \rangle_1{}^0 + (1 - \delta_1) \langle \boldsymbol{E} \rangle_3{}^0$$

where ε_0 is the overall dielectric constant of the powder sample without adsorbate, and the superscript zero indicates that $\delta_2 = 0$. Now $\langle \boldsymbol{E} \rangle_3$ is assumed to be unchanged on adsorption, so that

$$[12] \qquad \langle \boldsymbol{E} \rangle_3 = \frac{\langle \boldsymbol{E} \rangle}{1 - \delta_1} \left[1 - \frac{\varepsilon_0 - 1}{4\pi\chi_1} \right]$$

Considering the particles to be spherical and embedded in a medium of dielectric constant ε,

$$[13] \qquad \langle \boldsymbol{E} \rangle_1 = \frac{3\varepsilon}{2\varepsilon + \varepsilon_1} \langle \boldsymbol{E} \rangle$$

so that, from [4] and [9], one has

$$[14] \qquad \delta_2 \chi_2 \langle \boldsymbol{E} \rangle_2 = \frac{\varepsilon - 1}{4\pi} \langle \boldsymbol{E} \rangle - \delta_1 \chi_1 \frac{3\varepsilon}{2\varepsilon + \varepsilon_1} \langle \boldsymbol{E} \rangle$$

if ε_3 is assumed to be unity. Also [6] then becomes

$$[15] \qquad \delta_2 \langle \boldsymbol{E} \rangle_2 = \langle \boldsymbol{E} \rangle - \delta_1 \frac{3\varepsilon}{2\varepsilon + \varepsilon_1} \langle \boldsymbol{E} \rangle - \frac{\delta_3 \langle \boldsymbol{E} \rangle}{1 - \delta_1} \left[1 - \frac{\varepsilon_0 - 1}{4\pi\chi_1} \right]$$

Division yields an expression for χ_2, which is related to the complex dielectric constant ε_2 by [9]. A solution employing [7] instead of [6] yields an identical result for this model; this is not the case, however, if the "spherical void" model is used.

The spherical particle model has been used to determine the dielectric constant of butane adsorbed on sodium chloride (7), where $\delta_1 \simeq 0.1$ and δ_2 was calculated from the liquid state density. Good agreement with the liquid state dielectric constant indicates that the method is applicable, at least for adsorbates of low dielectric constant. Also, reasonable values for the dielectric constants of hydrogen and ethyl chlorides on sodium chloride were found, in contrast to the negative dielectric constants found from the spherical void model of McIntosh and his associates.

Part II
The Rotational Oscillator

If a dielectric constant is assigned to an adsorbed phase by a method similar to that described in the preceding section, the behavior should then be interpreted in terms of molecular properties. The adsorbed phase was considered in the development given in Part I to have the liquid state density. However, the intermolecular interactions are not as in the liquid, but, at least in the case of a gas-like film, are weakened by the increased distances between adsorbed molecules. In the treatment of the adsorbed film which follows, the most general and powerful approach to dielectric theory now available is applied. It is the adaptation of the correlation function method of Kubo (11, 12) by Glarum (13), and Cole (8).

Consider as a model of an adsorbate molecule the description given by Cole, in which each of the N molecules is assumed to have a permanent moment $\boldsymbol{\mu}$ and an induced moment represented by harmonic oscillator displacements $\boldsymbol{r}_i$ of charge e. We employ the change of origin introduced by Cole (14) in which these displacements are expressed in terms of the displacements $\boldsymbol{r}_i'$ from the equilibrium values $\boldsymbol{r}_{iE}$ in the presence of the field $\boldsymbol{E}_0$ due to external charges, so that

$$[16] \qquad e\boldsymbol{r}_i = e\boldsymbol{r}_i' + e\boldsymbol{r}_{iE}$$

and

$$[17] \qquad k\boldsymbol{r}_{iE} = e \left[\boldsymbol{E}_0(t) - \nabla_i \sum_{j \neq i} \frac{e\boldsymbol{r}_{jE} \cdot \boldsymbol{R}_{ij}}{|R_{ij}|^3} \right]$$

where k is the oscillator force constant and $\boldsymbol{R}_{ij}$ the vector separation of molecules i and j. Cole assumes cubic symmetry of the spherical sample, or an isotropic medium, so that the sum in [17] may be considered to vanish. This is not permissible in the case of a thin adsorbed film, however, and the optical polarizability of the medium must now be identified with the average value of a tensor $\tilde{\boldsymbol{\alpha}}$ defined by

$$[18] \qquad e\boldsymbol{r}_{iE} = \tilde{\boldsymbol{\alpha}}_i(p, q) \boldsymbol{E}_0$$

Also, the result given by Cole (8) for the mean moment in the field direction is generalized to

$$[19]\quad \langle \boldsymbol{M}(t)\cdot\boldsymbol{e}\rangle = N\langle\tilde{\boldsymbol{\alpha}}\boldsymbol{e}\rangle\cdot\boldsymbol{e}E_0 - \frac{1}{kT}\int_0^\infty d\tau \left\langle \dot{\boldsymbol{M}}(\tau)\cdot\boldsymbol{e}\sum_i\left[\boldsymbol{\mu}_i(0)\cdot\boldsymbol{e} - \mu_i(0)\cdot\nabla_i\sum_{j\neq i}\frac{\tilde{\boldsymbol{\alpha}}_i\boldsymbol{e}\cdot\boldsymbol{R}_{ij}}{|R_{ij}|^3}\right]\right\rangle_0 E_0(t-\tau)$$

where the applied field is written as $\boldsymbol{E}_0 = E_0\boldsymbol{e}$, and the subscript zero indicates an average over the unperturbed distribution, which is assumed to be canonical.

We now consider explicitly the rotational oscillator model employed by Kurbatov (9) and Benson, Channen, and McIntosh (10). The adsorbate molecules are assumed to be well separated so that there are no adsorbate–adsorbate interactions, and [19] reduces to

$$[20]\quad \langle \boldsymbol{M}(t)\cdot\boldsymbol{e}\rangle = N\alpha E_0 - N\left\langle\frac{\boldsymbol{M}(0)\cdot\boldsymbol{\mu}(0)}{3kT}\right\rangle_0 \times\int_0^\infty d\tau\, E_0(t-\tau)\dot{\Phi}(\tau)$$

where $\dot{\Phi}(\tau)$ indicates differentiation with respect to time of $\Phi(\tau)$ defined as

$$\Phi(t) = \langle\boldsymbol{\mu}(0)\cdot\boldsymbol{M}(t)\rangle_0/\langle\boldsymbol{\mu}(0)\cdot\boldsymbol{M}(0)\rangle_0$$

Some of the assumptions and transformations leading to [20] are worthwhile to indicate. We start with

$$\langle \boldsymbol{M}(t)\cdot\boldsymbol{e}\rangle = \int dpdq\sum_i(\boldsymbol{\mu}_i + e\boldsymbol{r}_{iE} + e\boldsymbol{r}_i')\times ef(p,q,t)$$
$$= N\alpha E_0 + \langle\sum_i(\boldsymbol{\mu}_i + e\boldsymbol{r}_i')\times ef(p,q,t)\rangle$$

The Hamiltonian of the system may be written as

$$H(p,q,t) = H^0(p,q) - \sum_i(\boldsymbol{\mu}_i + e\boldsymbol{r}_i)\cdot\boldsymbol{E}_0$$

and, if the change of origin employed by Cole (14) is utilized,

$$H(p,q,t) = H^0(p,q') - \sum_i\boldsymbol{\mu}_i\cdot\boldsymbol{E}_0 - \tfrac{1}{2}N\alpha E_0^2$$

We next take advantage of the fact that the time variation of the distribution function, given by $\partial f/\partial t = iLf$, is satisfied by the equation

$$f(t) = f_0 + \int_{-\infty}^t dt'\, e^{i(t-t')L_0}\{H_1(t'),f(t')\}$$

where f_0 is the equilibrium distribution function in the absence of the applied field. There is then obtained the integral equation for the distribution function

$$f(p,q,t) = f_0(p,q) - \int_{-\infty}^t dt'\, e^{iL_0(t-t')}\{\sum_i\mu_i(t'),f(t')\}E_0(t') - \frac{N}{2}\int_{-\infty}^t dt'\, e^{iL_0(t-t')}\{\alpha(t'),f(t')\}E_0^2(t')$$

where $\{\}$ are Poisson brackets, L_0 is the Liouville operator of the unperturbed system, and the field is applied subsequent to $t = -\infty$. To first order in the field E_0, the distribution function then becomes

$$f(t) = f_0(t) - \int_{-\infty}^t dt'\, e^{iL_0(t-t')}\{\sum_i\mu_i(t'),f_0(t')\}E_0(t')$$
$$= f_0(t) + \int_\infty^0 d\tau\, e^{iL_0\tau}\{\sum_i\mu_i(0),f_0\}E_0(t-\tau) \qquad \text{where}\quad \tau = t - t'$$

Since the distribution function is initially canonical,

$$f_0 = \frac{1}{Z}e^{-H^0/kT}\ , \qquad \{\sum_i\mu_i, f_0\} = -\frac{1}{kT}f_0\sum\dot{\mu}_i$$

and $$f(t) = f_0(t) + \frac{1}{kT}\int_0^\infty d\tau\, e^{iL_0\tau} \sum_i \dot{\mu}_i(0) E_0(t-\tau)$$

whence $$\langle \boldsymbol{M}(t)\cdot \boldsymbol{e}\rangle = N\alpha E_0 + \frac{1}{kT}\int_0^\infty d\tau \,\langle \boldsymbol{M}(0)\cdot \boldsymbol{e}\, e^{iL_0\tau}\sum_i \dot{\mu}_i(0)\cdot E_0(t-\tau) f_0\rangle$$

$$= N\alpha E_0 + \frac{1}{kT}\int_0^\infty d\tau\, \langle e^{-iL_0\tau} M(0) \times (-iL_0 \textstyle\sum_i \mu_i(0) f_0)\rangle E_0(t-\tau)$$

$$= N\alpha E_0 - \frac{N}{kT}\int_0^\infty d\tau \langle \dot{\boldsymbol{M}}(\tau)\cdot \boldsymbol{e}\mu_i(0)\cdot \boldsymbol{e}\rangle_0 E_0(t-\tau)$$

For systems in which the moment $\boldsymbol{M}$ and the dipoles $\boldsymbol{\mu}_i$ may be considered to lie in random directions with respect to the field, in the present case because of randomly oriented adsorption sites, we finally obtain

[21] $$\langle \boldsymbol{M}(t)\cdot \boldsymbol{e}\rangle = N\alpha E_0 - \frac{N}{3kT}\int_0^\infty d\tau \langle \dot{\boldsymbol{M}}(\tau)\cdot \boldsymbol{\mu}(0)\rangle_0 E_0(t-\tau)$$

We postpone for the present a discussion of the evaluation of the average $\langle \boldsymbol{\mu}(0)\cdot \boldsymbol{M}(0)\rangle_0$ and use [20] to obtain the relation among dielectric constant and distortion and orientational polarization. We note that $\boldsymbol{E}_0(t)$ is the external applied field, and introduce a definitition of dielectric constant in the usual way by consideration of a spherical sample. In this case the macroscopic field inside the sample is related to $E_0(t)$, which may be taken to be sinusoidal,

$$E_0(t) = E_0\, e^{-i\omega t}$$

so that $$E\, e^{-i\omega t} = \frac{3}{\varepsilon + 2} E_0\, e^{-i\omega t}$$

Thus we have

$$\frac{\varepsilon - 1}{4\pi} E e^{-i\omega t} = \frac{\langle \boldsymbol{m}(t)\cdot \boldsymbol{e}\rangle}{V}$$

and

[22] $$\frac{\varepsilon - 1}{\varepsilon + 2} = \frac{4\pi}{3}\frac{N\alpha}{V} - \frac{4\pi N}{9kTV}\langle \boldsymbol{M}(0)\cdot \boldsymbol{\mu}(0)\rangle_0 \int_0^\infty d\tau\, e^{i\omega\tau}\dot{\Phi}(\tau)$$

$$= \frac{4\pi N\alpha}{3V} - \frac{4\pi N}{9kTV}\sqrt{(2\pi)}\langle \boldsymbol{M}(0)\cdot \boldsymbol{\mu}(0)\rangle_0 \hat{\dot{\Phi}}(\omega)$$

where $\hat{\dot{\Phi}}(\omega)$ is the Fourier transform of $\dot{\Phi}(\tau)$, namely

$$\hat{\dot{\Phi}}(\omega) = \frac{1}{\sqrt{(2\pi)}}\int_0^\infty e^{i\omega\tau}\dot{\Phi}(\tau)\, d\tau$$

Using the conditions for very high frequency and for a static field, there results

$$\frac{\varepsilon_0 - 1}{\varepsilon_0 + 2} - \frac{\varepsilon_\infty - 1}{\varepsilon_\infty + 2} = \frac{4\pi N}{9kTV}\langle \boldsymbol{M}(0)\cdot \boldsymbol{\mu}(0)\rangle_0$$

which, after extensive re-arrangement, may be written

[23] $$\frac{\varepsilon(\omega) - \varepsilon_\infty}{\varepsilon_0 - \varepsilon_\infty} = \left[1 + \frac{\varepsilon_0 + 2}{\varepsilon_\infty + 2}\left(-\frac{1}{\sqrt{(2\pi)}}\frac{1}{(\hat{\dot{\Phi}}(\omega))} - 1\right)\right]^{-1}$$

Given the causal correlation function $\dot{\Phi}(\tau)$, the macroscopic response of the dielectric as a function of frequency may be ascertained.

It is now necessary to evaluate expressions of the form $\langle \boldsymbol{M}(t)\cdot \boldsymbol{\mu}(0)\rangle_0$. This is done by separating the expression into two terms,

[24] $$\langle M(t)\cdot\mu(0)\rangle_0 = \langle[\mu_i(t)+er_i'(t)]\cdot\mu_i(0)\rangle_0 + \sum_{j\neq i}\langle[\mu_j(t)+er_j'(t)\cdot\mu_i(0)]\rangle_0$$

In this connection it is convenient to identify the dipoles by the orientation of the sites on which they are located, that is to say, by the solid angle Ω_i which defines the orientation of the ith dipole. When this is done it may be seen that

$$\langle M(t)\cdot\mu(0)\rangle_0 = \langle[\mu_{\Omega_i}(t)+er'_{\Omega_i}(t)]\cdot\mu_{\Omega_i}(0)\rangle_0 + \langle[\mu_{-\Omega_i}(t)+er'_{-\Omega_i}(t)]\cdot\mu_{\Omega_i}(0)\rangle_0 + \sum_{\Omega_j\neq\Omega_i,-\Omega_i}\langle[\mu_{\Omega_j}(t)+er'_{\Omega_j}(t)]\cdot\mu_{\Omega_i}(0)\rangle_0$$

Consideration of the last term results in the conclusion that contributions from the Ω_j and $-\Omega_j$ positions cancel out and as it is assumed that terms of the form $er_i'\cdot\mu_i$ also make no contributions to the average, one obtains

[25] $$\langle M(t)\cdot\mu(0)\rangle = \langle\mu_\Omega(t)\cdot\mu_\Omega(0)\rangle_0 + \langle\mu_{-\Omega}(t)\cdot\mu_\Omega(0)\rangle_0$$

We now apply [25] in the case of rigid dipoles which perform rotational harmonic oscillations about the equilibrium positions so that

$$H^0 = \tfrac{1}{2}\sum_i(I\dot\gamma_i^2 + k_\gamma\gamma_i^2) = \tfrac{1}{2}\sum_i(P_{\gamma_i}^2/I + k_\gamma\gamma_i^2)$$

where I is the moment of inertia. We calculate first the moment

$$\langle M\cdot e\rangle = N\alpha E_0 - \frac{N}{3kT}\langle M(0)\cdot\mu(0)\rangle_0 \times\int_0^\infty d\tau\,\dot\Phi(\tau)E_0(t-\tau) = NE_0\left(\alpha+\frac{1}{3kT}\langle M(0)\cdot\mu(0)\rangle_0\right)$$

for the static case. The first term in [25] yields μ^2 and the second term

$$\langle\mu_{-\Omega}\cdot\mu_\Omega\rangle_0 = \int dpdq\, e^{-H0/kT}\,\mu_{-\Omega}\cdot\mu_\Omega \Big/ \int dpdq\, e^{-H0/kT}$$

The integrations over momenta, and over the position coordinates of all other dipoles, may be carried out immediately and cancel in numerator and denominator. There results

$$\langle\mu_{-\Omega}\cdot\mu_\Omega\rangle_0 = \frac{\int d\gamma_1\,d\gamma_2\, e^{-(k_\gamma\gamma_1^2+k_\gamma\gamma_2^2)/2kT}\,\mu(\gamma_1)\cdot\mu(\gamma_2)}{\int d\gamma_1\,d\gamma_2\, e^{-(k_\gamma\gamma_1^2+k_\gamma\gamma_2^2)/2kT}} = -\mu^2\frac{\int d\gamma_1\,d\gamma_2\,(\cos\gamma_1\cos\gamma_2-\sin\gamma_1\sin\gamma_2)\,e^{-k_\gamma(\gamma_1^2+\gamma_2^2)/2kT}}{\int d\gamma_1\,d\gamma_2\, e^{-k_\gamma(\gamma_1^2+\gamma_2^2)/2kT}}$$

The situation is illustrated in Fig. 1.

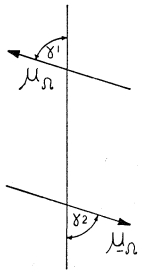

FIG. 1. Rotational oscillators.

For large k_γ, the limits of integration may be made $\pm\infty$. The integrals over odd functions vanish and there results

[26] $$\langle\mu_{-\Omega}\cdot\mu_\Omega\rangle_0 = -\mu^2\, e^{-kT/k_\gamma}$$

so that the static polarizability becomes

[27] $$\frac{\langle M\cdot e\rangle}{E_0} = N\alpha + \frac{N\mu^2}{3kT}(1-e^{-kT/k_\gamma})$$

which is the result given by Kurbatov (9). Expansion of the exponential term gives

[28] $$\frac{\langle M\cdot e\rangle}{E_0} = N\alpha + \frac{N\mu^2}{3k_\gamma}\left[1-\frac{1}{2}\frac{kT}{k_\gamma}+\frac{1}{3!}\left(\frac{kT}{k_\gamma}\right)^2+\ldots\right]$$

which, to first order in kT/k_γ is the result of Benson, Channen, and McIntosh (10).

We now consider the frequency dependence of the polarizability. This is determined by the correlation function involving two times t and t', so that we seek to evaluate $\langle \boldsymbol{M}(t) \cdot \boldsymbol{\mu}(t') \rangle_0$. As before, we recognize that the value will be given by the two terms

$$[29] \quad \langle \boldsymbol{M}(t) \cdot \boldsymbol{\mu}(t') \rangle_0 = \langle (\boldsymbol{\mu}_\Omega(t) + e\boldsymbol{r}'_\Omega(t)) \cdot \boldsymbol{\mu}_\Omega(t') \rangle_0 + \langle (\boldsymbol{\mu}_{-\Omega}(t) + e\boldsymbol{r}'_{-\Omega}(t)) \cdot \boldsymbol{\mu}_\Omega(t') \rangle_0$$
$$= \langle \boldsymbol{\mu}_\Omega(t) \cdot \boldsymbol{\mu}_\Omega(t') \rangle_0 + \langle \boldsymbol{\mu}_{-\Omega}(t) \cdot \boldsymbol{\mu}_\Omega(t') \rangle_0$$

if the electron and nuclear motions are uncorrelated with the rotational motion.

To evaluate the first term, which is the correlation of the dipole with itself, we should average over all phase angles in order to obtain the stationary value of the correlation function. The rigorous way to do this is to average over positions and momenta, since these determine the phase angle uniquely. A less rigorous method which seems equivalent is to find the correlation function for a given phase angle and then to average over phase angles assuming each to be equally probable.

The equation of motion of the oscillator is taken to be

$$[30] \quad \gamma(t) = \frac{\gamma_0}{2} \left(e^{i(\omega t + \alpha)} + e^{-i(\omega t + \alpha)} \right)$$

where γ_0 and α are respectively the amplitude and the phase angle. These are given by the initial conditions expressed in the relation

$$[31] \quad \frac{1}{2} k_\gamma \gamma_0^2 = \frac{1}{2} I \dot{\gamma}^2(0) + \frac{1}{2} k_\gamma \gamma(0)^2$$

and

$$\tan \alpha = -\omega \frac{\dot{\gamma}(0)}{\gamma(0)}$$

We next consider an oscillator of given phase angle, arbitrarily chosen to be zero.

$$[32] \quad \langle \boldsymbol{\mu}(t) \cdot \boldsymbol{\mu}(t') \rangle_0 \Big|_{\alpha = 0} = \frac{\int dp dq \, \mu^2 \cos [\gamma(t) - \gamma(t')] \, e^{-H_0/kT}}{\int dp dq \, e^{-H_0/kT}}$$

and

$$\gamma(t) - \gamma(t') = \gamma(t') \left[\frac{e^{i\omega t} + e^{-i\omega t}}{e^{i\omega t'} + e^{-i\omega t'}} - 1 \right]$$
$$= \gamma(t') b$$

We perform the integration for time t', extending the limits of integration for γ to $\pm \infty$.

$$\langle \boldsymbol{\mu}(t') \cdot \boldsymbol{\mu}(t) \rangle_0 = \frac{\int_{-\infty}^{\infty} d\gamma \, \mu^2 \cos b\gamma \, e^{-k_\gamma \gamma^2 / 2kT}}{\int_{-\infty}^{\infty} d\gamma \, e^{-k_\gamma \gamma^2 / 2kT}}$$

since b is assumed to be independent of γ and $\dot{\gamma}$ and the integrals over $\dot{\gamma}$ cancel in numerator and denominator. The result is

$$[33] \quad \langle \boldsymbol{\mu}(t) \cdot \boldsymbol{\mu}(t') \rangle_0 \Big|_{\alpha = 0} = \mu^2 \, e^{-kTb^2/2k\gamma}$$

In dealing with the second term of the correlation function we again consider one oscillator with a zero value of its phase angle, but because the phase angles are independent, we must consider the second to have a value of phase angle between $\pm \pi$ and which may be randomly chosen.

$$[34] \quad \langle \boldsymbol{\mu}_{-\Omega}(t) \cdot \boldsymbol{\mu}_\Omega(t') \rangle_0 = \langle \boldsymbol{\mu}_{\gamma_2}(t) \cdot \boldsymbol{\mu}_{\gamma_1}(t') \rangle_0 = \frac{\int d\dot{\gamma}_1 \, d\dot{\gamma}_2 \, d\gamma_1 \, d\gamma_2 \, e^{-H_0/kT} \, \mu^2 \cos [\gamma_1(t') + \pi - \gamma_2(t)]}{\int d\dot{\gamma}_1 \, d\dot{\gamma}_2 \, d\gamma_1 \, d\gamma_2 \, e^{-H_0/kT}}$$

We now use

$$\gamma_1(t) = \gamma_1^0 \cos \omega t, \qquad \gamma_2(t) = \gamma_2^0 \cos (\omega t + \alpha),$$

so that

$$\gamma_1(t') - \gamma_2(t) = \gamma_1(t') - \gamma_2(t') \left[\frac{e^{i(\omega t + \alpha)} + e^{-i(\omega t + \alpha)}}{e^{i(\omega t' + \alpha)} + e^{-i(\omega t' + \alpha)}} \right]$$
$$= \gamma_1(t') - C\gamma_2(t')$$

The averaging may now be carried out over the equilibrium distribution at t'. Since $\cos(\gamma_1 - C\gamma_2) = \cos\gamma_1 \cos C\gamma_2 + \sin\gamma_1 \sin C\gamma_2$, and the integral over $\sin\gamma_1$ will vanish since H^0 is an even function of γ_1, and assuming C to be independent of γ_1, γ_2, $\dot{\gamma}_1$, $\dot{\gamma}_2$, we arrive at

$$[35] \qquad \langle \boldsymbol{\mu}_{\gamma_1}(t) \cdot \boldsymbol{\mu}_{\gamma_2}(t') \rangle_0 \Big|_{\alpha_1 = 0, \alpha_2 = \alpha} = - \frac{\int d\gamma_1\, d\gamma_2\, e^{-k_\gamma(\gamma_1^2 + \gamma_2^2)/2kT}\, \mu^2 \cos\gamma_1 \cos C\gamma_2}{\int d\gamma_1\, d\gamma_2\, e^{-k_\gamma(\gamma_1^2 + \gamma_2^2)/2kT}}$$

$$= - \mu^2 e^{[-kT(1+C^2)]/2k_\gamma}$$

We now have $$\langle \boldsymbol{M}(t) \cdot \boldsymbol{\mu}(t') \rangle_0 = + \mu^2 e^{-kTb^2/2k\gamma} - \mu^2 e^{-kT(1+C^2)/2k\gamma}$$

Expanding the exponentials and keeping only those terms of first order in kT/k_γ gives

$$[36] \qquad \langle \boldsymbol{M}(t) \cdot \boldsymbol{\mu}(t') \rangle_0 \Big|_{\alpha_1 = 0, \alpha_2 = \alpha} \simeq \frac{\mu^2 kT}{2k_\gamma} [1 - b^2 + c^2]$$

To average over all values of α_2 is the same as averaging over all values of initial times t' assuming that these are equally probable within the period

$$-\frac{\pi}{\omega} < t' < \frac{\pi}{\omega}$$

We set $t = t' + \tau$ and obtain

$$1 - b^2 + c^2 = 2\cos\omega\tau - 2\tan\omega t' \sin\omega\tau + 2\cos\omega\tau \sin\omega\tau[\tan\omega t' - \tan(\omega t' + \alpha)] + \sin^2\omega\tau[\tan^2(\omega t' + \alpha) - \tan^2\omega t']$$

The averages over $t' = -\pi/\omega$ to $t' = \pi/\omega$ vanish for the terms $\int dt' \tan\omega t'$, $\int dt' [\tan\omega t' - \tan(\omega t' + \alpha)]$, and $\int dt' [\tan^2(\omega t' + \alpha) - \tan^2\omega t']$ for any value of α. Thus we obtain

$$[37] \qquad \langle \boldsymbol{M}(t) \cdot \boldsymbol{\mu}(t') \rangle_0 \simeq \frac{\mu^2 kT}{k_\gamma} \cos\omega\tau$$

which is now stationary.

However, dielectric loss must be accounted for, and in the present case of an isolated dipole, arises purely from interaction with the crystal surface. An appropriate model for this interaction would appear to be a small fluctuating random force on the dipole, caused by the thermal vibrations of the atoms composing the crystal, and the resulting deviations from linearity of the force binding the dipole. This additional perturbation to the Hamiltonian should properly be included at an early stage in the calculation.

Nevertheless, it is not obvious that the present calculation, with its other rather drastic simplifying assumptions, merits a detailed treatment of a loss mechanism. Also, one of our purposes was to rederive eq. [37] as obtained by other authors. Thus, in order to give an explicit expression for the susceptibility, we introduce loss by assuming an exponential decay of correlation, which is mathematically the simplest way of allowing for the effect. We write

$$[38] \qquad \langle \boldsymbol{M}(t) \cdot \boldsymbol{\mu}(t') \rangle_0 \simeq \frac{\mu^2 kT}{k_\gamma} e^{-\tau/\tau_0} \cos\omega\tau$$

This behavior results from the assumption that correlation is destroyed by a Poisson process, and exists for a mean free time τ_0. A process of this type would occur if the lattice vibrations were sharp impulses, randomly distributed in time with mean free time τ_0, and each sufficiently large to randomize completely the oscillator phases. Such a mechanism is similar to that of strong collisions in gases employed by Van Vleck and Weisskopf (16), but may not be a particularly good model for the physical situation considered here.

Equation [38] for the correlation function leads to the expression for the complex susceptibility of a rotational oscillator. We may write

$$\langle \Delta\boldsymbol{M} \cdot \boldsymbol{e} \rangle = \langle \boldsymbol{M} \cdot \boldsymbol{e} \rangle - N\alpha E_0$$

$$= - \frac{N}{3kT} \langle \boldsymbol{\mu}(0) \cdot \boldsymbol{M}(0) \rangle_0 \times \int_0^\infty d\tau\, \dot{\Phi}(\tau) E_0(t - \tau)$$

If a sinusoidal field is assumed we have $E_0\, e^{-i\omega t}$, and the susceptibility may be defined by

$$\chi(\omega) = \frac{\langle \Delta \boldsymbol{M} \cdot \boldsymbol{e} \rangle}{E_0\, e^{-i\omega t}}$$

$$= -\frac{N}{3kT} \langle \boldsymbol{M}(0) \cdot \boldsymbol{\mu}(0) \rangle_0 \int_0^\infty d\tau\, e^{i\omega\tau}\, \dot{\Phi}(\tau)$$

$$= -\frac{\sqrt{(2\pi)N}}{3kT} \langle \boldsymbol{M}(0) \cdot \boldsymbol{\mu}(0) \rangle_0 \hat{\dot{\Phi}}(\omega) \quad (39)$$

For the rotational oscillator this becomes

$$\chi(\omega) = -\frac{\sqrt{(2\pi)N}}{3k_\gamma} \mu^2 \hat{\dot{\Phi}}(\omega)$$

with $\Phi(\tau) = e^{-\tau/\tau_0} \cos \omega_0 \tau$

or

$$\Phi(t) = e^{-t/\tau_0} \cos \omega_0 t$$

with $\omega_0^2 = k_\gamma / I$

$$\hat{\dot{\Phi}}(\omega) = \frac{1}{\sqrt{(2\pi)}} \int_0^\infty dt \left[\left(\frac{i\omega_0 - 1/\tau_0}{2} \right) e^{i(\omega + \omega_0 + i/\tau_0)t} - \left(\frac{i\omega_0 + 1/\tau_0}{2} \right) e^{-i(\omega_0 - \omega - i/\tau_0)t} \right]$$

$$= -\frac{1}{2i\sqrt{(2\pi)}} \left[\frac{i\omega_0 - 1/\tau_0}{(\omega + \omega_0) + i/\tau_0} + \frac{i\omega_0 + 1/\tau_0}{(\omega_0 - \omega) - i/\tau_0} \right]$$

After some rearrangement this yields for $\chi(\omega)$

$$\chi(\omega) = \frac{N\mu^2}{6k_\gamma} \left[\frac{\omega_0(\omega + \omega_0) + (1/\tau_0)^2 + i\omega/\tau_0}{(\omega + \omega_0)^2 + (1/\tau_0)^2} + \frac{\omega_0(\omega_0 - \omega) + (1/\tau_0)^2 + i\omega/\tau_0}{(\omega - \omega_0)^2 + (1/\tau_0)^2} \right]$$

If we set

$$\Delta\chi = \frac{N\mu^2}{3k_\gamma}$$

we have

$$\mathrm{Re}\, \chi(\omega) = \frac{\Delta\chi}{2} \left[\frac{1 + \omega_0(\omega + \omega_0)\tau_0^2}{(\omega + \omega_0)^2 \tau_0^2 + 1} + \frac{1 - \omega_0(\omega - \omega_0)\tau_0^2}{(\omega - \omega_0)^2 \tau_0^2 + 1} \right]$$

$$\mathrm{Im}\, \chi(\omega) = \frac{\Delta\chi}{2} \left[\frac{\omega\tau_0}{(\omega + \omega_0)^2 \tau_0^2 + 1} + \frac{\omega\tau_0}{(\omega - \omega_0)^2 \tau_0^2 + 1} \right]$$

These results are in agreement with the expressions given by Fröhlich (15).

Appendix

If the sum in [17] is retained, the additional terms arising in the expression for the mean moment may be obtained as follows. Cole (14) gives the perturbed Hamiltonian to first order in the field, expressed in the primed coordinates as

$$[A1] \quad H(p, q, t) = H^0(p, q) - \textstyle\sum_i (\boldsymbol{\mu}_i + \boldsymbol{e}\boldsymbol{r}_i) \cdot \boldsymbol{E}_0$$

$$= H^0(p, q') - \textstyle\sum_i \boldsymbol{\mu}_i \cdot \boldsymbol{E}_0 + \sum_i \boldsymbol{\mu}_i \cdot \nabla_i \sum_{j \neq i} \dfrac{\boldsymbol{e}\boldsymbol{r}_{jE} \cdot \boldsymbol{R}_{ij}}{|R_{ij}|^3} + \sum_i \boldsymbol{e}\boldsymbol{r}_{iE} \cdot \nabla_i \sum_{j>i} \phi_{ij}$$

since r_{iE} is dependent on the field strength. A short range interaction term is included, and in the last term the potential ϕ_{ij} is considered to include all terms of higher order than dipole. The expression simplifies somewhat if this is disregarded, so that only dipole interactions are considered. Use of the definition [18] permits [A1] to be rewritten as

$$[A2] \qquad H(p, q, t) = H^0(p, q') - \sum_i \boldsymbol{\mu}_i \cdot \boldsymbol{E}_0 + \sum_i \boldsymbol{\mu}_i \cdot \nabla_i \sum_{j \neq i} \frac{\tilde{\alpha}_j \boldsymbol{E}_0 \cdot \boldsymbol{R}_{ij}}{|R_{ij}|^3}$$

$$= H^0(p, q') - \sum_i \left[\boldsymbol{\mu}_i \cdot \boldsymbol{e} - \boldsymbol{\mu}_i \cdot \nabla_i \sum_{j \neq i} \frac{\tilde{\alpha}_j \boldsymbol{e} \cdot \boldsymbol{R}_{ij}}{|R_{ij}|^3} \right] E_0$$

$$= H^0 + H^1(t)$$

where $\boldsymbol{E}_0 = \boldsymbol{e}E_0$. Thus H^1 is of the form

$$[A3] \qquad H^1(t) = -AE_0(t)$$

where A is a dynamical variable not explicitly dependent on time. We now evaluate the mean moment in the field direction, if $\boldsymbol{M}(t)$ is the total moment of the system

$$[A4] \qquad \langle \boldsymbol{M}(t) \cdot \boldsymbol{e} \rangle = \int \mathrm{d}p\mathrm{d}q \sum_i (\boldsymbol{\mu}_i + e\boldsymbol{r}_i) \cdot e f(p, q, t)$$

$$= N\langle \tilde{\alpha} \boldsymbol{e} \rangle E_0 \cdot \boldsymbol{e} + \int \mathrm{d}p\mathrm{d}q \times (\boldsymbol{\mu}_i + e\boldsymbol{r}_i') \cdot e f(p, q, t)$$

Solution of Liouville's equation by the method of Kubo (11, 12) yields [19], when only terms to first order in the field are assumed to be equally probable, and gives for the first term $N\alpha E_0$, where α may be defined as the optical polarizability of the medium. The second term in the correlation function is the electrostatic interaction of a permanent dipole with all other induced dipoles. If this is written explicitly in terms of the gradient of a dipole field, it is easily shown to vanish if the medium is isotropic; that is, if the pair distribution function is spherically symmetric.

Acknowledgments

Grateful acknowledgment is made to the National Research Council of Canada for the support of this work and for graduate fellowships to T. McMullen. Important help was rendered by C. Carter in the checking of the mathematical developments.

Vibrational spectra of thiocarbonyl chlorofluoride and a normal coordinate analysis of thiocarbonyl chlorofluoride and thiocarbonyl difluoride

D. C. MOULE AND C. R. SUBRAMANIAM
Department of Chemistry, Brock University, St. Catharines, Ontario

Received September 26, 1968

The previously unreported infrared and Raman spectra of thiocarbonyl chlorofluoride have been obtained and analyzed. An assignment has been made for the in-plane fundamental frequencies. The frequency of the out-of-plane fundamental has been obtained from a partial analysis of the near ultraviolet (π^*n) system. Normal coordinate analyses for thiocarbonyl fluoride and thiocarbonyl chlorofluoride have been carried out using the Urey–Bradley potential field. The value of the CS stretching force constant is found to show a marked change with the halogen substitution in contrast to the CO stretching constant in the carbonyl halides. This is attributed to the presence of ionic valence bond structures in the thiocarbonyl halides which are not significant in the carbonyl halides.

Introduction

The study of the vibrational spectrum of thiophosgene, $CSCl_2$, and the normal coordinate analysis have been carried out by many authors (1–6), with the most recent one giving a revised assignment for ν_3 and ν_4 (6). The electronic spectrum in absorption of thiophosgene has been analyzed in considerable detail (6) and from the combination differences of the vibrational levels in the lower electronic state, precise values of certain fundamental frequencies have been obtained. The infrared spectrum of thiocarbonyl fluoride has been reported by Downs (7) who has been able to assign the fundamental vibrational modes satisfactorily. From this analysis, Pillai and Ramaswamy (8) have carried out a normal coordinate analysis using an empirical valence force field.

The infrared and the Raman spectra of thiocarbonyl chlorofluoride have been obtained and the vibrational analysis carried out. The analysis of the ground state vibrations was undertaken as a necessary prelude to a detailed study of the electronic spectrum. In order to carry out a normal coordinate analysis of CSFCl required in a Franck–Condon analysis of the (π^*n) electronic transition, it was felt necessary to carry out first a normal coordinate analysis of CSF_2 and $CSCl_2$ in the Urey–Bradley force field, from which a transfer of force constants could then be made.

Experimental

Thiocarbonyl chlorofluoride was prepared by fluorinating thiophosgene, $CSCl_2$, using antimony trifluoride in the solvent tetrahydrothiophene-1,1-dioxide. A mixture of 5 ml of thiophosgene, 25–30 g of SbF_3, and 50 g of the solvent was refluxed at atmospheric pressure for more than 48 h at 78–80 °C.

After the reaction, the products were condensed and purified by trap-to-trap distillation followed by a low temperature distillation. The purified sample still contained small quantities of COS, CCl_3F, and CS_2. The sample and the impurities were identified by their mass spectral pattern.

The infrared spectrum was recorded in the gaseous phase using a Perkin–Elmer model 225 grating spectrophotometer which was provided with a dry air purging unit.

The Raman spectrum of liquid CSClF was excited by a 50 mW He–Ne laser and recorded with a Spexs double monochromator. The spectrum was recorded both with the polarized light parallel and perpendicular to the incident electric vector direction.

Results and Assignment

No structural data for CSClF have been reported, although electron diffraction data (9) modified by infrared data (6) are available for $CSCl_2$. The molecules CSF_2 and CSClF are presumably planar and belong to the point groups C_{2v} and C_s, respectively. The geometrical parameters assumed for CSClF were transferred from $CSCl_2$ (6) and COF_2 (10). They are: r(CS), 1.63 Å; r(CF), 1.32 Å; r(CCl), 1.746 Å; α(ClCF), 111° 54′; and α(SCCl), 124° 18′, where r and α are the interatomic distances and the bond angles, respectively.

TABLE I

Principal moments of inertia of thiocarbonyl chlorofluoride

	Moments of inertia (10^{-40}g cm^2)		
Molecule	I_A	I_B	I_C
CSClF	149.81	268.1	417.8

TABLE II

Observed fundamental frequencies of CSClF

Infrared frequency, gas (cm^{-1})	Intensity*	Raman frequency, liquid (cm^{-1})	Intensity†	Assignment
1257	100	1242	32 (P)	ν_1
1014	75	992	8 (P)	ν_2
612	28	608	100 (P)	ν_3
427	4	426	10 (P)	ν_4
323	2	326	50 (P)	ν_5

*The intensity of the band at 1257 cm^{-1} was arbitrarily taken as 100 and the other band intensities are normalized with respect to this band.
†The Raman line at 608 cm^{-1} is the most intense and is taken as of intensity 100; P stands for polarized.

There are five vibrations of a' species and one vibration of a'' species expected for CSClF. Both species are infrared and Raman active. Table I gives the principal moments of inertia of CSClF. Figure 1 shows the orientation of the inertial axis with respect to the molecule. The five in-plane vibrations of a' species will be polarized with their electric dipole vector in the ab plane, and their resulting rotational contours will consist of a superposition of type A and type B bands. The remaining vibration of a' species will give rise to a type C band.

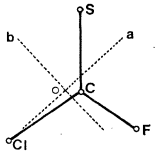

FIG. 1. Orientation of inertial axes of CSClF.

The infrared spectrum of CSClF obtained in the gas phase is shown in Fig. 2. Table II lists the observed infrared and Raman fundamental frequencies for CSClF. The strongest bands in the infrared spectrum of CSClF vapor are located at 1257 and 1014 cm^{-1}, and are found at 1242 and 992 cm^{-1}, respectively, in the Raman spectrum of the liquid. Both of the infrared bands have an AB type rotational envelope and their corresponding Raman lines are polarized. The 1257 cm^{-1} mode can be assigned to the CS stretch, $\nu_1(a_1)$; the corresponding modes in Cl_2CS and F_2CS appearing at 1139 and 1368 cm^{-1}, respectively. The assignment of the second band at 1014 cm^{-1} to $\nu_2(a_1)$, the CF stetching mode, was also straightforward.

The weaker infrared band at 612 cm^{-1} displays a complicated rotational band envelope containing five principal maxima which can not be rationalized in terms of type AB hybridization or an isotope effect, although it could be interpreted as a fundamental with several sequence bands superimposed on it. The corresponding intense Raman line at 608 cm^{-1} is polarized and must be assigned to $\nu_3(a_1)$, the CCl stretch.

The infrared band at 427 cm^{-1} has a rotational envelope similar to ν_1 and ν_3 and was assigned to $\nu_4(a_1)$, an in-plane bending mode. The remaining $\nu_5(a_1)$ mode was assigned to the weak infrared band at 323 cm^{-1} which had a contour different from that of the 427 cm^{-1} band. The corresponding Raman lines were at 426 and 326 cm^{-1}, respectively, and were found to be polarized.

The out-of-plane modes for $CSCl_2$ and CSF_2 have been found to be 471 and 622 cm^{-1}, respectively. Hence, the out-of-plane vibration is expected to be about 540–550 cm^{-1}. It has not been possible to identify this mode either in the infrared or in the Raman spectra because of the presence of certain strong impurity bands in this region. The sample contained small quantities of CS_2, COS, and CCl_3F. Information about ν_6 was obtained from a partial analysis of certain progressions observed in the ultraviolet spectra of CSClF. Attached to most of the prominent bands in the electronic spectra were hot band progressions extending to lower wavenumbers in the interval of 540 cm^{-1}. This progression can be assigned to the ν_6 mode on Franck–Condon ground since, as in the case of $CSCl_2$, CSClF is expected to assume a non-planar configuration in the excited electronic state (6).

Normal Coordinate Analysis

The normal coordinate analysis was carried out by the Wilson's [**F**] and [**G**] matrix method.

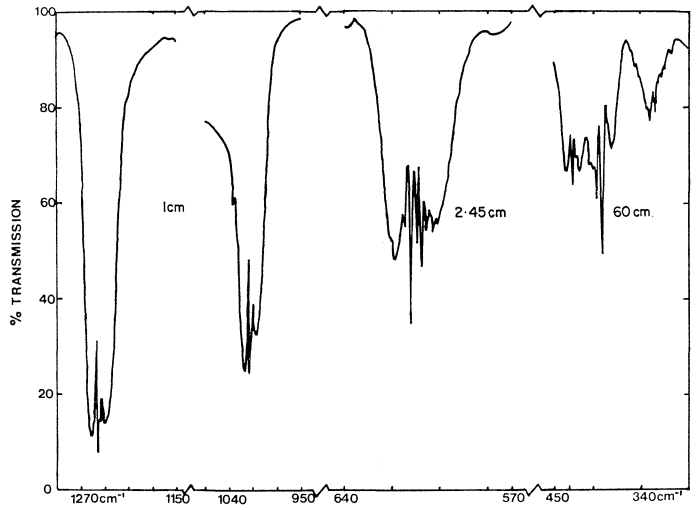

FIG. 2. Infrared bands of thiocarbonyl chlorofluoride vapor.

In order to reduce the number of force constants to a manageable size, the Urey–Bradley force field was employed and is given by

$$[1]\quad V = \sum_i [\tfrac{1}{2}K_i(\Delta r_i)^2 + K'_i r_i(\Delta r_i) + \sum_{i<j} [\tfrac{1}{2}H_{ij}r^2{}_{ij}(\Delta\alpha_{ij})^2 + H'_{ij}r^2{}_{ij}(\Delta\alpha_{ij})] + \sum_{i<j} [\tfrac{1}{2}F_{ij}(\Delta q_{ij})^2 + F'_{ij}q_{ij}(\Delta q_{ij})]$$

Here Δr_i, $\Delta\alpha_i$, and Δq_i are the changes in bond lengths, bond angles, and distances between non-bonded atoms, respectively. The symbols K_i, K'_i, H_{ij}, H'_{ij}, F_{ij}, and F'_{ij} represent the stretching, bending, and non-bonded interaction force-constants.

The [**G**] matrix elements were constructed by the method given by Wilson, Decius, and Cross (10). The [**F**] matrix elements were obtained from the transformation

$$[2]\qquad [\mathbf{F}] = [\mathbf{Z}][\mathbf{\Phi}]$$

where [**Z**] is a matrix representing a transformation between a vector of Urey–Bradley force constants [$\mathbf{\Phi}$] and a vector of valence force field constants.

In the case of CSF_2 both the [**F**] and [**G**] matrices were symmetrized and the secular equation

$$[3]\qquad [\mathbf{G}][\mathbf{F}][\mathbf{L}] = [\mathbf{L}][\lambda]$$

solved for the eigenvectors [**L**] and eigenvalues [λ]. The [**L**] matrix relates the normal coordinates [**Q**] to the internal coordinates [**R**] by the relation

$$[4]\qquad [\mathbf{R}] = [\mathbf{L}][\mathbf{Q}]$$

The initial set of force constants were transferred from similar molecules with the assumption that $F'_{ij} = 0.1F_{ij}$ (10), and then were refined using a Jacobian least squares procedure to obtain good agreement between the experimental and calculated values.

Table III shows the in-plane force constants for the three thiocarbonyl halides while Table IV shows the calculated frequencies for CSF_2 and

TABLE III

CSClF. Tables V and VI give the elements of the [**L**] matrix for CSF_2 and CSClF, respectively. The potential energy distribution in the Urey–Bradley coordinate space was calculated by the equation

$$[5] \qquad [\mathbf{V}] = [\mathbf{J}][\lambda]^{-1}[\Phi^*]$$

where $[\Phi^*]$ is a diagonal matrix with elements Φ_i. Tables VII and VIII list the distribution of potential energy in Urey–Bradley space for CSF_2 and CSClF, respectively. The mass-weighted cartesian displacement vector diagrams, which give a pictorial representation of the normal coordinates, are given in Figs. 3 and 4 for CSF_2 and CSClF respectively.

The number of Urey–Bradley force constants to be determined for CSF_2 and CSClF was 6 and 9, respectively, for the in-plane vibrations. The observed number of in-plane vibrations was 5 for each molecule. Hence, it was necessary to constrain certain force constants in order to see the variation of the Urey–Bradley force constant of CSF_2 and $CSCl_2$ as a function of the constrained force constants. The latter were varied

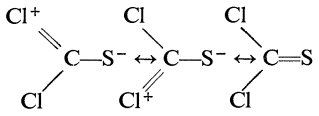
over a reasonable range and the other five constants calculated. Figure 5 shows the variation graphically for CSF_2.

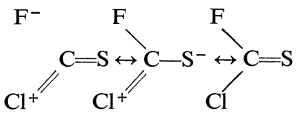
Discussion

Although small variations in the bending and nonbonded interaction force constants are not very significant because of their dependence on the value of the constrained force constant, it is interesting to compare the stretching force constants in Cl_2CS, F_2CS, and ClFCS which are relatively independent of the value of the constrained force constant. In contrast to a variation of 2% in the value of K_{CO} in the carbonyl halides (11), the value of K_{CS} varies by 18% between CSF_2 and $CSCl_2$. This can be explained in terms of the valence bond structures for the thiocarbonyl halides. For $CSCl_2$ the possible resonance structures are



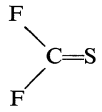
1a **1b** **1c**

Similarly for CSClF the plausible structures are



2a **2b** **2c**

For CSF_2, the structures similar to **1***a* and **1***b* would make very little contribution to the overall structure since they would require the presence of a positive charge on a fluorine atom. The prominent valence bond structure will be



3*a*

From a study of the infrared spectra of amides and thioamides, Jensen (12) has shown that structures of the form

have greater weight than structures

when X = S, whereas the reverse is true when X = O. A linear combination of atomic orbitals/molecular orbitals calculation on the CS molecule has likewise demonstrated that electron back donation should be easier to sulfur than it would be to the oxygen atom (13). Thus, the ionic structures like **1***a* and **1***b* play a greater role in determining the overall structure of the thiocarbonyl compounds than they do in the carbonyl compounds. Hence the C=S bond order and the K_{CS} force constant will be lower in $CSCl_2$ than in CSClF or CSF_2 because of the contribution of structures **1***a* and **1***b*. Likewise K_{CS} in CSClF will be lower than in CSF_2 because of the contribution of structure **2***b*.

The variation of K_{CCl} and K_{CF} with halogen substitution is more difficult to understand. One explanation for the increase in the value of K_{CCl} from $CSCl_2$ to CSClF is the presence of structure **2***a* in CSClF which is absent in $CSCl_2$. Likewise the decrease in K_{CF} in CSClF over CSF_2 can be attributed to structure **2***a* in CSClF which would not contribute to CSF_2.

Nuclear recoil reactions in polynuclear metal carbonyls

S. R. NARAYAN AND D. R. WILES
Chemistry Department, Carleton University, Ottawa, Canada

Received August 30, 1968

Nuclear recoil reactions have been studied in the compounds $Ru_3(CO)_{12}$, $Fe_3(CO)_{12}$, $Fe(CO)_5$, and $W(CO)_6$, with the objective of testing the hypothesis that the retention would be closely related to the molecular complexity. Retention values were found to be 41, 26, 41, and 52%, respectively, after exhaustive purification, and the hypothesis is concluded to be invalid for these compounds. A recoil yield of 26% is found for $Fe_3(CO)_{12}$ in $Fe(CO)_5$, and 17% for $Fe(CO)_5$ in $Fe_3(CO)_{12}$. Some reactions are suggested which can account qualitatively for the observed results. The critical stage of the reaction is assumed to be the hot-zone formation of a mononuclear radioactive species $M(CO)_3$ or $M(CO)_4$, which reacts further by various stepwise reactions.

A retention of 52 or 64% was found for $W(CO)_6$, depending on whether column chromatography or vacuum sublimation was used as the first step in the separation. The lower value is preferred.

Neutron irradiation of metal carbonyls gives rise to the production of the parent carbonyl, re-formed with a radioisotope of the metal atom. However, the mechanism whereby this re-formation occurs is unknown, and although some aspects of the reaction have been discussed in the literature, no general mechanism has been proposed. It has been calculated (1) that the strict billiard-ball re-formation could be as high as a few %, but this is far too low to account for the experimental data, and we are driven to try to find out more about the fundamental nature of the reaction. One of the intriguing aspects of those carbonyls which have been studied is that the mononuclear $Cr(CO)_6$, $Mo(CO)_6$, and $W(CO)_6$ have retentions which are much higher than is common among organometal compounds, and in some cases are quite high, while the retention in $Mn_2(CO)_{10}$, the only binuclear metal carbonyl which has been studied to date, is considerably lower. The retention values for such compounds have been found to vary widely according to the conditions of the irradiation, and are thus difficult to intercompare when the work has been done at different laboratories, but the above-mentioned grouping seems to be quite valid and outside of all reasonable uncertainties. The approximate ranges of the retention values found in the literature for metal carbonyls are given in Table I. Also shown in this Table are the values found for the yields of two metal carbonyls from neutron-irradiated arenemetal carbonyls.

Assuming that these data reflect the kinetic processes by which the molecules are reformed, we were led to the following postulate: *The extent of formation, or of re-formation, of metal carbonyls following nuclear transformation is closely related to the structural simplicity of the molecule.*

TABLE I

Reported retention and yield values for metal carbonyls and related compounds*

Compound	Retention (%)	Reference
$Cr(CO)_6$	35–70	2,3,4,5
$Mo(CO)_6$	23–74	3,4
$W(CO)_6$	26–52	6,7
$Mn_2(CO)_{10}$	9.8, 12	6,7

Target	Compound	Yield (%)	Reference
$C_6H_6Cr(CO)_3$	$Cr(CO)_6$	13.5	8
$C_5H_5Mn(CO)_3$	$Mn_2(CO)_{10}$	0.2	6
$CH_3C_5H_4Mn(CO)_3$	$Mn_2(CO)_{10}$	0.1	6
$Mn_2(CO)_{10}$	$\cdot Mn(CO)_5$	4.1	7
$C_5H_5Mn(CO)_3$	$\cdot Mn(CO)_5$	4.2	7

*Retention and yield, in this and the other Tables, is the fraction of the radioactivity appearing in the form of the target compound and any other compound, respectively.

This amounts to the imposition of an activation entropy for the re-formation reaction. The activation energy is clearly no barrier in a hot-zone. If this postulate were found to have any validity, one would predict the mononuclear carbonyls to have high retentions and the binuclear carbonyls to have markedly lower retentions. Similarly, one would expect the yield of a mononuclear carbonyl to be considerably higher than that of a binuclear carbonyl from the respective arenemetal carbonyls. Table I indicates that both of these anticipated results of our postulate are supported by the experimental data. Moreover,

TABLE II

Irradiation conditions used in the present work

Facility	Flux ($cm^{-2}s^{-1}$)	Cd ratio	Dose rate (rads h^{-1})	Temperature (°C)
AECL Pool	3×10^8		10^6	20
AECL Mobile	2.8×10^8		10^6	20
NRX Self-serve	5×10^{12}	1:50	13×10^6	65

as would be expected from the postulate, the yield of the mononuclear $\cdot Mn(CO)_5$ is higher than that of $Mn_2(CO)_{10}$. The fact that this radical is formed in rather lower yield than is $Cr(CO)_6$ in neutron-irradiated benzenechromium tricarbonyl, is perhaps not a serious challenge to the postulate since the systems are different. Moreover, the radical would be susceptible to destruction by various extraneous reactions which might not affect the more stable molecule.

It is this postulate which gave impetus to the present work, which was designed to test some further extrapolations:

The retention in the trinuclear $Ru_3(CO)_{12}$ and $Fe_3(CO)_{12}$ should be extremely low, perhaps 1% or less.

The retention in $Fe(CO)_5$ should be high, and very much greater than that in $Fe_3(CO)_{12}$.

The yield of $Fe(CO)_5$ in neutron-irradiated $Fe_3(CO)_{12}$ should be moderately high, while the yield of $Fe_3(CO)_{12}$ in neutron irradiated $Fe(CO)_5$ should be quite small.

Similarly, the yields of $Ru(CO)_5$ in irradiated $Ru_3(CO)_{12}$, and $Ru_3(CO)_{12}$ in irradiated $Ru(CO)_5$ should be high and very low, respectively. Unfortunately, we were unable to procure a sample of $Ru(CO)_5$, so that this last prediction could not be tested.

Experimental

Reagents

The target materials and carriers were commercially obtained and were repurified as follows:

$W(CO)_6$ was obtained from Metallomer Laboratories. It was resublimed in vacuo (10^{-3} Torr) at 50 °C, through a column of glass wool, and collected on a cold finger at 0 °C.

$Ru_3(CO)_{12}$ was obtained from K and K Laboratories, and was purified by column chromatography using neutral alumina (Woelm, grade 1) and cyclohexane.

$Fe(CO)_5$, from Alfa Inorganics, Inc., was repeatedly distilled in vacuo under subdued light, and the middle fraction was further purified by vapor–phase chromatography.

$Fe_3(CO)_{12}$, obtained from Strem Chemicals, Inc., was recrystallized from benzene and subsequently from petroleum ether. It was further purified by column chromatography on Florisil, using pentane as eluant. All these operations were done in subdued light.

All other reagents were the best available. Solvents were distilled under an atmosphere of dry air.

Separation Methods

In experiments of this sort, the exact value of the result is often less important than the purity of the separated products. Moreover, in systems such as these, it is not uncommon to produce radioactive compounds which are quite unexpected and often extremely difficult to identify. Thus, we have taken the precaution in several cases to apply a number of different separation methods to each sample, often varying the order of the methods in successive experiments. Generally the separation and purification methods were the following:

1. column chromatography on alumina
2. column chromatography on Florisil
3. vacuum sublimation at 50 °C for $W(CO)_6$ and at 80 °C for $Ru_3(CO)_{12}$
4. vapor–phase chromatography
5. pumping on the solid at room temperature
6. scavenging the solution with iodine during dissolution (6, 7)
7. fractional distillation

While no work was done below room temperature, we avoided any unnecessary rise in temperature, especially during the early stages of the separation.

Irradiations

The tungsten and ruthenium carbonyls were irradiated in the antimony–beryllium neutron facility of Atomic Energy of Canada, Ltd., Commercial Products Division, in Ottawa (9) while the iron carbonyls were irradiated for 10 h in a self-serve position in the NRX reactor at Chalk River. The conditions of irradiation are given in Table II, insofar as the information is available.

All samples were sealed in vacuo in quartz ampoules before irradiation. Samples were normally held at room temperature for the hour or so between the end of the irradiation and the time of chemical treatment. The iron samples, some of which were processed only after several weeks, were kept in dry ice in the dark after being received from Chalk River.

Results

The results are shown for tungsten carbonyl in Table III. These data are in general agreement with previous results, but are important in that they show a significant difference from one type

of separation to the other. In all cases, the use of sublimation as a first step results in a distinctly higher retention value. It is our feeling that the lower values, obtained by the use of chromatography as a first step, are closer to the real value. It may be that sublimation at even moderate temperatures causes the production of $W(CO)_6$ by pyrolysis of more complex species, perhaps unstable polymers. If this is so, then all results obtained from sublimation separations are to be viewed with caution, even though they may be reproducible, since the data could represent the sum of the original retention and the production by pyrolysis.

The results for ruthenium carbonyl are given in Table IV, and for the iron carbonyls in Table V. From Table IV it is evident that although the exact value of the retention is not to be deduced with great precision, the retention value for $Ru_3(CO)_{12}$ is surely between 35 and 45%. It is our opinion that the variation in results is to a

large extent caused by fluctuations in the conditions of irradiation, although we have not been able to test this speculation. Recoil studies on ruthenocene (10, 11) show retention values of 5–8%, suggesting at least 95% bond breakage. From this evidence, it seems clear that in the present case some type of re-formation process is required. We draw attention to the results from experiments starting with sublimation and those starting with chromatography. We note also that the difference between the first and second fractions in the sublimation experiments suggests the presence of a radioactive compound more volatile than the parent compound—perhaps $Ru(CO)_5$.

Retention values in the iron carbonyls can be evaluated in the same approximate fashion. Retention values in $Fe(CO)_5$ and $Fe_3(CO)_{12}$ are approximately 41 and 26%, respectively. The yield of $Fe(CO)_5$ in irradiated $Fe_3(CO)_{12}$ was found to be 17%. The yield of $Fe_3(CO)_{12}$ in irradiated $Fe(CO)_5$ was rather difficult to determine unambiguously, since the target compound was decomposed somewhat, presumably by the gamma radiation, to give $Fe_3(CO)_{12}$. This radiolysis is well known, and its mechanism has been fairly well elucidated (12, 13). The extent of the decomposition was determined to be approximately 2%. After correcting for this direct chemical production, we estimate the activity of ^{59}Fe found as $Fe_3(CO)_{12}$ to be 24% of the total. The results shown for the yield of $Fe_3(CO)_{12}$ must be regarded as only approximate values.

Discussion[1]

The retention found in $Fe(CO)_5$ is seen in Table IV to be high, in satisfactory agreement with expectations. Moreover, the yield of radioactive $Fe(CO)_5$ found in $Fe_3(CO)_{12}$ is seen to be qualitatively in agreement with prediction. It seems very likely that a rapid condensation of CO molecules on the metal atom occurs, much as was suggested in connection with the formation of the $Mn(CO)_5$ radical (6):

[1] $$M + nCO \rightarrow \rightarrow \rightarrow M(CO)_x$$

or, more specifically,

[1a] $$Fe + nCO \rightarrow \rightarrow \rightarrow Fe(CO)_5$$

[1]When it is useful in the following discussion to distinguish the radioactive atom from the others, an asterisk will be used. The asterisk thus does not imply a chemically excited species.

The earlier stages of this chain are purely speculative, including the starting point (14), but the later stages are supported by the results of recent annealing studies (5) on $Cr(CO)_6$, and by studies of the photo- and radiation chemistry of $Fe(CO)_5$ (12, 13). That the chain must quite rapidly go all the way to $Fe(CO)_5$ in the hot-zone is suggested by contrast with the known reaction of $Fe(CO)_4$ radicals with $Fe(CO)_5$ to give $Fe_2(CO)_9$ (13). It is possible, of course, that an S_N2-like exchange process occurs, at a temperature still too high for $Fe_2(CO)_9$ to be stable. Thus

[2] $$*Fe(CO)_4 + Fe(CO)_5 \rightarrow [*FeFe(CO)_9] \rightarrow *Fe(CO)_5 + Fe(CO)_4$$

although there seems to be no experimental evidence on this point.

From this point on, however, everything seems to be contradictory to our expectations, and we now examine the data and our postulates to seek reasons for the discrepancies. The test assumption as set forth is surely valid for cases in which the molecule is totally re-created from separated fragments in a single grand step, and there seems to be some suggestion that the distribution of products in the arenemetal carbonyls can be interpreted in this way (15). Since this appears not to be the case in these systems, however, we look for the alternative, perhaps stepwise, reactions. The stepwise nature of these more complex reactions is perhaps to be expected, since even the simpler mononuclear species are to some extent re-formed stepwise (3).

We suggest reaction [1] as the fundamental reaction leading to reconstitution. The test postulate can thus accommodate a high yield of $M(CO)_x$ fragments, where x could be 4 or 5. Following this one can write down plausible, although perhaps not unique, mechanisms to account for the observed results. Reactions involving this type of fragment have been suggested on occasion as short-lived reaction intermediates. Cohen and Basolo (16) have inferred the existence of the fragment $Fe(CO)_4$ to be formed during substitution reactions of $Fe(CO)_4X_2$.

For the formation of radioactive $Fe_3(CO)_{12}$ in neutron-irradiated $Fe(CO)_5$ we must find a mechanism different from that devised for the description of the same reaction induced by radiolysis or photolysis, since the yield of the radioactive product is some ten times higher than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

that of the non-radioactive form. Thus, the diffusive recombination of three $Fe(CO)_4$ groups (12, 13) can be eliminated. The reaction of one $*Fe(CO)_4$ with the bulk $Fe(CO)_5$ is known to give $Fe_2(CO)_9$, which does not react further. The instantaneous reaction of three $Fe(CO)_4$ radicals in the hot-zone is presumably ruled out by the failure of our initial hypothesis to predict the yields and retentions. We are left, then, with the following scheme for formation of $Fe_3(CO)_{12}$:

[3] $$*Fe(CO)_4 + Fe(CO)_4 \rightarrow *FeFe(CO)_8$$

[4] $$*FeFe(CO)_8 + Fe(CO)_5 \rightarrow *FeFe_2(CO)_{12} + CO$$

The second stage (reaction [3]) could well occur with fragments formed in the hot-zone; fragments which are only partially re-formed by the chain of reaction [1]. The final step (reaction [4]) would plausibly occur after some diffusion. No positive evidence can be adduced at present to test the validity of this suggested mechanism. It is apparent that a combination of $Fe(CO)_3$ and $Fe(CO)_4$ to give $Fe_2(CO)_7$ in reaction [3] would be equally defensible.

Less can be said, unfortunately, about the reactions in the trinuclear target compounds. Once again, our hypothesis would suggest that the retention should be very low, so we are led to search for stepwise reactions of greater specificity. Of the possibilities, most can be eliminated in the same way as was discussed above. One, however, remains plausible

[1] $$*M + nCO \rightarrow \rightarrow \rightarrow *M(CO)_x \qquad x = 3, 4$$

[5] $$*M(CO)_x + M_3(CO)_{12} \rightleftarrows *MM_2(CO)_{12} + M(CO)_x$$

The first of these, the reconstruction of the metal polycarbonyl radical or molecule is, as before, assumed to occur in the hot-zone. It seems likely that this reaction leads to the observed $*Fe(CO)_5$. The exchange step could well occur during the cooling stages or, less likely, later at ambient temperature. The little which can be drawn from the literature on these solid state exchanges suggests that it must occur in the hot- (or warm-) zone, if at all.

It has been shown (7) that the exchange reaction

[6] $$*Mn(CO)_5 + Mn_2(CO)_{10} \rightleftarrows *MnMn(CO)_{10} + Mn(CO)_5$$

does not occur subsequent to the irradiation time. The results found by Zahn, Collins, and Collins (5) for $Cr(CO)_6$, in which the retention was found to increase as a result of thermal annealing, could be explained as being an exchange, but in this case only a single carbonyl group need be transferred

[7] $$*Cr(CO)_5 + Cr(CO)_6 \rightleftarrows *Cr(CO)_6 + Cr(CO)_5$$

Thus, this reaction does not compare with the post-irradiation exchange of the type shown in reactions [5] and [6].

It is possible that the exchange shown in reaction [5] could be induced by the γ-radiation, especially in the case of $Fe_3(CO)_{12}$, in which photolytic excitation of the bridging carbonyls would weaken the ring structure. We have regrettably been unable to determine the effect of γ dose on the retention, and invite others to extend our experiments in this direction.

In summary, we have shown that the yields and retentions of the trinuclear carbonyls are far higher than can be accommodated by a simple single-stage hot-zone reconstitution mechanism. We have thus examined other possibilities and have concluded that the reaction must start with the hot-zone formation of a reactive radical, such as $M(CO)_4$, which reacts further in a stepwise, more selective reaction.

It is interesting to speculate that through these recoil studies a possible new area for investigation of inorganic exchange reactions has been revealed. Virtually all the exchange reactions of metal carbonyls studied to date (17) are those of a CO molecule with a metal carbonyl molecule (or a substituted metal carbonyl). We have here suggested two further reactions: the transfer of a carbonyl group from a molecule to a radical, as exemplified by reaction [2], and the transfer of larger groups, as exemplified by reactions [5] and [6]. It is suggested that recoil studies in scavenged liquid systems may provide a good approach to studying these new reactions.

Acknowledgments

We are grateful to Imperial Oil Ltd. and to the National Research Council of Canada for financial assistance. Atomic Energy of Canada, Ltd., has been most generous in extending to us the use of their Sb–Be neutron facilities, in which connection Mr. Pat Kennedy and Mr. Roger Murphy have been extremely helpful. Phosphinohydrazines. Part II. Reactions of N,N-dimethylhydrazine and trimethylhydrazine with substituted phosphines[1]

L. K. Peterson, G. L. Wilson, and K. I. Thé
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received September 3, 1968

Reactions between trimethylhydrazine and $(CF_3)_2PI$, and between N,N-dimethylhydrazine and CF_3PI_2 have been utilized as synthetic routes to phosphinohydrazine compounds. Two new compounds, trimethylhydrazino-bis(trifluoromethyl) phosphine (m.p. −47.00°, b.p. 130.5° extrapolated) and bis-(N,N-dimethylhydrazino)-trifluoromethylphosphine (m.p. 49.20°, b.p. 184° extrapolated), are described.

Canadian Journal of Chemistry, 47, 1025 (1969)

Discussion

The fundamental features of interest in the chemistry of metalloid-substituted hydrazines were described in Part I (1). We now report an extension of this work, describing reactions between hydrazines and phosphines of varied functionality. The hydrazinolysis of the P—Cl bond was first demonstrated by Nielson and Sisler (2) in the synthesis of $(C_6H_5)_2PNHNMe_2$ and related compounds. Our work shows the feasibility of this process in the reactions of fluoroalkylhalophosphines, $(CF_3)_2PX$ and CF_3PX_2, with alkyl-substituted hydrazines Me_2NNH_2 and Me_2NNHMe, in a suitable solvent such as ether. With hydrazine itself, the products were too unstable to be characterized (1).

Trimethylhydrazino-bis(trifluoromethyl) phosphine, $Me_2NN(Me)P(CF_3)_2$, **1**, obtained according to the equation

[1] $$2Me_2NNHMe + (CF_3)_2PI \rightarrow Me_2NN(Me)P(CF_3)_2 + Me_2NNHMeHI$$

was a colorless liquid (m.p. $-47.00 \pm 0.20°$) which was identified by its mass spectrum (parent peak: obsd., 242; calcd., 242), its nuclear magnetic resonance (n.m.r.) spectrum, and its quantitative cleavage by anhydrous hydrogen chloride into $(CF_3)_2PCl$ and $Me_2NNHMe2HCl$. The ^1H n.m.r. spectrum revealed the six protons of the Me_2N group (at τ 7.50, reference internal $SiMe_4$) and the three protons of the Me—N—P group. The latter absorption (τ, mid-point, 7.13) was split into a doublet by long range *P*—N—C—*H* coupling (J_{P-H}, 3 c.p.s.). This value is considerably smaller than the coupling constants reported by Pople *et al.*(3) for other P—N—C—H systems (viz. ca. 10 c.p.s.), reflecting electron withdrawal from the intervening bonds by the electronegative CF_3 groups attached to phosphorus. The peaks of the doublet showed further fine structure due to long range proton—fluorine coupling (J_{H-F}, ~0.7 c.p.s.), and were recognizable as two overlapping septets. The overall intensity ratio of 2:1 was consistent with our formulation of compound **1**. The familiar ^{19}F doublet was also observed (δ, mid-point, 63.4 p.p.m. above internal $CFCl_3$; J_{P-CF_3}, 82 c.p.s.). The main features of the infrared spectrum, given in Table I, are indicative of bands due to methyl, CF_3, and N—N.

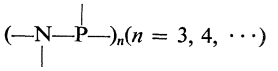
In theory, reaction between two difunctional species such as CF_3PI_2 and Me_2NNH_2 should provide potential synthetic routes to at least three distinct systems

(*a*) the molecular species,

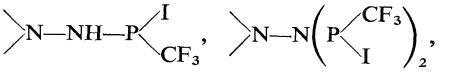
involving the $N_{(p)}$–$P_{(p)}$ π bond

(*b*) the linear polymer

and (*c*) cyclic oligomers



via the possible intermediates



and

The nature of the preferred product should provide clues about the mechanistic, stereochemical,

563	8	1109	68	2300	2	2995	16

*Intensities are quoted relative to the strongest band, at 1153 cm^{-1}, with a value of 100 arbitrary units.

and electronic factors controlling the reaction. In our work we found that solvent effects were of prime importance. Thus, in ether, cyclohexane, or tetrachloroethylene, reactions between CF_3PI_2 and Me_2NNH_2 afforded intractable, apparently polymeric, involatile materials, ranging in character from yellow oils to sticky brown solids. These products are probably analogous to the phosphonitrilic polymers derived from the thermal decomposition of $C_6H_5P(NHNMe_2)_2$ (4). With chlorobenzene as solvent, however, the new compound bis(N,N - dimethylhydrazino) - trifluoromethylphosphine, $CF_3P(NHNMe_2)_2$, **2**, was created in good yield according to the equation:

[2] $$CF_3PI_2 + 4H_2NNMe_2 \rightarrow CF_3P(NHNMe_2)_2 + 2Me_2NNH_2HI$$

The absence of CF_3H and nitrogen indicates stability against molecular rupture and fragmentation, in contrast to the analogous reactions involving N_2H_4 (1). Because of its low volatility, compound **2** is difficult to handle in the vacuum system. However, mass spectral data, as well as structural evidence from n.m.r., are consistent with our formulation. The ^1H spectrum consisted of distinct resonance adsorptions in 6:1 ratio, corresponding to 12 methyl protons [at τ 7.59, single sharp peak], and a doublet corresponding to the NH protons split by coupling with spin 1/2 ^{31}P (τ, mid-point, 5.92; J_{P-H}, 20 c.p.s.). The ^{19}F resonance was a doublet (δ, mid-point, +65.4 p.p.m.; J_{P-CF_3}, 83 c.p.s.). Our efforts to locate $Me_2N—N{=}PCF_3$, a system containing the unstable —P=N— bonding situation (5–7), were unsuccessful. Thus, the stability of compound **2**, $CF_3P(NHNMe_2)_2$, must stem from an enhancement of $N(p_\pi) \rightarrow P(d_\pi)$ π-bonding, a bonding situation favored by the electronegative CF_3 group on phosphorus (8, 9).

Experimental

Volatile materials were handled in a vacuum system, while dry-box techniques were used where nonvolatile substances were encountered. Reactions were carried out in specially constructed sealed Pyrex vessels, fitted with in situ filtration facilities. Nuclear magnetic resonance spectra were determined with a Varian A56/60 instrument, infrared spectra with a Beckmann I.R. 12 spectrophotometer, and mass spectra with a double focusing RMU-6E Hitachi Perkin–Elmer instrument.

The iodophosphines and dimethylhydrazines were obtained as previously described (1), and all solvents were rigorously dried and distilled. Trimethylhydrazine was prepared by the method of Class *et al.* (10). We found that the final stage, viz. the reduction of $Me_2NN{=}CH_2$ with lithium aluminium hydride, yielded dimethylhydrazine as well as trimethylhydrazine. Purification was effected by vacuum distillation, using a 36 in. low temperature distillation column.

Reaction of $(CF_3)_2PI$ with Me_2NNHMe

In a typical synthesis, a mixture of trimethylhydrazine (0.9179 g) in ether (1.4100 g) was treated with $(CF_3)_2PI$ (1.2068 g) in a filtration reaction vessel. After 12 h at room temperature, the products were separated by filtration and vacuum fractionation. The components isolated were $Me_2NNHMeHI$ (0.7977 g); excess Me_2NNHMe (0.2230 g); "ether fraction" (1.5671 g); and $Me_2NN(Me)P(CF_3)_2$, **1** (0.8143 g, 83% yield). The latter product was identified by its mass spectrum (parent peak: obsd., 242; calcd., 242); major fragments were Me_2NNMe (*m*, 73), CF_3 (*m*, 69), and Me_2N (*m*, 44). Infrared (Table I) and n.m.r. spectra were consistent with our formulation of compound **1**. In addition, compound **1** (0.0678 g) reacted quantitatively with anhydrous hydrogen chloride (0.0373 g) in chlorobenzene solution, yielding $(CF_3)_2PCl$ (0.0548 g; m_{obsd}, 202; m_{calcd}, 204.5) and $Me_2NNHMe2HCl$ (0.0402 g), determining the stoichiometry

[3] $$Me_2NNMeP(CF_3)_2 + 3HCl \rightarrow (CF_3)_2PCl + Me_2NNHMe2HCl$$

Physical Properties of $Me_2NN(Me)P(CF_3)_2$

The melting point of compound **1**, determined on samples sealed into capillary tubes, was $-47.00 \pm 0.20°$.

Saturated vapor pressures were measured with a mercury tensimeter. Compound **1** was stable at least to 110°, as shown by reproducible vapor pressures. Data for

47.0	41.6	41.4	81.2	170	170
54.5	58.3	58.3	91.4	247	242

*$\text{Log } P_{mm} = 6.7566 - 0.005896T + 1.75 \log T - 2445/T$.

TABLE III

Saturated vapor pressure data* for $CF_3P(NHNMe_2)_2$

T, °C	P_{mm}(obsd.)	P_{mm}(calcd.)	T, °C	P_{mm}(obsd.)	P_{mm}(calcd.)
49.4	1.70	1.75	93.2	21.4	21.4
63.1	4.10	4.13	115.0	56.4	59.2
72.5	7.00	7.11	134.0	128	130
86.6	15.3	15.3	151.0	248	249

*$\text{Log } P_{mm} = 5.9707 - 0.002678T + 1.75 \log T - 2985/T$.

the liquid–vapor equilibria are given in Table II. The extrapolated boiling point is 130.5°; the latent heat of vaporization at the boiling point is 8200 cal mole^{-1}; and the Trouton constant is 20.3 cal deg^{-1}.

The infrared spectrum over the range 400 to 4000 cm^{-1}, measured in the gas phase (10 cm cell, KBr windows), is given in Table I.

Reaction of CF_3PI_2 with Me_2NNH_2

In the solvents ether, cyclohexane, and tetrachloroethylene, CF_3PI_2 and Me_2NNH_2 reacted to form intractable, nonvolatile materials, ranging from yellow oils to dark brown, sticky solids. But when CF_3PI_2 (0.5635 g) was mixed with a solution of Me_2NNH_2 (0.9681 g) in chlorobenzene (2.8921 g), no discoloration was observed, even after 12 h at room temperature. The products were Me_2NNH_2HI (0.7486 g); "chlorobenzene fraction" (C_6H_5Cl plus excess Me_2NNH_2, 3.4730 g); and colorless, crystalline needles of $CF_3P(NHNMe_2)_2$, **2**, in good yield. The mass spectral pattern of compound **2** indicated a parent molecular weight corresponding to $CF_3P(NHNMe_2)_2$ (m_{obsd}, 218; m_{calcd}, 218), and intense peaks indicative of the fragments $CF_3PNHNMe_2$ (m, 159) and $NHNMe_2$ (m, 59). The n.m.r. spectrum, measured in chlorobenzene solution, was consistent with the above formulation for compound **2**.

Physical Properties of $CF_3P(NHNMe_2)_2$

The melting point of compound **2**, determined on samples sealed into capillary tubes, was 49.20 ± 0.20°.

Saturated vapor pressures were measured with a mercury tensimeter. At elevated temperatures (>100°), compound **2** was unstable; hence measurements were made on fresh samples in the minimal time required to establish equilibrium. The data are given in Table III. The extrapolated boiling point is 184°, and the latent heat of vaporization is 12 700 cal mole^{-1}.

γ-Radiolysis of disulfides in aqueous solution. II. D-Penicillamine disulfide[1]

J. W. PURDIE[2]
Defence Research Establishment Ottawa, Defence Research Board, Ottawa, Canada

Received July 10, 1968

The γ-radiolysis of D-penicillamine disulfide (PenSSPen) in 3×10^{-4} *M* aqueous solution has been studied under aerated and deaerated conditions. G values were determined for the following products: penicillamine sulfinic acid ($PenSO_2H$), penicillaminic acid ($PenSO_3H$), β-hydroxyvaline (PenOH), 2-amino-3-methylbut-3-enoic acid ($HOOC \cdot CH(NH_2) \cdot C(CH_3)=CH_2$), penicillamine (PenSH), penicillamine disulfide-*S*-monoxide (PenS(O)SPen), valine (PenH), penicillamine trisulfide (PenSSSPen), and ammonia. The low yield of $PenSO_3H$ in aerated solution indicated that PenSOH did not react with oxygen or O_2^-. The trisulfide, which was obtained in high yield, was found to come mainly from the reactions:

$$PenSSPen + \cdot OH \rightarrow PenSSOH + Pen\cdot$$

$$PenSSOH + PenSH \rightarrow PenSSSPen + H_2O$$

Experiments with ·OH radicals produced chemically ($TiCl_3/H_2O_2$) and irradiations with cysteine or penicillamine present were used to confirm these reactions. These and the other reactions were tested with radical scavengers; formate and monochloroacetate ions and nitrous oxide.

Canadian Journal of Chemistry, 47, 1029 (1969)

Introduction

In a previous communication (1) the γ-radiolysis of cystine in aqueous solution was reported and a mechanism proposed. Studies of cystine and related disulfides in aqueous solutions have been reported by several other workers recently (2–8) and the earlier literature has been reviewed (9).

The present paper reports a study of the radiolysis of D-penicillamine disulfide (2,2,5,5-tetramethylcystine) in dilute aqueous solutions. This compound was of particular interest for comparison with cystine since cysteine is a radioprotective compound whereas penicillamine is not radioprotective. Radiolysis of penicillamine disulfide has not been reported previously although the thiol, penicillamine, has been examined by several workers. Henriksen (10, 11) studied irradiated penicillamine in frozen aqueous solutions and in polycrystalline samples by electron spin resonance (e.s.r.) spectroscopy. Braams (12) obtained rate constants for reaction of the solvated electron with penicillamine using pulse radiolysis. It has also been investigated in solution by Armstrong and Humphreys (4) using e.s.r. spectroscopy. In this paper, the symbol "Pen" is used to represent $HOOCCH(NH_2)C(CH_3)_2S$— in structural formulae and hence PenSH is penicillamine and PenSSPen is the disulfide. The usual abbreviations, CySH and CySSCy, are used for cysteine and cystine respectively.

Experimental

A Technicon amino acid analyzer model NC-1 was employed with the modifications described previously (13). Columns of the following resins were used for analytical purposes: "Chromobeads" type A, 150 × 0.6 cm; "Chromobeads" type C2, 75 × 0.6 cm; Dowex 1-x8 (200–400 mesh) 150 × 0.6 cm. The nuclear magnetic resonance (n.m.r.) spectra were run on a Varian HA60I and infrared spectra on a Perkin–Elmer 221 G. Mass spectra and interpretations were performed by Morgan Schaffer Corp., Montreal.

D-Penicillamine (A grade) was purchased from Calbiochem and used for the preparation of the disulfide. Penicillaminic acid and β-hydroxyvaline were obtained from Calbiochem. Valine and other reference amino acids were purchased from Mann Research Labs. Nitrous oxide gas was supplied by Matheson, Coleman and Bell Ltd. and was purified by trap-to-trap distillation just before use. Monochloroacetic acid and sodium formate were Fisher certified reagents.

D-*Penicillamine Disulfide (PenSSPen)*

This compound was prepared by bubbling oxygen through an alkaline aqueous solution of penicillamine until a negative test was obtained with Ellman's reagent for thiols (14). The solution was neutralized, evaporated to dryness, and the product (crystallized from aqueous ethanol) had m.p. 198–199°.

Anal. Calcd. for $C_{10}H_{20}N_2O_4S_2$: C, 40.5; H, 6.7; N, 9.45; S, 21.6. Found: C, 40.3; H, 6.9; N, 9.5; S, 21.8.

This sample was chromatographically pure except for traces of the trisulfide (PenSSSPen) and was used for

[1]Presented in part at the 15th Annual Meeting of the Radiation Research Society, San Juan, May, 1967. Issued as DREO Report No 572.

[2]Present address: Division of Biology, National Research Council of Canada, Ottawa, Canada.

TABLE I

Elution times and color yields of products

Compound	Column	Elution time (min)	Color yield hw, 0.25 μE*	Notes
Glutamic	Dowex 1	200	15.3	Reference standard
$PenSO_2H$	Dowex 1	245	9.2	hw assumed equal to $PenSO_3H$
$PenSO_3H$	Dowex 1	300	9.2	
PenOH	Chromobeads A	180	9.3	
COOH CH_3 | | $CH(NH_2)C{=}CH_2$	Chromobeads A	250	12.1	Yield same as valine
PenSH	Chromobeads A	315	1.25	
PenS(O)SPen	Chromobeads A	370	7.5	Assumed equal to PenSSPen
PenH	Chromobeads A	460	12.1	
PenSSPen	Chromobeads A	590	7.5	
Norleucine	Chromobeads A	660	13.8	Reference standard
PenSSSPen	Chromobeads A	725	6.7	
NH_3	Chromobeads A	830	7.5	

*E = equivalent weight with respect to ninhydrin positive groups.

most of the radiation experiments. The nuclear magnetic resonance spectrum, run in trifluoroacetic acid, showed a broad peak at $\tau = 2.38$ due to the NH_3^+ and peaks at $\tau = 5.65$ (CH), $\tau = 8.21$ (CH_3), and $\tau = 8.38$ (CH_3).

Penicillamine Trisulfide (β,β′-divalyltrisulfide; PenSSSPen)

Preparation of this compound was attempted by the methods described by Fletcher and Robson for preparation of cystine trisulfide (CySSSCy) (15). The following preparation was the most successful. Sulfur (216 mg) was dissolved in chloroform (50 ml) and ethanol (200 ml) added. The solution was made alkaline by addition of concentrated ammonium hydroxide solution (5 ml) and penicillamine (1 g in 25 ml water) was added. The solution was stirred for 4 h and evaporated to dryness.

The product was purified by chromatography on a column of Dowex 50W-x8 cation-exchange resin using volatile buffers (16) and had m.p. 185° (corrected) after crystallization from aqueous ethanol; yield, 280 mg from half the starting material (40%).

Anal. Calcd. for $C_{10}H_{20}N_2O_4S_3$: C, 36.53; H, 6.09; N, 8.53; S, 29.26. Found: C, 36.34; H, 5.82; N, 8.44; S, 29.15.

The n.m.r. spectrum of the pure trisulfide was run in trifluoroacetic acid. It had peaks at $\tau = 2.40$ (NH_3^+) $\tau = 5.44$ (—C(H)—) and methyl peaks at $\tau = 8.17$ and 8.41 with integrals in the ratio 3:1:3:3 as required by the assignment given. This spectrum is very similar to that of the disulfide except for slight shifts and a greater separation of the methyl peaks. The occurrence of two sharp methyl peaks in the spectrum shows that it is a linear trisulfide.

Irradiation and Analysis

Irradiations were performed using 25 ml samples in 25 ml round-bottom flasks as described previously. Thrice-distilled water was used for all solutions and the irradiation flasks were cleaned with hot chromic acid, rinsed thoroughly and steamed before use. A total dose of 10 000 rads at a dose rate of 800 rads/min was used except where otherwise stated. The irradiated solutions were analyzed as described previously (1). In order to measure ammonia yields, samples were pumped directly into a "Chromobeads" C2 column without freeze drying and then eluted in the usual way.

Order of Elution of Products and Color Yields

The elution times and color yields for the products and reference compounds are listed in Table I. These are for a flow rate of 30 ml of eluent per h. The Dowex 1 column was operated at room temperature and the "Chromobead" type A column was maintained at 60° throughout the run.

Isolation of Products

The products were separated by chromatography on a column of Dowex 50W-x8 cation-exchange resin using volatile buffer systems (16). A solution of penicillamine disulfide (2.4 g) in 4 l of water was irradiated with a total dose of 100 000 rads, concentrated, and chromatographed with acetic acid – pyridine buffers. A small portion of the effluent was drawn into the amino acid analyzer by the proportioning pump so as to provide a continuous record of the separation. Nine major peaks were observed, including unchanged disulfide and ammonia. Each product was purified by re-running it on the same column, operated at 45 °C, until chromatographically pure samples were obtained.

Seven products were obtained in quantities sufficient to allow examination.

Results

Identification of Products

Products 1 and 2 (penicillaminic and penicillamine sulfinic acids) both occurred in the first group. They were resolved by chromatography on a column of Dowex 1 anion-exchange resin using aqueous formic acid as eluent (17). The first product eluted was a strong acid which decolorized iodoplatinic acid. This result, together

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

with its chromatographic behavior, showed that it was penicillamine sulfinic acid, (valine-β-sulfinic acid), ($PenSO_2H$). The second product, also a strong acid, was found to co-chromatograph with commercial penicillaminic acid ($PenSO_3H$).

Product No. ***4*** contained sulfur but was not identified.

Anal. Found: S, 17.2.

Mass spectrometric analysis of the acid and of the ethyl ester indicated a molecular weight of 161 for the acid.

Product No. ***5*** *(β-Hydroxyvaline)*

The infrared spectrum of this product had a sharp peak at 3410 cm^{-1} indicating a hydroxy group. β-Hydroxyvaline appeared to be a likely product so it was synthesized as described by Mix (18) and compared with the isolated product. The infrared spectra (KBr) differed considerably. However, the two compounds co-chromatographed on paper and with the amino acid analyzer. Both gave identical n.m.r. spectra when run in trifluoroacetic acid. The infrared spectrum of the synthetic compound differed from the radiolysis product because the former was a racemic mixture whereas the latter was a pure optical isomer (19). The n.m.r. spectrum had a broad band at $\tau = 2.48$ (NH_3), a broad band at

$$\begin{array}{c} | \\ \text{5.65 (—CH)} \\ | \end{array}$$

which could be decoupled from the NH_3 to give a sharp peak, and two sharp peaks at $\tau = 8.28$ and $\tau = 8.50$ (2 CH_3 groups).

Product No. ***6*** *(2-Amino-3-methylbut-3-enoic Acid)*

This compound will be referred to as the "vinyl" derivative for convenience.

The infrared spectrum of this product indicated it was a neutral amino acid without other functional groups and analysis showed sulfur was absent. The mass spectrum of the ethyl ester showed that the compound was a vinyl derivative of valine: $CH_2{=}C(CH_3)CH(NH_2)COOH$. A weak n.m.r. spectrum was obtained (capillary sample tube) which was consistent with this structure: peaks; $\tau = 8.05$ (CH_3); $\tau = 5.1$

$$\begin{array}{c} \diagdown \\ \text{(broad, —CH)} \\ \diagup \end{array}$$

$\tau = 4.62$ ($CH_2{=}$). Further evidence for the structure was obtained by catalytic hydrogenation. A mixture of the unknown and alanine in water was hydrogenated (H_2/Pt) and a portion of the solution examined using the amino acid analyzer before and after hydrogenation. The radiolysis product was reduced completely to valine whereas the alanine was unchanged.

Product No. ***8*** *(Penicillamine Trisulfide)*

The infrared spectrum of the product was very similar to that of penicillamine disulfide. The most noticeable difference was a sharp peak at 1695 cm^{-1} and another at 1270 cm^{-1} in the spectrum of the product. The n.m.r. spectrum was also very similar to penicillamine disulfide. The unknown had peaks at $\tau = 2.40$, 5.44, 8.17, 8.41, and 7.77. The peak at 7.77 was sharp and appeared to be due to acetic acid which had not evaporated during the freeze drying.

Anal. Calcd. for $C_{10}H_{20}N_2O_4S_3 \cdot CH_3CO_2H$: N, 7.22; S, 24.8. Found: N, 7.56; S, 23.54.

Penicillamine trisulfide (PenSSSPen) was synthesized and found to be identical with the radiolysis product as shown by infrared and n.m.r. spectra, and by chromatography. The synthetic sample also retained acetic acid when isolated by the same procedure.

Product No. ***9*** *(Valine)*

This product was shown to be identical to valine (PenH) by infrared analysis and chromatography.

Products not Isolated

The main product which was not isolated by the procedures described above was penicillamine. A peak was present in aerated and deaerated solutions which co-chromatographed with penicillamine but it was presumably oxidized to the disulfide during the preparative-scale chromatography and evaporations. The presence of penicillamine was confirmed using Ellman's reagent (5,5′-dithio-bis-(2-nitrobenzoic acid)) and the yields were checked by this method (14, 20). The other significant peak which remained unaccounted for appeared on chromatograms between penicillamine and valine. PenS(O)SPen seemed a likely possibility for this compound and it was found to decompose if the solution was made alkaline. Disulfide-*S*-monoxides are unstable in solutions above pH 6 and decompose to yield sulfinic acid and disulfide.

A double peak frequently appeared in the chromatograms corresponding to β-hydroxyvaline (PenOH). This may have been due to the presence of PenOOH which is probably the precursor of the PenOH.

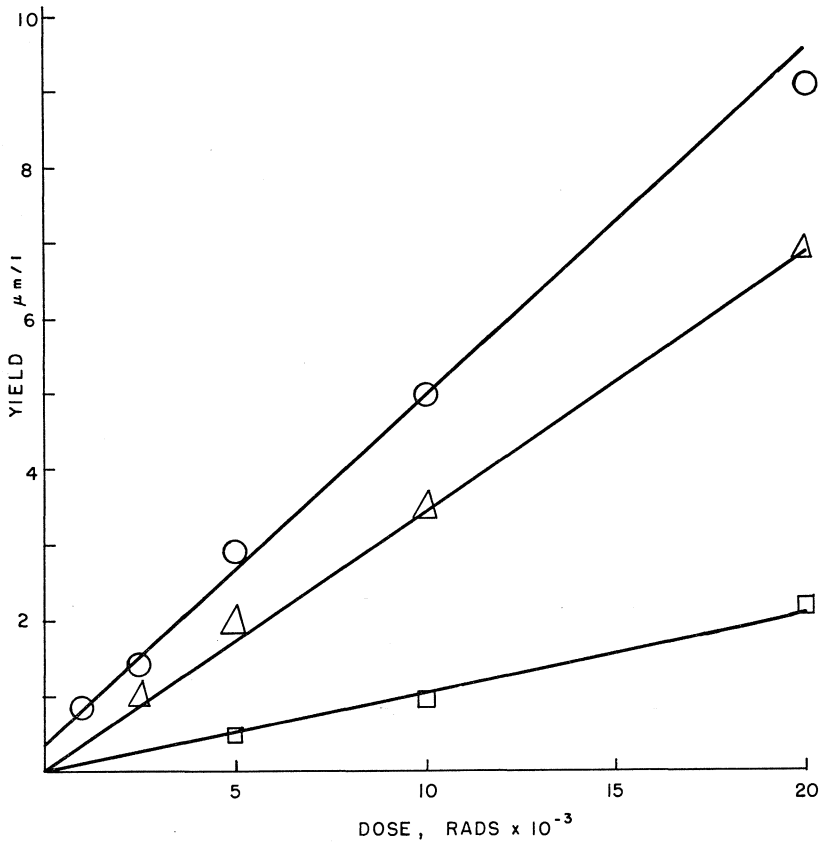

FIG. 1. Yield–dose plots for the major products of radiolysis of penicillamine disulfide in aerated solution: PenSSSPen (○); $PenSO_2H$ (△); $PenSO_3H$ (□).

Yields of Radiolysis Products

The yields of the main products in aerated solutions were measured at various doses between 1 000 rads and 20 000 rads. The results are shown in Fig. 1. The yields measured were linear with dose up to 20 000 rads.

The yields of all products identified were measured or estimated after irradiation of PenSSPen with 10 000 rads. The results for both aerated and deaerated solutions are listed in Table II. The figures are average values from a number of experiments and the average deviation is given. Table II also gives the G values in terms of nitrogen atoms in order to estimate the product balance. The nitrogen was used rather than the sulfur since products were measured with ninhydrin which reacts with amino groups and ammonia.

Dose-Rate Effects

The effect of dose rate was examined in aerated solution in view of the fact that it had a remarkable effect on the yields of sulfinic and sulfonic acids from cystine (1). With penicillamine disulfide however, there was no measurable change in the yields of $PenSO_2H$ and $PenSO_3H$ when the dose rate was reduced from 800 rads/min to 10 rads/min. Disulfide concentration and total dose were kept constant at $3 \times 10^{-4}M$ and 10 000 rads respectively, while dose rates of 800, 600, 300, 100, and 10 rads/min were employed.

Effect of Radical Scavengers on Yields

The effect of radical scavengers on the yields was investigated using formate ions and monochloroacetate ions in aerated solution, and monochloroacetate ions and nitrous oxide in deaerated solutions (21). Formate ions react readily with ·H and ·OH radicals but relatively slowly with e^-_{aq}. Monochloroacetate ions react rapidly with e^-_{aq}. Nitrous oxide reacts with e^-_{aq} but gives rise to an ·OH radical. The results of these experiments are given in Table III.

Effect of CySH and PenSH

Experiments were carried out with CySH or PenSH present during the irradiation in order to evaluate the mechanism proposed for trisulfide formation. The mercaptans were present in low concentrations (10^{-6} and 10^{-5} *M*) so as to avoid significant competition with the disulfide ($3 \times 10^{-4}M$) for the primary ·OH and e^-_{aq} radicals. The results are presented in Table IV. The irradiations without mercaptans present were performed at about the same time and using the same solution of disulfide. (Small variations were frequently encountered between irradiations performed at different times.)

Discussion

Radiolysis of penicillamine disulfide differs from radiolysis of cystine mainly in the relative

amounts of the various products. The yields of sulfonic acid and trisulfide were significantly changed; the sulfonic acid yield was much lower and the trisulfide yield much higher (Table II). The yields reported previously (1) for cystine trisulfide were high by a factor of four due to an error in calculation. As before it was difficult to measure the loss of disulfide accurately at low dose and this may account for some of the discrepancy in the nitrogen balance in Table II. Also, some assumptions had to be made with respect to the color yields of certain products as indicated in Table I. Some minor products remained unidentified and these could have contributed significantly to the nitrogen balance if their color yields with ninhydrin were very low. The peak which was thought to be PenOOH was not included in the Table. It was usually similar to PenOH in color yield.

The disulfide is attacked mainly at the sulfur atoms by e^-_{aq} and ·OH radicals with splitting of the sulfur–sulfur bond or a carbon–sulfur bond. Scission of the sulfur–sulfur bond probably occurs as follows:

[1] $\text{PenSSPen} + \cdot\text{OH} \rightarrow \text{PenSOH} + \text{PenS}\cdot$

[2] $\text{PenSSPen} + e^-_{aq} \rightarrow \text{PenS}^- + \text{PenS}\cdot$

Reaction [2] should occur mainly in deaerated solutions as the oxygen will scavenge the e^-_{aq} in aerated solutions. However, the solvated electron reacts rapidly with penicillamine ($k = 5.1 \times 10$ $M^{-1}\,s^{-1}$) (12), so it probably reacts rapidly with the disulfide also, allowing the latter to compete effectively with oxygen. (Solvated electrons react with cystine faster than with cysteine (12).) The PenS· radical has been detected in aqueous solutions by Armstrong and Humphreys using electron spin resonance spectroscopy (4). It was produced when ·OH radicals, from the $TiCl_3 - H_2O_2$ reaction, reacted with penicillamine in a flow system. Adams *et al.* (5) have suggested that the radical $RS\dot{S}R$ is an important intermediate in the radiolysis of cysteamine and cystamine. They observed a species with an absorption maximum at 4100 Å, obtained by ·OH oxidation and e^-_{aq} reduction of cysteamine and cystamine respectively. Since the $RS\dot{S}R$ decays to give the same products as reaction [2] it represents an intermediate in that reaction. With disulfides the radical anion is not produced by ·OH radicals so reaction [1] is satisfactory to explain the attack by ·OH at this position. A radical cation ($RS\dot{S}R^+$) has been suggested as an intermediate in the radiolysis of disulfides (7), but in the absence of any supporting evidence reaction [1] seems preferable since RS· is the only radical which has been identified in acidic solutions.

Sulfenic acids are unstable and usually decompose to sulfinic acid and disulfide. The following reactions are suggested for the decomposition of PenSOH in the irradiated solution:

[3] $2\,\text{PenSOH} \rightarrow \text{PenSO}_2\text{H} + \text{PenSH}$

[4] $\text{PenSOH} + \text{PenSSPen} \rightarrow \text{PenS(O)SPen} + \text{PenSH}$

[5] $\text{PenSOH} + \text{PenSH} \rightarrow \text{PenSSPen} + \text{H}_2\text{O}$

The sulfenic acid does not react with O_2 or O_2^- to form sulfonic acid as appeared to be the case with cysteine sulfenic acid. The PenS· radicals produced in reactions [1] and [2] may combine to give disulfide, or react with oxygen (in aerated solution) to produce sulfinic and sulfonic acids (1).

Rupture of the carbon–sulfur bond in the disulfide during radiolysis leads to products such

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

as trisulfide, valine, etc. In discussing the radiolysis of cystine (1) it was suggested that RS· radicals attacked the disulfide:

[6] $RS\cdot + RSSR \rightarrow RSSSR + R\cdot$

This seems unlikely in the light of results obtained with penicillamine disulfide. It appears that the carbon–sulfur bond is attacked by the ·OH radical giving an intermediate which reacts to yield trisulfide:

[7] $RSSR + \cdot OH \rightarrow RSSOH + R\cdot$

[8] $RSSOH + RSH \rightarrow RSSSR + H_2O$

In deaerated solution the disulfide may also be attacked at the same site by e^-_{aq} or ·H radicals with formation of a hydrodisulfide (22) and hence, trisulfide:

[9] $RSSR + e^-_{aq} \rightarrow RSS^- + R\cdot$

[10] $RSS^- + RSOH \rightarrow RSSSR + OH^-$

The tertiary radical Pen· formed from penicillamine disulfide should be more stable than the primary radical Cy· formed in the case of cystine and this may be the reason for the larger yield of trisulfide from penicillamine disulfide. Reaction [7] appears to be more important than [9] since the yield of trisulfide was increased in deaerated solution by addition of nitrous oxide. The Pen· radical produced in reactions [7] and [9] (in the case of penicillamine disulfide) could react with oxygen in aerated solution to form, eventually, hydroxyvaline (PenOH). In deaerated solutions it may react with e^-_{aq} or ·H to give valine (PenH). In both aerated and deaerated solutions it may lose a hydrogen to yield the vinyl compound: e.g.

[11] $HOOCCH(NH_2)\text{—}\dot{C}(CH_3)\text{—}CH_3 + PenS\cdot \rightarrow HOOCCH(NH_2)\text{—}C(CH_3)=CH_2 + PenSH$

An alternative mechanism which was considered for formation of trisulfides was production of RSS· radicals by the primary species followed by combination with RS· radicals: e.g.

[12] $RSSR + \cdot OH \rightarrow RSS\cdot + ROH$

However, this reaction is unsatisfactory since the yield of ROH (hydroxyvaline) is always much lower than the yield of trisulfide. Also, since hydroxyvaline is produced only in aerated solution, it must be formed by a different mechanism. Similar arguments apply in the case of e^-_{aq} or ·H atoms reacting with the disulfide to form RSS· and valine.

The formation of trisulfides was also investigated by reacting ·OH radicals (produced chemically from $TiCl_3$ and H_2O_2) with disulfides in solution, using a flow system similar to that described by Armstrong and Humphreys (4). Good yields of trisulfides were produced when a disulfide (CySSCy or PenSSPen) was present in solution when the ·OH radicals were produced. If the disulfide was added after a short time (3 s) no trisulfide was obtained. When ·OH radicals were reacted with a disulfide and a mercaptan added after 3 s, the yield of trisulfide was not significantly changed. However, if the mercaptan of a different disulfide was used, a mixed trisulfide was also produced. Thus when PenSSPen was reacted with ·OH radicals followed by addition of CySH, both PenSSSPen and PenSSSCy were produced. But when PenSSPen was reacted with ·OH and CySSCy was added, PenSSSPen was obtained with only trace amounts of CySSSPen. Reactions [7] and [8] provide a reasonable explanation of these results.

The experiments with PenSH and CySH present during the radiolysis offer further support for reaction [8]. As shown in Table IV, the presence of PenSH had almost no effect on the yield of trisulfide in aerated solution. Thus, reaction [8] is either very fast or else it is the only important reaction of the PenSSOH intermediate. This explains why the dose–yield plot of the trisulfide is linear within the limits of experimental error. When CySH was present, there was a decrease in the yield of PenSSSPen together with a yield of CySSSPen of similar magnitude in aerated solutions, but little change in deaerated solutions. The high yield of PenSH from reaction [2] probably swamped the CySH added in deaerated solutions. Only a small amount of the CySH and PenSH reacted directly with the primary radical as shown by the low yield of CySSCy in deaerated solution. The mixed disulfide produced in deaerated solution probably came from CySH and PenSOH (analogous to reaction [5]).

The effect of radical scavengers on the yields provided some information on the reactions

suggested (Table III). In aerated solutions, formate (·OH scavenger) reduced the yields of $PenSO_2H$ and PenSSSPen significantly. In deaerated solutions, the yield of $PenSO_2H$ increased slightly in the presence of chloroacetate and N_2O (both e^-_{aq} scavengers). However, the most significant change was the increase in PenSSSPen with N_2O present in deaerated solutions. At the same time the yield of PenSH was reduced to a trace while other products were virtually unchanged. This is consistent with reactions [7] and [8] being the main source of trisulfide. PenSH is produced in reactions [2] [3], and [4] and it may also be an intermediate in others.

The mechanism outlined above is sufficient to explain the main features of the radiolysis of penicillamine disulfide. The significance of these results to the theories of radiation protection will be discussed in the following paper on radiolysis of cysteine–penicillamine mixed disulfide.

γ-Radiolysis of disulfides in aqueous solution. III. L-Cysteine-D-penicillamine mixed disulfide[1]

J. W. PURDIE[2]

Defence Research Establishment Ottawa, Defence Research Board, Ottawa, Canada

Received July 10, 1968

L-Cysteine-D-penicillamine mixed disulfide (CySSPen) was irradiated in aerated and deaerated aqueous solutions with ^{60}Co γ-rays. G values were determined for all products identified after exposure to 10 000 rads. The major products were the sulfinic and sulfonic acids ($CySO_2H$, $CySO_3H$, and $PenSO_2H$), the sulfhydryl derivatives (CySH and PenSH), symmetrical disulfides (CySSCy and PenSSPen), three trisulfides (CySSSCy, CySSSPen, and PenSSSPen), and ammonia. Each half of the disulfide behaved in exactly the same way as the corresponding symmetrical disulfide. Products from the CyS— part of the disulfide were dose rate dependent while products from the PenS— part were independent of dose rate. The reactions proposed for the symmetrical disulfides were adequate to explain radiolysis of the unsymmetrical disulfide.

Radiolysis of a mixture of cystine and penicillamine disulfide was examined for comparison with the unsymmetrical disulfide and was found to give very similar results. It was concluded that the free radicals produced from the water attack each half at approximately equal rates.

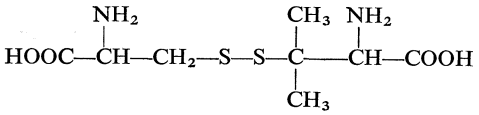
Introduction

Detailed studies of the γ-radiolysis of cystine (1) and penicillamine disulfide (2) have already been reported. In an extension of the investigation, the mixed disulfide of cysteine and penicillamine has been examined under similar conditions. This provided a direct comparison of the CyS and PenS sub-units which was of particular interest since cysteine is a radio-protective compound whereas penicillamine is non-protective. One object of this work was to determine the difference in reactivity, if any, between the cysteine and penicillamine sulfur atoms. Also, further information on the mechanism of radiolysis could be obtained since formation of disulfides from RS· radicals etc. would result in production of some symmetrical disulfides. Information on this aspect was not available from studies of the symmetrical disulfides. Studies of disulfides of cysteine in aqueous solution also contribute to an understanding of the effects of radiation on proteins containing sulfur.

Radiolysis of unsymmetrical disulfides related to cystine has not been reported previously. The recent literature on radiolysis of cystine, penicillamine, and related compounds is covered in the preceding paper in this series (2). The abbreviation CySSPen is used for the cysteine–penicillamine mixed disulfide (1,6-diamino-2,2-dimethyl-3,4-dithiahexane-1,6-dicarboxylic acid) i.e.:



CySSCy and PenSSPen are used to represent cystine and penicillamine disulfide respectively.

Experimental

Materials

Reference amino acids were obtained from Mann Research or Calbiochem as before. Sodium formate and chloroacetic acid were Fisher certified reagents and nitrous oxide was purchased from Matheson, Coleman and Bell.

Cysteine–Penicillamine Mixed Disulfide (CySSPen)

This compound was synthesized from cystine-*S*-monoxide by reaction with penicillamine.

$$CyS(O)SCy + 2\ PenSH \rightarrow 2\ CySSPen + H_2O$$

The monoxide of cystine was prepared as described by Savige *et al.* (3). Cystine (4.8 g) was dissolved in 2 *N* sulfuric acid (50 ml) and cooled to 0 °C. Performic acid, prepared by mixing 5 ml H_2O_2 (30%) with 50 ml formic acid (98%) and allowing the solution to stand 30 min, was added to the solution of cystine and the mixture kept at 5 °C for 3 h. The solution was filtered and adjusted to pH 4 with cold pyridine (28 ml). Addition of cold ethanol (100 ml) precipitated the monoxide. After 30 min at 0 °C the product was filtered off, washed with 50% ethanol (100 ml) and absolute ethanol (100 ml), and dried *in vacuo*. The crude product crystallized from 0.5 *N* acetic acid (500 ml) at 0 °C after addition of an equal

[1]Presented in part at the 15th Annual Meeting of the Radiation Research Society, San Juan, May 1967. Issued as DREO Report No. 573.

[2]Present address: Division of Biology, National Research Council of Canada, Ottawa, Canada.

volume of ethanol; yield 2.9 g (57%). The infrared spectrum had a strong absorption peak at 1060 cm^{-1} characteristic of an *S*-monoxide. The monoxide was stored at −18 °C.

Cystine-*S*-monoxide (1.3 g) in water (10 ml) was mixed with penicillamine (1.58 g) in water (10 ml). The mixture was stirred for 30 min then the precipitate was filtered off and washed with water. The product was recrystallized from 1 *N* HCl by raising the pH to 7 with pyridine; yield 1.0 g (37%), m.p. 198–199°.

Anal. Calcd. for $C_8H_{16}N_2O_4S_2$: C, 35.82; H, 5.97; N, 10.44; S, 23.88. Found: C, 35.64; H, 6.22; N, 10.3; S, 23.99.

This sample was chromatographically pure except for minor traces of impurities and was used for all the radiation experiments.

The nuclear magnetic resonance (n.m.r.) spectrum was run in trifluoroacetic acid. It had peaks at $\tau = 2.30$ ($NH_3^+ \times 2$), 5.23 (CH of CyS half), 5.47 (CH of PenS half), 6.32 (doublet, CH_2), 8.20 (CH_3), and 8.32 (CH_3).

All other amino acids were purchased or prepared as described in the preceding paper (2).

Methods for the preparation of solutions and irradiations were as described previously (2). Solutions of the mixed disulfide were prepared in 200 ml batches and kept at 5 °C. Fresh solutions were prepared each week although blank runs (unirradiated samples) indicated that disproportionation of the mixed disulfide did not occur in unbuffered aqueous solutions (pH 5.5). After storage for two weeks, solutions of CySSPen did not contain any symmetrical disulfide (CySSCy or PenSSPen). Solutions of disulfide 3×10^{-4} *M* were used in all experiments except those where the effect of disulfide concentration was being studied.

The analytical methods employed, ion-exchange chromatography with an amino acid analyzer, have been described in the preceding paper and in previous publications (4). Typical color yields were reported for the various amino acids used or resulting from the radiolysis.

Specimen analyses on "Chromobead" type A cation-exchange resin are illustrated in Fig. 1 for irradiations with 10 000 rads. The unirradiated sample (upper curve) showed only the mixed disulfide peak, ammonia, and slight irregularities in the baseline near the beginning. The middle chart was irradiated–aerated solution and the bottom chart was irradiated–deaerated solution. The irradiated solutions were also examined using Dowex 1 anion-exchange resin (4) in order to separate the sulfinic and sulfonic acids which co-chromatograph as peak 1 in the runs illustrated. Cysteine was usually measured using the absorption at 440 mμ (broken line on lower chart) rather than the usual 570 mμ absorption.

Results

Yields of the principal products were measured in aerated solutions at different total doses in the range 2 500 to 20 000 rads. Figure 2 illustrates the results for cystine, penicillamine disulfide, and the unsymmetrical trisulfide CySSSPen. The yields of the other products measured, CySSSCy, PenSSSPen, and the combined sulfinic and

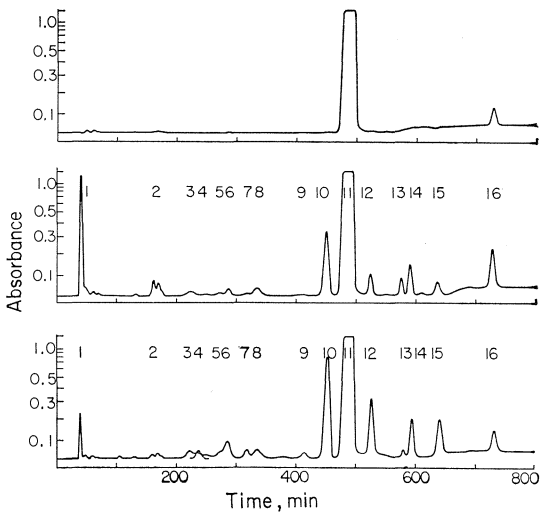


FIG. 1. Amino acid analyzer charts of CySSPen. Top, unirradiated solution; middle, aerated solution irradiated with 10 000 rads; bottom, deaerated solution after 10 000 rads. Peaks are: 1, sulfinic and sulfonic acids; 2, β-hydroxyvaline; 3, $CH_2{=}C(CH_3)CH(NH_2)$-COOH; 4, CySH (broken line); 5, alanine; 6, PenSH; 7, unknown; 8, PenS(O)SPen; 9, valine; 10, CySSCy; 11, CySSPen; 12, PenSSPen; 13, CySSSCy; 14, CySSS-Pen; 15, PenSSSPen; 16, NH_3.

sulfonic acids peak, were also linear with dose up to at least 20 000 rads. Thus 10 000 rads was a suitable dose to use for a general study of the radiolysis of cysteine–penicillamine mixed disulfide.

The yields of all products identified were measured in aerated and deaerated solutions after a dose of 10 000 rads at approximately 700 rads/min. The results are given in Table I in G values. The G values in terms of nitrogen atoms were used to calculate the product balance since the color reaction used in the amino acid analyzer, ninhydrin, detects amines and ammonia. The products of deamination have not been investigated. Values for G (—CySSPen) were 3.6 and 4.7 in aerated and deaerated solutions respectively. Minor products, e.g. lanthionine, (CySCy), cysteine thiosulfonic, and cysteine thiosulfuric acids ($CySO_2SH$ and $CySSO_3H$), which have been detected in irradiated cystine solutions, were probably present in small amounts. Similarly, $PenSSO_3H$ was probably produced in trace amounts. As with radiolysis of PenSSPen, β-hydroxyvaline was produced in aerated solutions together with an adjacent peak believed to be the peroxyvaline derivative (PenOOH). Trace

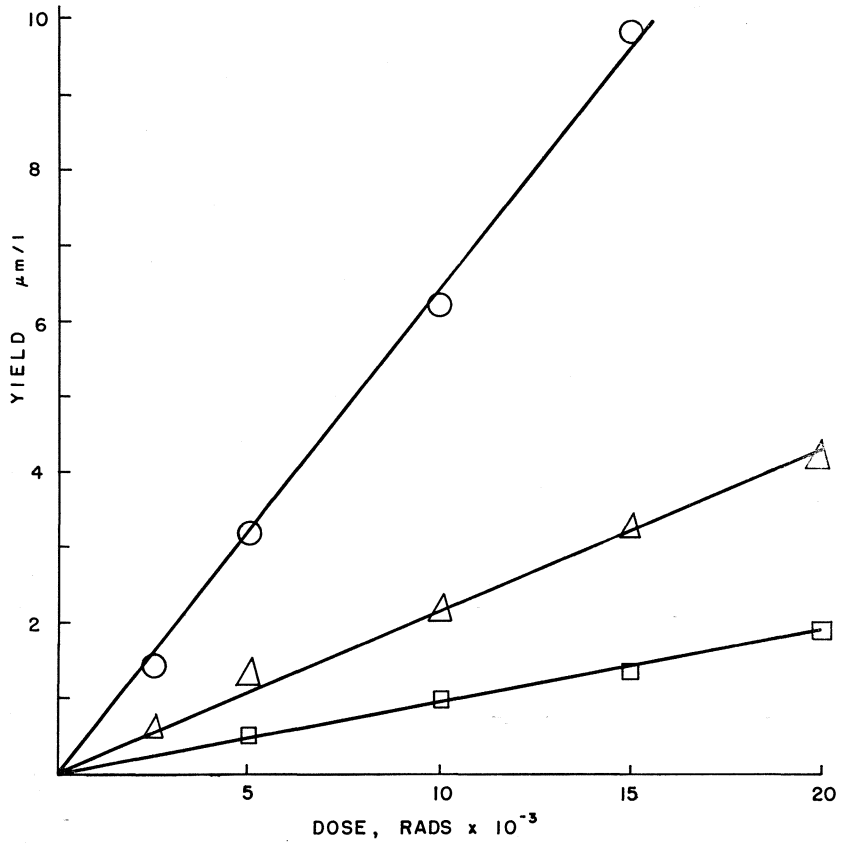

FIG. 2. Dose-yield plots for γ-radiolysis of CySSPen in aerated solution; CySSCy (○); CySSSPen (△); PenSSPen (□).

amounts of serine (CyOH) were also detected in aerated solutions. Estimates for the G value of these minor products and the PenOOH in aerated solutions gave a total of 0.2. When this was included, the nitrogen balance was approximately 80% in aerated solution and 90% in deaerated solution. In view of the number of products and the combined experimental errors this seems reasonably satisfactory. Some minor products remained unidentified and are not included in Table I. The average deviation for a number of experiments was ±0.05 for CySSCy, ±0.02 for PenSSPen, ±0.02 for the trisulfides, ±0.03 for $CySO_3H$ (aerated) and the sulfinic acids, and ±0.35 for PenSH (deaerated). The other products were estimated to be reproducible to within ±5%.

The yields followed the same general pattern obtained previously with the symmetrical disulfides, PenSSPen (preceding paper), and CySSCy (1). For example, sulfinic acids but not sulfonic acids were obtained in deaerated solution while in aerated solution the yields were in the following order:

$$CySO_3H > CySO_2H > PenSO_2H > PenSO_3H$$

High yields of the mercaptans, CySH and PenSH, were obtained in deaerated solutions. Cystine was obtained in much higher yield than penicillamine disulfide and the yield of each was higher in deaerated than in aerated solution. Variations in the yields of the trisulfides were unusual. In changing from aerated to deaerated solution, CySSSCy decreased, CySSSPen remained almost constant, and PenSSSPen increased. These effects were consistent and can be observed on the charts reproduced in Fig. 1 (peaks 13, 14, and 15 respectively).

In view of the fact that the yields from the mixed disulfide resembled those from the two

*Mixture = CySSCy + PenSSPen (each 1.5×10^{-4} *M*).

symmetrical disulfides, a solution containing a mixture of CySSCy and PenSSPen was irradiated for comparison. The concentration of each disulfide was 1.5×10^{-4} *M* giving a total disulfide concentration of 3×10^{-4} *M*, which was the concentration used for experiments described above. The mixture was irradiated with 10 000 rads and analyzed as before. The yields measured are reported in Table I. The Table also contains G values from the cystine and penicillamine disulfide studies. However, the concentration of each CyS and PenS unit would be twice that of the mixture, and comparison of the symmetrical disulfides with the mixture or the unsymmetrical disulfide does not allow for reactions between intermediates from the different halves which could occur in the latter cases. As can be seen from Table I, the yields from the mixture were very close to those from the unsymmetrical disulfide and similar to half the values from CySSCy or PenSSPen.

Dose-Rate Effects

The effect of irradiating at different dose rates was investigated by irradiating solutions with 10 000 rads at dose rates of 800, 650, 330, 110, 40, and 10 rads/min. The yields of the disulfides, CySSCy, and PenSSPen, and the three trisulfides, were independent of dose rate in both aerated and deaerated solutions. Yields of the acidic products, however, followed the pattern observed with the symmetrical disulfides. The yields of $PenSO_2H$ and $PenSO_3H$ in aerated solution and the yield of $PenSO_2H$ in deaerated solution, were independent of dose rate. In aerated solution, the yield of $CySO_3H$ decreased from 0.35 at 800 rads/min to 0.15 at 10 rads/min while the yield of $CySO_2H$ increased from 0.30 at 800 rads/min to 0.5 at 10 rads/min. In deaerated solution, the yield of $CySO_2H$ decreased from 0.30 to 0.10 at 800 and 10 rads/min respectively. The observation that the two halves of the disulfide behave independently with respect to dose rate is in agreement with reactions proposed earlier to explain the dose-rate effect in the radiolysis of cystine. The dose-rate effect must be due to competition between intermediates and not to the initial reactions of free radicals with the disulfide.

Disulfide Concentration

A disulfide concentration of 3×10^{-4} *M* was used in this and previous studies as this was the maximum concentration which could be obtained with cystine in neutral solution. The same concentration was used in all studies so that results could be compared without complications from concentration effects. The low concentra-

CySSCy	0.36	0.56	0.84	1.00
PenSSPen	0.04	0.06	0.14	0.16
CySSSCy	0.07	0.09	0.12	0.16
CySSSPen	0.14	0.18	0.24	0.26
PenSSSPen	0.03	0.04	0.07	0.08

tion used was also suitable as it minimized the chance of direct radiation effects. However, since the mixed disulfide was much more soluble than cystine, a study was made of the effect of different concentrations on the results. The results are presented in Table II and these show a general increase with concentration. The total dose was 10 000 rads at all concentrations. Thus it appears that a higher concentration than 3×10^{-4} *M* would be necessary in order to trap all the primary species formed in the water.

Radical Scavengers

Radical scavengers were employed to test the reactions postulated to explain the mechanism of the radiolysis. Experiments were carried out using deaerated solutions with formate ions present to react with ·OH radicals, chloroacetate ions to scavenge e^-_{aq}, or nitrous oxide which scavenges e^-_{aq} and produces an ·OH radical. From the results, listed in Table III, it can be seen that the combined yield of sulfinic and sulfonic acids is effectively reduced by formate ions, unaffected by chloroacetate ions, and increased with nitrous oxide present. This is also true for CySSSCy and CySSSPen and indicates that the ·OH radical is necessary for formation of these compounds. PenSSSPen appears to be an exception as it is not affected by chloroacetate or nitrous oxide but is slightly increased by formate ions. The yields of PenSH and CySH were reduced but not eliminated by nitrous oxide. The disulfides, CySSCy and PenSSPen, increased considerably with formate present but were little affected by chloroacetate or nitrous oxide.

Discussion

The reactions giving rise to the products obtained have been discussed in detail in the previous papers dealing with the symmetrical disulfides (1, 2). The same reactions are probably involved in the case of CySSPen with some changes due to interaction between cysteine and penicillamine intermediates. The following appear to be the more important of those discussed:

[1] $RSSR + \cdot OH \rightarrow RSOH + RS\cdot$

[2] $RSSR + e^-_{aq} + H^+ \rightarrow RSH + RS\cdot$

[3] $RSOH + RSOH \rightarrow RSO_2H + RSH$

[4] $RSOH + RSSR \rightarrow RS(O)SR + RSH$

[5] $RSOH + RSH \rightarrow RSSR + H_2O$

[6] $RSOH + O^-_2 \rightarrow RSO^-_3 + H\cdot$

[7] $RS\cdot + RS\cdot \rightarrow RSSR$

[8] $RSSR + \cdot OH \rightarrow RSSOH + R\cdot$

[9] $RSSOH + RSH \rightarrow RSSSR + H_2O$

Reactions [1] and [2] seem to occur with both cystine and penicillamine disulfide although reaction [8] may be more important than [1] in the case of penicillamine disulfide. Reactions [3], [4], and [5] probably occur with both CySOH and PenSOH and reaction [5] could be one of the reactions leading to the symmetrical disulfides. Reaction [6] is more specific as it does not occur with PenSOH. The details of this reaction are not clear but it was established that $CySO_3H$ was only produced when oxygen was present in solution and the yield was reduced by e^-_{aq} scavengers (1). It is possible that e^-_{aq} or O^-_2 has a catalytic effect on oxidation of CySOH by oxygen or perhaps the O^-_2 reacts with the initial disulfide – radical complex, i.e.:

[10] $RSSR \overset{\cdot OH}{+} O^-_2 \rightarrow RSO^-_3 + RSH$

Such a reaction would be favored by high dose rates leading to higher sulfonic acid yields, as was

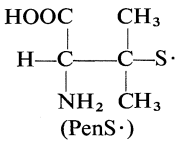
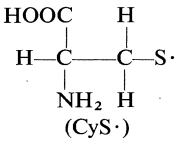
observed with $CySO_3H$ from both CySSPen and CySSCy.

Reaction [7] is probably the main source of symmetrical disulfides (CySSCy and PenSSPen) from the unsymmetrical disulfide. The yields of PenSSPen were lower than those of CySSCy which may be due to steric hindrance by the two methyl groups adjacent to the sulfur atom in the penicillamine radical:



(PenS·)



(CyS·)

When a mixture of CySSCy and PenSSPen was irradiated, a moderate yield of CySSPen was obtained (Table II).

It is difficult to establish a mechanism for formation of trisulfides. Reactions [8] and [9] appear to satisfy the experimental results better than the alternatives, as discussed in the previous paper. The results with nitrous oxide strongly indicate that the ·OH radical is involved in the initial step leading to the trisulfides. The work with the ·OH and e^-_{aq} scavengers, formate and chloroacetate, also supports this view although the effects are less dramatic. The variations in the yields of the three trisulfides are also noteworthy. In changing from aerated to deaerated solutions, CySSSCy decreases, CySSSPen remains approximately constant, and PenSSSPen increases. In the previous work on cystine and penicillamine disulfide, the trisulfide yield increased in deaerated solution. The explanation of this phenomenon may be that the high yield of PenSH in deaerated solutions (approximately 2.5×10^{-5} *M* after 10 000 rads) swamps the CySH in the competing reactions:

[9*a*] $\quad CySSOH + CySH \rightarrow CySSSCy + H_2O$

[9*b*] $\quad CySSOH + PenSH \rightarrow CySSSPen + H_2O$

[9*c*] $\quad PenSSOH + CySH \rightarrow CySSSPen + H_2O$

[9*d*] $\quad PenSSOH + PenSH \rightarrow PenSSSPen + H_2O$

A high concentration of PenSH would favor reactions [9*b*] and [9*d*], leading to the effect observed.

Comparison of the mixed disulfide, CySSPen, with the mixture, CySSCy + PenSSPen, (Table II) leads to some important conclusions. In studying the radiolysis of an unsymmetrical disulfide such as CySSPen it was thought that the two sulfur atoms would react at different rates with the primary free radicals, ·OH and e^-_{aq}. If such a difference did exist there should be a measurable difference in yield between the products from the mixed disulfide and those from the mixture. However, since the yields from the mixed disulfide were approximately equal to those from the mixture and half the yields from the pure disulfides, it follows that the two sulfur atoms react at almost equal rates with the primary species from water. Hence differences between cystine and penicillamine disulfide are due to different reactions following the initial attack. This conclusion will apply irrespective of the exact mechanism involved.

As mentioned above, cysteine is a radioprotective compound whereas penicillamine is not. Thus, studies of the radiolysis of these two compounds and of the corresponding disulfides

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

contribute to an understanding of the mechanism of radiation protection and of the effect of radiation on sulfur-containing proteins. The most outstanding difference observed between cystine and penicillamine disulfide was the almost complete absence of sulfonic acid from among the radiolysis products of the latter. Since the sulfonic acid is formed by reaction with ·OH radicals and oxygen (as O^-_2) this may be one of the important properties which determines whether or not a compound is radio-protective. In this connection it is interesting to note that Vos *et al.* (5) found that penicillamine protected cells almost as well as cysteine under anoxic conditions (i.e. in the absence of O^-_2). One possibility is that the amino group attracts and binds the O^-_2 to the protective molecule where it eventually reacts with the sulfur. This would explain the necessity for an amino group and the fact that the chain length between the nitrogen and the sulfur is very critical for protection (two or three carbon atoms).

The other notable differences observed were the low yields of penicillamine disulfide compared with cystine and the high yields of penicillamine (PenSH) and the trisulfide (PenSSSPen). There is no obvious connection between these observations and radio-protective properties other than the possibility that steric hindrance, which may be responsible for the low yield of PenSSPen, may also render the sulfur inaccessible at a critical stage in the radiation protection process.

It has been suggested that RS· radicals react with many disulfides in proteins causing a "scrambling" of disulfide bonds (6). This hypothesis was based on the high G values, up to 25 (7), reported for polymerization of lipoic acid which has a cyclopentane ring containing a disulfide unit. However, for the amino acid, cysteine-penicillamine mixed disulfide, the G value for reformed disulfides in aerated solutions was only about 1. Even in deaerated solutions the G value for regenerated disulfides was about 2.5. Since these disulfides could all result from reactions of the primary radicals followed by recombinations, it is clear that RS· radicals do not cause extensive rearrangement of disulfide bonds in proteins.

The $CdO–CdCl_2$ reaction studied by thermal analysis and X-ray diffraction: X-ray diffractogram and infrared spectrum of $CdCl_2 \cdot 2CdO$

P. Ramamurthy and E. A. Secco

Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia

Received September 6, 1968

CdO and molten $CdCl_2$ react to form $CdCl_2 \cdot 2CdO$ according to the equation:

$$2CdO_{(s)} + CdCl_{2(l)} \xrightarrow{560\ °C} CdCl_2 \cdot 2CdO_{(s)} \qquad \Delta H = -5.3 \text{ kcal/mole}$$

The compound $CdCl_2 \cdot 2CdO$ dissociates to the oxide and chloride at 680 °C. CdO and $CdCl_2$ form a solid solution of partial miscibility of 15% by weight of CdO.

The X-ray diffractogram of $CdCl_2 \cdot 2CdO$ was indexed to the orthorhombic system. The unit cell dimensions are calculated to be $a = 4.38$ Å, $b = 11.47$ Å, $c = 9.93$ Å with 4 molecules in the unit cell. The infrared spectrum shows a band structure of two doublets and a well-defined band in the region 370–550 cm^{-1}.

Introduction

Our knowledge of the reaction between cadmium oxide and cadmium chloride is incomplete. This limitation became evident to us when a recent study (1) on the decomposition of CdOHCl by differential thermal analysis (d.t.a.) revealed three unknown endotherms which were tentatively assigned to oxide–chloride interactions. The sole literature item on this interaction appears in Mellor (2) as an unconfirmed reference to the existence of cadmium oxychloride, $CdCl_2 \cdot 2CdO$. The purpose of this communication is to fill the existing gap and report on a study of the $CdO–CdCl_2$ reaction over the entire composition range.

Experimental

CdO and $CdCl_2 \cdot 2\frac{1}{2}H_2O$ used in this work were Fisher Certified and Baker Analyzed reagent grade, respectively. The $CdCl_2 \cdot 2\frac{1}{2}H_2O$ was dehydrated at 125 °C for 12 h before mixing with CdO to obtain the requisite composition. The physical mixtures of various compositions were prepared by thorough manual grinding and storing in a dessicator to preclude the uptake of moisture and subsequent formation of CdOHCl on long standing.

Most thermograms were recorded on a duPont thermal analyzer, DTA-900 using a low temperature cell (850 °C) as previously reported (1). Some experiments were carried out with the duPont 1200 °C cell. In all thermograms, the heating rate used was 20 °C/min with an ambient atmosphere of dry air. Cooling curves were obtained by self-cooling with dry air flowing through the d.t.a. cell. The peak temperatures reported here are reproducible within ±5 °C.

The X-ray diffractograms of the specimens were recorded on a Norelco X-ray diffractometer unit using CuK_α radiation and Ni filter as previously described (3). To obtain accurate values of θ for the compound $CdCl_2 \cdot 2CdO$ a slow scanning rate of $\frac{1}{4}° - 2\theta$/min was used.

The infrared (i.r.) spectra were recorded on the Perkin–Elmer 521 grating instrument using the standard KCl pellet technique. The compound $CdCl_2 \cdot 2CdO$ was prepared by heating a physical mixture of CdO:$CdCl_2$ in 2:1 mole ratio at 560 °C for 1 h as described above.

Results and Discussion

Heating thermograms at selected compositions to illustrate the salient features of thermal behavior with composition are shown in Fig. 1. Physical mixtures of composition greater than 85% by weight of $CdCl_2$ showed only the melting endotherm of $CdCl_2$ at the peak temperature of 560 °C; the peak temperature shifted slightly to 570 °C as the oxide content of the mixture reached 15% by weight. At the 85:15 $CdCl_2–CdO$ composition, a weak unidentified endotherm appeared at 680 °C accompanying the 560 °C endotherm. Increasing the CdO content in the mixture causes a decrease in the intensity (or area) of the 560 °C endotherm with a concomitant increase in the 680 °C endotherm until the $CdCl_2–CdO$ composition 35:65 is attained. Where the 680 °C endotherm attains a maximum area while the 560 °C endotherm is barely discernible and always accompanied by a weak exotherm at 565 °C. Further enrichment in oxide content effects a decrease in the 680 °C endotherm intensity and the appearance of a sharp weak endotherm at 640 °C above 75% by weight of CdO.

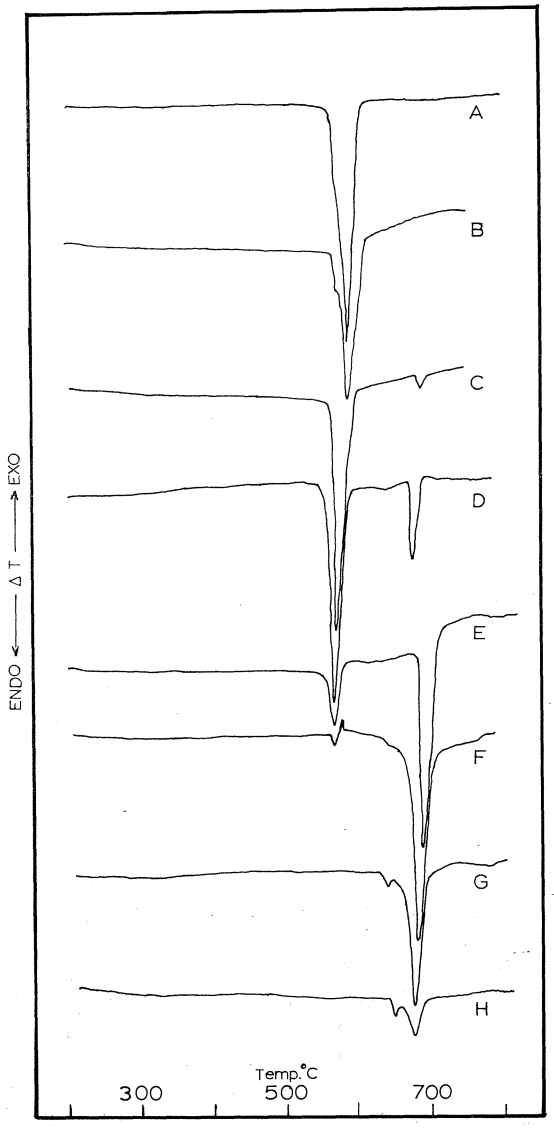

FIG. 1. Thermograms of CdO–$CdCl_2$ mixtures at different composition to display pertinent features as a function of composition (% by weight).
A, 100% $CdCl_2$; B, 90% $CdCl_2$, 10% CdO; C, 80% $CdCl_2$, 20% CdO; D, 60% $CdCl_2$, 40% CdO; E, 50% $CdCl_2$, 50% CdO; F, 35% $CdCl_2$, 65% CdO; G, 20% $CdCl_2$, 80% CdO; H, 10% $CdCl_2$, 90% CdO.

The disappearance of the $CdCl_2$ melting endotherm above 65% by weight of CdO was tentatively interpreted in terms of immediate interaction between the oxide and molten $CdCl_2$, where the fusion endotherm of $CdCl_2$ is exactly compensated by the oxide–chloride reaction exotherm. The possibility that the reduced heat requirement due to the decreasing $CdCl_2$ content might escape the instrumental sensitivity was ruled out when a physical mixture of 35% by weight of $CdCl_2$ in an inert matrix of 65% by weight of Al_2O_3 exhibited an intense endotherm at 560 °C.

The 65:35 CdO–$CdCl_2$ composition lies very near to 2:1 molar ratio in agreement with the compound $CdCl_2 \cdot 2CdO$ cited by Mellor (2). The thermogram of 2:1 molar CdO–$CdCl_2$ mixture heated to 600 °C showed a weak endotherm at 560 °C and a weak exotherm at 565 °C. The cooling curve from 600 °C to room temperature, Fig. 2, exhibited no thermal effect, therefore confirming an irreversible oxide–chloride interaction up to 600 °C. A second heating of the same sample to 700 °C produced the 680 °C endotherm. On cooling from 700 °C to room temperature, two exotherms appeared at 620 and 530 °C. These facts were interpreted in terms of decomposition of the compound $CdCl_2 \cdot 2CdO$ to its components at 680 °C on heating and the subsequent partial recombination of CdO and $CdCl_2$ to form $CdCl_2 \cdot 2CdO$ occurs at 620 °C on cooling. The unreacted $CdCl_2$ displays its exothermic effect due to crystallization with slight undercooling at 530 °C.

The areas of the weak endotherm at 560 °C and weak exotherm at 565 °C observed in the combination of 1 mole of $CdCl_2$ with 2 moles of CdO cancel out to show a net zero thermal effect. That is, the endothermic heat of fusion for 1 mole of

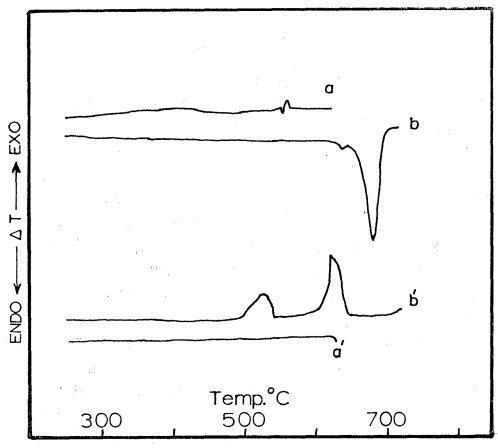

FIG. 2. Heating and cooling thermograms of 2:1 CdO–$CdCl_2$ molar composition. *a*, *a′*, first heating and cooling thermograms, respectively; *b*, *b′*, second heating and cooling thermograms, respectively.

$CdCl_2$, 5.3 kcal/mole, exactly equals the exothermic heat of reaction between molten $CdCl_2$ and solid CdO. The reaction given in equation form reads as follows:

$$2CdO_{(s)} + CdCl_{2(l)} \xrightarrow{560\ ^\circ C} CdCl_2 \cdot 2CdO_{(s)}$$
$$\Delta H = -5.3 \text{ kcal/mole}$$

Evidence from X-ray diffractograms presented in Fig. 3 confirm the above interpretation of $CdCl_2 \cdot 2CdO$ dissociation at 680 °C with partial recombination on cooling. $CdCl_2$–CdO physical mixture of 1:2 molar ratio heated to 500 °C gave a diffractogram which is a sum of the characteristic peaks due to CdO and $CdCl_2$. Heating the mixture of 565 °C yields a diffractogram distinctly different from the combined CdO and $CdCl_2$ pattern. The resultant diffractogram at 565 °C cannot be found in the literature and is assigned to the compound $CdCl_2 \cdot 2CdO$; the pattern remains unchanged to 660 °C. Heating the compound to 700 °C and recooling yields a diffractogram with peaks common to CdO, $CdCl_2$, and the compound.

The absence of the 680 °C dissociation endotherm in d.t.a. up to 15% by weight CdO was a point of interest and merited clarification by X-ray diffraction. Untreated $CdCl_2$–CdO mixtures up to 15% CdO showed characteristic CdO and $CdCl_2$ diffraction peaks, whereas the fused mixture revealed only $CdCl_2$ diffraction peaks. Furthermore, a fused mixture of 5% by weight of $CdCl_2 \cdot 2CdO$ in $CdCl_2$ gave diffraction peaks characteristic of both species, i.e. compound and chloride. We conclude, therefore, that a solid solution of limited miscibility of 15% CdO and $CdCl_2$ occurs prior to compound formation.

The additional endotherms at 745 and 796 °C for 1:1 mole ratio assigned earlier (1) to volatilization processes have been confirmed using a Mettler simultaneous d.t.a.–t.g.a. instrument, Fig. 4. Instead of distinct endotherms, we observe a broad endotherm, 720–820 °C, which arises from the volatilization of $CdCl_2$ from a system of variable composition, i.e. a two phase system of a saturated solution of CdO–$CdCl_2$ and excess liquid $CdCl_2$.

Cooling thermograms of mixtures were studied in more detail to account for the partial recombination. Alternate heating and cooling curves for a 55:45 $CdCl_2$–CdO mixture are presented in Fig. 5*a*; the decreasing intensity trend of the

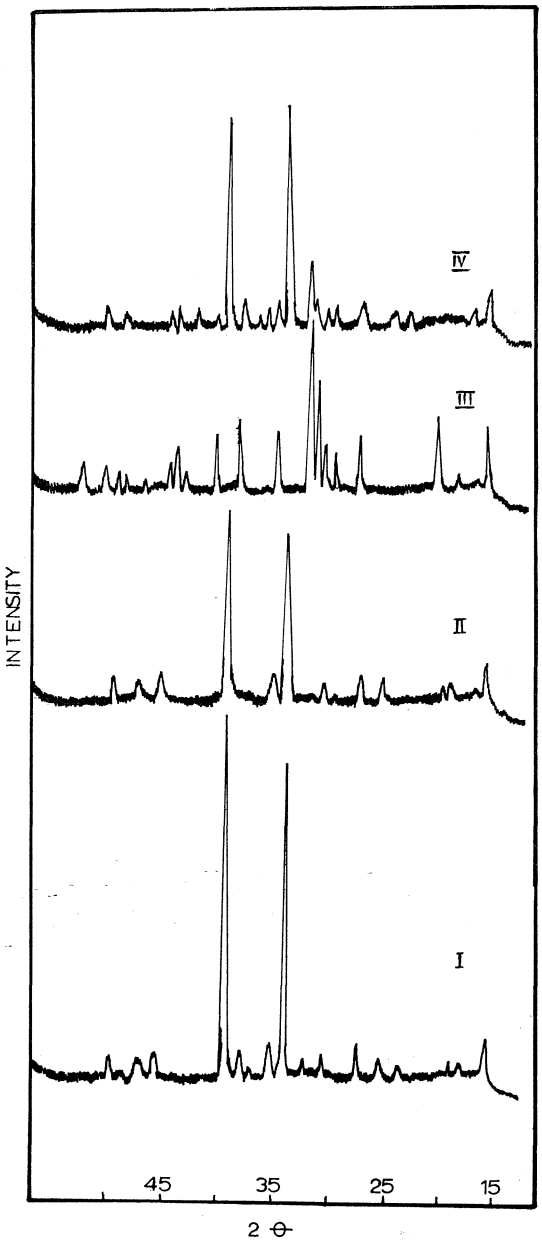

FIG. 3. X-ray powder diffractograms of 2:1 CdO–$CdCl_2$ molar mixture, recorded at room temperature following heat treatment. I, untreated; II, after heating to 500 °C; III, after heating to 565 °C; IV, after heating to 700 °C.

680 °C endotherm and the 620 °C exotherm accompanied by an increasing intensity trend of the 560 °C endotherm and the 530 °C exotherm with each heat–cool cycle are evident. In addition

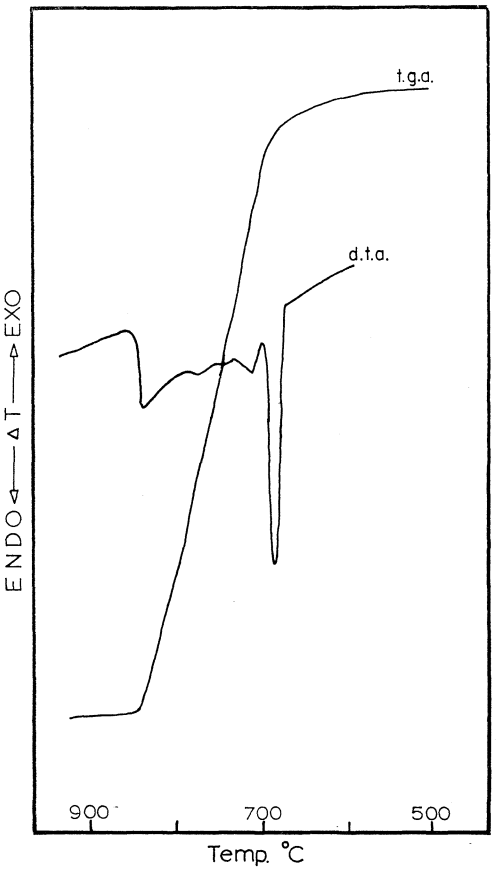

FIG. 4. Thermogram of 1:1 CdO–$CdCl_2$ molar mixture recorded by Mettler simultaneous d.t.a.–t.g.a. instrument.

to a kinetic factor responsible for only partial return of the compound after dissociation, the heat–cool cycle inactivates the oxide by particle growth, most likely through a solubility–precipitation sequence, thereby liberating previously bound $CdCl_2$ to intensify the $CdCl_2$ endo- and exo-therms at the expense of compound endo- and exo-therms. Cooling thermograms of mixtures containing excess CdO relative to the $CdCl_2 \cdot 2CdO$ composition reveal only the exotherm due to compound formation as shown in Fig. 5*b*.

Attempts to identify conclusively the sharp weak endotherm at 640 °C in oxide excess mixtures, i.e. above 65% CdO, have failed. We can only speculate on the possible origins of such an endotherm: (*i*) melting point of $CdCl_2 \cdot 2CdO$ prior to dissociation; (*ii*) phase transition of the $CdCl_2 \cdot 2CdO$; (*iii*) presence of higher oxychloride, i.e. $CdCl_2 \cdot nCdO$ where $n > 2$.

In summary, CdO and molten $CdCl_2$ react to form $CdCl_2 \cdot 2CdO$ according to the equation:

$$2CdO_{(s)} + CdCl_{2(l)} \xrightarrow{560\ ^\circ C} CdCl_2 \cdot 2CdO_{(s)}$$
$$\Delta H = -5.3 \text{ kcal/mole}$$

which is followed by the reverse reaction at 680 °C

$$CdCl_2 \cdot 2CdO_{(s)} \xrightarrow{680\ ^\circ C} 2CdO_{(s)} + CdCl_{2(l)}$$

CdO and $CdCl_2$ form a solid solution of partial miscibility of 15% by weight of CdO.

The X-ray powder lines were indexed to orthorhombic system using the Hesse–Lipson method (4, 5). The observed and calculated $\sin^2\theta$ values according to orthorhombic system along with their relative intensities and *hkl* values are given in

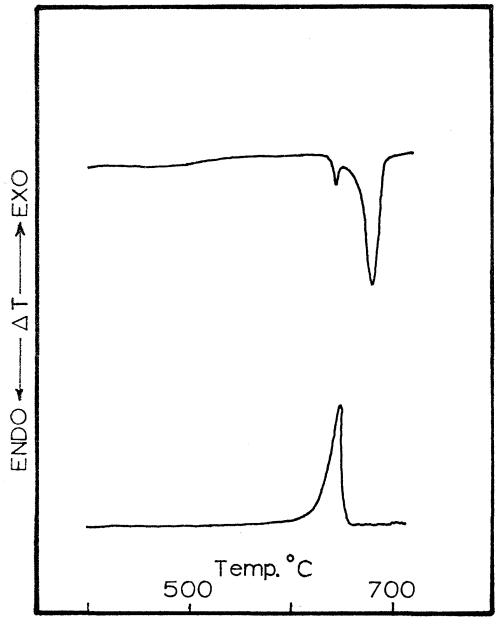

FIG. 5*b*. Heating and cooling thermograms of $CdCl_2$–CdO mixture with CdO in excess of 2:1 CdO–$CdCl_2$ molar ratio.

Table I. The unit cell dimensions are calculated to be $a = 4.38$, $b = 11.47$, and $c = 9.93$ Å.

The density of the compound was determined by the displacement method at 25 °C using benzene and dibutyl phthalate as displacing liquids. The average density value from six measurements in both liquids with its mean deviation was found to be 5.85 ± 0.03 g/cc. Water could not be used as a displacing solvent, because the compound decomposes in water with the evolution of heat.

With the density value of 5.85 g/cc, the number of molecules in the unit cell was calculated to be $3.994 \approx 4$. As there is no systematic absence of *hkl* values, the space group of the compound could not be assigned.

The i.r. spectrum of the compound, Fig. 6, showed a band structure consisting of two doublets and a well-defined band in the range between 370–550 cm^{-1}. Both $CdCl_2$ and CdO show no absorption in this region (6), and we conclude, therefore, that the observed bands are characteristic of the compound $2CdO \cdot CdCl_2$. In the absence of a point group, the factor group analysis could not be carried out, and under these circumstances it is very difficult to assign a structure and to give proper and complete assignments to these bands.

Kinetics and mechanism of the oxidation of formaldehyde by hexacyanoferrate(III) ion

V. N. SINGH, M. C. GANGWAR, B. B. L. SAXENA, AND M. P. SINGH
Chemical Laboratories, University of Allahabad, Allahabad, India

Received April 8, 1968

The kinetics of the reaction between formaldehyde and hexacyanoferrate(III) ion in alkaline medium has been investigated at four temperatures. The data show that the reaction is rapid initially, then follows a simple first order rate with respect to each of the hexacyanoferrate(III) ion, formaldehyde, and hydroxide ion. Calculations reveal that only 0.27% of the formaldehyde corresponds to the initial rapid reaction; the remaining 99.73% follows the kinetics described. The net rate of the oxidation of formaldehyde as measured by the consumption of hexacyanoferrate(III) ion, is given by

$$-\frac{d[Fe(CN)_6^{3-}]}{dt} = \frac{2k_1k_2[HC(OH)_2][OH^-][Fe(CN)_6^{3-}]}{k_{-1}[H_2O] + k_2[Fe(CN)_6^{3-}]}$$

Canadian Journal of Chemistry, 47, 1051 (1969)

Introduction

Potassium permanganate and the ferricyanide are the most common reagents used as oxidants in alkaline medium for a number of organic compounds. However, the kinetic features of the oxidation of formaldehyde are not well known. Conant and co-workers (1) were first to observe that there is no appreciable oxidation of formaldehyde with ferricyanide below pH 11. Holluta and co-workers (2) have studied the kinetics of oxidation of this organic substrate with neutral permanganate and found that it was base catalyzed. The present study aims at getting more definite information regarding the mechanism of the oxidation of formaldehyde with alkaline ferricyanide ion.

Results and Discussion

The oxidation of formaldehyde in basic aqueous solution has been investigated kinetically at constant ionic strength. Our measurements, covering a much wider concentration and temperature range, confirm that this reaction is strictly first order with respect to each reactant under the conditions used. The kinetic data for the oxidation of formaldehyde have been collected into Tables I to IX. The course of the reaction was followed by estimating the amount of ferrocyanide ion produced at different intervals of time, with the help of a standard solution of ceric sulfate and

the use of ferroin as a redox indicator. The first order rate constants (k'') given in Tables I to III are the averages obtained from the slope of the first order plot made for ferricyanide. The actual nature of the reaction is also shown graphically in Fig. 1. Figure 2 shows the first order plot for different runs of ferricyanide. It indicates that there is a possibility of two parallel reactions producing a common product, and shows similarity to the explanation of Brown and Fletcher

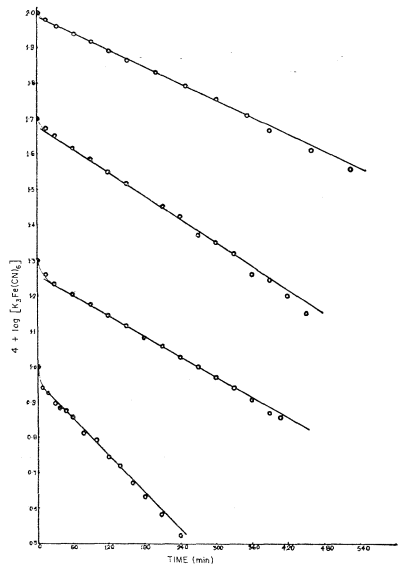

FIG. 2. First order plot for the rate of oxidation of formaldehyde by hexacyanoferrate(III) ion; temperature = 40°, [HCHO] = 0.02 *M*, [NaOH] = 1.0 *M*.

(3) for the hydrolysis of mixed tertiary aliphatic chlorides. The curves become linear and follow simple first order kinetics after some time, because the more reactive component has disappeared. From their intercepts, the concentration of the more reactive component (which is half the concentration of ferricyanide consumed) is estimated to be 0.27%. Thus the relative proportions of the components likely to be the hydrate and nonhydrate forms of formaldehyde are 99.73% and 0.27% of the original mixture.

Table I collects the values of k'' (first order rate constant values obtained from the slope) for different initial concentrations of ferricyanide. These values appear to be constant at moderate concentrations but there is some retarding effect at higher concentrations. They continue to decrease as the concentration of ferricyanide ion is increased. At least part of this decrease must be due to the fact that psuedo first order kinetics do not apply at high concentrations of hexacyanoferrate(III) ion. But the retarding effect of the hexacyanoferrate(III) ion cannot be omitted on this ground only, as the effect is apparent even in the initial part of the reaction where there is negligible change in the reductant concentration.

Table II contains the first order rate constants for different concentrations of formaldehyde. The last column shows that the second order rate constants obtained by dividing k'' by the initial formaldehyde concentrations are indeed constant. This confirms that the reaction is first order with respect to formaldehyde.

Similarly Table III demonstrates the effect of variation of hydroxide ion on the rate of the reaction. The last column shows that $k''/[OH^-]$ is almost constant for these base concentrations and thus confirms the first order dependence of the reaction rate on base concentration.

Further confirmation of the order has also been made by studying the reaction with respect to formaldehyde. The reaction velocity was again measured by estimating the amount of ferrocyanide produced after different intervals of time. It was observed that 2 equivalents of ferrocyanide ions are produced for 1 mole of formaldehyde. The first order rate constants (k'), in this case, were calculated from the standard integrated first order equation. Summarized data are given in Tables IV to VIII. The average deviation of k' given in these tables is $\pm 0.04 \times 10^{-2}$ units. Under these conditions the possibility of Can-

nizzaro reaction (4) is negligible. Tables IV and V show that the first order rate constant values are practically the same over a ten-fold range of formaldehyde concentration.

A standard first order plot between $\log (a - x)$ and time is also shown in Fig. 3 [$(a - x)$ = concentration of formaldehyde]. The reaction is first order to more than 90% completion. Though in this case the complete course of the reaction is

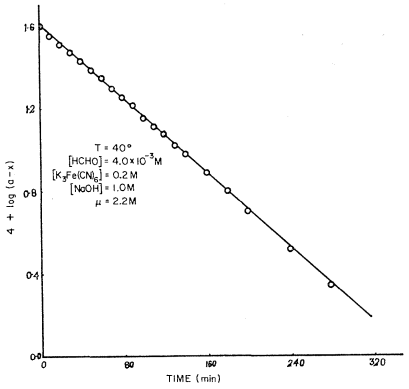

FIG. 3. First order plot for the rate of oxidation of formaldehyde by hexacyanoferrate(III) ion.

followed by a 4% change in the ferricyanide concentration, no apparent change in the first order rate constant is observed. In addition, the effect of the formation of the acid on the concentration of the base must be considered. The decrease in ferricyanide concentration increases the first order rate constants (Table I) while the decrease in base concentration will lower them. Probably these two effects counteract one another and no apparent change in the velocity constant is observed. These observations, therefore, confirm the first order dependence of the reaction rate on formaldehyde concentration.

Tables VI and VII show the k' values for different concentrations of ferricyanide, both at constant and varying values of μ. When μ is not constant the reaction shows a first order dependence on ferricyanide concentration, but at constant μ the $k'/[Fe(CN)_6^{3-}]$ values decrease with increasing concentration of ferricyanide. In this case some association of ferricyanide ion

with Na^+ or K^+ ion may also occur but the error involved is difficult to estimate at higher $[Fe(CN)_6^{3-}]$. Nevertheless, it is quite evident from Tables VI and VII that, if μ of the medium is kept constant, $k'/[Fe(CN)_6^{3-}]$ will not remain constant but will show the same dependence as is observed in Table I. All these observations clearly indicate that the reaction is first order at low ferricyanide concentrations, but it proceeds with a retarded velocity at higher concentrations.

Table VIII contains the k' values obtained for different concentrations of hydroxide ion. The almost constant $k'/[OH^-]$ values again show that the reaction is first order with respect to hydroxide ion.

Scheme of Oxidation of Formaldehyde by Alkaline Ferricyanide

From the experimental results it is clear that after a rapid initial reaction, the velocity follows a good first order dependence on ferricyanide concentration. It has been observed that 99% of the formaldehyde in aqueous medium is in the hydrated form (5). In many ways its oxidation resembles that of aliphatic alcohols (6). In the present case, one might assume that the hydrate has a lower rate than the non-hydrate as the oxidation of the alcohols is slower than that of the aldehydes. However, consider the equilibrium

$$H_2CO + H_2O \rightleftharpoons H_2C(OH)_2$$

The rapid initial reaction seen in Fig. 2 could not be the result of oxidation of the non-hydrate of formaldehyde unless the rate of oxidation of the hydrate was faster than that of its dehydration. Since the rate of oxidation is relatively slow, this does not seem to be a likely situation and this part of the problem still remains questionable.

Further, the probable scheme of the ferricyanide oxidation of the hydrated formaldehyde in alkaline medium might be considered as follows

[1] 
[2] 
[3] 
formate ion

If the concentration of the anion formed in step [1] reaches a steady state, the net rate of disappearance of ferricyanide is

$$[4] \quad -\frac{d[Fe(CN)_6^{3-}]}{dt} = \frac{2k_1k_2[HC(OH)_2][OH^-][Fe(CN)_6^{3-}]}{k_{-1}[H_2O] + k_2[Fe(CN)_6^{3-}]}$$

This rate law [4] predicts the observed retardation at higher concentrations of ferricyanide. Since k_1/k_{-1} equals K, the equilibrium constant for the step [1], the rate law reduces to

$$[5] \quad -\frac{d[Fe(CN)_6^{3-}]}{dt} = \frac{2Kk_2[HC(OH)_2][OH^-][Fe(CN)_6^{3-}]}{[H_2O] + \frac{k_2}{k_{-1}}[Fe(CN)_6^{3-}]}$$

If the concentration of ferricyanide is sufficiently small,

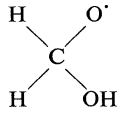
$$[H_2O] \gg \frac{k_2}{k_{-1}}[Fe(CN)_6^{3-}]$$

and eq. [5] becomes

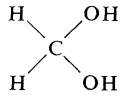
$$[6] \quad -\frac{d[Fe(CN)_6^{3-}]}{dt} = \frac{2Kk_2}{[H_2O]}[HC(OH)_2][OH^-][Fe(CN)_6^{3-}]$$

The observed third order rate constant would then be $2Kk_2/[H_2O]$. This has been calculated taking two different sets of conditions having approximately the same ionic strength. From Table I, the value of the third order rate constant is 0.092 mole^{-2} l^2 min^{-1} when $[Fe(CN)_6] = 0.01$ M, and from the Table IV it is 0.065 mole $^{-2}$ l^2 min^{-1} when $[Fe(CN)_6] = 0.20$ M. This degree of agreement is taken to substantiate the above mechanism.

The free radical



is rapidly oxidized to formic acid by reaction with more ferricyanide. Oxygen has a greater electron affinity than hydrogen; it shares immediately the hydrogen bonded electron of the carbon and the proton separates with simultaneous abstraction of the electron by hexacyanoferrate(III) ion. Although it is difficult to discuss the details of the oxidation of this free radical, it is apparent from the kinetic data that it is rapidly attacked by hexacyanoferrate(III) ion to yield formic acid as the final product. The formate ion is much more stable towards oxidation due to its mesomeric structure. A stoichiometric equation can be written as follows



$$[7] \quad + 3OH^- + 2Fe(CN)_6^{3-} \rightarrow HCO_2^- + 2Fe(CN)_6^{4-} + 3H_2O$$

The work has been extended to three temperatures and the summarized data are given in Table IX. The energy of activation is 12.0 kcal/mole.

TABLE IX

Effect of variation of temperature* on the psuedo first order rate constants† in formaldehyde

Temperature	$10^5 \times k'$
30	11.74
35	15.81
40	19.88
45	31.36

*Temperature in °C; [HCHO] = 0.25 × 10^{-2} M; [$K_3Fe(CN)_6$] = 0.20 M; [NaOH] = 1.00 M; μ = 2.2 M.
†Rate constants in s^{-1}.

Experimental

The kinetic study of the reaction was done with Analar (B.D.H.) grade samples. The reaction was initiated by mixing the requisite amount of formaldehyde solution with a solution of potassium ferricyanide and sodium hydroxide kept in a bottle coated with black Japan. The temperature of the reaction mixture was kept constant (±0.1°) using an electrically operated thermostat. The course of the reaction was followed at different intervals of time by estimating the amount of ferrocyanide ion produced. This was done by titration with a standard solution of ceric sulfate using ferroin as a redox indicator. The ionic strength of the medium was kept constant with a standard solution of sodium perchlorate.

Product Study

After complete reduction of the hexacyanoferrate(III) ion the organic acid was separated by extracting into ether followed by aqueous ammonia. The ammoniacal solution was employed to detect the anion of the organic acid by

paper chromatography. The stoichiometry of the reaction supports the conclusion that formic acid is the final product.

Nuclear magnetic resonance spectra of ortho-, meta-, and para-difluorobenzenes in a nematic liquid crystal solvent

C. T. YIM AND D. F. R. GILSON
Department of Chemistry, McGill University, Montreal, Quebec
Received October 4, 1968

The proton and fluorine magnetic resonance spectra of ortho-, meta-, and para-difluorobenzene dissolved in a nematic liquid crystal solvent have been analyzed. Expressions for the anisotropy of the fluorine chemical shift were obtained but an attempt to fit these to the Karplus and Das theory failed. Hydrogen atoms *ortho* to fluorine show small displacements from their expected positions.

Introduction

The use of nematic liquid crystal solvents for studying the nuclear magnetic resonance spectra of partially oriented solute molecules permits the determination of the anisotropies of chemical shifts, the absolute signs of indirect coupling constants, and, in certain cases, the geometry of the solute molecule (1–3). Saupe (4) has developed expressions for the average orientation of a solute molecule in terms of an order matrix $\boldsymbol{S}$, which Snyder (5) has re-defined in terms of the probability function of the orientation expanded in real spherical harmonics. In Snyder's notation the chemical shift in the nematic phase is given by

$$[1]\quad \bar{\sigma}_{zzi} = \tfrac{1}{3}(\sigma_{zzi} + \sigma_{xxi} + \sigma_{yyi}) + C_{3z^2-r^2}\frac{2}{3\sqrt{5}}[\sigma_{zzi} - \tfrac{1}{2}(\sigma_{xxi} + \sigma_{yyi})] + C_{x^2-y^2}\frac{1}{\sqrt{(15)}}(\sigma_{xxi} - \sigma_{yyi}) + C_{xz}\frac{1}{\sqrt{(15)}}(\sigma_{xzi} + \sigma_{zxi}) + C_{yz}\frac{1}{\sqrt{(15)}}(\sigma_{yzi} + \sigma_{zyi}) + C_{xy}\frac{1}{\sqrt{(15)}}(\sigma_{xyi} + \sigma_{yxi})$$

where $\sigma_{\alpha\beta}$ are the components of the nuclear shielding tensor, and the C terms are the motional constants.

The direct dipole coupling constants are given by

$$[2]\quad D_{ij} = \frac{\gamma_i\gamma_j}{\pi\sqrt{5}}\left\{C_{3z^2-r^2}\left[\left\langle\frac{(\Delta z_{ij})^2}{r_{ij}^5}\right\rangle - \frac{1}{2}\left\langle\frac{(\Delta x_{ij})^2}{r_{ij}^5}\right\rangle - \frac{1}{2}\left\langle\frac{(\Delta y_{ij})^2}{r_{ij}^5}\right\rangle\right] + C_{x^2-y^2}\frac{\sqrt{3}}{2}\left[\left\langle\frac{(\Delta x_{ij})^2}{r_{ij}^5}\right\rangle - \left\langle\frac{(\Delta y_{ij})^2}{r_{ij}^5}\right\rangle\right] + C_{xz}\sqrt{3}\left[\left\langle\frac{(\Delta x_{ij})(\Delta z_{ij})}{r_{ij}^5}\right\rangle\right] + C_{yz}\sqrt{3}\left[\left\langle\frac{(\Delta y_{ij})(\Delta z_{ij})}{r_{ij}^5}\right\rangle\right] + C_{xy}\sqrt{3}\left[\left\langle\frac{(\Delta x_{ij})(\Delta y_{ij})}{r_{ij}^5}\right\rangle\right]$$

where Δx_{ij}, Δy_{ij}, and Δz_{ij} are the components of the vector $\boldsymbol{r}_{ij}$ joining nuclei i and j, and the angular brackets indicate averages over the internal motions of the molecule.

For molecules with a threefold or higher axis of symmetry only one of the five possible motional constants is non-zero. Thus, for benzene (6), hexafluorobenzene (7), and 1,3,5-trifluorobenzene (2, 8) the anisotropy of the chemical shift can be determined directly. If a molecule has two perpendicular planes of symmetry but less than threefold symmetry, a suitable choice of axes leads to two non-zero motional constants and the anisotropy of the chemical shift is not

immediately defined. Snyder (5) has calculated the anisotropy of the fluorine chemical shift in monofluorobenzene by assuming that the C—F bonds in fluorobenzene and hexafluorobenzene are similar. The magnitude of the anisotropy obtained in this way was in reasonable agreement with the value obtained by Chan and Dubin (9) from molecular beam magnetic resonance measurements, but the values of $(\sigma_{yy} - \sigma_{xx})$ from the two methods were in considerable disagreement. Applications of the Karplus and Das theory (10) predicted the direction of the anisotropy found by Snyder but the relative magnitudes of σ_{xx} and σ_{yy} as found by Chan and Dubin.

In the present study we report the analyses of the proton and fluorine magnetic resonance spectra of ortho-, meta-, and para-difluorobenzene dissolved in a mixed nematic liquid crystal.

Experimental

Samples of difluorobenzenes were obtained from commercial sources and used without further purification. Spectra were recorded with a modified Varian DP60 spectrometer as previously reported (8). Solute concentrations and the temperatures of measurement were as follows

Compound	Amount (mole %)	Temperature (°C)
o-Difluorobenzene	36	64
m-Difluorobenzene	37	64
p-Difluorobenzene	33	67

Trifluoroacetic acid was used as an external reference for fluorine resonances. A solution of carbon tetrafluoride (4%) in the liquid crystal solvent showed a 13 Hz high field shift (at 56.4 MHz) on going from the nematic phase (65 °C) to the isotropic phase (104 °C) and a corresponding correction was made to all observed anisotropic shifts (11, 12).

Results

ortho-Difluorobenzene

The proton and fluorine magnetic resonance spectra of ortho-difluorobenzene are given in Fig. 1. The spectra are not symmetrical with respect to their centers due to the difference between the proton chemical shifts. Theoretical spectra were computed, using the program described previously (8), with initial values of the direct coupling constants calculated for a regular molecular structure with bond distances of C—C = 1.39 Å, C—H = 1.08 Å, and C—F = 1.31 Å, all bond angles were assumed to be 120°. The appearance of the spectra depend essentially on the ratio of the two motional constants. Trial calculations were commenced with an arbitrarily chosen value of −0.25 for $C_{3z^2-r^2}$ and neglecting the indirect spin coupling constants and proton chemical shift difference. After approximate values of $C_{3z^2-r^2}$ and $C_{x^2-y^2}$ were obtained, the indirect coupling constants and proton shifts were included, and the theoretical spectrum was recalculated. Examination of the spectrum showed that certain lines bore simple fixed relationships to the coupling constants, viz.

$$\nu_Q(F) \text{ and } \nu_{P'}(F) = 1/2(D_{12} + D_{13} + D_{25} + D_{26} + J_{12} + J_{13} + J_{25} + J_{26}) + 3/4D_{23}$$

$$\nu_I(F) \text{ and } \nu_{J'}(F) = 1/2(D_{12} + D_{13} + D_{25} + D_{26} + J_{12} + J_{13} + J_{25} + J_{26}) - 3/4D_{23}$$

The spectral parameters were optimized while maintaining a reasonable fit to the positions of the lines. The best fit to the fluorine spectrum was obtained with all J_{ij}, except J_{35} and J_{56}, positive with respect to D_{ij}, but for the proton spectrum the agreement between theoretical and experimental spectra was not as satisfactory under the combined variation of the two motional constants and the chemical shift with both possible

para-Difluorobenzene

The higher molecular symmetry of para-difluorobenzene led to a simpler method of spectral analysis. Instead of computing a theoretical spectrum and comparing it with the experimental spectrum, a perturbation method was used which gave simple expressions for the transition energies. This was possible because the spectrum was dominated by the dipole coupling between the ortho protons. Recently Bulthuis, Gerritsen, Hilbers, and McLean (13) have given a detailed discussion of this method and its application to the analysis of the spectra of symmetrically para-disubstituted benzenes, including para-difluorobenzene, dissolved in nematic 4,4′-di-*n*-hexyloxyazoxybenzene[1].

In the first order approximation the proton half-spectrum should consist of five triplets with a splitting equal to $1/2(D_{12} + D_{13} + J_{12} + J_{13})$. In the actual spectrum, Fig. 3*a*, only four triplets were observed, due to coincidence of lines C and D, H and I, M and N.

The fluorine spectrum, Fig. 3*b*, consisted essentially of ten lines based on a quintet, with a splitting $1/2(D_{12} + D_{13} + J_{12} + J_{13})$, each line of which was further split into a doublet with separation $3/2D_{14}$. A further small splitting due to second order effects was also observed. Analysis of the spectra only gave values of D_{14}, D_{23}, D_{25}, D_{26}, and $1/2(D_{12} + D_{13} + J_{12} + J_{13})$ and the magnitudes and signs of the remaining indirect coupling constants could not be obtained.

This perturbation method has been applied to the analysis of the spectra of some partially oriented para-substituted fluorobenzene derivatives and will be discussed further in a subsequent publication.

Final parameters for para-difluorobenzene are given in Table III and the computer simulated spectra are shown in Fig. 3.

Discussion

Indirect Coupling Constants

The magnitudes and absolute signs of the indirect coupling constants are listed in Tables I, II, and III and are in agreement with those reported from isotropic spectra in the literature (14–16). The signs of the indirect proton–fluorine

coupling constants are all positive except J_{HF}^{para} which is negative. J_{FF} in ortho-difluorobenzene is negative.

Anisotropy of the Fluorine Chemical Shifts

As discussed earlier, when two motional constants are required, the anisotropy of the chemical shift cannot be obtained directly. In Table IV the anisotropies are expressed as equations of the form

$$[4] \qquad A\sigma_{aa} + B\sigma_{bb} + C\sigma_{cc} = D$$

where the molecule fixed axes x, y, and z have been transformed to axes; a (perpendicular to the molecular plane), b (along the C—F bond), and c (in the molecular plane and perpendicular to the C—F bond). It is assumed that a, b, and c are the principal axes of the paramagnetic shielding tensor, which is an approximation for the ortho and meta derivatives. Also included in Table IV are the results for monofluorobenzene (5), 1,3,5-trifluorobenzene (8), and hexafluorobenzene (7). If, as Snyder has assumed, these results are consistent, then the expressions for any two molecules can be used to determine the anisotropy. Snyder obtained $(\sigma_{bb} - \sigma_{cc}) = 259$ p.p.m. for monofluoro- and hexafluorobenzene. With the most favorable cases, i.e. those without orthosubstituents, the values of $(\sigma_{bb} - \sigma_{cc})$ are; 96 p.p.m. (monofluorobenzene and meta-difluorobenzene), 70 p.p.m. (monofluorobenzene and para-difluorobenzene), 83 p.p.m. (meta-difluorobenzene and para-difluorobenzene), 123 p.p.m. (monofluorobenzene and 1,3,5-trifluorobenzene), and 162 p.p.m. (meta-difluorobenzene and 1,3,5-trifluorobenzene). The assumption that the carbon–fluorine bonds are sufficiently similar is not justified and this may account for the apparent disagreement between the results of Snyder (5) and those of Chan and Dubin (9). The latter results, however, disagreed in sign with the predictions of the Karplus and Das theory (10). This theory, originally intended for the calculation of isotropic chemical shifts, can be used to express the shielding tensor components, and hence the anisotropy, in terms of the bond parameters; hybridization s, ionic character I, and double bond character ρ.

$$[5] \qquad \sigma_{aa} = \frac{3}{2}\sigma_0\{1 - s - I + Is\}$$

$$[6] \qquad \sigma_{bb} = \frac{3}{2}\sigma_0\{\rho\}$$

$$[7] \qquad \sigma_{cc} = \frac{3}{2}\sigma_0\{1 - s - I + Is + \rho(s + I)\}$$

where

$$\sigma_0 = -\left(\frac{2e^2h^2}{3m^2c^2\Delta E}\right)\left\langle\frac{1}{r^3}\right\rangle_{2p}$$

ΔE = average excitation energy

$\left\langle\frac{1}{r^3}\right\rangle_{2p}$ = the expectation value of $\frac{1}{r^3}$ for the 2p orbital.

For monofluorobenzene, Karplus and Das assumed values of $s = 0.05$, $I = 0.75$ (from electronegativity considerations), and $\rho = 0.126$ (from Hückel molecular orbital calculations). For the difluorobenzenes double bond character was calculated but the changes in ionic character were obtained empirically. The value for ortho-difluorobenzene was unacceptable and will not be considered in the present study. If the values for s, I, and ρ given by Karplus and Das are substituted in eqs. [5]–[7] and the resulting σ_{aa}, σ_{bb}, and σ_{cc} substituted in eq. [4], acceptable values of σ_0 are not obtained. The calculated anisotropy in 1,3,5-trifluorobenzene is zero. There remain more unknown than known terms in the Karplus and Das treatment and it is possible that the adjustment of a sufficient number of empirical parameters could lead to agreement with the experimental results. It is also possible that the theory is strained too far in applying it to the calculation of chemical shift anisotropies. It should be noted that we have assumed that the anisotropies measured in nematic solvents represent the true values and do not involve large contributions due to the highly anisotropic environment (11, 12). The average excitation energy and the average inverse cube function for a p orbital are also assumed to be constant, and, for the difluorobenzenes these should be valid approximations.

Various other methods have been used to calculate isotropic chemical shifts in substituted fluorobenzenes (17–20). The trends in chemical shifts have been correlated with π electron densities with moderate success, although Emsley (20) remains sceptical that reliable predictions can be made by these methods. In all cases assumptions are made: an invariant sigma framework, empirical values for ionic character, empirical (sometimes negative) average excitation energies, which render these methods unsuitable for calculation of anisotropies.

Molecular Geometry

The optimized direct dipole coupling constants can be used to recalculate the molecular geometry but, since the nuclear coordinates in eq. [2] are multiplied by the motional constants, the derived distances are all relative and a linear change in the molecular geometry will be compensated by changes in the motional constants, and it is necessary to assume fixed values for certain nuclear coordinates. The direct dipole coupling constants, calculated for "ideal" geometry based on a regular hexagonal carbon skeleton, with C—C = 1.390 Å, C—H = 1.080 Å, and C—F = 1.310 Å, all bond angles 120°, disagreed with experimental values in some cases. For para-difluorobenzene a positive pseudo-dipole coupling constant of about 100 Hz occurred for the ortho hydrogen atoms; the geometry, therefore, is not ideal. The hydrogen atom positions were determined with respect to fixed fluorine atoms placed 2.700 Å from the origin at the center of the molecule. Trial values of the x and y coordinates were used to determine the motional constants from experimental values of D_{23} and D_{26} and then the motional constants and trial coordinates were used to calculate D_{25} and $(D_{12} + D_{13})$, which were compared with experiment. The process was repeated until agreement was within the experimental error. The final coordinates are given in Table V. The departure from ideal geometry is such that the hydrogen atoms are displaced toward neighboring fluorine atoms. In para-difluorobenzene this positional change cannot be accounted for by altering the C—C—H bond angle only, but also requires changes in the carbon–carbon bond lengths. Since, in this analysis, the fluorine coordinates were fixed, the changes appear as increases in the C_1—C_2, C_1—C_6, and C_3—C_4, C_4—C_5 bond distances but a decrease in C_2—C_3 and C_5—C_6 bonds could also be involved. These are the changes expected from a contribution from the quinoid type structure arising from conjugation of the fluorine substituent with the ring. To determine the actual bond shortening and lengthening and angular distortion would require further assumptions regarding nuclear coordinates and is not justified.

McLean *et al.* (13) have computed the geometry of para-difluorobenzene from their experimental dipolar coupling constants but by a different procedure. They compared the ratios

6	−2.139	(1.235)	(−2.338)	1.350	−2.141	1.261

*Assumed coordinates are in parentheses.

of the distances r_{26} to r_{23}, and r_{14} to r_{13}. These ratios are 1.6988 and 2.1335, respectively. The corresponding values from our analysis are 1.6979 and 2.1412.

The nuclear coordinates of ortho- and meta-difluorobenzene were calculated by a similar procedure and are given in Table V. A similar effect was observed. The hydrogen atoms ortho to fluorine were displaced toward the fluorine atom. If distortion of the carbon skeleton is assumed for ortho-difluorobenzene, it is in the direction opposite to that expected as a result of fluorine conjugation. The displacements are small but consistent and a similar effect has been reported for para-dichlorobenzene (21). In the discussion of internuclear distances derived from nuclear magnetic resonance spectra in nematic solvents it should be noted that a value appropriate to $(r^3)^{1/3}$, not r_0, is obtained, and then an average is taken over all internal motions of the molecule. Snyder and Meiboom (22) have explained discrepancies in bond lengths in cyclopropane as due to large amplitudes of vibration but the harmonic and anharmonic corrections to $(r^{-3})^{1/3}$ are of opposite sign (23) and cannot be applied without knowledge of their magnitudes from a complete vibrational analysis.

NOTES

Gas phase photochlorination of perfluorocyclohexene

J. J. Cosa, C. A. Vallana, and E. H. Staricco

Departamento de Fisicoquímica, Instituto de Ciencias Químicas, Universidad Nacional de Córdoba, Ciudad Universitaria, Córdoba, Argentina

Received September 9, 1968

The kinetics of the gas phase photochemical reaction between perfluorocyclohexene and chlorine was studied between 10 and 50 °C. The system was irradiated with light of 4360 Å. The rate of the photochlorination was independent of the perfluorocyclohexene pressure and of the total pressure. It was found to be proportional to the first power of the pressure of Cl_2 and to the square root of the intensity of absorbed light. At 30 °C, the quantum yield was found to be 200 when the initial Cl_2 pressure was 100 Torr, and intensity of light absorbed 9.89×10^{-9} einstein l^{-1} s^{-1}.

An activation energy of 5.1 kcal/mole could be assigned to the reaction $C_6F_{10}Cl + Cl_2$.

Canadian Journal of Chemistry, **47**, 1067 (1969)

Introduction

Much attention has been devoted to the gas phase photochlorination of olefins (1, 2) and recently some new contributions have been made (3, 4). It cannot, however, be regarded as yet completely understood in all respects. It was thought that studies on the photochlorination of cyclic olefins may contribute to the knowledge of the radical reactions involved subsequently to the addition of a chlorine atom to an olefin.

We found that cyclohexene and cyclopentene readily reacted in the gas phase when mixed with Cl_2 in the dark at room temperature, and that neither reaction was inhibited by NO or O_2. The replacement of the hydrogen atoms by fluorine decreased the thermal reaction and in fact, between Cl_2 and perfluorocyclohexene no thermal reaction took place up to 70 °C.

When the gaseous mixture was irradiated with light of 4360 Å a reaction occurred with a lowering of the total pressure. The present paper is concerned with the kinetics of the photochlorination of perfluorocyclohexene.

Experimental

Experiments were performed in a conventional high vacuum system. The reactor was a Pyrex cylinder 10 cm long, 174 ml in volume, and fitted with number 7740 Corning glass windows.

The course of the reaction was followed manometrically with a quartz spiral manometer connected to the reactor by a quartz glass graded seal. This manometer was used as a null instrument in connection with a mercury manometer.

The light source was an Osram HBO 200 mercury lamp. A practically parallel and homogeneous beam of wavelength 4360 Å was obtained by employing quartz lens, diaphragms, and Schott filters. The intensity of the incident light was measured with a compensated Kipp thermopile and a Microva galvanometer.

The use of any type of grease in the reaction system was avoided, and instead of stopcocks, aluminium valves with Teflon gaskets and nickel needles were employed.

The perfluorocyclohexene was purchased from Imperial Smelting Corp. It was purified by refluxing over KOH, distilled under nitrogen atmosphere, and then injected into a gas chromatograph equipped with a Porapak Q column at 180 °C. It was finally trap to trap distilled in vacuum at low temperature and stored in a trap cooled with liquid air. Chlorine and carbon dioxide were obtained from cylinders and conventionally purified.

Runs were performed in a darkened room and the reactor was protected against stray radiation. The experiments were carried out in the range of temperatures from 10–50 °C. Temperature was controlled by means of a circulating thermostat and the reactor was housed in such a way that the water did not intersect light beam.

Results

The variation of pressure of the system indicated that the stoichiometry of the reaction was

$$C_6F_{10} + Cl_2 = C_6F_{10}Cl_2$$

as could be proved in runs with excess Cl_2 and carried out to full conversion. Infrared and gas chromatographic determinations showed that the only product was $C_6F_{10}Cl_2$.

In order to determine the rate law, experiments were performed at 30 °C with variation of the initial pressure of Cl_2 between 25–200 Torr, and that of C_6F_{10} between 25–100 Torr. Most

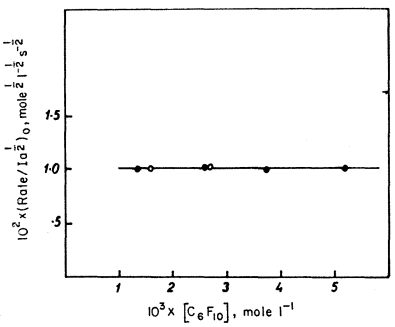

FIG. 1. Initial rate/$I_{abs}^{\frac{1}{2}}$ vs. initial pressure of C_6F_{10}. ○, runs with addition of 400 Torr CO_2. In all experiments pressure of Cl_2 = 50 Torr and temperature = 30 °C.

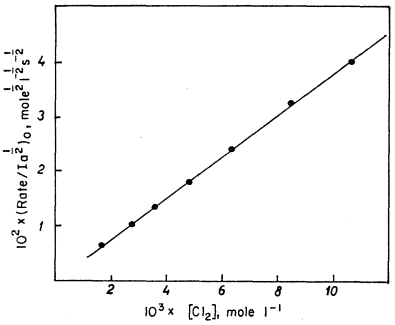

FIG. 2. Initial rate/$I_{abs}^{\frac{1}{2}}$ vs. initial pressure of Cl_2. Pressure of C_6F_{10} = 100 Torr in all experiments and temperature = 30 °C.

of the runs were performed up to 50% conversion or more. They showed excellent reproducibility and had no induction period.

In Fig. 1 it is shown that the rate of photochlorination for a given pressure of Cl_2 is independent of the pressure of C_6F_{10}. The plot of Fig. 2 shows that the rate was proportional to the first power of the pressure of Cl_2. In both figures the initial rate was obtained by the method of Letort (5).

The variation of total pressure by means of the addition of inert gases such as CO_2 does not affect the rate, as is also shown in Fig. 1.

The dependence of rate on the intensity of light was determined by inserting a calibrated neutral filter in the light beam. The filter transmitted 51% of the incident light and it was found that the rate of photochlorination diminished to 71% of the rate of runs carried out without the filter and with the same initial pressure of reactants, showing that the rate varied with the square root of the intensity of absorbed light. Therefore the rate of photochlorination can be represented by the following expression

$$[A] \qquad \frac{d(C_6F_{10}Cl_2)}{dt} = k(Cl_2)(I_{abs})^{\frac{1}{2}}$$

This rate law proved to be valid up to 25% conversion in runs with 100 Torr Cl_2 and 25 Torr C_6F_{10}, and to 80% conversion in runs with 200 Torr Cl_2 and 100 Torr C_6F_{10}.

Experiments carried out at 10, 20, 30, 40, and 50 °C enable one to obtain an apparent activation energy of 5.1 kcal/mole from the Arrhenius plot (Fig. 3). The value of k was calculated from the above equation with Cl_2 in units of mole l^{-1} and I_{abs} in einstein l^{-1} s^{-1}.

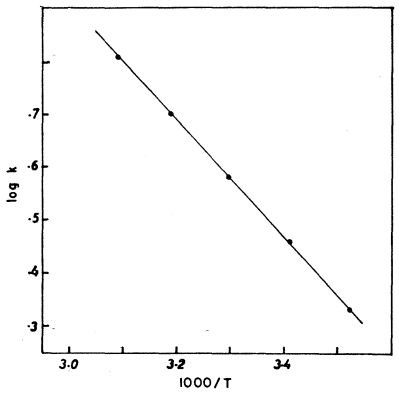

FIG. 3. Arrhenius plot of the reaction, k in mole^{-1} $l^{\frac{1}{2}}$ $s^{-\frac{1}{2}}$.

The light measurements gave a value for the intensity of the incident light to be 5.465×10^{-8} einstein l^{-1} s^{-1}. For a run at 30 °C, 100 Torr initial pressure of Cl_2, and 9.89×10^{-9} einstein l^{-1} s^{-1} of absorbed light, it was evident that a chain reaction took place with a quantum yield of 200.

Discussion

The results obtained support the following mechanism:

$$[1] \qquad Cl_2 + h\nu \rightarrow 2Cl$$

$$[2] \qquad Cl + C_6F_{10} \rightarrow C_6F_{10}Cl$$

$$[3] \qquad Cl_2 + C_6F_{10}Cl \rightarrow C_6F_{10}Cl_2 + Cl$$

$$[4] \qquad 2C_6F_{10}Cl \rightarrow C_6F_{10} + C_6F_{10}Cl_2$$

Stationary state treatment gives

$$\frac{d\,C_6F_{10}Cl_2}{dt} = (k_3/k_4^{\frac{1}{2}})(Cl_2)(I_{abs})^{\frac{1}{2}}$$

which is in agreement with [A] if one puts $k = k_3/k_4^{\frac{1}{2}}$.

The length of the chain does not permit an insight, from a kinetic point of view, of the nature of reaction [4], although experimental evidence of the product of the reaction rather supports a disproportionation. To a first approximation the value of the activation energy of reaction [4] may be considered negligible, and therefore the experimental value of 5.1 kcal can be assigned to the reaction $C_6F_{10}Cl + Cl_2$. This value is comparable with the corresponding activation energies for the reaction between the chloroalkyl radical and Cl_2 in the photochlorination of perfluoro-2-butene (6), tetrachloro- (7, 8) and trichloro-ethylene (8–10), and 1,1-dichloro-2,2-difluoroethylene (4).

From the values of $k_3/k_4^{\frac{1}{2}}$ and of the activation energy one obtains log $A_3/A_4^{\frac{1}{2}} = 4.3$ mole$^{-\frac{1}{2}}$ l$^{\frac{1}{2}}$ s$^{-\frac{1}{2}}$.

In a comparative study of the photochlorination of chloroethylenes, Dainton *et al.* (3) assume that a repulsive effect between the chlorine atoms on the carbon bearing the unpaired electron, and the chlorine molecule accounts for an increment in activation energy of the propagation reaction as the number of chlorine atoms in the chloroalkyl radical increases. If this view is also taken as valid in the interpretation of the data on the photochlorination of chlorofluoroethylenes (4, 11, 12) it may be concluded that the repulsive effect of fluorine atoms is lower than that of chlorine atoms. The rather high values of 5.1 kcal found in the present case can be justified assuming a repulsive effect between the ring and the chlorine molecule. An activation energy of approximately 5 kcal in the photochlorination of perfluorocyclopentene (13) supports, to some extent, this view.

Preparation of β-rhenium tetrachloride

P. W. Frais, A. Guest, and C. J. L. Lock[1]

Department of Chemistry and Institute for Materials Research, McMaster University, Hamilton, Ontario

Received October 21, 1968

β-Rhenium tetrachloride has been prepared by three different methods. Infrared, magnetic, and X-ray powder diffraction data are reported.

Canadian Journal of Chemistry, **47**, 1069 (1969)

Introduction

There are a number of reports of rhenium tetrachloride in the literature. However, early reports of the preparation of this compound (1–3) have been discounted (4, 5). More recently, Brown and Colton claimed to have prepared rhenium tetrachloride (6), but no detailed report on the properties of this material has been given. Cotton *et al.*

(7) subsequently reported a series of reactions on a material they called β-rhenium tetrachloride to distinguish it from Colton's material. Cotton *et al.* obtained β-rhenium tetrachloride under the name of rhenium(III) chloride from the Shattuck Chemical Company. The preparation conditions had not been recorded and the company was not able to make any more of the material. Thus, there exists the anomaly of an extensive chemistry of a material for which no preparative method is available. We now report three ways of making β-rhenium tetrachloride.

Experiments

Analyses for rhenium and chlorine were performed by neutron activation analysis in the McMaster University Reactor using a method described by us previously (8). Carbon and hydrogen analyses were performed by A. B. Gygli, Toronto.

Infrared (i.r.) spectra were recorded for solid samples ground into a mull with Nujol. The Nujol had been dried by reflux with phosphorous pentoxide followed by vacuum distillation. The mull samples were mounted between potassium bromide or polyethylene plates and spectra were recorded on Perkin–Elmer 337 and 301 spectrometers. X-ray diffraction photographs of powdered samples were recorded on a Debye–Scherrer camera. Samples were sealed inside quartz tubes. Copper radiation was used for recording the photographs. Line intensities were measured from the powder photographs using a Joyce–Loebl microdensitometer.

Measurements of magnetic susceptibility were made by the Gouy method. The apparatus used was based on the Gouy System sold by Alpha Scientific Laboratories, Inc., Berkeley, California. The cooling and temperature control were changed to a system similar to that described by Earnshaw (9)[2]. The electronic bridge was designed and built by Schonfeld of this University. Sample temperatures could be maintained to ± 0.01 °C at -180 °C and to ± 0.1 °C at 0 °C. Sample weight changes were recorded on a Sartorius Electrono I microbalance. Sample tubes were 3 mm outer diameter quartz tubes. The tubes were filled with finely ground sample in a dry-box and sealed. Packing errors in these small tubes were limited to $\sim 5\%$ by vibrating the tubes in the vibrator of a Hoover (Philadelphia) Unimelt melting point apparatus. The tubes and field were calibrated with powdered mercuric tetrathiocyanotocobaltate(II) (10). The magnetic apparatus is described in detail elsewhere (11).

Preparation (a)

Powdered rhenium metal (0.5 g) (99.9% pure by weight) and antimony pentachloride (mole ratio $Re:SbCl_5 \simeq 1:2.5$) were sealed in a "Vycor" tube. The tube was constricted in the middle so that it was composed of two sections, A and B, joined by a narrow neck. The sealed tube was heated in a tube-furnace at 600° C until all the metal had reacted (about 48 h). The tube was moved along the furnace, so that the end B was out of the furnace and at room temperature. Material condensed in B. When this material no longer increased in amount, the furnace temperature was reduced to 250 °C and the tube was reversed, so that B was at the furnace temperature and A was at room temperature. Excess antimony pentachloride and some antimony trichloride distilled into A, leaving a black solid in B. The tube was opened in a dry-box and the black solid transferred to a test-tube fitted with a ground-glass joint. The tube was stoppered, removed from the dry-box, and transferred rapidly to a vacuum line. The black solid was kept under vacuum at room temperature for 12 h. The temperature was raised slowly to 160 °C (4 h) and held at 160 °C for 48 h to remove all traces of volatile impurity. A small amount of impurity volatized at 160 °C and condensed at a cold spot in the vacuum line. Neutron activation analysis of the volatile material showed that the Re:Cl atom ratio was $1:5.2 \pm 0.1$, suggesting that it was mainly rhenium pentachloride. A black crystalline residue was left in the tube. The tube was sealed and the product stored in a dry-box. Yields up to 75% have been recorded.

Preparation (b)

Approximately equimolar quantities of rhenium pentachloride and antimony trichloride were sealed in a Pyrex glass tube similar to the tube used in preparation (*a*). The tube was heated for 48 h at 300 °C, and the resulting black product was purified in a manner similar to that described above. The yield was nearly quantitative.

Preparation (c)

Rhenium trichloride (0.25 g) and rhenium pentachloride (0.5 g) were sealed in a Vycor tube in a dry-box. The tube was heated to 600 °C for 24 h, then allowed to cool to room temperature. A black powder was obtained. The material was shown to be β-rhenium tetrachloride by comparison of an X-ray powder photograph of the product with that of a pure sample. The contaminants were rhenium pentachloride and rhenium trichloride. The yield was about 20%. No attempt was made to vary the conditions as the only purpose of the preparation was to confirm a possible way in which β-rhenium tetrachloride could have been made accidentally by the Shattuck Chemical Company. It may be possible to obtain better yields of a more pure product by this method but preparation (*b*) is a more satisfactory way of preparing β-rhenium tetrachloride[3].

The materials obtained from preparations (*a*) and (*b*) were shown to give identical powder photographs. Analysis of a number of samples showed the Re:Cl atom ratio was $1:4.01 \pm 0.08$. Exposure to air gave a sticky black mess. The material was insoluble in acetonitrile, tetrahydrofuran, benzene, and carbon tetrachloride. The material dissolved slowly in methanol, ethanol, acetone, and dimethyl sulfoxide, and, from the color changes, subsequently decomposed. The material reacted with hydrochloric acid to give a blue solution which later decomposed. Heating the material at 300 °C in nitrogen

[2]Variable-temperature Gouy balance system. Newport Instruments Ltd., Newport Pagnell, Buckinghamshire, England, 1966.

[3]Canterford and Colton have recently prepared β-$ReCl_4$ by a similar method (18).

caused slow decomposition to Re_3Cl_9 and Re_2Cl_{10}. These were separated in a thermal gradient and identified by neutron activation analysis. Rapid reaction of the material dissolved in concentrated hydrochloric acid with tetra(*n*-butyl)ammonium bromide gave blue tetra(*n*-butyl)ammonium octachlorodirhenate(III). The product was identical with that of an authentic sample prepared by a standard method (7).

Anal. Calcd. for $C_{32}H_{72}Cl_8N_2Re_2$: C, 33.6; H, 6.4; Cl, 24.8. Found: C, 33.1; H, 6.4; Cl, 23.1.

This reaction is considered by Cotton to be characteristic of β-$ReCl_4$. The i.r. spectrum of β-rhenium tetrachloride showed no bands between 4000 and 400 cm^{-1}. Observed bands were 369 cm^{-1}, strong; 294 cm^{-1}, weak; 244 cm^{-1}, weak; 166 cm^{-1}, shoulder; 158 cm^{-1}, medium.

Results and Discussion

Many properties of β-rhenium tetrachloride have been described (7) but no preparative method has been published. The black material produced by us appears to be identical to β-rhenium tetrachloride described by Cotton *et al.* (7). Analysis shows that the Re:Cl atom ratio was 1:4 and the absence of bands in the i.r. spectrum from 4000 to 400 cm^{-1} suggests that groups such as Re—O, Re—O—Re, Re=O, and O=Re=O which might be expected to cause absorption in this region (12), are absent. The far-infra-red spectrum was recorded for a Nujol mull of β-rhenium tetrachloride mounted between polyethylene plates and four bands were observed between 400 and 150 cm^{-1}. However, the polyethylene plates were attacked so that it cannot be stated whether the bands observed are caused by β-rhenium tetrachloride or decomposition products. The strong band at 369 cm^{-1} is in the range associated with metal–chlorine vibrations but is higher than the 318 cm^{-1} of ν_{Re-Cl} in the hexachlororhenates (14) and ν_{Re-Cl} observed in this laboratory for several rhenium complexes (15). However, 369 cm^{-1} is the frequency found for ν_{Re-Cl} in rhenium oxotetrachloride which might be present as a decomposition product (11).

The chemical reactions of the material are identical to those described by Cotton *et al.* (7) and it has proved possible to index the powder pattern of the material using the unit cell parameters given by Cotton for β-rhenium tetrachloride (13). These were a = 6.366 (5) Å, b = 6.282 (6) Å, c = 12.165 (6) Å, β = 93.17 (10)° space group Pc or $P2/c$. The calculation was done on an IBM 7040 computer using the program DESLID written by Robertson. The results are presented in Table I.

The magnetic susceptibility of β-rhenium tetrachloride was measured over the range 100–300 °K

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

at 20 °K temperature intervals. The susceptibility is independent of temperature and was 1010 × 10^{-6} c.g.s.u. in all measurements. The magnetic results can be interpreted as an indication that β-$ReCl_4$ contains no unpaired electrons in the ground state. Cotton *et al.* (13) cite a minimum Re–Re interatomic distance of 2.73 Å and consider this to be short enough to indicate some metal–metal interaction. Our observations also require such an interaction to force pairing of the unpaired electrons of pairs of d^3 Re(IV) atoms.

The mechanism of formation appears to be a simple reduction

$$2ReCl_5 + SbCl_3 \rightarrow 2ReCl_4 + SbCl_5$$

and the metal might also react through a similar path

$$SbCl_5 \rightarrow SbCl_3 + Cl_2$$

$$2Re + 5Cl_2 \rightarrow Re_2Cl_{10}$$

Further evidence in favor of this mechanism is that Re_2Cl_{10} and $SbCl_5$ do not give $ReCl_4$ even after heating to 600 °C for a week. In addition, the yield of $ReCl_4$ is reduced very greatly if chlorine is added to the Re + $SbCl_5$ reaction mixture. It has been stated (16) that rhenium metal is not attacked by chlorine when sealed in a static system, but this is not true as we have prepared $ReCl_5$ from the metal in this manner.

The original sample of rhenium tetrachloride was isolated from a reaction designed to give rhenium trichloride (7). It was noted that the temperature of reaction was somewhat lower than normal and we suspect that the flow rate of nitrogen was very low. Probably conditions were just right for the occurrence of reactions of the type

$$3Re_2Cl_{10} \rightarrow 2Re_3Cl_9 + 6Cl_2$$

$$3Re_2Cl_{10} + 2Re_3Cl_9 \rightarrow 6Re_2Cl_8$$

The reasons for failure to prepare $ReCl_4$ in subsequent preparations can be seen when it is realized that the last reaction proceeds from right to left at 300 °C if the products are allowed to separate. The normal conditions for the preparation of rhenium trichloride require a temperature of 450 °C (17) and a flow of nitrogen gas over the reactants which gives a facile separation of rhenium trichloride and rhenium pentachloride in the thermal gradient. It is hardly surprising that no rhenium tetrachloride is formed. Reaction of rhenium trichloride and rhenium pentachloride in a closed system produced some rhenium tetrachloride suggesting that this postulate is probably correct.

We conclude that we have successfully synthesized the elusive β-rhenium tetrachloride.

Infrared studies of *cis*- and *trans*-bis(halogenoacetato)bis(ethylenediamine)-cobalt(III) complexes

EDWARD B. KIPP AND ROLAND A. HAINES
Department of Chemistry, University of Western Ontario, London, Ontario

Received September 3, 1968

The infrared spectra have been studied for *cis*- and *trans*-isomers of complexes of the type $[Co(en)_2(halac)_2]ClO_4$, where en = ethylenediamine and halac = $CH_3CO_2^-$, $CH_2ClCO_2^-$, $CHCl_2CO_2^-$, $CCl_3CO_2^-$, $CHBr_2CO_2^-$, and $CF_3CO_2^-$. Characteristic differences between the spectra of *cis*- and *trans*-isomers have been examined and correlated with data for similar complexes. The most consistent variations are in the 500–610 cm^{-1} region where Co—N stretching modes occur.

Several methods (1) have been applied with varying degrees of success to the problem of differentiating between *cis*- and *trans*-isomers of bis(ethylenediamine)cobalt(III) complexes. Visible, ultraviolet, infrared, and proton magnetic resonance spectra all may be employed and have given reliable data when used in conjunction with one another. However, each method has shown some irregularities and it is desirable to examine more complexes of this type in order to evaluate the utility of any particular technique. A series of complexes of the type $[Co(en)_2(halac)_2]^+$ have been prepared[1] (2) and the geometric configurations have been assigned on the basis of visible and ultraviolet spectra (3). In the course of our studies on the resolution of the *cis*-isomers of these complexes, we have found interesting features in the infrared spectra of the *cis*- and *trans*-isomers which can be of help in assessing infrared assignments of isomerism and we wish to report them here.

Recently attempts have been made to correlate the configurations of bis(ethylenediamine)-cobalt(III) complexes with the positions and multiplicity of infrared absorption bands. Most of the interest has been centered on the vibrational modes of the NH_2 and CH_2 groups of the ethylenediamine cobalt ring system.

Merritt and Wiberley (4) have suggested that differentiation between *cis*- and *trans*-isomers of bis(ethylenediamine)cobalt(III) complexes may be made on the basis of a shift of the NH_2 asymmetric deformation in the 1550 – 1600 cm^{-1} region to larger frequencies, on changing from *cis*- to *trans*-isomers. The differences in the spectra of the complexes $[Co(en)_2(halac)_2]^+$ are in general agreement with this as indicated by the data in Table I. The one exception was the *trans*-dichloroacetato complex, where the band for the *trans*-isomer was at a lower frequency than that for the corresponding *cis*-isomer. However, with the series of complexes reported here, there is a possibility of the NH_2 asymmetric deformation mode overlapping with the CO asymmetric stretching mode of the halogenoacetato group and this could possibly cause some differences in this region.

Attempts have also been made to correlate configuration with the multiplicity (5) of bands in the 1600 cm^{-1} region. The *cis*-isomer has a lower symmetry than the *trans*-isomer and thus should have a more complex band structure. No such correlation could be made with the complexes studied, perhaps as a result of overlapping of the vibrational modes mentioned previously.

Baldwin (6) has suggested that the most consistent variations between the spectra of *cis*- and *trans*-isomers are found in the CH_2 rocking region (870–900 cm^{-1}). The *cis*-isomers always show two peaks, whereas the *trans*-isomers usually have only one. These bands are insensitive to changes in the ligands or anions. The data in Table I indicate that generally the complexes studied followed the previous trends. The drawback with this region is due to the fact that the CH_2 rocking bands are usually weak and are thus difficult to observe. This is shown with the trichloroacetato complex where both *cis*- and *trans*-isomers show only one band in this region. This is due to the weak CH_2 rocking mode being partially obscured by a strong band at 843 cm^{-1}

[1]Where en is ethylenediamine and halac is the anion of a halogenoacetic acid.

which can be assigned to the CCl_3 symmetric stretching mode (7).

The significant exception for this region is the *trans*-acetato complex which shows two bands, one of medium intensity. The presence of two distinct bands for this isomer may be due to coupling of the NH_2 and CH_2 rocking vibrations (8).

A satisfactory correlation between infrared spectra differences and geometric configuration can best be obtained from the 500–610 cm^{-1} region. Hughes and McWhinnie (9) found that in this region no *trans*-complex had more than three strong bands, while all *cis*-complexes had at least four bands, sometimes occurring as shoulders. These observations were also found in the complexes in this study, as indicated in Table I, the exception here being the *trans*-trichloroacetato complex which has one extra band. The band patterns also differ from *cis*- to *trans*-isomers, as shown in Fig. 1. The bands for the *trans*-complexes are generally evenly distributed in the range 500–610 cm^{-1}, whereas for the *cis*-complexes the bands in this region tend to occur in two groups with wide separation between them.

Tentative assignments were made by Hughes and McWhinnie for bands in the 500–610 cm^{-1} region to Co—N stretching modes (9). This was based on the work of Powell and Sheppard (10) on some ethylenediamine complexes of transition metals. A study of the single crystal spectrum of *trans*-$[Co(en)_2Cl_2]Cl$ (8) has supported these assignments. Of the six *cis*-isomers and six *trans*-isomers examined, all could be identified as such either by the number of bands or by the spacing of the bands in the 500–610 cm^{-1} region of the infrared spectrum.

Thus, although all three of the infrared regions which have been considered are useful for identifying *cis*- and *trans*-isomers, only spectra from 500–610 cm^{-1} region gave complete differentiation. This region is applicable to most complexes of the type $[Co(en)_2X_2]^+$ regardless of the ligands or anions involved. The data for the series of complexes studied in this note support the conclusions made by Hughes and McWhinnie (9) and give the same assignments

Diffusion of gases in liquids: the constant size bubble method

WING Y. NG AND JOHN WALKLEY

Simon Fraser University, Department of Chemistry, Burnaby 2, British Columbia

Received August 28, 1968

A method is described by which the diffusion of a gas in a liquid is measured by maintaining a bubble of the gas at constant size in the liquid. A steady state solution to the diffusion equation is seen to fit the observed experimental data. The measured diffusion coefficients for nitrogen, oxygen, and carbon dioxide in water at 25 °C are found in good agreement with previously determined values.

Canadian Journal of Chemistry, **47**, 1075 (1969)

Introduction

The diffusion of gases in liquids has recently become the study of several research groups. Together with accurate saturation solubility and entropy of solutions studies, such data are necessary for a fuller, theoretical understanding of the

For personal use only.

liquid state. We have recently developed a method which appears to allow a rapid and accurate determination of the diffusion coefficient. A bubble of the gas is maintained at a constant size in the solvent under investigation. The rate of solution of the gas from the bubble into the solution is compensated by introducing a known amount of gas into the bubble. The amount of gas required to do this is measured, as a function of time, using a micro-pipette. In previous work the diffusion of the gas into the liquid has been measured by observing the change in radius of the bubble as a function of time (1). This latter method has associated with it complicated hydrodynamic conditions existing at the interface and makes the results of this method difficult to interpret quantitatively (2, 3).

The steady state solution for the Fick's law of spherical diffusion (4) viz.

$$\frac{\partial c}{\partial t} = D\left(\frac{\partial^2 c}{\partial r^2} + \frac{2}{r}\cdot\frac{\partial c}{\partial r}\right) = 0$$

is given by

$$C = C_0(a/r)$$

where $C = C_0$ when $r = a$, with C_0 the equilibrium saturation concentration of the gas studied. This equation holds for $0 \leqslant t < \infty$. If a (the bubble radius) is kept constant then the rate of solution of the gas from the bubble is given as

$$V = \frac{4\pi a C_0 D}{\rho}\cdot t$$

where ρ is the density of the gas in the bubble. The above expression, implying a steady-state diffusion process, allows the diffusion coefficient of the gas in the liquid, D, to be found, upon knowing the experimental relationship between V, the volume of gas required to keep the bubble at constant radius, and the time t.

Experimental

The gas bubble is generated in the liquid under investigation at the tip of a micro-pipette (Manostat Corp: Digitpette). The pipette was pre-calibrated with mercury, and the capillary of the pipette was coated with "siliclad" (Clay–Adams Inc.) to prevent it from wetting. For the present experiments the solvent used is distilled water, thoroughly degassed at a low pressure. The apparatus is so designed that the pipette can be repeatedly flushed with the gas under investigation before being immersed into the solvent. The whole apparatus is thermostated to ± 0.01 °C, and mounted on a heavy concrete block to eliminate mechanical vibration.

The diameter of the bubble is measured with a microscope fitted with a calibrated filar eyepiece, (Gaertner Scientific Corporation). It has been observed that bubbles under 2.5 mm in diameter remain perfectly spherical at the tip of the pipette with less than 0.5% of contact area to the capillary. No correction is made for the bubble area in contact with the capillary since the uncertainty is much less than the uncertainty in the gas solubility data. The rate of solution of the gas into the solvent is compensated by operating the plunger of the pipette, so keeping the bubble at a constant size. The change in the position of the calibrated plunger is measured as a function of time.

Results

Measurements have so far been made on the rate of diffusion of N_2, O_2, and CO_2 in water at 25 °C. In each of these systems a steady state diffusion equation is seen to be obeyed. Typical results are plotted in Fig. 1 and the calculated diffusion coefficients for the three gases in this single solvent are given in Table I. Values taken from the literature for these systems are also given in Table I and agreement with these is seen to be good (5).

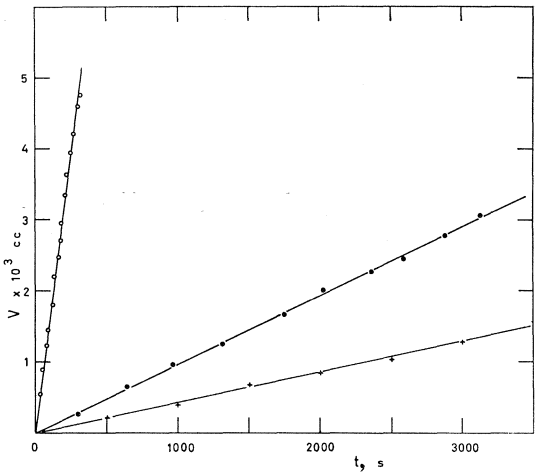

FIG. 1. Rates of absorption of constant size gas bubbles into water at 25 °C: ○, CO_2, $a = 0.767$ mm; ●, O_2, $a = 0.924$ mm; +, N_2, $a = 0.978$ mm.

Conclusion

The method described above has been found to be quick and accurate. It has the distinct advantage over the "open-tube" and more so over the "diaphragm" methods (6, 7) in that it allows diffusion coefficients to be measured for systems in which the solute gas has an exceedingly low saturation solubility. The apparatus can be easily

TABLE I

Diffusion coefficients of O_2, N_2, and CO_2 in water at 25 °C

adapted so that D can be measured over a wide temperature range. It could easily be designed to fit into a pressure bomb so that systems at a high pressure could be investigated. The advantages of this method over the dissolving bubble method, apart from the simplicity of the mathematics of the diffusion process, are that the "streaming" problem is reduced and that by retaining the constant bubble size we are not concerned with the convection problem associated with a changing size bubble.

Interactions of formic acid, formaldehyde, and methanol with germania surfaces

J. C. MCMANUS, KUN-ICHI MATSUSHITA, AND M. J. D. LOW
Department of Chemistry, New York University, New York, New York 10453

Received August 15, 1968

Infrared studies of the interaction of, respectively, formic acid, formaldehyde, and methanol with hydroxylated germania gel surfaces were made. Formic acid was dissociatively adsorbed to give covalently bonded formate species and new surface hydroxyl groups. Monomeric formic acid could not be observed. Degassing the treated sample at 246° removed most of the surface formate and the perturbing effects on the surface hydroxyls were also decreased. Two adsorbed species were observed when germania was exposed to high pressures (~10 Torr) of formaldehyde at room temperature. One species was very weakly bonded; it was removed by degassing at room temperature and its structure is tentatively taken as formaldehyde hydrogen-bonded to the surface hydroxyl groups. The other species had a spectrum very similar to polyoxymethylene, and it is proposed that it was in fact a surface polymer formed through the catalytic effect of the surface hydroxyl groups. Methanol was dissociatively adsorbed on germania surfaces. A species attributed to surface methoxide was formed and the concentration of the surface hydroxyl groups increased. Also, small concentrations of two other species were observed which gave absorptions at 2195 and 1727 cm^{-1}, respectively. The band at 2195 cm^{-1} is assigned to a Ge—H species formed, possibly, at non-stoichiometric portions of the surface, while the latter species is tentatively ascribed to a surface formate species.

Canadian Journal of Chemistry, **47**, 1077 (1969)

Somewhat surprisingly, in view of the great interest in germanium junction devices, there is relatively little direct information about the nature and structure of materials adsorbed on "real" germanium surfaces, perhaps because experimental emphasis has so far been placed on the measurement of electronic properties. Germania is, however, transparent to infrared radiation over a wide range, so that infrared spectroscopic techniques can be used to study

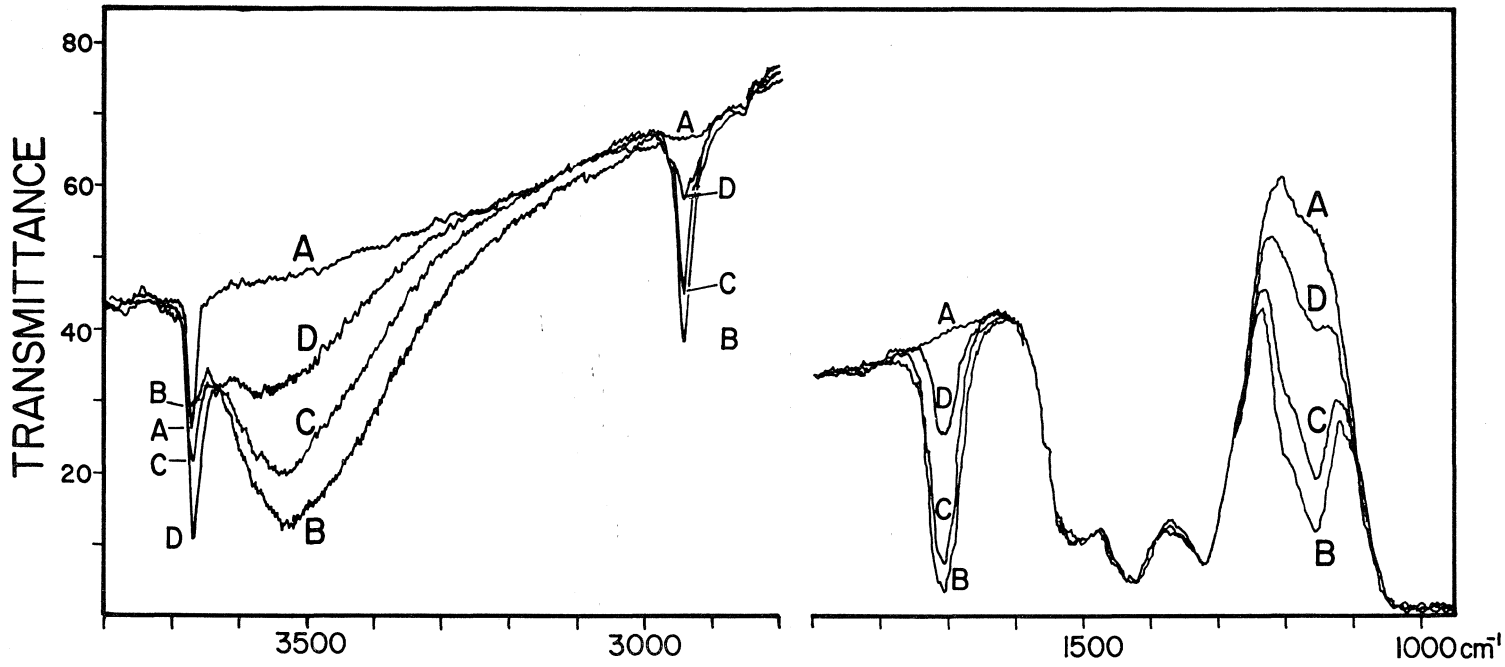

FIG. 1. Interaction of formic acid and germania. A germania sample was heated in 30 Torr O_2 at 520° for 6 h and degassed at 580° overnight (spectrum A). The sample was then exposed to 7 Torr formic acid at room temperature for 30 min and degassed for 1 h at room temperature (spectrum B). The sample was then degassed for 1 h at 146° (spectrum C) and at 230° (spectrum D).

reactions occurring on oxidized germanium. Using germania gel as analogue for real germanium, some information has recently been obtained about the surface species formed when water (1, 2), hydrogen (2), and propionic and acetic acids (3) were sorbed on germania. Those studies were extended in order to examine the interactions of formic acid, formaldehyde, and methanol with germania.

Experimental

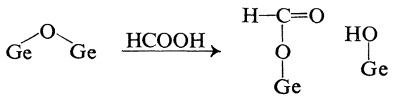
The procedures for preparing germania gel and compacted pellets suitable for infrared studies have already been described (2, 3). Methanol and formic acid were dried under vacuum with anhydrous copper sulfate and were degassed by freeze–pump–thaw cycles. Formaldehyde was prepared from paraformaldehyde according to the method of Spence and Wild (4). Spectra were recorded with a Perkin–Elmer Model 621 spectrophotometer using cells similar to those of Peri and Hannan (5). Contributions from the gas phase were nulled, in most instances, by the use of a reference cell.

Results and Discussion

Formic Acid–GeO_2

Spectrum A of Fig. 1 is that of pure germania after treatment with oxygen and degassing (2) at 550°. The sharp band at 3672 cm^{-1}, hereafter termed the free Ge—OH band, has been previously assigned to ν(OH) of "free" or isolated hydroxyls attached to surface germanium atoms. The intense absorptions in the 1600–1200 cm^{-1} region are caused by the oxide. Exposing the germania to 7 Torr formic acid at room temperature (spectrum B) decreased the free Ge—OH band intensity and caused the formation of a broad band centering near 3530 cm^{-1}, attributed to perturbed hydroxyls (2); also, taking into account the sloping background in the 1500–1000 cm^{-1} region, bands were observed at 2944, 1707, 1201 (shoulder), and 1157 cm^{-1}. Degassing at increasingly higher temperatures resulted in a marked decrease of the latter bands at temperatures greater than 100° and showed that they could all be related to the same surface species. The bands were completely removed by degassing at 270°. On degassing, the intensity of the free Ge—OH band increased and became greater than its initial value, while the broad band shifted from 3530 cm^{-1} to higher wavenumbers and decreased in intensity.

The bands at 2944, 1707, 1201, and 1157 cm^{-1} can best be interpreted in terms of a covalent formate species formed by dissociative chemisorption,



Although there are no published spectra of germyl esters, such compounds exist (6). Moreover, comparison of the present spectra with those of silyl formates (7) and organic formates (8) shows very good agreement, so that it is reasonable to make band assignments in an analogous fashion. On this basis, the band at 2944 cm^{-1} is attributed to ν_a(C—H), that at 1707 cm^{-1} to ν(C═O), while those at 1201 and 1157 cm^{-1} are the results of coupled modes with the main contribution coming from ν(C—O). The possibility that the surface species was solely monomeric formic acid held to the surface by hydrogen bonding is not given much credence. For gaseous monomeric formic acid it has been shown (9, 10) that, although there is much coupling of the modes, bands at 1229 and 1105 cm^{-1} are due mainly to δ(OH) and ν(C—O), respectively. Hydrogen bonding would be expected to shift these modes to higher frequencies and may cause a decrease in the intensity of δ(OH), but this model does not give a convincing explanation of the results. Also, hydrogen-bonding forces of the strength expected from the Δν(OH) shift would not be considered large enough to hold monomeric acid molecules to the surface at temperatures of 150–200°. Parenthetically, the model of a covalently bonded carboxylate species best explained the results obtained when acetic and propionic acids reacted with germania (3).

It seems clear that the adsorption of formic acid was dissociative and that the final products were formate and hydroxyl species. Comparison with previous work (2) seems to indicate that while Ge—OH groups were formed in the adsorption process, the band at 3530 cm^{-1} decreased to a greater extent with increasing temperature than would be expected if it were caused solely by OH—OH interactions. There may thus have been some hydrogen-bonding interaction between the carbonyl group of the surface formate and a neighboring Ge—OH group.

When the germania was exposed to 7 Torr formic acid at 270° (the temperature at which surface formate would be removed completely)

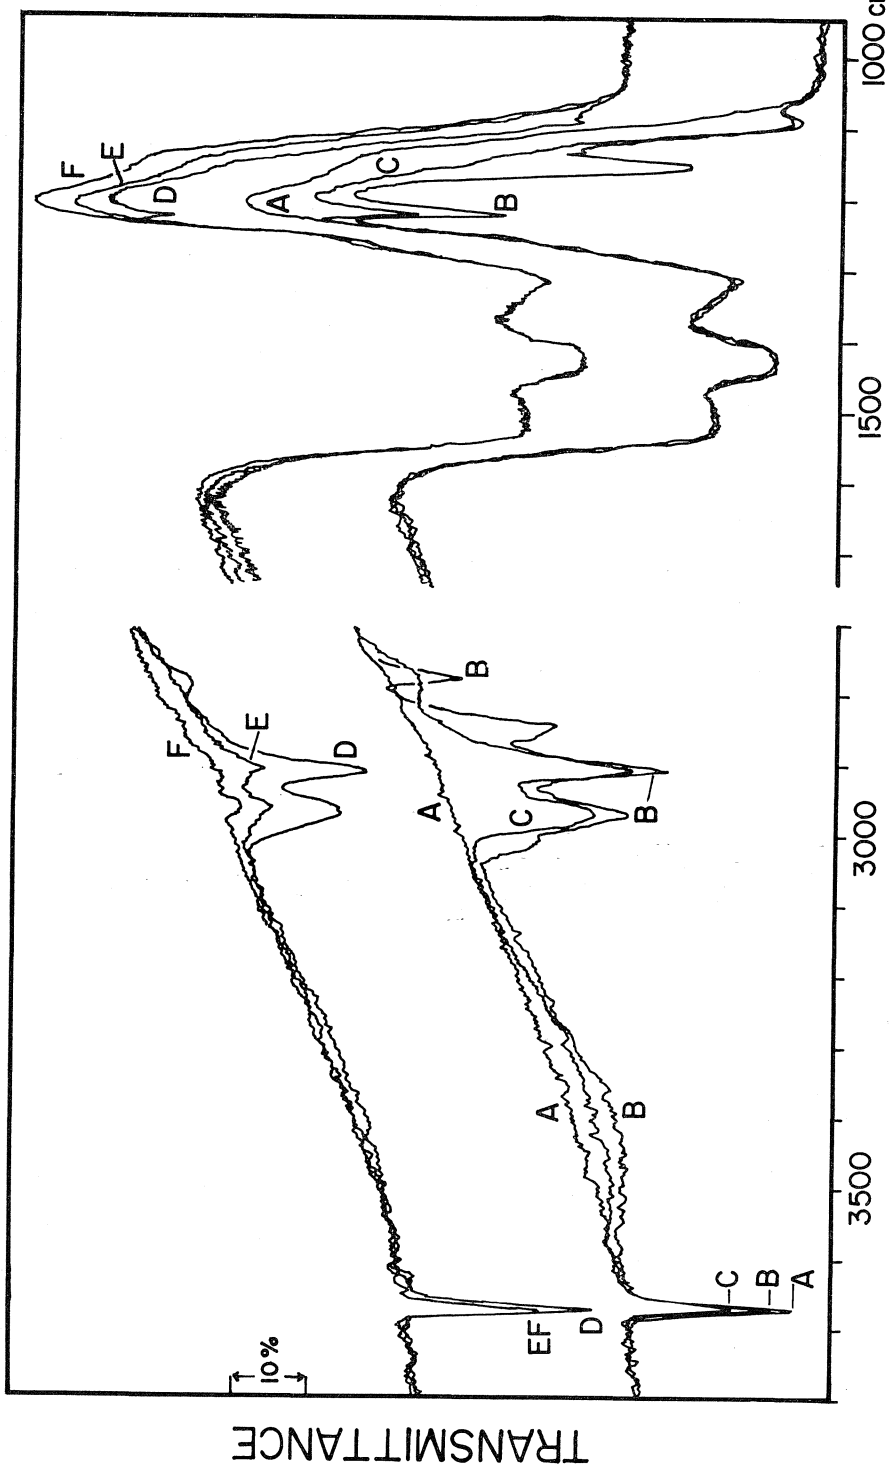

FIG. 2. Interaction of formaldehyde and germania. A well-degassed germania sample (spectrum A) was exposed to 9 Torr formaldehyde at room temperature for 1 h (spectrum B). The pressure was then reduced to 4 μ by pumping at room temperature (spectrum C). The sample was then degassed at the following temperatures and times in hours to obtain spectrum D, room temperature, 15; E, 125°, 1; F, 200°, 0.5. The ordinate of the group of spectra D, E, F is displaced to avoid overlapping of traces.

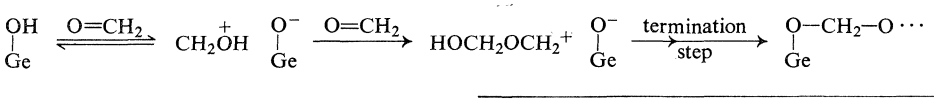
and degassed for 30 min at 100°, the intensity of the band due to perturbed hydroxyls at 3530 cm^{-1} compared to those due to surface formate, was much greater than that observed when germania was exposed to 7 Torr formic acid at room temperature and degassed at 140°. Thus, while there is no evidence against the adsorption process being reversible to some extent, it is clear that there was a decomposition involving a dehydration process.

Formaldehyde–GeO_2

From the spectra it is clear that two surface species were formed when germania was exposed to formaldehyde at room temperature (Fig. 2). One was weakly bound and could easily be desorbed by degassing at room temperature. Bands due to this species were observed at 3015, 2849, 2785, and 1167 cm^{-1}; in addition, it was noted that the free Ge—OH band increased and the band due to perturbed hydroxyls, which was formed in the region 3350–3400 cm^{-1}, decreased when the weakly bound species was removed. There was no evidence for a band in the 1750–1700 cm^{-1} region, but this could have been obscured by imperfect compensation of the reference beam. However, in spite of the fact that there was no band attributable to ν(C=O), we think that the bands can be best interpreted in terms of formaldehyde molecules, hydrogen-bonded to surface hydroxyl groups by means of the carbonyl groups, because there is good agreement with the spectra of formaldehyde (11, 12) recorded at 77 and 273 °K. However, the failure to observe ν(C=O) is disturbing and no satisfactory reason can be given for this.

The second species was much more strongly bound and was removed only by degassing at 200°. It gave rise to bands at 2972–2979, 2913, 2785, 1233, and 1100 cm^{-1}. These positions compare very favorably with those found in the spectrum of polyoxymethylene (13). Consequently, it seems probable that a polymerization had occurred on the surface. As the intensity of the free Ge—OH band was dependent on the surface concentration of the polymer, it is likely that the latter was bonded, at least in part, to surface hydroxyls by hydrogen bonds; with such a big molecule, van der Waals – London forces may also play an important role. The main details of the mechanism are obscure, but it was found that when the sample (upon which only the polymer was adsorbed) was heated in a closed cell, formaldehyde was present in the gas phase on cooling and the concentration of polymer was reduced quite markedly. Thus, the polymerization rate was sensitive to the formaldehyde pressure, so that a weakly bound form of formaldehyde, whose surface concentration is pressure-dependent, may play an important intermediate role in polymerization. It is well known that formaldehyde polymerization is catalyzed by acids (14), and so it may be that surface OH groups act as sites for a process such as



Methanol–GeO_2

Exposure of a highly dehydroxylated surface to 1 Torr methanol followed by evacuation at room temperature for 1 h (Fig. 3) resulted in the formation of new bands at 2999, 2952, 2848, 1475, 1360, 1180, 677, 1727, and 2195 cm^{-1}. Also, the intensity of the free Ge—OH band remained essentially unchanged, but a broad band centering near 3500–3450 cm^{-1} was formed and is attributed to perturbed OH. Intensity measurements made under different degassing conditions showed that each of the bands at 1727 and 2195 cm^{-1} belonged to a separate species and that the rest of the bands belonged to a third species. The band at 2195 cm^{-1} disappeared after evacuation at 230° and was formed only when the methanol was contacted at room temperature with a surface containing very few hydroxyl groups. Thus, in accordance with previous work (2), the 2195 cm^{-1} band was probably caused by a Ge—H structure which was formed only when methanol reacted with a non-stoichiometric portion of the germania surface.

An early study (15) of the spectrum of $Ge(OMe)_4$ showed strong bands at 2955, 1460, 1181, 1040, 897, and 670 cm^{-1}. Thus the main surface species observed in our work showed marked similarities with this, apart from the failure to correlate the band at 1370 cm^{-1}. Also, the present spectra are very similar to those of

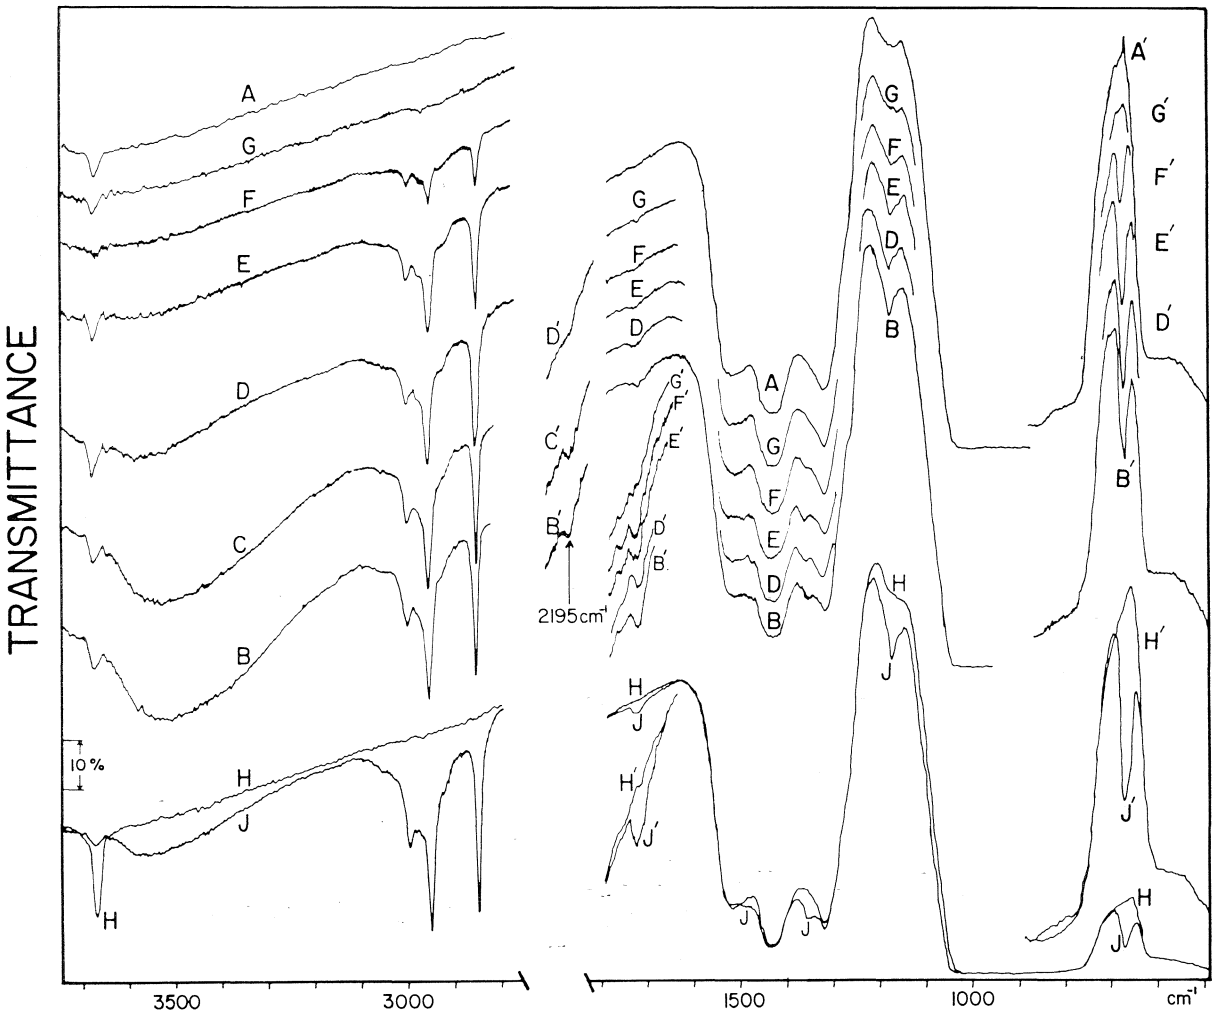


FIG. 3. Interaction of methanol and germania. A well-degassed germania sample (spectrum A) was exposed to 1 Torr methanol at room temperature for 1 h and degassed at room temperature for 1 h (spectrum B). The sample was then degassed at the following temperatures and times in hours to give spectrum C, room temperature, 9; D, 210°, 1; E, 300°, 0.5; F, 400°, 0.5; G, 450°, 0.5. A second well-degassed sample (spectrum H) was exposed to 5 Torr methanol at 210° for 1 h and was then degassed for 30 min at 210°(spectrum J). The ordinates of spectra A to G were displaced to prevent overlapping of traces. Letters marked with a prime indicate that the portion of the spectrum was re-recorded with 5 times ordinate scale expansion.

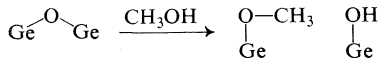
methoxide formed on siliceous surfaces (16). We therefore think that the spectrum of the surface species can be interpreted best in terms of a surface methoxide.

Intensity measurements show that there was no relation between the surface methoxide bands and that at 3500 cm^{-1}, indicating that hydrogen-bonding forces were involved with the methoxide only to a slight extent, if at all. The band at 3500 cm^{-1} disappeared on degassing at a much quicker rate than found when a hydrated fresh gel surface was degassed for the first time (2). Even so, the band was probably due almost in its entirety to perturbed hydroxyl groups which were formed together with methoxide radicals when the methanol was adsorbed. These hydroxyl groups were removed from the surface at a quite rapid rate. This was probably due to the fact that the sample was initially almost completely dehydroxylated. Previous work (2) showed that hydroxyl groups formed on a dehydroxylated surface were not as stable as those formed on a

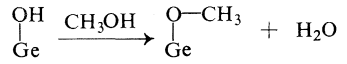
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

partially dehydroxylated surface, although the cause of this is not known.

At room temperature the predominant reaction appeared to involve a disruption of the germania surface:



The direct surface esterification,



appeared to be minimal. Only at higher reaction temperatures was there any significant removal of free Ge—OH groups (spectra H, J, Fig. 3).

The nature of the species giving the band at 1727 cm^{-1} is uncertain. Possibly the band indicates the presence of some type of carbonyl group. The stability of the surface species immediately rules out the presence of ketones, aldehydes, or esters. It has been shown by Greenler (17) that surface formate was formed when an alumina surface was heated at 170° in methanol. Our system is similar in that surface methoxide was formed when germania was exposed to methanol, although surface hydroxyl groups, rather than hydrogen, were also produced. We feel that it is possible that the reactions on alumina and germania are similar, although there are two factors against this. The formate species on germania surfaces were not stable at temperatures greater than 240°, whereas the 1727 cm^{-1} band was not removed until degassing temperatures of 300° were used; and the band positions do not agree in that formate species absorb at 1707–1717 cm^{-1}. However, these are not overwhelming objections and we think that the interpretation of surface formate is the best available.

Hydroboration of acyclic allenes with disiamylborane

D. S. Sethi, G. C. Joshi, and D. Devaprabhakara

Department of Chemistry, Indian Institute of Technology, Kanpur, India

Received June 10, 1968

The present investigation demonstrates the hydroboration of 1,2-nonadiene, phenylpropadiene, 3-phenyl-1,2-butadiene, 4,5-nonadiene, and tetramethylallene with disiamylborane. All the allenes except tetramethylallene underwent 100% conversion. Examination of the products indicated preferential electrophilic attack of boron on the least substituted terminal carbon atom in the case of 1,2-nonadiene, phenylpropadiene, 3-phenyl-1,2-butadiene, and on the central carbon atom in 4,5-nonadiene. In tetramethylallene boron, attack was exclusively on the central carbon atom. These results have been explained in terms of steric effects on a four-centered transition state.

Canadian Journal of Chemistry, 47, 1083 (1969)

In our preceding publication (1), the effect of ring size on hydroboration of cyclic allenes with disiamylborane has been demonstrated. In continuation of this study we undertook the hydroboration of representative acyclic allenes with disiamylborane, to achieve monohydroboration,

Hydroboration of acyclic allenes with disiamylborane

D. S. Sethi, G. C. Joshi, and D. Devaprabhakara
Department of Chemistry, Indian Institute of Technology, Kanpur, India

Received June 10, 1968

The present investigation demonstrates the hydroboration of 1,2-nonadiene, phenylpropadiene, 3-phenyl-1,2-butadiene, 4,5-nonadiene, and tetramethylallene with disiamylborane. All the allenes except tetramethylallene underwent 100% conversion. Examination of the products indicated preferential electrophilic attack of boron on the least substituted terminal carbon atom in the case of 1,2-nonadiene, phenylpropadiene, 3-phenyl-1,2-butadiene, and on the central carbon atom in 4,5-nonadiene. In tetramethylallene boron, attack was exclusively on the central carbon atom. These results have been explained in terms of steric effects on a four-centered transition state.

Canadian Journal of Chemistry, 47, 1083 (1969)

In our preceding publication (1), the effect of ring size on hydroboration of cyclic allenes with disiamylborane has been demonstrated. In continuation of this study we undertook the hydroboration of representative acyclic allenes with disiamylborane, to achieve monohydroboration,

Tetramethylallene	Diisopropyl ketone	73.1				

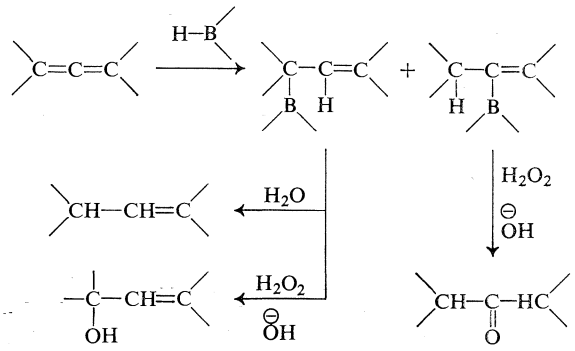
to examine the relative rates of reaction, and to study the selectivity in the direction of addition.

It has been shown by Brown and Zweifel (2) that the hydroboration of 1-hexene and styrene with disiamylborane followed by alkaline hydrogen peroxide oxidation provides 98–99% primary alcohols. From this observation, the authors have concluded not only the steric equivalence of phenyl and *n*-alkyl groups but also the absence of electrical effect by the phenyl substituent. In view of this, 1,2-nonadiene, phenylpropadiene, 3-phenyl-1,2-butadiene, 4,5-nonadiene, and tetramethylallene were subjected to hydroboration–oxidation under identical conditions, and the nature of the product(s) was explored.

Results and Discussion

Disiamylborane was prepared by the hydroboration of 2-methyl-2-butene under a static pressure of nitrogen (3). A solution of appropriate allene in diglyme was added to the above solution within 3–4 min. The mixture was allowed to attain room temperature (approx. 3 h). After stirring for a further 2 h at room temperature, the mixture was hydrolyzed by careful addition of water till hydrogen was no longer evolved. The resulting organoboranes were oxidized with alkaline hydrogen peroxide in the usual manner. The conversion of the allene to product(s) as determined by gas chromatography (4) was found to be 100% except in the case of tetramethylallene. The latter underwent conversion only to the extent of 30%.

A general scheme for the hydroboration of acyclic allenes may be represented as follows and the results are summarized in Table I.



The identity of each product was established by comparison of gas liquid chromatographic (g.l.c.) retention times (using several columns) and infrared spectra (i.r.) with those of an authentic sample. Wherever necessary, elemental analysis and preparation of known derivatives were also used in the characterization of products.

The ratio of electrophilic attack of boron on the terminal and central carbon atoms of the allenic linkage as calculated from the molar ratio of the products for each allene is shown in Table II.

The electrophilic attack of boron on the central vs. terminal carbon atom of the allenic linkage in the case of 1,2-nonadiene and phenylpropadiene suggests that the steric requirement of the phenyl group is almost the same as that of *n*-alkyl group, even in acyclic allenes when disiamylborane is used as the hydroborating reagent. The observed difference in the reactivity and selectivity in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

TABLE II

Molar ratio of products resulting from the electrophilic attack of boron on terminal and central carbon atoms of the allenic linkage

Allene	Molar ratio (terminal C/central C)
1,2-Nonadiene	3.54
Phenylpropadiene	3.99
3-Phenyl-1,2-butadiene	7.47
4,5-Nonadiene	0.48
Tetramethylallene	0.00

direction of addition of disiamylborane to these acyclic allenes could solely be dictated by the difference in steric requirements of the allenes in the Brown's well-known postulated transition state for hydroboration (5). The electronic effect seems to be of minor importance here. Our result with tetramethylallene suggests that complete selectivity in the hydroboration of a tetrasubstituted allene is possible using disiamylborane.

The formation of olefins is in complete agreement with our previous observation (6), where we have shown that allylic organoboranes undergo slow hydrolytic cleavage at the boron–carbon bond. The ready hydrolysis of allylic organoboranes from phenylpropadiene and 3-phenyl-1,2-butadiene may be interpreted through the formation of an extensive stabilized carbanion, which in turn picks up a proton to give a mixture of possible olefins. The most thermodynamically stable isomer was found to be the major product in each olefinic mixture. In particular it is interesting to know that the predominant formation of *cis*-2-phenyl-2-butene over its *trans* isomer is in complete agreement with Cram's observation (7).

Experimental

Boiling points are uncorrected. Melting points were performed in open capillaries and are uncorrected. All infrared spectra were recorded on a Perkin–Elmer model 521 spectrophotometer from compounds as films between salt plates or in cells. Gas chromatographic analyses were made with Aerograph model 90P instrument using 6 ft by $\frac{1}{4}$ in. columns. The following liquid phases were employed (percentage by weight on 60/80 mesh chromosorb W): 15% silicone rubber, 15% carbowax 20M, 15% ucon, and 15% carbowax 20M – silver nitrate. Samples were collected by g.l.c. for i.r. spectra. Microanalyses were carried out by Mr. A. H. Siddiqui of the Department of Chemistry, Indian Institute of Technology, Kanpur, India.

Materials

Diglyme (Ansul Co.) was kept over calcium hydride for 24 h, decanted, and distilled from slightly excess of lithium aluminium hydride under reduced pressure. Boron trifluoride ethyl etherate (Eastman) was treated with a small quantity of dry ethyl ether (to ensure an excess of this component) and distilled under reduced pressure from calcium hydride. Sodium borohydride from Metal Hydrides Inc. (98%) was used without purification. 2-Methyl-2-butene (Aldrich Co.) was used for the preparation of disiamylborane.

Tetramethylallene (K & K Co.) was used for hydroboration. It showed no detectable impurities by g.l.c. 1,2-Nonadiene, phenylpropadiene, 3-phenyl-1,2-butadiene, and 4,5-nonadiene were prepared by two-step sequence starting from a suitable olefin in each case according to the procedure of Moore and Ward (8). Their properties corresponded well with those reported (9–11).

Monohydroboration of 1,2-Nonadiene

Pulverized sodium borohydride (3.2 g, 0.083 mole) in dry diglyme (50 ml), and 2-methyl-2-butene (15.4 g, 0.22 mole) were placed in 250 ml three-necked flask equipped with a condenser, an equilibrating dropping funnel, a low temperature thermometer, and an inlet and outlet for dry nitrogen gas. Hydroboration was achieved by adding boron trifluoride etherate (15.8 g, 0.111 mole) in diglyme (20 ml) to the well stirred mixture kept at 0 to $-5°$ over a period of 0.5 h. Throughout the reaction a static pressure of nitrogen gas was maintained. After leaving the reaction mixture for 1 h at 0°, 1,2-nonadiene (12.4 g, 0.10 mole) was added in 3 min. The reaction mixture was allowed to attain the room temperature (approx. 3 h). The excess of the hydride was destroyed by careful addition of water until hydrogen was no longer evolved. The oxidation of the intermediate organoboranes was accomplished in the usual manner by adding 3 *N* sodium hydroxide (pH 9–10) followed by 30% hydrogen peroxide. The products were extracted with ether, dried over anhydrous magnesium sulfate and ether distilled over. At this stage the percentage conversion of allene to products was determined by g.l.c.

Fractionation of the reaction mixture afforded 2.68 g (21.3% yield) of olefinic product with a b.p. 40–42° at 15 mm, 2.4 g (16.9% yield) of 2-nonanone with a b.p. 87–90° at 15 mm, n_D^{30} 1.4182 (lit. (12), b.p. 195° at 760 mm, n_D^{20} 1.4211) and 5.48 g (38.6% yield) of 2-nonen-1-ol with a b.p. 107–109° at 15 mm, n_D^{30} 1.4461 (lit. (13), b.p. 98–99° at 10 mm, n_D^{19} 1.4480). Gas chromatographic analysis of the olefinic product on a carbowax – silver nitrate column indicated the presence of 1-nonene (26%), *cis*-2-nonene (4%), and *trans*-2-nonene (70%). The identity of the individual product(s) was established by comparison of g.l.c. retention times and i.r. spectra with those of the authentic samples. The 2,4-dinitrophenylhydrazone derivative with a m.p. 58–59°, did not depress the m.p. of authentic 2-nonanone 2,4-dinitrophenylhydrazone (lit. (12), m.p. 58–59°).

(15.4 g, 0.22 mole), sodium borohydride (3.2 g, 0.083 mole), and boron trifluoride etherate (15.88 g, 0.111 mole), we obtained 2.7 g (22.9% yield) of allylbenzene with a b.p. 65–66° at 40 mm, n_D^{32} 1.5038 (lit. (14), b.p. 72.5–73.5° at 45 mm, n_D^{25} 1.5071), 5.2 g, (44.1% yield) of 1-phenyl-1-propenes (*cis* and *trans*) with a b.p. 58–60° at 10 mm (lit. (15), b.p. 53° at 8 mm), and 2.25 g (16.8% yield) of 1-phenyl-2-propanone with a b.p. 96–97° at 10 mm, n_D^{32} 1.5126 (lit. (16), b.p. 122–125° at 50 mm, n_D^{28} 1.5136). Gas chromatographic analysis of the olefinic mixture showed 6% of *cis* isomer and 94% of *trans* isomer. The identity of each product was established on the basis of the comparison of g.l.c. retention times and i.r. spectra with those of authentic samples. The 2,4-dinitrophenylhydrazone of the ketone had m.p. and mixture m.p. 152–153° (lit. (16), 152–153°).

Monohydroboration of 3-Phenyl-1,2-butadiene

Following the procedure described for 1,2-nonadiene, from 3-phenyl 1,2-butadiene (9.75 g, 0.075 mole), 2-methyl-2-butene (11.5 g, 0.165 mole), sodium borohydride (2.4 g, 0.062 mole), and boron trifluoride etherate (11.8 g, 0.083 mole), there was obtained 7.86 g (79.4% yield) of olefinic mixture containing 3-phenyl-1-butene (24%), *cis*-2-phenyl-2-butene (62%), and *trans*-2-phenyl-2-butene (14%) with a b.p. 65–75° at 20 mm and 1.18 g (10.6% yield) of 3-phenyl-2-butanone with a b.p. 103° at 20 mm, n_D^{29} 1.5060 (lit. (17), b.p. 107–108° at 22 mm, n_D^{25} 1.5074). The products were identified by comparison of their g.l.c. retention times and i.r. spectra with those of authentic samples. The semicarbazone derivative of the ketone had m.p. and mixture m.p. 169–170° (lit. (17), m.p. 173°).

Anal. Calcd. for $C_{10}H_{12}$: C, 90.91; H, 9.09. Found: C, 90.82; H, 9.21.

Anal. Calcd. for $C_{11}H_{15}N_3O$: C, 64.39; H, 7.32; N, 20.49. Found: C, 64.34; H, 7.21; N, 20.23.

Monohydroboration of 4,5-Nonadiene

Following the procedure described previously for hydroboration–oxidation, 4,5-nonadiene (6.2 g, 0.05 mole), 2-methyl-2-butene (7.7 g, 0.11 mole), sodium borohydride (1.6 g, 0.041 mole), and boron trifluoride etherate (7.9 g, 0.055 mole) afforded 0.55 g (8.7% yield) of 4-nonene with a b.p. 50–51° at 15 mm, 4.3 g (60.5% yield) of 5-nonanone with a b.p. 76–78° at 15 mm, n_D^{30} 1.4186 (lit. (18), b.p. 186–187° at 760 mm, n_D^{15} 1.4210), and 1.45 g (20.4% yield) of 5-nonen-4-ol with a b.p. 85–86° at 15 mm, n_D^{30} 1.4398 (lit. (19), b.p. 96–100° at 35 mm, n_D^{20} 1.4405). The g.l.c. analysis of 4-nonene showed 97% *trans* isomer and only 3% *cis* isomer. Only *trans* isomer was separated by g.l.c. and identified by comparison of i.r. spectra with that of an authentic sample. The *cis* isomer was identified only by comparison of g.l.c. retention times with those of an authentic sample. On the basis of i.r. and g.l.c. analysis data of the authentic samples, the ketone and the alcohol were shown to be 5-nonanone and 5-nonen-4-ol respectively. The semicarbazone derivative of the ketone had m.p. and mixture m.p. 89–90° (lit. (18), m.p. 89–90°).

Anal. Calcd. for C_9H_{18}: C, 85.71; H, 14.29. Found: C, 85.61; H, 14.36.

Monohydroboration of Tetramethylallene

Following the procedure described previously for 1,2-nonadiene, from tetramethylallene (9.6 g, 0.1 mole), 2-methyl-2-butene (15.4 g, 0.22 mole), sodium borohydride (3.2 g, 0.083 mole), and boron trifluoride etherate (15.8 g, 0.111 mole), there was obtained only 2.5 g (73.1% yield based on consumed starting material) of diisopropyl ketone with a b.p. 122–124° at 742 mm, n_D^{31} 1.3950 (lit. (20), b.p. 121–126° at 760 mm, n_D^{20} 1.4001). The percentage conversion of tetramethylallene to the products as established by g.l.c. was 30%. The identity of the ketone was established by comparison of g.l.c. retention times and i.r. spectra with those of an authentic sample. The m.p. and mixture m.p. of the 2,4-dinitrophenylhydrazone of the ketone was observed to be 88–89° (lit. (20), m.p. 87–88°).

Anal. Calcd. for $C_{13}H_{18}N_4O_4$: C, 53.06; H, 6.12; N, 19.04. Found: C, 52.84; H, 6.10; N, 18.87.

The infrared absorption spectra of thiosemicarbazide and related compounds: NH_2 and NH vibrations[1]

D. M. WILES AND T. SUPRUNCHUK
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada

Received August 8, 1968

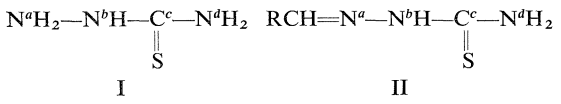
In the infrared absorption spectra of thiosemicarbazide (I), aldehyde thiosemicarbazones (II), and N-methyl derivatives of these compounds, the following assignments are proposed: $\nu_a(N^dH_2)$ absorbs in the vicinity of 3400 cm^{-1}; N^aH_2 vibrations are observed in the region of 1630 cm^{-1}; there is a significant contribution from $\nu(N^bH)$ at or near 3170 cm^{-1}. These conclusions probably apply to other thioamides and amides having related structures.

Canadian Journal of Chemistry, **47**, 1087 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Much information is available in the literature concerning the infrared spectra of amines and amides. Although less is known about infrared absorption by thioamides and thiosemicarbazones, studies have been published of the hydrogen bonding in these compounds (1), and of the C=S absorption in thiourea (2, 3) and in thioformamide (4). Mashima (5) has discussed in detail the infrared spectra of hydrazine-N,N′-bis-thiocarbonic acid amide, thiosemicarbazide, formyl thiosemicarbazide, and acetyl thiosemicarbazide and the spectra of the deuterated analogues. In this latter work, some success was achieved in attributing particular absorption bands to particular bonds, e.g., C=S, NH, and NH_2. Some of the assignments, however, are ambiguous, owing in part to the complexity of the molecules and the coupling between bond vibrations.

In earlier work from these laboratories (6, 7), the major contribution by C=S stretching vibrations to the infrared spectra of thiosemicarbazones was established as being in the 830 to 805 cm^{-1} region. In the present work we have used a similar approach to locate the absorption by



I II

N^aH_2, N^bH, and N^dH_2 both in thiosemicarbazide (I) and in thiosemicarbazones (II) of aliphatic and aromatic aldehydes (R = C_6H_{13}, C_7H_{15}, $C_{10}H_{21}$, and C_6H_5). Infrared spectra of these compounds were compared with those of the N^b-methyl, N^d-methyl, and N^d-dimethyl analogues in order to identify with some confidence the desired absorptions. The advantage of using the thiocarbonyl compounds rather than the corresponding carbonyl compounds is that the C=S stretching vibrations do not give rise to absorptions in the conventional "double-bond region", thus simplifying the spectra in this region.

Experimental

Thiosemicarbazide was obtained from commercial sources and was recrystallized from water, m.p. 183 °C.

All the methyl-substituted thiosemicarbazides were prepared by standard methods (8–12) and had melting points identical with those reported previously.

The aliphatic and aromatic aldehydes for synthesizing the thiosemicarbazones (II) were obtained from commercial sources and were used without further purification. The preparation of all but one of the aldehyde thiosemicarbazones listed in Table I has been reported previously (13).

Undecanal 4,4-dimethylthiosemicarbazone was synthesized as follows. To a solution of 4,4-dimethylthiosemicarbazide (0.036 mole) in warm water (100 ml) was added a solution of undecanal (0.036 mole) in ethanol (100 ml) containing 1 ml of glacial acetic acid. This reaction mixture was heated gently on the steam bath for 15 min, then cooled, and neutralized with 1 *N* NaOH solution. The white solid which was recovered, following evaporation of the solvents, was recrystallized repeatedly from *n*-hexane; m.p. 49 °C, yield 40%.

Anal. Calcd. for $C_{14}H_{28}N_3S$: C, 62.80; H, 10.02; N, 15.33; S, 11.67. Found: C, 62.57; H, 10.50; N, 15.37; S, 12.00.

The infrared spectra of the compounds described in this work were obtained from KBr pellets with a model 21 Perkin–Elmer double-beam spectrophotometer (NaCl prism) and with a Beckman IR-8 grating instrument. The frequency range 3500 to 700 cm^{-1} was covered. The frequencies reported in Table I are expected to be accurate within the following limits: for the region 3400 to 3000 cm^{-1}, ± 7 cm^{-1} (model 21), ± 2 cm^{-1} (IR-8); for the region 1700 to 1600 cm^{-1}, ± 5 cm^{-1} (model 21), ± 2 cm^{-1} (IR-8). The reproducibility in all cases was within the limits ± 2 cm^{-1}.

Results and Discussion

Table I lists the important bands in two regions

[1]Issued as NRCC No. 10 485.

TABLE I

Main infrared absorption bands in the 3500 to 3000 and 1650 to 1550 cm^{-1} regions

of the spectra of N-methyl substituted thiosemicarbazides and N-methyl substituted aldehyde thiosemicarbazones: 3500 to 3000 cm^{-1}, and 1650 to 1550 cm^{-1}. The concept here is that it should be possible to identify a contribution to these spectral regions by the vibration of a particular N—H or NH_2 group by comparison of the absorption bands for the compound with those observed when the relevant hydrogen atom has been replaced by a methyl group.

For thiosemicarbazide (compound **1**), strong bands at 3370, 3260, 3170, 1645, and 1620 cm^{-1} are observed. Replacement of either or both of the hydrogens on N^d by a methyl group (compounds **3** to **5**) results in loss of the 3370 band completely. Replacement of N^b—H by N^b—CH_3 results in a significant intensity loss of the band at 3170 cm^{-1}. It is reasonable to assume that the 3370 band should be attributed to $\nu(N^dH_2)$, presumably the asymmetric mode (14), and that there is a considerable contribution to the 3170 cm^{-1} band by $\nu(N^bH)$; the remainder probably includes N^dH_2 symmetric stretch. In the spectra of the aldehyde thiosemicarbazones (compounds **6** to **15**, Table I), the same phenomena are observed, i.e., methyl substitution at N^d eliminates the band at 3400 cm^{-1} and methyl substitution at the N^b position reduces the absorption in the 3140 to 3170 cm^{-1} region.

The bands near 1645 and at 1620 cm^{-1} are ascribed to $\delta(N^aH_2)$ and $\delta(N^dH_2)$ respectively, since the band near 1645 cm^{-1} occurs only when N^aH_2 is present and the 1620 cm^{-1} band appears only for compound **1** when N^dH_2 remains unsubstituted. The question remains as to why no absorption is observed in the 1620 cm^{-1} region for N^dH_2 deformations in compounds **6**, **7**, **11**, and **12**. The suggestion may be made that such absorption is at a lower frequency here, owing to the electron-withdrawing nature of the groups on the "left" of the thiocarbonyl group, and is obscured by C=N and other absorption bands. These conclusions appear to agree with the data of Campbell and Grzeskowiak (15), although not, apparently, with their interpretation of them.

In the spectra of all of the compounds, except **1** and **11**, appropriate strong absorptions for symmetric methyl group stretching vibrations are observed in the 2960 to 2930 cm^{-1} region. Finally, a medium to strong band for C=N stretch appears in the 1610 to 1560 cm^{-1} region of the spectra of all the thiosemicarbazones. There is likely to be overlap with aromatic ring absorptions in this latter region for compounds **11** to **15**.

Sadler (1) has reported bonded N—H frequencies at 3400 and 3200 cm^{-1} for the 3-thiosemicarbazone, the 3-4′-phenylthiosemicarbazone, and the 3-4′,4′-dimethylthiosemicarbazone of 1-methylisatin. According to the present work, there should be no absorption at 3400 cm^{-1} for the latter compound. It may be, however, that the degree of hydrogen bonding, the complexity, and the asymmetry of the molecule result in ν(NH) absorption at frequencies as high as 3400 cm^{-1}. These reasons could not account for the 3400 cm^{-1} band reported by Sadler (1) for benzaldehyde 4,4′-dimethylthiosemicarbazone; this absorption was not observed in the present work.

Most of the absorption bands and the assignments of them by Mashima (5) for thiosemicarbazide and related compounds are in agreement with the results shown in Table I and the conclusions based on them. In Mashima's work, however, the band at 3270 cm^{-1} in the spectrum of thiosemicarbazide is said to be "associated with the $\nu(N^aH_2)$ vibration of the $-NHNH_2$ group", i.e., with $\nu(N^aH_2)$. In the present work, there appears to be no contribution, or at most a very small one, to this band from $\nu(N^aH_2)$.

Further evidence for the validity of the assignments made here can be obtained from the absorptions characteristic of other compounds related to thiosemicarbazide. For example, in the infrared spectrum of ethylene dithiosemicarbazide, there are bands at 3340, 3200, and 1645 cm^{-1}; there is no thioamide N^dH_2 group in such dithiosemicarbazides. This is additional support, therefore, for the claim that $\nu_a(N^dH_2)$ absorbs in the 3400 cm^{-1} region and that the amine N^aH_2 group absorbs in the 1645 cm^{-1} region. It is probable that similar considerations apply in the case of related carbonyl compounds (e.g. 5, 16).

Acknowledgments

The authors are indebted to Dr. E. Whalley and Dr. Yoshinori Kato for helpful discussions and to Mr. R. Ironside for measuring some of the infrared spectra.

Conversion of tetracyclic triterpenes to steroids[1]

GEORGE R. PETTIT AND JERRY R. DIAS[2]
Department of Chemistry, Arizona State University, Tempe, Arizona 85281

Received January 24, 1969

An alternative procedure for converting the typical 3-hydroxy-4,4-dimethyl-substituted triterpene A-ring to a steroidal 3-oxo-4-ene system has been outlined. Application of the new method to 3β-hydroxy-5α-lanostane (**1**) was used for illustration. Key reaction steps involved Baeyer–Villiger oxidation of ketone **3** to lactone **4** and the latter to carboxylic acid **5** employing Jones' reagent. Proceeding *via* enol–lactone (**6**) and diketone (**7**) led to 3-oxo-14α-methyl-cholest-4-ene (**8**). The first example of an oxa-14α-methyl-steroid was also reported.

Canadian Journal of Chemistry, 47, 1091 (1969)

Lanosterol, a typical tetracyclic triterpene (1) contains the 3β-hydroxy-4,4-dimethyl substituted A-ring characteristic of many triterpenes. Synthetic transformation (2–4) of lanosterol to 14α-methyl-steroids requires extensive reconstruction of the A-ring. Indeed, removing the 4,4-dimethyl substituent is a major obstacle in triterpene → steroid conversions. Except for improvements (e.g. see 4) in experimental conditions, the important and useful procedure of Voser and colleagues (5) has remained sole chemical method for obtaining 3-oxo-4-ene-type steroids from triterpenes. Prior attempts[3] (e.g. 3, 6) to make available another method led instead to results more useful in other areas. Now we wish to report a comparable (yield) but potentially more versatile alternative.

Preparation of 3-oxo-14α-methyl-cholest-4-ene illustrates the new route. Isocholesterol (crude lanosterol) was used to synthesize 3β-hydroxy-5α-lanostane (**1**) as previously described (7). Wagner–Meerwein type rearrangement of alcohol **1** to olefin **2** (62% yield, m.p. 110–113°, reported in ref. 3, m.p. 110–112°) was conducted (at 0°) in benzene-toluene containing phosphorous pentachloride. Oxidative (ozone) cleavage of olefin **2** was performed essentially as reported (3) earlier. The product, 5β-ketone **3** (50%, m.p. 126.5–127.5°, positive Cotton effect optical rotatory dispersion curve) was treated (overnight at approximately 10°) with trifluoroperacetic acid (8) and lactone **4** (78%, plates from methanol, m.p. 170.5–172.5°, M^+ 402)[4] was isolated by chromatographing the product on silica gel. A new technique was devised for oxidizing lactone **4** to carboxylic acid **5**. Allowing lactone **4** (2.9 g) to react in acetone (300 ml) with Jones' reagent (4 ml, 8 *N* chromium trioxide, ref. 9) during 3 h afforded (80%) 2.4 g of acid **5** (m.p. 121–123°, needles from diethyl ether – ligroin). Brief contact between acid **5** in ethyl acetate with acetic anhydride-perchloric acid (10) gave enol–lactone **6** (55%, needles from methanol, m.p. 124–125°, M^+ 400). Adding precisely 4 equivalents, of methyl magnesium iodide (11) (in ether) to lactone **6** (0.25 g) in benzene–ether (at ice–salt temperature) over a 3 h period led to diketone **7** which, without further purification, was added to methanol (20 ml) containing 2 ml of 10% sodium hydroxide. The mixture was heated at reflux 1.5 h and ketone **8** (0.15 g, 58%, m.p. 113.5–115°, M^+ 399, reported: ref. 3, m.p. 113–114°) was isolated by preparative thin layer chromatography on silica gel HF_{254} with 5:1 benzene – ethyl acetate as mobile phase.

[2]National Institutes of Health Predoctoral Fellow 1968–1969.

[3]Recently Professor C. W. Shoppee kindly informed us of his studies toward the same objective.

[4]Acceptable elemental analyses, proton magnetic resonance and infrared spectra were obtained for each new compound. The yields reported correspond to material displaying one spot on a thin-layer chromatogram. Mass spectra were obtained using an Atlas CH-4B mass spectrometer equipped with a molecular beam type inlet system.

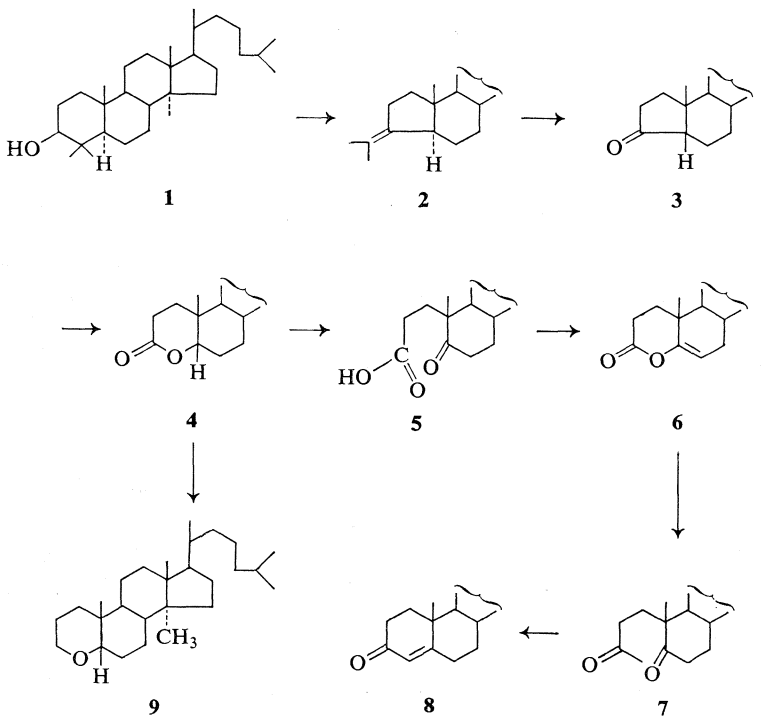

FIG. 1. Conversion of tetracyclic triperpenes to steroids.

The preceding method for transforming certain tetracyclic triterpenes to steroids also allows ready access to 4-oxa-5β-steroids. For example, boron trifluoride – sodium borohydride reduction (12) of lactone **4** easily led to 14α-methyl-4-oxa-5β-cholestane (**9**, 75%, m.p. 55–57°, M^+ 388).

A distorted tetrahedral copper(II) complex: 1,2-bis(diphenylphosphineoxido)ethane copper(II) chloride

M. MATHEW AND GUS J. PALENIK
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received January 21, 1969

The crystal structure of 1,2-bis(diphenylphosphineoxido)ethane copper(II) chloride has been determined by X-ray diffraction techniques. The compound is the first structual determination of a $CuCl_2$–phosphineoxide adduct and exhibits some very large distortions from the ideal tetrahedral symmetry. The Cl—Cu—O angle is 140.2° and the Cu—Cl distance of 2.195 Å is shorter than in other $CuCl_2$ complexes.

Canadian Journal of Chemistry, 47, 1093 (1969)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The bis-phosphine oxide adducts of copper(II) halides are assumed to be tetrahedral although no structural studies are available. Since a copper(II) ion in a tetrahedral field is subject to Jahn–Teller distortions, the structural details of tetrahedral copper(II) species are therefore of importance in understanding the Jahn–Teller theorem. We wish to report the first crystal structure determination of a bis-phosphine oxide adduct of copper(II) chloride, 1,2-bis(diphenylphosphineoxido)ethane copper(II) chloride, $CuCl_2$·DPPO. This compound, $CuCl_2$·DPPO, exhibits some of the largest distortions found in a nominally tetrahedral molecule as well as one of the shortest Cu—Cl bonds found in a copper(II) complex.

The reaction of 1,2-bis(diphenylphosphino)-ethane, DPP, with copper(II) chloride yields a product which is rapidly oxidized in air to the compound 1,2-bis(diphenylphosphineoxido)ethane copper(II) chloride (1). The preparation of $CuCl_2$·DPPO provided an opportunity to test the hypothesis of Goodgame and Cotton (2) that the bis(triphenylphosphine oxide) copper(II) chloride complex was tetrahedral. In addition, the presence of a seven-membered chelate ring involving the DPPO moiety was an interesting possibility.

Recrystallization of $CuCl_2$·DPPO from *n*-butanol yielded greenish-blue crystals. Preliminary measurements indicated the crystals to be monoclinic with $a = 12.206 \pm 0.002$, $b = 20.172 \pm 0.004$, $c = 10.559 \pm 0.002$ Å, and $\beta = 97.26 \pm 0.02°$. The density calculated for 4 molecules per unit cell is 1.454 g/cm^3, in good agreement with the measured value of 1.46 g/cm^3. The space group is either *Cc* or *C*2/*c* with the latter indicated by intensity statistics. Intensity data were measured from a small equidimensional crystal (0.15 mm an edge) using a General Electric XRD-6 automatic diffractometer. The stationary crystal – stationary counter method was used to measure all the reflections with $2\theta \leq 135°$ with copper radiation. A total of 2161 reflections was considered observed and used in the analysis.

A three-dimensional Patterson function was computed from which the positions of the copper, chlorine, and phosphorus were determined. A subsequent Fourier synthesis was used to locate the lighter atoms and a second Fourier synthesis used to refine the atomic positions. The refinement was completed by 3 cycles of least-squares with individual isotropic thermal parameters followed by 4 cycles with anisotropic thermal parameters for all atoms, bringing the usual residual (R) to 0.058. Atomic scattering factors for all atoms were taken from the International tables for X-ray crystallography (3).

The copper atom is situated on a twofold axis with the DPPO molecules being located on a center of symmetry. The resulting structure is an infinite polymer with the DPPO molecules linking $CuCl_2$ units. The copper atom is coordinated to two O atoms from two different DPPO molecules and two Cl atoms. The distances and angles illustrated in Fig. 1 demonstrate that the copper atom is definitely distorted from a tetrahedral configuration. In fact the Cl—Cu—O angle of 140.2° is the largest reported angle for a tetrahedral copper molecule. The large angle is not due to a steric effect since DPPO has only two phenyl rings per phosphorus compared to triphenylphosphine. Furthermore, the O—Cu—O angle is 91.3° while a repulsion between the phosphine–oxide groups might be expected to open the angle. The opening of the Cl—Cu—O angle, therefore, appears to be an electronic

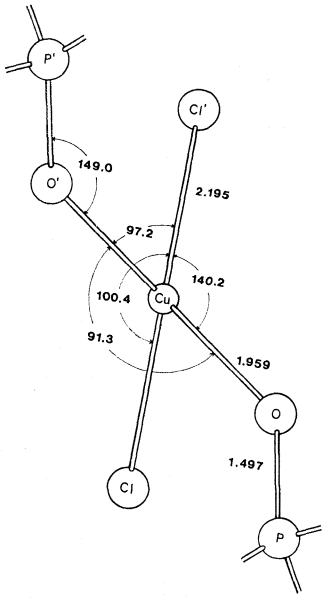

FIG. 1. The coordination around the copper(II) atom is illustrated, together with the pertinent bond distances (in Å) and angles (in degrees). The primed atoms are related by a two-fold axis to the unprimed atoms.

effect. The triphenylphosphine oxide adducts will probably be very distorted also and should only be considered as tetrahedral molecules in the widest sense.

The criteria, suggested by Cruickshank and Robertson (4), indicate that the Cu—Cl distance of 2.195 ± 0.001 Å is significantly shorter than that found in dimeric-μ-(pyridine oxide)-bis(dichlorocopper(II)), 2.211 ± 0.005 Å (5). The Cu—O distance of 1.959 ± 0.003 Å is also significantly shorter than the average Cu—O distance of 2.007 ± 0.011 Å found in the pyridine oxide complex (5). These observations are of importance since the magnetic moment of the pyridine oxide adduct is abnormally low. Therefore, any mechanism used to explain the low moment in the pyridine oxide compound must not involve a shortening of the Cu—O bonds since the bond distances are representative or longer than those found in other four-coordinated copper(II) complexes.
